A ZnS:Cu,I phosphor which exhibits only blue emission and a ZnS:Cu,Al phosphor which exhibits only green emission were used in order to facilitate the analyses of the phenomena. A "vacuum type" EL cell using no embedding material was used lest errors be introduced. Namely, phosphor powders were coated on a metal plate electrode with alcohol, and then were dried. "Nesa" electrode was placed on the phosphor layer, and the cell was mounted in a vacuum chamber. Two sheets of Mylar film were inserted between the two electrodes and the phosphor layer to prevent the carrier injection from the electrodes.

The pulse generator used is capable of producing both a-c and d-c pulses. D-c pulse was obtained by cutting the a-c component with the diode. For superposition of d-c voltage on the pulse voltage, a battery was connected to the output of the pulse generator in series with the EL cell. This pulse generator can supply voltages of 1500 peak-to-peak volts (vpp) at maximum and of frequencies ranging from 50 to 10,000 pulse per second (pps). Both the rise and decay time of the pulse voltage were below 0.5 μsec even an EL cell of about 30 pF was loaded.

The light emitted from the EL cell was detected by means of a type 1P21 photomultiplier tube whose output was displayed on a Tektronix 545 oscilloscope coupled with dual-beam preamplifiers.

Results

1. Brightness waves are independent of whether the EL cell is operated by a-c pulse or d-c pulse. Further, in the case of excitation by pulse, sinusoidal and half-wave sinusoidal voltage, superposition of a d-c voltage on the exciting voltage does not affect the brightness wave.

In Fig. 1, the brightness wave produced by half-wave sinusoidal voltage is compared with that when positive or negative d-c voltage is superposed on it. The peak height of the half-wave voltage in this figure is about 500v and the superposed d-c voltage is 360v. It is interesting that there is almost no difference between these brightness waves, although the superposed d-c voltage is nearly the same order in magni-

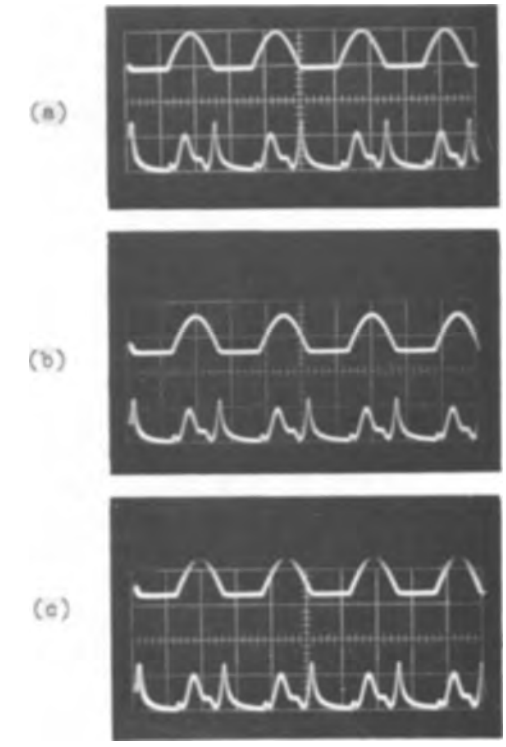

Fig. 1. Brightness waves under half-wave sinusoidal voltage. Frequency is 50 cps, phosphor used is ZnS:Cu,I. a (Top), no bias; b (center), negative bias; c (bottom), positive bias.

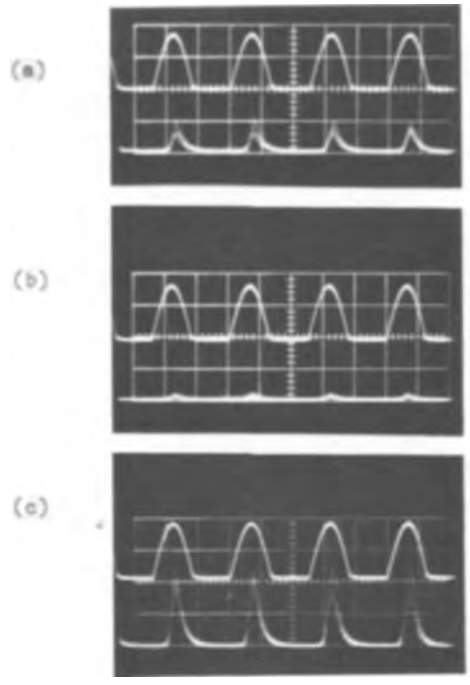

Fig. 2. Effects of superposed d-c voltage on the brightness waves of evaporated EL cell. Frequency of half-wave sinusoidal voltage is 150 cps and zero-to-peak voltage is about 180v. EL cell is made of evaporated ZnS:Mn thin film. a (Top), no bias; b (center) negative bias; c (bottom), positive bias.

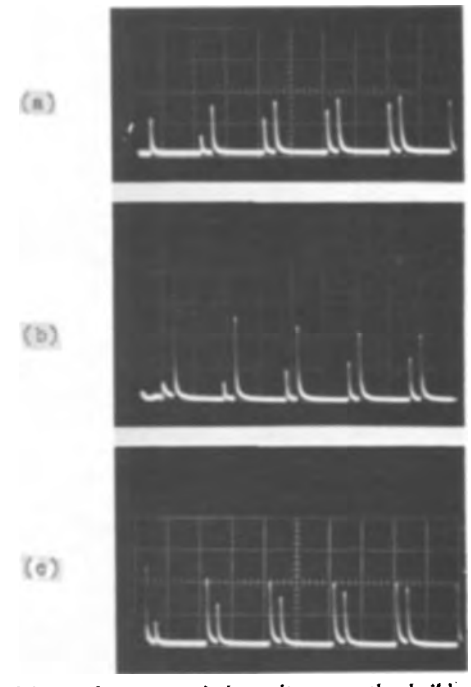

Fig. 3. Effects of superposed d-c voltage on the build-up characteristics. a (Top), no bias; b (center), negative bias on negative pulse; c (bottom), positive bias on negative pulse.

tude as the half-wave sinusoidal voltage and the shapes of these brightness waves are considerably complicated. It is inferred from this that an internal field, *i.e.*, a polarization field, which cancels the superposed d-c field, is set up in the phosphor crystal.

Brightness waves of an evaporated EL cell when excited by half-wave sinusoidal voltage are shown in Fig. 2. Here, as is clear from the figure, effects of the superposed d-c voltage are conspicuous. This EL cell was prepared by evaporating a ZnS:Mn phosphor in vacuum on a Nesa glass and by using aluminum as the metal electrode. Since the electrodes are in contact with the phosphor layer, it is expected that carrier injection from the electrodes takes place. Consequently, it is believed that brightness waves are greatly varied, because a polarization field large enough to cancel the superposed d-c field hardly grows up in this case.

2. Since the polarization field has not been set up in the EL cell or in the phosphor particles before the field application, it is expected that unusual phenomena may be found in the build-up of the brightness wave, as the build-up process of such a polarization field proceeds. Then, the build-up characteristics of the brightness wave were measured by using a pulse voltage superposed with a positive or negative d-c voltage. Frequency of the pulse voltage was 1000 pps, pulse width was 200 μsec, and the polarity of the pulse voltage was negative in all cases. Pulse voltage of 600 vpp was applied to the EL cell of about 100μ in thickness. D-c voltage superposed was +1000 or −1000v. Since the build-up of brightness wave is very sensitive to the historical state of the EL cell, the irradiation of infrared light was given to the cell in all cases before the field application so as to prevent the fluctuation of results.

The experimental results are given in Fig. 3. Let the emission peaks corresponding to the rise and fall of the pulse voltage be denoted by P_r and P_f, respectively. In general, when the EL cell was excited by the pulse voltage having a pulse width much shorter than the pulse-off period, the height of P_r was slightly smaller than that of P_f. In the case of d-c pulse excitation, both P_r and P_f increase gradually and approach the steady-state height. However, when a negative voltage of the same polarity as that of the pulse voltage is superposed, P_f is very large from the outset and then decreases gradually to the steady-state height, while P_r increases gradually. The opposite is the case with the superposition of a positive d-c voltage.

These facts show that the excitation due to the polarization field must be taking place, and that the transient process in which the polarization reaches the steady state corresponds to the bulid-up of the brightness wave.

3. The polarization field observed in the above experiments is not attributable to Mylar films used for electrical insulation. In order to ascertain this, similar experiments were performed by using pulse voltage of frequency 100 pps. It was found that the brightness wave reaches steady state within nearly a same number of cycles of the applied voltage as in the case of 1000 pps. If a polarization field is set up in Mylar film, it is expected that the brightness wave reaches steady state after a fixed period determined by the capacitance of the Mylar film. Consequently, it is concluded that the polarization field is set up within each phosphor particle.

Discussion

Experimental results described in the previous section provide a clear evidence for the new model of EL proposed by Fischer (6), that the excitation due to polarization field takes place during the EL process. That the delayed emission mechanism proposed by Zalm (7) takes place in this "vacuum"-type EL cell could be easily ascertained by the experiment using a sinusoidal voltage superposed with a short pulse voltage on it. Consequently, P_f of the brightness wave under a d-c pulse excitation corresponds to the emission from the region that has been previously excited at the rise of the pulse voltage, while P_r corresponds to the emission from the region that has been excited at the fall of the pulse voltage. Hence, it is concluded that the excitation due to the polarization field takes place at the fall of the d-c pulse voltage in almost the same degree as that due to the applied field. The re-

sult of experiment 3 also supports this inference and shows that the polarization field is set up within each phosphor particle. Therefore, the excitation and emission process in the case of d-c pulse excitation, can be interpreted in the following way. At field application, carrier generation from conducting lines within the crystal (6) or impact ionization at a local high field region (8) occurs. Generated free electrons are swept toward the positive electrode side and recombine with luminescence centers which have been produced at previous excitation process, giving rise to the emission peak corresponding to P_r while generated holes are rapidly trapped in unexcited luminescence centers and ionize them. As this process proceeds, a polarization field due to the ionized luminescence centers and excess electrons which have been swept to the positive electrode side and trapped there, grow up so as to be large enough to cancel the applied field.

At field removal, excitation process due to this polarization field occurs in almost the same degree of magnitude as that due to the applied field, giving rise to the light pulse corresponding to P_f.

On the other hand, in the case of a-c pulse and superposition of a d-c voltage, the polarization field is considered to be set up so that the applied field at an instant just before the field reversal is almost canceled in the steady state. Therefore, since the excitation at the field application and reversal are both nearly equal in magnitude to that due to the applied peak-to-peak voltage, light peaks P_r and P_f in these cases are considered to be the same in shapes and heights as those in the case of d-c pulse excitation, respectively.

Experimental results that steady state brightness waves produced by using sinusoidal and half-wave sinusoidal voltage are not affected by the superposition of a d-c voltage on the exciting voltage, are also explained in a similar way.

Experimental result shown in Fig. 3 can be interpreted by considering build-up of the polarization field. When a negative d-c voltage is superposed on a negative pulse voltage, the intense negative field is applied at the initial rise of the negative pulse voltage, giving a strong excitation. Consequently, the light peak at initial fall of the pulse voltage is large. Since a polarization field is built-up gradually, P_f at the fall of the successive pulses become small in height and approach steady-state height. On the other hand, when a positive high field is superposed on the negative pulse voltage, excitation at the fall of the pulse voltage is more intense than that at the rise, during the first several pulses. Hence, it is understandable that light peaks at the rise of the first several pulses are large in height and decrease to the steady-state height.

The Chemical Polishing of Single Crystal α-Alumina Using Silicon

J. D. Filby

Royal Radar Establishment, Malvern, Worcestershire, England

Epitaxial layers of silicon grown on single crystal alumina promise to be very useful for electronic devices. Details have been published of the preparation of these layers by either the hydrogen reduction of silicon tetrachloride (1, 2), or trichlorosilane (3, 4), or the pyrolysis of silane (2-4). The alumina substrates are normally prepared by mechanically polishing down to $< 1\mu$ diamond grade followed by a chemical polish to remove the mechanically damaged layer. A variety of chemical polishes have been used, the most common being based on either orthophosphoric acid, lead fluoride, or sodium borate. The resultant surface finish however is not usually of a very high standard, an orange-peel effect often being obtained as well as occasional small etch pits or facets. In addition the removal of the last traces of some of the polishing mediums from the substrate surface is difficult.

The work of Reynolds and Elliott (5) at the Post Office Research Station on the vacuum deposition of silicon on single crystal alumina suggests that it might be possible to polish chemically the alumina with silicon. This technique would have the advantage that polishing could be carried out in the silicon deposition apparatus thus eliminating contamination by residue from other chemical polishes or by handling between the polishing and deposition processes.

An investigation into the feasibility of such a polishing process has been carried out using silane diluted with hydrogen in a system operating at approximately atmospheric pressure. The apparatus essentially consisted of a water-cooled vertical quartz reaction chamber connected via suitable valves and flowmeters, to sources of high purity hydrogen and a 3% silane in hydrogen mixture. The system could be evacuated to 10^{-4} mm Hg. The alumina substrates were cut on the $(1\bar{1}02)$ or $(2\bar{1}\bar{1}3)$ planes from single crystal boules grown by the Verneuil process. They were mechanically polished down to 20μ diamond grade before placing on a susceptor in the reaction chamber. The original susceptor was made of silicon and induction heated. It contained a vitreous carbon insert to assist in the initial coupling.

Figure 1 is a micrograph of the $(1\bar{1}02)$ surface of alumina after heating at 1240°C for 30 min in a flow of 20 liters/min hydrogen and 25 cc/min of 3% SiH_4/H_2 mixture. The surface is very uneven consisting mainly of a large number of very shallow pits each associated with a globule. The globules were obviously molten at the operating temperature and therefore cannot consist entirely of silicon. Microprobe x-ray analysis has shown that in addition to silicon the globules contain an appreciable amount of aluminum. This explains how they could be molten at 1240°C as silicon-aluminum alloys can have a melting point as low as 577°C.

It has been previously suggested (1) that alumina can be etched by silicon at elevated temperatures according to the reaction

Fig. 1. Silicon-aluminum alloy globules and associated etch pits on a $(1\bar{1}02)$ alumina surface.

Fig. 2. Tracks left on the $(1\bar{1}02)$ alumina surface by migrating alloy droplets.

$$2Si + Al_2O_3 \xrightarrow{H_2} 2SiO\ (g) + Al_2O\ (g)$$

The above result indicates that, if the attack is severe enough, in addition to these two volatile compounds some free aluminum is also obtained. The exact mechanism for the formation of the free aluminum is doubtful. The reduction of alumina by silicon to form aluminum is thermodynamically unfavorable at 1240°C. However such thermodynamical calculations assume equilibrium conditions whereas the present reaction takes place in a flow system under conditions far removed from equilibrium.

The existence of silicon/aluminum globules on the alumina surface is obviously detrimental to obtaining a smooth finish. This is due to the enhanced etching rate of the alloy compared to pure silicon which results in pits if the globules are stationary and tracks, Fig. 2, if they are mobile on the substrate surface. This is not the first time that rapid attack of alumina by a silicon alloy has been observed. It has previously been reported (6) that silicon/gold alloys etch alumina at temperatures as low as 750°C.

To avoid the formation of alloy droplets the silane concentration in the gas flow was reduced. Figure 3 is a micrograph of the surface of a substrate after 20 min in a gas flow containing 10 cc/min of 3% SiH_4/H_2 mixture, other conditions were similar to those for the previous sample. The attack was now fairly uniform, and no alloy droplets were observed. However, the etching rate was very slow, only 2μ of material being removed in 20 min, and traces of scratches left by the 20μ diamond grade are still clearly visible.

To obtain more reasonable polishing rates higher temperatures were indicated and so the silicon susceptor was replaced by one of high purity graphite.

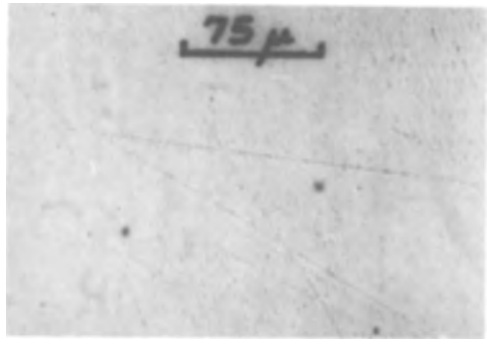

Fig. 3. Partially polished $(1\bar{1}02)$ alumina surface. Remains of mechanical scratches still visible.

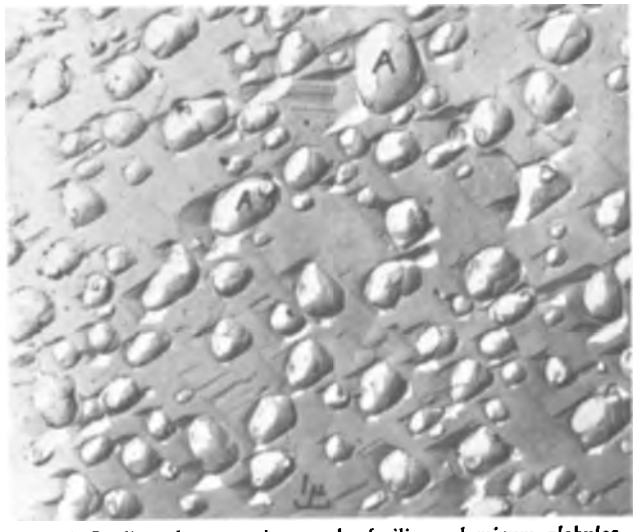

Fig. 4. Replica electron micrograph of silicon-aluminum globules, A, and etch pits on $(2\bar{1}\bar{1}3)$ alumina surface.

Fig. 5. Replica electron micrograph of etch pits on $(2\bar{1}\bar{1}3)$ alumina surface after alloy globules have been removed.

Figures 4-6 are replica electron micrographs of the $(2\bar{1}\bar{1}3)$ surfaces of two alumina samples which were etched by silicon at 1370°C for 8 min in a gas flow of 40 liters/min H_2 and 100 cc/min 3% SiH_4/H_2. The sample in Fig. 5 and 6 was subsequently heated *in situ* at 1250°C in a hydrogen flow of 20 liters/min for 20 min.

The surfaces of both these samples were sufficiently polished to remove the scratches left by the mechani-

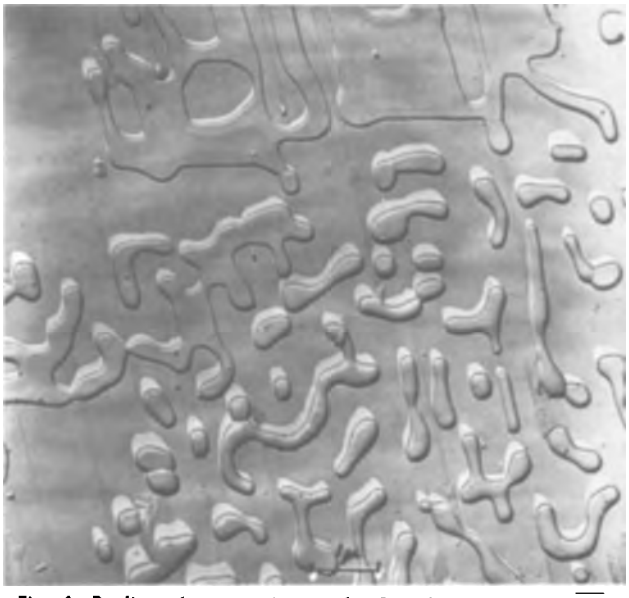

Fig. 6. Replica electron micrograph of etch figures on $(2\bar{1}\bar{1}3)$ alumina surface.

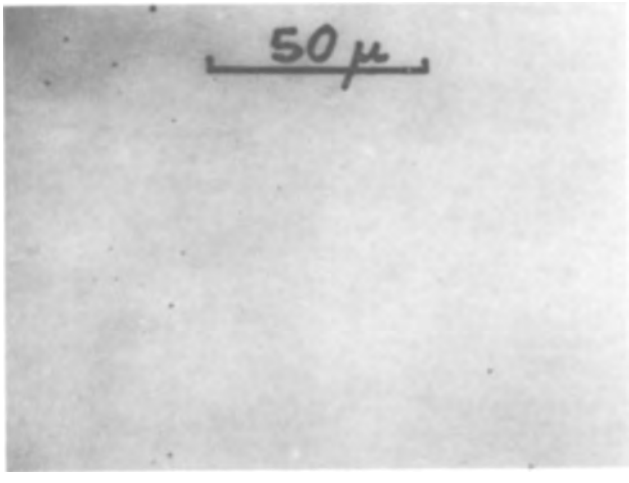

Fig. 7. Surface of $(1\bar{1}02)$ alumina polished with silicon at 1380°C

cal polishing. However small silicon/aluminum globules, approximately 1μ diameter, were obtained, and these had etched small pits. Fig. 4, which they almost fill. These alloy droplets were easily removed by the treatment described above of heating the substrate in hydrogen only. Auxiliary experiments have shown that during the removal of the droplets by this process any etching of the alumina surface is confined to the regions beneath the globules.

It is now possible to see the shape of the etch pits in more detail, Fig. 5. The sides are smooth and inclined at an angle of approximately 4° to the $(2\bar{1}\bar{1}3)$ substrate surface. They must therefore correspond to high index crystallographic planes. The fact that the pit sides are faceted in this manner and that the globules all penetrate the substrate in the same crystallographic direction indicates that the etching rate of the alloy is orientation dependent.

Figure 6 is a replica electron micrograph of another area of the surface shown in Fig. 5. In this region globules have not been formed and the etch figures consist of flat bottomed regions which have undergone uniform attack. A large proportion of the edges of these etched regions are approximately aligned along the same crystallographic directions as those traced by the intersection of the $(2\bar{1}\bar{1}3)$ alumina surface and the etch pit facets in Fig. 5. As the etched areas in Fig. 6 are all of similar depth, ~ 800Å, a continuation of the etching process should result in the removal of a uniform layer, *i.e.*, a polished surface should be obtained. The presence of alloy globules on another part of this sample indicates, however, that the silane concentration in the gas stream is still slightly too high.

A uniformly polished surface was obtained on $(1\bar{1}02)$ alumina at 1380°C using a gas flow of 20 liters/min of H_2 and 50 cc/min of 3% SiH_4/H_2. Figure 7 shows the completely featureless surface obtained over a wide area after polishing for 17 min. Examination by replica electron microscopy also failed to reveal any surface imperfections. Under the above conditions the alumina was removed at a rate of ½ μ/min.

This investigation has demonstrated that it is possible to polish chemically single crystal alumina using only the gases normally present in the silicon deposition plant. The presence of a graphite susceptor, necessary in this work to obtain the high substrate temperature (~ 1400°C) required for polishing, would not be satisfactory for the subsequent process of depositing the single crystal silicon layer on the alumina. This difficulty may be overcome by using a silicon carbide coated graphite susceptor which is compatible with both the high temperature and purity requirements. A silicon or silicon coated graphite susceptor could still be used if a very slow polishing rate was acceptable. This could be the case if the bulk of the polishing were done by the chemical techniques at present in use and the above technique was used only as a final cleaning and polishing procedure in the deposition plant.

Preparation of GaAs Specimens for Transmission Electron Microscopy

E. Biedermann and K. Brack

IBM Deutschland, IBM Laboratories, Boeblingen, Germany

The thinning of semiconductor specimens for transmission electron microscopy by the well-known jet etch technique (1, 2) requires special etching solutions for each material in order to obtain satisfactorily clean and smooth crystal surfaces. In the following note, we report on difficulties and results that were obtained in the preparation of GaAs specimens with different etching solutions.

Experimental

The apparatus we used is essentially identical to that of ref. (1). The GaAs specimens were [111]-oriented crystal wafers with a diameter of 3 mm and a thickness of 0.3 mm. Two different etching solutions have been used:

1. NaOCl-H_2O solution (ratio 1:5) at 80°C. (This solution is commonly used in GaAs device fabrication for chemical surface polishing.)
2. HCl-H_2O_2-H_2O solution (ratio 40:4:1) at 20°C.

Both solutions had been found to fulfill the basic requirements of giving reasonable etching rates of a few microns per minute on both the As and the Ga-sides of the specimens, at the same time yielding optically smooth and clean surfaces on both crystal faces.

Results and Discussion

In Fig. 1 and 2 transmission electron micrographs are shown of GaAs specimens prepared with etching solution 1 and 2, respectively. The microscope used is a Siemens Elmiscope I. The typical difference between the two preparation methods is evident. With solution 1 (Fig. 1) a coarse grainy structure appears all over the crystal which at first sight might be attributed to a high concentration of small precipitation particles. With solution 2, however, the crystals appear clear and almost faultless. Only a few of the familiar crystal defects, dislocations and stacking faults are found (shown in Fig. 2).

We conclude, therefore, that the grainy structure of Fig. 1 is not an intrinsic property of the GaAs crystal. It must, instead, be caused by the reaction of solution 1 with the GaAs surface. Our efforts to obtain more information on a possible surface layer by transmission electron diffraction, however, failed. No reflexes besides those of the GaAs crystal could be found. Thus, we are presently not in a position to give a detailed interpretation of the observed transmission contrast in Fig. 1. For the preparation of transmission specimens of GaAs, however, only solution 2 can be recommended.

Acknowledgments

The authors wish to thank Miss Heide Winkler for her capable assistance in preparation and electron microscopy.

The Vapor Pressures of Titanium Tetrabromide and Chromium Carbonyl

A. A. Boni

Department of the Aerospace and Mechanical Engineering Sciences, University of California, San Diego, La Jolla, California

For $TiBr_4$ solid-gas equilibrium, three independent results have been previously published (1-3). The results of Hall *et al.* (1) are lower than the results of Seki (2) by approximately one order of magnitude, but agree well with the data of Keavney and Smith (3). Furthermore, the heats of sublimation were found to be 16.2, 12.15, and 16.17 kcal/mole, respectively. The data of Seki (4) were obtained by the use of a glass spring manometer and those of Keavney and Smith (3) with a manometer utilizing mineral oil as the working fluid. The results of Hall *et al.* (1), however, were derived from measurements made on liquid titanium tetrabromide together with the heat of fusion and ΔC_p for the sublimation process.

The solid-gas equilibrium vapor pressure of chromium carbonyl has been obtained by Wilkerson (5) and by Hieber *et al.* (6). These results are in complete agreement, but differ considerably from those of Windsor and Blanchard (7).

Experimental

We have measured the equilibrium vapor pressure above $TiBr_4$ and $Cr(CO)_6$ by using a precision fused quartz-spiral, bourdon-tube gauge which is sold commercially by the Texas Instruments Company (Model No. 140A). The vapor pressure of the sample was determined by measuring the rotation of the bourdon tube from its equilibrium position due to the pressure of the vapor. The equilibrium position is defined by a zero pressure difference between the inside of the tube and the exterior environment, which was evacuated in order to provide a constant absolute reference pressure. The angular deflection of the tube is determined by the unbalance of a pair of photocells which were previously aligned in the equilibrium position. The quoted accuracy of the gauge is 0.003 mm Hg minimum resolution and 0.006 mm Hg repeatibility. In order to determine the pressure-rotation curve of the bourdon-tube, a McLeod gauge was used. The system was completely evacuated to a pressure level of less than 10^{-4} mm Hg for a period of several days. A small quantity of dry argon gas was admitted to the system and the pressure was read with the McLeod gauge. The system was then reevacuated and filled again in order to obtain calibration curve over the pressure range from 10^{-3} to 10 mm Hg.

The bourdon tube was connected to a sample reservoir and the vacuum pumping system through an all-glass apparatus. Pump oil from the diffusion pump was prevented from backstreaming into the system by using a liquid nitrogen cold trap. When a vapor pressure measurement was made, the cold trap was excluded from the system in order to prevent condensation of the sample vapor. The complete system was checked for leaks with a helium leak detector and the leak rate was found to be less than 1×10^{-9} scc/sec of helium, which was quite acceptable for the purposes of our measurements.

The test crystals were transferred from sealed glass ampoules in which they were received into glass sample reservoirs in a dry box which was filled with dry argon in order to prevent contamination of the sample. The purity of these samples was guaranteed by the respective manufacturers to be a minimum of 99.5%. The sample reservoir was surrounded with dry ice while still in the inert atmosphere and was then rapidly attached to the test apparatus. The test apparatus itself had been evacuated overnight to a pressure level of less than 10^{-4} mm Hg. The sample reservoir was evacuated for a period of several hours while maintaining the dry-ice bath. The dry-ice bath was then removed, and for a period of one day the crystals were distilled under vacuum into another sample reservoir which was connected to the remainder of the system. The rejected parts of the sample were then sealed off.

In order to obtain data at temperatures both above and below room temperature, the reservoir containing the test sample was surrounded by a water bath. The bath was heated with a standard electric heating unit, the heat input of which was controlled by a mercury thermoregulator. Low temperatures were attained by using an ice bath. Uniform composition of the water bath was maintained by using an electrical stirring unit, and the temperature was measured with an iron-constantan thermocouple. This system was capable of achieving over-all temperature control to within $\pm$ 0.3°C.

All portions of the system which were not in contact with the constant temperature bath were wrapped with electrical heating tape and heated to a temperature larger than the heat bath temperature at which the measurement was made in order to prevent condensation of the sample vapor in the system. The quartz bourdon tube itself was heated with a thermostat-controlled heating unit which is built into the instrument.

Results

The experimental data are presented in Tables I and II and plotted in Fig. 1 and 2. The heat of sublimation may be obtained from these data by integrating the Clausius-Clapeyron equation relating the equilibrium properties of the solid to those of the equilibrium vapor. After integration, a relationship of the following form is obtained

$$4.575 \log_{10} p = -(\Delta H/T) + B \qquad [1]$$

Results for $TiBr_4$.—A least squares fit of our data (see Table I) results in the following expression for the vapor pressure of $TiBr_4$

$$\log_{10} p \text{ (mm Hg)} = -(3621/T) + 11.26 \qquad [2]$$

Thus we find for the heat of sublimation, ΔH, the value 16,570 ± 200 cal/mole. We may compare this with that obtained in ref. (1) by using their vapor pressure equation to calculate a heat of sublimation corresponding to a temperature in the middle of the range reported in this study, *e.g.*, 293°K. This results in a value of 16,240 cal/mole. Thus, we are in good agreement with the results of Hall *et al.* (1).

Results for $Cr(CO)_6$.—For $Cr(CO)_6$, we obtained the relation

$$\log_{10} p \text{ (mm Hg)} = -(3737.7/T) + 11.750 \qquad [3]$$

Therefore, our value for the heat of sublimation is 17,092 ± 200 cal/mole, which is in good agreement with Wilkerson's estimate of 17,200 cal/mole and 17,180 cal/mole as reported by Hieber *et al.*

Brief Communication

Selected Area Deposition of Single Crystal Silicon on Amorphous Quartz

J. D. Filby and S. Nielsen

Royal Radar Establishment, Malvern, England

The authors recently reported progress toward the deposition of single crystal layers of silicon on amorphous quartz (1), showing that crystallites as large as 300μ in diameter could be achieved using an ultrathin layer of alloy (2), a variation of the V.L.S. process (3). In this work silicon was sublimed or evaporated on to a quartz substrate held at a temperature between 700° and 800°C. Immediately prior to the deposition of the silicon, the quartz surface was washed and degreased and coated with a layer of gold 1-2000Å thick. It was proposed that the gold produced an ultrathin gold-silicon alloy layer over the substrate surface and that this alloy layer influenced the nucleation and growth of the silicon, thus enabling the large crystallites to be formed. Further progress is now reported which enables single crystal regions of silicon to be deposited on preselected areas of the amorphous quartz.

It was first noticed that a selected area deposition on the quartz surface was often obtained accidentally (*e.g.*, Fig. 1). It was thought that this was caused by preferential deposition in a groove or depression on the quartz surface. Certainly preferential deposition was observed in artificially induced grooves, but the effect was not reproducible.

Experiments using ultrathin silicon-gold alloy layers have shown that the alloy attacks most substrates, including sapphire (4), magnesium oxide, quartz, tantalum pentoxide, and silicon nitride. The attack can remove a considerable thickness of the substrate and, since silicon takes part in the attack, very little deposition of silicon is obtained. This suggests that, if it is possible to prevent the attack in selected areas, preferential deposition could be obtained in those areas. One possible technique for protecting the quartz is to evaporate on it a metal which does not alloy with either silicon or gold below 1000°C. Two suitable metals are tantalum and tungsten and areas of these, 25μ square, were evaporated on to amorphous quartz substrates using electron microscope grids as masks. The evaporation took place in a conventional mercury pumped system at a pressure of $\sim 10^{-5}$ mm Hg using a Varian e-gun evaporation source. A 1000Å thick layer of gold was then evaporated over the entire substrate surface from a resistance-heated tantalum boat. Finally the substrate was transferred to a sublimation apparatus (5) where silicon was sublimed on to it at the rate of 1 μ/hr, the substrate temperature being in the range 850°-950°C.

Tantalum was used as the protective metal for the sample shown in Fig. 2. The only deposit between the protected areas consists of solidified silicon-gold alloy, whereas each of the tantalum areas is covered by a layer of silicon approximately 5μ thick. The silicon layers sit on top of quartz mesas, approximately 2μ

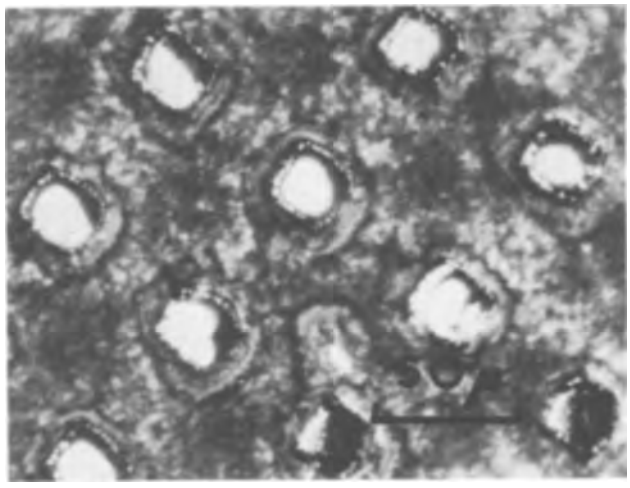

Fig. 2. Single crystal silicon areas deposited on amorphous quartz in regions preselected by covering with a tantalum film.

high, created by the etching of the unprotected quartz during the deposition process.

Examination of the silicon areas to ascertain whether they were single crystal was difficult. They were too small to examine individually by electron or x-ray reflection diffraction techniques, and electron transmission studies were complicated by the necessity to hold and thin these small areas. The evidence accumulated, however, indicates that the silicon areas are single crystal. The patterns obtained from an x-ray Laue back reflection examination of the region containing the silicon islands includes spots, as well as the diffuse rings due to the amorphous quartz. These spots could only have originated from the silicon areas, indicating that they are crystalline. Treating the sample with a Dash etch to reveal stacking faults produced no effect (Fig. 3). This etch normally reveals grain boundaries and in the case of amorphous or finely polycrystalline silicon very bad staining is obtained. Its lack of effect on the present sample is strong evidence that the silicon islands are in fact single crystal. Although selected area deposition using tantalum areas on quartz in the presence of an ultrathin layer of gold has been demonstrated in many experiments, the effect could not be obtained consistently, suggesting that the many variables in the system are not easy to control.

For some device purposes the ultrathin alloy zone crystallized technique has the disadvantage that the alloying metal, in this case gold, is incorporated in the silicon layer up to the limit of solid solubility at the deposition temperature. Also the existence of the alloy between the silicon islands means that they are not always electrically isolated from each other. Possible ways of eliminating the need for the gold layer have therefore been studied.

It has been the authors' experience that, besides reducing the temperature required for epitaxial deposition, the ultrathin layer of gold generally lowers the minimum temperature at which silicon will chemically attack the substrate. This suggests that silicon would still attack quartz, in the absence of gold, if the temperature were high enough. An attempt was therefore made to deposit selective areas of single crystal using a higher temperature instead of an ultrathin alloy. To achieve the higher substrate temperatures it proved necessary to use an evaporation rather than a sublimation procedure. The evaporation apparatus is shown diagrammatically in Fig. 4 and is similar to that used by Gasson (6).

Preliminary experiments showed that for an evaporation rate of approximately 1μ/min no silicon was deposited on plain quartz substrates above 1325°C, as measured by the thermocouple in the substrate holder. The measured temperature may, of course, be different from the actual temperature of the substrate surface. Having established the temperature above which deposition on the quartz surface did not take place, the plain quartz samples were replaced by those containing areas protected by tantalum or tungsten spots. These were heated to 1350°C and silicon evaporated on them at the above rate. Examination showed that there was no deposit on the unprotected areas, but that the protected areas were covered by irregular grains of silicon. Although the grains are quite large, single crystals covering the whole of a protected area have not been observed to date. The grain size at an early stage of the silicon deposition on areas of tantalum on quartz is shown in Fig 5.

If the substrate temperature was raised to above that for the formation of a liquid alloy between silicon and tantalum or tungsten (1385° or 1400°C, respectively), then no silicon was deposited at all, and the substrate was etched one and a half times more rapidly by the alloy than by the silicon. This resulted in a series of pits in the "protected" areas.

Periodic Variation of Exchange Current Density of Hydrogen Electrode Reaction with Atomic Number and Reaction Mechanism

Hideaki Kita

Research Institute for Catalysis, Hokkaido University, Sapporo, Japan

ABSTRACT

A survey of recent results shows that the activity log i_o is a periodic function of the atomic number for each long period. It is concluded that the bulk properties of electrode dominate its activity. Also, log i_o decreases linearly with heat of adsorption or increases linearly with work function for the transition metals, but remains unchanged for the metals following them (the ascending metals). These relations are qualitatively interpreted by the catalytic and the electrochemical mechanism for the transition and the ascending metals, respectively.

The hydrogen electrode reaction

$$2H^+ + 2e^- = H_2 \qquad [1]$$

is one of the simplest and the most fundamentally important reactions among various kinds of heterogeneous catalyses, and its solid understanding would be a milestone in the approach toward complicated features of catalysis. The electrochemical study of catalysis generally has the advantage in comparison with chemical studies that one can easily follow a reaction over a wide range of experimental conditions, especially of free energy difference between reactants and products, which makes it possible to observe kinetics even on a catalyst of little activity. The hydrogen electrode reaction has been studied most extensively on various metals, and work on it has accumulated increasingly especially during the last decade. Most of this work is much more reliable than earlier work, in the sense that particular precautions have been taken against contamination of solution and electrode surface.

The present comprehensive survey of the results shows that the activity of metals for the reaction, expressed by the exchange current density i_o (amp/cm^2), varies widely, namely from the largest value reported on Pd, of log i_o = −1.2, to the lowest one on Pd, of −12.9, and it varies even on the same metal, for example, from −3.15 to −7.04 on Au. Such variations in the activity should be caused by several factors, such as bulk property of the electrode material, surface state of the electrode, and composition of the solution.

The present paper is concerned with the decision about the determining factor for the activity and with the elucidation of the mechanism for the hydrogen electrode reaction. This is done by relating the activity of various metals to their properties such as atomic number, heat of atomization of the metal, heat of adsorption of hydrogen on the metal, work function, etc.

Review of Results Reported and the Determining Factor

Table I shows the results of observations and experimental conditions, reported during the past ten years mainly till 1964 (1-61), which were available to the author. The exchange current density, i_o, was determined by extrapolating the current density, i, to $\eta = 0$ according to the Tafel equation

$$\eta = a + b \log i$$

where a and b are constants and η is the overvoltage, defined as[1]

$$F\eta = \mu(e^-) - \mu(e^-)_{eq} \qquad [2]$$

in terms of the chemical potentials, $\mu(e^-)$ and $\mu(e^-)_{eq}$, of metal electrons under working and equilibrium conditions.

Activity and atomic number (62).—In Fig. 1, the logarithm of the exchange current density is plotted against the atomic number of electrode metals; the symbols, ●, ●, and ○, represent the values obtained, respectively, in acidic, alkaline, and neutral solutions. In the case where two linear parts appear in the η-log i plot, i was extrapolated from the part at lower η.[1]

Table I and Fig. 1 are discussed below.

1. *Periodicity of the activity.*—The results on the same metal fluctuate considerably, especially in cases of Rh, Pd, W, Au, and Pd, but still the log i_o values of the respective metals studied are basically a periodic function of the atomic number, as shown by the dotted lines in Fig. 1; in other words, in each long period of the Periodic Table, the activity increases first with atomic number, reaches a maximum at the metals of group VIII, decreases quite sharply with a minimum at the metal of IIB or IIIB, and then increases again with further increase of the atomic number. The activity varies in a particularly similar way in the second and the third long periods, revealing precise periodicity. It may be noted that the third metal of any triad of group VIII shows a tendency to have the highest activity. The present distinct max-

[1] Overvoltage as used in this paper, is the negative value of the potential of the test electrode referred to that of the reversible electrode under the same conditions.

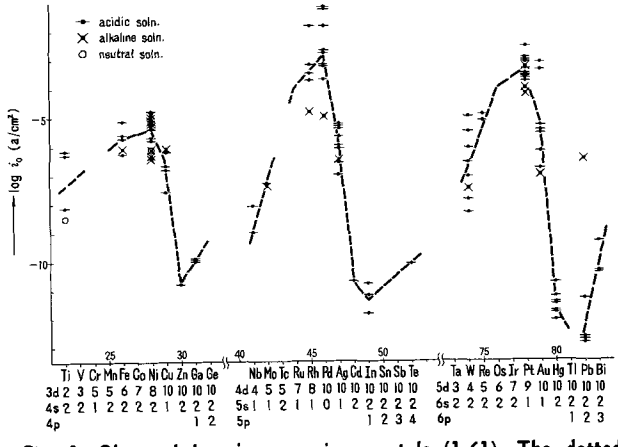

Fig. 1. Observed log i_o on various metals (1-61). The dotted lines indicate the periodic variation of log i_o with the atomic number. —●—, acidic solution; X, alkaline solution; ○, neutral solution.

* Values estimated from figures; ( ) uncertain values; [a] values of rest potential are referred to the reversible hydrogen electrode (r.h.e.) in the same solution and hydrogen atmosphere; [b] the region where a straight Tafel line is observed.

imum of the activity at metals of group VIII is also found in other heterogeneous catalyses, *e.g.*, the isotopic exchange in molecular hydrogen (63), the hydrogen-oxygen reaction (64), the synthesis and decomposition of ammonia (65), and the recombination of atomic hydrogen (66). The metals of group VIII have thus the largest activity for a host of important heterogeneous catalyses.

A similar periodicity for the hydrogen electrode reaction has been suggested by Bockris (29b) and recently by Khomutov (67) with regard to the overvoltage of metals at a certain definite current density. In the former work, however, the periodicity in the first long period is incomplete because of lack of observations, and in the latter only those in hydrochloric or sulfuric acid are included. Moreover, only one or two values for each metal are used in these works; this appears insufficient for remarks on the points 2 and 3.

2. *Effect of composition of the solution on activity.*— The log i_o value for the same electrode material fluctuates apparently without correlation with pH by 1 ~ 2 in most cases, whereas the fluctuation is much larger in the cases of Rh, Pd, and Pb, amounting to *ca.* 6 at most on Pb. The latter group of metals might have to be re-examined, since the observations in alkaline solution are scanty and extremely scattered. No correlation of activity is found either with respect to variation of the anion of the acid as seen, for example, in the case of Ni in Table I, where the log i_o values are, respectively, —5.4 (1*N* HCl) (30), —5.87 (8) and —5.24 (18) (both 0.1*N* HCl), —5.22 (0.5*N* H_2SO_4) (17), —5.2 (0.15*N* $HClO_4$) (32), and —5.7 (1M $HClO_4$) (36).

The activity appears similarly to have no correlation with the kind of solvent in the electrolyte solution, as exemplified by the log i_o values of the mercury electrode, *i.e.*, —11.8, —11.5, —10.8, and —10.8, respectively, for 0.1M HCl solution in water, methyl alcohol, ethyl alcohol, and n-propyl alcohol (26). The log i_o values in heavy water are, however, smaller in all cases than those in ordinary water, and its isotopic difference varies from 0.95 for Ag to 0.17 for Pt, being 0.55 on an average (8,20).

3. *Effect of treatment of the electrode.*—The electrode of nickel, which is one of the metals studied in detail, was subjected to a wide variety of treatments, as seen from the third column of Table I, *i.e.*, reduction of a wire in hydrogen atmosphere, electrodeposition of Ni from $NiSO_4$ solution, anodic or chemical polishing of a single crystal, quenching of the melt in helium atmosphere, evaporation of Ni on a glass wall, etc. However it is apparent from Fig. 1 that the log i_o values of nickel electrodes subjected to the above treatments are not very different from each other. Hence, the activity appears to depend not so much on the treatment as on the atomic number. The same is the case with most of the other metals.

Piontelli, Bicelli, and LeVecchia (32) and Weininger and Breiter (37) observed Tafel lines individually on (100), (110), and (111) lattice planes of the fcc crystal of Ni; Piontelli *et al.* observed with anodically treated electrodes that the log i_o values of the respective lattice planes differed by 0.35 at most, while Weininger *et al.* found, with chemically polished electrodes, practically no difference in the log i_o values between the lattice planes.

4. *Liquid and solid surfaces.*—It is of interest that the activity of liquid mercury conforms to the periodicity of the activity of solid electrodes as illustrated in Fig. 1. In the case of gallium, the activity is much the same whether the electrode is in the liquid or solid state, as observed in the respective cases at temperatures slightly above or below the melting point of 29.78°C (Table I).

These facts indicate that it is not essential in determining the activity of hydrogen electrode reaction whether the electrode is solid or liquid, which provides evidence for the crystal plane model of the catalyst and against the distribution model originating from the active center theory of Taylor (68a) and developed recently by Russian authors (68b).

Determining factor of the activity (62).—The above mentioned points 1 to 4 lead us to conclude that bulk property of the electrode material is the determining factor for the activity of hydrogen electrodes. In other words, the activity of a metal depends not so much on the kind of solvent, the electrolyte and its composition (point 2) as on the atomic number of the electrode metal. Further, the activity depends neither on the surface treatment (point 3), nor on the state of aggregation, *i.e.*, liquid or solid, of the electrode (point 4) within the fluctuation of results. Hence the periodic variation of the activity (point 1) is primarily effected by the bulk property of electrode material and only secondarily by other factors such as the solution and the surface state.

Activity and Properties of the Metal

The question arises from the above conclusion as to what property of electrode material effects essentially the activity. Many physical properties such as heat of atomization of the metal, melting point, metallic radius and work function are known to show periodic gradation within the long periods. These quantities are now considered in comparison with the periodic variation of the activity.

It may be noted qualitatively from the electron configuration of outer shells of the element attached to Fig. 1 that the activity in each long period increases first with successive addition of an electron to the d-orbital, reaches a maximum at nearly filled d-orbital, decreases quite sharply after its completion, with one or two electrons in the s-orbital, and then increases again with further addition of electrons to the p-orbital. In the following discussions, we denote the transition metals including IB metals by "d-metals" and the metals following them in the Periodic Table by "sp-metals."

The heights of the dotted line in Fig. 1 at the atomic number of each electrode metal are taken as the representative values for the respective metals and are denoted by [log i_o] in what follows.

Heat of atomization of the metal, $-\Delta H_{atom}$.—The heat of atomization of the metal is one of the measures of the cohesive strength of metal atom in the bulk. Surface metal atom may have unsaturated valencies directed outward from the surface on account of the absence of neighboring atoms above it. Thus unsaturated valencies may form bond with adsorbate, *e.g.*, intermediates of the hydrogen electrode reaction in the present case, with a strength depending on the nature of the metal, especially the cohesive strength of

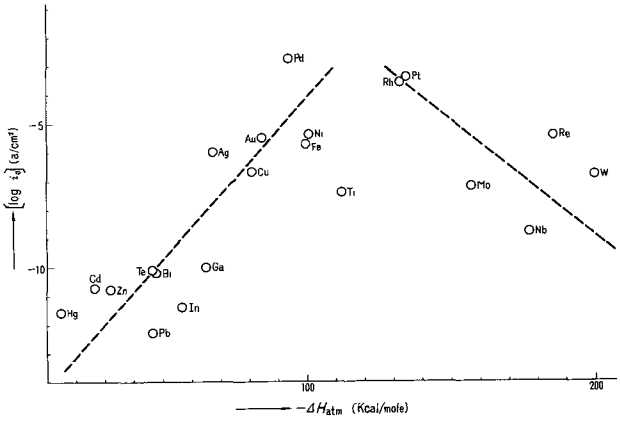

Fig. 2. Log i_o *vs.* heat of atomization of electrode metals, $-\Delta H_{atom}$

metal atom in the bulk. The [log i_o] values of respective metals are plotted against their heat of atomization after Sanderson (69) in Fig. 2. As seen in the figure, there exists a definite correlation between them and even an optimum value of the heat of atomization. The same relation is expected with respect to the melting point of the metal which changes with the atomic number in a way similar to that of the heat of atomization.

Metallic radius.—The metallic radius in any long period may also be taken as a measure of the cohesive strength, since it might appear that the smaller the radius the greater must be the strength of binding. This quantity, however, does not give any significant relation to the activity, as exemplified by W, Re, and Pt in the third long period whose metallic radii are almost the same, *i.e.*, 1.37, 1.37 and 1.38Å, whereas the [log i_o] values are quite different, *i.e.*, —6.8, —5.4, and —3.4, respectively. Hence the heat of atomization of the metal seems to be more closely related to the activity of the hydrogen electrode reaction.

Heat of adsorption of hydrogen, $-\Delta H_{ads}$.—The heat of adsorption of an adsorbate may not be the sole function of the heat of atomization of metal, since chemical bonds are usually more or less polarized. Eley (70) has proposed that the heats of chemisorption of gases on metals may be computed by means of Pauling's equation of bond energies (71), namely, in case of hydrogen chemisorption as

$$-\Delta H_{ads} = E(M-M) + 46.12(X_M - X_H)^2 \quad [3]$$

where $E(M - M)$ is the bond energy between metal atoms measured from the lowest potential energy and X_M or X_H is the electronegativity of metal atom or hydrogen atom, respectively. It has been pointed out by Stevenson (72) that if the electronegativities of metal atoms are calculated from their work function, ϕ, by the formula

$$X_M = 0.355\phi \quad [4]$$

and the values for $E(M - M)$ are taken as 1/6 of the heat of sublimation in the case of metals with "closest packed" lattices, a good agreement is obtained between the calculated and the observed heats of adsorption. In Fig. 3, the [log i_o] values are plotted against the heat of adsorption, $-\Delta H_{ads}$, as calculated by Eq. [3] and [4] and with the approximation of 1/6 of the heat of atomization (69) for $E(M - M)$. It is interesting to see from Fig. 3 that the behavior of d-metals is distinctly different from that of sp-metals, namely, the activity of d-metals has a tendency to decrease with increase of $-\Delta H_{ads}$, whereas the activity of sp-metals remains almost unchanged. Conway and Bockris (73) have studied hydrogen overvoltage

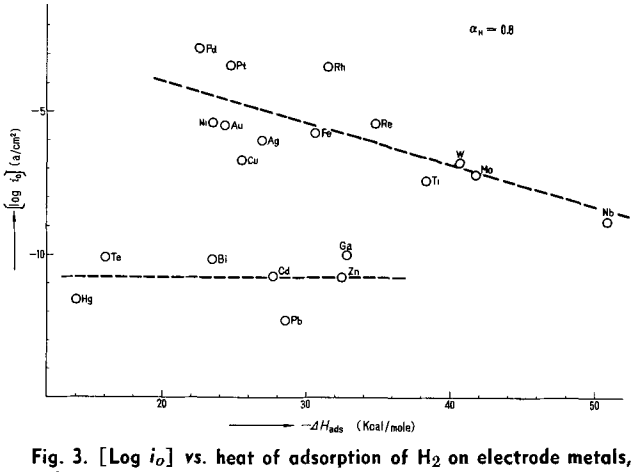

Fig. 3. [Log i_o] *vs.* heat of adsorption of H_2 on electrode metals, $-\Delta H_{ads}$.

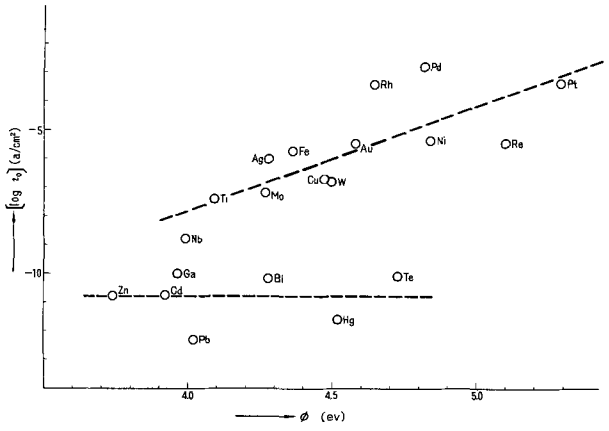

Fig. 4. [Log i_o] *vs.* work function of electrode metals, ϕ

on metals at a constant current density of 1 ma/cm² in comparison with $-\Delta H_{ads}$. The log i_o value and thus the activity should increase with decrease of the overvoltage quoted above, provided that the increment of the logarithm of the unidirectional current density per unit increase of overvoltage be universally constant. Their result is similar under this convention to the present one for the transition metals but not for the sp-metals, *i.e.*, some of them (Pb, Hg, and Tl) gained while others (Cd and Ga) lost in activity with increase of $-\Delta H_{ads}$. This discrepancy is attributed to the difference of the log i_o values they quoted from the present ones.

Work function, ϕ.—The correlation of work function, which is known to be a periodic function of the atomic number, with the activity is investigated by plotting the [log i_o] values against Michaelson's values of the work function (74) in Fig. 4. The activity of d-metals increases with work function, but that of the sp-metals remains again almost unchanged as seen in Fig. 4. The latter finding is not in agreement with that of Conway and Bockris (73).

Other properties.—The electronegativity of metal atoms, X_M, changes periodically with the atomic number with maxima and minima, respectively at IB and IIB metals in each period. The plot of [log i_o] against X_M does not, however, reveal any distinct correlation but only a rough tendency of decrease of [log i_o] with increase of X_M. Other properties such as mass magnetic susceptibility, electric resistance, and type of lattice are also periodic functions of the atomic number, but are not in a distinct correlation with the activity.

Reaction Mechanism of the Hydrogen Electrode Reaction

The facts shown in Fig. 3 and 4 definitely indicate that different mechanisms are operating on the respective groups of metals, *i.e.*, on the d-metals and the sp-metals, where the [log i_o] value of the former decreases or increases linearly with the heat of adsorption of H_2 or the work function, while that of the latter remains unchanged. This indication is supported by experimental results on the separation factors, S_D or S_T, of deuterium or tritium defined as

$$S_D(\text{or } S_T) = [C_H/C_D(\text{or } C_T)]_{gas}/[C_H/C_D \text{ (or } C_T)]_{soln}$$

where C_H, C_D, and C_T are the atomic concentrations of the isotopes, H, D, or T, with respect to the total amount of hydrogen atoms. A number of observations have been reported on various metals and conditions. Recent results obtained at a definite current density (17, 75-78), are summarized in Fig. 5, where ↘ and ↗ are the values of S_D in acidic and alkaline solution, ↙ and ↖ are those of S_T, respectively, all obtained at a current density of 0.01 amp/cm², and similar sym-

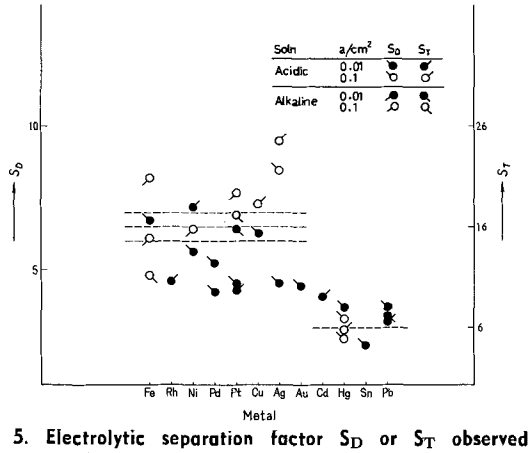

Fig. 5. Electrolytic separation factor S_D or S_T observed on various metals (17, 75-78). The dotted lines represent the theoretical values of $S_D = 6 \sim 7$ or 3 and $S_T = 16$ or 6 (80 ~ 82).

bols with open circles are values obtained at 0.1 amp/cm². As seen from Fig. 5, these results are widely scattered, but it can be concluded, in extension of the previous conclusion by Horiuti and Okamoto (79), that the separation factors fall into two groups: the larger values are those of the d-metals and the smaller ones those of the sp-metals. The dotted lines in Fig. 5 represent the theoretical values of Horiuti and his co-workers, *i.e.*, 6 ~ 7 of S_D (80) or 16 of S_T (81) for the former group and 3 of S_D (82) or 6 of S_T (81) for the latter group, respectively. The S_D and S_T scales in Fig. 5 are graded differently so that S_D = 6.5 and S_T = 16 on the one hand and S_D = 3 and S_T = 6 on the other hand fall, respectively, on the same levels. Some observed values of S_T, *viz.*, 4.1 on Ni in 0.5*N* NaOH and 6.0 and 4.4 on W in 0.5*N* H_2SO_4 and 0.5*N* NaOH solutions (17), are exceptionally small, but they are reported to increase with repetition of measurements and hence were not included in Fig. 5. The appearance of the two groups of separation factors supports the view that different mechanisms are operative on the respective groups of metals.

Horiuti and his co-workers (80, 82) have attributed the catalytic mechanism to the hydrogen electrodes of Ni, Au, Cu, Pt (at high η), and Pb (in alkaline solution) and the electrochemical mechanism to those of Hg, Sn, Pt (at low η), and Pb (in acidic solution); the catalytic mechanism proceeds through the two steps

$$H^+ + e^- \rightarrow H(a),\ 2H(a) \not\rightarrow H_2 \quad [5a], [5b]$$

and the electrochemical mechanism through

$$2H^+ + e^- \rightarrow H_2{}^+(a),\ H_2{}^+(a) + e^- \not\rightarrow H_2 \quad [6a], [6b]$$

respectively, with the rate-determining step signified by $\not\rightarrow$, where (a) denotes an adsorbed state. Recent results on the hydrogen electrode reaction on nickel, *i.e.*, the existence of a cathodic saturation current (35) and the coincidence of the experimental heat of activation with the theoretical one (83), confirm the catalytic mechanism.

We now proceed to interpret the results obtained in Fig. 3 and 4 applying the catalytic or the electrochemical mechanism respectively to the d- or sp-metals.

The unidirectional rate of an elementary step, v_+, has been given in general form by Horiuti (84) as

$$v_+ = (RT/h\nu)p^{\ddagger}/p^{\mathrm{I}} \quad [7]$$

where ν is the stoichiometric number of the rate-determining step and $r^{\ddagger}$ and r^{I} are factors defined as follows. Consider a macroscopic assembly, $\mathfrak{A}$, which consists of electrode, electrolyte solution, and 1 atm hydrogen gas at a definite temperature but comprises none of the critical system of the rate-determining step. The term $p^{\ddagger}$ is defined as the factor by which the partition function, $\Omega\mathfrak{A}$, of $\mathfrak{A}$ is multiplied by addition of a critical system to $\mathfrak{A}$ to form $\mathfrak{A}^{\ddagger}$, *i.e.*

$$p^{\ddagger} = \Omega\mathfrak{A}^{\ddagger}/\Omega\mathfrak{A} \quad [8a]$$

where $\Omega\mathfrak{A}^{\ddagger}$ is the partition function of $\mathfrak{A}^{\ddagger}$. It follows from the properties of the partition function that $p^{\ddagger}$ is the Boltzmann factor of the Helmholtz free energy increase of $\mathfrak{A}$ caused by the addition of the critical system to it, *i.e.*, that of its chemical potential

$$\mu(\ddagger) = -RT \ln p^{\ddagger} \quad [8b]$$

The factor p^{I} is similarly defined as

$$p^{\mathrm{I}} = \Omega\mathfrak{A}^{\mathrm{I}}/\Omega\mathfrak{A} \quad [9a]$$

where $\Omega\mathfrak{A}^{\mathrm{I}}$ is the partition function of $\mathfrak{A}^{\mathrm{I}}$ which is formed by addition of the initial system, I, of the rate-determining step to $\mathfrak{A}$. The factor p^{I} is similarly the Boltzmann factor of the chemical potential, $\mu(\mathrm{I})$, of I, *i.e.*

$$\mu(\mathrm{I}) = -RT \ln p^{\mathrm{I}} \quad [9b]$$

The factor $p^{\ddagger}$, as defined by Eq. [8a], has been expressed as (84)

$$p^{\ddagger} = \mathrm{N}^{\ddagger}\Omega\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}/\Omega\mathfrak{A}$$

where $\mathrm{N}^{\ddagger}$ is the total number of seats, $\sigma^{\ddagger}$, of the critical system and $\Omega\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}$ is the partition function of $\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}$, *i.e.*, the particular state of $\mathfrak{A}^{\ddagger}$ with a single critical system accommodated in a particular $\sigma^{\ddagger}$; $\Omega\mathfrak{A}^{\ddagger}$ is in consequence the total sum of $\Omega\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}$ over-all $\sigma^{\ddagger}$'s, *i.e.*, $\mathrm{N}^{\ddagger}\Omega\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}$. Dividing both the numerator and the denominator of the above equation by the partition function, $\Omega\mathfrak{A}_{\sigma^{\ddagger}(0)}$, of $\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(0)}$, *i.e.*, the particular state or $\mathfrak{A}$ where it has particular $\sigma^{\ddagger}$ unoccupied with certainty, we have (84)

$$p^{\ddagger} = N^{\ddagger}q^{\ddagger}\theta_{\sigma^{\ddagger}(0)} \quad [10]$$

where

$$q^{\ddagger} \equiv \Omega\mathfrak{A}^{\ddagger}_{\sigma^{\ddagger}(\ddagger)}/\Omega\mathfrak{A}_{\sigma^{\ddagger}(0)}$$

is the Boltzmann factor of the reversible work, $\epsilon(\ddagger)$, required to bring $\ddagger$ from its reference state to the preliminarily evacuated $\sigma^{\ddagger}$, *i.e.*

$$\epsilon(\ddagger) = -RT \ln q^{\ddagger} \quad [11]$$

and

$$\theta_{\sigma^{\ddagger}(0)} \equiv \Omega\mathfrak{A}_{\sigma^{\ddagger}(0)}/\Omega\mathfrak{A}$$

is the probability of $\sigma^{\ddagger}$ being unoccupied.

The probability $\theta_{\sigma^{\ddagger}(0)}$ is further developed in general form with respect to the adsorbate A, inclusive of I or part of it, as (84)

$$\theta_{\sigma^{\ddagger}(0)} = (p^{iA(a)}/q^{iA(a)})\theta_{\sigma^{\ddagger}(iA)} \quad [12]$$

where $q^{iA(a)}$ is the Boltzmann factor of the reversible work, $\epsilon(iA)$, required to bring i samples of $A(a)$ from their reference state to the preliminarily evacuated $\sigma^{\ddagger}$, *i.e.*

$$\epsilon(iA) = -RT \ln q^{iA(a)} \quad [13]$$

$p^{iA(a)}$ is the Boltzmann factor of $i\mu(A.a)$ or i times the chemical potential, $\mu(A.a)$, of $A(a)$, *i.e.*

$$i\mu(A.a) = -RT \ln p^{iA(a)} \quad [14]$$

and $\theta_{\sigma^{\ddagger}(iA)}$ is the probability of $\sigma^{\ddagger}$ being occupied by $iA(a)$.

The unidirectional rate of the hydrogen electrode reaction is now expressed in terms of current density, i_+, from Eq. [7] and [10] as

$$i_+ = 2e(kT/Ah)N^{\pm}q^{\pm}\theta_{\sigma^{\pm}(0)}/p^{\mathrm{I}} \qquad [15]$$

or from Eq. [7], [10] and [12] as

$$i_+ = 2e(kT/Ah)N^{\pm}q^{\pm}p^{iA(a)}\theta_{\sigma^{\pm}(iA)}/p^{\mathrm{I}}q^{iA(a)} \qquad [16]$$

remembering that $\nu = 1$ for both the catalytic and the electrochemical mechanism, where A is the surface area and e the elementary charge; the factor 2 cares for the transfer of two elementary charges at every occurrence of the step [5b] or [6b] in the steady state. Equations [15] and [16] are now applied to the respective mechanisms below.

Catalytic mechanism.—As regards the catalytic mechanism stated by [5a] and [5b], we have

$$\mathrm{I} = 2\,\mathrm{H}(a), A = \mathrm{H}(a) \text{ and } i = 2. \qquad [17a], [17b], [17c]$$

The chemical potential, $\mu(\mathrm{H}.a)$, of $\mathrm{H}(a)$ is expressed, on account of the partial equilibrium of step [5a], as

$$\mu(\mathrm{H}.a) = \mu(\mathrm{H}^+) + \mu(e^-)$$

or as

$$\mu(\mathrm{H}.a) = (1/2)\mu(\mathrm{H}_2) + F\eta \qquad [18]$$

from Eq. [2] and the relation

$$\mu(\mathrm{H}_2) = 2\mu(\mathrm{H}^+) + 2\mu(e^-)_{\mathrm{eq}} \qquad [19]$$

for the equilibrium of reaction [1].

The unidirectional current density is derived from Eq. [15], [17a], [9b], and [18] at $\eta = 0$ where $i_+ = i_o$ as

$$i_o = K_1 q^{\pm}\theta_{\sigma^{\pm}(0)} \qquad [20a]$$

or from Eq. [16] and [17a] to [17c] at $\eta = 0$ as

$$i_o = K_2(q^{\pm}/q^{2\mathrm{H}(a)})\theta_{\sigma^{\pm}(2\mathrm{H})} \qquad [20b]$$

where

$$K_1 = 2e(kT/Ah)N^{\pm}\exp\{\mu(\mathrm{H}_2)/RT\}$$

and

$$K_2 = 2e(kT/Ah)N^{\pm}$$

are, respectively, common to an electrode material in order of magnitude.

According to Horiuti-Polanyi's principle (85) that $\epsilon(\pm)$ varies by a positive proper fraction, α, of the variation of reversible work, $\epsilon(\mathrm{I})$, of the initial system, *i.e.*

$$\epsilon(\pm) = \alpha\epsilon(\mathrm{I}) + \text{const} \qquad [21]$$

the factor $q^{\pm}$ of Eq. [20a] and [20b] is approximately expressed by Eq. [21], [11], and [17a] as

$$-RT\ln q^{\pm} = \alpha_c\epsilon(2\mathrm{H}) + \text{const} \qquad [22a]$$

where α_c is a particular value of α for the catalytic mechanism. The reversible work $\epsilon(2\mathrm{H})$ defined as $-RT\ln q^{2\mathrm{H}(a)}$ is, on the other hand, expressed in terms of the heat of adsorption, $-\Delta H_{\mathrm{ads}}$, approximately as

$$\epsilon(2\mathrm{H}) = -RT\ln q^{2\mathrm{H}(a)} = \Delta H_{\mathrm{ads}} + R + \text{const} \qquad [22b]$$

where R is the repulsive potential of $2\mathrm{H}(a)$ in $\sigma^{\pm}$ with respect to the surrounding $\mathrm{H}(a)$'s.

The dependence of i_o on $-\Delta H_{\mathrm{ads}}$ is now discussed in the two limiting cases where the electrode surface is practically bare or practically fully occupied by $\mathrm{H}(a)$, *i.e.*, $\theta_{\sigma^{\pm}(0)} \simeq 1$ or $\theta_{\sigma^{\pm}(2\mathrm{H})} \simeq 1$, respectively.

1. $\theta_{\sigma^{\pm}(0)} \simeq 1$; here we have $R = 0$. From Eq. [20a], [22b], we obtain

$$\log i_o = -\alpha_c\Delta H_{\mathrm{ads}}/2.3RT + \text{const}$$

The above equation indicates an increase of $\log i_o$ with increase of the heat of adsorption, $-\Delta H_{\mathrm{ads}}$.

2. $\theta_{\sigma^{\pm}(2\mathrm{H})} \simeq 1$; here we obtain, assuming $R =$ const, the following equation from Eq. [20b], [22a], and [22b]

$$\log i_o = (1-\alpha_c)\,\Delta H_{\mathrm{ads}}/2.3RT + \text{const}$$

which shows an increase of $\log i_o$ with decrease of $-\Delta H_{\mathrm{ads}}$.

Case 2, where $\theta_{\sigma^{\pm}(2\mathrm{H})} \simeq 1$, is qualitatively in agreement with results for the d-metals in Fig. 3, but case 1 is not. From the slope of the dotted line for the d-metals, the value of α_c is estimated at about 0.8. This value satisfies the necessary condition that α_c is the positive proper fraction. The coverage of $\mathrm{H}(a)$ on electrode surface has been studied by various methods and concluded to be almost unity at $\eta = 0$ on Pt (86, 87) which has a relatively low value of $-\Delta H_{\mathrm{ads}}$ as seen from Fig. 3. The other d-metals with higher heat of adsorption hence may safely be taken to satisfy condition 2. As regards the IB metals of the Periodic Table, however, no reliable data of $-\Delta H_{\mathrm{ads}}$ or coverage seem to have been reported because of their slow rate of adsorption.

Conway and Bockris (73) have discussed the relation between $-\Delta H_{\mathrm{ads}}$, calculated by Eq. [3] using the respective values of the electronegativity of the metals, and the work function and found that $-\Delta H_{\mathrm{ads}}$ increases with decrease of the work function. The same relation is also derived from Eq. [3] and [4] identifying $E(\mathrm{M}-\mathrm{M})$ with 1/6 times the heat of atomization, and hence the relation of $\log i_o$ to the work function of the d-metals shown in Fig. 4.

Electrochemical mechanism.—As regards the electrochemical mechanism stated by [6a] and [6b], we have

$$I = \mathrm{H}_2^+(a) + e^-, A = \mathrm{H}_2^+(a), \text{ and } i = 1. \qquad [23a], [23b], [23c]$$

Thus the chemical potential, $\mu(\mathrm{I})$, of I is expressed on account of the partial equilibrium of step [6a] as

$$\mu(\mathrm{I}) = 2\mu(\mathrm{H}^+) + 2\mu(e^-)$$

or by Eq. [2] and [19] as

$$\mu(\mathrm{I}) = \mu(\mathrm{H}_2) + 2F\eta \qquad [24]$$

The unidirectional current density is derived from Eq. [15], [23a], [24], and [9b] at $\eta = 0$ where $i_+ = i_o$ as

$$i_o = K_1 q^{\pm}\theta_{\sigma^{\pm}(0)} \qquad [25a]$$

or from Eq. [16], [9b], [23a] to [23c], [14], and [2] at $\eta = 0$ as

$$i_o = K_2[q^{\pm}/q^{\mathrm{H}_2^+(a)}\exp\{-\mu(e^-)_{\mathrm{eq}}/RT\}]\theta_{\sigma^{\pm}(\mathrm{H}_2^+)} \qquad [25b]$$

The factor $q^{\pm}$ in Eq. [25a] and [25b] is expressed similarly to Eq. [22a], from Eq. [21], [11], and [23a], as

$$-RT\ln q^{\pm} = \alpha_E\{\epsilon(\mathrm{H}_2^+) + \mu(e^-)^2{}_{\mathrm{eq}}\} + \text{const} \qquad [26]$$

where α_E is a particular value of α for the electrochemical mechanism and $\mu(e^-)$ is independent of the electrode material as seen from Eq. [19], *i.e.*

$$\mu(e^-) = \text{const} \qquad [27]$$

The reversible work $\epsilon(\mathrm{H}_2^+)$, defined as $-RT\ln q^{\mathrm{H}_2^+(a)}$, has been discussed by Horiuti (88, 89) and is expressed by Eq. [3.3.H_2^+] and [5.1] of ref. (88), with additional term R for the repulsive potential of $\mathrm{H}_2^+(a)$ due to surrounding kindred species as

$$\epsilon(\mathrm{H}_2^+) = \epsilon(\mathrm{H}_2^+)_0 + FE_P + R$$

[2] Here the symbol, $\epsilon(e^-)$, is replaced by $\mu(e^-)$, since the electron is transferred into the conduction band of electrode material where we have no seat such as $\sigma^{\pm}$ on the electrode surface.

where E_P is the electrostatic potential of plane P on which $H_2^+(a)$ resides, and $\epsilon(H_2^+)_0$ is $\epsilon(H_2^+)$ minus its electrochemical part. We have from Eq. [5] in ref. (89)

$$\epsilon(H_2^+)_0 = \alpha_H \epsilon(H) + \epsilon(H^+)_0 - 2.7 \text{ ev}$$

where α_H is a positive proper fraction, $\epsilon(H)$ the reversible work required to bring $H(a)$ from its reference state to the preliminarily evacuated site, $\epsilon(H^+)_0$ that of $H^+(a)$ minus the electrostatic part which is taken as a constant in the absence of a specific adsorption potential, and 2.7 ev is the dissociation energy of H_2^+ in vacuum. It has been shown by Horiuti (88), on the other hand, that $\Delta E_P = -\alpha_w \Delta\phi$ from which we have

$$E_P = -\alpha_w \phi + \text{const}$$

where α_w is a positive proper fraction. Expressing $\epsilon(H)$ as

$$\epsilon(H) = (1/2)\,\Delta H_{ads} + \text{const}$$

the reversible work $\epsilon(H_2^+)$ is given finally from the above four equations as

$$\epsilon(H_2^+) = \alpha_H \Delta H_{ads}/2 - \alpha_w F\phi + R + \text{const} \quad [28]$$

The dependence of i_o on $-\Delta H_{ads}$ or ϕ is now discussed for the two limiting cases where the electrode surface is practically bare or practically fully occupied by $H_2^+(a)$, *i.e.*, $\theta_{\sigma+(0)} \simeq 1$ or $\theta_{\sigma+(H_2^+)} \simeq 1$, respectively.

1. $\theta_{\sigma+(0)} \simeq 1$; here we have $R = 0$. From Eq. [25a] and [26] to [28], we obtain

$$\log i_o = -\alpha_E\{\alpha_H \Delta H_{ads}/2 - \alpha_w F\phi\}/2.3RT + \text{const} \quad [29a]$$

2. $\theta_{\sigma+(H_2^+)} \simeq 1$; here we obtain from Eq. [25b], [26] to [28], [23b], [23c], and [13], assuming R = const,

$$\log i_o = (1-\alpha_E)\{\alpha_H \Delta H_{ads}/2 - \alpha_w F\phi\}/2.3RT + \text{const} \quad [29b]$$

Remembering that $-\Delta H_{ads}$ increases with decrease of ϕ as pointed out by Conway and Bockris (73), one can see from Eq. [29a] and [29b] that the increase of ϕ compensates more or less that of ΔH_{ads}, so that the log i_o's may run almost invariably with $-\Delta H_{ads}$ or with ϕ in either case of $\theta_{\sigma+(0)} \simeq 1$ or $\theta_{\sigma+(H_2^+)} \simeq 1$, in agreement with the results shown in Fig. 3 and 4 for the sp-metals. If we plot the work function against the heat of adsorption calculated by the Eley-Stevenson's method, we obtain the relationship with respect to the sp-metals as shown in Fig. 6. One can see that the work function decreases linearly with increase of the heat of adsorption with slope of −1.0. From this value, assuming $\alpha_H = \alpha_c$, we obtain 0.4 for α_w which again satisfies the necessary condition that α_w is a positive proper fraction.

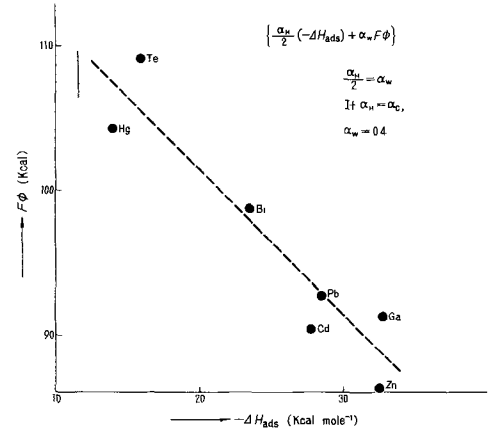

Fig. 6. $F\phi$ *vs.* $-\Delta H_{ads}$ with respect to sp-metals

Conclusion

1. Survey of the results on the hydrogen electrode reaction reported during the ten years previous to 1964 shows that the logarithm of the exchange current density, log i_o, is a periodic function of the atomic number for each long period.

2. The above periodic variation is primarily effected by the bulk property of electrode material but secondarily by the other factors such as the solution and the surface state of the electrode.

3. Two distinct relations are found between [log i_o] (the height of the dotted line in Fig. 1 at the atomic number of respective metals) and the heat of adsorption $-\Delta H_{ads}$, or the work function ϕ, where the [log i_o] value of d-metals depends linearly on $-\Delta H_{ads}$ or $-\phi$, while that of sp-metals runs practically invariably.

4. The above relations are qualitatively interpreted on the basis of the catalytic mechanism for the d-metals and of the electrochemical mechanism for the sp-metals respectively.

Acknowledgments

The present author wishes to express his sincere thanks to Professor J. Horiuti for his encouragement and stimulating discussions given throughout this work. He wishes also to express his thanks to Dr. I. Toyoshima for his deep interest and discussions on the present work.

SYMBOLS

i_o, activity	exchange current density, amp/cm^2
[log i_o]	height of the dotted line in Fig. 1 at the atomic number of respective metals
$-\Delta H_{atom}$	heat of atomization of metal, kcal/g-atom
$-\Delta H_{ads}$	heat of adsorption of hydrogen, kcal/mole
X_M	electronegativity of metal atom, ev
ϕ	work function of metal, ev
S_i	separation factor of isotope i
I	initial system of rate-determining step
$+$	critical system of rate-determining step
$\sigma+$	seat on the electrode surface which is available for $+$
$N+$	number of seats on electrode surface
A	surface area, cm^2
e	elementary charge
$\mu(\delta)$	chemical potential of species δ, kcal/mole
p^δ	Boltzmann factor of $\mu(\delta)$
$\epsilon(\delta)$	reversible work required to bring δ from its reference state to the preliminarily evacuated seat or site which accommodates δ, kcal/mole
q^δ	Boltzmann factor of $\epsilon(\delta)$
η	overvoltage, defined as $\{\mu(e^-) - \mu(e^-)_{eq}\}/F$, V
$\mathfrak{A}$	macroscopic assembly consisting of electrode, electrolyte solution, and 1 atm hydrogen gas at a definite temperature but comprising none of the critical system
$\mathfrak{A}^\delta$	macroscopic assembly formed by addition of δ to $\mathfrak{A}$
$\mathfrak{A}_{\sigma+(0)}$	particular state of $\mathfrak{A}$ with a particular seat $\sigma+$ being unoccupied with certainty
$\mathfrak{A}_{\sigma+(\delta)}$	particular state of $\mathfrak{A}$ with a particular seat $\sigma+$ being occupied by δ with certainty
$\Omega\mathfrak{A}$'s	partition function of $\mathfrak{A}$'s defined above
$\theta_{\sigma+(0)}$	probability of $\sigma+$ being unoccupied
$\theta_{\sigma+(\delta)}$	probability of $\sigma+$ being occupied by δ
α's	positive proper fractions
R	repulsive potential

Discussion

M. W. Breiter: A large amount of experimental data has been compiled for the interesting attempt to correlate the exchange current densities of hydrogen evolution on different metals with bulk properties of these metals. However, as discussed under A, the results in Fig. 1 and 2 of the paper may be interpreted in a different way. Some of the basic assumptions concerning the interpretation of the results in Fig. 3 and 4 are reexamined under B.

(*A*) As demonstrated[1,2] a "volcano"-type curve is to be expected when the exchange current densities of the Volmer reaction, of the Tafel reaction, and of the Heyrovsky reaction are plotted for different metals *vs.* the heat of hydrogen adsorption on these metals. If this result is accepted in contrast to the derivation of a linear relationship between the logarithm of the exchange current densities and the heat of adsorption in the paper, the three volcano curves in Fig. 1 may be easily correlated to $-\Delta H_{ads}$. The metals with relatively large values of $-\Delta H_{ads}$ are located on the left side of each of the long periods while the metals with small heat of adsorption are on the right side. Metals with intermediate values (d-metals) are located in the middle. A volcano type curve may be drawn through the points in Fig. 2. This results from the fact that ΔH_{ads} increases with ΔH_{atom}.

(*B*) Heats of adsorption calculated from Eq. [3] and [4] correspond to negligible hydrogen coverage in the gas phase ($\theta << 1$). Therefore these approximate values of $-\Delta H_{ads}$ should be used in the comparison between $-\Delta H_{ads}$ and exchange current densities only in the case that a small coverage has been established on the respective metal under H_2– evolution (as on mercury for instance). Experimental determinations [3,4] of $-\Delta H_{ads}$ as function of coverage show that the values of $-\Delta H_{ads}$ in Fig. 3 are too large for Pt, Rh, and Pd. The same statement applies to the d-metals Au, Cu, Ag, and the sp-metals Zn, Cd, Pd, Hg, Te since perceptible adsorption from the molecular gas was not found[5] at 300°K and $p_{H2} \approx 0.1$ mm Hg.

Any conclusions on the reaction mechanism from the results in Fig. 4 are very doubtful as it is demonstrated by two recent discussions[6,7] of electrode reactions and electrode material.

Hideaki Kita: It must be mentioned that the heat of adsorption is not the simple function of $-\Delta H_{atom}$ but also the function of the work function as shown by Eley and Stevenson.

Decrease of the heat of adsorption with coverage is taken into account in the present paper by R in Eq. [22b] of the text. This value is taken to be independent of electrode metal at $\theta_{\sigma^{\mp}(2H)} \simeq 1$ as a first approximation since R is the repulsive potential among hydrogen atoms on the surface, and the metal atoms would effect this potential only secondarily.

I agree with your opinion that IB metals, Cu, Ag, and Au, are poor adsorbents for hydrogen under very small pressure. However, in the region where we observe a Tafel relation, the situation is totally different as seen from the fact that, for example, the overvoltage of 0.4v corresponds to the very high pressure of 10^{16} mm Hg. The log i_o extrapolated from such conditions is generally a function of overvoltage and thus coverage (cf first paragraph in the reply to Dr. Schuldiner) which might be much higher than that obtained by the usual adsorption study of a gas-solid system. For the sp-metals, H_2^+-desorption mechanism is applied. It is open to question whether the surface is considerably covered with $H_2^+(a)$ or practically bare.

Roger Parsons: It is very useful to have confirmation of the Balandin volcano-like behavior of the exchange currents given by the two equations following [22b]. This prediction was first given independently by Professor Gerischer[8] and myself.[9] In fact, we gave the more general result that this type of behavior would occur for any mechanism involving adsorbed atomic hydrogen as an intermediate, and I extended the description to a heterogeneous surface described by Temkin's isotherm.

In regard to Dr. Kita's predictions for the mechanism involving slow discharge of the molecular hydrogen ion, I believe that equations [29a] and [29b] also lead to a Balandin volcano curve with heat of adsorption, because the coefficient α_w is likely to be very small. This coefficient in fact expresses the relation between the potential at the site of the reacting ion to the potential on the electrode and is given [according to ref. (88)] by

$$\alpha_w = \frac{1}{1 - X_p \cdot \frac{\partial}{\partial E_p}\left(\frac{\partial E}{\partial X}\right)_a + \frac{G F^2}{N_A R T}\textcircled{H}(1-\textcircled{H}) \cdot \frac{4\pi X_p}{D_p}} \qquad [1]$$

where X_p is the distance of the plane containing the centers of the reacting ions from the electrode, E_p is the average potential of this plane (bulk of the solution taken as zero), and D_p is the dielectric constant in this region. G is the number of sites in the plane at X_p, $\textcircled{H}$ is the fraction of these occupied by H^+ or H_2^+ ions and $1 - \textcircled{H}$ the fraction occupied by H atoms or empty. $(\partial E/\partial X)_a$ is the field strength at $X_p + dX$. Equation [1] may thus be written as

$$\alpha_w = \frac{1}{1 + \frac{C_D + C_{ads}}{C_H}}$$

where C_H is the capacity of the inner region $O < X < X_p$, C_D is the capacity of the diffuse layer, which is assumed in the model to begin at $X_p + dX$ and C_{ads}

is an adsorption capacity. It is well known that the diffuse layer capacity far exceeds the inner layer capacity except in very dilute solutions. Hence under the conditions of most hydrogen overvoltage experiments $C_D/C_H >> 1$. With G given the reasonable value of 10^{15} sites cm^{-2}, the value of C_{ads} is $6200\textcircled{H}(1-\textcircled{H})\mu F\ cm^{-2}$, so that C_{ads}/C_H will be large compared with unity except where H is very small or very close to unity. Hence it appears that α_w will be considerably less than the value of 0.5 required to substantiate the predictions of this theory given in the paper. It seems more probable that the exchange current of a hydrogen molecule ion mechanism depends on the heat of adsorption of hydrogen in the same way as that of the ion + atom mechanism discussed earlier by Gerischer and myself.

In fact there are objections to the hydrogen molecule ion mechanism which have been thoroughly discussed by many authors. One, to the model itself, is worth mentioning here. It seems improbable that the same adsorption sites will be occupied by H, H^+, and H_2^+ especially on metals such as mercury which adsorb hydrogen very weakly.

Finally, I should like to comment on the use of Eley's equation for weakly chemisorbed gases. This type of equation has had reasonable confirmation for gases which are strongly chemisorbed. However, it has an obvious defect for weak chemisorption since it predicts that for any metal M and any gas X_2 the M — X bond strength cannot fall below half the bond strength of X_2. Thus in the limit it makes an impossible prediction. Therefore, it seems reasonable to recommend extreme caution in applying this equation to weak chemisorption.

Hideaki Kita: It is unlikely at $\textcircled{H} \simeq 0$ or $\textcircled{H} \simeq 1$ that the coefficient α_w is very small. In the presence of a supporting electrolyte or in case of a concentrated solution, the factor $(\partial E/\partial X)_a$ in the above Eq. [1] of Dr. Parson's comment is expected to be small because of the lesser extent of the diffuse double layer. Thus the second term of the denominator of Eq. [1] might not be so large as pointed out in the comments. According to ref. (88) of my paper, the value of $\alpha_{w,o}$ defined as [Eq. (20.1α) of ref. (88)]

$$\alpha_{w,o} = 1/\left\{1 - X_p \frac{\partial}{\partial E_p}\left(\frac{\partial E}{\partial X}\right)_a\right\}$$

is estimated at 0.53 at 300°K for 1N uni-uni-valent neutral electrolyte solution, which is in agreement with the above expectation. The value of 0.4 for α_w obtained from the slope of Fig. 6 in my paper indicates that $\textcircled{H}$ is either very small or very close to unity.

The treatment in ref. (88) is developed in a general way by taking into account possible states of a physically identical site being either empty or occupied by one of H^+, H_2^+, and H exclusively. The probability of each state depends on many factors such as electrode material, overvoltage, solution, etc. It is concluded (88) that the reversible work, $w(\delta_i)$, required to fill up a specified, unoccupied site with δ_i [Eq. (3.4.ϵ) of ref. (88)] decreases in the following order on mercury

$$w(H) >> w(H^+) > w(H_2^+) > 0$$

Hence the probability of a site occupied by H on Hg might be extremely small.

I admit more or less an uncertainty included in the estimation of $-\Delta H_{ads}$ by the Eley-Stevenson method with respect to the sp-metals, although Eq. (3) of the text does not have the term corresponding to the bond strength of X_2. Nevertheless, the conclusion still holds valid, which is obtained from Fig. 3 of the text that the activity of the sp-metals does not depend on the heat of adsorption.

S. Schuldiner: Dr. Kita's compilation of log i_o's and comparisons with metallic properties are very interesting and useful. Such comparisons often appear to give real correlations, but on closer examination one realizes that limitations of data accuracy and assumed wide regions of linear behavior are really not justified. For example, the use of the extrapolated Tafel equation to zero overvoltage to obtain i_o is incorrect. The Hammett[10] relation to determine i_o correctly or Dolin, Ershler, and Frumkin's[11] $1/R_\eta$ as a characteristic of the rate of the over-all reaction would give much more reliable measures of catalytic activity. Of course, the range of orders of magnitude reflected in Fig. 1 are so broad that accuracy may not be too important. But accuracy is important in the other figures, because only with accurate data can one draw meaningful relations.

A fault of the Kita technique can be illustrated from his conclusion that the catalytic mechanism hold for d metals. Using the finding of several authors that a Pt electrode has an H_{ad} coverage of about unity and since Pt has a relatively low value of $-\Delta H_{ad}$, he concludes that other d metals with higher heats of adsorption must have essentially fully covered surfaces. Dr. Kita ignores the fact that Au has a very low H_{ad} coverage and that its $-\Delta H_{ad}$ is about the same as Pt.

In fact, one can justifiably draw one, or better, two parallel plateaus for the d metals from Pd to Re in Fig. 3. Just because the metals below Re appear to lie on a slope does not justify the extrapolation of this slope through the more active metals. A similar argument may be made for the data in Fig. 4. Here Ag, Fe, Au, Ni, and Re are essentially on a plateau and Rh, Pd, and Pt are on a higher plateau. Another factor not considered in this treatment is the change of $-\Delta H_{ad}$ with degree of coverage with H_{ad}. Also the fact that some metals (Pd, Pt, Fe, Ni, etc.) are known to absorb significant amounts of H atoms in their surface layers can in effect change both $-\Delta H_{ad}$ and the electrode material.

Hideaki Kita: 1. The value of log i_o obtained by the extrapolation of the Tafel line might not necessarily be in agreement with those obtained for example from i *vs.* η plot in the region near the reversible potential or the isotopic exchange reaction at $\eta = 0$. In case of the extrapolation, log i_o is expressed as

$$\log i_o = \log i - \eta \frac{\partial \log i}{\partial \eta}$$

which reduces to — a/b when Tafel line holds, but in general is a function of overvoltage or current density. Thus, the log i_o of the present paper is taken as a measure of the activity under the working condition of electrodes where the Tafel line is observed. Its accuracy depends on those of a and b.

2. About the coverage on Au, it must be mentioned that the kinetics on Au reported by many workers (Table I and Fig. 1 of the text) fluctuate very much and hence it might be required to re-examine.

3. The primary fact in Fig. 3 and 4 of the text is the separation of activities into two groups of d- and sp- metals. Further analysis of the tendency in the d-metals would require much precise values for log i_o and $-\Delta H_{ads}$.

4. The change of $-\Delta H_{ads}$ with coverage is taken into account in the present paper by R in Eq. [22b] of the text which is obviously zero in case 1 where

[10] Hammett, *J. Am. Chem. Soc.*, **46**, 7 (1924).

[11] Dolin, Ershler, and Frumkin, *Acta Physicochim. URSS*, **8**, 779 (1940).

$\theta_{\sigma^{\ddagger}(0)} \simeq 1$ and is taken to be independent of electrode metal as a first approximation in case 2 where $\theta_{\sigma^{\ddagger}(2H)} \simeq 1$ because the change of ΔH_{ads} is governed mainly by the repulsive interactions among hydrogen atoms on the surface.

5. There is a parallelism between the tendency to absorb hydrogen in the bulk of metal[12] and the heat of adsorption. However, the effect of surface layer absorption may be considered as a secondary one as seen from the results of nickel electrodes which were prepared by various kinds of treatments (Table I and Fig. 1 of my paper) and resulted in almost the same activity.

D. B. Matthews: The dependence of log i_o for the hydrogen evolution reaction on the electronic work function Φ reported by Professor Kita[13] differs from the correlation obtained by Matthews[14] which is in qualitative agreement with the work of Conway and Bockris.[15] The correlation obtained by Matthews[14] is shown in Fig. DM1.

The significance of such correlations is questionable in view of uncertainties in the value of Φ and i_o. Nevertheless, the correlation obtained by Matthews[14] is compatible with the present state of knowledge of the mechanism of the hydrogen evolution reaction. Thus the three groups of metals distinguishable in Fig. DM 1 correlate with three mechanisms of the hydrogen evolution reach on and with the three groups of protium-tritium separation factors measured on these metals.[16] Thus the slow discharge mechanism is believed to be operative on the low i_o group of metals (Hg, Pb, Cd, Sn, etc.), the slow electrochemical discharge mechanism on the medium i_o group of metals (Ag, Au, Ni, Fe, Cu, W, etc.) and the slow catalytic recombination mechanism on the high i_o group of metals (Pt, Pd, Ir, etc.)

The correlation shown in Fig. DM1 takes on even more significance when viewed in the light of the work of Conway and Bockris,[15] because the present correlation was obtained using the values of Φ assembled by Conway and Bockris.[15] Only the i_o values have been changed in order to take into account recent developments in technique which have led to new and/or better data. Thus the weak correlation obtained by Conway and Bockris[15] for the low i_o group of metals is greatly strengthened by the addition of data accumulated between 1957 and 1966.

The interpretation of these results remains the same as that proposed by Conway and Bockris.[15] The dependence of i_o on Φ arises primarily through the dependence of the heat of adsorption of atomic hydrogen on the electrode on Φ.

Fig. DM1. Dependence of the rate of hydrogen evolution on metal electrodes in acid solution on the electronic work function Φ of the metal.

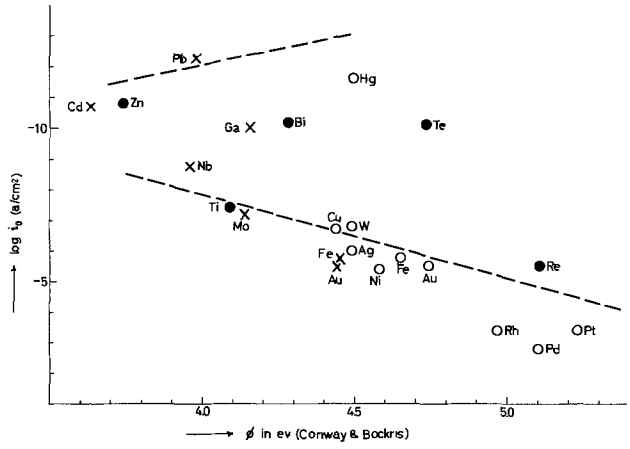

Fig. HK1. Log i_o vs. work function of electrode metals. Solid circles represent results not included in Fig. 1 of Conway and Bockris.[15]

Hideaki Kita: In Fig. HK-1 the present values of log i_o are plotted against the value of Φ quoted by Conway and Bockris.[17] Dotted lines in Fig. HK-1 are taken from Fig. 1 in the publication of Conway and Bockris.[17] From the comparison of these figures large difference can be noticed for the sp-metals. Namely, in the present paper the activity is taken as independent of Φ for the sp-metals, whereas in the paper of Conway and Bockris[17] and Fig. 1 therein, it is taken as dependent on Φ. Since the present values are obtained from Fig. 1 of my paper as averaged ones, they might be more reliable than those of Fig. 1 of Conway and Bockris.

Further division of the d-metals in Fig. 1 of my paper is questionable in view of uncertainties in the values of log i_o and Φ.

Frank Ludwig and *Ernest Yeager*: Dr. Kita has listed data for hydrogen discharge on platinum and platinized-platinum in Table I of his paper as well as in various figures. Some of these data probably need to be re-examined. Various electrochemists including A. N. Frumkin have suspected for some time that diffusion control may be involved in some and perhaps all of the hydrogen overpotential measurements on both bright and platinized-platinum in acid media reported in the literature. Consequently we have undertaken a study of hydrogen overpotential on bright platinum using the rotating disk-ring technique.[18] Preliminary results are now available.

The dependence of the overpotential measured on a bright platinum disk on rotation rate is shown in Fig. L-Y1. These measurements were made by the interrupter technique. Both activated and nonactivated electrodes exhibit a similar dependence. The usual precautions were taken to minimize impurity effects. The activation procedure consisted of maintaining the disk at a potential of +0.8v against a reversible hydrogen electrode in the same solution for 1 min, a

Fig. L-Y1. Dependence of hydrogen overpotential at bright platinum on rotation rate in 1*N* HCl at 25°C at constant current (—●—, activated platinum; —○— nonactivated platinum; slopes, 9.9 ± 0.9 mv/decade).

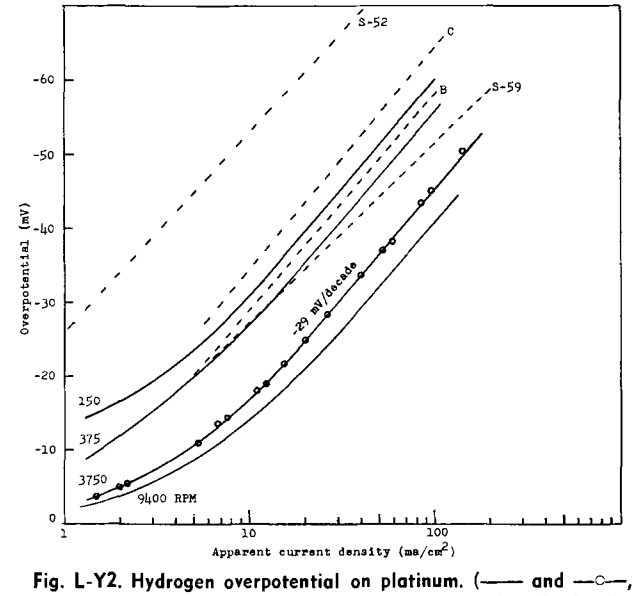

Fig. L-Y2. Hydrogen overpotential on platinum. (—— and —○—, present work at different electrode rotation rates, 1*N* HCl, bright, activated platinum at 25°C; S-52, Schuldiner[19] in 1952, 1*N* H_2SO_4, unstirred, bright activated platinum at 25°C; S-59, Schuldiner[19] in 1959, 1*M* H_2SO_4, bright activated platinum, stirred with 500 ml/min of gas flow through the solution at 25°C; C, Conway[20], 0.1*N* HCl, unstirred, platinized-platinum at 26°C; B, Bockris[21], 1*N* HCl, unstirred, bright activated platinum at 23°C).

condition insufficient to liberate any oxygen or chlorine and far less strenuous than that used by other authors for activation [see, for example, ref. (21)].

Figure L-Y2 shows the usual overpotential *vs.* log *i* plots for various rotation rates and also earlier data obtained by other workers. The curve for 3750 rpm was measured with increasing current at a constant rotation rate. Virtually identical results were obtained with decreasing current. The curves designated 150, 375, and 9400 rpm were calculated by applying corrections to the 3750 rpm curve with the correction determined from the dependence of the potential on rotation rate at constant current. Curves evaluated directly experimentally at other fixed rotation rates showed essentially identical slopes and similar dependence of the intercepts on rotation rates but reproducibility of the intercepts was somewhat poor.

In interpreting these results let us dismiss the idea that increased efficiency of mass transport of the hydronium ion to the electrode surface is responsible for the depression of the hydrogen overpotential with increased rotation rate. The concentration of HCl (1*M*) is just too high for this explanation to be valid. We believe that supersaturation of the solution with dissolved molecular hydrogen is involved. In particular the concentration of hydrogen in solution greatly exceeds the bulk value because of nucleation and transport problems, and increases with current density. This explanation was suggested by Yeager, Oey, and Hovorka[22] in 1953 and by M. Breiter *et al.*[23] in 1956. It should be understood that bubble formation relieves supersaturation only at the surface of the bubble and that substantial supersaturation is to be expected over the average of the electrode surface because of mass transport limitations associated with the diffusion of dissolved molecular hydrogen to the growing bubbles.

The —30 mv/decade slope can result from pure kinetic control with the desorption-recombination step rate determining, from pure diffusion control, or from mixed diffusion-kinetic control. To explain the present results on the basis of mixed diffusion-kinetic control, however, the rate of the back reaction must not be negligible and must in fact increase in direct proportion to the current density. Such is a reasonable possibility if the extent of supersaturation of the solution adjacent to the electrode is large compared to the bulk concentration of H_2 and the rate of transport of H_2 from the electrode surface is approximately proportional to the concentration of the dissolved H_2 at the electrode surface, *i.e.*

$$i = \kappa\,[(C_{H_2})_e - (C_{H_2})_\infty] = \kappa(C_{H_2})_e$$

with $(C_{H_2})_e >> (C_{H_2})_\infty$, where $(C_{H_2})_e$ and $(C_{H_2})_\infty$ are the concentrations of dissolved H_2 adjacent to the electrode and in the bulk of the solution, respectively, and κ is a proportionality constant. Our results indicate that, depending on the activation of the platinum, control may range from pure mass transport to combined mass transport-kinetic.

If the constant κ is directly proportional to $\omega^{-1/2}$, a slope of +15 mv/decade would be expected for plots of the type shown in Fig. L-Y1 for either pure diffusion control or combined diffusion-kinetic control provided the net rate is small compared to either the forward or reverse internal rates. The somewhat lower slopes evident in Fig. L-Y1 probably reflect complications associated with bubble formation in the vicinity of the electrode surface. Supersaturation is probably not uniform across the disk.

Only a few preliminary measurements have been made with the ring technique. The open-circuit potential of the ring exhibits approximately 30% of the overpotential measured on the disk by the interrupter method and is subject to a interesting oscillation phenomena which remains to be studied further. One would not expect the ring potential, however, to give a reliable indication of the average supersaturation at the disk surface since bubbles develop as the liquid spirals across the disk and the ring.

We believe that these observations are at least sufficient to require a re-examination of the whole question of the significance of now accepted overpotential measurements on platinum in acid media.

The authors acknowledge partial support of this research by the U.S. Office of Naval Research.

Roger Parsons: I would like to support the suggestion that the over-all process of hydrogen evolution

[19] S. Schuldiner, *This Journal*, 99, 488 (1952); *ibid.*, 106, 891 (1959).

[21] J. O'M. Bockris, I. Ammar, and A. Huq, *J. Phys. Chem.*, 61, 879 (1957).

[22] E. Yeager, T Oey, and F. Hovorka, *J. Phys. Chem.*, 57, 268 (1953).

[23] M. Breiter, H. Hammermaier, and C. Knorr, *Z. Elektrochem.*, 60, 34 (1956).

on active platinum electrodes is controlled by diffusion of molecular hydrogen. Results I obtained about 13 years ago[24] showed that the rate of the over-all reaction was unusually reproducible over a period of up to 16 days while the a-c impedance changed rather rapidly with time. Hence, it is probable that the over-all process does not depend on anything happening at the electrode surface. Similarly, the activation energy for the over-all process was about 5 kcal which is the order expected for a diffusion process. These results were interpreted somewhat differently in the paper cited. The more recent work by Frumkin's co-workers also supports the diffusion mechanism.

G. C. Barker (communicated): From discussion remarks there now seems to be recognition of the fact that the polarization observed with clean smooth platinum and with some other metals is largely concentration polarization resulting from nucleation difficulties in the formation of gaseous hydrogen. I wish merely to point out that bubble formation at a clean surface free from re-entrant cavities is made difficult by the fact that the metal surface is wetted by the solution.[25] With a more hydrophobic platinum surface produced by deposition of one or more monolayers of stearic acid, bubble formation occurs much more readily and, despite the contamination of the surface the overpotential during hydrogen deposition in unstirred solution, is often smaller than for a completely clean surface. Ready formation of bubbles during gas deposition at electrodes is often indicative of surface contamination.

B. E. Conway (communicated): An analysis of the type given by Kita was first developed by Ruetschi and Delahay[26] and by Conway and Bockris[27] who took into account the electronegativity difference between H and various metals in their calculation of MH bond energies in relation to the electronic work function ϕ_e. In the further development of relations between ϕ_e, the heat of adsorption of H and the exchange current i_o, or overpotential at a given c.d., it seems that more attention must be paid to the extent of H-coverage prevailing in the steady state at various metals and the effect this has on the ϕ_e and the current at a given potential. A treatment of this type given by Parsons[28] leads to a pyramidal relation between i_o and the standard free energy ΔG_H^o of adsorption of hydrogen for both ion discharge (I) and atom-ion desorption (II) mechanisms. However, as we have pointed out elsewhere,[29] it seems that I will tend to prevail with low coverage θ_H by H at numerically small or positive ΔG_H^o values with a consequent increase of i_o with decreasing ΔG_H^o, while II tends to prevail with the catalytic and adsorptive metals having more negative ΔG_H^o and the $i_o - \Delta G_H^o$ relation will then be on the descending part of the pyramidal relation, *i.e.*, i_o will decrease for a desorption step with increasing strength of adsorption of H as predicted previously.[27]

Hideaki Kita (communicated): The change of the heat of adsorption of hydrogen with θ_H is taken into account by R in Eq. [22b] of the paper, the value of which might be primarily determined by the nature of hydrogen atom, since R is the measure of mutual interaction among hydrogen atoms on the surface. Hence, in the first approximation R might be taken almost independent of metals and then be assumed to be constant at relatively high coverage. The relationship between log i_o and $-\Delta H_{ads}$ obtained under the above conditions with respect to the catalytic mechanism (case 2 of the paper) is qualitatively in agreement with the results (Fig. 3 of the paper) for the d-metals which are the catalytic and adsorptive metals.

The pyramidal relation between log i_o and $\{-\Delta H_{ads} + F\phi_e\}$ could be also expected as seen from Eq. [29a] and [29b] of the paper for the electrochemical mechanism where the rate is governed by the neutralization of the adsorbed hydrogen molecule ion $H_2^+(a)$, *i.e.*

$$H_2^+(a) + e^- \rightarrow H_2$$

However, the compensating effect between the changes of $-\Delta H_{ads}$ and ϕ_e by metals as discussed in the present paper depresses the above expected relation to a great extent, so that the log i_o may not apparently depend on $-\Delta H_{ads}$ or ϕ_e as shown from the results for the sp-metals (Fig. 3 and 4 of the paper). Hence it is concluded that the electrochemical mechanism is operative on the sp-metals.

The Pressure Coefficient of the Hydrogen Electrode Reaction

G. J. Hills and D. R. Kinnibrugh

Chemistry Department, The University, Southampton, England

ABSTRACT

The various criteria for the mechanism of the hydrogen electrode reaction are considered with particular reference to the pressure coefficient of the reaction rate. The techniques of studying electrode processes at pressures up to 1500 atm are described, and the volume of activation derived for the hydrogen evolution reaction has been found to be −3.4 ml mole^{-1}. This negative value is not in accord with either of the two mechanisms usually proposed for this reaction. It suggests that the rate-determining step is the stage

$$e(\text{metal}) \rightarrow e(\text{aq})$$

i.e., the emission and hydration of metallic electrons.

This paper is concerned with the measurement and interpretation of the pressure coefficient of the hydrogen evolution reaction on mercury. The reaction has been studied at moderate current densities and under applied hydrostatic pressures up to 1500 atm. The partial pressure of molecular hydrogen remained throughout at ~1 atm, and the principal effect of the applied pressure was to influence the free energy of activation *via* the volume of activation.

Pressure coefficients of reactions in condensed phases are peculiarly sensitive to the role played by the solvent, the free volume of which is a function of

changes in electric charge density, of degree of solvation, and of other intermolecular factors. By determination of the volume of activation for the hydrogen evolution reaction, it was hoped to delineate still further the exact mechanism of the rate-determining step and to offer additional evidence for one or other of the theories usually proposed.

Activation Parameters as Diagnostic Criteria

The mechanism of most reactions is discernible by analysis of the reaction order which, in effect, is to sense the response of the reaction to changes in the chemical potential of significant components. Additional intensive variables include the temperature and pressure of the system and, for charge-transfer reactions, the electrode potential. For electrode processes, the two coefficients $\left(\frac{\partial \ln i}{\partial \eta}\right)_{T,P,\mu}$ and $\left(\frac{\partial \ln i}{\partial \mu}\right)_{T,P,\eta}$ are the most commonly used criteria and, in the absence of complicating features, often delineate unambiguously the path of an electrode reaction. Complications can arise principally because the distribution of interfacial chemical potentials and that of the interfacial electrical potential are mutually interdependent. This is clearly to be seen in the hydrogen evolution reaction on mercury

$$2H^+ + 2e \xrightarrow[Hg]{} H_2 \qquad (A)$$

The electrochemical reaction orders of this electrode process have been summarized by Conway and Salomon (1) from which it is clear that in dilute solutions of hydrochloric acid

$$\left(\frac{\partial \ln i}{\partial \eta}\right)_{T,P,\mu} = \frac{F}{2RT} \qquad [1]$$

and that with an interfacial composition stabilized by supporting electrolyte,

$$\left(\frac{\partial \eta}{\partial \mu_{HCl}}\right)_{T,P,i} = \frac{RT}{F} \qquad [2]$$

Without supporting electrolyte, the corresponding reaction order is zero because the activity of hydrogen ions in the outer Helmholtz plane and the potential, ψ_1, of that plane are related by the theory of the diffuse double layer, such that

$$\left(\frac{\partial \eta}{\partial \mu_{HCl}}\right)_{T,P,i} = 0 \qquad [3]$$

These criteria by themselves do not distinguish between two possible rate-determining steps of the overall mechanism, A, namely

$$H^+ + e \xrightarrow[slow]{} H;\ 2H \xrightarrow[fast]{} H_2 \qquad (B)$$

$$H^+ + e \xrightarrow[fast]{} H;\ H + H^+ + e \xrightarrow[slow]{} H_2 \qquad (C)$$

The reaction scheme C has been strenuously advocated by Horiuti (2, 3) and others (4, 5) and requires that the interface be saturated with either atomic hydrogen or the hydrogen molecule ion, H_2^+, regarded as an intermediate in the second, slow stage of C. The experimental evidence for this is often denied, and additional evidence (6, 7) from studies of isotope separation factors has been adduced to support the former scheme, B. We have therefore been concerned to examine the other criteria to see if they support one or other of these proposed mechanisms.

Both the temperature and the pressure derivatives of the rate of the hydrogen evolution reaction can conveniently be examined in terms of the appropriate form of the transition state theory, as applied to this system, *i.e.*

$$i = nFa_{H^+}\frac{kT}{h}\exp-\frac{\Delta G_o^{\neq}}{RT}\exp-\frac{\alpha\eta zF}{\beta RT} \qquad [4]$$

The temperature derivative

$$\left[\frac{\partial \ln (i/T)}{\partial (1/T)}\right]_{a_{H^+},P,\eta}$$

then leads, approximately at least, to the enthalpy of activation (8). Before the details of the approximations are called into question, it may be noted that the observed value is unremarkably high, ~22 kcal mole^{-1} (9). It can be attributed to a number of energetic processes, which may include the desolvation of hydronium ions, the reaction of atomic hydrogen with its surroundings, and the emission of electrons from the metal. It involves intra- as well as intermolecular transformations, it is always a complex quantity and it is seldom a discriminating factor (10).

The corresponding pressure-derivative leads to the volume of activation, *i.e.*

$$RT\left(\frac{\partial \ln i}{\partial P}\right)_{T,\eta,a_{H^+}} = -\Delta V^{\neq} \qquad [5]$$

It is invariably the case that $\Delta V^{\neq}$ is controlled by intermolecular changes only, *i.e.*, it is particularly sensitive to changes in intermolecular separation and in solvent free volume. For reactions which involve a charged, activated state, *i.e.*, where an extra degree of polarity is generated, there is an associated negative volume of activation, and the reaction is therefore accelerated by pressure (11). It might be supposed that for neutralization reactions where ions are discharged, the opposite would be obtained, and we sought to confirm this.

The various assumptions underlying the significance of the derived volume of activation are discussed later. The fact that $\Delta V^{\neq}$ was in fact found to be large and negative required a re-examination of both mechanisms referred to above.

Experimental

The measurement of hydrogen overpotential at a mercury electrode is a simple and well-established procedure. The system must be scrupulously clean, and the worst effects of surface-active or electro-active impurities can be avoided if a freshly formed mercury electrode is used.

It was decided here that a dropping mercury electrode was undesirable, not so much because of the difficulty of controlling such a system inside a pressure vessel [this has been done twice before (12, 13)], but rather because of the associated charging current. Instead, an extruded mercury drop electrode was used which could be generated and rejected at will by an electromechanical device, which in turn could be remotely operated within a pressure vessel. Three problems therefore presented themselves: (*i*) the design of a high-pressure system; (*ii*) the construction of a miniaturized electrode cell assembly able to transmit hydrostatic pressures, and (*iii*) its coupling to a mechanically driven piston capable of generating accurately mercury drops of known surface area.

Apparatus.—The design and assembly of the high-pressure vessel, pump, gauges, and ancillary equipment presented few problems. The technique of so doing is described elsewhere (14, 15) and the present equipment is summarized in Fig. 1.

The cell presented many more problems and that shown in Fig. 2 was evolved only after many other designs had failed. It consists essentially of a number of concentric glass cylinders able to move telescopically in order to transmit the pressure from the pump oil to the solution within the cell. Additional seals of mercury prevented ingress of the oil into the cell either through the sliding joints or through the

fixed conical joints. All mercury exposed to the solution was maintained at a cathodic overpotential with relation to a large working anode of palladized palladium, presaturated with molecular hydrogen.

The extruded mercury drop electrode was generated at the end of a thin hooked capillary by movement of a stainless steel piston, through a Teflon bush, into precision-bore glass tubing which formed the base of the electrode capillary. This piston was driven by a micrometer plunger, the barrel of which was linked

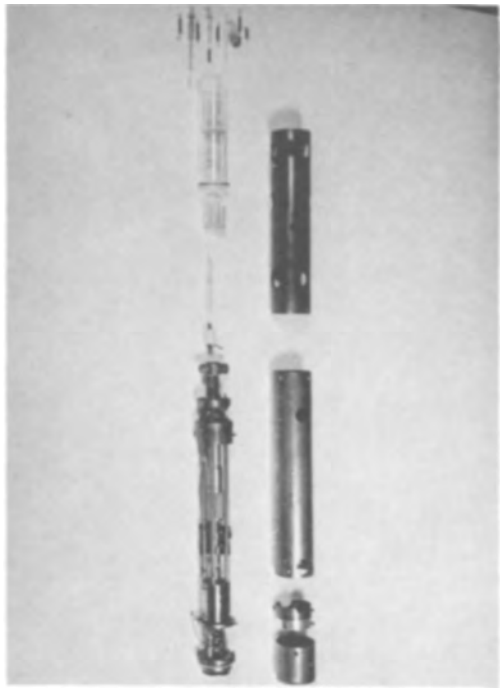

Fig. 3. Pulse-driven micrometer piston and cell

to a digital pulse-operated rotary solenoid (Ledex type 2E, N.S.F. Ltd.) by a micro gear-head (size 11, Vactric Control Ltd.) with a reduction ratio of 24.79:1. The apparatus is illustrated in Fig. 3 and its exact mode of operation will be described elsewhere (16). It need only be noted here that existing drops could be dislodged by an electric pulse applied to the electrode and that subsequently the volume of each extruded drop was directly proportional to the number of succeeding pulses applied to the drive. In terms of the characteristics of the rotary solenoid, the gear-head, the micrometer, and the area of the piston, the absolute volume of each drop could, in principle, be calculated. There is, however, always the possibility that when the drop breaks away, the mercury recedes into the capillary or a small drop is left. The first possibility was minimized by siliconing the capillary and by ensuring that the break-away was followed immediately by 5 pulses which then began a new drop. Even so, there was felt to be residual uncertainty as to the absolute area of each drop and to overcome the initial end-effects and the eventual distortion by sagging, it was decided to determine the current density from the linear part of the variation of observed current with surface area. For a constant density of mercury this is readily seen to be proportional to $n^{2/3}$, where n is the number of pulses.

The current flowing to the mercury electrode was determined potentiometrically, and the potential of the electrode itself was measured with respect to a microcalomel electrode joined to the cell by a very small "whisker" of drawn tubing filled with 1M KCl solution and serving as a Luggin capillary.

Procedure.—All the glass fitments were cleaned by boiling in perchloric acid solution. They were rinsed and soaked in conductivity water, dried in air, and assembled. The cell was mounted on the piston head, the capillary electrode filled with mercury (under vacuum) and the cell filled with hydrogen saturated oxygen-free solution. A short period of pre-electrolysis was allowed, using a sacrificial platinum electrode, and finally the system was sealed with mercury. It is seen in operation in Fig. 4.

The assembled apparatus was sheathed in a protective brass cylinder, to which electrical connections

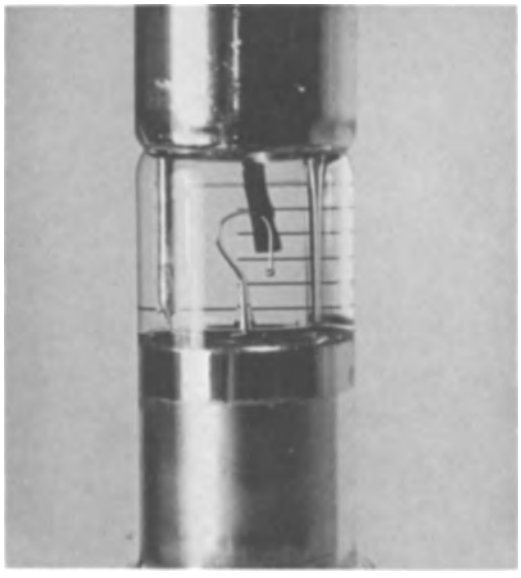

Fig. 4. Extruded mercury drop with upper and lower mercury seals

were soldered. This was inserted into the pressure vessel which was topped up with kerosene, sealed, and connected to the pump.

The proper functioning of the electrode was checked by various tests at 1 atm including the measurement of interfacial capacity. The pressure cycle was carried out in steps of 250 atm. At the highest pressures unstable conditions were often detected, and a new system had then to be used with another set of ascending pressures.

Results

The results relate to measurements made on the cell

$$Hg \mid 0.1M\ HCl \,||\, 1M\ KCl \mid Hg_2Cl_2 \mid Hg$$

Cathodic currents were measured as a function of overpotential, electrode area, and applied hydrostatic pressure.

At a particular value of overpotential and applied pressure, the current was measured at successive values of pulses, n, used to inject mercury into the electrode capillary. The observed current was a linear function of $n^{2/3}$, the slope of which was related, as above, to the current density. The results for one particular value of the overpotential are shown in Table I; the results for all values of η are summarized in Table II.

Table I. Observed currents, I, in μa at a fixed applied potential (—1.350v) as a function of electrode area and of applied hydrostatic pressure

	Pressure, atm				
n	250	500	750	1250	1500
15	1.68	1.92	2.18	2.20	2.63
25	2.45	2.69	3.04	3.07	3.60
35	3.16	3.34	3.85	3.81	4.40
45	3.79	3.99	4.48	4.53	5.16

65	4.89	5.33	5.60	6.17	6.54
75					7.17
$dI/dn^{2/3}$, amp $\times 10^{-7}$	3.20	3.34	3.53	3.60	3.90
i, $\times 10^{-4}$ amp cm^{-2}	1.26	1.32	1.39	1.42	1.54

Table II. A summary of observed current densities ($-\log_{10} i$) as a function of applied potential and applied hydrostatic pressure

Applied potential	Applied pressure, atm				
	250	500	750	1250	1500
−1.350	3.900	3.879	3.857	3.848	3.812
−1.400	3.418	3.383	3.391	3.370	3.334
−1.425	3.180	3.152	3.152	3.141	3.098
−1.450	2.934	2.913	2.906	2.883	2.857

The applied overpotentials are referred to the equilibrium potential of the above cell which is also pressure dependent. An allowance must be made for this pressure dependence and, in the absence of every relevant partial molar volume, it was determined experimentally using the cell

$$H_2,Pt \mid 0.1M\ HCl \,||\, M\ KCl \mid Hg_2Cl_2 \mid Hg$$

which utilizes a platinized platinum electrode and which has a more easily observed equilibrium emf. The HCl solution was saturated at 1 atm pressure, and it was assumed that its solution concentration remained, throughout the range of pressures, the same as that of the working cell.

The equilibrium emf of this cell was found to be a linear function of pressure and equal to 8.0×10^{-6}v atm^{-1}. This corresponds to a decrease in $\left(\frac{\partial \log i}{\partial P}\right)_{T,\mu,\eta}$ of 7.6×10^{-5} atm^{-1} in terms of the observed Tafel slope of 106 mv. This correction has therefore to be added to the observed pressure coefficient of current density. Results are summarized in Fig. 5 and 6 which show, respectively, Tafel slopes at 250 and 1500 atm, and the variation of (uncorrected) current density with pressure for four overvoltages. The average slope for all the measurements leads to a final pressure coefficient of cathodic current density of $13.8_5 \times 10^{-5}$ log^{-1} atm^{-1}.

Discussion

The significance of the pressure coefficient.—Although there is some scatter of the data presented in

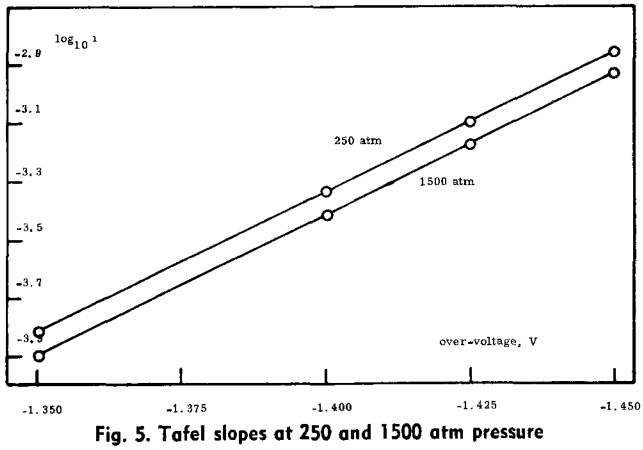

Fig. 5. Tafel slopes at 250 and 1500 atm pressure

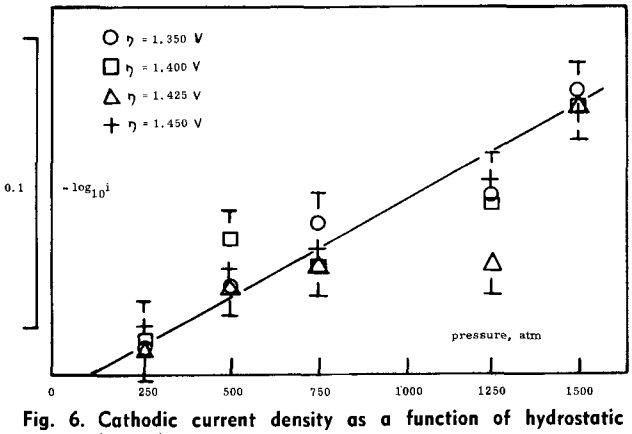

Fig. 6. Cathodic current density as a function of hydrostatic pressure; (|— —|) denotes limits of error.

Fig. 6, the results from a number of independent measurements confirm the sign and magnitude of the pressure coefficient. For a single, simple process this can then be translated into the corresponding volume of activation

$$\Delta V^{\ddagger} = -RT\left(\frac{\partial \ln i}{\partial P}\right)_{T,\mu,\eta} = -3.40 \pm 0.15 \text{ ml mole}^{-1} \quad [6]$$

The first requirement of the analysis is therefore to confirm that the coefficient relates predominantly to the single charge-transfer process under consideration.

There will normally be several contributions to the pressure coefficient of a rate process in solution, most of them not directly connected with the rate-determining step. Thus, the compression of the solution will increase the density and the volume concentration of all the components. The compressibility of water is not high, and over the range of pressures considered here, (~1500 atm), the total compression would not exceed a few per cent. A more serious change in composition arises in systems which are incompletely dissociated. An increase in pressure may then cause a large increase in ionic concentration because of the electrostrictive contraction of solvent resulting from ionization. This is no scope for such an effect in the present system.

Even if the stoichiometric concentration is not significantly altered by pressure, it is still possible that the absolute bulk activity of the reactants will change. The pressure-derivative of activity coefficient is related to the relative partial molar volumes, *i.e.*

$$2RT\left(\frac{\partial \ln \gamma_{\pm}}{\partial P}\right)_{T,\mu} = \overline{V} - \overline{V}_0 \quad [7]$$

For dilute solutions of hydrochloric acid, it may safely be estimated from the Debye-Hückel theory in terms of the pressure coefficient of solvent dielectric constant. Such a calculation suggests that this is also a very small effect.

It has also to be remembered that because the measurements are ultimately related to the standard hydrogen electrode, both working and reference electrodes have a common standard state. The thermodynamic effect of pressure on the bulk phase components is therefore zero.

The last and most important potential complication to the simple significance of $\Delta V^{\ddagger}$ is the possible effect of pressure on ionic distribution in the double layer. There is no evidence that pressure seriously disturbs the structure of the double layer, especially at cathodic potentials. The equilibrium between hydrogen ions in the bulk of the solution and those in the outer Helmholtz plane is an electrostatic one and is unlikely to be significantly influenced by pressure.

It may therefore be concluded that at high pressures, as at 1 atm, the rate of the hydrogen evolution reaction in dilute solution without supporting electrolyte is independent of the chemical potential of dissolved HCl and that the observed pressure-coefficient represents the volume of activation of the rate-determining process.

The significance of the volume of activation.—As indicated earlier, atoms and molecules are relatively incompressible whereas the free volume of a molecular assembly is sensitive to compressive stresses either from an externally applied pressure or from internal electrostrictive forces arising, for example, from the creation or introduction of charged centers. Thus, reactions in solution which proceed through a charged or polar activated state have negative volumes of activation and are therefore accelerated by applied pressure (11).

It is therefore surprising that the hydrogen evolution reaction, in which charge in the solution disappears, should also have a negative volume of activation. To appreciate this apparent anomaly, it is necessary to consider each aspect of the supposed rate-determining steps. The simple charge-transfer step

$$H^+(aq) \xrightarrow[Hg]{+e} H(ads) \quad (D)$$

can be resolved into at least three separate stages: (*i*) the dehydration of the hydronium ion and/or its transfer to the reaction site, (*ii*) the neutralization step in which a hydrogen atom is formed and then (possibly) adsorbed, (*iii*) the transfer of an electron from the mercury.

It is not easy to estimate the partial molar volume of hydration of a hydrogen ion. It may be noted with certainty that $\overline{V}^{\circ}$ for HCl does not differ from that of, say, NaCl. Mukerjee (17) and Conway and Desnoyers (18) have gone further than this and have reasonably argued (from size considerations and suitable extrapolations) that $\overline{V}^{\circ}_{H^+(aq)} = -5$ ml g-ion^{-1}. Whatever the significance of this result, it is evident that dehydration of the hydronium ion involves a large increase in volume.

Hills and Payne (19) made a detailed study of the effect of the transfer of ions into the double layer at mercury electrodes. They showed that when a specifically adsorbed ion displaces water molecules from the inner layer, there is a considerable increment of volume of the system. It follows that any similar process involving the transfer of hydrogen ions or atoms to the metal surface will likewise involve a positive volume change.

It may, however, be remarked that migration of hydrogen ions at 25°C requires a negative volume of activation, ~ −3 ml mole^{-1} (20), and that transfer of hydrogen ions from the outer Helmholtz plane to the reaction site might therefore involve the same process of contraction. This argument is untenable because the negative volume of activation of protonic migration is common to most ions and is associated with disengagement of water molecules from the structured solvent in the path of the ion (20).

Finally, some speculation may be made concerning the size of the hydrogen atom. There is evidence that this is a relatively large molecule and, for example, its disappearance in the gaseous recombination reaction

$$H^+ + H \rightarrow H_2^+ \quad (E)$$

is accompanied by a large decrease in volume (21). The volume of formation of hydrogen atoms would no doubt be influenced by its degree of adsorption on the metal surface. This cannot be a large factor on mercury and even if the process of adsorption largely nullified the partial molar volume of formation of atomic hydrogen, it is still difficult to see how the neutralization of the hydrogen ion can give rise to other than an increment of volume and *inter alia* to a positive volume of activation.

It remains to consider the transfer of electrons from the metal. Only if this is the predominant stage of the neutralization reaction and one with a large negative volume change, could adequate compensation for the other contributions be achieved. It is possible that the appearance of negative charges in the inner part of the double layer could give rise to further degrees of electrostriction, although the experimental evidence of Hills and Payne (19) is against this. They showed that the net volume of the interface (*i.e.*, of the inner layer) was independent of the degree of polarization beyond −10 μC cm^{-2} and therefore inferred that the closest packing of the water molecules had already been achieved. However, there is a distinction between a uniform potential gradient and that arising from discreet electronic charges, and it is therefore necessary to consider in greater detail the interaction between electrons and water. Before this is done, some

consideration will be given to the second possible rate-determining charge-transfer step, namely the ion-atom step

$$H^+_{(aq)} + H \xrightarrow[Hg]{e} H_2 \qquad (F)$$

This reaction continues to be advocated in spite of strong arguments against it. Experimental evidence for the existence of the intermediate ion, H_2^+, is strong, although frequently denied. It has been estimated (5) that in the gaseous state, the free energy change of reaction B is ~ -60 kcal mole^{-1}. This would accommodate the energy of desolvation of the proton and allow a high concentration of H_2^+ in solution. The small size of this ionic species has already been commented on and, if the activated state has a similar structure, then the observed negative volume of activation could readily be accounted for. Indeed, the pressure coefficient reported here might be considered to be the strongest evidence so far for the ion-molecule mechanism.

This mechanism also satisfies all the other criteria provided the activity of atomic hydrogen or of the hydrogen molecule ion is constant, *i.e.*, independent of potential. In the present formulation this implies a "coverage" of unity. Observed interfacial capacities of mercury in HCl solution allow no significant coverage, *i.e.*, displacement of water molecules. although they would not be inconsistent with a high concentration of H_2^+. Even so, the activity of H_2^+ is still dependent on the steady-state concentration of hydrogen atoms. If this activity is potential-dependent, and there is no reason why it should not be, the electrochemical reaction order could not lead to the Tafel slope observed.

One must therefore return to the slow ion-discharge step, A, and reconsider the evidence for electron emission as the principal feature of the rate-determining step. The inner layer adjacent to the electrode is known to be populated only with water molecules; cations are excluded and anions are further repelled. The main act of charge transfer can therefore be considered to be the transfer of electrons from the metal surface to the outer Helmholtz plane.

The possibility that classical electron emission is the rate-determining step of the hydrogen evolution reaction has been considered earlier (22), but rejected on the grounds that it leads to impossibly small rate constants. A rough calculation in terms of the thermionic work function of mercury, 4.5 ev (23) and the probable depth of the potential well of a hydrated electron, $\sim$ 2 ev (24) leads to an energy of electron abstraction of $\sim$60 kcal mole^{-1} which is nearly three times the observed activation energy. There is, however, the possibility of tunneling and, in spite of recent arguments to the contrary (6, 7), Christov (25, 26) maintains that this is an important feature of the hydrogen electrode reaction. Bockris (22) argues otherwise and suggests that the "work of forming the transition state is almost entirely made up of that of stretching the bond between the cation and the hydration sheath." If this were so, it would certainly be detected as a positive volume of activation as it is in most translational processes (27, 28).

Support for the independent existence of the aquated electron has recently come from several sources (24, 29, 30). The electrochemical consequences have been examined by Yurkov (31) and further evidence for its importance in electrode processes is furnished by the work of Barker (30) who studied photoemission currents at the mercury electrode in aqueous systems. In contrast with electrode systems *in vacuo*, the energy barrier associated with electron abstraction in the present system is strongly potential-dependent, since almost all of the potential gradient occurs in the double layer and the effective work function is altered. In the absence of electron scavengers, the photoemission current was negligible, since the hydrated electrons were continuously returning to the electrode. In acid solutions, an appreciable photocurrent was observed and was attributed almost entirely to electron-capture by the hydronium ion which is known to be a fast reaction [$k = 2.36 \times 10^{10}$ mole^{-1} sec^{-1} (30)]. The partial molar volume of the electron in water is not known, but in keeping with every other small ion, it must be negative. The transfer of electrons through the inner layer to the reaction zone beyond would therefore also require a negative volume of activation and this would not conflict with the results from the equilibrium studies of Hills and Payne (19). The pressure coefficient reported here is therefore advanced as further evidence for the participation of the aquated electron in electrode processes.

The assumption that the rate-determining step of the hydrogen electrode reaction is simply

$$e(\text{metal}) \rightarrow e(\text{aq})$$

would go far to explain the great sensitivity of this reaction to the nature and state of the metal surface, to the presence of adsorbed material and, even for a pure metal surface, to its thermionic work function. It follows that the succeeding steps of the reaction are all fast. Electron capture by the hydronium ion leads to hydrogen atoms which react immediately and exothermically with further hydronium ions to form the hydrogen molecule ion. This in turn also acts as an electron scavenger and reacts immediately to form molecular hydrogen. This mechanism is in accord with much of the independent experimental evidence; it does not invalidate any of the other criteria mentioned above and the results of the analysis of reaction order remain the same. At least, in the case of the hydrogen evolution reaction on mercury, the heat of adsorption of hydrogen on mercury no longer appears a necessary feature of the argument. This will conflict with many other theories and it may be that they will need to be re-examined in the light of this fresh experimental evidence.

Discussion

Dennis B. Matthews: First let me correct some wrong impressions one might obtain from the paper by Hills and Kinnibrugh. The impression has been given that the work of Bockris, Srinivasan, and Matthews[1] excludes electron tunneling. Such is not the case, however, as the theory of charge transfer at electrodes proposed by Bockris and Matthews[2, 3] is strongly dependent on electron tunneling. Also, the work of Christov[4, 5] is concerned with proton tunneling and not with electron tunneling.

Although by far the major contribution of this paper is the new experimental results, I would like to touch on several points regarding the interpretation of the results, in particular on the newly proposed mechanism

$$Me^- \rightarrow e^-(aq) \qquad [1]$$

First, such a mechanism would lead to no hydrogen isotope effect for the hydrogen evolution reaction, in contrast with experiment. Second, the energetics of reaction [1] are such as to lead to a negligible rate of reaction. Consider the potential energy profile for electron transfer from the metal to the solvent (Fig. DM 1).

The electronic work function Φ for mercury is about 4.5 ev while the solvation energy of the electron L_e is about 2 ev or less. This means that in order for the electron to undergo tunnel transfer from the metal to the solvent, it must undergo excitation from the Fermi level by about 2.5 ev or greater ($\simeq$60 kcal mole^{-1}) in contrast to observed value of 21 kcal mole^{-1} for the activation energy of the hydrogen evolution reaction on mercury.

Fig. DM 1. Potential energy profile for electron transfer from a metal to the solvent.

L. I. Kristalik (communicated): Very interesting results on the dependence of the cathodic hydrogen evolution rate on hydrostatic pressure have been obtained in the Hills and Kinnibrugh paper, but it seems to me that the interpretation of these data is not rigorous. The authors maintain that the derivative of the logarithm of the current with respect to pressure at a constant overvoltage is directly determined by the change in the volume on activation

$$RT\left(\frac{\partial \ln i}{\partial p}\right)_\eta = -\Delta V^{\neq} \qquad [1]$$

In reality, however, $\Delta V^{\neq}$ determined by Eq. [1] is not the true value of the change in the volume on transition from the H_3O^+ ion in the double layer and the electron in the metal to the activated complex, but some effective value $\Delta V_r^{\neq}$. The true volume change during activation is determined not by the pressure dependence of the current at a constant overvoltage but by that at a constant potential

$$RT\left(\frac{\partial \ln i}{\partial p}\right)_\phi = -\Delta V_{id}^{\neq} \qquad [2]$$

At a constant overvoltage, however, the change in the pressure results in that of the total potential difference equal to the change in the equilibrium potential.

The situation is in many respects similar to the relations to be encountered in the investigation of the temperature dependence of the electrode processes rates where the determinable real activation energy (at η = const) does not represent the true energy change of the transition from the initial to the activated state (ideal activation energy), but differs from it by a quantity proportional to the latent heat of the over-all electrode process, which cannot be determined experimentally.[6]

Likewise, $\Delta V_r^{\neq}$ differs from $\Delta V_{id}^{\neq}$ by a similar quantity associated with the pressure dependence of the equilibrium potential.

It can be readily seen that

$$\left(\frac{\partial \ln i}{\partial p}\right)_{\phi} = \left(\frac{\partial \ln i}{\partial p}\right)_{\eta} - \left(\frac{\partial \ln i}{\partial \phi}\right)_{p} \frac{d\phi_e}{dp}$$

$$= \left(\frac{\partial \ln i}{\partial p}\right)_{\eta} + \frac{\alpha F}{RT}\frac{d\phi_e}{dp} \quad [3]$$

where ϕ_e is the equilibrium value of ϕ.

$$F\phi_e = \mu_e + \mu_{H3O^+} - \mu_{H2O} - \frac{1}{2}\mu_{H_2} \quad [4]$$

It follows from Eq. [2]-[4] that

$$RT\left(\frac{\partial \ln i}{\partial p}\right)_{\eta} = -\Delta V_{id}^{\neq} + \frac{\alpha}{2}\overline{V}_{H_2} + \alpha\overline{V}_{H2O} - \alpha\overline{V}_{H3O^+} \quad [5]$$

The same result can be obtained by the differentiation of the kinetic equation of the H_3O^+ ions discharge. The derivative $d\mu_e/dp$ is omitted in Eq. [5]. It is difficult to estimate it accurately, but its value can be shown to be not large.

The partial molar volume of dissolved hydrogen is $\overline{V}_{H_2}$ = 26 cm³/mole [7] $\overline{V}_{H2O} - \overline{V}_{H3O^+} = -\overline{V}_{H^+}$ can be estimated to be +5 cm³ [ref. (17), (18) in Hills and Kinnibrugh's paper].

From these values, α = 1/2 and the experimentally obtained value $\Delta V_r^{\neq} = -RT(\partial \ln i/\partial p)_{\eta} = -3.4$ cm³, we have

$$\Delta V_{id}^{\neq} \simeq -3.4 + 6.5 + 2.5 = +5.6 \text{ cm}^3/\text{mole}$$

Although the accuracy of the determination of this value is not very high, there is no doubt that $\Delta V_{id}^{\neq}$ is positive. Therefore, it is not necessary to assume the electron emission from the metal to be the slow step of the process. By the way, it does not seem possible that the dependence of the overvoltage on *p*H of the solution could be explained on the basis of this assumption.

G. J. Hills: The issue raised by Dr. Krishtalik is an important one. The fact that we have already taken it into account was no doubt obscured by our definition of η as "overvoltage." In fact, throughout this paper, η is the overpotential, and the scale of overpotential was derived from the observed pressure coefficient of the reference electrode cell

$$\text{Pt, } H_2 \mid \text{HCl} \,\|\, \text{1M KCl} \mid Hg_2Cl_2 \mid \text{Hg}$$
(partial pressure, 1 atm)

It follows that the overpotential is equated to the derived overvoltage for the cell

$$\text{Hg} \mid H_2, \text{HCl} \mid \text{Pt}$$

assuming only that ohmic and concentrational overpotentials are negligible.

The advantage of this procedure is that the standard states of both working and reference electrodes are the same and that there are ∴ no differential pressure effects on the thermodynamic properties of the system. In more specific terms, changes in chemical potential of the initial and final states embracing the transition state are compensated by corresponding changes in the reference electrode.

There is no question of differentiating at constant potential. The appropriate differential is

$$\left(\frac{\partial \ln i}{\partial P}\right)_{T,\eta}$$

Roger Parsons: I think that this is an elegant piece of experimental work, and the results are presented in the most satisfactory form, namely as the result of pressure changes on the rate at constant overpotential. However, I believe that the interpretation requires some modification.

If the rate is expressed in terms of the overpotential, then the corresponding free energy of activation may be expressed in a form such as

$$\Delta G^{\neq} = \mu^{\neq} - (1-\alpha)\mu_{H^+} - \frac{\alpha}{2}\mu_{H_2}$$

where $\mu^{\neq}$ is the standard chemical potential of the activated complex, μ_{H^+} that of the hydrogen ion solution, μ_{H_2} that of the final product, molecular hydrogen, in this case dissolved in solution, and α is the cathodic transfer coefficient. This equation is quite general independent of the mechanism of the hydrogen electrode reaction.

The pressure coefficient of the electrode reaction rate at constant overpotential is then

$$-RT\left(\frac{\partial \ln i}{\partial P}\right)_{\eta} = \left(\frac{\partial \Delta G^{\neq}}{\partial P}\right)_{\eta} = \Delta V^{\neq}$$

$$= \overline{V}^{\neq} - (1-\alpha)\overline{V}_{H^+} - \frac{\alpha}{2}\overline{V}_{H_2}$$

It is likely that the largest contribution to $\Delta V^{\neq}$ is $\overline{V}_{H_2}$, the partial molal volume of dissolved hydrogen, and this would explain the negative value experimentally found whatever is the mechanism.

The usual assumption that the discharge mechanism is rate-determining on mercury would suggest that $\overline{V}^{\neq} - (1-\alpha)\overline{V}_{H^+}$ is approximately zero if one uses the approximate model proposed by Temkin[8] in which the electrical properties of the activated state correspond to a charge of $(1-\alpha)$ (cf. the Marcus and Hush theories of electron transfer reactions).

G. J. Hills: Dr. Parsons raises a question similar to that of Dr. Kristalik but not so easily answered. The initial and final states are undoubtedly pressure-dependent and the terms $\overline{V}_{H^+}$ and (especially) $\overline{V}_{H_2}$ are finite and large.

However, both terms contribute to the corresponding two pressure coefficients $(\partial E/\partial P)_i$ and ∴ $(\partial \ln i/\partial P)_{\eta}$ of the reference electrode.

This apparent compensation may not, however, completely eliminate the contributions to $\Delta\overline{V}^{\neq}$ from the initial and final states. On qualitative grounds it is clear that to whatever degree the transition state

[6] M. I. Temkin, *Zhur. fiz. Khim.*, 22, 1081 (1948).

[7] I. R. Krichevsky and A. A. Ilyinskaya, *Zhur. fiz. Khim.*, 19, 621 (1945). No corrections have been made here for a certain dependence of $\overline{V}_{H_2}$ on pressure and solution composition (change in the activity of dissolved H_2) since such corrections cannot change the orders of magnitudes of the values obtained. A more detailed analysis, which cannot be given here, shows that the corrections associated with the activity coefficients of H_3O^+ and H_2O are almost exactly compensated for by the change in the activity coefficient of the activated complex (L. I. Krishtalik, *Elektrokhimiya*, In press; *Zhur. fiz. Khim.*, In press).

[8] M. I. Temkin, Trudy Soveshchaniya po Elektrokhimii Moscow, 181 (1953).

volume is influenced by the partial molar volumes of H^+ and H_2, the fact that these are, respectively, negative and positive is support for the view that the

$$2H^+ \xrightarrow[Hg]{2e} H_2$$

conventional mechanism should have a positive volume of activation, which experimentally it has not.

Dr. Kristalik also raises the important issue of the pH dependence and *inter alia* of the 1st-order reaction mechanism required to explain it. I would agree that the simple step

$$e_{Hg} \rightarrow e_{aq}$$

would not by itself satisfy this criterion. It is likely, however, that the rate-determining process requires a particular cavity or solvent cage for the aquation of the electron to be permanent and that this is a function of hydrogen ion concentration in the outer Helmholtz plane. A similar agreement would presumably be required to sustain the observed H_2/D_2 separation factor.

R. A. Marcus: I should like to comment on the interpretation of the extremely interesting data of the authors on pressure effects for electrode reactions, and to suggest that the experimental data may well be consistent with conventional mechanisms.

For simplicity, we consider first the case of a simple redox reaction. The derivative of a theoretical expression[9] for the rate constant with respect to pressure may be equated to the corresponding derivative of the expression $k_{rate} = (kT/h)\exp(-\Delta F^{\ddagger}/kT)$. As shown later, one finds thereby that ln k_{rate} depends on pressure only through a term $E(P) - E_o'(P)$, if work terms w^r and w^p are neglected and if [1] is assumed.

$$V^{\ddagger} \cong \frac{1}{2}(V^r + V^p), \text{ when } \alpha = 0.5 \text{ and } w^r \cong w^p \cong 0 \quad [1]$$

[$E(P) - E_o'(P)$ is the cell potential minus the "standard" cell potential for the prevailing medium, pressure P, and temperature. V^r, V^p, and $V^{\ddagger}$ are the volumes of the system before reaction, after reaction, and in the activated state, respectively. α is the transfer coefficient. w^r and w^p are the work terms to transport the reactant and the product to the electrode, respectively.]

The assumption embodied in Eq. [1] can be tested by plotting ln i *vs.* $E(P) - E_o'(P)$ and seeing if all points lie on the same curve, regardless of P. (i = current of forward step.) Deviations permit the determination of a "volume excess" at $\alpha = 0.5$, $V^{\ddagger} - \frac{1}{2}(V^r + V^p)$. It should be noted that approximation [1] is merely a rough conjecture, designed hopefully to account for major volume changes such as those discussed by the authors.

When there is more than one step in the reaction the preceding remarks apply to each step if all properties mentioned are taken to be those for that step. [For any step one then plots its ln k_{rate} *vs.* its $E(P) - E_o'(P)$.]

When the reaction is not a simple redox one but is some proton or other transfer there is some reason to believe that an equation of the same functional type (*i.e.*, the same as Eq. [3] below) applies to k_{rate} for any step, at least when $\alpha \cong 0.5$. Now, however, the E_o' is one corrected for any change of standard translational entropy during the reaction because of adsorption or because of gain or loss of particles.[10] One would again conclude that ln k_{rate} (at a given surface coverage) for any step would depend only on $E(P) - E_o'(P)$ for that step if assumption [1] were valid.

A preliminary examination of the authors' Fig. 5 and 6 suggests, interestingly enough, that a plot of ln i *vs.* $E(P) - E_o'(P)$ follows the above behavior, using $E_o'(P)$ for the over-all reaction. To be sure, the more detailed significance of this result depends on the mechanism, and, in particular, on the difference between the pressure dependence of $E_o'(P)$ for the slow step and that for the over-all reaction and, in some cases, on the pressure dependence of surface coverage.[11] We omit any detailed discussion here, although one could readily formulate such a treatment, utilizing mechanistic considerations in the literature[11] and, if one wished, using [1] as above.

When the work terms w^r and w^p are not negligible, they exhibit a pressure dependence because of the usual volume changes caused by bringing the charges together. By differentiation of a theoretical expression for k_{rate} containing these terms[12] and utilization of the preceding results (*e.g.*, in the following notation, utilizing the value found for $d\lambda/dP$ from data when $w^r \simeq w^p \simeq 0$) one obtains an expression for the pressure dependence of the current. Some model could then be introduced for dw^r/dP and dw^p/dP.

To conclude these remarks we justify below the statement regarding a plot of ln i *vs.* $E(P) - E_o'(P)$ for a redox reaction. At any temperature and pressure, the rate constant of the forward step, k_+, for reaction [2] was given by [3], when $w^r \simeq w^p \simeq 0$.[9]

$$A_{ox} + e - M \underset{k_-}{\overset{k_+}{\rightleftharpoons}} A_{red} + M \quad [2]$$

$$-kT \ln k_+/Z = \frac{1}{4}\lambda(1 + \Delta/\lambda)^2 \quad [3]$$

where $Z \cong 10^4$ cm sec^{-1}. $\Delta = ne(E - E_o')$ at pressure P. λ is an intrinsic reorganization term which depends on differences of properties of A_{ox} and A_{red} (*e.g.*, differences of bond lengths in the coordination shell, etc.). k_- is obtained from k_+ by replacing Δ by $-\Delta$.

When $\Delta << \lambda$, the transfer coefficient is 0.5 and, in this region, differentiation of [3] yields [4] since $d\Delta/dP = V^p - V^r$.

$$-kT(\partial \ln k_+/\partial P)_E = \frac{1}{4}d\lambda/dP + \frac{1}{2}(V^p - V^r) \quad [4]$$

However, from the relation $k_+ = (kT/h)\exp(-\Delta F^{\ddagger}/kT)$ one also finds that the left side equals $V^{\ddagger} - V^r$. Thus

$$\frac{1}{4}d\lambda/dP = V^{\ddagger} - \frac{1}{2}(V^r + V^p) \quad [5]$$

Hence, when assumption [1] is made, $d\lambda/dP$ vanishes and, one sees from [3], the statement has been proved for reaction [2]. The actual value of $V^{\ddagger} - \frac{1}{2}(V^r + V^p)$ can be evaluated from ln i *vs.* $E(P) - E_o'(P)$ plots. Points for different pressures will fall on different though parallel lines if this "volume excess" is nonzero. On theoretical grounds $d\lambda/dP$ is expected to be small for redox reactions, an examination of the expression[9] for λ shows.

In concluding these remarks I should like to add that the authors are to be congratulated for their interesting and, for electrochemistry, pioneering study of pressure effects. It would be useful to make simi-

[9] R. A. Marcus, *J. Chem. Phys.*, 43, 679 (1965), or earlier papers of the author cited therein.

[10] Such a correction was made [*J. Chem. Phys.*, 43, 3477 (1965)] for E_o' in reactions of solvated electrons, because their reactions with simple redox systems involve a loss of one particle and so a decrease in the standard translational entropy of the system.

[11] In considering possibilities of mechanism we have been guided by the excellent discussion in R. Parsons, *Trans. Faraday Soc.*, 54, 1053 (1958). When the slow step on mercury is the discharge reaction, $H_3O^+ + e(Hg) \rightarrow H_2O + H - Hg$ (see Parsons) and when the surface coverage is small, only the pressure dependence of the difference between the $E_o'(P)$ of the slow step and that of the over-all reaction, $H_3O^+ + e(Hg) \rightarrow H_2O + \frac{1}{2}H_2 + Hg$ is relevant. This term depends on $V^{M-H} - V^M$, where M denotes electrode and surrounding solution.

[12] Ref. (1), Eq. (82).

lar studies for redox systems at electrodes, since they may be simpler to understand.

B. E. Conway: I do not think that it is necessary for the volume of the final state molecule H_2, or even of adsorbed H, to be considered in the basic kinetic interpretation of volumes of activation $\Delta V^{\neq}$. Only the volume change between the initial state and the activated state is involved in any kinetic process. The volume change must, however, be deduced with proper consideration of any pressure variation of the reference electrode potential ϕ (which will be determined by the volume change in the single electrode process $2H_3O^+ + 2e \rightleftharpoons 2H_2O + H_2$, at equilibrium), as I have pointed out elsewhere.[13] This matter, Professor Hills claims, has apparently been taken into account by calculating his pressure effects at constant overpotential. We also pointed out in the above reference the similarity, noted by Kristalik here, to the problem of temperature effects at constant overpotential η which leads to the determination of an apparent activation energy discussed by Temkin.[14] It is the pressure dependence of the hydrogen electrode potential which we considered previously[13] which introduces the partial molar volumes of H^+ and H_2 considered by other contributors to this discussion.

The negative $\Delta V^{\neq}$ may, in fact, be connected with penetration of the proton from the outer layer where it is in the "$H_9O_4^+$" configuration, to a more compressed configuration in the inner layer[15] at the interface of the electrode. In H_2O itself, the H_3O^+ entity in $H_9O_4^+$ occupies effectively a relatively large volume since it tends to promote structure around it as the $H_9O_4^+$ hydrogen bonded complex. It seems possible that under conditions near the surface where the water is already electrostricted by the double-layer field,[16] the volume of the hydrated proton may well become decreased. Such an effect may not, however, be expected to apply to other cations owing to the special relation of the hydrated proton to the water structure.[17]

Some Problems in Electrodeposition

J. A. Harrison, S. K. Rangarajan, and H. R. Thirsk

Department of Physical Chemistry, The University of Newcastle-upon-Tyne, England

ABSTRACT

The investigations described refer predominantly to the study of the kinetics of electrocrystallization by potentiostatic methods. Experimental and theoretical investigations have been made over many years of both metallic, cathodic, and nonmetallic, anodic deposition processes, and it is shown how these are beginning to fit into a framework. Theoretical work from the school is described in which a fairly complete description (including diffusion in the solution and on the surface), of an electrode process has been formulated. This is given for potentiostatic conditions and for the application of small a.c. and is discussed in general terms. Some possibilities arise for a stricter examination of the diffusion phenomena.

Fundamental studies of electrodeposition, or more specifically electrocrystallization, in the sense of including both anodic and cathodic processes is a major interest of but few schools of electrochemistry. Quite recently a number of reviews of work have been published, and two in particular give a very wide survey of the present position (1, 2), so wide, in fact, that the nonspecialist might, with apparent justification, query the usefulness of the present paper. At the outset, we therefore wish to make the point that, to-date, little of the speculation concerning the fundamental mechanisms relevant to deposition has been proved; our object in describing in outline, in the present paper, the more recent work of the Newcastle School includes, as one of its major aims, the hope that the expression of our own ideas will stimulate a continued and unbiased examination and development of both theory and experiment.

Nonmetallic Deposition

Much of the experience in the study of electrocrystallization, forming the background for the present paper, has arisen through studies of nonmetallic deposition explored, in the main, by potentiostatic techniques in the nonsteady state. The method was first employed successfully in the examination of a well-known phase change, that of $PbSO_4 \rightarrow PbO_2$ (3), and the same method was subsequently used for direct deposition, in the investigation of the deposition of α and β lead dioxide on to platinum (4). The power of the experimental procedure lay in the fact that the growth of the new phase proceeded on isolated sites with, initially, no overlapping and, moreover, the types of deposit formed were in many cases ideal for electron optical studies defining topology, structure, and epitaxy.

Methods of handling the kinetic data, obtained as current time transients, using the ideas of a potential dependent nucleation process followed by growth according to a simple geometric scheme and indeed, analogous to methods of treating solid reactions, has been adequately described in a number of papers; we quote here the most important (4, 5, ref. 2, p. 168-201).

In the above publications the ideas concerning the evaluation of the values of the potential dependent rate constants for one-, two- and three-dimensional centers growing freely by electrodeposition were formulated together with a discussion of cases with a random distribution of growth centers, in which the effect of overlapping could be dealt with in order to permit the kinetic evaluation of the current/time transients.

Two references above refer to specific systems (3, 4), the others are quite general in application. Other papers relevant to single systems are: (*a*) formation of calomel on mercury (7), (*b*) formation of cadmium hydroxide on cadmium amalgams (8), (c) electrodeposition of γ MnO_2 on platinum (9); formation of thallous chloride on thallium amalgams (10).

Reactions on mercury and mercurous amalgam substrates have been particularly informative kinetically, and the deposits lend themselves to electron optical studies. A general account of such studies was given very recently (11). We shall complete this section of the paper and deal with very recent work with such systems in which some further progress and confirmation in interpretation has been made.

Further reference to the mechanism of formation of calomel on mercury is necessary. This process was discussed structurally in some detail in earlier work (12, 13). From the kinetic evidence (7) it was deduced that the highly oriented deposit was formed on the surface by the laying down in that position of layers of a monomolecular order in height. This finding was at variance with the conclusions arrived at much later by other workers using a galvanostatic-ellipsometric technique (14) who based their conclusions on a dissolution-precipitation sequence. This involved the dissolution of mercury as Hg_2Cl^+, which partially disproportionated to Hg^o and mercuric species and when Hg_2Cl^+ attained a certain critical surface concentration, calomel was supposed to precipitate in the solution. A reinvestigation of the process was thought necessary in view of the importance we attach to our general proposals for electrocrystallization in these systems; this has now been completed, and we consider that the earlier proposals (7) are confirmed. The system was examined, in the first place, potentiostatically and also by impedance measurements. The potential-time profiles given in Fig. 1 were used, selected on the basis of the galvanostatic and potentiostatic transients shown schematically in Fig. 2.

Figure 2A and B are galvanostatic transients (the dotted line is the reversible potential for the system) and C and D potentiostatic transients. According to Ives *et al.* (16a, b, c) transients of type A were supposed to be due to the anodic dissolution of mercury, involving mainly mercuric entities, and B to the formation of a layer (monolayer) of "chloromercury" with subsequent growth or rearrangement of this layer.

Calomel was considered to form by the disproportionation of the "chloromercury." In the work by

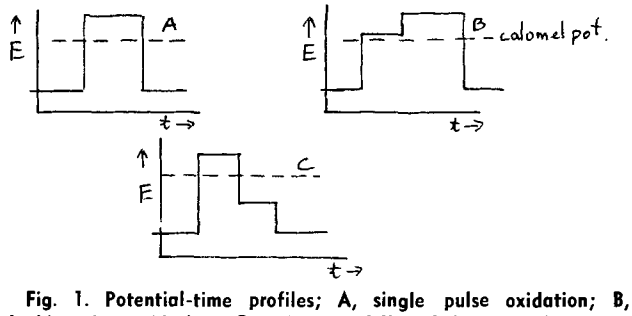

Fig. 1. Potential-time profiles; A, single pulse oxidation; B, double-pulse oxidation; C, oxidation followed by reduction.

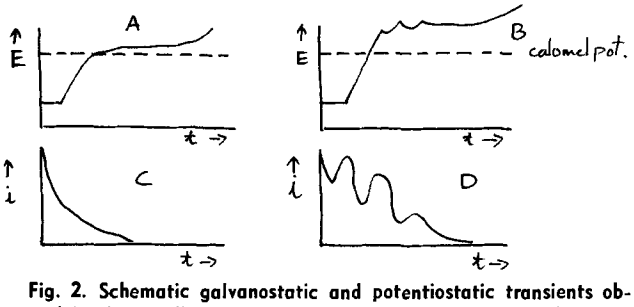

Fig. 2. Schematic galvanostatic and potentiostatic transients observed in the anodic polarization of Hg in Cl^- solutions. A and C under dissolution conditions; B and D for electrocrystallization conditions.

Armstrong *et al.* (15), for potentials held at less than the calomel reversible potentials, and particularly in solutions of concentration 2M, linear plots of i. vs. $t.^{-1/2}$ were obtained with t as little as 100 μsec indicative of mass transfer control for dissolution transients. At intermediate potentials +ve to the reversible potentials single peaks were obtained with an integrated charge of about 500 μC; at higher potentials this peak split into several peaks as in the earlier work of Bewick *et al.* (13). The nature of the complex associated with the diffusion process was examined by impedance measurements.

The current for the diffusion controlled process followed the equation

$$i = nFC_oD_o^{1/2}/\pi^{1/2}t^{1/2} \qquad [1]$$

where C_o is the concentration of the complex at the electrode surface. From the potential dependence of the current at constant time a two-electron transfer process was indicated.

In confirmation of these results from the Faradaic impedance, at lower frequencies the value of the Warburg impedance may be written as

$$|Z| = RT/n^2F^2C_o(D_o\omega)^{1/2} \qquad [2]$$

Again, from the variation of Z with potential, $n = 2$. From an assumption of $D_o = 10^{-5}$ cm^2 sec^{-1} estimates of $(C_o)_{\eta=0}$ were made giving satisfactory evidence for $HgCl_4^{2-}$ as the dissolving species. This evidence seems to be in essential agreement with (16) but makes the proposal of the Hg_2Cl^+ intermediate of Bockris (15) and Hills and Ives (17) unlikely. The evidence reaffirms the previous conclusions (7) concerning the mechanism of the electrocrystallization of the calomel by two-dimensional growth in monolayers with the additional ideas that, as in the case of mercuric oxide formation (18 and below) and thallous chloride (10) the multilayer peaks may well be due to the generation and growth of screw dislocation by a Frank-Read mechanism.

A somewhat similar impedance study was made in the examination of the growth of mercuric oxide on mercury (18) where again there is evidence for the dissolution of a mercury complex at a potential just negative to the Hg/HgO reversible potential; a similar analysis of the impedance results identifies this as an uncharged $Hg(OH)_2$ complex, which continues to be produced even when a HgO monolayer is formed. The covalently bonded, orthorhombic HgO is formed in these experiments with the (010) plane parallel to the mercury surface, that is the zig-zag HgO chains lie in the surface (Fig. 3).

The crystallite size was extremely small ($< 2\mu$ in diameter). An extension of the double pulse method employed previously to nucleate crystals at a high potential and then grow them on at lower potentials was used. Providing, and this is our usual assumption, that the slow stage in the growth process is the incorporation of the material at the periphery, then

$$i'/i = k'/k \quad \text{where } i \text{ and } k \text{ correspond to } \eta_1 \qquad [3]$$

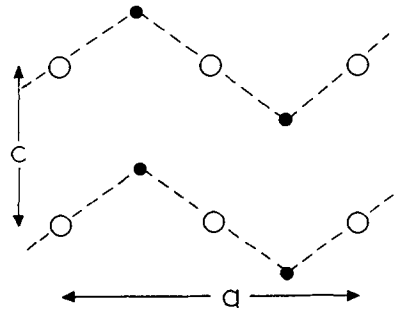

Fig. 3. The (010) plane of mercuric oxide: • O; ○ Hg

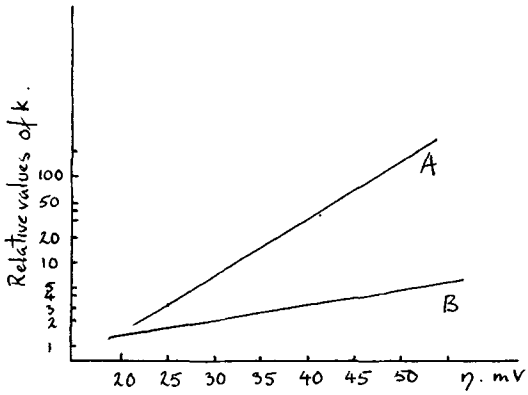

Fig. 4. Relative values of growth constant for HgO in M NaOH: A, multilayer rising section; B, multilayer falling section.

and i' and k' to η_2; $\eta_1 > \eta_2$. The potential was changed just before the current maximum since it was considered that the proportion of the current due to other causes was a minimum at that point and i' was taken as the minimum current after the potential step. Relative values of k are plotted in Fig. 4 as a function of potential.

The problem of the multilayer peak, as observed in the growth of TlCl (10) mercurous oxalate (19) and calomel (7, 15) is discussed further in this paper. A somewhat more elaborate model is chosen than in any previous treatment of the geometric model [see ref. (4), (5), (2)], in that two crystal growth rate constants, k_1 parallel to the electrode and k_2 orthogonal to the surface, are employed. t^3 dependence rather than the t^2 dependence follows for cylindrical growth.

The equation is of the form

$$i = nFk_2[1 - \exp(-\pi M^2 k_1{}^2 A t^3/3\rho^2)] \exp(-\pi M^2 k_1{}^2 A t^3/3\rho^2) \quad [4]$$

(M = molecular weight, ρ density, A, the nucleation rate constant) so that, for example, the plot in Fig. 5

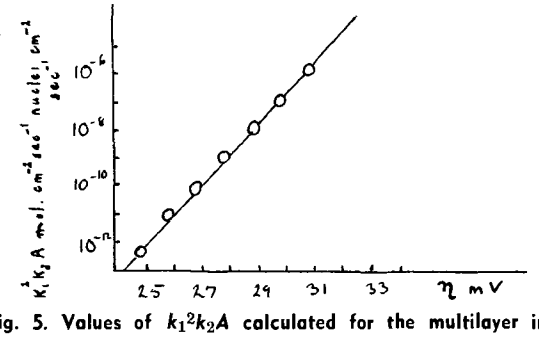

Fig. 5. Values of $k_1{}^2k_2A$ calculated for the multilayer in 5M NaOH from data as for Fig. 6.

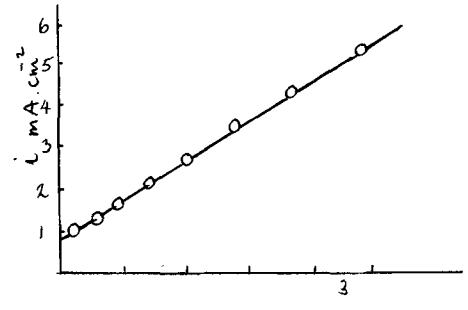

Fig. 6. Plot of i. vs. t.^{3} (unit of base 13.3 x 10^{-3} sec^3). η = 26 mv, 5M NaOH.

is of $k_1{}^2k_2A$ derived from Fig. 6. k_2 can be found from the relation from the transient, that is the current at the maximum $i_m = nFk_2/4$. We are still confronted with the difficulty of separating k_1 and A which in many of our studies appears as a composite constant k_1A, and this problem has been discussed elsewhere, for example (11).

To date we have not made any significant experimental determination in this problem excepting in the possibilities referred to briefly in the section on relaxation methods. An appendia to the paper on mercuric oxide does however discuss overlap with growing centers in three-dimensional systems with two growth constants; this will not be discussed further here.

Relaxation Methods

Relaxation methods, to be discussed here, are still potentiostatic in character but operate through a programmed pulse train. From the description of experiments involving the nonsteady state of electrode processes and designed to determine rate constants of fast reactions, it emerges clearly that the electrocrystallization process is in competition with diffusion processes; indeed, the measurable effect due to the electrode reaction, in which the interest lies, may be small.

It is intended, in this section, to give a brief outline of recent work on nucleation and crystal growth using as an illustration the deposition of PbO_2 on platinum showing how potentiostatic relaxation techniques may be employed; a more complete account is in the course of publication (20).

From solutions of the differential equations for an assumed reaction sequence, expressions for the variation of observable parameters in terms of the rate constants of the reaction steps may be obtained; the chosen parameters are, yield of product, and time.

It is helpful to consider steady and nonsteady states of the following reaction scheme

$$A \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} B \xrightarrow{k_2} C \quad [5]$$

where any one of the rate constants k_1, k_1', and k_2 may be potential dependent. The steps are linked through the coverage θ of the adsorbed state B.

The time-dependent coverage is given by

$$\Omega\, \partial\theta/\partial t = k_1C_A(1 - \theta) - k_1'(\theta) - k_2\theta \quad [6]$$

where Ω, in moles cm^{-2}, is the saturation coverage for a monolayer, k_1' and k_2 are in moles cm^{-2} sec^{-1}, k_1 in cm sec^{-1}, C_A in moles cm^{-3}, and it is assumed the rate constants are independent of coverage, *i.e.*, no site interaction.

In the steady state the over-all rate R may be written as

$$R = k_2\theta = k_1k_2C_A/(k_1C_A + k_1' + k_2) = \partial C_c/\partial t$$

At low coverage, when $k_1' > k_1\, C_A$, $R \simeq k_1k_2C_A/k_1'$ [7]

and at high coverage, when $k_1C_A > k_1'$, $R \simeq k_2$ [8]

For the nonsteady state it is assumed that in the simplest case $\theta = 0$ at the beginning of each potential pulse. The time dependence of the coverage θ is then obtained by integration of Eq. [6].

$$\theta = k_1C_A/(k_1C_A + k_1' + k_2)[1 - \exp\{-(k_1C_A + k_1' + k_2)t/\Omega\}] \quad [9]$$

and the rate of formation of product is

$$R = k_2\theta \quad [10]$$

Equation [10] has a steady-state value identical with Eq. [7] and gives for the characteristic a (relaxation) time τ

$$\tau = \Omega/(k_1C_A + k_1' + k_2) \quad [11]$$

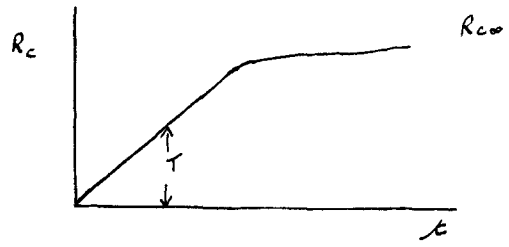

Fig. 7. Sketch of the steep approach of the yield to the steady-state value.

It will be seen that the rate constant of the over-all reaction depends on the smallest k_1, that is the slowest step of the sequence, but the relaxation time is determined by the largest k_1. Thus, by means of a relaxation technique it is possible to determine the rate constants of the fast steps in reaction sequences, particularly if the over-all rate is low.

To examine the time dependence of the yield of product, $C_c = 0$ when $t = 0$, and integration of [10] gives

$$C_c = k_1k_2C_At(k_1C_A + k_1' + k_2) - k_1k_2C_A\Omega/(k_1C_A + k_1 + k_2)^2 [1-\exp-\{k_1C_A + k_1' + k_2)\ t/\Omega\}] \quad [12]$$

where C_c is the integral yield after time t, the length of the applied pulse.

If R_c is the yield per second, *i.e.*, $R_c = C_c/t$

$$R_c = R_{c\infty} - R_{c\infty}(\tau/t)(1-\exp-t/\tau) \quad [13]$$

where $R_{c\infty}$ is the steady-state value given by [7]. A sketch of the function showing the steep approach of the yield to the steady-state value is shown in Fig. 7.

In practice it is usually impossible to measure the yield for a single pulse, and so a suitable program of repetitive pulses is employed. R_c is calculated from the total yield and the over-all time of polarization T, where $T = \Sigma t$. In choosing the pulse program it is important to select a duty ratio such that the condition $\theta = 0$ at the beginning of each pulse is satisfied.

The relaxation time may be estimated from plots of yield *vs.* pulse time as in Fig. 7. The potential and concentration dependence of the relaxation times so obtained provide tests on the interpretation of reaction mechanisms in addition to those obtained by more conventional measurements, the distinction being that relaxation measurements refer to the fast steps in the mechanism.

The application of the technique may be illustrated by considering the electrodeposition of PbO_2. We will consider a mechanism suggested in an earlier paper.

$$OH^- \rightleftharpoons OH_{ads} + e \quad (a)$$

$$OH_{ads} + Pb^{2+} + OH^- \rightarrow PbO_2 + 2H^+ + e \quad (b)$$

This is formally analogous to the discharge-electrochemical mechanism of the hydrogen evolution reaction. In examples of crystal growth there is, however, a complicating factor in that the free formation of the lattice must be preceded by the nucleation of growth centers. This nucleation process proceeds by the same mechanism as the lattice formation, but the activation energy will be modified by the electrochemical surface free energy of the embryonic nucleus. The formation of nuclei will therefore have a different (longer) relaxation time than the crystal growth process. The study of these relaxation times should enable a more detailed model to be built up of the initial stages of aggregation.

The nucleation of lead dioxide was studied with the pulse train shown in Fig. 8a; that of the subsequent

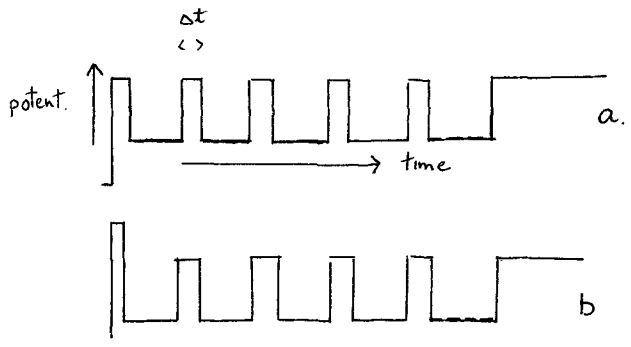

Fig. 8. Pulse trains to examine nucleation and crystal growth

growth by that of 8b. For the experiments the electrolysis of an aqueous solution of molar sodium acetate and molar acetic acid was undertaken for a series of polarization pulse times at the potential of + 2.3 or + 2.5v and the base potential of + 120 mv. Since nucleation requires a higher activation energy than crystal growth, an initial single high potential pulse was applied to form a number of nuclei on the electrode surface (4). This pulse was followed by a train of pulses having a lower amplitude which tested the relaxation of crystal growth. As the pulse length was below that required to form nuclei, further nucleation could be neglected during this polarization. The base potential chosen was low enough to permit the relaxation of the growth of the centers but high enough to maintain the stability of the deposit. The value was varied to examine possible effects. The final section of the profile was a continuous application of the polarization potential.

The current-time curves observed for the formation of lead dioxide, in the absence of the section of the pulse train used to investigate the relaxation effects, Fig. 8a, b, are illustrated in Fig. 9a, b, [see ref. (20)]. The initial section of the plots can be shown to be proportional to t^3, and this is due to the combined effects of the progressive nucleation of growth centers coupled with the three-dimensional growth of these centers (2). If nuclei are first formed by an initial short polarization at a high potential, the initial section of Fig. 9b is proportional to t^2, *i.e.*, three-dimensional growth of a fixed number of centers. The relaxation of nucleation and of crystal growth can be simply investigated by using the form of these curves. If the pulse train shown in Fig. 8b precedes the polarization at the upper potential and the total length of the polarization "on" time (Σt) is chosen to be equal to that required to reach point B in Fig. 9a then, if there has been no relaxation of the formation of nuclei, the initial current on finally maintaining the continuous polarization will correspond to that at point B, and there will be no current-time transient. On the other hand if relaxation has been complete, then

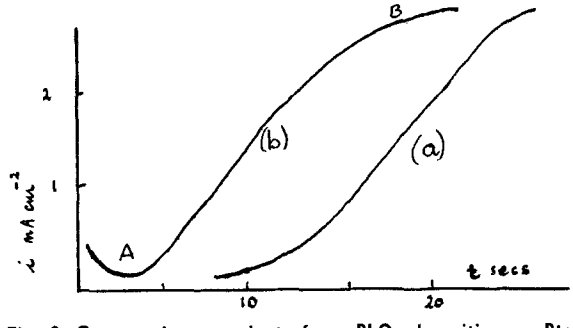

Fig. 9. Current time transients for α-PbO_2 deposition on Pt: (a) at constant η = 275 mv; (b) nuclei preformed at η = 425 mv for 0.1 sec and then grown at 275 mv. Sol. 0.1M $PbAc_2$, M NaAc, M HAc.

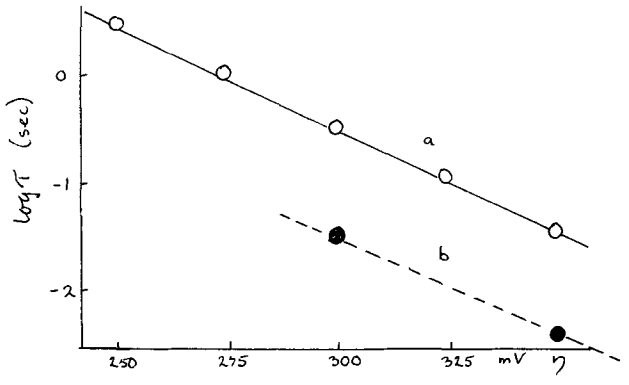

Fig. 10. Effect of base potential and η on relaxation times: a, base potential +50 mv; b, base potential +100 mv.

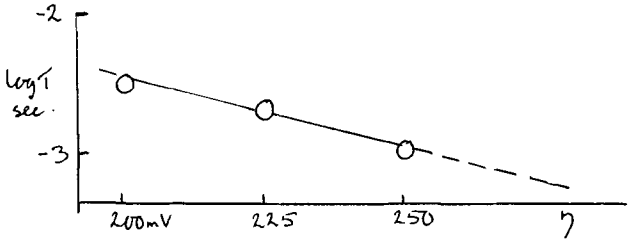

Fig. 11. Variation of relaxation time of crystal growth of α-PbO_2 with overpotential. Nuclei formed at 425 mv for 0.1 sec.

the system will be found initially at point A and the complete current-time curve of Fig. 9a will be traced. In practice the relaxation is sharp.

The variation of the relaxation times with polarization potential is illustrated in Fig. 10 for a solution 0.1M with respect to lead acetate and molar with respect to acetic acid and sodium acetate. The lines given refer to two different base potentials, positive to the reversible βPbO_2 potential.

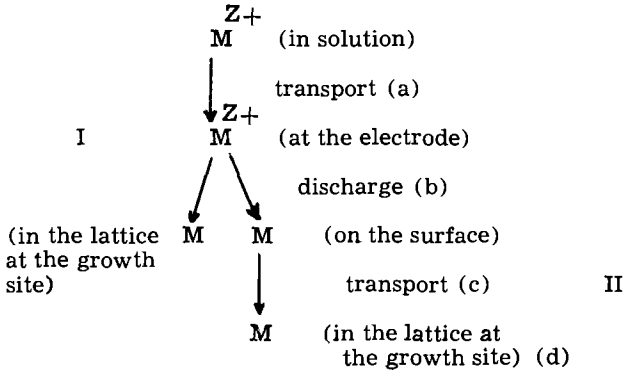
The relaxation of lattice growth was measured in a similar manner to that of nucleation. In the event of no relaxation, the initial current on maintaining the final steady potential of Fig. 8b was that corresponding to point B on Fig. 9b, while in the event of complete relaxation, the current corresponded to A and the complete curve was again traced. The variation of the relaxation time with potential is illustrated for the same solution in Fig. 11.

A variation of the relaxation time with overpotential is observed for the crystal growth of lead dioxide, showing that the fastest process is again a charge transfer step. In this case the relaxation time however decreases with overpotential so that the forward direction of the charge transfer, that is, the discharge reaction, has the highest rate constant. According to the mechanism which has been suggested, *i.e.*, Eq. (*a*) and (*b*), this could be assigned to either of the stages. Further information can, however, be obtained from the fact that the relaxation is only observable over a restricted potential range. According to the arguments which have been given above, this can be explained if the highest rate constant is assigned to a preequilibrium, the slowest step succeeding this equilibrium. For such a mechanism the relaxation can only be observed for a restricted portion of the potential range in which a significant yield due to the over-all reaction may be obtained. The fastest step must therefore be attributed to the forward reaction of Eq. (*a*), and crystal growth takes place in a layer of adsorbed hydroxyl radicals present at high coverage. The same conclusion was drawn previously from an examination of the concentration dependence of the over-all rate constants.

Some Problems Concerning the Electrocrystallization of Metals

Metal electrodeposition is a complex phenomenon, and electrodeposits formed on solid metals have a complicated geometry. It is therefore not surprising that little is known in detail about the primary processes involved. In the past, inference about the kinetics of electrodeposition has usually been made from stationary current voltage measurements. In some cases galvanostatic potential-time curves and, rarely, potentiostatic current-time curves have been measured. Some measurements have been made using a-c techniques. On solid metals, the results are not easily interpreted. This has led us to start to investigate the kinetics of metal deposition on mercury and graphite substrates where the initial stages of crystal growth can be observed. We have also attempted to show the limitations of the older measurements theoretically. What follows is for the most part an abbreviated review of this work and our personal approach to the problem.

Theories of the mechanism of the electrodeposition of metals have tended to follow vapor phase studies and assume that lattice growth occurs from mobile adsorbed species (adatoms) on the surface. They are formed electrochemically at the metal solution interface by discharge of the "aqueous metal ion." An alternative route into the lattice is by direct deposition of the metal ions at the growth sites (step lines). Diagramatically the two mechanisms for a general electrochemical reaction are as follows:



Mechanism I will be discussed first in view of the experimental work available for soft metals, and then work on the transition metals. Mechanism II is then considered when (*i*) the lattice growth step (d) alone is rate determining; (*ii*) deposition (b) and surface diffusion (c) are important. It is also shown in this section how this theory (which assumes a parallel step line model) can be extended to include the lattice growth step (d).

Recent experimental data, some of which are now under investigation, are mentioned, to show how the theory is related to measurement.

A recent review (1) has assumed that the adatom mechanism II occurs exclusively. Evidence for this mechanism however derives from the low melting point metals, mercury, lead, zinc, cadmium, tin, and silver. These metals have rather weak surface bonds, and adatoms might be expected to form easily and be mobile on the surface. Unfortunately, these metals have a large exchange current and diffusion in the solution can become the main mode of transport to the growth site. Gerischer (21) (Mehl and Bockris have carried out essentially similar experiments) has shown that, if silver is dissolved potentiostatically in a stirred silver perchlorate solution to a stationary current, then the concentration overpotential is in excess of that calculated from the Nernst diffusion theory for linear diffusion. This extra overpotential has been

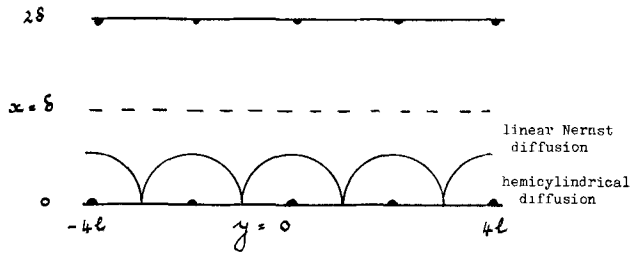


Fig. 12. Model used to calculate the effect of the discrete nature of an electrode surface along x = 0. The line sinks are separated by impervious material.

attributed to adatoms on the surface. However, this is not necessarily true as material can also arrive at the site by hemicylindrical diffusion.

In Fig. 12 the surface of a metal on to which ions are being electrodeposited by mechanism I is visualized as a row of line sinks, the step lines, where material is incorporated on to the lattice. Each line sink receives material from a linear Nernst diffusion of thickness δ and a hemispherical diffusion zone radius l. $2l$ is distance between the step lines. The method of Kasper (22) can then be used to calculate, in the stationary state, the relative concentration changes in the solution due to linear and hemicylindrical diffusion (23). The result is

$$\frac{\Delta C}{\Delta C_{\text{Nernst}}} = \frac{l}{\delta\pi} \ln \frac{16\,\delta^2}{\pi^2 a^2} + \frac{2l}{\delta\pi} \sum_{1}^{\infty} \ln \left\{ \frac{1 + \cosh \dfrac{\pi n l}{\delta}}{\cosh \dfrac{\pi n l}{\delta} - 1} \right\} \quad [14]$$

where ΔC is the total concentration change in the solution and a is here an arbitrary radius, of atomic dimensions, surrounding the line sink. If $a = 2 \times 10^{-8}$ cm and $\delta = 10^{-3}$ cm then $\Delta C/\Delta C_{\text{Nernst}}$ can be evaluated as a function of l/δ. This curve has a limiting value of approximately 1.3 when l/δ is small. In experiments on a solid metal such as silver, it would seem likely that the step lines are generated by dislocations in the surface and l/δ would be small. In agreement with this, Gerischer (21) gives $\Delta\eta/\Delta\eta_{\text{Nernst}}$ (identical to $\Delta C/\Delta C_{\text{Nernst}}$ when the total overpotential is small) as 1.5. The interpretation of the excess polarization as due solely to adatoms on the surface, is therefore not unambiguous.

An interesting aspect of Eq. [14] is that when at the other extreme l/δ is large $\Delta C/\Delta C_{\text{Nernst}}$ is also large. Thus it should be possible to measure high rates of reaction by, for example, the deposition at constant potential of silver or mercury onto graphite or on a noble metal. This would perhaps alleviate the need for very high-speed electronic equipment for these reactions.

The electrodeposition of the low melting point metal copper from acidified cupric sulfate solution onto a plated copper electrode, has recently been reinvestigated (24) by means of a rotating disk. This shows that the lattice growth step on a cathode of this type is very fast and the mechanism is dominated by the cuprous/cupric redox couple. Similar conclusions have been drawn by previous workers (25).

The high melting point metals, on the other hand, have low exchange currents, and diffusion effects in the solution are less likely. A complicating feature, however, when such transition metals are deposited from aqueous solution is the possibility of complex formation or the codeposition of hydrogen. Gierst (26) has suggested from polarographic and galvanostatic measurements that for nickel, in solutions of simple salts the hydrated nickel is discharged, the rate of dehydration of the ion at the surface being the rate-determining step. The depression of the polarographic limiting current on adding an inert electrolyte was interpreted in these experiments as a double layer effect, the shift of the Gouy layer potential.

Another example is the potentiostatic deposition of Co on to mercury from unbuffered potassium nitrate solutions where in addition to the metal a hydroxide can also be formed (27). We propose that this occurs by a mechanism

$$Co^{2+} + H_2O \rightleftharpoons H^+ + CoOH^+ \xrightarrow{2e} Co + OH^-$$

$$Co^{2+} \downarrow \text{ on the electrode surface}$$

$$Co(OH)_2 \text{ or } CoO \quad [15]$$

This mechanism depends on the fact that, due to the differing diffusion constants of H^+ and OH^-, a gradient of OH^- ions can exist in the region adjacent to the interface. An alternative mechanism would be the liberation of OH^- ions from H_2O in the interfacial region.

$$H_2O \xrightarrow{e} \tfrac{1}{2}H_2 + OH^- \quad [16]$$

This would mean the absorption of a hydrogen atom or molecule into the oxide film, as the production of gaseous hydrogen, even at high rates of formation of oxide, is usually not observed. There is evidence that in general cathodic oxide formation is greatly influenced by the amount of indifferent electrolyte present. In mechanism [15] this could occur by changing the concentration of the reducible species Co^+OH. Mechanism [16] would allow these effects as an alteration of the activity of OH^- in the interfacial region. Similar phenomena of the formation of cathodic oxide or hydroxide occur during the reduction of the chromate anion. When the aquo-complex is replaced by the thiocyanate complex this complication is removed and the potentiostatic initial current, as a function of potential, shows the usual Tafel slope. The current-time curves from this complex onto mercury, and other metals onto graphite, show that the growth of a metallic layer can be interpreted in terms of nucleation and lattice growth in a similar way to the deposition of nonmetal films.

When the slow step in an electrocrystallization process is incorporation at the edge of a growing nucleus and all transport processes to the nucleus are fast, then, in the early stages of growth, before overlapping becomes important, simple geometrical arguments can be used to predict the form of the potentiostatic current time curves. If one considers a single hemispherical nucleus growing on a surface, then if $V(t)$ is the volume of the nucleus at any time, r is the radius, and $i(t)$ the current

$$i_{(t)} \propto \frac{\partial V_{(t)}}{\partial t} \propto \frac{\partial}{\partial r}\left(\frac{2}{3}\pi r_{(t)}^3\right) \cdot \frac{\partial r}{\partial t} \propto 2\pi r_{(t)}^2 \quad [17]$$

$$r_{(t)} \propto t$$

and

$$i_{(t)} \propto t^2$$

Another possibility is that if the slow step is round the basal periphery (for instance by the movement of adatoms along the basal plane), then the rising transient can be calculated as follows

$$i_{(t)} \propto 2\pi r_{(t)}^2 \frac{\partial r}{\partial t} \propto 2\pi r_{(t)}$$

$$r_{(t)} \propto t^{1/2}$$

$$i_{(t)} \propto t^{1/2} \quad [18]$$

The constant of proportionality involves the lattice growth and nucleation rate constants and is easily

Table I

a) Type of nucleation; b) geometry; c) site of slow step; d) transport in solution.

calculated as shown in many previous publications from this school [see for example (2)]. Similar relations can be written for other combinations of geometry, reaction site, and mode of transport to the growing center and type of nucleation. These equations are not, however, unique, as can be seen by reference to Table I, in which some possible dependences are given. For example, it is generally not possible to distinguish directly between adatoms and diffusion in the solution although a possible way is given later. A knowledge of the geometry by means of electron diffraction is a prerequisite. Not all of these dependences, some of which are new, have been observed, but it seems likely that in practice even more complicated cases will occur, particularly that of preceding chemical reaction. An important example is when another electrochemical reaction goes simultaneously with the growing metal layer. Arguments similar to that used in deriving Eq. [17] and [18] then show that, depending on whether the second reaction goes preferentially on the growing metal lattice (either at the edge or on top of the nuclei) or on the uncovered substrate, then different potentiostatic current time curves are obtained. In fact, a whole family of dependences can be formulated easily and are too numerous to be given easily in a table. These dependences are, however, not unique, as in the example Table I, and extra evidence is necessary to deduce a reaction mechanism. An example investigated in this laboratory, among other noble metal depositions (27), is the reduction of the $PtCl_4^{2-}$ anion at a pyrographite electrode. Here there is the possibility of discharge from the various complexes in solution and also the possibility of the catalytic deposition of hydrogen either at the edges or on top of the growing nuclei, depending on the potential. We think it might be possible to explain in these terms the polarographic curves for the reduction of the $PtCl_4^{2-}$ anion, about which there is some controversy in the literature. Because of the 3-4 sec drop time used in polarography, quite a large number of platinum nuclei must be present on the mercury in these experiments, and in our experience this can have a profound effect on the current flowing.

At longer times when overlap becomes important, provided that the slow step is at the edge, the current-time curve can be calculated theoretically in a few simple cases. This has been demonstrated for the formation of some nonmetallic lattices on Hg, *e.g.*, calomel and references given in the section on nonmetallic deposition.

When the slow step is not at the edge and lattice growth is no longer governed by purely geometrical considerations, it is more difficult to set up a model to calculate the current time-transient. This has proved to be the case for the nickel thiocynate complex, mentioned above; here the kinetics are controlled by the rate of discharge, surface diffusion and lattice growth (28).

As this is a system which has been investigated in some detail it would be useful here to give the principal results. The potentiostatic current time curves, which correspond, by the amount of charge, to the formation of a monolayer one unit cell thick, have a maximum similar to that for the formation of some nonmetallic films, *e.g.*, calomel. A symmetrical curve would be expected if the slow step is at the edge that is if (*d*), in scheme II, alone is rate determining. The curves are, however, unsymmetrical. This immediately suggests that some process precedes lattice incorporation. Possibly this could be a preceding chemical reaction in the solution or the diffusion of adatoms to the growth site. The initial currents, plotted as a function of potential, show a Tafel slope corresponding to the discharge step. At higher negative potentials the initial current becomes kinetically controlled by the rate at which the preceding chemical reaction

$$Ni^{2+} + SCN^- \rightleftharpoons Ni\,SCN^+ \xrightarrow{2e} Ni + SCN^-$$

can produce the reducible species. In the region at lower potentials where the initial current is the discharge rate and this is followed by the effects of crystal growth, in that the curves go through a maximum, the inescapable conclusion would seem to be that these two processes are linked by adatom diffusion on the surface. The experimental fact that by switching instantaneously to more positive potentials some of the charge is removable, presumably that in transit to the growth site, gives more confidence in this suggestion. In such a complex situation, especially when overlap is important, the easiest way of reproducing the current-time curves is by means of simulation, and this has been attempted. At short times the problem can be approached analytically, if the number of nuclei is constant, by means of the parallel step line model shown in Fig. 13.

This model was originally proposed for the growth of solids from the gas phase by the adatom mechanism. The more difficult problem of how diffusion in the solution can be included in the theory will be discussed later. If c is the concentration of adatoms on the surface at a point between the step lines, then for a cathodic deposition at constant potential

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} + k_1' - k_2'c \qquad [19]$$

where

$$k_1' = \frac{i_o}{ZF}\exp\left[\frac{\alpha Z\eta_1 F}{RT}\right],$$

$$k_2' = \frac{i_o}{ZFc_o}\exp\left[\frac{(\alpha-1)Z\eta_1 F}{RT}\right]$$

D is the adatom diffusion constant, c_o is the adatom

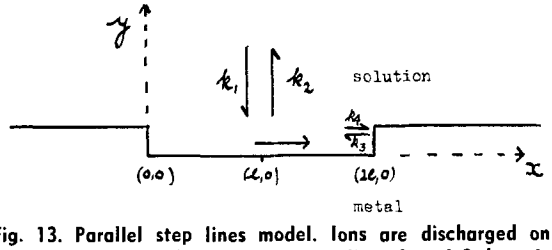

Fig. 13. Parallel step lines model. Ions are discharged on the surface from solution between the step lines 0 and 2 *l*, and then diffuse along the surface to the step lines.

concentration at the equilibrium potential, and the other symbols have their usual electrochemical significance. The boundary conditions are as follows

$$c = c_o \qquad 0 > x > l \qquad t = 0 \qquad [20]$$

$$c = c_o \qquad x = 0 \qquad t > 0 \qquad [21]$$

$$\frac{\partial c}{\partial x} = 0 \qquad x = l \qquad t > 0 \qquad [22]$$

These equations can be solved by the Laplace transform method to give a current-time transient. The result will not be quoted here as it is not directly amenable to experimental verification. It is more interesting to calculate the effect of an experiment of the type proposed by Gerischer (21). This involves polarizing the electrode to a stationary state at a potential η_1 and then instantaneously switching the potential to a second smaller overpotential η_2 (at constant l) such that this initial current is zero. This applies only to very rapid reactions where at short times the double layer charging can be neglected. These are just the reactions where changes in the solutions are expected. An experimental test of whether transport is by adatoms or diffusion in the solution to the step lines is suggested by the theory (23). As a result of a Gerischer experiment the theory gives

$$0 = i_{t\to 0} = ZFk_2 \left[\frac{k_1}{k_2} - \frac{k_1'}{k_2'} + \frac{k_1' - k_2' c_o}{k_2' l} \left(\frac{D}{k_2}\right)^{1/2} \frac{\sinh\left(\frac{k_2'}{D}\right)^{1/2} l}{\cosh\left(\frac{k_2'}{D}\right)^{1/2} l} \right] \qquad [23]$$

where the quantities without a prime belong to η_2. By substitution of the rate constants in terms of i_o and overpotential then

$$i_o \exp\frac{\alpha Z\eta_1 F}{RT} \left[\exp\left[\frac{ZF}{RT} (\eta_2 - \eta_1) \right] - 1 \right] = -i_{stat} \qquad [24]$$

where i_{stat} is the stationary current at η_1. This consequence of the theory could presumably be tested, after correcting the η values for concentration changes in the solution, by comparing it with

$$i_o \exp\frac{\alpha Z\eta_1 F}{RT} \left\{ \exp\left(-\frac{Z\eta_2 F}{RT} \right) - \exp\left(-\frac{Z\eta_1 F}{RT} \right) \right\} = -i_{stat} \qquad [25]$$

This equation is derived by considering a Gerischer experiment in which concentration changes, only, occur in the solution. It must be noted that these equations may equally well be deduced from any other model provided that, in one case, concentration changes take place before, and, in the other case after, electron transfer.

Equilibrium at step lines during metal growth is probably only achieved for metals with high exchange currents (29). In other cases it is necessary to replace boundary conditions [22] by [26]

$$D\frac{\partial c}{\partial x} = k_4 c - k_3 \qquad [26]$$

where k_4 is the rate constant governing growth at the step lines and k_3 that of the back reaction. A solution of Eq. [19] with [20], [26], and [22] corresponding to a Gerischer experiment can be obtained using the Laplace transform method. This leads when the metal deposition is relatively irreversible, *i.e.*, $k_3 = 0$ and the potentials such that $k_2' = 0$, $k_1 = 0$ to

$$i = -\frac{2ZFDk_2k_4^2k_1'}{l} \sum_0^\infty \frac{\exp -(D\alpha_n^2 + k_2)t}{(D^2\alpha_n^2 l + Dk_4 + k_4^2 l) D^2\alpha_n^2} \qquad [27]$$

that is, a transient due only to the removal of adatoms and the lattice continues to grow during the transient. In Eq. [27] α_n is the root of the transcendental equation

$$l\alpha_n \tan l\alpha_n = \frac{k_4 l}{D} \qquad [28]$$

It would therefore be possible, by setting up calibration curves in terms of the parameters $k_4 l/D$ and D/l^2, to compare the experimental and theoretical results. Experimental data are not sufficiently adequate at present to test these equations.

It seems that only by a detailed fitting of an equation of this type can unequivocal evidence for the adatom mechanism be obtained. These equations, however, presuppose that diffusion of adatoms along the surface is the only mode of transport to the growth sites. A more complete theory has been formulated (30). Differential equations corresponding to Eq. [19] can be written for potentiostatic conditions as follows

$$D\left[\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2}\right] = \frac{\partial c}{\partial t} \qquad 0 \leqslant x < l \qquad y > 0 \qquad [29]$$

$$D_a\frac{\partial^2 c}{\partial x^2} + k_1 c - k_2 C_a = \frac{\partial C_a}{\partial t} \qquad 0 \leqslant x < l \qquad y = 0 \qquad [30]$$

As before x is the distance co-ordinate in the surface as shown in Fig. 13. y extends into the solution. In contrast to the previous, C_a,D_a, now refer to adatoms, and C,D, to the ions in solution. c^o,$c_a{}^o$ are now the concentrations at the equilibrium potential. The boundary conditions corresponding to [20], [21], and [22] now become sets for the x and y directions, respectively.

Initial conditions

$$C_{(x,y,t)} = c^o \qquad t = 0 \qquad [31]$$

$$C_{a(x,t)} = c_a{}^o \qquad t = 0 \qquad [32]$$

Boundary conditions

$$\begin{aligned} C_{(x,y,t)} &= c^o && y \to \infty \\ \frac{\partial c}{\partial x} &\to 0 && x = 0 \\ c_a &\to c_a{}^o && x = 0 \\ D\frac{\partial c}{\partial y} &= k_1 c - k_2 c_a && y = 0 \qquad 0 < x \leqslant l \\ D\frac{\partial c}{\partial x} &= D_a\frac{\partial c}{\partial x} = 0 && x = l,\ \delta \to 0 \qquad y \geqslant 0 \end{aligned} \qquad [33]$$

To make the problem symmetrical in both phases it is of advantage to rewrite Eq. [29]-[33] in terms of a surface layer of thickness δ. It can be shown that solving the amended equations and allowing $\delta \to 0$ gives a correct solution of [29], [30]. The transform of the solution is complicated and is at present being programmed for the computer. It is hoped later to publish potentiostatic i/t curves as a function of k_1, k_2, D, D_a, l, which can be directly compared with experimental data in the literature. However, it is pos-

sible to discuss limiting cases. The actual transform of the solution is

$$\bar{i} = ZF(k_1c^o - k_2c_a^o)\,(p\sqrt{pD}/x_{oo}(p))\cdot\left\{1 + \left(\frac{k_2\sqrt{pD}}{x_{oo}(p)}\right)(S_1(p))^{-1}\right\} \quad [34]$$

where

$$x_{oo}(p) = (k_1 + \sqrt{pD})p + k_2\sqrt{pD}$$

$$S_1(p) = \sum_0^\infty \epsilon_m \left(k_1 + \sqrt{\left(p + \frac{1}{\tau_m}\right)D}\right) p/x_{m.o(p)}$$

$$x_{m.o(p)} = \left(k_1 + \sqrt{\left(p + \frac{1}{\tau_m}\right)D}\right)\left(p + \frac{1}{\tau_m{}^a}\right) + k_2\sqrt{\left(p + \frac{1}{\tau_m}\right)D}$$

where

$$\epsilon_m = 1\ ,\ m = 0$$
$$= 2\ ,\ m = 1, 2 \ldots..$$

$$k_1 = i_o/ZFC_o \exp\left(\frac{\alpha ZF\eta}{RT}\right),$$

$$k_2 = i_o/ZFC_a^o \exp\left[\frac{(\alpha - 1)ZF\eta}{RT}\right]$$

also

$$\frac{1}{\tau_m} = \frac{m^2\pi^2 D}{l^2}\ ,\ \frac{1}{\tau_m{}^a} = \frac{m^2\pi^2 D_a}{l^2}$$

$\bar{i}$ is the Laplace transform of the current defined by

$$\bar{i}(p) = L\,i_{(t)} = p\int_0^\infty \exp - pt \cdot i_{(t)}\,dt \quad [35]$$

For two limiting cases the inverse transforms of [34] can immediately be written down

(*i*) Allowing $D_a \to \infty$ leads to a dependence

$$i_{(t)} = i_o\left[\exp\frac{\alpha ZF\eta}{RT} - \exp\frac{(\alpha - 1)ZF\eta}{RT}\right] \cdot \exp k_1{}^2\frac{t}{D}\operatorname{erfc}\left(k_1\sqrt{\frac{t}{D}}\right) \quad [36]$$

Equation [36] is the well-known equation for semi-infinite diffusion to a planar electrode, and at long times reduces to $i \propto t^{-1/2}$

(*ii*) When diffusion in the solution is neglected by allowing $D \to \infty$ the equations published earlier (6) are reproduced. A particularly significant property of these equations is that when $t \to \infty$ a stationary state is reached, namely

$$i_{t\to\infty} = \frac{ZF}{l}(k_1c^o - k_2c_a^o)\tanh\left(\sqrt{\frac{k_2}{D_a}}\cdot l\right)\left(\sqrt{\frac{D_a}{k_2}}\right) \quad [37]$$

By putting $l \propto 1/\eta$ in this equation then at low overpotential the stationary i/η curve can be calculated for surface diffusion alone.

In an actual current time transient represented by [34] it can be shown that, if surface diffusion is important, it might be expected that the stationary state for surface diffusion would appear before the decay for diffusion in the solution and a plateau would appear.

The a-c method for measuring the impedance of an electrochemical system, and interpreting this in terms of i_o and α, is well known. An early attempt to obtain the elements of an equivalent circuit analogous to the potentiostatic case with diffusion in the solution given above was made by Lorenz (31). His measurements probably represent the largest body of evidence in favor of the adatom mechanism, and it is important to look at his method of calculation in view of the ambiguous nature of the potentiostatic and galvanostatic measurements mentioned earlier. The Lorenz calculation is, however, approximate. An accurate solution for this model can be obtained easily for a small a-c perturbation, from [34]. Using the previous nomenclature and also

$$\Delta i = |\Delta i| \cos(\omega t + \phi) \quad [38]$$

then from [34]

$$\Delta i = \text{real part of } \frac{i_oZF|\Delta\eta|}{RT}\cdot\left\{j\omega\sqrt{\frac{j\omega D}{x_{oo(j\omega)}}}\left[1 + k_2\sqrt{\frac{j\omega D}{x_{oo(j\omega)}S(j\omega)}}\right]\right\} \quad [39]$$

where $j = \sqrt{-1}$, $k_1 = i_o/ZFc_o$, $k_2 = i_o/ZFc_a^o$.

The limiting cases of this will now be briefly discussed under some simplifying conditions. The reader is referred to the original papers for the details

(*i*) When

$$\frac{D_a}{2} >> k_2 \text{ and } \omega << \frac{D_a}{2}$$

Equation [39] reduces to the well known equation derived by Randles. These conditions are then sufficient to ensure that bulk diffusion and the electrochemical step alone are rate determining. Experimental work based on this limiting case is well understood. The equivalent circuit elements are then the Warburg impedance in series with the transfer resistance and in parallel with the double layer impedance.

(*ii*) When surface diffusion is rate determining a sufficient condition is

$$\frac{k_1 l}{D} \to 0 \quad [40]$$

Equation [39] now reduces to the one published earlier (6).

(*iii*) In actual experiments the region where mixed control operates, that is when

$$\frac{k_1}{D} \to 0 \qquad \sqrt{\frac{k_2}{D_a}}\cdot l >> l \quad [41]$$

will dominate the behavior. This aspect of the theory is new and will be discussed further. It is shown by inserting this condition into [39] that the equivalent circuit in this limit is now a transfer resistance in series with both Warburg impedance and an impedance consisting of a capacity in parallel with surface diffusion impedance. If

$$\frac{\omega}{k_2} << \left(\sqrt{\frac{k_2}{D_a}}\cdot l\right)^{-1}$$

then the surface diffusion impedance (Zad) becomes very significant and of the form

$$RT\sqrt{\frac{k_2}{D_a}}\cdot\frac{l}{ZFi_o}$$

That is Zad degenerates into a pure resistance. The faradaic reaction now exhibits classical behavior, in that the impedance R_D, C_D exhibit a linear dependence, as found *e.g.*, for deposition at amalgam electrodes, where the metal lattice is continuously removed. However the intercept of the $R_D/\omega^{-1/2}$ plot is no longer RT/ZFi_o but $(RT/ZFi_o)\ (1 + \sqrt{k_2/D_a}\cdot l)$. The Lorenz treatment coincides with the above only under the special conditions

$$\frac{\omega}{k_2} << \left(\sqrt{\frac{k_2}{D_a}}\cdot l\right)^{-1}$$

If $\omega >> k_2$ then the discrepancy between Lorenz and this work would be expected to be significant. A detailed calculation of the impedance as a function of frequency is being made and will be published later [30].

The next step is to relax boundary condition $c = c_a^o$ at $x = 0$ in [33] by replacing it by

$$D_a\left(\frac{\partial c}{\partial x}\right)_{x=0} = k_4(c_a - c_a^o) \qquad [42]$$

This is exactly equivalent to replacing [22] by [26], and treats the case when equilibrium is not maintained at the step line and there is a finite rate of incorporation at the step line. The most interesting result is that from the general equation a number of steady states are possible showing that a square law dependence between i and η cannot prove by itself that surface diffusion is rate determining.

To sum up the implications of the new theoretical considerations presented in outline in the previous pages, it would seem that solutions of the diffusion problem for much more realistic general models are possible. Important limiting cases and a heuristic approach can give valuable pointers to experimental interpretations, while emphasizing that less general models can give an utterly misleading interpretation of the experiment, especially when different combinations of events can lead to similar results.

Conclusion

We have endeavored, in this paper, to review the very recent theoretical and experimental developments arising particularly from our own investigations and the activities of the research group with which we are associated. Electrodeposition has been treated in the broadest possible sense including the deposition of both metallic and nonmetallic phases.

Thus, progress in this field allows one to characterize the various steps in a very general type of electrochemical reaction. Nonmetallic and metallic deposits behave very similarly, the differences being a reflection of the electronic properties of the individual lattice structures. In many cases nonmetallic films grow with the slow step at the edge; this is not surprising in view of the complex nature of these lattices. Metallic lattices which are simpler chemically tend to form at much higher rates and therefore preceding transport processes can become rate determining.

As shown by the time dependence these processes can be detected and experiments designed to overcome the effects of diffusion in the solution by, for example, growing a large constant number of nuclei at the outset potentiostatically, and then growing these at a much lower potential as shown in the text. More sophisticated relaxation technique such as a-c impedance, or trains of pulses can be used to elucidate the mechanism of deposition or dissolution of various complexes in solution and species adsorbed on the surface. In general it would seem to us that metal deposition is likely to be dominated by study of complexes and equilibria in solution as precursors to lattice growth.

We have found the technique of growing lattices of a known structure on inert substrates to be a powerful one which, in fact, corresponds to the method of measuring initial rates, common in chemical kinetics. Lattices grow with well-defined crystal habits and as thin films lending themselves to electron optical examination. It should be possible to determine experimental rate constants especially for the formation of metal lattices and we feel that it is with these that future theories of electrocrystallization will be concerned.

The theoretical treatment of the diffusion problems involved are clearly possible with more realistic models, and this will undoubtedly permit the design of more soundly based experiments to test the relative importance of surface diffusion in the over-all scheme; this is a matter which we think to be of particular importance and where, to date, we consider considerable uncertainty to lie.

Acknowledgment

Finally we must express our gratitude to our many colleagues for frequent and continual discussion, without which progress would be negligible.

Discussion

H. Gerischer: I would like to make a short comment on this very important and stimulating paper which concerns the model used for describing the electrolytic deposition and dissolution of a metal. In this model as represented in Fig. 13 the assumption is made that only the rate of the reaction step in which an atom (or ion) moves perpendicularly to the surface plane depends on the electrical charge in the double layer, *i.e.*, on the electrode potential. This model has given a great deal of very valuable information and can give more. It is therefore of very great value to have now a rigorous mathematical solution for this model as given in this paper. One may not forget, however, that this model has a serious weakness in the way in which the transfer of atoms from kink sites to the surface planes is treated. This process is obviously not independent of electrode potential in contradiction to the model used here. I think that this is one of the reasons for the fact that no limitation of the anodic dissolution rate of a metal can be observed. It is obviously very difficult to modify the kinetics in this model as to take into account this kind of complication in the calculations. In a very preliminary way, we have already had to apply such a treatment to the surface migration and the exchange of adatoms with kink sites, but these ideas have to be developed much further in such a rigorous way as shown in this paper.

H. Thirsk: I think we are very conscious of the fact that the complete model examined mathematically is still very much simplified. The boundary condition in a sense summarizes our assumptions concerning the nature of the surface diffusion involved; that is, the step is a continuous line-sink/source and this is dependent on the assumption that the mean free path of the diffusing atoms is much greater than the mean distance between two consecutive sinks and that equilibrium is maintained for the exchange and is not influenced by mass transfer through the solution. We have not tried to treat the effects of the potential field at this present stage, although I am certain the probable importance of such a complication has been raised in earlier papers in electrocrystallization, written in collaboration with Dr. M. Fleischmann.

H. B. Urbach: I would like to confirm Professor Gerischer's remarks concerning the electrostatic character of the mechanism of surface migration of adatoms. The question of the mechanism of transport resolves itself into two alternatives. Is the mechanism a random walk (pure diffusion) process or is it an electrostatic process? Naumevets and Gavrilyuk[1] in the U.S.S.R. have actually observed, by means of the field ion microscope, that the motion of particles at a gas-solid interface is influenced by the direction of the local fields impinging on the interface. They were in fact able to influence the direction of motion of the adatoms at will. Their calculations showed that the observed forces were consistent only with an electrostatic interpretation based on the interaction of dipoles (the adsorbed adatom complex with its image) and the field. Prior to my discovery of the Russian paper, I had performed an analysis[2,3] of the mathematical problem associated with the electrolyte-metal interface where it is expected that the field intensity at the interface would be much greater than at the gas metal interface. It is based on taking the tangential (to the interface) component of the gradient of the scalar product of the dipole moment and the field intensity and is similar to the Russian analysis.

H. Thirsk: We are assuming a normal surface diffusion process. I must say that I had not thought of the Russian work to be of immediate relevance to electrodeposition, although of great elegance and interest. However, in view of your mathematical treatment indicating that the effect would be greater in electrolytic deposition, the whole assumption merits further consideration. We look forward to more information on your calculations.

R. G. Buck: Inasmuch as you have obtained an exact solution for the current transform in the potentiostatic case, you could make direct use of the result realizing that it gives, on substitution of $j\omega$ for the transform variable, the frequency dependence of the impedance. Use of the transform in this manner would save the effort required to invert the transform. Providing it is electrochemically sound and experimentally feasible to apply a small amplitude sinusoidal ripple potential in addition to the d-c bias, the impedance spectrum could be measured and could be compared by curve fitting with the derived impedance function. This type of experiment related to work of Sluyters[4] seems to be a reasonable way of getting at the rate constants for the cases where coupling occurs between mass transport and a slow surface reaction.

H. Thirsk: We have dealt with the a-c case by substituting $j\omega$, but the i *vs.* t relationships are of direct interest to us in the nonsteady state following the application of a potential jump.

E. Gileadi: A new relaxation technique is suggested in this paper for the measurement of the rate of the fast charge transfer reaction in a reaction sequence such as given in Eq. [5]. I would like to ask whether this method is considered by the authors in any way superior to the long established bridge method first suggested by Frumkin, Dolin, and Erschler[5] in 1940. Is the accuracy of the measurement improved? If a fast charge transfer step is at quasi-equilibrium, followed by a slower rate-determining step, a substantial pseudocapacity may arise, in which case the system is less than ideally suitable for application of potential steps, unless very small electrodes are used.

H. Thirsk: What we are proposing is a method of studying electrochemical process by relaxation methods employing a potentiostat with a fast rise time. The possibility of the method is the point of interest and not the question as to whether another method is more accurate. In any case, I am unaware of the satisfactory application of an a-c bridge method of the type you describe to crystal growth problems of a type precisely relevant to the present paper. We are fully aware of the problems of pseudocapacity.

J. O'M. Bockris (communicated): We welcome Professor Thirsk's summary of the work which his team has been carrying out in Newcastle. In a general way, we think that the goals which they seem to seek in

[5] A. Frumkin, P. Dolin, and B. Ershler, *Acta Physicochim. URSS*, 13, 779 (1940).

their work,—rate-determining step and path,—are those which we seek, too, at the University of Pennsylvania. We would like, nevertheless, to make some comments on the studies carried out at Newcastle.

(*i*). Much of the work summarized in Professor Thirsk's paper is work done not on electrodeposition in any conventional sense, but, rather, on electrocrystallization, for example, the formation of thallous chloride on thallium amalgams. Although these studies are complementary to those of metal deposition, which Thirsk *et al.* also study, there are of course considerable differences in growth of A on B (the most frequent objective of the Newcastle work) and electrodeposition of A on A, for instance of Cu on copper substrate.

(*ii*). The technique which Thirsk *et al.* use predominantly is that of the potentiostatic transients. It is a powerful one. Nevertheless, conclusions regarding the rate-determining step based on behavior at times such that monolayer build-up is in its early stages need not always be valid in respect to the steady state at longer times.

(*iii*). There seems to be a danger in relying too much on one technique. The number of steps between the observations of the transients and the model is a long one, and, if unconfirmed by an alternative method, the model may not always be secure.

Thus, electron microscopy, with Thirsk *et al.* use, does have special disadvantages in electrochemical studies because it is impractical to use it *in situ*. We would like here to mention the use of the Nomarski system of optics for *in situ* studies of metal deposition. This uses polarized light; it allows microscopy and interferometry in the same small apparatus and can be used to make studies, *e.g.*, of the movement of growth steps over the crystal surface. Ellipsometric techniques perhaps may be developed usefully here, as well.

The differences between Professor Thirsk's work and ours are in details of some models.

The mechanism of the formation of calomel.—This is that mechanism in which the Newcastle and Philadelphia groups have come into definite disagreement. The disagreements have significance outside a direct interest in the mechanism of calomel formation, because the mechanism of anodic crystallization reactions, the main area in which the Newcastle group has worked, is to be treated either along a dissolution precipitation path or along that of anion deposition and subsequent crystal growth steps. Although, of course, both types of mechanisms may function under different conditions, were the latter type of mechanism (which the Newcastle group have proposed be true for calomel, too) to be disproved in this case, it would tend to suggest some revision in other mechanisms. A second reason why the disagreement is important has to do with the fact that the counter case to that of the Newcastle work is based on an ellipsometric technique which has the advantage of giving direct information on the state of the surface and the disadvantage[6] of being brand new in electrochemistry.

The principal pieces of experimental evidence which made Bockris, Devanathan, and Reddy[7] favor the dissolution-precipitation mechanism for calomel formation are:

(*i*) The fact that, in galvanostatic transient measurements of mercury dissolution, the current passes for a significant time (corresponding to the dissolution of many layers of Hg) before the ellipsometer registers any new phase on the surface. This time increases with decreasing current density. Constant electrode potential close to that of calomel electrode is, however, established in much earlier time.

(*ii*) The fact that the time (analogous to a transition time) which elapses between the switching on of a galvanostatic current and the beginning of ellipsometer signals of a new phase is stirring-dependent. At low current densities effective stirring prevents the formation of calomel completely.

(*iii*) The (very significant) fact that the ellipsometric studies indicate a continuation of film growth of calomel after the current has been cut off during the initial period of growth.

These three facts seem to be consistent only with a dissolution-precipitation model, which is also what is found with Ni.[8]

It does seem that, in his paper at this meeting, Professor Thirsk has not perhaps been quite sufficiently revealing in the presentation of the position, *e.g.*, he did not call attention to the above facts. Further, the formula for the complex which dissolves has been overstressed at the expense of the controversy concerning the basic model. Bockris, Devanathan, and Reddy found their work to be consistent with Hg_2Cl^+ (as has Hills and Ives[9]), and Thirsk prefers $HgCl_4^{2-}$. This seems of lesser importance than the type of mechanism for the anodic formation of halide films.

What chance can there be that both mechanisms occur? Most of the Newcastle work was done under potentiostatic conditions where the initial currents would be several orders of magnitude greater than with the Philadelphia work. The dissolution-precipitation stage would be immeasurably quick on the Newcastle time scale for potentiostatic work, or, possibly the mechanism actually changes. Alternatively, could the presence of impurities in one solution have given nucleation centers for crystallization on the metal which changed this stage from what was observed in the other?

The main thing which must be done is to establish independent verifications of the ellipsometric results, for, if verified, the position is then quite unambiguous.[10]

Is surface diffusion a step in over-all metal deposition mechanism?—Professor Thirsk's position is that he doubts it. For low melting point metals, he favors diffusion in solution, and considers that a hemicylindrical diffusion model with a growth step serving as a line sink can explain experimental facts. Our position is that, at least on Cu, Ag, and Ga, surface diffusion is involved in the mechanism of deposition, and, at low overpotentials (and with certain preparation of the electrode surface), may be rate-determining.

The surface diffusion position is, we submit, past the hypothesis stage. For example: (i) In systems where a surface diffusion model has been proposed, support comes from the reasonable values (*e.g.*, 0.1 of total coverage) of the adion concentrations at the reversible potential. Certainly, the equations we have used concern a crude model for the surface and surface diffusion, but were it wrong, as Professor Thirsk implies it might be, c_o values (verified by independent work and techniques) would hardly be in the region expected.

(*ii*) It was shown by Mehl and Bockris[11] (1957) that an analysis of galvanostatic transients for silver dissolution gives also i_o, the exchange current density for the transfer reaction, on the assumption of rate-determining surface diffusion control near the reversible potential. At overpotentials above 100 mv's, there is behavior clearly indicating charge transfer

[6] Although Reddy, Genshaw, and Bockris [A. K. N. Reddy, M. Genshaw, and J. O'M. Bockris, *J. Electroanalyt. Chem.*, **8**, 406 (1964)] have shown that in respect to platinum oxides, the ellipsometric studies agree almost exactly with coulometric ones.

[7] J. O'M. Bockris, M. A. V. Devanathan, and A. K. N. Reddy, *Proc. Roy. Soc.*, **A279**, 327 (1964).

[8] J. O'M. Bockris, A. K. N. Reddy, and M. G. B. Rao, To be published.

[9] G. H. Hills and D. J. G. Ives, *J. Chem. Soc.*, 305, 311 (1951).

[10] The solution of the ellipsometric equations is quite easy for calomel because the films are not conducting.

[11] W. Mehl and J. O'M. Bockris, *J. Chem. Phys.*, **27**, 818 (1957).

control and i_o can be readily obtained in a direct way, without the application of surface diffusion theory. The values agree well.

(*iii*) Despic and Bockris found that the parameters of the surface diffusion steps, and hence whether it was rate-determining, was dependent on solution purity. This would, of course, effect only surface diffusion.

Particularly (*ii*) and (*iii*) seem to offer strong evidence for surface diffusion as one of the consecutive steps[12] before lattice building commences. Although the evidence from our own work extends only over Cu, Ag, and Ga, we suggest that surface diffusion is always a step in metal deposition processes (not necessarily rate determining, of course).

Another point concerns the prediction which Professor Thirsk makes concerning the metals for which surface diffusion is most likely to occur. He considers it to be the high melting point, or "hard" metals, where the bond strength to the adatoms will be high. If the question is the competition between diffusion from site A to site B via the surface or via the solution, then we are dealing with alternative parallel paths and the easier will be favored. If the bond strength of substrate to surface atom is high, then the heat of activation for surface diffusion will tend to be high and hence a tendency (not necessarily resultful) will arise to take the solution path and *vice versa* for the soft metals. Of course, the reverse indications pertain to the rate-determining step.

In respect to the initial contributions to the surface diffusion kinetics, the 1957 note of Mehl and Bockris[11] gave the first quantitative values of surface adion concentrations and the first equations in which galvanostatic transients were related to surface diffusion velocity, rate of charge transfer and adion concentration. Gerischer and Tischer's[13] work, reported in the same year, was qualitative.[14] The 1957 equations also allowed determination of the fast rate constant as well as the slow one (cf. Eq. [11] of Thirsk).

H. R. Thirsk (communicated): We are grateful to Professor Bockris for his comments on our paper, since this seems to justify a rather more detailed treatment of certain aspects of our work which still do not seem to be well understood. To consider the general points raised by Professor Bockris:

(*i*) *Electrodeposition.*—If this term means anything at all, it must refer to the growth of a deposit on a substrate due to the passage of a current across the interface. It is irrelevant whether the process is anodic or cathodic. The question of A on A or A on B is equally of importance in either process.

(*ii*) *The potentiostatic technique.*—Admittedly we have used this method very extensively. It has the major advantages of allowing an analysis of the nonsteady state to be undertaken. Galvanostatic methods must always involve drastic approximations when the treatment of nonsteady state conditions is required, since electrochemical rate constants are potential dependent.

(*iii*) Other techniques.—*In situ* techniques are obviously very desirable. Although the techniques of electron diffraction and electron microscopy cannot be used for *in situ* investigations in electrodeposition, they are nevertheless extremely necessary for (*a*) the examination of the surface of the substrate, and (*b*) the identification of the nature of the electrodeposited material. As I understand it, I would not be happy in using ellipsometry as a means of identifying a surface layer without confirmation by other techniques.

[12] J. O'M. Bockris and G. Razumney, in "The Electrocrystallization of Metals," in press, Plenum.

[13] H. Gerischer and R. P. Tischer, *Z. Elektrochem.*, **61**, 1159 (1957).

[14] But, Lorenz [W. Lorenz, *Z. Elektrochem.*, **58**, 912 (1954)] discussed surface diffusion quantitatively in 1954.

We consider now the criticisms made of our treatment of the kinetics of formation of calomel, since this is a particularly well defined problem. The observations which seem to us the most important in this case are the following. The deposits of calomel which are formed electrochemically invariably have the (110) plane parallel to the electrode surface[15] independently of crystal size. Potentiostatic experiments at high chloride ion concentrations give i—t transients which follow the equation

$$i = nFC_oD_o^{1/2}/\pi^{1/2}t^{1/2}$$

and are consistent with the view that the mercury is dissolving as $HgCl_4^{2-}$.[16] Potentiostatic experiments at lower chloride ion concentrations give a series of peaks, the charge under each peak being constant at $\sim$ 100 μC cm^{-2} [16,17] in both HCl and KCl solutions. Exactly equivalent galvanostatic observations have been reported by Ives *et al.*,[18] though Bockris *et al.*[19] using only one solution (1*M* KCl) have not been able to reproduce these results. "Adsorption" prewaves are found for the anodic polarography of chloride ions at [Cl$^-$] 10^{-3}M.[20-23] These adsorption waves arise from the formation of one monomolecular layer of Hg_2Cl_2 on the electrode surface.

So far as these observations are concerned, which we believe can only be explained on the basis of the mechanism which we have described in detail previously, the only point in dispute between ourselves and Professor Bockris concerns the form of the galvanostatic transients which should be observed. Since both the Newcastle and Birkbeck College groups have published C-E curves demonstrating the cleanliness of their systems, dare I suggest that a possible cause of the discrepancy could arise from contamination of the electrode surface.

The points considered by Professor Bockris and thought by him to favor a dissolution precipitation mechanism are now taken in turn:

(*i*) We agree. The arrest close to the calomel potential is due to the dissolution of $HgCl_4^{2-}$ and also to the high differential capacity at this point.

(*ii*) Again we agree. Under galvanostatic conditions with a reversible dissolution reaction the electrode potential (and of necessity the rate of change of electrode potential) is a function of stirring conditions.

(*iii*) This point concerns the behavior of an electrode on open circuit. Here the significant principle is that the net current crossing the interface shall be zero. Thus further growth of a calomel film

$$2Hg + 2Cl^- \rightarrow Hg_2Cl_2 + 2e$$

is possible since this can be compensated for by the reaction

$$2e + HgCl_4^{2-} \rightarrow Hg + 4Cl^-$$

Thus the points raised by Bockris *et al.* do not unambiguously favor either mechanism.

There are some further internal inconsistencies in the dissolution-precipitation model to which attention should be drawn. These are

[23] R. D. Armstrong, M. Fleischmann, and J. Koryta, *Coll. Czech. Chem. Comm.*, **30**, 4342 (1965).

(*i*) The formation of calomel is written

$$Hg_2Cl^+ + Cl^- \rightarrow Hg_2Cl_2 \qquad [1]$$

Now Hg_2Cl_2 is a solid, and as is well known, the formation of a solid from a solution requires (*a*) appreciable supersaturation, (*b*) nucleation and subsequent growth of small crystals of the solid. Thus the kinetics of reaction [1] cannot be described by rate constants of a type which would be appropriate if Hg_2Cl_2 were a solution soluble species, but rather by a nucleation rate and an expression for the rate at which nuclei, once formed, grow. This Professor Bockris does not attempt to do. It would also be interesting to know the fate of small crystals once formed in the vicinity of the electrode. Does passivation occur because these crystals fall onto the mercury surface due to gravitational forces?

(*ii*) The disproportionation reaction

$$\text{"Mercuric Entities"} + Hg^o \rightleftharpoons Hg_2Cl^+ \qquad [2]$$

is considered first order in "Mercuric Entities." Neglecting for the moment the fact that the evidence for Hg_2Cl^+ is slight, the first order approximation for [2] requires

$$[\text{Mercuric Entities}] << [Hg^o]$$

which cannot possibly be true, since $[Hg^o] \approx 10^{-7}$M.[24]

I think a cautionary word about the structural aspects of the three systems Professor Bockris and his collaborators have studied to date is relevant; I am referring to the calomel, nickel, and platinum passivation. The nature of the passivating layer in the first case is well known and might incidentally make a better subject for the polarized light in active studies than most systems; the second case is structurally far more difficult and I would have considerable reservations concerning the proposals without good secondary evidence from something other than ellipsometry.

[24] H. C. Moser and A. F. Voigt, *J. Am. Chem. Soc.*, 79, 1837 (1957).

Here, also, at the *p*H of the experiments from an estimation using recent data, it should be noted that

$$\frac{[NiOH^+]}{Ni^{2+}} \approx 2 \times 10^{-7}$$

and the final product in the oxide layer (Jones, Wynne-Jones) was much nearer to $NiO_{1.84}$.

The platinum oxide system is even less well understood. We would certainly not expect the same kinetic analysis to suffice for these three very dissimilar system.

Metal deposition.—Professor Bockris bases his experimental evidence for the adatom mechanism on essentially galvanostatic measurements. Clearly here, theoretically, he is at a disadvantage, in that the exact mathematical analysis of such transients is impossible. Potentiostats have been used for many years simply to obviate this difficulty. As is shown in our paper we believe previous estimates of the adatom contribution to be totally due to hemicylindrical diffusion to dislocation or growth sites on the solid metal surface.

In the past, not sufficient was known about the nature of nucleation and subsequent growth in metal deposition to define this complex problem sufficiently. It is, however, a change of phase and has parallels in the chemistry of solid reactions and metallurgy. We suggest that from the point of view of surface diffusion studies the A on A system, because of the structure of metal A, is far too complex. On the other hand when a metal ion is deposited potentiostatically on an inert substrate it is easy to control the number and formation of nuclei and observe growth alone. We hope further that measurement of lattice incorporation constants, as have been very successfully measured in this Department for nonconducting salts and for solid-solid transformations for suitable systems will shed some light on the kinetics of metal deposition.

An Ellipsometric Determination of the Mechanism of Passivity of Nickel[1]

J. O'M. Bockris, A. K. N. Reddy, and B. Rao

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The capacity of nickel in acid solution have been followed by means of ellipsometry under conditions of potentiostatic control of the material at various points in the passivation current-potential diagrams and also with automated equipment which allows the recording of the ellipsometer reading under transient conditions. It is found possible to evaluate the refractive index, thickness, and light adsorption of the film at all parts of the process. The film begins to form at the first inflection on the current-potential diagram, but after the current reaches its maximum point, it does not change further in thickness. When the current begins to descend, there is a parallel rapid increase in the electronic conductivity of the film. Passivation arises from a critical increase in semiconduction of the film on the surface. The increase in electronic conductivity reduces the field available for the encouragement of anodic dissolution and transport through the film. Hence, dissolution ceases, *i.e.*, passivity, occurs.

The phenomenon of passivity has been studied for over a century. In fact, the first theory of passivity was intuited in 1844 when Faraday stated: "My strong impression is that the surface . . . is oxidized, or that the superficial particles of the metal are in such relation to the oxygen of the electrolyte as to be equivalent to an oxidation, and that having their affinity for oxygen satisfied and not being dissolved by the acid . . . there is no renewal of the metallic surface. . . ." With these words, Faraday glimpsed the critical role of the surface in determining the stability of a metal in a corrosive environment. In addition, he not only distinguished two possible modes of interaction between the reactive metal surface and oxygen (*viz.*,

[1] Paper summarized by Halina Wroblowa (Mrs. J. O'M. Bockris) at the Cleveland Meeting.

oxidation and an oxygen-metal relationship which is equivalent to surface oxidation), but also implied the difficulty of deciding between these alternatives.

Despite Faraday's century-old statement of the fundamental problem in passivity, no definitive solution has been forthcoming. The critical issue has, however, been cast into modern terminology, and the two principal views are that the basic cause of passivity is a three-dimensional oxide film with particular properties or a two-dimensional chemisorbed oxygen film. Of course, these two views are only the basic themes, and modern proponents have developed several subtle variations of them (1-14).

The resolution of the controversy has been delayed by continued reliance on the measurement of the electrical characteristics of the metal-solution interface, *viz.*, the potential, current, or capacity. Such measurements do not always lead to an unambiguous determination of the mechanism of electrochemical phenomena at interfaces. What has been lacking is an *in situ*, preferably nonelectrochemical method of revealing the state of an electrode surface under the normal conditions of electrochemical experimentation. A technique which satisfies these requirements is ellipsometry, but while its principles have been available for several decades (15-17), it is only recently that the difficulties of applying it to electrochemical systems have been overcome (18).

Ellipsometry is based on the sensitivity with which polarized light reflects changes in the state of a metal surface. In particular, the technique is based on the measurement of the changes which surface films induce in the polarization state of reflected light. These changes (represented by a relative phase retardation Δ and a relative amplitude diminution ψ) of an elliptically polarized light beam reflected from a film-covered surface are related to the complex refractive index n_F^* and thickness L_F of the film, by the film-optics equation (17)

$$\tan \psi e^{i\Delta} = f(n_F, \kappa_F, L_F, n_M, \kappa_M, n_1, \theta_i, \lambda)$$

$$\tan \psi e^{i\Delta} = \frac{r_{p,12} + r_{p,23}\, e^X}{1 + r_{p,12}\, r_{p,23}\, e^X} \Big/ \frac{r_{s,12} + r_{s,23}\, e^X}{1 + r_{s,12}\, r_{s,23}\, e^X} \qquad [1]$$

where $r_{p,12}$, $r_{p,23}$, $r_{s,12}$ and $r_{s,23}$ are the Fresnel reflection coefficients (19). The subscripts p and s refer to the reflection coefficients for the light vibrations, parallel and perpendicular to the plane of incidence. The subscripts 1, 2, 3 refer to the medium, film and substrate, respectively (Fig. 1). Further,

$$r_{p,12}, r_{p,23}, r_{s,12}, r_{s,23} = f(n_F, \kappa_F, L_F, n_M, \kappa_M, n_1, \theta_i, \lambda)$$

$$r_{p,12} = \frac{n_F^* \cos\theta_i - n_1 \cos\theta_t}{n_F^* \cos\theta_i + n_1 \cos\theta_t} \qquad [2]$$

$$r_{s,12} = \frac{n_1 \cos\theta_i - n_F^* \cos\theta_t}{n_1 \cos\theta_i + n_F^* \cos\theta_t} \qquad [3]$$

$$r_{p,23} = \frac{n_3^* \cos\theta_t - n_F^* \cos\theta_t'}{n_3^* \cos\theta_t + n_F^* \cos\theta_t'} \qquad [4]$$

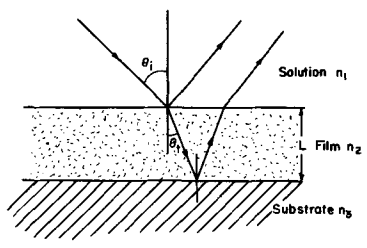

Fig. 1. Basic principle of ellipsometry

$$r_{s,23} = \frac{n_F^* \cos\theta_t - n_3^* \cos\theta_t'}{n_F^* \cos\theta_t + n_3^* \cos\theta_t'} \qquad [5]$$

$$X = -4\pi i\, n_F^* \cos\theta_t\, L_F/\lambda \qquad [6]$$

$$n_F^* = n_F + i\kappa_F \qquad [7]$$

$$n_3^* = n_M + i\kappa_M \qquad [8]$$

where $i = \sqrt{-1}$ and θ_i is the angle of incidence at the metal surface; θ_t is the angle of refraction in the film; θ_t' is the angle of refraction in the metal; n_1 is the refractive index of the medium (sulfuric acid solution in the present case); λ is the wavelength of the light used; n_M and κ_M are the refractive index and absorption coefficient of the metal; n_F, κ_F, and L_F are the refractive index, absorption coefficient, and thickness of the film, respectively.

Ellipsometry is particularly noted for the fact that monolayer films are theoretically expected to give easily measurable changes in the parameters of the polarized light. It constitutes, therefore, an excellent method of making *in situ* examination of the formation, growth, and characteristics of anodic films. In the present communication, a detailed report is given of a steady-state ellipsometric study (20) of the passivation of nickel in acid solution.

Experimental

Electrolyte.—All the experiments were carried out at room temperature (~20°C) in solutions of 0.01*N* H_2SO_4 + 0.5*M* K_2SO_4 (pH = 3.15) kept under a prepurified nitrogen atmosphere.

Electrodes.—Nickel tape of 99.5% purity (thickness 0.0375 cm) was found to have sufficient mirror finish to be used as the reflecting electrode. The counter electrode consisted of a rectangular platinized platinum sheet, and the reference electrode, a saturated calomel electrode. The cell arrangement is shown in Fig. 2.

Electrode preparation.—After degreasing in hot alcohol, the nickel tape was washed in conductivity water. In order to remove air-formed oxides, it was etched for 2 min in a 50-50 mixture of nitric and sulfuric acids, washed in conductivity water, and then maintained at a potential of — 0.25v (*vs.* NHE) by means of a Wenking 61-R potentiostat. The optical constants of the nickel were found to be consistent with those given in the literature for pure nickel surfaces (21).

Cell.—The cell (4.5 x 2.19 x 4.65 cm) was made of transparent Corning synthetic fused quartz (refractive index n = 1.458). The top of the cell was made of Teflon, with openings for the electrode and the gas.

Electrochemical measurements.—Steady-state experiments.—The current density-potential curve was obtained using a Wenking 61-R potentiostat, the current being measured by a Sargent SR recorder via a Keithley 610 electrometer. Steady state was assumed to exist when, in a period of 15 min, the current changed by less than 1% of the total current.

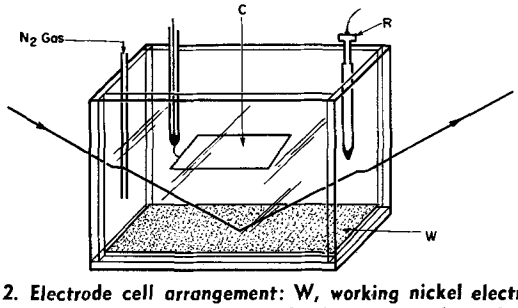

Fig. 2. Electrode cell arrangement: W, working nickel electrode; R, saturated calomel electrode; and C, the counter electrode.

Galvanostatic reduction.—The electrode was maintained at steady state in the passive region by means of a potentiostat; thereupon a switch with a rise time of ~ 10 μsec was used to impose a constant cathodic current on the nickel electrode. The resulting potential-time transients were recorded using a Tektronix RM-35A oscilloscope and a C-12 Polaroid camera.

Potentiostatic reduction.—The procedure consisted of switching from a potential in the passive region to a more negative one, and recording the current-time plots on a Sargent SR recorder. Care was taken to choose a lower, final potential which was, significantly above the potential for hydrogen evolution, so that the only cathodic process could be the reduction of the surface entity.

Ellipsometric measurements.—A standard procedure (22) was adopted for finding the extinction positions of the polarizer and analyzer. From the settings thus determined, a calculation was made of the values of the relative phase retardation, Δ, and the relative amplitude diminution, ψ, of the vibrations parallel and perpendicular to the plane of incidence. In this calculation, cell corrections (23) were introduced to take into account the fact that the incident and reflected light beams were not entering and leaving the cell at normal incidence.

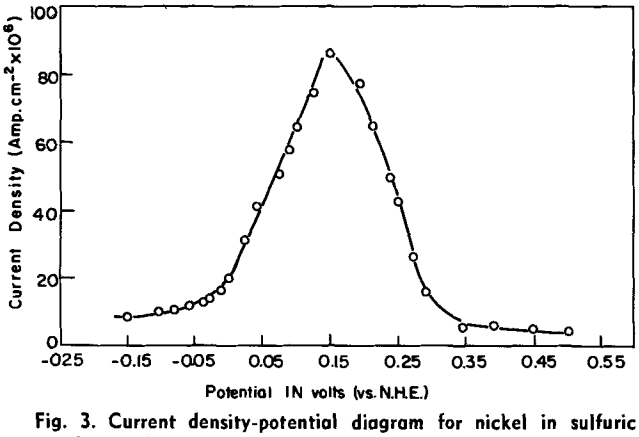

Fig. 3. Current density-potential diagram for nickel in sulfuric acid solutions (pH = 3.15).

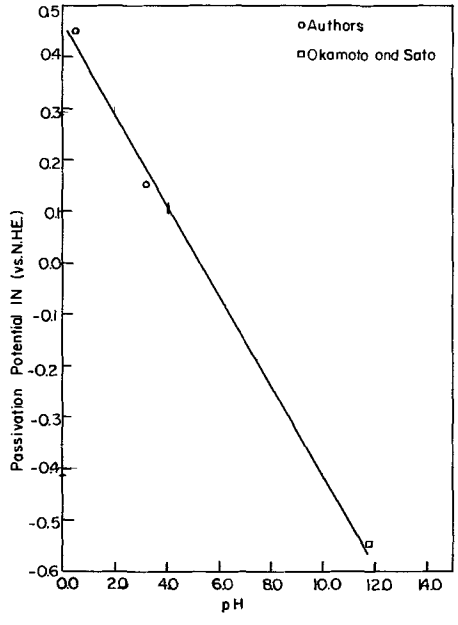

Fig. 4. pH vs. E_{pp} during the passivation of nickel in sulfuric acid solutions (pH = 3.15).

Results

Steady-state current density-potential plots.—The current density-potential curve for the pretreated nickel foil electrode in acid solutions of 0.5M SO_4^{--} concentration (pH = 3.15) is shown in Fig. 3. The passivation potential E_{pp} was + 0.15v (*vs.* NHE). The transition from the active to the passive state is clear. The pH dependency of the passivation process is given in the form of E_{pp} — pH plot in Fig. 4 with a slope of 95 mv/pH unit.

Galvanostatic reduction.—The potential-time curves obtained from the galvanostatic reduction are shown in Fig. 5. The potential falls rapidly to the value at which hydrogen evolution occurs after passing through a potential arrest. At a galvanostatic current density of 0.1 ma cm^{-2}, about 100 μC cm^{-2} are used at the arrest.

Potentiostatic reduction.—Typical current-time curves for the potentiostatic reduction of passive nickel are shown in Fig. 6. After an initial fall in current, there is a region of constant cathodic current, signifying a reduction process. This region corresponds to about 21 mC/apparent cm^2 when the reduction

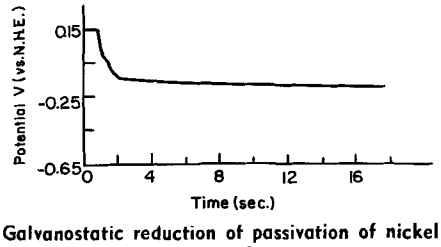

Fig. 5. Galvanostatic reduction of passivation of nickel at a constant current density of 0.1 ma cm^{-2}.

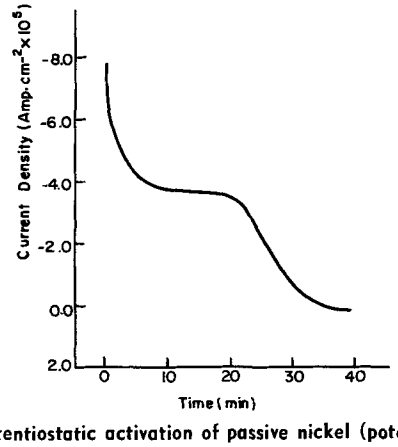

Fig. 6. Potentiostatic activation of passive nickel (potential before activation: +0.17v (vs. NHE).

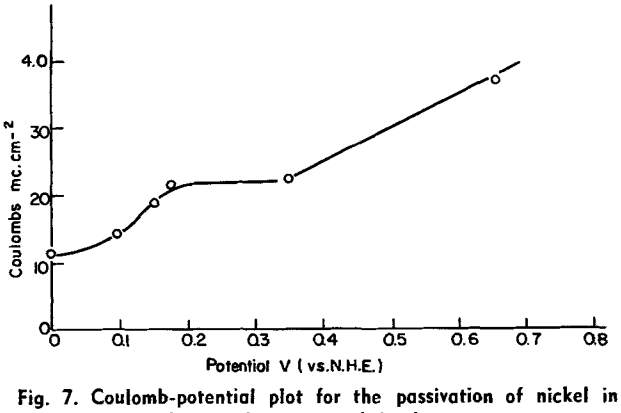

Fig. 7. Coulomb-potential plot for the passivation of nickel in acid solutions (under steady-state conditions).

was commenced on an electrode maintained at a steady-state potential of +0.3v. The quantity of electricity used for this reduction process depends on the initial steady-state potential from which the reduction was commenced (Fig. 7).

To check whether the potentiostatic reduction is effective in reducing the material on the nickel surface, an ellipsometric examination was carried out after the potentiostatic transient. It was found that the optical constants of the surface after potentiostatic reduction were the same as those of bare nickel.

Steady-state ellipsometry.—The steady-state values of Δ and ψ as a function of the potential of the nickel electrode are shown in Fig. 8 and 9. Figure 10 shows a $\Delta - \psi$ plot during the passivation of nickel, and Fig. 11 projects a three-dimensional plot of the variation

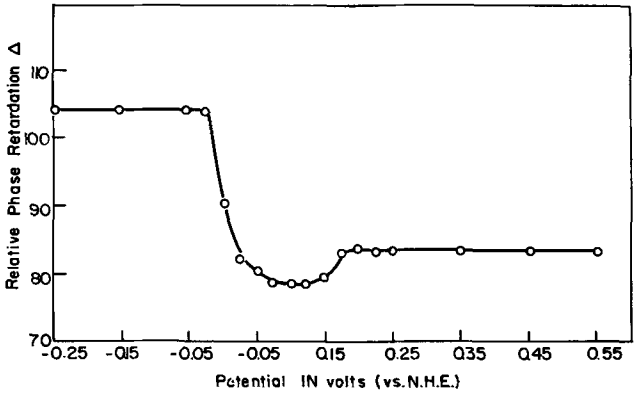

Fig. 8. Variation of relative phase retardation Δ as a function of potential, during the steady-state anodic passivation of nickel in sulfuric acid solution (pH = 3.15).

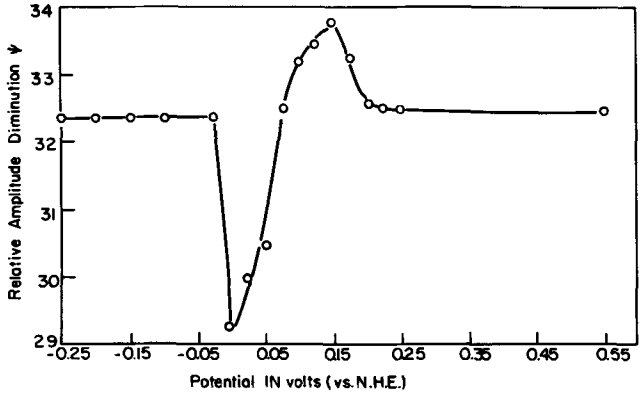

Fig. 9. Change of relative amplitude diminution ψ as a function of potential during the anodic passivation of nickel.

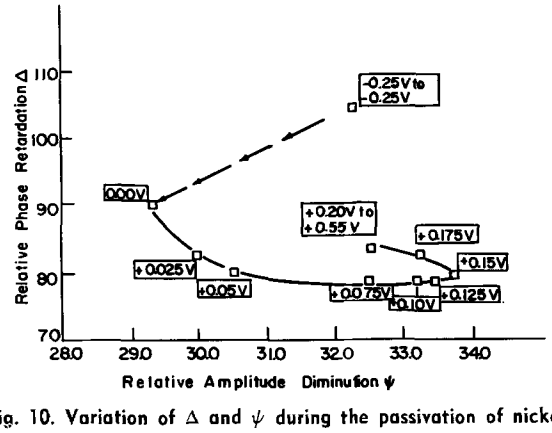

Fig. 10. Variation of Δ and ψ during the passivation of nickel

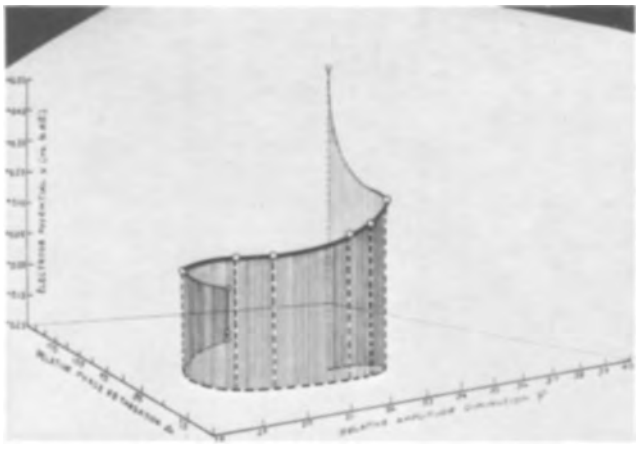

Fig. 11. Three-dimensional plot of the variation of Δ, ψ during the passivation of nickel.

of Δ, ψ as a function of the applied potential. Between — 0.250 and — 0.025v (*vs.* NHE), it is seen that there is no change in either Δ or ψ. There is, however, a drastic change ($\sim$ 14° in Δ and $\sim$ 3° in ψ) in Δ and ψ in the potential range between —0.025 and 0.000v. A feature of the observed Δ—ψ plot is that there is a characteristic inflection precisely at the passivation potential. In fact, an inflection of this type may be regarded as the ellipsometric criterion of passivation.

Discussion

Anodic dissolution of nickel.—At — 0.250v, it can be taken that the nickel is in a film-free condition, since the nickel has been etched and potentiostated at a potential in the immunity domain of the potential-pH diagram (24) for nickel. This expectation has also been confirmed by a comparison between the optical constants of nickel calculated from the Δ and ψ at — 0.250v and those found in the literature for pure nickel.

Since there is no change in either Δ or ψ in the potential range between — 0.250 and — 0.025v (*vs.* NHE), it means that one is working with a film-free nickel electrode. In this potential range, however, the current-potential curve indicates an increasing anodic current. Hence, the nickel must be dissolving anodically without film formation.

Previous electrochemical studies (25, 26) and the chronoellipsometric investigations (27) indicate that the nickel dissolves anodically via a soluble intermediate

$$Ni + OH^- \rightleftharpoons Ni\,OH_{ads} + e$$

$$NiOH_{ads} \rightarrow NiOH^+ + e$$

This mechanism is quite similar to the well-established mechanism for the anodic dissolution of iron in acid solutions (28).

Evaluation of the ellipsometric data.—The problem with the rigorous film-optics Eq. [1] is that, while only two quantities, Δ and ψ, are experimentally determined, there are three characteristics n_F, κ_F, and L_F, of the film, which have to be evaluated. Under these circumstances, the following procedure was adopted:

(*A*) At the outset, certain ranges for the maximum expected variation of film thickness (L), refractive index (n_F), and absorption coefficient (κ_F) were chosen on the following basis: For the thickness, a minimum of zero and a maximum of 100Å were considered; the minimum corresponds to a film-free surface and the maximum value is based on the fact that passive films thicker than 100Å have not been reported (29). The limits of film refractive index were taken to be 1.0 (physically adsorbed oxygen) and 4.0 (to allow for the maximum value found in the literature for solid oxides) (30). The absorption

index of the film was taken to be between 0.0 (a nonabsorbing film) and 1.9 (the absorption index of the metal).

(*B*) Choosing some particular value, L_F, (say 10Å), the film optics equation was used to calculate Δ and ψ for various values of n_F and κ_F chosen within the range stated above. A typical calculation of Δ and ψ from assumed values of n_F, L_F, and κ_F is given below. The following constants are known: n_1 the refractive index of the medium 1.334; n_M, the refractive index of the metal 1.793; κ_M, the absorption index of the metal — 1.834; θ_i the corrected angle of incidence 68.05°; and finally the wavelength of the light used 5461Å. A value of $L_F = 54$Å, $n_F = 3.1$, and $\kappa_F = -1.2$ were chosen for the typical calculation. Then the following quantities were calculated in the order given below

$$\cos\theta_t = \left[1 - \frac{n_1^2 \sin^2\theta_i}{(n_F + i\kappa_F)^2}\right]^{1/2}$$

$$= 0.948 - i\,0.049$$

$$\cos\theta_t' = \left[1 - \frac{n_1^2 \sin^2\theta_i}{(n_M + i\kappa_M)^2}\right]^{1/2}$$

$$= 1.030 - i\,0.044$$

$$X = -4\pi i(n_F + i\kappa_F)\cos\theta_t L_F/\lambda$$
$$= 0.160 - i\,0.357$$
$$e^X = 0.797 - i\,0.298$$

Making use of these results in Eq. [2]-[5], the Fresnel reflection coefficients come out to be

$$r_{p,12} = -0.011 - i\,0.159$$
$$r_{p,23} = 0.021 - i\,0.371$$
$$r_{s,12} = -0.741 + i\,0.098$$
$$r_{s,23} = -0.113 + i\,0.357$$

The above values are then used to calculate the numerator and denominator of Eq. [1]:

$$\text{NUM} = \frac{r_{p,12} + r_{=0.23}\,e^X}{1 + r_{p,12}\,r_{p,23}\,e^X} = -0.119 - i\,0.482$$

$$\text{DEN} = \frac{r_{s,12} + r_{s,23}\,e^X}{1 + r_{s,12}\,r_{s,23}\,e^X} = -0.816 + i\,0.235$$

Thus,

$$(\tan\psi\cos\Delta + i\tan\psi\sin\Delta) = -0.022 + i\,0.585$$
$$\tan\psi\cos\Delta = -0.022$$
$$\tan\psi\sin\Delta = 0.585$$

$$\therefore \tan\Delta = -26.547$$
$$\Delta = 92.157$$
$$\tan\psi = 0.585/0.999$$
$$\psi = 30.345$$

In practice, one chooses the lower limit of n_F, *viz.*, 1.0, and carries out calculations by varying κ_F in steps of 0.05 from 0 to 1.9. Then, the calculations are repeated for values of n_F increasing in steps of 0.05 from 1.0 to 4.0. Then, the whole set of calculations are repeated for other values of film thickness increasing in steps of 1.0Å within the range 0 — 100Å. In all, some 10^5 calculations of Δ and ψ were made.

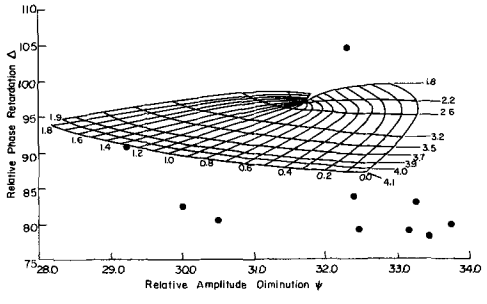

Fig. 12. Δ — ψ computed reactions for a film of constant thickness 40Å. The black circles ○ represent the experimental Δ — ψ plots observed during the passivation of nickel.

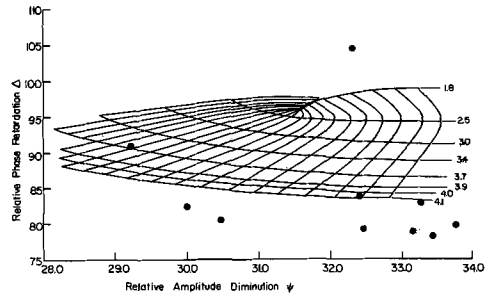

Fig. 13. Δ — ψ computed relation for film of constant thickness 50Å.

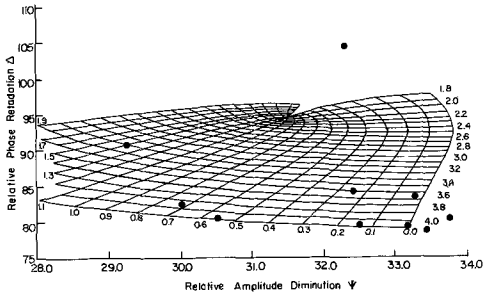

Fig. 14. Δ — ψ relations (computed) for a film of thickness 60Å

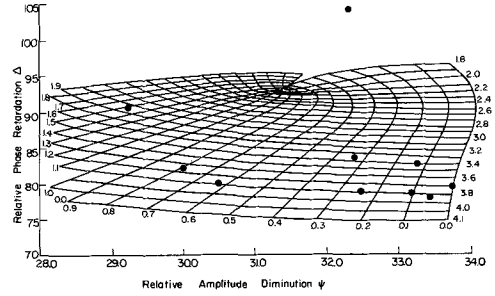

Fig. 15. Computed Δ — ψ relations for a film of constant thickness 70Å.

(*C*) For every value of film thickness, the values of the calculated Δ and ψ are plotted by joining points which correspond to the same κ_F but varying n_F, and those which correspond to the same n_F but varying κ_F. The former give rise to "vertical" lines and the latter to "horizontal" lines. In this way, one obtains, for every value of film thickness, a grid of lines in the Δ — ψ diagram.

(*D*) Finally, the experimental Δ — ψ plots are superimposed upon the calculated Δ — ψ grid for the various thicknesses (Fig. 12-17).

By this comparison between the experimental and calculated Δ— ψ diagrams, it can be demonstrated that for film thicknesses of less than 45Å, the experimental Δ, ψ values do not fall inside the grid in the calculated diagram (Fig. 12).[2] Thus, the film that is formed at 0.0v (*vs.* NHE) cannot be less than 45Å. For higher thicknesses, however, there is a fit. Thus, the values of film thickness, refractive index and absorption coefficient are in the range shown in Fig. 18-20.

[2] At potentials greater than 0.0 (*vs.* NHE), the value of the minimum thickness consistent with the ellipsometric values is 70Å.

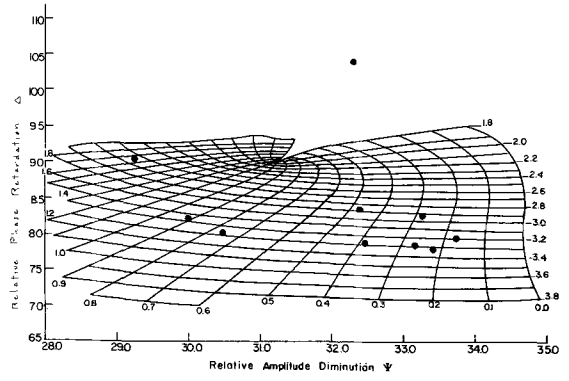

Fig. 16. Computed $\Delta - \psi$ relations for a film of thickness 90Å

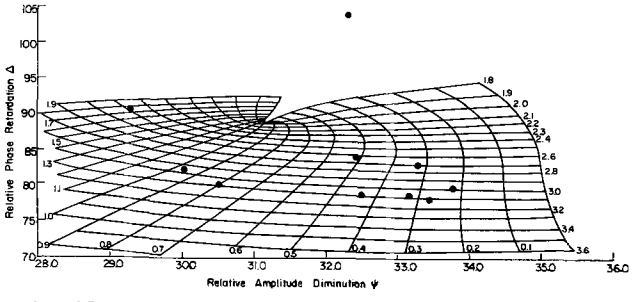

Fig. 17. $\Delta - \psi$ computed relations for a film of constant thickness 100Å.

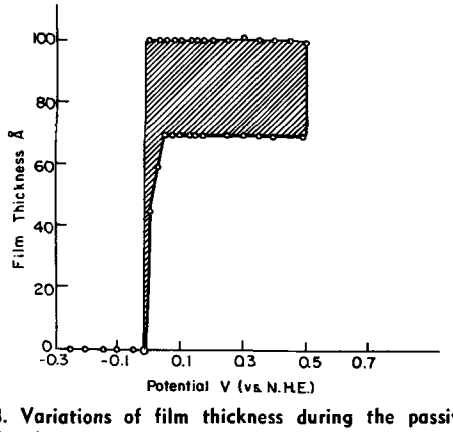

Fig. 18. Variations of film thickness during the passivation of nickel. The thick line refers to the minimum thickness that can be attained.

To narrow down these film characteristics more definitively, the potentiostatic activation results were used. From the quantity of electricity used to reduce the surface film present at various steady-state potentials, the film thickness was calculated. The film formed at 0.0v (*vs.* NHE) was taken, on the basis of chronoellipsometric data (27), to be nickel hydroxide. Using the molecular weight and density of nickel hydroxide, with a roughness factor of 2, the $Ni(OH)_2$ film thickness was calculated to be 60Å (20). In the case of the films present at other potentials, there is uncertainty in the particular compounds present. But, whatever the nickel compound (subhydroxide, various nickel oxides NiO_x), the film thickness at potentials more anodic than 0.0v (*vs.* NHE) turned out to be within 10% of the initial value, *viz.*, 60Å.

Since the potentiostatic activation experiments have yielded a value of film thickness of 60 ± 6Å, the $\Delta - \psi$ diagrams calculated for a 60 ± 6Å film can be used to read off those values of n_F and κ_F which correspond to the experimentally-observed values of Δ and ψ.

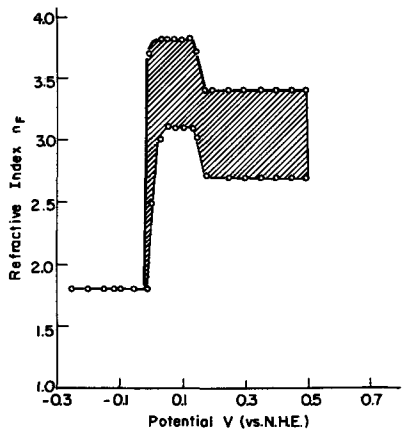

Fig. 19. Variation of refractive index. n_F as a function of potential, during the passivation of nickel. The thick line refers to the minimum refractive index of the film that can be obtained by using a value of film thickness computed from coulometry.

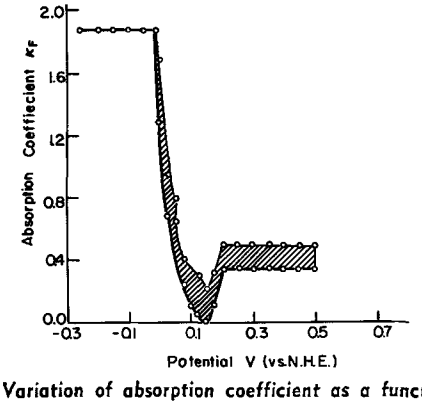

Fig. 20. Variation of absorption coefficient as a function of potentials during the passivation of nickel. The thin line refers to the maximum κ_F that can be obtained.

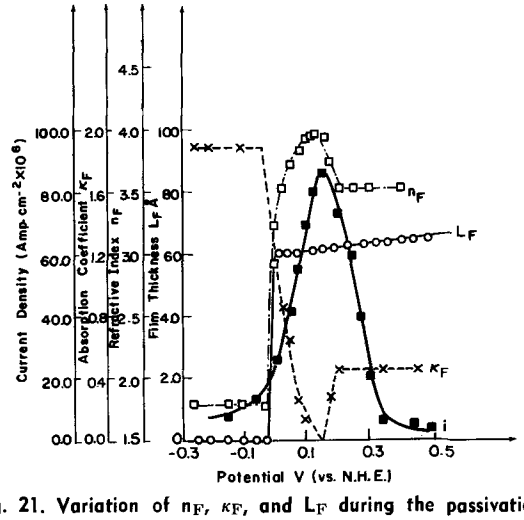

Fig. 21. Variation of n_F, κ_F, and L_F during the passivation of nickel in acid solutions.

Thus, one obtains the film thickness (L_F), refractive index (n_F) and absorption coefficient (κ_F) which have been reported earlier (20). Figure 21 shows a three-way plot of the variation of n_F, κ_F, and L_F as a function of potential.

Film formation.—The sudden large change in Δ and ψ in a narrow 25 mv potential range between — 0.025 and 0.000v (*vs.* NHE), is the ellipsometric evidence of film formation. This film has been shown by unambiguous interpretation of the ellipsometric data to be not less than 45Å, and with the help of coulometric data to be about 60Å.

It will be noticed, however, that the onset of film formation is not accompanied by any decrease in the dissolution current (the gradient of the current-potential line, however, is decreased). The inescapable conclusion is that the film formed at 0.0v (*vs.* NHE) does not *per se* cause passivity. It can only be a precursor or prepassive film.

Analysis of the chronoellipsometric data (27) on the mechanism of precursor film formation supports a dissolution-precipitation mechanism (18). Nickel dissolves anodically to form a soluble intermediate, $NiOH^+$, which accumulates near the electrode until there is precipitation of $Ni(OH)_2$.

The potential at which film formation takes place can be estimated by the following calculations: Assuming that, for a prepassive film to form by precipitation in solution, the current for anodic dissolution i_a is greater than the limiting current i_L required for the ionic species ($NiOH^+$) to form the precipitate, one has, say

$$(i_a)_{\text{film formation}} = 10\, i_L$$

$$(i_o)_a\, e^{\eta F/RT \cdot 3/2} = 10 \cdot \frac{DzF}{\delta} c_{NiOH^+} \qquad [9]$$

Taking the concentration of the $NiOH^+$ species from chronoellipsometric data (27) as 10^{-3} m/l and $(i_o)_a$ (28) as 7×10^{-7}, Eq. [9] can be expressed as

$$(\eta F/RT)\,(3/2) = 2.303 \log (1.4 \times 10^6)$$

$$\eta = +\,0.248\text{v}$$

Taking into account the reversible potential for nickel dissolution at this pH (3.15), as — 0.2v (*vs.* NHE), the potential of inflection where the film formation should occur is + 0.048v (*vs.* NHE), in excellent agreement with the experimentally observed value of + 0.000v (*vs.* NHE).

Passivation process.—It is seen (Fig. 21) that the quantities n and κ undergo two marked qualitative change, the first of which is associated with film formation. The second of these two changes is that which is more important from the view point of the mechanism of passivity, for it occurs at the potential at which the current begins to fall, *i.e.*, at the passivation potential. The decreasing trend of κ, which began at the film formation potential, is reversed and κ begins to increase.

The absorption coefficient is known from classical optics to be related to the electrical conductivity, σ_ν, of the film at optical frequencies (31)

$$\sigma_\nu = n\kappa\nu \qquad [10]$$

where σ_ν is the e.s.u. conductivity at the frequency.

Thus the changes in κ_F are a direct measure of the potential-variation of electrical conductivity at the optical frequencies (under steady-state conditions) during the passivation of nickel in acid solutions (pH = 3.15). There is a decrease in the electrical conductivity until the passivation potential, and immediately afterwards an increase in the conduction is observed. Further, the final values of conductivity are of the order observed with semiconductors at optical frequencies (32). This indicates that the passivation process is associated with the formation of a semiconducting film. Although the difference in conduction of a metal and a semiconductor at zero frequency would be many orders of magnitude, at optical frequencies (10^{14} cps), this difference would be expected to be much smaller, since the relaxation time of the electrons in the metal is 10^{12} sec^{-1}, and thus only a small response would be expected from the electrons in the metal to radiation of 10^{14} cps (33).

Composition changes in the passivation process.—The changes of refractive index from an initial precursor film of $Ni(OH)_2$ to the final semiconducting passive film probably arise from the anodic oxidation of $Ni(OH)_2$. Some indications concerning the nature of the passive film can be obtained by comparing the refractive indices calculated theoretically for various types of oxides with those experimentally observed from ellipsometry.

It is possible to calculate the refractive indices (real) from the well-known Lorentz-Lorenz equation

$$\frac{n^2-1}{n^2+2}\frac{M}{d} = \frac{4\pi}{3} N\alpha_o \qquad [11]$$

where M and d are the molecular weight and density of the material, respectively; α_o is the total molar polarizability of the molecule comprising the material, and n is the real refractive index of the material medium. The important aspect of the calculations is to obtain the value of the molar polarizability α_o of the molecule. For a diatomic molecule, α_o is given by

$$\alpha_o = \frac{b_1 + 2b_2}{3} \qquad [12]$$

where b_1 and b_2 are polarizabilities in the direction of line centers joining the two atoms and perpendicular to the line of centers, respectively, are given by

$$b_1 = \frac{\alpha_1 + \alpha_2 + 4\alpha_1\alpha_2/r^3}{1 - 4\alpha_1\alpha_2/r^6} \qquad [13]$$

$$b_2 = \frac{\alpha_1 + \alpha_2 - 2\alpha_1\alpha_2/r^3}{1 - \alpha_1\alpha_2/r^6} \qquad [14]$$

where α_1 and α_2 are the electronic polarizabilities of the atoms 1 and 2 comprising the molecule and r is the bond distance between them.

There exists an apparent uncertainty in the available electronic polarizability data, as also in the averaging of the individual polarizabilities (in three mutually perpendicular directions) to obtain the molar polarizability α_o. It was assumed that the structure of the nickel oxide would also represent the nonstoichiometric nickel oxides (NiO_x, $x \geq 1$).

Nickel oxide has a cubic structure with the unit cell side, a = 4.17Å. The densities of the various nonstoichiometric oxides were calculated on a proportional basis of the oxygen present in those compounds. The following electronic polarizability data were taken

$$\alpha_{Ni^{++}} = 0.27 \times 10^{-24}\ \text{cc/mole}$$

$$\alpha_{O^{--}} = 2.4 \times 10^{-24}\ \text{cc/mole}$$

It was further assumed that a proportional increase of $\alpha_{O^{--}}$ takes place with change of radius of the O^{--} with increasing nonstoichiometry ($O_{1.0} \rightarrow O_{1.7}$).

The above electronic polarizability data were fed into Eq. [12] to [14] to calculate the molar polarizability, α_o. Using Eq. [11] and the above information, the refractive index of the medium was calculated. It was found that the refractive indices of the compounds $NiO_{1.5}$ — $NiO_{1.7}$ varied from 3.3. — 3.7. The experimentally observed value of the refractive index in the passive region was 3.5. Thus, a comparison between the experimental and calculated values establishes that the passive layer is of composition $NiO_{1.5\text{-}1.7}$.

But the conversion of $Ni(OH)_2$ to a nonstoichiometric oxide has been studied by Briggs and Wynne-Jones (34). Using x-ray diffraction studies in conjunction with electrochemical measurements, they suggested the actual final product to be $NiO_{1.7}$ in agreement with ellipsometric determinations. It has been established, therefore, that in the anodic conversion

of the precursor film $Ni(OH)_2$ to the final passive film, a nonstoichiometric change takes place, and that this change is associated with a marked increase of electronic conductivity and a marked decrease of corrosion rate.

The existence of a semiconducting passive film does not preclude the possibility of oxygen chemisorbing on its surface. In fact, such a chemisorbed oxygen layer must be involved in the evolution of oxygen at ~ 1.5v. When, however, one attempts a galvanostatic reduction, the charge used ($\sim$100 μC cm^{-2}) indicates that only the chemisorbed oxygen on top of the passive oxide is reduced before the potential falls to that corresponding to hydrogen evolution. That the passive oxide is not reduced under galvanostatic conditions is proved by the fact that after such an experiment the ellipsometer still reveals a film-covered surface even in the presence of hydrogen evolution.

Mechanism of anodic passivation.—The present results have brought out several clear diagnostic criteria which permits for the first time a direct testing of the various suggestions regarding the mechanism of passivity. It has been demonstrated unambiguously that a thick (not less than 45Å) three-dimensional film is formed at a potential distinctly cathodic to the passivation potential and that this is a necessary, but not sufficient, condition for passivity. It is the conversion of this precursor film into a semiconductor that constitutes the essential step in the mechanism of passivation, because the development of electronic conductivity prevents high-field ion transport through the film and thus prevents metal dissolution. Metal dissolution is thus drastically reduced and the metal has become passive.

Most of the theories of passivity (1-14) are at variance with either or both of the fundamental experimental conclusions that have emerged from this study. It appears that with regard to the mechanism of precursor film formation, the view of Müller which is based on a dissolution-precipitation mechanism is in closest correspondence with facts indicated by ellipsometry. The existence of electronic (13) conductivity has been stressed by Weil (13), by Vetter (12), and by Pryor (14). But, an integrated view requires a picture, not only of what characteristics the passive film must have, but also an indication of how and when they are introduced. The present study leads to a unified picture of the passivation process: a prepassive film is formed by a dissolution-precipitation mechanism, and this film starts becoming an electronic conductor at the passivation potential. The essential cause of passivity is neither a monolayer nor a multilayer of oxide. It is the conversion in the multilayer from ionic to electronic conduction at the passivation potential probably by the introduction of nonstoichiometry.

Discussion

W. Mehl: The work by Bockris, Reddy, and Rao shows that ellipsometric measurements can lead to significant contributions to the understanding of passivation phenomena. It also shows, however, that the interpretation of ellipsometer readings in terms of parameters which are meaningful to electrochemistry is by no means simple and straightforward; rather it requires additional assumptions and numerical data obtained by other means. It is interesting to note for example that the value of the thickness of the passivating oxide film was actually not determined in this work by ellipsometry but rather by an electrical method. The optical method does permit one, however, to follow the all-important changes of the electrode surface at the Flade potential (which can be either a "passivation" or an "activation" potential depending on the direction of the potential sweep).

Weil[1] and Vetter[2] have shown that the thickness of the oxide film for passive iron is potential dependent

[1] K. G. Weil, *Z. Elektrochem.*, 59, 711 (1955).

[2] K. J. Vetter, *Z. Elektrochem.*, 58, 230 (1954).

and with an acidic electrolyte a linear relationship was found between film thickness and the difference between the applied potential and the Flade potential. This would lead in the steady state to a value $d = 0$ for the film thickness at the Flade potential, and one could now argue that the smallest value for the thickness of a passivating oxide film is that of a monolayer. On nickel Arnold and Vetter[3] measured a thickness of the passivating oxide film of about 40Å. They did, however, speculate that at the Flade potential a nonporous monolayer was formed, which grew only at more anodic potentials to the above-mentioned thickness of 40Å.

What struck me most about this work was the similarity between the model proposed here for the passivation of nickel and the model proposed by Bonhoeffer, Vetter, Weil, and Pryor[4] and Gohr and Lange[5] for the passivity of iron. Nickel and iron are chemically rather similar elements; this agreement is thus very reasonable.

Going into the details of the work presented here, two points seem to be somewhat questionable. The first and minor point is the high index of refraction found for the surface oxide. The value 3.5 is very high for a nickel compound; the highest value reported previously was 2.4 for NiO.[6] It can perhaps be argued that the value for FeO (cubic) is 2.3 while the value for Fe_2O_3 (rhombohedric) is 3.0.[6] Nevertheless, it seems unsatisfactory to calculate by a somewhat involved method an index of refraction of 3.5 for $NiO_{1.5\text{-}1.7}$ without showing that the same method leads to the correct value for NiO.

The second and more important objection is concerned with the passivation mechanism proposed by the authors. The mechanism proposed in the section on "Composition changes in the passivation process" of the paper has to be reconciled[7] with the observed values of the Flade potential. For iron this was for a long time a controversial point. From the work of Franck[8] it was known that the pH dependence of the Flade potential for iron E_{Fe}^F follows the relationship

$$E_{Fe}^F = 0.58 - 0.058\ pH$$

Only fairly recently Vetter[9] and Gohr and Lange[5] have shown that it can be reconciled with the following electrode mechanism

$$2Fe_3O_4 + H_2O \rightarrow 3\ \gamma\text{-}Fe_2O_3 + 2H^+ + 2e^-$$

i.e., passivation is preceded by the formation of Fe_3O_4. The Flade potential is now defined as that potential at which the oxygen partial pressure reaches the value for the equilibrium between γ-Fe_2O_3 and Fe_3O_4.

While in acidic solutions, Fe_3O_4 is dissolved so rapidly that no continuous film can form below (at potentials more negative than) the Flade potential, this oxide is rather stable in alkaline solutions and the existence of a prepassive film below the Flade potential has been shown.[10,11] The ideas of Pryor are somewhat different from those of Vetter, but they also involve a similar sandwich structure.

For nickel, Arnold and Vetter[3] have shown that the pH dependence of the Flade potential is described by

$$E_{Ni}^F = 0.355 - 0.058\ pH$$

The value for E_{Ni}^F at pH = 3.15 obtained by the present authors agrees excellently with the above expression while the other point of Fig. 4 and the value taken from Okamoto [ref. (11) of the authors] do not.

It appears from the present paper that the authors propose for the electrode mechanism responsible for passivation the mechanism of the nickel hydroxide electrode, but the potential of this electrode is unfortunately roughly 1v more positive[12] than the experimental values given above for the Flade potential.

In spite of these objections to certain details, I find the demonstration of the importance of the Flade potential by ellipsometric measurements most impressive.

J. O'M. Bockris and H. Wroblowa (partially communicated): Ellipsometry determines the situation in a passivation process, and this can essentially be read from the last figure in the paper. The result contains elements of several theories associated with the names of Muller, Ibl, Vetter, and Pryor. It does not correspond to anyone of these theories. Further, there are gaps in our knowledge of the causes for the happenings which ellipsometry indicates: the most important of these is the reason for the rise in conductivity; the explanation offered in terms of a change of valency state of the metal and a consequent increase in conductivity is largely speculative. An alternative speculation could be in terms of the effects of ionic adsorption at the prepassive oxide-solution layer and effects of the ionic field on the conductance of the oxide (cf. the effects found by Paul Schmidt for cation adsorption on the conductance of surface films of oxide).

Note that ellipsometry is a technique in which the use of computors is virtually essential. This is probably the reason for the long delay in realization of a technique ideally suited to electrode studies, the theory of which has been available for several decades.

The refractive index which ellipsometry gives for the passive film is indeed high. However, values as high and higher do characterize some transition metal oxides and sulfides. If one solves the Lorenz-Lorentz equation for refractive index (n), it can be seen that the theoretical value of n would be expected to increase rapidly as the polarizability approaches $(3M)/(4\pi N_A \rho)$ where M = molecular weight, ρ = density, and N_A = Avogadro's number. It is likely that the effective polarizability of oxygen is greater in a nonstoichiometric oxide than in a stoichiometric oxide.

Regarding the validity of the calculation method for refractive indices which we used in our paper, the method was indeed tested by us for NiO. The theory (which we later used to interpret the value of $n = 3.5$ in the passive region) gave $n = 2.47$ whereas experimental values for the refractive index of NiO were 2.2-2.5.

Regarding the thermodynamics of the active and passive transition for which we have suggested an oxidation to $NiO_{1.5}$-$NiO_{1.7}$ (on the basis that this would fit, by calculation the refractive index determined ellipsometrically): calculation of the standard potential for a transition of $Ni(OH)_2$ to this nonstoichiometric oxide would be impossible to make in the absence of appropriate thermodynamic data (which would be clearly difficult to obtain). The value reported by Conway and Gileadi refers to bulk phases of a different constitution from that suggested in our papers. It lies 1v above the observed passivation potential. The potential of the NiO-Ni_3O_4 couple lies below that determined by us. The range for various oxidation potentials of NiO thus extends over more than a volt and includes that determined.

Regarding the pH dependence on the passivation potential; that experimentally reported here agrees

with the observations of Okanoko and Sato [ref. (25) of our paper], although it differs from that of Arnold and Vetter [ref. (3) of Mehl's comments]. The latter authors record only three points through which one could draw lines with slopes between 58 and 90 mv.

Regarding the constancy of film thickness; cf. our reply to Dr. Vermilyea's comment later in the discussion of our paper.

H. R. Thirsk: I think that in many ways the choice of the word "precipitation" by the authors is unfortunate. The optical measurements imply a coherent layer on the surface with quite well-defined structural and electrical properties. It is as reasonable to consider such a layer as deposited as it would be so described in metal deposition. I think this is a matter more of semantics than electrodics, and I would urge some agreement on what word to use.

J. O'M Bockris (communicated): Professor Thirsk's comment could only be made in the absence of contact with the unpublished chrono-ellipsometric evidence in the nickel passivation. The dependence of τ on i from this work is consistent only with metal dissolution terminated at τ with the formation of a substance, the solubility product of which follows from the measurements as equal to that of $Ni(OH)_2$.

Other strong evidence is available to support a dissolution-precipitation mechanism for nickel at $pH = 3.1$: (*a*) τ is affected by stirring; (*b*) The growth of the deposit is linear with respect to time (cf. unpublished work by Reddy and Bhimasina-Rao on transient ellipsometry), where the ellipsometer is balanced in times of the order of 0.02 sec.

Thus, the prepassive layer cannot be formed in the sense of a Faradaic process of OH^- or water discharge but must be "precipitated," the Ni first forming $Ni(OH)^+$ and then $Ni(OH)_2$ when the critical concentration is exceeded.

D. A. Vermilyea: In both the passive and the prepassive conditions the steady current is determined by the rate at which the film dissolves. Suppose the film changes from insulating to semiconducting during the transition, as found by the authors, but dissolves at the same rate. Because of the reduced electronic field the ion transport would decrease, giving a temporarily reduced current. Continued dissolution will then reduce the film thickness until ion transport is again in balance with dissolution rate, and the current will then be equal to that in the prepassive condition. The authors' observations show, however, that the film thickness remains unchanged after the transition while the steady current decreases. It is therefore not a change in the rate of ion transport which is responsible for passivity, but rather a decrease in the dissolution rate of the film. It is then the dissolution rate which should be considered in connection with the observed changes in film properties.

H. Wroblowa and J. O'M Bockris: According to the mechanism suggested in the paper, under conditions of anodic polarization, the prepassive film does not dissolve chemically, nor is the steady-state current equal to the rate of this film's dissolution. This situation arises from the fact that the vicinity of the electrode is always saturated with the corresponding nickel ions, as shown below.

Upon anodic polarization, the bare metal surface dissolves to form $NiOH^+$ ions which diffuse away from the electrode. This corresponds to the exponential rise of current with potential (cf. Fig. 21). The limiting diffusion current density is

$$i_{L,NiOH^+} \frac{2FD\, c_{NiOH^+}}{\delta\, 1000}$$

where $D_{NiOH^+} \cong 10^{-5}$ cm/sec, $\delta \cong 5 \times 10^{-2}$ cm for an unstirred solution, and c_{NiOH^+} corresponds to the saturation concentration in moles/liter, *i.e.*, $c_{NiOH^+} = K/OH^-$ where K is the solubility product [$K = (NiOH^+)\ (OH^-)$]. When with increasing potential the current becomes higher than $i_{L,NiOH^+}$, the prepassive film of $Ni(OH)_2$ precipitates on to the electrode and cannot dissolve since the saturation concentration of $NiOH^+$ ions is continuously maintained at the saturation value by the nickel dissolution current and the high field transport through the film. This corresponds to the region between the potential at which the film first appears and the passivation potential (cf. Fig. 21).[13]

(The fact that in this region the thickness changes little, although the current increases some five times, can be easily explained by the increased rate of diffusion away of $NiOH^+$ ions, arising from the increased value of c^* with potential. This would be expected because of a *p*H decrease expected for currents above[14] $\sim 4 \times 10^{-5}$ amp cm^{-2}, resulting in corresponding increase of c^*_{NiOH}.)

Under those conditions the rate of chemical dissolution of the prepassive film is practically equal to 0. Thus, passivation cannot be connected with the changes in the dissolution rate of the film, but with the observed appearance at the passivation potential, of the electronic conductivity which decreases the field across the film and consequently decreases the rate of the nickel ion transport through it.

B. N. Kabanov: The passivation theory of metals suggested by Bockris, Reddy, and Rao, according to which passivation is caused by an increase in the electronic conductivity of a nonpassivating thick (not less than 45Å) phase layer, is simple and elegant and unites the theories of Müller, Bonhöffer, and Vetter. This theory has been verified for a particular case of the passivation of commercial nickel in 0.5M K_2SO_4 solution at $pH = 3.15$.

However, in principle, the theory is not applicable to a large group of systems in which passivation occurs before a thick nonpassivating layer of a non-electron conducting substance is formed on the metal surface.

Such systems include primarily those in which the metal is passivated by an amount of oxygen smaller than that required to form a continuous monoatomic layer, *e.g.*, platinum in HCl solutions,[15] iron is not very strong (say 0.1N) NaOH solutions.[16] One oxygen monolayer suffices for zinc passivation in dilute KOH solutions,[17] for indium passivation in citric acid and other solutions,[18] etc.

In some systems (*e.g.*, iron in acid sulfate solutions, zinc in alkaline solutions) a phase oxide layer can be formed as well (not necessarily as the result of precipitation from the solution, but often owing to the reaction occurring in the solid phase without the metal ions passing into the solution). There are a number of cases, however, when the phase layer is formed only after passivity has set in, *i.e.*, after a strong slowing down of the process of anodic oxidation of the metal, which is due to adsorption of oxygen or other atoms.[17]

[13] It may be seen from Fig. 21 that the film appears exactly at the potential where an inflection appears on the i-E curve and the current starts to increase linearly, rather than exponentially, with E.

[14] This is the value of the limiting current of hydrogen ions produced in the reaction

$$Ni + H_2O \rightarrow NiOH^+ + H^+ + 2e^-$$

[15] B. Ershler, *Z. Fiz. Khim.*, **14**, 357 (1940); **18**, 131 (1944).

[16] B. Kabanov and D. Leikis, *Doklady Akad. Nauk SSSR*, **58**, 1685 (1947).

[17] T. Popova, V. Bagotzky, and B. Kabanov, *Z. Fiz. Khim.*, **36**, 1433 (1962); B. Kabanov, *Izv. Acad. Nauk SSSR, Otd. Khim. Nauk*, **1962**, 980.

[18] T. Popova and N. Symonova, *Izv. Acad. Nauk SSSR, Ser. khim.*, **1963**, 1187.

At the present time one cannot draw a general conclusion about the applicability of the theory of Bockris *et al.* to the passivation of different metals. In our opinion, the wide diversity of cases of metal passivation cannot be explained by any single theory. A large group of passivation phenomena can be accounted for by a concept, which I should call adsorption theory of passivity. In the paper under consideration[19] (Tables 1 and 2) I have been wrongly ascribed the point of view that the passivating layer "acts as barrier layer and prevents the particles of the solution from reaching the electrode surface." According to my concept, for metal passivation to occur a strong chemical bond between the passivating agent (O, OH, SO_4, I, etc.) and the metal surface is required.

In some cases the formation of nonpassivating oxide or salt layers does exert an indirect influence on passivation. The thickness of the nonpassivating layer may vary in different cases from 1-2 molecules to 50-100Å. As a rule, after the passivating layer has been formed (or the nonpassivating layer has been transformed into the passivating one), it proves to be permeable to ions. Therefore, the statement of the authors of the paper under discussion that after passivation the ion penetration and hence continued corrosion (dissolution) of the metal stops should be considered as an over simplification.

It should be noted that the bond between the passivating agent and metal atoms (in the case of a weak bond between the metal atoms) might facilitate the tearing away of this group of atoms from the electrode, *i.e.*, bring about the activation of the metal by the same substance, which in other cases or under different conditions causes passivation (O, OH, SO_4, etc.).

J. O'M Bockris (communicated): Of course, there is no doubt of the literal correctness of Professor Kabanov's assertion that our use of an ellipsometric technique to show that the passivation of nickel in solution of *p*H 3.15 occurs by dissolution-precipitation of a prepassive hydroxide layer, followed by an increase in its electronic conductivity at higher potentials (and hence its passivation) does not constitute a mechanism determination applicable to all systems. There is no doubt, for example (as also determined ellipsometrically[20]) that metals which become passive in the sense that, at a given potential and reaction, they suddenly cease to be good electrocatalysts (*e.g.*, Pt in the oxidation of ethylene) do so by forming a thin film and that there is a considerable change in surface properties whilst the amount of O is less than that which would correspond to a monolayer.

In respect to the mechanism of the cessation of dissolution or corrosion of a substrate at a given potential, it may be that there are systems where the mechanism which we have established for one system involving Ni is not general. However, it does not seem too much to submit that the application of ellipsometric technique under potentiostated conditions makes a radical break in the history of the examination of passivity and corrosion and that it gives so much more direct information compared with that obtained before (which was always interpretive, *e.g.*, current-potential behavior) that it would be perhaps incautious to be confident concerning the mechanism in other systems, until typical ones have been examined ellipsometrically. In unpublished work, we have established a qualitatively similar phenomenology with Fe to that with Ni, and it appears that in the presence of Cl^- ions, the rise in electronic conductivity does not occur, an interesting indication of the mechanism of the effect of the depassivating action of Cl. We make two specific points:

1. The description we made of the mechanism associated with Professor Kabanov's papers represented our understanding of it. The occurrence of "a strong chemical bond between the passivating agent and the metal surface" is not by itself a statement of a mechanism.

2. Regarding Professor Kabanov's penultimate paragraph, there is perhaps some misunderstanding. It may well be that the permeation coefficient (and the corresponding mobility) of the metal ion in the film is unchanged on passivation. We have no information on this point from the ellipsometry. The point is that the electronic conductivity increases so that the field gradient in the film is reduced and hence ionic transport through the film is reduced. It is this reduction of the rate of transport of the metal cation through the film (which may well have unchanged permeability to the ions concerned) which is the immediate cause of the reduced dissolution rate, or passivation.

S. Schuldiner: It was observed that the film thickness found on a passive Ni electrode was ≈60Å. This demonstrates that a film thickness above 60Å is unnecessary for passivation, but does it prove that the effective film has to be this thick?

J. O'M. Bockris (communicated): Dr. Schuldiner's question is indeed well taken. It is, of course, analogous to that of Professor Kabanov.

There can of course be no "virtually certain" answer until a dozen or so systems exhibiting metal-dissolution passivation have been measured. I can give two points in favor of the answer that it is essential that the film which "causes" passivity must be more than a mono-layer in thickness.

(*A*). Under conditions of transient ellipsometry, measuring down to 0.02 sec, and a correspondingly timed potential transient, the film is still 10-20Å thick for nickel in a solution of $pH = 3.1$.

(*B*). What the steady-state measurements indicate is that there is a quite sudden (in respect of the potential at which it switches on) deposit of a film which at this switch-on potential attains a thickness which hardly varies as the potential is increased. At the point at which the thickness-potential plot suddenly rises to its final value, the current inflects, its rate of increase with potential rapidly falling. Chronoellipsometry shows the deposit to have a solubility product equal to that of $Ni(OH)_2$. At potentials positive to the switch-on point of the layer, the current rises still, with decreasing rate of rise; and then, at the passivation potential, the electronic conductance rises from zero to a large value. These are facts. It is difficult, for the Ni case under the given conditions, to avoid from these facts, a model in which the critically important factor is the change in conductance with potential. But, in this case, the film must have a corresponding lattice, *i.e.*, must be "several monolayers" thick. Of course, no claim is made particularly for the 60Å which was ellipsometrically determined for Ni under steady-state measurements as being a critically low value of film thickness for passivation in general. What is claimed to have been established is that before passivation occurs a film is layed down, in the case reported, 60Å thick. The critical point is that this thick film lies down before passivation. This is the fact which is inconsistent with the views of those workers who agree with the evidence, long available from coulometry, that a film in the 50-100Å region is associated with passivity but maintain that it is not the cause of it, the latter being often attributed to effects on the double layer potential difference of an adsorbed O layer. The present results show that the passivation is associated with a rise in the electronic

[19] *Editorial Note*: In the preprint of the paper the authors included two tables (1, Views of Various Authors on the Theory of Passivity and 2, Summary of Our Conclusions Compared with Other Authors) which they have chosen to withdraw from final publication.

[20] A. K. N. Reddy, M. Genshaw, and J. O'M. Bockris, *J. Electroanal. Chem.*, 78, 406 (1964).

conductance of the film, *i.e.*, not with the action of a monolayer.

Clearly, it can always be argued, *cf.* Professor Kabanov's comment, that the qualitative result is not a general one; and this possibility can only be met by extending the ellipsometric work to several systems. But it must be taken into account that the model which the ellipsometry so unambiguously suggests contains elements from various theories formerly suggested for metal dissolution passivation, and eliminates one of two classes of such theories. It seems quite probable, on the present evidence, that a qualitatively similar model will be favored by the forthcoming evidence for the other transition metals.

F. W. Will: It is agreed that the ellipsometric method is a valuable *in situ* method for the study of surface films on electrodes. Its major shortcoming, however, is that it does not lead to an unambiguous identification of the species constituting the surface films. Furthermore, little is known about the effect of the ionic double layer and of adsorbed species on the elliptically polarized light.

It ought to be mentioned that other *in situ* methods have emerged recently that are of considerable importance. (The advantage of two of these, like x-ray diffraction and infrared absorption techniques, lies in the fact that an unambiguous identification of surface species is possible.

J. O'M. Bockris (communicated): X-ray analysis of electrodeposits *in situ* has been made occasionally, *e.g.*, by placing a rotating disk electrode so that it is half out of solution and submitting the top half to the beam. The difficulty is not only that the deposits hitherto must be relatively thick, but of course the x-rays decompose the aqueous layer and this may lead to unexpected electrode reactions. Infrared studies have been attempted (through thin film electrodes, from the back, to avoid absorption by water). Hitherto, no successful identification of a surface compound has been thus recorded. Electron microscopy could hypothetically be used were a machine of sufficient power constructed so that the electron energies could overcome absorption in the solution. Its cost would be astronomical. Electron spin resonance gives quite good theoretical predictions for sensitivity in detecting radicals with unpaired spins. Attempts at its use in electrode reactions have not yet succeeded.

A general difficulty concerning the first three of these is that of solution absorption. In ellipsometry, the effect of the solution is not simply corrected for, but is an essential part of the analysis of the effects of the three media, solution, film, and metal, on the state of the polarization of light. Further, ellipsometry not only gives evidence concerning the identity of a new phase, but also a determination of its thickness down to monolayer values and its properties in respect to light absorption (*i.e.*, in many cases, its electronic conductance). Again, it lends itself to automation and can hypothetically be made to give information on the above parameters on a micro second time scale (in Reddy and Bhimasina-Rao's unpublished, work, the time was as little as 0.02 sec). A laser as a source in ellipsometry could give a considerable increase in range of applicability, for example, adsorption on electrodes could be measured. By varying the frequency of the incident radiation, a kind of ellipsometric spectroscopy could be produced.

I do not think these facts and prospects are consistent with the implication of Dr. Will's comment that ellipsometry is one of several techniques for looking at electrode surfaces *in situ*. In respect to detecting and measuring the appearance and behavior of a new phase on an electrode in solution, the ellipsometric method (under potentiostatic control) seems to have considerable advantages over any other method as yet publicly discussed.

Re Dr. Will's thought that ellipsometry gives ambiguity in respect to the identification aspects of a new phase: it rests on the assumption that the refractive index determined is already that of the bulk; and if it is known and sufficiently different from that of alternative possibilities, the phase can be identified. There may indeed be difficulty here if one of these conditions is not fulfilled, but no more difficulty than exists in x-ray analysis which also depends normally on comparison with spectra of known entities.

Oxide Involvement in Some Anodic Oxidation Reactions

B. E. Conway, N. Marincic, D. Gilroy, and E. Rudd

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

A comparative study of the involvement of surface oxides of platinum in the anodic oxidation of (*a*) formate, (*b*) hydrocarbons, and (*c*) hydrazine has been made. In case (*a*) the oxidation has also been studied in two rigorously dehydrated nonaqueous solvents, acetonitrile and propylene carbonate, to which were successively added initially traces and later larger quantities of water. Activation and inhibition effects arise and are related to the water content of the solutions. The oxide coverages were determined at various potentiostatically held potentials E by cathodic galvanostatic and differentiated galvanostatic transients for ascending and descending directions of change of E. Complications which may arise in the quantitative interpretation of results obtained from the repetitive potentiodynamic method are illustrated.

In cathodic organic reductions, the two general pathways of direct electron transfer or of indirect electrochemical hydrogenation by adsorbed H atoms produced by discharge from the solution have for many years been recognized (1-3). A similar situation arises in anodic oxidation: the anodic reaction pathway may be one in which direct electron withdrawal with subsequent reaction of the resulting free radical ion or free radical with the solvent occurs; alternatively, it may be one in which surface oxides (or adsorbed oxygen-containing species,[1] *e.g.*, OH or O) are produced in a charge-transfer step from entities in the solution or from the sol-

[1] The distinction between "surface oxides" and adsorbed O or OH is to some extent an academic one. A film of the order of a monolayer cannot be described in terms of formal stoichiometry, particularly if there is heterogeneity of adsorption sites originally at the bare metal. Surface films must presumably become of the order of 20-50 atomic layers thick before they can be spoken of in terms of bulk behavior and corresponding stoichiometry and thermodynamic behavior (13). However, recent ellipsometric studies (48) indicate a qualitative change of the properties of the surface "oxide" on Pt at *ca.* 0.9-1.0v to those more characteristic of a bulk species. Presumably this oxide may be identified with the so-called "dermasorbed" oxygen proposed by Schuldiner.

vent, and then react in the steady-state with substrate reductant either diffusing to the surface or coadsorbed at the electrode surface. These two types of process were first discussed for anodic oxidation of organic molecules by Fichter and by Perkin (4, 5) for some hydroxylation, halogenation and pseudohalogenation reactions with benzene and other organic substrates. More recently, this type of reaction has been considered in anodic hydrocarbon oxidation mechanisms (6, 7) and in the electrochemical oxidation of formate ion (8). The presence of adsorbed O species (henceforth we shall refer to the adsorbed oxygen-containing species as simply "O" except where otherwise explicitly stated) can also be responsible for initial passivation effects as suggested by Kolotyrkin (9) and treated by Breiter *et al.* (10). When the surface coverage by "O" species is potential dependent (as it usually is) this can give rise to kinetic inhibition effects which manifest themselves in the current-potential curve as a reversal which is most marked in processes such as dissolution of iron, but also arises in anodic oxidations of hydrogen and organic substrates. This type of effect, it seems, was first treated by Nord (11), developed by Bagotskii and Vasilev (12; *cf.* 13) and treated in detail for a variety of reaction mechanisms by Gilroy and Conway (8) in terms of the adsorption isotherm for the inhibiting species. The latter authors also showed that self-inhibition effects with reversal of current-potential relations can occur in the absence of coadsorbed oxides when the products of a reaction step (*e.g.*, in formate oxidation) occupy more sites than the reactant. Passivity effects in hydrocarbon oxidation through involvement of adsorbed O have also been proposed by Bockris *et al.* (7) and their mechanism of the effect involves changes in the type of surface oxide species present (*v.* 8; *cf.* 12); the importance of conductance changes in the oxide film in passivation of metals (*e.g.*, Ni) has been stressed by Bockris and Reddy (14) on the basis of interpretations of ellipsometric measurements and this must be considered an important advance (*cf.* 13) in the experimental understanding of the onset of effective passivity in metal dissolution. Such effects are, however, probably not necessarily involved in passivation of those anodic oxidation reactions which do not involve metal dissolution.

In most of the organic oxidation reactions in which passivation effects have been indicated, little attempt has been made until recently to characterize (in relation to the kinetics) the nature and extent of adsorption of the passivating species, *e.g.*, by electrochemical transient techniques. In the present paper, we have examined comparatively [*cf.* ref. (12) for other systems] the potentiostatic current-potential behavior for anodic oxidations of several simple substances: formate ion in aqueous KOH; hydrazine in acid and alkaline solutions; ammonia in alkaline (KOH) solution; and C_2H_4 and C_3H_8 in perchloric and phosphoric acids. The kinetic behavior has been related to determinations both of the extent of surface oxide coverage as a function of potential and the corresponding H atom accommodations at more cathodic potentials evaluated by use of the differential galvanostatic charging method from potentiostatically controlled anodic potentials. An important aspect of the present work is the use of completely nonaqueous solutions in one or two cases, with subsequent controlled additions of small concentrations of water, in order to establish semiquantitatively the role of water in (*a*) producing the surface oxide and (*b*) the corresponding kinetic effects of this oxide in current-potential curves, since the extent of surface oxide coverage can then be determined not only by anode potential but by the concentration of added water. Related matters concerning the hysteresis of the current-potential curves and irreversibility in formation and reduction of surface oxides at Pt are examined. Here we shall concentrate on recording the principal experimental observations.

Experimental

Procedures.—Steady-state potentiostatic procedures have been employed in most of this work using a Wenking short rise-time potentiostat. Current-potential relationships were determined, point by point, manually at controlled intervals of time sufficiently long (30 sec-1 min) for surface charging processes to have become completed. Further long-time effects which may be associated with deactivation or poisoning (15) were thus avoided. In some experiments, the potentiodynamic procedure was also used, the potentiostat then being controlled by a Servomex type LF 141 function generator (using single ramp and repetitive linear voltage-time characteristics).

In most of the measurements, galvanostatic reduction transients were taken from the potentiostatically held potentials and differentiated by means of an operational amplifier using the procedure of Kozlowska and Conway (16). Both direct and differentiated transients were displayed simultaneously on a dual-beam oscilloscope. This method gives much better resolution of structure in the charging curve than is apparent in the latter itself and provides information analogous to that available from the potentiodynamic method, except that steady-current kinetics apply and this facilitates quantitative interpretations of rate effects (17, 18). The differentiated transient gives directly the reciprocal of the electrode capacitance (including adsorption pseudocapacitance) as a function of potential, and the distances (times) between the minima in C give precise estimates of the corresponding charges passed between various potentials in the charging curves, without the necessity of integrations.

Systems studied. Formate.—Potassium formate for experiments in aqueous medium was recrystallized from water and dried under vacuum for 48 hr. For experiments in nonaqueous media, triethylammonium formate[2] was prepared *in situ* by adding a controlled amount (stoichiometric quantity) of formic acid to a known weight of triethylamine in the solvent. The exact amounts were determined outside the cell in a separate experiment by means of a conductance titration. Separate kinetic experiments showed that a slight excess of the amine did not interfere with the kinetics of oxidation of the formate ion.

The reactants were purified as follows: formic acid was dried over anhydrous $CuSO_4$ and the triethylamine over $LiAlH_4$. The components were mixed slowly in a bath cooled in liquid N_2 to about −10°C until part of the solution became solid. The containing vessel was maintained in a polyethylene bag to minimize contamination by atmospheric moisture.

The solvents used were water, acetonitrile and propylene carbonate.

Distilled water was redistilled from alkaline permanganate and distilled once again in a stream of purified N_2 directly into the cell.

Acetonitrile was distilled *in vacuo* once from anhydrous $CuSO_4$ and once from P_2O_5 (19-22) and finally into the cell. All operations were conducted in a stream of N_2 dried by passage through a solid reactant drying train and passed through three liquid air traps. The dried cell and all ancillary apparatus were contained in a polyethylene bag into which a steady stream of dry N_2 (from boiling liquid N_2) was passed during the preparation of the solutions and during the runs.

In some experiments, final drying of the solution was achieved *in situ* in the cell by lowering into the liquid a large ampoule containing a molecular sieve material, previously baked out in a vacuum oven. After agitation for 12 hr, the ampoule was withdrawn

[2] Most inorganic formates were insufficiently soluble to be used. Tetramethylammonium formate was prepared, but could not be obtained in a sufficiently dry state.

and the runs commenced. This procedure gave the driest solutions (see below).

Propylene carbonate was dried over anhydrous $CuSO_4$ and distilled *in vacuo*. The electrolyte was made up as in the case of the acetonitrile solutions. Drying with P_2O_5 or the molecular sieve was impracticable owing to chemical reactions which were observed to take place.

Hydrazine and hydrazine sulfate.—Hydrazine was prepared from the analytical grade chloride or sulfate salts by distilling from strong aqueous KOH. The resulting aqueous solution of "hydrazine hydrate" was redistilled and the middle fraction was made up in aqueous H_2SO_4 or KOH to give various concentrations in the 1*N* supporting electrolyte of acid or alkali. Nitrogen was used for bubbling the solutions, and a rotating wire electrode was used in some experiments to achieve uniform stirring. In other experiments, a rotating disk electrode (23) was used to examine the role of diffusion control.

Hydrocarbons.—A number of experiments were carried out on the oxidation of ethylene and propane at various temperatures at platinized Pt electrodes in hydrogen peroxide purified H_3PO_4 (85%) and in analytical grade $HClO_4$ which has a better impurity level (with respect to anodically oxidizable impurities) than has H_3PO_4. The cell was capable of being operated up to 150°C and was provided with an internal heater and thermostat, and presaturator tubes for the purified gas supplies. Potentiostatic preelectrolysis for 24-hr periods at a sacrificial electrode was found to be beneficial in diminishing background current in the absence of hydrocarbon. The potential was set to that giving a maximum current, viz. at *ca.* 0.8v E_H, since the background current suffers passivation effects at higher potentials. Oxide co-coverage and H accommodation were determined during the steady-state hydrocarbon oxidation runs by the galvanostatic procedure mentioned above. In some runs, the rate of charging of the platinum electrode itself (in the absence of hydrocarbon) could be studied by rapid controlled current measurements for known times, provided that the electrode was large enough. From the known capacitance of a platinized electrode per cm^2, it is easy to show that the current-potential relation for anodic charging of the electrode can be measured up to 10^{-2} amp cm^{-2} (apparent) without increasing the coverage by oxide by more than 10% if the measurements are made over *ca.* 20-sec intervals or less.

Reference electrodes.—The hydrogen reference electrode was used in most of the solutions including the nonaqueous ones where it also seems to function satisfactorily (*cf.* 24). In the KOH solutions, the Hg/HgO electrode was used with a sealed probe communicating to the compartment of the cell otherwise used for the hydrogen reference electrode. The probe was terminated by a 7/10 joint wetted with the solution. Liquid junction potential corrections were made where necessary.

Electrode preparation.—Platinum wires, previously cleaned in acetone, were sealed in glass bulbs in a stream of hydrogen as described previously (25). The electrodes were mounted in the cell in sliding tubes according to techniques developed previously. In all experiments, the electrodes were subjected to the following electrochemical pretreatment before steady-state kinetic observations were commenced: polarization at 0.5 cps (triangular pulse) between the potentials −0.2 to +1.6v E_H for 10 min. This achieved best reproducibility of the current-potential curves.

Palladium electrodes were prepared similarly. Platinized Pt electrodes were prepared by the usual method (26) for obtaining a black velvety deposit; this procedure was preferred to the method employing no additive which leads to coarser and less reproducible deposits.

Results and Discussion

Formate oxidation.—A number of studies of formic acid oxidation on platinum have been reported (27-31) using various approaches, particularly the potentiodynamic one (31). A detailed constant current study was reported by Conway and Dzieciuch (32) who examined (*a*) the electrochemical behavior in terms of steady-state consecutive reaction kinetics and (*b*) the involvement of electrochemically detectable intermediates. In aqueous medium, the steady-state (potentiostatic) log i-v curve is characterized by reversals of the direction of the current-potential relations for the ascending and descending directions (with much hysteresis) which can be treated theoretically in terms of inhibition effects discussed previously (8, 11, 12). Theoretically (8), the maximum current in a single electron, ion-discharge controlled anodic oxidation inhibited by a single "univalent" oxide species should arise at *ca.* half coverage of the electrode by such a species. The differential (cathodic) galvanostatic measurements from controlled-potential steady states indicate, however, that surface oxide coverage at the potential of the current maximum is quite small ($<$ *ca.* 0.2) on smooth Pt in the oxidation of formate in alkaline solutions. In neutral solutions (8), however, the current maximum occurs at *ca.* 1v E_H and adsorbed species are then hardly detectable at this potential [*cf.* ref. (30) for the HCOOH case]. This situation could arise because (*a*) the formate oxidation occurs only on a small fraction of the surface which is then covered relatively to a greater degree by oxide or (*b*) because inhibition arises from coadsorption of another, electroinactive species arising from the decomposition of formate ion itself. The latter possibility seems likely and is consistent with conclusions (*cf.* 30) of other workers who have examined formic acid oxidation. Such a species may be the "reduced CO_2" entity of Giner (33) or an adsorbed dehydrogenated formate ion "CO_2^-," but the inhibiting species discussed by other workers is only found at rather lower potentials. Alternatively, the mechanism suggested previously (32) involving the steps.

$$HCOO^- + M \rightarrow M/HCOO^\cdot + e$$
$$M/HCOO^\cdot \rightarrow M/H + M/CO_2$$
$$M/H \rightarrow H^+ + e$$
$$M/CO_2 \rightarrow CO_2$$

can explain the observed behavior if the discharge step is not rate-determining. Self-inhibition (8) can arise since, in the second step, two adsorption sites are formally required for each one occupied by the

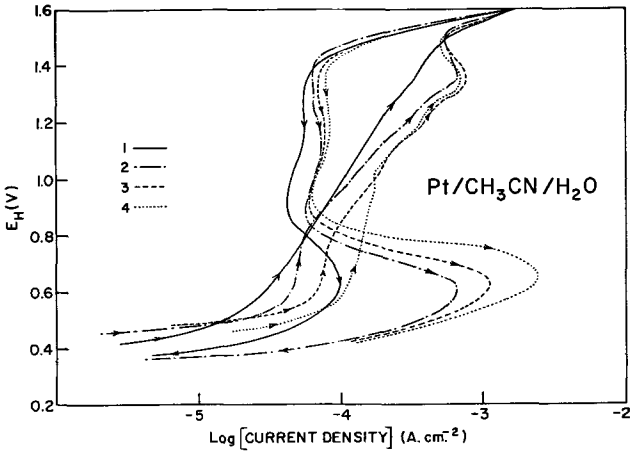

Fig. 1. Potentiostatic steady-state log i-E curves for formate oxidation in anhydrous and water-containing acetonitrile (Pt; 5°C). Points taken at 50 mv intervals. 1, 0 ml; 2, 2 ml; 3, 5 ml; 4, 10 ml solution.

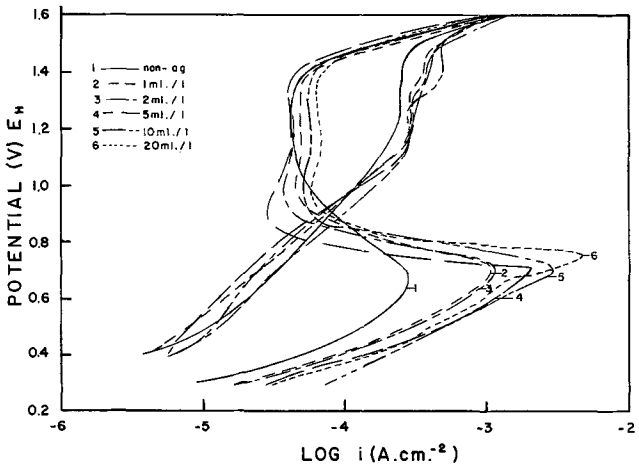

Fig. 2. Potentiostatic steady-state log i-E curves for formate oxidation in anhydrous and water-containing propylene carbonate (Pt; 5°C). Points taken at 50 mv intervals.

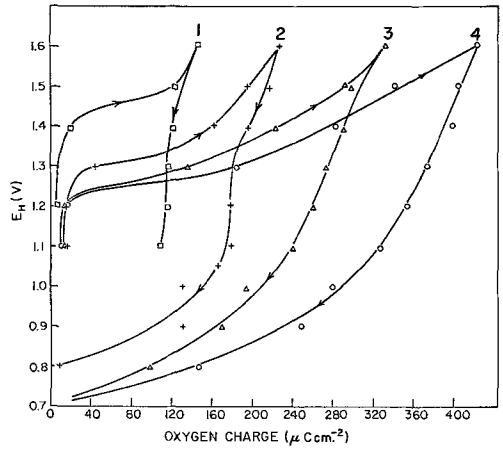

Fig. 3. Oxide coverage on Pt for formate oxidation in acetonitrile as a function of potential and water content (5°C). Numbers on curves correspond to those in Fig. 1.

reactant. A current-potential curve with reversal then arises and the auto-inhibiting species are adsorbed H and CO_2. The coverage by the adsorbed species ($HCOO^{\cdot}$) must be potential-dependent in order to explain (8) the reversal of the log i-E curve, and this requirement is met for the reaction scheme above. Oxide coverage seems to become appreciable only at higher anodic potentials of 1.0-1.2v, in the direction of ascending electrode potentials.

The experiments in nonaqueous media [other than formic acid itself; *cf.* (32), (34)] have been performed in order to examine the effects of controlled amounts of water in the solution. Under these conditions, surface coverage of the electrode by oxide can be controlled by the water content as well as by potential. The results in acetonitrile and propylene carbonate are shown in Fig. 1 and 2, and the general features are similar; the corresponding oxide coverages as a function of potential and water content are shown in Fig. 3. The oxide coverages in terms of charge Q_o can be related to the water concentration c through a relation similar to a Langmuir adsorption isotherm (Fig. 4) by plotting c/Q_o *vs.* c; satisfactory linear relations are obtained. Presumably, the adsorption is an electrochemical one involving a process which can be represented formally as an electrochemical equilibrium (below the O_2 reversible potential)

$$Pt + H_2O_{(ads)}\,Pt \rightleftharpoons \text{“}Pt(OH)\text{”} + H^+ + e$$

The important conclusion from the results in Fig. 1 and 2 is that the current for formate ion oxidation

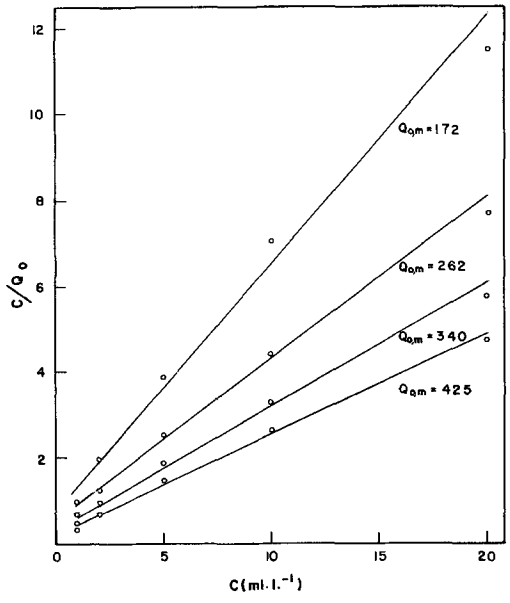

Fig. 4. Test of electrochemical Langmuir isotherm for oxide charge as a function of water concentration for various maximum charges $Q_{o,m}$ at the higher potentials.

does not become appreciable in the descending current-potential curve until almost all the electrochemically detectable oxide has been removed (Fig. 3). However, the magnitude of the current maximum is related to the amount (in terms of charge for cathodic oxide reduction) of oxide that was present at higher anodic potentials and not to the total apparent free surface available. The effect is not connected with, *e.g.*, specific poisoning by acetonitrile, since the results in a chemically very different solvent (propylene carbonate) are remarkably similar (Fig. 2). The reaction therefore seems to proceed only on that fraction of the surface that has just become reduced from previously being in an oxide-covered state. Since the minimum current seems to arise at a potential for which oxide again just cannot be detected, this current presumably does not arise from reactions such as

$$Pt/OH + HCOO^- \rightarrow Pt + CO_2 + H_2O + e$$

or

$$Pt/O + HCOO^- \rightarrow Pt/OH + CO_2 + e$$

Similarly, if the chemical step

$$Pt/HCOO^{\cdot} + Pt/OH \rightarrow Pt + CO_2 + H_2O$$

were involved, the rate would tend to be maximal at *ca.* half coverage by both species (cf. 6,8). It seems that these mechanisms involving “O” are likely to participate appreciably in the kinetics only at higher anodic potentials, as suggested previously (8).

The general similarity in the log i-E curves and in the hysteresis in formation and reduction of the oxide at various contents of water (Fig. 3) in the solution, suggests that oxide may be present in patches on the surface (at each of which normal oxidation and reduction occurs with associated kinetics of formate oxidation) rather than as a uniform, but correspondingly more dilute, layer with fractional coverage dependent on water content.

The behavior in various concentrations of KOH in aqueous medium is also of interest. At smooth Pt, the oxide charge at 0.8, 1.0, and 1.2v (E_H) decreases with increasing formate ion concentration in 0.1M KOH aq. (Fig. 5).

At 1.4v, it only decreases to a small value rather critically at 6-7 molar formate, and at 1.6v there is only a small steady decrease. In 0.5M KOH aq., (Fig. 6) however, the oxide charges at various potentials do

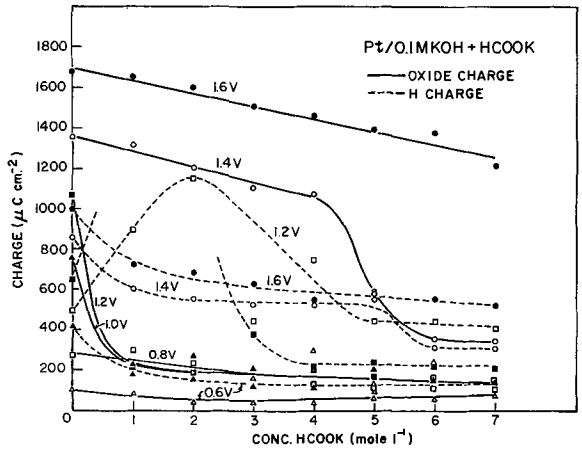

Fig. 5. Oxide charge and H accommodation at smooth Pt for formate oxidation in 0.1M KOH aq. as a function of HCOOK concentration and potential (E_H).

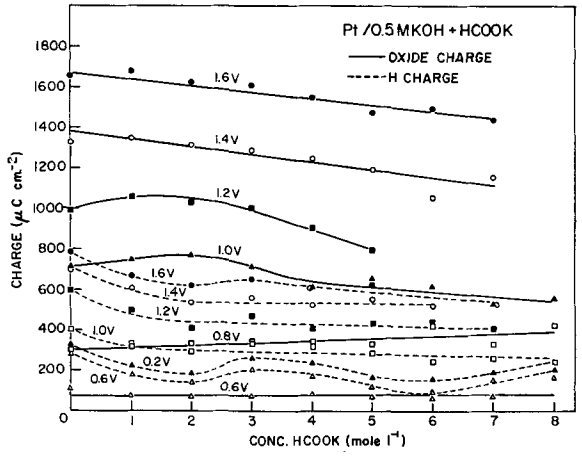

Fig. 6. Oxide charge and H accommodation at smooth Pt for formate oxidation is 0.3M KOH aq. as a function of HCOOK concentration and potential (E_H).

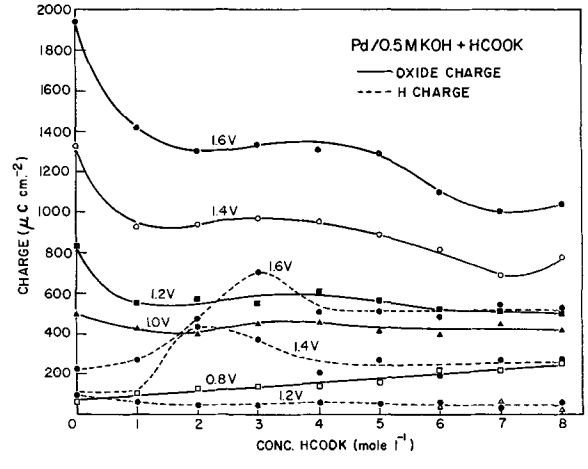

Fig. 7. Oxide charge and H accommodation at smooth Pd for formate oxidation in 0.5M KOH aq. as a function of HCOOK concentration and potential (E_H).

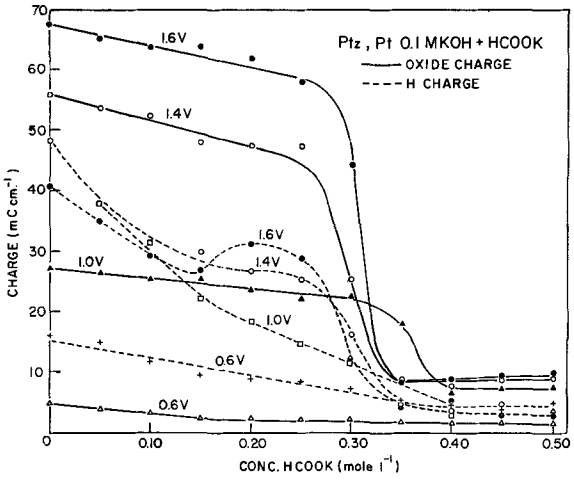

Fig. 8. Oxide charge and H accommodation at platinized platinum for formate oxidation in 0.1M KOH aq. as a function of HCOOK concentration and potential (E_H).

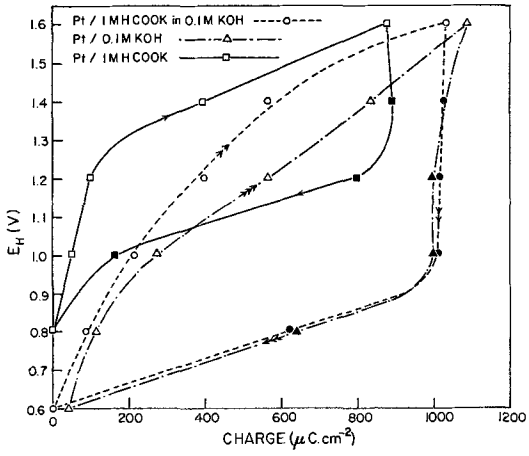

Fig. 9. Comparison of oxide charges at smooth Pt under various conditions in aqueous formate oxidation.

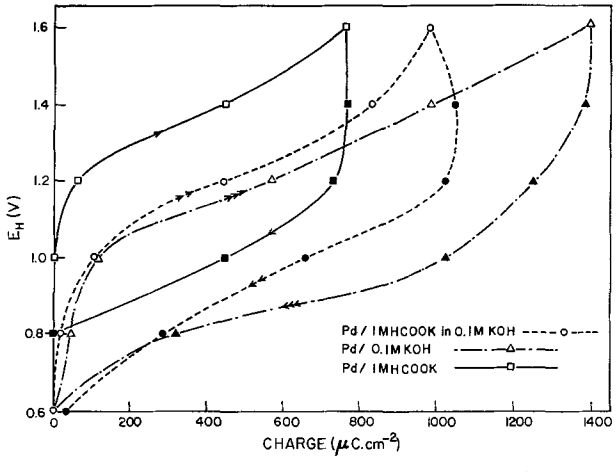

Fig. 10. Comparison of oxide charges at smooth Pd under various conditions in aqueous formate oxidation.

not show any sharp decrease in the presence of formate but only a progressive small diminution at 1.2-1.6v (E_H). Analogous effects arise at Pd electrodes (Fig. 7). On platinized platinum, however, a very marked critical decrease of oxide coverage arises between 0.3 and 0.4M formate in 0.1M KOH aq. (Fig. 8).

Similarly, the hydrogen accommodation (at more cathodic potentials) measured in differential transients from various anodic potentials, decreases in a similar way.

Oxide charges determined under various conditions are compared in Fig. 9 (Pt) and 10 (Pd) for various potentials.

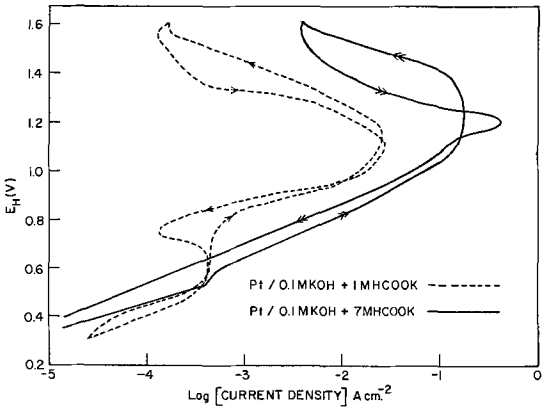

Fig. 11. Comparison of potentiostatic steady-state log i-E curves for formate oxidation at smooth Pt in 1 and 7M HCOOK in aq. 0.5M KOH.

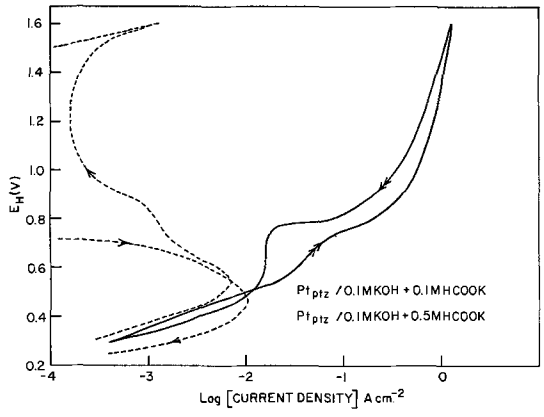

Fig. 12. Comparison of potentiostatic steady-state log i-E curves for formate oxidation at platinized Pt in 0.1 and 0.5M HCOOK in 0.1M aq. KOH.

Corresponding to the relation between oxide coverage and KOH/HCOOK ratio discussed above, a marked dependence of the shapes of the log i-E curves for formate oxidation on formate ion concentration is apparent in Fig. 11 and 12 for smooth and platinized Pt electrodes.

Some inhibition effects still arise around 0.55-0.75v (E_H), but the behavior above 0.8v is quite different when the formate to KOH ratio is high: the hysteresis is much diminished and much higher currents pass at higher anodic potentials when the oxide coverage is found to be diminished (Fig. 5-8). Again, the kinetic behavior changes critically between 0.1 and 0.5M formate in 0.1M KOH at platinized Pt (Fig. 12). At higher KOH concentration (0.5M), the critical change in the kinetics occurs between 1 and 3.5M formate. There is evidently a critical competitive situation between adsorption of oxide species and "formate" species depending on the KOH concentration. Presumably at sufficiently high formate concentrations, the rate of reaction between discharged formate species and the oxide produced by discharge of OH^- (or from water) is large enough to maintain a low steady state oxide coverage. Also there will be mutual inhibition effects; the presence of a greater coverage by formate species will tend to inhibit oxide formation by discharge from OH^- ion, *cf.* the inhibition of oxygen evolution in the aqueous Kolbe reaction (32).

Hydrazine oxidation.—Mechanisms.—It is found experimentally (cathodic transients) that no significant oxide coverage is involved in hydrazine oxidation up to 1.0v and surface oxide only appears in oxidation in acid media at low concentrations <0.01M when diffusion control just becomes significant. It remains on

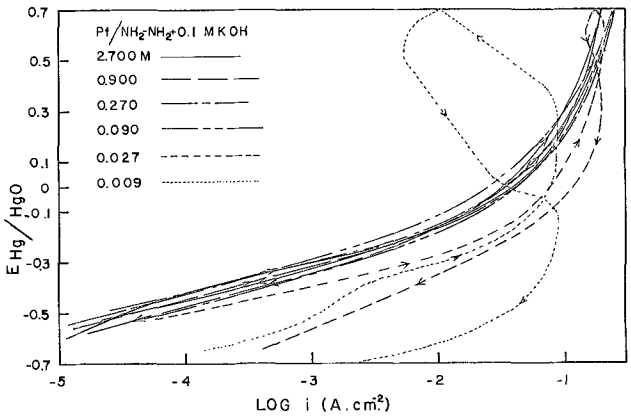

Fig. 13. Potentiostatic log i-E relations for N_2H_4 oxidation at smooth Pt in 0.1M KOH aq. at various concentrations and 25°C (oxide coverage and associated hysteresis only arises at low concentrations when diffusion control begins to become significant).

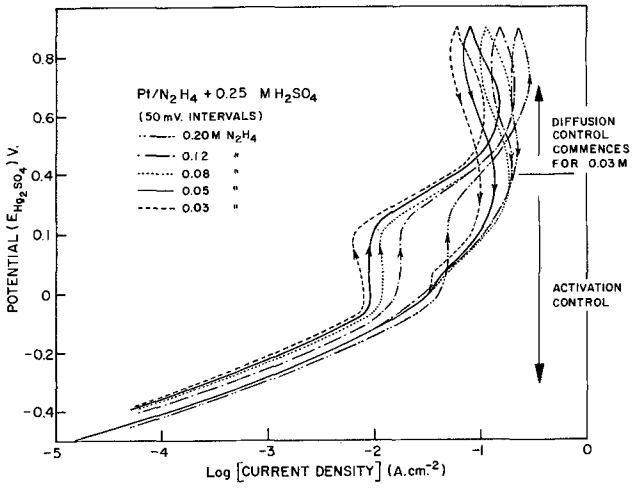

Fig. 14. As in Fig. 13, but with 0.25M H_2SO_4 at 25°C

the electrode to lower potentials in a descending i-E curve and then well-known hysteresis and current oscillations characteristic of passivity are observed (Fig. 13 and 14). Under most conditions, only dehydrogenation and dissociation steps need therefore be considered. Following physical adsorption, possible consecutive reaction steps involving dissociation of the N-N bond in hydrazine are:

Scheme A

$$N_2H_4 \rightarrow NH_2 + NH_2 \qquad \text{I}$$

$$NH_2 \rightarrow NH + H \qquad \text{II}$$

$$(H + OH^- \rightarrow H_2O + e) \qquad \text{IIa}$$

or

$$NH_2 + OH^- \rightarrow NH + H_2O + e \qquad \text{IIb}$$

followed by

$$NH \rightarrow N + H \text{ (with IIa)} \qquad \text{III}$$

or

$$NH + OH^- \rightarrow N + H_2O + e \qquad \text{IIIb}$$

$$2N \rightarrow N_2 \qquad \text{IV}$$

Alternatively, a scheme B involving progressive dehydrogenation with the indicated chemisorbed species (without N-N dissociation), may be involved

$$N_2H_4 \rightarrow N_2H_3 + H \text{ (or } N_2H_4 + OH^- \rightarrow N_2H_3 + H_2O + e \text{ Va)} \qquad \text{V}$$

$$(H + OH^- \rightarrow H_2O + e) \qquad \text{(IIa)}$$

$$N_2H_3 \rightarrow N_2H_2 + H \text{ (with IIa)} \qquad \text{VI}$$

$$N_2H_2 \rightarrow N_2H + H \text{ (with IIa)} \qquad \text{VII}$$

$$N_2H \rightarrow N_{2(ads)} + H \text{ (with IIa)} \qquad \text{VIII}$$

$$N_{2(ads)} \rightarrow N_2 \qquad \text{IX}$$

or steps of type Va in reactions VI, VII, and VIII. In scheme B, N_2H_3 may be singly bonded to the surface, and succeeding radicals may be bonded through two sites. It has been concluded previously (44) that a mechanism involving free-radical intermediates is preferable to one (45) involving dissociated hydrogen. However, these two types of reaction must be related since successive dehydrogenation would leave adsorbed species on the electrode as in the schemes A and B.

The kinetics in the presence of added acid or alkali are characterized by: (*a*) current-potential relations (Fig. 13 and 14) with continuously increasing slopes towards a limiting current, but with initial slopes at low current density of about 0.1-0.12v (*ca.* 2.3 $2RT/F$); (*b*) reaction orders in acid (Fig. 15) which are between 0.3 and 1 and tend to decrease with increasing concentration[3] but show no systematic dependence on potential; and (*c*) reaction orders in alkali which are near zero (Fig. 13) at moderate and high concentrations but tend to become negative at low concentrations (ascending curves prior to diffusion control and oxide formation).

The absence of surface oxide at potentials where it is normally formed suggests that (*a*) adsorbed species from N_2H_4 inhibit its formation and/or (*b*) it is removed as fast as it is formed by reaction with N_2H_4 or derived radicals so that its steady-state concentration on the surface is always small. When diffusion-controlled conditions are approached and the electrode is starved of hydrazine, oxide formation can be detected (Fig. 13); it is removed on stirring the solution when the latter is near the critical concentration for diffusion control. The present results seem to indicate that the presence of oxide, when at appreciable coverage, is inhibitive rather than catalytic as was concluded previously (46). In NH_3 oxidation, oxide is found even at quite high concentrations of NH_3.

[3] Further studies at more closely spaced concentration intervals are in progress. The upper and lower limits are, however, restricted by the limited solubility of the salt and the onset of diffusion control, respectively.

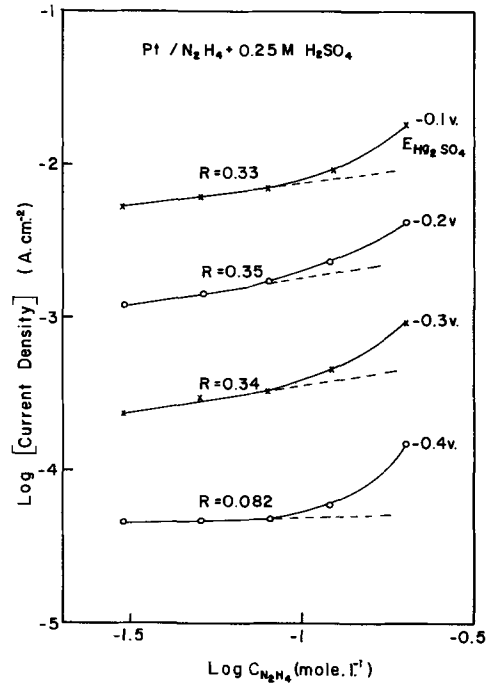

Fig. 15a. Rates of N_2H_4 oxidation at smooth Pt as a function of concentration at various potentials (0.25M H_2SO_4 at 25°C).

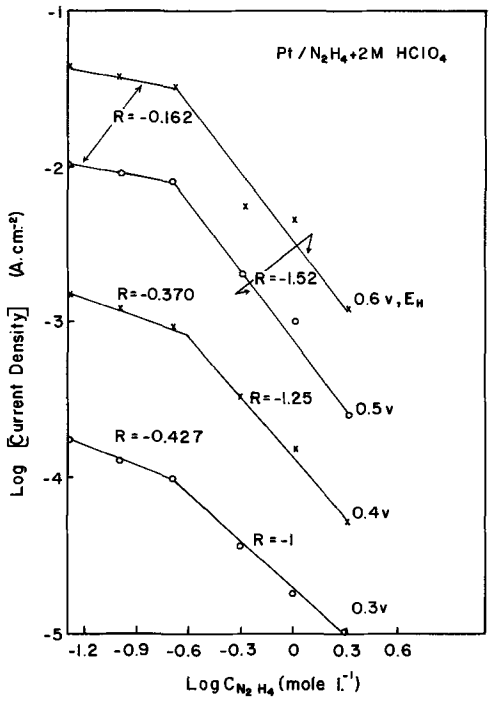

Fig. 15b. As in 15a but in 2M $HClO_4$ at 25°C. (Differences from Fig. 15a arise because of greater degree of ionization.)

Tafel slopes and reaction orders.—The initial region of the log i-E relations ($b \doteq 2.3\ 2RT/F$) corresponds either to an electrochemical step of ionization of an intermediate, the surface coverage of which is independent of V or to a primary discharge process in the first step of the reaction (*e.g.*, $N_2H_4 + OH^- \rightarrow N_2H_3 + H_2O + e$ or $N_2H_4 + OH^- \rightarrow NH_2 + NH + H_2O + e$). Other steps in the sequences A or B above would tend to give Tafel slopes less than $2.3\ 2RT/F$ (*cf.* 36, 37). The approach to a limiting current (*cf.* 44) suggests (35, 36) that either (*a*) a recombination controlled process such as IV becomes rate-determining with coverage θ_N by the intermediate tending limitingly to unity or (*b*) a first order chemical dissociation step becomes rate-limiting. The limiting current is not diffusion controlled except at the lowest concentration. The possibility (*a*) is to some extent supported in alkaline solution since the reaction order $\mathcal{R}$ is initially small or zero (Fig. 13). Except at complete coverage, *e.g.*, by N or N=N species in reactions IV or IX, respectively, $\mathcal{R}$ will be a function of potential.

This conclusion may be reached by deducing the reaction order as a function of potential in one or two cases and relating it to the Tafel slope; in fact, this procedure turns out to be useful for the examination of mechanisms giving this type of current-potential behavior. Several examples will be considered.

If the reaction involves successive electrochemical dehydrogenation steps (*cf.* 44) similar to Va, and if the rate-determining step were, say, the desorption IX, the velocity of IX is

$$v_9 = k_9\,\theta_{N_2} \qquad [1]$$

and θ_{N_2} (N_2 is chemisorbed "N=N") can be expressed in terms of c through K_5 and three potential-dependent quasi-equilibrium constants for prior steps if V is involved (case I), and through four potential-dependent equilibrium constants if Va is involved (case II). Then

$$v_9 = \frac{k_9 K_5 K_6 K_7 K_8 \exp 3VF/RT \cdot c}{1 + cK_5 + cK_6 \exp VF/RT + cK_7 \exp 2VF/RT + cK_8 \exp 3VF/RT} \quad [2]$$

and correspondingly for the electrochemical pathway in Va

$$v_9 = \frac{k_9 K_5 K_6 K_7 K_8 \exp 4VF/RT \cdot c}{1 + cK_5 \exp VF/RT + cK_6 \exp 2VF/RT + cK_7 \exp 3VF/RT + cK_8 \exp 4VF/RT} \quad [3]$$

where potential-dependent equilibrium constants have been introduced for steps VI, VII, and VIII if they proceed like Va by proton transfer; the latter type of step seems more likely and is consistent with a similar step in the oxygen evolution reaction (36).

The reaction orders may be readily obtained for both these cases as a function of potential by appropriate differentiations and give, in general, relations of the type

$$\mathcal{R} = 1/[1 + c f(K, V)] \quad [4]$$

where $f(K,V)$ is the sum of terms such as K_5, $K_6 \exp VF/RT$, $K_7 \exp 2VF/RT$ in Eq. [2] or corresponding terms in Eq. [3]. It is clear that quite generally $\mathcal{R}$ will tend to decrease with increasing c and increasing potential, but the relation to the latter will not be simple since it involves sums of exponentials in V. If in some cases, one of the exponential terms in V together with its K value in the product were predominant in the denominator of Eq. [2] or of Eq. [3], then $\mathcal{R}$ would be simply related to V by

$$\ln\left(\frac{1}{\mathcal{R}} - 1\right) = \ln c + \ln K_n + n\, VF/RT \quad [5]$$

where K_n is now a particular equilibrium constant for the step involving the n'th electron transfer. Hence

$$d \ln\left(\frac{1}{\mathcal{R}} - 1\right)/dV = nF/RT \quad [6]$$

Similar conclusions would follow if another first order chemical step were rate-determining. For a second order recombination step, $\ln\left(\frac{2}{\mathcal{R}} - 1\right)$ would be a function of c and V.

If the mechanism involves the second-order recombination desorption IV (scheme A)

$$v_4 = k_4 \theta_N^2 \quad [7]$$

and if θ_N is related to coverage by antecedant species

$$\theta_N = \Pi K . \theta_{NH_2} \quad [8]$$

where ΠK is a combination of quasi-equilibrium constants; also, if two-site adsorption is involved, *e.g.* in step 1,

$$\frac{\theta_{NH_2}}{(1 - \theta_{NH_2} - \Sigma\theta_x)^2} = K_1 c \quad [9]$$

where $\Sigma\theta_x$ is the coverage by other species on the surface and may be potential dependent. An explicit expression in terms of c is unwieldly but in terms of θ, the reaction order is

$$\mathcal{R} = 2(1 - \theta_{NH_2} - \Sigma\theta_x)/(1 + \theta_{NH_2} - \Sigma\theta_x) \quad [10]$$

θ_{NH_2} will be potential dependent if I is an electrochemical step such as

$$N_2H_4 + OH^- \rightarrow NH_2 + NH + H_2O + e$$

or if $\Sigma\theta_x$ is potential dependent. A simple form for the Tafel slope may be obtained for IV only when $\Sigma\theta_x$ is negligible; then

$$b = \frac{1 - \theta_{NH_2}}{1 + \theta_{NH_2}} \cdot \left(\frac{RT}{2F}\right) \quad [11]$$

where only θ_{NH_2} is potential dependent; b is therefore related to the reaction order at any potential by

$$b = \frac{1}{\mathcal{R}}\left(\frac{RT}{F}\right) \quad [12]$$

and includes any case where the b refers simply to a tangent of slope $dV/d \ln i$ in a curve approaching a limiting current.

In 0.1M KOH, the reaction velocity initially has little dependence on concentration, but at low concentration the rate tends to increase (Fig. 13) with decreasing concentration until it becomes diffusion controlled, whereupon an inhibition and reactivation effect of the type found in other anodic oxidations is observed. The current for descending potentials is then greater at low potentials than that for ascending potentials, *i.e.*, an activation analogous to that in formate oxidation occurs. The behavior at low concentrations implies a negative reaction order, similar to that observed in ethylene oxidation (6). In that case, a reaction between adsorbed ethylene and the surface oxide was envisaged.

The velocity of any process involving an adsorbed intermediate N_2H_x (x = 0, 1, 2, or 3) can be expressed in terms of coverages of intermediates in prior steps and the corresponding equilibrium constants (providing prior steps are not entirely irreversible; *cf.* 36, 43). This implies that the reaction order in N_2H_x, with which the intermediates and first chemisorbed species will be in adsorption equilibrium, will always tend to be positive (or zero for full coverage). A competitive adsorption situation (*cf.* 6) is required to account for a negative reaction order.

If a step such as

$$N_2H_3 \rightarrow N_2H_2 + H$$

for example, (following the initial adsorption) were involved as a rate-determining process, its velocity would be

$$v_6 = k_6 \theta_{N_2H_3} (1 - \theta_{N_2H_3}) \quad [13]$$

since two sites for adsorption of N_2H_3 and H would be required (*cf.* 8, 49). If N_2H_3 were in equilibrium with N_2H_4 in the bulk at concentration c through the electrochemisorption

$$N_2H_4 \rightarrow N_2H_3 + H^+ + e$$

then

$$v_6 = k_6 \frac{K_{5a}c}{1 + K_{5a}c}\left(1 - \frac{K_{5a}c}{1 + K_{5a}c}\right) \quad [14]$$

where K_{5a} is an electrochemical equilibrium "constant" (potential dependent)

Hence

$$v_6 = \frac{k_6 K_{5a} c}{(1 + K_{5a}c)^2} \quad [15]$$

which gives a potential dependent rate and a reaction order

$$\mathcal{R}_6 = (1 - K_{5a}c)/(1 + K_{5a}c) \quad [16]$$

after differentiating v_6 w.r.t. c and multiplying by c/v_6. Equation [16] gives first order kinetics at low concentration, zero when $K_{5a}C = 1$ and negative order kinetics when $K_{5a}C > 1$ (limitingly $\mathcal{R}_6 = -1$ as $K_{5a}C >> 1$). This is in the wrong direction to explain the trend of $\mathcal{R}$ in the present results for alkaline solutions.

It may be suggested tentatively that an adsorbed O or OH radical mechanism of the type involved in ethylene oxidation (6) therefore seems the only one that could account for the negative reaction order at low concentrations. In these terms, the reaction $OH^- + Pt \rightarrow$ "PtOH" $+ e$ would proceed on a surface appreciably covered by N_2H_x species at a rate given (*cf.* 38) by

$$v_{OH} = k_{OH}C_{OH^-}\,(1 - \theta_T)\, e^{\beta VF/RT}\, e^{-(1-\beta)r\theta_T/RT} \quad [17]$$

where θ_T is the total coverage by adsorbed species and $r\theta_T$ is a Temkin term reflecting the change of energy of adsorption of OH with increasing coverage θ_T (*cf.* 13, 38, 39). The reaction with hydrazine then would be envisaged as a chemical one (*cf.* 46).

$$N_2H_x + x\text{"PtOH"} \rightarrow xH_2O + N_2$$

with the OH^- discharge initially rate-determining.[4] v_{OH} in Eq. [17] would tend to be smaller (cf. 6) as θ_T (due to increased $\theta_{N_2H_x}$) were increased. Hence a negative reaction order is predictable as in the ethylene oxidation (6). Equation [17] also gives the correct Tafel slope of 2.3 $2RT/F$. The limiting current obtained at high potentials must result from a chemical step, *e.g.*, IV or IX, could not be rate-determining at lower potentials since they could only give rise to slopes $< 2.3\ 2RT/F$. At lower potentials, $\theta_{OH} << 1$ in the steady-state, since no intermediates are detectable in cathodic transients from anodic potentials.

At the higher concentrations of N_2H_4 where $\mathcal{R} \doteq 0$, but the Tafel slope is still 2.3 $2RT/F$, a direct electrochemical reaction with an adsorbed species at full coverage seems the only possibility, *e.g.*

$$N_2H_3 + OH^- \rightarrow N_2H_2 + H_2O + e$$

with $\theta_{N_2H_3} \rightarrow 1$.

In acid solutions, the reaction order behavior is more normal and $\mathcal{R}$ is fractional and tends to decrease with increasing concentration of N_2H_4 (Fig. 15) as required for any direct adsorption process I or V or for following steps indirectly dependent on the primary adsorption step. There is less tendency for a limiting current to be reached and the Tafel slope is *ca.* 2.3 $2RT/F$ over a wide range of current densities.

Shape of current-potential relation.—The shape of the current-potential relation for alkaline solutions indicates an approach to a limiting current which could arise because of activation or diffusion control. The latter possibility is excluded (except at much lower concentrations) since the currents passing in the limiting region are independent (within 2%) of rotation rate at the rotating disk electrode. The Tafel slopes at lower potentials eliminate the possibility of IX or IV being rate-determining and hence giving at higher coverage a limiting current, although this may still arise if the mechanism changes with increasing potential.

The limiting behavior must therefore originate from the potential-independent rate of some chemical step along the sequences described above. At higher potentials, it is evident that some preceding step is unable to meet the current that would normally be associated exponentially with increasing potential, and this step must presumably be a chemical step of dissociation such as II, III, etc., or VI, VII, etc., or possibly the primary adsorption step itself (I or V).

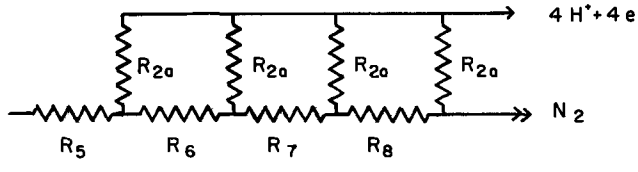
The kinetics of oxidation of successive H atoms in N_2H_4, NH_3 and similarly in the case of hydrocarbons poses some special problems in electrochemical kinetics since current contributions arise from successive steps in the reaction and not just in one step in the reaction. A simpler but analogous case arises in the hydrogen evolution reaction proceeding by the mechanism

$$H^+ + e + M \rightarrow MH$$

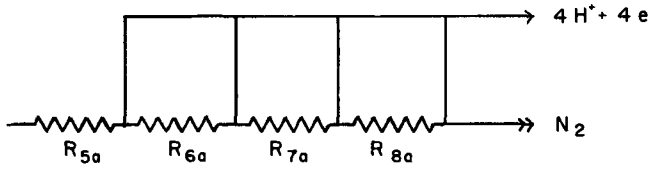
$$MH + H^+ + e \rightarrow H_2$$

where current passes in both steps of the coupled mechanism; a similar situation occurs in the mechanism of the oxygen evolution reaction (36).

Thus, in the chemical scheme B (V-IX), the coverages by N-containing intermediates in the steady state will be indirectly dependent on potential since the H atoms produced in the dissociation steps will be removed with increasing velocity at higher anodic potentials when their steady-state coverage may well approach zero, so that in scheme B with chemical (rather than electrochemical) dissociation steps, it is difficult to speak of equilibria in steps prior to the rate-determining one since entities in the prior steps are "drained off" rapidly by electrochemical H ionization in side-reactions. The "equivalent circuits" for the indirect (*e.g.*, steps such as V coupled with IIa) and direct (*e.g.*, Va and following analogous steps) dehydrogenations are of some special interest and can be represented (neglecting capacitance contributions for simplicity) as



for the chemical dehydrogenation pathways in B and



for electrochemical dehydrogenation steps. R_9 and R_5 to R_8 in the chemical pathway are resistance analogues corresponding to reciprocal chemical rates while R_{5a} — R_{8a} are potential-dependent analogue resistances.

Hysteresis.—No hysteresis characteristic of co-adsorbed oxide (contrast the cases of formate and hydrocarbon oxidation) is observed, and no oxide can be detected as mentioned above. However, in alkaline media, the descending current line is always above the one for ascending anodic potentials suggesting that with increasing potential, increasing coverage by intermediates is involved and these remain on the electrode at a nonequilibrium concentration as the potential is lowered.

[4] This would apply only, of course, at moderately anodic potentials.

Conversely, in acid media, the hysteresis is in the opposite sense and the descending curves are somewhat lower than the ascending ones. Hysteresis characteristic of oxide formation is again only observed at low concentrations when diffusion control is approached (Fig. 14). Rotation of the electrode then causes the oxide to disappear presumably by reaction with the N_2H_4 which can then reach the electrode. Similar effects occur in hydrocarbon oxidation at the region of the peak current.

Hydrocarbon oxidation.—Passivation effects in hydrocarbon oxidation at Pt are well known but, the involvement of co-adsorbed oxide has not been examined in detail quantitatively. Wroblowa, Piersma and Bockris (6) mentioned the coverage by oxide at Pt in ethylene oxidation, but it is unclear if this coverage was measured during the ethylene oxidation. In Fig. 16-18 are shown the current-potential relations for ethylene and propane oxidation in phosphoric acid together with the corresponding oxide charges (Q_o) and H accommodations (Q_H) at more cathodic potentials (fast galvanostatic discharge). The H charge is independent of potential and hence probably does not include any contribution from H participating in rehydrogenation of adsorbed C skeletal species (40); this is supported by the fact that the Q_H in the presence of hydrocarbon is less than that determined at the same electrode in its absence (*cf.* 40) (Fig. 16, 18).

In the hydrocarbon oxidations studied, significant oxide charge appears just at the beginning of the inhibition inflection and continues to increase with increasing anode potential. The coverage is much less

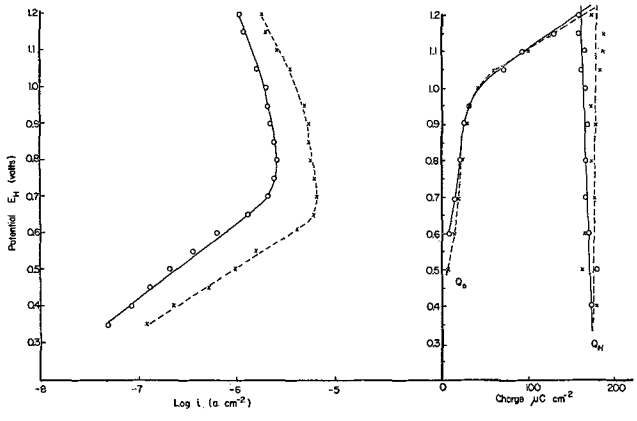


Fig. 16. Potentiostatic log i-E curves for ethylene oxidation with oxide charge Q_o and hydrogen accommodation Q_H as a function of potential, determined in the presence of ethylene. ○, 60°C, x, 90°C, both Q_H and Q_o values. Corrected to real cm^2 on basis of Q_H = 0.21 mC cm^{-2} at 25°C. Solution 1M $HClO_4$ (similar results in H_2SO_4).

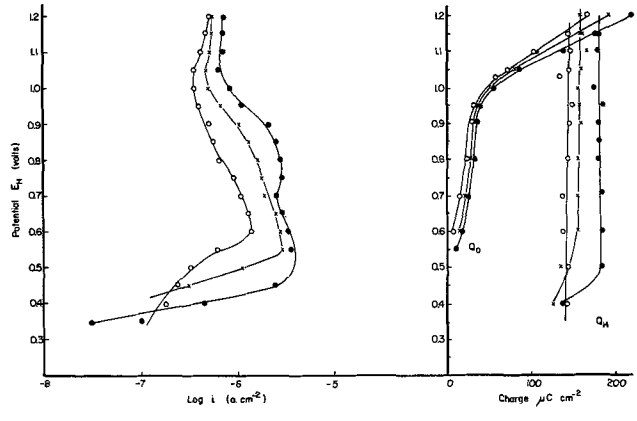

Fig. 17. As in Fig. 16 but for propane in 85% H_3PO_4. ○, 90°C, x, 120°C, •, 150°C, all Q_o and Q_H corrected to real cm^2 at 25°C.

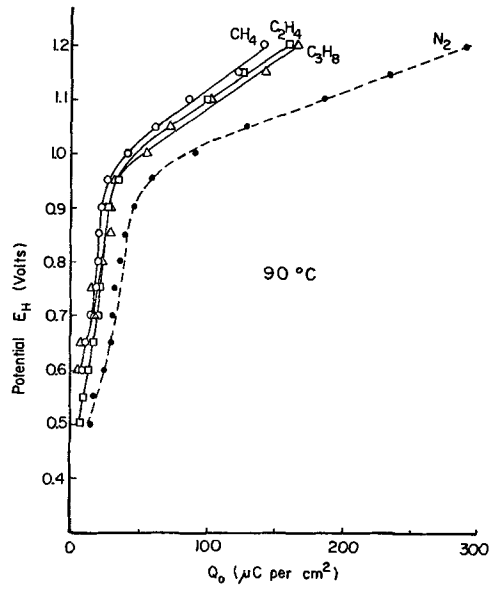

Fig. 18. Comparisons of oxide coverage in hydrocarbon oxidations at 90°C in 85% H_3PO_4. Q_o includes d.l. charges at all potentials (same in Fig. 16 and 17).

than 0.5 at the current maximum (*cf.* 8) and suggests that the catalytic reaction may proceed only on a fraction of the available surface but that this fraction is then relatively more covered by oxygen species. This view is in accord with general theories of active centers in catalysis. The extent of the inhibition in anodic current is however less than that in formate oxidation and a relatively potential-independent current passes above *ca.* 0.8v E_H. Since the oxide coverage is then appreciable, this current may be maintained by reaction of the adsorbed hydrocarbon with the surface oxide (*cf.* the N_2H_4 case). Below *ca.* 0.55v (E_H), surface oxide is undetectable by the differential charging method and the hydrocarbon oxidation proceeds in an uninhibited manner. The kinetic involvement of an oxide at these lower potentials in a mechanism such as that envisaged by Bockris *et al.*, (6 ,7) cannot, however, be excluded since anodic discharge of "OH" species at the surface may still proceed at a relatively high rate but the steady-state or equilibrium coverage could be small. The detectable limit by transient studies is somewhat arbitrary and Q_o ten or one hundred times smaller at lower potentials may still be kinetically significant. Direct measurements of the current densities for oxide charging at large platinized electrodes indicates that the rates can be quite high (10^{-1} amp cm^{-2}) at relatively low anodic potentials (*ca.* 0.3v E_H) and the potential is seemingly determined mainly by the extent of oxide coverage that has accumulated during the rate measurements (if these are sufficiently fast, three decades of anodic charging current density can be examined with less than 10% oxide coverage on the electrode). This "accumulated oxide charge" effect can be extrapolated out approximately by making measurements at various time intervals or charging rates; the polarization in charging is then quite small; however, it is indicated significantly by shifts of the pseudocapacitance maximum with increasing charging (or discharging) rate at higher rates or at greater sweep speeds.

Sweep-rate effects in processes involving surface oxides.—For a number of processes, *e.g.*, formate and formic acid oxidation, significant oxidation rates arise in regions of potential where the oxide coverage is appreciable and potential-dependent. The currents passing as a function of potential in a potentiodynamic sweep experiment can therefore be determined by (*a*)

the Faradaic current i_F for the over-all oxidation reaction; (b) what may be called the "pseudo"-Faradaic current i_c associated with the charging of the adsorption pseudo-capacitance C (this current is zero in the steady state at a given potential except when the over-all reaction proceeds by a chemical depolarization of an electrochemically formed film of adsorbed species); and (c) the non-Faradaic double-layer charging current, $i_{d,l}$; normally $i_{d,l} << i_c, i_F$.

Current peaks can arise in potentiodynamic runs for two reasons: (a) because of an intrinsic inhibition effect such as we have discussed previously (8); and (b) because the adsorption capacitance C is usually potential-dependent (38, 39) and the charging current ($i_c = CdV/dt$) is hence a maximum when C is a maximum. However, if there is any "irreversibility" (this is of course a relative matter; see below) in the charging process producing or removing surface oxide as the potential is changed, then C itself may depend at a given potential on the rate of sweep dV/dt ($= S$). Effects of this kind are quite marked at Pt (41); similarly the coverage attained at a given potential in a sweep may depend on S since the coverage will usually be "out of phase" with the potential (42).

The charging current for a process such as

$$M + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MOH + e + H^+$$

is given (42) as a function of potential by

$$i_c = k_1 (1 - \theta)\, e^{V/b} - k_{-1}\, \theta\, e^{-V/b} \qquad [18]$$

if the symmetry factor is 0.5 and the Tafel slopes for the above processes are b. In the nonsteady state

$$i_c = C\, dV/dt = k \frac{d\theta}{dV} \cdot \frac{dV}{dt} \qquad [19]$$

where k is a proportionality constant relating charge to coverage θ.

Hence θ, at a given potential, is a function of S and V, determined by the differential equation

$$\theta = \frac{e^{V/b} - k \dfrac{d\theta}{dV} \cdot \dfrac{S}{k_1}}{e^{V/b} + \dfrac{1}{K_1} e^{-V/b}} \qquad [20]$$

where $K_1 = k_1/k_{-1}$ and a reduced sweep-rate S/k_1 is introduced. The relative effect of S on coverage at a given potential therefore depends, as expected, on how large is the rate-constant k_1 for the charging process. This result, it will be seen, is analogous to that which we previously calculated for rate effects in galvanostatic charging (42). Equation [20] must be solved numerically.[4a] The derived θ as a function of V for various values can then be used in a kinetic inhibition equation (8) to obtain the shape of an inflected current-potential relation for i_F for some oxidation process as a function of S when i_c and i_F are comparable in the same range of potentials. Qualitatively, the effect of S is shown in Fig. 19. It is to be noted, as we have mentioned previously (42), that the principal difficulties with the sweep method arise when it is used repetitively so that neither a steady current nor a steady state is ever involved and V is $f(t)$. The use of the potentiodynamic successive individual pulse method (single potential ramps) applied by Gilman (e.g., 40) appears preferable (42) since in the sweep, the charge passed is related to steady-state conditions obtaining prior to the initiation of the sweep; in this respect, the method is analogous to that employed here using the differential galvanostatic procedure. However, some complications can still arise if the potential range swept includes any region where new Faradaic processes arise.

[4a] Quantitative calculations on this effect are in progress, using a computer solution for Eq. [20].

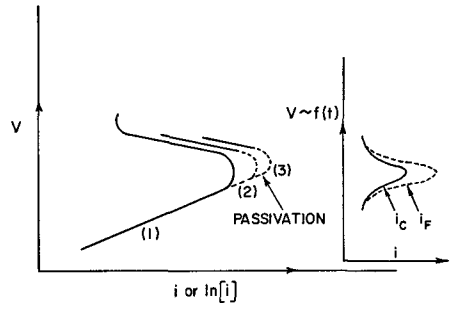

Fig. 19. Current-potential relations (schematic) for an inhibited process at increasing sweep speeds (no diffusion control). 1, Steady-state; 2, 3, increasing S. Inset: Faradaic and pseudocapacitative current contributions.

Discussion

E. Gileadi: There seems to be some degree of disagreement between our results and yours with regard to the effect of hydrocarbons on oxide formation on Pt. We have measured the potential at which formation of a measurable amount of oxide is observed in 1*N* H_2SO_4 solutions saturated with N_2, ethylene, or butadiene.[5] Ethylene seemed to have no effect on the potential of oxide formation, while in the presence of butadiene an approximately 0.1v shift toward more positive potentials was observed. Similarly the quasi-passivation region observed in hydrocarbon oxidation on Pt starts at a higher anodic potential in the case of butadiene than in the case of ethylene and other olefins studied.

B. E. Conway: It must be remembered that our curves for cathodic charge in the oxygen region include the double-layer contribution and that our results refer to platinized Pt.

It is difficult to establish precisely the potential at which "oxide" is just detectable in galvanostatic cathodic transients (*e.g.*, see our Fig. 18), unless these are differentiated.[6] However, at a given potential well in the "oxide" region, the Q_o is undoubtedly appreciably smaller in the presence than in the absence of hydrocarbon.

S. Gilman: Low values of "oxide charge."—The charge corresponding to oxidation of the Pt surface (Q_o) may be smaller in the presence than in the absence of an organic substance (at low potentials where the surface is partially covered with the organic material). However, some of the effects of concentration of organic material on Q_o appear suspicious (*e.g.*, Fig. 5). Negative errors in Q_o may be caused by accidental oxidation of the organic compound during the cathodic pulse used to reduce the surface and to evaluate Q_o. For instance, at a concentration of 4*M*, diffusion (non-steady-state linear diffusion) alone would allow an 800 μC error (due to formate oxidation) to occur during less than 1 μsec. One way to avoid such difficulty is to reduce the surface at a constant potential[7] chosen sufficiently low so that oxidation of the organic substance may not occur.

High values of hydrogen codeposition charge.—Values of hydrogen coverage in the presence of hydrocarbons at low potentials (*e.g.*, Fig. 16) seem too high according to my experience. Hydrogenation-desorption of the adlayer is a common problem with the hydrocarbons[8] and may be responsible for an error in the data. Such desorption may apparently occur at very high sweep speeds (using linear sweeps) or current densities (using galvanostatic pulses) as well as at low sweep speeds. Hence the conditions of such an experiment must be chosen with great care.[9]

Activation of the surface through oxide reduction.—The enhancement of anodic current which has been observed following reduction of the passivated Pt surface may be due to such effects as: (*a*) a smaller surface concentration of relatively inactive species; (*b*) a more favorable coverage of the surface with active intermediates. For example[10] the oxidation of CO is first order in adsorbed CO and first order in "vacant sites" and hence is "self-poisoned" at high coverages with CO.

B. E. Conway: We do not consider the diffusion effect mentioned by Dr. Gilman as likely to account for the dependence of Q_o on formate concentration for the following reasons: (*a*) at a given formate concentration, the Q_o is dependent on the [formate]; [KOH] ratio; (*b*) the Q_o behavior with varying formate concentration also depends critically on the nature of the electrode, *e.g.*, if it is Pd, or smooth or platinized Pt. Thus the concentration at which the decrease of Q_o arises depends on the KOH concentration and the nature of the electrode surface.

While we had considered in our paper the point regarding rehydrogenation desorption of hydrocarbon residues at low potentials (and mentioned Gilman's work in this respect), the results we obtained with fast galvanostatic pulses seem to indicate in our work that this is not an appreciable effect under our conditions; the reasons are (*a*) the Q_H is less in the presence of hydrocarbon than in its absence; (*b*) the Q_H is more or less independent of the potential from which the cathodic galvanostatic transient was initiated.

The matter of surface activation in the direction of descending potentials in the formate oxidation we agree could in principle be explained in such terms as Dr. Gilman suggests. However, the important point is

that the extent of the activation depends on the previous degree of "oxide" coverage and that a maximum in the descending i-v curve is always seen. This must imply a potential dependent adsorption of some inhibiting intermediate as we have discussed elsewhere.[11]

M. W. Breiter: It has been claimed in the short abstract of this paper and in several other papers of Professor Conway and co-workers that the differential galvanostatic technique should be preferred to the potentiostatic sweep technique because the charging conditions are better defined. The claim is based on a kinetic treatment of galvanostatic charging in which the adsorption is assumed Langmuirian. However, this assumption is rarely fulfilled for the heterogeneous surfaces of solid metals. If a more complex isotherm or the superposition of several Langmuir isotherms with different adsorption coefficients is required for the adequate description of the adsorption on a heterogeneous surface like platinum, only numerical solutions are possible for galvanostatic and potentiostatic charging. The charging conditions are equally complex. A computer analysis of potentiostatic and galvanostatic charging has been made by me recently in which the capacitive charging was considered in both methods and the effect of the ohmic potential drop between Luggin capillary and test electrode for the sweep technique. The treatment is more comprehensive than the recent treatment of the charging processes by Professor Gileadi.

A similar statement applies to the study of the oxygen layer by the two techniques. A qualitative discussion of the inhibiting effect of the oxygen layer on the anodic oxidation of methanol at platinum was given for different sweep rates by Dr. Gilman and myself. Any attempt to interpret the inhibiting effect by Langmuirian kinetic expressions appears futile to me. Since only a blocking of the very active centers (less than 10% of the surface area) seems to be involved in the inhibition of the H_2 oxidation and the oxidation of many organic species on platinum, a kinetic treatment is difficult and should not be based on expressions for the total surface area which is electrochemically available for the formation of the oxygen layer.

B. E. Conway: The calculations Dr. Breiter has performed seem to confirm what we have previously implied[12-14] namely that the sweep and galvanostatic procedure will not always give the same results. In the sweep method for a charging process, the current depends on potential in a complex way, being determined by the sweep rate and the adsorption pseudocapacitance at any given potential. The pseudocapacitative charging current, therefore, corresponds to various degrees of polarization in the charging process, and neither steady-state current nor chemical steady-state kinetics apply; the potential also is not constant. It is in this sense that the sweep method is more complex in regard to interpretation of the kinetics of charging processes than is the direct or differential[15] galvanostatic method.

When a current-potential curve which shows a passivation inversion is involved, further complications can arise, as we point out in the paper, since the rate of formation of the passivating species can depend on sweep speed. The current maximum is then a complex function of sweep rate because both pseudo-Faradaic currents (*e.g.*, for surface oxide formation) and Faradaic currents for the over-all reactions are involved, and the latter depends in a critical way on the coverage produced by the former at a given potential in the sweep. Again, the galvanostatic analysis of the kinetics is simpler. Treatment of inhibition effects under Temkin conditions was the basis of our earlier paper.[11]

E. Gileadi: We have recently calculated the variation of the apparent adsorption pseudocapacity with potential, current density,[16] and sweep rate[17] for the simple case of a single adsorbed intermediate, for galvanostatic and potential sweep transients, respectively. The physical quantity which is indicative of the degree of departure of the system from quasi-equilibrium is the current density. Its magnitude, relative to the values of the forward and reverse specific rate constants, essentially determines the behavior of the system. Thus, as long as the current density is maintained constant, a simple qualitative physical interpretation can be made[16] even for complex systems, and an algebraic solution of the problem is possible for the simple case.

In potential sweep transients the quasi-equilibrium is disturbed to a degree which is indirectly related to the sweep rate. Since the current density can vary an order of magnitude or more during the transient, the reaction may be almost at equilibrium part of the time and far away from equilibrium at other times during the same transient. Thus it is hard to see how a single sweep rate equivalent to a given current density during a galvanostatic transient can be defined. No algebraic solution is possible here, even for the simplest case unless the further assumption that the reverse reaction is negligible during the transient is made. Further the IR correction, either numerically or by a compensation method, is much more simple when galvanostatic transients are used.

On the other hand I do agree that for the purpose of obtaining the charge associated with the adsorbed species on the surface only, either method can be used with equal success. Also in more complicated systems involving several types of surface sites, several intermediates or if a Temkin type adsorption isotherm applies, one has to resort to numerical computation in any case.

S. B. Brummer: The authors attempt to indicate that passivation in the current-potential behavior for a number of organic reactions at Pt electrodes is the result of inhibition by surface oxides formed as the potential is raised. In a number of instances, however, they do not observe any oxide, or at least an insufficient amount of oxide, to be present. They postulate alternatively a mechanism for the inhibition in terms of coverage of the electrode by an inhibiting adsorbed species, perhaps an intermediate in the reaction.

The difficulty with such an explanation is that for almost every case that has been studied (*e.g.*, $HCOOH$[18,19], C_3H_8[20,21]; an exception is CO[22,23]) there is no appreciable coverage of the electrode in the appropriate potential region. Thus, to take HCOOH as an example, neither H-atom deposition nor anodic stripping shows the presence of any adsorbed material. Thus the authors' explanation, which requires high

coverage of the electrode, is not possible unless it be assumed that the inhibiting adsorbed species cannot be oxidized at all, even at potentials approaching O_2 evolution, and yet is reversibly desorbed at relatively cathodic potentials. At the very least, such material should show up as an inhibitor of the transient oxidation of the electrode[24] and/or should show a double layer "desorption" peak.

A possible alternative to the authors' explanation, which appears to agree with the data for HCOOH oxidation,[18, 19] is to postulate that a nonelectrochemical (*e.g.*, adsorption) step is rate-limiting and that all subsequent steps are fast. For example:

$$\text{HCOOH solution} \rightleftharpoons \text{HCOOH}_{\text{electrode}} \quad [1]$$

$$\text{HCOOH}_{\text{electrode}} \xrightarrow{\text{slow}} \text{H}_{\text{ads}} + \text{COOH}_{\text{ads}} \quad [2]$$

$$\text{H}_{\text{ads}} \xrightarrow{\text{fast}} \text{H}^+ + \text{C} \quad [3]$$

$$\text{COOH}_{\text{ads}} \xrightarrow{\text{fast}} \text{CO}_2 + \text{H}^+ + \text{C} \quad [4]$$

(Whether or not the initial species is HCOOH or $HCOO^-$ is not relevant to the present discussion.) In this scheme, [2] is slow and, therefore, θ_{COOH} must be small. The slow step must be nonelectrochemical because of the almost potential-independent current frequently observed.[18, 25] The authors' suggestion that H_{ads} could be the inhibiting species for their mechanism would hardly seem likely. Nor can the "reduced CO_2" species of Giner[26, 27] be used to explain the phenomenon since this species is only found on the electrode at lower potentials.

An additional complication could also arise because of rejection of the reactant from the double layer by anion or solvent adsorption as the potential is raised. This was tentatively suggested previously,[18] on the basis of the current-coverage relationships at various potentials. Such an effect, depressing $HCOOH_{electrode}$, could account for a decrease (or an increase for that matter, if the conditions were appropriate) of the rate of reaction [2] with increase in potential. The extent of this decrease is difficult to estimate without more definite information that is presumably available about the Pt-solution double layer.

B. E. Conway: The difficulty mentioned by Dr. Brummer is recognized in our paper, and in fact we have specifically suggested both with respect to formate and hydrocarbon oxidations that the reactions may be proceeding only on an active fraction of the total sites available for kinetic processes (*cf.* active centers in catalysis) and that the inhibition occurs on these active sites. In fact, in general chemical terms, the active sites would tend to be the first to be oxidized since they would tend to be stronger Lewis bases, or less noble, than the bulk of the metal. It seems that some inhibiting species, the surface concentration of which is potential dependent, is clearly required to account for the rather symmetrically reversed i-v curves that are normally involved in formate and other oxidations.

It is of interest that in alkaline solutions (although not in neutral or acid solutions) "oxide" can be detected in the cathodic transients to an appreciable extent in the "inhibition" region (Fig. 5 and 6).

A nonelectrochemical step is difficult to accept as rate limiting since a well-defined Tafel region arises initially in the direction of ascending anodic potentials[28] and current reversal occurs at higher potentials. A nonelectrochemical step could give a limiting current but, it seems, not a subsequent change of sign of Tafel slope for formate oxidation.

The "limiting" current observed by Brummer [his ref. (18)] may arise only apparently since the anode potential was only taken up to 0.75v. In our work with $HCOO^-$ ion, a true current reversal occurs at rather higher potentials (after an apparent limiting current) and would not be seen at such low potentials as Dr. Brummer went up to. Similarly the coverage by the intermediate studied by Dr. Brummer in his ref. (19) has already diminished to near zero by *ca* 0.65v E_H; the reducible species seen in our experiments only appears at higher potentials and therefore may more legitimately be identified as an "oxide" species.

This matter also brings up another point of general importance, namely that the course of an electrochemical reaction cannot simply be judged on the basis of adsorption studies alone. These must be used in conjunction with the steady-state kinetic characteristics of the reaction, *e.g.*, Tafel slopes, current reversal effects and reaction orders.

Finally, all our work has referred to formate ($HCOO^-$) ion in neutral or alkaline solutions, so that the species HCOOH is not actually the primary reactant under our conditions; thus the formate ion is probably not necessarily adsorbed in the same way as the formic acid molecule to which Dr. Brummer's discussion refers. The conclusions made previously for formic acid oxidation probably are not entirely applicable to the formate ion case, particularly under our conditions of alkalinity.

J. O'M. Bockris (communicated): I think that the usual difficulty of determining oxide as apart from adsorbed OH is not difficult any more and taking this into account would help to clarify some points in the paper of Conway and co-workers.

Thus, there is difficulty only if there is a monolayer. Then, it is adsorbed O (or OH) if the oxygen has a single bond and adsorbed oxide. However, if it is more than one bonded and coordinated by the metal on more than one side, it is a two-dimensional oxide.

This is the structural definition: the empirical definition arises from the ellipsometry which switches in in the neighborhood[29] of 0.9v.

Thus, in the section of their paper on Hydrocarbon oxidation, Conway *et al.* do not distinguish between adsorbed OH and oxide. They refer, for example, to the absence of oxide giving the rate "lack of inhibition." It is adsorbed O (or OH) which exits at these more negative potentials, and this must get into organic oxidations in some way from stoichiometric grounds: one does not have to have an oxide. Again, ellipsometry would be the main distinguishing point.

I think that, in reference to the Bagotsky and Vasiliev paper, we must note that the maxima there observed below that near 0.9v is certainly due to a pseudocapacitance charging process as implicitly pointed out by Bagotsky and Vasiliev[30] who found that in the steady-state no such curves could be seen.

B. E. Conway (communicated): The question of the identity of "surface oxide" at Pt was discussed in our paper, and the distinction between adsorbed oxygen species and oxide was recognized in our footnote in relation to the ellipsometric evidence. In our own and other electrical transient measurements, no distinction can, of course, be made between one type of species and another. However the well-known hysteresis in the formation and reduction of "oxide" at Pt undoubtedly arises in part from the irreversible transformation that occurs between "adsorbed" species and a two-dimensional "phase oxide." It is worth noting that quite independent evidence for the effect of ad-

[24] Compare the recent results of Gilman, [*J. Phys. Chem.*, 69, (1965)] on Cl^- adsorption.

sorbed O atoms in causing modification of the arrangement of metal atoms in the adsorbent surface has been obtained by low energy electron diffraction studies;[31] these changes in surface structure in the presence of adsorbate O-species may be similar to those encountered at the platinum anode surface above 1v.

We agree regarding the Bagotsky and Vasiliev results. In our work all the maxima observed are, however, true kinetic inhibition maxima since they were observed in the steady state[32] and arise presumably because of the presence of an inhibiting species, the surface concentration of which is dependent on potential.[32,33]

M. C. B. Hotz (communicated): Some years ago we made some conductivity measurements on aqueous solutions of hydrazinium perchlorate and hydrazinium chloroplatinate using platinized-platinum electrodes. We noted a change of conductivity with time; the chloroplatinate ion was found to have been reduced to metallic platinum. and evidence was obtained for production of chloride ion in the perchlorate solution. The reactions were much faster when platinized-platinum electrodes were used than with bright platinum, and we believed that the reduction was due to molecular hydrazine produced by the reaction

$$N_2H_5^+ + H_2O \rightleftharpoons H_3O^+ + N_2H_4$$

Even if Professor Conway used a substantial excess of perchloric acid, the possibility of this reaction cannot be ruled out.

B. E. Conway: We agree that free N_2H_4 can arise by hydrolysis; this effect may in fact be enhanced near the electrode surface where at anodic potentials the *p*H in the double-layer will tend to be higher than in bulk owing to repulsion of hydronium ions. Nevertheless, the concentration of free N_2H_4 must be very much smaller than that of $N_2H_5^+$ in 1M strong acid solutions. However, if the free energy of activation for oxidation of N_2H_4 were sufficiently less than that for $N_2H_5^+$, the disadvantageous difference of concentration of these two species could be outweighed by different rate constants for the respective oxidation reactions. Since the kinetic features of the reaction in acid and alkaline solutions are so different these possibilities must, however, be largely ruled out.

T. O. Rouse (communicated): The authors have presented an interesting correlation between water content in nonaqueous solutions and inhibition of formate oxidation by platinum "oxide." Some ambiguity still exists when the results for anhydrous propylene carbonate (PC) are considered (curve 1, Fig. 2). It is unfortunate that the log *i vs. V* curve for anhydrous acetonitrile or the oxide coverages for PC are not presented. If we assume, as the authors do, that the behavior in the two systems is comparable, it would appear that little or no oxide is present throughout the potential range in anhydrous PC. A comparison between curves 1 and 2 of Fig. 2 indicates considerable inhibition occurs between 0.8 and 1.1v when appreciable water is present, even though the authors are unable with their present technique to detect oxide formation over much of this range. The lack of inhibition in the anhydrous case in this potential range reinforces the authors' contention that the reaction in this range does not proceed via an oxide intermediate. However, it also follows that between 0.8 and 1.0v range, the reaction does not proceed only on sites just freshly uncovered of oxide. The reaction proceeds most readily when presumably little or no oxide was present at the higher potentials (the anhydrous situation).

Have the authors considered in greater detail the situation in anhydrous acetonitrile and PC?

B. E. Conway: The question concerning the results for anhydrous solutions in the case of CH_3CN arises from an error in the caption of Fig. 1 in the preprint. The solid line in this figure actually represents the behavior for the anhydrous case as it does in Fig. 2. The other solutions contained 2, 5, and 20 ml l^{-1} of water. The same applies to the curves in Fig. 3. It is likely (see Fig. 4) that even our best anhydrous solution still contained electrochemically significant traces of water; in all respects, however, the results in acetonitrile and propylene carbonate are entirely comparable, including the oxide coverages as a function of water content. Further work carried out in the absence of formate but with $NaClO_4$ as the electrolyte in CH_3CN confirms the dependence of oxide coverage on water content.

We agree regarding the remaining comments concerning the role of oxide as inhibitor or coreactant.[32]

Electrochemistry of Surface Oxides

A. C. Makrides

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

The electrochemical properties of surface oxides, particularly as they affect redox reactions at electrodes, are discussed. Experimental results on the effects of surface oxides on hydrogen evolution on nickel, on redox reactions on iron, on the hydrogen peroxide reactions on gold, and on oxygen evolution on lead are presented and discussed. The kinetics of formation and reduction of surface oxides are also examined with particular reference to gold electrodes where extensive measurements have been obtained.

Surface oxides play a role in a number of electrochemical reactions either directly by modifying the energetics of adsorption of reactants or intermediates or indirectly by changing the potential distribution at the surface. Some aspects of the electrochemistry of surface oxides have been of particular interest at our laboratory and have been explored in some detail. In particular, we have been concerned with the effects of oxides on oxygen reduction and evolution, on the hydrogen peroxide reactions, on the hydrogen reaction, and on the kinetics of simple redox reactions involving ions in solutions. In addition, we have studied the kinetics of formation and reduction of surface oxides using the gold electrode as a model system. In this paper we present a summary of these series of investigations and outline some of the general features of electrochemical reactions on superficially oxidized electrodes.

Experimental

The range of conditions covered by the investigations referred to is too wide to permit a detailed description here of the experimental procedures. In general, three-compartment, Pyrex cells were used and only glass, Teflon, and the electrode came in contact with the solution.

Solutions were made up of triply distilled water (one distillation being from dilute, alkaline $KMnO_4$) and C.P. or A.R. or recrystallized reagents. Purification included in some cases preelectrolysis or treatment with hydrogen peroxide. Certain potential sequences for cleaning the electrode were used, and these are described below or appropriate references are given. Gases were of highest purity available and were further purified by passage through appropriate traps or diffusion barriers, depending on the gas. Finally, the cells were thermostated to ± 0.1°C of the desired temperature.

Results and Discussion

Kinetics of formation and reduction of very thin oxide films.—The gold system was chosen for a detailed study of the kinetics of formation and reduction because of certain features which simplify its experimental study: the electrode can be electropolished with relative ease and it can be cycled between negative potentials (*vs.* RHE) and about + 2.0v without any permanent change in its surface or bulk properties; the reduction of anodically formed gold oxide films is particularly straightforward, the potential-time curve during most of the reduction occurring at a more or less constant potential; and, finally, the reproducibility of the measurements is very good generally about ± 3% in charge and ± 2 mv in potential.

The general technique we have used is to measure by cathodic, galvanostatic pulses the charge required for the reduction of a film formed anodically at a fixed potential. The cathodic pulse was generally of the order of 10 ma/cm^2; in fact, in the range of 1-100 ma/cm^2, the charge does not depend (< 1% variation) on the cathodic current density. This is true whether the film is allowed to reach a steady-state thickness or whether its formation is interrupted at a shorter time and the film reduced cathodically.

The steady-state charge (Q_∞) determined as described above, and corrected for double-layer charging, is shown as a function of potential in Fig. 1. Data previously published (1) are also given in this figure. The charge is a linear function of potential in the range of interest here with a slope of 1.25 x 10^{-3} coul/v.

The equivalent thickness of the anodic film has not been determined independently, but we know from results presented previously (1) that a monolayer of oxide corresponds to about 400 μC/cm^2 and has a thickness of about 10Å. Figure 1 shows, therefore, that a continuous transition occurs, as the potential is increased, from one to two equivalent layers (and beyond this to about three equivalent layers). We are dealing, therefore, with very thin films which range in thickness between 10 and 30Å. At potentials higher than 2.0v, the protective character of the film breaks down and films of essentially unlimited thickness can be grown (2).

The data in Fig. 1 suggest that the rate of growth of the film becomes negligibly small at a field which is independent of the thickness (E/Q_∞ = const.). It was attractive, therefore, to examine the model proposed by Mott (3, 4) for the growth of very thin films, which has already been applied to films of the same order of thickness as those encountered here. Of the two possible rate-determining steps, transport of ions through the oxide and reaction at an interface, the latter is rate controlling in the very thin film region. Without going into details of this model, which has been discussed at great length in the literature (5), the rate expression is

$$dX/dt = u \exp (X_1/X) \qquad [1]$$

with $X_1 = qaV/kT$, $u = u_0 \exp(-W/kT)$, and $u_0 = N'\Omega\nu$. Here, q is the charge on the ion, a the half-width and W the height of the energy barrier at the interface, N' the number of ions per unit surface area at kinks, etc., ν their frequency of vibration, and Ω the volume of oxide per metal ion. Since X_1 is of the order of 10^{-6} to 10^{-5} cm for the case considered here [and previously, (4)], Eq. [1] may be integrated approximately to yield

$$X_1/X = \ln [(X_1 u/X_\infty) t] \qquad [2]$$

Thus, at constant potential the thickness depends on time through an inverse logarithmic relation.

We have examined in detail the relation between Q and t over a sixfold range of time (~2.10^{-4} to 3.10^2 sec) and over the range of potentials included in Fig. 1 (E = 1.4 to 1.9v). These results, which encompass the kinetics of formation of the first monolayer (Q < 400 μC/cm^2), will be discussed in detail elsewhere (6). In the present context, we may simply state that the kinetics predicted by the Mott model are not obeyed during the formation of these very thin films, but on the contrary one observes a direct logarithmic relation between Q and t as shown in Fig. 2 for E = 1.8v.

This result was not entirely unexpected, since inverse logarithmic X-t relations have been rarely found in practice, direct logarithmic relations being more frequent. A direct logarithmic relation for oxidation has been attributed by Hauffe and Ilschner (7) to electron tunnelling being rate-determining for the growth of very thin films; however, such an explanation is obviously not applicable to the anodic formation of very thin films.

Grimley and Trapnell (8) have discussed the rate of growth of very thin films under conditions of saturation by chemisorbed, field-creating ions and have derived a linear law for both n- and p-type oxides assuming that the field is constant and independent of the oxide thickness. For a more complicated case, namely, for conditions of equilibrium between neutral

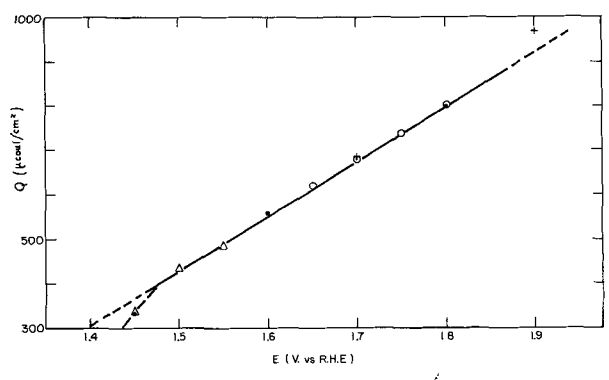

Fig. 1. Steady-state charge for reduction of anodic film on gold as a function of potential of formation ($NHClO_4$, 30°C).

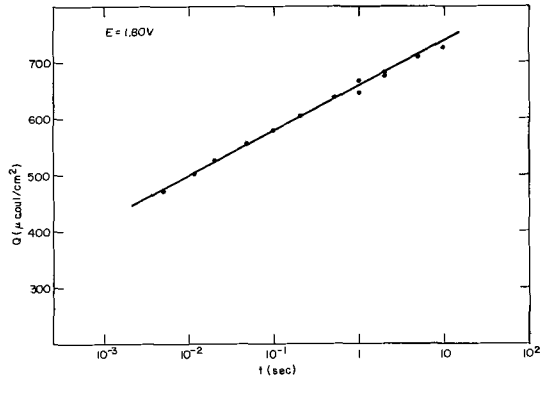

Fig. 2. Charge for reduction of anodic film formed on gold at 1.80v *vs.* RHE as a function of time of formation ($NHClO_4$, 30°C).

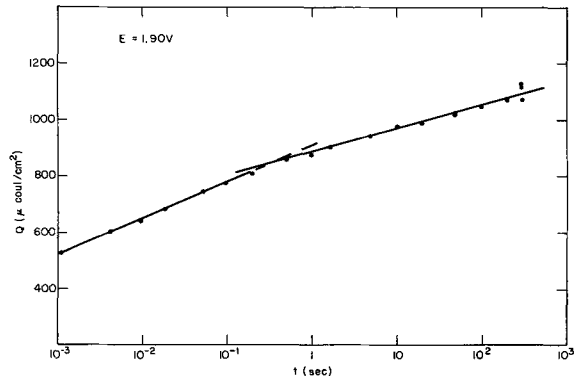

Fig. 3. Charged for reduction of anodic film formed on gold at 1.90v *vs.* RHE as a function of time of formation ($NHClO_4$, 30°C).

pairs and adsorbed ions, and for coverages by ions well below unity, they find an inverse logarithmic law if surface reactions (creation or destruction of vacant sites) are rate-determining.

It may be useful here to refer again to Fig. 1 and to emphasize that one of the implicit assumptions of these models may not hold true for our results in the very thin film region. In these models, the film is treated essentially as a continuum. In the calculation of the field, the thickness is assumed to be continuously variable by amounts presumably small in comparison to the thickness of a single layer. In fact, since we are dealing with a very few layers, in this case two or three, such a concept of film thickness is questionable. The fact that the charge measured is highly reproducible both for a given electrode and from electrode to electrode, suggests that layers are formed sequentially and that it is extremely unlikely that we are dealing with a film of variable thickness which happens to yield an average, equivalent thickness between, say, one and two layers. We must, therefore, examine the kinetics of growth of each layer separately and probably consider that during the formation of a layer, the thickness of the film is essentially constant. Results at 1.90v bear out this point (Fig. 3): we observe here a change in the kinetic constant as we go from the second layer (400-800 $\mu C/cm^2$ to a third (>800 $\mu C/cm^2$).

The two surface reactions which can be rate-determining are the reactions at the film-solution and at the metal-film interfaces. We may describe these in electrochemical terms, if we wish, and represent them by the usual chemical symbols. If we assume that the formation of oxygen ions (be they O^-, $O^=$, OH^-, etc.) is slow, we can attribute the logarithmic kinetics to an Elovitch-type relation as proposed for monolayer formation on platinum (9), that is to a relation of the type

$$\frac{dQ}{dt} = i = nFk \exp(-mQ) \exp(\alpha nFE/RT)$$

However, the physical basis of such a relation is obscure, particularly as a layer builds up to saturation; furthermore, m must be assumed to vary (arbitrarily) as each layer is formed; finally, it is not clear how this kinetic model can account for the gradual build-up of successive layers. A model easier to interpret can be constructed using the same general postulates as in the Mott theory, but modifying these for the particular conditions encountered here. The rate-limiting reaction is still assumed to be the passage of metal ions from metal to film, but the condition of constant potential drop across the film is abandoned. With this postulate, a direct logarithmic rate law can be derived, the rate constant being a function of the applied potential and of the film thickness. This model accounts for the general features of the kinetics of formation of anodic films on gold and also for their kinetics of reduction (1, 10). However, certain features of the reduction kinetics, *e.g.*, a dependence of the rate at a fixed reduction potential on the potential of formation of the film, are still not clear.

Effects of Surface Oxide Films on Electrochemical Processes

A number of reactions occur under conditions where the electrode may have either an adsorbed layer of oxygen or a very thin oxide film. We consider here a number of systems studied at our laboratory specifically for possible effects of oxide films on the reaction kinetics.

Hydrogen evolution on nickel.—We showed some time ago (11) that nickel electrodes in alkaline solution at 30°C behave in two distinct ways with respect to the hydrogen evolution reaction: electrodes in what we called the "initial state" show Tafel slopes of about 0.130v, exchange currents of about 2×10^{-5} amp/cm², and stoichiometric numbers $\nu = 2$; electrodes in a state arrived at by passivation show Tafel slopes of about 0.080v, exchange currents of about 0.8×10^{-5} amp/cm², and stoichiometric numbers of $\nu = 1$. Further studies with this system suggest strongly that the passive film formed on anodic polarization is reduced very sluggishly and that, in fact, in 0.1*N* NaOH solutions the anodically formed film, or some residual part of it, is present even at potentials of —0.200v *vs.* RHE.

Nickel electrodes can be prepared in an apparently completely reduced state by pretreatment with cathodic pulses of the order of 200 ma/cm². Results on the hydrogen reaction on such electrodes are shown in Fig. 4 and 5. The behavior of the same electrode after a passivating treatment is also shown in Fig. 4 and 5. The effect of the residual oxide or chemisorbed oxygen layer on the kinetics of the hydrogen reaction is to change the mechanism from

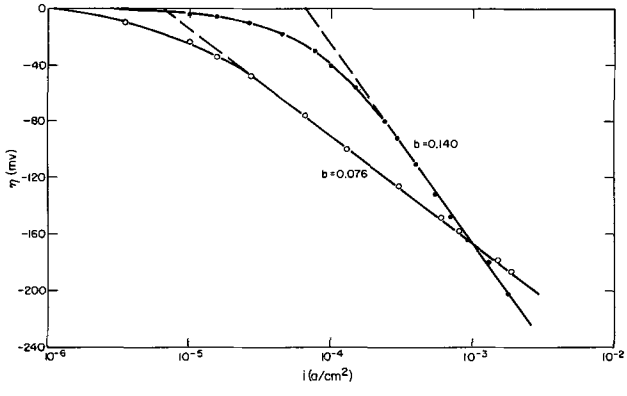

Fig. 4. Hydrogen overpotential on Ni in reduced state (●) and after anodic passivation (○) (0.1N NaOH, 30°C).

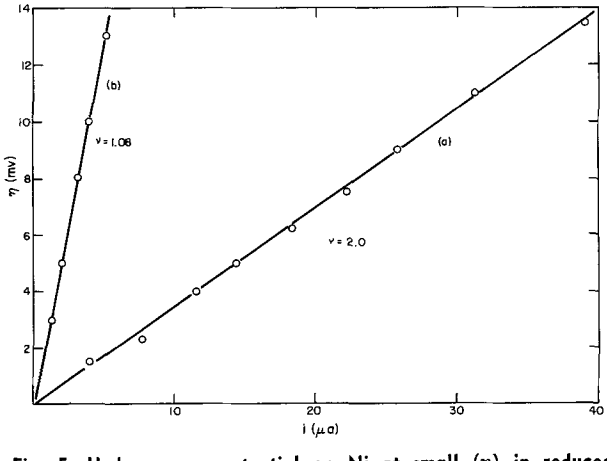

Fig. 5. Hydrogen overpotential on Ni at small (η) in reduced state (a) and after anodic passivation (b) (0.1N NaOH, 30°C).

$$H^+ + e \rightarrow H_{ads} \quad \text{(slow)}$$

$$H_{ads} + H_{ads} \rightleftharpoons H_2$$

to the sequence

$$H^+ + e \rightleftharpoons H_{ads}$$

$$H + H^+ + e \rightarrow H_2 \quad \text{(slow)}$$

with the consequent changes in the Tafel parameters and stoichiometric numbers given above. This change is probably also accompanied by a substantial decrease of θ_o, the extent of coverage by adsorbed hydrogen at the equilibrium potential; the value of θ_o for electrodes cycled to anodic potentials is vanishingly small.

Redox reactions on passive electrodes.—The kinetics of redox reactions involving ions in solution, specifically the Fe^{+3}/Fe^{+2} couple, were studied on passive electrodes of Ni, Fe, Ti, and Fe-Cr electrodes (12).

Aside from specific effects, *e.g.*, changes in the energy of adsorption of reactants or of intermediates, surface oxides may influence the kinetics of an electrochemical reaction by providing a barrier to electron transfer between the metal and an ion or molecule at the oxide/electrolyte interface. With thick films, the oxide is the electrode, and the chemical character of the bulk oxide and its electrical properties, *e.g.*, its semiconducting properties, determine its electrode characteristics. At the other extreme, very thin oxide films may be considered as simply providing a barrier through which electrons must tunnel in order to participate in the reaction. The electrical characteristics of films of intermediate thickness, in the range of about 30 to 200Å, are probably influenced strongly by the underlying metal.

A simple way of examining the general electrochemical effects of surface oxides is to compare the kinetics of an elementary electron transfer reaction on oxide-covered and oxide-free electrodes. Specific effects, *e.g.*, adsorption, should be at a minimum for the redox couple chosen. The Fe^{+++}/Fe^{++} couple was selected for study because its kinetic behavior on oxide-free electrodes is straightforward. Furthermore, since its reversible potential falls in about the middle of the potential region over which a number of common metals and alloys are passive, both the oxidation of ferrous ion and the reduction of ferric ion can be followed without gross interference from corrosion reactions.

Overpotential measurements for the Fe^{+++}/Fe^{++} couple on passive Ni, Fe, Ti, and Fe-Cr alloys carried out in solutions of fixed ionic strength but of varying *p*H. Tafel lines were generally obtained with exchange currents between 10^{-7} and 10^{-5} amp/cm^2. Typical polarization curves are shown in Fig. 6 (12).

The cathodic transfer coefficients are about 0.45 for this redox reaction on essentially all passive electrodes studied. The anodic transfer coefficients are less, particularly on Ti and Fe electrodes. The sum of the apparent transfer coefficients, calculated from the anodic and cathodic polarization curves, is significantly less than unity.

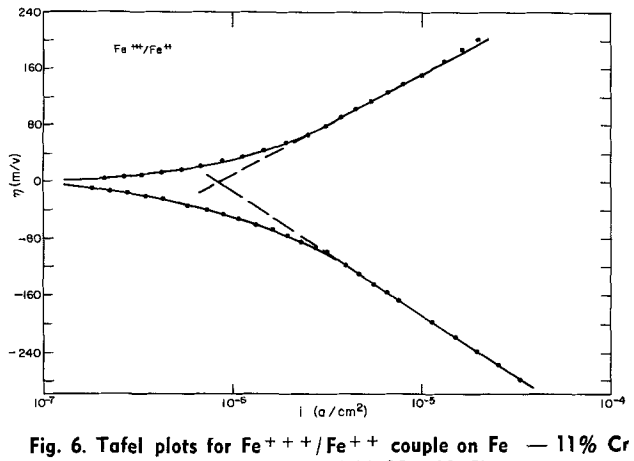

Fig. 6. Tafel plots for Fe^{+++}/Fe^{++} couple on Fe — 11% Cr alloys (C = 0.050M, pH = 2.2, M $MgSO_4$, 30°C).

The polarization behavior of the Fe^{+++}/Fe^{++} couple on passive Ni and Ti can be summarized by an expression of the form (potentials in units of RT/F)

$$i = i_o \{\exp(-\alpha_r \eta) - \exp[\beta_r(1-\gamma)\eta]\}$$

with the sum of the apparent transfer coefficients, α_c and α_a, being given by

$$\alpha_c + \alpha_a = \alpha_r + \beta_r(1-\gamma) = 1 - \gamma\beta_r$$

and an apparent stoichiometric number is

$$\nu = \pm\, i_o \Big/ \left(\frac{\partial i}{\partial \eta}\right)_{\eta=0} = 1 - \gamma\beta_r$$

The fraction of the overpotential drop within the film is given by γ. These equations are followed by passive Ni at *p*H = 2.3 and by Ti at *p*H = 1.5 and for $T \leq 20$°C. The coefficient γ is 0.15 for Ni and 0.60 for Ti. Fe, Ni at low *p*H, and Ti at higher temperatures show a more complicated behavior on anodic polarization. A limiting anodic current, which is unrelated to diffusion of Fe^{+2} in solution is observed on these passive metals under these conditions, and it appears that here $\gamma \simeq 1$.

These results show that an appreciable fraction of the total potential drop on anodic polarization occurs within the passive film. This potential drop is probably associated with changes in the average oxidation state of cations between the inner and outer layers of the surface oxide.

Other reactions.—We have examined a number of other cases where it has been postulated that oxide or chemisorbed oxygen (or OH) films are involved in the kinetics. For example, the H_2O_2 reactions on gold have been assumed to involve adsorbed OH groups (13) or adsorbed oxygen (14). In this particular case, we find that the H_2O_2 reactions proceed on a surface which is free of oxide and, in fact, essentially free of any other adsorbed intermediate (15). For example, the double layer capacity of a gold electrode in a N_2-saturated, *N* $HClO_4$ solution containing 0.1M H_2O_2 is the same as in *N* $HClO_4$; also, chronopotentiograms in H_2O_2 show no evidence for the adsorption of an intermediate prior to H_2O_2 oxidation or reduction. This result is in harmony with our studies of oxidation of gold since these show that no significant amount of adsorbed oxygen should be present in the relevant potential region.

Another reaction studied in some detail was oxygen evolution on lead dioxide. Here, we are dealing with a bulk oxide electrode, but one where the possibility of specific effects was strongly suggested by other work. It has been reported (16, 17) that α- and β-PbO_2 electrodes show different mechanisms for oxygen evolution (substantially different Tafel slopes and exchange currents). Previous work with this system was carried out using PbO_2 electrodes deposited under arbitrary conditions. Actually, it appears that PbO_2 electrodes as commonly prepared are highly porous and, consequently, the reported kinetic results (including values of the Tafel constant for oxygen evolution) are in error. We have prepared low surface area α- and β-PbO_2 electrodes and for these we find no difference in the kinetic parameters for oxygen evolution (18) and no evidence for adsorbed intermediates during oxygen evolution. Therefore, specific effects attributable to the structure of the oxide are minor with this system.

Discussion

Roger Parsons: It seems to me that the introduction of the factor $(1 - \gamma)$ into the anodic transfer coefficient and not into the cathodic transfer coefficient means that the proposed model will not produce a Nernst equation of the correct form. At least at the reversible potential the anodic and cathodic transfer coefficient must add up to unity. Thus it seems that, if this model applies, there must be a change in transfer coefficient near the reversible potential. Is this observed? Do the electrodes obey the Nernst equation for systems like Fe^{3+}/Fe^{2+}?

A. C. Makrides: Professor Parsons' comments on the requirement that the transfer coefficients must add to unity at the reversible potential is, of course, correct. These electrodes obey the Nernst relations (see reference cited above), which suggests that they are sufficiently good electronic conductors so that electrons are close to equilibrium when no current flows. Under conditions of current flow, this is no longer true and a potential drop appears within the film; the apparent transfer coefficients must be changing, therefore, as one departs from equilibrium.

B. E. Conway: It may be of interest to note that Meyer[1] considered the effects of barrier layer type oxide films on the kinetics of electrode processes occurring at the film-solution interface. This treatment gives rise to an over-all apparent transfer coefficient α given by

$$\alpha = \alpha_f \alpha_r / (\alpha_f + \alpha_r)$$

where α_f is the symmetry factor for the film charge transfer process and α_r is the transfer coefficient for the interface reaction. Generally the apparent α is less than the α_r, and this may account for some high anodic Tafel slopes observed. Meyer also gave a treatment for the equilibrium condition for a redox system at an oxide covered electrode.

The kinetics of oxygen evolution at gold or gold palladium alloys were studied by MacDonald and Conway[2] who took into account the role of the oxide film on the oxygen evolution kinetics at gold.

We have found that a direct logarithmic growth law for the oxide may also be demonstrated at Pt in terms of the charge Q_o required for reduction of the surface oxide. In this case, however, the film grows only to a thickness much less than that attainable in gold.

Finally it may be of interest to record that the Kolbe reaction in aqueous solution is another example of a process that occurs in the steady state on an oxide covered surface, *e.g.*, at Pt and in some cases at gold.[3]

A. C. Makrides: The comments of Professor Conway on the Meyer model are appreciated, but as we have shown in connection with one of these studies,[4] the assumption of a barrier to electron transfer in the film and of a potential drop across this barrier which depends on the current does not lead to reasonable values for the apparent transfer coefficients. According to this model, the apparent cathodic and anodic transfer coefficients for the over-all reaction are

$$\alpha_c = \frac{\alpha_f \alpha_r}{\alpha_f + \alpha_r} \qquad \alpha_a = \frac{\beta_f \beta_r}{\beta_f + \beta_r}$$

where $\alpha_f + \beta_f = 1$ and $\alpha_r + \beta_r = 1$, with the subscripts f and r referring to the film and to the redox reaction in solution, respectively. If $\alpha_f \simeq \beta_f \simeq 0.5$, then for $\alpha_r \simeq \beta_r \simeq 0.5$, we expect $\alpha_c = 0.25$ and $\alpha_a = 0.25$. Typical values for the apparent coefficients in our case are $\alpha_c = 0.45$ and $\alpha_a = 0.36$. If we choose α_f so as to make the cathodic apparent coefficient agree with the experimental value, then the apparent anodic coefficient is not reasonable. For example, if $\alpha_f = 0.90$ and $\alpha_r \simeq \beta_r \simeq 0.5$, then $\alpha_c = 0.35$, reasonably close to 0.45, but α_a is now only 0.08, far from the experimental value.

H. Gerischer: It is very interesting and important to characterize oxide layers on metals by their behavior in electron transfer reactions. It is only regrettable that these processes are not yet fully understood; for example I cannot yet see a satisfactory interpretation for the unusual charge transfer coefficients you have obtained for the anodic and cathodic reactions. The assumption that a constant part of the voltage variation is lost in the interior of the oxide for the driving force of the redox reaction remains to be understood. Without external electronic current you can obtain the equilibrium redox potential. This means electronic equilibrium is realized in the over-all electrode. It seems now very unlikely that just in the region of equilibrium potentials the charge transfer coefficient should vary so rapidly, and this is even more unlikely since this coefficient remains remarkably constant in the other regions of your Tafel plots. The loss of free energy of the electrons in the redox reaction going on should therefore be related to the transport of electrons through the oxide layer to give such as analogous semilogarithmic correlation. In this case the same values for the ineffective part of the voltage should be found for different redox reactions. Has this already been investigated?

A. C. Makrides: The point raised by Professor Gerischer is a very real difficulty with our attempt to interpret the observed kinetics. As he points out, it is not likely that the transfer coefficient will vary rapidly at potentials close to equilibrium and then remain constant at substantial overpotentials. We have tried to explain this behavior by assuming a structure of the film which might account for rectification in one direction, namely, in the direction of increasingly positive potentials. It was proposed that in a mixed valency oxide there is a change in the average oxidation state as one proceeds from the metal to the solution interface even in these very thin films. A structure of this kind will show rectification in the observed direc-

tion. However, this is a speculative suggestion and although it is in harmony with other results from studies of the reduction characteristics of passive films, there is no solid evidence that it is valid.

James P. Hoare: I wish to take this opportunity to commend Dr. Makrides and his group at Tyco Laboratories for the excellent work they have done with these interesting electrochemical systems. This work brings to mind several controversial areas which offer excellent opportunity for those in attendance to express their viewpoints.

In these cases discussed, the electrode under investigation may be considered as an inert electrode at least in the experimental regions where the electrode kinetics were studied. The role of the inert electrode in electrode kinetics is to act as a source or sink for electrons and the catalytic surface on which the electrode reaction may take place. One facet of such studies relates to the effect which the presence of a thin film on the electrode surface has on the catalytic activity of the surface for a given electrode process.

Consider, for example, the oxygen-platinum system. Under ordinary conditions a monolayer film of adsorbed oxygen is formed on the platinum surface.[5] The nature of this film is still not unambiguously determined since the dispute between a layer of oxide and a layer of adsorbed oxygen atoms is not settled.[6] Even the latest ellipsometric evidence[7] may be adequately explained by oxygen dissolved in the metal surface layers. There is evidence from potential sweep data,[8] steady-state polarization data,[9] and rotating ring studies[10] that the reduction of oxygen is inhibited by the presence of adsorbed oxygen on Pt electrodes. It also appears to be true for Pd,[11] Rh, and Ir electrodes. However, the presence of a layer of adsorbed oxygen seems to increase the rate of reduction of H_2O_2.[12] Possibly the reduction of O_2 is electron-transfer controlled, and the film inhibits the transfer of electrons whereas the reduction of H_2O_2 can proceed chemically, accelerated by the presence of adsorbed oxygen. In the absence of oxide, the decomposition of H_2O_2 most likely proceeds by a local cell process[13] which is a slower one than the chemical process.

When oxygen is dissolved in the Pt metal through anodization and when the adsorbed oxygen on the surface is removed by reduction with H_2 or a redox system, the electrode surface is a better catalyst for many electrode reactions, as demonstrated by the preanodized indicator electrode in electroanalytical systems.[14] By treating the Pt with HNO_3, it is possible to cause even more oxygen to be dissolved in the Pt as an alloy of O and Pt atoms as found from x-ray and vacuum fusion analyses.[15] Such electrodes have a relatively low overvoltage for the reduction of O_2 and for the reduction of H_2O_2.[16] However, the overvoltage for the evolution of O_2 is the same for HNO_3-treated[16] and untreated Pt anodes.[17] For the evolution of O_2 on Pt anodes, the electrode reaction takes place on an oxide surface which is the same for treated and untreated electrodes, but for the reduction of O_2 it takes place on a bare surface so that the presence of dissolved oxygen makes a difference between the rates on a treated and untreated Pt electrode.

It appears that the evolution of oxygen on Pt and Rh anodes takes place on an electronically conducting film of adsorbed oxygen since the film does not grow with prolonged anodization[5] and since the double layer capacity does not fall as oxygen is adsorbed.[18] In this case the film is the catalytic surface on which the electrode reaction takes place. With respect to Pd anodes, the adsorbed oxygen film actually participates in the evolution of oxygen by the decomposition of PdO_2 to PdO and O_2.[11] The current goes into the conversion of PdO to PdO_2. On Au anodes, the evolution of O_2 probably proceeds with difficulty on the oxide covered surface since the films of Au_2O_3 are likely to be ionic conductors as shown by continued growth of the film with anodic polarization[19] and by a lowering of the double layer capacity as oxygen is adsorbed on Au.[20] However, these films of Au_2O_3 are poorly adherent and easily flake off.[19] In this case the current goes into the simultaneous formation of Au_2O_3 and the evolution of O_2, probably on bare gold sites.[21]

It is seen, then, that one must distinguish between oxygen adsorbed on the surface and that dissolved in metal surface layers in studying the effects of adsorbed oxygen films on the electrode kinetics. Another point to be considered is the possibility that the film is the catalytic surface on which the reaction may proceed or that it may actually participate in the electrode reaction itself.

A. C. Makrides: Dr. Hoare's comments on the solution of oxygen in platinum point out one of the difficulties in interpreting results from anodic oxidation experiments with noble metals. In the particular case discussed by us, the over-all kinetics are such that it is unlikely that any appreciable amount of oxygen is dissolved into the metal. In general, one expects this process to be relatively slow around room temperature. Because of this difficulty, it seems to me that the explanation of certain observations on the electrochemical behavior of platinum in terms of dissolved oxygen should be treated with caution.

T. O. Rouse and J. L. Weininger: At this meeting of the Theoretical Division of the Society we are reporting the study of a redox reaction at a Li-doped semiconducting single crystal NiO electrode.[22] Comparison with the results obtained in the present paper is appropriate, although it should be pointed out that our electrode is structurally well-defined whereas some uncertainty exists regarding the structure of the passive layer.

In our case, it was first necessary to characterize the semiconducting electrode quite thoroughly. The initial results indicated a potential distribution across both the solution side and the semiconductor side of the interface in the absence of a faradaic process.[23] This potential distribution has now been demonstrated

quantitatively[22] in the presence of the redox couple ferrocyanide-ferricyanide.

The extension of the double layer across the electrode interface is in agreement with the work reported by the author. In our chronopotentiometric study we obtained different results with regard to the electrode reaction. We found that the oxidation of $Fe(CN)_6^{-4}$ proceeds in a kinetically irreversible manner. The reduction of $Fe(CN)_6^{-3}$ is hindered. Consequently, there is a pronounced rectification effect at the semiconductor electrode, which will also be reported by Greef and co-workers at this meeting.[24]

Our findings are that the exchange current, i_o, for the oxidation of ferrocyanide depends on the degree of doping of the NiO electrode, on the concentration of the oxidized and reduced species, C_O and C_R, in the solution, and on *p*H. Linear relations of i_o with $\sqrt{C_O \cdot C_R}$ and with *p*H, respectively, show that a portion of the double layer extends into the solution. The quantitative estimation of the two diffuse portions of the double layer is obtained from galvanostatic measurements. An apparent transfer coefficient, α, of 0.5 is obtained from plots of E *vs.* $\log\left[1-\left(\frac{t}{\tau}\right)^{1/2}\right]$, based on the kinetic expression of E as a function of time at constant current density for an irreversible electrode process

$$\eta = \frac{RT}{\alpha nF}\log\left[1-\left(\frac{t}{\tau}\right)^{1/2}\right] + \frac{RT}{\alpha nF}\log\frac{i}{i_o}$$

where E is the electrode potential at time t, and τ is the transition time when diffusion control is established. The theoretical implication of $\alpha = 0.5$, *i.e.*, a coefficient of 120 mv/decade in the right-hand terms of the above equation, is that the potential distribution is that shown in Fig. TOR1, where η stands for overvoltage, ϕ for potential, the subscripts refer to the bulk of the solid phase, the surface, and the solution, and the superscript ^{o} denotes equilibrium or condition of rest potential. It is seen that on applying an overvoltage $\eta = \phi_B - \phi_B^o$, a corresponding overvoltage, η_S, of the same magnitude appears at the electrode surface. Thus, the electrode polarization due to the anodic reaction appears across the Helmholtz portion of the double layer.

Our experimental results are in agreement with a model which predicts that an appreciable potential drop in the solution will occur only for a large concentration for charge carriers in the semiconducting oxide. The remarkable similarity in exchange currents and apparent transfer coefficients between our work and the author's previous results[25] indicates that the anodic films also contain a large number of charge carriers (of the order of 10^{20} cm^{-3}). Because NiO is a mixed valency semiconductor one can discuss valence states in terms of charge carriers, *e.g.*, Ni(III) in the lattice of NiO is equivalent to a hole (defect-electron). At the surface the concentration of the charge carrier depends on the applied potential. Therefore, it seems possible that the properties of some passive films can be deduced from a comparison of experimental results with semiconductor theory. Further experimental work on both anodically formed and single crystal NiO is needed to complete such a description.

Fig. TOR1. Effect of redox couple

A. C. Makrides: The results quoted by Drs. Rouse and Weininger are very interesting, and it is quite likely that we will not understand passive films until we have examined in some detail the electrochemical behavior of analogous bulk oxides. It is indeed remarkable that there is such a similarity in exchange currents and apparent transfer coefficients for these redox reactions on single crystal NiO electrodes and on passive nickel electrodes. This is probably more than a coincidence, and further work with these systems will certainly be extremely interesting.

Paul C. Milner: In the formation of very thin oxide films on gold, what pertinence do continuum models have, especially during the formation of less than a monolayer? If layers form successively and should be treated individually, what halts the growth of a layer at a particular potential? Thermodynamics (as in the Temkin isotherm)? Kinetics (because of varying dissolution rates or because of formation rates dependent on the degree of completion of the layer being formed)? Both? Is the reduction process the reverse of the formation process? In reduction at constant current, is the effective current density constant or does it depend on the amount of oxide remaining in the layer being reduced?

In the oxygen evolution reaction at α-PbO_2, is it certain that there has been no recrystallization of the surface to give β-PbO_2, the thermodynamically stable form in acid solutions? This might take place fairly readily by way of the plumbous ions which are present in the solution in fairly sizeable quantities at potentials close to the equilibrium lead dioxide/lead sulfate potential. Are previous results semiquantitatively explicable on the basis of porous electrode theory?

A. C. Makrides: The questions formulated by Dr. Milner are of course very much to the point and parallel those raised in the paper. In the formation of very thin oxides, one questions the applicability of a continuum model, and this objection was raised above. The factors which limit the growth of the particular layer are undoubtedly kinetic and they must arise from a lowering of the field as the layer grows.

The oxygen evolution studies on α-PbO_2 were carried out on electrodes which were potentiostatically held above the reduction potential at all times. Recrystallization did not occur as was evident from studies in dilute $HClO_4$(0.01*N*) where differences between the α and β modifications were noted. Previous results can be explained with the usual assumption of a change in the apparent Tafel slope when dealing with porous electrodes. The difference of a factor of two in this constant is consistent with what one expects from theory.

A. Riga and E. Yeager: As part of a study of the electrochemical properties of single crystal lithiated nickel

[25] A. C. Makrides, *This Journal*, **111**, 392 (1964).

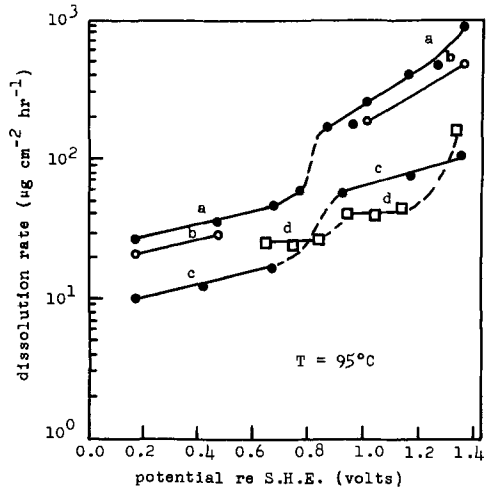

Fig. AR1. Dissolution rates of lithiated NiO as a function of potential. Curve a, 1M HCl, x = 1.1%; b, 1M HCl, x = 0.92%; c, 1M HCl, x = 0.85%; d, 0.5M H_2SO_4, x = 0.80%.

oxide, we have measured the rates of dissolution as a function of the potential of the oxide relative to the solution. Dissolution rates have been determined at controlled potentials in HCl and H_2SO_4 solutions by subsequently analyzing the solutions for nickel spectrophotometrically. Elevated temperatures (95°C) have been used to increase the otherwise very slow rates of dissolution to a point where measurements would be carried out over a few hours. The use of a Teflon cell with Kel-F window permitted *in situ* photomicrographs. Experimental details will be presented in a paper now in preparation.

In Fig. AR1 is shown the dependence of the logarithm of the dissolution rates on potential for lithiated single crystal nickel oxide prepared by the method of Cech and Alessandrini[26] and infused with lithium at 1600°C with a technique similar to that used by Rouse and Weininger.[27] The dissolution of $Li_xNi_{(1-x)}O$ with $x = 0.9\%$ was followed as a function of time for 5 to 6 hr at potentials of +0.5, 1.0, and 1.4v re standard hydrogen electrode (SHE) and the rates found to be constant over this period of time. From Fig. AR1, it can be seen that the dissolution rate increased very substantially over the relatively narrow voltage range of +0.8 to 0.9v re SHE. The flat band potential and the anodic peak in the voltammetry curve ascribed to the $Ni^{+2} - Ni^{+3}$ conversion also fall in this range. A pronounced change in the mode of attack at potentials below +0.8v and above 0.9v re SHE is evident in the photomicrographs. Typical micrographs are shown in Fig. AR2 for 1*N* HCl. At potentials cathodic to 0.8v re SHE, the surface is uniformly attacked with no etch pits evident at magnifications of 800 fold. At potentials anodic to 0.9v re SHE, etch pits of the type shown in Fig. AR2b develop with the number of etch pits per unit area generally constant after the first 10 to 20 min.

Some tendency for an exponential dependence of the dissolution rate on potential above and below the region of rapid change is apparent in Fig. AR1, but the range of dissolution rates is too limited for a good test of such a relationship within the precision of the measurements. The dependence of the dissolution rate on carrier concentration remains to be fully established.

The dependence of the dissolution rate on potential shown in Fig. AR1 can be explained on the basis that dissolution involves the transmission of the cations and anions of the lattice over potential energy barriers, the heights of which are dependent on the potential drop across the oxide-solution interface. If the cation barrier is higher than that for anions, then an increase in dissolution rate with increasing anodic potential would be expected. This explanation is similar to that of Engell.[28] While such an explanation has obvious appeal to the electrochemical kineticist (particularly those of the Tafel school), the predominant factors may not be so much the effects of the applied potential directly on the heights of the potential energy barriers but rather the effects of the applied potential on the adsorption of ions on the oxide surface and the valency state or carrier concentration in the equivalent of a plane of closest approach within the oxide phase.

J. L. Weininger and M. W. Breiter: Reference is made to our work on the anodization[29] and hydrogen evolution[30] on single crystal and polycrystalline nickel electrodes. Although our measurements were made in 4*N* KOH as compared to 0.1*N* NaOH in the author's work there was generally a great difference between the experimental results on a freshly prepared surface and one which had been through one or more passivation cycles. Similar Tafel slopes (0.130 and 0.090 mv/decade) and even exchange currents of the same order of magnitude (10^{-5} μa/cm^2) were observed. We apparently differ, however, in interpretation. What is meant by an "electrode in a state arrived at by passivation"? In our case, the equivalent of about ten monolayers of $Ni(OH)_2$ and higher oxide was produced on the metallic surface. Subsequently, the oxides were reduced at —300 mv (*vs.* RHE) for 8 min. After this treatment we obtained the experimental behavior comparable to that of the author's passivated electrode.

It is readily agreed that the kinetics of hydrogen reduction is complex and that under different experimental conditions, and different pretreatment of the nickel electrode, the extent to which the steady state is determined by the Volmer, Heyrovsky, or Tafel reaction may vary. But there was no indication that anodic-cathodic cycling produces a more tenacious oxide film. Our conclusions of a rate-determining Volmer reaction are based on the measurements of cath-

$$Ni + H_2O + e = Ni - H + OH^-$$

odic current-potential curves and the capacities at negative overvoltage. The possibility that nickel hydroxide may be present at $\eta = 0$ in 0.1*N* NaOH makes the application of the stoichiometric number ν as a criterion doubtful.

Charge Transfer Processes at Organic Insulator Electrodes

W. Mehl, J. M. Hale, and F. Lohmann

Cyanamid European Research Institute, Cologny/Geneva, Switzerland

ABSTRACT

Charge transfer reactions at insulator electrodes are discussed in terms of the model developed for such processes at semiconductor electrodes. A simplifying condition here is that only such reactions are possible which lead to the injection of holes into the valence band or of electrons into the conduction band. Measurements at anthracene electrodes showed complete agreement with the predictions derived from the model including the possibility of having reversible charge transfer reactions.

Insulators are, by classical definition, materials which provide electrical insulation, *i.e.*, which permit the passage of no current or only a small amount even at high applied voltages. A project using insulators as electrode materials for electrochemical studies would thus not seem to be a very promising one.

Since the development of the energy-band theory of the electronic structure of solids by the application of quantum mechanics to the solid state, it has been understood, however, that insulators should be able to carry currents if somehow electrons can be raised into the conduction band which is normally empty (1). In certain cases, this can be done by excitation with light or heat; another possibility is the injection of charges from suitably chosen contacts (1,2). We shall discuss here the conditions under which electrons can pass from electrolyte solutions into insulators.

The interface between insulators and electrolytes has to be discussed as a part of the general problem of the interface between semiconductors and electrolytes because insulators can be defined as semiconductors with a large interval between the Fermi-level and the allowed energy bands, e.g., at least 1 ev.

The band representation of an insulator-electrolyte interface is shown in Fig. 1 for two important cases (3). In Fig. 1a the concentration of electrons at the contact is higher than in the bulk of the material: we define this as an "ohmic contact for electrons." In Fig. 1b, the concentration of holes at the contact is higher than in the bulk of the material; we define this as an "ohmic contact for holes." With these definitions, we can now formulate the subject of this paper as an investigation of the question under which circumstances electrolytic contacts to insulators are ohmic.

Redox Reactions at Insulator Electrodes

At insulator electrodes only those redox reactions can take place which result in the net injection of electrons in the conduction band or in the net injection of holes in the valence band. A formula for the exchange current of a redox reaction at an insulator electrode can be derived with the aid of any of the theories which describe the Franck-Condon restricted transitions of electrons involving solvated species.

$$i_o^n = F\nu C_R \exp\left\{ -\frac{\lambda}{4kT}\left[\left(\zeta - \frac{-\Delta\epsilon_s^n - kT\ln C_O/C_R}{\zeta\lambda}\right)^2 + \frac{4\Delta\epsilon_s^n}{\lambda}\right]\right\} \quad [1a]$$

$$i_o^p = F\nu C_O \exp\left\{ -\frac{\lambda}{4kT}\left(\zeta + \frac{\Delta\epsilon_s^p + kT\ln C_O/C_R}{\zeta\lambda}\right)^2\right\} \quad [1b]$$

Here i_o^n and i_o^p are the electron exchange current with the conduction band and the hole exchange current with the valence band, respectively: ν is the velocity of movement along the reaction coordinate, C_O is the concentration of the oxidized species, and C_R that of the reduced species at the outer Helmholtz plane at the equilibrium potential. λ is an energy parameter which in magnitude equals the energy required to reorient the solvation atmosphere about the oxidized species until it becomes identical with that about the reduced species in equilibrium. ζ is the number of electrons involved in the electron transfer reaction, $\Delta\epsilon_s$ is the magnitude of the forbidden gap between the Fermi level and the allowed energy state for the carrier in the surface (the bottom of the conduction band for an electron and the top of the valence band for a hole) at the equilibrium potential. Equations [1a] and [1b] can be derived from the theories of Dewald (8), who used Marcus' theory of the electron transfer reaction, Gerischer (5) and Dogonadze and Chizmadzhev (6) under equivalent approximations. These are (*i*) the energy distribution of electrons, holes, oxidized and reduced species are described by Boltzmann statistics; (*ii*) the cross section through the potential energy surface for the reaction, made by the reaction coordinate, consists of two intersecting parabolae.

As the penetration of a medium by an electric field depends on the concentration within the medium of free charges, the potential difference applied across an insulator electrode-electrolyte interface will be shared between the interior of the insulator and the Helmholtz inner layer in such a manner that most of the potential drop occurs across the insulator (9). This argument is valid only if surface states can be excluded. Any assumptions about the potential distribution at the insulator-electrolyte interface have thus always to be verified by experiments.

Let us assume that all of the interfacial potential variation exists within the solid. The $\Delta\epsilon_s$ can be expressed through the Nernst equation

$$\Delta\epsilon_s^n = \Delta^n + e_o(E_R - E_{FB}) = \Delta^n + e_o(E_s - E_{FB}) + kT\ln C_O/C_R \quad [2a]$$

$$\Delta\epsilon_s^p = \Delta^p - e_o(E_s - E_{FB}) - kT\ln C_O/C_R \quad [2b]$$

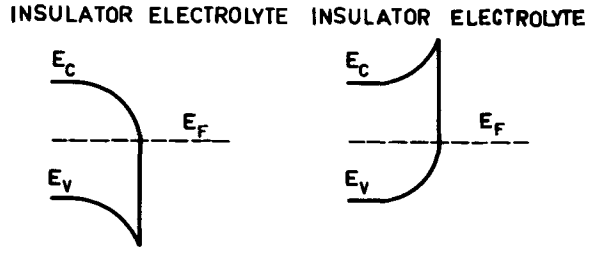

Fig. 1. Schematic energy-band diagram for injecting electrolytic contacts in thermal equilibrium.

Δ^n and Δ^p are the intervals of energy between the Fermi level and the conduction band and valence band, respectively, in the bulk of the insulator; E_R is the equilibrium potential, E_s the standard potential of the redox system, and E_{FB} the flat band electrode potential of the insulator; e_o is the electronic charge. Insertion of these relations into Eq. [1a] and [1b] yields the simplified forms

$$i_o^n = F\nu C_R \exp\left\{\frac{-[\zeta^2\lambda + \Delta^n + e_o(E_s - E_{FB})]^2}{4\,\zeta^2\lambda\, kT}\right\} \quad [3a]$$

$$i_o^p = F\nu C_O \exp\left\{\frac{-[\zeta^2\lambda + \Delta^p - e_o(E_s - E_{FB})]^2}{4\,\zeta^2\lambda\, kT}\right\} \quad [3b]$$

Two consequences of these formulas are of special interest for this investigation: (*i*) the exchange current is proportional to either C_O or C_R whereas at a metal electrode $i_o \alpha \sqrt{C_O C_R}$; (*ii*) the magnitude of the exchange current is determined by the standard potential of the redox couple. If the couple is strongly oxidizing with $E_s - E_{FB} >> 0$ then $i_o^p >> i_o^n$; furthermore, when $e_o(E_s - E_{FB}) \sim \Delta^p$ the exchange current has the order of magnitude that it takes at a metal.

A similar relationship was derived previously and confirmed experimentally for germanium electrodes (5).

For insulators, concentration polarization of the charge carriers in the solid is of major importance for the discussion of the current voltage characteristic. The relevant boundary value problem has recently been discussed in detail (10). Expressed in terms of the steady-state current with the assumption of first order kinetics, the boundary condition at the insulator-electrolyte interface has the form

$$i_n = A_n\,(n^* C_O^* - N_c C_R^*) \quad [4a]$$

$$i_p = A_p\,(N_v C_O^* - p^* C_R^*) \quad [4b]$$

in which the A's are constants, the asterisks connote the transition state of the electron transfer reaction, and N_c, N_v are the densities of states in the conduction band and the valence band. The forward and backward currents are equal to the exchange current at the equilibrium potential, whence

$$i_o^n = A_n n_o^*\, C_O^* = A_n N_c C_R^* \quad [5a]$$

$$i_o^p = A_p N_v C_O^* = A_p p_O^*\, C_R^* \quad [5b]$$

The carrier concentrations at the equilibrium potential are distinguished with a zero subscript. Only the concentration of the carriers in the solid phase varies with the current because of our assumption that all the potential drops in the insulator. Hence

$$i_n = i_o^n\left(\frac{n^*}{n_o^*} - 1\right) \quad [6a]$$

$$i_p = i_o^p\left(1 - \frac{p^*}{p_o^*}\right) \quad [6b]$$

$$n = n_o^*\left(1 + \frac{i_n}{i_o^n}\right) \quad [7a]$$

$$p = p_o^*\left(1 - \frac{i_p}{i_o^p}\right) \quad [7b]$$

We thus come to the important conclusion that the partial electron and hole currents are limited on the anodic and cathodic sides respectively to the values of the exchange currents. The total current shows this limitation in the one carrier problem.

Transport Problem for Insulators

A one-carrier current passing through an insulator is necessarily associated with a space charge because each injected carrier contributes one excess charge to the insulator, negative in the case of electrons, positive in the case of holes. The physical situation is closely analogous to the familiar case of the formation of a space charge in a vacuum tube.

For the formulation of the transport problem for electrons in the conduction band of an insulator we consider a crystal of thickness d through which a current is passing. We assume an electrolyte to make an ohmic contact for electrons at $x = d$ while, for $x = 0$ we assume we have a metallic contact which is non-ohmic for holes. Let $E(x)$ be the electric field at a distance x from the metal contact, $n(x)$ the number of electrons per unit volume, and μ their mobility. $\psi(x)$ is the electrostatic potential in the insulator, ϵ the dielectric constant, and ϵ_o is the permittivity of free space.

The exact theory is based on three equations: a current flow equation, Poisson's equation, and an equation relating the electrostatic field vector to the gradient of the scalar potential

$$i = e_o\, n(x)\, \mu\, E(x) \quad [8]$$

$$\frac{dE(x)}{dx} = \frac{-4\pi}{\epsilon\epsilon_o} e_o\, n(x) \quad [9]$$

$$E(x) = -\frac{d\psi}{dx} \quad [10]$$

As boundary condition we have Eq. [7a] which in the one carrier case reduces to

$$n^* = n_o^*\left(1 - \frac{i}{i_o}\right) \quad [11]$$

and a relation between the potentials corresponding to the bottom of the conduction band at the metal ($x = 0$) and electrolyte ($x = d$) interfaces

$$\psi_d - \psi_o = -V_D - \eta \quad [12]$$

V_D is the degree of bending of the bands under equilibrium conditions, and η is the applied overpotential (zero at equilibrium) defined negative for cathodic polarization. Substituting for E in Poisson's equation in terms of n, and integrating from $x = d$ to $x = 0$, we find

$$\frac{1}{n^2} = \frac{1}{(n^*)^2} - \frac{8\pi e_o^2 \mu}{\epsilon\epsilon_o i}(d - x) \quad [13]$$

Combination of Eq. [8], [10], and [13] and subsequent integration from $x = d$ to x yields the current voltage relation at $x = d$

$$\frac{12\pi e_o^3 \mu^2 (n^*)^3}{\epsilon\epsilon_o i^2}(V_D + \eta) = \left[1 - \frac{8\pi e_o^2 \mu\, d\,(n^*)^2}{\epsilon\epsilon_o i}\right]^{3/2} - 1 \quad [14]$$

If n^* is large enough so that

$$i << \frac{2\mu k\, T n^*\, d}{(L_D^*)^2} \quad [15]$$

where L_D^* is the Debye length in the insulator surface, Eq. [14] reduces to Child's law for solids

$$-i = \frac{9}{32\pi}\epsilon\epsilon_o \mu \frac{(V_D + \eta)^2}{d^3} \quad [16]$$

Since $n^* \to 0$ for $-i \to i_o$, this relationship can only be observed for currents $i < i_o$.

In this derivation of Child's law with the proper boundary conditions we have neglected any diffusion current, any carrier density present in thermal equilibrium, and any traps. Lampert (11) has shown, that the first approximation is not very serious. The second approximation means only that any linear current-

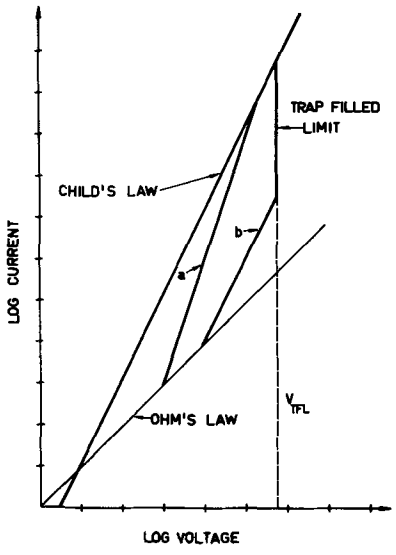

Fig. 2. Schematic current-voltage characteristic for one carrier space charge limited current: (a) quasi continuum of trapping states with exponential energy distribution; (b) single set of trapping states lying in energy above the Fermi level.

voltage relationship at very low voltages is not covered by this treatment. The third approximation is very serious, however, because a perfect solid has never been found. In a real crystal, charges residing in traps set up a space charge which impedes injection into the crystal in the steady state. In many cases, however, the traps are filled at a threshold voltage called the trap-filled limit (2, 11), V_{TFL}, at which the current rises steeply. Thereafter the current is limited by the mobile space charge in transit within the solid and the current-voltage curve obeys Child's law. Rose (2) and Lampert (11) have dealt in detail with the voltage dependence of the space charge limited (S.C.L.) currents for various trap distributions and trap levels. Some of their results are summarized in Fig. 2.

Band model.—Anthracene is the best investigated organic insulator and is therefore well suited as a model substance. A schematic structural representation of the anthracene molecule is given in Fig. 3 (15) together with the averaged values for the bond lengths. The anthracene crystal is monoclinic with two

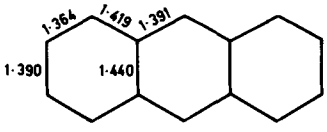

Fig. 3. Schematic structural representation of an anthracene molecule with averaged values for bond lengths (in Angstrom units).

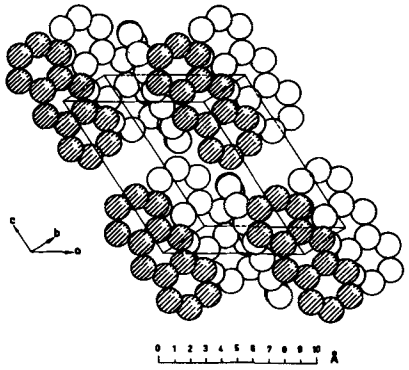

Fig. 4. Unit cell structure for anthracene

molecules per unit cell. The unit cell structure is shown in Fig. 4 (15). If $\vec{a}$, $\vec{b}$, $\vec{c}$ are the unit cell vectors, then $\alpha = \frac{1}{2}(\vec{a} + \vec{b})$, $\beta = \frac{1}{2}(-\vec{a} + \vec{b})$ and $\vec{c}$ connect the geometrical centers of nearest neighbor molecules.

The drift mobility of injected carriers has been shown to decrease with increase in temperature (12, 13) so that the band approximation can be used to describe the behavior of injected electrons and holes. This was confirmed by theoretical calculations which showed that the structure of the bands appropriate to an excess electron or hole can be calculated with the tight binding approximation (14). Le Blanc has called the band which contains the excess electrons the "electron band" and the one which contains the excess holes the "hole band" rather than using the conventional expressions "conduction band" and "valence band" (14). This was done in order to emphasize the fact that one is dealing with the electronic states of two distinct systems rather than two states of the same system.

Experimental Details

Single crystals of anthracene were grown by three conventional methods: a modified Bridgeman technique, vacuum sublimation, and growth from solution. Semiconductor grade purity is required for our measurements. We started off with material of the best available commercial purity (Fluka "For Scintillation") which showed the characteristic blue fluorescence of anthracene. Most of the tetracene, a very efficient fluorescence quencher and a common impurity for anthracene, was thus already removed. This material was further purified by zone-refining it up to 80 times, depending on the quality of the starting material.

The solution grown crystals have the highest degree of structural perfection and show the greatest mechanical strength. They are relatively thin (20-200μ) so that the high field strengths which are often desired can be obtained more conveniently. Inadvertently, however, impurities were introduced into these crystals from solution so that the trap density was always considerably higher for these crystals than for other types. The electrochemical phase boundary reaction was, however, unaffected by these impurities.

The melt-grown crystals were unmatched in purity but they showed frequently poor mechanical strength. In rapidly cooled crystals up to 500 dislocations per cm^2 were counted, usually accompanied by cracks (31). By careful annealing, it was possible to reduce this number to 10 and less. The crystals cleave readily parallel to the $\vec{a},\vec{b}$-plane (Fig. 4) which is also the prominent plane of the melt- or sublimation-grown crystals (16). Structural perfection and chemical purity of sublimation-grown crystals take up an intermediate position between the melt-grown and the solution-grown types.

Samples varying in thickness from 0.05 to 5 mm were prepared from melt-grown crystals by cutting with a chemical saw followed by cleavage. The crystals were cemented with an epoxy resin between two electrolytic half-cells made of glass. The cells were mounted on aluminum carriages, which moved on tracks made of the same material and which could be fixed to incorporate the crystals (Fig. 5). The electrolyte was stored in vessels V_1 and V_2 so that repeated washing of the crystals with the solutions was possible. The electric field was applied by means of two platinum electrodes K_1 and K_2 with a Keithley power supply type 240 or 242. The current was measured with a Keithley electrometer type 610B. Light intensities were determined with a calibrated photomultiplier Philips 150 UVP. During the measurement the cell was kept in a Faraday cage; only shielded cable was used.

Redox Reactions

Anthracene has a width of the forbidden gap of about 4 ev (17) and is thus a perfect insulator. The hole band is completely filled, and the electron band is completely empty. Charge transfer across the anthracene-electrolyte interface is possible only with such redox systems which lead to either

Mn^{4+}/Mn^{3+}	10^{-2} mol/l
Ce^{4+}/Ce^{3+}	10^{-2} mol/l

injection of holes into the hole-band or electrons into the electron band.

Mn^{4+}/Mn^{3+}	10^{-2} mol/l
Ce^{4+}/Ce^{3+}	10^{-2} mol/l

Figure 6 shows a current voltage curve which was obtained when both electrode compartments (Fig. 5) were filled with 0.2M NaCl-solution. The current is independent of the polarity of the applied voltage. Surface currents and currents through the cement probably contribute appreciably to our measured value which we shall be using as reference scale only. Also plotted in Fig. 6 are current values which were obtained when the half-cell with the positive electrode was filled with a solution of 0.1M $Ce(SO_4)_2$ in 15N H_2SO_4 while the other half-cell was filled with the NaCl-solution. On voltage reversal the zero current was measured. As 15N H_2SO_4 alone also injects holes to a certain degree, this effect has also been plotted.

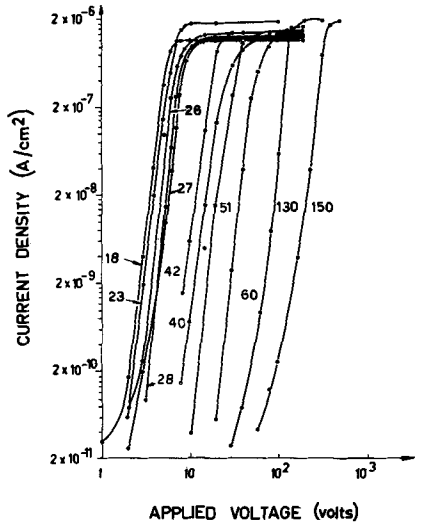

Fig. 7. Cathodic current-voltage curves at various thicknesses (in microns) of the anthracene crystals Electrolyte: 10^{-2}M $Ce(SO_4)_2$ in 0.5M H_2SO_4.

Table I. Hole exchange currents for various redox systems

System		Electrolyte	Standard redox potential (NHE)	i_o^p, amp/cm²
I_3^-/I^-	0.1M	1M KI	+0.54	5×10^{-8}
$IrCl_6^{2-}/IrCl_6^{3-}$	0.1M	0.5M HCl	+0.96	5×10^{-6}
$Cr_2O_7^{2-}/Cr^{3+}$	0.1M	2M H_2SO_4	+1.10	5×10^{-7}
Mn^{3+}/Mn^{2+}	0.1M	7.5M H_2SO_4	+1.5	1×10^{-4}
MnO_4^-/Mn^{2+}	0.1M	0.5M H_2SO_4	+1.5	5×10^{-5}
Ce^{4+}/Ce^{3+}	0.1M	2M H_2SO_4	+1.44	2×10^{-5}
		2.5M H_2SO_4	+1.40	1×10^{-4}
Fe^{3+}/Fe^{2+}		0.5M H_2SO_4	+0.77	10^{-11}
$Fe(CN_6)^{3-}/Fe(CN_6)^{4-}$		1M H_2SO_4	+0.69	10^{-11}

Figure 7 provides a proof that the limiting currents are indeed caused by a phase boundary reaction. It is shown that the limiting current does not depend on the thickness of the sample while the rest of the curve does, as predicted by S.C.L. current theory.

In Table I exchange currents for various redox systems are listed showing at least qualitatively the predicted dependence of these currents on the redox potential. (The table also shows that the system I_3^-/I^- is obviously not covered by our model.)

Both for the systems Mn^{4+}/Mn^{3+} in 15N H_2SO_4 and Ce^{4+}/Ce^{3+} in 15N H_2SO_4 the exchange current at an anthracene electrode is roughly equal to that for the same system at a metal electrode assuming equal concentration of the reduced and the oxidized component.

Vetter (18, 19) found the following values at a platinum electrode

15N H_2SO_4	$i_o = 1.3 \times 10^{-5}$ amp/cm²
1N H_2SO_4	$i_o = 2.3 \times 10^{-4}$ amp/cm²

The values for the exchange currents at the anthracene electrode are

15N H_2SO_4	$i_o = 2 \times 10^{-5}$ amp/cm²
15N H_2SO_4	$i_o = 8 \times 10^{-5}$ amp/cm²

here only the concentration of the oxidized component is of interest.

Considering the high inaccuracy which is inherently connected with the measurement of exchange currents, the excellent agreement of the values for the exchange currents measured on anthracene with those measured on platinum has to be considered somewhat fortuitous Nevertheless, these results have to be considered as an experimental proof of our prediction that redox reactions can be "reversible" at insulator electrodes.

The similarity in the magnitude for the exchange current of the redox systems Ce^{4+}/Ce^{3+} (E_S = 1.4v) and Mn^{4+}/Mn^{3+} (E_S = 1.5v) measured at platinum and at anthracene electrodes proves according to Eq. [3b] that $e_o(E_s - E_{FB}) \cong \Delta^p$. The injection of electrons into the electron band is possible with the system Li^+/e^- ($E_s = -3.0$v). This reaction will be discussed in more detail in the following paragraph. The rate of this reaction is so high that we were not able to determine it. It seems thus very likely that also for this system $e_o(E_s - E_{FB}) \cong \Delta^n$. We have thus as a rough estimate of the distance between hole and electron-band $\Delta\epsilon$ = 4.5v. This value agrees very well with a recently quoted value (17) $\Delta\epsilon$ = 4.4v which was determined from photoconductivity data.

Corrosion.—The hole injecting contacts are highly oxidizing, and thus an oxidative attack of the anthracene crystal is inevitably connected with the hole injection process. Very little is known about this process.

The reaction of anthracene with a solution of $Ce(SO_4)_2$ in sulfuric acid, however, was used commercially at the turn of this century for the manufacture of anthraquinone (20). Measurements of the infrared absorption spectrum of partially oxidized crystals did indeed show that anthraquinone was formed on the electrode surface; nothing is known about intermediates and about the reaction mechanism.

It was found that the rate of dissolution of the oxide film increased with increasing concentration of sulfuric acid in the supporting electrolyte. Because of this effect we tried to make most measurements in 15*N* sulfuric acid.

Reactions of Anthracene Ions on Anthracene Electrodes

Helfrich and Schneider (21) have shown that electrons can be transferred to an anthracene crystal from negative anthracene ions dissolved in tetrahydrofuran (THF). They prepared the ions by reduction of anthracene, dissolved in THF, with sodium. Injection of electrons can also be achieved from the blue solution of lithium in ethylenediamine (22) but in this case, the anthracene crystal itself is attacked by the reducing agent and the situation is more complicated. Figure 8 shows a current potential-plot determined with this system. No limiting current was found indicating that all electrochemical processes are fast and that the shape of the curve is completely determined by concentration polarization of electrons in the bulk of anthracene. A trap-filled limit can be recognized as can be transition into the $i = kV^2$ relationship of Child's law.

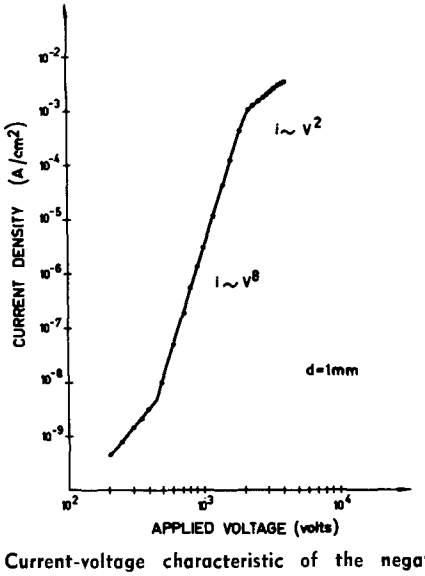

Fig. 8. Current-voltage characteristic of the negative space charge limited current.

The injection of holes by oleum (23) or a solution of anthracene and $AlCl_3$ in nitromethane (21) is similar to the lithium/ethylenediamine case; the strong electron acceptors attack the anthracene crystal directly, and these systems are thus not very suitable for an investigation of the electron exchange reaction. Hole injection by anthracene cations in solution can be studied if these are generated electrolytically. Stable anthracene cations can be produced electrolytically from a solution of anthracene in trifluoroacetic acid in the presence of boron trifluoride (24).

The reaction rate constant k for homogeneous electron transfer processes of the kind $X + X^- \rightarrow X^- + X$, where X is an aromatic hydrocarbon molecule and X^- is the paramagnetic radical ion can be determined from the broadening of hyperfine lines in the EPR spectrum of X^- as a function of the concentration of X (25). For aromatic hydrocarbons the value for k is about 10^7 to 10^9 liter mole^{-1} sec^{-1} (25, 26). For the anthracene system [anthracene] + [anthracene]$^-$ → [anthracene]$^-$ + [anthracene] the value k = 4.8 $\pm 1.10^8$ liter mole^{-1} sec^{-1} was recently found for a solution in dimethylformamide (26).

According to Marcus (27) a relationship of the form $(10^{-11}\ k_h)^{1/2} = 10^{-4}\ k_{el}$ should exist between the chemical (k_h) and electrochemical (k_{el}) rate constants for redox systems, provided the extent of overlap between molecular orbital and electrode orbital is about the same as between two molecular orbitals. In our case the approximation should certainly be a good one as the hydrocarbon forms the electrode. Unfortunately, it is not quite clear, however, if these reactions are covered by Marcus' theory (29). Nevertheless, thus far the rate constants for electron transfer at metal electrodes involving ions of aromatic hydrocarbons have turned out to be too large for determination by electrochemical means (30), and the rate constants at anthracene electrodes should also be very large.

We have tried to get some information on these rate constants by measurements with a rotating disk electrode made from anthracene. A rotating disk electrode was made by mounting solution grown crystals with paraffin on the hollow shaft of a trubore stirrer. The arrangement permitted measurements from 20 to 1000 rpm. Electrical contact to the anthracene was made with a droplet of mercury (23). In case of a diffusion limited current i the following relationship between i and ω, the speed of rotation should be obtained (31)

$$\frac{i}{\omega^{1/2}} = \frac{\xi F C_O D^{2/3}}{1.6\bar{\nu}^{-1/6}} \qquad [17]$$

where C_O is the concentration of active species in the

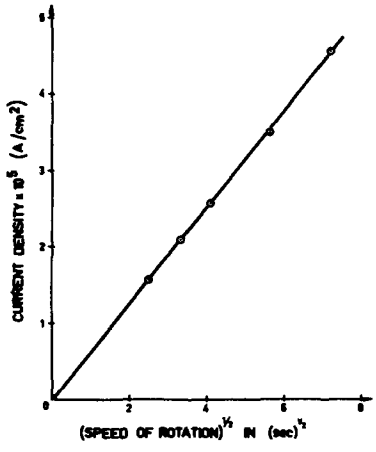

Fig. 9. Dependence of the current density at a rotating anthracene disk electrode on the speed of rotation for anthracene cations.

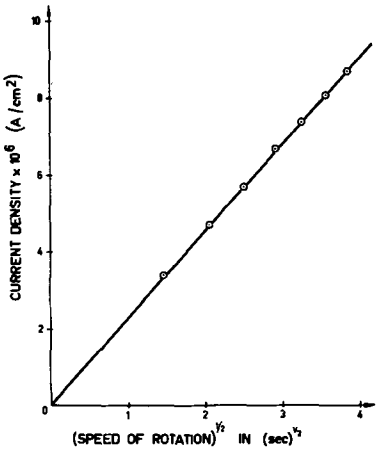

Fig. 10. Dependence of the current density at a rotating anthracene disk electrode on the speed of rotation for anthracene anions.

bulk of the solution, D is the diffusion coefficient, and $\bar{\nu}$ the kinematic viscosity of the solution used.

Equation [17] was verified both with solutions of positive anthracene ions in a mixture of trifluoroacetic acid and boron trifluoride-water (Fig. 9) and with solutions of negative anthracene ions in dimethylformamide (Fig. 10). In each case, the ions were generated electrolytically. From these measurements, the following diffusion coefficients were determined:

$$D\,(\text{anthracene}^+) = 2 \times 10^{-6}\,\text{cm}^2\,\text{sec}^{-1}$$

$$D\,(\text{anthracene}^-) = 8 \times 10^{-6}\,\text{cm}^2\,\text{sec}^{-1}$$

The rate constants for the exchange reactions were in both cases too high to be determined. As a lower limit of the exchange current for the exchange reaction between the anthracene electrode and positive ions $i = 2 \times 10^{-1}$ amp/cm² was determined, and for that between the electrode and negative ions 4×10^{-1} amp/cm². These values were obtained by extrapolating from our experimental data (24) to 1M solutions of ions.

Double Injection

In the cell depicted in Fig. 5 one vessel was filled with a solution of anthracene and $AlCl_3$ in nitromethane as hole injecting agent and the other vessel

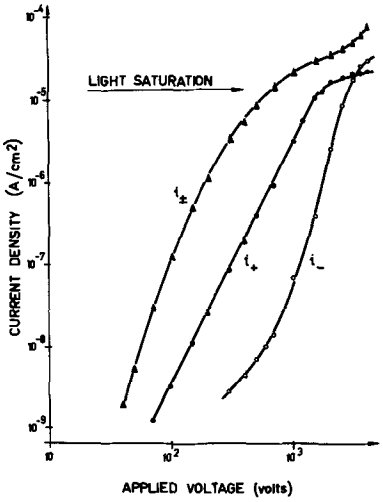

Fig. 11. Current-voltage characteristic of the space charge compensated current $i_\pm$ and the positive i_+ and negative i_- space charge limited current. with a solution of lithium in ethylenediamine as electron injecting agent. With a properly oriented electric field (positive electrode in the oxidizing agent, negative electrode in the reducing agent) simultaneous injection of electrons and holes is then possible. As predicted by theory (11), it is observed that in this case the current is several orders of magnitude larger than the space charge limited current at the same applied voltage (Fig. 11). Also recombination of holes and electrons leads to the excitation of the fluorescence spectrum of anthracene. With a photomultiplier the intensity of the light emission was measured as a function of the current density and linearity was found over four orders of magnitude (21, 32, 33). The result is interpreted as being due to the formation by recombination of holes and electrons of the first excited singlet state of anthracene, which is responsible for the emission of the fluorescence spectrum. When the current reached the limiting value for the hole injection reaction, the light intensity saturated and decreased with further increase of voltage and current (Fig. 12).

This observation fits very well into our model of the injecting processes: as long as the contacts are ohmic, all the current near them is carried by either electrons or holes through diffusion. As soon as the hole-limiting region is reached, the current at the hole contact is obviously carried partially at least by electrons. The oxidation products at the electrode surface can now provide centers for radiationless recombination resulting in a decrease in the intensity of light emission. Figure 13 shows a cross-section through a luminescing anthracene crystal. The light intensity is highest near the positive contact which is proved by changing the contacts.

Acknowledgments

Many thanks are due to Mr. G. Duccini for his patient efforts to increase the quality of our anthracene crystals and to Miss E. Pobitschka for valuable contributions to the experiments.

LIST OF SYMBOLS

A_n, A_p	Constants in the boundary condition for the concentration polarization of charge carriers in the solid
C_O	Concentration of oxidized ions in solution
C_R	Concentration of reduced ions in solution
D	Diffusion coefficient of ions in solution
d	Thickness of the insulator
E	Electric field
E_{FB}	Flat band electrode potential
E_R	Equilibrium potential
E_s	Standard potential
e_o	Electronic charge
F	Faraday constant
i	Current
i_o	Exchange current

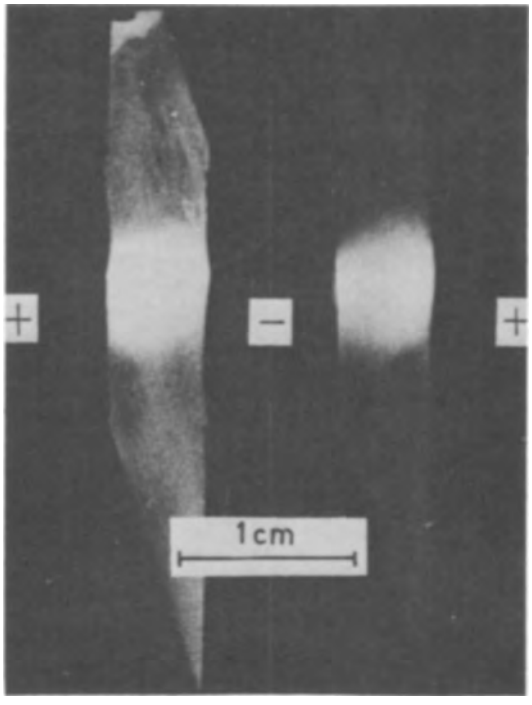

Fig. 13. Photograph of cross section through luminescing anthracene crystal. The second photograph was taken after exchange of the contacts. Positive injecting contact, oleum; negative injecting contact, solution of lithium metal in ethylenediamine; contact area, 0.2 cm^2; current, 2 x 10^{-6} amp/cm^2.

i_o^n	Electron exchange current with the conduction band
i_o^p	Hole exchange current with the valence band
k	Boltzmann constant
L_D	Debye length
n	Electron density
p	Hole density
T	Absolute temperature
V_D	Degree of banding of bands under equilibrium conditions
x	Distance variable
Δ^n	Interval of energy between Fermi-level and the conduction band in the bulk of the insulator
Δ^p	Interval of energy between Fermi-level and the valence band in the bulk of the insulator
ϵ	Dielectric constant
ϵ_0	Permittivity of free space
$\Delta\epsilon_s^n$	Forbidden gap between Fermi-level and conduction band in the surface of the insulator
$\Delta\epsilon_s^p$	Forbidden gap between Fermi-level and valence band in the surface of the insulator
$\Delta\epsilon$	Forbidden gap between valence and conduction band
ζ	Number of electrons involved in the electron transfer reaction
η	Overpotential
λ	Energy parameter
μ	Mobility of carrier
ν	Velocity of movement along the reaction coordinate
$\bar{\nu}$	Kinematic viscosity
ω	Speed of rotation
*	Connotes the transition state of the electron transfer reaction

Discussion

H. Gerischer: One interesting question I feel arises from your observations that strong acidic solutions such as H_2SO_4 at higher concentrations can inject holes. What is the redox reaction in this case? I suppose it could be the reduction of oxygen if this oxidant is present in high enough concentrations. This reduction may then be catalyzed by the acid. That the H_2SO_4 is reduced itself seems to be very unlikely for these concentrations if it was pure. As another possibility, one could ask whether protons could be associated with the aromatic molecules on the surface by some kind of π-bonding. If this would be the mechanism of hole injection by protons directly, the anthracene molecules will be hydrogenated by this injection. Is there any indication available what mechanism may occur?

W. Mehl: An investigation of the role played by sulfuric acid in the hole injection reaction is in progress in our laboratory and the suggestions by Professor Gerischer are most helpful. No conclusive evidence for a particular mechanism has thus far been obtained.

R. E. Visco: We have been studying a system similar to that described by Dr. Mehl.[1,2] In nonaqueous aprotic solvents it is possible to generate electrochemically the radical cation, $R^{+\cdot}$, and the radical anion, $R^{-\cdot}$, of aromatic hydrocarbons. We have generated these radicals for rubrene and 9-10 diphenylanthracene in acetonitrile and recently in benzonitrile. Using the treatment of Feldberg[3] it has been possible to estimate a lower limit for the chemical rate constant for the homogeneous cation-anion annihilation reaction to give an electronically excited state of the hydrocarbon. We estimate a rate constant of 5×10^6 liters mole $^{-1}$ sec^{-1} as the lower limit. Despite the observation of singlet fluorescence, the excited state formed as a consequence of the ion-ion annihilation reaction may be either the first excited singlet or the lowest lying triplet. Our data at present do not allow an unambiguous determination since two triplets can undergo a subsequent annihilation to give an excited singlet.

J. L. Weininger: The outstanding features of this very interesting work, as well as the questions arising from it, are related to exchange currents of various redox couples at the anthracene electrode, the charge transport within the anthracene crystals, and the space charge distribution at the interface.

The measurements of the exchange currents demonstrate very clearly the importance of matching up energy states at the electrode surface with those of the redox couple at the solution-side of the interface, *i.e.*, that these must be in close proximity on an energy scale to give large exchange currents at equilibrium. In measuring the exchange current, how is the chemical interaction with anthracene prevented? A strongly oxidizing couple, or the large potential differences used, should result in oxidation of the anthracene to anthraquinone. Alternately, there may be present some adsorbed material or products of photooxidation, which should strongly affect the electrode kinetics on the semiconducting or insulating electrode. Similarly, reduction to the negative anthracene ion should change the condition of the surface. As an example, in work on semiconducting single crystal NiO electrodes[4] we have found that the mere evolution of hydrogen suffices to alter irreversibly the nature of the semiconducting electrode, possibly by changing the doping of the surface layer.

The experimental data on the Ce (IV)/Ce(III) and Mn(IV)/Mn(III) exchange show that the exchange currents, $i_{o,p}$ and $i_{o,M}$, respectively, for the hole conduction at an insulator electrode and at a Pt electrode, are of the same magnitude. One of the authors has shown[5], with the same assumptions as those used in deriving Eq. [3] that

$$i_{o,p}/i_{o,M} = \exp - [(E_F - E_V)/2kT]$$

If $i_{o,M} \sim 2.7\, i_{o,p}$, then $-(E_F - E_V) \sim 2kT$ which is about the limit of applicability of Boltzmann statistics. Have the authors considered the consequences of the band-gap picture becoming degenerate, *i.e.*, $-(E_F - E_V) < 2kT$, both on the redox reaction at the interface and on the charge transport within the electrode?

What conclusions can one reach regarding the charge transport within the insulator (with dark conduction of 10^{-19} ohm^{-1}cm^{-1}), into which a substantial number of charge carriers, corresponding to a conductivity of 10^{-8} ohm^{-1} cm^{-1} are injected? Neither hole-hopping nor transport in bands can be singled out as the appropriate mechanism of conduction. One difficulty is the identification and influence of traps known to be present. What are these traps? Do they only limit conduction by capturing charge carriers, or do they also facilitate charge transport by providing suitable donor and acceptor levels? Further electrochemical work on anthracene electrodes with deliberate doping or special structural defects would be of particular interest. In this connection the work of Hoesterey and Letson[6] is a first quantitative study of the effect of controlled impurities on the conductivity of anthracene. As for structural defects, what would be the results of electrochemical measurements on the anthracene crystals with their original large number of dislocations as contrasted to the annealed crystal electrodes which were used here?

The linear relation between the cathodic exchange current and the concentration of ceric ion is in accord with the potential drop being almost entirely on the insulator side of the interface. For the same system Pope and co-workers[7] have reported a dependence on the 0.6 power, *i.e.*, $i_o \propto c_{Ce(IV)}^{0.6}$. This latter discrepancy may be due to surface states. It is mentioned here to indicate the pitfalls and experimental difficulties besetting studies of semiconductor electrodes. The authors are to be commended for tackling the insulator electrode in a semiquantitative manner and for their experiments resulting in luminescent recombination of electrons and holes as well as the exchange current measurements.

W. Mehl: Dr. Weininger raises a number of very basic questions which deserve a much more thorough discussion than can be given here. Some of the points

Fig. WM1. Anthracene after exposure to 0.01M $Ce(SO_4)_2$ + 0.5M H_2SO_4 for 12 hr at cathodic limiting current.

mentioned are dealt with in some detail in a forthcoming publication.[8] Briefly it can be said at this point that in order to achieve hole injection in anthracene crystals fairly strong oxidation agents have to be used, and the formation of an anthraquinone film at the electrode surface is indeed a major problem. In accordance with our model the formation of such a film can, however, be prevented if one works in the limiting current region. Apparently in this case anthracene radical ions which are formed on the anthracene surface transfer their charge under the influence of the electrical field to the bulk of the crystal and the surface remains unattacked. This is demonstrated in Fig. WM1 which shows a photograph of an anthracene electrode which has been exposed for 12 hr to a 0.01M solution of $Ce(SO_4)_2$ in 0.5M sulfuric acid while a cathodic limiting current was flowing. The dark part is the unoxidized anthracene surface opposite a mercury drop which served as contact at the rear of the crystal. The light area is a thick oxide film. If a current smaller than the limiting current is drawn through the crystal, an oxide film forms resulting in a reduction of the limiting current. Special precaution has therefore to be taken in order to be able to make, *e.g.*, meaningful measurements of the concentration dependence of the exchange current.

It has also been found that surface oxides completely inhibit the injection of electrons from reducing agents, and only after these oxides have been removed can appreciable electron currents be measured.

The question of trap distribution etc. has been dealt with extensively by Helfrich and Mark.[9]

Electrochemical Behavior of Semiconductors under Illumination

H. Gerischer

Institute of Physical Chemistry, Technical University, Munich, Germany

ABSTRACT

In contrast to metals, the average free energy of electrons can be changed in semiconductors to a great extent by illumination. Especially the concentration of minority electronic carriers can differ by orders of magnitude from the equilibrium value. This has two major effects on electrode processes: (*a*) change of charge distribution and potential drops in the space charge layer; and (*b*) variation of the rate of electrode reaction in which minority carriers are involved. Some examples are given for those effects at various semiconductors.

A great number of photogalvanic or photovoltaic effects are known, often summarized under the name "Bequerel effects." Many of these phenomena are the consequence of photochemical reactions in the electrolyte; others are connected with irreproducible changes in the electrode composition. We shall limit our considerations here to such cases where the "photoelectrochemical" effect is caused by absorption of light in a semiconducting electrode, and the composition of the electrode is not changed.

The absorption of light by an electrode means that electrons are excited and that the statistical equilibrium of energy distribution among solid-state electrons is disturbed. At the energy level and local position where the electron has absorbed the light quantum a hole is left and the excited electron is transferred to energy states above the normally occupied levels. Due to the strong interaction between the electrons in the metal themselves and between the electrons and the atomic constituents of the lattice, the excess energy is distributed rapidly over the solid and is converted into lattice vibrations, *i.e.*, heat. As one of the consequences of this rapid energy exchange, electron emission from a solid surface by excitation with light has a very small efficiency. In accordance with this, the currents attributed to electron emission from electrode surfaces, as investigated by a few authors (1, 2) in the past years at the dropping mercury electrode, are relatively small. This subject is discussed in the following paper by Barker, Gardner, and Sammon.

Inside a metallic conductor the mean free energy of the electrons cannot be changed noticeably, even under strong illumination, because too many electrons with energies near the Fermi level are present and equalize the average value. The situation is quite different for a semiconductor. Although there is similar interaction between the electrons and lattice atoms as in a metal and although the exited electrons and holes rapidly lose some of their excess energy, there is a barrier for the final restitution of statistical equilibrium given by the slow transition from band to band, *i.e.*, the slow recombination of electrons and holes. By slow, we understand this rate relative to that one of energy exchange between electronic and vibrational quantum states in the same energy band of electrons.

As a consequence of this retarded redistribution of excess energy in a semiconductor, electrons and holes are accumulated under illumination in equal amounts on energy levels near the band edges until a steady state has been reached where the recombination compensates the generation of electron hole pairs by light.

This process of electronic excitation is illustrated in Fig. 1 for a metal and for a semiconductor.

How much the effective free energy of electrons and holes is altered in the steady-state depends on the recombination rate and on the number of electrons and holes present under equilibrium conditions. If we assume that the energy distribution of each of the electronic carriers corresponds to equilibrium distribution in their separate energy bands also under illumination, then the change in free energy relative to equilibrium can be expressed by the following equations

$$\Delta\mu_{e^-} = RT \ln\left(1 + \frac{\Delta n^*}{n_0}\right) \qquad [1]$$

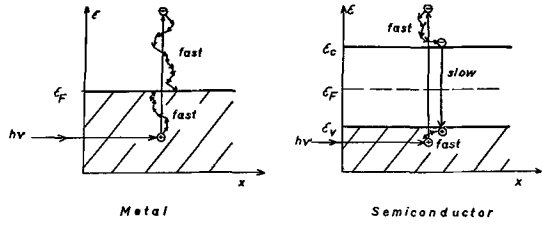

Fig. 1. Light absorption and energy redistribution in a metal and a semiconductor.

$$\Delta\mu_p = RT \ln\left(1 + \frac{\Delta p^*}{p_o}\right) \quad [2]$$

In the absence of specific traps for the electrons or holes, the excess concentrations Δn^* and Δp^* must be equal to fulfill the condition of electroneutrality in the interior of the semiconductor. n_o and p_o are the equilibrium concentrations related to the band gap energy ΔE_g by

$$n_o \cdot p_o = n_i^2 = N_c \cdot N_v \cdot \exp\left(-\frac{\Delta E_g}{RT}\right) \quad [3]$$

Equations [1] and [2] show that the change in free energy under illumination is much greater for minority carriers than for majority carriers. When the equilibrium concentration of minority carriers is very small, an enormous change in free energy can be caused for those species by illumination. We must therefore expect that all important chemical and electrochemical effects will be due to this large deviation from equilibrium for the minority carriers, while the respective change in activity of majority carriers will have minor or negligible importance.

We can calculate the concentration change of electronic carriers in the semiconductor under illumination by standard procedures (3). To do this for the simplest case, we will assume that the illuminated specimen is n- or p-type and that the increase of minority carrier concentration remains small compared with the equilibrium concentration of majority carriers. We then have the situation as designed in Fig. 2 for a n-type material.

From the diffusion theory, the steady-state equation for the region where light absorption is negligible is given by

$$D_n \cdot \frac{\partial^2 \Delta p^*}{\partial x^2}$$

$$= r(p_o \cdot \Delta n^* + n_o \Delta p^* + \Delta n^* \cdot \Delta p^*) \approx r \cdot n_o \cdot \Delta p^* \quad [4]$$

where $n_o >> p_o$, $\Delta p^* << n_o$, and r is the rate constant for recombination.

Since $\Delta p^* \to 0$ for $x \to \infty$, the solution is

$$\Delta p^* = \Delta p_o \cdot \exp\left(-\frac{x}{L_p}\right) \quad [5]$$

where Δp_o^* is the concentration change in the surface region where the light is absorbed, and L_p is the mean free path for diffusion of holes.

$$L_p = \sqrt{\frac{D_p}{r \cdot n_o}} = \sqrt{D_p \cdot T_p} \quad [6]$$

and $(1/r \cdot n_o) = T_p$ = mean life time of holes.

The surface concentration change Δp_o^* is obtained by introducing the production of carriers in the surface area as a boundary condition for the flux of carriers into the interior. This assumption is justified as long as the depth of the region of light absorption is small compared with L_p.

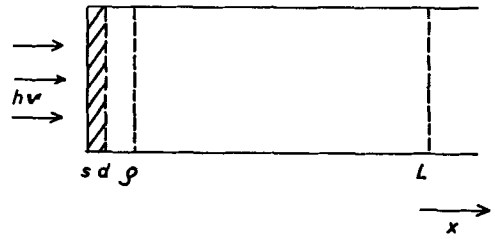

Fig. 2. Model assumed for discussion of photoresponse by illumination of the surface: s, surface; s-d, main light absorption region; s-ρ, space charge layer; s-L, mean free path of minorities.

$$-D_p \cdot \left(\frac{\partial \Delta p}{\partial x}\right)_{x=0} = I_L - I_{SR} \quad [7]$$

where I_L is the absorbed light intensity in quantum units and I_{SR} the surface recombination rate.

The result is

$$\Delta p_o^* = \frac{I_L - I_{SR}}{D_p/L_p} = \sqrt{\frac{T_p}{D_p}} \cdot (I_L - I_{SR}) \quad [8]$$

Introducing $D_p/L_p \cdot p_o = I_{p,o}$, the saturation current for transfer of holes from the interior to the surface, we get

$$\frac{\Delta p_o}{p_o} = \frac{I_L - I_{SR}}{I_{p,o}} \quad [9]$$

The concentration of electrons is altered by the same amount, but, according to our assumption, Δn^* remains small compared to n_o. Therefore an equal flux of electrons, as given in Eq. [7] for holes, flows from the light absorption area in the interior. Also, when the majority carriers have a different mobility, their migration rate is controlled by the diffusion coefficient of the minority carriers as long as $D_n \cdot n >> D_p \cdot p$. The Dember potential difference (the equivalent of diffusion potentials in electrolytes) which gives the force for equalizing the two migration rates remains insignificant under this condition (3).

Up to now we have not included in our considerations the space charge in a semiconductor surface region which is of great importance for electrochemical experiments. The carrier distribution in this space charge zone determines the potential difference between the surface and the interior. This is the most important part of the electrical double layer in the semiconductor electrode (4-10). Any change in this potential difference causes an equivalent change in the electrode potential. Simultaneously, the space charge layer structure controls the drift of electrons and holes through the surface region. This seriously complicates the discussion of photoeffects in a semiconductor because we have to deal now with a double layer which is not in the equilibrium state but only under steady-state conditions.

We shall see that the main effects of illumination on electrochemical processes at semiconductors are due to the two following principle deviations from equilibrium condition in the steady-state situation: (*i*) deviation from equilibrium for minority carrier concentration in the region under the surface outside the space charge layer, as given in Eq. [4]-[9]; and (*ii*) deviation from equilibrium for charge distribution in the space charge layer to distribute the flow of electrons and holes to the interior and the surface as necessary.

Before we come to the details, I would like to recall in this connection the late J. F. Dewald, who was one of the most brilliant scientists who has dealt with semiconductor electrochemistry. In one of his fundamental papers (8) he gave a stimulating outlook on the great importance of photoeffects at semiconductors for the understanding of electrochemical reactions.

Space Charge Capacitance under Illumination

The space charge distribution controls the capacitive charging currents during rapid variation of the electrode potential at a semiconductor. That has been discussed theoretically by various authors and proven experimentally for germanium electrodes (4-7, 11-13). The easiest case to discuss is an intrinsic semiconductor with carrier concentration: $n_o = p_o = n_i$. In this case the space charge capacity is

$$C_{sc} = \left(\frac{2\epsilon\epsilon_o e_o^2}{kT}\right)^{1/2} \cdot \sqrt{n_i} \cdot \cos h \frac{\Delta\psi_s}{2\phi} \quad [10]$$

$$\Delta\psi_s = \psi_s - \psi_i$$

$$\phi = \frac{kT}{e_o} = \frac{RT}{F}$$

ψ_s = electrostatic potential in the surface, ψ_i = electrostatic potential in the interior of the semiconductor, and the other symbols are standard.

Under illumination, the concentration at the interior end of the space charge layer may be changed to: $n_o^* = n_i + \Delta n^* = p_o^*$, where Δn^* depends on the illumination intensity. For an intrinsic semiconductor the recombination kinetic is of second order, and therefore we have no linear relationship between light intensity and Δn^*. Nevertheless the simple relation of Eq. [10] remains valid; one has only to replace n_i by $n_i + \Delta n^*$. The relation between space charge capacities with and without illumination at the same $\Delta\psi_s$ is therefore

$$\left(\frac{C_{sc^*}}{C_{sc}}\right)_{\Delta\psi_S} = \sqrt{1 + \frac{\Delta n^*}{n_i}} \qquad [11]$$

Easiest to compare is the value at $\Delta\psi_s = 0$, because this is the minimum in the capacity curve. Since we cannot measure absolute $\Delta\psi_s$ values, it is very helpful to have such a diagnostical reference point in the capacity *vs.* electrode potential plots. Plotting the log C_{sc} values against electrode potential, measured against an arbitrary reference electrode, a linear shift in vertical direction for the log C_{sc} values should be found when the minima are brought to the same point in the potential scale.

As an example such a plot is given in Fig. 3 for an intrinsic Ge electrode. The capacities have been measured in this case by a rapid pulse method (11). These measurements were made while going continuously through the interesting range of polarization in about 1 sec, to avoid changes of the Helmholtz layer potential drop.

With n- or p-type materials, the capacity is little changed under illumination as long as the majority carriers are enriched in the surface region by the polarization potential. On the other hand, there is a great increase in capacity in the depletion range of polarization, especially in the case of inversion. A quantitative analysis will not be given here. In principle, the changes of the capacity values under illumination can be used to gain information about the carrier distribution and the surface potential.

Photovoltage under Constant Current

The theory of surface photovoltage for a semiconductor interface in contact with nonconducting gases was developed by Brattain and Bardeen (14) for the case when the charge is kept constant in the space charge layer. Brattain and Garrett (15), and later Dewald (6), applied this theory to semiconductor electrodes. This instantaneous photovoltage always has the tendency to flatten the energy bands, *i.e.*, to diminish the potential difference at the interface caused by excess charge, due to the increase in capacity. It changes sign therefore with the sign of excess charge present at the applied polarization, and this effect can be used to indicate the flat band condition or zero point of space charge. This technique has been used, *e.g.*, by Pleskov and Tyagai (16).

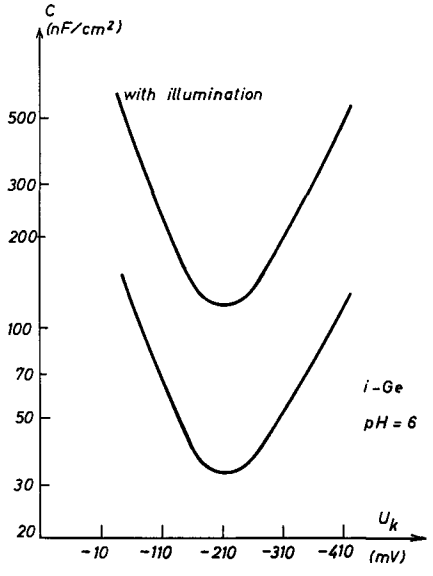

Fig. 3. Capacity data without and with illumination for i-Ge-electrodes in phosphate buffer solution at pH 6.

As Dewald pointed out, this theory is only applicable to describe the so-called instantaneous photoeffect where one assumes that the time for reaching the steady state of carrier distribution under illumination is small compared with the time of discharge of the double layer by an electrochemical reaction. This is a rather serious limitation for the quantitative analysis of photovoltage at semiconductor electrodes since in nearly all systems electrochemical reactions occur simultaneously.

Therefore we shall discuss here photovoltages under the condition of a constant current. Since the electrochemical reactions at a semiconductor electrode are normally controlled by the surface concentration of one type of carrier, this condition means that the concentration of the discharge determining electronic carrier is kept constant at the surface. Only in such cases, where more than one electrochemical reaction with charge transfer in different bands occurs simultaneously, as is the case in some corrosion processes, this boundary condition is not longer justified. The discussion of such conditions is much more complicated (17), and theoretical conclusions are difficult to verify.

Under the above assumption, the steady-state photovoltage can be derived from Eq. [2] and [8] for a surface reaction which is controlled by holes, *i.e.*, an oxidation process via the valence band. On the other hand, from Eq. [1] and the relation for Δn^*, corresponding to Eq. [8], the photovoltage for a reduction reaction via the conductance band as the rate-determining step can be calculated.

If we assume that the charge distribution in the space charge layer corresponds to equilibrium in spite of the fact that there is a flow of carriers through this layer, we can apply the equilibrium correlation for holes, to calculate the surface potential from

$$\rho_{\mu_p} = s_{\mu_p} + F\,(\psi_s - \psi_\rho) \qquad [12]$$

The index ρ means the value at the termination of the space charge layer in the interior and index s the surface values. From Eq. [2] we obtain the photovoltage $\Delta\psi_R^*$

$$\Delta\psi_{R^*} \equiv \psi_s^* - \psi_s - (\psi_\rho^* - \psi_\rho)$$

$$= \frac{1}{F}\left[\rho_{\mu_p}^* - \rho_{\mu_p} - (s_{\mu_p}^* - s_{\mu_p})\right] \qquad [13]$$

With $^*\psi_s = \psi_\rho = \psi_i$ (no Dember potential) and $s_{\mu_p}^* = s_{\mu_p}$ (p_s = const as boundary condition), we get from Eq. [2] and [9] for an electrode process controlled by holes at constant current

$$\Delta\psi_R^* = \frac{\Delta\mu_p^*}{F} = \frac{RT}{F}\ln\left(1 + \frac{\Delta p^*}{p_o}\right)$$

$$= \frac{RT}{F}\ln\left(1 + \frac{I_L - I_{RS}}{I_{p,o}}\right) \qquad [14]$$

Contrary to the instantaneous photopotential this reaction controlled photovoltage $\Delta\psi_R^*$ does not change its sign with the sign of the surface charge. Equation [14] shows further that the magnitude of $\Delta\psi_R^*$ depends mainly on p_o, so that in this case a large effect can be found only for n-type materials.

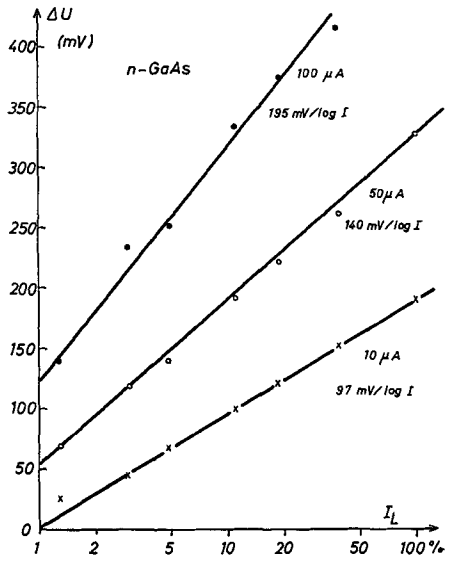

Fig. 4. Photovoltage in relation to light intensity for n-GaAs-electrodes (0.001 ohm cm) under constant anodic current in 1N H_2SO_4.

The photovoltage as measured in a galvanic cell against a reference electrode has the opposite sign of $\Delta\psi_R^*$, since a galvanic cell of this type includes the potential difference $(\psi_i - \psi_s)$ as one of the additive potential jumps at the interfaces of the cell. We see, therefore, that the electrode potential of a semiconductor with an anodic process at constant current is shifted to the negative (cathodic) direction by illumination.

Analogously, an electrode under cathodic polarization and with rate control by electrons will show the corresponding photovoltage

$$\Delta\psi_R^* = -\frac{\Delta\mu_n^*}{F} = -\frac{RT}{F}\ln\left(1+\frac{\Delta n^*}{n_o}\right) = -\frac{RT}{F}\ln\left(1+\frac{I_L - I_{RS}}{I_{n,o}}\right) \quad [15]$$

This photovoltage has the negative sign in $\Delta\psi_s$; therefore the electrode potential is shifted to more positive (anodic) values.

We have tried to verify these simple relations with GaAs electrodes where we know that the anodic dissolution is controlled by holes (18, 19) and the cathodic hydrogen evolution by electrons (20). A plot of the photovoltage ΔU_L in the galvanic cell formed by the reference electrode and the GaAs electrode is represented in Fig. 4 for a n-type electrode at three different currents. The photovoltage at p-type electrodes was negligible under anodic polarization as expected.

According to Eq. [8] we can expect that $\Delta p^* \sim \log I_L$ when $I_{RS} << I_L$. It is found indeed that a linear relation exists between ΔU_L and log I_L for the region $I_L >> I_{p,o}$ as shown in Fig. 4. But in disagreement with the theory above, the slope of this linear relationship is greater than the theoretical value 2.3 RT/F = 60 mv, indicating that this theory is not yet complete.

It is not difficult to see qualitatively where our assumptions will not be justified under the experimental conditions. In the derivation of Eq. [14], we have assumed that the equilibrium distribution is retained in the space charge layer. But if $I_L >> I_{p,o}$ and $I_{SR} << I_L$, the majority of electron hole pairs which are produced in the space charge layer have to drift to the interior. We have used light from a mercury lamp which is absorbed within a depth smaller or comparable with the extension of the space charge layer (compare Fig. 2). Therefore, an additional potential difference is necessary to adjust the flow rate of both carriers to the steady-state condition of equal drift rate through the space charge layer. This additional value of $\Delta\psi^*_{SC}$ is like a diffusion potential (Dember potential) for carrier drift through the space charge layer. We cannot yet present a rigorous calculation of this effect, but the results in Fig. 4 indicate a relationship similar to Eq. [4].

The experimentally obtained relation for large enough illumination intensities is approximately as follows

$$\Delta U_L = -(1+a)\frac{RT}{F}\cdot\ln I_L + \text{const} \quad [16]$$

The sign and magnitude of $\Delta\psi^*_{SC}$ depends on the excess charge at the surface. For enrichment of rate-controlling carriers in the space charge layer, the sign is the same as $\Delta\psi^*_R$. That is certainly the case for an inversion layer as we had in the experiments of Fig. 4. For depletion of rate-controlling carriers in the space charge, the sign is opposite to $\Delta\psi^*_R$.

A proof for this explanation of the photoresponse in Fig. 4 could be given by the following experiment. If one uses a thin slice electrode with a thickness comparable to the mean free path of minority carriers, and illuminates this slice from the back side, which is in contact with air, then the minority carrier concentration at the inner side of the space charge of the electrode should vary linearly with I_L. But in contrast to the direct illumination of the electrode surface itself, a smaller number of electron hole pairs is drifting under this condition to the electrode surface from the interior. When the surface recombination is negligible, pratically no drift should transverse the space charge layer to the electrode surface, and $\Delta\psi^*_{SC}$ should be very small.

The photovoltage under constant current for such a slice electrode under illumination of the front and back electrode sides has been studied. We found indeed that at small current the photovoltage under illumination of the back side had about the theoretical slope of 60 mv. Such experiments seem to allow us to distinguish between these two sources of photovoltage.

But as seen already in Fig. 4 the constant current load of the electrode itself also causes a deviation of the equilibrium distribution in the space charge layer since the slope of the ΔU_L — log I_L plots increases for greater currents. The reason is that the anodic current applied to the electrode needs an additional voltage difference in the space charge layer to drive the excess holes, necessary for the reaction, to the surface. This effect would be negligible only for the case where $j << I_{p,o}$. Unfortunately, this condition cannot be fulfilled in such experiments since other difficulties then arise.

At n-type GaAs of 0.1 ohm cm the saturation current $I_{p,o}$ is of the order of 10^{-6}-10^{-5} amp cm^{-2}. If we used anodic currents of the order of 10^{-6} amp cm^{-2}, then the surface concentration of electrons was changed under strong illumination to such an extent that in parallel to the anodic process hydrogen discharge occurred which consumes electrons. Under these conditions the external current is no longer equivalent to the anodic reaction rate, and the assumption, p_s = const, no longer holds. Therefore, we had to do our experiments at higher anodic polarization, and the results under too weak illumination cannot be compared with theory.

The technique of backside illumination for thin slices may be a useful device to supplement the analytical tools for studying semiconductor electrode reactions by investigating the effects of carrier injection from other sources, as was first done in the transistor-

like arrangements of Brattain and Garrett (15) or Pleskov (21).

It may be mentioned briefly that the shift of corrosion potential under illumination with cathodic control of the oxidant in an etching solution with injection of holes can be explained in the same way as a photovoltage under constant current, as was shown earlier for germanium (22). Much more difficult to discuss is the corrosion situation with hydrogen evolution as the cathodic process because both bands are then involved in the surface reactions, and again no simple boundary condition for the space charge layer surface can be given. In general, it may be concluded that the photovoltage at electrodes where electrochemical reactions disturb the balancing conditions for the motions of electrons and holes have to be analyzed with great caution.

Photocurrent under Constant Electrode Potential

Another experimental condition very easy to verify is the control of electrode potential under illumination. When only one electrode reaction controlled by one kind of charge carriers determines the faradaic current, the illumination must in any case increase the electrode reaction rate. Assuming again equilibrium distribution throughout the space charge layer, the surface concentration of both carriers at constant $\Delta\psi_s$ should be proportional to their concentration at the inner side of the space charge layer at distance ρ from the surface.

$$n_s = n_\rho^* \exp\left(+\frac{\Delta\psi_s}{\phi}\right)$$

$$p_s = p_\rho^* \cdot \exp\left(-\frac{\Delta\psi_s}{\phi}\right) \qquad [17]$$

With the assumption that the current is proportional to either n_s or p_s, the increase in current should be directly proportional to this increase in carrier concentration at point ρ

$$\Delta j_p^* = \Delta p_\rho^* \cdot \exp\left(-\frac{\Delta\psi_s}{\phi}\right)$$

$$\Delta j_n^* = \Delta n_\rho^* \cdot \exp\left(\frac{\Delta\psi_s}{\phi}\right) \qquad [18]$$

These equations show how greatly the photocurrent depends on the value of $\Delta\psi_s$.

So far, this kind of photoresponse seems to be easily understood. Unfortunately, it is largely impossible to fulfill the assumptions in this derivation over a greater region of light intensities. The reason is once again the necessity for the flow of carriers through the space charge layer disturbing the equilibrium distribution there. Worse than in the preceding section, in the case of a photocurrent at constant potential, a unipolar drift through the space charge layer becomes necessary which increases rapidly with illumination intensity. Therefore, the relation between Δj^* and Δp_ρ^* or Δn_ρ^* will no longer be linear.

Another simple correlation can only be expected under saturation current conditions where the transport of the reacting carriers to the surface is rate determining, that is in the potential range of saturation current for the electrode reaction. This can be verified experimentally for an electrode specimen where these carriers are in the minority. We have then an inversion layer at the surface, if the electrode is biased into reversal direction. If the applied voltage is high enough, then all carriers which reach the space charge region are then separated by the strong electrical field in this inversion layer. One kind of carrier only moves to the surface; the other is either held back or is rapidly transferred to the interior. The quantum efficiency for the photocurrent for illumination of the front side will reach at high polarization the value of one since the chance for recombination will then become very small.

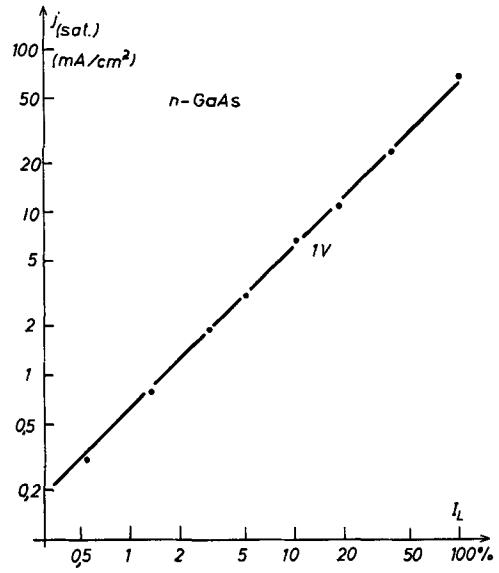

Fig. 5. Saturation current light intensity plot for n-GaAs under anodic polarization of +1v.

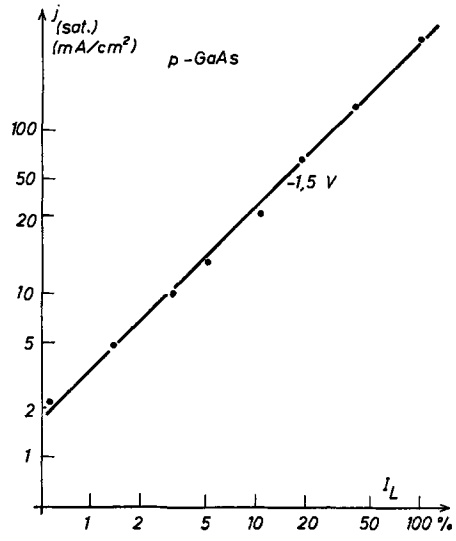

Fig. 6. Saturation current light intensity plot for p-GaAs under cathodic polarization of —1.5v.

Figure 5 represents the result of such an experiment for a n-type GaAs electrode under anodic polarization showing the linearity of photocurrent with light intensity.

Figure 6 gives the analogous results for p-type GaAs under cathodic polarization.

Photodecomposition of a Semiconductor Electrode with Large Energy Gap

Photoeffects at semiconductors are more pronounced as the band gap energy increases. This can be concluded from Eq. [1] and [2] since either n_o, p_o, or both concentrations are extremely small in such a semiconductor. The electrochemical reactions will then be controlled simply by one type of charge carrier, and simultaneous reactions in both bands at the same electrode become very improbable. Typical examples for such systems are CdS (b and gap: 2.4 ev) and ZnO (band gap: 3.2 ev).

Williams (23) has discussed the photovoltaic effect for this and other binary compounds in a very stimu-

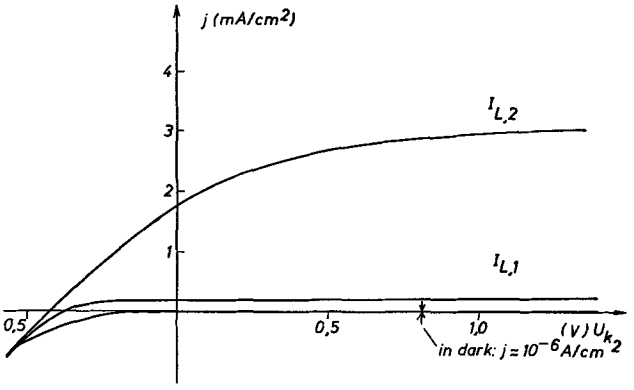

Fig. 7. Current voltage curves for CdS in 1N KCl (pH 5.6) under illumination.

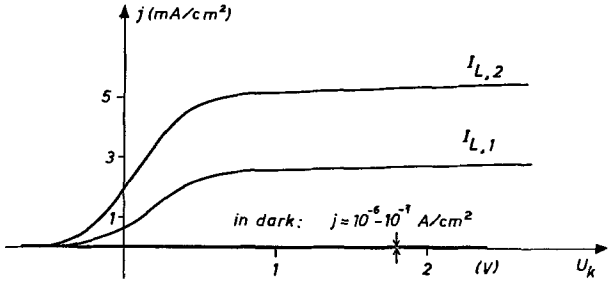

Fig. 8. Current voltage curves for ZnO in H_2SO_4 (pH 3) under illumination.

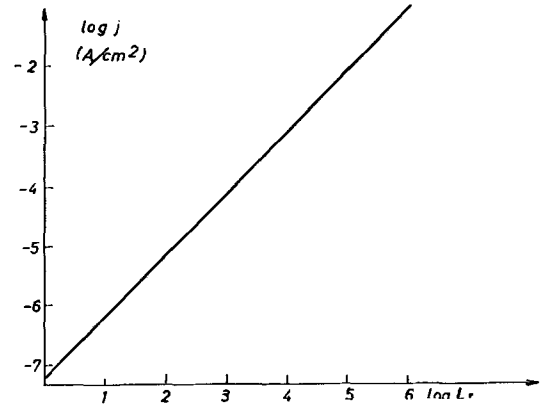

Fig. 9. Photocurrent in dependence on light intensity for ZnO electrode in saturation region.

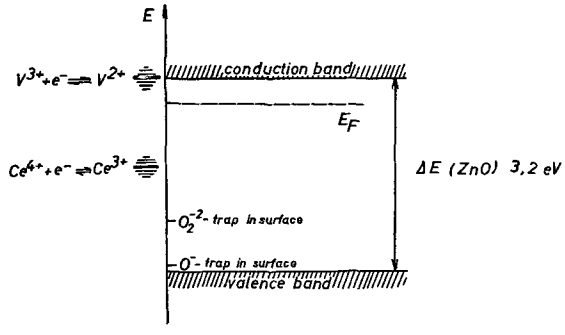

Fig. 10. Schematic correlation between semiconductor and electrolyte electronic energy levels for ZnO electrode.

lating paper. He observed that CdS is decomposed under illumination with anodic polarization into Cd^{+2} ions and sulfur. Two electrons are liberated in this process, which must be written as

$$CdS + 2h\nu \rightarrow Cd^{2+} \cdot aq + S + 2e^-_{CdS} \qquad [19]$$

By this reaction the semiconductor becomes negatively charged with respect to the solution as long as the electrons are not led away from the CdS electrode. This can be done by anodic polarization. Therefore, an anodic current flows through the electrode under illumination as shown in the current voltage curves for a CdS electrode in Fig. 7. The anodic saturation current at sufficiently high anodic polarization is proportional to the light intensity, as Williams already has found.

Without illumination, the anodic current is extremely small and depends on the rate of chemical dissolution of the crystals and on the metal excess in the ZnO. The behavior of ZnO electrodes is very similar as shown in Fig. 8. The cathodic branch of the current voltage curve represents hydrogen evolution (including some reduction to metallic zinc on the surface), and it is not influenced by illumination, as in the case of CdS electrodes. In the anodic region ZnO is decomposed under illumination, to give $Zn^{2+} \cdot aq$ and oxygen according to the following reaction

$$2ZnO + 4h\nu \rightarrow 2Zn^{2+} \cdot aq + O_2 + 4e^-_{ZnO} \qquad [20]$$

The photocurrent under sufficiently high anodic polarization increases linearly with light intensity as shown in Fig. 9. The quantum efficiency reaches the value of one within the limits of the accuracy of our analysis.[1]

This behavior can be explained in full analogy to the results with nonpolar or less polar semiconductors like Ge or GaAs. Figure 10 gives a schematic representation of the energy correlation between the bands in ZnO at flat band situation and the electronic energy terms in an electrolyte characterized by the electronic energy levels of two typical redox systems. Since all obtainable specimens of ZnO are n-type and the reduction of hydrogen ions can occur easily via electron transfer from the conduction band, the conduction band must be in the region of the electronic levels of the hydrogen redox system to allow this kind of charge transfer (7, 24, 25). This picture is confirmed by data of Dewald (8) on the electrode potential for flat band situation derived from capacity measurements.

Due to the large band gap in ZnO, no interacting redox energy levels in the electrolyte can be expected in the energy region of the valence band, because this energy would correspond to redox couples with standard potentials in the order of +3v.

Under illumination at flat band condition, the holes produced by the light diffuse through the crystal until they can recombine with an electron. Few holes reach the surface, but since there is no electron donor of this energy level available in the solution, these holes will be reflected to the interior, if they are not to recombine there.

It seems to be only a small chance that a hole may be trapped on the surface. A trapped hole on the surface is something like an O^- ion on the surface when we accentuate the partial ionic character of the chemical bond in the ZnO crystal. Such an incompletely charged ion is more weakly bonded to the crystal lattice and may therefore be able to change its local position in the lattice. By such a process, a stable trap level should be formed above the normal valence band energy levels. If such an O^- ion is able to accept a second hole, the bond to the lattice will be completely broken and an adsorbed O atom will be formed. Such surface traps have already been discussed frequently, *e.g.*, by Collins and Thomas (26) and by Heiland (27).

As our results indicate, the second hole may be more easily trapped at the neighboring oxygen ion forming in the second step primarily $(O\text{-}O)^{-2}$ ionic

[1] After this paper was written, an investigation of the behavior of ZnO electrodes under illumination was published by Lohmann (28) in which fully analogous current voltage curves are reported as given here.

groups with two remaining bonds attached to the lattice. In this way more energy can be gained by the formation of the O-O bond and the O_2 molecule structure is obtained on the surface. This process is emphasized by the observation that almost no hydrogen-peroxide could be found in the solution as a product of the photodecomposition. (Analytical results indicated a small formation of H_2O_2, but to less than 6% and confirmed, on the other hand, the production of O_2 by the illumination with about 95% efficiency.) After addition of two more holes the final molecular oxygen bond is formed by retaining two electrons from the original lattice bonds. Thereafter the O_2 molecule can easily be desorbed from the surface. Such hypothetical energy levels for O^- and $(O\text{-}O)^{-2}$ are included in the schematic plot of Fig. 10.

The probability for this process described above will become very high under anodic polarization. Since no inversion layer can be formed for such a semiconductor, due to the fact that the thermal generation of holes is by far too slow, the surface area is depleted of electrons, and the space charge is built up only by the immobile positively charged donors. The Mott-Schottky approximation is valid in describing the charge distribution. For our purpose, it is only important to know that under anodic polarization a strong electrical field is built up in the space charge layer which completely separates electrons and holes generated in this area. The electrons are driven to the interior, and the holes accumulate at the surface. The same happens with holes produced further inside in so far as they reach the space charge layer by diffusion. This situation is represented in Fig. 11.

Obviously, the formation of oxygen at the surface according to the reaction described above now becomes very probable since the complete separation of electrons and holes in the space charge layer fully prevents recombination at the surface. If the space charge layer is extended so far into the interior as to include the whole region of light absorption, the quantum efficiency for this charge separation and the following decomposition reaction should approach the value of one, as was confirmed in the experiments.

The current transfer to the electrolyte is completed by Zn^{2+} ions easily leaving their surface position in the lattice at those points where the neighboring oxygen ions have already left their normal lattice places. Rate determining for this photochemical decomposition are the reactions of the holes in the surface. The overall reaction may be summarized in the following steps

$$ZnO + 4h\nu \rightleftharpoons ZnO + 4e^- + 4p^+$$
$$O_s^{-2} + p^+ \rightarrow O_s^- \quad \text{slow}$$
$$O_s^- + O_s^{-2} + p^+ \rightarrow (O\text{-}O)^{-2} \quad \text{slow}$$
$$(O\text{-}O)^{-2} + 2p^+ \rightarrow O_2 \quad \text{fast}$$
$$2Zn_s^{2+} + aq \rightleftarrows 2Zn^{2+} \cdot aq \quad \text{fast}$$
$$2Zn + 4h\nu \rightarrow 2Zn^{2+} \cdot aq + O_2 + 4e^- \qquad [21]$$

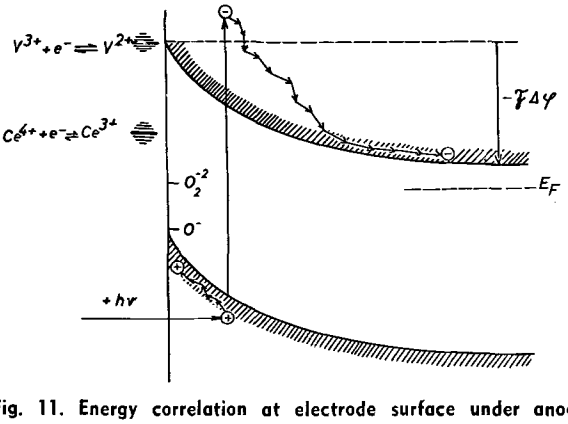

Fig. 11. Energy correlation at electrode surface under anodic polarization.

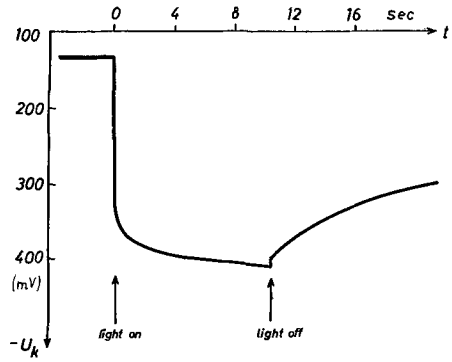

Fig. 12. Photoresponse of ZnO electrode at zero current in H_2SO_4 (pH 3).

The photochemical decomposition of CdS can be described analogously due to the accumulation of holes on the surface.

The photoresponse of a ZnO electrode in an open circuit is seen in Fig. 12. Characteristically, a very small fast photovoltage is built up after the beginning of illumination, followed by a slower increase of the photovoltage over a relatively long period. The photovoltage disappears very slowly after stopping the illumination apart from a first fast drop. This can be explained by the small efficiency of the hole trapping process in Eq. [21] without an applied anodic polarization, due to the unprevented recombination. In an open-circuit electrons accumulate in the electrode in parallel with the rate of the irreversible oxygen formation in the surface. This causes the observed slow photo response in the negative direction. The fast response must represent the Dember potential. A steady state is reached when electrons leave the surface by means of a cathodic reaction at the same rate as holes are consumed in the anodic reaction Eq. [21]. This cathodic reaction for electrons will be the hydrogen evolution

$$2H^+ \cdot aq + 2e^- \rightarrow H_2 \qquad [22]$$

or any other electron accepting reduction process. We have observed, in agreement with this assumption, that the restitution of the reference potential in the dark is largely accelerated by a depolarizing redox system (as *e.g.* H_2O_2). Further, the photopotential in an open circuit is smaller in the presence of such a depolarizer.

All these experiments indicate clearly that the reactions of minority carriers are the controlling processes in such systems. For any process in which a crystal lattice is to be destroyed, holes will play this part in a semiconductor, since their presence weakens directly the strength of a chemical bond in a crystal. The equivalent role for electrons can only be expected at such semiconductors where electrons are the minority carriers and their reactions with electron acceptors in the electrolyte will control the reactivity. The last examples show that the combination of photochemical and electrochemical investigations can be very useful for the understanding of semiconductor reactions.

Acknowledgments

The author would like to thank his co-workers Miss I. Mattes, W. Mindt, and H. Tributsch for making the experiments analyzed in this paper. He would also like to thank Dr. M. H. Miles for correcting the English text. He is further much indebted to Professor G. Heiland for delivering the single crystals of ZnO used in these experiments.

Discussion

W. Mehl: The depth of penetration of light seems to play an important role in the investigation of the photoeffects of electrode processes. As the extinction coefficient varies strongly with frequency near the absorption edge, I wonder if the author has done measurements in this frequency range.

H. Gerischer: The wavelength of the light is indeed a very important parameter. We have usually used light with energy much higher than the band gap. The light is absorbed then in a range very near to the surface and with relatively low anodic polarization the space charge layer is extended far enough into the interior as to achieve the situation indicated in Fig. 2. This is shown in the current-voltage curves by the fact that the anodic currents does not further increase with increasing voltage. For light with energy close to the band gap the current increases over a much greater voltage range as can be seen in a Fig. HG1.

In this figure, photocurrents at CdS electrodes are shown for two different wavelengths. The current under illumination of light with 4080Å wavelength reaches the saturation value at a polarization of 1v while the current under illumination with 5400Å light

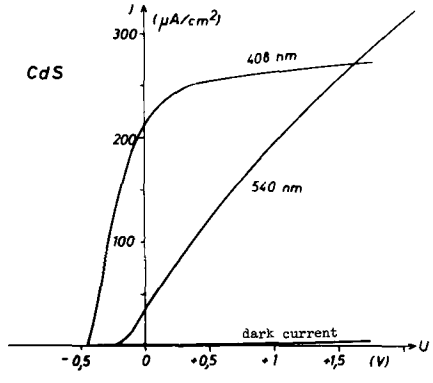

Fig. HG1

continues to increase up to much higher voltages. Since the space charge layer according to the Schottky-Mott theory for such systems expands proportionally to $\sqrt{u}$, it is possible to obtain from such measurements information on the absorption coefficient of the light of a particular wavelength.

W. W. Harvey: The quantitative discrepancies between measured photoeffects for GaAs electrodes reported by Professor Gerischer and the predictions of the relations developed in his paper are likely the result of inadequacies in the physical model. In single-crystal germanium electrodes (to which the model does pertain) the mean lifetime of the minority carriers is sufficiently long that the minority carrier diffusion length is generally large in comparison to the extent of the space charge region. Consequently, thermal generation of carriers in the latter region makes a small contribution to the limiting flux of minority carriers arriving at the surface by diffusion from the interior. In essence, then, for germanium it is necessary to take into account thermal generation of carriers only in the body and at the surface.

Turning now to a compound semiconductor such as GaAs, we note first that the best available crystals have lifetimes which are orders of magnitude smaller than those of germanium and silicon. Thus the diffusion lengths of minority carriers in compound semiconductors are generally very short, and it will no longer be valid to neglect thermal generation in the space charge region in comparison to that taking place within several diffusion lengths of the surface. Moreover, the statistical theory of generation and recombination of charge carriers in semiconductors indicates an enhancement of the net rate of generation in the field of the space charge. In semiconductors of short body lifetime and large gap, therefore, the major contribution to the limiting current of minority carriers arriving at the electrode surface may (in the absence of illumination) be made by thermal generation in the region of space charge (see, for example, Pleskov's initial paper[1] on GaAs electrochemistry and

[1] Yu. V. Pleskov, *Doklady Akad. Nauk SSSR*, **143**, 1399 (1962).

Myamlin's treatment[2] of anodic limiting currents for silicon electrodes).

The foregoing considerations lead me to question not only the applicability of Professor Gerischer's model to the semiconductor electrodes considered in his paper, but also whether, in fact, for the thin-slice experiments with GaAs the thickness was comparable with the diffusion length (certainly not with the "mean free-path," as stated) of the minority carriers. As I showed some years ago,[3,4] for thin-slice electrodes it is necessary to take into account thermal generation in the vicinity of the back surface. For n-type germanium, the measured limiting anodic current at the front surface increased linearly with the intensity of light incident upon the back surface, and a family of intersecting lines was obtained whose slopes were determined by the magnitude of recombination velocity at the back surface. Similar considerations probably also apply to the GaAs experiments reported by Professor Gerischer, with the additional complications resulting from space-charge generation.

H. Gerischer: I agree with you that the analysis of the thin slice experiments with GaAs is rather questionable. The deviations in results from the assumptions of our simplified model can be caused to a substantial extent by the effects you have mentioned. We found rather poor reproducibility of these results with slices made from different crystals which obviously indicates a great influence of the recombination properties in the surface region. Much more work will have to be done before we understand the details.

Concerning the limiting current under saturation conditions, I think that the situation is much clearer since recombination at the surface where minority carriers are consumed becomes very unlikely then. Also in the exhaustion layers, recombination should be very small. I would expect therefore that in this case the influence of field strength on recombination should not be detectable. Our results with regard to the saturation current under illumination are in good agreement with this assumption.

G. C. Barker (communicated): Professor Gerischer is clearly correct in suggesting that when there is a minority carrier drift in the space charge region it is not possible to derive an expression for the potential drop across the region that is both simple and exact. This is a difficulty which will persist, and I wonder what attempts have been made to tackle this problem theoretically. It clearly is one which also arises in connection with transistors, and I would imagine that workers in the transistor field must have given some thought to it. Of course it is easy today to construct electrical analogues of the diffuse double layer near an electrode and of the related space charge region within a semiconductor or within an ion exchange membrane. Further one can see that, in principle, it is possible to devise an analogue circuit which also takes account of drift of current carriers. The latter step is, however, more difficult and less elegant than the simulation of a space charge or a diffuse double layer at equilibrium, and I am not sure whether the effort would be worth while.

My second comment has to do with the results obtained with zinc oxide and cadmium sulfide crystals. I would like to ask what happens when the illuminated and anodically polarized crystal is in contact with a solution containing a common or related ion. Is there still corrosion of CdS in a sulfide solution and enhanced dissolution of zinc oxide in slightly alkaline solution. According to the mechanism proposed in the ZnO case there is no removal of holes at the interface by electrons supplied by ions or water molecules at the interface and I suspect that Professor Gerischer may say that the mechanism is unchanged in alkaline solution. However, it has to be noted that the $OH\text{-}OH^-$ standard potential is thought to be in the vicinity of 3v *vs.* NHE and direct transfer of electrons from adsorbed OH^- ions to holes in the valence band seems not impossible.

Finally I would suggest the addition of aliphatic alcohols or other organic OH scavengers to the anodically polarized ZnO system. Such additions might throw some light on the mechanism by which holes are consumed at the surface though I doubt whether it would be possible to distinguish between reactions induced by OH radicals and those induced by O^- ions formed in the way suggested in Professor Gerischer's paper.

Photocurrents Produced by Ultraviolet Irradiation of Mercury Electrodes

II. Factors Influencing Photocurrents Caused by Electron Emission

G. C. Barker, A. W. Gardner, and D. C. Sammon

Atomic Energy Research Establishment, Harwell, Didcot, Berkshire, England

ABSTRACT

The influence on the photocurrent of factors such as wavelength, scavenger concentration, ionic strength, diffusion coefficient of the hydrated electron, and the nature of products of the scavenging reaction, is considered. The discussion is illustrated by experimental data obtained by a variety of methods, and some preliminary results for substantially monochromatic light are described which lead to approximate relative rate constants for the scavenging of hydrated electrons by some simple inorganic ions and molecules.

The presence of certain reducible solutes (1-3) in an inert electrolyte solution in contact with a uv irradiated mercury electrode gives rise to a photocurrent (i_p) proportional at low concentration (C_s) to $C_s^{1/2}$. This current might be caused by: (*a*) homogeneous or heterogeneous photolysis (4) followed by reduction at the electrode of one or more products of the photolytic reaction; (*b*) excited water molecules (5) that

are formed at the electrode surface and react with the solute as they diffuse away from the surface; (*c*) excited mercury ions at the surface that react with solute present in the compact part of the double layer; (*d*) hydrogen atoms formed by the dissociation of adsorbed water molecules (6) that reduce the solute as they diffuse away from the electrode surface, their oxidation at the electrode surface being a fairly slow process; (*e*) hydrated electrons formed directly at the interface by electron transfer to water molecules situated in the compact part of the double layer. These electrons, although thermodynamically unstable as regards oxidation by the electrode, return to the electrode fairly slowly (apparent rate constant of the order of 100 cm s^{-1}) and some of them diffuse away from the electrode. While so doing they are captured by the solute molecules or ions; (*f*) a variant on (*e*) involving the indirect formation of hydrated electrons (1) at varying distances from the electrode surface. The electrons ejected from the electrode leave with a variable amount of kinetic energy and travel some distance through the solution before being hydrated.

Although at high solute concentration currents due to (*a*) may occur with certain solutes (NO_3^-, BrO_3^-) this mechanism cannot account for the concentration dependence of the photocurrents considered in this paper. Mechanism (*c*), could lead to a current that is not linearly related to C_s, but is not consistent with (*i*) the observed rather slight dependence of i_p on supporting electrolyte concentration (1) and (*ii*) the insensitivity of i_p to the charge on the solute ion or molecule when the ionic strength is small. All of the remaining mechanisms involve the diffusion away from the electrode of an entity produced by the radiation, and each is superficially consistent with the observed concentration dependence. In the present paper attention is largely focussed on mechanisms (*e*) and (*f*). Studies of the influence of ionic strength on i_p show that the current is partly if not entirely due to one of these mechanisms, and comparative and competitive photocurrent experiments lead to rate constants for electron scavenging in fair agreement with those obtained in other ways. Although H atoms may well be formed they probably contribute little to the photocurrent as scavenging rate constants are often two or more orders of magnitude smaller than the corresponding rate constants for the scavenging of hydrated electrons (13). The same may be true for excited water molecules.

Experimental

In all experimental work the test electrode has been a dropping mercury electrode (DME) as the initial experiments showed clearly that surface contamination could greatly influence the potential dependence of i_p when H_3O^+ is the scavenger. Advanced polarographic equipment has been used exclusively to study i_p as such equipment makes it possible to measure a minute photocurrent in the presence of a very much larger faradaic current due either to the reduction of the scavenger or to the reduction of small amounts of species such as oxygen arising from slow photolysis of the electron scavenger.

Measurements of i_p have invariably been made at controlled potential. Five related experimental approaches have been employed. In the first experiments (MP 1) square wave modulated light from a 100w medium pressure mercury lamp was used, the lamp (quartz envelope) being mounted alongside a quartz polarographic cell (solution light path *ca.* 5 mm). The potential dependence of the amplitude of the square wave (225 cps) component of the photocurrent was studied with a square wave polarograph (SWP). Later a more elaborate apparatus (MP 2) was used to make more precise comparative measurements of i_p for different scavengers. A four electrode cell was used (DME, reference electrode, cathodically polarized mercury pool counter electrode, and Ag polarizing electrode) with a solution light path of about 1 cm. The mean value of the lamp voltage was automatically regulated by controlling the temperature of the air in a quartz jacket surrounding a 100w medium pressure lamp, and the lamp current waveform was regulated electronically. Appreciably higher light intensity than in the MP 1 experiments was obtained by forming an image of the mercury discharge in the plane of the test electrode using quartz lenses. The square wave component of i_p was again measured with a SWP.

To study the residual current in the absence of a scavenger a 250w high-pressure mercury arc (compact source) was used. Square wave modulated intense light was obtained in these experiments (HP) by placing a slotted rotating disk in the light path. As in the MP 2 work an image of the arc was formed at the surface of the test electrode. The solution light path was *ca.* 2 cm.

Recently in comparative and competitive scavenging experiments substantially monochromatic 2537Å light from a low-pressure mercury discharge lamp (5w Vycor envelope) has been used. In these experiments (LP) rectangular modulation of the light was needed, and this was produced by increasing the power dissipated in the lamp by a factor of *ca.* 4 for a time interval of about 1/25 sec starting about 2.5 sec after the start of growth of the mercury drop, this delay time being controlled by a pulse polarograph (PP). This polarograph was used to study the potential dependence of the average change in the current supplied to the DME at constant potential over a time interval of 1/50 sec starting 1/50 sec after the increase in light intensity. Owing to the diffuse nature of the light source no attempt was made to focus light on the test electrode, and the lamp was merely mounted alongside a cell with a cylindrical quartz section which surrounded the mercury drop (solution light path *ca.* 1 cm). The current flowing through the lamp was stabilized, and the laboratory temperature was held constant to $\pm$ 0.5°C.

Studies have been made of the time dependence of i_p using the HP apparatus, by varying the phase of the modulation relative to the phase of the current sampling circuit of the SWP. Also an inexpensive 25 J electronic flash source (xenon in Pyrex envelope, flash duration 400 μsec) has been used for the same purpose. The variation of i_p with time at substantially constant potential was studied with an oscilloscope connected to the output terminals of the main current amplifying circuit of the PP. This instrument controlled the potential of the DME, and it also could be used to record the potential dependence of the integrated charge lost by the DME during the light flash.

The transparency of the various solutions to the radiations employed was studied with a Unicam spectrophotometer Type SP 500, and quantitative deductions from experimental data have not been made without applying corrections if the absorption of any wavelength contributing appreciably to the photocurrent exceeded 5%. Such absorption was only of importance in work with NO_3^- and NO_2^- and prior exposure to uv light was minimized as far as possible in experiments with these scavengers.

With both the SWP and the PP measurements were made at predetermined times in the drop life and the constancy of the mercury flow rate was monitored by measuring the double layer capacity of the DME at the measurement time using the normal circuits of the polarographs. Information such as the potential dependence of i_p was usually automatically recorded, and over the years some 10^5 bits of recorded information have accumulated. Throughout the paper experimental values of i_p are expressed in arbitrary units. "Saturation" photocurrents (amp cm^2) were not larger than $2\ 10^{-6}$ (MP 1), 10^{-5} (MP 2), $4\ 10^{-5}$ (HP), $2\ 10^{-6}$ (LP), and 10^{-3} (unfiltered flash).

Solutions were prepared from triply distilled water.

Reagent grade chemicals were used, and in some instances, where freedom from impurities which might act as scavengers was important, recrystallization or calcination was resorted to, usually without producing a marked improvement. A complicated pretreatment of the solutions which is mentioned later was made use of in studies of the residual current. Normally the solutions were deoxygenated (often before forming the mercury pool counter electrode to avoid H_2O_2 formation) by bubbling purified nitrogen through the solution in the cell, hydrogen or argon being used occasionally. Anaesthetic grade N_2O was used without purification as it contained virtually no oxygen and negligible amounts of other impurities which were either polarographically reducible (NO,NO_2) or which could act as electron scavengers. Solutions containing known concentrations of N_2O were prepared by mixing known volumes of N_2O saturated electrolyte solution and argon saturated electrolyte solution and then rapidly injecting the mixture into an argon filled cell. Alternatively if an exact knowledge of the N_2O concentration was not vital, solutions containing N_2O at a low concentration were obtained by introducing a known volume of electrolyte solution into the cell, saturating this with N_2O, and then bubbling argon through the cell at controlled rate for a known length of time. The N_2O concentration decreased exponentially with time, and concentrations down to 10^{-4}M could be obtained with an accuracy better than 10% if the temperature of the solution and of the inflowing gas was held constant.

Early measurements were made at the ambient temperature (20° ± 2°C). Recent measurements (LP) have been made in a small thermostatted room (17° ± 0.5°C).

Diffusion Coefficient of the Hydrated Electron

The diffusion coefficient of the hydrated electron has been determined by studying the transient change in the electrical conductivity[1] of very dilute NH_4OH solutions (~3 10^{-6}M) when irradiated with a pulse of 4 Mev electrons from a linear accelerator. These solutions were prepared from conductivity water taking steps to destroy organic matter and to eliminate CO_2 and other inorganic impurities and then were carefully deoxygenated and saturated with hydrogen to destroy OH radicals formed by the decay of H_2O^+. A large voltage had to be applied to the electrodes of the conductivity cell to obtain a signal well above interference signals from the accelerator, and this voltage was applied in the form of a rectangular pulse starting shortly before the accelerator pulse (~3 μsec duration) and lasting 10^{-4}—5 10^{-4} sec. Figure 1 is typical of the results obtained. During the accelerator pulse an increase in conductivity is observed which is partly due to the formation of hydrated electrons in the solution and partly to H_3O^+ ions (~3 10^{-7}M)

[1] Similar experiments have recently been reported by Schmidt and Buck. The Argonne workers find a value for D_e of 4.7 10^{-5} cm^2 sec^{-1} in agreement with the later value here reported.

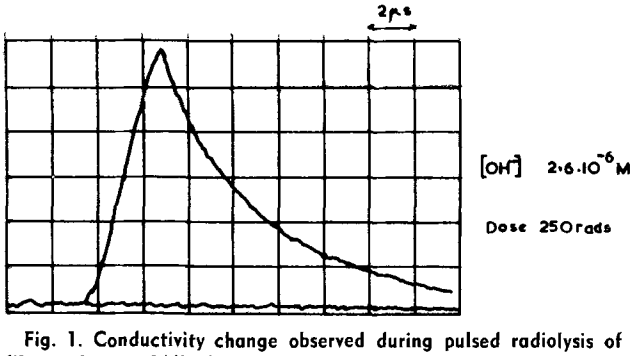

Fig. 1. Conductivity change observed during pulsed radiolysis of dilute solution of NH_4OH.

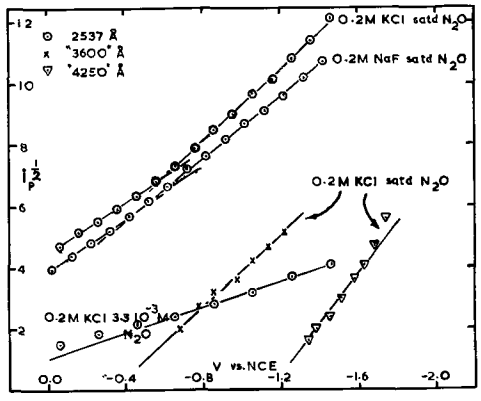

Fig. 2. Influence of wavelength on i_p

formed by the decomposition of H_2O^+. The H_3O^+ ions are mainly consumed by OH^- ions in the solution, and the hydrated electrons are removed somewhat more slowly by reaction with H_3O^+, and with OH radicals, as well as by a second order reaction of the electrons with themselves. One thus might expect the conductivity decay to be rather complex, but in reality it is almost exactly a simple exponential decay. As the consumption of H_3O^+ by OH^- tends to produce a solution which contains hydrated electrons and an equivalent deficit of OH^- ions, this simple first order decay of the change in conductivity indicates that the electron mobility is almost equal to that of the OH^- ion. In the present paper a value for *De*, the diffusion coefficient of e^-_{aq} of 5 10^{-5} cm^2 sec^{-1} is used.

Photoemission of Electrons

It is to be expected that the photoemission of electrons using monochromatic light will be influenced by the potential of the electrode in much the same way as the yield for photoemission into a vacuum is affected by the quantum energy.

Ignoring for the moment possible complications introduced by the discreteness of the charges in the double layer the effective work function should decrease steadily as the potential becomes more negative and, as has been suggested by Delahay (3), a linear relation between $i_p^{1/2}$ and potential should be observed. Such a relation holds for emission *in vacuo* and some degree of linearity is predicted by Fowlers theory (14). Figure 2 shows the dependence of $i_p^{1/2}$ on potential for several solutions containing N_2O. This electron scavenger is ideal for such studies as experiment suggests that electron capture over a wide range of potential is an irreversible process and that the way in which i_p varies with potential is unaffected by reactions following the scavenging reaction. The photocurrent is time invariant for elapsed times in the range 0.1-20 msec and, as it is unlikely that N_2O^- has a half-life in neutral or slightly alkaline solution larger than 0.1 sec, the complete photocurrent mechanism is probably

$$e^-_{aq} + N_2O \rightarrow N_2O^- \qquad (a)$$

$$N_2O^- \rightarrow N_2 + O^- \text{ (fast homogeneous reaction)} \qquad (b)$$

$$O^- + H_2O \rightarrow OH + OH^- \text{ (neutral or slightly alkaline solution)} \qquad (c)$$

Almost all the OH radicals so formed will be directly or indirectly reduced (*e.g.*, $OH + Cl^- \rightarrow Cl + OH^-$, $Cl + e \rightarrow Cl^-$) at all accessible potentials. Over a wide range of potential the capture of a hydrated electron by N_2O leads to the loss of a further electron by the electrode, and two electrons are thus permanently lost by the electrode.

Considering first the results for substantially monochromatic 2537Å light it is seen that the plots for

0.2M KCl and 0.2M NaF saturated with N_2O (3.1 10^{-2}M) at atmospheric pressure appear to have two linear portions which intersect at potentials close to the ECM potentials (E_{ecm}) for these solutions. Superficially the presence of specifically adsorbed Cl^- at the interface does not greatly influence the plot (the slightly smaller values of i_p for the fluoride solution are probably due to a trace of mercurous ion). Extrapolation to the potential axis of the linear portions for $E > E_{ecm}$ gives a value of 0.85 ± 0.15v *vs.* NCE for the apparent threshold potential when 2537Å radiation is used. With solutions saturated with N_2O a substantial fraction of the hydrated electrons are captured, and the photocurrents are comparable with the saturation photocurrent i_{ps}. With lower values of C_s the experimental accuracy decreases somewhat but for a scavenger concentration of 3.3 10^{-3}M there is still some indication of a change in slope near E_{ecm}.

The general behavior with 2537Å light seems to be indicative of photoemission, but the change in slope suggests that emission may be slightly influenced by ions adsorbed at the electrode. It was shown earlier (1) that the photocurrent produced by H_3O^+ is not noticeably dependent on the nature of the cations adsorbed at the surface when the electrode carries a large negative charge. Early work also showed that the magnitude of the current was little affected by the electrolyte concentration for concentrations between 1 and 0.2M. Thus it would seem that the factor influencing the rate of emission of electrons with light of constant wavelength (or polychromatic light of constant chromatic composition) is the potential of the electrode with respect to the bulk of the solution, rather than some factor closely connected with the double layer structure and composition. One suspects immediately that the current is produced mainly by electrons having energies sufficiently large to travel distances large compared with the half-thickness of the diffuse double layer. However, it would be remarkable if the electrical double layer did not in some way affect the potential variation of the photocurrent.

The change in the slope of the $i_p^{1/2}$ plots near the ECM may possibly be due to discreteness of the charge in the double layer. With an idealized compact double layer of constant thickness one imagines that the effective work function of the mercury surface would decrease steadily as the potential became more negative, the rate of decrease of work function being only slightly smaller than the rate of change of potential if e^-_{aq} is formed indirectly. Let us assume that the probability of emission of electrons is determined by some function such as $\exp \gamma/f$ where f is the local field strength at the mercury surface. [Functions such as this arise in field emission (7).] Introducing discreteness of charge into the picture gives a change from a uniform field to one with large fluctuations from the average value. Negative fluctuations due to a surface excess of cations will have a greater effect on emission than the positive ones due to an excess of anions. Expressed somewhat differently, the presence of discrete negative charges only tends to suppress emission over a small fraction of the surface, and the average rate is much the same as if the negative charge is evenly distributed over the plane of closest approach for the anions. A surface excess of cations, however, greatly enhances emission over a small fraction of the total surface and produces a larger increase in the average rate as compared with the value when the charge is smoothed out over the plane of closest approach. Tentatively the change in slope thus will be attributed to preferential emission in the vicinity of adsorbed cations. This effect should presumably be most readily detected at high scavenger concentration but it should still influence i_p at low scavenger concentration if the average range of the electrons prior to thermalization is large compared with the thickness of the compact part of the double layer.

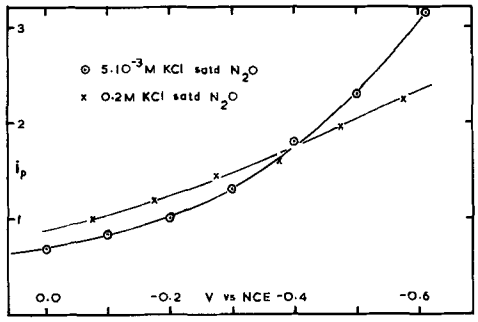

Fig. 3. Influence of ionic strength on N_2O photocurrent

Influence of Adsorbed Anions on the Ψ Potential

Although at high ionic strength i_p is not very sensitive to the ionic strength, double layer effects can be detected at low ionic strength.

Figure 3 shows the variation with potential of the "saturation" photocurrent for 0.2M and 5 10^{-3}M KCl saturated with N_2O (no correction has been made for the slight decrease with increasing electrolyte concentration of the solubility of N_2O). At $E < E_{ecm}$ the current is larger for the more dilute solution. This effect is predicted qualitatively by theory given later. Due to electromigration of electrons in the diffuse double layer, the current approaches more closely i_{ps}. More surprising is the decrease in current when the electrolyte concentration is reduced if the electrode is positively charged. A similar but smaller decrease was observed with 2 10^{-2}M KCl when the electrode carried an appreciable positive charge. According to the model introduced by Grahame (8) which is often used in the interpretation of electrocapillary data, specific adsorption of anions produces a reversal in the sign of the Ψ potential. The photocurrent measurements suggest that if such a reversal does occur it is quite localized and that the Ψ potential over an appreciable fraction of the surface changes sign when the sign of the charge on the electrode changes. The decrease in photocurrent can be attributed to electromigration of hydrated electrons in regions where the Ψ potential is positive in sign. If this interpretation of the experimental results is correct, the study of photoemission at electrodes may cast new light on the structure of the double layer.

Energetics of Photoemission

It was suggested in Part I (1) that photoemission should commence close to the ECM with light of wavelength 2500Å as the quantum energy then roughly equals the work function of mercury. This naïve suggestion ignored many factors, one of which was the change in energy level on transferring an electron from *vacuo* to a medium of finite electronic polarizability. There is some doubt as to the effective dielectric constant of water when a fast moving charge is involved, but it is conceivable that the change in energy level could be sufficient to account for the threshold potential for 2537Å light. Taking the effective radius of the free electron in water to be of the order of 2Å, an effective dielectric constant of 2 would produce a change of energy level of about 40 kcal, *i.e.*, 1.7 ev. The conversion of a thermal electron to a hydrated electron involves a further change in energy level. It is currently believed (9) that the heat of hydration is about 50 kcal. This is with respect to the electron *in vacuo* and the heat of hydration for a thermal electron in water is presumably appreciably smaller, possibly no larger than 10-15 kcal. Clearly the possibility that there may be a small number of free electrons in water containing hydrated electrons cannot be ruled out.

It is generally assumed that when hydrated electrons are formed homogeneously by light absorption by cer-

tain anions they are formed directly within the solvent cage round the ion. However, as Dainton (10) has pointed out, the rapid approach to a limiting quantum yield in scavenging experiments is not consistent with theory based on such a small separation of the partners. This difficulty vanishes if it is assumed that free electrons are ejected from the ions and that these electrons travel a short distance before becoming hydrated. In this case also one can postulate emission made possible not by the hydration energy of the hydrated electron but by the polarizability of the medium.

It will be clear by now that the mechanism which we favor for the photocurrent is indirect formation of hydrated electrons some distance away from the electrode. Three distinct steps are envisaged. First the ejection of an electron from the electrode,[2] second the thermalization of the electron, and finally its hydration. The last step may take place fairly slowly, and thermal electrons may travel a short distance before hydration takes place. Undoubtedly an appreciable fraction of the ejected electrons will return to the electrode before being hydrated, but those which escape from the double layer region are eventually converted into hydrated electrons. All the experimental facts known to us are consistent with this mechanism, but as the evidence in some instances cannot be regarded as conclusive the general behavior if the photocurrent were caused by hydrated electrons formed directly at the interface is briefly considered in later sections.

Influence of Wavelength

An obvious parameter to vary is wavelength. The importance of doing this has long been recognized, but the work of early workers (11) did not lead to results of permanent value. Unfortunately the photocurrent is often small, and after the insertion of a monochromator in the light path the current may be too small to measure.

In Fig. 2 there are two plots of $i_p^{1/2}$ obtained with 0.2M KCl saturated with N_2O and the flash source. Combinations of Wratten filters were used to vary the position of the pass band and to reduce the bandwidth of the light path. The characteristics of the shorter wavelength radiation were maximum intensity I_m close to 3600Å, 0.5 I_m at 3450 and 3750Å, 7.5% I_m at 3200Å and 2% I_m at 3000Å. Those of the longer wavelength radiation were I_m close to 4250Å, 9.5% I_m at 4000Å, 31% I_m at 4400Å, 1% I_m at 3800Å, 1% I_m at 4800Å. These radiations were not as monochromatic as one would wish, but they provide some semiquantitative information about the behavior when long wavelengths are used. In both cases the plot of $i_p^{1/2}$ against potential is fairly linear. There are no reliable points for potentials more negative than about —1.6v *vs.* NCE because at such potentials the reduction of N_2O commences and a spurious photocurrent due possibly to heating of the interface by the absorbed radiation is observed. The "4250Å" radiation was closer to being monochromatic than the "3600Å" radiation and consequently the apparent threshold potential obtained by extrapolation of data for the former radiation is more reliable. Extrapolation gives —1.14 ± 0.05v *vs.* NCE for the "4250Å" radiation and —0.36 ± 0.1v *vs.* NCE for the "3600Å" radiation, the latter value being in all probability somewhat too positive due to the presence of wavelengths somewhat shorter than 3600Å.

Approximate though these results are they serve to show that the apparent threshold potential changes considerably as the wavelength increases, changing by 1.99 ± 0.25v when the wavelength changes from 2537Å (4.86 ev) to 4250Å (2.92 ev). Actually the change in threshold potential should be somewhat larger than the change in work function as ejected energetic electrons presumably lose a little energy while passing through the compact part of the double layer. It should be mentioned that our results do not agree with the recent work of Heyrovsky (2b). For N_2O and several other scavengers the rate of change of threshold potential with quantum energy (E/ev) was found by him to be close to 0.5. Such a value and a mechanism based on electron emission are mutually inconsistent.

[2] The quantum efficiency is dependent on wavelength and potential and is about 0.07% at —1.5v *vs.* SCE for 2537Å light.

Influence of Scavenger Concentration

Results reported earlier (1) for solutions containing H_3O^+ ions were interpreted on the basis of scavenging by H_3O^+ of hydrated electrons diffusing away from the electrode surface. A simplified model was employed in which all the hydrated electrons are deposited in a deposition plane distance δ away from the surface. Capture within the region $0 < x < \delta$ is ignored but for $x > \delta$ hydrated electrons are consumed by

$$e^-_{aq} + S \rightarrow S^- \qquad (d)$$

and

$$i_p/i_{ps} = Q\delta/(1 + Q\delta) \qquad [1]$$

where $Q = (k_sC_s/D_e)^{1/2}$, D_e is the diffusion coefficient of the hydrated electron, k_s is the rate constant of the scavenging reaction ($M^{-1}s^{-1}$), C_s is the scavenger concentration, i_p is the photocurrent, and i_{ps} is the saturation photocurrent for $C_s \rightarrow \infty$. In the derivation of [1] it is assumed that hydrated electrons move only by diffusion and that their motion is uninfluenced by the field in the diffuse double layer. Strictly i_p and i_{ps} refer to 1 cm² of electrode surface.

The aperiodic equivalent electrical circuit for this model is the one shown in Fig. 4a. The diffusion of e^-_{aq} in the region $x > 0$ is represented by the motion of charge along a resistive transmission line (12) (no inductance) with constant series resistance R_{tl} and shunt capacity C_{tl} per unit length, and the homogeneous capture of hydrated electrons is allowed for by uniformly distributing shunt resistance R_s along the line for $x > \delta$. The deposition of e^-_{aq} is represented by an infinite impedance current generator of magnitude i_{ps} at $x = \delta$, and the photocurrent i_p is the difference between i_{ps} and the current at $x = 0$. The short circuit at this point implies diffusion-controlled capture of electrons by the electrode.

$$R_{tl} = \theta/D_e, C_{tl} = 1/\theta, \text{ and } R_s = \theta/k_sC_s \quad [2], [3], \text{ and } [4]$$

where θ is arbitrarily chosen (it is connected with the equivalence of voltage and hydrated electron concentration) and has the dimensions ohm cm sec^{-1} if the circuit refers to 1 cm² of electrode surface.

In the rapidly attained steady state (see later section) for constant i_{ps} the shunt capacity is of no importance and looking to the right the impedance at $x = \delta$ equals $(R_{tl}R_s)^{1/2}$. The circuit thus reduces to

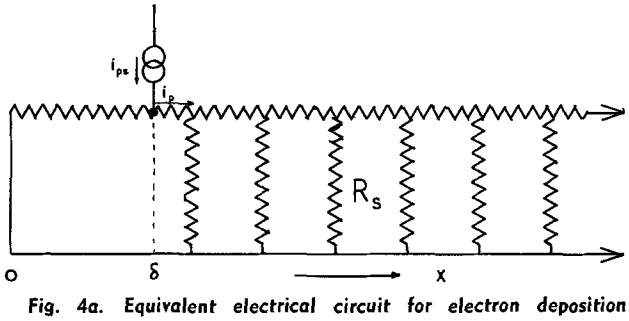

Fig. 4a. Equivalent electrical circuit for electron deposition model: exact circuit.

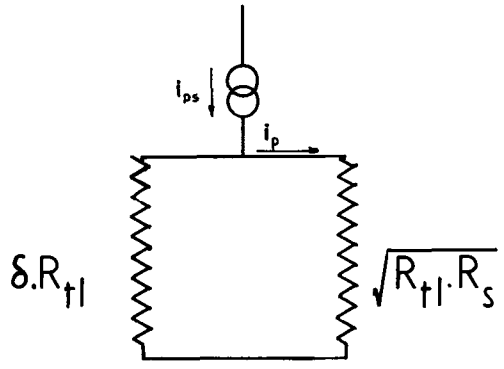

Fig. 4b. Equivalent electrical circuit for electron deposition model: reduced form for constant light intensity.

the one in Fig. 4b. The injected current i_{ps} is now partitioned between two resistors of value $R_{tl}\delta$ and $(R_{tl}R_s)^{1/2}$ and Eq. [1] readily follows.

If it cannot be assumed that every encounter of a hydrated electron with the electrode results in transfer to the electrode the short circuit at $x = 0$ is replaced by a resistance $R_e = \theta/k_e$, where k_e (cm sec^{-1}) is the electron transfer rate constant (the apparent rate constant if dissociation of e^-_{aq} precedes transfer and is the rate-controlling step). In this case

$$i_p/i_{ps} = Q\delta'/(1 + Q\delta') \qquad [5]^3$$

where $\delta' = \delta + D_e/k_e$. Thus the apparent range prior to hydration is increased by D_e/k_e and the δ values given later could possibly be attributed to a value for k_e of the order of 10^2 cm sec^{-1}.

Distributed Deposition of Charge

To estimate the effect of distributed charge deposition and to take account of scavenging in the region in which hydrated electrons are formed, it is necessary first to derive an expression for the photocurrent produced by deposition at the plane x^1 when the scavenger concentration is uniform for $x > 0$. The equivalent circuit for zero electron concentration at $x = 0$ takes the form shown in Fig. 5. The semi-infinite line used previously is replaced by an infinite line with the same electrical characteristics, and zero concentration at $x = 0$ is obtained by placing at $-x^1$ a negative image of the current source at x^1. The photocurrent di_p is the difference between the current di_{ps} deposited at x and the current flowing at $x = 0$, and

$$di_p = di_{ps}\,(1 - \exp\text{-}Qx) \qquad [6]$$

Thus, if the rate of deposition of charge is $F(x)$

$$i_p/i_{ps} = \int_0^\infty (1 - \exp\text{-}Qx)F(x)\,dx / \int_0^\infty F(x)\,dx \qquad [7]$$

As yet the form of $F(x)$ is unknown and only two special cases will be considered.

(*i*) $F(x) = A(2\delta - x)$ for $0 < x < 2\delta$ and 0 for $x > 2\delta$, A being a constant. This might be approximately

[3] Equation [5] holds for scavenging of other entities produced by radiation (H atoms excited H_2O molecular) after appropriate changes in parameters.

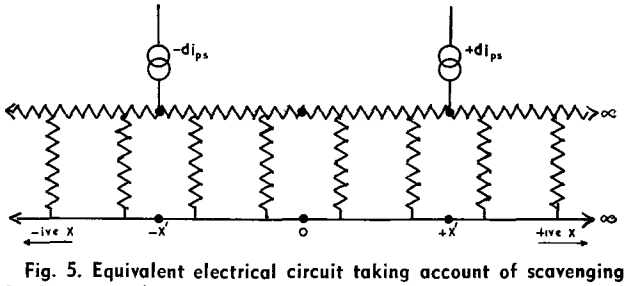

Fig. 5. Equivalent electrical circuit taking account of scavenging for $0 < x < \delta$.

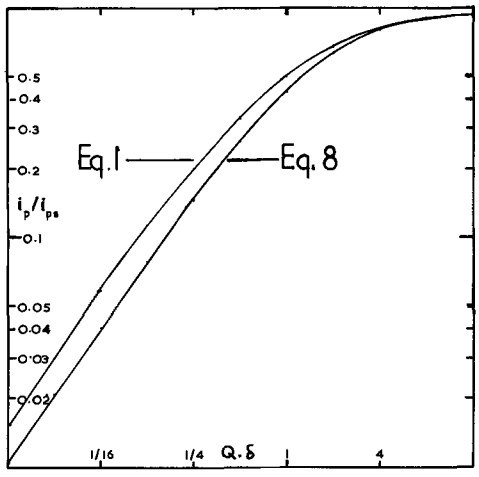

Fig. 6. Dependence of i_p/i_{ps} on $Q\delta$

applicable when unfiltered polychromatic light from a high-pressure mercury arc or from a flash source is used. Equation [7] leads to

$$i_p/i_{ps} = 1 - \tfrac{1}{2}Q^{-2}\delta^{-2}\exp\text{-}2Q + \tfrac{1}{2}\delta^{-2}Q^{-2} - \delta^{-1}Q^{-1} \qquad [8]$$

Figure 6 shows that the variation of i_p/i_{ps} with $Q\delta$ predicted by this equation is similar to that given by Eq. [1].

(*ii*) $F(x) = A\exp\text{-}x/\delta$. This case arises if the hydration of thermal electrons is a slow process. Using Eq. [7] it follows that i_p/i_{ps} is given by Eq. [1]. Without exact knowledge of $F(x)$ there must be uncertainty about the variation of i_p at high C_s and, of course, i_{ps} cannot be readily determined. However, the order of magnitude of the apparent range prior to

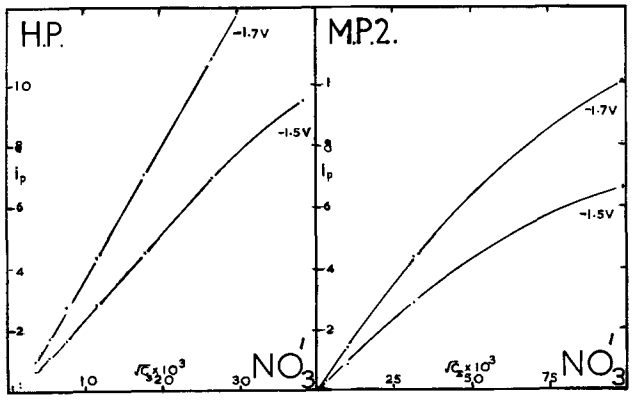

Fig. 7a and b. Dependence of i_p on $C_s^{1/2}$:KNO_3 in 1M KCl

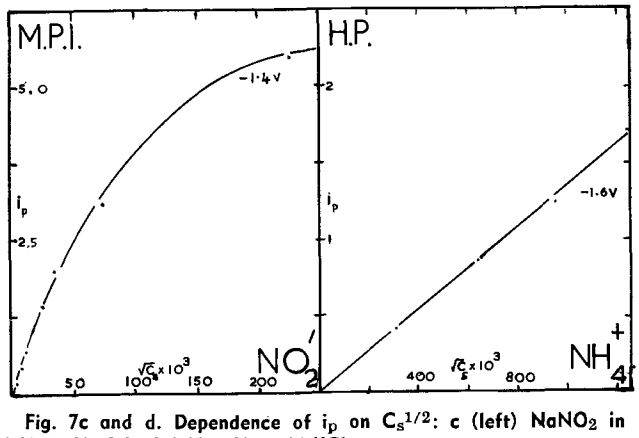

Fig. 7c and d. Dependence of i_p on $C_s^{1/2}$: c (left) $NaNO_2$ in 0.2M KCl; d (right) NH_4Cl in 1M KCl.

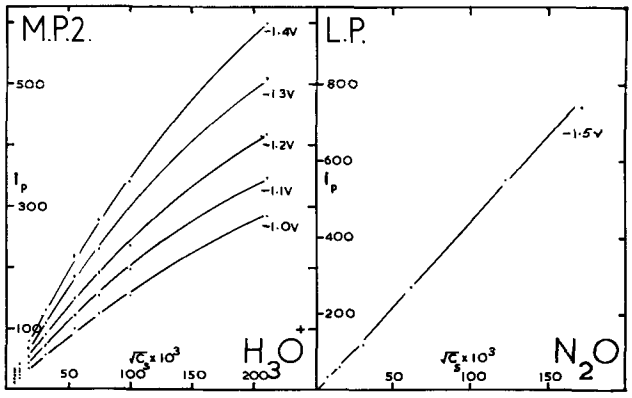

Fig. 8. Dependence of i_p on $C_s^{1/2}$: a (left) $HClO_4$ in 1M KCl; b (right) N_2O in 0.2M KCl.

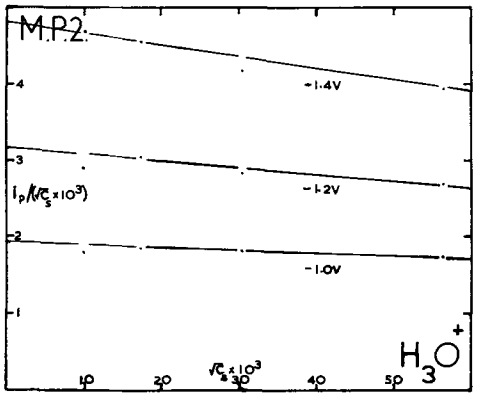

Fig. 9. Variation of i_p $C_s^{-1/2}$ with $C_s^{1/2}$

hydration probably can be estimated using Eq. [1] or [8].

There is no uncertainty about the variation of i_p when C_s is small. Provided that the light intensity is not so large as to cause depletion of the solution, and that due allowance is made for competing scavenging by impurities and by the solvent, it is to be expected that i_p at low C_s will be proportional to $C^{1/2}$. This expectation has been confirmed by us (1) and by Delahay (3) and it is well borne out by the graphs in Fig. 7 and 8.[4] In the NH_4^+ case the linearity is maintained to the highest concentration as k_s in this case is unusually small. In other cases (H_3O^+, NO_3^-, NO_2^-) some departure from linearity is observed at high scavenger concentration which cannot in the H_3O^+ case be attributed to light absorption, although this is a contributory factor with NO_3^- and NO_2^-. Only the experimental data for H_3O^+ are suitable for the evaluation of δ. For localized deposition and the two types of distributed deposition considered earlier i_p/i_{ps} can be written in the approximate form

$$i_p/i_{ps} \cong AQ\delta(1 - BQ\delta) \qquad [9]$$

Thus a plot of $i_p/C_s^{1/2}$ against $C_s^{1/2}$ should be linear up to moderately large values of $Q\delta$ with a slope ABi_{ps} $\delta^2 k_s/D_e$. If Eq. [1] is used $AB = 1$, while Eq. [8] leads to a value for AB of 1/3. Three such plots based on the H_3O^+ data are given in Fig. 9. The slopes lead to values for δ of 34, 41, and 48Å, respectively, at the potentials —1.0, —1.2, and —1.4v *vs.* SCE if $AB = 1$, and to values larger by the factor $3^{1/2}$ if $AB = 1/3$. A value for k_s of 1.4 10^{10} M^{-1} sec^{-1} is here assumed, and i_{ps} is obtained by extrapolation.

It is to be expected that δ will increase as the potential becomes more negative if during the thermalizing process the electrons travel an appreciable distance. Slow hydration after very rapid thermalizing should not lead to a dependence of δ on potential if the

[4] All potentials refer to SCE.

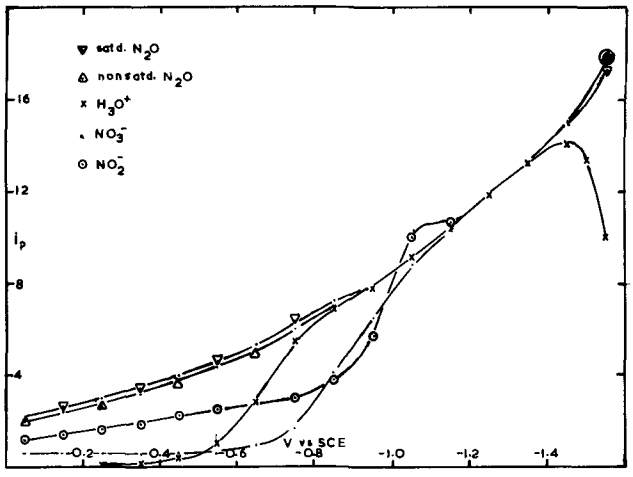

Fig. 10. i_p curves for various scavengers in 0.2M KCl normalized at —1.3v, 2537Å radiation.

transfer of electrons back to the electrode is a diffusion controlled process. It is doubtful whether the experimental data are sufficiently precise for the above potential dependence of δ to be regarded as significant. However, evidence for such a dependence is also provided by measurements of i_p/i_{ps} using a high and a low value of C_s. For H_3O^+ this current ratio increases by 18 ± 5% when the potential is changed from —1.0 to —1.4v *vs.* SCE. A similar but slightly smaller increase has been found for N_2O in 0.2M KCl. These results suggest that the rather long range of the electrons prior to hydration cannot be entirely attributed to slow hydration of thermal electrons.

Dependence of i_p on Potential and Nature of Scavenger

Photocurrents are observed with many inorganic and organic scavengers, but it is profitable, when considering evidence for electron emission, to give most attention to simple systems in which there is no strong adsorption of the scavenger at the interface and which are relatively free from complications introduced by homogeneous or heterogeneous photolysis of the scavenger. Thus in the present paper only experimental results for scavenging by N_2O, H_3O^+, NO_3^-, NO_2^- and by the ions of Cd, Zn, and Ni are considered in any detail. Even some of these systems turn out to be quite involved.

Although polychromatic light is often entirely satisfactory for comparative measurements of i_p at low C_s using different scavengers, it is generally desirable in studies of the potential dependence to use either monochromatic light of wavelength below 3000Å or at least polychromatic light (line or continuum) containing no wavelengths longer than 3000Å. These desiderata were not fully appreciated in our early work and effects to be observed with light of short wavelength were sometimes partly masked.

In Fig. 10 are plotted photocurrent curves for various scavengers in 0.2M KCl. The curves are normalized at —1.3v *vs.* SCE; 2537Å radiation was used, the scavenger concentration was 10^{-3}M and 0.2M KCl was used to avoid light absorption by mercurous ions (the solubility of Hg_2Cl_2 increases as the Cl^- concentration increases). An important feature of the curves is their tendency to coalesce at values of the potential more negative than —1.2v *vs.* SCE. The fall in i_p in the H_3O^+ case at potentials more negative than —1.5v is, of course, due to the fall in scavenger concentration at the electrode surface connected with the onset of the h.e.r. This coalescence points to a common factor which we believe to be electron emission followed by scavenging of hydrated electrons.

At more positive potentials the behavior is more complex. Only with N_2O does i_p increase smoothly as

the potential becomes more negative. With H_3O^+ hardly any photocurrent is observed until the potential reaches —0.45v *vs.* SCE. Shortly after this potential the current rises rapidly and the curve then merges into the N_2O curve. With NO_3^- as the scavenger a small current is observed at the most positive potential which can be used. This current at first changes only slowly as the potential becomes more negative, but in the vicinity of —0.8v *vs.* SCE the i_p curve rises fairly rapidly to join the N_2O curve. NO_2^- behaves in yet another way. An appreciable current roughly equal to half the normalized current for N_2O is observed at potentials positive with respect to —1.0v but i_p increases rapidly at about —1.0v and the current curve slightly overshoots the N_2O curve before joining it at still more negative values of the potential. These peculiar but not unexpected effects can be attributed to reactions involving the unstable products of the scavenging reactions. Only in the case of N_2O do such reactions not influence the shape of the i_p/E curve although electron scavenging in this case is followed by homogeneous and heterogeneous reactions.

If the entity S^- formed by electron capture is stable in solution (possibly only because second order reactions of S^- in pairs are unimportant due to the low concentration) it may be oxidized by the electrode and the captured electron, if this happens, is returned to the electrode. In such circumstances i_p clearly will be small. Thus the rather rapid increase in the H_3O^+ photocurrent might be attributed to the cessation of the oxidation of either H atoms formed by electron capture or H_2^+ ions formed heterogeneously at the electrode surface [homogeneous formation is too slow (13) a process to account for suppression of i_p at small values of elapsed time]. Examination of the rising part of the curve shows that it resembles in shape a polarographic wave for an irreversible reduction, rising from 10-90% of its "limiting" value in a potential interval of about 200 mv. This is consistent with a totally irreversible oxidation process involving 1 electron and having an α value of about 0.5. However, the position of the "wave" seems to be not markedly temperature dependent, a fact which is possibly not consistent with a high degree of irreversibility. As some results considered later suggest that i_p for H_3O^+ at more negative potentials is partly due to the participation of H atoms (formed in the scavenging reaction) in the atom-ion reaction[5]

$$H + H_3O^+ + e \rightarrow H_2 + H_2O \quad \text{(irreversible c.t.r.)} \quad [e]$$

it is possible that the rapid rise in i_p is due to competition between this reaction and the oxidation reaction

$$H_2O + H \rightarrow H_3O^+ + e \quad \text{(irreversible c.t.r.)} \quad [f]$$

If the rates of both reactions are similarly influenced by temperature, the "half-wave" potential will be insensitive to changes in temperature.

Speculative explanations for the behavior of NO_3^- and NO_2^- can also be advanced. In the NO_3^- case the half-life of NO_3^{2-} may be sufficiently long to permit oxidation of it at the electrode surface when the potential is more positive than —1.0v *vs.* SCE. At more negative potentials this oxidation ceases and NO_3^{2-} is removed by

$$NO_3^{2-} + H_2O \rightarrow NO_2^- + OH + OH^- \quad \text{(homogeneous)} \quad [g]$$

The OH radicals are then directly or indirectly reduced by the electrode and hence the capture of one electron leads, when the potential is very negative, to the permanent loss of 2 electrons by the electrode. The small current observed at the most positive potential which can be employed with 0.2M KCl might be due to incomplete oxidation (see next section) of NO_3^{2-} or even to scavenging of H atoms formed by the radiation. In this connection it should be noted that the H atom scavenging reaction is presumably

$$H + NO_3^- \rightarrow NO_2 + OH^- \quad \text{(homogeneous)} \quad (h)$$

and if the reduction of NO_2 is a rapid charge transfer reaction

$$NO_2 + e \rightarrow NO_2^- \quad \text{(c.t.r.)} \quad [i]$$

the small contribution of the H atoms to the photocurrent might conceivably change only slowly with potential.

In the NO_2^- case the variation of i_p with potential is similar to the d-c polarogram for NO in a buffered solution of *p*H 7. The latter exhibits a large step following a small slowly rising wave, and the half-wave potential for the large step is roughly coincident with the rapid increase in the photocurrent. Also, if the solution is made strongly alkaline, the large step in the polarogram vanishes and so does the greater part of the step in the photocurrent curve. Thus it is likely that these two steps are due to the same electrode reaction. Presumably NO_2^{2-} is formed by electron capture in the photocurrent case and this unstable entity is possibly rapidly converted to NO

$$NO_2^{2-} + H_2O \rightarrow NO + 2OH^- \quad \text{(homogeneous)} \quad [j]$$

The NO then tends to be reduced at the electrode surface, but the polarographic experiments suggest that this reaction is slow, and little therefore of the NO formed would actually be reduced during the small time between the increase in light intensity and the current measuring time. Thus at potentials positive with respect to the sudden rise in i_p the photocurrent probably is roughly equal to the rate of capture of hydrated electrons. What happens at more negative potentials is less certain but the sudden increase in i_p, we believe, is initiated by a sudden change in the mechanism by which NO is reduced at the electrode surface. At more negative potentials than —1.0v *vs.* SCE it seems likely that reaction (j) may be followed by

$$NO + e \rightarrow NO^- \quad \text{(c.t.r.)} \quad [k]$$

and that NO^- (possibly after conversion to HNO) may be further reduced. In strongly alkaline solution (1M NaOH) the situation is clearer as polarographic experiments suggest that the reduction of NO then stops at NO^- and thus the capture of a hydrated electron by NO_2^- in strongly alkaline solution presumably leads to the permanent loss by the electrode of 2 electrons if the potential is very negative.

From the above discussion it is evident that the capture of a hydrated electron does not generally result in the permanent loss of 1 electron by the electrode. It is thus necessary to introduce a type of stoichiometric number which we shall term the electron transfer number v_s. This number, which may not in all cases be an integer, is defined as the number of electrons permanently lost by the electrode as a result of the capture of a hydrated electron in the solution. Thus the saturation current i_{ps} is the product of v_s and i_d, the rate of deposition of charge in the solution. The value of v_s may change in the presence of other scavengers and in what follows the superscript o is used to indicate the absence of other scavengers. A knowledge of v_s^o for different scavengers is often vital for the evaluation of rate constants from photocurrent data.

Electron Scavenging Followed by Oxidation of Reaction Product

The approximate equivalent electrical circuit (1 cm^2 of interface) for the case in which the product S^- of the scavenging reaction is stable as regards reaction with the solvent, and with any solute present, but is oxidized by a heterogeneous charge transfer process

[5] Or in the related reaction where the H_3O^+ is replaced by a water molecule, *i.e.*

$$H + H_2O + e \rightarrow H_2 + OH^-$$

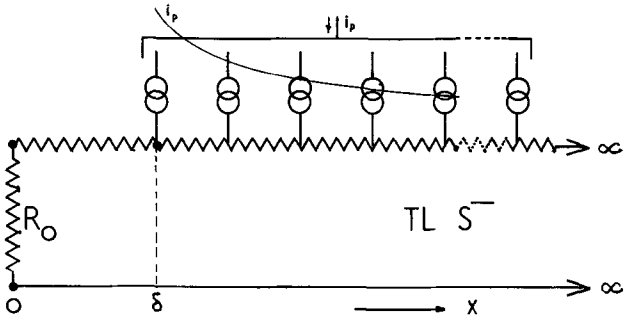

Fig. 11. Equivalent circuit taking account of oxidation of S^-

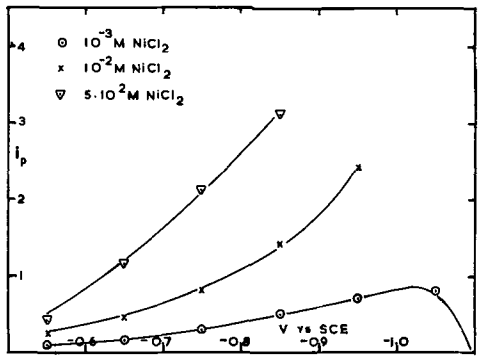

Fig. 12. Photocurrent observed with 0.2M KCl containing $NiCl_2$; polychromatic light.

involving only 1 electron, is the one shown in Fig. 11. The formation of S^- in the solution is represented by a vast number of current generators distributed along the length of a semi-infinite resistive transmission line connected with the linear diffusion of S^-. A resistance R_o linking the input terminals ($x = 0$) of the line takes account of the finite rate of oxidation of S^- at the electrode surface. The various electrical components are defined by

$$R_{tl} = \theta/D_{S-},\ C_{tl} = \theta^{-1},\ R_o = \theta/k_o \quad [10],\ [11],\ [12]$$

where k_o is the rate constant of the charge transfer process and D_{S-} is the diffusion coefficient of S^-. Using the localized electron deposition model the current generators supply current per unit length equal to $i_p\, Q \exp -Q(x-\delta)$ for $x > \delta$ where i_p is the photocurrent which would be observed if S^- were not oxidized. The actual photocurrent i_p^o is the difference between the total injected current and the current flowing through R_o. For large values of elapsed time a generator di_p at x gives rise to a photocurrent di_p^o given approximately by

$$di_p^o = di_p(x + D_{S-}/k_o)\,(\pi D_{S-}t)^{-1/2} \quad [13]$$

where t is the elapsed time since the application of the current di_p (*i.e.*, since the start of irradiation). It readily follows that the total observed photocurrent i_p^o is given approximately by

$$i_p^o = i_p(Q^{-1} + \delta + D_{S-}/k_o)\,(\pi D_{S-}t)^{-1/2} \quad [14]$$

if (*a*) the light intensity (alternatively the increase in light intensity) is constant for $t > 0$, (*b*) i_p is appreciably smaller than i_{ps}.

If $k_o \to \infty$ the photocurrent, which is connected solely with the diffusion of S^- away from the electrode, is small and relatively independent of C_s. Inserting typical values for the parameters ($D_{S-} = 10^{-5}$ cm^2 sec^{-1}, $k_s = 2\ 10^{10}$ M^{-1} sec^{-1} $C_s = 10^{-3}$M) it is found that $i_p^o/i_p \cong 5\ 10^{-4}\ t^{-1/2}$. In our experimental work with light from mercury discharges t has not usually been smaller than $2\ 10^{-3}$ sec, and hence any photocurrent produced by ions such as Cd(II) or Zn(II) should have been quite small. Experiment (MP1) showed that with these ions at concentrations up to 10^{-3}M i_p^o/i_p was not larger than 0.03 (taking for i_p one half of the H_3O^+ i_p for the same concentration of H_3O^+). This somewhat negative result is not inconsistent with electron capture followed by oxidation of S^-, but it clearly is desirable to repeat these experiments with more sensitive apparatus.

With 0.2M KCl containing Ni^{2+} or Mn^{2+} measurable photocurrents were observed up to the potentials at which reduction of the scavenger occurred. The results (MP.1) for Ni^{2+} are given in Fig. 12. At constant potential the photocurrent is roughly proportional to $C_s^{1/2}$ and as pulsed radiolysis (15) has shown that k_s for scavenging of e_{aq}^- by Ni^{2+} corresponds to diffusion control, it is conceivable that the photocurrent is due to slow oxidation of Ni^+ at the electrode surface. If the experimental data are fed into Eq. [14] it is found that k_o only increases slowly as the potential becomes more positive and has a value of the order of 0.25 cm sec^{-1} at -0.8v *vs.* SCE electrode. It is, however, doubtful whether this interpretation of the results is correct. It can be envisaged that electron capture sometimes may not lead instantaneously to the formation of S^- but rather to the formation of a type of ion pair e_{aq}^- S, the formation of S^- from the ion pair being an appreciably slower process than electron capture. So far no evidence for such a mechanism has been revealed by photocurrent studies using many different scavengers. This mechanism tends to destroy the linear relation between i_p and $C_s^{1/2}$ as the average life of the "ion pair" is dependent on its average distance from the electrode at the time it is formed, which increases as C_s diminishes (it is here assumed that encounters of "ion pairs" with the electrode will lead to rapid electron transfer to the electrode). It seems possible, however, that the Ni^{2+} photocurrent may be due to rapid reaction of a small fraction of the excited Ni^+ ions formed by electron capture with water molecules

$$Ni^{+*} + H_2O \to Ni^{2+} + H + OH' \quad \text{(homogeneous)} \quad [l]$$

the remainder being de-excited in other ways and oxidized by the electrode. This hypothetical photocurrent mechanism leads to the observed dependence of i_p on C_s.[6]

The photocurrent observed with Mn^{2+} is slightly smaller and can be similarly interpreted in at least two ways. Clearly all these systems require further study, but this is not a task to be lightly undertaken, especially in the case of ions of metals such as Pb, Tl, Cd, In, Cu, and Zn, because of the small value of i_p^o and the occurrence of apparent photocurrents due simply to heating of the interface by the absorbed radiation. With unfiltered light from a flash source or a high pressure mercury arc, i_{ph}, the heating current connected with the temperature coefficient of the double layer charge density, when largest is of the same order of magnitude as the residual photocurrent at the most negative potential in the absence of added scavenger.

Residual Photocurrent

The hydrated electron has a finite life in water and in dilute electrolyte solutions of pH < 9, decaying by the reaction

$$e_{aq}^- + H_2O \to H + OH^- \quad \text{(homogeneous)} \quad [m]$$

Early pulsed radiolysis experiments indicated a half-life of the order of 50 μsec, but more recent work (16) using lower electron concentrations and water stored in silica or polythene has given a value close to 500 μsec. Treating the decay reaction as a scavenging reaction the product k_sC_s has a value of about $2\ 10^3$ sec^{-1}, and a residual photocurrent is to be expected

[6] Yet another explanation would be that on arrival at the interface some of the Ni^+ ions are reduced although a substantial fraction are oxidized.

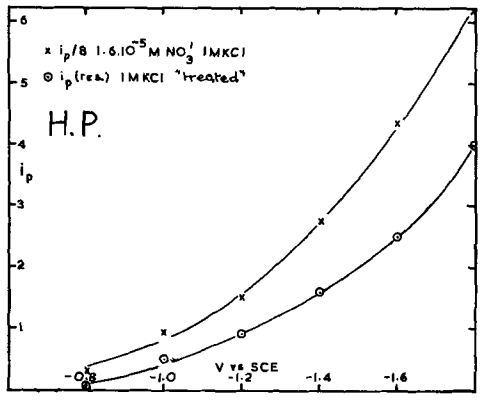

Fig. 13. Photocurrent produced by NO_3^- and the corresponding residual photocurrent.

which should be about 300 times smaller than $i_{ps}(v_s = 1)$.

The residual current has been studied using various light sources. The HP data are possibly the most reliable as greatest care was then taken in the preparation of solutions and also the measured currents then greatly exceeded the noise level of the SWP. Figure 13 shows the potential dependence of residual current with the measurement time interval adjusted to make the measurements insensitive to i_{ph} (the heating photocurrent). A scaled down i_p curve for NO_3^- ($1.6\ 10^{-5}$M) obtained under identical conditions is included in the figure, and it will be seen that the two currents vary in much the same way with potential. C_e^0, the electron concentration at the hypothetical deposition plane calculated using NO_3^- data, a value of $k_{NO_3^-}$ assumed later, and the equation

$$i_p = FC_e^0(k_sC_sD_e)^{1/2} \quad (1) \qquad [15]$$

did not exceed 10^{-11} mole cm^{-3} in these experiments and consequently removal of e_{aq}^- by the diffusion controlled second order reaction [17]

$$e_{aq}^- + e_{aq}^- \rightarrow H_2 + 2\ OH^- \quad \text{(homogeneous)} \quad [n]$$

was not of importance.

Calculations of the electron half-life based on the relative magnitudes of the residual and NO_3^- photocurrents (assuming $v_s = 1$ for the residual current) yielded values in the range 100-200 μsec for 1M solutions of KCl, Na_2CO_3, and Na_2SO_4 (solutions which were first made 10^{-2}M in SO_3^{2-}, irradiated with light from a high-pressure mercury lamp, oxygenated to destroy SO_3^{2-}, deoxygenated and irradiated to destroy H_2O_2). This treatment destroys impurities such as NO_3^-, NO_2^- but generally it did not reduce the residual i_p by more than a factor of 3. The *p*H after treatment was ~9 for the Cl^- and SO_4^{2-} solutions.

The slight discrepancy between the half-life deduced from the residual current and that now accepted by radiation chemists cannot be attributed to impurities in our solutions that are reduced at potentials more positive than −1.6v *vs.* SCE.

It is possible that the half-life may decrease in relatively concentrated electrolyte solutions. It has been suggested that there is some slight tendency for ion pair formation between inert cations at high concentration and hydrated electrons (18). Accelerated decay thus might be connected with the scavenging by protons produced by field dissociation of water molecules lying between the electron and the cation.

Time Dependence of the Photocurrent

As few experimental studies have been made of the time dependence of i_p it would be inappropriate to discuss this dependence at length, but it is important to show that the results so far obtained do not clash with the electron emission mechanism. Adopting once more the localized deposition model it follows from the solution of a closely related problem in heat conduction (19) (involving radiation from a semi-infinite rod with appropriate initial and boundary conditions) that for irradiation of constant intensity starting at $t = 0$

$$i_p/i_{ps} \cong Q\delta\ (1 - Q\delta)^{-1}\ [(\pi C_sk_st)^{-1/2} \exp - k_sC_st + \text{erf}\ (k_sC_st)^{1/2}] \qquad [16]$$

if i_p is appreciably smaller than i_{ps} and $t >> \delta^2/D_e$. It is assumed that $v_s = 1$. For small values of t, i_p tends to be large but a pseudosteady state is rapidly established, the current for $t = 2(k_sC_s)^{-1}$ being only 5% larger than the steady-state value. For diffusion-controlled scavenging ($k_s = 2\ 10^{10}$M^{-1} sec^{-1}) and a typical scavenger concentration (10^{-4}M) the steady state is virtually attained in 1 μsec.

Studies have been made (HP) of the variation of i_p with elapsed time using square wave modulated light and 1M KCl containing H_3O^+ at concentrations between 10^{-4}M and 1M. No variation was observed for values of t between the minimum value imposed by the SWP (~500 μsec) and the maximum value (~2.5 msec). More recently the i_p waveform at substantially constant potential for filtered (3200-3800Å) light produced by the flash source has been studied oscilloscopically. With 0.2M KCl solutions containing H_3O^+ at concentrations from 10^{-4}M upwards the waveform shape was independent of C_s and at all times it appeared to be almost identical with that observed when a uv vacuum photocell was irradiated. Even the residual current waveform at potentials where this current is largest, although slightly affected by a current connected with heating of the electrode-solution interface, was similar in shape to the light waveform.

In the case of the H_3O^+ photocurrent it is believed that at $E < -1.0$v *vs.* SCE $v_s = 2$. The results of the experiments with the flash source indicate that for steady illumination the current associated with the transfer of the second electron would attain a constant value in a time not greater than 100 μsec for H_3O^+ concentrations above 10^{-4}M. H atoms formed homogeneously have only a short distance to travel to arrive at the electrode and, although some must inevitably diffuse away from the electrode, the fraction so doing for values of the elapsed time greater than 100 μsec is small if the reduction of H_3O^+ ions by reaction (*e*) is a rapid process. There should however, be some slight variation in i_p for very small values of elapsed time. As yet our experimental techniques have not permitted a search for this second order effect.

Influence of Ionic Strength

Thus far the influence of the nature and concentration of the inert supporting electrolyte has not been considered and it has been implicitly assumed that the diffuse double layer field is insufficiently large to influence the motion of hydrated electrons. Studies of the influence of this field when it is large are of considerable diagnostic importance. Clearly the motion of electrons will be affected in much the same way as the motion of charged reactants and the diffusion problem is closely related to the dynamic Ψ effect which has been studied theoretically by many workers (20). A relatively simple approach is outlined below.

In the absence of a scavenger the diffusion equation when Ψ, the potential relative to the bulk of the solution, is time invariant is

$$\partial C_e/\partial t = D_e\ \partial/\partial x\ [\partial C_e/\partial x - FC_e/RT \cdot d\Psi/dx] \qquad [17]$$

A term must be added to the right-hand side when a scavenger is present, and since the system is at equilibrium as regards the spatial variation of C_s, this is $-k_sC_sC_e \exp(-z_s\Psi F/RT)$, where C_e is the hy-

drated electron concentration (mole cm^{-3}) and z_s is the number of positive charges carried by the scavenger. The complete equation is

$$\partial C_e/\partial t = D_e\,\partial/\partial x\,[\partial C_e/\partial x - (FC_e/RT)\,d\Psi/dx] - k_s C_s C_e \exp(-z_s\Psi F/RT) \quad [18]$$

After making the substitution $V = C_e \exp(-\Psi F/RT)$ this equation can be written in the form

$$\partial V/\partial t = \exp(-\Psi F/RT)\,\partial/\partial x\,[D_e \exp(+\Psi F/RT)\,\partial V/\partial x] - k_s C_s V \exp(-z_s\Psi F/RT) \quad [19]$$

This is the equation for the motion of charge along a resistive transmission line with nonuniform series resistance, nonuniform shunt capacity, and nonuniform shunt resistance; R_{tl}, C_{tl}, and R_s are defined by

$$R_{tl} = \theta/D_e \exp -\Psi F/RT \quad [20]$$

$$C_{tl} = \theta^{-1} \exp \Psi F/RT \quad [21]$$

$$R_s = \theta(k_s C_s)^{-1} \exp(z_s - 1)\,\Psi F/RT \quad [22]$$

Thus it follows that for localized deposition the equivalent electrical circuit is the one shown in Fig. 14, if it is assumed that the heterogeneous rate constant for the transfer of electrons from the solution to the electrode is infinite. The only important differences between this circuit and the one in Fig. 4a are that the resistance per unit length at any point is increased by the factor $\exp -\Psi F/RT$ where Ψ is the potential at the corresponding plane in the solution, and that the electron concentration is now proportional to the product of V, the line voltage, and $\exp \Psi F/RT$ instead of being proportional to V.

For very low $k_s C_s$ it is evident from the circuit that the diffuse double layer field increases the stationary concentration of e^-_{aq} at $x = \delta$ and, hence i_p, by the factor

$$\phi = \delta^{-1} \int_0^\delta \exp -\Psi F/RT \cdot dx \quad [23]$$

Further, for a 1:1 supporting electrolyte and a value of δ appreciably larger than the half-thickness of the diffuse double layer, on writing ϕ in the form

$$\phi = 1 + \delta^{-1} \int_0^\delta (\exp -\Psi F/RT - 1)\,dx \quad [24]$$

we see that the factor reduces to

$$\phi = 1 + \Gamma_+/C_{se}\delta \quad [25]$$

where Γ_+ is the surface excess (mole cm^{-2}) of the univalent cations of supporting electrolyte and C_{se} is the electrolyte concentration (mole cm^{-3}). Thus with a 10^{-2}M solution ϕ is of the order of 40 when the potential is very negative with respect to E_{ecm} if δ = 40Å. In practice the increase in i_p is considerably smaller, but this is not unexpected for reasons mentioned below.

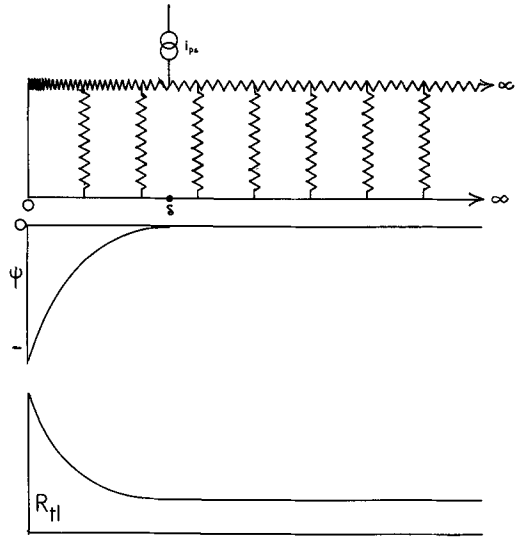

Fig. 14. Influence of the double layer field on the equivalent circuit when deposition is localized.

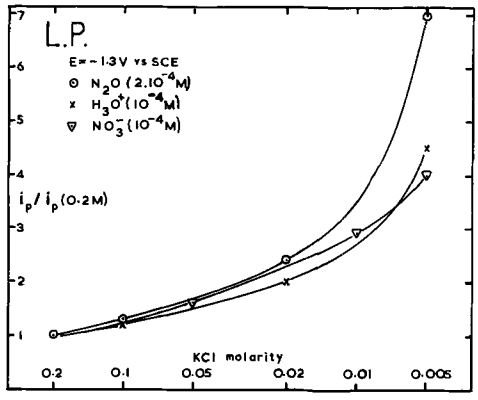

Fig. 15. Influence of ionic strength on i_p

In Fig. 15 are given the results of some preliminary studies of the influence of ionic strength on i_p for three scavengers (H_3O^+, N_2O, and NO_3^-). The data refer to KCl solutions and 2537Å light and undesirably high scavenger concentrations had to be employed ($1\text{-}2.10^{-4}$M). The figure shows that the ratio of i_p to i_p for the same scavenger concentration in 0.2M KCl increases as the ionic strength falls, the variation being roughly the same for each of the three scavengers. These results suggest that the photocurrent is caused partly, if not entirely, by a diffusing negatively charged entity.

A detailed comparison with theory will not be made for several reasons. First because the equivalent circuit in Fig. 14 becomes inexact if there is slight ion pair formation between the cations of the supporting electrolyte and the hydrated electrons. The effect of the diffuse double layer field is then reduced. An alternative circuit taking account of ion pair formation can be written down immediately, but such a circuit is of no immediate value as no quantitative information about ion pair formation is available and absolutely nothing is known about the effect of slight dielectric saturation in the double layer region on pair formation. The second and most important reason is concerned with discreteness of charge in the diffuse double layer. Due to random motion of ions in the double layer *it seems* inevitable that the average velocity of translation of a charged particle through the layer will be considerably larger than that predicted by classical theories of the layer. What is needed to make a comparison between theory and experiment is the time average of $\exp -\Psi F/RT$ while all that is currently available is $\exp -\bar{\Psi}F/RT$ where $\bar{\Psi}$ is the time average of Ψ. The final and less compelling reason is that due allowance must be made for distributed deposition of charge. In principle the single current generator in Fig. 14 should be replaced by an infinite number of generators distributed along the line.

A marked increase in residual photocurrent with decreasing ionic strength for 1:1 electrolytes was first observed by Heyrovsky (3a). A change in concentration from 0.1 to 10^{-3}M produced a tenfold increase. We have recently observed a fourfold increase with KCl solutions on reducing the concentration from 0.2 to 2 10^{-3}M. Such changes are to be expected as the stationary electron concentration in the solution outside the double layer rises as the ionic strength falls and a larger fraction of the deposited hydrated electrons decay in the solution (or react with trace impurities). Heyrovsky found that the effect became progressively smaller as the cationic charge increased. This is qualitatively predicted by theory since for

constant double layer charge the integral $\int_0^s \exp - \Psi F/RT$ decreases as the cationic charge increases.

Slow Heterogeneous Oxidation of the Hydrated Electron

It was indicated earlier that the possibility of slow direct transfer of electrons from the solution to the electrode cannot be ruled out *a priori*. Taking slow transfer into account the equivalent circuit in Fig. 14 has to be modified. The short circuit at $x = 0$ is replaced by a resistance R_e' defined by $R_e' = \theta/k_e \exp - \Psi^o F/RT$ where k_e is the heterogeneous rate constant for the transfer of electrons from hydrated electrons at the interface to the electrode. Clearly the introduction of this resistance will tend to make the photocurrent for constant C_s much more sensitive to ionic strength. The experimental facts seem to rule out the possibility of slow direct transfer (coupled possibly with direct formation of e^-_{aq}) as the main path for electron transfer from the solution to the electrode.

There remains the possibility that direct transfer of an electron from e^-_{aq} to the electrode may be a moderately slow process ($K_e < 10$ cm sec^{-1}) and that transfer to the electrode is preceded by the dissociation reaction

$$e^-_{aq} \underset{k_r}{\overset{k_d}{\rightleftharpoons}} e^- + H_2O \qquad [o]$$

Making use of standard diffusion theory for a chemical reaction followed by a fast charge transfer reaction, and assuming an infinite rate constant for the latter reaction, the apparent heterogeneous rate constant for electron transfer is $k_d\ (D_e'/k_r)^{1/2}$ and the reaction layer thickness is $(D_e'/k_r)^{1/2}$, where D_e' is the diffusion coefficient of a free thermal electron. To account for the rather slow variation in the photocurrent with ionic strength the reaction layer thickness would have to be somewhat larger than the half-thickness of the diffuse double layer for 5 10^{-3}M KCl solution. Assuming a value for the reaction layer thickness of the order of 50Å, and a value for D_e' of 10^{-1} cm^2 sec^{-1}, a value for k_r of the order of 4 10^{11} sec^{-1} (pseudo-first order rate constant) is obtained. Such a value would mean that thermal electrons travel some distance before becoming hydrated.

The equivalent circuit for this system ($v_s = 1$) takes the form shown in Fig. 16 if the influence of the double layer field is neglected. The deposition of thermal electrons in the solution is represented by distributed current generators, but these now supply current to $TL(e^-)$ which is connected with the linear diffusion of free electrons in the solution. The short-circuit at $x = 0$ implies instantaneous capture of any free electron arriving at the electrode surface. $TL(e^-)$ is linked by distributed resistance to the line $TL(e^-_{aq})$ which represents the linear diffusion of hydrated electrons in the solution. These linking resistances are connected with the homogeneous conversion of e^- into e^-_{aq} and the reverse process and the linking resistance per unit length of line is given by $R_l = \theta/k_d$ if the series resistance, shunt capacity, and shunt resistance of $TL(e^-_{aq})$ are defined by Eq. [2], [3], and [4]. The resistance and capacity per unit length of $TL(e^-)$ are defined by

$$R_{tl}(e^-) = \theta k_r/D_e'k_d \text{ and } C_{tl}(e^-) = k_d/k_r\theta$$

It is assumed that unbound electrons are not captured by scavengers but this is not an essential assumption. If it is not made, the scavenging of unbound electrons is represented by shunt resistance distributed uniformly along $TL(e^-)$.

The most general form of the circuit contains a resistance R_e' (defined above) linking the terminals of $TL(e^-_{aq})$ at $x = 0$ to take account of slow transfer of electrons from hydrated electrons at the interface to the electrode. If there is an appreciable field in the region of the diffuse double layer, the circuit is basically the same but $R_{tl}(e^-)$, R_l, and $R_{tl}(e^-_{aq})$ are increased by the time average of exp $- \Psi F/RT$ and the shunt capacities of the two lines are reduced by the same factor. Apart from possible complications introduced by pair formation and by capture of unthermalized electron the resulting circuit should be reasonably exact. Unfortunately it is impossible at the present time to assess accurately the relative importance of the various components in the circuit, and it is not clear how the various uncertainties are to be resolved conclusively.

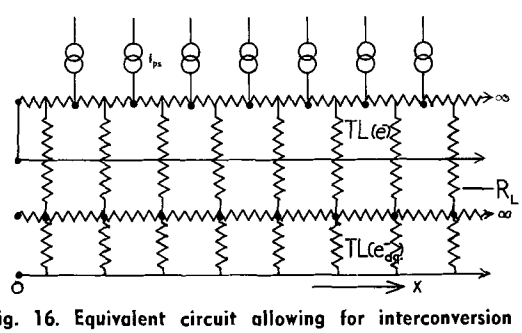

Fig. 16. Equivalent circuit allowing for interconversion of e^- and e^-_{aq}.

Comparative, Competitive, and Successive Scavenging

Perhaps the most crucial test of the proposed mechanism is to ascertain whether relative rate constants deduced from photocurrent measurements bear any resemblance to those obtained by pulsed radiolysis. This may demand a knowledge of the electron transfer numbers for the scavenging reactions.

Comparative Scavenging

From earlier discussion it follows that when the scavenger concentration is very large i_p approximates to v_s^o times the rate of deposition of electrons in the solution (i_d). Thus for two scavengers A and B, the ratio v_A^o/v_B^o, in principle, can be determined by making measurements of the photocurrent with high concentrations of A and of B. This method cannot always be used owing to light absorption by the scavengers at high concentration. However, in such determinations it may not be necessary to use light of very short wavelength and the possibility of evaluating v_s^o ratios for uv absorbing species such as NO_3^- and NO_2^- using "violet" light is currently being investigated. Once v_A^o/v_B^o has been evaluated k_A/k_B can be determined by making measurements with very low concentrations of A and of B as

$$i_p(A)/i_p(B) = v_A^o(k_AC_A)^{1/2}/v_B^o(k_BC_B)^{1/2} \qquad [26]$$

It is, of course, here assumed that the electron transfer numbers are independent of C_s, and that a high scavenger concentration does not influence the rate of deposition of hydrated electrons in the solution. The latter is not a permissible assumption if the scavenger is strongly adsorbed at the interface, and it is possible for v_s^o to vary with C_s in a range of potential in which a heterogeneous charge transfer reaction following electron scavenging is not completely diffusion-controlled. Consequently i_p measurements must be made at a potential where the variation of i_p with potential is independent of the reaction scheme.

Competitive Scavenging

Competitive experiments with solutions containing two scavengers A and B also lead to relative electron transfer numbers and to relative rate constants. The term $-k_sC_sC_e$ in the diffusion equation (1) has to be replaced by $-(k_AC_A + k_BC_B)C_e$ and it follows that for constant light intensity and $i_p << i_d$ the rate of capture of electrons is proportional to

$$(k_A C_A + k_B C_B)^{1/2}$$

As each electron captured by A and B leads to the permanent loss by the electrode of v_A and v_B electrons, respectively, the current at constant potential is

$$i_p = i_d G (v_A k_A C_A + v_B k_B C_B)/(k_A C_A + k_B C_B)^{1/2} \quad [27]$$

where G is a constant. By varying C_A/C_B, v_A/v_B and k_A/k_B can be determined. Low scavenger concentrations must be used in such determinations.

If the two scavenger concentrations are very large and almost all the emitted electrons are captured, the observed photocurrent is given by

$$i_p \cong i_d (v_A k_A C_A + v_B k_B C_B)/(k_A C_A + k_B C_B) \quad [28]$$

If $v_A = v_B$ the current tends to be independent of C_A/C_B, but if $v_A > v_B$ the introduction of a large concentration of A into a solution already containing B at a high concentration produces a marked increase in current. The earlier remarks about light absorption apply in this case also, and it is desirable (*a*) that the electron transfer numbers should be independent of scavenger concentration and (*b*) that there should be no interactions between the over-all photocurrent mechanisms. Ambiguity may result if an entity produced directly or indirectly by electron capture reacts with the other scavenger to produce an intermediate capable of oxidation or reduction. If $v_A = 0$ (*e.g.*, due to oxidation of A^-) Eq. [27] and [28] reduce to

$$i_p = i_d G v_B k_B C_B/(k_A C_A + k_B C_B)^{1/2} \quad (i_p << i_d) \quad [29]$$

and

$$i_p \cong i_d v_B k_B C_B/(k_A C_A + k_B C_B) \quad [30]$$

Extensive use has been made of these two equations which do not demand a knowledge of v_B for the evaluation of k_A/k_B.

If $k_B C_B << k_A C_A$ Eq. [27] can be written in the approximate form

$$i_p \cong i_d\, G v_A (k_A C_A)^{1/2} [1 + (2v_B - v_A) k_B C_B/2 v_A k_A C_A] \quad [31]$$

Thus by studying the change in i_p produced by the addition of a small amount of B it is possible to decide between the three following possibilities

$$2v_B > v_A$$

$$2v_B = v_A$$

$$2v_B < v_A$$

It has to be borne in mind that any conclusion so arrived at may not hold for v_A^0 and v_B^0, the transfer numbers in the absence of other scavengers.

Successive Scavenging

One further way of evaluating homogeneous rate constants deserves mention. Consider the reaction scheme

$A + e^-_{aq} \rightarrow A^-$	(homogeneous)	[p]
$A^- + B \rightarrow C$	(homogeneous)	[q]
$C \rightarrow D + e$	(fast c.t.r.)	[r]

where B does not react with e^-_{aq}. The photocurrent associated with electron capture by A (and possibly with following reactions which for simplicity are omitted from the scheme) is reduced when species B is present because ultimately some of the captured electrons are returned to the electrode by charge transfer reaction (r). This reaction scheme is encountered with alcoholic solutions. The aliphatic alcohols are known to be efficient scavengers for H atoms and OH radicals and scavenging reaction usually involves hydrogen abstraction from the α carbon atom.

Two distinct types of behavior can be distinguished if reaction (r) is diffusion-controlled. The behavior is simplest when v_A^0 is unity. Then, if reaction (q) is a moderately rapid homogeneous reaction and a small amount of B is present, at normal values of the elapsed time almost all A^- is converted into the intermediate C and this is virtually all oxidized at the electrode. Thus the observed photocurrent is very small in comparison with the value prior to the introduction of scavenger B.

More interesting is the behavior when v_A is larger than unity due to a charge transfer reaction involving A^- at the electrode surface. In this case the reaction, which may be written formally

$$A^- + e \rightarrow A^{2-} \quad [s]$$

competes with homogeneous reaction (q) for A^- and the current is very small only if the concentration of B is so large that there is little possibility of A^- (formed within the very thin electron scavenging reaction zone) arriving at the electrode surface. Without writing down any equations it is evident that an appreciable current will be observed if $k_A C_A$ is comparable with $k_B' C_B$ where the superscript ' denotes scavenging of a species other than e^-_{aq}. An approximate expression for the current is most readily obtained by the equivalent circuit approach and Fig. 5 is directly applicable if reaction (r) is diffusion-controlled. The current generator di_{ps} is identified with the deposition of A^- in the solution by reaction (p) and the transmission line takes account of linear diffusion of this entity, while the distributed shunt resistance allows for the homogeneous consumption of A^- by scavenger B. In this instance we are interested in the rate of arrival of A^- at the electrode surface and making use of equations analogous to [2], [3], and [4] this current is found to be

$$di_p = di_{ps} \exp - (k_B' C_B/D_B)^{1/2} x \quad [32]$$

where D_B is the diffusion coefficient of B. Now for small $k_A C_A$ the rate of deposition of A^- in the solution is approximately

$$\alpha\, i_d (k_A C_A) \exp - (k_A C_A/D_e)^{1/2} x$$

and using Eq. [32] it follows that the rate of arrival of A^- at the electrode is proportional to $i_d k_A C_A\, (Q + Q')^{-1}$ where $Q = (k_A C_A/D_e)^{1/2}$ and $Q' = (k_B' C_B/D_{A^-})^{1/2}$. For each A^- ion or molecule arriving at the electrode v_A^0 electrons are permanently lost by the electrode if the presence of scavenger B does not influence the transfer number.

Thus for constant light intensity[7] and constant C_A

$$i_p \propto [1 + (Q'/Q)]^{-1} \quad [33]$$

and a plot of the reciprocal of i_p against $C_B^{1/2}$ is linear and permits the evaluation of k_B' if D_B, D_e, and k_A are known.

We have discussed this special type of successive scavenging at some length because it appears to be the only conclusive way of evaluating v_s^0 for i_p when e^-_{aq} is scavenged by H_3O^+.

Scavenging Rate Constants

The evaluation of rate constants (strictly relative rate constants) using equations given in the preceding section is a task which is as yet hardly begun. Values for a variety of electron scavenging reactions are tabulated in Table I. To make comparison with pulsed radiolysis data easier we have assumed that for our solutions (1 and 0.2M) the rate constants deduced from pulsed radiolysis and chemical experiments at low ionic strength should be multiplied by antilog-$0.2z$ where z is the number of electronic charges carried by the scavenger ion or molecule. This correction is nu-

[7] Equation [33] is also valid for varying light intensity if i_p approaches its pseudosteady-state value rapidly.

Table I. Comparison of rate constants deduced from i_p measurements with pulsed radiolysis values [K_A(pr)]

System	Scavenger A	Scavenger B	Method	C_A (M)	C_B (M)	Potential, v *vs.* SCE
(a)	H_3O^+	N_2O	Compet. LP	0, 10^{-3}-10^{-2} 0, 10^{-2}-10^{-1}	$3.1\ 10^{-2}$ $7.9\ 10^{-3}$	−0.2 to −0.4

$\phi\ k_A(i_p)$ refers to 0.2M KCl unless otherwise indicated. No allowance for uncertainty in the assumed values of $k_{H_3O^+}$ and k_{N_2O} is made nor have any small corrections for the effect of ionic scavengers on the dynamic ψ effect been applied.

* Pulsed radiolysis rate constants have been multiplied by anti-log $-0.2Z_s$.

merically slightly smaller than is predicted by the Brönsted theory (21), but an examination of experimental data (22) for a variety of reactions suggests that the assumed correction is more realistic (at least for 0.2M solutions) than the theoretical value.

Several of the rate constants have been obtained by competitive experiments with N_2O as one scavenger and a metallic ion as the second scavenger. In these experiments v_s for the second scavenger was virtually zero and hence a knowledge of v_s for the first scavenger was not needed. In much of the work i_p was rather small and undesirably high scavenger concentrations had to be used to minimize errors due to low signal to noise ratio and due to slight drifts in the zero of the pulse polarograph. The equations used in the interpretation of the data were in some instances thus not strictly applicable. Similar difficulties sometimes were encountered in competitive experiments between H_3O^+ and metallic ions. The results are only to be regarded as preliminary results but there is little possibility that they are greatly in error and they are included in the paper because they show clearly that the studied N_2O photocurrents are largely, if not entirely due to electron capture.

One important fact should be borne in mind when considering the results of competitive experiments. The entity formed by electron capture by one of the scavengers may react with the second scavenger. Unstable metal ions formed by electron capture are likely to react slowly with H_3O^+. The rate constants in Table I suggest that the reaction of Zn^+ with H_3O^+ must be fairly slow ($k' < 10^8 M^{-1}\ sec^{-1}$) and also that the second order rate constants for the capture by N_2O of the species formed when e^-_{aq} is captured by the ions of Zn, Cd, and Ni are $< 10^{10}\ M^{-1}\ sec^{-1}$. However, exploratory experiments with solutions containing H_3O^+ and Ni^{2+} suggest that Ni^+ may react rather rapidly with H_3O^+, as the introduction of Ni^{2+} did not produce the expected reduction in i_p. This fact may be not unrelated to the anomalously large photocurrent observed with Ni^{2+} which was discussed earlier. In this connection it should be mentioned that if a solution contains a very large amount of scavenger A, all the deposited electrons will be rapidly converted into A^- and, if A^- is scavenged by B at low concentration, the photocurrent can be regarded as one due to the outward diffusion, and slow capture by B of A^-. Further if the second scavenging reaction is diffusion-controlled, the photocurrent will be of the same order of magnitude as if scavenger A were not present.

Some rate constants obtained by comparative scavenging are also included in Table I. In the interpretation of these results relative values of v_s° were needed, and the reasons for choosing the values indicated in the table are summarized below. The main foundation stones in our calculations of absolute rate constants (0.2 and 1M electrolyte) have been values of 1.4 10^{10} and 5.6 10^9 $M^{-1}\ sec^{-1}$ for the scavenging of e^-_{aq} by H_3O^+ and N_2O, respectively.

N_2O.—It was mentioned earlier that the most probable value for $v_{N_2O^\circ}$ in neutral solution is 2. This electron transfer number is not likely to change in acidified solutions as OH radicals will presumably be formed even more readily by the homogeneous reaction

$$O^- + H_3O^+ \rightarrow OH + H_2O \qquad [t]$$

The addition of EtOH to 0.2M KCl (natural *p*H) saturated with N_2O (1 atm) reduces the photocurrent, and for a solution which is 1M with respect to EtOH the photocurrent at potentials more positive than −1.6v *vs.* SCE is only about 10% of the value without ethanol. Some indication of a rapid rise at more negative potentials (<1.7v *vs.* SCE) is seen, and with an acidified solution (10^{-4}M H_3O^+) a rapid increase in photocurrent at about −1.4v *vs.* SCE is detected. These results can be interpreted in terms of the following reaction scheme

$$e^-_{aq} + N_2O \rightarrow N_2O^- \qquad [a]$$

$$N_2O^- \rightarrow N_2 + O^- \qquad [b]$$

$$O^- + H_2O \rightarrow OH + OH^- \qquad [c]$$

$$OH + CH_3CH_2OH \rightarrow H_2O + CH_3CHOH \qquad [t]$$

$$CH_3CHOH + H_2O \rightarrow CH_3CHO + H_3O^+ + e \quad \text{(rapid c.t.r. at } E > -1.4\text{v)} \qquad [u]$$

Some of these steps may well be bypassed (*e.g.*, O^- may react directly with EtOH). The reverse of reaction (u) is in all probability the first step in the reduction of acetaldehyde, and we believe it is relevant that the polarographic reduction of this compound [23] in solutions of *p*H ~ 7 commences at a somewhat more negative potential than the rise in the photocurrent (neutral solution). Thus the suppression of i_p by EtOH is to be attributed to the oxidation of the α ethanol radical and the accompanying return of the scavenged electron to the electrode. It should be noted that the experimental data indicate that the oxidation of this radical at potentials more positive than −1.4v must be a moderately rapid process.

H_3O^+.—The evidence for a value for v_s^0 in this case of 2 is; (*i*) The addition of ethanol to 0.2M KCl 10^{-3}M H_3O^+ at first produces a fairly rapid fall in i_p at potentials positive with respect to —1.4v *vs.* SCE. Further additions have a progressively smaller effect, and with a solution 0.5M with respect to EtOH the photocurrent is still roughly half the value in the absence of EtOH. It is well established that EtOH is an efficient H atom scavenger and that the main product of the scavenging reaction is the α ethanol radical. In the absence of a competing reaction virtually all the H atoms produced by electron capture should thus be converted to these radicals and as bimolecular combination of radicals (H or CH_3CHOH) is ruled out by the low concentrations prevailing in the photocurrent experiments (LP) almost all the captured electrons should be returned to the electrode by reaction (u). This is not in accordance with the experimental facts, and hence it may be concluded that there is a competing reaction which might be the well-known atom-ion reaction (e). The reaction must be quite fast at potentials in the range —0.8 to —1.3v *vs.* SCE and able to compete effectively with the scavenging of H by EtOH. A plot of the reciprocal of i_p against the square root of the EtOH concentration is fairly linear up to 1.5M EtOH and using Eq. [33] a value of the rate constant for scavenging of H by EtOH of 2.8 10^7M^{-1} sec^{-1} is obtained [assuming $k_{H3O+} = 1.4\ 10^{10}$M^{-1} sec^{-1} (see Table I), $D_e = 5\ 10^{-5}$ cm^2 sec^{-1}, $D_H = 5\ 10^{-5}$ cm^2 sec^{-1}]. The corresponding values obtained by other methods are 1.5 10^7 and 1.65 M^{-1} sec^{-1} (24). The measure of agreement is rather striking and supports the interpretation placed on the experimental results.

(*ii*) The "saturation" photocurrent for N_2O is almost identical with that for H_3O^+ at a concentration smaller by the ratio of the rate constants.

(*iii*) The addition of small amounts of H_3O^+ to 0.2M KCl containing ~5 10^{-3}M N_2O produces a small but progressive increase in i_p. If $v_{H3O+} = 1$ while $v_{N2O} = 2$, a progressive decrease should be observed. This however, does not prove that $v_{H3O+}{}^0 = 2$ as H atoms react slowly with N_2O ($k'_{N2O} = 1.25\ 10^4$M^{-1} sec^{-1}) producing OH radicals which would be reduced by the electrode.

NO_3^-.—It was suggested earlier that v_s^0 in this case is 2 when the photocurrent is well developed. The supporting evidence for this is that the addition of small amounts of NO_3^- to 0.2M KCl, ~4 10^{-3} MN_2O leads, at the more negative potentials, to an increase in i_p. If a value for v_{N2O} of 2 is assumed it follows that v_{NO3-} is certainly not unity. At more positive potentials the effective value of $v_{NO3-}{}^0$ solution produces a decrease in i_p. This indicates an effective value of v_s smaller than unity. This evidence however, does not show conclusively that the transfer number has these values when NO_3^- is the only scavenger present.

NO_2^-.—The experimental evidence in this case is even weaker but, such as it is, it suggests that at potentials positive with respect to —0.9v *vs.* SCE the effective electron transfer number in the presence of N_2O is close to unity since the introduction of small amounts of NO_2^- into 0.2M KCl containing N_2O at concentrations in the range 10^{-3} to 5 10^{-3}M seems to have little effect on the photocurrent. Other facts leading tentatively to the same conclusion were mentioned earlier. In 1M NaOH for reasons given earlier v_{NO2-} is assumed to be 2 at potentials more negative than —1.3v *vs.* SCE.

The rate constants deduced from comparative experiments (MP 2) which are given in Table I agree reasonably well with values obtained by pulsed radiolysis. This suggests that the relative electron transfer numbers have been assigned the correct values, but it is possible that the absolute values may not be correct. In particular we have found it difficult to accept a value for $v_{H3O+}{}^0$ of 2 despite the fact that the atom-ion reaction has long been considered by some workers to be important in the normal hydrogen evolution reaction at electrodes.[8] However, all attempts to establish a value of unity have so far failed.

Second Order Reactions

In all experiments other than those with the flash source the stationary electron concentration at any point in the solution has not exceeded 10^{-8}M, and the concentrations of species, produced as a consequence of electron capture, which are consumed heterogeneously have also been very small. If a long-lived entity is produced which is not rapidly consumed by a homogeneous or heterogeneous reaction, its concentration in the solution near the electrode surface slowly rises as time progresses, and second order reactions between such entities and with other species slowly become more likely. It is conceivable that the behavior under intense radiation of some of the systems considered in this paper may change with flash illumination. This change in most cases should be detectable as the linearity between photocurrent and light intensity should be affected. High intensity radiation should in the future cast light on disproportionation reactions between unstable species and fast reactions such as reaction (o). With low light intensities the behavior is in all cases simplest, and the photocurrent is expected to be proportional to light intensity. The latter expectation has been confirmed by experiment (HP) with solutions containing both large and small (10^{-4}M) concentrations of H_3O^+.

Conclusions

All the reliable experimental facts currently available indicate that photocurrents characterized by a dependence on the square root of the scavenger concentration are mainly due to the photoemission of electrons from the electrode surface. The dependence of the apparent threshold potential on wavelength, the values of relative rate constants deduced from competitive and comparative scavenging experiments, and the influence of ionic strength on the photocurrent are the main evidence for this conclusion. The apparent range deduced from the departure from linearity of the relation between current and the square root of the scavenger concentration indicates that the electrons travel an appreciable distance through the solution before becoming hydrated, a conclusion which is supported by the slight dependence of apparent range on potential and by variations with potential in the ratio of nonsaturation current to a "saturation" current with potential. No reliable evidence is yet available to show whether after thermalization the electrons travel a further distance prior to hydration, but it is possible that this happens, and also that the return of hydrated electrons to the electrode may be preceded by dissociation of the hydrated electron. The hard core of evidence for electron emission has in the present paper been embellished with much speculation mainly concerned with the nature of the reactions following the scavenging reaction. It will be remarkable if none of it proves to be wrong, but such speculative excursions from reality are unavoidable at the present time. It is clear that the study of photocurrents offers to the electrochemist and to the radiation chemist a simple way of studying fast homogeneous processes and a way to extend our understanding of the processes which follow electron capture. It should also clarify the mechanisms of certain slow charge transfer reactions and cast new light on the structure of the electrical double layer.

Discussion

P. Delahay (discussor) and *G. Tessari*: Dr. Barker has presented some good evidence to support his general mechanism, and I do not plan to question this mechanism here. I shall also leave for the Discussion of Photocurrents some points of theory on electron emission. My comments will rather cover three points in the analysis of experimental data.

First, I would suggest caution in drawing conclusions from plots of the square of the photocurrent against potential, and particularly from variation in the slope of this plot. Such a dependence is not of analytical character, and indeed calculated plots (square root of current against field) are not linear when the range of field is sufficiently large. This comment applies particularly to Dr. Barker's detailed implications he derived from his Fig. 2.

Second, I like to stress the importance of irradiation with monochromatic light or the best that can be achieved toward that aim. Furthermore, it is important that currents be compared for equal fluxes of photons at different wavelengths. Analysis of the electrode potential and wavelengths dependence demands that kind of experimental information. Comparison of results, otherwise, becomes more tentative.

Third, the study of the time dependence of photocurrents is essential whenever consecutive solvated electron-scavenger reactions are involved. The course of these reactions may be affected by potential and by wavelengths, and these effects may escape in measurements involving only a narrow range of time. Dr. Tessari recently found a pronounced time dependence for N_2O in 0.1M NaF long after irradiation had stopped. Dr. Barker has warned us about this effect, but I like to stress the necessity of experimental study before the deduction of detailed mechanisms.

In conclusion, I believe we can all admire Dr. Barker's extensive pioneering work, but we should realize, as he does, that mechanisms can only be tentative, at least in certain cases. More definitive results hopefully may result by consideration of the experimental points I raised. I hope so anyhow.

G. C. Barker: I find myself in broad agreement with the comments made by Professor Delahay. Exact linearity in the plot of $i_p^{1/2}$ against field over a wide range of field certainly is not predicted by theory, but results obtained for emission *in vacuo* often fit a plot of $i_p^{1/2}$ against quantum energy over a range of 1 or more electron volts. Also of the methods available for the determination of the apparent threshold potential the $i_p^{1/2}$ *vs.* potential plot is the only nonsubjective method.

It is clearly essential when studying the emission of electrons rather than their subsequent fate to work with monochromatic light of variable wavelength and also to have some knowledge of the incident light intensity. Our experiments show that the yield at constant potential falls progressively as the wavelength increases. In this connection it should be mentioned that the current units in the case of the data plotted in Fig. 2 of our paper vary with wavelength.

I am somewhat puzzled by the slow variation in potential with time observed for N_2O in 0.1M NaF solution. This I would not expect as OH radicals should rapidly be directly or indirectly reduced at the electrode surface. Of course fluorine may be produced as an intermediate, but it is not easy to see why this should not be rapidly reduced. This system is one which we have not yet studied oscilloscopically. Only long-term average current measurements have been made with 0.2M saturated with N_2O and using 2537Å radiation.

P. J. Boddy: The result reported by Professor Delahay that the electrode potential changes abruptly to a more positive value during a brief light pulse and then subsequently drifts even more positive by a few millivolts over times of the order of tens of milliseconds is not necessarily inconsistent with Dr. Barker's mechanisms (e) and (f). The only necessary assumption is that the photo-emitted electrons are stopped (*i.e.*, reduced to ordinary diffusional motion) by collisions with molecules or ions before travelling more than approximately one Debye length (appropriate to the particular solution) away from the electrode surface. The extra positive charge left on the metal surface as a result of electron emission gives rise to a small increase in the field at the surface, and this of course is the origin of the immediate electrode potential change. The additional negative charges appearing in the solu-

tion phase (and it is immaterial now whether these are electrons, hydrated electrons, or anions) will not in general be distributed in a way consistent with the already existing potential profile in the diffuse part of the double layer and will hence have a tendency to drift either toward or away from the electrode as the electrostatics demands. If in fact the over-all tendency is to drift away from the electrode, then, since the field due to the additional positive charge on the electrode is acting over a greater distance, a positive increase in the electrode potential could be expected.

P. Delahay: Dr. Boddy made an interesting point, but I am not sure whether he is right for the following reasons: (*A*) Diffusion surely must occur well beyond the diffuse double layer in a time of 50 msec in a 0.1 or a 1M electrolyte. (*B*) The same effect should be observed regardless of the scavenger, but is hardly found when 1M $HClO_4$ is used instead of N_2O.

Regardless of whether Dr. Boddy is right or wrong, the drift of potential we observed at open circuit would result in a current-time dependence at constant potential (Dr. Barker's conditions). My original comment still stands about the necessity of considering time dependence.

H. Gerischer: The very good efficiency of H_3O^+ ions as irreversible electron scavengers seems very surprising to me. I would have expected that, due to the very negative redox potential of dissolved hydrogen atoms, each H-atom approaching the electrode surface would be reoxidized. Reaction (f) which you have discussed should be very fast if no other stabilization of the hydrogen atom occurs. Such a stabilizing process would be the formation of $H_2^+ \cdot aq$ in a homogeneous reaction between $H \cdot aq + H_3O^+$. According to your Fig. 10, the scavenger efficiency of the H^+ ions decreases rapidly in a critical range of polarization. Does this not indicate that some stabilization of the H atoms takes place due to interaction with an unknown species which prevents reoxidation of those radicals below this critical potential range?

G. C. Barker: The variation of the H_3O^+ photocurrent with potential might be interpreted in the way suggested by Professor Gerischer, but there are some additional experimental facts to be considered. Experiment suggests that when this photocurrent is well developed and, tending to vary with potential in the same way as the N_2O photocurrent, the electron transfer number is the same for both photocurrents. Now LP experiments with solutions which were saturated with N_2O and which contained a relatively small ($\sim 10^{-4}$M) amount of H_3O^+ have shown that when the potential is such that the reduction of H_3O^+ is largely diffusion controlled there is a substantial apparent fall in the N_2O photocurrent. This is due to the production of OH^- ions by the photocurrent mechanism which react homogeneously with hydrogen ions which otherwise would have been reduced at the electrode surface. In such LP experiments it is of course the change in current produced by the rectangular light pulse which is measured, and little change will be observed when the H_3O^+ reduction is largely diffusion controlled if, for each electron lost by the electrode as a consequence of photo-emission, one OH^- ion is produced. The behavior points to OH^- and N_2 as the final products of the N_2O photocurrent reaction and thus to a value for $v_{N_2O}^{\circ}$ of 2. It follows that $v_{H_3O^+}^{\circ}$ is probably 2 at potentials more negative than —0.9v *vs.* SCE. Such a value suggests that the H atoms participate in a charge transfer reaction leading to the loss of a further electron by the electrode. The reaction is presumably either the so-called atom-ion reaction or the related reaction in which the H_3O^+ ion is replaced by a water molecule. At potentials more negative than —0.9v the reaction in question must take place much more rapidly than the oxidation of hydrogen atoms, the latter reaction being the main path for the removal of hydrogen atoms only at much more positive values of the potential.

Panel Discussion on Electrode Photocurrents

Introductory Remarks

Paul Delahay

The topic of electrode photocurrents was selected for discussion for two reasons: (*a*) recent work, and particularly that of Dr. Barker and co-workers, is of interest in relation to current, intensive work on the solvated electron; (*b*) electron emission from a metal into a solvent such as water is a poorly understood phenomenon which possibly may be of significance in the interpretation of double layer phenomena and electrode processes. The first aspect was treated in detail in Dr. Barker's paper, and I like to examine briefly the second problem.

We recently pointed out (1) that Fowler's treatment (2) of the effect of an electrical field on photoemission in vacuum could provide a basis for the interpretation of electrode photocurrents. This matter was further examined by Mr. Susbielles (3) and led to the following conclusions: (*A*) The calculated photocurrent-field curves for monochromatic irradiation have the same general shape as the experimental saturation photocurrent-electrode potential curves (in the absence of secondary complications due to consecutive solvated electron-scavenger reactions). (*B*) Plots of the square root of the photocurrent against field for monochromatic irradiation are essentially linear (although the relationship is not a simple analytical one). (*C*) The photocurrent at a given field increases with frequency of irradiation much in the same way as for photoemission in vacuum. These conclusions were obtained either by assuming that the transmission coefficient for electron emission is equal to unity or by calculating the transmission coefficient as a function of energy.

These results hopefully should allow determination of the field at the electrode and might lead to a new kind of information on double layer phenomena. However, preliminary experimental results do not seem to confirm these calculations. The square root dependence seems to be observed experimentally, but the effect of wave length, according to Tessari's recent work (4), differs from the calculated behavior. It is possible that electrode contamination accounts for these abnormal results, but this may well not be the case. We plan further work in this respect. One might also argue that the theoretical model is not a realistic one.

Discussion

H. Gerischer

I would like to contribute only two very brief comments to this discussion. The most problematic question in connection with photocurrents by electron emission seems to me to be the emission process itself. One will have to take into account the probability of reflection at the boundary between condensed phases. It is unlikely that the interaction with the liquid phase can be taken into account by considering electrical polarization forces solely. Specific interactions with higher electronic states of the solvent molecules may provide some preferential energy ranges for electrons entering into the solution. This may be shown in the unexpected dependence of the photoemission on wavelengths which Professor Delahay has reported.

On the other hand, electrons emitted into the solution will be scattered by the ions of the electrolyte. I would expect therefore that the mean distance which will be reached by the electrons should decrease with increasing electrolyte concentration. This would increase the probability of recapturing electrons by the electrode.

We have tried to study the emission processes and recapturing process separately by using very short light flashes (of the order of 1-2 μsec). Until now, however, we could not reach high enough resolution for the analyzing electronic system to find the true response of the cell (dropping mercury electrode). Obviously the recapturing process has a too short time constant, which is in agreement with the assumption, made by Dr. Barker, that the electrons reach distances below 100Å. The mean free life time, with the assumption of 100% recapturing efficiency at the electrode, should be then of the order of 10^{-7} sec, which is indeed too fast for our measuring circuit.

R. A. Marcus

The subject of hydrated electrons has been one of considerable interest to chemists in the past few years. This printed version of my remarks will be abbreviated to avoid duplicating a description given elsewhere of the reaction theory and properties of this species. There are several points which should be mentioned, however, as well as one experiment which has so far eluded some chemical kineticists but which may be accessible to electrochemists.

Experimental data on the hydrated electron are of several types: visible absorption spectra, "thermodynamic" (as determined from the ratio of the forward and reverse rate constants of $e + H_2O \rightleftharpoons H + OH^-$), reaction rates of solvated electrons, and mobility measurements. The second item indicates that the solvation free energy is quite large, about —35 kcal mole^{-1} perhaps. Reactions of a solvated electron with simple redox systems are extremely rapid, principally because its standard potential is so negative (about —2.7v), and partly because its intrinsic reorganization parameter [¼λ in our equations (1)] is so low: Per reactant, ¼λ is about 5, 10, and 15 kcal mole^{-1} for the solvated electron, Fe^{+2} — Fe^{-3}, and $Co(NH_3)_6^{+2}$ —$Co(NH_3)_6^{+3}$ species, respectively (1). (¼λ for the reaction is essentially the sum of those for the two reactants.)

Most of the homogeneous reactions of the solvated electron are so fast that they are diffusion-controlled. [It may be recalled that $(1/k_{obs}) = (1/k_{act}) + (1/k_{diff})$, where k_{obs}, k_{act}, and k_{diff} are the observed, activation-controlled, and diffusion-controlled rate constants, respectively (1). When $k_{act} >> k_{diff}$, then $k_{obs} \cong k_{diff.}$) The theory indicates that the rates for reaction with redox systems having typical λ's are diffusion-controlled or almost so, when the standard potential is less negative than —1.5 to —2.0v or less positive than +1.0 to +0.5v (1). To learn more about the chemical behavior of the solvated electron, *i.e.*, to study k_{act}, it would be useful to investigate reactions with redox reactants having E_o's outside this interval. Although the interval outside is an elusive one for stable redox systems, it may be accessible for study with the short-lived species which are generated electrochemically.

When the second reactant is strongly oxidizing, its reaction with the solvated electron is so exothermic that an excited state of the product could form. Chemiluminescence could then ensue, either by emission from this excited state or from one formed from it. A theory of chemiluminescent electron transfer reactions has been described elsewhere (2) and applied to the solvated electron reaction (1). It appears that no chemiluminescence has been observed in solution as yet, however, as a result of a hydrated electron reaction. The electrochemist may have a better chance of observing it:

Let us suppose that the potential of an electrochemical cell is switched back and forth between large positive and large negative values in the presence of a suitable reducible species. Let us suppose further that the electrode is illuminated, either with steady or with synchronized pulsed illumination. During part of the negative half of the cycle photoelectrons are ejected, and during part of the positive half the reducible species yields some powerful unstable oxidizing agent, if it was suitably chosen. Reaction between this oxidizer and the solvated electron can then occur if the concentration of the former is high enough. The system could then be examined for chemiluminescence.

The theory of reactions of solvated electrons can readily be adapted to the calculation of the scavenging rate of metal electrodes for these electrons. One finds that at typical potentials reaction is extremely efficient. Similarly, it could be adapted to calculate the rate of spontaneous emission of electrons as a function of potential. It is clear from the redox potential of the solvated electron[1] that the potential would have to be very negative.

[1] For the effective E_o' for use in the theory should take (1) —2.9v (Stockholm convention) rather than the actual one of —2.7v, to correct for the effects of changes of standard translational entropy. The value of $\lambda/4$ is that cited earlier in the present remarks.

Hydrocarbon Fuel Cells with Fluoride Electrolytes

Elton J. Cairns[1]

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Fuel cell investigations using saturated hydrocarbon fuels with aqueous cesium salt electrolytes and Teflon bonded platinum electrodes have shown that the acidic system CsF-HF-H_2O comprises a suitable set of electrolytes for high performance hydrocarbon fuel cells. The effects of electrolyte composition and temperature on cell performance were studied with emphasis on propane as the fuel. Cell performance was also determined as a function of the molecular structure of the fuel using the homologous series of normal paraffins from C_1 to C_{16}. Maximum performance at 150°C was obtained at the composition F/Cs = 2.0, H_2O = 10 mole %. The HF-H_2O azeotrope showed good performance at 110°C on several hydrocarbons. No current or voltage cycling was observed under any conditions, in contrast to other acidic electrolytes.

During the last several years, there has been an increased interest in obtaining fuel cells which can carry out the direct anodic oxidation of saturated hydrocarbons to carbon dioxide and water at useful current densities and low overvoltages. Most of the early hydrocarbon fuel cell work was concerned with acidic electrolytes (1-3) because hydroxide electrolytes react with the products of the anodic oxidation process, yielding formate and carbonate in place of hydroxide (1). An invariant alkaline electrolyte suitable for use with such fuels as methanol, carbon monoxide, and ethylene was reported by Cairns and MacDonald (4), who found that fuel cell operation at temperatures as high as 200°C could be achieved at atmospheric pressure with aqueous Cs_2CO_3 or Rb_2CO_3 electrolytes. Further work with methanol using the Cs_2CO_3 electrolyte indicated that the temperature range between 100° and 200°C provided significant performance increases over the lower temperature region below 100°C (5).

The investigations using Cs_2CO_3 and Rb_2CO_3 electrolytes were extended to include saturated hydrocarbons, but unexpectedly low current densities were obtained, a result which was attributed to the very low solubilities of the saturated hydrocarbons in strong carbonate solutions (6). Meanwhile, higher current densities had been achieved using strong acid electrolytes in the same temperature range (7, 8).

With the above results in mind, an attempt was made to increase the solubility of the hydrocarbons in the cesium-salt electrolyte by substituting fluoride anion for a portion of the carbonate anion. This choice was made because HF is known to increase the solubility of hydrocarbons in aqueous solution (9), and because the fluoride anion is not expected to be specifically adsorbed on the electrodes (10, 11). The effect of fluoride content of the Cs_2CO_3-CsF-HF-H_2O electrolyte system on the rate of the anodic oxidation of propane was studied at 150°C. The effect of the chain-length of the normal paraffin fuel molecule on the rate of anodic oxidation was studied at 150° and 105°C.

[1] Present address: Chemical Engineering Division, Argonne National Laboratory, Argonne, Illinois.

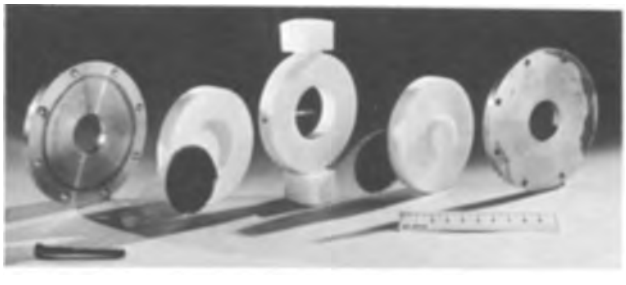

Fig. 1. Photograph of cell parts

Experimental

The fuel cell was constructed of PTFE and platinum in order to minimize any possible contamination of the electrodes and electrolyte. Figure 1 shows the cell parts arranged in the order of assembly. The fuel and oxygen compartments were 3.81 cm in diameter (11.38 cm^2 area) and 0.3 cm deep; the electrolyte compartment was the same size (the 1.2 cm thick electrolyte spacer in the center of Fig. 1 was replaced by a thinner one). The electrodes were made from platinum black (~20 m^2/g) and PTFE by procedures similar to those already reported (12), and contained 50 mg Pt/cm^2. The 45-mesh platinum gauze electrode support also served as current collector. The active geometric area of each electrode was 11.38 cm^2. The cell was held together by Monel end plates and bolts; the PTFE surfaces were self-gasketing.

The assembled fuel cell was mounted, together with an identical cell, which contained reversible hydrogen reference electrodes, in the apparatus shown schematically in Fig. 2. The dashed line represents a forced-convection air thermostat. The electrolyte was circulated by gravity from a PTFE reservoir through the reference cell and the fuel cell to a lower reservoir, from which it was returned to the upper reservoir by

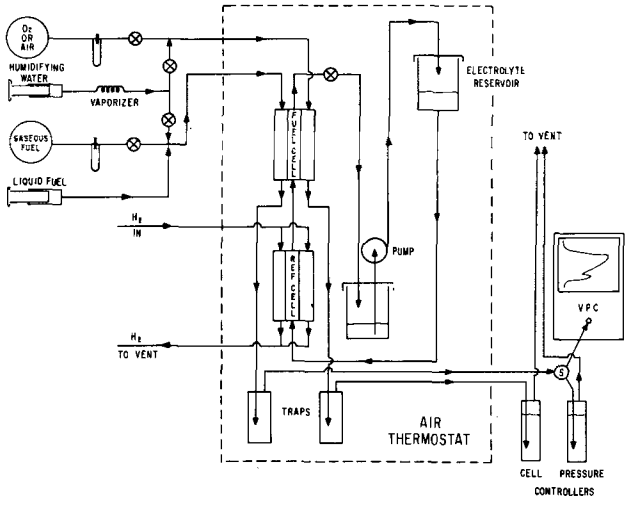

Fig. 2. Schematic diagram of apparatus

an all-PTFE bellows pump. The circulation rate was 4 to 10 cc/min. All surfaces which contacted the electrolyte were PTFE, except for the electrodes themselves which were Pt and PTFE.

The gaseous hydrocarbon fuels were metered by means of a needle valve and a capillary-tube flow meter, and the liquid fuels were fed by a constant-speed syringe drive. Fuel vaporization, where necessary, was carried out with an electrically heated vaporization unit in the feed line (13). Product analysis could be carried out on a chromatograph as desired, using sampling valves in the exit lines.

The normal saturated hydrocarbon fuels and their purities were: methane, Matheson ultra high purity, 99.95% min.; ethane, Matheson, cp, 99.0% min.; propane, Matheson instrument grade, 99.5% min.; butane, Matheson instrument grade, 99.5% min.; pentane, Phillips research grade, 99.84%; hexane, Phillips research grade, 99.99%; octane, Phillips research grade, 99.85%; decane, Phillips research grade, 99.49%; hexadecane, Phillips pure grade, 99.0% passed through silica gel for further purification. The oxygen was electrolytic grade, 99.6% minimum purity. The electrolytes were prepared from Cs_2CO_3 having less than 100 ppm impurities, purified using procedures already reported (14, 15), from Baker and Adamson reagent grade 48% HF, with less than 20 ppm impurities, and from quartz-redistilled H_2O. Electrolyte compositions were determined by acid-base titrations for HF, and by a gravimetric method for Cs as Cs_2SO_4; water was determined by difference.

The electrical measurements were carried out using a modified Kordesch-Marko interrupter (16, 17), yielding potentials on a resistance-free basis. The reference electrode was a reversible hydrogen electrode in the same electrolyte at the same temperature as the cell. All potentials reported are on a resistance-free basis unless otherwise specified. The current density-voltage data were usually measured starting at open circuit, increasing the current in a stepwise manner, and taking readings after electrical steady-state was indicated on a strip-chart recorder. Usually, a period 2-5 min was required to reach steady state at each current. Little or no hysteresis was observed when readings were taken by stepwise decreases in current, except at current densities below about 2 ma/cm².

Results and Discussion

Cesium-salt electrolytes at 150°C.—In order to investigate the effect of replacing the carbonate anion of the Cs_2CO_3 electrolyte by fluoride anion, the temperature of 150°C was selected because the cell C_3H_8(Pt)/85 w/o (weight per cent) Cs_2CO_3/(Pt)O_2 had shown the highest performance at that temperature (6). After taking the current density-voltage data for that cell, the electrolyte (about 200 cc) was drained from the system, a small (1-2 cc) sample was taken for analysis, and an addition of 25 cc of 48% HF was made, converting a portion of the Cs_2CO_3 to CsF. The electrolyte was then reconcentrated to a composition having a boiling point of 160°C, and returned to the system. After gathering current density-voltage data, the sampling and HF addition procedures were repeated.

The results for the performance of the propane anode are summarized in Fig. 3, where the numbers on the curves indicate the number of 25 cc HF additions that had been made to the initial Cs_2CO_3 electrolyte prior to taking the data. The first few additions resulted in essentially no change in anode performance. The shape of these curves is characteristic of a mass-transport limited electrode reaction and the low value of the limiting current density is probably associated with the very low solubility of propane in the electrolyte. Beginning with the seventh HF addition, the shape of the current density-voltage curve changed to a semilogarithmic form, characteristic of an electrochemical rate limiting process, and the current density at a given overvoltage increased by nearly

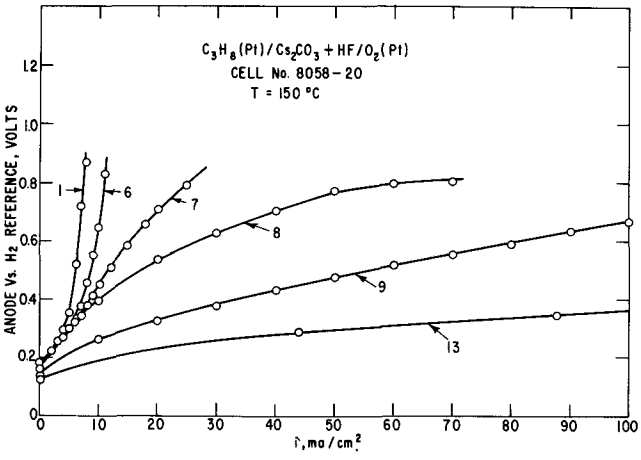

Fig. 3. Propane anode performance for various numbers of HF additions to the initial Cs_2CO_3 electrolyte.

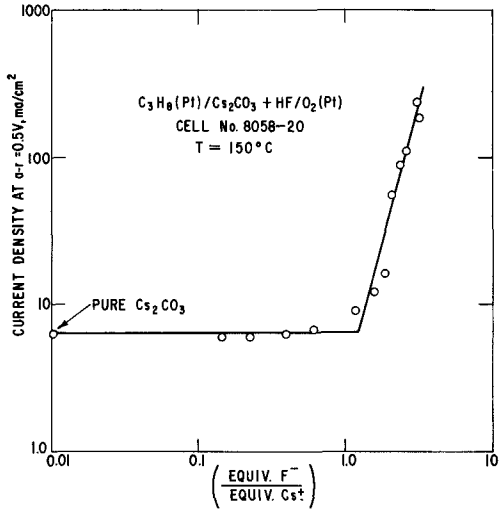

Fig. 4. Effect of fluoride:cesium ratio (by equivalents) on the anode current density at 0.5v *vs.* rhe, for propane on platinum black at 150°C.

two orders of magnitude. The large increase of current density necessitated a concomitant increase in the solubility-diffusion coefficient product for propane in the electrolyte.

The results shown in Fig. 3 were related quantitatively to the electrolyte composition by plotting the current density at an anode *vs.* reference potential of 0.5v as a function of the fluoride:cesium ratio in the electrolyte (as determined by analysis), as shown in Fig. 4. The datum point at $F^-/Cs^+ = 0.01$ is actually the 25 mole % Cs_2CO_3 —75 mole % H_2O point, and it is clear that substitution of the fluoride anion for the carbonate anion has no effect on the rate of propane oxidation, until the F^-/Cs^+ ratio exceeds a value of 1.2. It is probably significant that the electrolyte is still alkaline at a F^-/Cs^+ ratio of 1.0, and at about 1.2, the electrolyte becomes acidic, accompanying an increase in anodic oxidation rate. Further additions of HF cause an exponential increase of current density with F^-/Cs^+ ratio. The slope of the ascending portion of the line in Fig. 4 corresponds to the equation

$$i_{(E_{ar}=0.5)} = k\left(\frac{F^-}{Cs^+}\right)^{3.7} \qquad [1]$$

which indicates a very strong dependence of the propane oxidation rate on the HF content of the electrolyte. The F^-/Cs^+ ratio was not increased beyond 3.3 because further HF additions would bring the boiling point below 160°C (18).

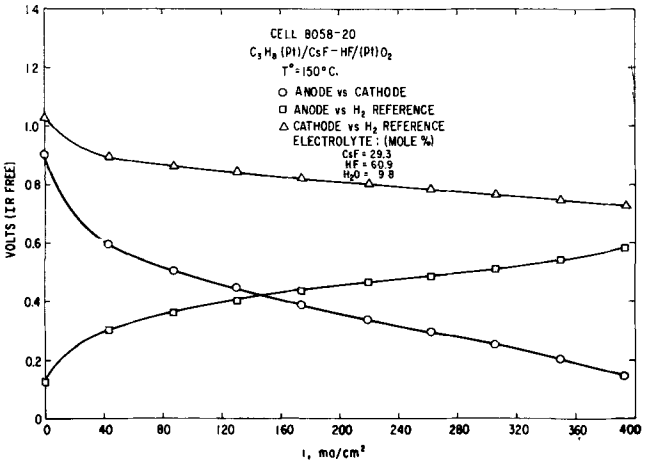

Fig. 5. Performance of propane at 150°C using optimum electrolyte composition

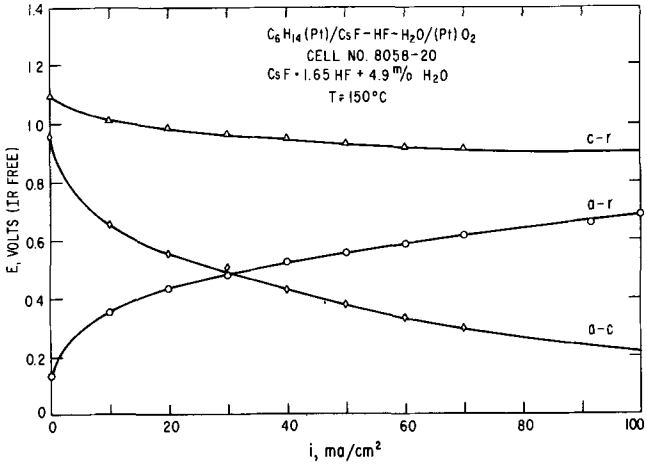

Fig. 7. Hexane performance at 150°C

The results shown in Fig. 3 and 4 suggest that the solubility-diffusion coefficient product for propane in the electrolyte was increased sufficiently by the HF additions so that at F^-/Cs^+ ratios above about 2, the diffusion of dissolved fuel no longer limited the anode performance. Furthermore, additional increases in the HF content of the electrolyte resulted in improvements in the rate of the electrochemical oxidation process at a given overvoltage, probably aided by the lack of fluoride anion adsorption.

The current density-voltage curves for the propane cell having an electrolyte of the optimum composition for operation at 150°C are shown in Fig. 5. The HF:CsF ratio was 2.08, and the water content was 9.8 mole %, corresponding to curve 13 of Fig. 3. A current density of 400 ma/cm² was obtained at a resistance-free cell voltage of nearly 0.2v; the anode *vs.* reference potential was 0.58v at 400 ma/cm². The maximum power density was 80 mw/cm², at about 0.3v, resistance-free.

Several other normal saturated hydrocarbon fuels were tested in the same cell at 150°C, using an electrolyte of the composition HF:CsF = 1.65, H_2O = 4.9 mole %. The methane performance is shown in Fig. 6. Note that current densities above 100 ma/cm² were obtained, indicating that methane is not as unreactive as might have been expected based on the usual organic chemistry experience at these temperatures. The current density supported by the methane anode at anode *vs.* reference potentials below about 0.3v is greater than that from the other saturated hydrocarbons, probably because of the higher H:C ratio of methane, and the absence of C-C bonds associated with the formation of a difficultly oxidized species on the anode surface (19). The maximum power density for methane was about 25 mw/cm², near 0.3v anode *vs.* cathode.

The current density-voltage curves for n-hexane at 150°C using the electrolyte HF:CsF = 1.65 H_2O = 4.9 mole % are presented in Fig. 7, from which it can be seen that the current densities obtained are similar to those for methane, and lower than those for propane. The maximum power point for n-hexane was 21 mw/cm², resistance-free.

The results for all of the normal saturated hydrocarbons investigated can be summarized by plotting the current density at selected anode potentials against the number of carbon atoms in the fuel molecule, as shown in Fig. 8. All of the normal saturated hydrocarbons, methane to n-octane, could be oxidized at practical current densities at 150°C, and all showed reactivities within a factor of five of one another. The data of Fig. 8 can be used to reconstruct the current density-voltage curves for the anodes.

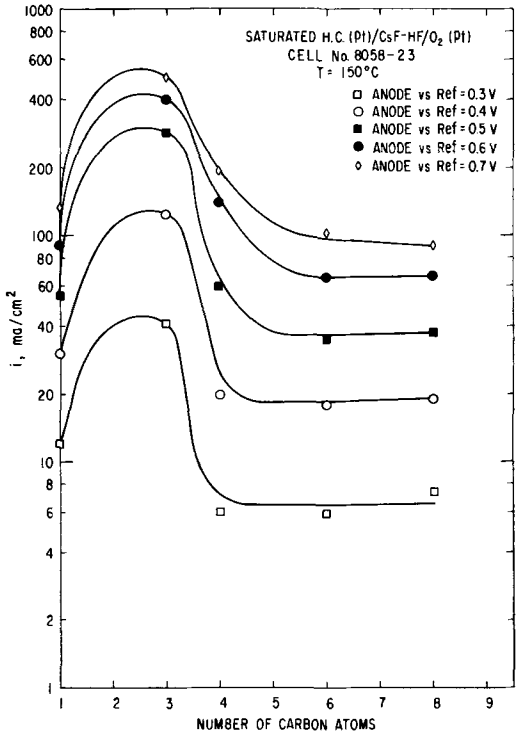

Fig. 8. Effect of fuel carbon number on rate of anodic oxidation at 150°C.

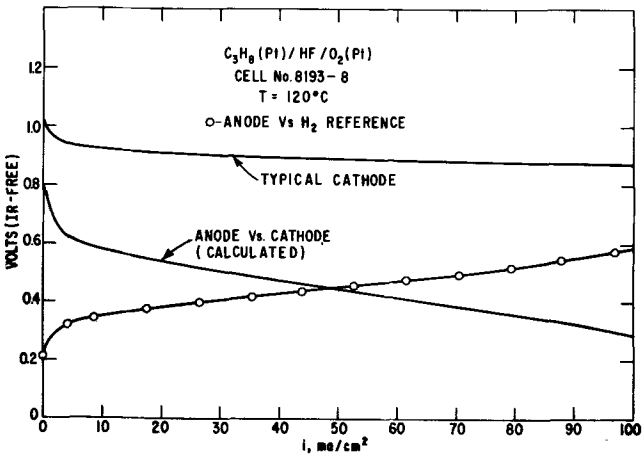

Fig. 9. Propane performance at 115°C, using 36 mole % HF electrolyte

Hydrofluoric acid azeotrope electrolyte at 105°C.— Because of the fact that the rate of anodic oxidation of propane increased rapidly with increasing HF content in the CsF-HF-H_2O system, it was decided that the HF concentration should be maximized by eliminating the CsF. The operating temperature was maximized by using the 36 mole % HF azeotrope (bp~ 115°C) (18) as the electrolyte. The elimination of the CsF made it necessary to operate the cell at temperatures in the range 105°-115°C, since the boiling-point elevation caused by the cesium fluoride could no longer be used to achieve the higher operating temperatures.

The current density-voltage curve for propane on platinum black (50 mg Pt/cm²) is given in Fig. 9, together with a typical cathode curve and the corresponding anode *vs.* cathode curve. The current density at a given anode potential is lower for the HF azeotrope at 115°C than for the optimum CsF-HF-H_2O electrolyte at 150°C (Fig. 5), but the propane performance at 105°C is still high enough to have practical interest, the maximum power density being 30 mw/cm², resistance-free.

The performances of methane, ethane, propane, butane, pentane, hexane, octane, decane, and hexadecane were determined at 110°C, in addition to that of propane, the usual fuel. These fuels fell into three classes: gas at both room temperature and the cell operating temperature (CH_4, C_2H_6, C_3H_8, C_4H_{10}), liquid at room temperature and gas at the cell temperature (C_5H_{12}, C_6H_{14}), and liquid at both temperatures (C_8H_{18}, $C_{10}H_{22}$, $C_{16}H_{34}$). There were no differences in cell performance which could be attributed to the physical state of the fuel in the cell, except for the fact that in general, the fuels which were liquids in the cell had lower partial pressures than the gaseous ones, resulting in relatively lower performance for octane, decane, and hexadecane. The performance results for the various normal saturated hydrocarbon fuels at 110°C are summarized in Fig. 10. The curve shapes are similar to those of Fig. 8, and generally agree with those found for hydrocarbons on Pt black in other strong acid electrolytes (20, 21).

The current densities obtained for the various hydrocarbons at 110°C in hydrofluoric acid are significantly higher per unit weight of Pt than those obtained with other acidic electrolytes at the same temperature, suggesting that there is a significant difference specific to HF. It is possible that this difference is related to the relative absence of anion adsorption with the HF electrolyte (22).

It should be mentioned that under no conditions has either current or voltage cycling been observed with

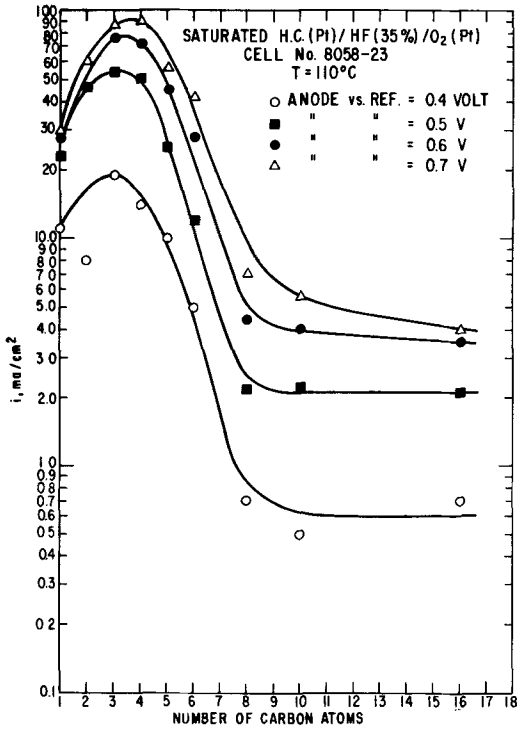

Fig. 10. Effect of fuel carbon number on rate of anodic oxidation at 110°C.

any of these fluoride electrolytes when operating on any hydrocarbon fuel, in contrast to other acid electrolytes (20, 23, 24).

Product identification and material balances.—Product identification was carried out on the chromatograph connected to the anode exit stream as indicated in Fig. 2. In order to prevent HF vapor from entering the chromatograph, a bubbler containing a saturated aqueous KF solution was placed in the fuel exit stream, efficiently absorbing the HF vapor. The product identification analyses showed that only CO_2 and H_2O were produced from the propane fuel.

Material balances, in which fuel disappearance rates as well as CO_2 production rates were measured and compared to the current drawn from the cell, indicated that the CO_2 yield was 95 ± 10% of theoretical, and the fuel consumption rate was about 100 ± 10%. These values correspond to measurements made in the temperature range 100° to 166°C, and at current densities from 5 to 100 ma/cm², using both HF-H_2O and CsF-HF-H_2O electrolytes. The major source of error was the measurement of the very low gas flow rates involved (sometimes less than 1 cm³/min).

Conclusions

1. The ternary system CsF-HF-H_2O comprises a set of electrolytes useful for high-performance saturated hydrocarbon fuel cells operating near 150°C, the performance increasing with increasing HF content.

2. The maximum performance is obtained using C_2-C_4 normal saturated hydrocarbons. Somewhat lower performance is obtained with C_1 and n-C_5-C_{16} paraffins.

3. Good performance is obtained with normal paraffins (particularly C_2-C_4) with the HF-H_2O azeotrope at 105°C.

4. Complete conversion of propane to CO_2 and H_2O has been observed for the temperature range 105° to 166°C, over a wide range of current densities for both the HF-H_2O and the CsF-HF-H_2O electrolytes.

5. No current or voltage cycling has been observed under any conditions.

Acknowledgments

It is a pleasure to thank Mr. G. J. Holm for his aid in performing the experiments, and Mr. L. D. Sangermano and Dr. E. L. Simons for their analyses of the electrolyte solutions.

This work is a part of the program under contracts DA-44-009-AMC-479(T) and DA-44-009-ENG-4909, ARPA Order No. 247 with the U.S. Army Engineer Research & Development Laboratories, Ft. Belvoir, Virginia, to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plants for operation on ambient air and hydrocarbon fuels.

Manuscript was received June 8, 1966. This paper was presented at the San Francisco Meeting May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

The Effect of Anodic Films on the Gaseous Oxidation of Tantalum

R. E. Pawel and J. J. Campbell

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The influence of anodic films up to 3000Å thick on the subsequent high-temperature oxidation characteristics of tantalum was studied. At a given temperature, the anodic films decreased the gross oxygen consumption rate to an extent dependent on their thickness and also delayed the onset of the "breakaway" increase in the oxidation rate common to this metal. The result that very thin anodic films pass comparatively large quantities of oxygen to the metal while postponing the appearance of the crystalline oxide phases permitted some oxygen solution effects during the early stages of oxidation to be observed.

While a considerable amount of interest exists in studies of the properties and behavior of anodic oxide films formed on the "valve-metals," only a few investigators have attempted to assess quantitatively the effect of an existing anodic film on the subsequent thermal oxidation characteristics. Polling and Charlesby (1) used optical and gravimetric techniques to observe the changes in thickness of anodic oxide layers on zirconium during gaseous oxidation at elevated temperatures. They found that in the thin-film range, oxidation proceeded along the same path as if the anodic layer were formed thermally. From this and other observations, they concluded that there was no essential difference between the thermal and anodic oxide films for this metal over the range of conditions used in their experiments.

Lakhiani and Shreir (2) observed the anodization of niobium at several temperatures in a variety of electrolytes. When the metal was anodized at low current density, (1 ma/cm^2), the growth of the initial oxide layer, its breakdown, and the development of a nonprotective oxide was observed to be qualitatively similar to the events during the early stages of thermal oxidation. The breakdown of the protective film in this case, by virtue of the physical similarity, was likened by Lakhiani and Shreir to a form of Vermilyea's "field crystallization," (3) where regions of crystalline oxide were assumed to nucleate within the film and consume the amorphous oxide. While Vermilyea (3, 4) had visualized field crystallization, at least for films on tantalum, in a different way, *i.e.*, a mechanical displacement process beginning at the oxide-metal interface, it may still be that the important event responsible for film breakdown in both cases is indeed closely related.

Some comparisons of the general behavior of the thermal and anodic oxidation processes of tantalum and niobium have also been made by Harvey, Draper,

and Wilman (5-7). They likewise picture that for both metals an initially amorphous, anodic-like film forms during the decreasing-rate period of thermal oxidation. Breakaway was proposed to be associated with the formation of "crystal nuclei," followed by cracking of the overlying amorphous pentoxide film.

Also of interest in comparing thermal and anodic oxide films is the growing amount of information on the high-temperature annealing characteristics of anodic films (4-9). If an anodized tantalum specimen is held in vacuum at elevated temperatures, the anodic film will lose oxygen to the metal with no apparent change in thickness, resulting in drastic changes to its electrical properties. At temperatures above 500°C, the anodic films have been reported to crystallize and/or dissolve into the metal. In any case, there appears to be considerable mobility in these films at temperatures above 200°-300°C.

Although the similarities noted above between the anodization process and of some of the important low-temperature thermal-oxidation characteristics might indicate that similar mechanisms, if not identical systems, are involved, it has been established elsewhere that several important differences also exist, particularly for the oxidation of tantalum. For example, effects of oxygen solution and the appearance of the metallic suboxides of tantalum during thermal oxidation (10-11) present a complication that is not faced during anodic oxidation. For specimens oxidizing, prior to breakaway, in the temperature range 300°-550°C, at least two crystalline oxides other than the pentoxide have been identified. The particular physical form associated with suboxide growth (platelets) is difficult to rationalize in terms of conventional oxidation behavior.

The present paper reports the results of a series of experiments in which anodized tantalum specimens were subjected to further oxidation in dry oxygen at elevated temperatures. The characteristics of the anodic films are compared to the thermally formed oxide products especially with regard to the delaying effect an existing anodic film exerts on the "breakaway" process.

Experimental Procedure

For the kinetic studies, tantalum specimens were prepared from 1 × 2 cm and 1 × 4 cm coupons cut from 0.020-in. sheet. The coupons were annealed in vacuum for 2 hr at 1600°C, mechanically polished through 0.3μ alumina, and finally electropolished in a 90% H_2SO_4-10% HF solution. (Nominal analysis of tantalum is about 99.7-99.8% with Nb, Fe, W, and Si being major metallic impurities; interstitial content after vacuum anneal is approximately 200-300 ppm.) A short length of 0.010-in. tantalum wire was discharge welded to one end of the specimen to serve as electrical contact during anodization and support during subsequent handling. Several anodization procedures were utilized, including (*i*) anodizing in 0.5% Na_2SO_4 after boiling the specimens in distilled water to remove, or at least nullify the effect of, any residual fluoride from the electropolish; and (*ii*) anodizing the electropolished specimen in 0.2% KF. These procedures result in highly adherent and poorly adherent anodic films, respectively. However, when heated for short times at 400°C or above, both types of film were adherent, and each resulted in specimens which behaved similarly for the experiments reported in this paper. Our present results are thus based on anodic films formed in the above dilute electrolytes. As is the case for many other properties of anodic films, it is highly probable that films formed in different media, particularly concentrated solutions, would exhibit behavior different in degree, if not in kind, from that reported here.

The specimens were anodized at constant voltage by allowing the current to discharge through a variable resistor in series with the cell. The current density was generally maintained at less than 20 ma/cm² by manually reducing the series resistance as anodization proceeded. In order to utilize a voltage-thickness calibration, the specimens were anodized for an arbitrary "standard" time of 3 min, sufficiently long so that the film thickness was insensitive to minor variations in the anodization time. Our previously reported value (12) of 16.7Å per applied volt was used to obtain the oxide film thickness.

The specimens were heated quickly in oxygen to the desired reaction temperature and the oxidation rates were measured by a manometric technique previously described (13). Pressure changes during an experiment were small enough (generally less than 15 mm Hg) to consider the oxidation conducted at constant pressure. All oxidation experiments were carried out in dry oxygen at atmospheric pressure.

The development of stresses in the oxidizing specimens was followed in a series of "flexure" experiments. Tantalum coupons, 1 × 4 cm, prepared as noted above, were anodized and one side protected with a thin film of vapor-deposited aluminum. The flexure of such specimens during oxidation was measured and converted to maximum bending stress values in a manner already reported (14).

Results and Discussion

The initial stages of the gaseous oxidation of tantalum metal in the intermediate temperature range 400°-600°C have been described on both kinetic and phenomenological bases (10, 11). These studies have shown that this part of the oxidation process is comparatively complicated, distinguished by the formation and growth of platelets of oxide rather than reasonably uniform oxide films. Platelet formation is related to oxygen solution effects and the particular mode of formation of the suboxides of tantalum. If the tantalum specimen surface is electro- or chemically polished so that a disturbed surface layer is not present, these developments during oxidation can be followed easily in a hot-stage microscope or by standard metallography.

As oxidation proceeds, the formation of the pentoxide is associated with an abrupt increase in the oxidation rate. While there is still disagreement in the literature concerning the particular phenomenon or "important event" responsible for the increased rate, all investigators agree that the bulk of the pentoxide, once formed, offers little resistance to oxygen permeation and thus serves poorly as a protective oxide film. It seemed reasonable to us to suggest that the films formed on tantalum during the postbreakaway part of gaseous oxidation were poorly protective because of the manner in which they were formed and not necessarily because of some inherent property.

The nonuniform oxide morphology which exists during the decreasing-rate period of oxidation prior to breakaway certainly does not resemble the product of anodic oxidation, although as will be discussed later, a superficial anodic-like layer may enhance platelet formation. However, because of the differences in properties, studies of the thermal oxidation of anodized tantalum permit certain aspects of the early stages of this process to be emphasized.

Vacuum treatments.—In this phase of the research, we have been concerned with the oxidation characteristics of anodized specimens at temperatures below which the rate of crystallization or oxide dissolution becomes appreciable. Preliminary experiments in which anodized specimens with films 250Å and thicker were held in vacuum showed that at temperatures as high as 500°C the dissolution rate of the oxide was extremely low. Such vacuum treatments could, however, result in a lessening in the degree of protection afforded an anodized specimen during subsequent oxidation. Vermilyea (7) and Smith (9) have pointed out that while the thickness of the anodic film on tanta-

lum remains constant during low-temperature annealing (at least the interference color does not change perceptibly), some oxygen from the oxide is taken into the metal with a resulting large change in the electronic properties of the oxide. In addition, Vermilyea showed a slight sharpening of the diffraction halos from the essentially amorphous oxide films during such treatments. We have also observed by electron diffraction similar structural changes during annealing of films stripped from the metal (15). Actual crystallization of the stripped films within reasonable times did not occur at temperatures below 550°-600°C (6, 8, 15); higher temperatures appear to be required for complete crystallization of films-in-place on the metal.

While films held in vacuum at 500°C were stable for long periods of time, or dissolved extremely slowly, an appreciable rate of anodic film dissolution was observed on specimens held at 600°C, the films exhibiting a behavior very much like that reported by Pemsler for diffusion-controlled film dissolution on zirconium (16) and hafnium (17). Of particular interest was the observation that the dissolution process in the case of b.c.c. tantalum also was not completely isotropic; *e.g.*, several interference colors sharply defined by the grain boundaries existed after annealing an anodized polycrystalline specimen. Furthermore, observations on annealed anodized single-crystal cylinders with <110> axes indicated that the dissolution rate at this temperature was almost uniform (at least along the [110] zone) except within about ±10° of a (100). At the (100), the dissolution rate, at least for the first few hours, was observed to be slightly more than twice as great as the other areas. In all regions, the dissolution rate decreased with time. However, while the amount dissolved on the (100) showed a parabolic time dependence, at least up to 24 hr, our rather limited data for dissolution in the slower region could not be satisfactorily described in this way over this time range.

Oxidation.—If the anodized tantalum specimens were held in dry oxygen at atmospheric pressure instead of vacuum, dissolution of the films was not generally observed. Instead, at temperatures of at least 500°C, the films exhibited a very high degree of stability and resistance to thickening as well as dissolution. Insofar as could be judged from the lack of change in the interference color of an anodic film before and after such treatments, the film thickness and the appearance of the metal surface was not altered despite the fact that oxygen solution was occurring through the film into the metal.

Anodized tantalum specimens having film thicknesses of approximately 250-2500Å were oxidized for extended periods of time at 500° and 600°C in order to assess systematically the degree of protection which results and to observe the eventual "failure" of the film. For example, after 24 hr at 500°C for films 500Å and thicker, visual comparison with an as-anodized, standard specimen revealed no significant changes in the interference colors or general specimen appearance; unanodized specimens subjected to the same treatment underwent substantial oxidation, with white scales of the pentoxide as the prominent feature. While it quickly became apparent that the degree of protection at a given temperature was directly dependent on the thickness of the anodic layer, it was also observed that imperfections in the films play an important role. Anodic films exhibiting low leakage currents formed on well electropolished surfaces were more efficient in "protecting" the metal from oxidation. Local breakdown of the film at a point of weakness may, instead of being self-healing, lead to an accelerated deterioration of the remainder of the film. This is particularly noticeable in the case of films less than 250Å in thickness where the oxidation behavior is difficult to reproduce. Once local breakdown has occurred, the metal oxidizes rapidly and the voluminous pentoxide which is formed propagates the disturbance. The topography more closely resembles the breakdown of the slowly oxidizing (100) face of niobium (13) than that of any stage of oxidation of plain electropolished tantalum.

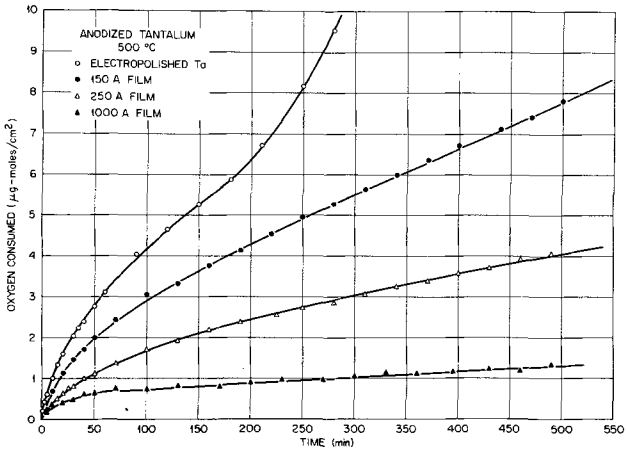

Fig. 1. Effect of anodic film thickness on the oxidation rate of polycrystalline tantalum at 500°C. ○ plain electropolished tantalum; ● 150Å anodic film; △ 250Å anodic film; ▲ 1000Å anodic film.

While it was difficult to tell by visual inspection if the anodized specimens were undergoing change during the exposure to oxygen prior to breakdown, metallographic examination, flexure experiments, and x-ray analysis indicated that oxygen was being dissolved into the metal in substantial quantities. Smyth *et al.* (9) as part of their studies of the dielectric properties of anodic films, have also reported that oxygen penetrates the film to the metal during heat treatment in air. Furthermore, because of the nature of the property changes, they were able to conclude that the oxygen passes through the film itself and not by way of cracks or pores.

Kinetics.—The effect of thin anodic oxide films on the early stages of oxidation of tantalum is illustrated quantitatively in Fig. 1 which shows the kinetics of oxygen uptake at 500°C for plain electropolished tantalum and anodized tantalum having film thicknesses of 150, 250, and 1000Å. During the decreasing-rate period of reaction for plain tantalum, most of the total oxygen consumed is going into solution in the metal. After about 10 min, platelets of a suboxide of tantalum extending into the metal begin to form; after about 3 hr, the increasing oxidation rate signals the occurrence of "breakaway," and the specimen is soon covered with a thickening, porous film of the pentoxide. On the other hand, the presence of an anodic film obviously impedes the reaction to an extent dependent on the film thickness. Since the film thickness does not change appreciably during this period,[1] the oxygen consumed is thus going into solution in the metal. Nevertheless, compared to plain tantalum, the appearance of oxide platelets in the metal beneath the anodic film is postponed, both on a time basis and on the basis of the total oxygen consumed. It may be that the oxygen concentration in the metal surface layers beneath the anodic film remains less than that during oxidation of the plain metal. Another possibility is that the presence of the anodic film affects the pertinent surface energies so as to make it energetically expensive for a new oxide phase to form. In either case, a greater total amount of oxygen would be necessary to initiate platelet formation. Because of this, or the associated increased strain energy, the observation

[1] It might be argued that the refractive index of the film and perhaps the metal change in such a direction and with such magnitude so as to mask the observation of a thickness change. While in principle this is possible, the probability is small that such an effect would not be noticed over the wide range of film thicknesses, annealing times, and temperatures studied.

that platelets formed on anodized tantalum are generally larger than those on plain tantalum is consistent with either explanation. Also postponed on both bases is the breakaway increase in the oxidation rate. While comparatively thick anodic films, 1000Å and up, afford effective protection for long times, films as thin as 40Å produce dramatic differences in breakaway oxidation behavior compared to the plain tantalum. It is to be noted, however, that films in this thickness range pass oxygen at a rate comparable to that used during the oxidation of the plain tantalum. Thus, an anodic oxide film on tantalum has the unusual property of serving both as a semi-inert barrier film and as a repressor of the formation of the crystalline oxides during subsequent thermal oxidation.

The effect of temperature on the oxidation kinetics of anodized specimens was also studied. The oxidation rate curves at temperatures from 425° to 575°C for plain tantalum and for anodized tantalum with film thicknesses of 250 and 1000Å are presented in Fig. 2, 3, and 4. The protection afforded by these films is seen to persist over the whole temperature range. Films thicker than 1000Å were generally even more resistant; for example, even at 600°C a 3000Å film prevented breakaway for at least 4 hr. However, the thicker films become increasingly susceptible to electrical breakdown during their formation, especially in poorer quality films where certain flaws are "activated" at comparatively low voltages. In such films,

breakaway oxidation is initiated quickly in these local regions, resulting in a general loss of oxidation resistance. Vermilyea (4) has described in detail the importance and nature of some of the imperfections in anodic films. Presumably, flaws in the thinner films also represent points of weakness with respect to oxidation as well as electrical and chemical attack, and eventual breakdown of the films would begin at these points.

It is difficult to place much confidence in the pertinence of a particular analytical expression describing the prebreakaway oxidation kinetics of anodized tantalum. After an initial decreasing-rate period, the time dependence is more-or-less linear until the onset of breakaway. The oxygen consumption rates in this region were obtained from the data in Fig. 3 and 4 and are plotted as a function of reciprocal temperature in Fig. 5. Within the limits of accuracy of the experimental values, the data for the 250 and 1000Å films describe two near-parallel lines differing by a factor of about four in ordinate values. That the rate ratio for oxygen consumption at each temperature is ap-

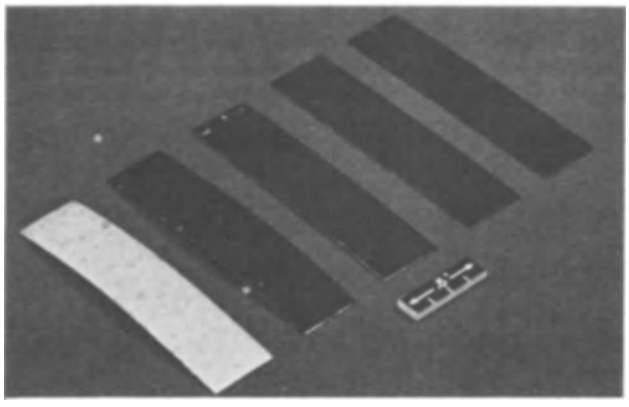

Fig. 6. Flexure and surface appearance of plain and anodized tantalum after oxidation for 2 hr at 530°C. From left to right, the specimens are plain electropolished tantalum and tantalum having film thicknesses of 40, 80, 160, and 250Å, respectively. The underside of each specimen was protected by a vapor-deposited aluminum layer.

proximately equal to the inverse of the thickness ratio is evidence in favor of the oxygen mass transport mechanism in the anodic film as being rate controlling. The decreasing rate period at the beginning of the reaction is, in this light, simply a transient in the approach to a steady-state diffusion condition. If the above reasoning is correct over the whole temperature range, the activation energy for oxygen transport in amorphous anodic films on tantalum is, from Fig. 5, about 45,000 cal/mole.

Flexure.—The fact that the thin anodic films suppressed the formation of additional oxide while allowing oxygen to penetrate to the metal during exposure to oxygen permitted a critical test to be made of the authors' earlier conclusion (14) that oxygen solution effects, rather than the formation of oxide, were primarily responsible for the observed surface stresses in the preliminary stages of tantalum oxidation. Thus, measurements were made of the flexure of thin anodized specimens exposed to oxygen on one side. The occasion of a definite flexure of such specimens during a period of time when no additional oxide was observed to form seemed conclusive evidence that oxygen in solution is a major source of stress.

A typical set of tantalum specimens used in the flexure experiments is shown in Fig. 6. This photograph illustrates the flexure and surface appearance of plain tantalum and tantalum with anodic oxide films thicknesses of 40, 80, 160, and 250Å after oxidation for 2 hr at 530°C. The plain tantalum surface is heavily oxidized and the specimen is bent. The anodized specimens show varying degrees of flexure but, with the exception of the 40Å specimen, show no metallographic or x-ray evidence of additional oxides. Despite their dark appearance in the figure, the surfaces of these specimens are still bright, in sharp contrast to that of the plain tantalum. In the microscope, the 40Å specimen shows only little physical evidence of the comparatively large amount of oxygen taken into solution. Distortion markings and a few large platelets, common to the earliest stages of oxidation of plain tantalum are visible. The topography of the plain tantalum specimen and 40Å anodized tantalum specimen is compared in Fig. 7 and 8. Specimens with thicker anodic films exhibit essentially the same microstructure as in the as-anodized condition.

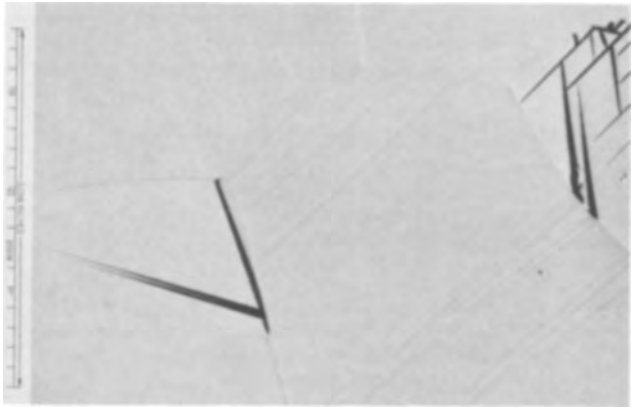

Fig. 8. Surface appearance of anodized polycrystalline tantalum having a film thickness of 40Å after 2 hr in oxygen at 530°C.

Quantitative measurements of the degree of flexure were made during oxidation of the anodized specimens. As shown in Fig. 9, the maximum bending stress, computed from the physical properties and radius of curvature of the specimen as a function of time, varied similarly to the total amount of oxygen going into solution, reaching a value of about 16,000 psi after 6 hr of oxidation. Because of the obviously different set of boundary conditions applicable in this case, the actual surface stress and stress distribution due to oxygen solution cannot be computed in the manner previously reported for plain tantalum (14). However, since the total strain energies in both cases (for specimens with very thin anodic films, at least) are about the same, it is reasonable to suspect stresses in the surface region to approach that observed in plain tantalum, approximately 50,000 psi compression.

X-ray results.—X-ray data consistent with the above arguments were also obtained. Before and after exposure to oxygen, diffraction measurements were made through the anodic film of the lattice spacing of metal planes parallel to the surface. Lattice param-

eters were also determined by the Debye-Scherrer techniques for thin surface layers filed from the metal. The results by these two techniques correlated very well if it was assumed that an oxygen concentration gradient existed in the metal. For the case of both plain tantalum and anodized tantalum, exposure to oxygen at 500°C quickly increased the tantalum lattice parameter, calculated from the interatomic spacings of planes parallel to the surface, to 3.330Å, a dilation of about 0.025Å compared to unoxidized control specimens. This dilation, since it is limited only to a thin surface layer and because of the constraints imposed by the remainder of the specimen outside the gradient, is larger by about a factor of two than that which would result from the same uniform concentration of oxygen (18). On the basis of a uniform distribution, the appropriate lattice parameter would have been 3.317Å, corresponding to an oxygen concentration of about 3.7 a/o (atomic per cent) (19). It was observed that this latter parameter value agreed much better with that obtained from similar specimens by the Debye-Scherrer method, 3.312-3.314Å, especially considering the deeper section employed. Since a rather steep oxygen concentration gradient may develop during oxidation, the maximum oxygen concentration immediately beneath the surface may rise to values higher than that reported here.

Conclusions

The results of this investigation have shown that anodic films formed on electropolished tantalum specimens can exert a surprisingly great influence on the gaseous oxidation characteristics. Films as thin as 40Å, for example, were observed to double the length of the "protective" period for tantalum at 500°C. During the time that the anodic films remain protective, they are substantially amorphous in structure, and pass oxygen to the underlying metal without "growing" or changing in thickness. The activation energy for oxygen permeation of these films was calculated to be about 45,000 cal/mole. The anodic films appear to slow down the oxidation process in two ways: (*i*) the oxygen flux is reduced, being related inversely to the film thickness; and (*ii*) the nucleation of the crystalline suboxides of tantalum is postponed to higher total oxygen levels. This may be a result of a changed oxygen concentration gradient near the surface, or of a change in other properties at the metal surface due to the film. The anodic films lose their protective properties as breakdown occurs first at localized points and then spreads across the specimen mainly by lateral growth of the fast-oxidizing regions. Presumably these localized points are associated with imperfections in the film or metal causing crystalline oxides to form more quickly at the metal-anodic oxide interface. While the films dissolve into the metal at measurable rates when held in vacuum at temperatures above 500°C, their retarding effects during oxidation may be observed at temperatures of at least 600°C. The occurrence of oxygen solution in the metal during oxidation of anodized tantalum was observed by several methods. Flexure and x-ray measurements correlated well with the concept that high stress levels exist along the oxygen concentration gradient in the metal.

Acknowledgments

The authors would like to thank J. V. Cathcart for his assistance during the course of this investigation and in the preparation of the manuscript. We also acknowledge the efforts of C. J. Sparks and R. M. Steele for the x-ray measurements. Research on this paper was sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

Manuscript was received June 23, 1966. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Technical Notes

Corrosion of Zircaloy-2 by Hydrogen Peroxide at Elevated Temperature

R. J. Davis, T. H. Mauney, and J. R. Hart

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

It has been shown that fission fragment (1, 2) or fast neutron (3) bombardment accelerates the corrosion of Zircaloy-2 by oxygenated aqueous media. The corrosion occurs at constant rates, and for fast neutron bombardment the corrosion rate, R, in terms of weight gain ($\mu g/cm^2/day$) and neutron flux of energies greater than 1 Mev, ϕ ($n/cm^2/sec$) is

$$R = 7 \times 10^{-12}\phi$$

The acceleration of corrosion in hydrogenated media (3) under fast neutron bombardment is much less or perhaps nil. Ionizing (β-γ) irradiations (4, 5) do not accelerate Zircaloy-2 corrosion in oxygenated aqueous media.

Since β-γ radiations do not accelerate corrosion, it has been concluded in the past (1, 2) that the heavy particle effect was due to damage in the metal or oxide, but not due to species generated in the aqueous solution. This conclusion followed from the fact that β-γ radiations produce the same species in solution as do heavy particles, and it was assumed that the concentrations were not enough different to explain the results.

Cox (6) recently pointed out that some in-pile loop results (7) indicate accelerated corrosion of Zircaloy-2 exposed to solution, one second downstream of the irradiated part of the loop. This suggested the possibility that hydrogen peroxide, probably the only specie with a half-life approaching one second, was responsible for the corrosion. [The authors had (7) considered this possibility, but did not believe the data justified any conclusions.] Subsequently Jenks (8) showed that corrosion effects of the two types of radiations could be qualitatively explained by assuming that corrosion is accelerated by low concentrations of H_2O_2 and that the acceleration increases with concentration. It was estimated that in water at 280°C, a steady-state H_2O_2 concentration in the neighborhood of 10^{-5}M would exist under reactor irradiation at moderate intensities. Furthermore, the concentration would increase with dissolved oxygen in stoichiometric excess and would decrease with dissolved hydrogen in excess. The concentration of H_2O_2 under β-γ irradiation would be much lower. These findings suggested the following experiment.

Experimental

Specimens of Zircaloy-2 were exposed to 10^{-5}M H_2O_2 at 280°C for 297 hr. A control group of specimens was exposed in the same set-up to oxygenated water.

The peroxide exposure was accomplished by the feed and bleed system shown in Fig. 1. Hydrogen peroxide solution (0.05M) was pumped into an autoclave by a pulse-feeder pump at the rate of about 800 cc/hr. The autoclave was completely liquid-filled, and the solution in the autoclave was stirred with a magnetically operated dash pot stirrer. The solution

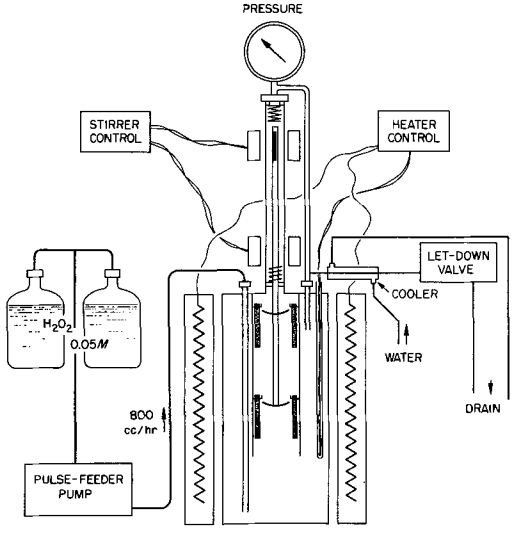

Fig. 1. Feed and bleed autoclave system

Table I. Summary of weight gains

Weight Gain Results			
Specimens exposed to:	10^{-5}M H_2O_2		Oxygenated water
Specimens pretreated by:	Prefilming 20 hr	Chemical polishing	Chemical polishing
No. of specimens	4	2	8
Weight gain, avg value ($\mu g/cm^2$)	91*	88	104
Weight gain, range ($\mu g/cm^2$)	80-100*	87-90	89-119

* Total weight gains including that during 20-hr prefilming.

coming out of the autoclave was quickly cooled to room temperature, and then bled out of the system at 1500 psi through a let-down valve. Periodic samples of the output solution were analyzed and found to contain about 10^{-5}M (range 0.6 to 1.2 x 10^{-5}M) hydrogen peroxide. All parts of the system which were heated were constructed of titanium.

The controls were run in the same autoclave at the same temperature for the same length of time. The autoclave was initially filled with the same 0.05M peroxide solution which quickly decomposed on heating to provide an environment of oxygenated water. No peroxide was pumped through the system.

Both sets of specimens were chemically polished in $HF-HNO_3$ and some of them were prefilmed by exposure to 280°C water for 20 hr before exposure to the peroxide. Corrosion was measured by weight gain.

The weight gains are summarized in Table I.

Discussion

The data demonstrate that corrosion of Zircaloy-2 by oxygenated water is not enhanced by continuous feeding of hydrogen peroxide at a concentration of 10^{-5}M.

Estimates (8) of peroxide concentrations in oxygenated water indicate that the 10^{-5}M is about the peroxide concentration which exists during irradiation by a fast neutron flux of 10^{13} n/cm²/sec (> 1 Mev). This flux, in turn, is known to result in a corrosion rate of about 70 $\mu g/cm^2$/day.

From the observed rates of 7-8 $\mu g/cm^2$/day, it followed that hydrogen peroxide in solution is not responsible for the corrosion acceleration which results from irradiation by fast neutrons.

Electroluminescence and Photoresponse of Ta_2O_5 and TiO_2 Diodes

T. W. Hickmott

General Electric Research and Development Center, Schenectady, New York

Electroluminescence has been observed from rectifying Ta-Ta_2O_5-Au and Ti-TiO_2-Au diodes under d-c forward bias and the photoresponse of such diodes has been measured in the visible portion of the spectrum. In each case, the photoresponse threshold is approximately equal to the energy of electroluminescent radiation from the diode.

Tantalum strips, 1 mm wide and ~6000Å thick, were deposited on heated glass microscope slides by electron beam evaporation through a mask (1). Titanium strips of high resistivity, indicative of low purity of the metal, were deposited on microscope slides by sputtering in argon. Oxide films were formed by anodizing at constant current, followed by curing at constant voltage until the current through the oxide decreased to low levels. For tantalum, 0.5% H_2SO_4 was used as electrolyte while a formic acid electrolyte was used to anodize titanium (2). The thickness of the oxide film is proportional to the final forming voltage; for Ta_2O_5, the thickness is ~17 Å/v, for TiO_2, ~22Å/v. Diodes of 1 mm² area were formed by evaporating semitransparent Au or Cu electrodes, 200Å thick, through a mask. Procedures used to measure conductivity, electroluminescence and photoresponse have been described (3, 4).

Both Ta-Ta_2O_5-Au and Ti-TiO_2-Au diodes are rectifying, with high conductivity occurring when the Au counterelectrode is positive. Figure 1 shows the

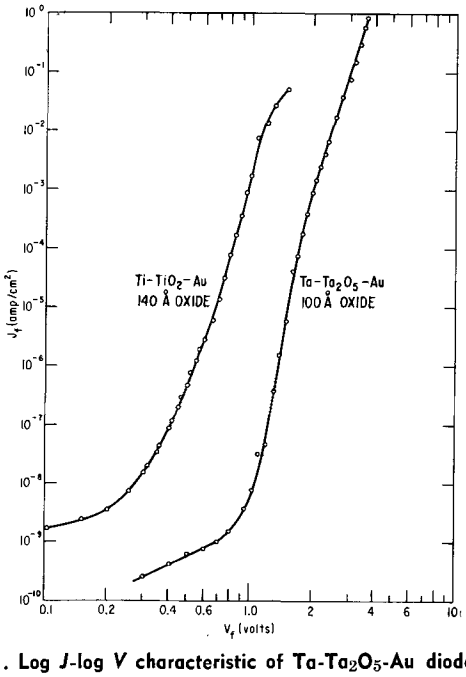

Fig. 1. Log *J*-log *V* characteristic of Ta-Ta_2O_5-Au diode and Ti-TiO_2-Au diode. $T = 295°K$.

current-voltage characteristic under forward bias for a Ta-Ta_2O_5-Au and a Ti-TiO_2-Au diode formed to 5v. The current density, J, was derived from the measured currents by using the geometric area of the diode. The J-V characteristic of the Ta-Ta_2O_5-Au diode is very similar to that reported by Standley and Maissel (5). Below 0.9v, currents reached a steady-state value very slowly after applying a step voltage; it was necessary to wait several minutes to record each value of current. In the steeply rising portion of the J-V curve there was no appreciable drift of current values until high current densities were reached. The J-V characteristic of the Ti-TiO_2-Au diode closely resembles the J-V characteristic of a Nb-Nb_2O_5-Au diode of comparable thickness although the currents are higher. Anodic films are difficult to form on titanium and the quality of anodized TiO_2 films is much poorer than anodized films on Ta or Nb.

High field electroluminescence of valve metals such as Al or Ta under reverse bias or during anodization has been known for many years (6). Very faint visible radiation may be observed under such conditions. Only in Nb-Nb_2O_5-Au diodes has electroluminescence been reported to occur in rectifying oxide films at low diode voltages under d-c forward bias (3).

Electroluminescent radiation from Nb-Nb_2O_5-Au diodes was detected by means of a cooled 7102 photomultiplier with S-1 sensitivity, and glass filters were used to show that it had energy between 1.2 and 1.3 ev (electron volts), independent of diode voltage or oxide thickness. Figure 2 shows the ratio of photomultiplier current, I_p, to diode current, I_f, and I_f, at different diode voltages, V_f, for a Ta-Ta_2O_5-Au and Ti-TiO_2-Au diode with the same oxide thicknesses as in Fig. 1. The diode temperature was ~0°C. The operating conditions of the photomultiplier were the same as used in measurements of electroluminescence from Nb-Nb_2O_5-Au diodes. The energy of electroluminescent radiation can only be determined approximately because of the spectral characteristics of the filters. For Ta-Ta_2O_5-Au diodes, no radiation with energy greater than 1.8 ev was detected. The peak electroluminescent intensity lies between 1.5 and 1.7 ev, appreciably higher than for Nb_2O_5 diodes. For Ti-TiO_2-Au diodes, emitted radiation had energy between 1.2 and 1.4 ev. Electroluminescence from Ta_2O_5 diodes also

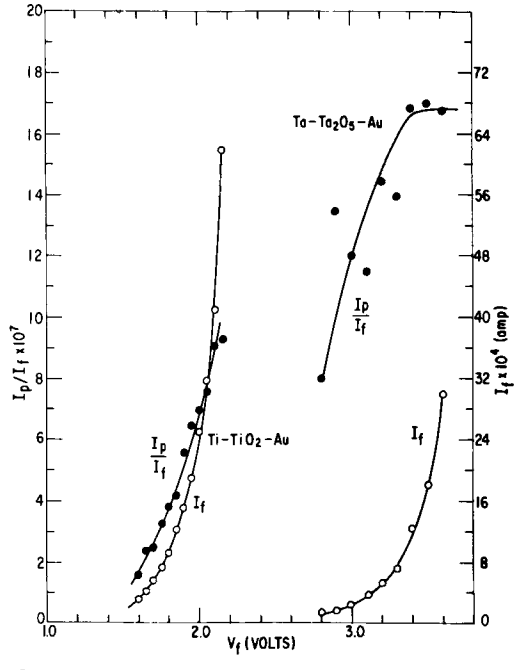

Fig. 2. Relative electroluminescent efficiency and diode current for Ta-Ta_2O_5-Au diode (100Å oxide) and Ti-TiO_2-Au diode (140Å oxide).

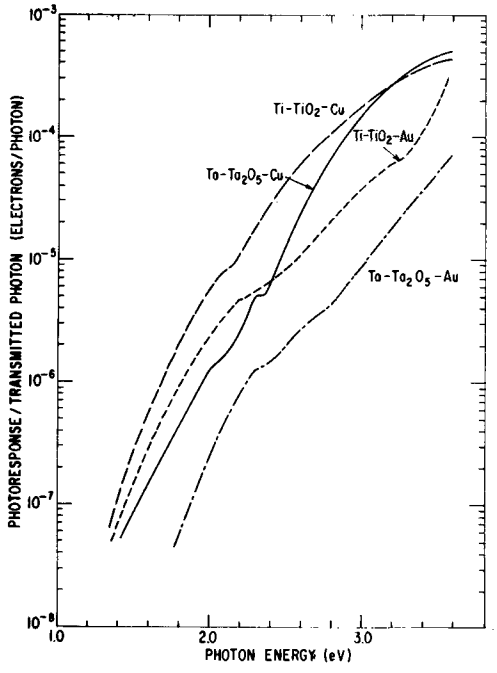

Fig. 3. Photoresponse/transmitted photon of Ta_2O_5 and TiO_2 diodes.

differed from electroluminescence from Nb_2O_5 and TiO_2 diodes in that $I_p \alpha I_f$ above 3.2v while $I_p \alpha I_f^2$ for the latter two oxides.

The observation of photoconductivity in the system valve metal/anodic oxide/electrolyte generally requires uv-radiation (7). For Ta_2O_5, the threshold for photoconductivity is 4.3 ev (8), for Nb_2O_5, 3.3 ev radiation (9). In contrast the threshold for photoconductivity in Nb-Nb_2O_5-metal diodes, where the metal counter electrode is Au, Ag, or Cu, is 1.2 ev, the same energy as electroluminescence from Nb_2O_5 diodes (3). The short-circuit photoresponse/transmitted photon for Ta-Ta_2O_5-Au, Ta-Ta_2O_5-Cu, Ti-TiO_2-Au, and Ti-TiO_2-Cu diodes is shown in Fig. 3. In each case, the oxide is so thin (5v) that optical interference phenomena in the oxide do not affect the photoresponse (4). Corrections have been made for the variation of transmission of the metal counter electrode with wavelength in calculating the photoresponse/transmitted photon.

As is the case with Nb_2O_5 diodes, the threshold for photoresponse in TiO_2 diodes, 1.3 ev, is the same with Au and Cu counter electrodes and is approximately equal to the energy of electroluminescence from Ti-TiO_2-Au diodes. In contrast, while the threshold for photoconductivity in Ta-Ta_2O_5-metal diodes is shifted into the visible it differs by 0.4 ev when Au and Cu counter electrodes are used. The quantum efficiency of Nb_2O_5, Ta_2O_5, or TiO_2 diodes is markedly smaller with Au counter electrodes than with Cu counter electrodes. For TiO_2 and Ta_2O_5 diodes with Cu counter electrodes, there is an inflection in the photoresponse at 2.1 ev while diodes with Au counter electrodes show a similar inflection at 2.3 ev. This is the energy of the maximum value of the transmission of thin evaporated films of these metals; similar inflections occur in the photoresponse of thin Nb_2O_5 with Cu and Au counter electrodes (4). Maximum photovoltages for the diodes of Fig. 3 due to intense visible radiation have been measured by focusing the light from a 40w zircon arc lamp onto the diodes. Maximum photovoltages at 295°K were; Ta-Ta_2O_5-Au, 0.94v, Ta-Ta_2O_5-Cu, 0.79v, Ti-TiO_2-Au, 0.39v, and Ti-TiO_2-Cu, 0.18v. The values for Au diodes are about 0.1v less than has been reported for maximum photovoltages developed when an electrolyte contact was made to the oxide and excitation was done with uv radiation (10).

Electroluminescence and photoresponse of Ta_2O_5 and

TiO_2 diodes is very similar to that in Nb_2O_5 diodes. It has been proposed that hole injection in Nb-Nb_2O_5-Au diodes occurs in an impurity band 1.2 ev below the conduction band of the oxide (3). Similar impurity bands may occur in oxides such as Ta_2O_5 and TiO_2.

In general, the conduction, optical and dielectric breakdown properties of oxide films whose thickness is large enough (>100Å) that tunneling is not an important conduction mechanism appear to fall in two groups, depending on the band gap of the individual oxides. Insulators such as Al_2O_3, SiO_2, or SiO characterized by band gaps of about 8v, have electrical properties significantly different from oxides such as TiO_2 or Nb_2O_5 whose band gaps are around 3v. Ta_2O_5 with a band gap of 4.5v, appears to occupy an intermediate position.

Acknowledgment

The assistance of J. R. Rairden in providing tantalum films, of D. T. Marple in loaning a photomultiplier and filters, and of J. A. Bergeron for the loan of a monochromator is gratefully acknowledged.

The Cathodoluminescence of Terbium Activated Indium Orthoborate

Frank J. Avella

General Telephone & Electronics Laboratories, Inc., Bayside, New York

Cathodoluminescence from Tb^{3+} in a borate matrix was demonstrated over forty years ago by Nichols and Howes (1); however, no Tb activated borates have been reported to cathodoluminesce with significant efficiency as compared with other green-emitting phosphors. Indeed, the same statement applies to non-borate phosphors activated by Tb. In 1964 Wanmaker and Bril (2) described the photoluminescence of Tb^{3+} in alkaline earth borates, but did not report on the cathodoluminescence. Concomitant investigation of the same systems in these laboratories showed $3CaO \cdot B_2O_3$:Tb to have the best response to cathode ray excitation of any Tb activated phosphor then known. This paper describes the cathodoluminescence of Tb^{3+} in a new host, $InBO_3$. Data are presented which show that $InBO_3$ is the most efficient host yet reported for the cathodoluminescence of Tb^{3+}. Furthermore, it is shown that $InBO_3$:Tb is comparable in efficiency and luminous output to Zn_2SiO_4:Mn, a widely used commercial phosphor. Comparisons are also made with related Tb activated phosphors.

$InBO_3$:Tb is prepared by reaction between the constituent oxides using conventional multiple firing techniques in air. $InBO_3$ is white to light yellow in body color and crystallizes in the rhombohedral crystal system with the calcite structure (3). Since the Tb^{3+} ion is larger than In^{3+}, $TbBO_3$ has the hexagonal vaterite structure (4). Therefore, partial substitution of In by Tb is equi-valent but not isostructural. Optimum activator concentration is 0.02 to 0.03 g-atom/mole of phosphor, and no lattice distortion is evident from routine x-ray powder diffraction analyses.

For cathodoluminescence measurements the phosphors were settled at optimum densities on 1-in. square sheets of conductive glass, which were then positioned in a demountable cathode ray tube and excited at 15 kv. Emission spectra were recorded directly in terms of relative energy by the method of Wiggins (5), and C.I.E. color coordinates (6) and values of lumen equivalent (7) were calculated therefrom. The luminous output was measured with an RCA 1P21 photomultiplier equipped with a Kodak Wratten 106 filter. Persistence was determined using a pulsed defocused electron beam for excitation and an oscilloscope for recording the decay characteristics.

The cathodoluminescence spectrum from Tb^{3+} in $InBO_3$ (Fig. 1) is dominated by the group of emission lines between 530 and 567 nm arising from $^5D_4 \rightarrow {}^7F_5$ electronic transitions. Fifteen distinct lines are resolved in this group with the two at 542 and 550 nm being most intense. A very small fraction of the emitted energy is produced by $^5D_4 \rightarrow {}^7F_{6,4,3}$ transitions and appears at 476-513, 577-603, and 614-640 nm, respectively. This nearly total domination of the spectrum by transitions to the $^7F_5$ levels distinguishes the Tb^{3+} emission in $InBO_3$ from that reported for other borate hosts. Wanmaker and Bril (2) show relatively intense $^5D_4 \rightarrow {}^7F_{6,4,3}$ transitions from ultraviolet excited

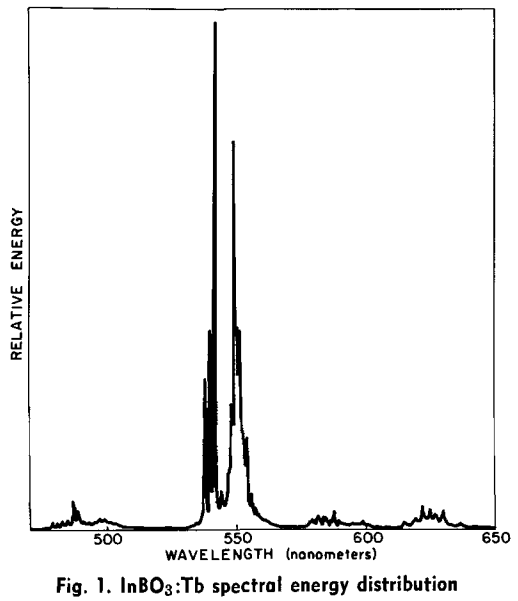

Fig. 1. $InBO_3$:Tb spectral energy distribution

Table I. Cathodoluminescence data for green-emitting phosphors

Phosphor	Relative luminosity	Decay to $I_0/10$ (msec)	C.I.E. color coordinates x	y	Lumen equivalent (lumen/rad watt)	Relative conversion efficiency
$Zn_{0.72}Cd_{0.28}S$:Ag	100	0.05	0.27	0.62	500	1.00
Zn_2SiO_4:Mn	60	15	0.22	0.71	540	0.56
Y_2O_3:Tb	15	—	—	—	—	—
$InBO_3$:Tb	65	15	0.31	0.66	610	0.54
$3CaO \cdot B_2O_3$:Tb	25	4	0.32	0.63	550	0.23
YBO_3:Tb	20	5	0.31	0.64	570	0.17
$M^{III}BO_3$:Tb (M^{III} = Sc,Lu,Gd,La)	15	—	—	—	—	—

$3CaO \cdot B_2O_3$: 0.06Tb. In the Sr and Ba analogues they show these transitions to be considerably reduced in intensity relative to the $^5D_4 \rightarrow {}^7F_5$, but not to the degree observed here for $InBO_3$:Tb. A similar comparison can be made with the $Tb_{0.2}Na_{0.2}Zn_{0.7}B_2O_4$ reported by Brixner (8).

Table I presents cathodoluminescence data on the Tb activated orthoborates with Y_2O_3:Tb (9), Zn_2SiO_4:Mn, and $Zn_{0.72}Cd_{0.28}S$:Ag cathode ray phosphors included for comparison. In terms of relative luminosity, $InBO_3$:Tb is slightly superior to Zn_2SiO_4:Mn and considerably superior to $3CaO \cdot B_2O_3$:Tb and the other Tb activated phosphors. The ratio of relative luminosity to lumen equivalent yields a value for the efficiency with which the exciting energy is converted into luminous energy. In Table I the sulfide phosphor is arbitrarily assigned a conversion efficiency of 1.00. Despite its high value of lumen equivalent resulting from the intense $^5D_4 \rightarrow {}^7F_5$ transitions, $InBO_3$:Tb is comparable to Zn_2SiO_4:Mn in efficiency and is considerably more efficient than the other Tb activated borates.

The Ga-As-Si Ternary Phase System

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Studies of the condensed phase diagram of the Ga-As-Si ternary system have been undertaken because of the current interest in gallium arsenide p-n junctions made by diffusion or solution growth. This work is a continuation of previous studies done in this laboratory on the ternary phase diagrams of group four elements with gallium and arsenic (1). These elements are of particular interest because of their "amphoteric" nature when in solid solution with GaAs and other III-V compounds.

Unlike the Ga-As-Sn and Ga-As-Ge ternary systems (1), the GaAs primary phase field is not the most extensive one in the phase diagram. Most of the data in this study, however, have been obtained in that phase field since it is the study of GaAs which is the primary objective of this work.

Binary Phase Systems

Ga-As.—Gallium and arsenic form a single congruently melting compound, GaAs, with a melting point of 1238°C (2). Thurmond (3) has utilized the solubility measurements of Köster and Thoma (2) and Hall (4), along with an adaptation of the regular solution treatment of Vieland (5) to construct the binary GaAs liquidus curve. The melting point of GaAs was recently measured by this author (6) and a value of 1237° ± 2°C was obtained.

GaSi.—Gallium and silicon form a simple eutectic system with a eutectic temperature of 30°C at 5×10^{-8} a/o (atom per cent) silicon (7). The binary liquidus was studied by Keck and Broder (8) and Klemm *et al.* (9), and their experimental data were used by Thurmond and Kowalchik (7) to construct a binary liquidus curve which is consistent with other thermodynamic data. The latter binary phase diagram has been used in this work.

As-Si.—The binary phase diagram for the As-Si system which has been constructed by Hansen (10) from the data of Klemm and Pirscher (11) was used for this work. This system contains two compounds, SiAs which melts congruently at 1083°C and $SiAs_2$ which decomposes below the melting point. There is one eutectic point between Si and SiAs at 1073°C and 40.5 a/o As and another at 786°C and about 90 a/o arsenic between As and $SiAs_2$. The peritectic temperature for $SiAs_2$ is 944°C.

Experimental

Semiconductor grade arsenic and silicon with purities better than 99.99% were used in this work. Reclaimed gallium with purity better than 99.99% was used and for many of the runs reclaimed GaAs with purity better than 99.99% was used instead of the elements. The use of GaAs was necessary when the relative amounts of Ga and As were high in order to prevent explosions resulting from the exothermic reaction of the elements. On the high arsenic side of the phase diagram GaAs and As were used as the source of arsenic and gallium. It was possible to heat these mixtures to the molten state without explosions if the heating was done slowly in the range 700°-825°C ($\approx$ 10°C/hr).

Fused silica capsules with a volume of about 2 cc which were about 2/3 filled with melt were used for the differential thermal analysis experiments. The experimental details are similar to those which have already been described for the study of the Ga-As-Zn system (12) except that the cells used in this work

* A ternary eutectic or peritectic occurs in the gallium corner of the phase diagram at a temperature below 100°C but is not observable by the method used in this work.

were similar in shape but much smaller in volume than those used previously.

For most of the previous DTA studies with GaAs it has been convenient to hold the molten mixtures in the fused silica DTA cells at 200°-300°C above the temperature at which the first solid is expected to precipitate, and in general temperatures above 1250°C were not required since the highest melting compound was GaAs at 1238°C. For the system containing silicon, however, the 200°-300°C criteria would require temperatures much above 1250°C. In this work it was found that melts containing up to 30 a/o silicon required homogenization temperatures of about 1300°C and for mixtures containing more than 30 a/o Si homogenization temperatures of 1350°C and above were necessary. The practical working limit for fused silica in this work was found to be 1350°C and this limited the range of silicon compositions which could be studied.

X-ray analysis of the differential thermal analysis samples was done by the standard powder technique.

Results

The temperatures at which thermal effects were observed when melts of various compositions were cooled are given in Table I. T_1 represents the temperature at which the surface of primary crystallization is reached, T_2 is the temperature at which a second solid phase precipitates, and T_3 is the temperature at which a ternary eutectic or peritectic transition occurs.

Some of the data given in Table I are plotted in Fig. 1 through 4. The melting point of pure Si was taken as 1410°C (7). Figures 1 through 4 show the thermal effects observed for DTA samples with starting compositions along cuts A through D in the ternary system (Fig. 5). For these samples, lines attributable to the presence of GaAs and Si were always observed in the x-ray powder photographs. Solid solubility of Si in GaAs or As or Ga in Si was not observed.[1]

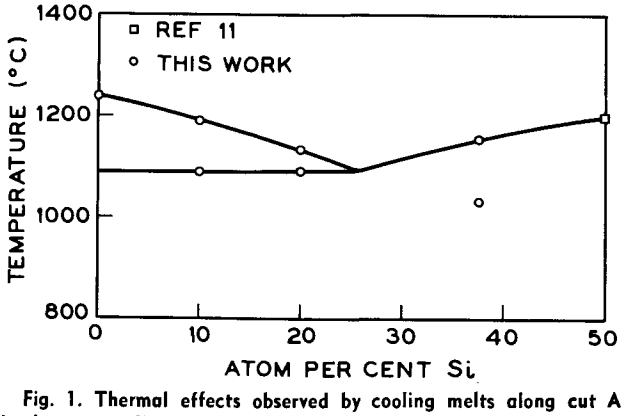

Fig. 1. Thermal effects observed by cooling melts along cut A in the ternary diagram.

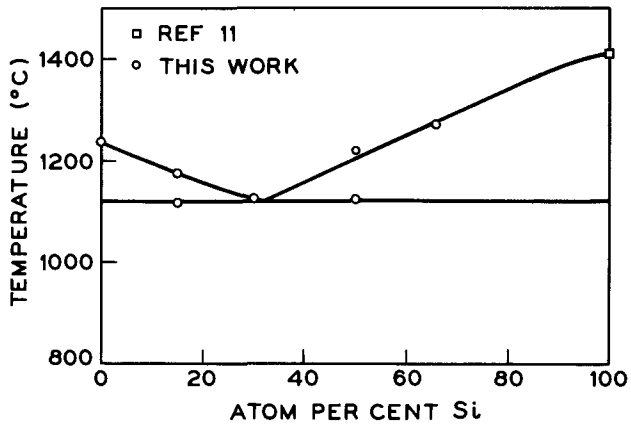

Fig. 2. Thermal effects observed by cooling melts along cut B (the GaAs-Si pseudobinary) in the ternary diagram.

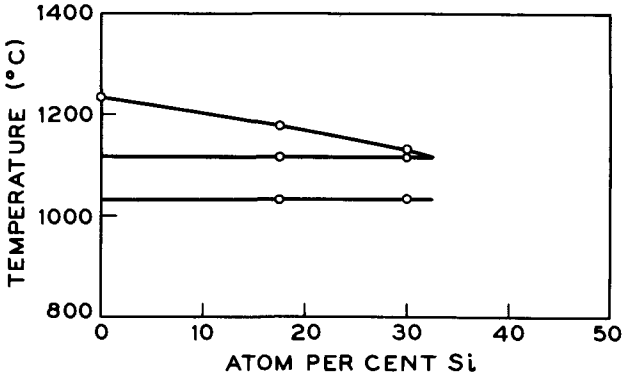

Fig. 3. Thermal effects observed by cooling melts along cut C in the ternary diagram.

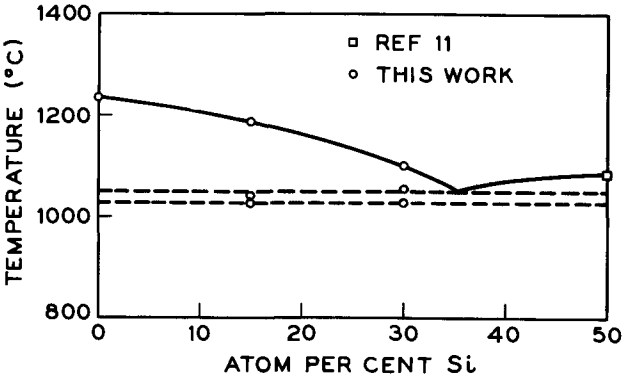

Fig. 4. Thermal effects observed by cooling melts along cut D in the ternary diagram.

DTA cooling curves were obtained for several other compositions not on cuts A-D in the ternary system. The data obtained from these experiments were used with the data from cuts A-D to construct the ternary phase diagram as described below.

Construction of the Ternary Diagram

The Ga-As binary diagram of Thurmond (3), the Ga-Si binary diagram of Thurmond and Kowalchik (7), and the As-Si binary diagram of Klemm and

[1] It should be noted that the precision of the x-ray powder photographs was insufficient to reveal small degrees of solid solubility. These studies simply reveal the solid solubility to be sufficiently small, that for the purpose of constructing the ternary diagram, it can be assumed that the liquidus compositions of cooling melts is along tie lines drawn through the primary phase and the melt compositions.

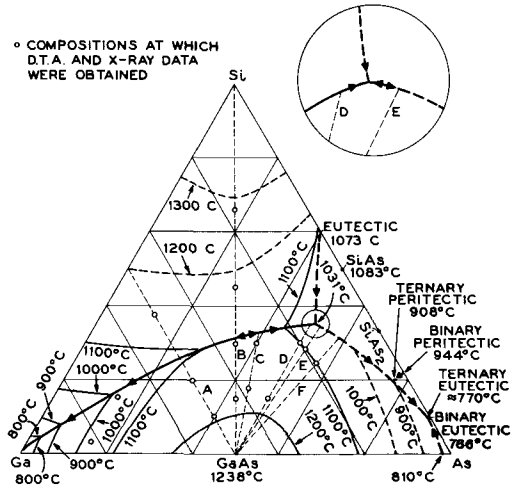

Fig. 5. Ga-As-Si ternary phase diagram. Concentrations are in atom per cent.

Pirscher (11) were used as the boundaries of the ternary diagram (Fig. 5) without modification.

By analogy with the Ga-As-Ge system the T_2 thermal effect for cuts A, B, C, and D (Fig. 5) was taken to be due to the intersection of the cooling melt with a second primary phase field. The major fields separated by the curve drawn through T_2 intersection points on these cuts are the Si primary phase field on the Si side of the diagram and the GaAs primary phase field on the GaAs side of the diagram. The curve representing the boundary between Si and GaAs primary phase field was further delineated from DTA data obtained from several other experimental points outside of cuts A, B, C, and D in the ternary system.

The T_3 thermal effect noted for cuts C and D at 1031°C is consistent with a ternary eutectic from which Si, GaAs, and SiAs precipitate. The location of the eutectic was established as being between cuts D and E on Fig. 5 from the shapes of the DTA cooling curves. The cooling curves for samples on cut D showed T_3 as the last thermal effect. The cooling curves for the two data points on the 1100° isotherm on cuts E and F had thermal effects at about 908° and 770°C. These result from a ternary peritectic and a ternary eutectic which correspond to the 944° and 786°C thermal effects on the Si-As binary, respectively.

The x-ray photographs of DTA samples from cuts C, D, E, and F did not show definitive evidence for the presence of SiAs and $SiAs_2$. There were many additional weak lines not attributable to GaAs or Si. These were, however, difficult to measure. There are no standard powder patterns available for comparison for SiAs and $SiAs_2$.

Electron beam microprobe studies of several of the cooled DTA samples provided data which is essentially in agreement with the phase diagram in Fig. 5. A sample from cut B contained only GaAs and Si, while one on cut D contained large crystals of GaAs plus a much more finely divided group of crystals some of which were GaAs and others a phase containing As and Si. A sample from cut E was similar to that on cut D, and one on cut F contained GaAs plus two closely associated phases containing silicon and arsenic. No region characteristic of the 770°C ternary eutectic was observed. It is probable that the 908°C ternary peritectic reaction is incomplete.

It was noted that for cuts A and B the shape of the liquidus in the GaAs primary phase field was almost identical to that previously reported for the Ga-As-Ge system. Isotherms up to 1100°C in the Ga rich region of that phase field were therefore drawn with the Ga-As-Ge diagram as a guide. The 1200°C isotherm was drawn on the basis of cuts A-D. The 1100°C isotherm in the arsenic rich region was drawn through the experimental points.

Because of the high pressures involved, these studies were not extended to the high arsenic portion of the phase diagram and the curves in that portion of the diagram are therefore drawn to be consistent with the available data. Similarly, because of the high temperatures required, not much experimental data was obtained in the Si primary phase field. Isotherms in this region were simply drawn smoothly through the experimental data available.

Conclusions

A major portion of the ternary condensed phase diagram of the Ga-As-Si system has been constructed on the basis of differential thermal analysis studies. The diagram consists primarily of the primary phase fields of Si and GaAs with smaller fields due to SiAs and $SiAs_2$. No ternary compounds were observed.

Acknowledgments

The author is indebted to C. D. Thurmond for his helpful suggestions during the course of this work. The aid of Mr. S. Sumski with some of the experimental work, and of Miss D. R. Margel for the x-ray analysis is gratefully acknowledged. Electron beam microprobe analyses were done by H. Schreiber.

The Influence of Crystallographic Defects on Device Performance

J. M. Fairfield and G. H. Schwuttke

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

Imperfections in the crystallographic structure of silicon diodes influence their reverse characteristics (1-5), and an understanding of this phenomenon is necessary for the effective design of high-quality semiconductor devices. Usually investigators have shown a statistical or circumstantial relation between crystal imperfections and device performance; however, Queisser and Goetzberger (4) have shown that excessive leakage currents may occur at stair rod dislocations, and Barson (6) has observed such leakages at arbitrary points on stacking faults in epitaxial material.

This paper describes a study of the effects of crystallographic imperfections introduced during typical fabrication procedures and shows that leakage currents do occur at edge dislocations. It also discusses methods by which such imperfections can be controlled and their effects minimized. This investigation has been accomplished by studying simple diffused silicon diodes that were made using standard diffusion techniques. Their reverse characteristics were measured and compared with the crystallographic perfection of the silicon wafers, examined by means of transmission x-ray diffraction microscopy.

Procedure

Silicon wafers were cut from Czochralski crystals, lapped, and chemically polished. Planar diffused P^+—N and N^+—P diodes were made using standard SiO_2 masking techniques and boron or phosphorus diffusions. For the boron diffusion, we used a two-step process consisting of a capsule deposition cycle at 1108°C (using a Si-B powder source) (7) and an oxidation drive-in cycle at 1150°C. The phosphorus diffusion was a single-cycle dynamic process (1000°C) with PH_3 as the source (8). In both cases, the wafers were supported vertically in a quartz boat. The junction depths were typically 1-2μ, and surface concentrations were about 10^{19} atm/cc for the boron and 10^{20} atm/cc for the phosphorus diodes. Alternate rows were made with diffused guard rings to suppress surface breakdown (9). The geometry of these diodes is shown in Fig. 1.

The crystallographic perfection of these silicon wafers was examined at specific points in the process by means of x-ray transmission diffraction microscopy (10). Large-area topographs of entire wafers were recorded using the Scanning Oscillator Technique (SOT) and the imperfections were identified [see ref. (10)]. Initially, the wafers were dislocation free. (There were some bulk precipitation effects through the crystal; however, these had no significant effect upon the reverse characteristics of the diodes.) The x-ray technique is particularly well adapted to this type of study because it is nondestructive: the wafers may be examined and reexamined at any or all points in the process.

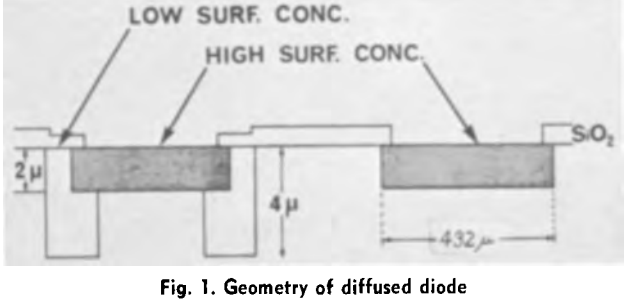

Fig. 1. Geometry of diffused diode

The reverse I-V characteristics were studied by probing the diffused diodes on the wafers. The diodes were classified as either reasonably hard or soft using the following two requirements for a hard diode. (*I*) Low current: the voltage at 20 μa reverse current must be within 10% of the voltage at 200 μa. (*II*) High current: the voltage at 200 μa must be within 10% of true avalanche breakdown voltage.

In this way the wafers were mapped for device performance and compared with the x-ray topographs. In addition, the soft diodes were examined for microplasmas to determine the nature and location of the leakage currents within the device area. The locations of the microplasmas were noted and compared to the crystallographic structure.

Results and Discussion

From the consideration of device performance, the most significant crystallographic defects in this study are bands of dislocations created during the heat cycling of the diffusion processing (in both phosphorus and boron diffused wafers). These are illustrated in Fig. 2 and 3, which are examples of x-ray topographs of diffused wafers, by the anomalous contrast near the edges. These dislocations are nucleated at the edges of

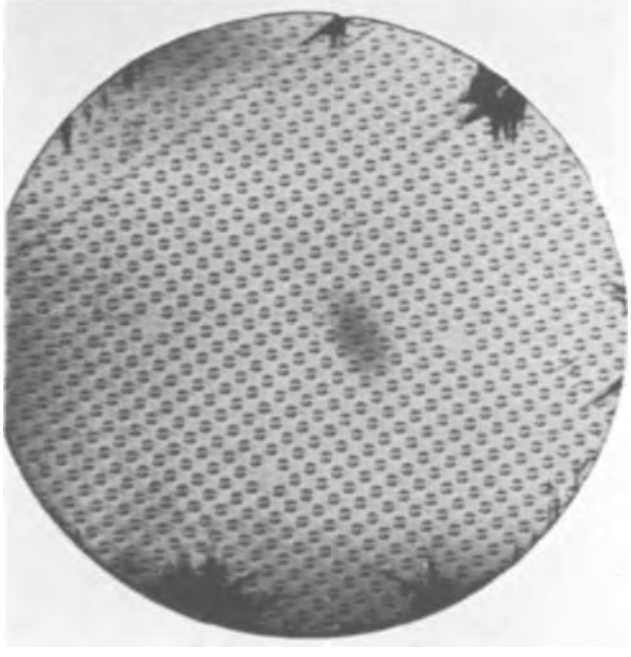

Fig. 2. Large-area SOT topograph of boron-diffused wafer. Heavy contrast near periphery of wafer results from edge dislocations nucleating at chips. Lesser contrast to right of wafer can be related to strain during heat cycles. (Note also that diffraction contrast, due to elastic strain from the oxide mask, delineates the diffused diodes.)

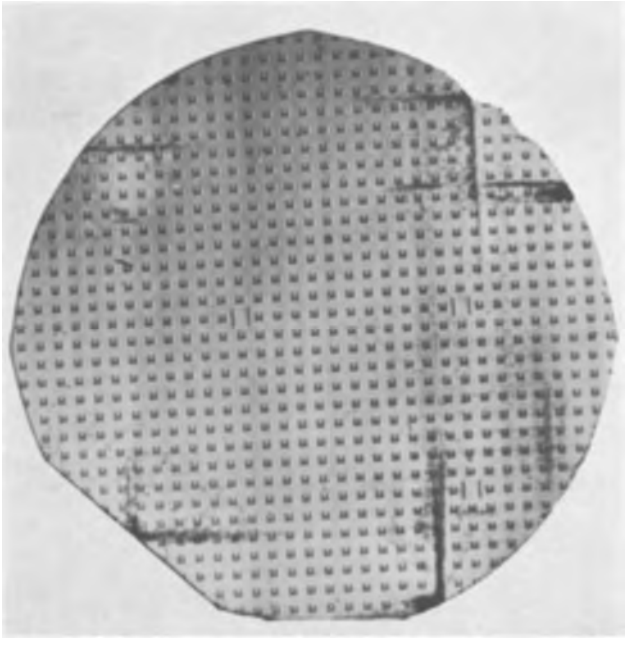

Fig. 3. Large-area SOT topograph of phosphorus-diffused wafer showing the same heavy contrast as Fig. 2.

the wafers and extend a few tenths of an inch into the interior. Favored points of nucleation are small chips, scratches, and other forms of physical damage introduced before the heat cycling. (These occasionally include points of apparent microalloying.) An example of dislocations nucleated at scratches is illustrated in Fig. 4. Finally, lesser degrees of imperfection could be associated with mechanical strain during the heat cycles, due to faulty support in the diffusion boat (see Fig. 2).

These dislocations significantly degrade the hardness of the diode reverse characteristics. Diodes in the undamaged areas yielded 90% as reasonably hard; whereas, those diodes in the areas of dislocations yielded about 20% as hard. A typical wafer yield map

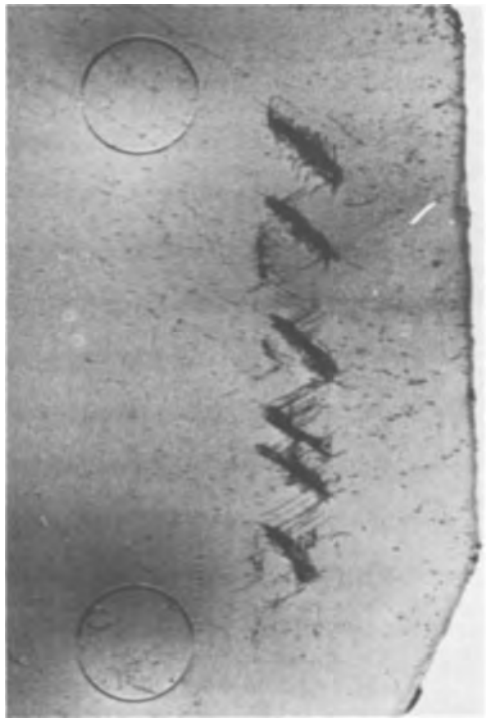

Fig. 4. Small area topograph of diffused silicon wafer illustrating dislocations nucleating at scratches on the wafer surface.

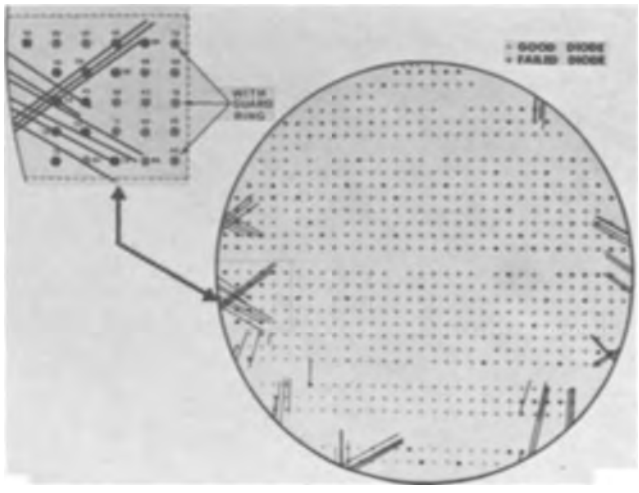

Fig. 5. Typical wafer yield map of a diffused wafer (boron). Heavy lines indicate bands of dislocations as indicated from the topograph. Area set off by broken line is enlarged to give reverse voltages at 20 μa. Apparent variations in such voltages of good diodes are due either to the presence (or lack) of the guard ring or to significant variations in wafer resistivity near the edge.

is shown in Fig. 5. The true avalanche breakdowns varied between 60 and 110v and reflected the background doping of the material. With only a few exceptions, all diodes with dislocations in their active areas were soft.

The reverse characteristics of failed diodes are "soft" rather than linear with specific points of discontinuity (as, for example, a double break characteristic). Goetzberger and Shockley have shown that such softness can be due to metallic precipitation in the active region of the diode (11). The microplasma structure of many soft diodes indicates that the high leakage currents occur at specific points along the dislocations; this is illustrated in Fig. 6. Thus, it is reasonable that metallic precipitates nucleate as specific points along the dislocations and cause the excessive leakage currents at sub-avalanche voltages, in the manner discussed by Goetzberger and Shockley. It has been suggested previously that microplasmas associated with stair-rod dislocations can be caused by

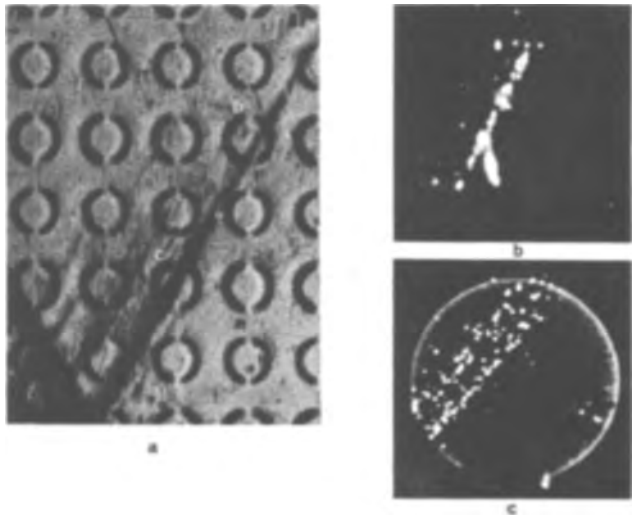

Fig. 6. X-ray topograph and microplasma structure of soft diodes: (a) topograph; (b) microplasma structure of diode marked "b"; (c) microplasma structure of diode marked "c". These microplasmas were always red.

metallic precipitates at these dislocations (4).

Finally, the diffused guard ring did not significantly effect the yield factors (although it did raise the apparent avalanche breakdown by about 25%). Thus, the mechanism of softness seems to be similar. It should be noted, however, that microplasmas for soft diodes without guard rings tended to be at or very near the outer periphery of the planar diodes.

One obvious method of reducing device softness from this mechanism is to eliminate the sources of nucleation for these dislocations. The chips, scratches, etc., from which these dislocations nucleate, usually occur during handling. Thus, one should carefully avoid any procedure that might result in physical damage. Some of the sources that we have found for this damage are listed below:

1. Handling wafers with stainless steel tweezers, or other hard objects.
2. Poor cleaning precedures. Cotton swabs can introduce scratches. If ultrasonic cleaning is used, chipping may occur if wafers are in contact with each other or other hard substances (*e.g.*, wire cleaning boats).
3. Contaminated or poorly designed diffusion boats. Wafers should be supported so as to eliminate strain during diffusion. Also contaminants, including devitrified quartz, may introduce strains during diffusion.
4. Failure to remove saw damage at the edges during polishing procedures.

In general, one should handle wafers as little as possible and use extreme care when it is necessary. Diffused wafers can be made that are virtually free of such damage as illustrated in Fig. 7. The yield of the wafer illustrated in Fig. 7 is well over 90%.

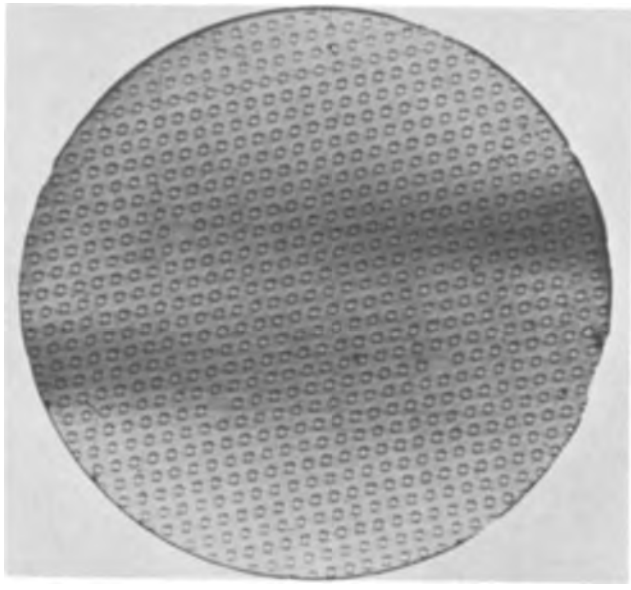

Fig. 7. Large area SOT topograph of diffused wafer without dislocations.

Acknowledgments

The authors gratefully acknowledge the x-ray work of C. Hoogendoorn and T. A. Hansen and the help of R. Racicot for diffusions. The research reported in this paper was sponsored in part by the Air Force Cambridge Research Laboratories, Office of Aerospace Research, Contract No. AS 19(628)-5059.

Brief Communications

Galvanic Effects in Vacuum Deposited Thin Films

M. Hacskaylo

Physical Electronic Laboratory, Melpar, Inc., Falls Church, Virginia

and R. T. Foley

Chemistry Department, The American University, Washington, D. C.

During the investigation of the electrical properties of vacuum-deposited dielectric films, formed in layered configurations, some interesting galvanic effects have been observed. The purpose of this communication is to report the observations and present an explanation.

The "thin films" referred to are those in the micron- and millimicron thickness range and should not be considered in the thicknesses of those fabricated for solid electrolyte galvanic cells (1, 2). Techniques for vacuum depositing the capacitor configuration have been described in detail by Feldman and Hacskaylo (3, 4). Aluminum and gold electrodes were deposited from tungsten boats. The CeO_2 films (5) were deposited at both fast (approximately 2000 Å/min) and slow (approximately 200 Å/min) rates using com-

mercial material[1] from tungsten boats, and at slow rates only from boron nitride liners (6). Film thicknesses were measured with a Zeiss interference microscope. Cerium (IV) oxide films formed at the slow deposition rate had a slight straw color, whereas the films formed at the fast rate were colorless. The dielectric layers were analyzed by x-ray diffraction and all exhibited characteristic CeO_2 patterns. Cerium metal was detected in the films formed at a slow rate. However, after heating to 500°C in air, the films lost their coloration and Ce metal was no longer detected. Films formed at the faster rate gave no indication of Ce metal. The starting material for the deposition was determined to be CeO_2 species, whereas the residue in the tungsten boats after the deposition consisted of Ce metal without traces of CeO_2. Suboxides, if present, were not detected.

A typical configuration and deposition sequence is as follows: glass substrate (25 x 25 x 1 mm), aluminum (1600Å), CeO_2 (1.0μ), aluminum (300Å). The top and bottom electrodes were suitably isolated by the dielectric layer, and the common cell plate area was 0.50 cm^2.

The voltages of the samples were measured by a Hewlett-Packard VTVM model 410B across a 4000 ohm load, and the current was measured with two Weston microammeters, model 301 (0-50 μa and 0-200 μa ranges full scale with internal resistances of 1140 and 660 ohm, respectively). The values of the voltages and current densities reported here have been recalculated taking into consideration all external resistances.

Galvanic effects (*i.e.*, an emf developed between the top and bottom metallic electrodes) in these films are readily produced by introducing traces of moisture. For example, the moisture generated by cupping a hand over the cell was sufficient to generate an open circuit voltage of 0.1-0.2v and a short circuit current of about 30 μa/cm^2. When a drop of water was placed on the top electrode of an Al-CeO_2-Al sample an open circuit voltage of 0.8v was measured with a short circuit current of 350 μa/cm^2. The top film (electrode exposed to water) of the array that exhibited the galvanic effect was always positive, *i.e.*, acted as the cathode, whereas the bottom was negative. In a typical experiment, the lower and the upper films were electrically connected across a 4000 ohm load and the current and voltage were measured simultaneously. The sample was then moistened with a drop of water, and placed on a hot plate. The output was recorded at 20 sec intervals. The results are shown

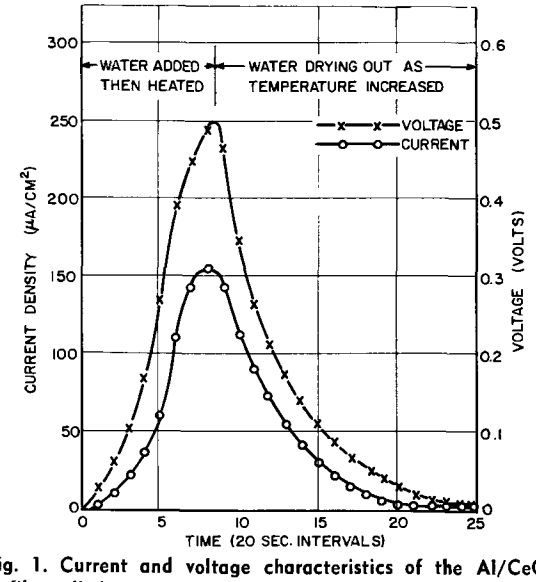

Fig. 1. Current and voltage characteristics of the Al/CeO_2/Al thin film cell that was moistened and then heated to dryness. Lower electrode, Al, 1800Å; CeO_2, 1.5μ; top electrode, Al, 500Å.

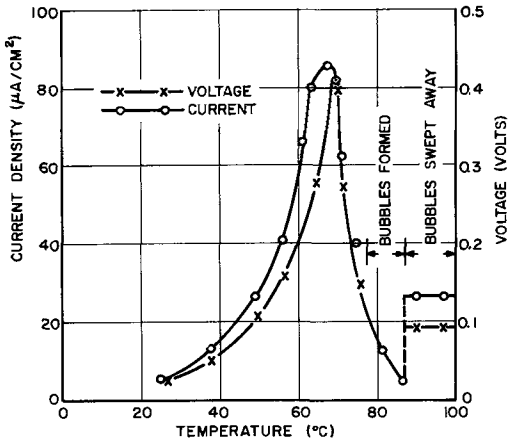

Fig. 2. Temperature dependence of current and voltage characteristics of Al/CeO_2/Al thin film cell immersed and heated in water.

in Fig. 1. The voltage and current increased with temperature up to a point at which the water appeared to have evaporated. When the sample appeared to be completely dry the output decreased to zero. The peak output during the test was 160 μa/cm^2 at 0.5v. The sample was then immersed in distilled water and the water heated. The current, voltage, and water temperature were recorded, as indicated in Fig. 2. The current and voltage exhibited peaks at about 68°C of 85 μa/cm^2 and 0.42v, respectively. The output of the galvanic cell decreased irregularly from 68° to 85°C reaching a fairly constant voltage of 0.1v and 28 μa at 100°C. The output remained constant for about 15 min. The experiment described above and illustrated in Fig. 2 exhibited galvanic effects for 2.5 hr. A similar cell was totally immersed in water at room temperature and it exhibited a voltage of 0.32v and a current density of 18 to 25 μa/cm^2 for 65 hr.

During the immersion of the cell in water, definite physical changes were observed. The top electrode lost its metallic appearance. The portion of the CeO_2 film that was not covered with the top electrode was unaffected by the water or current flow. The bottom aluminum electrode changed from a metallic to a milky translucent appearance. This transformation occurred only underneath the area covered by the top electrode.

A number of cells were made in which the thickness and materials of the electrodes were varied. Gold and aluminum electrodes were interchanged. The galvanic action corresponding to these variations is given in Table I. It was observed that it was necessary for water to diffuse through the top plate before an appreciable galvanic effect would occur. This was manifested by a time delay in the beginning of the effect. The presence of a "thick" top layer (2.5μ) prevented

Table I. Galvanic characteristics of vacuum-deposited thin film cells with various materials and thicknesses

Top electrode		Dielectric CeO_2	Bottom electrode			
Material	Thickness, Å	Thickness, μ	Material	Thickness, Å	Open circuit voltage, v	Short circuit current, μa/cm^2
Al	300	1.0	Al	1600	0.48	30
Al	550	1.5	Al	3000	0.80	120
Al	1000	1.5	Al	1400	0.48	85
Al	6000	0.8	Al	4500	0.80	350
Al*	1070	1.5	Al	300	0.35	75
Al	1070	1.9	Al	300	0.23	30
Al	25000	1.4	Al	2000	0	0
Au	300	3.0	Al	2800	0.62	160
Au	500	1.1	Al	5000	0.60	140
Au	300	0.9	Au	2100	0	0
Au	500	1.0	Au	2500	0	0

* Al-CeO_2 layers heated to 500°C in air for 45 min prior to top plate deposition.

the diffusion of water as well as the exhibition of the galvanic effect. When a film of gold was deposited for the top plate, galvanic action was observed when water diffused through the film. However, when a gold film was used for the bottom electrode (*i.e.*, the one coated with CeO_2 and with air access restricted to it) there was no galvanic action even though water had diffused through the top electrode of aluminum or gold. The galvanic action is apparently not affected by the Ce content of the CeO_2 film.

The effect is not restricted to samples with CeO_2 as the dielectric component. A thin film cell was constructed with $PbCl_2$ as the dielectric film separating the two Al electrodes. When water was placed on the top electrode an open circuit voltage of 0.6v and a short circuit current of about 1000 $\mu a/cm^2$ was observed. The cell functioned for only a few minutes.

A few other general observations can be made concerning the phenomena. When the cells were subjected to heat but no moisture, no galvanic effect was produced. There was no evidence of a photovoltaic effect upon illumination with white or u.v. light.

It appears reasonable to explain all of these observations in terms of an air-depolarized galvanic cell. The lower film, next to the glass substrate, functions as the anode. The usual polarization of the aluminum electrode is limited by a restricted oxygen supply. The (corrosion) current is increased by the presence of chloride ions ($PbCl_2$ experiment). The reaction product is a hydrated aluminum oxide.

The electrolyte is the added water or moisture containing dissolved oxygen. The high cross-sectional area to length ratio allows sufficient electrical conductivity. The CeO_2 acts simply as a separator holding the electrolyte. The use of inorganic separators in conventional batteries is being investigated currently (7). It is unlikely that CeO_2 contributes ionic conductivity as temperatures in the 700°-800°C range would be required before appreciable values of specific conductivity would be achieved (8).

The cathode is the upper electrode at which the reaction

$$2H_2O + O_2 + 4e \rightarrow 4OH^-$$

takes place. Thus, the reaction takes place whether the top electrode is Au or Al. The active metal is required at the anode. The temperature dependence of the cell immersed in water is approximated by the temperature relationship of iron corrosion in water when the rate controlling step is diffusion of dissolved oxygen to the cathode as discussed by Uhlig (9).

These observations are of interest in several areas of electrochemistry. First, they illustrate troublesome effects encountered in the preparation of solid state devices such as thin-film capacitors. Second, they confirm accepted mechanisms of the electrochemical theory of corrosion which would have galvanic cells operating at the microscopic scale. Third, the implication is that similar effects can operate over an extended period of time and limit the shelf life of solid-state batteries. Finally, the observations suggest the development of air-depolarized thin-film batteries recognizing, of course, the inherent limitation of capacity.

Acknowledgment

It is a pleasure to acknowledge the efforts of W. C. Conlon for sample preparation, Dr. Hannibal de-Schmertzing for chemical and x-ray analysis and Dr. Charles Feldman for valuable discussions.

Manuscript received July 18, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Corrosion and Growth of Silver Crystals under Hydrothermal Conditions

R. R. Monchamp, R. C. Puttbach, and J. W. Nielsen

Airtron Division, Litton Precision Products, Inc., Morris Plains, New Jersey

In a recent paper Levinson and Carter (1) discussed a limited observation of silver corrosion and the morphology of the resultant silver crystals.

The formation of silver crystals under hydrothermal conditions has been observed in this laboratory during the growth of ruby using K_2CO_3 (2), $Y_3Fe_5O_{12}$ using K_2CO_3, and ZnO using KOH (3).

Silver corrosion has also been noted by Laudise and Kolb in some of their ZnO work (4) and by Hill and Harker (5) in the hydrothermal growth of BeO using KOH as the solvent.

In the hydrothermal growth of ruby in K_2CO_3 at high pressures (>1000 atm), we have observed only slight silver attack; however, when the working pressure was below 1000 atm and the concentration was less than 3*M*, severe corrosion occurred. We have reported previously that under these latter conditions it appears that the silver can contains two immiscible fluids (6). Silver attack and growth of silver crystals occurred at the interface region of the fluids. This attack and growth is similar to that reported by Levinson and Carter (1) and Harker and Hill (5).

With ZnO in KOH and $Y_3Fe_5O_{12}$ in K_2CO_3 under conditions commonly used for crystal growth (7), only a single fluid phase exists; however, silver corrosion and growth of silver crystals is still observed. Thus it should be stressed that a two-phase fluid condition is not necessary for the corrosion and growth of silver.

The corrosion in the single phase cases occurs below the baffle in the nutrient zone, and the growth of silver crystals occurs predominantly on the top of the can and just at the baffle area. To a lesser degree some silver crystals have been observed on the seed support ladder and also within grown ZnO or $Y_3Fe_5O_{12}$ crystals. It is significant that the major part of the silver growth takes place at the baffle plate and top

of the can which are the two locations of the largest temperature changes within the fluid.

We propose that the following mechanism is operative in all the examples cited. The initial attack of silver is caused by oxygen dissolved in the basic solutions and in the air entrapped in the silver can during its closure. In the nutrient zone, the hottest part of the can, a soluble silver complex is formed which is convectively transported to the cooler regions of the can. Because of thermal disturbance of the equilibrium a disproportionation reaction occurs which yields metallic silver and a silver complex of higher oxidation number.

Similar thermally dependent disproportionation reactions are popularly used for the vapor phase growth of III-V compounds. The lack of thermodynamic data for the possible silver species at the elevated pressures and temperatures makes it impossible to assign definite oxidation states to the silver in the transporting complex ions. In the single phase, growth occurs in the two regions where the temperature drops are greatest, at the baffle plate (its purpose is to divide the fluid into two temperature regions), and the top of the can where the heat loss to the ambient is greatest. In the two-phase system the same mechanism is applicable except that the disproportionation in this case may not be due to a thermal disturbance of the equilibrium. Rather the equilibrium is displaced by the relative solubilities of the species in both phases. As a result of the solubility change at the interface, the equilibrium is displaced so that this is the region in the silver can where the greatest attack and crystal growth are noted.

Support for the above proposition has been obtained in two independent experiments. First in the case of ZnO, a 2½ times increase in reactor volume size and thus in the amount of solvent greatly increased the amount of silver corrosion although the measured conditions remained the same. Second, in the growth of $Y_3Fe_5O_{12}$, H_2O_2 was added to the system to try to produce oxidizing conditions. Whereas no silver attack was observed in previous experiments, the addition of H_2O_2 caused the most severe case of corrosion and silver crystal growth ever observed even though the exact conditions were duplicated.

For crystal growth it is highly desirous to eliminate this silver corrosion for many reasons. Having proposed the above mechanism it is obvious that an effective remedy would be the inclusion of a reducing agent within the can. In the ZnO crystal growth 2-3g of metallic zinc added to 2830 ml of 6M KOH have been found to eliminate completely any trace of silver corrosion. Furthermore, zinc does not add any contamination since it is oxidized to Zn^{+2} which is already present as a dissolved species. The obvious metals to add for ruby and $Y_3Fe_5O_{12}$ are aluminum and yttrium, respectively. Additions of metallic aluminum to the K_2CO_3 solution used for ruby have also eliminated any traces of silver attack which were noted under the single phase condition. It is observed that the solubility of oxygen in K_2CO_3 is much less than in KOH.

Current Distribution on a Rotating Disk below the Limiting Current

John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The uniform current density on a rotating disk electrode at the limiting current is not achieved at lower currents because the edge of the disk is more accessible than the center as a result of the ohmic potential drop in the solution. The current distribution is calculated for well-stirred solutions and also for lower rotation speeds where surface overpotential, concentration overpotential, and ohmic drop are all significant. The current density at the center can vary between 50 and 100% of the average current density, and the ohmic potential drop to the center of the disk is 27.3% greater for the uniform current than for the primary current distribution.

The rotating disk electrode is popular for studying both diffusion in electrolytic solutions and the kinetics of moderately fast electrode reactions because the hydrodynamics (1,2) and the mass-transfer characteristics (3) are well understood and because the current density on the disk electrode is supposed to be uniform. However, the current distribution is uniform only at the limiting current where the concentration of the reactant is zero at the electrode surface. In the other extreme, the primary current distribution (7), applicable in the absence of concentration overpotential and surface overpotential, shows an infinite current density at the edge and a value equal to half the average current density at the center of the disk.

It is of interest to assess the degree of nonuniformity of the current distribution due to the nonuniform ohmic potential drop. Newman (4) has indicated how to treat current distribution in cells where the potential distribution in the bulk of the solution and the concentration distribution in the diffusion layer must be calculated simultaneously. These ideas are applied in the present paper to the specific case of a rotating disk electrode. It is assumed that the disk electrode, of finite size, is embedded in an infinite, insulating plane and that the walls of the cell and the counter electrode are removed to infinity. Dilute-solution theory, with constant diffusion coefficients, mobilities, and activity coefficients, is assumed to be applicable. For simplicity, only two cases are treated, metal deposition from a single-salt solution and electrode reactions with an excess of supporting electrolyte, in which the transference number of the reactant is zero.

Those readers who wish to skip the mathematical development can go directly to the section on results, keeping in mind that the current distribution depends on several important parameters defined in Eq. [21], [27], [30], and [37].

Concentration Profile in the Diffusion Layer

The concentrations differ from their bulk values only in a thin region near the electrode surface, and in this region the fluid velocity can be approximated by (1-4)

$$v_r = a\,r\,y\,\Omega\sqrt{\Omega/\nu} \text{ and } v_y = -a\,y^2\,\Omega\sqrt{\Omega/\nu} \quad [1]$$

where $a = 0.51023$. This approximation, which is valid for large values of the Schmidt number $Sc = \nu/D$, can be expected (5, 6) to cause an error of about 3% in calculated rates of mass transfer when $Sc = 1000$. The concentration is to be determined from the equation

$$v_r\frac{\partial c}{\partial r} + v_y\frac{\partial c}{\partial y} = D\frac{\partial^2 c}{\partial y^2} \quad [2]$$

or

$$a\,y\,\Omega\sqrt{\Omega/\nu}\left[r\frac{\partial c}{\partial r} - y\frac{\partial c}{\partial y}\right] = D\frac{\partial^2 c}{\partial y^2} \quad [3]$$

where only the dominant diffusion term $D\partial^2 c/\partial y^2$ needs to be included on the right because of the thinness of the diffusion layer. This equation applies to diffusion of a single salt if D denotes the diffusion coefficient of the salt. The equation also applies to a minor ionic component in a solution with supporting electrolyte where ionic migration can be neglected. Then D denotes the ionic diffusion coefficient.

Since the diffusion layer is thin, it is appropriate to replace the normal distance y by the variable

$$\zeta = y\,(a\nu/3D)^{1/3}\sqrt{\Omega/\nu} \quad [4]$$

In terms of this variable the concentration in the diffusion layer can be expressed as a series solution

$$c = c_\infty\left[1 + \sum_{m=0}^{\infty} A_m (r/r_o)^{2m}\theta_m(\zeta)\right] \quad [5]$$

This is a power series in r, but only even powers are included since the concentration must be an even function of r.

The functions $\theta_m(\zeta)$ satisfy the differential equation

$$\theta_m'' + 3\zeta^2\theta_m' - 6m\zeta\theta_m = 0 \quad [6]$$

which can be obtained by substituting the series [5] into Eq. [3].

The boundary conditions are

$$\theta_m = 1 \text{ at } \zeta = 0 \text{ and } \theta_m = 0 \text{ at } \zeta = \infty$$

In this way the concentration given by Eq. [5] equals the bulk value c_∞ far from the disk, and the concentration at the surface of the electrode is

$$c_o = c_\infty\left[1 + \sum_{m=0}^{\infty} A_m (r/r_o)^{2m}\right] \quad [7]$$

The coefficients A_m are yet to be determined.

The normal current density i at the electrode surface is related to the derivative of the concentration

$$\frac{i}{nF} = \frac{D}{1-t}\frac{\partial c}{\partial y}\bigg|_{y=0} = \frac{Dc_\infty}{1-t}\left(\frac{a\nu}{3D}\right)^{1/3}\sqrt{\frac{\Omega}{\nu}}\sum_{m=0}^{\infty} A_m\left(\frac{r}{r_o}\right)^{2m}\theta_m'(0) \quad [8]$$

where t is the transference number and c the concentration of the reactant and n is the number of electrons

Table I. Derivatives at the surface of the functions in the concentration series

m	$\theta_m'(0)$	m	$\theta_m'(0)$
0	−1.11984652	6	−2.47384276
1	−1.53298792	7	−2.59428724

4	−2.18998277	10	−2.90150549
5	−2.34045076		

produced when one reactant ion or molecule reacts. With excess indifferent electrolyte, $t = 0$. The calculation of the current density by this series requires values of $\theta_m'(0)$, which are given in Table I.

Potential Distribution outside the Diffusion Layer

In the region where the concentrations are uniform, the potential satisfies Laplace's equation

$$\nabla^2\Phi = 0 \qquad [9]$$

For this problem we use rotational elliptic coordinates ξ and η related to the cylindrical coordinates r and y by [see ref. (7)]

$$y = r_o\xi\eta \text{ and } r = r_o\sqrt{(1+\xi^2)(1-\eta^2)} \qquad [10]$$

In this coordinate system Laplace's equation is

$$\frac{\partial}{\partial\xi}\left[(1+\xi^2)\frac{\partial\Phi}{\partial\xi}\right] + \frac{\partial}{\partial\eta}\left[(1-\eta^2)\frac{\partial\Phi}{\partial\eta}\right] = 0 \qquad [11]$$

Since the ohmic drop for a small disk is concentrated in the solution near the disk, we adopt the following boundary conditions:

$$\left.\begin{array}{l}\partial\Phi/\partial\eta = 0 \text{ at } \eta = 0 \text{ (on the insulating annulus).}\\ \Phi = 0 \text{ at } \xi = \infty \text{ (far from the disk).}\\ \Phi \text{ well behaved at } \eta = 1 \text{ (on the axis of the disk).}\end{array}\right\} \qquad [12]$$

These imply that the disk electrode is embedded in a sufficiently large insulating plane and that the counter electrode is far enough away so that the current distribution is not influenced by its position.

The solution of Eq. [11] satisfying conditions [12] can be expressed as a series

$$\Phi = \frac{RT}{ZF}\sum_{n=0}^{\infty} B_nP_{2n}(\eta)M_{2n}(\xi) \qquad [13]$$

where $P_{2n}(\eta)$ denotes the Legendre polynomial of order $2n$ and $M_{2n}(\xi)$ is a Legendre function of imaginary argument satisfying the differential equation

$$\frac{d}{d\xi}\left[(1+\xi^2)\frac{dM_{2n}}{d\xi}\right] = 2n(2n+1)M_{2n} \qquad [14]$$

and the boundary conditions

$$M_{2n} = 1 \text{ at } \xi = 0 \text{ and } M_{2n} = 0 \text{ at } \xi = \infty \qquad [15]$$

The coefficient RT/ZF is introduced with regard for the expression to be used later for the concentration overpotential. For the two cases treated in this paper we have

$$\left.\begin{array}{l}Z = -z_+z_-/(z_+-z_-) \text{ for the single salt}\\ Z = -n \text{ with supporting electrolyte}\end{array}\right\} \qquad [16]$$

At $\xi = 0$, Eq. [13] yields

$$\Phi_o = \frac{RT}{ZF}\sum_{n=0}^{\infty} B_nP_{2n}(\eta) \qquad [17]$$

This should be regarded as the potential just "outside" the diffusion layer or as the potential extrapolated to the electrode surface if the actual current distribution prevails, but there is no concentration variation near the electrode surface. Effects due to the concentration variation are to be included in the concentration overpotential.

The current density is related to the derivative of the potential just outside the diffusion layer

$$i = -\kappa_\infty\left.\frac{\partial\Phi}{\partial y}\right|_{y=0} = \frac{-\kappa_\infty}{r_o\eta}\left.\frac{\partial\Phi}{\partial\xi}\right|_{\xi=0} = \frac{-\kappa_\infty}{r_o\eta}\frac{RT}{ZF}\sum_{n=0}^{\infty} B_nP_{2n}(\eta)M_{2n}'(0) \qquad [18]$$

where κ_∞ is the conductivity of the bulk solution. From the properties of Legendre functions one finds that

$$M_{2n}'(0) = -\frac{2}{\pi}\frac{(2^n n!)^4}{[(2n)!]^2} \qquad [19]$$

Since the diffusion layer is thin, the current density evaluated from the potential derivative outside the diffusion layer (Eq. [18]) must equal the current density evaluated from the concentration derivative at the electrode surface (Eq. [8]). See also ref. (4). This provides a relationship between the coefficients B_n of the potential series and the coefficients A_m of the concentration series.

$$B_n = \frac{\pi}{4}N\sum_{m=0}^{\infty} Q_{n,m}A_m \qquad [20]$$

where

$$N = -\sqrt{\frac{r_o^2\Omega}{\nu}}\left(\frac{a\nu}{3D}\right)^{1/3}\frac{nZF^2Dc_\infty}{RT(1-t)\kappa_\infty} \qquad [21]$$

and

$$Q_{n,m} = (4n+1)\frac{4\theta_m'(0)}{\pi M_{2n}'(0)}\int_0^1 \eta(1-\eta^2)^m P_{2n}(\eta)\,d\eta \qquad [22]$$

This relationship is obtained by equating the two expressions for the current density, multiplying by $\eta P_{2n'}(\eta)$, integrating with respect to η from zero to one, and making use of the orthogonality relation

$$\int_0^1 P_{2n}(\eta)P_{2n'}(\eta)\,d\eta = \begin{cases}1/(4n+1) & \text{if } n = n'\\ 0 & \text{if } n \neq n'\end{cases} \qquad [23]$$

and the relation

$$(r/r_o)^2 = 1 - \eta^2 \text{ at } \xi = 0 \qquad [24]$$

Some values of $Q_{n,m}$ are given in Table II.

Overpotentials

The potential V of the metal disk electrode is the sum of the potential drop in the solution Φ_o, the concentration overpotential η_c, and the surface overpotential η_s

$$V = \Phi_o + \eta_c + \eta_s \qquad [25]$$

The three terms on the right will vary with radial position on the disk in such a way that V is constant. The potential drop in the solution Φ_o is evaluated from Eq. [17].

For the concentration overpotential we adopt the expression [see ref. (4)]

Table II. Matrix $Q_{n,m}$ relating the coefficients of the potential series to the coefficients of the concentration series

$$\eta_c = -\frac{RT}{ZF}\left[\ln\left(\frac{c_\infty}{c_o}\right) - t\left(1 - \frac{c_o}{c_\infty}\right)\right] \quad [26]$$

This applies approximately to metal deposition from a solution of a single salt. It also applies approximately to the reaction of a minor component from a solution with excess indifferent electrolyte, in which case $t = 0$.

The current density and the surface overpotential are assumed to be related by the expression

$$i = i_o\left(\frac{c_o}{c_\infty}\right)^\gamma\left[\exp\left\{\frac{\alpha ZF}{RT}\eta_s\right\} - \exp\left\{-\frac{\beta ZF}{RT}\eta_s\right\}\right] \quad [27]$$

where i_o is the exchange current density at the bulk concentration and is assumed to be proportional to the concentration to the γ power. Thus the exchange current density at the surface concentration c_o is expressed as $i_o \cdot (c_o/c_\infty)^\gamma$ in Eq. [27]. It is convenient to refer the current density to the limiting current density

$$i_{lim} = -\frac{nF\,Dc_\infty}{1-t}\left(\frac{a\nu}{3D}\right)^{1/3}\sqrt{\frac{\Omega}{\nu}}\,\theta_o'(0) \quad [28]$$

so that Eq. [27] becomes

$$\frac{i}{i_{lim}} = \frac{J}{N\theta_o'(0)}\left(\frac{c_o}{c_\infty}\right)^\gamma\left[\exp\left\{\frac{\alpha ZF}{RT}\eta_s\right\} - \exp\left\{-\frac{\beta ZF}{RT}\eta_s\right\}\right] \quad [29]$$

where

$$J = i_o r_o ZF/RT\,\kappa_\infty \quad [30]$$

These expressions for the overpotentials have been used so that conclusions of some generality can be drawn without introducing too many parameters. The evaluation of the concentration overpotential requires only the concentration values in the bulk and at the surface, but not a detailed knowledge of the concentration profile. In the case of the solution with supporting electrolyte, there are other species besides the limiting reactant whose concentrations are not being calculated but should perhaps enter into the determination of the overpotential. An example would be the product species in a redox reaction. The present results could be applied approximately to such a case since the product species is not so decisive in the determination of the current distribution, or the calculations could be refined to include the concentration of the product species.

The overpotential relationships cited in this section constitute an additional connection between the coefficients A_m of the concentration series and the coefficients B_n of the potential series. The concentration at the surface and the current density must adjust themselves so that the overpotentials add up to the applied voltage V according to Eq. [25]. However, it is not possible to obtain an explicit expression similar to Eq. [20].

Numerical Calculation Method

In numerical calculations it is necessary to truncate the concentration and potential series. The potential series works very well, but the coefficients A_m of the concentration series are found to have alternating signs, large absolute values, and considerably different values depending on how many terms in the series are retained. This can be avoided, to some extent, by re-expressing the concentration on the surface in terms of orthogonal polynomials

$$c_o = c_\infty\left[1 + \sum_{l=0}^{\infty} a_l P_{2l}(r/r_o)\right] \quad [31]$$

Then the coefficients a_l are small, decrease in magnitude with increasing l, and are roughly independent of the number of terms retained in the series. Furthermore, they can be evaluated by an integration over the surface concentration

$$a_l = (4l+1)\int_o^1\left(\frac{c_o}{c_\infty} - 1\right)P_{2l}(r/r_o)\,d(r/r_o) \quad [32]$$

It does become a little more difficult to evaluate the current density according to Eq. [8], and the problems arising from the fact that the coefficients A_m are large and of alternating sign are not entirely eliminated. This can be seen from the expression for the Legendre polynomial of order 20

$$\begin{aligned} P_{20}(x) = [&34{,}461{,}632{,}205\,x^{20} - 167{,}890{,}003{,}050\,x^{18} \\ &+ 347{,}123{,}925{,}225\,x^{16} - 396{,}713{,}057{,}400\,x^{14} \\ &+ 273{,}491{,}577{,}450\,x^{12} - 116{,}454{,}478{,}140\,x^{10} \\ &+ 30{,}117{,}537{,}450\,x^8 - 4{,}461{,}857{,}400\,x^6 \\ &+ 334{,}639{,}305\,x^4 - 9{,}699{,}690\,x^2 \\ &+ 46{,}189]/262{,}144 \end{aligned} \quad [33]$$

The coefficients become as large as 1.5×10^6; yet the absolute value of $P_{20}(x)$ is never greater than one for the range of interest! Consequently the calculation of the contribution to the current density arising from the Legendre polynomial of order 20 in Eq. [31] requires accurate values for $\theta_m'(0)$ as given in Table I. Because of these difficulties it was decided to truncate the series [5 and 31] at $m = 10$ and $l = 10$.

The coefficients B_n and A_m or a_l were calculated by an iterative procedure:

1. The current density and the surface concentration were specified at the center of the disk. As an initial guess this was taken to apply to the whole disk so that $a_o = A_o = c_o/c_\infty - 1$ and all the other coefficients are zero.
2. The coefficients B_n were calculated according to Eq. [20].
3. The potential outside the diffusion layer was calculated at selected values of r according to Eq. [17].
4. The potential V of the electrode was calculated by applying Eq. [25] to the center of the disk where η_c and η_s could be calculated from the specified current density and surface concentration.
5. The overpotential $\eta = \eta_c + \eta_s$ was calculated at selected values of r from Eq. [25].
6. At these same values of r, the overpotential η and the assumed current density were used to calculate the surface concentration c_o by a trial-and-error solution of Eq. [26] and [27].
7. The coefficients a_l were calculated according to Eq. [32]. In order to achieve convergence it was usually necessary to average these in some way with the previous set of a_l.
8. The current density was calculated from Eq. [8].
9. The calculations enumerated in items 2 through 8 above were repeated until no significant changes occurred in the values.

This procedure was modified slightly for the well-stirred case ($N = \infty$) where all the concentrations have their bulk values.

Results

Primary and limiting current distributions.—As a point of departure it is worthwhile to examine two limiting cases. The primary current distribution corresponds to a uniform potential Φ_o in the solution just outside the diffusion layer and was calculated by Newman (7). The current density on the disk is

$$i = 0.5\,i_{avg}/\sqrt{1 - (r/r_o)^2} \quad [34]$$

and the total current to the disk is

$$I = 4\kappa_\infty r_o \Phi_o \quad [35]$$

This result is shown in Fig. 1. In the case of the primary current distribution, the surface overpotential

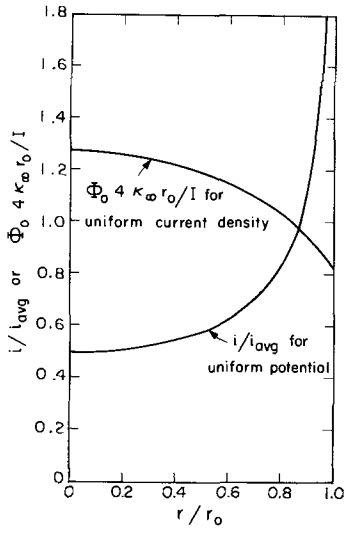

Fig. 1. Primary current distribution and potential distribution for a uniform current density.

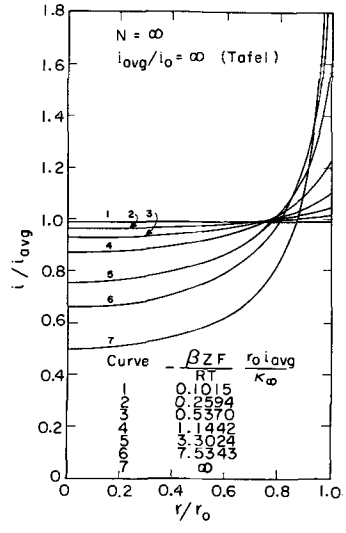

Fig. 3. Secondary current distribution for Tafel polarization

and concentration overpotential are negligible, and the current distribution is completely determined by the ohmic drop in the solution, with the result that the current density is infinite at the edge of the disk and is half of the average value at the center of the disk.

Levich (3) has shown that the current density is uniform on the disk surface and is given by Eq. [28] when the current is limited by the rate of mass transfer of a reactant to the disk. The corresponding potential Φ_0 just outside the diffusion layer can be calculated from Eq. [17] and [20] with $A_0 = -1$ and all the other A's set equal to zero. The result is shown in Fig. 1, normalized in such a way that it can be compared conveniently with the value $\Phi_0 4\kappa_x r_0/I = 1$ for the primary current distribution. For the same total current, the current density at the center of the disk is twice as high as the primary current, and this requires a potential 27.3% higher in order to force the higher current density to the center of the disk. At the same time the current density at the edge of the disk is finite, and the potential is lower than for the primary distribution.

Secondary current distribution.—If the rotation speed is high, so that $|i| << |i_{lim}|$, then the concentration overpotential is negligible, and the so-called secondary current distribution prevails. The current distribution is then determined by the balance between the surface overpotential and the ohmic drop in the solution. The result is shown in Fig. 2 and 3 for two limiting cases corresponding to linear polarization and to Tafel polarization.

For sufficiently small current densities $|i| << i_0$, Eq. [27] becomes linear, and the slope of the polarization curve at zero current is

$$\left.\frac{di}{d\eta_s}\right|_{i=0} = (\alpha+\beta)\frac{ZF}{RT}i_0 \qquad [36]$$

The parameter J is thus similar to that identified by Hoar and Agar (8) for the characterization of the influence of electrolytic resistance, polarization, and cell size on current distribution. In the linear range the current distribution depends only on the parameter $(\alpha + \beta)J$, as shown in Fig. 2 with $\alpha + \beta = 1$. In particular, the current distribution i/i_{avg} does not depend upon the level of the current. The curve for $J = \infty$ is the primary current distribution.

At higher currents where the condition $|i| << i_0$ no longer holds, the current level becomes important. This can be characterized by the dimensionless ratio

$$\delta = |i_{avg}|\frac{ZFr_0}{RT\kappa_\infty} \qquad [37]$$

In the other extreme, when $|i| >> i_0$, one of the exponential terms in Eq. [27] is negligible, and Tafel polarization is said to apply

$$\eta_s = -\frac{1}{\beta}\frac{RT}{ZF}(\ln|i| - \ln i_0) \qquad [38]$$

(For current flow in the opposite direction, the term involving α would be retained.) In the Tafel region the actual value of the exchange current density is no longer important in determining the current distribution since it just contributes an additive constant to the surface overpotential, as shown in Eq. [38]. The current distribution i/i_{avg} is completely determined by the parameter $\beta\delta$ and is shown in Fig. 3. Curve 7 for $\beta\delta = \infty$ is the primary current distribution.

It does not seem worthwhile to plot the current distribution for intermediate current levels between the linear and Tafel regions. Instead Fig. 4 and 5 give just the values for i/i_{avg} and Φ_0 at the center of the disk. The current ratio can vary between 0.5 and 1.0 in the extreme cases of the primary current distribution and the uniform current distribution. The ohmic drop to the center of the disk is expressed in Fig. 5 in the

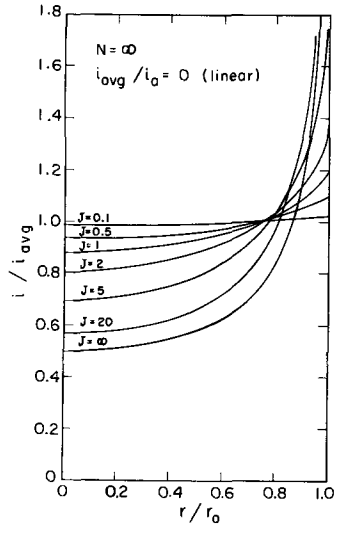

Fig. 2. Secondary current distribution for linear polarization

form $\Phi_0 4\kappa_\infty r_0/I$, a dimensionless effective resistance which can vary between the values 1.0 for the primary current distribution and 1.273 for the uniform current distribution. For large currents the Tafel results apply. As the current is decreased, the distribution becomes more uniform but approaches at low currents the linear results for the given value of J rather than a completely uniform current density. At intermediate current levels, all four parameters J, δ, α, and β can affect the current distribution. Figures 4 and 5 show the effect of J and δ when $\alpha = \beta = 0.5$.

Effect of concentration polarization.—The current density can also be limited by the rate of mass transfer of the reactants to the electrode. An important parameter in this regard is N, defined in Eq. [21]. This parameter is proportional to the square root of the Reynolds number $\mathrm{Re} = r_0^2\Omega/\nu$, the one-third power of the Schmidt number $Sc = \nu/D$, and the ratio c_∞/κ_∞. It represents the importance of the ohmic potential drop relative to the concentration overpotential at a given fraction of limiting current. An increase in disk size r_0 increases the distance over which current flows and thus increases the magnitude of the variation of the potential Φ_0. An increase in rotation speed Ω is accompanied by an increase in current at a given fraction of limiting current and thus increases the potential variation due to the ohmic drop. On the other hand, supporting electrolyte can be added so that κ_∞ increases but not c_∞. This reduces the importance of the ohmic drop.

Since the limiting current density is given by Eq. [28], the condition for the concentration overpotential to be negligible and for the secondary current distribution to apply, $|i_{avg}| << |i_{lim}|$, can be expressed as $\delta << N$.

Figures 6 and 7 show the concentration and current distributions on the disk for Tafel kinetics and for various levels of current and rotation speed. The corresponding curves on the two graphs can be found by the relationship between the current and the surface concentration at the center of the disk: $i/i_{lim} = 1 - c_0/c_\infty$ at $r = 0$. The higher currents correspond to lower surface concentrations.

The distributions of concentration and of current shown on Fig. 6 and 7 become more nonuniform for larger values of N, but they still become limited by the rate of mass transfer. The local current density is able to exceed the average limiting current only because the current is less than that value near the center of the disk. This situation can be compared to a disk with an insulator in the center and an annular or ring electrode. For such a system the local limiting current density would be infinite at the inner edge of the ring electrode and would decrease toward the outer edge. Some of the curves on Fig. 7 show this situation: the current rises as the local overpotential increases with increasing r but begins again to decrease after the concentration has effectively gone to zero and the increasing overpotential can have no more effect.

Figure 8 shows the correction factor for the current density at the center of the disk. The curve for $N = \infty$ corresponds to no concentration polarization and was shown on Fig. 4. The curves for $N = 5$, 10, and 20 depart from the curve for $N = \infty$ and terminate with a uniform current at their respective limiting currents.

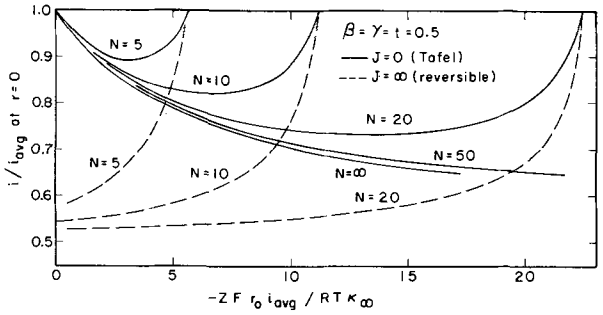

Fig. 8. Current density at the center of the disk

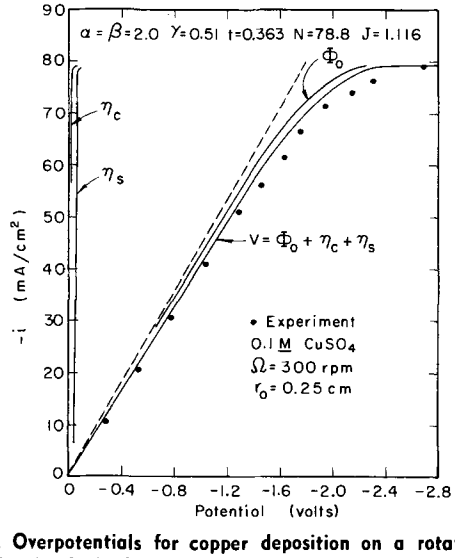

Fig. 9. Overpotentials for copper deposition on a rotating disk. Dashed line is ohmic drop for the primary current distribution.

For a sufficiently large value of the exchange current density, the surface overpotential is negligible compared to the ohmic drop in the solution and the concentration overpotential. The electrode is then said to be reversible. The current-density ratios for reversible electrodes are shown as dashed curves on Fig. 8. The distribution is more nonuniform than for Tafel kinetics, becomes more nonuniform for larger values of N, and still becomes uniform at the limiting current.

Copper deposition. Figure 9 shows a polarization curve for copper deposition from a solution containing no supporting electrolyte. Measured potentials reported by Hsueh and Newman (9) have been corrected (7) for the fact that the reference electrode was not at infinity. The following parameters were used in the calculation of the surface overpotential, the concentration overpotential, and the ohmic drop at the center of the disk:

n = −2, Z = 1, κ_∞ = 0.00872 (ohm-cm)$^{-1}$ [ref. (10)],
i_0 = 1 ma/cm², $\alpha = \beta = 2$, γ = 0.51 (ref. 11),
r_o = 0.25 cm, Ω = 300 rpm = 31.416 rad/sec
i_{lim} = 79.20 ma/cm²,
D = 0.642 x 10^{-5} cm²/sec [integral value, ref. (12)],
t = 0.363 (ref. 13), ν = 0.94452 x 10^{-2} cm²/sec,
J = 1.116, N = 78.8.

Most of the polarization is due to ohmic drop in the solution since the conductivity is so low. The curve shows how the ohmic resistance changes as limiting current is approached due to the current density becoming more uniform. The agreement with the experimental values is considerably better than that obtained with the ohmic drop for the primary current distribution (dashed line). Possible explanations for the discrepancy which remains are uncertainties in the surface overpotential and the fact that the insulating plane of the disk was not infinite, but would allow current to flow in the region above the plane of the disk. The discrepancy is roughly equal to the correction for the fact that the reference electrode is not at infinity.

Conclusions

The present results can be applied most simply to practical problems in studies of electrode kinetics if the actual current density at the center of the disk and the potential drop to the center of the disk can be obtained, perhaps by means of Fig. 4, 5, and 8, from the measured average current density and the parameters N, J, α, β, γ, and t related to the properties of the solution and the electrode reaction and the size and rotation speed of the disk electrode. Since some of these properties probably are not known in advance, trial-and-error calculations are involved.

The rotating disk is usually used for moderately fast reactions, that is, reactions for which the exchange current density is not too low. The effect of mass transfer can be corrected for (by assuming a uniform current density) or eliminated by an extrapolation to infinite rotation speed. However, the effect of a nonuniform current density is not eliminated. To assess the degree of nonuniformity, one should calculate or estimate J, δ, and N. Unless J and δ are both small, there will be a significant nonuniformity, and unless $\delta << N$ a correction must be made for the different concentration at the electrode surface.

Suppose that the 0.1M $CuSO_4$ solution studied earlier is made 1.53M in H_2SO_4 for the purpose of suppressing the ohmic potential drop in the solution. For the same current density, say 70 ma/cm², the values of the parameters N, δ, J, and t would be

N = 1.6 instead of 78.8,
δ = 2.5 instead of 78,
J = 0.037 instead of 1.116,
t = 0 instead of 0.363.

These changes are primarily results of the increased conductivity (0.548 instead of 0.00872 ohm^{-1}-cm^{-1}).

It should be noted that with the addition of sulfuric acid the current density is now above the limiting current since the contribution of migration to the mass transfer has now been suppressed by the high electrical conductivity. We might next try to eliminate the mass transfer effect altogether by increasing the rotation speed. If the criterion is taken to be $N = 20\ \delta$, the rotation speed must now be increased to 290,000 rpm, at which speed the flow becomes turbulent at about r = 0.18 cm. Few people would consider operating even at speeds as high as 30,000 rpm. Nevertheless, let us assume that mass transfer effects can be ignored.

With δ = 2.5 and β = 1 and $J \approx 0$, the results presented earlier indicate that the current density at the center of the disk is 79% of the average current density and the ohmic drop is 29.5 mv.

Finally one might note that the a-c resistance to a disk should be somewhat different from the actual value since the a-c resistance would correspond more closely to the primary current distribution. For the same reason it would be inconsistent to use current step methods to study electrode kinetics with the rotating disk. In current step methods the initial jump of the potential is taken as a measure of the ohmic drop. This would be proper for a sphere where the initial current distribution is the same as the quasi-steady current distribution (before mass-transfer limitations become important).

Studies on the Oxygen Gradients in Oxidizing Metals

V. The Oxidation of Oxygen-saturated Zirconium

J. P. Pemsler

Ledgemont Laboratory, Kennecott Copper Corporation, Lexington, Massachusetts

ABSTRACT

Oxygen-saturated zirconium was oxidized at temperatures between 840° and 1300°C. In the range 1100°-1300°C a parabolic film growth rate was observed which is more rapid than that observed during oxidation of oxygen-free metal. However, rational rate constants k_r, which characterize transport properties through the film, are identical. In the range 840°-975°C a rapid initial growth is followed by a parabolic rate more rapid than that observed on oxygen-free metal. Values of k_r are somewhat larger for oxidation of oxygen-saturated metal, the difference becoming greater at the higher temperature. Oxygen solution during oxidation of oxygen-free zirconium at 840°-975°C is believed to result in a more protective film due to the formation of voids within the film.

During the high-temperature oxidation of zirconium, significant quantities of oxygen dissolve in the metal substrate simultaneously with the growth of oxide, so that a metal zone rich in oxygen forms beneath the oxide layer. At sufficiently high-temperature oxygen solution may account for the major portion of the weight gain of the sample. The role that this oxygen solution plays in the mechanism of oxidation has not been clearly understood. In previous papers (1-3) evidence has been presented that oxygen solution obeys diffusion kinetics and remains parabolic for sufficiently thick samples. However, the kinetics of the oxide film growth is complex (4). Between 550° and 650°C film growth is approximately parabolic with an activation energy of about 30 kcal/mole. Between 750° and 910°C no normal rate law is obeyed; a rapid initial growth is followed by a much slower growth. At 975°C coincident with void formation the rate increases. Between 1100° and 1300°C voids no longer form, and the rate becomes parabolic and rapid with an activation energy of 35 kcal/mole.

Several inconclusive studies concerned with the effect of dissolved oxygen on the oxidation rate of zirconium have been previously published. Osthagen and Kofstad (5) reported an increase in the rate of oxidation when dissolved oxygen is present in zirconium. The rate increased gradually between 0 and 4 a/o (atomic per cent), then rapidly between 4 and 10 a/o, where it leveled off. Interpretations concerning the

mechanism of oxidation were made based on these observations. Cox and Harder (6) criticized this work on the basis of the fact that no examination of the microdistribution of oxygen in the samples was made. They find that the increases in oxidation rate of Zircaloy-oxygen alloys up to about 0.5 fraction saturated can be ascribed largely to inhomogeneous distribution of oxygen and that the closer a homogeneous oxygen distribution is approached, the closer the oxidation rate approaches that of low oxygen-containing material.

The difficulties inherent in the above studies are: (*i*) the inability to obtain homogeneous zirconium-oxygen alloys and (*ii*) the brittle nature of the high oxygen content alloys which prevents formation of an adherent oxide layer.

It is the purpose of this paper to determine the effect of oxygen solution on the kinetics of film formation by oxidizing sound metallurgical samples which are saturated with oxygen.

Experimental

The zirconium used in this investigation was obtained in the form of rods, and the analysis has been given previously (3). Tapered zirconium disks 1.5 cm in diameter and ranging in thickness from about 0.9 to 1.25 mm were oxidized for 1 hr at 1100°C. This resulted in an oxide film about 110μ thick, which when dissolved into the disk would just saturate the metal substrate with oxygen where the disk was about 1 mm in thickness. After oxidation, oxygen was removed from the system and the sample annealed in vacuum at 1100°C for 36 hr. This was sufficient time to diffuse the oxide film into the sample and to create a nearly homogeneous oxygen distribution throughout the metal substrate. In this manner, disks were produced which had a thin residual oxide coating on their thin end and metal which was about 85% saturated on the thick end. Between these extremes was metal of gradually increasing oxygen content all the way up to the saturation value where the metal met the remaining oxide film as shown in Fig. 1. The temperature of the furnace was then adjusted to the temperature of the final oxidation, and oxygen was admitted. Samples were oxidized for the appropriate length of time and the experiment concluded. Samples were then sectioned, and the oxide film thickness formed on metal that was saturated and near-saturated with oxygen was measured.

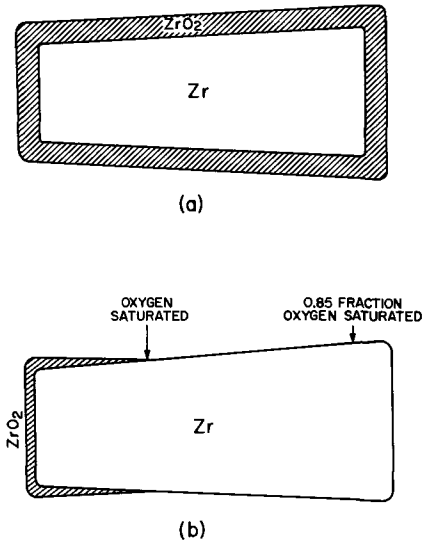

Fig. 1. Preparation of oxygen-saturated zirconium: (a) zirconium disk oxidized for 1 hr at 1100°C; (b) oxidized disk vacuum annealed 36 hr at 1100°C.

Difficulty was found in growing sound oxides on oxygen-saturated samples at temperatures below 840°C. In order to minimize possible thermal cycling effects due to cooling of samples diffused at 1100°C to the final oxidation temperature of 750°C or lower, additional experiments were performed using 0.1 mm thick foil and a preoxidation and oxygen dissolution temperature of 840°C.

Results

Oxidation of oxygen-saturated metal at temperatures of 750°C and below resulted in a spotty white oxide, even for times as short as 1 hr. This occurred whether the sample was a disk saturated at 1100°C or a foil saturated at 840°C. The white oxide resulted in a cracked film, and it was not possible to obtain meaningful kinetic data at 750°C and lower.

Film growth data at temperatures of 840°-1300°C are shown in Fig. 2-5, along with the corresponding data for the oxidation of samples with negligible initial oxygen content (henceforth called "oxygen-free" zirconium). Open circles represent film thickness on oxygen-free zirconium, filled circles represent data obtained from oxygen-saturated zirconium, and the lines without circles represent the total weight gain obtained during oxidation of oxygen-free zirconium (3) (*i.e.*, film thickness plus oxygen in solution expressed as equivalent film thickness).

Oxidation of oxygen-saturated zirconium in the range 1100°-1300°C conforms to a parabolic film growth rate which is more rapid than that observed during oxidation of oxygen-free material. The increased film growth on the oxygen-saturated zirconium brings the film thickness up to that approximately equivalent to the total weight gain found on oxygen-free zirconium oxidized for the same period of time. This does not say that the total weight gain is the same in both cases since oxygen-saturated zirconium is already equivalent to $ZrO_{0.4}$ and needs

only 1.6 atoms of oxygen per zirconium atom to bring it to ZrO_2.

At 840°, 910°, and 975°C the film formation rate is more rapid on oxygen-saturated zirconium than on oxygen-free metal. The kinetic curves for both materials are similar: a rapid initial rate is followed by a parabolic region. Unlike the oxidation behavior at 1100°-1300°C, the increase in oxide film thickness is not sufficient to result in a weight gain equivalent to that observed as the total weight gain for oxygen-free metal.

During oxidation of oxygen-free zirconium at 975°C, after about 4 hr voids are found at the oxide/metal interface; at later times these voids continue to form at the oxide/metal interface and are also found buried within the oxide (4). No such voids were found during oxidation of oxygen-saturated zirconium. Furthermore, with oxygen-free zirconium, taper sections at 910°C show a band of small voids which form between about one and four hours within the oxide (4). Taper sections on saturated material did not reveal such a structure.

Similar to oxygen-free zirconium, oxidation of oxygen-saturated zirconium at 1025° and 1050°C resulted in the formation of large voids and a highly irregular oxide/metal interface. It was therefore difficult to evaluate any differences in the oxidation behavior at these temperatures.

Discussion

Zirconium is generally considered to oxidize by an anion vacancy diffusion mechanism. The transport processes through the oxide film are supposed to be

$$Zr = Zr^{+4} + 2\square_{O}^{=} + 4e^{-} \quad \text{at the metal/oxide interface} \quad [1]$$

and

$$O_2 + 4e^{-} + 2\square_{O}^{=} = 2\,O^{=} \quad \text{at the oxygen/oxide interface} \quad [2]$$

where $\square_{O}^{=}$ is an oxygen ion vacancy.

During oxidation of oxygen-free zirconium the simultaneous process of oxygen solution into the metal substrate occurs at the metal/oxide interface, and also generates oxygen ion vacancies according to the reaction

$$O^{=} = O_{(M)} + \square_{O}^{=} + 2e^{-} \quad [3]$$

where $O_{(M)}$ indicates an interstitial oxygen atom in the metal lattice.

As a result of the occurrence of the reaction in Eq. [3], whether oxygen-free or oxygen-saturated zirconium is being oxidized, the reaction at the metal/oxide interface should not be written as in Eq. [1] but must rather be written as

$$(ZrO_{0.4})_{sat} = Zr^{+4} + 1.6\square_{O}^{=} + 3.2e^{-} \quad [4]$$

where $(ZrO_{0.4})_{sat}$ represents oxygen-saturated zirconium which has the composition $ZrO_{0.4}$.

The oxygen ion vacancy concentration in the oxide at the oxide/metal interface is determined by the thermodynamic equilibrium between the oxide and oxygen-saturated metal. This value will be the same whether oxygen-free or oxygen-saturated zirconium is being oxidized. It might then be expected that the transport rate of oxygen ions across the film would be the same in both cases. In order to examine this, we will make use of the rational rate constant, k_r, defined by the equation

$$\frac{\dot{n}}{A} = \frac{1}{2}\frac{k_r}{\Delta x} \quad [5]$$

where $\dot{n}/A$ is the rate of oxygen transport in g-atom/cm²-sec, Δx is the instantaneous film thickness of the oxide layer, and k_r is in units of equivalents/cm²-sec for unit thickness. The factor 1/2 is due to the fact that oxygen is divalent. For oxygen-free zirconium $\dot{n}/A$ must be read from the total weight gain curve, while the corresponding value of Δx is obtained from the film growth curve; values of k_r may then be calculated from Eq. [5]. For oxygen-saturated zirconium $\dot{n}/A$ and the corresponding value of Δx are read from the same curve. Values of k_r are then calculated from the equation

$$\frac{\dot{n}}{A} = \frac{1}{1.6}\frac{k_r}{\Delta x} \quad [6]$$

which expresses the fact that the metal phase was present initially as oxygen-saturated zirconium corresponding to $ZrO_{0.4}$.

Values of $\dot{n}/A$ and Δx from 840°-1300°C were obtained from Fig. 2 through 5. Data for calculating k_r for oxygen-free zirconium in the temperature range 550°-750°C were obtained from a previous investi-

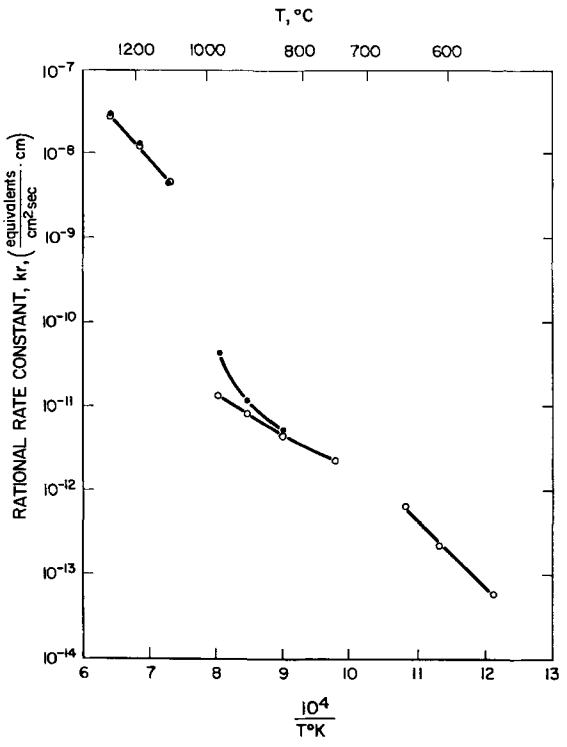

Fig. 6. Arrhenius plot of the rational rate constant, k_r, for oxidation of oxygen-free and oxygen-saturated zirconium. ○ oxygen-free zirconium; ● oxygen-saturated zirconium.

gation (4). Data for oxygen-saturated zirconium in this temperature range could not be obtained for reasons discussed previously. In the temperature range of 1100°-1300°C the calculations are straightforward. At temperatures below 1100°C where the simple parabolic rate law does not hold, $\dot{n}/A$ is read directly from the parabolic portion of the curve, while Δx is obtained by extrapolating the parabolic portion of the film growth curve to zero time and subtracting the intercept value of the ordinate from the observed film thickness. If the period during which the rapid initial growth occurred is short, then the value of k_r obtained by this procedure should be a good approximation to the true value.

An Arrhenius plot of k_r is shown in Fig. 6. In the temperature range 1100°-1300°C where the film is believed to be the high defect tetragonal oxide, values of k_r for oxygen-free and oxygen-saturated metal are identical, indicating that the transport properties of the film are the same whether it grows on oxygen-free or oxygen-saturated zirconium. In the temperature range 840°-975°C values of k_r are somewhat larger for the oxidation of oxygen-saturated metal, the difference becoming greater at the higher temperature. Thus, at 840°-975°C the process of oxygen solution during oxidation results in a more protective film than would occur were there no oxygen solution. It has been previously stated that the formation of voids is suppressed during the oxidation of oxygen-saturated zirconium. These voids have been ascribed to a condensation of oxygen ion vacancies triggered by the tetragonal/monoclinic transformation in zirconia (4). Since oxygen solution is a source of anion vacancies, it is reasonable that void formation might be accelerated by the additional contribution of vacancies formed during the process of oxygen solution. That void formation is not altogether eliminated by eliminating the oxygen solution process is apparent from observations on oxygen-saturated zirconium oxidized at 1025° and 1050°C.

Since the decrease in the rate appears to parallel the increase in void formation, it is reasonable to associate the two phenomena although it is not obvious by what mechanism the presence of voids in the oxide film would decrease the transport rate through the oxide. It has been shown that under certain circumstances nonlattice diffusion through the oxide predominates during the oxidation of zirconium (4), and the initiation and termination of these unidirectional paths may be affected by the occurrence of voids within the oxide.

Although there is a difference in film growth behavior of oxygen-free and oxygen-saturated zirconium in the range 840°-975°C, the shape of the film growth curves are nevertheless similar. These data are consistent with the hypothesis previously advanced (4) wherein the rate is determined by transport through an initial tetragonal oxide which transforms to the monoclinic structure.

It is interesting to speculate on the reasons why an adherent oxide film could not be obtained when oxidizing oxygen-saturated zirconium at temperatures below 840°C. It may be related to the increased embrittlement of the oxygen-saturated metal at the lower temperatures. The strains produced at the metal/oxide interface during oxide growth could then cause cracking in the brittle oxygenated metal, and hence an accelerated attack. It is also possible that the tetragonal phase, hypothesized to occur at the metal/oxide interface, may not be stabilized to as low a temperature during oxidation of oxygen-saturated zirconium. The monoclinic oxide may exhibit less plasticity than the high defect tetragonal oxide and undergo cracking while still quite thin.

Current work is directed toward investigating nonlattice mechanisms in the oxide film and details of the role of the tetragonal/monoclinic inversion on the kinetics.

The Mechanical Properties of Thin Anodic Films on Aluminum

D. H. Bradhurst[1] and J. S. Llewelyn Leach

Department of Metallurgy, Imperial College of Science and Technology, London, England

ABSTRACT

The measured stresses associated with the growth of oxide on the surface of aluminum are much lower than those calculated from the Pilling-Bedworth ratio. The magnitude of the stresses in alumina formed anodically on pure aluminum is shown to be dependent on the rate of formation. Some experiments are described which show that, even at low temperatures, the presence of a large ionic flux will permit the deformation of alumina providing a mechanism by which the growth stresses can be relieved.

The degree of protection against corrosion or oxidation afforded by the oxide film on a metal surface depends in part on its integrity, its thickness, and on the diffusion constants in the oxide.

The ultimate thickness to which an oxide film may grow before it cracks, *i.e.*, the protective thickness, depends on its ability to withstand or relieve the stresses which may arise during growth. If the accumulated stress exceeds the strength of the film, cracking or detachment will occur resulting in an increase in the corrosion rate.

In order to improve corrosion resistance by increasing the protective thickness of the oxide film, data are required both on the stresses which are produced during film growth and on the mechanical properties of oxide films. Considerable effort has been directed toward understanding the diffusion processes, for example in the Wagner-Hauffe (1) theory of oxidation. However, attempts to investigate experimentally the factors influencing the protective thickness to which an oxide grows have been few (2, 3).

Anodic films on aluminum are especially suited to initial studies in this field due to the ease with which films having reproducible properties may be formed and separated from the metal. In addition, the relatively low mechanical strength of pure aluminum makes it possible to study the mechanical properties of the oxide while it is still attached to the metal. The mechanical properties of these films are substantially different from the bulk material (4); it was therefore essential to make measurements directly on oxide rather than to attempt the extrapolation from the known properties of oxides in bulk.

This paper describes experiments made to measure the stresses in anodic films under different conditions of growth and some observations which support the concept that plastic deformation of a growing oxide film may occur at room temperature, if the ionic diffusion is sufficient. The stresses in the oxide were calculated from measurements of the bending of aluminum foils anodized on one side only while the evidence for low-temperature plasticity was obtained from measurements of the deformation of thin wires covered with a layer of oxide.

Experimental

The aluminum, on which the anodic films were formed, was 99.99% pure and in the form of wire 0.01 cm diameter or foil 0.005 cm thick.

Foil specimens were prepared by cutting to form parallel-sided strips either 6.00 or 8.00 cm in length which were then lightly rolled to remove the burred edge and finally annealed. The surfaces of the specimens were de-oxidized in chromic-phosphoric acid solution, etched in sodium hydroxide solution, washed in distilled water, and allowed to dry.

An electrical contact was made to one end of the strip which was then mounted in a glass tube using a cold setting resin. One side of the specimen was coated with Lacomit, a flexible lacquer, and allowed to dry.

Deflections of up to 0.4 cm were measured to a precision of $\pm$ 0.001 cm. However, reproducibility was not good. At a current density of 1 ma/cm^2 deflection *vs.* oxide thickness curves were reproduced to within about $\pm$ 20%. This figure was probably greater at lower current densities, although a precise estimate of the variation was not made in these experiments.

The annealed aluminum wires of lengths between 9 and 15 cm were mounted, using the cold setting resin, in tubular glass end-pieces. Some wires were mounted with only the air-formed oxide film on them and these are described as "clean" wires. Other wires, before mounting, had been anodized to produce thick (3000Å) oxide films. These films were formed in ammonium borate solution (*p*H 9.7) at a constant current density of 5 ma/cm^2 up to the required voltage (v), usually 200v. This was then held constant for 5 min by which time the current had decayed to a small value and the oxide thickness (θ) was given by the relation $\theta = 15v$ Å. The constancy of this relation was checked, using foil specimens, by measurements of surface capacity.

During measurements on foils the anodic oxide films were formed at constant current density. The values of current density and the solutions used varied from test to test but, with the exception of interruptions necessary for measurements of the zero field deflection, constant current conditions were used throughout any one test. In addition to the ammonium borate solution similar to that used for anodizing the wires, two 3% ammonium citrate solutions of *p*H 6 and 9.7 (adjusted with ammonium hydroxide) were used during stress measurements on the foils.

In order to determine the stress in the oxide film from the observed bending of the foil during anodizing, the force required to deflect the strip was measured by means of a sensitive torsion balance. The stress, S, within an oxide film grown on the exposed surface of the strip can be calculated from the expression

$$S = \frac{2F \cdot l}{A\,(t-d)} \qquad [1]$$

where F is the force required to bend the strip a given distance (obtained from the torsion balance measurements), l is the length of the strip of thickness t, and A the cross-sectional area of the oxide film of thickness d. Alternatively, the expression

$$S = \frac{E \cdot t^2 \cdot x}{3\,l^2 \cdot d} \qquad [2]$$

[1] Present address: Australian Atomic Energy Commission, Research Establishment, Sutherland, New South Wales, Australia.

may be used, where E is the Young's modulus of aluminum, and x the deflection of the end of the strip.

The techniques used for the measurements of the mechanical properties of anodic oxide films under static conditions, *i.e.*, when negligible ionic diffusion is present in the film, have been described previously (4). For measurements of the deformability of oxide films during growth, the following technique was used.

Stress-strain curves were obtained for both clean and anodized wires, using an "Instron" hard beam recording tensometer. Similar anodized specimens were then mounted as for the tensile tests, but re-immersed in the anodizing solution, and loaded by hanging a weight on the lower glass end-piece so that the load corresponded to a known point on the stress-strain curve. A small anodic current was then passed which was recorded together with the voltage. The additional extension of the wire, if any, was observed using a travelling microscope focussed on the end of the wire. The current density was increased in steps, the voltage, current, and extension being continuously observed. Experiments were made to determine both the critical load, and the critical current at which additional extension of the wires occurred.

Results

Stresses in the oxides.—Two main factors were found to influence the deflection of the aluminum strips during anodic oxide growth. The primary factor was the stress inherent in the film, but superimposed on this was a voltage dependent deflection which always acted on the strip in such a way as to indicate an apparent compressive stress in the oxide film. In order to eliminate this "electrostatic" effect, deflection measurements were made at zero field, by switching off the current and allowing the strip to come to rest under the influence of the stresses in the film.

Both methods already outlined for the calculation of stress were used, and the results are compared in Fig. 1, which shows the deflection with and without the applied field for an aluminum strip anodized at 3.3 ma/cm^2 current density. The deflection is plotted as a function of the film thickness (which is proportional to the anodizing voltage). The stress in the film calculated from Eq. [1] and [2] is shown on the same axes. The similar values of stress obtained by both methods show that the Lacomit protective layer does not alter the elastic properties of the aluminum strip to any significant extent at these small deflections.

The stress in the oxide calculated from the deflection of the foils was in general not a function of the thickness of the oxide and in many cases was nearly constant. In some experiments, however, the stress appeared to decrease as the oxide thickened, as in Fig. 1, and in others the stress increased as the oxide thickness increased. In view of this lack of consistency the data have been presented in the form shown in Fig. 2 where the vertical lines on the stress axis represent the total range of stress observed in each experiment for oxide films of thicknesses within the range 150-3000Å. These results are shown in Fig. 2 as a function of the current density used for anodizing.

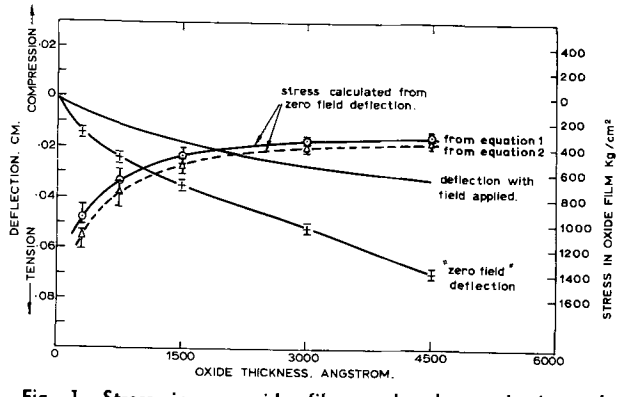

Fig. 1. Stress in an oxide film produced on aluminum by anodizing in ammonium borate solution (pH 9.7) at 3.3 ma/cm^2. Stress was calculated using Eq. [1] (calibration) and Eq. [2] (theoretical).

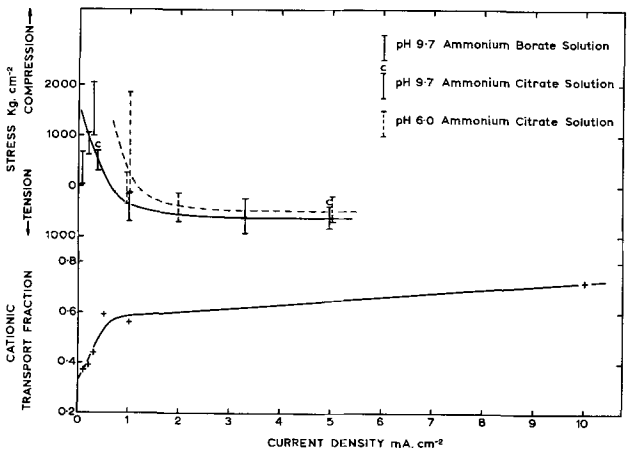

Fig. 2. Curve 1, stress in anodic oxide films on aluminum as a function of current density of formation (in ammonium borate and ammonium citrate solutions); curve 2, fraction of cationic transport in oxide films on aluminum as a function of current density of formation [determined by Davies et al. (6)] in ammonium citrate solution.

It may be seen that the current density is important in determining the nature of the stress developed in the film. At low current density there is a greater tendency for compressive stress to develop. The results shown for 3% solutions of ammonium citrate and ammonium borate of *p*H 9.7 are similar. The results obtained for 3% ammonium citrate solution (of unadjusted *p*H 6) also exhibit a similar trend, but the current density at which stress reversal occurs appears to be somewhat higher than for the more alkaline solutions.

Davies *et al.* (5, 6) have shown that during anodic oxidation of aluminum in ammonium citrate solution the relative amounts of the two ionic species diffusing in the oxide are dependent on the rate of oxidation. The anodic films referred to in Davies' work were formed in 3% ammonium citrate solution which was the electrolyte used for the stress measurements shown as dotted lines in Fig. 2. His results (6), expressed as the cationic transport fraction, are included in Fig. 2 for comparison with the stress data.

The measurements of stresses in anodic oxide films reported by Vermilyea (7) are in qualitative agreement with the results obtained in the present work. The effect of the forming voltage on the measured stress is qualitatively the same for both investigations. The effect of rate of formation of the oxide on the stresses observed is also noted by Vermilyea, but a detailed investigation and interpretation was not attempted.

Deformation of the oxides.—The results of the deformation experiments during anodic growth are shown in Fig. 3 and 4. The results of a typical experiment appear in Fig. 3 in which the extension of a previously anodized wire, loaded with 35.5g, is shown as a function of time during the course of further anodizing. The current density was increased in steps, rapid deformation commencing only when the current density exceeded the leakage current density. During such an experiment the voltage across the film usually did not exceed 240v and was always less than the dielectric breakdown voltage which, under these conditions, is about 350-400v.

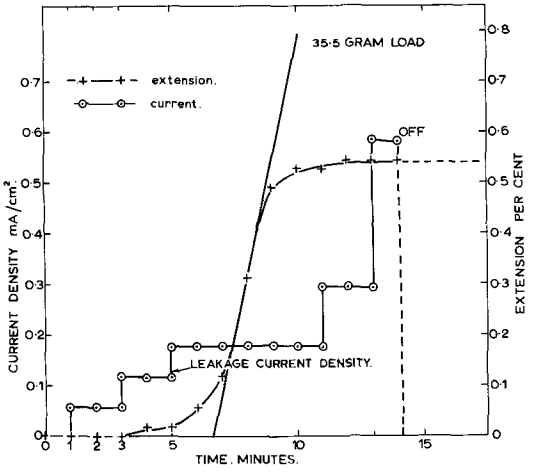

Fig. 3. Extension of a loaded anodized wire as a function of time as the anodic current is increased.

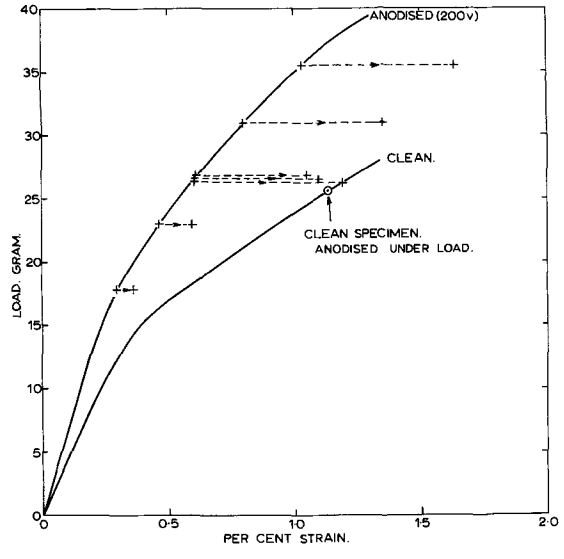

Fig. 4. "Additional" extension produced by passing anodic current through anodized wires under tensile load.

The extension recorded in this experiment together with data from other experiments are shown in Fig. 4 as a function of load; each dotted line represents one experiment. The load, voltage, and current data for each experiment are given in Table I.

Changes in the length of the wire due to grown-in stresses in the oxide may be shown to be small compared with the extensions observed. Experimentally this was demonstrated by anodizing two freely suspended wires of similar length to the test specimens. Measurements at current densities of 0.1 and 5 ma/cm² showed that no significant change in length of the wires occurred.

A blank experiment was carried out on a clean wire loaded at 26.6g. No extension occurred during a period of 1 hr during which anodizing was carried out at different current densities in the range from 0.125 to 7.5 ma/cm².

Discussion

Stress measurements.—Stresses in growing oxide films are sometimes assumed to arise from the volume change which occurs when a specific quantity of metal is converted into metal oxide. Experimental evidence shows that this is an oversimplification and that in many instances other factors may partly or wholly determine the nature and magnitude of the stress which develops in a growing oxide film. These factors include the nature of the diffusing ionic species involved in the film formation, epitaxy, surface roughness, and residual stresses in the metal. The evidence obtained from the present experiments supports the suggestion that the nature of the diffusing species is of primary importance in determining the stress in oxide films.

Table I. Load, voltage, and current data for results appearing in Fig. 4.

* "Clean wire" experiment.

The specimens used in these experiments were chemically polished and annealed, and the anodic film produced is known to be extremely fine grained. Stresses within the film arising from surface roughness and residual stresses were therefore minimized and epitaxial stresses confined to a few atom layers. As the volume ratio for aluminum oxide is greater than 1, compressive stress is expected if it can be shown that film growth proceeds by the inward diffusion of oxygen. A rough calculation of the magnitude of this compressive stress may be made under these conditions. The linear elastic strain at the metal oxide interface is given by $\sqrt[3]{V_R}$ where V_R is the volume ratio for γ-alumina ($= 1.28$). This corresponds to a linear strain of 0.0857 and a stress of 36,000 kg/cm² [Young's modulus for the film is 4.2 x 10^5 kg/cm² (4)].

The observation of compressive stress at low current density appears qualitatively consistent with this model, although the observed compressive stress (up to 2000 kg/cm²) is much less than the calculated value. The work of Davies *et al.* (5, 6) seems to offer a possible explanation. There it was shown that, at low current density (0.1 ma/cm²), the anodic film formed on aluminum predominantly by oxygen movement although cations did pass into solution. At higher current densities the proportion of cationic movement increased as shown in Fig. 2, and it also contributed to the film formation. At the low current density the requirement for film formation by the inward diffusion of oxygen is fulfilled, thus giving rise to the compressive stress as observed. The occurrence of tensile stress in the aluminum oxide films formed at the higher current densities suggests that the volume ratio is no longer the predominant stress-determining factor under conditions where the film forms by the movement of both ions. Oxide formed by movement of metal ions would be expected to form without restraint at the oxide-environment interface and to be relatively free of stress.

Furthermore, it seems reasonable that the low values of compressive stress might be explained in terms of the cationic movement through the oxide film even at low current density. There are now many instances (7-9) in the literature where the concept of two moving species has been invoked to explain oxidation phenomena.

A second possible explanation, namely, the occurrence of plastic deformation of the oxide film in the crystallographic sense, seems at first sight very unlikely at room temperature due to the absence of sufficient thermal activation to allow movement of dislocations or of lattice ions. However, during oxidation there is a significant ionic flux, which in the case

of anodic oxidation is field-activated and related to the ionic current flowing. The results of the experiments on thin wires suggest that deformation of the oxide by a creep mechanism must be considered possible under conditions where a sufficiently high ionic current is passing through the oxide film as can occur during anodic growth.

Oxide deformation experiments.—The influence of the presence of a thin oxide film on the mechanical properties of aluminum has been considered by a number of workers including Barrett (10) and Holt (11). Two effects are recognized. The first, for very thin films, operates by pinning surface dislocation sources, thereby increasing the elastic strain which the underlying metal can tolerate before yielding. In the second type, of which the present results are an example, the whole stress-strain curve is raised as may be seen in Fig. 4. In this case the film is thick enough to act not only in pinning surface dislocation sources but also as a barrier preventing the escape of dislocations having internal sources. The series of extensions indicated as dotted lines in Fig. 5 show how the influence of the film is removed during the passage of an ionic current slightly in excess of the experimentally determined "critical" value. Deformation of the film undoubtedly occurred during extension of the wires since cracking of the film would have been accompanied by a transient voltage drop due to the finite quantity of charge required to heal the crack by anodizing. No such transients were observed, and it seems likely from previous work on the mechanical breakdown of these films (4) that the sensitivity of this method would have been sufficient to detect any cracks formed.

Creep deformation of alumina in bulk is not normally significant at temperatures less than 1000°C (10). However, during anodic oxidation the current density may be sufficient for the ionic diffusion flux in the direction of the applied field to equal that attained by thermal diffusion at a much higher temperature.

Nabarro (12) has derived an equation for the creep rate ds/dt resulting from thermal motion of single ions in a lattice. The expression

$$\frac{ds}{dt} = \frac{D P a^3}{A^2 kT} \qquad [3]$$

involves the diffusion coefficient D, the applied stress P, the volume of a vacancy a^3, and the grain size A. In the form given the equation applies only when $Pa^3/kT < 1$.

Such a relation implies that the ionic movement is thermally activated whereas in the present case of anodic oxidation the ionic movement is primarily field activated. In order to employ this equation to interpret the present results, it is necessary to eliminate D from the equation and to incorporate a term involving the ionic current.

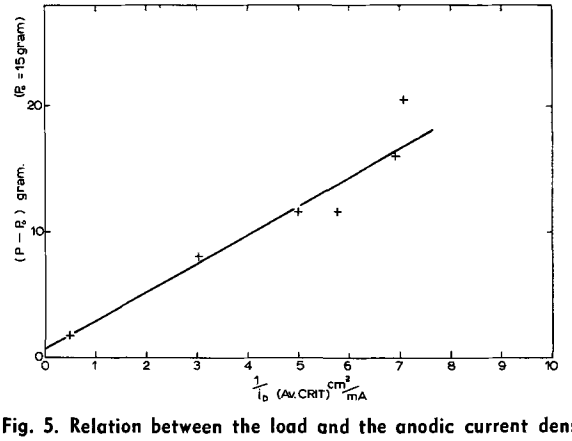

Fig. 5. Relation between the load and the anodic current density for initiation of extension.

The equation for ionic conduction in the presence of a high field has been shown to have the form

$$J = 2qan\nu \exp\frac{-W}{kT} \exp\frac{+qaE}{kT}$$

where W is the height of the activation barrier for ionic movement, q, a, and E are the ionic charge, the jump distance, and the applied field, n is the number of moving ions per cubic centimeter, and ν is the vibration frequency of a lattice ion.

The thermally activated diffusion coefficient D is given by the equation

$$D = \frac{1}{6} a^2 \nu \exp\left(\frac{-W}{kT}\right)$$

In the present circumstances additional diffusion arises from field activation, and it is suggested that an enhanced diffusion coefficient should be used defined as

$$D = \frac{1}{6} a^2 \nu \exp\left(\frac{-W}{kT}\right) \exp\left(\frac{qaE}{kT}\right)$$

The resulting equation for the deformation rate has the form

$$\frac{ds}{dt} = \frac{a^4 PJ}{12A^2 kTnq}$$

which shows that the deformation rate should be proportional to the product PJ and terms which are approximately constant for a given material and temperature.

In the present experiments it has not been found possible to show a relation between the rate of deformation, the current, and the load. In the deformation equation as formulated, J represents the ionic flux whereas the currents shown in Fig. 3 are total currents and the leakage current densities in Table I are those for zero oxide growth. The relatively large and to some extent irreproducible leakage current leads to uncertainty in the true value of J, particularly at low current densities. Experimentally, it is found that the current density required to initiate the additional extensions is inversely proportional to the applied load as seen in Fig. 5.

It might be expected that, in a material such as alumina which contains two ionic species, both species must diffuse to permit deformation. In the present experiments it has only been possible to show that at high stresses the minimum current for deformation approaches the leakage current below which no oxide is formed and presumably no ions move. Davies (5, 6) has shown that, even at very low rates of anodic oxide formation, there is some movement of cations even though the formation of the oxide occurs exclusively by anionic movement. Thus this system does not seem suitable for testing whether or not deformation can occur with only one ion diffusing.

In the present experiments the stresses which were relieved by diffusion were tensile in character. However, there seems to be no appropriate reason why the compressive stresses which should result from anionic movement in the oxidation of these metals could not be relieved by similar processes.

In previous studies (4) it was shown that the deformability of anodic oxide films at room temperature and in the absence of a diffusion flux was considerably greater than that of the oxide in bulk. This deformation which was shown to be entirely elastic was as large as 2%. This is greater than the largest total extension measured in the present work, independently supporting the suggestion that the additional extension observed is not due to fracture of the oxide.

The small grain size of this anodic oxide (13), which may account for properties previously reported (4), also provides ample internal surface to which the dif-

fusing ions may be added to allow extension or from which they may be removed to allow compression of the oxide film.

The results of the present experiments show that, in the presence of an ionic diffusion flux, the mechanical properties of the oxide film are still further changed from those of the bulk material. Thus measurements made of the plasticity of oxides in bulk and in the absence of the large fluxes of ions associated with oxidation processes are of little help and can be misleading when applied to the solution of oxidation problems. It is interesting to consider the possibility of deliberately enhancing the ability of these oxides to relieve the grown in stresses and thus improve their protective nature by increasing the protective thickness.

Acknowledgments

The authors wish to thank Professor J. G. Ball for his support throughout this work and for the provision of laboratory space in his department. The financial support for the work and the provision of a stipend for one of them (D.H.B.) by the Central Electricity Generating Board is also gratefully acknowledged.

Manuscript received Dec. 21, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Diffusion Coefficients, Oxygen Activities, and Defect Concentrations Across a p-Type Oxide Layer on a Metal

F. S. Pettit

Advanced Materials Research and Development Laboratory, Pratt & Whitney Aircraft, Division of United Aircraft Corporation, North Haven, Connecticut

ABSTRACT

Oxygen activities, diffusion coefficients of metal ions, and defect concentrations across an oxide layer on nickel, cobalt, iron, and manganese have been determined from the parabolic rate constants for growth of the oxide on the metal in different pressures of oxygen. Theoretical expressions are presented which account for the observed results.

During the oxidation of a metal where a dense, thick, adherent oxide is formed and the oxide thickness increases in accordance with the parabolic rate law, the oxide composition varies from that of the oxide in equilibrium with the metal to that of the oxide in equilibrium with the gas. Consequently, within the oxide layer, parameters such as diffusion coefficients, activities of metal and oxygen, and the concentration of atomic defects change continuously from the metal/oxide interface to the oxide/gas interface. The purpose of this paper is to show that, for cases where the oxidation rate is pressure dependent (*i.e.*, cation deficient oxides), one may use equations derived by Wagner (1) to obtain diffusion coefficients, oxygen activities, and the concentration of atomic defects across the oxide layer by determining parabolic rate constants for growth of the oxide in fixed pressures of oxygen.

Theoretical Considerations

Metal deficit oxides on metals are usually formed by diffusion of metal ions and electron holes across the oxide with the slower moving cations determining the oxidation rate. The diffusion coefficient of oxygen is usually small compared to that of metal and the flux of oxygen ions can be neglected. For thick oxide layers where the effect of space charge boundary layers is negligible, Wagner (1) has shown that the flux of metal ions and the flux of electron holes across the oxide can be written as

$$\tilde{j}_M = -(\tilde{C}_M D^*_M/RT)\left(\frac{d\mu_M}{dx} + z_M F \frac{d\rho}{dx}\right) \quad [1]$$

$$\tilde{j}_\oplus = -(\tilde{C}_\oplus D^*_\oplus/RT)\left(\frac{d\mu_\oplus}{dx} + F\frac{d\rho}{dx}\right) \quad [2]$$

where the symbols are as follows:

$\tilde{j}_M$, $\tilde{j}_\oplus$ the flux of metal ions and the flux of electron holes, respectively, in equivalents per unit area; per unit time.

$\tilde{C}_M$, $\tilde{C}_\oplus$ the concentration of metal ions and electron holes, respectively, in equivalents per unit volume.

D^*_M, $D^*_\oplus$ the self-diffusion coefficient of metal ions and electron holes, respectively (cm^2/sec).

μ_M, $\mu_\oplus$ the chemical potential of metal ions and electron holes, respectively (cal/mole).

z_M the valence of the metal ion (eq./mole).

F Faraday constant (cal/eq. volt).

ρ the electrical potential (volts).

R the gas constant (cal/mole-deg).

T absolute temperature.

x reaction coordinate across the oxide layer (cm).

In view of electroneutrality requirements, $\tilde{j}_\oplus = -\tilde{j}_M$. Thus on rearranging Eq. [1] and [2] and then sub-

tracting Eq. [2] from Eq. [1], the expression for the flux of metal ions may be written as

$$\tilde{j}_M = -(1/RT)\left(\frac{\tilde{C}_M D^*_M \tilde{C}_\oplus D^*_\oplus}{z_M \tilde{C}_M D^*_M + \tilde{C}_\oplus D^*_\oplus}\right)\left(\frac{d\mu_M}{dx} - z_M \frac{d\mu_\oplus}{dx}\right) \quad [3]$$

For an electronic conductor, $D^*_M << D^*_\oplus$. Furthermore, within the oxide, the following relations are valid

$$\mu^o_M = \mu_M - z_M \mu_\oplus \quad [4]$$

$$d\mu^o_M = -(z_M/z_o)\, d\mu_o \quad [5]$$

where μ^o_M and μ_o are the chemical potentials of metal and oxygen, respectively, and z_o is the valence of oxygen. Substitution of Eq. [4] and [5] into Eq. [3] yields

$$\tilde{j}_M = (z_M \tilde{C}_M D^*_M / z_o RT)\, d\mu_o/dx \quad [6]$$

or

$$\int_o^x \tilde{j}_M\, dx = (\tilde{C}_M)\int_{a'_o}^{a_o} (z_M D^*_M/z_o)\, d\ln a_o \quad [7]$$

where a'_o is the activity of oxygen at the metal/oxide interface (*i.e.*, $x = 0$) and a_o is the oxygen activity in the oxide layer at a distance x from the metal/oxide interface. In view of Eq. [7], one may write

$$\int_o^x \tilde{j}_M\, dx \Big/ \int_o^{x_T} \tilde{j}_M\, dx = \tilde{C}_M \int_{a'_o}^{a_o} (z_M/z_o) D^*_M\, d\ln a_o \Big/ \tilde{C}_M \int_{a'_o}^{a''_o} (z_M/z_o) D^*_M\, d\ln a_o \quad [8]$$

where x_T is the total oxide thickness and a''_o is the oxygen activity at the oxide/gas interface. The integrals on the left-hand side of Eq. [8] can be integrated provided $\tilde{j}_M$ is independent of x. This will be the case for oxides with small homogeneity ranges. Furthermore, according to Wagner's theory of metal oxidation (1) the numerator and denominator on the right-hand side of Eq. [8] are equal to the "rational rate constant," k_r, for growth of the oxide in atmospheres with oxygen activities of a_o and a''_o, respectively. The rational rate constant and the parabolic rate constant, k_p are interrelated by,

$$k_r = z^2_o \tilde{V}\, k_p / 2M^2_o \quad [9]$$

where $\tilde{V}$ is the equivalent volume of the oxide, and and M_o is the molecular weight of oxygen. k_p is defined as

$$(\Delta m/A)^2 = k_p\, t \quad [10]$$

where $(\Delta m/A)$ is the weight gain per unit area and t is the time. Substitution of Eq. [9] into Eq. [8] and integration of the left-hand side of Eq. [8] yields

$$x/x_T = k_p^{(a_o)}/k_p^{(a''_o)} \quad [11]$$

where $k_p^{(a_o)}$ and $k_p^{(a''_o)}$ are parabolic rate constants for oxidation of the metal in gas atmospheres with oxygen activities of a_o and a''_o, respectively, and the quantity (x/x_T) is a normalized reaction coordinate. For a given temperature, one may determine k_p experimentally at different oxygen pressures over the interval a'_o to a''_o, and Eq. [11] can then be used to determine (x/x_T) for specific values of a_o. From this information the oxygen activity across an oxide layer formed in a gas with an oxygen activity of a''_o can be obtained. Furthermore, if the concentration of atomic defects as a function of a_o is known, the defect concentration across the oxide layer can also be determined.

Finally, the variation of the self-diffusion coefficient across the oxide layer can be determined if D^*_M is known as a function of a_o. From the definition of the "rational rate constant" and Eq. [9], k_p can be written as

$$k_p = 2(M_o/z_o \tilde{V})^2 \int_{a'_o}^{a_o} (z_M/z_o) D^*_M\, d\ln a_o \quad [12]$$

For a given temperature a'_o is constant and Eq. [12] can be differentiated with respect to a_o for constant a'_o (2, 3). This differentiation yields

$$(dk_p/d\ln a_o)_{a'_o} = 2(z_M/z_o)(M_o/z_o \tilde{V})^2 D^{*(a_o)}_M \quad [13]$$

where (z_M/z_o) has been assumed to be constant and $D^{*(a_o)}_M$ is the self-diffusion coefficient of metal ions in an oxide with an oxygen activity of a_o. Equation [13] can be used to calculate $D^{*(a_o)}_M$ as a function of a_o providing $(dk_p/d\ln a_o)_{a'_o}$ is known. $(dk_p/d\ln a_o)_{a'_o}$ can be determined by plotting k_p *vs.* $\ln a_o$ and calculating the slope of the resulting curve for given values of a_o.

In the following sections of this paper, parabolic rate constants for the growth of oxides on nickel, cobalt, iron, and manganese will be used to determine self-diffusion coefficients of metal ions, defect concentrations, and oxygen activities across oxide layers on these metals.

Growth of NiO *on Nickel*

Fueki and Wagner (4) have studied the oxidation of nickel and determined parabolic rate constants as a function of oxygen pressure. Their results for a temperature of 1190°C are given in Fig. 1 where the parabolic rate constants are plotted *vs.* the logarithm of

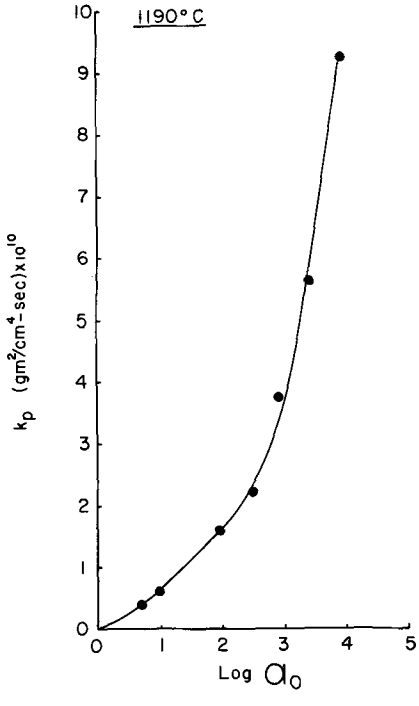

Fig. 1. Parabolic rate constants for the growth of NiO on nickel as a function of oxygen activity in the gas phase. The range of oxygen activities covered correspond to oxygen pressures from the Ni/NiO equilibrium to 1 atm [Fueki and Wagner (4)].

the oxygen activity in the gas phase.[1] (In the present paper unit oxygen activity will be taken for the oxide in equilibrium with the metal as a reference basis, *i.e.*, $a_o = 1$ for metal/oxide equilibrium.) The data presented in Fig. 1 were used with Eq. [11] to determine the normalized reaction coordinate, x/x_T, for specific values of a_o. The results of these calculations, which are presented in Fig. 2, give the activity of oxygen across an oxide layer formed on nickel by oxidation in 1 atm of oxygen at 1190°C. Fueki and Wagner have used Eq. [13] to determine self-diffusion coefficients of nickel in NiO as a function of oxygen pressure. Since the oxygen activity across a layer of NiO on nickel is given in Fig. 2, the results of Fueki and Wagner were used with the data of Fig. 2 to obtain values for the self-diffusion of nickel across a layer of NiO formed on nickel in 1 atm of oxygen at 1190°C. These results are presented in Fig. 2 and show that D^*_{Ni} is a linear function of the normalized reaction coordinate.

Growth of CoO on Cobalt

Pettit and Wagner (5) have studied the oxidation of cobalt at 1150°C and determined parabolic rate constants as a function of oxygen pressure. These data, which are presented in Fig. 3, were used to determine a_o as a function of x/x_T with the help of Eq. [11]. The activity of oxygen across a layer of cobaltous oxide formed on cobalt by oxidation in 1 atm of oxygen at 1150°C is given in Fig. 4. The self-diffusion coefficient of cobalt in cobaltous oxide was obtained as a function of oxygen activity by graphically determining the slope of the curve in Fig. 3, (*i.e.*, $(dk_p/d \ln a_o)_{a'_o}$) for given values a_o, and then $D^{*(a_o)}_{Co}$ was calculated

[1] Fueki and Wagner performed experiments at low oxygen pressures by using CO_2 which contained small amounts of CO. The buffer capacity of such mixtures is poor, and the establishment of the equilibrium oxygen pressure can be questioned because of evolution of CO during the oxidation reaction and because of the presence of a diffusion boundary layer adjacent to the oxide surface. Pettit and Wagner (5) found such effects to be negligible for the oxidation of cobalt in CO_2-CO mixtures containing as little as 2 v/o (volume per cent) CO. The smooth curve formed by the data of Fueki and Wagner (see Fig. 1) suggests that these effects are also negligible for the oxidation of nickel in CO_2 containing 0.25 v/o (volume per cent) CO. Moreover the shape of the curve in Fig. 1 is predominantly fixed by the results obtained in oxygen containing atmospheres. Therefore, the results obtained in CO_2-CO mixtures are not critical in the present paper.

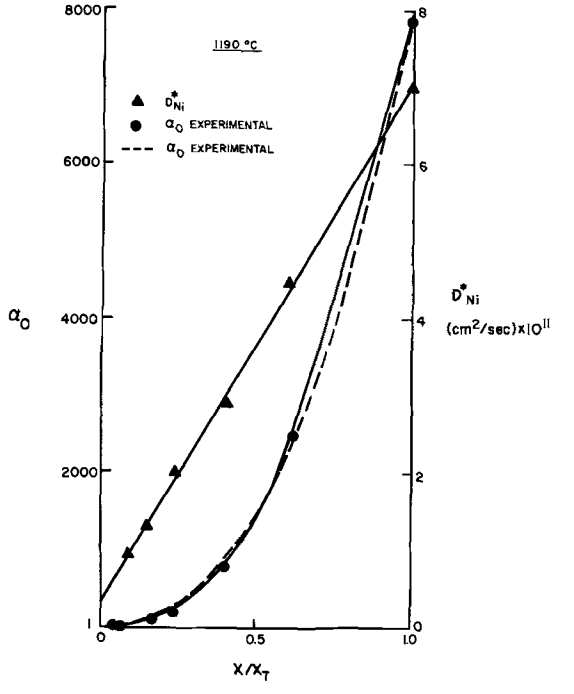

Fig. 2. Oxygen activity and the self-diffusion coefficient of nickel across a layer of NiO formed on nickel by oxidation in oxygen at 1 atm.

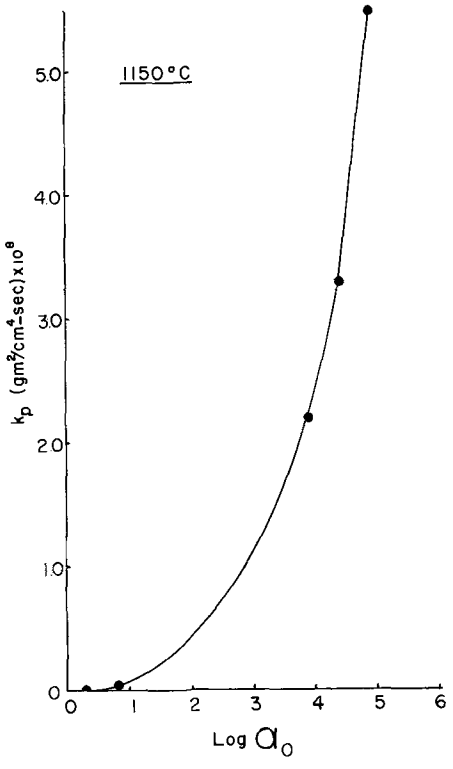

Fig. 3. Parabolic rate constants for the growth of CoO on cobalt as a function of oxygen activity in the gas phase. The range of oxygen activities covered correspond to oxygen pressures from the Co/CoO equilibrium to 1 atm [Pettit and Wagner (5)].

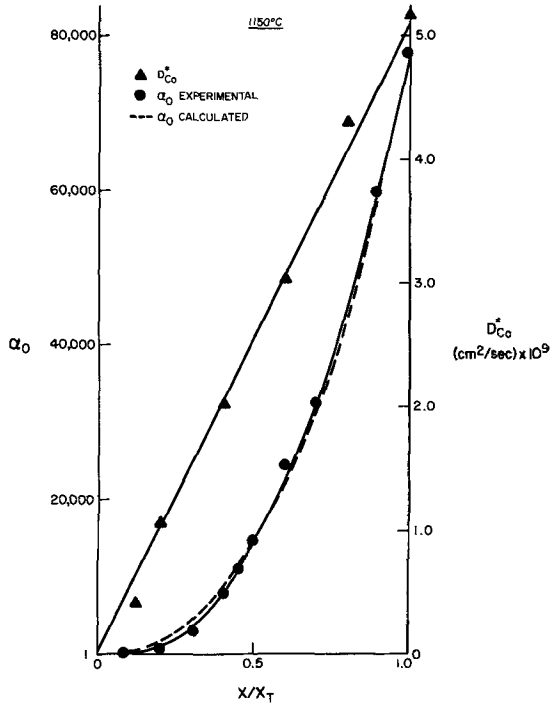

Fig. 4. Oxygen activity and the self-diffusion coefficient of cobalt across a layer of CoO formed on cobalt by oxidation in oxygen at 1 atm.

with the help of Eq. [13]. The results of the calculations are presented in Fig. 4 where D^*_{Co} has been plotted *vs.* the normalized reaction coordinate. It can be seen that D^*_{Co} is a linear function of the normalized reaction coordinate. Self-diffusion coefficients for cobalt in cobaltous oxide have been determined by

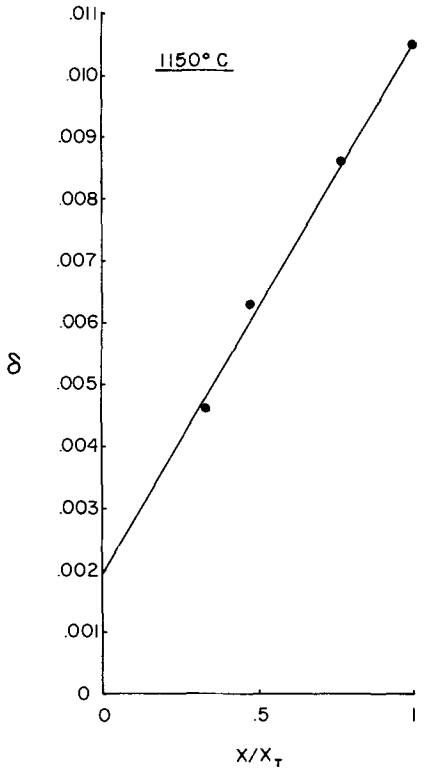

Fig. 5. Cobalt deficit across a layer of $Co_{1-\delta}O$ formed on cobalt by oxidation in oxygen at 1 atm pressure.

Carter and Richardson (6) from measurements using radioactive tracers. A value for D^*_{Co} of 9 x 10^{-9} cm^2/sec was obtained for 1148°C and 1 atm of oxygen. In the present work D^*_{Co} was found to be 5.2 x 10^{-9} cm^2/sec for a temperature of 1150°C and 1 atm of oxygen.

Eror (7) has determined the cobalt deficit, δ, in $Co_{1-\delta}O$ using gravimetric techniques. Eror's results for 1150°C are given in Table I. Eror's data give δ as a function of a_o. Since a_o across the oxide layer is given in Fig. 4, the cobalt deficit across the oxide layer was obtained. The cobalt deficit across an oxide layer formed on cobalt by oxidation in 1 atm of oxygen at 1150°C is presented in Fig. 5. Figure 5 shows that the cobalt deficit is a linear function of the normalized reaction coordinate.

Growth of FeO *(Wüstite) on Iron*

Equation [11] has been obtained for the growth of oxides which have small homogeneity ranges, since it has been assumed that the flux of metal ions is independent of the reaction coordinate. This is not the case for wüstite, since at 1100°C, $Fe_{0.95}O$ is in equilibrium with iron while $Fe_{0.87}O$ is in equilibrium with Fe_3O_4. Therefore, the flux of iron ions near the iron/wüstite interface can be greater than the flux of iron ions near the wüstite/gas interface by as much as 10%. For wüstite, Eq. [11] gives values of x/x_T which are about 10% too large. The error in x/x_T is largest (*i.e.*, 10%) for small values of x/x_T and decreases as x/x_T increases, approaching zero as x/x_T approaches unity. Thus even though wüstite exhibits a large homogeneity range, Eq. [11] can be used as approximation.

Table I. Cobalt deficit, δ, in $Co_{1-\delta}O$ for the oxide in equilibrium with oxygen at 1150°C

δ	P_{O_2}	a_o
0.0046	4.7 × 10^{-2}	3.7 × 10^{3}
0.0063	1.5 × 10^{-1}	1.2 × 10^{4}
0.0086	5.1 × 10^{-1}	4.0 × 10^{4}
0.0105	1.0	7.8 × 10^{4}

Pettit (8) has studied the oxidation of iron in CO-CO_2 mixtures under conditions such that wüstite was the only stable oxide. Parabolic rate constants for the growth of $Fe_{1-\delta}O$ on iron for a temperature of 1100°C are presented in Fig. 6 as a function of oxygen activity in the gas phase. These data were used with Eq. [11] to determine a_o across a layer of wüstite formed on iron by oxidation in a CO-CO_2 mixture with a CO_2/CO ratio equal to 4 (see Fig. 7). The data presented in Fig. 6 were also used with Eq. [13] to determine D^*_{Fe} across the wüstite layer; D^*_{Fe} was found to be 1 x 10^{-7}

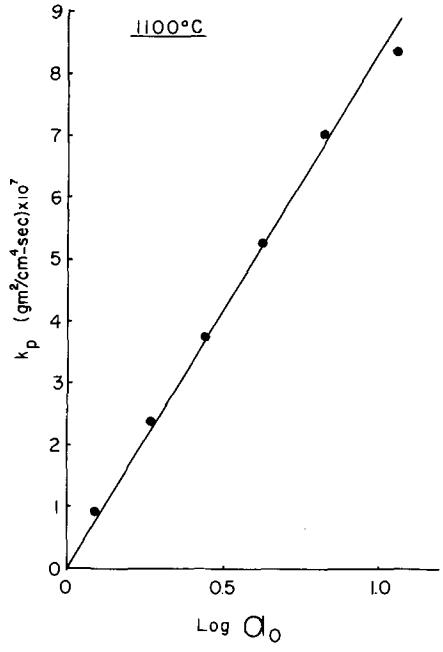

Fig. 6. Parabolic rate constants for the growth of wüstite on iron as a function of oxygen activity in the gas phase. The range of oxygen activities covered correspond to CO_2/CO ratios from 0.36 (*i.e.*, iron-wüstite equilibrium) to 4 [Pettit (8)].

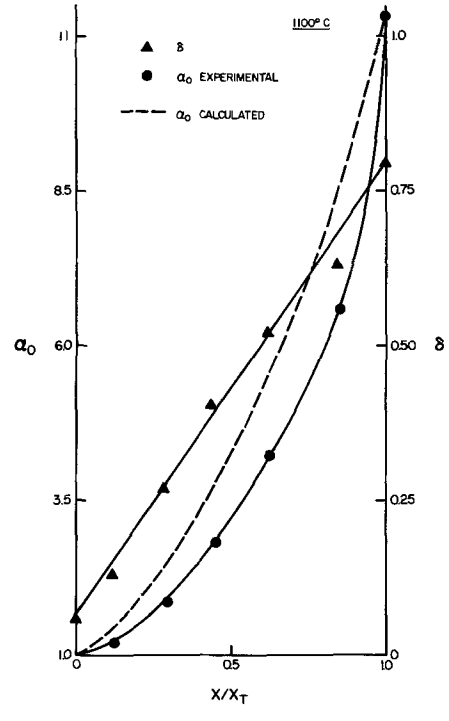

Fig. 7. Oxygen activity and the iron deficit across a layer of $Fe_{1-\delta}O$ formed on iron by oxidation in a CO-CO_2 mixture with CO_2/CO = 4.

cm²/sec for all values of x/x_T, *i.e.*, $Fe_{0.95}O$ to $Fe_{0.88}O$. Levin and Wagner (9) have extrapolated data obtained by Birchenall *et al.* (10) to 1100°C and found D^*_{Fe} to be 0.9 x 10^{-7} and 2.2 x 10^{-7} for wüstite of the composition $Fe_{0.95}O$ and $Fe_{0.91}$, respectively.

Darken and Gurry (11) have determined the iron deficit, δ, in wüstite as a function of a_o at 1100°C. These results along with oxygen activities presented in Fig. 7 were used to obtain δ as a function of the normalized reaction coordinate. As can be seen in Fig. 7, δ is a linear function of the normalized reaction coordinate. Engell (12) used an electrochemical method to measure δ across a FeO layer formed on iron at 900°C and found that δ was a linear function of the reaction coordinate.

Growth of MnO *on Manganese*

Fueki and Wagner (13) have studied the oxidation of manganese in CO-CO_2 mixtures over the temperature interval 800°-1200°C. The oxide layer was found to be MnO, and marker experiments revealed that manganese ions played the major role of material transport in manganese oxide. Parabolic rate constants for the growth of MnO on manganese are presented in Fig. 8 for a temperature of 1100°C. The activity of oxygen and D^*_{Mn} across a layer of MnO formed on manganese by oxidation in a CO-CO_2 mixture with $CO_2/CO = 100$ (*i.e.*, $a_o = 10^{6.64}$) were obtained from these data with the help of Eq. [11] and [13]. The results are presented in Fig. 9. D^*_{Mn} was found to be a linear function of the normalized reaction coordinate.

Discussion of Results

In developing the equations which were used to obtain the preceding results, it was not necessary to make any assumptions with regard to the dependence of D^*_M on a_o. If the self-diffusion coefficient is assumed to be proportional to the concentration of atomic defects which in turn is related to the activity of oxygen by (14)

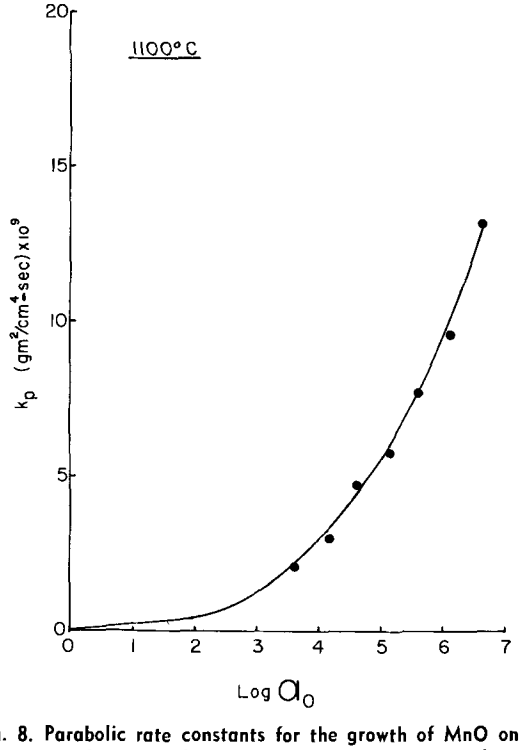

Fig. 8. Parabolic rate constants for the growth of MnO on manganese as a function of oxygen activity in the gas phase. The range of oxygen activities correspond to oxygen pressures from the Mn/MnO equilibrium to the oxygen pressure for a CO-CO_2 mixture with $CO_2/CO = 100$ [Fueki and Wagner (13)].

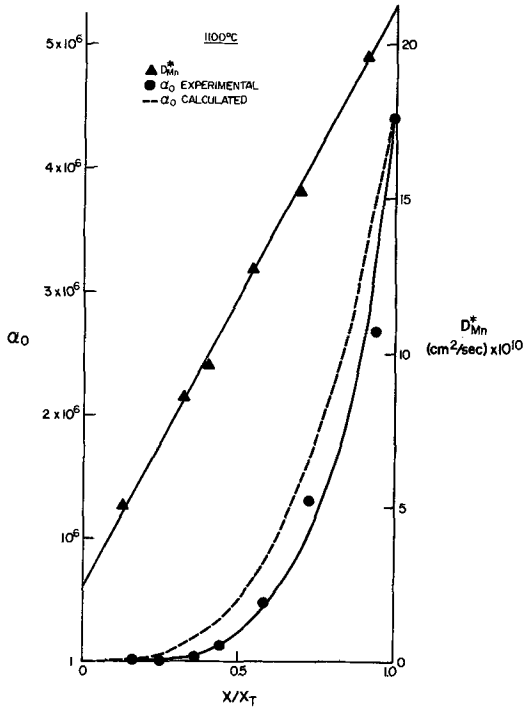

Fig. 9. Oxygen activity and the self-diffusion coefficient of manganese across a layer of MnO formed on manganese by oxidation in a CO-CO_2 mixture with $CO_2/CO = 100$.

$$C_d = C_d^{(o)} a_o^n \qquad [14]$$

then the self-diffusion coefficient can be written as

$$D^*_M = D^{*}_{M}{}^{(o)} a_o^n \qquad [15]$$

where C_d is the concentration of defects in the oxide (*i.e.*, one type of defect mechanism is assumed to predominate; for the oxides under consideration in this paper cation vacancies and electron holes), $C_d^{(o)}$ and $D^{*}_{M}{}^{(o)}$ are the defect concentration and self-diffusion coefficient in an oxide with an oxygen activity of unity and n is a parameter which indicates the degree of association between atomic and electronic defects. In the present discussion n will be assumed to be constant for a given temperature. Substitution of Eq. [15] into Eq. [8], and integration, yields

$$a_o^n = 1 + (a''_o{}^n - 1)x/x_T \qquad [16]$$

If n is known, Eq. [16] may be used to calculate a_o as a function of the normalized reaction coordinate for a given a''_o. The following values of n were used to calculate a_o, 1/2.55 for NiO (4), 1/2.5 for CoO (5), 1/3 for FeO (15), and 1/3 for MnO (13). Calculated and experimental values of a_o across oxide layers on nickel, cobalt, iron, and manganese are compared in Fig. 2, 4, 7, and 9, respectively. Calculated values of a_o for MnO and FeO are slightly larger than experimental values. However, as mentioned previously, Eq. [11] is an approximation for oxides with large homogeneity ranges.

Substitution of Eq. [16] into Eq. [14] and [15] gives the following expressions for the defect concentration and for D^*_M

$$C_d = C_d^{(o)} (1 + (a''_o{}^n - 1)x/x_T) \qquad [17]$$

$$D^*_M = D^{*}_{M}{}^{(o)} (1 + (a''_o{}^n - 1)\, x/x_T) \qquad [18]$$

In Eq. [17] and [18] $C_d^{(o)}$, $D^{*}_{M}{}^{(o)}$, and a''_o are constants and thus C_d and D^*_M should be linear functions of x/x_T. The defect concentration across oxide layers on iron and cobalt are in agreement with Eq. [17]. Furthermore, the self-diffusion coefficients for metal ions across oxide layers on nickel, cobalt, and manga-

nese agree with Eq. [18]. The self-diffusion coefficient of iron across a layer of wüstite on iron was found to be virtually constant in the present study. These results do not agree with Eq. [18] nor with the results obtained by extrapolating the data of Birchenall *et al.* (9) to 1100°C although the value of D^*_{Fe} obtained in the present studies was of the same order of magnitude as the extrapolated values. These results are difficult to explain since atomic disorder in wüstite is complicated (16, 17).

The results obtained for nickel and cobalt show that Eq. [14] and [15] are valid for these systems, and therefore the disorder type in NiO and CoO does not appear to change throughout the oxygen activity range covered by the available data. The results obtained for manganese indicate that these equations are also valid for MnO; however MnO has been found to be an n-type semiconductor at low oxygen activities (7). Even then a metal deficit may be present; however it is also possible that MnO coexisting with the metal contains an excess of the metal. Thus Eq. [14] and [15] cannot be used for MnO because at present there is not sufficient experimental data to present a rational treatment of the oxidation process. Substitution of Eq. [15] into Eq. [12] and integration yields the following expression for the parabolic rate constants of nickel and cobalt

$$k_p = 2\ (M_o/z_o \tilde{V})^2 (D^*_{M^{(o)}}/n)\ (a''^n_o - 1) \qquad [19]$$

If the oxidation rate is expressed in terms of the total oxide thickness (*i.e.*, $x^2_T = 2kt$), then Eq. [19] becomes

$$k = D^*_{M^{(o)}}\ (a''^n_o - 1)/n \qquad [20]$$

For oxygen pressures in the vicinity of 1 atm, $a''^n_o >> 1$ for p-type oxides and Eq. [20] can be written as

$$k/D^*_{M}{}^{(a''_o)} = 1/n \qquad [21]$$

Equations [19], [20], and [21] are equivalent to an equation introduced by Mott and Gurney (18) under the assumption that the defect gradient across the oxide layer was linear. Carter and Richardson (14) have suggested that the Mott and Gurney equation is not valid for the oxidation of cobalt because experimentally determined k/D^*_{Co} ratios did not agree with the theoretical k/D^*_{Co} ratio of 3 which they obtained from the Mott and Gurney equation. Equation [21] shows that for $k/D^*_{Co} = 3$, n must equal 1/3. A value of n equal to 1/3 corresponds to the following reaction

$$Co^{++} + 1/2\ O_2 = CoO + V_{Co} + 2\oplus \qquad [22]$$

where V_{Co} indicates a cobalt vacancy. In other words, k/D^*_{Co} equals 3 only when there is no association of cobalt vacancies and electron holes. If some association occurs, n will be greater than 1/3. In the present study at 1150°C, a value of $n = 1/2.5$ for cobaltous oxide gave oxygen activities which were in good agreement with experimental values. For $n = 1/2.5$, Eq. [21] gives $k/D^*_{Co} = 2.5$ which agrees with the experimental value of 2.59 determined by Carter and Richardson at 1148°C.

ABSTRACT

The rate of growth and properties of the first layer of compact γ-Nb_2O_5 to form are important for elucidation of the oxidation reaction for niobium. It was found possible to maintain this oxide in contact with the metal for sufficient time in the temperature range 720°-825°C to make measurements of its growth rate at various oxygen pressures. This layer, which accounts for the major proportion of the oxygen uptake during the time of its formation, was found to grow at a parabolic rate by a process in which the dominant diffusing species is oxygen. The growth rate of this oxide was highly sensitive to the environmental pressure of oxygen; but it was not pervious to molecular oxygen.

The oxidation of niobium has been studied by many workers and the literature was reviewed recently by Seybolt (1). This metal exhibits unusual oxidation features for at each temperature and pressure the oxidation rate is found to follow a complex series of time laws. However, the reaction rate becomes time independent over the temperature range 400°-1200°C at pressures not too far removed from atmospheric. Particularly at lower temperatures the time independent reaction is usually preceded by a short period of approximately parabolic oxidation behavior.

The defect structure of γ-Nb_2O_5, the modification that forms on specimens oxidized below about 830°C (2, 3) is not well known. However, there is agreement on the basis of marker studies (4) that the most mobile ionic species in this oxide is oxygen. Also, the suboxides, NbO_x and NbO_z, and lower oxides, NbO and NbO_2, have been observed at the metal/oxide interface during oxidation (2, 5-7). During oxidation oxygen dissolves in the metal core of specimens. On the basis of microhardness measurements Klopp *et al.* (6) have calculated the diffusion coefficient of oxygen in niobium.

The parabolic oxidation stage before onset of linear kinetics has been shown by Pawel *et al.* (8) to involve the growth of a protective layer of γ-Nb_2O_5 which cracks at some critical thickness. Kofstad and Kjollesdal (9) further define the linear kinetics as representing a rate-determining transport of oxygen ions through an oxide barrier next to the metal having an approximately constant thickness. This type of mechanism for the transition from parabolic to linear reaction kinetics has been given also in the description of the oxidation behavior of tantalum (10).

A most tractable and important part of the oxidation mechanism appears to be the growth of the first γ-Nb_2O_5 layer. This paper describes an investigation into the growth of this layer where experimental conditions have been selected in order that formation of this compact scale would account for over 95% of the total oxygen consumed by a specimen.

Experimental Procedure

Specimens were cut in the form of squares approximately 1.2 cm^2 from sheets 1 mm thick produced by Fansteel. The hardness of the niobium was V.P.N. 150 (50g load) and the grain size approximately 25μ diameter. Oxidation runs were performed in a conventional all-glass vacuum system with a silica reaction tube using commercial oxygen dried over phosphorous pentoxide.

Experimentation showed that surface preparation of the metal was important. The preparation that was least prone to blistering and hence failure of the oxide formed was abrasion up to 600 grade silicon carbide paper. Above 830°C, the γ-αNb_2O_5 transition appeared to disrupt the oxide layer at an early stage of the reaction.

Niobium oxidizes more heavily on the edges of specimens than on the main faces. Hence, except for short oxidation times at low oxygen pressures kinetic data for a specimen as a whole is not meaningful. The technique used was to oxidize specimens for varying periods of time under different conditions. The rate constants of oxidation were then estimated from scale thickness measurements taken by microscopic examination of polished cross-sections of specimens.

Estimates of specimen self heating upon reaction were made by suspending specimens on 5 mil Pt/Pt-Rh thermocouple wires with the thermocouple bead embedded in the specimen suspension hole. Typically, on lowering a specimen into the hot zone of a furnace at 788°C at an oxygen pressure of 40 Torr the specimen temperature rose 50°C above the furnace temperature. The specimen then cooled to a steady value in about 6 min. To minimize such non-isothermal conditions specimens were oxidized attached to a thermocouple connected to a high-speed recorder. By adjusting the specimen position in the furnace hot zone temperature control within ± 5°C was attained on entry and ± 1°C throughout the reaction.

Results

A series of specimens was oxidized for increasing periods of time at 788°C and 750 Torr oxygen to demonstrate that the first layer of oxide to form on a niobium specimen was protective. Scale thickness measurements are presented in Table I. The evaluations of the parabolic oxidation rate constants for growth of the compact scale from results for these exposures were reproducible within 10%. The rate of γ-Nb_2O_5 scale formation was equivalent to 8.4×10^{-6} $(gO)^2$ cm^{-4} min^{-1} which may be compared to the measured rate of oxygen solution into the metal of

$1.4 \times 10^{-9}(gO)^2$ cm^{-4} min^{-1}. Oxidation of the metal was therefore associated predominantly with formation of the oxide scale. As one is restricted to the study of the rate of formation of the first layer of scale, the scale measurement technique is not practical under all oxidation conditions. However, a reasonable range was covered and the values obtained for temperatures in the range 720°-825°C are given in Table II and plotted in Fig. 1.

Oxidized specimens exhibited compact oxide on the main faces surrounded by a frame of cracked oxide. The amount of this edge oxide increased with increasing temperature. In cross-section the black oxide is an almost featureless compact layer, Fig. 2, though at low pressures the oxide/metal interface tended to be irregular and at high temperatures a line of porosity formed beneath the oxide/gas interface, Fig. 3. In polarized light the γ-Nb_2O_5 layer appeared to be composed of columnar grains with the major axis normal to the metal surface, Fig. 4. Scales formed at 760 Torr showed a gradation of color from black at the metal/oxide interface to white at the oxide/gas interface. Scales formed at lower pressures exhibited a greater proportion of dark oxide until at 1 Torr oxygen the scale was completely black. Color gradients evident in polarized light suggested a stoichiometry gradient but this aspect was not pursued when it was found that the ratio of black to white oxide depended on the rate at which a specimen was quenched to room temperature. After etching (11), layers of NbO and NbO_2 could be seen at the metal interface of all the oxidized specimens. These oxides are shown in the taper section of Fig. 5 and their identification was confirmed by x-ray diffraction.

In so far as could be ascertained by light microscopy, the adherent scales were essentially compact. The mechanism of their growth appeared to be consistent with previous findings for predominant diffusion of oxygen. This was evidenced by the sustained appearance of polishing defects from the initial speci-

men preparation on the free oxide surface of specimens oxidized below 800°C. However, a line of pores was observed in the oxide just beneath the oxide/gas interface, Fig. 3, for specimens oxidized above 800°C.

The scales appeared to be impervious to molecular oxygen. As illustrated in Fig. 6, voids were occasionally seen in an otherwise compact scale. Since the metal interface has not receded as far under the void as elsewhere, the void was acting as a barrier to oxygen transport and not as a short circuit for molecular oxygen. To obtain confirmatory evidence, specimens were oxidized in oxygen atmospheres containing an argon mole fraction of 0.74. If molecular oxygen transport through pores in a scale was playing an effective role in the reaction mechanism, the presence of argon would be expected to markedly reduce the magnitude of the reaction kinetics (10). The plots of the results for this experiment shown in Fig. 7 illustrate, however, that argon had little effect on the magnitude of the parabolic reaction rate.

Discussion

Although the oxidation behavior of niobium under all possible conditions of temperature, oxygen pressure, and specimen geometry is most complex, the formation of a compact γ-Nb_2O_5 scale under well-defined conditions at relatively high temperatures may be represented by a parabolic equation. Relatively minor amounts of oxygen were associated with formation of thin layers of NbO and NbO_2 adjacent to the metal surface and oxygen solution in the metal. Since oxygen solution in the metal core obeyed parabolic kinetics, the occurrence of parabolic γ-Nb_2O_5 scale growth demonstrated that one stage of the oxidation reaction before onset of linear kinetics is an example of a multiphase diffusion process.

The evidence from this investigation, with exception of porosity observed in the scales formed at temperatures above 800°C, suggested that oxygen was the migrating species in the scales. The line of porosity in scales near the oxide/gas interface (Fig. 3) perhaps could be interpreted as showing a minor amount of metal migration. This evidence, nevertheless, is ambiguous for the pores encased in the scale could be caused by formation of voids at the metal/oxide interface during the early stages of the reaction by condensation of vacancies and/or local separation of the scale from the metal by plastic deformation. Accordingly, the present findings substantiate previous marker measurements (4) to the effect that oxygen is the major diffusion species.

Since the parabolic rate constants were unusually sensitive for an ionic transport process to the environmental oxygen pressure (Fig. 1), it was necessary to demonstrate that the apparently compact scale was impervious to molecular oxygen. The evidence against such a possibility was twofold. First, voids in an otherwise compact layer (Fig. 6) acted as a barrier to oxygen transport, and not as a short circuit as it would be if the compact scale were porous to molecular oxygen. Second, the presence of an inert gas in the oxidizing atmosphere had little effect on the parabolic rate of scale formation (Fig. 7). Stringer (10) has shown recently that when there is a possibility of molecular oxygen transport through pores greatly reduced oxidation rates can be obtained in such reaction conditions.

Insufficient data are available to attempt an analysis of the parabolic kinetics or the sensitivity of these kinetics to oxygen pressure. If γ-Nb_2O_5 exhibits the same lattice defect structure as α-Nb_2O_5, concentrations of two types of oxygen vacancies in an oxide scale would depend on the levels of oxygen activity. Singly and doubly ionized oxygen vacancies have been shown to predominate in α-Nb_2O_5, at high and low oxygen pressures (12), respectively, but information is not available on their mobilities. The parabolic rate constants at pressures less than 1 Torr oxygen follow a different pressure dependency (Fig. 1). It is feasible accordingly that the complex pressure dependency of the parabolic kinetics is associated with the concentrations and mobility properties of two types of oxygen vacancies in the oxide scale at different oxygen pressures. Experimental work is being carried out in an attempt to elucidate these features.

Acknowledgments

This contribution is based on a thesis submitted by J. S. Sheasby to the School of Graduate Studies, University of New South Wales in partial fulfillment of the requirements for the Ph.D. degree. He wishes to acknowledge financial assistance from the Australian Government. The studies completed at McMaster University were carried out under the auspices of the U.S. Air Force Office of Scientific Research, Office of Aerospace Research. The authors were indebted to A. E. Jenkins, University of New South Wales, and J. Stringer, Battelle Memorial Institute, for helpful discussions.

Correlation Between Ellipsometric and Electrical Measurements on Passive Iron

ABSTRACT

Optical measurements of surface layers on passive iron electrodes are compared with electrical measurements of capacitance and other overpotential parameters. Results of these studies show that the surface layer on the electrode may be regarded as consisting of more than one part. Specifically, in neutral electrolyte there is a thin conducting layer of constant thickness present on the surface in addition to an electrically limiting layer of variable thickness, while in acid electrolyte there is a layer located outside the electrically limiting layer which grows at a constant rate to large thickness. This thick layer can be removed by holding the electrode at a potential slightly below the passive region. Changes in thickness of the electrically limiting layer, determined optically, are consistent with a field dependent conduction mechanism.

Many experimental investigations of passivity have employed electrical and electrochemical methods to determine the state of a passive electrode. The properties of the passive electrode, such as layer thickness, are then deduced from these measurements (1). These indirect determinations inevitably depend on a number of assumptions concerning the state of the electrode, such as the roughness of the surface, the potential profile between the electrode and the electrolyte, the position of the current limiting barrier, etc. Also, only the simplest measurements can be performed without disturbing the system in some manner.

Optical measurements (2, 3) avoid most of these difficulties, since one can use an ellipsometer to measure the thickness of a film without altering the system being studied. Even though the interpretation of optical measurements may involve certain assumptions about the system, these assumptions will be independent of those made for the electrical measurements. If both methods yield results which agree, this lends credence to the assumptions.

Experimental studies of passive iron electrodes (4-7) indicate that the thickness of the passive layer, obtained from the interpretation of electrochemical measurements, increases linearly with the passivating potential when the current density is held constant. The present work has been undertaken in order to determine whether this relationship could be verified by ellipsometric measurements. This work was further motivated by the observation that a passive iron electrode held at constant potential in acid electrolyte slowly changes its capacitance with time, although the current density remains constant.

Experimental

Electrodes were prepared from single crystals of iron obtained from Research Crystals Inc. of Richmond, Virginia. The crystal was first turned to a diameter of 0.2 in. and cut to a length of 0.3 in., and then a small hole was drilled along the axis for the mounting assembly. The surface on which the optical measurements were made was prepared by grinding a flat surface of about 0.08 x 0.3 in. on the side of the cylinder, followed by hand lapping of this surface on a tungsten carbide plate. The electrode was then clamped between Teflon washers in the electrode assembly (8), given a brief chemical polish, x-rayed to check the orientation, and finally reduced in neutral electrolyte to remove any film left by the chemical polish. The orientation of the surface on which the data presented in this work were obtained was 8° off a (110) plane.

The cell in which the experiments were performed consists of an equilateral hollow prism. A platinum cathode is mounted permanently in the cell, and standard taper joints are used to mount the electrode assembly, the reference electrode, and a gas dispersion tube. The surface of the sample under study was mounted vertically in this cell.

The electrical equipment and circuitry are similar to those used in an earlier work (7). A mercurous sulphate electrode with a 0.1*N* K_2SO_4 salt bridge is used as a reference electrode, and all potentials are given with respect to this reference. The two electrolytes used in this work were (*i*) an equivolume mixture of 0.15*N* sodium borate and 0.15*N* boric acid, of *p*H 8.4 and (*ii*) 1.0*N* sulphuric acid. These electrolytes have been used in several studies of the passivity of iron (5, 7, 10). Electrolytes were bubbled with argon for at least 12 hr prior to the beginning of an experiment in order to free the system of dissolved gases. This bubbling was continued throughout the course of an experiment.

The ellipsometer used was a Gaertner Model L119, in which light passes through the compensator before reflection. Monochromatic light of wavelength 5461Å was used throughout the experiments. All measurements were made by holding the compensator fixed at an angle of 45° with respect to the plane of incidence and varying the polarizer and analyzer orientations alternately until a null was found. Iris diaphrams of about 1 mm in diameter were placed adjacent to the cell immediately before and after reflection, so that the optical measurements were made on a portion of the surface of about 1 mm in diameter. The angle of incidence for all results contained herein was 60°. A computer program written by McCrackin and Colson (9) was used in the calculations of the theoretical curves needed in order to estimate the thickness and refractive index of the thin films from the polarizer and analyzer readings.

Results

The first measurements were performed on an iron electrode in the neutral borate buffer electrolyte. The electrode was first reduced cathodically and then

transferred to the optical cell. The initial optical measurement on the surface agreed closely with the measurement made when the electrode was reduced cathodically in the optical cell at the end of the experiment. This optical measurement is assumed to be characteristic of a bare iron surface. A constant oxidation current was then applied to the system and was interrupted at regular intervals for short periods of time (60-80 sec), during which the null settings of the polarizer and analyzer were determined.[2] The open circuit transients were recorded and analyzed to determine the values of the parameters V_0 and i_0 appearing in the expression relating the current density, i, to the overpotential, V

$$i = i_0 \exp (V/V_0) \qquad [1]$$

The analysis of the transient also yields a value for the capacitance of the electrode.

The results of this experiment for an oxidation current density of 5 $\mu a/cm^2$ are plotted in Fig. 1 and 2. Figure 1 shows the analyzer setting at null, A, and the corresponding polarizer setting, P, for each open circuit transient. These parameters are chosen to represent the optical data since they are the numbers read directly from the instrument for the zone used for most measurements (11). A theoretical curve for a layer of index 2.6-0.4i on a substrate of index 3.50-3.66i, which fits the experimental points well, is shown in the figure. (Points on the curve corresponding to 20 and 40Å are marked.) Other curves corresponding to slightly different values of the layer index can be found which fit the experimental data almost as well, and this introduces an uncertainty of about 20% in the determination of the absolute thickness of the layer. The relative layer thickness, however, varies almost linearly with the polarizer setting for all such curves, thus ΔP is a good measure of relative thickness.

In Fig. 2, ΔP, V_0, and $1/C$ are shown as functions of the passivating potential (the potential on the oxidation transient at which the circuit is opened). One can see by examining this figure that V_0 and $1/C$, which are presumed directly proportional to the thickness of the electrically limiting layer, and ΔP, the change in the polarizer setting from that of a film-free electrode, all vary linearly with passivating potential. However if these parameters are extrapolated to their respective zeros, V_0 and $1/C$ are found to intersect the potential axis at the same point while ΔP still indicates the presence of a layer. Thus the electrically limiting layer is not the only layer present on the surface.

A similar experiment in acid electrolyte is complicated by the dissolution of the layer into the electrolyte and by the high current density required to passivate the electrode. The electrode geometry in the optical cell is not suitable for passivation at high current density, hence the electrode is passivated in another cell and transferred to the optical cell while passive. This technique is also used with neutral electrolyte when active state reaction products are to be excluded from the cell, as it is not convenient to exchange the electrolyte in the optical cell during an experiment.

The simplest optical measurements which can be performed in acid electrolyte are those made on an electrode in the so-called "steady state." To reach this state the potential is held constant until the current shows no further time dependence. Usually an hour is sufficient to reach this state after the potential has been raised by a 0.1v increment, and a somewhat longer time is required when the potential is lowered by the same amount.

In the first experiment attempted in acid electrolyte, the electrode was passivated and allowed to reach a steady state at a low potential in the passive region. The P and A values were then determined, and a 20-sec open circuit transient was recorded to determine the values of the electrical parameters. The potential was then raised by 0.1v increments and the measurements were repeated after the electrode reached a steady state. The values for the electrical parameters obtained from this experiment differ little from those reported in an earlier work (7), but the optical results show little regularity and are not reproducible, *i.e.*, the P and A values at null do not return to their initial values when the electrode is returned to a steady state at the initial potential.

A very simple experiment shows the reason for this behavior. If the electrode is held in a steady state at a fixed potential, and both optical measurements and open circuit transients are repeated at regular intervals for several days, then results such as those shown in Fig. 3 and 4 are obtained. Figure 3 shows the optical data alone. The curve in Fig. 3 is a theoretical curve for a layer of index 1.65-0.4i on a substrate of index 3.50-3.66i. (Actually a layer of thickness 35Å and index 2.6-0.4i, the passive layer found in neutral electrolyte, is assumed to lie between the 1.65-0.4i index layer and the substrate, but this assumption shifts the curve only slightly.) This value of index is chosen since it gives a theoretical curve which fits the experimental data well, except at high thickness, and it is needed in order to estimate the magnitude of the thick-

[2] Subsequent measurements with a following ellipsometer show that the null settings do not change appreciably over a brief open circuit transient.

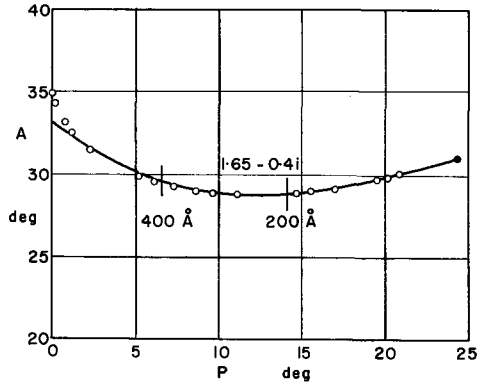

Fig. 3. *A vs. P* for an iron electrode in a "steady state" at 0.7v in 1*N* H_2SO_4. The curve is a theoretical curve for a layer of index 1.65-0.4*i* with the 200 and 400Å points indicated.

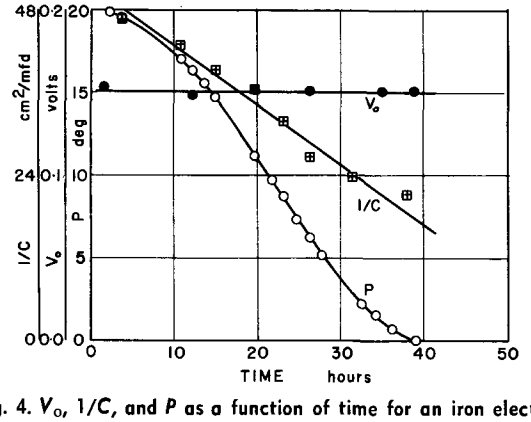

Fig. 4. V_o, 1/*C*, and *P* as a function of time for an iron electrode in a "steady state" at 0.7v in 1*N* H_2SO_4.

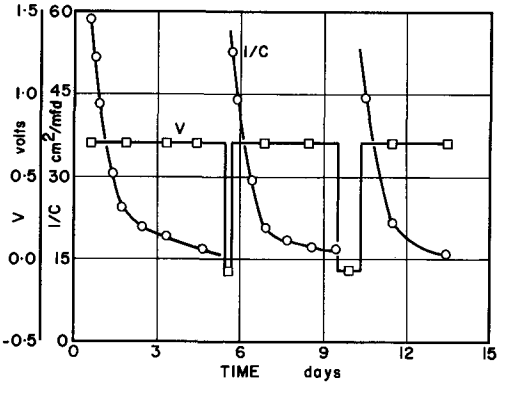

Fig. 6. 1/*C* as a function of time for an iron electrode in 1*N* H_2SO_4 cycled between the potentials shown in the figure.

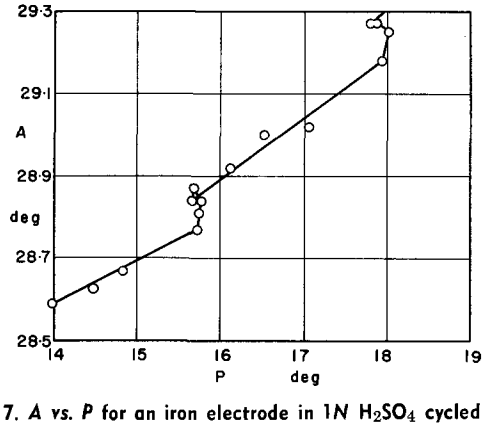

Fig. 7. *A vs. P* for an iron electrode in 1*N* H_2SO_4 cycled between 0.2 and 0.7v at the times indicated in Fig. 8.

ness involved. The correlation between the thickness of the film and the electrical parameters of the system is shown in Fig. 4, in which *P*, V_o, and 1/*C* are plotted as functions of time (again *P* is chosen to represent thickness). This figure shows that V_o has no appreciable time dependence, but 1/*C* has a time dependence similar to that of *P*.

These figures show that a relatively thick film builds up on the electrode with time. The buildup of this film has little or no effect on the steady state current density and V_o, although it does affect 1/*C*. This effect on capacitance is not caused by the concentration of reaction products in the electrolyte, since a complete change of electrolyte has no effect on the dependence of capacitance on time.

This thick layer can be removed from the electrode in a few hours by lowering the potential to a point at which the current density in the steady state is an order of magnitude higher than it is in the passive region. The results obtained by doing this are shown in Fig. 5. Note that the optical changes lag behind the change in current density, and that several hours are required after the current becomes constant before the layer is completely removed. During the layer removal, the *P* and *A* values do not retrace the locus shown in Fig. 3. Hence the layer removal process does not proceed by uniform thinning. Figure 6 shows the effect on 1/*C* of a number of cycles of buildup and removal of the layer.

Since the layer which builds up approximately linearly with time does not affect the current density or V_o, it is not the electrically limiting layer. In order to detect the electrically limiting layer optically the potential is switched back and forth between 0.2 and 0.7v at regular time intervals. The results of this experiment are plotted in Fig. 7 and 8. (Note that the scales used for *P* and *A* are greatly expanded over the scales used in Fig. 3. The experimental accuracy required to detect changes in the thickness of the electrically limiting layer and the extent of scatter in the results both show up clearly in this figure.)

Figure 7 shows the optical data alone. A *P-A* locus is obtained whose structure cannot be produced by changes in thickness of a single layer with a constant refractive index. Figure 8 gives the times and potentials at which measurements were made. Reference to Fig. 3 gives the amount that the outer layer was allowed to grow before the switching was started.

Discussion

The optical results in neutral electrolyte show that a dielectric layer with thickness up to 40Å is present

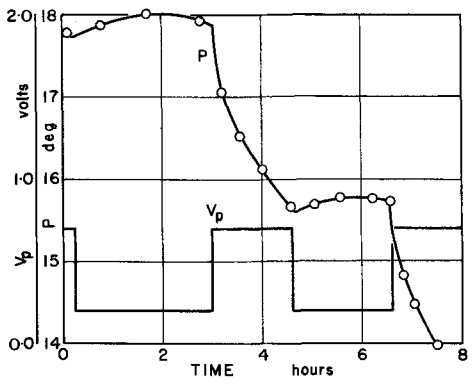

Fig. 8. P vs. time for an iron electrode in 1N H_2SO_4 cycled between the potentials shown in the figure.

on the surface of the electrode. Nagayama and Cohen (10) deduced this result earlier using cathodic reduction measurements. Recently Kruger and Calvert (12) obtained similar optical results in this system. The electrical measurements in neutral electrolyte are in agreement with those presented in an earlier paper (7) in which it is concluded that V_0 is proportional to the thickness of the electrically limiting layer, and the reciprocal capacitance is a linear function of layer thickness, provided a parallel plate model is valid and the roughness factor remains constant.

The V_0 and $1/C$ data plotted in Fig. 2 show that the electrically limiting layer changes in thickness by a factor of five across the passive region. The optical data show that over this region the total thickness of the dielectric layer on the surface changes by a factor of slightly more than two. Therefore the electrically limiting layer does not make up the total thickness of the dielectric layer. If the change in thickness of the dielectric layer in the passive region is attributed to a change in the thickness of the electrically limiting layer only, a two-layer model results with a 15Å conducting layer in series with an electrically limiting layer of variable thickness up to about 25Å. Two-layer models have been proposed by other workers (10) for this system. Extremely accurate measurements would be required to determine whether the two layers have different indices of refraction.

The results in acid electrolyte show that the steady state is not truly steady, although V_0 and the current density are independent of time. A layer builds up on the surface at an approximately constant rate for several days. The only electrical parameter which changes as this layer builds is the capacitance. To interpret this behavior we choose a model in which the electrode surface is covered by a thin electrically limiting layer which is in turn covered by a layer which builds up with time to a considerable thickness.

The effect of several cycles of buildup and removal of the outer layer on capacitance is shown in Fig. 6. The fact that the capacitance values follow this cycling shows that the changes in the capacitance are not due to changes in the roughness factor. This conclusion is also supported by the fact that the current (which is also area dependent) does not follow the capacitance variations. The cycling experiment also changes the thickness of the electrically limiting layer, hence it is not possible to conclude whether the changes in the capacitance of the passive layer are due to the buildup of the outer layer, or to some change in the structure of the electrically limiting layer with time.

The optical detection of changes in the thickness of the electrically limiting layer is complicated by the continuous buildup of the thick outer layer. Direct analysis of the optical data for thickness and refractive index is difficult. We will attempt to show only that the optical data are consistent with the electrochemical mechanism proposed for thickness changes of the passive layer (4, 6).

It is usually assumed that the steady-state current density gives a measure of the oxidation current required to balance the dissolution of the passive layer. It is assumed further, but not without reservation (13), that the dissolution rate is the same when the thickness of the layer is varying as it is when the thickness is held constant in the steady state. The current density through the layer depends exponentially on the field within the layer. The rate of change of thickness of the layer is proportional to the difference between the instantaneous field-limited current density and the steady-state current density. The thickness changes which result when the potential is switched back and forth between 0.2 and 0.7v at intervals of a few hours can be predicted from this mechanism. When the potential is raised, the exponential field dependence causes the current density to increase greatly, and produces a relatively rapid buildup of the layer until the field falls to a value at which the oxidation current balances the layer dissolution. When the potential is lowered, the exponential field dependence lowers the current density by a smaller amount, hence the layer thickness decreases relatively slowly.

The data presented in Fig. 7 and 8 are consistent with all of these predictions. Changes in the thickness of a layer of constant refractive index would generate a smooth P-A locus. The expanded scale used in Fig. 7 shows the P-A locus to have a structure which is shown in Fig. 8 to correlate with the potential switching. Hence layers of differing refractive indices must be present on the surface and undergo simultaneous changes in thickness after the potential is switched. In the proposed model the passive layer has an index of 2.6-0.4i whereas the outer layer has an index of 1.65-0.4i, and the thickness of both layers will be changing after a switch in the potential.

The variation of P with time during growth of the outer layer at fixed potential is shown in Fig. 4 (P decreases as the thickness increases). Figure 8 shows what happens to a segment of Fig. 4 when the potential is switched back and forth. When the potential is switched down, P first increases, then begins to decrease. (If the lower potential is maintained long enough P will eventually decrease at the rate shown in Fig. 4.) This result is consistent with a decrease in the thickness of the passive layer (at a time-dependent rate) opposing the steady increase in the thickness of the outer layer. When the potential is switched up, P decreases very rapidly at first, but eventually decreases at the rate shown in Fig. 4. This result is consistent with an increase in the thickness of both the passive layer (at a time-varying rate) and the outer layer. The magnitude of the change in P attributed to the change in thickness of the passive layer is similar to that measured in neutral electrolyte for the same change in potential.

Environmental Factors Affecting the Critical Potential for Pitting in 18-8 Stainless Steel

H. P. Leckie and H. H. Uhlig

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The concept of a critical potential below which pitting of 18-8 and other passive alloys does not occur in aqueous Cl^- media is affirmed. Increasing Cl^- concentration shifts the critical potential to more active values. The potential is shifted to more noble values by presence of other anions, *e.g.*, ClO_4^-, SO_4^{--}, NO_3^-, OH^-, sufficient concentrations of which act as pitting inhibitors. Lowering of temperature similarly enobles the critical potential. The shift at 0°C exceeds the oxidation-reduction potential for $Fe^{++} \rightarrow Fe^{+++} + e$ accounting for resistance of 18-8 to pitting in $FeCl_3$ solutions at ice temperature but not at room temperature. The critical potential is not affected appreciably in the acid *p*H range; it moves markedly in the noble direction in the alkaline range corresponding to observed resistance to pitting in alkaline Cl^- media. These results are interpreted in terms of competitive adsorption of Cl^- and other anions for sites on the alloy surface. Only at a sufficiently high surface concentration of Cl^- is oxygen, making up the passive film, displaced locally, and passivity thereby destroyed resulting in a pit. The special behavior of NO_3^- inhibition and factors affecting reproducibility of measurements are discussed.

The tendency for 18-8 and other stainless steels to corrode locally by pitting when immersed in chloride solutions including sea water was recognized soon after stainless steels became available. Early investigations showed that pitting corrosion is an electrochemical process in which the pit acts as a fixed anode and the remainder of the passive surface is cathode (1). Early measurements also showed a so-called "break through" or "critical" potential at which pitting initiates. Recent measurements of such critical potentials for stainless steels are reported by Rosenfeld and Maximtschuk (2), Rocha (3), Brauns and Schwenk (4), Defranoux (5), Pourbaix *et al.* (6), Herbsleb (7), Tomashov *et al.* (8), and by Fokin *et al.* (9). An excellent review of the subject has been published by Kolotyrkin (10).

It was not clear, however, from early short-time laboratory investigations whether pitting in any degree would occur below the so-called critical potential, or whether pitting was only delayed in time. Discussions on this matter continue to the present day. Perhaps the first satisfactory demonstration that pitting can be permanently suppressed came from an experiment in which 18-8 stainless steel was immersed at room temperature in 10% $FeCl_3$ inhibited with 3% $NaNO_3$. No pitting or appreciable weight loss of duplicate specimens occurred over a period of 25 years (1, 11). A similar specimen immersed in 10% $FeCl_3$ without NO_3^- addition was riddled with pits within a few hours. Uhlig and Gilman (11) explained the observed inhibition in terms of a supposed shift of the critical potential for pitting, brought about by nitrate addition, to a value more noble than the oxidation-reduction potential of ferric chloride. This explanation is confirmed by results reported in this paper.

Actually, the satisfactory inhibition of pitting by polarizing a passive metal to a potential below (more active than) its critical value has been practiced for many years, even though the corresponding explanation was not understood. For example, cathodic protection of stainless steels against pittting in sea water by attaching an equal or greater area of iron has been used with success over a period of years (12). Similarly aluminum in practice has been cathodically protected against pitting by coupling it to a galvanically more active metal like zinc (13). The iron in galvanic contact with stainless steel polarizes it below the critical potential of the latter (approximately 0.2v, hydrogen scale in 3% NaCl). Iron cannot, in any case, polarize 18-8 to its open circuit anode potential, as is required for the cathodic protection of nonpassive metals, since the anode potentials of the two metals are nearly the same. Iron by the same token is not suited to protecting aluminum because its approximate corrosion potential in 3% NaCl (—0.4v) is more noble than the critical potential of aluminum (—0.48v) (14); the corresponding more favorable corrosion potential of zinc, on the other hand, is —0.8v. Obviously zinc does not and cannot polarize aluminum to its very active anode potential in the order of —1.7v; it is only required that aluminum be polarized to a value more active than its critical potential. Protection of any passive metal against pitting continues as long as all portions of the metal surface are adequately polarized to a value below (more active than) its critical potential in the given environment.

The importance of the critical potential both to an understanding of the pitting mechanism and to practical applications, as mentioned above, suggests the value of a systematic study of critical potentials for 18-8 stainless steels focussed first on environmental factors, and second on metallurgical factors. Environmental factors make up the subject of the present paper.

Experimental

Stainless steel electrodes (17.7% Cr, 8.7% Ni) were prepared as cylinders measuring 4 mm diameter and 1.4-2 cm long. The original cast type 304 rod was homogenized in vacuum at 1050°C for 20 hr and water quenched; it was then swaged to diameter, annealed at 1050°C for 1 hr, and again water quenched. The elec-

trode was drilled and tapped allowing attachment to a threaded small diameter Ni wire. The nickel wire was enclosed within a glass tube and a water-tight seal was maintained by means of a Teflon gasket between glass and electrode held in constant contact by a rubber grommet and nut attached to the nickel wire at the other end. Specimens were polished to 3/0 emery paper followed by pickling in a solution containing 15% HNO_3, 2% HF by volume at 60°C for 5 min. The latter treatment produced a smooth shiny surface.

The all-glass cell used for polarization studies incorporated the following features: (*i*) provision for a centrally located anode surrounded by four equispaced platinum cathodes, (*ii*) inlet for gas agitation and deaeration, and (*iii*) a further inlet to permit a Luggin capillary from a saturated calomel reference electrode to reach near the anode surface.

All electrolytes were deaerated for one or more hours using prepurified nitrogen which was further purified before entering the cell by passing it over copper turnings at 400°C. The cell was placed in a large constant temperature cabinet maintained by heating or refrigeration to 25° ± 0.2°C. This cabinet also permitted tests to be carried out between temperature limits of —1° and 50°C. At the latter temperature, the limits of control were ±1°C.

Reproducible measurements demanded a crevice-free mounting and a homogeneous alloy surface. Either crevices or concentration gradients at some portion of the electrode surface, *e.g.*, caused by carbide precipitation, tend to lower the critical potential in chloride solutions, causing scatter of results. Deaeration of electrolyte as practiced in the present measurements helped avoid crevice corrosion if there was any tendency in this direction.

For polarization measurements, a Wenking potentiostat was employed in conjunction with a chart recorder capable of measuring current to 0.1 μamp. A potentiostatic step-by-step polarization technique was followed, in most cases allowing a period of 5 min to elapse at each 50 mv potential increment before recording the current. In neutral halide solutions, where the critical and passive current densities are not large, the electrode was first held at a potential in the passive region for a period of 15 min before further polarizing in the noble direction. In this way a more nearly steady-state condition was achieved. Where no passive breakdown (pitting) occurred, polarization was continued in most instances to 1.2v (H_2 scale), a value approaching or being within the transpassive region. To obtain more exact values of the critical potential, the step-by-step technique was often supplemented by current-time curves at a constant potential maintained close to the approximate critical value. The final breakdown potential called V_c was taken as the most active (least noble) value for which no continued increase of current with time (corresponding to pitting) was observed over a period of about 24 hr. Reproducibility of critical potentials obtained in this manner was within ±5 mv. Because such measurements were unduly time-consuming, much of the data was obtained with no more than 5 min intervals between shifts of potential. Critical potentials of this kind are labeled V'_c, values of which in 1*N* NaCl, for example, are found to be about 0.09v more noble than values of V_c (Fig. 1). This difference represents the probable order of magnitude between all the short-time and steady-state critical potentials presently reported. Incidence of pitting by current-time curves was confirmed by examination of the electrode under a low power microscope.

Results and Discussion

The potentiostatic anodic polarization curves (5 min each point) of 18-8 stainless steel in deaerated 0.1*N* NaCl and 1*M* H_2SO_4 are shown in Fig. 2. In H_2SO_4 no pitting occurs; the increase of current above about 1.0v in the transpassive region corresponds to uniform corrosion with CrO_4^{--} formation, whereas in the passive region Cr^{+++} forms instead (plus Fe and Ni corrosion products). In 0.1*N* NaCl, on the other hand, the current increases at the critical potential V'_c equal to 0.36v, denoting the onset of visible pitting. The upward sweep of potential at higher current densities is related to polarization effects at anodic regions constituting the pits. Corrosion products within the pits, the inner surface of which is in the active state, are mostly Fe^{++} combined with Ni^{++} and probably Cr^{+++}. The critical potential observed in Fig. 2 is unaffected by

aeration of the electrolyte provided crevice corrosion is avoided.

The effect of temperature of 0.1*N* NaCl on V'_c for 18-8 within the range —1.0° to 50°C is shown in Fig. 3. The critical potential does not change sensitively above room temperature, but there is a remarkable shift of potential in the noble direction below room temperature. At 0°C, V'_c is more noble than the oxidation-reduction potential for $Fe^{++} \rightarrow Fe^{+++} + e$. From this behavior it could be predicted that 18-8 would be appreciably more resistant to pitting at low compared to room temperatures. This prediction was confirmed in preliminary experiments in which 18-8 sheet specimens immersed in 0.5*M* $FeCl_3$, 0.5*M* NaCl solution at 0°C clearly showed no pitting, weight loss, or visible reduction of $FeCl_3$ after 24-hr immersion, whereas control specimens at 25°C were badly pitted and the brown-yellow $FeCl_3$ solution had reduced to green $FeCl_2$. In another experiment lasting two weeks, with some variation of temperature in the neighborhood of 0°C, specimens of 18-8 similarly did not show pitting nor did the $FeCl_3$ solution undergo reduction.

The critical potential is not greatly affected in acid 0.1*N* NaCl ranging in pH from 1 to 7 (adjusted by HCl additions) as shown in Fig. 4. In alkaline solutions, pH 7-10 (adjusted by NaOH additions), however, the critical potential becomes much more noble corresponding to increased resistance to pitting. Brauns and Schwenk (4) reported a similar shift of potential in the noble direction on addition of 0.5*N* NaOH to 1*N* NaCl. It has been known for some time that NaOH (15) or Na_2CO_3 (16) additions to NaCl effectively inhibit pitting of stainless steels. Furthermore, Uhlig and Morrill (17) showed that pitting of 18-8 in 4% NaCl at 90°C decreases markedly as the pH is increased above 7. Rocha (3) presented data at 50°C showing only small effect of pH on critical potentials in the acid range of pH, similar to data of Fig. 4.

Above pH 10, Fig. 4 shows that the apparent value of V'_c decreases with pH. However, the increases of current observed at corresponding values of potential do not correspond to pitting but to attainment instead of the transpassive state with formation of CrO_4^{--}. This shift is in accord with the analogous anodic reaction for pure Cr

$$Cr + 4H_2O \rightarrow CrO_4^{--} + 8H^+ + 6e$$

the potential for which also moves in the active direction as (H^+) decreases or pH increases. The calculated slope of potential *vs.* pH, according to the above reaction, is —0.08 v/pH unit which is in reasonable agreement with the corresponding observed slope of Fig. 4 equal to —0.09 v/pH unit.

The comparatively small shift of V'_c in the acid region was confirmed by determining values in 0.25, 0.5, and 1*N* HCl. Potentiostatic curves showed that, within the limitations of the few experimental points that were obtained, the critical value V'_c shifts in the active direction a maximum of only about 0.05v which is probably accounted for mostly by increasing Cl^- activity rather than by change of H^+ activity. It is of interest that characteristics of passivity can be maintained in an acid so strong as 1*N* HCl, although the passive and critical current densities are higher than for neutral chloride solutions by orders of magnitude.

The effect of increasing Cl^- concentration in neutral NaCl solution is to shift V_c in the active direction by about 0.09v for a 10-fold change in concentration. This compares with a 0.13v shift for Al found by Kaesche (14). Data are given in Fig. 5 for steady-state conditions, each point representing the final value derived from numerous potentiostatic polarization measurements at potentials near V_c extending over hours. Note that these values are somewhat more active than corresponding values of V'_c cited previously. Values of V_c in volts are linear with logarithm of Cl^- activity, following the equation

$$V_c = -0.088 \log(Cl^-) + 0.168$$

Rosenfeld *et al.* (2) and Kolotyrkin *et al.* (18) reported that various anions when added to chloride solutions shift the critical potential to more noble values, accounting for an increased resistance to pitting. Pourbaix *et al.* (6) noted a similar shift of potential on adding HCO_3^- to NaCl solutions, and Brauns and Schwenk (4) reported analogous behavior for OH^- or SO_4^{--} additions. This effect can be noted in the potentiostatic curves of Fig. 6 for 18-8, showing that V'_c in 0.1*N* NaCl moves to more noble values with increasing Na_2SO_4 concentration. At and above 0.15*M* Na_2SO_4 no pitting occurs at all, the observed current increase being characteristic of transpassivity in absence of Cl^-. In other words, sufficient SO_4^{--} added to a Cl^- solution inhibits pitting of 18-8. Other anions also act as inhibitors, the amount necessary for complete inhibition varying with the anion. In all cases, the greater the Cl^- concentration, the greater is the required amount of inhibiting anion. Based on potentiostatic measurements extending over hours, it was found that the logarithm of the minimum amount of anion for inhibition expressed in terms of anion activity, is linear with the logarithm of the corresponding Cl^- activity. This relation for inhibition by SO_4^{--}

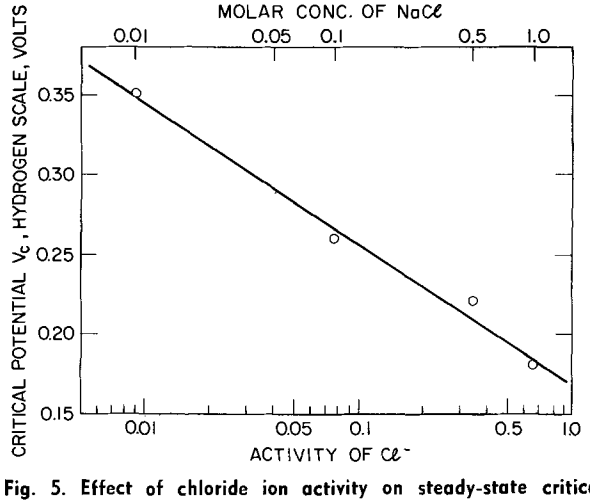

Fig. 5. Effect of chloride ion activity on steady-state critical potential for pitting, 25°C.

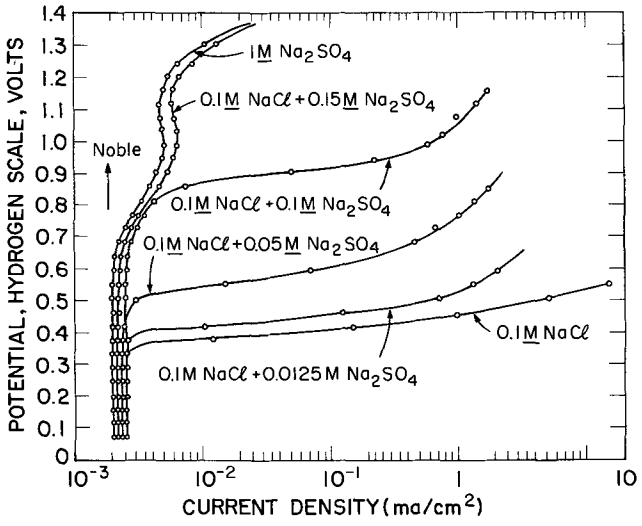

Fig. 6. Potentiostatic polarization curves in 0.1M NaCl showing increasingly noble values of the critical potential with additions of Na_2SO_4, 25°C.

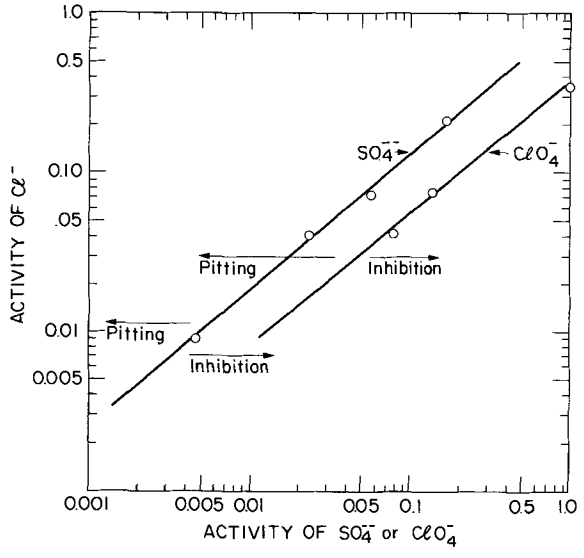

Fig. 7. Activity of SO_4^{--} or ClO_4^- required to inhibit pitting as a function of Cl^- activity, 25°C.

and by ClO_4^- is shown in Fig. 7. Similar data for OH^- and NO_3^- inhibition are shown in Fig. 8. The corresponding equations expressing minimum anion activity necessary to inhibit pitting of 18-8 in a solution of given Cl^- activity are as follows

$$\log (Cl^-) = 1.62 \log (OH^-) + 1.84$$
$$= 1.88 \log (NO_3^-) + 1.18$$
$$= 0.85 \log (SO_4^{--}) - 0.05$$
$$= 0.83 \log (ClO_4^-) - 0.44$$

These equations express the fact that efficiency of inhibition for $(Cl^-) > 0.1$ decreases in the order: $OH^- > NO_3^- > SO_4^{--} > ClO_4^-$. In solutions of unit activity Cl^-, for example, corresponding to 1.5*N* NaCl, values for the activity of OH^-, NO_3^-, SO_4^{--}, and ClO_4^- required for inhibition are respectively 0.07, 0.24, 1.15, and 3.4.

Uhlig and Gilman (11) found a comparable equation to hold: $\log (Cl^-) = 1.92 \log (NO_3^-) + 1.34$ expressing the activity of NO_3^- necessary to inhibit pitting of 18-8 in $FeCl_3$ solutions of given Cl^- activity. This equation agrees reasonably well with the present equation obtained potentiostatically in NaCl-$NaNO_3$

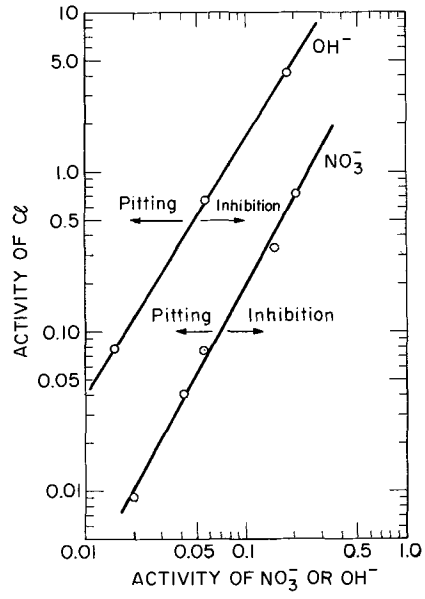

Fig. 8. Activity of OH^- or NO_3^- required to inhibit pitting as a function of Cl^- activity, 25°C.

mixtures, especially considering the fact that activity coefficients of $FeCl_3$ solutions required estimation from values for $LaCl_3$ solutions.

Figure 8 shows that in 0.1*N* NaCl, corresponding to an activity of Cl^- = 0.078, the required activity of OH^- for inhibition = 0.015, corresponding to *p*H 12.2. This value is consistent with the critical *p*H shown in Fig. 4 for inhibition of pitting in 0.1*N* NaCl up to potentials corresponding to onset of transpassivity remembering that steady-state values V_c are approximately 0.09v more active. In other words, corrected potentiokinetic values of Fig. 4 shift the curve down and to the right, which then places the critical potential at a *p*H of 11 or 12, above which the alloy does not pit if polarized to approximately 1v.

The potentiostatic curves for 18-8 in Cl^- solutions to which the other anions cited above are added, resemble those shown in Fig. 6 for SO_4^{--} additions, with the exception of NO_3^-. For nitrate additions, the critical potential for pitting is shifted in the noble direction, but further polarization of the alloy in a given ratio NO_3^-/Cl^- electrolyte may inhibit pitting again. This behavior was first pointed out by Brauns and Schwenk (4) and is shown in Fig. 9. It is reason-

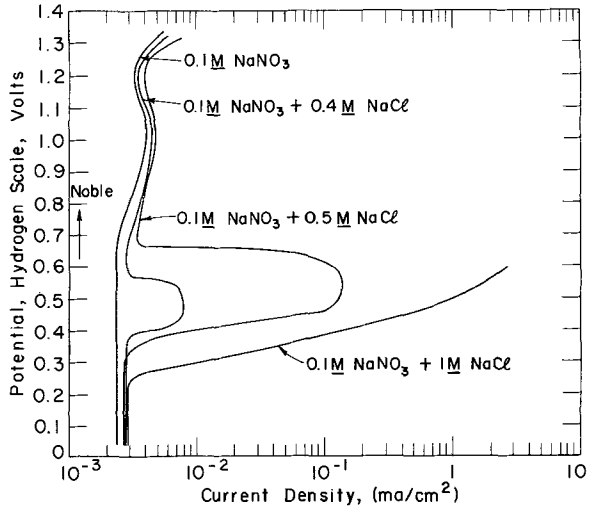

Fig. 9. Potentiostatic polarization curves in 0.1*N* $NaNO_3$ containing increasing amounts of NaCl, 25°C.

ably explained by the reduction of nitrates by Fe^{++} produced as an anodic corrosion product of 18-8 both generally and within pits in the less noble portion of the passive region. On exceeding the oxidation-reduction potential for $Fe^{++} \rightarrow Fe^{+++} + e^-$ (standard potential = 0.77v), surface concentration of Fe^{+++} then predominates over Fe^{++} concentration, and reduction of NO_3^- is diminished. Hence, at some potential more noble than V'_c, NO_3^- becomes available in greater concentration to inhibit pitting, and previously formed pits may be repassivated provided their geometry and adequate stirring of electrolyte allow sufficient NO_3^- to enter the pit cavities.

Analogous behavior does not occur with the other anions that were investigated because they are not readily reduced by Fe^{++}. The inhibiting concentrations of NO_3^- shown in Fig. 8 are those which produced no breakdown in any portion of the passive region, allowing 5 min at each potential, the electrolyte behaving essentially as do solutions of $NaNO_3$ free of Cl^-. Brauns and Schwenk (4) reported, as we do, that OH^- and SO_4^{--} additions enoble values of V_c, but they found that NO_3^- additions, contrary to our results, do not affect the critical potential. It is likely that their observation is explained by the appreciable reduction of NO_3^- by Fe^{++} accruing during prolonged anodic polarization below the $Fe^{++} \rightarrow Fe^{+++} + e$ potential. At faster rates of potential change, as in our measurements, NO_3^- does not have time to reduce, and V_c therefore moves toward more noble values with increasing NO_3^- concentrations, similar to the shift which occurs with SO_4^{--} or OH^- additions. In agreement, Herbsleb (7) showed through potentiokinetic measurements of 18-8 that a critical potential V_c in 1M NaCl + 0.5M $NaNO_3$ solution, which we find according to Fig. 8 to be in the inhibiting range, is observed only at slow (0.2 v/hr) but not at fast (2 v/hr) rates of potential change. It is expected that rate of stirring also enters such observations, fast rates tending to dilute surface concentration of Fe^{++} and thereby decreasing the rate of NO_3^- reduction.

Theory of the critical potential.—Hoar, Mears, and Rothwell (19) described initiation of pitting as one preceded by adsorption of aggressive ions, *e.g.*, Cl^-, on a supposed oxide film, followed by penetration of the film (without exchange) under the influence of an electrostatic field. When the field across the film-solution interface reaches a critical value, pitting occurs. Other ions may also penetrate the passive oxide, depending on size and charge, contaminating the oxide and making it a better ionic conductor, thereby favoring oxide growth. The oxide is presumably either undermined by vacancy condensation at the metal interface or it releases cations rapidly at the electrolyte interface so that in either case pitting proceeds. The induction period for pitting to occur is related to the time required for supposed penetration of ions through the oxide film. Streicher (20) previously expressed a less detailed but similar viewpoint.

It would seem from this model of pitting behavior that anions other than Cl^-, *e.g.*, SO_4^{--}, ClO_4^-, NO_3^-, OH^-, should in some measure accelerate pitting by contaminating the supposed oxide, whereas in fact they are inhibitors as present and previously published data show. Inhibition occurs despite applied potentials across the passive film that otherwise readily cause pitting in absence of inhibitor. Also, oxide films, being soluble in acids, ought to be thinner or more porous hence more easily penetrated at low *p*H than at high *p*H values, yet the critical potential is not appreciably altered in 0.1N NaCl on going from *p*H 7 to 1 (Fig. 4). Furthermore, anion size appears to be less important than specific interaction of anions with the metal surface. For example, Cl^- is more effective than SO_4^{--} in causing pitting of passive iron in presence of CrO_4^{--}, but SO_4^{--} is more effective than Cl^- in presence of NO_2^- (21).

An alternative model, which in the authors' opinion offers advantages in describing the facts, is based on reversible competitive adsorption of aggressive ions like Cl^- with oxygen for sites on the stainless steel surface. Adsorbed oxygen rather than metal oxide is considered to make up the passive film (22). This is the model discussed in detail by Kolotyrkin (10, 23). Also Rosenfeld and Maximtschuk (2), and Brauns and Schwenk (4) in their discussion of pitting mechanism refer to a similar model. Oxygen normally has higher affinity than Cl^- for adsorption sites on a stainless steel surface, but as the potential of the alloy is shifted in the positive (noble) direction, more Cl^- ions move into the double layer. At a sufficient concentration corresponding to the critical potential, Cl^- ions succeed at favored sites in destroying passivity by displacing adsorbed O ions. The anodic overvoltage for dissolution of alloy ions is then appreciably reduced wherever the metal is in contact with Cl^- compared to metal in contact with adsorbed O, and hence metal ions rapidly enter solution resulting in a pit. Preferred transport of Cl^- (transference number of Cl^- in 0.1N NaCl = 0.61) into anodic areas because of the continuous corrosion current, and still higher transference number of Cl^- in heavy-metal chlorides, insures that the anode areas remain active. The induction time for pitting is explained in part by the slow process of competitive adsorption. When anions other than Cl^- are present, these also tend to adsorb on the passive alloy surface displacing Cl^-. Hence, in their presence the competitive process requires a shift of potential to still more noble values so as to enable Cl^- ion to reach a concentration in the double layer adequate to displace oxygen of the passive film thereby destroying passivity locally. Should pitting not occur up to a potential of about 1.0v, which is the order of magnitude open-circuit cathode (oxygen) potential of 18-8 in aerated electrolytes, pitting is effectively inhibited because it then becomes impossible for Cl^- to displace oxygen on the metal surface at any available galvanic potential. The more readily an anion adsorbs on the passive surface, and the higher its affinity for the metal surface, the more effectively does it exclude Cl^- and inhibit pitting. Hence OH^- is usually a better inhibitor than is ClO_4^-, the latter adsorbing least of all common anions.

Rosenfeld and Maximtschuk (2) using radioactive Cl^{36} proved that more Cl^- adsorbs on Cr, the passive properties of which 18-8 approximates, as the potential of Cr is shifted in the noble direction. They also showed that SO_4^{--} or OH^- added to chloride solutions decreases adsorption of Cl^- and that at sufficiently high concentrations of either anion, practically no adsorption of Cl^- occurs at all, even in the noble potential region. These results support the mechanism of pitting described above based on competitive adsorption.

Following from the supposition that the amount of anion adsorbing depends on its activity in solution in accord with the Freundlich adsorption isotherm, and that pitting is inhibited when a critical ratio of anion to Cl^- activity is reached, it was shown (11) that the relation log (Cl^-) = constant + n_1/n_2 log (anion) should hold where n_1 corresponds to the exponent in the Freundlich adsorption isotherm: amount adsorbed = $k_1(Cl^-)^{1/n_1}$ and n_2 is the corresponding exponent for inhibitor ion. This equation describes the present data and it also describes the amount of CrO_4^{--} or NO_2^- needed to inhibit pitting of iron in presence of Cl^- or SO_4^{--} where again competitive adsorption is the probable underlying mechanism (21).

With reference to the constants for the above equation listed earlier for various inhibiting ions, it is noted that values of n_2 as judged from the coefficients for log (OH^-) and log (NO_3^-) are smaller than for log (SO_4^{--}) and log (ClO_4^-) assuming that n_1 for adsorption of (Cl^-) is the same in all cases. These values are perhaps in line with the expected higher

affinity of OH^- and NO_3^- for the metal surface compared to SO_4^{--} or ClO_4^-. At low concentrations of Cl^- ($<0.01N$), however, the critical activities of inhibiting ion may be no longer in the same order, indicating that some additional factor enters the adsorption mechanism. The part played by Cl^- concentration may explain why Rosenfeld and Maximtschuk (2) found efficiency of inhibition to decrease in the order $NO_3^- > ClO_4^- > SO_4^{--}$ whereas we find $NO_3^- > SO_4^{--} > ClO_4^-$.

The critical potential is insensitive to pH in the acid region presumably because H^+ does not competitively adsorb on the passive 18-8 surface in this range. In the alkaline region, however, OH^- in sufficient concentration is available for adsorption; its high affinity for the metal surface makes it an effective inhibitor at relatively low concentrations. At temperatures below room temperature, the chemical affinity of 18-8 for oxygen is probably not changed appreciably judging from the small change in Flade potential of Fe with temperature. However, affinity of 18-8 for H_2O at low temperatures may increase appreciably making it more difficult for Cl^- to displace both adsorbed H_2O and oxygen, and accounting for the marked noble shift of potential. It would be difficult to explain such a high temperature coefficient on the basis of any supposed change of anion diffusion rate through an oxide lattice.

It should be noted that the effect of increasing Cl^- concentration to shift V_c in the negative (active) direction can account for an apparent induction time for pitting in stagnant solutions because the small continuous passive current serves to transport NaCl to the alloy surface. This is one of the reasons why crevices, if they exist, are the first to pit because they harbor higher concentrations of Cl^-. This factor, and also perhaps nonuniform composition alloy surfaces, or exposed edges compared to faces of cold-rolled alloy (7) (caused probably by differing crystal orientation), may account for the scattered values of critical potentials reported in the literature. It may also account for an apparent induction time beyond the time normally required for competitive adsorption to occur.

Our present results support the view that for specific environmental conditions and nonstagnant electrolytes, the critical potential is observed at well-defined reproducible values. On the other hand, whether pits once formed will again repassivate at some potential lower than the critical value as reported by Pourbaix *et al.* (6) depends, in our opinion, on accidental favorable geometry of the pit cavities and a stirring rate high enough to mix electrolyte inside the pits with electrolyte outside.

A Dilatometric Study of the Cathodic Hydrogenation of Nickel

Kenneth A. Moon and Edward T. Clegg

United States Army Materials Research Agency, Watertown, Massachusetts

ABSTRACT

Hydrogen content and specimen elongation were measured as functions of reaction time during cathodic hydrogenation of nickel strip specimens of various thicknesses. In contrast to earlier work, the hydride appears to have a composition close to NiH. The reaction follows the parabolic rate law. The relation between elongation and hydrogen content depends on specimen thickness in a manner which can be simply interpreted in terms of the elastic and plastic properties of the hydride and metal, together with a residual stress in the newly formed hydride about 10^5 psi.

There has been a renewed interest in recent years in the role of volume changes in reactions where a new phase forms on the surface of a metal (1). Most of the work (2-7) has employed strip-deflection measurements as an indication of the stresses produced by the reaction. Only two papers (8, 9) are known to us in which dimensional changes of a specimen were reported. In this paper we report the results of a dilatometric study of the cathodic hydrogenation of thin strip specimens of nickel, in which both elongation and hydrogen content were followed as functions of time and specimen thickness. The results have been interpreted in terms of a residual compressive stress in the newly formed hydride, with subsequent relaxation conditioned by specimen dimensions and the elastic and plastic properties of the solids.

Nickel forms a hydride of reported (10-12) composition about $NiH_{0.7}$. The hydride has a fcc arrangement of nickel atoms, as in pure nickel, but the lattice constant is 6% greater (13, 14). The decomposition pressure of the hydride is about 20 kbar (15), but surface concentrations of hydrogen atoms equivalent to pressures exceeding this can be maintained in cathodic discharge by using a high current density and a suitable catalyst (16), although it has not so far been possible to obtain a hydride layer thicker than about 30μ. The amount of hydrogen which passes beyond the interphase surface to dissolve in the nickel core is negligibly small (11). Janko (17) has shown that hydrogenation and subsequent dehydrogenation of a nickel single crystal leave the outer layers of the crystal only slightly disoriented. The reaction is not perfectly reversible, as shown by x-ray diffraction (17), electrical resistance changes (18, 19), and microscopic examination (14).

Materials and Procedures

The nickel specimens were purchased from the H. Cross Company in the form of rolled "A" nickel strips 0.476 cm wide and of nominal thickness 0.5, 1, 2, 4, 8, and 12 mils. The calculated thicknesses, assuming a density of 8.9 g/cc, were 0.00124, 0.00250, 0.00468, 0.00980, 0.0197, and 0.0296 cm. Specimens 5.2 cm long were cut from the strips. To provide for mounting in the dilatometer, two 0.11-cm-diameter holes spaced 4.8 cm apart were punched near the ends of the specimens. In calculations, we used 4.6 cm as the effective specimen length, because the ends of the specimens were shielded from the electric current by the silica specimen holders of the dilatometer. Before use, the specimens were rinsed with ether and annealed for 4 hr at 900°C in a stream of hydrogen purified by permeation through palladium-silver alloy. Heating and cooling rates were 4°/min. After annealing, the stream of pure hydrogen was continued until the specimen was removed just before the start of a hydrogenation.

The dilatometer was constructed of fused silica, as shown in Fig. 1. The differential transformer was a Schaevitz Engineering Company Model 100SS-L. The power supply and amplifier was a Daytronic Corporation Model 300-C-60, and its recorder output was connected to a L&N Model H AZAR recorder. The specimens were mounted in the dilatometer by means of a silica pin through the upper hole in the specimen and corresponding holes in the transmission rod, and a platinum pin (for electrical connection) through the lower hole in the specimen and corresponding holes in the dilatometer body. After causing the assembly to settle into a stable position by gentle tapping, no further change occurred (in absence of hydrogenation) even with the ½ mil specimens. In several experiments, nickel reinforcing plates were fastened to the ends of a ½-mil specimen; the results were similar to those obtained in absence of reinforcing plates. Six sensitivity ranges were available, varying from ±0.1 in. to ±0.001 in. full scale. All scales used in this work were calibrated periodically with a special jig using a commercial micrometer. The force exerted by the dilatometer spring on the specimen was 37g.

Cathode current was supplied from a Harrison Laboratories Model 6202A power supply. The reported current density is subject to systematic errors due to uncertainty in the corrections applied to account for end effects and for the wire used to make electrical connection. The anode consisted of two identical perforated platinum sheets arranged symmetrically opposite the specimen faces about 6 cm from the faces. The electrolyte was 1250 ml of 1*N* sulfuric acid, in which 0.45g of thiourea was dissolved just before use. Before use, the electrolyte was brought to room temperature, preelectrolyzed with platinum electrodes, and then raised into position around the specimen. Voltage was applied to the specimen before the electrolyte touched it. Electrolyte temperature and room temperature remained constant within a few tenths of a degree throughout all runs, usually between 21° and 22°.

At the time chosen for terminating the hydrogenation, the electrolyte was removed, a central portion of the specimen was cut out with scissors, and this portion was rinsed with pure water and dropped to the bottom of a glass tube immersed in liquid nitrogen. Only a few seconds elapsed from the termination of hydrogenation to the chilling of the specimen. The tube was then connected to the hydrogen-analysis apparatus and the air and liquid oxygen were pumped away for a ten-minute period during which the specimen was kept at liquid-nitrogen temperature. The ap-

paratus was a glass vacuum system of conventional design, as shown in Fig. 2. At the end of the 10-min period, the condensation trap was chilled with liquid nitrogen, the valves were adjusted to the positions for collecting hydrogen, and the specimen tube was allowed to warm up. When the water had evaporated from the specimen tube, the specimen was heated to 250° and the evolved hydrogen was transferred to the gas buret and measured.

Results and Discussion

Figure 3 shows hydrogen content *vs.* reaction time for our experiments in which cathode current density was 75 ma/cm². Hydrogen content is expressed in cubic centimeters of hydrogen gas (STP) per square centimeter of specimen surface area, ignoring the area of the edges. The reaction initially follows the parabolic rate law, whereas earlier workers (20) obtained a linear relation between hydrogen content and square root of reaction time only after an initial induction period. We presume that the induction period was due to an oxide layer on the specimens. The parabolic kinetics indicate that the reaction is controlled by volume diffusion in an unbroken surface layer of uniform thickness. For long reaction times the reaction becomes stationary and eventually retrograde, with poor reproducibility. This is not unexpected. The hydride is unstable at atmospheric pressure, so any paths which may exist for the outward passage of hydrogen molecules from the hydride layer will set up a counter-current reaction and bring the over-all reaction to a steady state. If such a path arises during the course of hydrogenation (*e.g.*, a crack), its conductance for hydrogen molecules will increase as time passes, because of localized shrinkage due to loss of interstitial hydrogen. We doubt that there is any need (15) for more elaborate arguments to explain the limited penetration of the hydride layer. An analogous situation exists in the oxidation of metals (1, p. 30), except in that case a failure of the surface layer produces an increase in the reaction rate, since the oxide is stable.

Earlier workers (10-12) have concluded that the hydride composition is about $NiH_{0.7}$, but our ½-mil specimens attain a hydrogen content about 1 cc/cm², corresponding to a minimum hydrogen content in the hydride equal to $NiH_{0.96}$. The reason for the discrepancy is unknown, but it might be due to oxygen impurity in the electrodeposited nickel specimens used in the earlier work. Since the hydrogen atoms in the hydride occupy octahedral interstitial sites (21), the

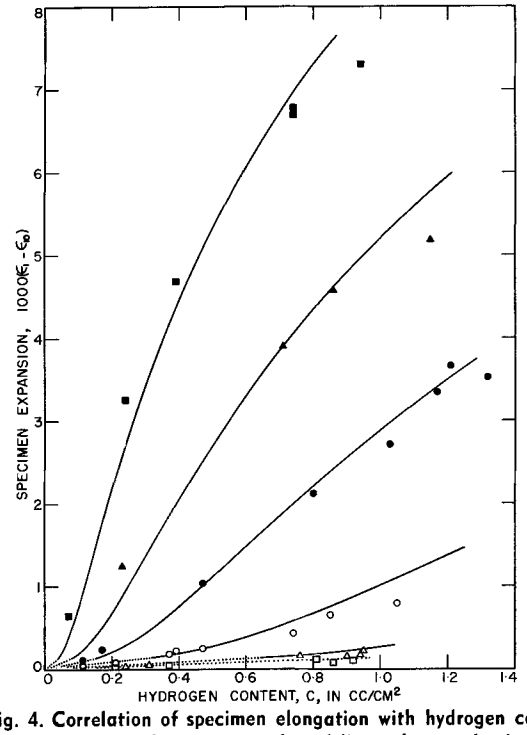

Fig. 4. Correlation of specimen elongation with hydrogen content. Solid lines, theory, plastic range; dotted lines, theory, elastic range; point symbols same as in Fig. 3.

probable upper limit of the hydride composition is NiH. Since our minimum value for the average hydride composition is very close to this upper limit, we conclude that the homogeneity range of the hydride is quite narrow.

Figure 4 shows the relation between specimen elongation and hydrogen content for the cathode current density of 75 ma/cm². A few experiments were run at other current densities, and the results suggest that the elongation *vs.* hydrogen content relationship is independent of current density. This is to be expected in view of the evidence, cited above, that the homogeneity range of the hydride is narrow.

We present here a simplified theoretical treatment which gives some insight into the results shown in Fig. 4. We assume that the hydride composition is NiH, and the density of nickel is 8.9 g/cc, so that the thickness of the unreacted nickel core is given by

$$T = T_o - BC \qquad B = 1.18 \times 10^{-3} \qquad [1]$$

where T_o is the initial specimen thickness in centimeters and C is the hydrogen content as defined above. If we let $R^{1/3}$ be the ratio of lattice parameter of hydride to that of nickel, to a good approximation

$$2D = R(T_o - T) \qquad R^{1/3} = 1.06 \qquad [2]$$

where D is the thickness of the hydride layer in centimeters. We next make some simplifying assumptions concerning the nature of the stress system in the specimen, since a rigorous analysis appears to be prohibitively difficult. We imagine the specimen sliced into a large number of laminae parallel to the faces of the specimen. We assume that in each lamina there is a uniform plane state of stress with one principal direction along the dilatometer axis and the other perpendicular to the dilatometer axis and parallel to the faces of the specimen. Edge effects are ignored. Coherency stresses at the metal/hydride interface are ignored; they must be of very short range, and exist in pairs of opposing effects relative to elongation of the specimen. We assume that the distension of the laminae is the same for all laminae. Thus, the nickel

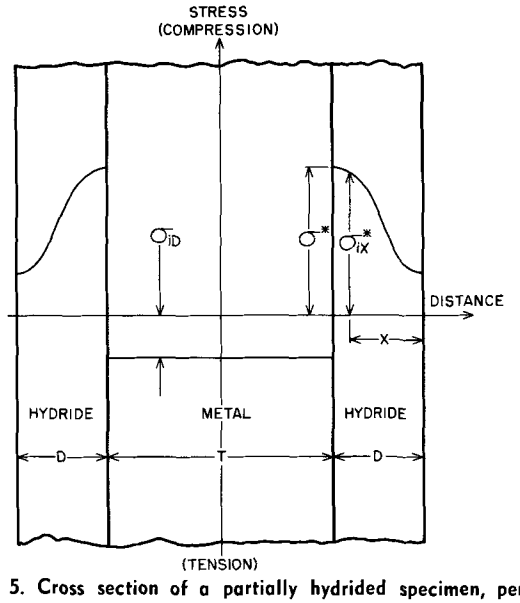

Fig. 5. Cross section of a partially hydrided specimen, perpendicular to specimen faces, showing the assumed distribution of stress.

core can be treated as a single lamina, but not the hydride laminae, since in them the strain (relative to the state of zero stress) will depend on their position relative to the reaction interface. The residual compressive stress in the newly formed hydride is assumed to have a fixed value σ^*, regardless of any strains existing in the nickel from which it was formed. Figure 5 shows the situation schematically.

We use the symbols σ_{iy}, ϵ_{iy}, E, ν, and σ^*_{ix}, ϵ^*_{ix}, E^*, ν^* for the stress, strain, Young's modulus, and Poisson's ratio of the nickel and hydride, respectively. Subscript i (1 or 2) refers to the principal directions in the laminae, 1 being the direction of the dilatometer axis. Subscript x indicates the depth of the hydride lamina relative to the outer surface of the hydride. The symbol y is the instantaneous value of the thickness of the hydride layer; that is, y increases from 0 to D during the course of the hydrogenation. Balance of forces gives $T\sigma_{1D} = T_0E\epsilon_{10} + 2\int_0^D \sigma^*_{1x}dx$, and $T\sigma_{2D} = 2\int_0^D \sigma^*_{2x}dx$, where $\epsilon_{10} = 3.685(10^{-8})/T_0$ is the initial strain due to the dilatometer spring. We assume that Hooke's law applies in the hydride laminae; that is, $E^*\epsilon^*_{ix} = \sigma^*_{ix} - \nu^*\sigma^*_{jx}$. (Note that this implies absence not only of plastic flow or cracking in the hydride, but also of any interdependence of strain and composition in the hydride.) Noting that $\epsilon^*_{ix} = \epsilon^* - (\epsilon_{iD} - \epsilon_{ix})$, where $\epsilon^* = (1-\nu^*)\sigma^*/E^*$ is the initial residual strain in the hydride, and combining all the above equations, we obtain

$$T(\sigma_{1D} - \sigma_{2D}) = T_0E\epsilon_{10} + 2E^*\{\int_0^D (\epsilon_{1y} - \epsilon_{2y})dy - D(\epsilon_{1D} - \epsilon_{2D})\}/(1+\nu^*) \quad [3]$$

$$T(\sigma_{1D} + \sigma_{2D}) = T_0E\epsilon_{10} + 2E^*\{\int_0^D (\epsilon_{1y} + \epsilon_{2y})dy - D(\epsilon_{1D} + \epsilon_{2D}) + 2D\epsilon^*\}/(1-\nu^*) \quad [4]$$

We first consider the case where strains in the nickel core are purely elastic, so that by Hooke's law, $E\epsilon_{iD} = \sigma_{iD} - \nu\sigma_{jD}$. In this case the solution of Eq. [3] and [4] is

$$\epsilon_{1D} - \epsilon_{1O} = (1/2)\epsilon_{1O}(1+\nu)(a_1F + + a_nF^n..) + (1/2)(1-\nu)(\epsilon_{1O} + 2R\sigma^*/E)(b_1F + + b_nF^n..) \quad [5]$$

where $F = BC/T_o$, $a_1 = b_1 = 1$, $a_n/a_{n-1} = 1 - RE^*(1+\nu^*)(n-1)/E(1+\nu)n$, and $b_n/b_{n-1} = 1 - RE^*(1-\nu^*)(n-1)/E(1-\nu)n$. Note that for small F, $(\epsilon_{1D} - \epsilon_{1O})$ is proportional to F, the slope being $\epsilon_{1O} + R\sigma^*(1-\nu)/E$.

The other case we consider is that in which specimen distension is great enough to produce plastic flow in the nickel core, but not in the hydride. Instead of Hooke's law, we use the Prandtl-Reuss equations of plastic flow in the form presented by Hill (22). Reduced to the form appropriate for our stress system, these are

$$d\epsilon_{iD} = (d\sigma_{iD} - \nu d\sigma_{jD})/E + (2\sigma_{iD} - \sigma_{jD})d\bar{\sigma}_D/2\sigma_DH'_D \quad [6]$$

where the generalized stress $\bar{\sigma}_D = (1/2)\{3(\sigma_{1D} - \sigma_{2D})^2 + (\sigma_{1D} + \sigma_{2D})^2\}^{1/2}$ is the same function, H, of a generalized plastic strain integral that stress is of plastic strain in a uniaxial tensile test. Rostoker's work (23) suggests that for nickel this functional relationship is of the form $(\bar{\sigma} - \bar{\sigma}_o)^2 = K\bar{\epsilon}^P$ where $\bar{\sigma}_o$ is the stress at the elastic limit, so the derivative H' in Eq. [6] is equal to $K/2(\bar{\sigma}_D - \bar{\sigma}_o)$. To simplify the computations, we have made the assumption $RE^* = E$ and $\nu^* = \nu$, in which case exact solutions are possible for the elastic range, as follows (with subscript D henceforth omitted)

$$\sigma_1 - \sigma_2 = E\epsilon_{10}e^F \quad [7]$$

$$(\bar{\sigma}/E)^2 = \epsilon^{*2}(e^F-1)^2/(1-\nu)^2 + \epsilon_{10}\epsilon^*(e^{2F}-e^F)/(1-\nu) + (\epsilon_{10}e^F)^2 \quad [8]$$

$$\epsilon_1 = \epsilon_{10}e^F + \epsilon^*(e^F-1) \quad [9]$$

For the plastic range

$$d\ln(\sigma_1 - \sigma_2) = dF - 3EF(\bar{\sigma} - \bar{\sigma}_o)d\bar{\sigma}/K\bar{\sigma}(1+\nu) \quad [10]$$

$$\frac{d\bar{\sigma}}{dF}\left\{4\sigma + \frac{EF(\bar{\sigma} - \bar{\sigma}_o)}{K\bar{\sigma}}\left[\frac{9(\sigma_1 - \sigma_2)^2}{1+\nu} + \frac{(\sigma_1 + \sigma_2)^2}{1-\nu}\right]\right\} = 4\sigma^2 + \frac{2\sigma^*}{R}[\sigma_1 + \sigma_2] \quad [11]$$

$$\frac{d\epsilon_1}{dF} = \epsilon^* + \frac{(\sigma_1 - \sigma_2)(1+\nu)}{2E} + \frac{(\sigma_1 + \sigma_2)(1-\nu)}{2E} + \frac{(2\sigma_1 - \sigma_2)(1-F)(\bar{\sigma} - \bar{\sigma}_o)}{K\sigma}\frac{d\bar{\sigma}}{dF} \quad [12]$$

The curves in Fig. 4 were constructed from Eq. [7]-[12], using numerical integration in the plastic range. We used the values $\nu = 0.31$ and $E = 3\text{x}10^7$ psi (24). By trial and error we selected as best values: $\epsilon^* = 0.0035$, $\sigma_o = 6000$ psi, and $K = 10^{11}$ psi^2. The values of σ_o and K cannot be compared directly with known experimental values because these two properties are strongly dependent on grain size, purity, specimen history, and testing conditions. However, we note in Fig. 5 of ref. (23) that for six specimens K ranged from $1.2\text{x}10^{10}$ to $8.0\text{x}10^{10}$ psi^2, and σ_o ranged from 2920 to 8810 psi. The value of ϵ^* would be 0.06 if no reorganization of the nickel lattice occurred at the reaction interface. Presumably the interface is semicoherent, and dislocation climb accounts for the discrepancy between 0.06 and 0.0035 (25). The value 0.0035 corresponds to $\sigma^* = 1.3\text{x}10^5$ psi, which is comparable to residual stresses found in some other systems (2, 3, 6, 7, 26), but is an order of magnitude greater than values reported previously (4, 5) for nickel hydride. Although the agreement between theory and experiment in Fig. 4 is only approximate, we cannot reasonably adjust σ^* appreciably lower than $8\text{x}10^4$ psi. In both of the earlier studies (4, 5) the estimate of the thickness of the hydride layer is open to criticism, and we believe that our value for the residual stress is to be preferred.

Acknowledgment

The authors are grateful to Mrs. Anna Hansen for performing the numerical integrations.

The Heat-Treatment of Anodic Oxide Films on Tantalum

V. The Thermal Redistribution of Incorporated Phosphorus

D. M. Smyth

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Dielectric measurements and radiotracer techniques have been used to follow the migration of incorporated phosphorus in anodic oxide films on tantalum during heat-treatment at temperatures above 400°. The phosphorus moves away from the tantalum, accumulating into a region of very high phosphorus content on the tantalum side of the phosphorus-containing layer. Little or no migration occurs on the other side of the layer. Redistribution is much more extensive when heat-treatment is carried out in air than when the ambient is a vacuum.

The effect of anodization electrolyte on the dielectric properties of heat-treated, anodized tantalum was reported in the preceding paper in this series (1). In particular, it was found that phosphoric acid has a profound effect, and this was correlated with a non-uniform incorporation of significant amounts of phosphorus in the anodic oxide, as reported by Randall, Bernard, and Wilkinson (2), and with the observation that the incorporated phosphorus inhibits the rate of diffusion of oxygen through the oxide during heat-treatment. The result is that the heat-treated oxide has an inner, shallow gradient of conductivity in the phosphorus-free region adjacent to the tantalum, and an outer, steep gradient of conductivity in the phosphorus-containing region which had formed adjacent to the electrolyte. The distinction between the two gradients increased with increasing H_3PO_4 concentration in the anodization electrolyte.

This work was based on the results of heat-treatments carried out at 400°, and it appeared that the distribution of phosphorus in the oxide was not affected by the heating. Efforts to extend these experiments to higher temperatures of heat-treatment led to substantial deviations from the earlier results. This is the subject of the present paper.

Experimental

The experimental details have been described previously (1, 3-5). Unless specifically stated otherwise, all work reported here concerns samples anodized in 14.6M H_3PO_4 (the commercial 85% acid) to 75v with the heat-treatment being carried out in air. Dielectric measurements were made in a 40% aqueous solution of H_2SO_4.

Results and Discussion

The pertinent results are shown in Fig. 1 in the form of plots of log frequency *vs.* the reciprocal series capacitance. As shown previously (5), this is equivalent to a plot of log conductivity *vs.* position in the film with the Ta_2O_5-electrolyte interface at $1/C = 0$. The measurements were made over a frequency range of 50-3200 Hz at two temperatures, 34° and 0°. The results were then all normalized to 34° by use of the activation energy of conduction of 0.6 ev previously reported (5). This, in effect, extends the frequency range at 34° to 55,000 Hz. The mathematical basis for this is contained in the expressions

$$\sigma_0 = Ae^{-E/kT} \quad [1]$$

$$\sigma_0 = \omega\epsilon\epsilon_0 \quad [2]$$

where [1] represents the temperature dependence of semiconduction, and [2] expresses the relationship between σ_0, the level of conductivity which defines the boundary between effective dielectric and effective electrode and the frequency ($\omega = 2\pi f$). These relations are discussed in detail in ref. (5). This technique is used to extend the data range to frequencies which would otherwise be prohibitive because of the low sample impedance.

According to our usual interpretation of these data, each plot in Fig. 1 represents a portion of a conductivity profile across the heat-treated oxide. The data do not extend to sufficiently high frequencies to show

the profile all the way to the Ta-Ta_2O_5 interface which presumably lies in the vicinity of the curve shown for an unheated sample, *i.e.*, at about $1/C = 0.3\ \mu f^{-1}$. In each case, the effective dielectric thickness at low frequencies is represented by the region between the conductivity profile and $1/C = 0$.

The results show two main factors. As the heat-treatment conditions become increasingly severe in terms of either temperature or time, the interface between effective dielectric and effective electrode moves toward the Ta_2O_5-air interface, and it becomes sharper in the sense that it remains nearly vertical to higher frequencies. This effect reaches saturation for heat-treatment at 600°. The effect of the phosphorus content becomes particularly evident at 600°, since samples formed in 0.01M H_2SO_4, for instance, undergo almost complete physical deterioration at this temperature. The anodic oxide film is extensively disrupted by powdery, white oxide, whereas those samples anodized in 14.6M H_3PO_4 survive with clear, unimpaired oxide films.

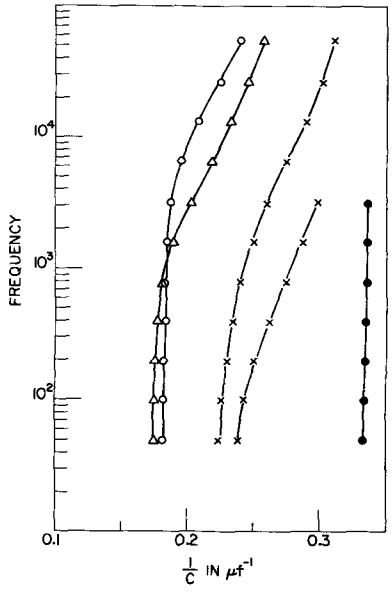

Fig. 2. Effect of heat-treatment on the dielectric properties of tantalum anodized to 37.5v in 14.6M H_3PO_4, then to 75v in 0.01M H_2SO_4. From right to left: • Unheated; X 300°, ½ hr; X 300°, 4 hr; ○ 500°, ½ hr; △ 550°, 1 hr.

Figure 2 shows similar results obtained from samples anodized first to 37.5v in 14.6M H_3PO_4 and then to 75v in 0.01M H_2SO_4. It has been shown that the oxide film formed from this type of anodic oxidation contains a phosphorus-containing layer sandwiched between outer and inner phosphorus-free layers (2). It is seen that heat-treatment has less effect on this type of sample.

When samples which have been anodized in 14.6M H_3PO_4 and extensively heat-treated in air are subjected to reanodization at the original anodization voltage, the results are rather complicated. Some of this behavior is shown in Fig. 3. Reanodization decreases the capacitance to values substantially below the original, preheated value. Moreover, a distinct change in interference color indicates that additional oxide growth has occurred. The dielectric properties of the reanodized samples drift with time, however. Without bias the capacitance returns to the vicinity of the preheated value and becomes much more frequency-dependent. From the results shown in Fig. 3 it appears that the application of a substantial bias, as is done during reanodization, results in a severe polarization effect which decays very slowly. This behavior is not understood at the present time.

If we are to accept the dielectric behavior at face value, the results indicate that the dielectric-electrode interface, and hence the interface between phosphorus-containing and phosphorus-free oxide, is moving toward the Ta_2O_5-air interface during heat-treatment at 400° and above. This movement is greatly reduced when the phosphorus-containing layer is sandwiched between two phosphorus-free layers (anodization in H_3PO_4, followed by anodization in H_2SO_4). Fortunately, the radiotracer technique described by Randall, Bernard, and Wilkinson offers a direct test of this interpretation (2).

In the initial radiotracer experiment, two samples were anodized to 75v in 14.6M H_3PO_4 containing P^{32}. The anodization was carried out at 1 ma/cm^2 to 75v

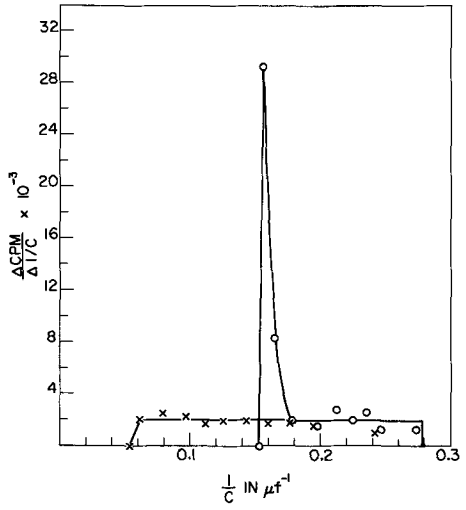

Fig. 4. Effect of heat-treatment on the distribution of phosphorus in anodized tantalum. X Unheated; ○ heated, 500, 1 hr, in air.

and then at 0.1 ma/cm^2 to the same voltage. The samples were not held at constant voltage. Two other samples were similarly anodized to 37.5v in the radiotracer H_3PO_4 and then to 75v in 0.01M H_2SO_4. One sample of each kind was heated at 500° in air for 1 hr. The phosphorus profile across the oxide was then determined for each sample by the removal of successive thin layers of oxide in HF. The results are shown in Fig. 4 and 5 in which $\Delta CPM/\Delta 1/C$ has been plotted against 1/C. ΔCPM represents the difference in counts-per-minute of the sample before and after a particular etching and therefore is the amount of activity removed by the etching. $\Delta 1/C$ is the related difference in the reciprocal series capacitance and thus represents the thickness of oxide removed. It follows that $\Delta CPM/\Delta 1/C$ is proportional to the concentration of phosphorus in the dissolved oxide, and this has been plotted against position in the film as determined by 1/C. These plots thus represent the distribution of phosphorus in the oxide. In the case of the heated samples, a portion of the oxide adjacent to the tantalum is conducting, and the capacitance values are consequently greater than those of the unheated samples. In order to get a meaningful geometric picture of the phosphorus distribution, a constant value of 1/C has been added to each value for the heated samples in order to normalize the results at the Ta_2O_5-electrolyte interface. In actuality, the residual radioactivity and the reciprocal series capacitance went to zero at the same point in the oxide for the heat-treated samples. This correlation has been discussed previously (1).

The initial observation was that the total radioactivity of the samples was unchanged, within experimental accuracy, by the heat-treatment. Hence no phosphorus was lost from the films. The results show that the interface between phosphorus-containing and phosphorus-free oxide has indeed moved toward the Ta_2O_5-air interface as a result of heat-treatment. The movement has taken place in a very peculiar manner. The phosphorus has accumulated into a concentrated region at the interface, apparently by the complete depletion of the phosphorus content of the oxide on the side toward the tantalum. The phosphorus content of the oxide on the other side of the accumulation region has not been disturbed. Moreover, in the case of the buried phosphorus-containing layer, the accumulation has occurred only on the tantalum side of the layer.

The radiotracer analysis confirms the conclusions drawn from the capacitance measurements. The apparent movement of the boundary between conducting and nonconducting oxide is in good agreement with the movement of the boundary between phosphorus-containing and phosphorus-free oxide. Moreover, the high concentration of phosphorus at the interface accounts for the observation that the log f *vs.* 1/C plots shown in Fig. 1 remain vertical to higher frequencies as the extent of heat-treatment is increased. However, the nature of the accumulation of phosphorus is most peculiar and deserves further consideration. First of all, the migration is clearly against the direction of the concentration gradient; and, second, in the case of the buried layer, Fig. 5, the migration took place only on the side facing the tantalum. It is interesting to note that for the latter situation, the two sides of the phosphorus-containing layer differ greatly in oxygen deficiency and conductivity during and after heat-treatment, according to the model discussed previously (1). This is depicted schematically in Fig. 6. Possibly the phosphorus diffuses more readily where the oxygen vacancy concentration is high, or the potential distribution in the oxide may be very important.

A further attempt was made to clarify the situation as follows. Two identical samples were made, as before, to have buried radiophosphorus-containing layers. One of these was heated at 500° for 1 hr in air, while the other was heated at 500° for 1 hr in a vacuum of 5 x 10^{-7} Torr. The latter sample was then reanodized at 50v for 1 hr in 0.01M H_2SO_4 in order to form an outer, insulating layer so that capacitance measurements could be used to determine the thick-

ness of oxide removed during each etching of the phosphorus profile determination. Prior to this reanodization the capacitance was extremely high, indicating that the oxide film was oxygen deficient and conducting throughout. The reanodization should not affect the distribution of phosphorus in the oxide (2). The usual radiotracer analyses indicated the phosphorus distributions shown in Fig. 7. (Again the results have been normalized so that the apparent Ta_2O_5-electrolyte interfaces coincide, in this case at $1/C = 0.52\ \mu f^{-1}$.) The sample heated in air behaved as before, but the vacuum-heated sample shows much less rearrangement of phosphorus.

The behavior of the vacuum-heated sample could be explained in two ways. Some initial migration of phosphorus could have occurred prior to the completion of the oxygen depletion throughout the film, at which point migration ceased; or, a form similar to that of the air-heated sample may have initially formed, and, after the entire region became oxygen-deficient and conducting, the sharp hump of phosphorus content may have started to decay by ordinary diffusion. The latter explanation is preferred, since all of the air-heated samples have shown an abrupt interface at the junction between phosphorus-containing and phosphorus-free oxide. In addition, all of the dielectric measurements have indicated a sharp boundary, even for very small amounts of boundary movement. No transient situation has ever been seen in an air-heated sample which would suggest a phosphorus distribution similar to that of the vacuum-heated sample in Fig. 7.

If the preferred sequence just described is correct, it suggests that the original accumulation of phosphorus is a field-driven process, since ordinary diffusion behavior occurs once the film becomes uniformly conducting (ordinary diffusion behavior in the sense of the flattening of peaks and rounding of edges of a concentration profile). A field-driven mechanism seems more likely to build up the sharp peak of concentration of phosphorus than a diffusion process. Even if there were a tendency for the phosphorus-containing region to separate into a phosphorus-rich phase and a phosphorus-free phase, it seems unlikely that the phosphorus-rich phase would separate out into such a neat pile. It would be more likely to collect into isolated clumps. Thus, although the precise mechanism is not clear, it appears more likely that the phosphorus is driven by an electric field associated with the boundary between the two conductivity gradients.

The extent to which the phosphorus accumulates is quite remarkable. According to Randall *et al.*, the concentration of phosphorus in the phosphorus-containing region of a tantalum oxide film formed in 14.6M H_3PO_4 corresponds to about a phosphorus atom for each five tantalum atoms (2). The radiotracer work reported here shows accumulations of phosphorus up to at least ten times that present prior to heat-treatment. It is thus a major constituent of that portion of the oxide. Oxides of niobium and tantalum with high contents of phosphorus are not unknown. Shtin and Sharova have described amorphous precipitates obtained by the addition of phosphoric acid to solutions of niobium and tantalum (6, 7). Compositions of $2M_2O_5 \cdot P_2O_5 \cdot 6H_2O$ and $M_2O_5 \cdot P_2O_5$ (after calcining at 1000°) were reported, where M = Ta or Nb. A variety of crystalline compounds having the general composition $A_2O_5 \cdot 9M_2O_5$ have been characterized by Waring and Roth, where A = P, As, or V, and M = Ta or Nb (8). Although the relationship between these various materials and the amorphous, phosphorus-containing, anodic films is not clear, the chemical compatibility of phosphorus with niobium and tantalum oxides is demonstrated.

Acknowledgment

The author gratefully acknowledges the assistance of Dr. J. J. Randall, Jr., and Mr. Stanley Szpak, who carried out the radiotracer analysis, and the experimental assistance of Miss Marjorie Cutler.

Effects of Growth Conditions on Microstructures in CdS:Cu Single Crystals

Arthur Dreeben

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

The sublimation temperature used to grow large boules of CdS:Cu affects the concentration of incorporated copper, while temperature differences along the boule affect the distribution of the impurity in the crystal. Lower sublimation temperatures tend to form crystals with dislocation tangles in which decorated loops, helices, dipoles, and cardioid configurations have been identified. Rapid growth leads to polygonization and formation of grain boundaries where precipitates, which are affected by the degree of crystallographic misorientation around the boundary, differ in size and geometry from those in the grains.

It was previously shown that the acceptor elements copper, silver, and gold form precipitates in CdS crystals (1). In the case of copper, the presence of extraneous phases shaped as needles, rods, or disks were related to different concentrations of the copper impurity. Gold, under the initial growth conditions, formed a single type of discrete hexagonal platelets lying in the CdS (0001) plane. Later, two kinds of platelets, differing in size, orientation, composition, and associated dislocations, were identified as resulting from a variation in growth conditions (2).

In this paper, the influence of growth conditions on microstructures directly observable in CdS:Cu single crystals by optical microscopy is described in terms of crystal perfection and a variety of decorated dislocations, some of which have not previously been identified in II-VI compounds.

Crystal Growth

The crystals were grown from the vapor phase in a pointed quartz tube which slowly advanced into a decreasing temperature gradient, as shown in Fig. 1, to produce boules 1-2 in. long and ½ in. in diameter (1, 3). The sintered CdS charge, containing the added impurity, sublimes at the temperature, T_{max}, and, as the growth run starts, the tip of the tube is at temperature T_2. In practice, the position of the tube is adjusted so that T_2 is 14°-20° lower than T_{max}. At the end of the run, the crystal boule is between the gradient temperatures, T_3 and T_4, at the moment when slow cooling to room temperature begins.

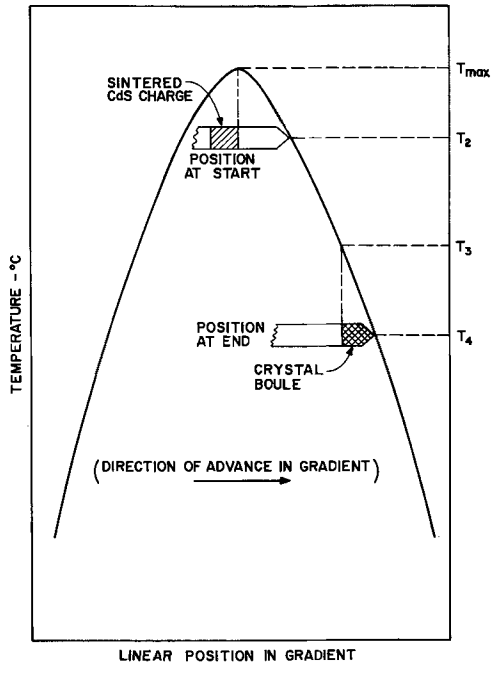

Fig. 1. Temperature profile and growth tube positions for preparing CdS crystal boules.

Although many parameters undoubtedly influence the growth characteristics of the crystal, the present work indicates that the amount and distribution of copper in the boule, the morphology of the precipitate phase, and the types of dislocations depend to some extent on T_{max} and $\Delta t = (T_3 - T_4)$. Grain boundary formation in the boule depends on T_{max} and also on the rate at which the growth tube passes through the gradient, slower rates favoring fewer grains. The results pertain to as-grown crystals slowly cooled at the same rate to room temperature, and will be illustrated with reference to crystallographically oriented, mechanically polished slices from representative boules.

Effects of Growth Conditions

Copper concentration.—The concentration of copper found in the boules is always less than that originally in the corresponding CdS charges, some copper (along with other impurities) concentrating in the unsublimed CdS.[1] This result, obtained consistently in many growth runs, was often obvious from the distinct difference in color and transparency between charges and the resulting boules. The observation was confirmed by chemical analyses. For example, 0.04-0.05 w/o Cu were found in two representative boules prepared with T_{max} at 1227°C, from charges containing 1 and 1.5 w/o copper. There was, in addition, an indication from only a few experiments that the final amount of copper in the boules may also depend on the particular T_{max} used, more copper apparently being incorporated at higher temperatures. A quantitative relationship between copper concentration and temperature has not been established, but this trend was suggested by chemical analyses of a few boules for which T_{max} differed by about 20°. For smaller differences, the effect was not well defined.

The total amount of copper in as-grown samples is partly in solid solution and partly precipitated. Examination of many boules revealed variations in the color and precipitation patterns of individual crystal slices from a given boule, thus showing that the copper is not always homogeneously distributed. In general, there is a larger amount of copper at the higher temperature end, T_3. This concentration gradient appears to result from the progressive change in charge composition caused by the fractionation effect, re-

[1] Similar fractionation effects have also been observed by others using this growth method (17).

ferred to above, and from the temperature difference across the boule as it grows. This difference, which reaches 40°-60° toward the conclusion of a growth run, is sustained by the boule for many hours, and it has previously been shown that temperature differences of 20° cause a similar marked segregation of copper in CdS crystals (4). Slight variations in precipitate segregation were occasionally found in adjacent regions of a boule over which the local temperature difference was small compared with Δt. Chemical analyses have shown that such samples may, nevertheless, have virtually the same amounts of total copper. These effects are influenced by slight fluctuations in growth rate and are related to a temperature dependence of solubility (5).

Precipitation and dislocations.—Precipitation in the interior of a CdS:Cu crystal grown with T_{max} = 1228°C, and containing about 0.05 w/o copper, occurred in the form of rods with a tendency to align in hexagonal arrays in the basal plane (1). However, other boules, grown in the same way, but with T_{max} =1217°C, had the same final amount of copper, but entirely different precipitation patterns and dislocation arrays which will be described. Temperatures were maintained at ± 1°-2° as shown by periodic, recorded monitoring for extended periods. This variation would occur as a gradual drift rather than as abrupt changes. The 11° difference between the nominal T_{max} values, which were the only deliberately altered parameter, is, therefore, regarded as a significant factor in determining the microstructure characteristics. Some contribution, however, from another, presently undefined parameter, is not entirely excluded. Previous evidence (1) indicated that the precipitate phase was copper sulfide; however, changes in composition may also accompany the changes in morphology.

Precipitation in the present crystals is characterized by randomly distributed particles and dislocation tangles. As viewed in the basal plane, the crystals often have relatively clear subgrains, partially denuded by preferential precipitation along the low angle boundaries that enclose them, as seen in Fig. 2. These boundaries extend in depth, approximately parallel to the c-axis, with many decorations emanating from them and extending into the clear areas in which the observed patterns change with the focal length selected.

Helical dislocations are among the several configurations observed in these crystals. The example in Fig. 3 shows evidence of climb, while others were clearly seen to be held up by precipitates in their paths. Heavier local precipitates, similar in appearance to those acting as obstacles, are also found in linear arrays not directly associated with other dislocations. In Fig. 4, for example, the symmetry of the decorations taken in pairs suggests that they occur at sites where successive turns of a helical dislocation intersect the (0001) plane.

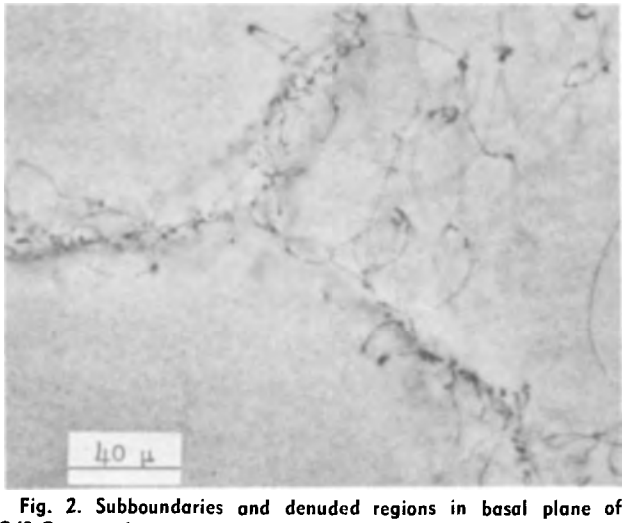

Fig. 2. Subboundaries and denuded regions in basal plane of CdS:Cu crystal.

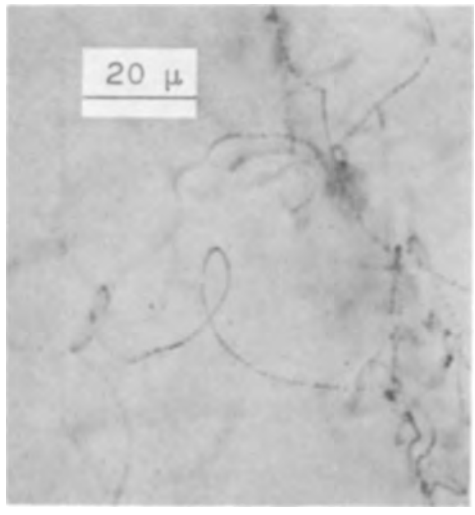

Fig. 3. Helical dislocation

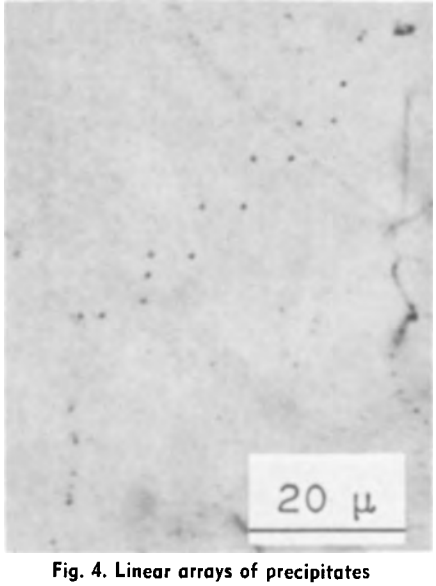

Fig. 4. Linear arrays of precipitates

Some illustrations of elliptically shaped loops lying in the basal plane with their major axis in crystallographic a-directions, are seen in Fig. 5A. The two loops in Fig. 5B lie in the [11$\bar{2}$0] direction, but one is about 10μ below the other. The formation of such a succession of coaxial loops may occur from the repulsion between successive turns of a growing helix as observed and discussed by Dash for the formation of prismatic loops in silicon doped with gold (6). When the present work was concluded, Möhling and Peibst (7), employing the Lang technique, reported their observation of helical dislocations and prismatic rings in pure CdS platelets. These configurations were also thought to have been formed by the Dash mechanism, and even in the pure crystals, the presence of trace impurities was believed necessary for the generation and climb of the dislocations.

Another typical dislocation form is comprised of two curved segments extending toward each other from subboundaries to meet at a cusp where a more prominent circular precipitate is found. Often, several parallel systems of this type are grouped together as

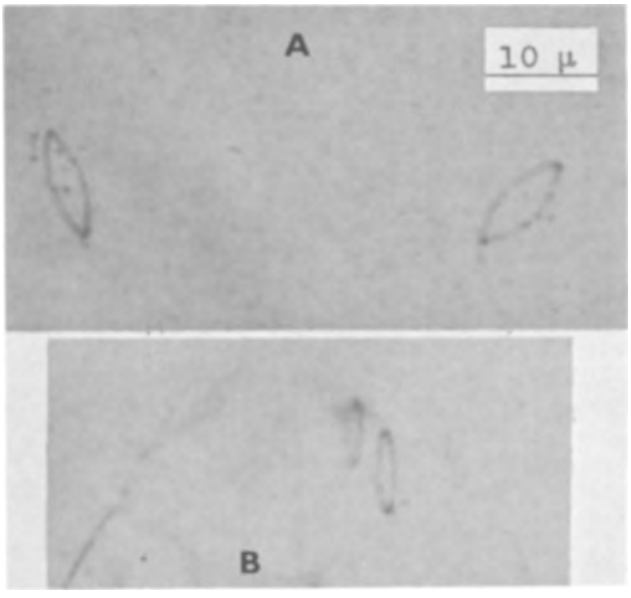

Fig. 5. Dislocation loops in basal plane

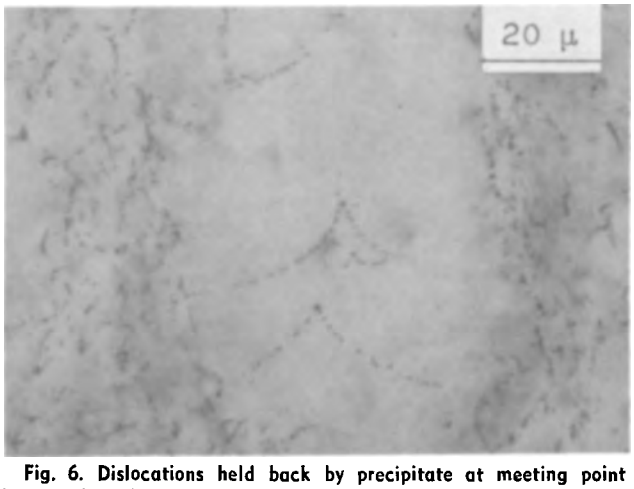

Fig. 6. Dislocations held back by precipitate at meeting point between boundaries.

shown in Fig. 6. Although these curved decorations generally lie in the basal plane, a portion of an arm will occasionally incline into the crystal. Other similar hairpin-like configurations, not necessarily between boundaries, have additional parallel extensions as in Fig. 7A, or segments closer together as in Fig. 7B. All of these formations are suggestive of dislocation dipoles that can result from an obstacle in the path as discussed by Gilman and Johnston (8), and Stokes and Olsen (9). Barber and Tighe (10) have pointed out that a smaller obstacle results in a larger curvature of a dipole.

An example of well-formed cardioid decorations observed within these hexagonal crystals, is shown in Fig. 8. Configurations of this type suggest the operation of a Frank-Read source (11), or a recent modification by Damiano and Brown (12), to account for the generation and multiplication of dislocations nucleated at inclusions, to form closed loops in a (0001) plane of hexagonal zinc crystals.

So far, only the new dislocations resulting from growth conditions employing a relatively low T_{max} have been described. It will now be shown that more rapid growth leads to the formation of gross defects. The growth rate can be affected by increasing either T_{max} or the rate of advance into the gradient. It was found that even at 1234°C, or at a rate of 0.02 in./hr (twice the usual rate) the boules contained more grain boundaries and polygonized regions. The boundaries of

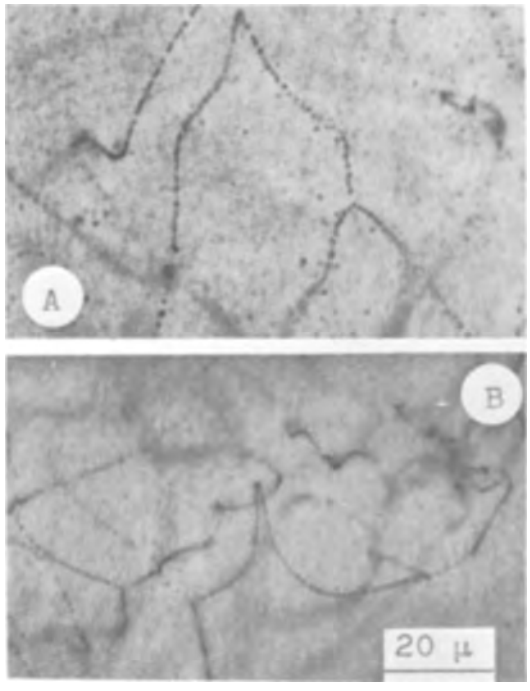

Fig. 7. Dislocation dipoles in (0001) plane

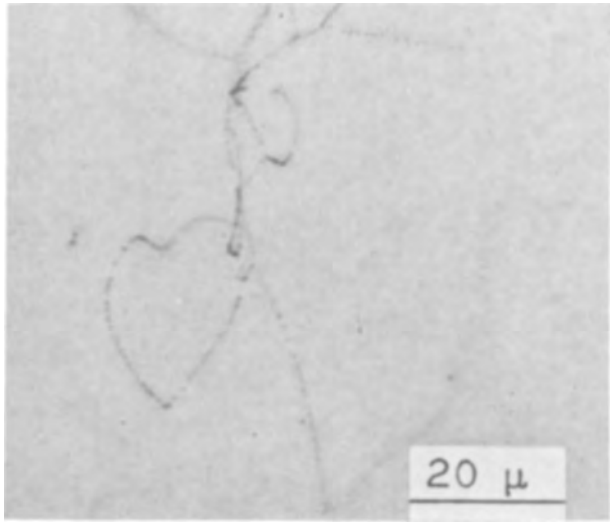

Fig. 8. Cardioid dislocation in basal plane

the hexagonal polygonization network shown in Fig. 9, for example, are decorated with disk-shaped precipitates[2] previously found to occur in single crystals with copper concentrations of about 0.8-1.0 w/o (1). This heavy segregation at the boundaries has substantially denuded the enclosed regions, many of which nevertheless contain rod-like precipitates characteristic of 0.2 w/o copper (1).

In another crystal, the grain boundary shown in Fig. 10 extended along the entire boule, parallel to the growth axis, and it can be seen that here, also, the preferential precipitation along the boundary has denuded the surrounding areas. The grain below the boundary has a (0001) face parallel to the plane of observation, while the angular misorientation of the upper grain is 17° with respect to the c-axis. The boundary extends through the crystal inclined at an angle of 10° to the plane of observation. The lines visible in Fig. 10B, extending into this region, are not

[2] Some details, such as the shape of the precipitates in this case, can be seen with greater clarity under the microscope than they can in the photomicrograph.

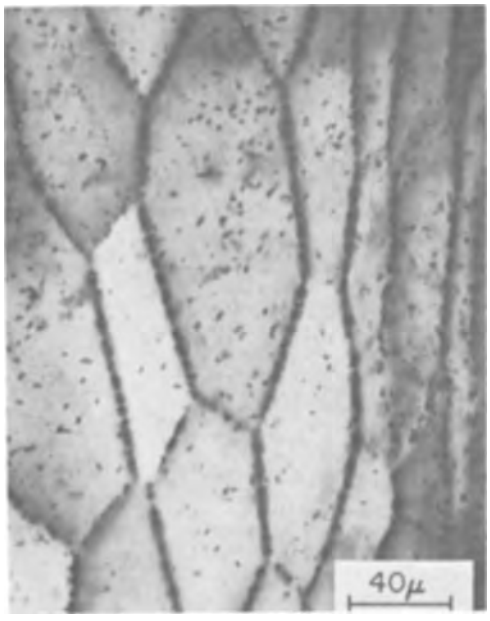

Fig. 9. Polygonization in CdS:Cu crystal

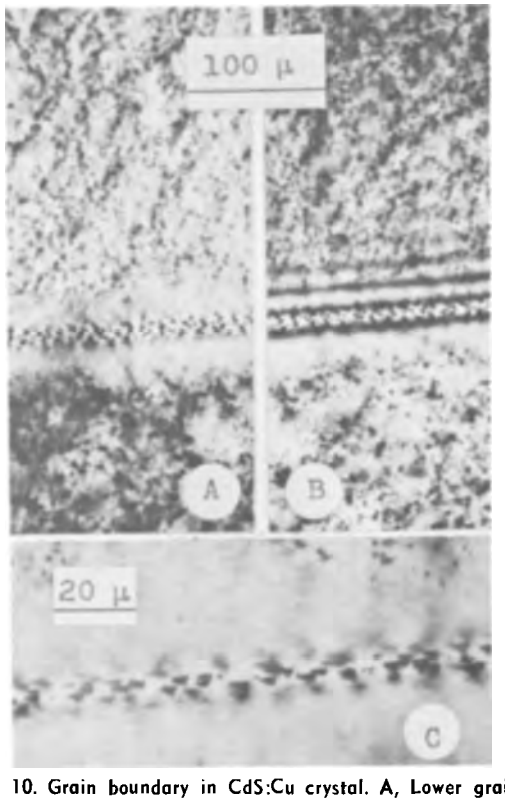

Fig. 10. Grain boundary in CdS:Cu crystal. A, Lower grain with (0001) face, upper grain misoriented by 17°; B, same field between crossed polaroids showing strain birefringence bands; C, high magnification showing discrete triangular precipitates in boundary region.

dislocation lines, but rather strain birefringence bands seen between crossed polaroids. It is noteworthy that in this higher energy boundary region, the nature of the precipitate is quite distinct from that in either grain. The outstanding differences, as seen under high magnification in Fig. 10C, are the larger size and triangular shape of the discrete platelets which are oriented with their bases along a $[2\bar{1}\bar{1}0]$ direction, and an apex pointed in a $[01\bar{1}0]$ direction toward the lower (0001) grain.

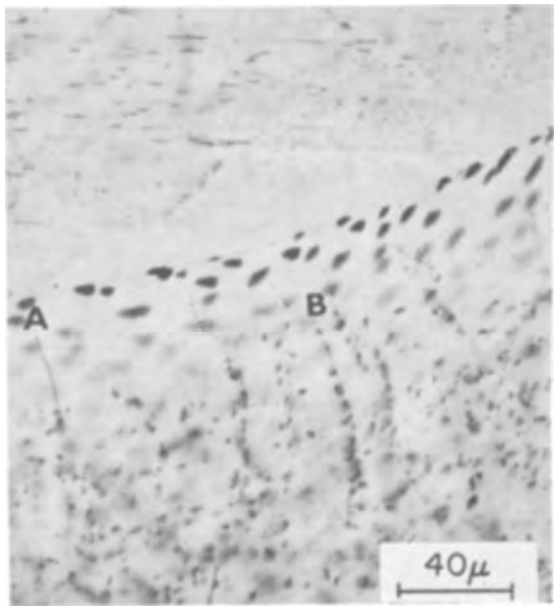

Fig. 11. Grain boundary in CdS:Cu crystal with greater misorientation than in Fig. 10; upper grain, $(10\bar{1}0)$ face; lower grain—c-axis inclined away from boundary at 29° angle. Note larger size of boundary precipitates compared with Fig. 10C, and dislocation lines at A and B.

Another example of this kind of boundary, in a similar crystal, is shown in Fig. 11, but here there is an even greater crystallographic misorientation of the two grains. The upper grain is a $(10\bar{1}0)$ face in which the precipitate needles are normal to the c-axis, [0001], and parallel to the a-direction, $[11\bar{2}0]$. Although the boundary itself does not lie entirely in this $[11\bar{2}0]$ direction, a flat side of the larger precipitates in the boundary region, is oriented this way. In the lower grain, the c-axis is inclined at an angle of 29° to the face, rotated away from the boundary about an a-axis approximately parallel to the $[11\bar{2}0]$ direction in the upper grain. The discrete precipitates in this boundary are almost twice the size of those in Fig. 10C, suggesting that different energies are associated with the two boundaries. Changes in these boundary precipitates have also been observed as a function of the impurity concentration in the grains. Similar effects, related to the orientation of grains have been reported for precipitation along boundaries in metals (13, 14). These effects may also depend on differences in nucleation rates within boundaries and on differences in precipitate growth rates which result from the more rapid solute diffusion along the boundaries (15). It is possible that there is also a local variation of composition (16).

Although these boundaries seem to be the source for some dislocations (at A and B, Fig. 11, for example), there is no extensive system of tangles as with the sub-boundaries previously described (see Fig. 2). The reason may be related to differences in local energies associated with the two kinds of boundaries.

Summary and Conclusions

Effects of growth conditions on large, vapor phase grown crystals of CdS:Cu have been examined. The concentration of copper incorporated in a boule has some dependence on the sublimation temperature, while its distribution in the crystal is sensitive to temperature differences that exist during growth and cooling. Crystals prepared using a sublimation temperature of about 1217°C often have dislocation tangles and sub-boundaries that act as sources for dipoles and

helices from which single loops are also formed. Cardioid decorations suggest the operation of a modified Frank-Read mechanism. If crystal growth is too rapid, polygonization and grain boundary formation increase. The boundaries act as sinks for precipitates which differ in geometry and size from particles in the grains. The size is affected by the degree of misorientation between grains.

Preparation and Properties of Pyrolytic Silicon Nitride

V. Y. Doo, D. R. Nichols, and G. A. Silvey

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Silicon nitride has very attractive electrical, physical, and chemical properties which are of great interest for microelectronic devices. Until recently, most methods that have been reported in literature produce silicon nitride in the form of powder, needles, ribbons, or flakes. Recently, Sterling and Swann reported that continuous films of silicon nitride have been obtained. A new pyrolytic method for preparing pinhole-free continuous silicon nitride film is described. Films have been successfully prepared in the temperature range of 750°-1100°C. Some physical and chemical properties of those films are summarized.

Silicon nitride has many attractive properties, such as high electrical resistivity (~10^{14} ohm-cm), high dielectric strength (~10^7 v/cm), and extremely high resistance against chemicals, which are of great interest for microelectronic devices.

Several methods (1-6) of preparing silicon nitride have been reported in the literature. Most of those methods yield silicon nitride in the form of powder, needle, ribbon, or flake. Commercial silicon nitride particles are produced by heating elemental silicon in either nitrogen (1-3) or in dehydrated ammonia (4). Silicon nitride powder also has been prepared by heating silane and dehydrated ammonia (5). Sterling and Swann (6) reported that silicon nitride film has been obtained by the reaction of silane and ammonia at a pressure of about 0.1 Torr under r.f. discharge. Kuntz (9) reported preparation of nitride films by the reaction of silicon tetrafluoride with ammonia in the temperature range of 1200°-1900°C.

Film Preparation and Structural Properties

In the pyrolytic process described here, silane and ammonia react in the presence of excess hydrogen. It is known that silane decomposes at about 500°C. The presence of excess hydrogen suppresses the premature decomposition of silane. The deposition of silicon nitride is performed in a quartz reaction chamber. The apparatus is similar to that used in silicon epitaxial growth. The gases are mixed prior to entry into the reaction chamber. The flow rate of hydrogen is 4 liters/min with the silane-to-ammonia ratio of 1 to 20-40. The substrate temperature ranged from 750°-1100°C. The substrates used were single crystal silicon unless otherwise specified. The growth rate (G) is plotted as

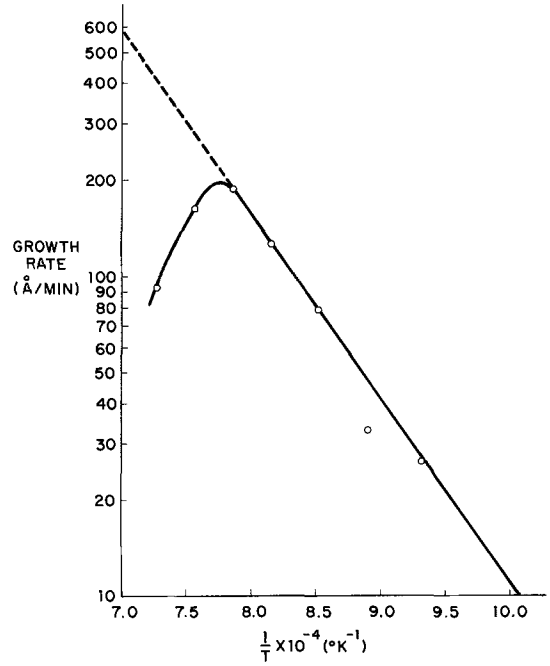

Fig. 1. Growth rate vs. inverse of substrate temperature

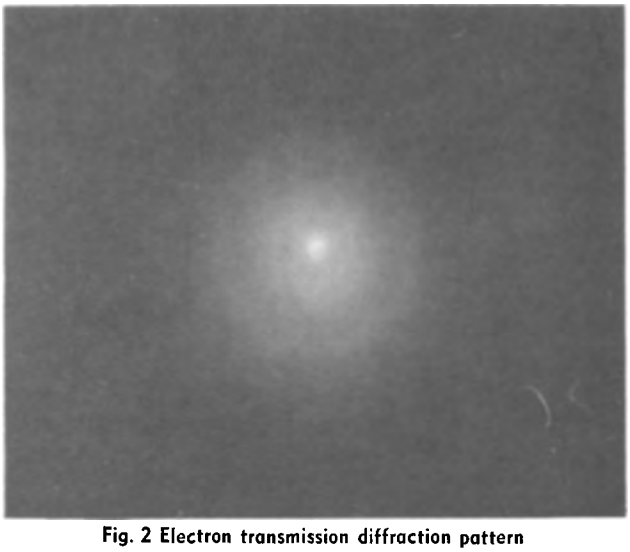

Fig. 2 Electron transmission diffraction pattern

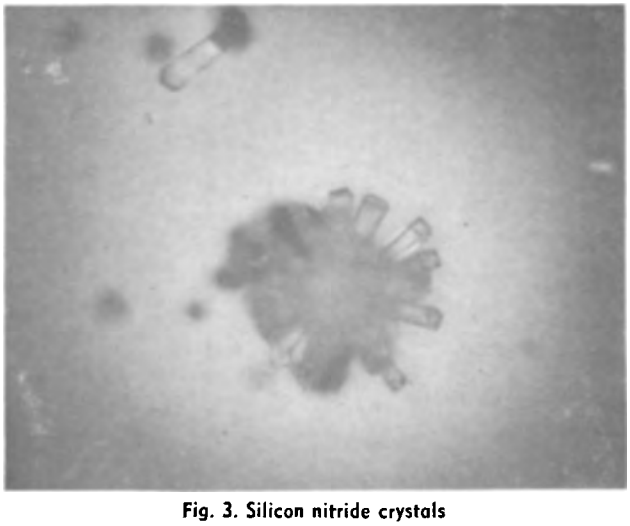

Fig. 3. Silicon nitride crystals

a function of reciprocal temperature ($1/T$) as shown in Fig. 1. Note the maximum growth rate occurred at 1000°C. In the temperature range between 750°-1000°C, the points are essentially on a straight line from which an activation energy of about 26.5 kcal/mol was obtained. The decrease in growth rate at temperatures above 1000°C is probably caused by the depletion of silane in the region near the substrate due to the premature decomposition of silane.

The structure of the silicon nitride films was investigated. The transmission diffraction pattern shows two very diffused rings as shown in Fig. 2. This indicates that the films are amorphous. The transmission electron micrographic examination confirmed this conclusion. Scattered large crystals of silicon nitride, however, were observed on films grown at 1100°C. Figure 3 shows some of those crystals.

Cracks have been observed on thick silicon nitride films ($>1\mu$) deposited on silicon substrates. The density of cracks increases with increasing film thickness and film growth rate. Usually cracks started to appear on films grown at 500 Å/min. Figure 4 shows an extremely high density of cracks on a 4μ thick film was grown at 950°C with a growth rate of 850 Å/min which is a factor of seven higher than the normal rate. Cracks were also found on films less than 1μ thick after annealing at high temperatures. Figure 5 shows the cracks of a 0.7μ film after annealing for 15 min at 1200°C in a nitrogen atmosphere.

Occurring with the cracks was substrate warping along an axis almost perpendicular to the cracks. The

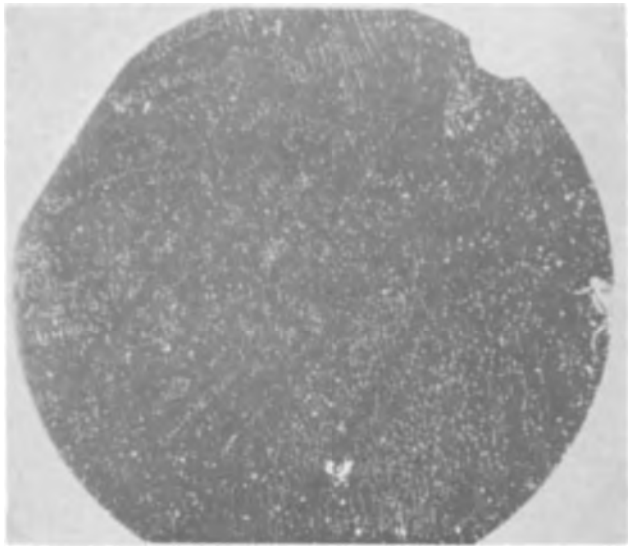

Fig. 4. Cracks on a 4μ silicon nitride film grown at 950°C at unusually high rate (850 Å/min).

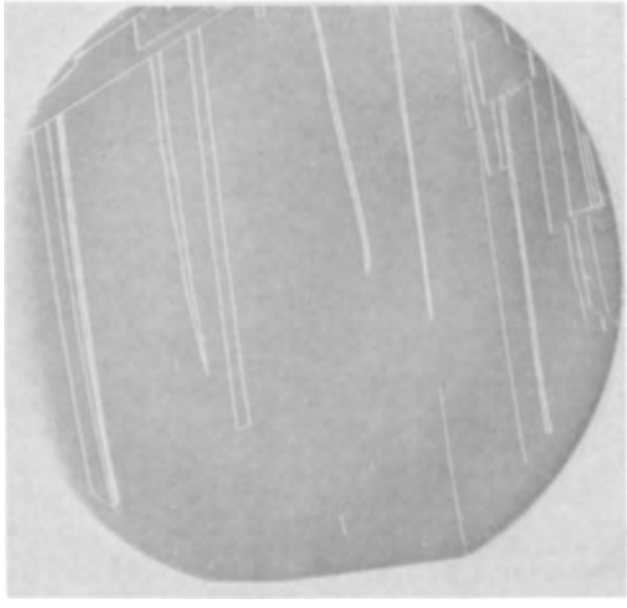

Fig. 5. Cracks on a 0.7μ silicon nitride film after annealing at 1200°C for 15 min.

cracks and warping apparently are caused by strong interfacial stresses between the silicon nitride and silicon substrate. The origin of the interfacial stresses was not determined. The structural mismatch, the difference in thermal expansion coefficient, and the densification of the film during annealing could have generated sufficient interfacial stresses to cause cracking and warping.

Physical and Chemical Properties

Some physical and chemical properties of the silicon nitride films have been investigated. The infrared absorption peak of commercial silicon nitride crystals is reported at 10.7μ (7). Sterling and Swann (6) reported that the IR absorption peak of the silicon nitride films prepared by r.f. discharge is very broad, from $10\text{-}14\mu$ with a maximum at 12μ. The films prepared by the pyrolytic process show a peak from $10\text{-}12\mu$. Figure 6 shows a typical IR absorption spectrum. No shifting of the peak position was detected after the film was annealed in nitrogen 3 hr at 1100°C.

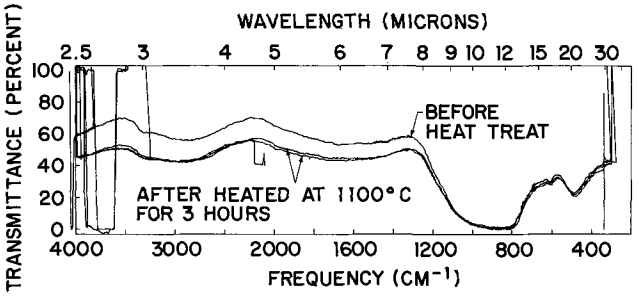

Fig. 6. Infrared spectrum of silicon nitride film, as grown and after annealing at 1100°C for 3 hr in N_2 atmosphere.

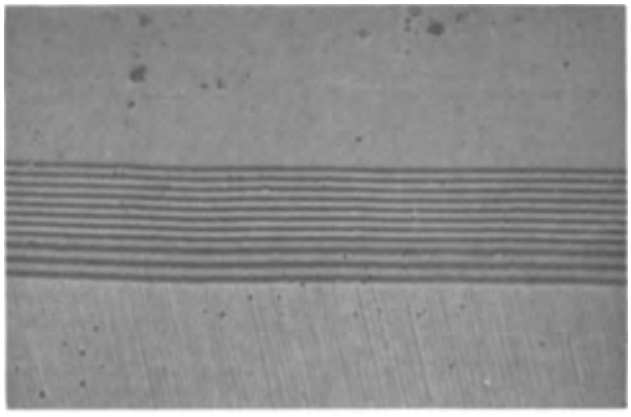

Fig. 7. Interference fringes of silicon nitride deposited on a SiO_2 coated-silicon substrate.

The index of refraction was determined by measuring the film thickness and the number of interference fringes from a monochromatic incident light whose wavelength is known. Figure 7 shows the interference fringes on a bevel of the silicon nitride film which was deposited on an oxidized silicon substrate. Note the difference in inter-fringe spacing between the silicon nitride and silicon dioxide that was caused by their difference in index of refraction. Since the index of refraction of steam oxide is known, the measured difference in inter-fringe spacing provides another method of determining the index of refraction of the silicon nitride film. The measured index of refraction of silicon nitride is about 2.0-2.06.

The dielectric constant was determined by capacitance measurements. Aluminum dots of about 0.1 in. diameter were evaporated onto the film. The capacitance between the aluminum dot and the silicon substrate was then measured. The measured capacitance per unit area is plotted against the reciprocal of film thickness as shown in Fig. 8. The straight line indicated in the figure corresponds to a dielectric constant of 6.34 $\pm$ 0.08.

The density of the commercial silicon nitride crystals is 3.44 g/cm³ (8). The pyrolytic silicon nitride films showed a density of 3.02-3.21 g/cm³.

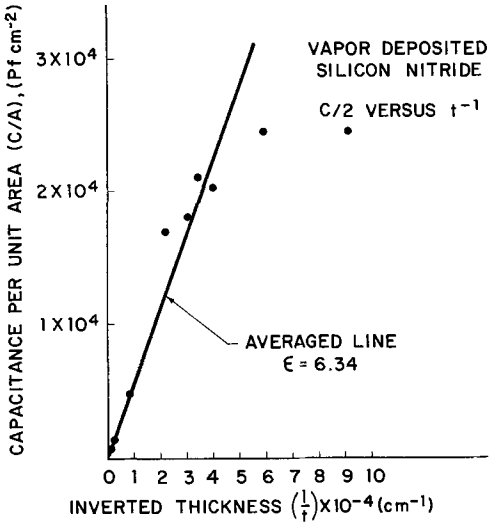

Fig. 8. Capacitance per unit area vs. reciprocal film thickness

The dielectric strength of the silicon nitride was determined by the breakdown voltage of approximately 10^7 v/cm.

As previously stated silicon nitride has extremely high resistance to chemicals. Only hydrofluoric acid attacks it at room temperature. The etch rate of the as-grown films in 48% HF at room temperature was found to be 75-100 Å/min. Because of its high chemical inertness, the permeability to impurity diffusion of silicon nitride may be very low. In diffusion experiments, it was found that many impurities which silicon dioxide fails to mask are held back by silicon nitride. The results of those experiments will be reported subsequently.

Acknowledgment

The authors wish to thank Dr. R. E. Jones and Messrs. J. S. Makris and J. Regh for their assistance in this investigation.

Semiconductor Joining by the Solid-Liquid-Interdiffusion (SLID) Process

I. The Systems Ag-In, Au-In, and Cu-In

Leonard Bernstein

Research & Development Laboratory, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

The acronym SLID is used to describe a process whereby high-temperature phases are formed by diffusion in the presence of liquid. A technique is discussed which utilizes these phenomena in producing high-temperature-stable bonds which have been fabricated at low temperatures. The binary systems Ag-In, Au-In, Cu-In among others exhibit these characteristics. Photomicrographs and electron probe microanalysis data are presented to identify and describe the phases formed in these bonds. Some applications for the use of this joining technique are suggested in addition to the feasibility of extending this method to the use of ternary and higher order alloy SLID systems.

Semiconductor device fabrication, electronic component part assembling, and all other sequential processes which require a number of brazing or soldering steps, have, for a long time, been hampered by the fact that successive operations must be performed at lower and lower temperatures to avoid remelting and the possibility of disturbing a joint made in a previous operation. In many cases, this severely limits the use of the particular component. For example, a device which requires five soldering operations during assembly might use at its last stage an alloy whose melting point is so low that it would be virtually destroyed in use under any conditions that were the least bit severe. In addition, many of the inherent properties of the materials and device characteristics may never be realized due to limited operating temperatures imposed by the low-temperature processes and/or materials. Another shortcoming of conventional bonding techniques is that components can be rated at no higher temperatures than that temperature at which the assembly operation was performed.

It was therefore concluded that if some multicomponent system for bonding materials could be designed, which did not have the built-in temperature limitations, it would find immediate practical application.

Many of the properties of metals and alloys are structure sensitive. The phases which occur in alloys and constitute their structure are represented as areas of homogeneity in equilibrium phase diagrams. By developing or removing these phases, one of the properties of systems that can be changed irreversibly is the melting range of the constituents of the system. If this can be accomplished while a metallurgical bond is produced between two components, then this bond, if its components undergo a phase transformation, can melt at a different temperature than that at which its transformation occurred (the temperature at which the bond was made).

It is the purpose of this paper to describe a technique whereby bonds can be made at a low temperature and subsequently withstand higher temperature use. If necessary, these bonds can withstand further fabrication processes without melting or otherwise being adversely affected. The physical mechanisms describing these phenomena can be understood by a study of phase equilibria and diffusion theory. This process occurs by solid-liquid interdiffusion, hereafter referred to as SLID. This differs from conventional diffusion or wide-gap brazing techniques which may or may not occur in the presence of liquid phase but which do, however, rely on diffusion into the bulk body to be bonded to for their properties. SLID, since it most generally requires a separate preform, requires diffusion to occur within its self-contained structure only.

Although many systems are capable of producing bonds meeting the aforementioned requirements, this paper will concentrate on a discussion of experiments in the three simple binary systems: Ag-In, Au-In, and Cu-In. As seen from the discussion in the section below on Theory, this joining technique relies on the use of a laminated system, in which at least one layer is composed of a low-melting phase (in this case indium) and at least one layer is high melting (*i.e.*, Au, Ag, Cu, etc.).

From the theory and experimental data presented, other binary, ternary, and complex multicomponent systems having similar characteristics will be suggested.

Although the terms brazing and soldering have been strictly defined by both the American Welding Society and American Society for Metals by a fabrication temperature criterion, they have in common usage come to mean much more. For example, soft solders, in addition to being used at temperatures below 800°F, are accepted as being composed of the elements Pb, Sn, In, Bi, etc. Hard "solders," on the other hand, are by strict definition really brazes. They are primarily composed of the precious metals. The hard solders have properties such as strength, thermal conductivity, thermal fatigue, etc., differing greatly from the soft solders. With the growth of the semiconductor industry, a new class of alloys became generally commercially available. These materials such as the Au-Sn, Au-Ge, and Au-Si eutectics are used at soft soldering temperatures but have hard solder or braze properties. The materials used in this study are a combination of "hard" and "soft" solders. Since, the process is a diffusion limited one, however, the fabrication temperature may fall in either the strictly defined soldering or brazing range. It does have the capability, however, of being fabricated at low temperatures and having subsequent braze joint properties, such as remelt temperature, thermal conductivity and fatigue, strength, etc.

Review of the literature.—Much has been written in the past with regard to solid-state bonding of materials (1-11) utilizing diffusion phenomena and the physical mechanisms and principles describing and governing these phenomena (6, 12-31). With the growth of nuclear technology, new impetus was given to the interdiffusional aspects of diffusion bonding problems (32-38), particularly relating to the formation of intermetallic phases in fabricating clad fuel elements and isothermal mass transfer in liquid metals. A literature search indicated that very little had been written describing techniques utilizing the mechanism of liquid

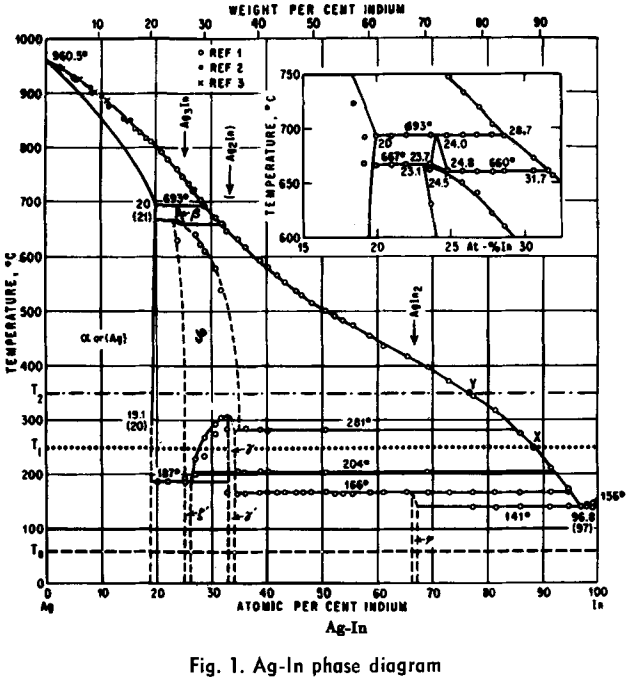
phase diffusion with its subsequent transformations to enhance bonding. Harman (39-42) extended the well known mercury amalgam techniques to gallium, limiting his study to powder mixtures, but attributed the high-temperature characteristics of the bond to a liquid phase sintering mechanism (41). A more recent study (43) describes some more practical liquid diffusion soldering techniques with particular emphasis on avoiding formation of pores and intermetallic compounds in the seam joints of structural members.

The semiconductor industry has created new problems pertaining to material interfaces subjected to elevated temperatures in fabricating electronic devices and in subsequent use (44-62).

Theory.—Many families of systems have characteristics which lend themselves to SLID bonding. These systems must have one component with a low melting point, and another with a high melting point and an equilibrium phase diagram such that elevated temperature processing will result in a phase transformation of the liquid component to a higher melting point material. Systems with peritectic reactions are typically of this type. Examination of the phase diagrams (63) shown in Fig. 1, 2, and 3 will aid in the comprehension of this phenomenon.

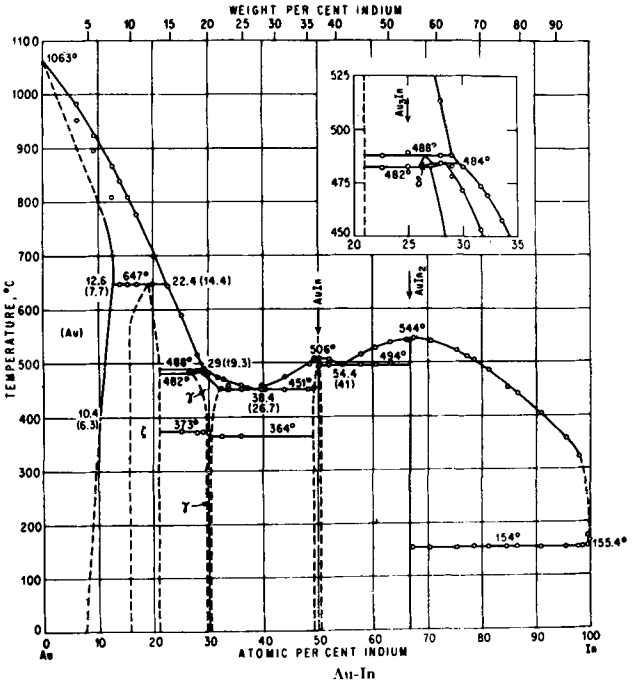
If one placed two blocks of silver and indium together and permitted them to lie in intimate contact for an extended period of time (days or weeks) at a temperature corresponding to T_0 in Fig. 1, (at this temperature no liquid phase is present at any time) there will develop layers in this system corresponding to each one-phase region crossed by this horizontal line T_0. These phases will form by isothermal diffusion. If diffusion is permitted to continue until close to equilibrium conditions are reached, according to Gibb's phase rule no more than two layers could exist in this system. These phases would correspond to any two adjacent phases of the system, depending on the gross composition of the sample. If the gross composition falls within a one-phase region, the system will be composed of but a single phase. Diffusion theory (6) dictates that there can be no two-phase layers in isothermal diffusion structures. All of the phases predicted by the equilibrium diagrams, however, do not always appear (33-35) as distinct layers (6, 64).

In the silver-indium system the following phases can be present at the same time at temperature T_0: α, ζ', γ', ϕ, and In.



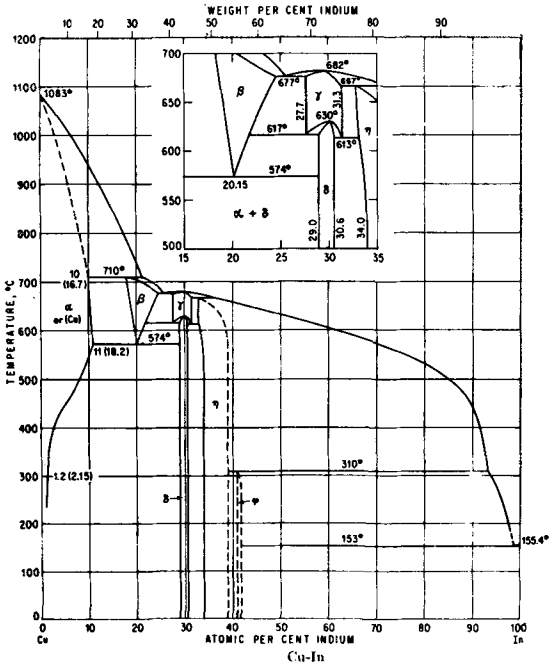
Ag-In

Fig. 1. Ag-In phase diagram



Au-In

Fig. 2. Au-In phase diagram



Cu-In

Fig. 3. Cu-In phase diagram

At temperatures above the melting point of indium, T_1 and T_2 shown in Fig. 1, this system can be used for producing high-temperature bonds. At temperature T_1, liquid indium will form and dissolve a given quantity of silver, as shown by composition X on the phase diagram. The saturated liquid will be separated from the silver substrate by finite layers of γ and ζ. Indium from liquid X will, in time, diffuse through γ and ζ while silver is diffusing in the opposite direction until complete transformation of the liquid to the solid phases takes place. As soon as the last of the liquid phase disappears, the system is capable of withstanding temperatures of greater than 600°C (the probable decomposition point of ζ) before liquid phase reappears. Only if the system were inadvertently heated to where liquid phase forms would danger (64) of creating a low-temperature bond exist.

At temperature T_2, indium from the liquid of composition Y need only diffuse through the ζ phase to complete the reaction with $\alpha : \alpha + \text{In} \rightarrow \zeta$.

The feasibility of producing high-temperature diffusion bonds in the presence of liquid phase was demonstrated by the work of a number of investigators. Castleman and Seigle (33) encouraged the growth of the high melting point phases δ and ϵ by annealing an Al-Ni diffusion couple above its eutectic temperature of 640°C. Lashko and Lashko (43) eliminated the liquid phase completely from the seam area of diffusion bonds in a variety of systems by annealing at elevated temperatures.

Powell and Braun (65), in their study of diffusion in the Au-In system below the melting point of indium, discovered inadvertently the effect of a molten zone, due to faulty temperature control, on the structure of the intermediate phases (see their Fig. 3b). The structural change associated with the phase transformation in turn affects the values for the diffusion coefficients. Investigating the mechanism of peritectic reactions, Sartell and Mack (64) pointed out the importance of structure and its effect on the nature of the diffusion process.

In the diffusion of Cd, In, and Sn in Ag, Tomizuka and Slifkin (6) found that, for temperatures below 600°C, the effects of grain boundaries become significant. Achter, Birks, and Brooks (67) in measuring grain boundary diffusion of Zn and Cu using electron-probe techniques determined that the ratio of grain boundary diffusion coefficient of lattice diffusion coefficient, D_B/D_L, to be approximately 10^6. Similar results were obtained for self diffusion in Ag by LeClaire (14) and in Ni by Upthegrove and Sinnott (68) with the ratios increasing with decreasing temperature. McLean (69) points out that, nevertheless, the diffusant will not usually penetrate much further along the grain boundaries than through the lattice, because the diffusing substance, when it has travelled further along a boundary, will diffuse sideways into the single crystals neighboring the boundaries. With diffusion times on the order of 100 hr, D_B/D_L must be approximately 10^5 for grain boundary diffusion to penetrate twice as far as lattice diffusion.

The Au-In (55) and Cu-In (55) systems, shown in Fig. 2 and 3 can be expected to produce bonds capable of withstanding minimum temperatures of 451°C and 667°C, respectively, after complete liquid diffusion. The physical mechanism accounting for SLID bonding in these systems is similar to that described for the Ag-In system.

The SLID process goes through five distinct stages during the bonding cycle:

Wetting.—During this stage the conventional surface free energy relationships (45, 70-84) play primary roles in achieving optimum wetting.

Alloying.—During this stage there must be some liquid solubility, even if only extremely limited, of the high melting component or components and the surfaces to be bonded, in the low melting phase or phases. This stage terminates when the liquid is completely saturated according to the appropriate phase diagram.

Liquid diffusion.—In this stage the liquid and solid components begin to interdiffuse to form more of the high melting point components.

Gradual solidification.—The quantity of liquid phase diminishes and the bond gradually solidifies until all liquid disappears.

Solid-diffusion.—During the preceding two stages, diffusion in the solid state is also taking place, but after complete solidification, solid diffusion is the only mechanism driving the reaction to equilibrium as dictated by the appropriate phase diagram.

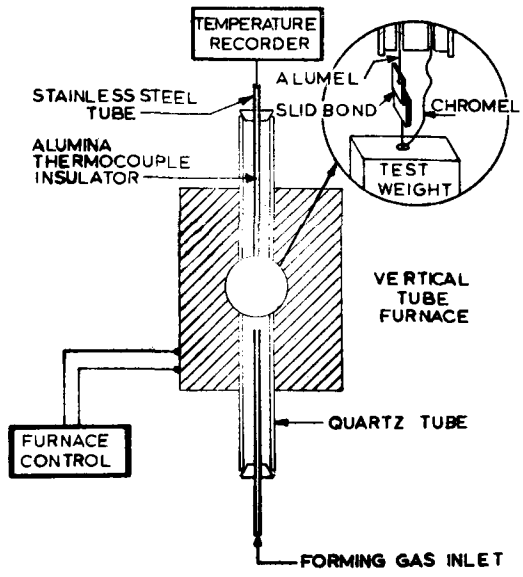


Fig. 4. Apparatus for determining unbonding temperatures of SLID bonds.

Experimental Procedure and Results

Clad materials were chosen for the preforms for SLID bonding. Three variables, temperature, time, and gross composition, control the process. Temperature was varied between 200°-450°C; time from 10-120 min; gross composition was controlled by adjusting thickness of layers such that equilibrium composition was always in the solid solution region. All bonds were made in a tube furnace in a gas ambient (hydrogen, forming gas, nitrogen or argon) low in oxygen or water vapor using parts 0.175 x 0.250 in. stamped from clad sheets, 5-40 mils thick.

The formation of internal In_2O_3 bands in silver-indium alloys has been studied by Rapp and coworkers (85) and the thermodynamic stability of In_2O_3 is well known (86). Oxygen and water vapor content therefore must be kept low to minimize their effects on wetting and diffusion. All parts were well cleaned using conventional cleaning and degreasing techniques. The importance of cleanliness and its effects on diffusion were pointed out by Rhines (6) and on bonding by Williams (5).

Bonded couples were evaluated in a furnace shown schematically in Fig. 4. To determine the temperature capabilities of the systems, the 0.175 x 0.250 in. parts were bonded in a lap joint configuration so that the bond area was approximately 0.175 x 0.175 in. The sample was suspended in the hot zone of a vertical tube furnace connected to a chromel-alumel thermocouple via a clamping fixture. A weight was hung from one leg of the thermocouple wire, which placed the couple in tension, in such a way that when the sample broke, the thermocouple circuit would open. The load on the bond was applied as a shear stress, and it was assumed that when continuous liquid phase formed in the interfacial bond region, rupture would occur. As a calibration of the test equipment used, rupture tests were periodically run on standard simple eutectic bonds (Au-Sn mp 280°C; Au-Ge mp 356°C; Al-Si mp 577°C; Ag-Cu mp 779°C) which always broke within 3°C of their respective melting points.

After bonding, samples were prepared metallographically by angle (approximately 15°) lapping. Some samples were subjected to electron probe x-ray microanalysis (87) for phase identification in the bond regions.

Figures 5, 6, and 7 show the high temperature results of some SLID bonds made in the Ag-In, Au-In, and Cu-In systems respectively. The anomalous low-tem-

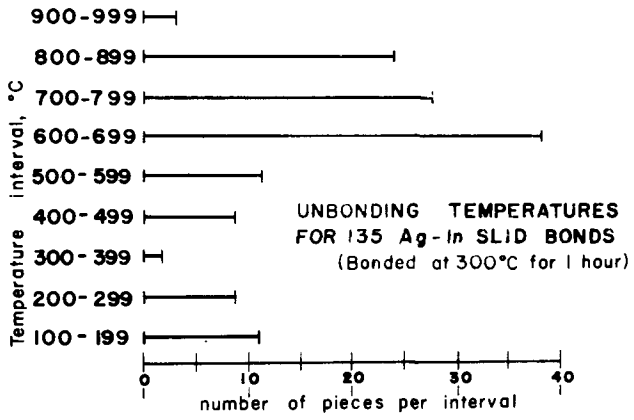

Fig. 5. Unbonding temperatures for Ag-In SLID bonds

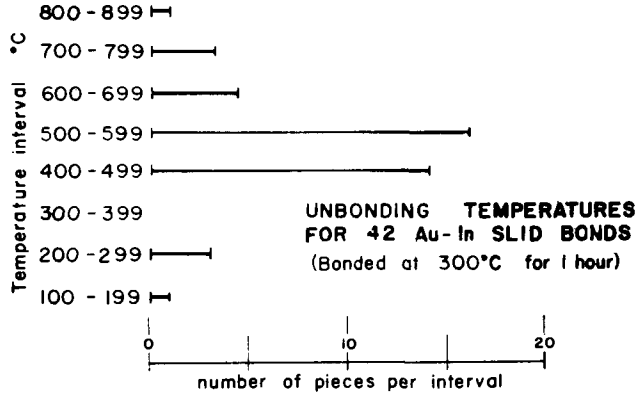

Fig. 6. Unbonding temperatures for Au-In SLID bonds

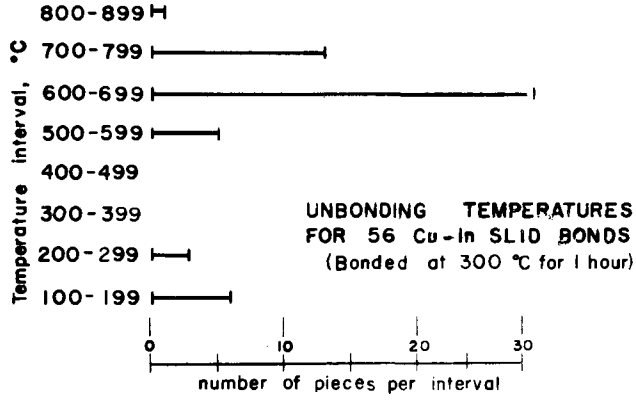

Fig. 7. Unbonding temperatures for Cu-In SLID bonds

perature ruptures found in all three binary systems were correlated with incomplete transformation to high-temperature phases in the interface. This is thought to be due to only partial completion of one or more of the five bonding stages for reasons such as poor wetting, unsatisfactory mating of parts, the kinetics of a particular reaction, etc. In the silver and copper systems, this anomaly accounted for 16% of the units tested; in the gold system, 9%. In one ternary system investigated (88), no low-temperature results were observed, possibly due to the lesser sensitivity of this system to the aforementioned effects.

Table I shows the results of electron probe x-ray microanalysis on some of the bonds made. In Table II the identification and extent of formation of phases in the Ag-In system is shown as observed from metallographic taper sections of SLID bonds. Tables III and IV show similar results, respectively, for the Cu-In and Au-In systems. Figures 8-13 are photomicrographs of some of the bonds identified in the previous tables.

Some hybrid bonds were made for the purpose of determining feasibility of the technique in complex systems. These were made in the following systems: those involving a third or fourth element; those to silicon surfaces; and those to surfaces in order to produce hermetic enclosures. The results were described in detail elsewhere (88). In general, however, it can be reported here that in those cases in which the phase diagrams indicated a favorable condition, SLID bonding occurred.

Table I. Electron probe x-ray microanalysis of interfacial bond regions

Sample No.	Bond	Diffusion cycle	Phase chemistries (analytically measured in wt %)	Probable interface identification

36	400°C/30 min	Major: α solid solution Major: Ag_2In

* Black and white photomicrography is unable to distinguish subtle color differences between phases which the eye can. These tables therefore may differ from the corresponding figures.

Discussion

It appears on examination of cross sections that there is most liquid available for bonding in the Ag-In system and the least in the Au-In system for a given temperature level. These observations agree with what one would expect from the phase diagrams. From Tables III, IV, and V, the interdiffusion of indium is greatest with gold and least with copper. Wetting of

* All phases present, at all temperatures, appear as continuous bond structures except the black and white phase which is discontinuous.

Fig. 8. Ag-In SLID bond made at 200°C for 30 min. Etchant: 2g $K_2Cr_2O_7$, 8 ml H_2SO_4; 4 ml NaCl (sat. sol.), 400 ml H_2O; swab for 10 to 30 sec; at temperatures as low as 200°C transformation of indium to higher melting phases is complete.

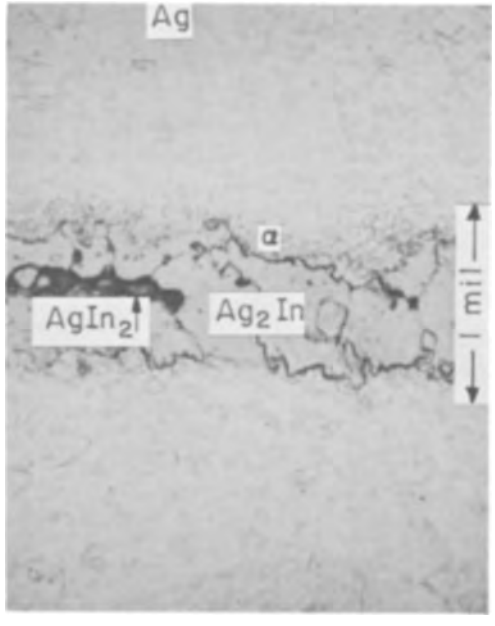

Fig. 9. Ag-In SLID bond made at 300°C for 30 min. Etchant: same as Fig. 8. The darkened area of the silver adjacent to Ag_2In is solid solution.

the indium to Ag, Cu, or Au appears to be most critical in the silver system, probably due to its high oxygen solubility, and least critical in the gold system.

From the high-temperature rupture results shown in Fig. 5, 6, and 7, bonds made at 300°C in these systems withstood subsequent loads at 400°-900°C in most cases. These results have been correlated with phases identified in the bond regions and shown in Tables II, III, and IV.

Ag-In *system.*—At temperatures up to 400°C for 30 min no Ag_3In could be detected either metallographically or by electron probe techniques. It would be interesting to photograph the α-Ag_2In interface with an electron microscope in an attempt to detect this phase which should exist according to diffusion theory. All of the phases formed during the diffusion cycles grew in layers only. We would, therefore, not expect any short-circuiting effects in diffusion usually associated with columnar phase growth. When bonding at 300°C and above, for all practical purposes, only high-temperature phases exist.

Cu-In *system.*—Although all of these bonds withstood elevated temperatures without rupturing, electron probe results and metallographic analysis seem to indicate that some lower melting phases persist even at the 400°C diffusion cycle. The phase transformation in this system does seem sluggish. Perhaps the black and white phase which shows up in Fig. 12, but unfortunately not in Fig. 13 is very discontinuous, thereby enabling one to apply a load to the bond region up to temperatures at which the copper-rich

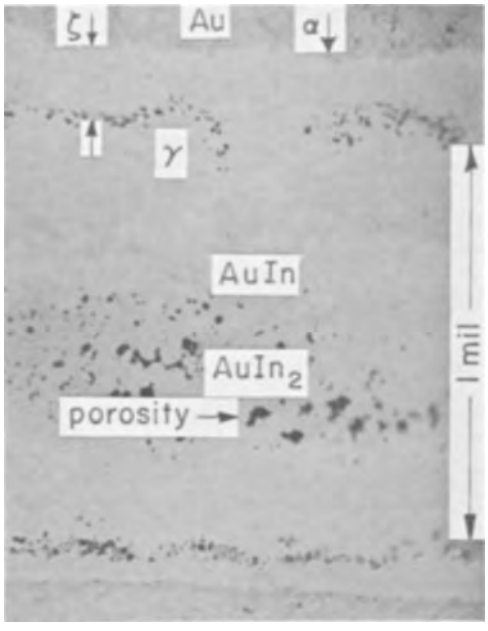

Fig. 10. Au-In SLID bond made at 250°C for 30 min. Visual identification is clearer than B&W photomicrographs due to the vivid color contrast of phases. Porosity shown in center is due to factors such as mating and pressure not investigated in this study.

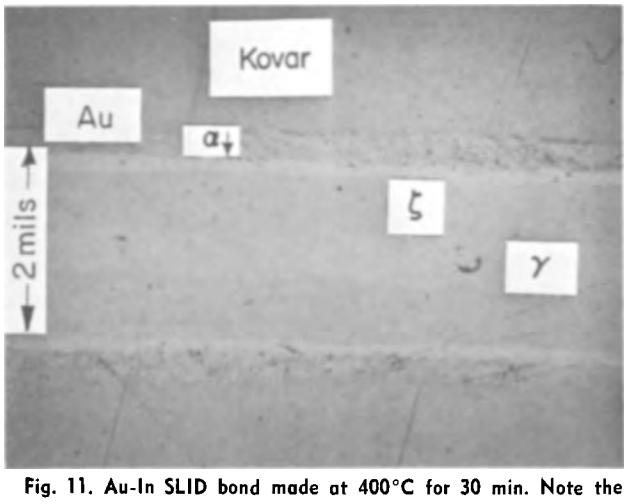

Fig. 11. Au-In SLID bond made at 400°C for 30 min. Note the complete absence of voids and phases richer in indium than γ.

phases melt. Results shown in Fig. 7 indicate this possibility.

Au-In *system.*—This system produced the most colorful phases. Transformations occurred very rapidly and at very low temperatures. Table IV shows that an increase of time at 200°C from 10 to 30 min resulted in a decrease in the quantity of the lowest melting phase in the bond area from 80% of the volume to a minor portion. At 250°C and above, the structure is composed entirely of high melting phases. At 250° and 300°C small voids appear in the interface between the ζ and γ phases. If the voids are the result of the Kirkendall effect it is not understood why they should not also appear at temperatures above 300°C. At temperatures of 350° and 400°C, voids entirely in the γ phase, appear, which are probably due to density difference between the phases.

Conclusions

The processes thus far described and experimented with are feasible, not only theoretically, but in a practical manufacturing process for producing high-temperature bonds using lower temperature processing

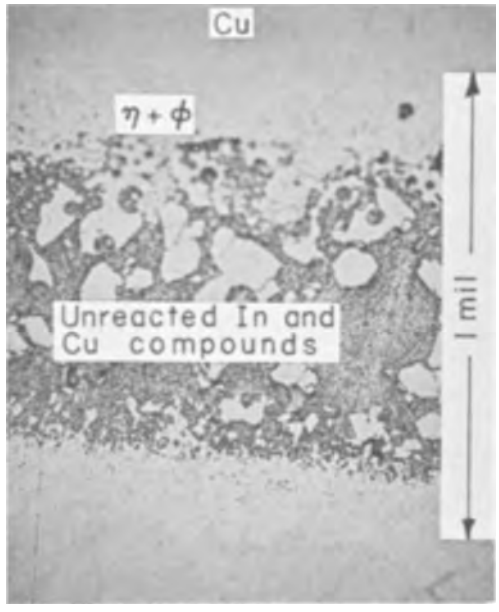

Fig. 12. Cu-In SLID bond made at 200°C for 30 min. Unreacted indium darkens in metallographic preparation due to pick-up of alumina abrasive.

conditions for a multitude of both semiconductor and nonsemiconductor brazing or bonding applications.

It is expected that by going to more complex systems, one could combine the effects of different elements to achieve optimum results. For example, the greater quantity of liquid in the Ag system compared to Au at comparable temperature levels together with the fast diffusion of the Au system would suggest a Ag-Au-In SLID bond; the improved oxidation resistance of tin alloys compared with indium might result in a Au-Ag-In-Sn system. The systems of Ni, Pd, Pt, Fe, Co, and Mn seem promising when combined with In and/or Sn. The specific contributions of other elements and fabrication techniques affecting the phase diagrams and diffusion phenomena provide unlimited conditions for future experiments.

Acknowledgments

The author would like to thank S. Prussin for the many stimulating discussions early in the investigation which led to the development of the technique and H. Bartholomew for the many suggestions and ingenious gadgets in addition to being a patient "sounding board."

Manuscript received Jan. 25, 1966; revised manuscript received June 1, 1966. This paper was presented at the San Francisco Meeting, May 9-13, 1965 while employed at Alloys Unlimited, Inc.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Superconducting Niobium Stannide (Nb_3Sn) Films on Metallic Substrates

T. L. Chu and J. R. Gavaler

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Niobium stannide, Nb_3Sn, has been transported from a sintered source material onto various substrates by hydrogen halides in the presence of a temperature gradient. The superconducting transition temperature of the deposited films was found to depend, among other factors, strongly on the separation between the source and the substrate. At large separations, the deposited films were nonstoichiometric due to the differences in reactivities of niobium and tin toward hydrogen halide and the ease of reduction of niobium and tin halides with hydrogen. At small separations, the films deposited on metallic substrates were found to have a superconducting transition temperature of 18°K and a critical current density of up to 6×10^4 amp cm^{-2} in magnetic fields of 50 kG.

Niobium stannide Nb_3Sn, a Type II superconductor, has been prepared by metallurgical and chemical techniques. The sintering of a stoichiometric mixture of the elements was the method first used to prepare this compound. Three intermetallic phases are known to exist in the Nb-Sn system. Nb_3Sn does not form below 805°±5°C and exists as an equilibrium phase up to the melting point of the compound, approximately 2000°C (1). Because of the brittleness of niobium stannide, the sintering process is usually carried out after a mixture of niobium and tin has been fabricated into its final form. Various techniques have been devised to produce niobium stannide wires capable of carrying currents higher than 10^5 amp cm^{-2} at 4.2°K in fields of 100 kG (2).

The sintering technique is not sufficiently flexible for producing niobium stannide in forms desirable for other purposes. Chemical approaches have produced interesting results. For example, the simultaneous reduction of mixtures of niobium and tin chlorides with hydrogen in a flow system has been used for the deposition of niobium stannide on substrate surfaces in the temperature range of 900°-1200°C (3-5). The chemical reaction is represented by the equation

$$3NbCl_4(g) + SnCl_2(g) + 7H_2(g) = Nb_3Sn(s) + 14HCl(g)$$

The reductions of niobium and tin chlorides show different dependence on temperature and on H_2/halide molar ratios because of their differences in activation energies and free energy changes. Thus, the composition of the deposited material depends on the substrate temperature and the composition of the reactant. Although deposited material with a composition deviation as much as 5% from stoichiometry was found to retain a single phase β-tungsten structure, this compositional variation resulted in significant changes in transition temperature (6). Thus, the stoichiometry of the deposited material, and therefore the control of substrate temperature and reactant composition are of extreme importance. Under proper conditions, niobium stannide has been prepared in various forms such as films on metallic substrates which have been used to construct solenoids capable of generating fields in excess of 100 kG (7).

Chemical approaches are more flexible for the preparation of niobium stannide. However, the thermal reduction technique requires the precise control of reactant composition and substrate temperature, and the yield of the reduction process is only moderate. We have investigated the usefulness of the chemical transport technique, because of its inherent simplicity, for the deposition of niobium stannide films on various substrates. Using this technique, niobium stannide has been efficiently transported from a sintered source material onto substrate surfaces by hydrogen halides in the presence of a temperature gradient. Aside from other factors, the superconducting transition temperature of the deposit was found to depend on the separation between the substrate and the source material. At small separations, the deposited films have transition temperatures of 18°K and a critical current density of up to 6×10^4 amp cm^{-2} in magnetic fields of 50 kG. The chemical transport of niobium stannide under various conditions and the properties of resulting deposits are described in this paper.[1]

Experimental

The transport of solid substances by chemical reactions has been used widely for the preparation of electronic materials during recent years (8). Niobium stannide reacts reversibly with hydrogen halides, such as hydrogen chloride and hydrogen bromide to yield a mixture of metallic halides. For example

$$Nb_3Sn(s) + 14HBr(g) = 3NbBr_4(g) + SnBr_2(g) + 7H_2(g)$$

Where $NbBr_4$ and $SnBr_2$ are assumed to be the predominant species. Since the hydrogen reduction of most metallic halides becomes thermodynamically more favorable at higher temperatures, hydrogen halides are capable of transporting niobium stannide from a low temperature region to substrates at higher temperatures. In the source region, hydrogen bromide reacts with the source material to produce $NbBr_4$, $SnBr_2$, and H_2, which are transported to the substrate region at higher temperatures. The reverse reaction takes place in the substrate region because of the change in temperature, depositing Nb_3Sn.

The transport of niobium stannide onto various substrates by hydrogen halide was carried out using both closed tube and flow system techniques. Sintered niobium stannide plates, prepared by pressing a blend of niobium and tin powder and sintering at 900°-1400°C for various durations, were used as the source material. Substrates used for the deposition of niobium stannide included quartz, stainless steel, silver, Hastelloy, and many other common metals. Matheson anhydrous hydrogen bromide and hydrogen chloride, of 99.8 and 99.0% purity, respectively, were used as transport agents, and the noncondensable impurities were

[1] Subsequent to the submission of our paper, a paper "The Growth of Single Crystals of Nb_3Sn by Chemical Transport," by J. J. Hanak and H. S. Berman was presented at the Internation Conference on Crystal Growth, Boston, June 20-24, 1966. In this work, Nb_3Sn single crystals were grown by the conventional chemical transport technique in contrast to the close-spacing transport for the deposition of thin films emphasized in our paper.

removed by evacuating the solid which was refrigerated with liquid nitrogen. Fused silica tubes of 2.5 cm I.D. or 2.5 x 2.5 cm cross-section were used horizontally as reaction tubes in most experiments.

To carry out the closed-tube transport, the reaction tube containing the source material and the substrate was evacuated to 10^{-5} Torr or less, a known amount of the transport agent was distilled in, and the reaction tube was sealed. When a large substrate-source separation, say 10 cm or more, was desired, the reaction tube was placed in a horizontal tube furnace containing two independently controlled temperature zones. The region of the tube containing the substrate was placed in the high temperature zone, 800°-1000°C, and the source material was usually maintained at 600°-800°C. When a small substrate-source spacing was desired, the substrate was placed on the bottom of a square cross-sectioned tube, and the source plate was placed at about 1 mm above the substrate. To establish a temperature gradient across the reaction tube, only the bottom side of the tube was heated by a flat horizontal heater. The substrate thus assumes a higher temperature than the source material. However, the temperature difference between the source and the substrate, determined by the geometry of the reaction tube, is small and cannot be varied at will.

In many close-spacing experiments, the substrates were heated resistively so that the temperature difference between the substrate and the source material could be readily adjusted. A fused silica tube of 2.5 cm diameter, enclosed in a horizontal furnace, was used as the reaction tube. One end of the tube was provided with inlet tubes for the transport agent and the diluent, and the other end was provided with two demountable electric leads and the exhaust tube. The metallic substrates, in the form of hair-pins, were connected to the electric leads. Two sintered niobium stannide plates were placed approximately 1 mm above and below the substrate. After the reaction tube was purged with the diluent, such as helium, the reaction tube was heated to approximately 700°C to prevent the condensation of metal halides on the wall of the reaction tube. The wire substrate was then further heated resistively to about 850°C, and a temperature difference between the source and substrate of 50°C or more was readily achieved. The transport agent was then introduced at a low flow rate, say 5 ml/min, and the flow of the transport agent and the diluent was maintained through the transport process. Alternatively, the reaction tube was evacuated and backfilled with the transport agent to a pressure of 10-15 cm. The transport process then was carried out in a closed system under similar temperature conditions as in the flow system.

The superconducting transition temperature of niobium stannide specimens was determined by conventional techniques. The measurement of the resistive voltage drop across a specimen was used when electrical contacts could be applied to the specimen. For small or irregular specimens, the specimen was placed inside a small coil which was a part of a tank circuit, and its resonant frequency was measured. When the specimen becomes superconducting, the inductance of the coil decreases, resulting in a decrease in the frequency. The critical current density of niobium stannide deposited on wire substrates was measured on specimens approximately 2 cm long. The ends of the test specimen were copper plated and then indium soldered onto heavy copper leads. When the voltage drop across the specimen exceeded 5 μv, the sample was considered to have passed from the superconducting to the normal state.

Results and Discussion

The transport of niobium stannide by hydrogen halides has been established in both closed tube and gas flow systems under a variety of conditions. Since the separation between the source material and the substrate was found to be the most important variable determining the transition temperature of the deposit, the following discussion is divided into two parts according to the source-substrate separation used in the transport experiments.

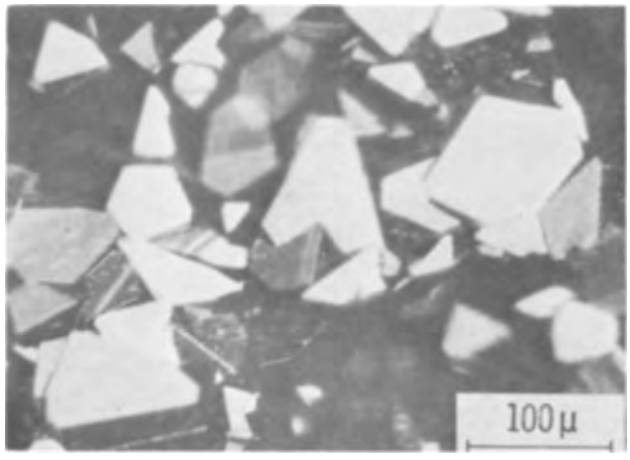

Fig. 1. Niobium stannide transported onto a quartz substrate by hydrogen bromide in a closed tube with a source-substrate separation of 10 cm. This film, approximately 250μ thick, had transition temperature of 13°-18°K, indicating that the film was nonstoichiometric.

Transport of niobium stannide with large source-substrate separation.—In most transport experiments, a bright metallic film was deposited in the high temperature zone of the reaction tube. The transport rate was determined predominately by the composition and pressure of the transport agent, the source and substrate temperatures, and the distance between the source and the substrate. For example, a film 250μ thick was deposited at a rate of 3 μ/hr using hydrogen bromide at 2.5 atm as the transport agent. The source and substrate were 10 cm apart and their temperatures were 600° and 900°C, respectively. This film was found to be polycrystalline and consisted of many crystallites 20-30μ wide (Fig. 1). It was also found to be a single phase material by Picklesimer's anodization technique (9). The source material used in this transport experiment was sintered at 1200°C for 20 hr and had a transition temperature of over 18°K. However, the transition temperature of the transported film was found to be in the range of 13°-18°K. This broad transition of the transported film indicates its nonstoichiometry. This is due to the difference in reactivity of niobium and tin toward hydrogen bromide and the difference in the ease of reduction of niobium and tin bromides. Thus the composition of the film changed gradually as the transport proceeded. Niobium stannide films prepared by using other substrate temperatures or using source material sintered at different temperatures (900°, 1050°, and 1400°C) had similar or lower transition temperatures.

Among the metallic substrates used in the transport process, silver and Hastelloy were found to be relatively inert in hydrogen bromide up to about 900°C. At substrate temperatures below 800°C, the deposited films had low transition temperature, less than 10°K, indicating that they were not stoichiometric. At substrate temperatures of 950°C or higher, the substrates were severely attacked. Therefore most experiments were carried out at substrate temperatures of 850°-900°C, and the temperatures of the source material were maintained 250°-300°C lower. Under these conditions, the properties of the transported films were also found to be affected by the sintering temperature of the source material. When the source material was sintered at low temperatures, both silver and Hastelloy substrates were attacked to some extent. The deposited

Table I. Deposition of Nb_3Sn films on silver and Hastelloy substrates by chemical transport using a source-substrate separation of 10 cm

Sintering temp of source Nb_3Sn, °C[a]	Substrate temp, °C	Film quality	Transition temp, °K[b]
900, 1050, 1200, and 1400	≤800	Fair to good	10
900, 1050, 1200, and 1400	≥950	Very poor, substrate severely attacked	5-18 depending on source material
900	850-900	Poor	10-18
1050	850-900	Poor	10-18
1200	850-900	Fair	13-18
1400	850-900	Good	9-13

[a] All sintering times were a minimum of 4 hr after an initial sintering of 70 hr at 900°C.
[b] The transition temperatures given were measured on films deposited on metallic substrates whenever possible. In cases where the deposits on metallic substrates were not of sufficiently good quality for measurement, the transition temperatures given are for films deposited on quartz under the same experimental conditions.

films, with transition temperatures in the range of 10°-18°K, were not tightly adherent and were of poor appearance. The degree of attack was found to decrease with increasing sintering temperature of the source material. The substrates were not significantly attacked when the source material was sintered at 1400°C, and continuous and adherent films were obtained. However, these films exhibited lower transition temperatures, 9°-13°K, due to the presence of excess niobium in the films. Thus, the attack on substrate when using source material sintered at low temperatures was probably due to the alloying of tin with the substrate at the deposition temperature. The source material sintered at very high temperatures, say 1400°C, was likely to be tin-deficient due to evaporation, thus minimizing the attack of the substrates. Results of a number of experiments showing the effects of substrate temperature and the temperature of the source material are summarized in Table I. Similar results were obtained when a hydrogen-hydrogen bromide mixture was used as the transport agent. Therefore the transport technique using a large source-substrate separation was not able to produce films of stoichiometric niobium stannide.

Close-spacing transport of Nb_3Sn.—When niobium stannide is transported by using a large source-substrate separation, the composition of the resulting material varies along the length of the reaction tube due to the difference in reactivity of niobium and tin halides. By using a very small source-substrate separation, all components of the source material can be transported simultaneously and quantitatively to the substrate. The change in composition between source and substrate is therefore extremely small. This advantage has been utilized for the transport of chemical compounds which differ widely in properties, such as the III-V semiconducting compounds (10).

When the source-substrate spacing was 1 mm and the external heating of substrate was used, as described earlier, the source temperature was estimated to be approximately 20°C lower than the substrate. Despite the much smaller temperature gradients, the deposition rate of Nb_3Sn by the close-spacing technique was similar to that achieved by the large-spacing transport technique. For example, niobium stannide films were deposited on quartz substrates at 850°C at a rate of approximately 3 μ/hr by using hydrogen bromide at 2.5 atm as the transport agent. When a niobium stannide plate sintered at 900°C for 70 hr was used as the source material, the film was found to have a sharp transition temperature in the range of 17°-18°K. Similar results were obtained by using source material sintered at 1050° and 1200°C. These results confirm that sintered Nb_3Sn can be chemically transported with no significant change in stoichiometry. According to the composition-transition temperature relation of vapor deposited Nb_3Sn (5, 6), the deviation of the transported film from stoichiometry is presumably less than 2%. However, the deposition of niobium stannide on silver and Hastelloy substrates was also complicated in many cases by the attack on the substrates. Results of a series of experiments are summarized in Table II. At substrate temperatures of 800°C or below and 950°C or above, the close-spacing transport technique yielded results very similar to those obtained by the large-spacing transport technique. However, at substrate temperatures of 850°-900°C, the use of source material sintered at 900°, 1050°, or 1200°C yielded deposits with high transition temperatures, in contrast with the large-spacing transport technique (cf. Table I). But the attack of the substrate during the transport process prevented the formation of adherent films. The deposited films obtained from source material sintered at 1400°C exhibited low transition temperature, due presumably to a tin deficiency in the source material.

Table II. Deposition of Nb_3Sn films on metallic substrates by close-spacing technique using external heating of substrates

Sintering temp of source Nb_3Sn, °C	Substrate temp, °C	Film quality	Transition temp, °K
900, 1050, 1200, and 1400	≤800	Fair to good	≤10
900, 1050, 1200, and 1400	≥950	Very poor, substrate severely attacked	5-18, depending on source material
900	850-900	Poor	17->18
1050	850-900	Poor	17->18
1200	850-900	Fair	17->18
1400	850-900	Good	11-14

When the substrate was heated resistively in the close-spacing transport experiments, a considerably larger temperature difference between the substrate and the source material, and consequently a corresponding higher deposition rate, 5 μ/min or higher, were achieved. This rate was obtained in both closed and flow systems and was about 100 times that obtained by the external heating technique. This high deposition rate of niobium stannide sufficiently eliminated the attack of the substrate to permit the deposition of high quality, adherent, and continuous films. When a helium-hydrogen bromide mixture was used as the transport agent in a flow system or when hydrogen bromide at a pressure of 10-15 cm was used as the transport agent in a closed system, films with high transition temperature, ≥18°K, were deposited reproducibly on Hastelloy substrates. A typical film deposited on Hastelloy at 850°C is shown in Fig. 2.

Fig. 2. Niobium stannide film deposited on a Hastelloy substrate by the close-spacing transport technique. The source and substrate temperatures were 800° and 850°C, respectively, and the transition temperature of this film was 18°K.

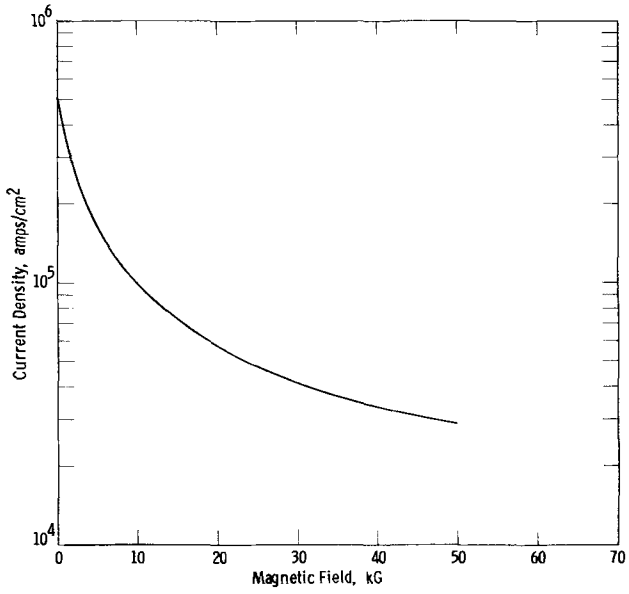

Fig. 3. A typical current density *vs.* field curve of niobium stannide films deposited on Hastelloy by the close-spacing transport technique.

This film, deposited at a rate of approximately 2 μ/min, was 30μ thick and had a transition temperature of 18°K. The current density of a number of niobium stannide films transported by the close-spacing technique was measured in magnetic fields up to 50 kG. A typical current density *vs.* external field curve is shown in Fig. 3. The current density was approximately 6 x 10^5 amp/cm^2 in zero field and was 3 x 10^4 amp/cm^2 in a field of 50 kG. The highest current densities achieved thus far, measured in a field of 50 kG, were greater than 6 x 10^4 amp/cm^2. Thus, it has been demonstrated that by using a large temperature difference between the source and the substrate, niobium stannide films with good superconducting properties can be deposited on a metallic substrate. This technique is considerably simpler than the thermal reduction technique in a flow system and has potential applications for the construction of superconducting solenoids.

Summary and Conclusions

Niobium stannide, Nb_3Sn, has been transported from a low temperature zone to higher temperature regions by using hydrogen bromide or hydrogen chloride as a transport agent, as expected from thermochemical considerations. It has been established that the large-spacing transport technique, in which the source material and the substrate are 10 cm or more apart, is not readily adaptable for the deposition of stoichiometric Nb_3Sn films. This is due mainly to the differences in reactivities of niobium and tin toward hydrogen halide and the ease of reduction of niobium and tin halides with hydrogen. On the other hand, the close-spacing technique has been proven to be capable of reproducibly depositing niobium stannide films with good superconducting properties.

To accomplish the deposition of adherent niobium stannide films on metallic substrates, it is essential to carry out the transport process at high rates to minimize the attack of the substrates. The resistance heating of substrates provided a large temperature difference between the substrate and the source material and therefore, a high transport rate. Niobium stannide films deposited on Hastelloy substrates were found to have high transition temperatures, $\geq$18°K, and reasonable current densities. The feasibility and reproducibility of this process for the preparation of stoichiometric niobium stannide have been established.

Acknowledgment

We wish to thank Drs. J. K. Hulm and S. A. Autler for their encouragement during the course of this work, Mr. W. T. Reynolds for supplying the sintered niobium stannide plates, and Dr. C. K. Jones and Mr. A. Patterson for their contribution in the transition temperature and current density measurements.

Manuscript reecived May 14, 1966; revised manuscript received Aug. 1, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

The Application of Gas Chromatography to the Analysis of Gas/Vapor Atmospheres in Semiconductor Processes

R. Nuttall

Ferranti Limited, Wythenshawe, England

ABSTRACT

Some of the problems which have been investigated using gas chromatography are discussed. The atmospheres examined are those concerned with the epitaxial deposition of silicon, the components estimated including the chlorides of boron, silicon, and phosphorus. The results indicate the source of some of the variations observed in the epitaxial process and also suggest a common feature of the reactions involving silicon chlorides.

Gas chromatography is a method by which gases and vapors may be separated. It depends for its operation on the differences in the distribution coefficients of the gases and vapors (components) between a fixed phase and a gaseous mobile phase. In practice the sample of mixed components is injected into a carrier gas stream, usually hydrogen or helium, which passes through a column containing a suitable absorbent. The components separate in the column according to their distribution coefficient with regard to the carrier gas and the absorbent and pass out of the end of the column in a specific order as the individual components. These are detected as they emerge by using a thermal conductivity cell or one of the many other types of detectors. The components are detected and registered on a recorder, but as they are not identified nor is the quantity present indicated directly it is necessary to calibrate the equipment initially with known components. This requires measuring their retention time, *i.e.*, the time taken for the sample to reach the detector after injection and also to measure the sensitivity to a given quantity of a component. It is not proposed to discuss the theory or the many other aspects of gas chromatography further in view of the large range of literature available on the subject (1-4).

Apparatus

Figure 1 shows the apparatus used in the investigations and is typical of the standard commercial units available. The basic differences from the commercial units were (*a*) the whole system was constructed from Teflon and stainless steel because of the reactivity of the components to be examined; (*b*) the sampling valve used was based on a design described by Hamlin (5); and (*c*) an auxiliary flow of hydrogen for sampling purposes was incorporated. There are several references (6-8) to work carried out in investigating inorganic halides by gas chromatographic techniques in the literature, and the column packing which gave the most satisfactory separation of the compounds investigated was similar to that described by Abe (6). The column details were: support material, Kieselguhur, 72-85 grade; stationary phase, 15% silicone oil, 85% support material; column temperature, 50°C for chlorides, 90°C for bromides or mixtures of chlorides and bromides. The column length was 300 cm and was constructed from 3/16 in. ID stainless steel tubing. Other column packings which were investigated and proved unsatisfactory due to poor resolution and "tailing" were: support material, powdered Teflon 72-85 grade; stationary phases, Kel-F40 oil, Apiezon grease, Squalene and liquid paraffin.

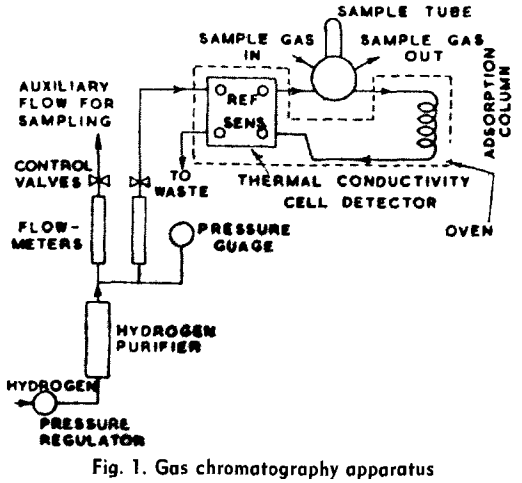

Fig. 1. Gas chromatography apparatus

A typical differential chromatogram obtained with this equipment is shown in Fig. 2. The area under the peak is a measure of the concentration of the component, and its position is indicative of the particular component. Where good resolution is obtained the peak height will be a measure of the concentration.

The peaks shown are for $SiCl_4$,$SiHCl_3$, SiH_2Cl_2, and HCl. This chromatogram was obtained during the investigations subsequently carried out and was typical of reaction 9, Table I.

Results of Investigations

Two-component systems.—(*a*) The effect of water vapor on the composition of certain two-component systems found in the epitaxial silicon field were investigated. The mixtures were $SiCl_4/PCl_3$ and $SiCl_4/BCl_3$. The equipment could not be adapted readily to estimate accurately differences in concentrations of two components less than 1% so that all the studies had to be carried out with initial concentrations greater than 1%.

Figure 3 shows the change of $PCl_3/SiCl_4$ concentration with evaporation using dry hydrogen and wet hydrogen. An initial concentration of molar ratio 0.1 $PCl_3/SiCl_4$ was used. The wet hydrogen was produced by first passing the hydrogen through water at 20°C before passing it into the $PCl_3/SiCl_4$. It is interesting to note that an increase in the relative concentration of $PCl_3/SiCl_4$ is observed using wet hydrogen, suggesting that the $SiCl_4$ is preferentially hydrolyzed. This is fortunate in that in $SiCl_4$ doped with trace amounts of PCl_3 the amount of PCl_3 is relatively unaffected by contact with moist air.

Figure 4 shows the results obtained by evaporation of a mixture of 10% BCl_3 in $SiCl_4$ using wet and dry hydrogen. In this case the tendency is for the BCl_3

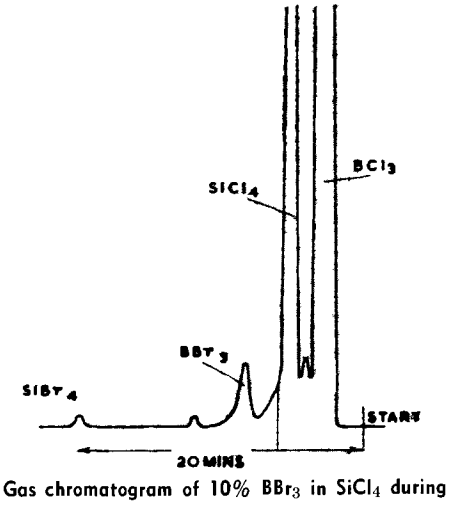

Fig. 5. Gas chromatogram of 10% BBr_3 in $SiCl_4$ during evaporation.

to be hydrolyzed preferentially, which may account for the fact that $SiCl_4$ doped with trace quantities of BCl_3 appears to lose its boron content on repeated handling and storing. This is reflected in the resistivity and type of epitaxial layers produced from such $SiCl_4$. The tendency is for the epitaxial layers of silicon produced to revert to n-type conductivity when the $SiCl_4$ is repeatedly removed from the equipment for storage, unless great care is taken to avoid ingress of air.

(b) The behavior of $BBr_3/SiCl_4$ mixtures on evaporation was also investigated. Figure 5 shows a chromatogram obtained during the evaporation of 10% BBr_3 in $SiCl_4$. It can be seen that the bulk of the boron in the vapor phase is present as the chloride and that other mixed halides are present. The presence of the chloride has already been reported using infrared transmission for detection (9). In further experiments several other small peaks have been observed which could correspond to the other silicon and boron chlorobromides judging from the boiling points of these compounds recorded in the literature. The identification of similar compounds on a basis of boiling point/retention time (2) is possible in some cases, and in view of the similarity of the compounds involved in this particular case it would be expected that the retention time would be a function of the bp of the compound. Figure 6 shows the change in peak heights of BCl_3 and $SiCl_4$ during the evaporation of 10% BBr_3 in $SiCl_4$. The behavior of the BCl_3 is interesting in that the number of moles present in the vapor phase remains relatively constant after an initial decrease. On standing the behavior is repeated. The $SiCl_4$ decreases steadily at a faster rate than expected because a proportion is converted to the relatively involatile $SiBr_4$ and other chlorobromides. Only the BCl_3 and $SiCl_4$ peak heights have been plotted as these are the only components which have high concentrations in the vapor phase.

Examination of the oxidation, reduction, and etching reactions associated with $SiCl_4$.—*Equipment.*—The equipment used to study the reaction products produced by the various reactions associated with $SiCl_4$ is shown in Fig. 7. This is simply a modified version of the standard vertical epitaxial deposition cell described in the literature (10, 11) with provision to take a continuous flow of gas from just above the wafer surface and pass this through the sampling valve on the gas chromatographic equipment.

Procedure.—Initially the gas chromatograph was calibrated with individual known compounds and, in some

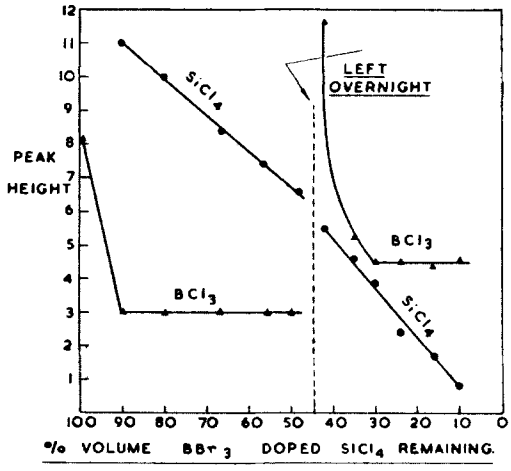

Fig. 6. Change in peak height of the components BCl_3 and $SiCl_4$ on the evaporation of 10% BBr_3 in $SiCl_4$.

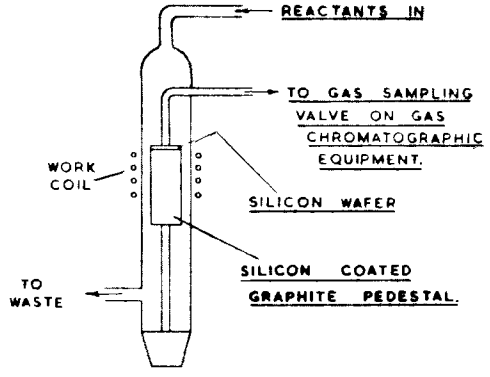

Fig. 7. Reaction cell

cases, mixtures of these compounds. The compounds were selected as being those expected to be found during the studies, and any unexpected peaks were identified during the experiments by again using known compounds. Unfortunately, it was soon apparent that quantitative measurements would be unreliable as the equipment did not have facilities for changing the sensitivity with the accuracy necessary for reliable quantitative measurement. This change in sensitivity was necessary because of the large variations in peak height which was found during these experiments. It was, however, possible to assess whether the particular component was there as a major or minor constituent. The experiments were carried out by taking gas samples from the reaction cell while various reactions were in progress. The reaction conditions, namely temperature and concentration, were varied and samples again taken.

Results.—Table I shows the reactions studied and the results from the chromatograms obtained.

In addition to these results it was observed that all the reactions involving $SiCl_4$ or $SiHCl_3$ as one of the reactants did not commence until 850°C. Only above 850°C were any peaks other than the reactants observed, and their presence coincided with the initiation of reaction at the surface of the silicon substrate. This suggests that the reactions are surface dependent, *i.e.*, heterogeneous. The reactions involving water vapor did tend to show a small HCl peak below 850°C due to some homogeneous hydrolysis taking place. This increased in height rapidly above 850°C, with the deposition of silicon dioxide on the silicon substrate.

Consider the reactants studied in the order indicated.

Table I. Results obtained from reaction studies

	Reactants	Components observed on gas chromatogram
[1]	$SiCl_4 + H_2$ Molar Ratio $\frac{SiCl_4}{H_2} < 0.28$	$SiCl_4$(M), $SiHCl_3$(L), SiH_2Cl_2(T) + HCl(M)
[2]	$SiCl_4 + H_2 + Si$ Molar Ratio $\frac{SiCl_4}{H_2} > 0.28$	$SiCl_4$(M), $SiHCl_3$(M), SiH_2Cl_2(L) + HCl(M)
[3]	$SiCl_4 + A + Si$	$SiCl_4$(M) + Cl_2(T)
[4]	$SiCl_4 + H_2 + H_2O$	$SiCl_4$(M) + HCl(M)
[5]	$SiCl_4 + H_2 + CO_2$	$SiCl_4$(M) + HCl(M)
[6]	$SiCl_4 + A + H_2O$	$SiCl_4$(M) + HCl(M)
[7]	$Si + HCl + H_2$	$SiCl_4$(L), $SiHCl_3$(M), SiH_2Cl_2(L) + HCl(M)
[8]	$SiHCl_3 + H_2$	$SiCl_4$(L), $SiHCl_3$(M), SiH_2Cl_2(L) + HCl(M)
[9]	$SiHCl_3 + A$	$SiCl_4$(L), $SiHCl_3$(M), SiH_2Cl_2(L) + HCl(M)
[10]	$SiHCl_3 + H_2 + H_2O$	$SiHCl_3$(M) + HCl(M)

M, Major constituents; L, minor constituents; T, trace constituents.

1. The reaction of H_2 with $SiCl_4$ above 850°C produces the deposition of silicon at molar ratios $SiCl_4/H_2 < 0.28$ and also the intermediate products $SiHCl_3$ SiH_2Cl_2 + HCl. SiH_3Cl was also detected, but as its peak tended to be masked by the HCl peak its presence was not always conclusive. Above molar ratios $SiCl_4/H_2 > 0.28$ the silicon substrate is etched (10) and reaction 2 applies.

2. The reaction products are identical to those in reaction 1, but all the peak heights show a marked increase. The appearance of the silicon wafer after etching is similar to that obtained using HCl/H_2, being of a mirror finish free from oxide.

3. The reaction of $SiCl_4$ with Si using an argon carrier gas results in etching of the silicon. Chlorine was detected during this reaction and, of course, $SiCl_4$. The appearance of the wafer was similar to that produced by chlorine etching, *i.e.*, any oxide remained unattacked. Large quantities of an involatile deposit which consists of polymerized $SiCl_2$ molecules (12) were observed on the cell walls at the exhaust end of the cell. Because $SiCl_2$ polymerizes so readily and is then relatively involatile it cannot be observed on the gas chromatogram. It should be noted that this reaction is useful in replacing chlorine as an etchant in the examination of oxidized wafers for pinholes in situations where the use of chlorine is hazardous from safety aspects and also where its purity is suspect. When the substrate was silicon heavily doped with phosphorus, PCl_3 was observed on the chromatogram.

4 and 5. In the reaction of $SiCl_4$ with H_2O using a hydrogen carrier gas, only HCl and $SiCl_4$ (and CO_2 in reaction 4) were observed on the chromatogram. No other intermediates were observed. The oxide deposition rate was very temperature dependent (13) and was indicated on the chromatogram by a rapid increase in the HCl peak height with increasing temperature. As the H_2O concentration was decreased the simultaneous deposition of Si and SiO_2 was observed, and this coincided with the appearance of $SiHCl_3$, SiH_2Cl_2 on the chromatogram.

6. In the above reaction using argon as the carrier gas HCl and $SiCl_4$ were observed, but there was a suggestion that more homogeneous hydrolysis was taking place prior to deposition than with hydrogen. There was a small HCl peak observed when pedestal and slice were at room temperature, but this increased rapidly above 850°C. If the H_2O concentration was decreased below a specific level, then both deposition

of SiO_2 and etching of the silicon substrate were observed.

7. The reaction of HCl with the silicon substrate using a hydrogen carrier gas results in reaction products as found for the reduction of $SiCl_4$. The etch rate was not greatly temperature dependent. The most predominant peak, excluding HCl, was $SiHCl_3$.

8. The reduction of $SiHCl_3$ with H_2 results in the deposition of silicon and the production of $SiCl_4$, SiH_2Cl_2, ($SiHCl_3$) and HCl. This reaction does not remove silicon at high molar ratios and temperature, but the deposition rate does decrease above 1200°C (11).

9. On passing $SiHCl_3$ in argon over the heated Si substrate apparent disproportionation of the $SiHCl_3$ occurs, *i.e.*, $2SiHCl_3$ $SiH_2Cl_2 + SiCl_4$.

HCl was also present, and some polymer was deposited on the walls on the reaction cell which suggests that the reaction $SiHCl_3 \rightarrow SiCl_2 + HCl$ is also taking place. There was no apparent deposition of silicon or etching of the silicon substrate, which also suggests that the reaction is independent of the substrate material. This was confirmed by using graphite as the substrate when the same chromatogram was produced.

10. The reaction of $SiHCl_3$ with H_2O using a hydrogen carrier gas deposits SiO_2 on the silicon substrate. Only $SiHCl_3$ and HCl were observed on the chromatogram, and the oxide deposition rate was very temperature dependent.

Discussion

As previously stated a common feature of all the reactions studied using $SiCl_4$ and $SiHCl_3$ as one of the reactants was the fact that no reaction involving the surface occurred before 850°C. Not until this temperature was reached did any change in the chromatogram occur, and this coincided with some surface reaction. This would therefore suggest that each reaction proceeds through the same initiation step. In all the reactions which initially contained reactants consisting of H_2, Cl_2, and Si, the same components were also observed on the chromatogram. It would appear therefore that, depending on the concentrations of Cl: Si: H involved in the vapor phase and the reaction temperature, a reaction balance is attained consisting of $SiCl_4$, $SiHCl_3$, SiH_2Cl_2, $SiHCl_3$, HCl, Si, and $SiCl_2$. Lever (16) and Sedgwick (17) have considered these reactions on a theoretical basis, but a quantitative comparison of their results with those obtained in these experiments is not feasible due to the limitations of the particular equipment used. This would, however, be possible with more sophisticated equipment having facilities to enable the sensitivity to be changed accurately during the actual tracing of the chromatogram.

Conclusion

The experiments described suggest that gas chromatography can be a valuable tool in investigating many problems found in the semiconductor field. It is limited in investigating solids and liquids at low vapor pressure or reaction products which are short lived, *e.g.*, in the silicon deposition studies described it was impossible to detect $SiCl_2$ monomer as this readily polymerized to an involatile solid. However, it may be feasible to estimate the amount of $SiCl_2$ by difference, but this would, of course, involve a total analysis of all the gases passing out of the system.

Nondestructive Determination of Thickness and Perfection of Silica Films

Lawrence A. Murray and Norman Goldsmith

Electronic Components and Devices, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

Analysis of the infrared reflection system of silica on silicon shows that the silica film thickness can be deduced from both the short-wavelength interference pattern and the reflection height of the 9μ silicon-oxygen resonance. Marked disagreements between these two independent measurements can be ascribed to a lack of comparative perfection of the oxide film. The effect of heat-treatment on both the reflectivity at 9μ and the etch rate of deposited silica films is discussed.

Experimental

Prior to oxide growth, silicon wafers were prepared by either chemical or mechanical polishing. Both n- and p-type substrates were used, with resistivities varying from 0.001 to 50 ohm-cm. These samples were steam-oxidized at 1000°C.

The reflection spectra were recorded with a Perkin-Elmer "Infracord" double-beam spectrophotometer equipped with two reflectance attachments. The instrument was adjusted to read 100% with gold reflectors in both beams. The angle of incidence was 26.5°. When a polished silicon wafer was placed in the sample position, the trace in the 2.5-15μ region varied from 39 to 37%. The spectra of the oxidized wafers were measured, and the points of interest were recorded. The oxide thickness for each sample was then determined by the Tolansky method to an estimated accuracy of ±150Å. Figure 1 shows a typical reflection spectrum of a silica film on silicon with the pertinent points indicated.

Thickness Determined from Interference

For oxide thicknesses between 4500 and 9000Å, a minimum reflectivity exists in the short wavelength region because of interference. The thickness, d, of the film can be determined by the following usual equation (1):

$$d = \frac{P\lambda_{min}}{2(n^2 - \sin^2\theta)^{1/2}} \qquad [1]$$

where n is the index of refraction of the silica and θ is the angle of incidence. The order number, P, is 1/2 for such films.

For films thicker than 9000Å, a maximum appears with order number of unity. Figure 2 shows the variation of d with λ_{min}, with n taken as that of fused silica and $\sin^2\theta$ as 0.2. This method has been used for film thicknesses exceeding 50,000Å by first determining P and then multiplying the value read from Fig. 2 by 2P.

Thickness as a Function of R_{max}

In the neighborhood of 9μ, the silica lattice begins to absorb energy as a result of resonant stretching of the silicon-oxygen bonds. In this region, the indices of refraction (n) and absorption (k) change rapidly. The variable k increases at wavelengths short of resonance and then falls rapidly beyond the resonance wavelength, while n increases to a maximum just beyond resonance. In principle, reflectivity as a function of film thickness can be calculated (2) from a knowledge

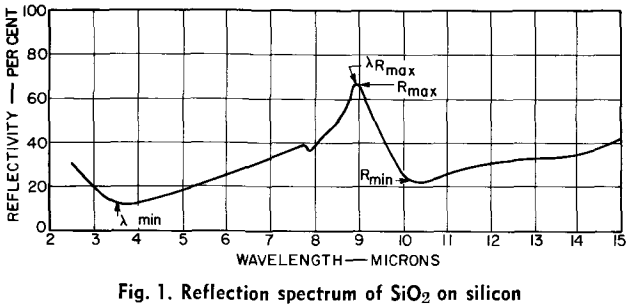

Fig. 1. Reflection spectrum of SiO_2 on silicon

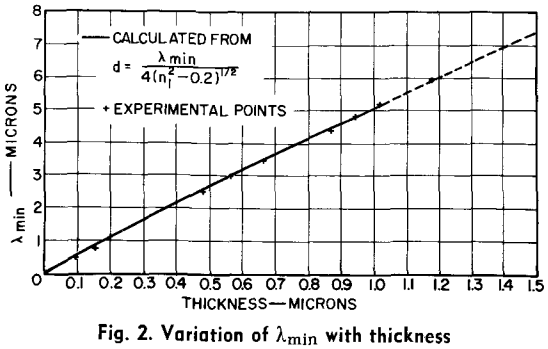

Fig. 2. Variation of λ_{min} with thickness

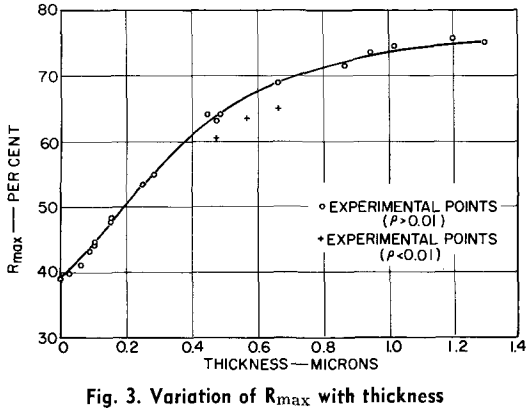

Fig. 3. Variation of R_{max} with thickness

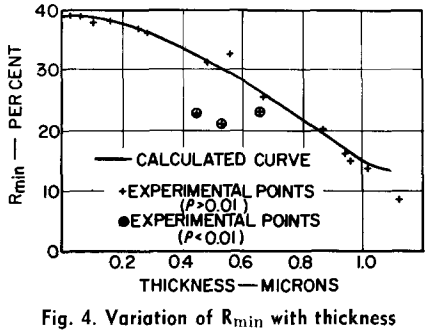

Fig. 4. Variation of R_{min} with thickness

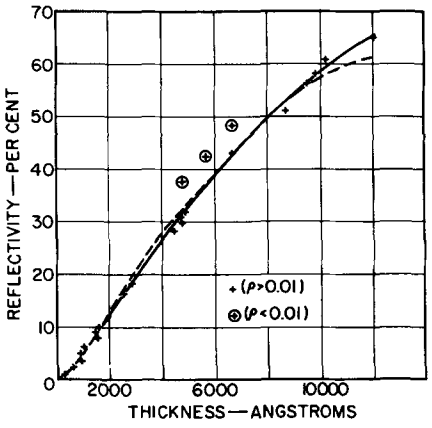

Fig. 5. Variation of $R_{max} - R_{min}$ with thickness

of n and k of the film, n of the substrate, and the angle of incidence.[1] This tedious calculation was not performed because conflicting values for n and k are given in the literature (3, 4). The value of λR_{max}, the wavelength of maximum reflectivity near 9μ, is itself a function of thickness, requiring the use of varying values of n and k in the calculation.

The experimentally determined values of reflectivity as a function of thickness are shown graphically in Fig. 3. The reflectivity of fused silica, equivalent to an infinite film thickness, was found to be 75%. These results are applicable only to the particular angle used in this work and to wafers having nonpolished rear surfaces. The measured reflectivity is dependent on both the angle of incidence and, as indicated, the reflectivity of the back surface. With these quantities held constant, measurement of the reflectivity near 9μ is a practical method for the determination of the thickness of silicon dioxide films on silicon for layers thinner than 7000Å.

Thickness as a Function of R_{min}

At wavelengths beyond the 9μ resonance, the refractive index again decreases to a low value, and normal reflection characteristics reappear. Experimentally it was found that a pronounced reflection minimum exists in the 10.5μ region, and that the value of R_{min} is dependent on thickness. In this region, n for fused silica is approximately 2.2 (3, 4). For the thicknesses considered the quarter-wave plate conditions are approximated [*i.e.*, $n_2 = (n_1 n_3)^{1/2}$ and $d = \lambda/4n_2$]. The oxide layer then begins to act as an antireflection coating, and the reflectivity decreases as the film thickness increases. The experimental points are shown in Fig. 4, along with a computed reflection curve.

[1] The equations in ref. (2) do not include a term for the reflectivity from the back of the substrate. This reflection may be accounted for by adding an additional term, $R_b \exp(-2\,n\nu)$, to the calculated reflectivities. For the wafers used in this study, R_b is estimated to be 0.08. Because unpolarized light is used, the computations must be made for both parallel and perpendicular polarization, and the two reflectivities must be averaged.

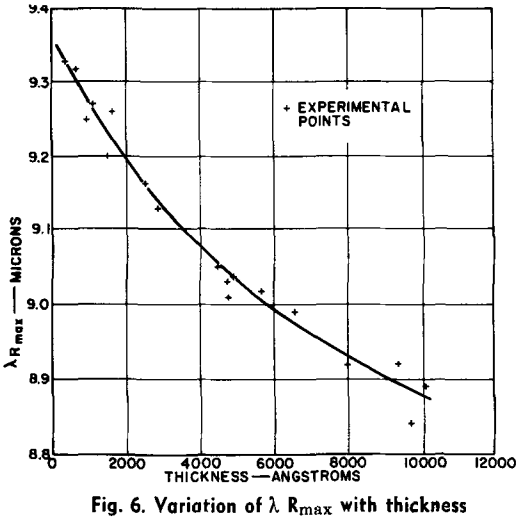

Fig. 6. Variation of λR_{max} with thickness

Thickness as a Function of R_{max}-R_{min}

As thickness increases, R_{max} saturates; however, R_{min}, which was constant at low values, begins to rise and then decreases as R_{max} saturates. Thus, a plot of $(R_{max})-(R_{min})$ is quasi-linear. The practical result of this behavior is that the difference in the two reflectivities yields accurate values of thickness over the range from 300 to 10,000Å. Figure 5 shows the variation of $(R_{max})-(R_{min})$. Low-resistivity points are further from the curve, and there is some disagreement between calculation and experiment at oxide thicknesses near 10,000Å. This thickness range spans that commonly used in device processing and is a useful method for in-process control of oxide thickness.

Resistivity of the Substrate

For most substrates, the amount of light absorbed by the wafer is negligible because the absorption coefficient is small. Provided the resistivity is greater than 0.01 ohm-cm, there is little influence from the substrate on radiation traversing the substrate. The anomalous reflectivity of the 10^{19} p-type sample is caused by plasma resonance which occurs in heavily doped low-mobility semiconductors (5). Measurements of film thickness using the 9μ reflection height, cannot be made reliably on in-process wafers which have surface concentrations exceeding 10^{19}. In fact, for doping levels of 10^{21}, a pronounced minimum in the reflectivity occurs in the region of 3μ, which also invalidates the use of the interference equation to determine the film thickness.

Variation of λ_{max} with Thickness

The wavelength at which R_{max} occurs depends on the thickness of the oxide, as shown in Fig. 6. Although the accuracy in determining thickness is poor because of the slow variation of λ_{max} with thickness, a knowledge of the approximate value of this point is useful as a check on other measurement values. The extreme values, $d \to 0$ and $d \to \infty$, occur at wavelengths at which n and k, respectively, are reported to reach their maximum value (3).

Oxide-Perfection Studies

The use of infrared transmission to study the properties of deposited silicon dioxide films has been reported previously (6). Similar information can be obtained from a study of the reflection spectrum, obviating the need for specially prepared high-resistivity substrates. The reflection spectrum of a silica film obtained by the controlled oxidation of silane at low temperatures is shown in Fig. 7.

Comparison of the thickness predicted from the short wavelength minimum and that indicated by the 9μ reflection height shows that the latter method predicts a much smaller thickness than actually exists. Furthermore, the wavelength of the maximum is shifted to-

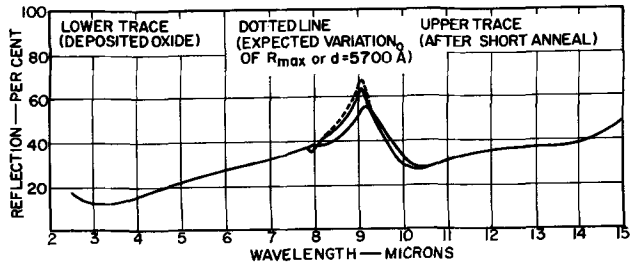

Fig. 7. Deposited SiO_2 reflection spectrum before and after heat-treatment.

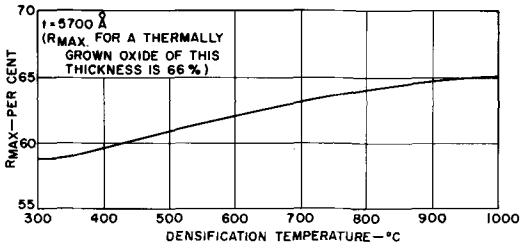

Fig. 8. R_{max} of deposited oxide as a function of densification temperature.

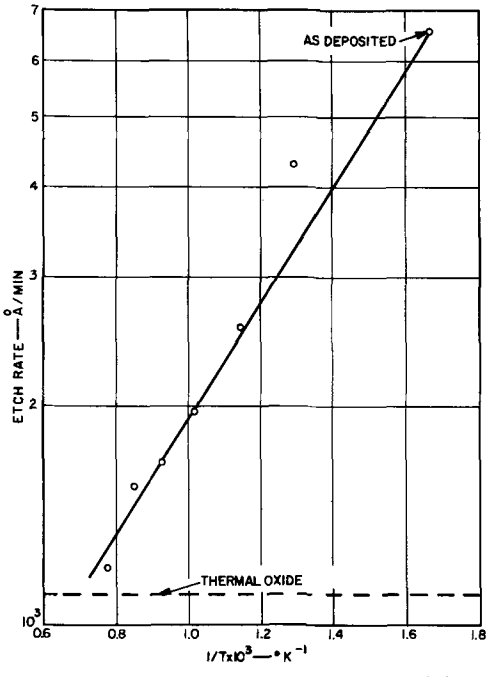

Fig. 9. Etch rate of deposited oxide as a function of densification temperature.

ward longer wavelengths. These facts imply that the bonding in the deposited film differs from that of the grown films, resulting in differing values for the optical constants responsible for the reflection height. As reported (6), the deposited films etched faster than thermally grown oxides.

For study of the densification of the films, samples were heat-treated at various temperatures in argon or oxygen. The results did not depend strongly on the ambient. After heat-treatment, the reflectivity increased and the etch rate decreased. Figure 8 shows the variation of reflectivity at 9μ with heat-treatment temperature for one sample. Although the length of heat-treatment influenced the reflection height for short periods, in all cases the reflectivity became sensibly constant after certain treatment times. These times varied from 1 hr at 500°C to less than 1 min at 1000°C. All values reported are for the saturated case. For the sample shown, a calculation of thickness determined from the short wavelength pattern predicts that the reflectivity should reach 70%. However, the temperature-reflectivity curve saturates at 68%, indicating that a structure comparable to that of a steam-grown oxide was not reached. When the sample was heat-treated at 1000°C in steam, however, the predicted reflectivity was reached.

The variation of the etch rate in buffer etch[2] with the temperature of densification was also determined. The results of such a measurement are shown in Fig. 9. The etch rate does not quite reach the rate of thermally grown oxide, yet because it is required in many

[2] 682 cc H_2O, 164 cc HF, 1 lb NH_4F at 25°C.

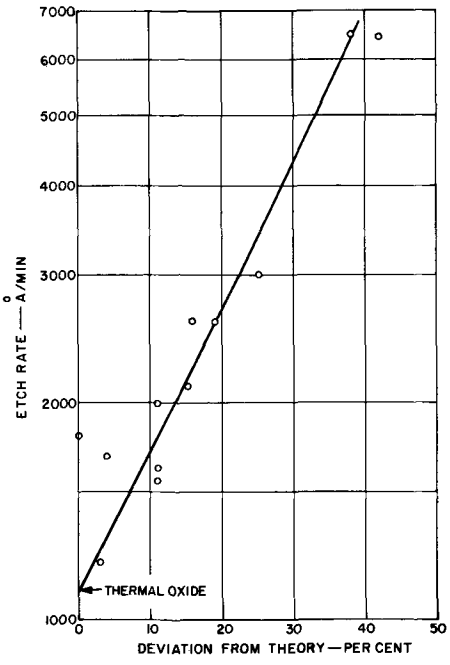

Fig. 10. "Perfection Index" vs. etch rate of deposited oxide

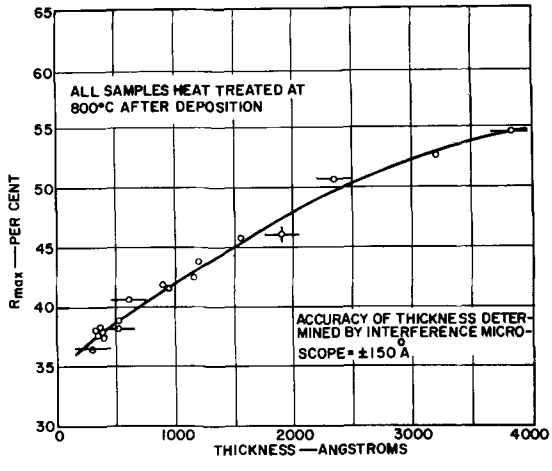

Fig. 11. R_{max} of deposited oxide (700°C) on GaAs as a function of thickness.

instances during device fabrication, a nondestructive method for etch-rate determination is useful.

Empirically, the convenient relationship $A = \log 100/(140 - R_{max})$ is used to express the 9μ peak height. The percentage deviation of the deposited film from the expected value can then be defined as $\%D = 100\ (A - A'/A)$, where A' refers to the measured value, and A to the value expected for the known thickness. The deviation curve as a function of etch rate in Fig. 10 shows a fair correlation, particularly in view of the fact that measurement of reflectivity results in large errors in the computed value of A', especially at peak heights very close to the expected values.

Sometimes, densification at elevated temperatures is not feasible, as in the case of silica layers deposited on gallium arsenide by the pyrolysis of ethyl silicate. In this instance, however, the thermal history of the sample is controlled, and the thickness can be obtained from a measurement of R_{max}. Figure 11 shows the variation of R_{max} with thickness.

Controlled Vapor-Liquid-Solid Growth of Silicon Crystals

R. S. Wagner and C. J. Doherty

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The experimental procedure for controlled vapor-liquid-solid, or VLS, crystal growth is discussed for silicon. The hydrogen reduction of $SiCl_4$ was used as transport reaction, and gold as the liquid-forming impurity. The stability of the liquid droplet, which is the main criterion for controlled VLS growth, is discussed in detail. It is shown that an adverse temperature gradient or an oversupply of silicon from the vapor may render the liquid droplet unstable, thereby terminating controlled VLS growth. Silicon crystals can be grown epitaxially on perfect or imperfect silicon substrates. The control of both location of crystal growth and of diameter and length of the crystals is demonstrated.

The vapor-liquid-solid (VLS) method of crystal growth, discussed in detail by Wagner and Ellis (1, 2) is distinctly different from the commonly used vapor-solid (VS) technique. In the VLS method the crystal grows from a supersaturated liquid solution. The supersaturation of the vapor can be kept small enough to suppress the VS deposition, yet large enough to vapor deposit at the liquid alloy. Atoms arriving from the vapor diffuse, in a concentration gradient, through the liquid and deposit at the solid-liquid interface. The liquid solution is formed by alloying a proper material with the substrate crystal. Many advantages are obtained if silicon crystals are grown by the VLS method using the hydrogen reduction of $SiCl_4$ (3). For this process many metals such as gold, platinum, or nickel can be used as liquid-forming agents (2). It has been shown (2) that silicon atoms are preferentially deposited on the liquid alloy. The vapor-liquid deposition rate can be orders of magnitude larger than the vapor-solid deposition rate. The difference in deposition rates increases with decreasing deposition temperature. Therefore, silicon crystals can be grown at deposition temperatures as low as 800°C. In addition, the liquid alloy protects the growing crystal, at the solid-liquid interface, from oxidation, etc., and from foreign particles which could result in the formation of crystalline defects. Highly perfect crystals can be grown by the VLS method at a low deposition temperature, because crystal growth occurs via the liquid-solid transformation. The VLS method is uniquely suited to grow silicon crystals on selected sites on a silicon substrate. Furthermore, both the diameter and the length of the VLS crystal are controllable.

It is the objective of this paper to describe in detail the experimental procedure for controlled VLS growth of silicon crystals. Three factors should be emphasized. First, great care must be taken to keep undesired impurities from the deposition region. Second, a temperature gradient may be either advantageous or adverse during VLS growth, depending on geometry. Third, the supply of silicon from the vapor must be kept within certain limits determined by the transport process of silicon through the liquid alloy.

Sample preparation and deposition apparatus.— Single crystal silicon wafers, preferably with {111} main faces are used as substrates because the usual VLS growth direction for this material is <111>. An exact orientation of the substrate surface is not necessary for subsequent VLS growth. Even a {211} surface may be used. The VLS crystals grown on such a substrate are then inclined by 19.47° with respect to the <211> substrate normal. The number of the dislocations in the substrate crystal has no observable effect on VLS growth. Dislocation-free crystals were successfully grown on dislocation-free and on plastically deformed crystals containing up to 10^7 dislocations/cm^2. We have never observed the growth of silicon whiskers (4) from dislocations which terminate at the substrate surface. We found for silicon, the growth of whisker crystals invariably occurs by the VLS mechanism only, on the site of the liquid alloy.

The silicon substrate crystals (1-100 ohm-cm, n- or p-type) were prepared using the following procedure: (*i*) The main faces are ground with 600 grit Carborundum. (*ii*) The wafers are washed in acetone and toluene to remove any traces of mounting wax. (*iii*) They are next washed in Alconox solution. (*iv*) The wafers are etched for 5 min in 1:4(HF, HNO_3) solution followed by an etch in 1:2:6 (HF, acetic, HNO_3) for 5 min. Subsequently the wafers are rinsed in deionized filtered water and dried at 110°C.

The gold (99.999% purity) used for alloying may be prepared by filing, slicing a fine wire or sheet, or by evaporation through a mask. Of these the sliced wire or sheet is the least contaminated material. The gold pieces were cleaned in acetone and toluene and boiled in Alconox solution. This was followed by an etch in aqua regia for a few minutes. The particles were rinsed in deionized, filtered water and dried. In most cases the gold pieces were placed either manually or with the aid of a mask on the silicon substrate.

The apparatus used for controlled VLS growth of silicon is discussed in ref. (2). In the present work, two different heating systems were used. In one, the reaction tube of silica was placed inside a resistance furnace. With such a system a rather long isothermal deposition zone can be obtained, and an adverse temperature gradient avoided. The other system consisted of a graphite tube, serving as an r-f susceptor, placed inside the reaction tube. The graphite tube was first

baked at 1200°C and subsequently coated with silicon. It was found that frequently numerous fine silicon whiskers grew inside the graphite tube. The whisker crystals were removed from the tube by scraping and more silicon deposited. This procedure was repeated until no more whisker crystals were observed. For both heating systems, the silicon substrate crystal was placed either on a silicon or silica support situated in the isothermal deposition zone. Great care was taken to keep the whole deposition apparatus as clean as possible. The hydrogen used for the experiment was purified by a palladium diffuser. The temperature in the deposition zone was controlled to within ±2°C. The $SiCl_4$ to hydrogen mole ratio used in the experiment ranged from 0.01 to 0.1, with a total hydrogen flow rate of 300-1000 cc/min. It should be noted that etching of the silicon substrate may occur, even for an extremely small hydrogen to $SiCl_4$ mole ratio, if an isothermal reaction zone is used. In such a system the ratio of HCl to unreacted $SiCl_4$ increases along the deposition zone. Therefore, the proper location of the silicon substrate for subsequent VLS growth must be found empirically; it depends strongly on the geometry of the reaction zone, the total gas flow and hydrogen to $SiCl_4$ mole ratio. The silicon substrate was placed in a down stream region where no silicon deposit occurred on a clean silica substrate. This deposition region is also useful for VLS growth of silicon crystals on silicon substrates partly masked with SiO_2.

Alloying and initial VLS growth.—The most difficult and least understood aspects of VLS growth are the alloying process of the impurity agent with the substrate and the initial stages of VLS growth, the rise of the liquid droplet from the substrate. It has been found that alloying gold with the silicon substrate is difficult to control. The temperature at which the liquid alloy forms may vary from 600°C to well over the melting point of gold (1063°C). For freshly cleaned gold and silicon, the alloying temperature is about 600°-800°C. An oxide layer on the silicon substrate may prevent alloying at the gold-silicon eutectic temperature (370°C).

The shape of the liquid droplet, determined by the liquid-solid contact angle, depends on the rate of temperature increase during alloying. We have not found a satisfactory procedure to control the spreading of the liquid over the substrate surface. It is suggested that the spreading may be controlled to some extent by masking the substrate around the intended alloy region with an SiO_2 layer. This would result in preferred dissolution of silicon from the substrate interior and also would control the shape of the droplet. The observed contact angle at 1050°C is about 10°-20° which would indicate good wetting of the substrate by the liquid. This contact angle is however most likely not the equilibrium contact angle but rather a consequence of the dissolution kinetics.

The small contact angle remains constant or decreases slightly when $SiCl_4$ is introduced to the carrier gas. However, sometimes a sudden increase in contact angle is observed. The sequence of events during alloying and the initial VLS growth is shown in Fig. 1 (5). In Fig. 1a is shown a piece of gold on the silicon substrate before alloying. In Fig. 1b the temperature has been increased to about 1050°C. Figure 1c, photographed after about 10 min of VLS deposition, shows a marked increase in contact angle. As a consequence, the diameter of the growing crystal decreases during the initial stage of VLS growth. Finally, in Fig. 1d, photographed after about 30 min of VLS growth, the contact angle has become stabilized. From this point on, there is no more change and the diameter of the growing crystal remains constant if the deposition temperature is held constant. The gradual increase in contact angle results in the formation of a tapered section at the base of a VLS crystal as shown in Fig. 1. At the substrate surface the crystal is either six or three sided, depending on deposition temperature

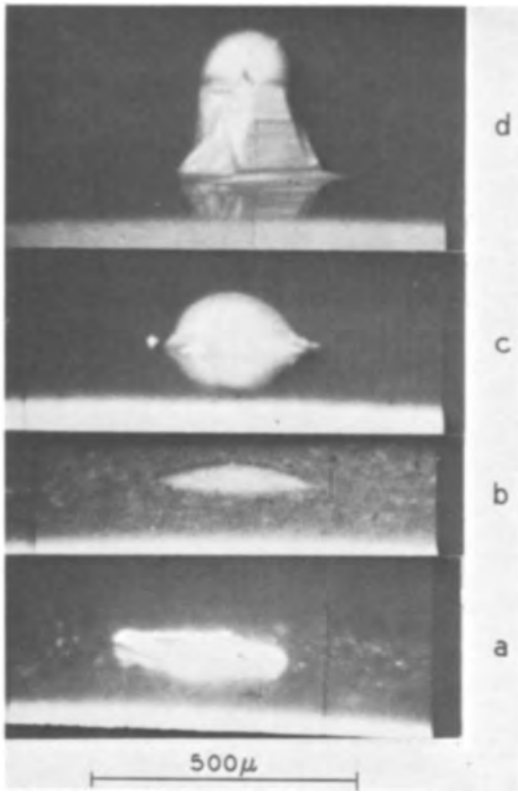

Fig. 1. Time lapse sequence of alloying and initial VLS growth. (a) Gold particle on silicon substrate at room temperature, (b) liquid droplet of gold-silicon alloy at 1050°C, (c) and (d) after 10 and 30 min respectively of growth at 1050°C. Magnification 100X.

and time. At temperatures higher than about 1050°C, the VS deposition is considerable at the base, resulting in a three-sided form.

In the first stage of VLS growth, the liquid alloy is very sensitive to a temperature gradient or oversupply from the vapor phase. Apparently the droplet is not in a stable configuration. Too much vapor supply

may result in a partial break up of the liquid into smaller droplets, each new droplet then giving rise to VLS growth as shown in Fig. 2. Once the crystal grows beyond the tapered section, it is rather stable with respect to changes in temperature and deposition rate. The effect of a temperature gradient or deposition oversupply on the stability of a liquid droplet is discussed in detail in the following sections of this paper.

Vapor Supply

At steady state VLS growth, the same number of silicon atoms which enter the liquid from the vapor are deposited at the solid-liquid (S-L) interface. This flux of silicon atoms diffuses through a concentration difference ΔC across the liquid alloy of thickness L. The value of ΔC is an important factor for the stability of the liquid alloy. We assume for the following discussion that convective mixing in the liquid is negligible and a disk-like shape of the liquid alloy. In Fig. 3 is shown a section of the silicon liquidus Si_L and the deposition isotherm T_E. With no vapor deposit the composition of the liquid will be C_E, the equilibrium concentration. For steady state VLS growth, the composition of the liquid is C_L at the liquid-gas interface and C_g at the liquid-solid interface. C_g, which may be very small, is the supersaturation required for nucleation and growth of new crystal layers.

The concentration gradient in the liquid disk is given by

$$\frac{\Delta C}{L} = \frac{V}{D} \qquad [1]$$

where V is the speed of advancement of the S-L interface and D is the diffusion coefficient of silicon in the liquid alloy. From the phase diagram Fig. 3 it follows that for a given V, D, and L the concentration difference in the liquid $\Delta C = C_L - C_E$ (atom fraction) corresponds to a liquidus supercooling ΔT. Homogeneous nucleation theory (6) predicts a ΔT_{max} of about 300°C for pure Si or a liquid Si alloy. For $\Delta T > 300$°C the supercooling is high enough to nucleate silicon crystal by homogeneous nucleation in the liquid alloy. This sets an upper limit for ΔC during VLS growth, ΔC can be about 0.25 for $T_E = 950$°C. It has been found experimentally that this consideration is extremely important in order to avoid instability of the liquid alloy by nucleation. For example for $L = 10^{-2}$ cm, $D = 5\text{x}10^{-5}$ cm²/sec, and $T_E = 950$°C the critical growth velocity $V_{max} \sim 3.5$ mm/hr.

The VLS growth rate V (cm/sec) for a given total gas flow f (cm³/sec), a $SiCl_4/H_2$ mole ratio m_R and for a reaction tube of cross section A (cm²) can be estimated as

$$v = \frac{f m_R M}{A V_o} \qquad [2]$$

where M = molecular weight of $SiCl_4$, V_o = standard volume of perfect gas, and ρ = density of solid silicon. The assumptions implicit in Eq. [2] are a dynamic system of high flow rate, a condensation coefficient of unity for the liquid alloy and the absence of the disproportionation reaction. It is also assumed that silicon atoms on the side faces of the growing crystal do not migrate to the liquid. For $f = 6$ cm³/sec, $m_R = 0.014$, and $A = 5$ cm² the calculated VLS growth rate $V = 0.3$ mm/hr. For these conditions in the temperature range 950°-1100°C, the observed growth rate is only slightly larger than the calculated value.

Both Eq. [1] and [2] are only crude approximations of the true state of affairs. Convective mixing of the liquid alloy, which may be considerable when using r-f heating, will increase the critical velocity V_{max}. A more static reaction system (slow flow rate) will increase V because of higher impingement rate of $SiCl_4$ molecules. The reader is referred to a more rigorous calculation of the vapor phase deposition rate of silicon given by Shepherd (7). Finally, ΔT_{max} may be much smaller than 300°C if heterogeneous nucleation sites are present in the liquid alloy or on the surface of the liquid.

It is evident from the previous discussion that a sudden decrease in deposition temperature T_E during VLS, results in a sudden increase in ΔC and therefore ΔT. During the transient the ΔT can become large enough for homogeneous or heterogeneous nucleation. In Fig. 4 is shown a silicon crystal which was originally grown at 1000°C. During growth the temperature was suddenly reduced to 600°C for about 30 sec and subsequently raised to 950°C. The breakup of the liquid alloy is dramatic, giving rise to the formation of numerous small crystals which are in random orientation with respect to the main crystal.

Effect of Temperature Gradient on VLS Growth

Pfann (8) has shown that a liquid alloy zone in contact with solid solvent material can migrate through the solvent material under the influence of a temperature gradient. This phenomenon, called temperature-gradient zone melting (TGZM), arises be-

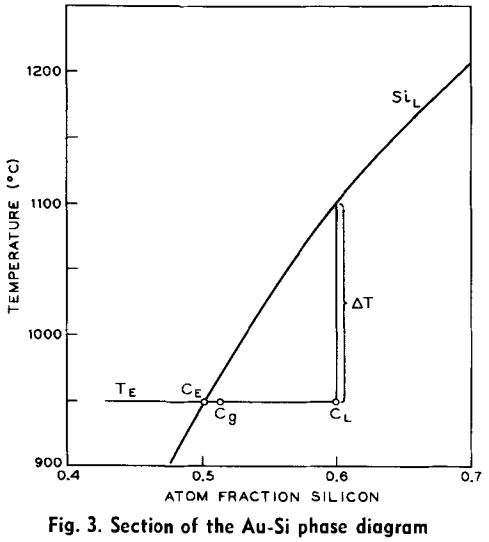

Fig. 3. Section of the Au-Si phase diagram

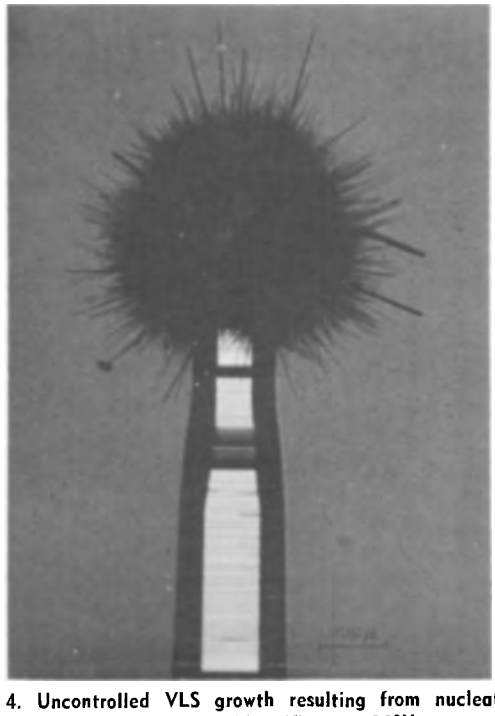

Fig. 4. Uncontrolled VLS growth resulting from nucleation of silicon crystals in liquid alloy. Magnification 250X.

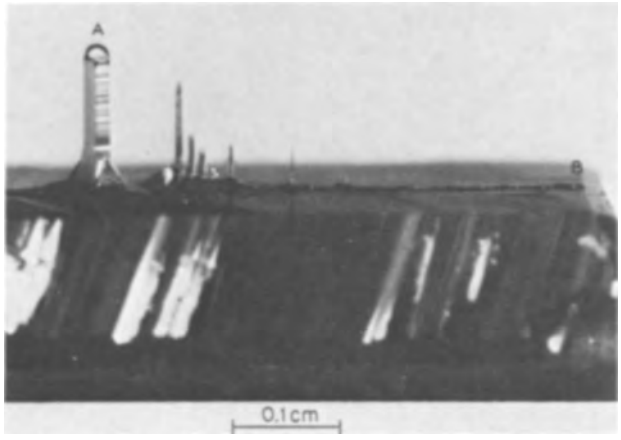

Fig. 5 Adverse effect of a lateral temperature gradient on VLS growth. A single alloy droplet, initially at position A, broke up into smaller droplets which migrated toward a higher temperature region. All droplets but the smallest one at position B gave rise to VLS crystals. Magnification 30X.

cause of continuous melting and freezing of solvent at the hotter or colder section of the liquid zone. The liquid alloy droplet on a silicon substrate comprises such a system if a temperature gradient is imposed. If the gradient is such that the substrate interior is hotter than the substrate surface, the liquid alloy will migrate into the substrate, until no more liquid is exposed to the vapor. It is evident that VLS growth is impossible under such condition. If the temperature gradient is along the substrate surface, the alloy droplet may move along the substrate toward a higher temperature region. The silicon entering the liquid from the vapor will be preferentially deposited at the colder side of the droplet. This gives rise to the build up of silicon on the substrate surface in the form of a ramp. On a (111) substrate, the ramp surface can be an extremely smooth (111) face. An additional consequence of a lateral temperature gradient can be that the liquid droplet may break up into smaller droplets. During TGZM on the substrate surface the liquid-solid contact angle becomes nonuniform, being smallest at the hot end of the liquid zone. This can lead to partial break up of the liquid droplet. This is shown in Fig. 5, where a large lateral temperature gradient was imposed during growth. The initial position of the alloy droplet was close to A where the largest crystal grew. The droplet broke up during migration giving rise to smaller crystals. The smallest droplet migrated to B. The liquid droplet can rise from the substrate surface even with a lateral temperature gradient, if the VLS growth rate is larger than the rate of TGZM.

From the previous section it follows that a temperature gradient in which the vapor-liquid interface is hotter than the S-L interface would be of great advantage during VLS growth. The liquid supercooling, ΔT as shown in Fig. 3, could be reduced by an amount equal to the temperature difference across the liquid alloy. By this means the stability of the liquid could be greatly improved.

Control of Diameter

The diameter of a VLS crystal is controlled by three factors, namely the initial amount of gold used for alloying, the deposition temperature, and the vapor-solid (V-S) deposition rate which also depends on the deposition temperature. For a given deposition temperature, the amount of gold determines the diameter of the growing crystal. The volume of the liquid droplet is given by the phase diagram. For a given amount of gold, the diameter of the crystal can be varied over a wide range by simply changing the

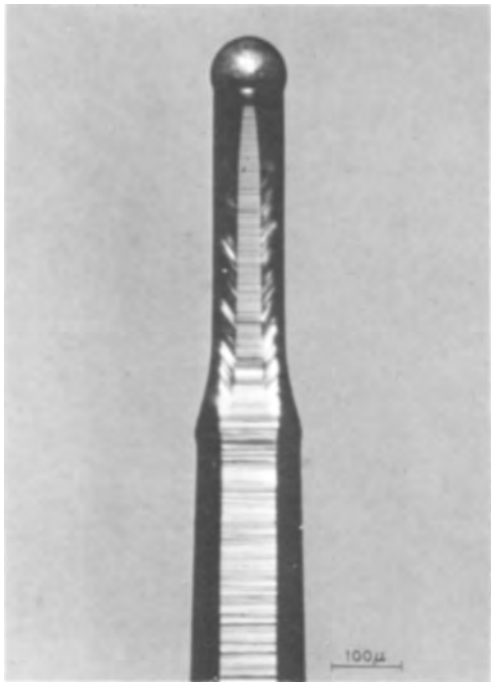

Fig. 6. Change of diameter during VLS growth, the lower section was grown at 1050°C, the top section at 950°C. Magnification 250X.

deposition temperature. Figure 6 is a photograph of an end-section of a VLS crystal. The lower part has been grown at about 1050°C, the upper part at about 950°C. Note the gradual decrease in cross-section which occurred during the temperature change. It is advisable to reduce or even stop completely the $SiCl_4$ supply and to reduce the temperature gradually. Too rapid a temperature change may cause a "pinching off" of small droplets from the main body of the liquid, giving rise to the formation of branches. An increase in diameter can be obtained by raising the deposition temperature. In this case it is helpful to increase the $SiCl_4$:H_2 mole ratio during the gradual temperature increase. This prevents remelting of silicon at the S-L interface which may cause the (111) interface to become unstable. In the extreme case the droplet may run down the side faces of the crystal, leading to subsequent uncontrolled growth.

Crystals grown at temperatures higher than about 950°C have hexagonal cross-section, with {211} side faces. At lower temperatures the cross-section becomes twelve-sided by the formation of six {110} faces. This change in morphology probably occurs because of the increase in liquid surface tension with decreasing temperature. The meniscus of the liquid droplet tends to be more circular. The edge angle of the crystal increases from 120° to 150° by changing from a six-sided to a twelve-sided morphology.

If the temperature is increased, for example from 850° to 1050°C, the {110} side faces will rapidly disappear by V-S deposition until the crystal is six-sided. While at this temperature the V-S deposit on the {211} side faces is extremely small, the {110} faces must be very favorable nucleation sites for V-S deposition. There is yet another change in morphology at a deposition temperature close to 1100°C; the crystal becomes three-sided. Three of the six {211} faces grow at the expense of the other {211} faces. At this temperature, the rate of evaporation of gold from the liquid is considerable. When all the gold has been consumed, the tip of the crystal will be bounded by three {111} faces.

Finally, the diameter of the crystal depends on the amount of V-S deposit. This sharply increases with deposition temperature. It has been estimated (2)

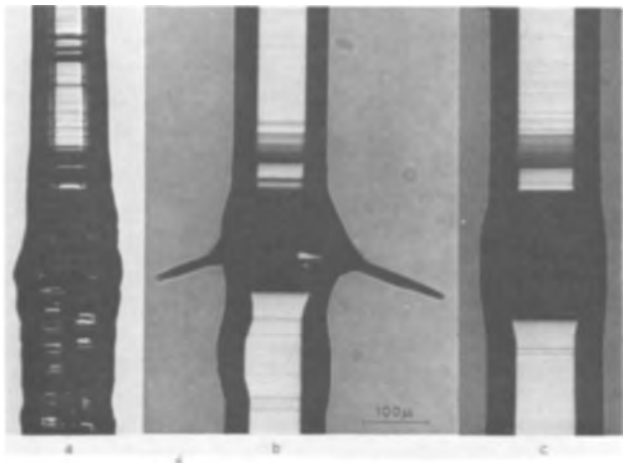

Fig. 7. Continuation of VLS growth after the crystal was cooled to room temperature and kept for 16 hr in (a) air, (b) and (c) in dry hydrogen. In (b) two side branches formed during regrowth. Magnification 250X.

that the VLS and V-S growth rates become comparable between 1200°-1300°C.

Regrowth.—It may be desirable, for practical purposes, to stop VLS growth, cool the crystal to room temperature, keep it there for a considerable time and subsequently continue growth. This procedure has been carried out many times and the following observations were made. It was found that the crystal must be kept in a nonoxidizing atmosphere such as hydrogen. Exposing the crystal to air may result in polycrystalline deposit on the existing side faces if the subsequent deposition temperature is below 1100°C; however, the newly VLS grown side faces are not affected. Second, it is also desirable to keep the initial regrowth deposition temperature slightly higher than the previous one. This results in proper melt-back during alloying and avoids formation of branches.

Figure 7 shows three silicon crystals which were regrown at 1000°C after being kept at room temperature for about 16 hr. The crystal in Fig. 7a was exposed to air. The regrown top section has the usual high degree of perfection; the lower section, however, is overgrown with polycrystalline deposit. The crystals in Fig. 7b and 7c were kept in a dry hydrogen atmosphere after cooling. Branches which formed upon regrowth are shown in Fig. 7b, and perfect regrowth is shown in Fig. 7c.

VLS growth of crystal patterns.—A goal of controlled VLS growth is the preparation of arrays of silicon crystals on silicon substrates. The growth of such arrays is not very difficult if all the experimental results discussed in the previous chapters are considered in detail. In Fig. 8 are shown six growth patterns of different form and dimension. Crystals of up to 1.5 cm in length have been grown with a maximum diameter of about 0.3 mm. The smaller the diameter of the crystal, the fewer are the difficulties encountered. For the growth of a crystal pattern, it is very important to use an isothermal reaction zone. A lateral temperature gradient may distort the intended growth pattern by TGZM during the initial stages of growth. The length of the crystals on an individual substrate may vary considerably, depending on the position of the crystals in the reaction tube. In Fig. 8b, the substrate was situated perpendicular to the gas flow. The outermost crystals were close to the susceptor wall. In Fig. 8f, the crystal array grew parallel to the gas flow direction. The crystals growing "downstream" are shorter, reflecting the depletion of $SiCl_4$ along the reaction tube. This effect can be eliminated by proper geometrical design of the

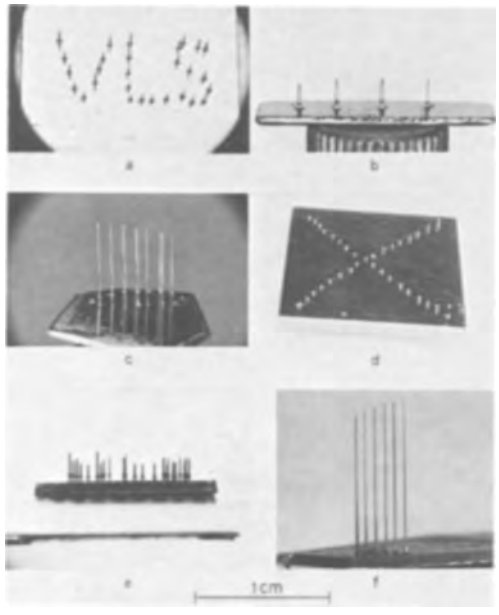

Fig. 8. Controlled VLS growth of silicon crystals in various arrays on silicon substrates. Magnification 5X.

reaction zone. X-ray measurements, using the Lang technique, have shown that the crystals in an array are "epitaxial" with respect to each other and therefore with the substrate. The observed angular misorientation between the crystals is smaller than 140 sec of arc, which is the resolution of the measurement technique employed.

Arrays of crystals have been grown with as many as 30 crystals on a 1 x 2 cm substrate. When conditions of cleanliness and proper temperature and gas phase conditions were observed, one crystal grew on each and every site where a gold particle had been placed manually. Another method, more suitable for production of arrays of many crystals, was to place a mask or template of pyrolytic graphite on the substrate crystal. An impurity particle was placed in each hole in the template and alloying was accomplished with the template in place. Subsequently, the template was removed and the VLS growth begun. Patterns of alloy dots also were made by evaporation of impurity agents through a mask onto the wafer. However, not every alloy dot produced only one crystal. A center crystal normally grew surrounded by fine whiskers of micron dimension. More work will be required to eliminate the breaking up of evaporated alloy dots.

Summary

Silicon crystals can be grown readily by the VLS technique under controlled conditions. Both the location of growth, the diameter of the crystal, and its ultimate length can be controlled. However, two important points must be considered, the presence of undesired impurities in the deposition region and the stability of the liquid alloy droplet. The first point requires extreme cleanliness of substrate, alloying agent, reaction tube, and carrier gas. The second point demands the absence of undesirable temperature gradients during alloying and VLS growth and proper adjustment of the total $SiCl_4$ concentration in the carrier gas. A temperature gradient may cause the alloy droplet to migrate into the substrate interior, or along the substrate surface, or may cause the formation of kinking or branching during growth (9). Proper gas composition is necessary to keep the concentration gradient in the liquid, and therefore the corresponding liquidus supercooling, small enough to avoid nucleation of silicon crystals in the liquid. It has been shown that the diameter of a VLS crys-

tal depends both on the amount of the alloying agent used and also on the deposition temperature. Crystals with sections of different diameter can be prepared simply by changing the deposition temperature during growth. The growth of arrays of crystals in various patterns has been demonstrated.

Crystalline defects have been studied in silicon crystals grown by the VLS technique. The majority of these crystals are highly perfect. However, some crystals contain defects such as dislocation, impurity striation, elastic strain, and second phase entrapment. The origin of such defects and their prevention will be discussed in a forthcoming paper (9).

Electrode Overvoltages in Molten Fluorides

The Anodic Behavior of Nickel Electrodes in Fluoride Melts

S. Pizzini, R. Morlotti, and E. Römer

High Temperature Chemistry, Euratom C.C.R. ISPRA, Varese, Italy

ABSTRACT

Anodic overvoltage measurements on nickel electrodes in NiF_2-KF, LiF-NaF-KF, NaF-KF, and LiF-KF melts of eutectic composition have been carried out by the galvanostatic, potentiostatic, and potential-sweep methods at temperatures ranging from 450° and 800°C. In oxide-free melts no activation overvoltage for the anodic and cathodic reactions has been observed. It was, however, observed that nickel behaves as a "covering-layer electrode" in the presence of traces of oxides, added to the melts as NiO, or resulting from the hydrolysis of the residual water in the melt after a high vacuum drying process. The semiconducting behavior of nonstoichiometric NiO surface layers has been considered and the results of the present work have been compared with the literature data on the Ni/NiO electrode in molten salts.

It does not seem to be widely recognized at present that the corrosion behavior of metallic electrodes in halide melts depends mainly on the oxidizing environment, if the corrosion of metal electrodes, due to reactions with the dissolved water, hydroxides, or halide-acids, is taken as an exception rather than a common phenomenon (1).

It was, however, shown, in the excellent reviews of Grimes (2) and of Baes (3) that nickel-base alloys exhibit very good corrosion resistance to fluoride melts, provided that a careful preparation of the melt and of the covering atmosphere is carried out. Littlewood and Argent (4) observed that unknown or uncontrolled factors affect the Nernst potential of nickel in alkali-chloride melts. Moreover it was shown in some previous investigations, dealing with overvoltage measurements on aluminum electrodes in molten KHF_2 (5), on lead electrodes in molten PbF_2-NaF eutectic mixtures (6), and on iron electrodes in molten alkali fluorides (7) that the contamination of the melts by oxides or water leads to the open circuit or anodic passivation of the electrode.

This paper deals with the anodic behavior of nickel in oxide-containing fluoride melts together with the kinetics of the anodic dissolution and cathodic deposition reactions in oxide-free fluoride melts.

Experimental Procedures

Suprapur or Pro Analysis LiF, NaF, and KF were supplied by Merck A. G. and used without further purification. NiF_2 was prepared by hydrofluorination of $NiCl_2 \cdot 6H_2O$, supplied as Reagent Pure by Merck A. G., or by high vacuum decomposition of $NiF_2 \cdot 2H_2O$ supplied by BDH. The products obtained contained more than 99% of NiF_2. Spectrographically standardized nickel rods were obtained from Johnson & Matthey or from Leytess Metal Inc.

Cells were assembled in vacuum tight quartz containers (see Fig. 1) for atmosphere control and the experiments were performed under high vacuum as well as under dry (10 ppm H_2O max) and deoxygenated argon, which was purified by passage through Linde's Molecular Sieves and Zr-Ti (50-50) chips at 600°C.

The tensiometric cell consists of a nickel working electrode and a nickel reference electrode. A Luggin capillary of about 0.5 to 0.1 mm diameter connects the reference electrode compartment to the electrode compartment.

The emf of the tensiometric cell has been shown reproducible within 1 mv in concentrated NiF_2 solutions or in NiO saturated melts. In Ni^{2+}-free melts the emf of the tensiometric cell is of course poorly reproducible. As insulating material, boron nitride (BN), supplied by Union Carbide, was used.

This cell design allows cylindrical symmetry of the current density distribution and avoids convective motions due to thermal gradients near the electrode surface. Any screening effects due to the reference electrode are avoided too. Temperature, measured in the hole (F) with a 1 mm diameter chromel-alumel thermocouple, was kept constant to ± 0.5°C.

The fluoride mixtures were dried under high vacuum prior to melting with step-wise increasing temperature from 100° up to 400°-450°C.

The high vacuum drying process was followed and standardized with samples of LiF in BN crucibles using an Omegatron-Type mass spectrometer (8) for residual gas analysis and by a polarization technique on Pt microelectrodes in LiF-NaF-KF melts for the analysis of dissolved hydrolysis products (9). It was shown that water can be removed at temperatures lower than 550°C without hydrolysis. Results are

Fig. 1. Assembly of the cell. given in Table I, where the partial pressures are indicated as the ratios p/P (p = partial pressure, P = total pressure) .

From this table [see also ref. (8) for more detailed information] it is seen that the partial pressure of the species with mass 20 (HF) increases with temperature above 600°C. The same statement applies to species with mass 49, which corresponds to BF_3, resulting from reaction of B_2O_3 (contained in BN) with HF.

Furthermore anodic limiting current measurements on Pt electrodes in LiF-NaF-KF melts (9) demonstrated that the content of hydrolysis-products (as OH^-) in the melt is of the same order or smaller than the one calculated from chronopotentiometric measurements in the same melts pretreated with HF and H_2 (10) or with $NH_4HF_2+H_2$ (11), and ranges between 10^{-5} and 10^{-4} moles cm^{-3}. With reference to the results of ref. (11) it is worthwhile to consider that the absence of reducible materials was qualitatively indicated ($i\tau^{1/2} < 5x10^{-3}$ amp cm^{-2} $sec^{1/2}$) whereas no information was given on the presence of oxidable materials.

Overvoltage measurements have been carried out by the galvanostatic, potentiostatic, and potential sweep methods.

In the galvanostatic measurements, the AMEL Model 561 or 557 potentiostats (rise time less than 10^{-3} sec) were used as constant d-c supply or the John Fluke Model 351.

In the potentiostatic measurements, a d-c amplifier was used as a high impedance buffer amplifier, because the input impedance of the 557 AMEL Potentiostat was considered too low (10^5 ohms). A fully transistorized delay time unit supplied by the Electronic Service of C.C.R. Euratom Ispra, was used as a source of triggering pulses for the oscillograph (Tektronics 535 A) and as electronic relays for the modulation of the potentiostat. A high speed noise-free, Claire Model Hg 1002 relay was used Oscillograms were recorded by use of a Polaroid camera. Chronopotentiograms were also recorded by a Sargent Recorder, whose input impedance was increased by Keithley Electrometer Model 610 R used as a pre-amplifier.

Results and Discussion

Cathodic and anodic processes at nickel electrodes in oxide free melts.—In molten NiF_2-KF (10-90% in moles) eutectic the reaction[1]

$$(\alpha)\ {}_{I}Ni^{2+} \rightleftharpoons {}_{II}Ni^{2+}$$

is shown to occur at 800°C without activation overvoltage and concentration (diffusion + reaction) polarization up to relatively high current densities (2 amp/cm^2). The measured polarization merely corresponds to the ohmic drop across the electrolyte, as the ϵ *vs.* c.d. plot (not reported here) shows satisfactory evidence for Ohm's law behavior. The blue color of the melt, after contacting it with nickel metal, and the appearance of unidentified peaks in the x-ray powder spectra of the solidified mixture, probably indicates a certain solubility of Ni metal in NiF_2 containing melts (12). Apparently this process does not influence the anodic dissolution and cathodic deposition of nickel.

This result, together with previous ones (5-7) indicates that in fluoride melts also the condition of a zero or extremely low activation overvoltage for the cathodic reduction and anodic dissolution of metals can be considered as a general rule (13, 14).

In oxide-free and Ni^{2+}-free or very dilute NiF_2 solutions in LiF-NaF-KF (46.5-11.5-42 mole %) melts the rate-controlling step for the anodic dissolu-

tion process of nickel has been shown to be the mass-transfer across the diffusion layer.

The Tafel law is followed in the c.d. range 10^{-3} to 10^{-1} amp/cm² as shown in Fig. 2, where the steady-state polarization values are plotted; the slope of the Tafel plot closely corresponds to $RT/2F$, in good agreement with the theoretical slope for a diffusion-controlled anodic dissolution process (15).

No evidence has been obtained in these dilute solutions of an activated rate-determining step.

Anodic processes at nickel electrodes in oxide-containing melts.—Evidence has been given on the influence of oxides (dissolved or as surface layers) on the anodic dissolution process.

It was, in fact, observed that both saturation of the melt with NiO and relatively high partial pressures of water lead to the open circuit passivation of the electrode. Traces of O^{2-} or OH^- resulting from hydrolysis of residual water in the melt (9) are also sufficient for the passivation of the electrode under current flow. The anodic polarization of both active and passive electrodes in alkali fluoride melts leads at a certain critical c.d. or voltage (according to the kind of experimental technique), to an instability shown by oscillations of the electrode voltage or of the cell current as is shown in the following figures.

Figure 3 shows the beginning of the oscillation of the electrode voltage of nickel electrodes in LiF-NaF-KF melts.

The high overvoltage peak, which is observed in Fig. 3, corresponds to the sudden passivation of the electrode. No peaks have been detected in the polarization of passive electrodes in LiF-NaF-KF and LiF-KF (50-50% in moles) melts. The oscillatory behavior of the electrode has also been found less reproducible in frequency than on initially active electrodes.

Figure 4 shows the corresponding instability of the cell current observed by the potentiostatic method at potentials higher than + 400 mv *vs.* a Ni reference electrode in a NiO saturated LiF-NaF-KF melt at 550°C. It is assumed that under these circumstances the Ni reference electrode works as a Ni/NiO electrode.

Figure 5 shows the potentiostatic anodic and cathodic polarization of a passive nickel electrode, determined by the potentiodynamic (potential-sweep) method at a traverse rate of 0.1 v/min, in NaF-KF (40-60% in moles) melts at 800°C. The anodic and cathodic activation of the electrode is observed; it is also worthwhile to observe that passivation occurs without the characteristic passivation loop (29, 30).

The dashed line shows the corresponding ϵ *vs.* c.d. plot obtained by the galvanostatic method in a sep-

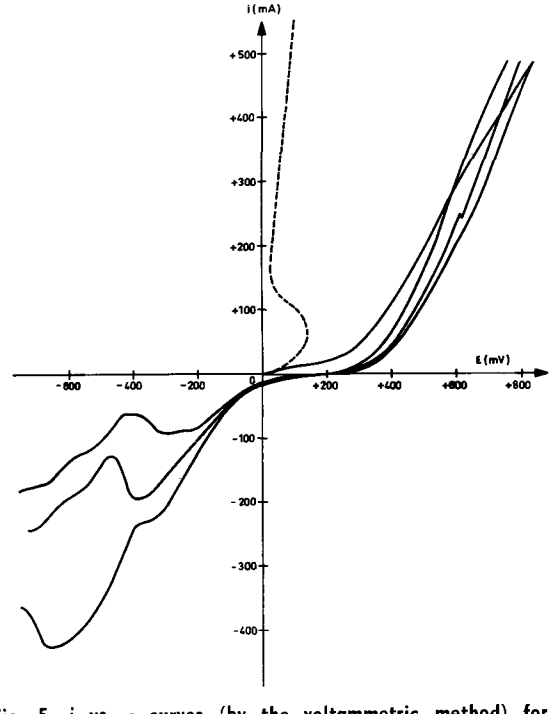

Fig. 5. *i vs.* ϵ curves (by the voltammetric method) for the cathodic and anodic polarization of Ni in NaF-KF melts at 800°C. Sweep 0.1 v/min. The dashed line (from galvanostatic measurements) reports the corresponding iR drops.

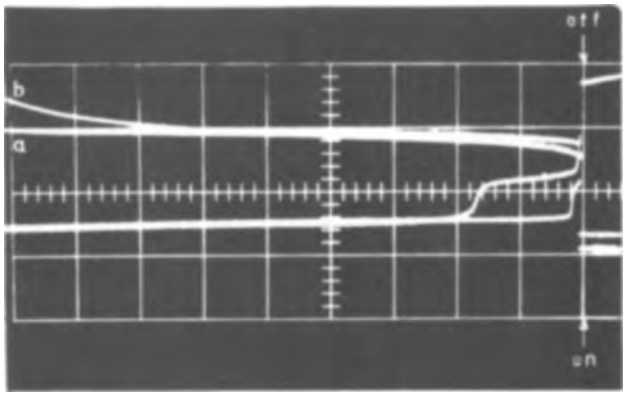

Fig. 6. Oscillograms for the anodic polarization of nickel electrodes in LiF-KF melts at 560°C. $P = 10^{-3}$ Torr. X axis, 50 m sec/cm; y axis, 200 mv/cm; c.d., 900 ma/cm^2.

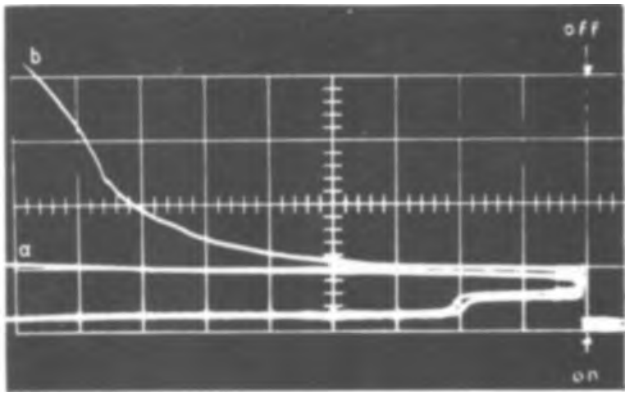

Fig. 7. Oscillograms for the anodic polarization of nickel electrodes in LiF KF melts at 560°C. $P = 10^{-3}$ Torr. X axis, 50 m sec/cm; y axis, 500 mv/cm; c.d., 1.1 amp/cm^2.

arate experiment. The increase of layer thickness in the passive zone is indicated by the deviation from linearity of the experimental curve.

The cathodic activation (due to the reduction of the oxide layer) takes place at a potential very close to the reference potential, whereas the anodic activation occurs at a potential between + 300 and 400 mv *vs.* the reference electrode.

Figures 6 and 7, which refer to the anodic polarization of nickel at 560°C in LiF-KF melts, show the galvanostatic charging curves and the corresponding potential decay curves oscillographically recorded at current densities higher than the critical current density.[2] The corresponding curves in NiO saturated LiF-KF melts and NiO saturated LiF-NaF-KF melts are quite similar.

The transition times, as well as the persistency of the voltage plateau which is observed at about + 200 mv *vs.* the reference electrode, clearly depend both on the total charge passed and on the previous history of the electrode. For this reason any attempt to plot the transition times in an i *vs.* $\tau^{1/2}$ plot is unsuccessful.

In order to account for this active-passive behavior of nickel let us suppose that the passivation of nickel electrodes at open circuit or under current in Li^+-free and in Li^+-containing melts results from an insulating NiO surface film. Indeed we shall discuss the anodic behavior of nickel in terms of the mass transport and charge transfer reactions across the phase boundaries Ni/NiO and NiO/solution as well as across the bulk of NiO.

All the possible reactions occurring at a Ni/NiO electrode, considering both the case of a stoichiometric and a nonstoichiometric oxide layer, are reported in

[2] In each figure two traces are reported: curve (a) refers to the first polarization, curve (b) to a subsequent polarization at the same c.d.

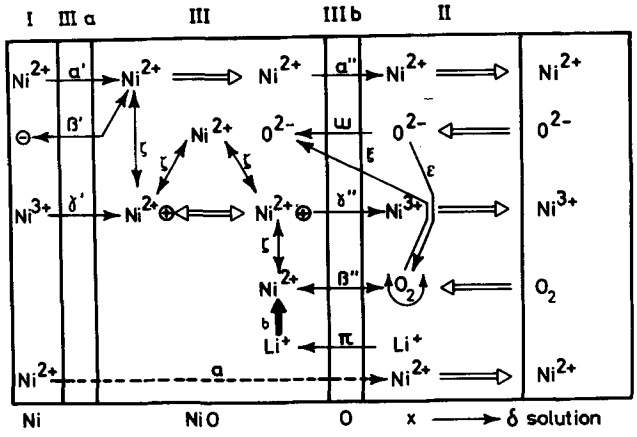

Fig. 8. Phase-scheme according to ref. (28) for a Ni/NiO_{1+x}/ electrode. I indicates the metal phase, III the oxide phase, II the solution phase, IIIa and IIIb being the interphases between the metal and the oxide phase and between the oxide and the solution phase, respectively. → Indicates a charge-transfer process at the interphases IIIa IIIb or in the bulk of the oxide-phase. Open arrow indicates a mass-transfer process across the bulk of a phase. Solid dark arrow indicates the substitutional exchange of a lattice position. $Ni^{2+}\oplus$ indicates a positive hole in the lattice and δ is the thickness of the diffusion layer.

the phase-diagram of Fig. 8 (5) on the basis of the generally accepted conduction mechanism in NiO (16-21). In this diagram the reactions which involve the exchange of electrons have been described (reaction ζ) in terms of jumps of holes between $Ni^{2+}\oplus$ and Ni^{2+}, where Ni^{2+} is a nickel ion in a regular position of the cationic sublattice and $Ni^{2+}\oplus$ corresponds to a hole freed from a cation-vacancy and trapped at a Ni^{2+} site (*i.e.*, corresponds to a Ni^{3+}-ion).

In the same diagram the build-up of nonstoichiometric NiO due to excess oxygen dissolution is indicated by the reaction

$$\beta'' + \zeta + \xi : \tfrac{1}{2}{}_{II}O_2 + 2_{III}Ni^{2+} \hookrightarrow {}_{III}O^{2-} + 2_{III}Ni^{2+}\oplus \quad [1]$$

and the substitutional Li^+ dissolution in the cationic sublattice is indicated by

$$\pi + \sigma + \zeta : {}_{II}Li^+ + {}_{III}Ni^{2+} \rightarrow {}_{III}Li^+(Ni^{2+}) + {}_{III}Ni^{2+}\oplus \quad [2]$$

In the latter case the mass balance is satisfied by the simultaneous occurrence of the reaction

$$(\omega) \qquad {}_{II}O^{2-} \rightarrow {}_{III}O^{2-}$$

However, if the rates of the reactions [1] and [2], both of which lead to a nonstoichiometric oxide layer, are lower than the rate of the Ni diffusion by cation vacancies or grain boundaries into the oxide layer, the NiO surface layer remains at its stoichiometric composition, according to the reaction

$$_{I}Ni + 2_{III}Ni^{3+} \rightarrow 3_{III}Ni^{2+} \quad [3]$$

which corresponds to the coupling of the reactions

$$(\alpha') \qquad {}_{I}Ni^{2+} \rightarrow {}_{III}Ni^{2+}$$

and

$$(\beta') \qquad 2_{I}e + 2_{III}Ni^{3+} \rightarrow 2_{III}Ni^{2+}$$

where ${}_{I}Ni^{2+} + 2_{I}e$ corresponds, according to the formalism used in this paper, to ${}_{I}Ni$.

Evidence has been found from the results of the present work and from the comparison of these results with the literature data, that the surface layer is of stoichiometric composition over a broad range of experimental conditions.

As the present measurements have been done under high vacuum or under oxygen-free argon, it appears that reaction [1] does not affect the stoichiometry of the surface layer.

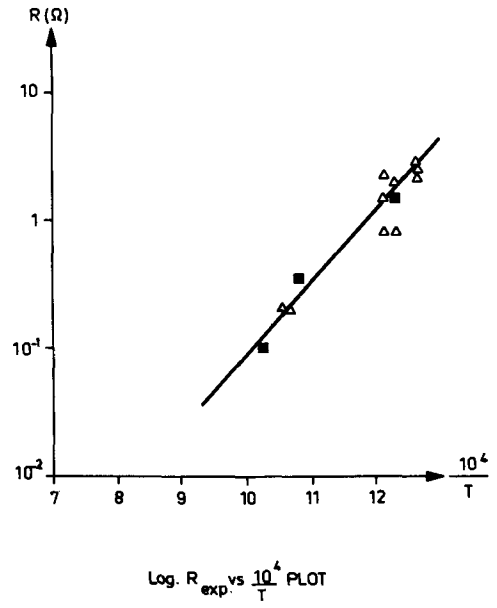

Fig. 9. Log R vs. $1/T$ plot for the electrical resistivity of the NiO layer on nickel electrodes. △ LiF-NaF-KF melts; ■ LiF-KF melts; R is given in ohm/cm^2.

Furthermore, measurements of the self-diffusion coefficients of oxygen and nickel in NiO single crystals in the temperature range 700°-1400°C (22-24) indicate that the diffusion of oxygen in NiO is of several orders of magnitude lower than that of Ni.[3]

From the iR drops, measured on passive nickel electrodes at different temperatures, corrected for the corresponding iR drops due to the electrolyte resistance [about 20-50 mv at 1 amp/cm^2, as measured at iron electrodes, which are perfectly reversible in dilute solutions of FeF_2 in alkali fluoride melts (7)], the value of the d-c resistance of the passivating layer has been obtained.

The slope of the Arrhenius plot[4] obtained with these experimental resistance values, as it is seen in Fig. 9, where R is given in ohm-cm^{-2}, is in quite good agreement with the figures given in ref. (17, 20, 21) for the nearly stoichiometric NiO.

The work of Hill *et al.* (25) indicates that in the molten Li_2SO_4-K_2SO_4 eutectic melt the Ni/NiO electrode behaves reversibly up to about 650°C, where a break in the emf *vs.* T plot is observed. They accounted for this result by suggesting a deviation from the stoichiometry of NiO at temperatures higher than 650°C due to the Li^+-dissolution in solid solution, and supposing a high solubility of the solid solution at temperatures lower than 650°C.

This result is qualitatively in agreement with our results, as it was also shown that in Li^+-containing melts the surface layer is nearly stoichiometric, at least at temperatures lower than 650°C. We do not agree, however, with the suggestion of a high solubility of the Li_2O-NiO solid solution at low temperatures, as it seems much more probable that a slow rate-determining step affects the over-all rate of reaction [2].

We found in fact (26) that reaction [1], which was investigated on sintered pellets of NiO at oxygen partial pressures between 3 to 760 Torr, is a very slow one in the same temperature range.

Finally it is worthwhile to note that the curves of the cathodic reduction of the oxide layer in Fig. 5 (cathodic activation) demonstrate that the reduction occurs at the reversible potential with an uncertainty of few millivolts (which is of the same order as the emf of the tensiometric cell) under the assumption that the reference electrode reaction is that of an oxide electrode.

It appears indeed that the anodic dissolution of nickel at passive electrodes is described by reaction [4] (see Fig. 8)

$$\alpha' + Ni^{2+}\text{-transfer} + \alpha'' \qquad [4]$$

at current densities or potentials lower than the critical transition current or the transpassive potential, respectively, at temperatures lower than 650°C in Li^+ containing melts and at higher temperatures in Li^+-free melts.

As for the activation of passive nickel electrodes and the oscillatory behavior of nickel under strong anodic polarization, only a qualitative picture of the phenomenon results from the experimental data. We discuss only the case of the activation of a passive nickel electrode, which is assumed as before to be initially covered with a layer of nearly stoichiometric nickel oxide. Differing from the iron-oxide system, the stability range of the wüstite-type NiO_{1+x} phase is not well defined and the higher nickel oxides are known to be unstable as bulk phases at high temperature.

Furthermore, x-ray diffraction patterns obtained at room temperature from these higher oxides do not reveal a structure different from that of NiO (27).

However, the steps in the potential decay curves (see Fig. 6 and 7) and the reproducibility of the activation potential (see Fig. 5) seem to indicate the formation of a higher nickel oxide surface phase with good electronic and (or) ionic conductivity under sufficiently strong anodic polarization.

The proposed model for such an electrode is given in Fig. 10, where the oxide phase (NiO_{1+y}) is supposed to have a composition near to Ni_3O_4 ($y \leq 0.33$).

If only electronic conduction is supposed, via electron holes or electrons only the reactions

$$(\epsilon) \qquad {}_{II}O^{2-} \rightarrow \tfrac{1}{2}\,{}_{II}O_2 + 2_{IV}e$$

$$(\epsilon') \qquad {}_{II}O^{2-} + 2_{IV}\oplus \rightarrow \tfrac{1}{2}{}_{II}O_2$$

$$(\lambda) \qquad {}_{II}Ni^{2+} \rightarrow {}_{II}Ni^{3+} + {}_{IV}e$$

$$(\lambda') \qquad {}_{II}Ni^{2+} + {}_{IV}\oplus \rightarrow {}_{II}Ni^{3+}$$

should occur in the transpassive[5] range, as the fluo-

[3] $D^{O}_{NiO} = 1.0 \times 10^{-5} \exp(-54\ \text{kcal}/RT)\ \text{cm}^2\ \text{sec}^{-1}$ (22)
$D^{Ni}_{NiO} = 1.7 \times 10^{-4} \exp(-56.0\ \text{kcal}/RT)\ \text{cm}^2\ \text{sec}^{-1}$ (23)
$D^{Ni}_{NiO} = 1.83 \times 10^{-3} \exp(-45.6\ \text{kcal}/RT)\ \text{cm}^2\ \text{sec}^{-1}$ (24)

[4] Which is taken as a measure of the activation energy of the electrical resistivity according to the relationship
$\rho = \rho^0 A \exp(\Delta E/RT)$

[5] The transpassive range (28-30) is considered here as the anodic c.d. range lying at c.d. higher than the activation current.

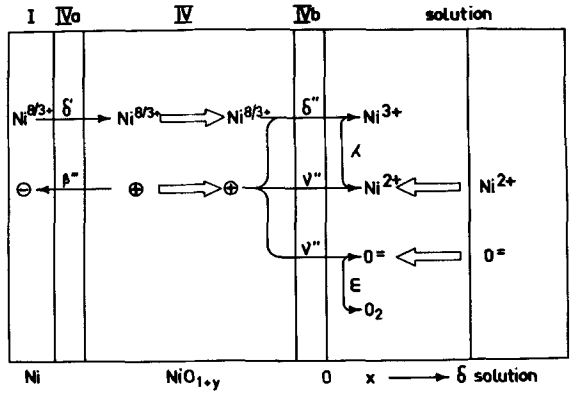

Fig. 10. Phase-scheme, according to ref. (28) for a Ni/NiO_{1+y} electrode. I indicates the metal phase, II the solution phase, IV a magnetite-type NiO_{1+} phase, IVa and IVb the interphases between the metal and the oxide phase, and between the oxide and solution phase, respectively. → Indicates a charge-transfer process. Open arrow indicates a mass-transfer process. δ is the thickness of the diffusion layer.

rine discharge reaction occurs at much more anodic potentials, as compared with the potential at which activation occurs (see Fig. 5).

However, the melt is a very dilute solution of both Ni^{2+} and $O^{=}$ and reactions ϵ, ϵ', λ, and λ' should occur under diffusion limiting current conditions.

Actually, from previous measurements which have been carried out in fluoride melts (9) in order to investigate the oxygen evolution reaction on bright platinum electrodes, there is the evidence that the limiting current for the anodic reaction

$$O^{=} \rightarrow \tfrac{1}{2} O_2 + 2e$$

in melts prepared with the same experimental procedure ranges between 2-10 ma/cm^2. It is apparent that other reactions, different from the ϵ and λ ones, are to be considered, as their contribution to currents as high as 500 ma, observed in the transpassive range, is negligible.

We consider indeed a mass transfer reaction, indicated as $Ni^{8/3+}$ transfer[6] in Fig. 10, which occurs, simultaneously with the ϵ and λ ones, across a very thin layer of NiO_{1+y}. It is worthwhile to note that the cracking of this layer could be responsible for the oscillatory behavior of nickel electrodes observed both under galvanostatic and potentiostatic polarization and of the high currents observed in the transpassive range.

In this latter case, under potentiostatic polarization (by the potential-sweep method) both the reactions

$$\delta' + Ni^{8/3+}\text{-transfer} + \delta''$$

and

$$(\alpha) \qquad {}_{I}Ni^{2+} \rightarrow {}_{II}Ni^{2+}$$

occur, at a rate which only depends on the characteristics of the *i vs.* ϵ curves for the separate reactions.

As the activation potential and that of the potential steps seem to be independent of the oxygen partial pressure over the melt, we postulate that the over-all anodic activation reaction is

$$3\,NiO + O^{2-} \rightarrow Ni_3O_4 + 2e \qquad [5]$$

The coupling of reaction [5] with reaction [6]

$$NiO + 2e \rightarrow Ni + O^{2-} \qquad [6]$$

(which is the electrode reaction at the reference electrode) corresponds to the reaction

$$Ni + Ni_3O_4 \rightleftharpoons 4\,NiO \qquad [7]$$

From the figures for the activation potential (+380 mv at 800°C) and of the steps in the potential decay curves (+ 200 mv at 550°C) we obtain for the free energy of reaction [7]

$\Delta G_7 = -2FE = -9000 \pm 460$ cal at 550°C and $\Delta G_7 = -16.000 \pm 460$ cal at 800°C.

Acknowledgments

The authors wish to acknowledge Dr. G. Sternheim for many stimulating discussions, Dr. M. A. Bredig (Oak Ridge National Laboratory) for his suggestions about nickel solubility in molten fluorides, Dr. Vos and Mr. Toussaint for their x-ray analyses and Dr. Becker and Mr. Termanini for the construction of the electronic relay.

Manuscript received April 22, 1966; revised manuscript received July 7, 1966. This paper was presented at the San Francisco Meeting, May 9-13. 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

[6] ${}_{IV}Ni^{8/3+} = \frac{1}{3}\,{}_{IV}Ni^{2+} + \frac{2}{3}\,{}_{IV}Ni^{3+}$ [ref. (28)]

SYMBOLS

ϵ	Potential difference measured at the terminals of the tensiometric cell
$I^{Me^{z+}}$	Corresponds to $Me - z_I e$, where the subscripts at the left indicates the phase (28)
I	Metal phase
II	Solution phase
III or IV	Oxide phases
$\ominus$	Indicates an electron
$Me^{2+} \oplus$	Indicates a hole trapped at a cationic site
$\oplus$	Indicates a free electron hole

The Oxidation of Silicon Carbide at 1150° to 1400°C and at 9 x 10^{-3} to 5 x 10^{-1} Torr Oxygen Pressure

Earl A. Gulbransen, Kenneth F. Andrew, and Fred A. Brassart

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A kinetic study was made of the oxidation of high-purity silicon carbide using a dynamic-type reaction system. Two types of oxidation behavior were found. Passive oxidation occurred for conditions where silica films were formed on the surface. Active oxidation occurred for conditions where volatile silicon monoxide was formed. The transition conditions between the two types of oxidation were studied as a function of oxygen pressure and temperature. The transition temperatures and pressures were related to thermochemical conditions for the reaction of silicon carbide with silica to form silicon monoxide and carbon monoxide.

The oxidation of silicon carbide has been studied extensively at normal pressure where silica films are formed (1-7). Several of the workers (2, 6, 7) showed that amorphous silica films were formed during oxidation below 1300°C and cristobalite at 1300°C and higher.

Webb, Norton, and Wagner (8) suggest that, in the oxidation of carbides, protective oxide films form provided the carbide does not react with its oxide. If reaction occurs, rupture of the oxide may occur.

At low oxygen pressures Ervin (1) showed high rates of reaction could occur with the formation of silicon monoxide. Following Wagner's analyses (9) of the analogous silicon oxidation reaction we will call this fast region of oxidation the active region, and the slow region where silica films are formed, the passive region. The purpose of this paper is to extend Ervin's (1) work and to study the transition conditions for the two regions of oxidation.

Thermochemical Analyses

Table I shows the reactions which can occur in the silicon carbide oxygen system and associated reactions. Reactions [1]-[4] show large positive values for log K_p. Rupturing of the oxide film could occur when silica films are formed. Oxidation can also occur without the formation of an oxide film by reactions [2] and [4]. Reaction [5] shows silicon carbide dissociates under vacuum conditions if silicon vapor is removed. The solid phase reactions of silicon carbide with silica, reactions [6] and [7], can occur if the gaseous reaction products are removed. Reactions [6] and [7] can be compared to the reaction between silicon and silica. The silicon monoxide equilibrium pressures (for reactions [6] and [8]) can be calculated from the data of Table I. If sufficient silicon monoxide exists in the gas phase, reactions [6] and [8] can be reversed with the formation of silica films on silicon.

Apparatus and Samples

The apparatus and method have been described (11, 12). A Cahn (13) type of vacuum microbalance was used in the flow reaction system.

Table I. Thermochemical analyses, silicon carbide-oxygen system

Reactions	Equilibrium constants (log K_p) (10) 1127°-1527°C		
	1127°	1327°	1527°
[1] $SiC(s) + 3/2O_2(g) \rightleftarrows SiO_2(s) + CO(g)$	30.60	26.26	22.89
[2] $SiC(s) + O_2(g) \rightleftarrows SiO(g) + CO(g)$	14.17	13.51	12.99
[3] $SiC(s) + 2O_2(g) \rightleftarrows SiO_2(s) + CO_2(g)$	36.61	30.96	26.58
[4] $SiC(s) + 3/2O_2(g) \rightleftarrows SiO(g) + CO_2(g)$	20.18	18.22	16.69
[5] $SiC(s) \rightleftarrows Si(s) + C(s)$	−2.828	−2.428	−2.018
[6] $SiC(s) + 2SiO_2(s) \rightleftarrows 3SiO(g) + CO(g)$	−18.70	−11.98	−5.58
[7] $SiC(s) + 3SiO_2(s) \rightleftarrows 4SiO(g) + CO_2(g)$	−29.12	−20.02	−13.00
[8] $1/2Si(s) + 1/2SiO_2(s) \rightleftarrows SiO(g)$	−4.106	−2.520	−1.347

Single crystals of light green silicon carbide were obtained through the courtesy of Hamilton (14). Most of the crystals had small twin crystals attached at some point on the surface. The crystals were of high-purity grade having a total impurity level of 10^{15}-10^{17} atoms/cc.

The crystals had the α-SiC 6H structure (15, 16). The basal plane (0001) was in the surface. No attempt was made to distinguish the silicon and carbon faces of the crystals.

The crystals weighed 0.01-0.025g, had surface areas of 0.12 to 0.28 cm^2, and were 0.06 to 0.07 cm thick. Individual crystals were suspended from the end of the balance by using 0.06 cm diameter quartz fibers. Reagent grade oxygen was used in all experiments.

Method.—The method in brief was to heat the sample to temperature in vacuum. After equilibrium was achieved, oxygen was added to the desired pressure over a time period of 1 to 1½ min to prevent serious disturbances to the sample and balance. During this period of changing pressure, the sample may have undergone reaction under varying oxidation conditions.

Results and Discussion

Active and passive oxidation processes.—Figure 1 shows a series of experiments at 4 x 10^{-2} Torr oxygen pressure which were made to evaluate the transition conditions between active and passive oxidation.

Zone 1 of Fig. 1 shows an active type of oxidation occurs at 1300°C. Passive oxidation occurs with the formation of an oxide film as shown in zone 2 at 1250°C. The rate of oxidation decreases in zone 3 as the silica film grows in thickness.

Active oxidation occurs again on raising the temperature to 1300°C in zones 4 and 5. The presence of a silica film prevents the occurrence of a rapid type of active oxidation. Removal of the oxide film by reactions [6] and [7] was a slow process at 4 x 10^{-2} Torr pressure.

To remove the silica film at a more rapid rate, it was necessary to heat the sample in vacuum. A test was made on the effect of heating in a vacuum at 1300°C for 75 min (zone 7). A rapid weight loss type of oxidation occurred on reoxidizing in zone 8.

These experiments show two basic oxidation processes occur in the oxidation of silicon carbide. The first was a weight loss or active type of reaction. Volatile silicon monoxide was formed together with carbon monoxide. Protective oxides may exist on the surface, but these were not formed during oxidation under the given conditions. The second was a weight gain or passive type of oxidation. Here, a silica film was formed. Since carbon monoxide was also formed, fast reactions could occur due to rupturing of the oxide film.

We term oxidation reactions occurring slowly in the active region in the presence of previously formed silica films as intermediate types of oxidation reactions.

Effect of pressure on transition temperature for active and passive oxidation.—Figure 2 shows weight change *vs.* time curves at pressures of 9 x 10^{-3}, 4 x 10^{-2}, 1 x 10^{-1}, and 5 x 10^{-1} Torr at 1300°C. Figure 2 shows passive oxidation occurs at 1300°C for pressures of 1 x 10^{-1} and 5 x 10^{-1} and active oxidation for pressures of 9 x 10^{-3} and 4 x 10^{-2} Torr. Similar plots were made for the same pressures at 1350° and 1400°C. Active oxidation was found to occur at 1350°C for 9 x 10^{-3} and 4 x 10^{-2} Torr pressures and passive oxidation at 1 x 10^{-1} and 5 x 10^{-1} Torr pressures. At 1400°C, active oxidation was found to occur for 9 x 10^{-3}, 4 x 10^{-2}, and 1 x 10^{-1} Torr pressures.

The weight gain curves at 1300°, 1350°, and 1400°C initially show fast rates of oxidation. After several minutes of oxidation, a protective film of silica was formed and the rates of oxidation decreased. We conclude that the transition pressure at 1300°C was between 4 x 10^{-2} and 1 x 10^{-1} Torr, at 1350°C it was about 1 x 10^{-1} Torr, and at 1400°C the transition pressure was above 1 x 10^{-1} Torr.

Light microscopic observations on the reacted samples were made. One side showed lightly etched regions while the other side was smooth. The edge near where the original crystal was grown also showed evidence of selective reaction.

We interpret the weight loss curves as reaction of both Si and C atoms from the SiC surface. The initial

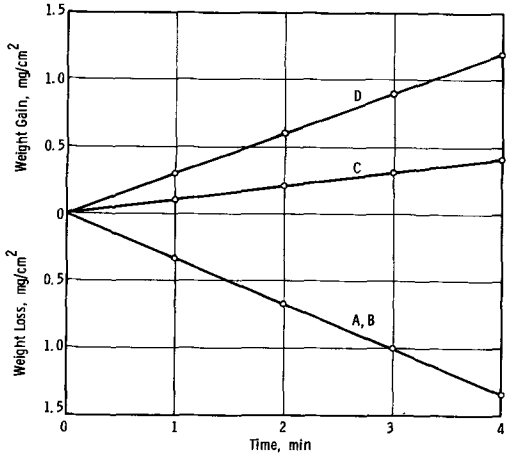

Fig. 2. Oxidation of SiC, effect of pressure, 1300°C: A, 9 x 10^{-3}; B, 4 x 10^{-2}; C, 1 x 10^{-1}; D, 5 x 10^{-1} Torr.

weight losses were a linear function of time. Since an oxide film was not formed and the reaction products were removed by the gas flow, no evidence was found for a change in the mechanism of reaction as the reaction proceeded.

We interpret the weight gain curves as the difference between oxygen reacted to form silica and the weight of carbon lost by reaction with oxygen. For each 32g of oxygen reacted with silicon, 12g of carbon were reacted with oxygen. From stoichiometry, the weight of silica formed was 3 times the weight gain.

Kinetics of active type oxidation of SiC.—Table II shows a summary of the kinetic data for the active or weight loss region of oxidation. The following reactions were proposed to account for the oxygen consumed in the reaction.

$$SiC(s) + O_2 \rightleftarrows SiO(g) + CO(g) \quad [2]$$

$$SiO(g,s,l) + \tfrac{1}{2} O_2 \rightleftarrows SiO_2(s) \quad [9]$$

Reaction [2] occurs at the sample-gas interface while reaction [9] occurs after the SiO(g) leaves the surface and condenses on the furnace tube. Total oxygen consumed was the sum of that used in reactions [2] and [9], *i.e.*, 3 atoms of O per SiC molecule.

The data at 9 x 10^{-3} Torr for 1300°, 1350°, and 1400°C show little effect of temperature on the rate of oxidation. Pressure or gas flow had a major effect on the kinetics of oxidation. This was seen in values of dn'/dt at 1400°C for the three pressures 9 x 10^{-3}, 4 x 10^{-2}, and 1 x 10^{-1} Torr. The data indicates a $P^{0.8}$ dependence. We would suggest that gas diffusion of oxygen to the reaction interface was rate controlling.

Kinetics of the passive-type oxidation of SiC.—Figure 2 also shows weight gain curves. These curves show part of the initial fast stage of the reaction since part of the oxidation was not observed while the oxygen pressure and gas flow were adjusted. After several minutes of reaction, a protective film was formed and the rates of oxidation decreased to small values.

Table II. Summary kinetic data oxidation SiC, active region

Temp, °C	Reaction conditions: Pressure, Torr	Flow, atoms O/sec	Kinetic data: Wt. loss, g/sec	dn'/dt, molecules/cm²-sec	Efficiencies: Flow, %	Kinetic theory, %	Comments, type reaction
1250	9 x 10^{-3}	2.2 x 10^{17}	1.87 x 10^{-7}	1.47 x 10^{16}	3.8	1.0	Intermediate
1300	9 x 10^{-3}	2.26 x 10^{17}	1.56 x 10^{-6}	8.6 x 10^{16}	32	6.1	Active
1350	9 x 10^{-3}	2.08 x 10^{17}	1.65 x 10^{-6}	8.9 x 10^{16}	36	6.4	Active
1400	9 x 10^{-3}	1.23 x 10^{17}	1.31 x 10^{-6}	1.67 x 10^{17}	49	12.3	Active
1300	4 x 10^{-2}	1.74 x 10^{18}	7.5 x 10^{-7}	8.5 x 10^{16}	2.0	1.4	Intermediate
1350	4 x 10^{-2}	1.86 x 10^{18}	8.6 x 10^{-7}	6.8 x 10^{16}	2.1	1.1	Intermediate
1400	4 x 10^{-2}	1.62 x 10^{18}	5.22 x 10^{-6}	6.6 x 10^{17}	15	11	Active
1400	1 x 10^{-1}	1.33 x 10^{19}	9.3 x 10^{-6}	1.2 x 10^{18}	3.2	8	Active

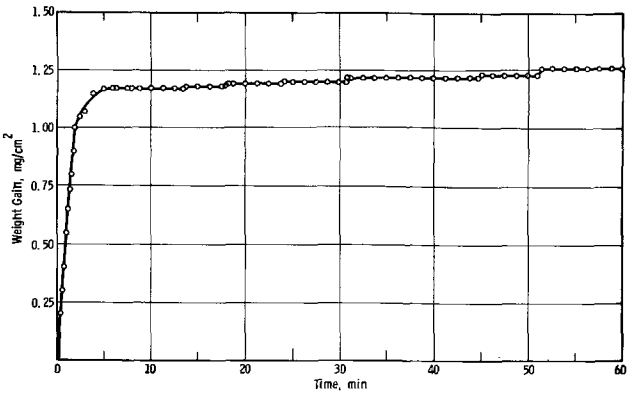

Fig. 3. Oxidation SiC, 1250°C and 4 x 10^{-2}

Figure 3 shows a weight gain *vs.* time curve, after the initial period, for the oxidation of SiC at 1250°C and 4 x 10^{-2} Torr pressure. Figure 3 shows a rapid oxidation for the first 5 min after which a slow reaction was found. A fast rate of oxidation of 7.5 x 10^{-6} g/cm²-sec was observed in the early stages of reaction. This rate decreased to 2.7 x 10^{-8} g/cm²-sec during the slow part of the oxidation. The oxidation in the latter stages of reaction appeared to occur in small increments. This suggested a cracking and healing of the silica film on the SiC for conditions near transition.

Table III shows a summary of the data for the weight gain region of oxidation. It was of interest to calculate the thickness of silica films, required for slow reaction, from an analysis of curves as shown in Fig. 3. These thickness values are given in Table II in units of grams per square centimeter and in angstroms.

Mass spectrometer study of the reaction products.—A liquid helium cooled trap was attached to the reaction system, and the gases were collected from the 1350°C and 9 x 10^3 Torr experiment. The gas analysis showed carbon monoxide as the major reaction product. We also conclude that carbon monoxide was not oxidized in the furnace tube after leaving the SiC surface.

Flow and kinetic theory efficiencies.—To compare this oxidation reaction with other fast oxidation reactions, it is of interest to calculate the flow and kinetic theory efficiencies. The flow efficiency is calculated as the ratio of the oxygen gas which reacts to the oxygen gas passed over the sample. The equation is

$$E = \frac{3\,dn/dt}{F} \qquad [10]$$

Table IV. Comparison theoretical and experimental values of maximum oxygen pressures for oxide free surfaces on silicon carbide

Temp, °C	Theoretical, p_{O_2}(max) Torr	Experimental, p_{O_2}(max) Torr	Ratio, p_{O_2} theory/p_{O_2} expt.
1200	3.5×10^{-2}	10^{-2}	3.5
1300	2×10^{-1}	$4 \times 10^{-2} - 1 \times 10^{-1}$	~3
1400	1.5	5×10^{-1}	3

Here F is the flow rate in atoms of O passing over the specimen per second and dn/dt is the actual reaction rate in molecules of SiC reacting per second. Table II gives values of the flow efficiencies for the various reaction conditions. Flow efficiencies up to 49% were calculated for active oxidation.

The kinetic theory efficiencies were calculated from the expression for the number of collisions of oxygen molecules with the surface per cm²-sec, n, and the rate of oxidation dn'/dt. The expression is

$$\epsilon = \frac{dn'/dt}{n} \qquad [11]$$

Table II gives the values for the various reaction conditions. Kinetic theory efficiencies up to 12.3% were calculated.

Calculation of transition conditions between active and passive oxidation.—Wagner (9) considered the transition between active and passive oxidation of silicon for various partial pressures of oxygen in a flowing oxygen-helium gas mixture. The following equation was developed for calculating the maximum partial pressure of oxygen, p_{O_2} (max), for maintaining an oxide free surface of silicon

$$p_{O_2}\,(\max) \cong \tfrac{1}{2}\,(D_{SiO}/D_{O_2})^{1/2}\,p_{SiO}\,(eq) \qquad [12]$$

Here p_{SiO} (eq) is the equilibrium pressure of silicon monoxide from Eq. [8] of Table I. D_{SiO} and D_{O_2} were the diffusion coefficients of SiO and O_2 in the boundary layer gas mixture. Wagner estimated D_{SiO}/D_{O_2} to have a ratio of 0.64 from the molecular weights and diameters of SiO and O_2 molecules.

The same analysis can be made to calculate the transition conditions for the oxidation of silicon carbide. Since mass spectrometer analyses showed the formation of carbon monoxide, Eq. [6] of Table I was used to calculate the equilibrium values for p_{SiO}. A ratio of 0.64 was assumed for D_{SiO}/D_{O_2} and a value of ½ for the exponent of the ratio. Values of p_{SiO} were taken from Eq. [6] of Table I.

Table IV shows the theoretical and experimental values for the values of p_{O_2} (max) and the ratio of the theoretical and experimental values for 1200°, 1300°, and 1400°C. The theoretical values were larger

Table III. Summary kinetic data oxidation SiC, passive region

Reaction conditions			Kinetic data			Oxide thickness

The Mechanism of Demineralization at Carbon Electrodes

S. Evans and W. S. Hamilton

Research Division, Rocketdyne, A Division of North American Aviation, Inc., Canoga Park, California

ABSTRACT

The results of coulometric and mass-balance analyses were used to establish the mechanism of demineralization and regeneration at chemically treated carbon paste electrodes. The chemical treatment results in the formation of weak acid groups on many carbon surfaces. The acid groups are ionized in the cathodic cycle by the electrochemical generation of hydroxyl ion. Anionic groups thus produced result in depletion of cations from solution. During regeneration, the hydrogen which was adsorbed on the carbon during the demineralization cycle is oxidized, giving rise to acid conditions. The anionic groups are thus converted back to the acid form, and cations are released to the solution.

Several mechanisms have been proposed to account for the adsorption of alkali or acid on carbon. Schilow (1) postulated that such adsorption arose by interaction with acidic and basic oxides on carbon surface. Garten and Weiss (2) explained the adsorption of cations from basic solution (*e.g.*, NaOH) on cathodically polarized charcoal and platinized charcoal by the reduction of quinone to hydroquinone. Recently it has been reported that considerable adsorption of alkali occurred under experimental conditions which excluded the presence of quinone or hydroquinone groups (3). Frumkin and co-workers (4) proposed an electrochemical theory wherein activated charcoal functions as a gas electrode in the presence of oxygen or hydrogen. In the presence of hydrogen, hydrogen ion appears in solution, leaving the charcoal negatively charged; the negatively charged surface attracts an equivalent quantity of cations. The electrochemical sorption of active gases (oxygen, hydrogen) on activated carbon has been used in analytical radiochemistry for the selective adsorption of ions from solution (5, 6).

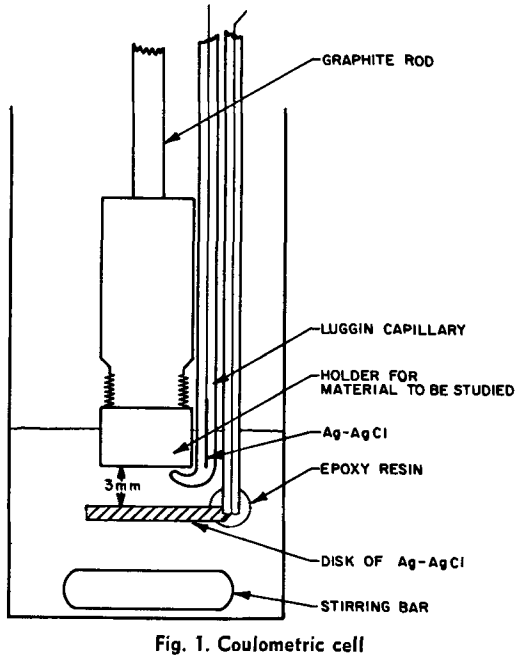

Fig. 1. Coulometric cell

In contrast to the above studies, the objective of this effort is to elucidate the mechanism of exchange of cations from neutral NaCl solutions. Coulometric and mass-balance experiments were used to establish the relationship between coulombs passed and extent of exchange.

Experimental

The cell (Fig. 1) was a small glass vial in which the three electrodes were fixed in the positions shown. The auxiliary electrode was made by anodizing a disk of porous silver in HCl solution. The test electrode (Fig. 2) consisted of a Teflon cup threaded to fit a Teflon plunger through which a ¼-in.-diameter graphite rod was cemented. A graphite disk was placed between the graphite rod and the carbon paste to improve electrical contact to the paste. A 25-mg sample of the material to be studied was supported on a disk of Whatman No. 42 filter paper. The potential at the test electrode was detected through a Luggin capillary which contained a silver wire coated with silver chloride. This Ag-AgCl electrode was in contact with the electrolyte (*e.g.*, 300 ppm NaCl). The electronic instrumentation has been described previously (7).

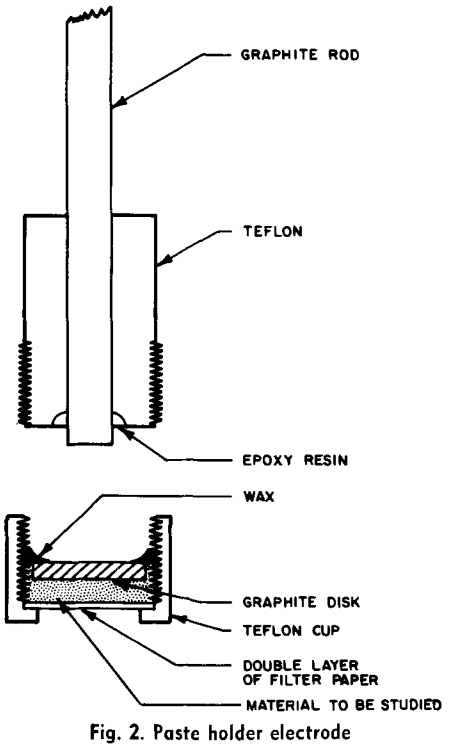

Fig. 2. Paste holder electrode

The materials studied included Air-Spun graphite, Norit-A, Carbolac-1, the sulfonic acid exchange resin Dowex 50W-X4 (J. T. Baker), and the carboxylic acid ion-exchange resin Amberlite IRC-50 (Mallinckrodt). The carbon materials (Air-Spun graphite, Norit-A, and Carbolac-1) were oxidized in a mixture of nitric and sulfuric acids in accordance with a procedure developed at the University of Oklahoma (8).

The cation exchange capacity of the above materials was determined chemically by suspending a sample in 0.2M NaOH for about 24 hr. The material was then filtered, washed with deionized water, and vacuum dried. A 25-mg portion of the dried sample was suspended in 10 cc of 0.12M HCl solution for about 24 hr. The solution was filtered and the filtrate was analyzed for sodium. The concentration of sodium ion in solution can be expressed in terms of milliequivalents of sodium adsorbed per gram of material.

All of the test solutions were analyzed for sodium ion with a Beckmann DU Spectrophotometer with flame attachment and were titrated potentiometrically for chloride ion.

Results

Ion Uptake and Release

The tabulated results of several experiments are shown in Tables I and II. An entire series of experiments was performed sequentially (*e.g.*, B-1 through B-19) with one 25-mg sample of the material. Each experiment in a series involved pipetting 10 cc of 300 ppm NaCl solution into the cell and passing a constant current (0.2 ma) between the paste electrode and the auxiliary Ag-AgCl electrode. The efficiencies were calculated from the ratio of the coulombic equivalent of the measured change in sodium or chloride ion concentration to the actual number of coulombs passed. The approximate *p*H at the paste electrode was determined by contacting a piece of *p*H indicator paper to the bottom surface of the test electrode. The recorded values are therefore not the *p*H of the bulk solution.

The results of six replicate experiments with different samples of acid-treated Norit-A were similar; some of the results of one series of experiments are shown in Table I. The minimum number of tests for a series was 40. During this time there was no evidence of electrode deterioration. Alternate cathodic and anodic cycles resulted in removal and release of sodium ion, respectively.

At high efficiencies for sodium ion (Table I) there was no change in surface *p*H and a mass-balance analysis for sodium ion was experimentally obtained. Decrease in the efficiency for sodium ion uptake or release was accompanied by an increase and decrease in surface *p*H, respectively; under these conditions a mass balance for NaCl was not obtained. One test series was carried out in a nitrogen atmosphere; the results were much the same as those shown in Table I. There was no release of sodium ion to the solution when the electrodes were allowed to remain on open circuit for several hours.

It can be seen (Table II) that similar results were obtained when a weak-acid ion-exchange resin (Amberlite IRC-50) was used as the active material.

Representative data from all of the experiments were condensed and are plotted in Fig. 3. Each point represents one sequential experiment of a test series. The cumulative number of equivalents of sodium adsorbed on the electrode during a continuous series of cathodic cycles (*e.g.*, JA-1 through JA-11) is plotted against the efficiency for each cycle.

It can be seen (Fig. 3) that with Air-Spun graphite (HJ), acid-treated Air-Spun graphic (HI), and a 2:1 mixture of Norit A and Air Spun graphite (HD), exchange capacities were low, and the exchange process

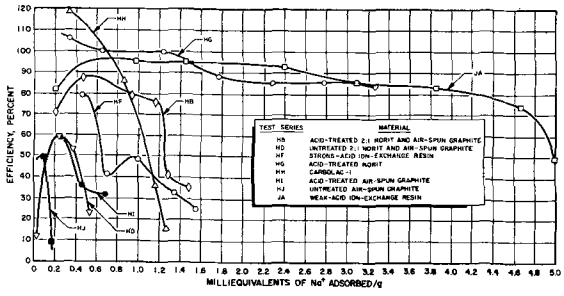

Fig. 3. Exchange characteristics of cation-exchange materials

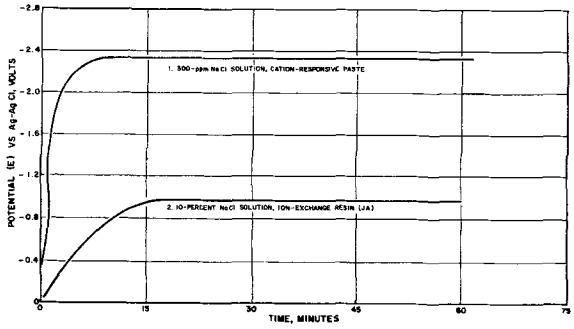

Fig. 5. Potential of paste electrode during demineralization (0.2 ma/mp).

was inefficient. The exchange was accompanied by rapid changes in pH.

The strong acid ion-exchange resin mixed with untreated Norit-graphite (HF) has a capacity of the order of 1.55 millieq./g. The process, however, is inefficient and is accompanied by pH changes.

The Carbolac-1 (HH), has been electrochemically titrated to the extent of 1.3 millieq. of acid per gram. Titration of Carbolac-1 with NaOH (9) yielded 1.8 millieq./g.

The total exchange capacity of the acid-treated Norit and graphite mixture (HB) was of the order of 3 millieq./g; the process was efficient for the exchange of 1.2 millieq./g. Changes in pH were observed only after exchange had occurred to this extent (*i.e.*, 1.2 millieq./g). This material was studied extensively. The exchange characteristics were similar when nitrogen was present. Good reproducibility was found in replicate experiments.

The exchange capacity of acid-treated Norit-A (HG) varied from about 2.6 to 3.5 in the six replicate experiments. In test series HG (Fig. 3), exchange corresponding to 3.3 millieq./g occurred relatively efficiently with only small change in pH. The material was successfully regenerated with H_2SO_4.

The weak-acid ion-exchange resin, Amberlite IRC-50 (JA, Table II), exchanged efficiently to the extent of 4.7 millieq./g with no changes in pH. Regeneration of this material occurred with equal efficiency (Fig. 4). Test JA-17, in 1000 ppm NaCl solution (Table II), was 88% efficient, demonstrating good recycling capability. There was no significant release of sodium ion to the solution when the electrode was allowed to remain on open circuit for 2 hr (JA-3).

Electrode Potential

The potential of the test electrode with respect to the Ag-AgCl electrode contained in the Luggin capillary was monitored for each of the constant-current experiments.

Demineralization (ion uptake).—A typical potential curve obtained during a demineralization cycle (0.2 ma, 300 ppm NaCl, test electrode is cathode) consisted of two regions (curve 1, Fig. 5); an initial region of rapid potential change generally covering the range from 5 to 10 min, followed by a region of constant potential. All of the curves were of similar shape; the magnitude of the potential in the constant-potential region varied from about 2 to 2.8v for carbon-paste materials. The value was about two times greater in experiments with the weak-acid resin (test series JA) where no carbon paste was present and where the entire electrochemical reaction took place on the graphite backing. Potential measurements with this electrode during demineralization in a 10% NaCl solution were of the same general shape (curve 2, Fig. 5).

A current interruptor technique (7) was used in a few of the experiments to establish the extent of the IR contribution to the potential measured between the reference electrode contained in the Luggin capillary and the test electrode. It was found that during the demineralization cycle the magnitude of the IR drop rose continuously for the first several minutes at constant current and achieved a steady value during the constant-potential region of the curve.

The assumption was made that the difference between the end potential during a demineralization cycle and the potential recorded immediately on breaking the circuit is a measure of the IR drop. Values determined in this manner were in qualitative agreement with these determined using a current interruptor technique. The value of the final IR drop for various materials has been plotted with respect to the efficiency of removal of sodium ion for the cycle in which the recording was made (Fig. 6). It can be seen that when demineralization was occurring efficiently the magnitude of the final IR drop was high. At such times no surface pH changes were detected.

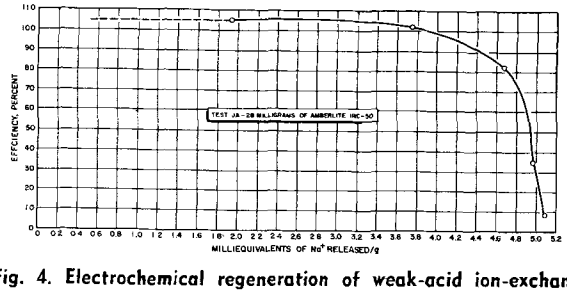

Fig. 4. Electrochemical regeneration of weak-acid ion-exchange resin.

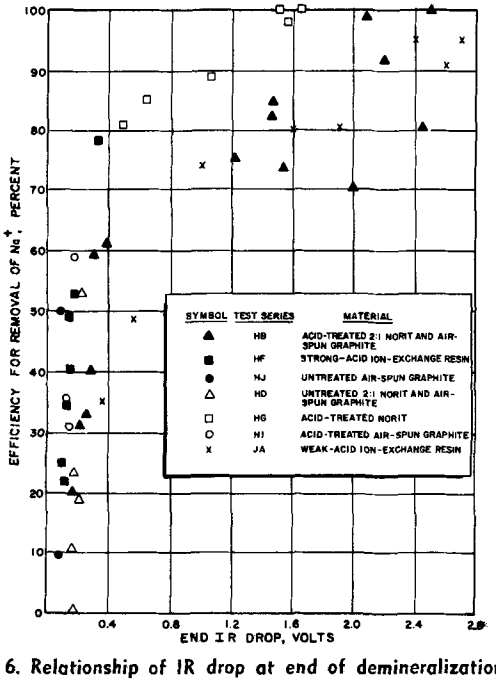

Fig. 6. Relationship of IR drop at end of demineralization cycle to measured efficiency of the cycle.

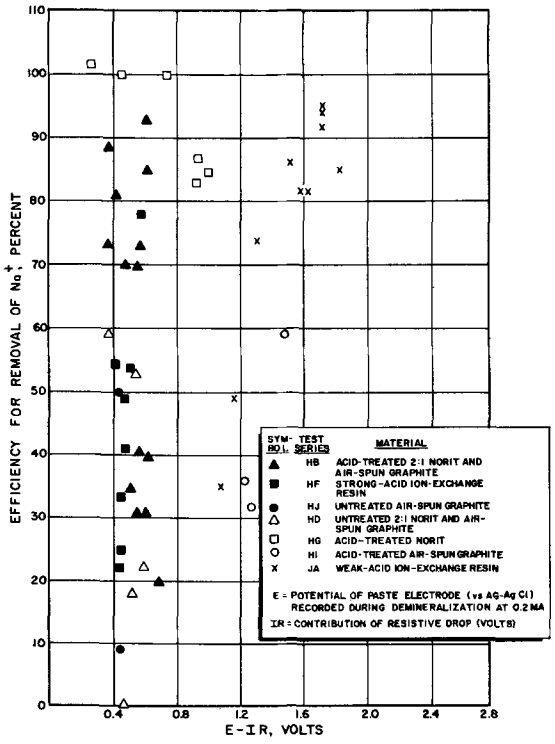

Fig. 7. Relationship of E-IR at end of each cycle to efficiency for the cycle.

At low demineralization efficiencies, the IR drop was low and appeared to be independent of the material used, and the surface *p*H was higher (generally between 10 and 11).

Subtraction of the IR drop from the final potential should give a measure of the remaining forms of polarization. It appears (Fig. 7) that for the bulk of the materials studied, the value E-IR is relatively independent of the demineralization efficiency. Exceptions are the weak-acid resin where the electrochemical reaction was occurring at the graphite backing and the acid-treated Air-Spun graphite.

Regeneration.—The potentials at which regeneration occurred varied with the previous history of the electrode. When regeneration followed immediately after demineralization (cathodic pretreatment), polarization was low. The regeneration process could be achieved below a few tenths of a volt with respect to the Ag-AgCl reference. Prolonged regeneration generally resulted in potential values between 0.6 and 1v. Regenerations undertaken a day after demineralization exhibited higher values (between 0.6 and 1v *vs.* Ag-AgCl). It seems probable that hydrogen adsorbed during demineralization was oxidized during regeneration.

A series of experiments was designed to highlight the above behavior. A 25-mg sample of acid-treated Norit was placed in an NaOH solution to determine the effect of chemical conversion of surface groups. The material was then placed in the holder electrode and studied. The results are shown in Table III. The

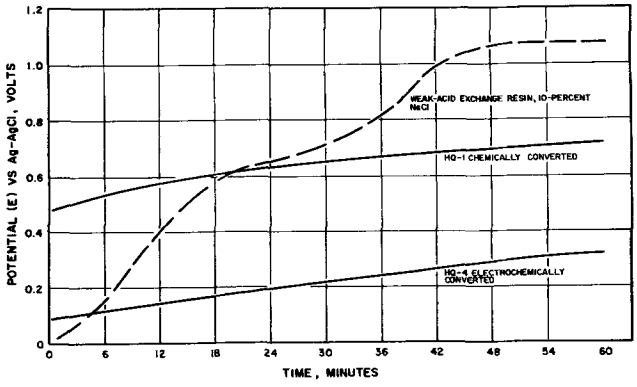

Fig. 8. Potential of paste electrode during regeneration (0.2 mamp).

chemically converted material was regenerated at 0.2 ma in two steps (HQ-1 and HQ-2). Electrochemical demineralization followed (HQ-3). The material was again regenerated (HQ-4, 5, and 6). Potentials recorded during regeneration (Fig. 8) of a surface which was chemically converted (HQ-1) were higher than those recorded on regeneration of an electrochemically converted surface (HQ-4). The dashed curve represents regeneration of a weak-acid exchange resin (which had been previously used for electrochemical demineralization) in a 10% NaCl solution. In this latter case, the electrochemical processes were taking place at the graphite backing. The two steps indicate that hydrogen was adsorbed on the graphite backing during demineralization and that it is reoxidized during the first plateau.

Open-Circuit Exchange

The extent of exchange occurring at acid-treated Norit-A and Amberlite IRC-50 in various concentrations of neutral NaCl solution is shown in Table IV. The materials were continuously stirred in NaCl for 5 days, and then were filtered, washed thoroughly with deionized water, and vacuum dried. The adsorbed sodium ion was regenerated to the solution (see Experimental section).

The exchange capacity in NaOH was also evaluated (Table IV). The values determined for acid-treated Norit-A varied from batch to batch; the variation was between 2.5 and 3.5 millieq./g.

Discussion

The reactions which occurred at the Ag-AgCl auxiliary electrode involved the removal and release of chloride ion.

$$\text{Anode reaction:} \quad Ag + Cl^- - e^- = AgCl \quad [1]$$

$$\text{Cathode reaction:} \quad AgCl + e^- = Ag + Cl^- \quad [2]$$

When demineralization and regeneration proceeded efficiently, a mass-balance analysis for sodium chloride was obtained. Changes in chloride ion concentration were in quantitative agreement with Eq. [1] and [2], and it is concluded that sodium ion was adsorbed and released when the test electrode was cathode and anode, respectively.

Mechanism of Demineralization

The primary electrochemical reaction which occurs when the test electrode is made the cathode, is

$$H_2O + e^- = H_{ads} + OH^- \quad [3]$$

The basic condition localized about the cathode provides an environment favorable to the ionization of weak-acid groups

$$RCOOH + OH^- + RCOO^- + H_2O \quad [4]$$

and gives rise to the demineralization reaction

$$RCOO^- + Na^+ = RCOONa \quad [5]$$

where

R carbon (Norit)
COOH = any suitable acid group

The faradaic reaction involves the adsorption of hydrogen on the carbon surface and the generation of OH^- (Eq. [3]); at constant current, the true efficiency (Eq. [3]) is approximately 100%. The efficiency for demineralization is of this order only when Eq. [4] and [5] occur equally efficiently.

The results showed that at high efficiency (Eq. [5]), no change in *p*H occurred. The OH^- generated was efficiently used in demineralization (Eq. [4]). Marked *p*H changes were observed at low efficiencies. In such cases, the OH^- which was generated did not result in ionization of the acid (Eq. [4]), and the *p*H rose.

While weak-acid, ion-exchange resins can be titrated with NaOH, the reaction with neutral NaCl solution is small (10) as seen in Table IV. A weak-acid, carboxylic resin is slightly ionized

$$RCOOH = RCOO^- + H^+$$

Anionic groups (*e.g.*, $RCOO^-$) are necessary for exchange, and the weak acid groups are predominantly nonionic at low *p*H. The efficient removal of sodium ions from NaCl solution at carboxylic acid ion-exchange resins (test series JA) provides direct confirmation of the mechanism presented. The demineralization reaction is analogous to the titration of an ion exchange resin, but in this example, the base for the titration is electrochemically generated.

The groups on the carbon surface need not be carboxylic. Evidence has been presented for other weak acid groups which have exchanged with sodium ion (11). Recently the acidity of various carbon surfaces has been determined by neutralization with bases of various basicities (11). The results of the coulometric titration of Carbolac-1 (test series HH) were in agreement with those obtained by direct titration with NaOH (9). The exchange capacity of Norit-A was found to be of similar magnitude when determined chemically or electrochemically.

The increase in the IR drop during demineralization can be explained in terms of the cell design. The volume of the paste electrode compartment was about 0.016 cc compared to a bulk solution volume of 10 cc. At high demineralization efficiencies, electrolysis of the solution in the paste electrode compartment resulted in the depletion of sodium chloride (by Eq. [5] and ionic transport) with no concomitant change in *p*H. This resulted in an increase in the IR drop. A steady value of IR drop was observed after a steady-state diffusion rate from the outer solution had been attained. It was found that the magnitude of this IR drop depended on the stirring rate, confirming that it was controlled by the rate of diffusion of bulk solution into the paste electrode compartment.

When demineralization was not efficient, the OH^- produced was not consumed, and there was no marked change in the contribution of the IR drop. Examination of the results (Fig. 6) indicated that at high efficiencies the magnitude of the contribution of IR drop was substantial. A marked decrease in drop at low efficiencies was accompanied by a rise in *p*H. Subtraction of the IR drop from the measured potential (Fig. 7) indicated that the contribution of other forms of potential was relatively independent of efficiency. The values associated with the carboxylic acid ion-exchange resin were higher, since the current density was greater at the graphite backing.

It is concluded that the potential recorded during efficient demineralization consisted mostly of IR drop; the magnitude of which is peculiar to the design of the paste holder electrode. The extent of this contribution can be markedly decreased by proper design of electrodes.

The electrochemical reaction did not involve the evolution of hydrogen on the graphite surface. Recently it has been reported (12) that hydrogen gas is not formed free, but is adsorbed by the active carbon. Experiments with coherent electrodes, wherein acid-treated Norit-A was affixed to a carbon backing have been performed in this laboratory. There was no visual evidence of gas evolution. The potential recorded during demineralization was too low to account for hydrogen evolution. This work is being prepared for publication.

Mechanism of Regeneration

The main electrochemical reaction which occurs when the test electrode is made the anode, is

$$H_{ads} - e = H^+ \quad [7]$$

This results in a localized low *p*H which aids the recombination to form acid groups.

$$RCOONa + H^+ = RCOOH + Na^+ \quad [8]$$

At high regeneration efficiency there was no change in *p*H. The hydrogen was adsorbed during previous cathodic (demineralization) cycles. Oxidation waves for hydrogen have been observed after the cathodic cycle (13), as evidenced from the appearance of a limiting current during anodic potentiostatic scanning experiments. An equivalent limiting current was noted for potentiostatic curves obtained after a demineralization cycle (14). No such limiting current appeared on the fully oxidized surface. It can be seen (test series HQ) that an electrochemically converted surface is regenerated at lower potentials than one which was converted chemically (Fig. 8). The chemical conversion was accomplished without the adsorption of hydrogen.

$$RCOOH + NaOH = RCOONa + H_2O \quad [9]$$

The localized acidic condition which resulted in recombination to the acid form (RCOOH) was created by the oxidation of water.

$$H_2O - e = \tfrac{1}{2} O_2 + 2H^+ \quad [10]$$

Figure 8 shows that regeneration of the carboxylic acid resin (test series JA) involves the oxidation of hydrogen which was adsorbed to a limited degree on the graphite backing, and subsequently, the oxidation of water. The quantity of hydrogen adsorbed was greater with carbon paste electrodes; the hydrogen was adsorbed on the carbon paste material. Since the oxidation of hydrogen is energetically easier than the oxidation of water, the incorporation of acid-treated Norit with ion-exchange resins would result in more favorable conditions for regeneration.

Exchange Capacity

Figure 3 shows that the acid treatment of Norit and of the Norit-graphite mixture increased the cation capacity. It is proposed that the acid-treatment resulted in the formation of weak-acid exchange groups. Acid-treated Norit exhibited exchange characteristics superior to any of the carbon-type materials studied

(Fig. 3) and is competitive with commercial ion-exchange resins.

Strong-acid exchange groups are almost completely ionized under any conditions so that their exchange characteristics are relatively independent of pH (10). Such materials exchange with sodium ion in NaCl solution and are not amenable to electrochemical control. The bulk of the exchange at such groups (test series HF) is not electrochemically induced. The pH changes which occurred during demineralization did not appear to be dependent of the efficiency.

Manuscript received May 12, 1966; revised manuscript received July 14, 1966. This work was supported by the Office of Saline Water, Department of the Interior, under Contract 14-01-0001-334.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Short-Pulse Techniques

II. Perturbation Times in Alkali-Halide Systems

B. J. Piersma,[1] Sigmund Schuldiner, and T. B. Warner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

A new technique involving the perturbation of a system from equilibrium using very short galvanostatic pulses and miniature cells has been applied to study the electrical double layer at Pt electrodes. The perturbation time, the time required for the double layer to begin charging, was determined for hydrogen- and alkali metal-halide systems and for reversible hydrogen systems in several acids and NaOH. The perturbation time was essentially independent of charging current density and of the anion in solution but was strongly dependent on the cation species and electrolyte concentration. Models to explain the absence of electrode polarization during the initial flow of charge into the double layer are discussed. A model which involves a very fast faradaic process and which is consistent with the experimental observations is proposed. It is suggested that the perturbation time, which is less than 100 nanosec for 1M solutions, represents the time required for movement of ions into or out of the compact double layer.

In a previous paper (1), a galvanostatic short-pulse technique was developed to study the kinetics of the I_3^-/I^- reaction on a Pt electrode. Oscilloscopic traces at very short times (less than 0.1 μsec) showed delays or perturbation times in the charging of the electrical double layer from the equilibrium potential. It was suggested that a short-pulse technique could be applied to determine the perturbation times of ions in the compact double layer. This study was undertaken to explore this possibility further.

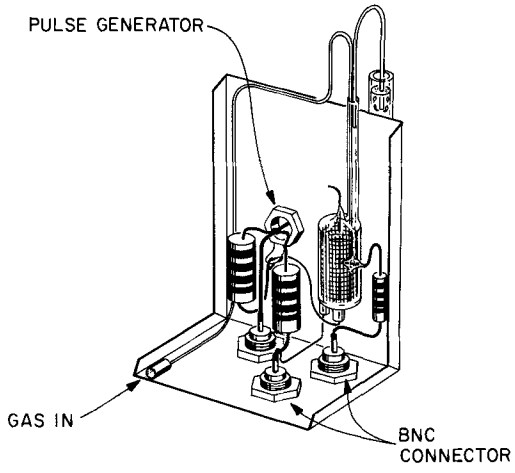

Fig. 1. Miniature cell

Experimental

The miniature glass cells (Fig. 1) used were designed to be terminated coaxial cables. This minimized the effects of overshoot and ringing inherent in short-pulse measurements. Two central Pt wires, approximately 1 cm long and 0.025 cm diameter, were less than 0.05 cm apart and served as the working and reference electrodes. The counter electrode was a Pt gauze cylinder of size approximately the inside dimensions of the cell (about 1 cm diameter x 1 cm length). Two 22 gauge Teflon tubes, one of which was supplied with a female luer fitting, were sealed in the cell with polyethylene, as shown in Fig. 1. Solution was added or removed with a gas-tight syringe (Hamilton Model 1001). Gas was bubbled through the cell from a glass pipe system connected to the cell with a male luer fitting.

The basic circuit is similar to that used previously (1, 2), and is shown in Fig. 2. The cell was mounted

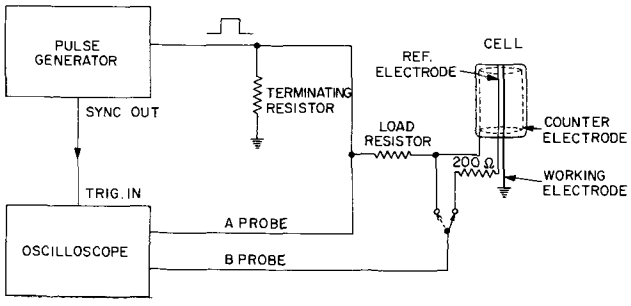

Fig. 2. Block diagram of basic electrical circuit

in an aluminum chassis which was attached directly to the pulse generator (E-H Research Laboratories, Inc., Model 121) with a BNC connector. The leads from the cell to BNC connectors on the chassis were made as short as possible, being only a few millimeters long. Since changes in electrolyte concentration varied the solution resistance, the terminating resistor and load resistor were changed such that the output impedance of the pulse generator was matched and the cell IR drop was not excessive. The 200 ohm resistor connected to the reference electrode reduced ringing and overshoot by balancing the impedance in the cable to the oscilloscope. Measurements were made with a Tektronix Type 585 oscilloscope. Long current pulses to examine system cleanliness were obtained with an Electro-Pulse Model 3450D pulse generator (4).

Values of the charging currents were determined as usual (1). The shape of the pulse itself was constantly checked using a dummy circuit with only resistive components. A typical trace of an acceptable pulse is shown in Fig. 3. During the course of the experiments the pulse generator required periodic adjustments to retain the flatness of the pulse and the short rise times (4 nsec). The experimental technique was also carefully examined using dummy cells with known resistive and capacitative components to completely insure that the perturbation times observed with the electrolytic cells were not instrumental artifacts.

The purification systems for hydrogen and helium were as described previously (3). Chlorine was Matheson, research grade, and was used without further purification. Other reagents were as follows: KI, I_2, KBr, Br_2, LiCl, NaCl, KCl, NaOH, HCl, H_2SO_4, and HNO_3 all "Baker Analyzed" reagent; RbCl and CsCl were prepared from hydroxide solutions by reaction with HCl and recrystallized. All solutions were prepared with triply distilled H_2O (3). All systems were at equilibrium at open circuit.

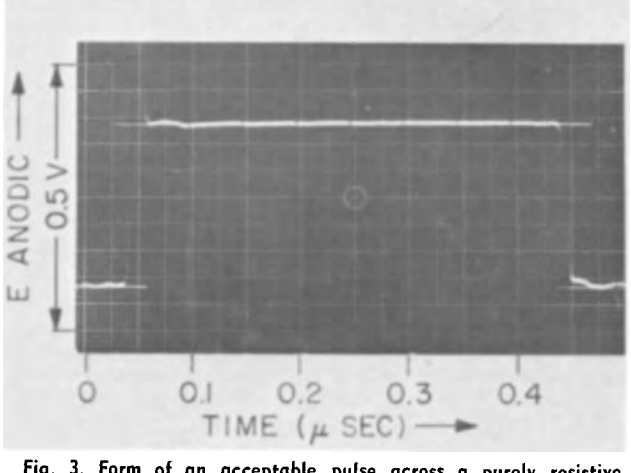

Fig. 3. Form of an acceptable pulse across a purely resistive dummy circuit.

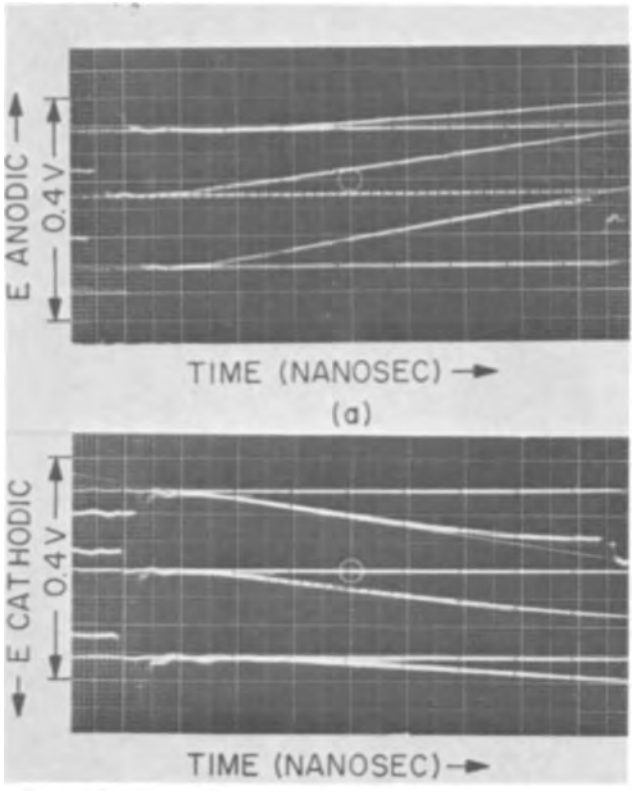

Fig. 4. Oscilloscope traces of pulses in 1M KI/0.0025M I_2 systems, i = 2.2 amp/cm². (a) Anodic pulses, time scales: lowest trace 50 nsec/cm, middle trace 40 nsec/cm, upper trace 20 nsec/cm; (b) Cathodic pulses, time scales: lowest trace 20 nsec/cm, middle trace 40 nsec/cm, upper trace 50 nsec/cm. Note: Each major division = 1 cm on oscilloscope screen.

After the cell had been suitably cleaned,[2] solution was added and He (in chloride systems Cl_2 was substituted) was bubbled through the cell, for about 1 hr, to reduce the oxygen concentration in the system. Gas flow was stopped during the few seconds required for measurements because of the large effects of gas bubbles on the cell resistance. Pulses were applied repetitively at rates of 100-500 cps. For the pulses used (less than 0.5 μsec) this spacing was sufficient (1) so that the electrodes were at equilibrium at the onset of each perturbation.

Results

Initial studies were carried out with KI solutions containing 0.0025M I_2 for comparison with previous results (1). Typical charging curves for anodic and cathodic pulses are given in Fig. 4. As the concentration of the KI solution was decreased, the cell resistance increased and the terminating and load resistors were changed to keep the IR drop within the limits of the oscilloscope screen at the more sensitive amplitude ranges (0.1-0.5 v/cm). The effect of changing the charging current on the perturbation time was examined carefully for the KI/I_2 system.

After the KI/I_2 system had been thoroughly examined, KBr/Br_2 and KCl/Cl_2 systems were studied in a similar manner. For the latter system, Cl_2 was bubbled through the cell rather than an inert gas. The study was then extended to MCl/Cl_2 systems with different cations and to reversible hydrogen systems with several electrolytes. All of the systems examined were reversible systems to provide stable base potentials. In an attempt to obtain a clean cell with an H_2SO_4/H_2 system after KI/I_2 solutions had been used,

[2] The cleaning procedure included: (i) warm (approx. 60°C) concentrated NaOH solution, (ii) warm conc. HNO_3, (iii) warm 50% HNO_3/50% H_2SO_4, (iv) 10-12 rinses with triply distilled H_2O over a period of 24 hr. Each step was followed with 10-12 rinses with triply distilled H_2O.

it was found, by using the reported cleanliness tests (4), that it was extremely difficult to remove all traces of iodide from the Pt electrodes. It was thus necessary to use different cells for the different halides and for the acid/H_2 systems studied. In light of these results, the recent suggestion by Devanathan and Tilak (5) of treating Pt electrodes with KI solution prior to capacity measurements to obtain a base capacity of 20 $\mu F/cm^2$ would seem open to question. This treatment might explain the difference in their results from those obtained in this laboratory (3), *i.e.*, a capacity of 40 $\mu F/cm^2$ was obtained with bright Pt, in the so-called double layer region of potentials, in a highly purified system, containing H_2SO_4.

The effect of changing the charging current on the perturbation time in the 1.0M KI/0.0025M I_2 system is presented in Table I, together with the double layer capacitance. These data are representative of the reproducibility obtainable with this technique. The perturbation times were determined from the oscilloscopic traces in two different ways. As seen from Fig. 4, the perturbation time is readily obtained by simply measuring the time between the onset of the pulse and the point at which double layer charging begins. Alternatively, the IR drop was measured at pulse cutoff and this value was marked off from the initial foot of the pulse. The time at which the polarization, due to charging of the double layer, became larger than this IR drop was taken as the perturbation time. Identical perturbation times were obtained with these two procedures, within the scatter of measurements, being in general ±3 nanosec. Scatter of data in more dilute solutions in some cases became as large as ±10 nanosec. Here the smaller charging currents used (because of higher solution resistance) resulted in slower charging of the double layer. Since perturbation times were also longer in the more dilute solutions, the scatter was always less than ±10%. With more dilute solutions, the IR correction method was more precise since a sharp break due to double layer charging was not obtained. Close examination of oscilloscope traces at every current density used (0.1 to 5 amp/cm^2) indicate small transition regions before double layer charging becomes linear.

The variation of perturbation time, t_p, with concentration is shown in Fig. 5, for KI/I_2, KBr/Br_2, and KCl/Cl_2 systems. It is evident that: (*a*) a good linear relation between the perturbation time, t_p, and log concentration is obtained, (*b*) anodic pulses result in different perturbation times from cathodic pulses, however, t_p becomes the same at a salt concentration of about 5M, and (*c*) changing the anion has surprisingly little influence on t_p. Further experiments to examine the influence of the nature of the anion on t_p are summarized in Table II. It is evident that the anion has very little to do with the perturbation times observed.

The variation of t_p with concentration of MCl/Cl_2 systems with different cations is given in Fig. 6 and 7 for anodic pulses and cathodic pulses, respectively. In addition to the linear t_p *vs.* log concentration relations and the differences between $t_{p,a}$, anodic and $t_{p,c}$ cathodic, a rather startling dependence on the cation is observed. The largest difference is between H^+ and the first alkali metal ion Li^+, while the higher alkali metal ions, K^+, Rb^+, and Cs^+, give similar behavior.

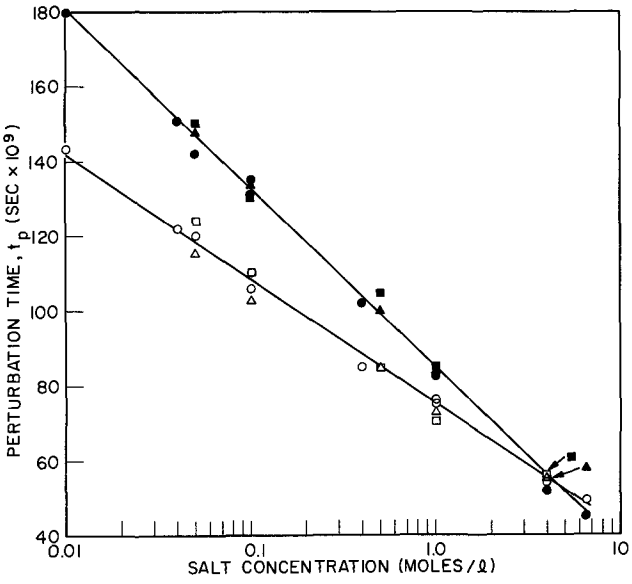

Fig. 5. t_p *vs.* log conc. for KI/I_2: (⊙) cathodic, (●) anodic, KBr/Br_2 (△) cathodic, (▲) anodic and KCl/Cl_2 (□) cathodic, (■) anodic systems.

Discussion

The experimental observations which must be considered in discussion of the perturbation times are summarized as follows:

(*i*) $t_p \neq f(i)$ within the limits of i used (0.1-5 amp/cm^2)

(*ii*) $t_p \neq f(E_{rev})$

Table I. Perturbation times and double layer capacitances at different current densities for 1.0M KI/0.0025M I_2 solution

Current density, amp/cm^2	Cathodic pulse t_p, sec × 10^9	Cathodic pulse C_{dl}, $\mu F/cm^2$	Anodic pulse t_p, sec × 10^9	Anodic pulse C_{dl}, $\mu F/cm^2$
1.65	75	6.3	85	7.5
2.49	74	7.1	83	8.3
3.09	76	6.1	80	7.3
3.34	74	6.4	82	6.9
4.76	75	7.3	84	8.6
Averages	75 ± 1	6.6 ± 1	83 ± 3	7.7 ± 1

Table II. Perturbation times in reversible hydrogen systems

1M solutions	t_p, Cathodic, sec × 10^9	t_p, Anodic, sec × 10^9
H_2SO_4	19	38
HNO_3	18	36
HCl	20	40
NaOH	70	78

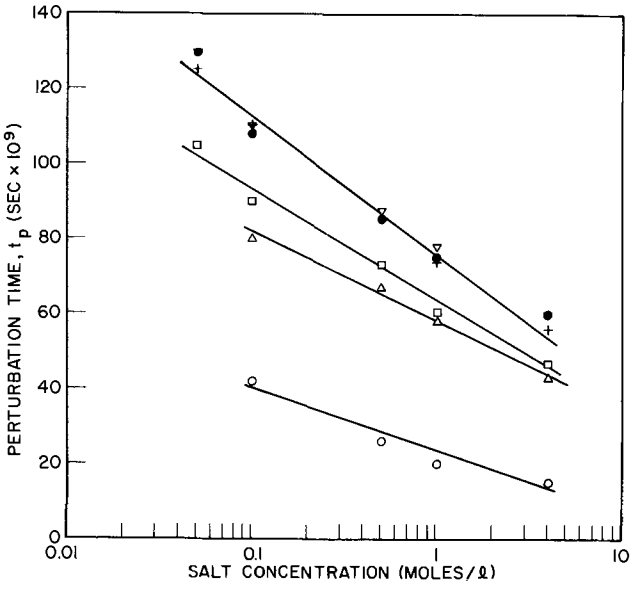

Fig. 7. t_p vs. log conc. from cathodic charging in MCl/Cl_2 systems: (○) H^+, (△) Li^+, (box with dot) Na^+, (+) K^+, (triangle up side down with dot) Rb^+, (●) Cs^+.

(*iii*) $t_p = f(\text{cation})$, $t_{p,H+} < t_{p,Li+} < t_{p,Na+} < t_{p,K+} \approx t_{p,Rb+} \approx t_{p,Cs+}$
$t_p \neq f(\text{anion})$, $t_{p,SO_4^=} \approx t_{p,NO_3^-} \approx t_{p,Cl^-} \approx t_{p,Br^-} \approx t_{p,I^-}$

$$(iv)\quad \frac{dt_p}{d\log \text{conc.}} = -\text{const.},$$

$$\left(\frac{dt_{p,a}}{d\log \text{conc.}}\right) > \left(\frac{dt_{p,c}}{d\log \text{conc.}}\right)$$

(*v*) $t_{p,a} > t_{p,c}$ for conc. $< 4M$
$t_{p,a} \approx t_{p,c}$ for conc. $> 4M$

A prime consideration for a model to explain the perturbation time is the fact that energy is being passed into the double layer while the measured potential difference across the double layer remains constant. The observations tend to indicate that two processes are involved, *i.e.*, one which is time dependent but independent of the charging current and which determines t_p, and another process which can use the charge passed during t_p without altering the potential difference, *i.e.*, without charging the double layer.

The latter process can be understood on a physical basis from the equation for a capacitor if we assume that the double layer does act essentially as an ideal unit area capacitor

$$C = \frac{Q}{E} = \frac{\epsilon}{4\pi d}$$

where the dielectric constant in the double layer $\epsilon \approx 6$ and the distance d, normally the distance between the plates of a capacitor, is equated to the thickness of the compact layer and is approximately 3.5Å. To obtain constant E while Q changes requires either a change in the dielectric constant, ϵ, or a change in the double layer thickness, d, *i.e.*, a change in position of the outer Helmholtz plane. If we assume for $E = 0.6$v, that $Q = 10$ μcoul/cm^2 and $d = 3.5$Å, then $\epsilon = 6.6$. Hence, for a typical change in Q from an anodic pulse of 1 amp/cm^2 during a perturbation time of 100 nanosec, $\Delta\epsilon = 0.06$, *i.e.*, the dielectric constant would have to increase by about 1% to give the required result. Alternatively, if we assume constant ϵ, the thickness d would have to decrease by about 1% during the anodic perturbation time. Whether ϵ and d would have to increase or decrease would of course depend on the potential with respect to the potential of zero charge, p.z.c., *i.e.*, whether Q increases or decreases. In any case, the changes required are on the order of 1%, which seems entirely reasonable.

A more detailed model is obtained by examining the chemical nature of a change in ϵ or a change in d. The dielectric constant is increased by removal of ions from the double layer, either by mass transfer or by neutralization through charge transfer, or by a relaxation of restriction on the movement of dipoles. Since a net transfer of ions into or out of the double layer would result in actual charging of the capacitor, *i.e.*, a change in E with Q, this cannot occur during the perturbation time. Further, the time required for ions to move into or out of the double layer is very possibly on the same order as the observed perturbation times. Grahame (6) has suggested, from calculations for a simple RC circuit and based on data from a mercury electrode, that the time required for establishment of ionic equilibrium within the double layer is on the order of 100 nanosec.

The double layer thickness is changed by a shift of the outer Helmholtz plane. This could occur by a slight relaxation of the plane, *e.g.*, by a movement of the cations within their solvation sheaths. The kinds of shifts involved, *i.e.*, approximately 0.05Å, could readily be achieved simply by a movement of the cations within the sheaths of water molecules surrounding them, and as such do not require movement of ions into or out of the double layer.

The perturbation time can be viewed either as the time required for the transfer of ions, *i.e.*, a type of inertia which must be overcome before ions can begin to move, or as the time required to saturate some initial process in the compact layer, *e.g.*, dielectric saturation, before the effects of the charging pulse are communicated to the diffuse layer and the bulk of the solution. By this we mean that either the ions require a finite time, *i.e.*, t_p, before they can begin to move, quite analogous to the relaxation times observed in solution, or that they can respond at faster times but that some initial process must be first satisfied. Any consistent model must include the cation dependence and anion and charging current independence of the perturbation times. The process which accepts energy without changing the potential difference across the double layer could involve dipole rotation or orientation, a movement of electrical center of ions in the outer Helmholtz plane, or an electron transfer process with the transfer of an equivalent number of oppositely charged ions out of or into the compact layer (or possibly only the shift of the outer Helmholtz plane), the charge on the electrode remaining effectively constant. These processes are very likely not separable, but for purposes of argument we shall discuss them separately.

From the frequency dependence of the double layer resistance and capacitance at solid electrodes measured by a-c impedance methods, Bockris and coworkers (7, 8) proposed a relaxation time for water dipoles. To explain relaxation times of about 10^{-8} sec on Hg and about 10^{-6} sec on Cu in primarily sulfate solutions, they assumed that water molecules which are adsorbed on the electrode are restricted in motion so that their relaxation time is made large enough for it to fall within the frequency range of measurement. The relaxation of water dipoles at the copper-solution interface was considered as qualitatively resembling that in ice, with a relaxation time of 10^{-3} sec, rather than that in water, 10^{-10} sec. A slow relaxation process in the oriented water layer at charged interfaces has also been proposed from the effects of superimposing an a-c field over a d-c polarizing potential at a dropping mercury electrode (9). Another indication of the times involved in the motion of water dipoles can be taken from water-water exchange rates (10). The substitution rates of the first-hydration-shell water molecules by ligands for alkali-metal cations have been reported for Li^+ as

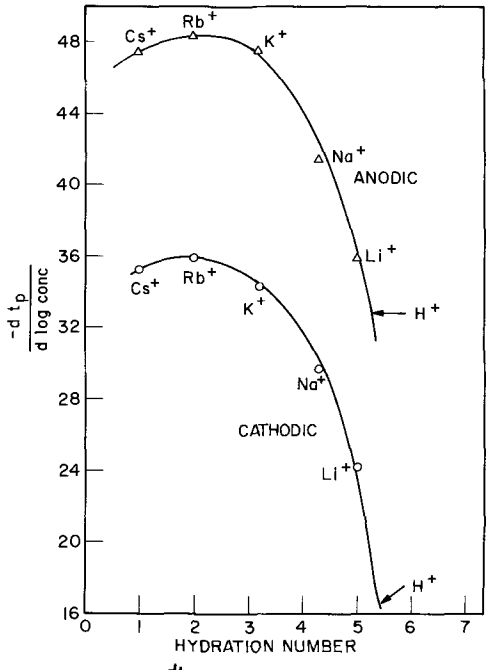

Fig. 8. — $\frac{dt_p}{d \log c}$ vs. hydration number (11).

0.47-9.0 x 10^8/sec and for Cs^+ as 2.1-50 x 10^8/sec. The water molecules held in the first hydration shell, particularly for Li^+, should be somewhat analogous to water oriented in the double layer. It would appear that the times involved for the rotation and orientation of water dipoles in the double layer agree reasonably well with the observed perturbation times. The influence of cations on the perturbation time may be attributed to hydration and to the effect of ordering of the water dipoles in the compact layer by the cations. A correlation of the perturbation times with hydration number (11) is shown in Fig. 8. In this case the change in t_p with concentration has been plotted since this is a constant for each cation. It is interesting to note that if this correlation is correct, the hydration number for H^+ is between 5 and 6. Initially it would appear that the cation effect on t_p is in the wrong direction. For example, following the suggestion of Samoilov (12) that the larger cations (K^+, Rb^+, and Cs^+) have a negative hydration number, *i.e.*, are structure breaking, the rotation of water dipoles would be expected to be easier and thus faster for these cations. However, if we view the process as one which must become saturated, *i.e.*, completed, before double layer charging begins, then the least oriented systems should require more time to become fully oriented. For example, the double layer with Li^+ would be expected to have a more ice-like water structure than a double layer with Cs^+. Thus it should require less time for the dipoles to become completely oriented in the field in the presence of Li^+ since a higher degree of order is already established. Of course the water dipoles adsorbed directly on the Pt surface should be highly oriented at potentials away from the p.z.c. (13, 14), so that the molecules which rotate are possibly in the diffuse layer. This model also explains the concentration dependence. As the solution becomes more dilute, there are fewer ions, resulting in a more loose structure in the double layer and thus longer times are required to completely orient the water dipoles. The similarity in perturbation times for K^+, Rb^+, and Cs^+ are well in agreement with the suggested negative hydration or structure breaking properties of larger cations. Anions, which are not strongly hydrated, would thus not be expected to influence the perturbation times in this model.

The one experimental observation which is completely contrary to this model and which cannot be explained is that of the current independence of t_p. If the process occurring during the transition time is the orientation of dipoles and double layer charging begins when this orientation is essentially complete, *i.e.*, the dielectric is saturated, then t_p would have to depend on the amount of charge flowing into the double layer. Any model which proposes the completion of a process in the compact layer before the double layer begins to charge up must be dependent on charge and hence t_p would have to change with charging current density. For a given system, t_p was found to be independent of the charging current over more than one order of magnitude. The apparent independence of t_p on the reversible potential could also argue against this model. For example, for 1M systems of KI/I_2, KBr/Br_2, and KCl/Cl_2, the reversible potentials differ by about 1v, as seen from the following equilibria (15)

$$3\,I^- = I_3^- + 2e^-, \quad E_o = +0.536v$$

$$2\,Br^- = Br_{2(aq)} + 2e^-, \quad +1.087v$$

$$2\,Cl^- = Cl_2 + 2e^-, \quad +1.3595v$$

It is expected that a shift of potential difference across the double layer would strongly affect the structure of the adsorbed layer and orientation of water dipoles. The possibility does exist that the p.z.c. would shift in such a direction to balance this change in equilibrium potential. Recent determinations of the p.z.c. of Pt in halide solutions using radiotracer methods indicate that the p.z.c. does shift in the positive direction in going from I^- to Cl^- solutions, possibly by as much as 0.7v (16). The change in equilibrium potential could therefore be accompanied by a corresponding shift in p.z.c. such that the double layer structure would not be altered appreciably. In the absence of more detailed information, this point will not be further considered except to indicate that it need not be a serious consideration.

In a recent study, Grantham (17) has concluded that there is a complete absence of relaxation times of water molecules in the double layer in the range 10^{-8}-10^{-2} sec, and attributes the observed frequency dependence of resistance and capacitance to improper electrode design. On the basis of this and other studies (18), Devanathan (5) concludes that water molecules are not oriented in up and down positions (14) but are adsorbed flat and are insensitive to field. This conclusion seems premature with the lack of evidence on a-c frequency variation of the double layer resistance and capacitance at frequencies above about 10^5 c.p.s. on solid electrodes, which is just the range where the relaxation process should become important, and particularly in light of the success which the water dipole model has had in interpreting organic adsorption. On the basis of the previous argument our results suggest that it is not the saturation of dielectric constant as brought about by dipole orientation which determines the perturbation time. However, our results do definitely establish that a perturbation time exists, which may be similar to the frequency variation observed in a-c impedance measurements, and the rotation of dipoles should not be ruled out, even though t_p is not determined by such a process.

A model which permits a t_p independent of charge is based on the specific adsorption of ions, particularly anions. We first postulate, in line with earlier reasoning, that two fundamentally different processes occur, the first of which is the means by which charge is used up without actual charging of the double layer and may include more than one type of process, *i.e.*, dipole orientation, charge transfer, ion movement within solvation sheaths, etc., and a second process which involves the movement of ions into or out of

the compact layer and determines t_p. The first process has been considered on a physical basis and we shall now examine it in greater detail. Following the double layer model of Grahame (6), the charge on the metal will equal the sum of charges in the inner and outer Helmholtz layers and the charge in the diffuse layer

$$-q_M = q_i + q_o + q_d$$

where the q's will be negative for anions and positive for cations. In the presence of specific adsorption, which is expected for the systems examined here, there will be additional charge in the inner layer and hence also in the outer layer to maintain a constant q_M at a given potential difference (with respect to the p.z.c.), *i.e.*, superequivalent or contact adsorption. Thus ions could undergo discharge in the inner layer and a corresponding transfer of oppositely charged ions out of the outer layer, or possibly only a shift of the outer Helmholtz plane, would maintain constant q_M. Charge transfer, which could be a fast process from ions already present in excess in the inner layer, with a corresponding shift of the outer Helmholtz plane could therefore occur while the charge on the metal remains constant and thus energy could be used up without actual charging of the double layer capacitor.

Two cases should be distinguished, one for electrodes positive to the p.z.c., which is the case for most of the equilibrium systems considered here, and one for electrodes negative to the p.z.c., which is probably the case for reversible hydrogen systems on Pt. In the first case, an anodic pulse would require electron transfer from anions specifically adsorbed on the Pt with a simultaneous shift of cations within their hydration sheaths away from the electrode. The actual movement of cations during this time may be suggested, however, in view of the proposal that the perturbation time is determined by the time required for appreciable movement of ions into the double layer, this would seem less likely than the smaller movement of many cations corresponding to a single anion discharge. A cathodic pulse would then require reduction of atoms to anions in the inner layer with a corresponding movement of the outer Helmholtz plane toward the electrode surface. Since the amounts of specifically adsorbed ions become appreciable, particularly for the halide systems (19), this process would not be limited by the charging current in the times under consideration. For the second case, *i.e.*, electrode surface negative to the p.z.c., an anodic pulse would require discharge of atoms to form cations (probably $H \rightarrow H^+ + e^-$) with a subsequent shift of anions away from the electrode. A cathodic pulse would then involve electron transfer to H^+ to form H atoms and movement of anions toward the surface.

Following a recent suggestion by Delahay (20), the amounts of specifically adsorbed ions participating in this process can be examined using the relation

$$q_{measured} = q + \frac{V_{sr}}{V_{sr} + V_{tr}} ZF\Gamma$$

where q is that due to the usual double layer charging process and the other term is due to a Faradaic process, where V_{sr} is the rate of the charge separation process and V_{tr} is the rate of the mass transfer process. During t_p, $q = O$, so that from the charging current and t_p, the surface excess should be obtained directly. For typical values of $i = 1$ amp/cm^2 and $t_p = 100$ nanosec, we obtain $ZF\Gamma_- = 0.1$ μcoul/cm^2, assuming that V_{tr}, the term relating to mass transfer, is zero since mass transfer has not yet begun. This gives a surface excess of $\Gamma_- = 10^{-12}$ g.equiv./cm^2 for anions involved in the Faradaic process and if we assume that cations are pushed out of the double layer, a Γ_+ of 10^{-12} g.equiv./cm^2 would be required. This value compares well with the Γ_+ reported from radiotracer measurements on Pt electrodes for alkali halide systems (16). At high enough current densities, essentially all of the superequivalently adsorbed anions, *i.e.*, those adsorbed in excess of the amount expected on the basis of the charge on the metal surface and hence balanced by cations in the outer Helmholtz plane and the diffuse layers, should be used up in the Faradaic process. Thus at high enough current densities, this should be a method for determining directly the amount of superequivalent or contact adsorption.

This process should not be particularly sensitive to the ions in solution, so long as they are adsorbed in sufficient excess to satisfy the charge requirements during the perturbation time and the rate of electron transfer is sufficiently fast. The cation effect must be explained in terms of the second process, *i.e.*, in terms of the actual movement of ions into or out of the double layer. These two processes should not be viewed as occurring exclusively but that some diffusion will begin during t_p and only when appreciable mass transfer can occur does the potential begin to change. The fact that both processes occur together is seen from the slight curvature in the charging curves between the flat initial region and the linear double layer charging region. The manner in which cations can influence the diffusion process is difficult to see, however, their influence is an experimental fact. The effect of cations is most probably related to hydration and the structure of the solution as already discussed.

Summary

The experimental observations obtained using the discussed short pulse technique are new and perhaps somewhat difficult to accept in light of the commonly accepted concepts of the double layer structure. However, when comparisons are made with well established relaxation times observed in bulk solution, the results appear reasonable. It should be remembered that the results refer to events in the double layer which occur before the charging process and which have not been previously examined. Further, it should be remembered that every effort was made to eliminate instrumental artifacts and we feel that the results presented reflect actual properties of the double layer. The model proposed has limitations but it does essentially account for the experimental observations. Further measurements particularly using doubly and triply charged cations are required before a more detailed model can be proposed. These results tend to confirm the recent suggestion of Delahay that two processes can occur in the charging process, however, they suggest that the Faradaic contribution is less than 1% of the total charge. Finally these results point to the discrete particle nature of the electrical double layer and the method holds real promise for obtaining more detailed information about the structure of the double layer at electrodes.

Acknowledgment

The authors are grateful to Mr. C. H. Presbrey, Jr. for assistance with the electronic circuits and adjustments of the pulse generator.

Manuscript received June 23, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Electrochemical Processes in Thin Films

II. Preliminary Quantitative Treatment of Film Stabilization by the Marangoni Effect

E. N. Lightfoot and V. Ludviksson

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin

ABSTRACT

This paper is concerned with the mechanism of formation of stable supermeniscus electrolyte films, observed on gas diffusion electrodes. The Marangoni effect associated with surface tension gradients in liquids is considered and found to give film characteristics which are in agreement with many observations made to date. By numerical example it is shown that a temperature gradient of −0.4 C/cm in water or a concentration gradient of 0.035 mole/liter·cm in aqueous KOH solution each can produce a typical liquid film, 1μ thick and unlimited in height. This mechanism is shown to provide more vigorous water recirculation in films than vapor phase transport, and a preliminary unsteady-state analysis is shown to give the right magnitude for the climbing rates observed for the spreading of many hydrocarbons on vertical surfaces. The mechanism is unable to explain effects observed in the absence of concentration or temperature gradients, but apparently could have a pronounced effect under operating conditions of gas diffusion electrodes.

Recently there has been published a number of reports showing experimental evidence for the existence of stable films of electrolyte above the intrinsic meniscus on gas-diffusion electrodes. This evidence has been obtained both by indirect measurements, *i.e.*, measurements of current densities as a function of height above the meniscus (1-5, 8, 13) and by direct observation (6, 7). As yet no satisfactory explanation for the existence of these films is available. Electrocapillary, double-layer and surface-energy-of-formation effects, which are often suggested, appear too weak to produce the observed film thickness (*ca.* 1/20 to 2μ). Gravitational flow, made possible by concentration polarization and vapor phase water transport (9), appears likely in the large scale systems used by Will (1) and others. However, calculations have shown (10) that for such small pore radii as are found in fuel-cell electrodes, vapor transport becomes incapable of supplying even the reactant water needed for such processes as

$$O_2 + 2H_2O + 4e = 4\,OH^-$$

let alone allowing the formation of a flowing film. However, the probable existence of such films in microporous systems has been shown (8) and since all above-cited analyses agree that the thickness of these supermeniscus films has a large effect on electrode performance, a search for better understanding of the film behavior is well justified.

No single known effect appears capable of explaining all observed characteristics of supermeniscus films, and it is possible that such films are produced by some truly novel phenomenon. However, it seems more likely that they are produced by a more or less subtle combination of well known forces, and the probable effects of such forces should be very carefully reviewed before more esoteric ones are sought. The well known Marangoni effect is one possible source of stabilization and is treated in this paper.

As suggested in the first paper of this series (9), surface tension gradients resulting from either temperature or concentration inequalities provide a possible mechanism for water transport and film stabilization. It is the purpose of this paper to give a convenient basis for discussion of this mechanism, and to assess its importance under conditions likely to occur in practical electrochemical devices.

Qualitative Description of Mechanism

From a qualitative standpoint the importance of surface tension gradients in promoting the spreading of liquid films has long been known. Examples of such effects include "tears of strong wine" and the tendency for liquids, such as lubricating oils, to "crawl" out of open containers. The explanation of such phenomena, commonly included in the term "Marangoni effect," was suggested as early as 1855 by Thomson (11). More recently a very convincing demonstration of the nature of what may be called the "oil-can" effect was given by Bascom, Cottington, and Singleterry (12). The basic mechanism both here and in the case of tears of strong wine is the evaporation of one component of a mixture from the upper regions of a meniscus or a surface diffused primary film. If the liquid layer remaining has a higher surface tension than the bulk liquid, then the surface layer, and some

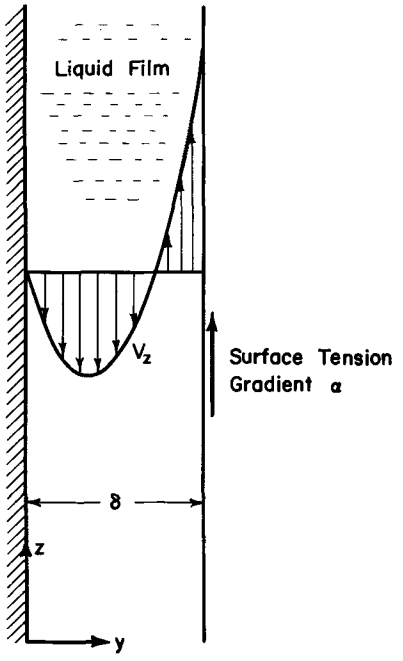

Fig. 1. Liquid film on a vertical, solid surface stabilized by surface tension gradient.

bulk liquid with it will be pulled upward. By analogy, if electrochemical reaction on an electrode can give rise to appreciable surface tension gradients in the upper regions of the meniscus or on a previously wetted electrode, by virtue of concentration or temperature inequalities, then a stable electrolyte film can be maintained or even formed spontaneously as observed by Müller (6). It is our purpose to explore this possibility.

Since, to our knowledge, no quantitative treatment of surface spreading has been attempted we begin by describing a simple model system quantitatively.

Quantitative Description of a Surface Tension Supported Film

For our present purposes it is sufficient to consider steady one-dimensional flow in a thin film on a flat vertical plate as shown in Fig. 1. Extension to a system in which film thickness is appreciable relative to the local radius of curvature is easily accomplished, but gives no further information at the level of the present treatment.

The film behavior is governed by the following relations. (*i*) a momentum balance (the equation of motion); (*ii*) a flux equation (Newton's law of viscosity); (*iii*) a set of boundary conditions.

These relationships may be written in the following form:

$$-\frac{d\tau_{yz}}{dy} + \rho g_z = 0 \qquad [1]$$

$$-\mu\frac{dv_z}{dy} = \tau_{yz} \qquad [2]$$

As boundary conditions we shall use:

$$\text{B.C. 1} \qquad \text{at } y = 0 \qquad v_z = 0 \qquad [3]$$

$$\text{B.C. 2} \qquad \text{at } y = \delta \qquad \tau_{yz} = \tau_0 \qquad [4]$$

Implicit in Eq. [1] to [4] is the assumption of local equilibrium, *i.e.*, the local film behavior is independent of upstream or downstream conditions other than those imposed by the requirement of conservation of mass. This assumption, amply justified by analysis and experiment for the much thicker and faster moving films encountered in steam condensation and elsewhere, should not introduce any appreciable error. Thus, these simple equations are in fact quite general.[1] The second boundary condition permits a nonzero shear stress at the gas-liquid interface. In the special but likely case of negligible velocity gradients in the gas phase, and infinite radius of curvature, this surface stress can be equated to the local surface tension gradient

$$\tau_0 = -\frac{d\sigma}{dz} = -\alpha \qquad [5]$$

We can now easily integrate [1] and [2] to get

$$v_z = \left(\frac{\alpha\delta}{\mu}\right)\eta - \left(\frac{\rho g\delta^2}{\mu}\right)\left(\eta - \frac{1}{2}\eta^2\right) \qquad [6]$$

where $\eta = y/\delta$. Thus, the local velocity profile is parabolic, and as shown in Fig. 1 it may have regions of both negative and positive velocity. The flow average velocity

$$\langle v_z \rangle = \frac{1}{2}\left(\frac{\alpha\delta}{\mu}\right) - \frac{1}{3}\left(\frac{\rho g\delta^2}{\mu}\right) \qquad [7]$$

can clearly either be positive, negative, or zero.

For the common case where μ and ρ do not vary significantly with position, it is convenient to write Eq. [7] in dimensionless form

$$Re = \frac{1}{2}R^2 Mr - \frac{1}{3}R^3 \qquad [8]$$

where $Re = Q/\nu P$, a film Reynolds number and $Q/P = \delta \langle v_z \rangle$ is the volumetric flow rate per unit width of film, $R = \delta(g/\nu^2)^{1/3}$, a dimensionless film thickness; and $Mr = (\alpha^3/\rho^3 g^2 \nu^2)^{1/3}$, a dimensionless group characteristic of films which we call Marangoni number. This Reynolds number *vs.* film thickness relation is plotted in Fig. 2. For positive Marangoni numbers, which give a stable film, there is clearly a flow maximum of

$$Re_{max} = 1/6\, Mr^3 \qquad [8a]$$

when the dimensionless film thickness is equal to the Marangoni number ($R = Mr$). There are also two film thicknesses yielding no flow

$$R = 0 \text{ and } R = 3/2\, Mr$$

Note that so far we have not specified the value of δ, nor can we evaluate its magnitude from the above

[1] For multicomponent systems the fluid velocity must be the mass-average velocity. For these, and for nonisothermal systems, the possible variation of μ across the film requires, in principle, that the equations of energy conservation and continuity of species also be used. However, calculations to be published later have shown that, for the very large length-to-thickness ratios typical of these films, temperature and concentration variation across the film will always be negligible in practice.

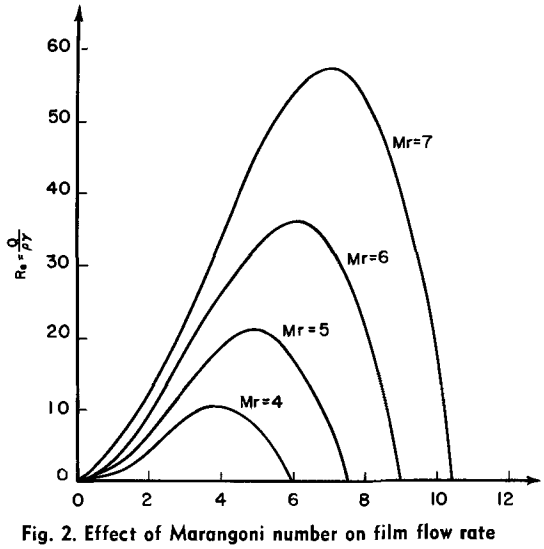

Fig. 2. Effect of Marangoni number on film flow rate

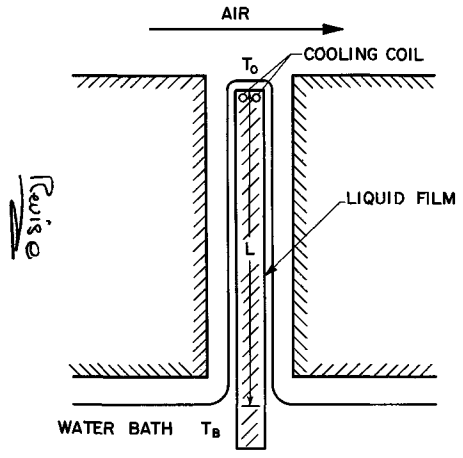

Fig. 3. Vertical plate covered by a liquid film with evaporation possible at the top.

information alone. Therefore, we have to provide one additional restriction. For the purpose of illustration we now consider the slightly more complex system of Fig. 3. We picture here a vertical plate of height L in contact with water at temperature T_B at the lower edge and a cooling device at the top maintaining it locally at a temperature of T_0 where $T_0 < T_B$. On both sides there are closely placed surfaces isolating the system from radiation and convective currents. We now consider some limiting cases.

No net flow in film.—If we assume that the air above the assembly in Fig. 3 is saturated with vapor at T_0, then no evaporation from the film will take place and no net flow of liquid will occur. This means $< v_z >$ must equal zero and now δ is fixed by Eq. [7]

$$\delta_{loc} = \frac{3}{2}\frac{\alpha}{\rho g}$$

since the solution $\delta = 0$ is not physically interesting in our analysis.

As an illustration let us consider a plate 10 cm high and with a temperature difference between bottom and top $T_B - T_0 = 4°C$. Further we let the properties of water be given by $\rho = 1$ g/cc, $\mu = 1$ cp, and $\partial\sigma/\partial T = -0.163$ dyne/cm °C. For this system we expect a nearly linear temperature gradient over the height of the plate with an average value of $dT/dz = -0.4°C/cm$. With the above physical data this gradient will give a film of thickness

$$\delta = \frac{3}{2} \cdot 0.163 \cdot 0.4 \frac{1}{980.1} = 10^{-4}\,\text{cm}$$
$$= 1\ \text{micron}$$

This is of the order of magnitude observed in many electrochemical systems and the temperature gradient of 0.4°C/cm is not unreasonable for many physically interesting situations. The maximum velocity observed is obviously in the surface, and its value provides a measure of the recirculation rate in the film

$$v_{max} = \frac{\alpha\delta}{\mu} - \frac{\rho g \delta^2}{2\mu}$$
$$= \frac{0.163 \cdot 0.4 \cdot 10^{-4}}{0.01} - \frac{1 \cdot 980 \cdot 10^{-8}}{2 \cdot 0.01}$$
$$= 1.64 \cdot 10^{-4}\,\text{cm/sec} = 0.59\,\text{cm/sec}$$

The system thus described is dynamic but steady with the film stabilized by opposition of body and surface forces.

Film with net upward flow.—If the ambient air is unsaturated and evaporation occurs at the top of our wetted plate, then there will be a net upward flow equal to the evaporation rate

$$Q_{Film} = \delta < v_z > P = Q_{evap}$$

where P is the wetted perimeter of the plate. If we neglect vapor phase transport along the film height, which will often be reasonable for small pores (10), Q will not vary with position. For the system under consideration, in which a pure fluid is flowing and T_0 is fixed, evaporation will determine the film thickness until the maximum flow rate is reached. However, for conditions permitting evaporation at a volumetric rate greater than $1/6\ Mr^3\ P_\nu$ (see Eq. [8a]) the supply capacity of the film is reached. Evaporation rate is then controlled by the surface tension-gravity balance and Eq. [8a] applies. At this maximum rate the thickness of the steady state film is given by

$$\delta_{lim} = \left(\frac{\alpha}{\rho g}\right)$$

where δ_{lim} is really that value of δ which corresponds to the smallest maximum flowrate $(Q/\rho)_{max}$ over the film height. For the conditions of the above numerical example $(\alpha/\rho g)$ is essentially constant over the film height and the film thickness providing the maximum volumetric flow is $2/3\mu$. This corresponds to an evaporation rate of $4.83 \cdot 10^{-9}$ cm³/sec cm. The maximum velocity, that of the surface, is 0.785 cm/hr.

If instead of the evaporation process at the top of the film we postulate a long plate with the same temperature gradient, the film will tend to climb up the plate. Such unsteady flows are quite complex and cannot be discussed in detail here. However, a semi-quantitative description can be obtained rather easily (see appendix at the end of paper) if surface curvature of the advancing film is neglected. On this basis it appears that an advancing front moves up the wall at a dimensionless velocity $3/16\ Mr^2$ and with a thickness $3/4\ Mr$. Behind the advancing front the film gradually broadens to a dimensionless thickness Mr corresponding to that for maximum steady flow rate. The speed of the advancing front is about $8 \cdot 10^{-5}$ cm/sec for our illustrative problem, which is very close to the climbing rates of $4 \cdot 10^{-5}$ to $8 \cdot 10^{-5}$ cm/sec observed for many hydrocarbons which give comparable film thickness (12).

It is clearly important to investigate further the dynamics of film formation as well as the much more complex problems associated with electrochemical processes on the wetted surface. In such systems surface tension gradients will result from concentration inequalities (concentration polarization) as well as thermal. These will be treated in future papers of this series.

Discussion

The above simple analysis together with the qualitative but detailed discussion of Bascom, Cottington, and Singleterry (12), provide a picture of stable "Marangoni films" suitable for our present purposes. It only remains to assess their probable importance in electrochemical processes.

First it is important to note that only very small gradients of surface tension are needed to produce films of the thickness believed to exist on electrodes. Thus, it was shown that a few tenths of a degree per centimeter are needed to produce 1μ thick films. Correspondingly small concentration gradients are required for isothermal films, especially for such electrolytes as KOH, the surface tension of which increases rapidly with concentration as shown in Fig. 4. In fact, one can show that for KOH a change in concentration of 0.035 mole/liter/cm of plate height has the same effect as the temperature gradient of −0.4°C/cm in the previous illustrative example.

Second, it should be pointed out that the vertical circulation produced in stable but dynamic films by

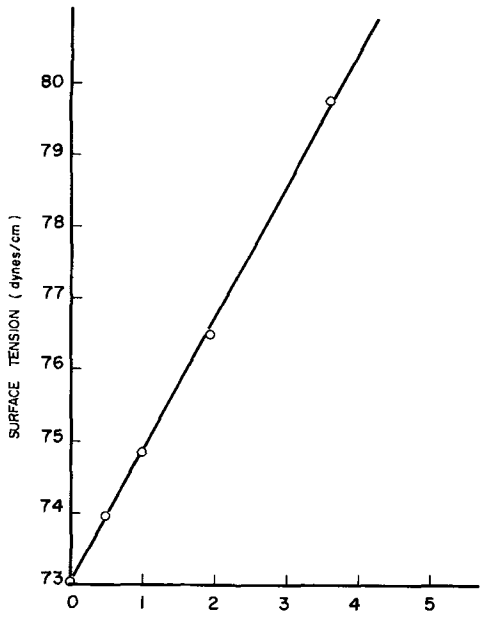

Fig. 4. Surface tension of aqueous solutions of KOH vs. molar concentration.

surface tension gradients tends to reduce concentration polarization in much the same way as the vapor-phase water recirculation predicted for large systems in the first paper of this series. It may therefore provide a further explanation for the small amount of concentration polarization observed in these films to date.

Third, it should be remembered that gravitational influences tend to become small in most electrode structures while surface forces tend to become predominant. Thus, more pronounced surface tension effects can occur, with the primary restraint provided by viscous forces and mass-balance requirements. It seems, therefore, entirely possible that complex dynamic patterns could be obtained in porous electrodes such as those used in ion-exchange membrane cells.

Very little reliable quantitative data are yet available for actual electrochemical operations. However, it may be of interest to compare the results of above equations with typical data of Bennion. He calculates the concentration profile in the film necessary to supply the reaction water by vapor-phase transport. These profiles show gradients from ~0.07 mole/liter cm to 1.0 mole/liter cm. A typical current of 50 μa/cm needs in his estimate a gradient of about 0.55 mole/liter cm at the bottom of the film to supply the reaction water in the area of the fastest reaction rate. At the same time our proposed mechanism requires a gradient of only 0.042 mole/liter cm to supply the reaction water for this value of the current. Thus, the surface tension mechanism is much more powerful than the vapor phase transport mechanism even in large systems.

Despite the rather encouraging agreement with experimental data which these illustrations show, there are still some observations left unexplained by this mechanism. Müller (6) has recently reported the existence of stable films in the apparent absence of surface tension gradients and the growth of a concentrated electrolyte film over a dilute one, apparently against a downward directed surface tension gradient. The explanation of these phenomena can apparently not be found in the Marangoni effect.

However we think the explanation need not necessarily be sought in a previously unknown physical effect but rather in the correct interpretation of already known factors or combination of them. A much more thorough analysis of the Marangoni effect is possible and an unsteady-state analysis is intended.

The dynamic aspects required by the Marangoni effect and the vapor recirculation mechanism for film stabilization can be tested by closer study of the hydrodynamics of supermeniscus films using tracer methods. This paper lays the ground for the interpretation of such experiments.

Although surface tension gradients may not be the only factor determining the film behavior they certainly are likely to arise and have an important effect under operating conditions of a gas diffusion electrode.

Manuscript received Dec. 13, 1965; revised manuscript received June 13, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

APPENDIX

Preliminary Analysis of Unsteady-State Behavior

The spreading (*i.e.*, unsteady) behavior of liquid films is quite complex and cannot be described accurately without allowance for surface curvature at the advancing film front. It must, therefore, be left to a later paper. We can, however, demonstrate some important transient film characteristics by the following very simple analysis.

We begin once again with a very simple system: a film initially of zero height and the following assumptions: (*i*) constant surface tension gradient α in the direction of film flow, (*ii*) negligible film curvature; and (*iii*) negligible mass transfer with respect to the vapor phase. Since inertial effects in the film can be safely neglected the film may be described by

$$Re = \frac{1}{2}R^2 Mr - \frac{1}{3}R^3 \qquad (A)$$

$$\frac{\partial R}{\partial \tau} = -\frac{\partial Re}{\partial Z} \qquad (B)$$

At

$$\tau = 0, \quad Z = 0, \quad 0 < R < Mr \qquad (C)$$

Here $\tau = \nu t/L^2$, a dimensionless time, $Z = z/L$, a dimensionless distance from the top of the intrinsic meniscus, $L = (\nu^2/g)^{1/3} = \delta/R$. Equation (B) states the requirement of mass conservation for a nonvolatile film. Equations (A) and (B) are readily combined to obtain a formal relation for film thickness as a function of position and time. For the assumed boundary conditions this relation takes the simple form

$$Z = (R\,Mr - R^2)\tau \qquad (D)$$

Equation (D) is used in Fig. 5 to show calculated film shapes for several times (solid lines). It is seen immediately that the calculated R is a double-valued function of position: a physically meaningless result obtained by neglect of surface curvature. Analogous

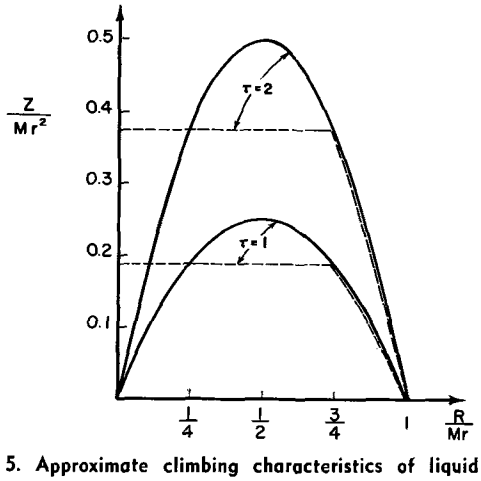

Fig. 5. Approximate climbing characteristics of liquid films

multiple-valued profiles are obtained for concentration waves in fixed sorbent beds when solute dispersion is neglected and for shallow-water waves if viscous dissipation is not taken into consideration.

Just as in these analogous situations a useful asymptotic result can be obtained by replacing the double-valued front by a combination of sharp (or discontinuous) and diffuse portions satisfying the same mass balance. Such an asymptotic front is represented in Fig. 5 for $\tau = 1$ by a heavy dotted line. The position Z_d of the sharp portion of the front, and the film thickness R_d where it meets the diffuse portion, are determined for our boundary conditions by means of the mass-balance relation:

$$\left(\frac{dZ}{d\tau}\right)_d R_d = \int_0^{R_d} \frac{dZ}{d\tau}\, dR \qquad \text{(E)}$$

$$(R_d\, Mr - R_d^2)\, R_d = \int_0^{R_d} (R\, Mr - R^2)\, dR$$

$$= \frac{1}{2} R_d^2\, Mr - \frac{1}{3} R_d^3 \qquad \text{(F)}$$

so that

$$R_d = \left(\frac{3}{4}\right) Mr \qquad \text{(G)}$$

$$Z_d = \frac{3}{16} Mr^2\, \tau \qquad \text{(H)}$$

Thus we find that the film climbs at a steady rate expressed by Eq. (H), and that the advancing front is three-quarters as wide as the steady-state film corresponding to maximum flow rate (see Eq. [8a]). The dimensionless speed $dZ_d/d\tau = 3/16\, Mr^2$, at which this front advances is just slightly in excess of the dimensionless average velocity $Re_{max}/R_{max} = 1/6\, Mr^2$ of the steady film at maximum flow. However, it is also important to note the final thickness of the climbing film $R_{max} = Mr$ is only approached asymptotically for $\tau/Z \to \infty$ as seen from Eq. (D).

These conclusions are probably sound even though they are based on an incomplete model of the film front. The correspondingly idealized description of concentration waves has, for example, been shown to be: (*i*) a proper limiting solution for large τ/Z (14),(*ii*) a useful engineering approximation (15). Equations (G) and (H) can then most probably be considered useful approximations for the large length-to-thickness ratios of postulated electrochemical films.

Technical Notes

Automatic Registration of Electrolyte Specific Gravity in Lead-Acid Batteries

Jeanne Burbank

U. S. Naval Research Laboratory, Washington, D. C.

and Emmanuel Goldstein[1]

Quanta Laboratories Incorporated, Falls Church, Virginia

The refraction of light is a fundamental property of matter and a manifestation of the interaction of electromagnetic radiation with the electrons belonging to atoms, ions, and molecules. The laws of refraction are well known, and numerous basic studies are available; only a few representative articles and reviews are cited for examples here (1-8). Refractive index is the ratio of the speeds of light in two media, and tables giving these indices for various pure liquids, gases, many solids, and solutions list the speed in the given material relative to air or vacuum as a standard (9, 10).

For determination of the refractive index of liquids, a small sample is sometimes removed from the bulk material and the index measured by visual observation with a refractometer. Continuously recording instruments are available, but their application has usually been limited to pipelines and processing tanks handling large volumes of a single material. Several are described as research instruments (2, 5, 11-20).

Measuring the refractive index is relatively so simple and the amount of sample required so small that these determinations may be used as an alternative to density or specific gravity measurements (2, 11, 12). It is frequently desired to monitor the specific gravity of a solution during the course of a production operation, and a continuously recording refractometer may be used conveniently for this purpose under suitable conditions.

It is common practice to follow changes in specific gravity of the sulfuric acid electrolyte in the lead-acid cell. The "over-riding importance" of this as-

[1] Present address: Alpha Micro-Optics Company, Beltsville, Maryland.

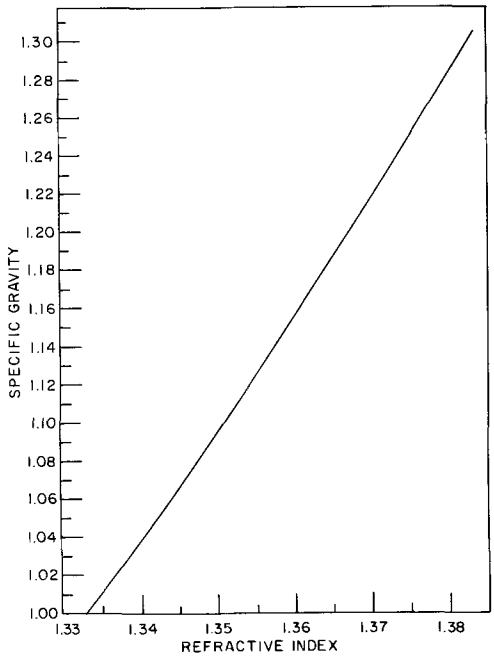

Fig. 1. Relation of specific gravity and refractive index of aqueous H_2SO_4 solutions at 20°C (10).

pect of the behavior of the lead-acid battery has recently been emphasized by Robinson and Heinson (21). Specific gravity gives an indication of the condition as well as the state of charge of the cell, and the end-of-charge is determined by constancy in the readings. For these determinations, small samples of electrolyte are usually removed periodically by hand, and the specific gravity determined by hydrometer. In large batteries, the specific gravity is measured only on selected pilot cells because of the excessive time and labor required to sample each individual cell.

The reaction of the lead cell is usually written

$$PbO_2 + Pb + 2H_2SO_4 = 2PbSO_4 + 2H_2O$$
$$\text{charge} \longleftrightarrow \text{discharge}$$

and Vinal (22) presents a full description of the electrolyte and the variation of specific gravity with the state of charge of the cell. Figure 1 shows the relation of specific gravity to refractive index of aqueous H_2SO_4 solutions throughout the concentration range employed in batteries (3, 10, 23-25), and clearly indicates that refractive index may be used to follow changes in specific gravity of the electrolyte in the lead-acid battery.

It was to fill the need of a simple inexpensive continuously recording device to monitor the electrolyte in individual cells of large batteries that the present work was undertaken; however the instrument described is not limited to this use and was originally developed for other applications (26).

The Instrument and Its Use in a Battery

A compact inexpensive dipping refractometer was fashioned from a U-shaped rod, the two ends of which were sealed in a mounting head. The head may be of a suitable material and geometry to fit as a plug in any desired container, and the length of the probe is chosen so that the rod is partially or totally immersed in the liquid being monitored. Within the mounting head a miniature light source and photodetector were located at either end of the tubulation. The amount of light falling on the detector depends on the loss through the walls of the rod, which in turn is a function of the indices of refraction of the material of the rod and the medium surrounding it. The rod is chosen so that its index of refraction is greater than that of the medium it is used to monitor. Any change in refractive index of the surrounding medium results in a change in the critical angle of total internal reflection for the light traveling through the rod and, therefore, in the amount of radiation falling on the photodetector. The sharp radius of curvature at the tip of the probe produces an area particularly sensitive to changes in refractive index of the medium. The signal output from the photodetector may be readily converted by conventional instrumentation for registration on standard recorders.

To illustrate the application of this instrument to lead-acid battery monitoring, the probe was fabricated from glass rod, the light source and photodetector circuit were powered from an external battery, the photodetector replacing one arm in a bridge circuit. The bridge imbalance was sensed by a Keithley electrometer amplifier-microammeter. The output of this device fed a standard L&N 20-mv multipoint recorder. Initial bridge balance for a null was accomplished by variable resistive arms in the bridge circuit. A number of cells could be monitored at one time by using a probe and bridge circuit for each cell, and a nonshorting switch to scan the cells, connected to a recorder through a coupling circuit, if necessary. The instrument may be modified for internal calibration and temperature compensation.

A commercial 30 amp-hr cell was used in this work. The cell was charged and the specific gravity adjusted to 1.257. A small hole was drilled in the cell top and the probe partially submerged in the electrolyte at the edge of the element. The cell was cycled at the 4- and 8-hr rates. During the cycling, samples of electrolyte were temporarily removed at intervals and the specific gravity measured by conventional methods. The probe was calibrated by preliminary submersion in a series of standard sulfuric acid solutions. The tests described here were carried out at room temperature. A small sheet of polyethylene was placed in the cell between the probe and the cell element to serve as a deflector for gas bubbles for some of the tests.

Results and Discussion

A photograph of a section of recorder chart showing the registration of the change in refractive index and cell voltage for a capacity discharge of the cell is shown in Fig. 2. A comparison of this recording with the usual plot of specific gravity readings taken during such a discharge (22) shows that the two are indistinguishable. At the end of a charge when the negative plates began to gas vigorously, the refractometer readings became erratic owing to the hydrogen bubbles in the electrolyte. This was eliminated by placing the plastic sheet between the element and the probe to shield it from direct impingement of the bubbles.

Several interesting phenomena were observed during this work, which suggest that this instrument or

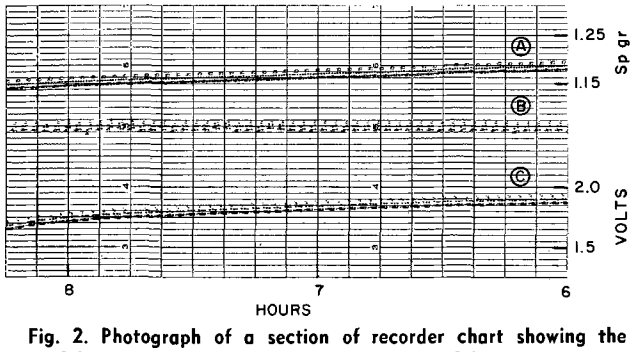

Fig. 2. Photograph of a section of recorder chart showing the final 2.25 hr of a capacity discharge at the 8-hr rate at room temperature. A, Specific gravity (refractive index); B, discharge current, 5 amp; C, cell voltage.

modifications of it may be useful for more fundamental electrochemical investigations. The lead-acid cell used for this test contained no provision for stirring the electrolyte, and during charge as the positive plates began to gas significantly, before the negatives finished, the refractive index passed through a maximum. As the charge continued, the specific gravity decreased again as mixing took place and ultimately rose to the final and constant value. These effects are attributed to oxygen bubbles carrying high density electrolyte to the top of the cell from the reaction of charge at the positive plate. This was followed by a second rise as the negative plates finished charge and began to gas freely, and ultimately by a leveling off as the electrolyte became thoroughly mixed. The rates of these changes might be used, under suitable experimental conditions, to measure the difference in rates of charge of the positive and negative plates, and in diffusion rate studies.

Immediately on application of the charge or discharge current, the indicator showed a transitory response that may merit further investigation. It is possible that the deflection was caused by differences in the rates of response of the anions and cations to the application of the electric field. The response time of the device is essentially limited only by the time constant of the photodetector and its associated circuitry. Capillary probes may be used, and the sensitive tip placed in close proximity to an electrode surface, within the diffusion layer. This suggests its possible use for estimating concentration gradients near the surface of an electrode, supplementing Schlieren, interferometric, and analytical techniques (27-29).

Manuscript received June 22, 1966; revised manuscript received Sept. 1, 1966. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Blue Luminescence in Calcium Chlorovanadates

M. A. Aia and Paul Lublin

The Bayside Laboratory, Research Center of
General Telephone & Electronics Laboratories Inc., Bayside, New York

Reports on luminescence in the vanadates of calcium have been widely scattered and inconsistent, probably owing to the scarcity of definitive x-ray diffraction data on the alkaline earth vanadates. The phase diagram for CaO-V_2O_5 shows 3 phases, $CaO \cdot V_2O_5$, $2CaO \cdot V_2O_5$, and $3CaO \cdot V_2O_5$ (1). In 1926 Robl (2) reported reddish-brown photoluminescence for $Ca_2V_2O_7$. A few years later Schloemer (3) reported very weak red luminescence for CaV_2O_6. In an extensive study of alkaline earth vanadates Rothschild (4) observed no measurable luminescence in either $Ca_2V_2O_7$ or $Ca_3(VO_4)_2$. Brixner and co-workers (5, 6) were the first to prepare large crystals (monoclinic) of $Ca_3(VO_4)_2$ suitable for structural studies, but these were not luminescent at room temperature. European patents (7, 8) have disclosed luminescence in the halovanadates of Sr, Ba, Mg, and Zn, but not those of Ca. Kotera and Sekine (9) have reported strong blue luminescence under 2537Å excitation in what they reported was $Ca_2V_2O_7$, although they added large excesses of CaO, as well as 3% by weight NH_4ClO_4, before firing. We prepared $Ca_2V_2O_7$, but observed no measurable luminescence at room temperature; in agreement with Rothschild (4). However, we did observe bright blue luminescence in calcium chlorovanadates under excitation by short-wave ultraviolet light. We found that all of our luminescent compositions contained $Ca_5Cl(VO_4)_3$ with the hexagonal structure of the well-known phosphate mineral, apatite.

Experimental

Luminescent calcium chlorovanadates were prepared by heating mixtures of high-purity $CaCO_3$, NH_4VO_3, and $CaCl_2$ (100-200% excess Cl) in covered silica crucibles for up to 20 hr in air at 450°C, followed by mortaring and refiring at 1000°C for 1 hr. Calcium chlorovanadates of lower brightness were

prepared by heating nonluminescent, chloride-free calcium orthovanadates with Ca/V mole ratios $\geqq 1.67$ in a dried stream of 10% HCl — 90% O_2 for 1 hr at 800°C. X-ray diffraction analysis confirmed the formation of the apatite structure. At higher temperatures, or in the absence of O_2, large quantities of vanadium chlorides were volatilized, leaving black, nonluminescent residues. Similar problems occurred when NH_4Cl was used as the source of chloride in the air-firing process. We also prepared $Ca_5F(VO_4)_3$ with the apatite structure and found no visible luminescence at room temperature or at liquid nitrogen temperature.

X-ray diffraction data were obtained from a calibrated Philips-Norelco Diffractometer, using Ni-filtered CuKα radiation and scanning at 1°/min. Photoluminescence data were obtained in the region 200-700 nm on an Aminco-Bowman spectrophotofluorometer using a xenon lamp as the source and an RCA 1P28 or 6217 photomultiplier as the detector. Cathodoluminescence was tested in a demountable cathode-ray tube operated at a 15-kv accelerating potential and a 0.5 $\mu a/cm^2$ anode current density on the phosphor screen. The phosphor was settled at 5 mg/cm^2 on 1 x 1 in. plates of Corning EC (electrically conducting) glass.

Structural Studies.—Klement and Harth (10) prepared calcium halovanadates with the apatite structure from melts of NaCl, NaBr, and NaI, but did not give data on either the luminescence or the cell parameters for these compounds. The d-spacings and relative intensities of $Ca_5Cl(VO_4)_3$ differ considerably from those of the corresponding chlorophosphate due to the larger a unit-cell dimension of the chlorovanadate and to the greater scattering power of V *vs.* P. Lattice parameters of both the fluorovanadate and chlorovanadate of Ca are compared to those of the corresponding phosphates in Table I. The parameters were determined by the method of least squares.

It is not yet known whether the same structural differences that exist between the chloro and fluorophosphates (13) also exist between the chloro and fluorovanadates.

We prepared chlorovanadates and fluorovanadates of Sr and Ba and found that these also had the apatite structure, with larger lattice parameters than those of the corresponding calcium vanadates. The results will be presented in a more comprehensive report on x-ray diffraction studies of group II vanadates.

Luminescence studies.—The blue emission band of calcium chlorovanadate is similar to that of $CaWO_4$ (14) although slightly narrower. The emission under short uv extends from approximately 340 to 590 nm and peaks at 445 nm, as compared to $CaWO_4$ which peaks at 450 nm. It is known that the true emission peak for $CaWO_4$ is close to 425 nm; hence the true emission peak for calcium chlorovanadate probably lies near 420 nm. The excitation band is also broad (220-380 nm), and overlaps that of the emission band. Peak excitation was obtained near 305 nm as compared to 274 nm for $CaWO_4$, which is consequently much brighter under 2537Å light. The absolute values of the excitation peaks are in doubt because the apparent excitation curves were not readily corrected for the varying output of the xenon source as the range 200-400 nm was scanned. Unlike $CaWO_4$, the chlorovanadates exhibited only very weak blue emission when excited by cathode rays.

The intensity of photoluminescence, as well as the structure of the material, was considerably influenced by the Ca/V mole ratio of the chlorovanadate phosphors and best results were obtained when excess $CaCO_3$ was added, as shown in Table II. The brightest phosphor (Ca/V = 2.5) actually consisted of 3 phases which were present in the following amounts by weight: $Ca_5Cl(VO_4)_3$ about 50%, $Ca_3(VO_4)_2$ about 40%, CaO about 10%. On a molar basis the CaO content was close to 25%. The $Ca_3(VO_4)_2$ was identified by comparing the d-spacings to those we obtained from a single crystal.[1] Similar samples prepared without chloride did not exhibit either luminescence or apatite structure until they were refired in an atmosphere of 10% HCl —90% O_2 at 800°C. In no case was $CaCl_2$ or its hydrates detectable by x-ray diffraction analysis. Because neither the excitation nor the fluorescence peaks for photoluminescence shifted detectably with the appearance of free CaO in the x-ray diffraction patterns, the luminescence appears to originate in the vanadate groups and not in the CaO. This was confirmed by experiments, in which CaO was leached out with dilute HCl without loss in brightness.

The brightness of samples containing free CaO was found to deteriorate on prolonged standing in ambient air. Concurrently, the formation of $Ca(OH)_2$ was detected by x-ray diffraction. The free CaO seemed to be leached out with 2% HCl solution, as evidenced by the disappearance of the intense diffraction lines at d = 2.40 and 1.70Å. However, an even more intense line at d = 2.77Å was not affected. Furthermore, the HCl treatment sometimes caused the surface of the white powders to turn yellow and in no case improved the initial brightness significantly. The persistent, intense line at d = 2.77Å is puzzling since it was not observed in either pure $Ca_5Cl(VO_4)_3$ or $Ca_3(VO_4)_2$ and was believed due entirely to CaO, in which case it should have been diminished by the HCl treatment.

Despite the proximity of the ionic radius of Mn^{2+}, Tb^{3+}, or Ho^{3+} to that of Ca^{2+}, it was not possible to obtain efficient emission at room temperature by adding $MnCl_2$, Tb_2O_3, or Ho_2O_3 to the calcium chlorovanadates even when Na^+ was added (as NaCl) for charge compensation. The results were somewhat better with Eu_2O_3 doping. The range 0.04-0.16 mole Eu per mole $Ca_5Cl(VO_4)_3$ was investigated; both the blue host emission and the characteristic red Eu^{3+} emission were obtained, the former in lowest yield and the latter in highest yield at 0.04 Eu (1% by wt). As with many other self-activated phosphors, the

* 2 molecules per unit-cell; the hexagonal space group of apatite is $P\ 6_3/m = C^2_{6h}$.

Table II. Effect of Ca/V mole ratio on intensity of photoluminescence and structure of calcium chlorovanadates (Cl/V mole ratio = 1.0)

Mole ratio Ca/V	Relative intensity* at 445 nm (τ_X = 305 nm)	Phases found (x-ray diffraction)
1.67 (theor.)	18	$Ca_5Cl(VO_4)_3$
2.0	87	$Ca_5Cl(VO_4)_3$ + $Ca_3(VO_4)_2$** + CaO
2.5	105	Ditto but more CaO
3.0	60	Ditto but still more CaO

* Intensities are given *vs.* $CaWO_4$ (Sylvania No. 2402) excited at λ = 274 nm where the power output of the xenon source was less than at 305 nm.

** The 4 more intense x-ray diffraction lines for monoclinic $Ca_3(VO_4)_2$ in the range 4-90 degrees 2θ occur at d = 3.307 (25), 2.943 (100), 2.832 (20), and 2.698Å (50). Relative intensities are given in parentheses.

intensity of photoluminescence in all the calcium chlorovanadates prepared, doped or undoped, was much higher at liquid nitrogen temperature than at 25°C. For example, at 77°K, the respective emissions of Tb^{3+} (yellow-green) and Ho^{3+} (blue-green) were clearly visible in samples doped with the appropriate rare earth oxide, although at room temperature no luminescence at all was seen under uv excitation.

We prepared $Sr_5Cl(VO_4)_3$, $Sr_5F(VO_4)_3$, $Ba_5Cl(VO_4)_3$, and $Ba_5F(VO_4)_3$ powders with the apatite structure and found they were efficiently excited by long-wavelength uv, as might be expected (8). The excitation peak for all four of these compounds was in the wavelength region 338-348 nm; the emission from the strontium vanadates was bright yellow-white at room temperature while that from the barium vanadates was bright green-white. These phosphors were also much brighter when reduced to the temperature of liquid nitrogen.

Discussion and Conclusions

It is significant that chloride is essential in the preparation of luminescent calcium vanadates since, without it, the apatite structure is not formed. There is little doubt that the blue luminescence arises in the tetrahedrally coordinated VO_4 groups of $Ca_5Cl(VO_4)_3$ and that the process is critically affected by the local site symmetry. For example, there is no visible fluorescence in $Ca_5F(VO_4)_3$ which may have a slightly different structure. It now seems possible that the blue-emitting materials prepared by Kotera and Sekine (9) actually contained $Ca_5Cl(VO_4)_3$ since all the essential ingredients were present in their procedure. A large influence of the cations (*i.e.*, Ca^{2+}, Sr^{2+}, or Ba^{2+}), as well as the halide ions on the luminescence in halovanadates with the apatite structure has also been suggested by the present work.

Acknowledgment

The System $PbNb_2O_6$ and Its Bearing on the Growth of Single Crystals of the Ferroelectric Polymorph

V. G. Hill and R. I. Harker

Tem-Pres Research, Incorporated, State College, Pennsylvania

Lead metaniobate exists as tetragonal, rhombohedral, and orthorhombic polymorphs. Francombe (1) and Roth (2, 3) showed that the orthorhombic modification, which was first discovered by Goodman (4) is metastable at atmospheric pressure. Francombe also reported that the most stable low temperature phase was the rhombohedral polymorph, which transforms at 1200°-1250°C to the tetragonal form. The orthorhombic polymorph is a ferroelectric material with a Curie point of 560°C (5). It is unique among the structures which contain a highly polarizable ion with a noble gas electronic configuration, in that it is not pseudo-cubic. Good single crystals of this polymorph are desirable for electronic studies and devices because polycrystalline materials are neither reliable nor as strongly ferroelectric.

Polycrystalline samples are obtained by firing at temperatures above 1250°C. Columnar crystals 2-3-mm in length have been obtained by heating the material above 1350°C and then crystallizing the melt by slow cooling (1). In both cases, the tetragonal polymorph was formed stably at high temperatures, preserved metastably on cooling, and prevented from passing through a rather sluggish inversion to the stable rhombohedral form. The resultant material then passed through the enantiotropic inversion to the ferroelectric, metastable orthorhombic form.

No data was found in the literature on the effect of pressure on the stability relations of the orthorhombic form. The calculated specific gravities of the orthorhombic, tetragonal, and rhombic polymorphs are 6.7, 6.5, and 7.3, respectively. On the basis of these figures, and disregarding the effect of temperature, increasing pressure might be expected to increase the stability field of the rhombohedral polymorph at the expense of the tetragonal polymorph. However, considering the metastable equilibrium similarly, pressure might be expected to increase the field of the orthorhombic form relative to the tetragonal form. It was argued that if the latter consideration prevailed, then high pressure techniques might be used to grow large crystals of the ferroelectric form. An alternative growth method might also be indicated by the phase relations.

Starting Materials and Equipment

The phase relationships in the system were determined using (*a*) externally heated cold seal test tube vessels of Stellite or René in conjunction with a Tem-Pres Model HR-1B-4 hydrothermal unit (6, 7, 8), (*b*) internally heated hydrostatic pressure apparatus, Tem-Pres Model PV-3C-2 (7), and (*c*) eternally heated uniaxial pressure device, Tem-Pres Model SJ-100 (9). The sample, and a small amount of water or other solvents where necessary, were sealed in gold or platinum tubes for reaction in the first two

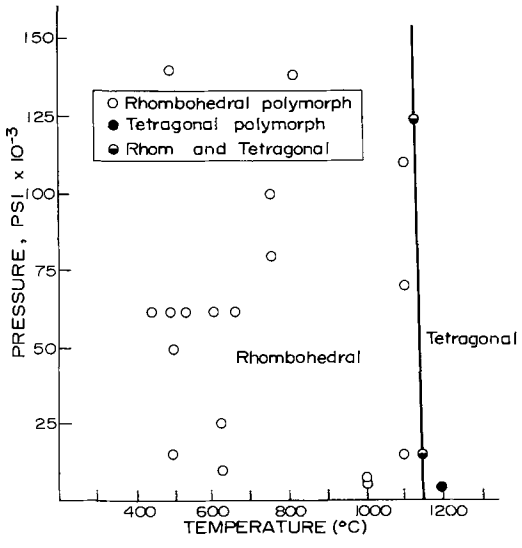

Fig. 1. Phase diagram of the system $PbNb_2O_6$

units. In the uniaxial press, the sample was a small wafer surrounded by a nickel ring sandwiched between platinum foil disks, and pressed between the faces of carbide anvils. The duration of the runs varied, depending on the conditions employed. Runs were from half an hour, when very high pressure and high temperature runs were made, to about two weeks for runs at the lowest temperatures and pressures. Runs made at atmospheric pressure in platinum wound quench furnaces were on samples sealed in 2.5 or 5 mm diameter platinum tubes to prevent changes in the compositions of mixtures due to volatilization of lead.

Phases were identified by x-ray diffraction methods, supplemented with the petrographic microscope.

The starting materials used were: (*i*) Stoichiometric mixture of PbO and Nb_2O_5: This mixture was prepared by grinding the weighed amounts of the two previously dried oxides under acetone for about 2 hr. (*ii*) Polycrystalline rhombohedral $PbNb_2O_6$: This was prepared by heating the stoichiometric mixture to 1000°C for about 1 hr in a sealed platinum tube. (*iii*) Polycrystalline orthorhombic $PbNb_2O_6$: This was prepared by firing the rhombohedral form at 1250°C in a sealed platinum tube for 1 hr.

Experimentation and Results

Figure 1 shows the stability relations among the phases in the system $PbNb_2O_6$ as determined in this work. The orthorhombic form has no stability field in the p-t range studied. When the mixed oxides were used as starting material a mixture of rhombohedral $PbNb_2O_6$, a pyrochlore type compound (probably $3PbO \cdot 2Nb_2O_5$), and orthorhombic $PbNb_2O_6$ were formed below 500°C and pressures over 50,000 psi. The orthorhombic $PbNb_2O_6$ obtained was probably a solid solution containing excess Nb_2O_5. The $3PbO \cdot 2Nb_2O_5$ phase and orthorhombic $PbNb_2O_6$ formed metastably in runs of a few days, but rhombohedral $PbNb_2O_6$ resulted when the duration of the run exceeded seven days.

On the basis of the data obtained, the only possibility of obtaining single crystals of the orthorhombic form is by metastable transformation. This approach introduces the problem of avoiding the sluggish transformation to the stable rhombohedral polymorph. There is also the problem of going through the tetragonal-orthorhombic transformation without damaging the crystal extensively. A study was therefore made of the effects of dopants on both the tetragonal-rhombohedral and tetragonal-orthorhombic transformations. It was found that the addition of up to 4% ZrO_2 or TiO_2 did not affect the equilibrium phase relations shown in Fig. 1, but had a marked effect of decreasing the rate of inversion when the reaction was done "dry." Under "wet" or hydrothermal conditions the rate of this inversion to the rhombohedral form was increased by the dopants and the doped orthorhombic polymorph easily inverted to the rhombohedral polymorph in its stability field.

Since it was not possible to stabilize the orthorhombic polymorph by using dopants, the tetragonal-orthorhombic inversion was studied to determine if crystal damage could be minimized. The D.T.A. curve for orthorhombic $PbNb_2O_6$ was obtained between 300° and 650°C at a heating rate of 10°C/min. An exothermic reaction was detected at 560° ± 10°C at 1 atm pressure. The peak obtained on the heating cycle was relatively sharp while that on the cooling cycle was somewhat broadened. It was also found that the observed orthorhombic to tetragonal inversion temperature increased slightly with increased particle size. This may be simply the result of the restraining effect of the larger crystal. The rate of inversion to the rhombohedral form was very sluggish and this form was not detected in material which had been through three heating and cooling cycles encompassing the inversion. Attempts were made to study the effects of pressure on the orthorhombic to tetragonal inversion using a Tem-Pres high pressure D.T.A. attachment (10). However, the small enthalpy involved (about 8% that of cryolite) prevented detection of the inversion with any degree of certainty.

The Bridgman method of crystal growth was selected for more detailed study as a possible method for growing the orthorhombic polymorph. Because of the high melting temperatures involved, and the variable valences possible for niobium, precautions had to be taken to prevent the loss of oxygen from the composition; otherwise a darkening of the crystals resulted. A stoichiometric mixture of PbO and Nb_2O_5 was first heated to 900°C and homogenized by grinding. The product was transferred to a special Bridgman crucible which was sealed by arc welding, and then fired at 1200°C for 2 hr. Finally the entire contained charge was melted by heating to 1350°C. In these experiments the sealed crucible was lowered through the furnace at 4-6 cm/hr, which corresponded to an initial cooling rate of less than 0.4°C/hr and a mean rate of 4°C/hr until the temperature of the charge was 1150°C. At this temperature the charge was cooled rapidly to 650°C in order to avoid inversion to the rhombohedral form. The slow cooling was again resumed in an attempt to minimize the disrupting effect of the inversion. Various programs including much slower and much faster cooling rates of the tetragonal polymorph were tried in an effort to reduce significantly the damage done to the crystals. It was found that when the melt was slowly cooled from

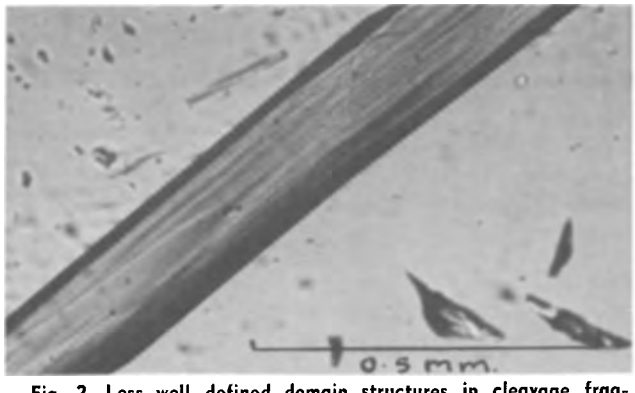

Fig. 2. Less well defined domain structures in cleavage fragments from $PbNb_2O_6$ which was cooled slowly to 1250°C, and then cooled rapidly to room temperatures.

Fig. 3. Intricate domain structures in orthorhombic $PbNb_2O_6$ which was cooled slowly. Thin cleavage fragment as seen in transmitted light.

1350° to 1200°C, and then immediately removed from the furnace the resulting product showed only minor amounts of cracking. Some fragments of this did not show the usual coarse domain structures, and their quality was good, see Fig. 2. The fine domains in these were of the order of 0.002 mm as compared to 0.01 mm in other specimens, see Fig. 3.

Petrographic examination of thin sections from other specimens showed that several nuclei developed in the cone of the crucible but a dominant one finally extended into the main body of the crucible. One section did not extinguish under crossed incols, but the cleavage and domain structures appeared to have the same orientation throughout the main mass of the sample, indicating that a large single crystal existed before the inversion took place and shattered the material.

Examination of the surfaces of uncleaved and freshly cleaved flat flakes showed an intricate pattern of related features, in addition to the obvious cracks (Fig. 4). These features do not resemble any of the domain patterns which had been seen in transmitted light, and perhaps are not related to them. We conclude that they are growth features exposed by cleavage along a single crystallographic plane.

The products from these runs were cracked to varying degrees. Some of the pieces (weighing 1-3g) appeared to be fragments from a single crystal. This was supported by x-ray diffractometer tracings obtained from polished faces of these fragments. In all cases the only reflections obtained were the different orders from the same plane.

Laue photographs from the upper surface of the melted products of the other runs indicate that the surfaces contained areas which were misoriented with respect to the main mass. This was probably confined to the upper surface which definitely appeared to be a polycrystalline mosaic, and usually cracked.

The crystals grown varied in color from colorless to pale straw.[1] Examination of the larger fragments with a binocular microscope showed that they are all cracked, badly strained, and twinned. Many of them have a well developed network of fractures. By petrographic examination of thin fragments and sections, a marked mosaic structure bounded by (110) twin pairs was apparent. Domain structures as small as 0.005 mm were observed, but size and density varied. A few pieces, however, do not contain domain structures but instead a fibrous or interwoven pattern. These fragments would immediately develop a domain structure when stressed by simple mechanical techniques such as squeezing or probing. It logically follows that the preparation of the thin sections may have induced much twinning and domain structure. It was also noted that some of the features developed

[1] Nonstoichiometric $PbNb_2O_6$, which was formed when the material was fired in air varied in color from pale green to much deeper green, and was opaque in thicker sections.

Fig. 4a.

by mechanical stress strain relaxed in a few minutes while the samples were under the microscope.

Discussion of Results

It appears that orthorhombic lead metaniobate, even when doped with small amounts of ZrO_2, has no stability field at temperatures below 1150°C and pressures up to 25 kilobars and it is, therefore, unlikely that large single crystals of this material can be grown hydrothermally. A choice of methods involving the growth of the tetragonal phase in its stability field and converting this to the orthorhombic phase remains. The tetragonal to orthorhombic inversion produces a discontinuous change in cell dimension, and large anisotropic strains develop. Francombe and Lewis (5) relate this to the appearance of spontaneous ferroelectric strain, and an increase in the covalent character of the Pb-O bonds. The latter could result in 001-type cleavage as was found in orthorhombic $PbNb_2O_6$. This mechanism could explain the frequent fracturing of crystals grown by the Bridg-

man technique. The crystals tend to fracture but the degree of fracturing has no simple relationship to conditions of growth of the crystals. The rapid quenching of the run after the tetragonal phase has crystallized, but before it inverts to the rhombohedral phase, seems to result in an improved product. It was also observed that the crystals became twinned and even fractured because of ordinary handling. In some experiments, clean $PbNb_2O_6$ splinters were observed to develop cracks and otherwise relieve strain under the microscope. Annealing the crystals at the Curie point does relieve some of the stresses but results in increased fracturing.

The ability to re-orient the crystallographic axes of the crystals by mechanical stresses does, however, appear to offer some hope for a method of producing single domain crystals, or at least crystals with fewer large domains from a crystal which has passes through the Curie point.

Acknowledgments

The authors wish to express their thanks to Dr. W. C. Luth, formerly of the Materials Research Laboratory, The Pennsylvania State University for performing some of the runs in the internally heated pressure vessel system. This work was sponsored by the U.S. Air Force Materials Laboratory, Wright-Patterson Air Force Base, under contract AF 33(615)-1712 R. L. Hickmott, project engineer.

Epitaxial InAs on Semi-Insulating GaAs Substrates

G. R. Cronin, R. W. Conrad, and S. R. Borrello

Texas Instruments Incorporated, Dallas, Texas

The preparation of high-purity indium arsenide has been reported by several laboratories working with crystals grown from the melt (1-3). Both horizontal ingot growth and vertical pulling techniques have been employed in obtaining high-purity n-type material with excess carrier concentrations of about 1-2 x 10^{16}/cm^3 at 300°K. Excess carrier concentrations less than 10^{16}/cm^3, however, have not been easily achieved. By extensive purification of both indium and arsenic, Effer (2) prepared an apparently uncompensated sample of InAs whose electron concentration at 77°K was 8.0 x 10^{15}/cm^3 with a mobility of 75,700 cm^2/v-sec. Vapor growth of InAs has been achieved by a halide transport technique analogous to that which transports GaAs (4-6). Some difficulty of electrical evaluation exists, however, unless measurements can be made on discrete crystals of vapor grown material or the material is deposited on an insulating substrate. In this series of experiments the substrate chosen for deposition was chromium-doped GaAs since the semi-insulating property of this material allows unambiguous electrical evaluation of the deposit. Furthermore, semi-insulating GaAs is readily available, easy to polish, and has the same crystal structure as InAs.

Experimental

The reactor and flow systems are shown in Fig. 1. All hydrogen is purified by palladium diffusion. The HCl required for indium transport is prepared as needed by bubbling hydrogen through pure $AsCl_3$ in a gas-saturator system. The arsenic trichloride used in these experiments is distilled from commercial reagent grade anhydrous $AsCl_3$. Distillation is accomplished with a twelve foot column packed with Pyrex helices and operated with a reflux ratio of about 30 to 1. The distilled $AsCl_3$ contains no detectable impurities. This mixture of $AsCl_3$ and hydrogen passes through a quartz tube filled with quartz chips and heated to about 880°C. The reduced arsenic condenses on the cool walls of the quartz tube outside the reduction furnace and the resulting HCl-hydrogen mixture is introduced into the reactor. An advantage of this technique is that the HCl is prepared as needed and storage of the compressed gas in steel containers is unnecessary.

Table I. Temperature and flow conditions for epitaxial InAs deposition

	Temperature, °C	Flow rate, cc/min
Arsenic	430	30 (H_2)
Indium	870	60 (HCl/H_2)
Substrate	740	—
Excess hydrogen flush	—	30
$AsCl_3$ reduction furnace	880	—

A detailed sketch of the reactor proper is shown in Fig. 2. A three-zone furnace is used to provide independent control over the arsenic, indium, and substrate zones of the reactor. Typical operating conditions of flow rates and temperatures are shown in Table I. Temperatures are controlled to within ± 1°C with proportional control equipment. Arsenic vapor is transported to the substrate zone by passing hydrogen over heated arsenic. Indium transport is achieved with the volatile monochloride prepared by passing a mixture of pure HCl and hydrogen over elemental indium maintained at a temperature of 870°C. Both the arsenic and the indium are commercially available research grade materials, 99.9999% pure.

GaAs substrates, 30 mils thick, were cut on the (100) orientation and polished on a paper pad wet with sodium hypochlorite solution after the manner of Reisman and Rohr (7).

Initially, three substrate orientations were examined: the (100), (111)A, and (111)B. Since the best crystalline structure and highest growth rate were obtained with the (100), all further work was done on (100) substrates. Polishing time is approximately 2 hr during which time about 3 mils are removed from the surface of the substrates. Since the substrates are polished in batches and some storage is necessary, they are given one further chemical etch individually just before being placed in the reactor. This final etch consists of 15 cc of $5H_2SO_4$-H_2O-H_2O_2 mixture for 5 min followed by 5 additional minutes in the same solution to which 5 cc of H_2O have been added. The latter etching is carried out in a rotating beaker.

Hall coefficient and resistivity measurements were made by either of two procedures: (*i*) an a-c technique using ultrasonically cut six-armed specimens to which contacts were indium-soldered, and (*ii*) a d-c method using rectangular shaped samples, contacts being made with indium plated phosphor bronze strips. Both methods yielded the same results and were used interchangeably.

The epitaxial layer thicknesses were determined by microscopic examination of cleaved edges or by bevel lap techniques. Single crystallinity and epitaxial orientation were established by optical microscopy and x-ray diffraction.

In addition, spectral transmission measurements were made on the epitaxial layers and the absorption coefficient in the absorption edge region was found to be the same as that for melt-grown material.

Results

Under the operating conditions shown in Table I, we have observed growth rates of 30-40 μ/hr on (100) oriented substrates. Figure 3 shows the surface and cleaved edge of a layer produced under these conditions. The layer is easily seen under a microscope because of a faint but distinct color difference. For the purpose of obtaining clearer pictures the cleaved edge shown in Fig. 3 was stained for about 1 sec in the same sodium hypochlorite solution used to polish the substrates. This solution darkens the substrate but leaves the InAs layer apparently unchanged. The defect density revealed by etching the surface with a 3:1 mixture of HNO_3-HF is relatively low. The smooth cleavage characteristics on (110) planes, similar to bulk material, are generally associated with smooth, shiny layers having low surface defect density.

For our particular reactor system, any significant departure from the arsenic temperature and HCl-H_2 mixture flow rate shown in Table I adversely affects the physical properties of the deposits. Figure 4 shows the etched surface and cleaved edge of a layer prepared under arsenic-deficient conditions. The poor surface and cleavage characteristics and irregular interface are typical of layers grown indium-rich and are suggestive of alloying between excess indium and the GaAs substrate. Growth under indium-deficient conditions generally results in sharp, planar interfaces but dull surfaces with high defect densities and poor cleavage characteristics.

In general, most of the surface irregularities we have observed have the appearance of line defects lying in <110> directions. They bear a marked resemblance to line defects which have been observed in both GaAs(8) and silicon (9). Although these defects appear to originate at the epitaxial interface, we believe that in general they are not only a result of substrate imperfections but also appear to be associated with incorrect vapor composition. Analogous effects of vapor composition on the morphology of epitaxial GaAs layers has been described by Ewing and Greene (10).

The electron mobilities and excess carrier concentrations at room temperature and 77°K for a number of samples are shown in Table II. Samples 1 through 6 were prepared at or near the operating conditions of Table I. Samples grown over a wide range of temperature and flow rate conditions have invariably been n-type. Material with excess electron concentrations less than $2 \times 10^{16}/cm^3$ seems to be rather easily obtained. The best sample we have prepared has an electron mobility at 77°K of 7.04×10^4 $cm^2/v\text{-}sec$ at 6.1×10^{15} electrons/cm^3.

We have also obtained samples which, unlike melt-grown material, show unusually low excess electron

concentrations (see samples 7 and 8 of Table II). These samples also show low mobilities at both room temperature and 77°K, suggesting a high degree of compensation. This kind of material is obtained only when arsenic temperatures much higher than optimum are used. However, we have not been able to prepare p-type InAs by this method.

Two possible explanations for the dependence of the electrical properties of epitaxial InAs on the vapor composition can be proposed. First, large deviations from the optimum vapor composition may promote the formation of physical defects. At high arsenic concentrations, arsenic interstitials and indium vacancies are the simplest point defects which could show acceptor properties (11). Second, changes in vapor composition might significantly alter the vapor-solid segregation coefficients of residual impurities present in the arsenic.

The Repeatability of the Anode Effect in Cryolite-Alumina Melts

B. J. Welch and R. J. Snow

School of Chemical Technology, The University of New South Wales, Kensington, New South Wales, Australia

Hitherto, studies of the anode effect have been primarily confined to correlations with the critical current density (1-3), but the various correlations between concentration and the point of anode effect have not been in substantial agreement.

The complexity of factors affecting these correlations has recently been illustrated by both Piontelli (3) and Schmitt (4). Piontelli found that correlations between critical current density and alumina concentration held only for a fixed orientation and design of the working anode. Results of Schmitt's investigations showed that, at a fixed critical current density, the alumina concentration decreased as the temperature increased.

Because the anode is often consumed at an uneven rate during electrolysis the true surface area could change. Also the true surface area for different carbons varies considerably, so the differences between correlations of apparent critical current density are not surprising.

Provided the total cell resistance is low the cell voltage would be less dependent on these variables, and therefore, a more reproducible parameter than critical current density. This is because the overpotential at the anode is high (5) while the cathode overvoltage is small (3), and therefore the only current dependent contribution to the cell voltage would be that arising from the cell resistance.

In this work the reproducibility of the point of anode effect was studied for an anode of fixed surface area by simultaneously determining the cell voltage and apparent geometric current density at the point of anode effect. The reproducibility was studied as a function of alumina concentration by making successive measurements with all other conditions constant and also by doing repeat experiments for constant conditions.

Experimental

A schematic view of the cell arrangement is presented in Fig. 1. The exposed surface area of a Union Carbide A.U.C. grade graphite rod (A) was defined by a boron nitride insulator (B), and this graphite surface was used as the working anode. The counter electrode (C) had a much larger surface area than the anode and was positioned so that the inter electrode distance was kept to a practical minimum to reduce the cell resistance. Concentric insulated inconel (D, E) tubes served as electrode contact leads.

A protective argon atmosphere was maintained within the sealed furnace tube at all times. All measurements were made at 985° ± 2°C using a constant solvent composition of Na_3AlF_6 + 5 w/o AlF_3 + 5 w/o CaF_2.

The anode effects were induced by slowly increasing the applied potential to the cell using a variable stabilized d-c power supply. The current and cell voltage were simultaneously recorded on an E.A.I.

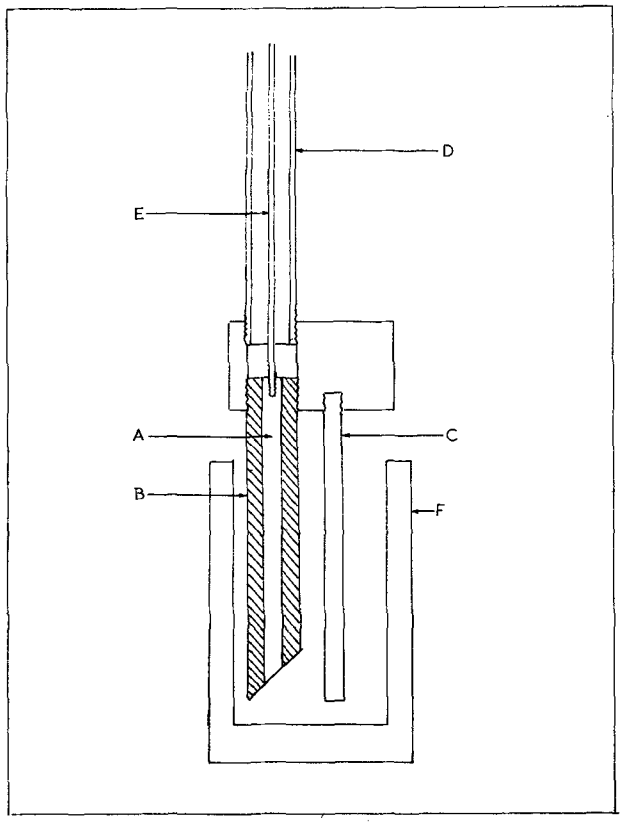

Fig. 1. Schematic view of cell assembly: A, graphite anode rod; B, boron nitride insulator; C, counter electrode; D, E, concentric inconel electrode leads; F, graphite crucible.

model 1130 X-Y Recorder. For each new electrode assembly a short period of electrolysis was carried out to present a uniform electrode surface before measurements were made.

Results

The point of the anode effect was determined for melts containing between 2 and 8 w/o alumina. At least 10 determinations of the point defining the anode effect were carried out during an experiment, and repeat experiments were also carried out for a given melt composition.

The results obtained for the critical current density as a function of alumina concentration are plotted in Fig. 2, and they are compared with curves constructed from the data of Piontelli (3).

The mean critical cell voltage *vs.* alumina concentration curve is presented in Fig. 3. Table I summarizes the variations observed during an experiment for repeated measurements of the parameters describing the point of anode effect.

It is seen from Table I that, for all alumina concentrations, both the accuracy and reproducibility of the critical cell voltage is better than those observed for the critical current density. The variations observed in the cell voltages were generally random in nature. During a series of measurements the values of the critical current density decreased with each successive measurement. Although the rate of decrease as a function of measurement was not always the same, the decrease was invariably more gradual for lower alumina concentrations. This was probably due to the change in angle of the anode surface, which was sometimes (particularly for higher alumina concentrations) apparent from the appearance of the electrode surface after an experiment. This explanation would be consistent with Piontelli's observation.

Because of this the initial measurements were considered to be the more comparable data, and therefore the initial critical current density, as well as the mean values are presented in Fig. 2.

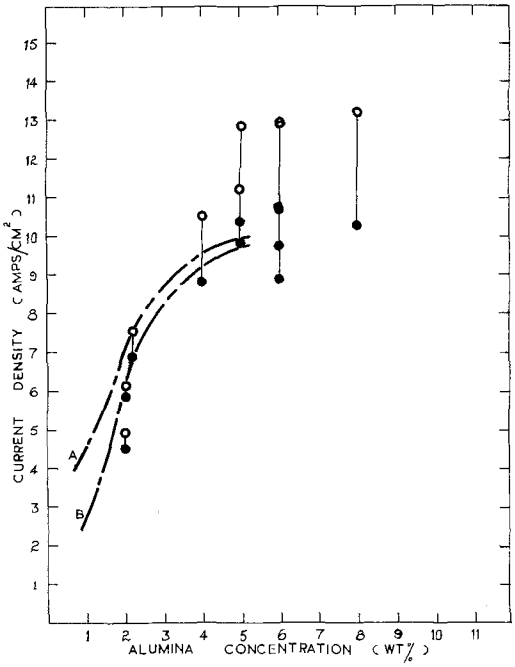

Fig. 2. Variation in critical current density with alumina concentration. Curve A, from Piontelli's data for hemispherical anode; curve B, from Piontelli's data for plane anode, ○ initial critical current densities, • mean values of critical current density.

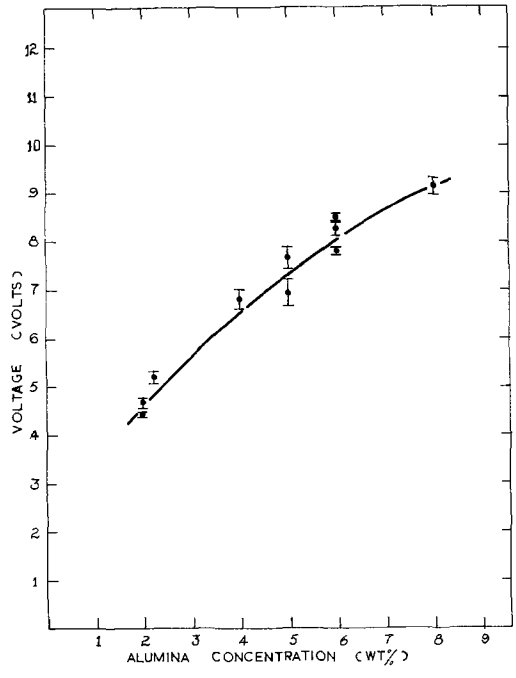

Fig. 3. Variation in cell voltage at point of anode effect with alumina concentration.

The scatter from the best curve would be less for the initial measurements than the mean measurements, but both curves would differ from Piontelli's results. This would be expected because of the different carbon type and anode design.

Conclusions

For applications such as *in situ* analysis of alumina concentrations in a Hall Heroult cell, it is evident that the critical cell voltage is a more reproducible parameter for designs where the cell has a low resistance. The variations in critical current density are more

Table I. Accuracy and reproducibility of measurements for the point of anode effect at 985° ± 2°C

Alumina concentration, w/o	Number of measurements	Variation of critical cell voltage, % of mean	Variation of critical anode current density, % of mean
2.00	10	2.3	11.2
2.00	20	1.1	2.9
2.23	50	2.3	4.6
4.00	19	2.9	10.2
4.98	33	3.0	14.6
4.99	31	4.0	6.0
6.00	25	1.6	6.3
6.00	29	1.0	12.4
6.00	31	0.9	20.2
7.98	26	2.0	12.1

pronounced because of their dependence on both the anode carbon and its orientation which in turn is dependent on previous electrolysis of the electrode.

Discussion Section

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 112, No. 8, 9, 10, and 12 (August, September, October, and December 1965), and Vol. 113, No. 1, 3, 5, and 6 (January, March, May, and June 1966).

Notes on the Chemical Polishing of Gallium Arsenide Surfaces

R. D. Packard (pp. 871-872, Vol. 112, No. 8)

K. E. Mironov[1]: The chemical polishing of compound semiconductor gallium arsenide by means of etching with solutions based on mineral acids is usually explained by the considerable viscosity increasing in such etchants, but the chemical nature of etchant must be more responsible for polishing action.

From some papers[2-5] it is possible to produce the dependence of action mode for such etchant as H_2SO_4: H_2O_2: H_2O. Minimal etch rates for GaAs corresponds to 2-4% of H_2O_2 content in solutions. Selective or polishing action of such etchants is dependent on acid concentration. There are typical triangular etch pits on the {111} faces in the presence of less than 35% H_2SO_4; only conic pits instead of typical triangular ones on the Ga{111} face and polishing action for any other face, if the acid content is between 35-67%, and polishing action only, if etchant content is more than 67% H_2SO_4.

The viscosity of concentrated H_2SO_4 solutions changes in a rather complicated manner because of acid monohydrate formation.[6] Smoother and more regular changes increase the quantity of undissociated molecules in these solutions.[7] Therefore, it seems more correct to connect the polishing action of etchants on the base of concentrated acid with a predominance of undissociated H_2SO_4 species that are forming in such solutions in the presence of the hydrogen peroxide, the peroxomonosulfuric acid H_2SO_5.[8] The latter may also help for polishing action of etchants.

A viscosity maximum for water solutions of HNO_3 corresponds to 70% of acid. The etchants based on the concentrated HNO_3 with the addition of strong HCl reveal the polishing. The dilution of such etchant with the glycerin does not make the increase of HNO_3 dissociation since this one usually decreases in alcohol solutions. Therefore the action of such etchant or an etchant diluted by glycol, ethanol, or benzene as stated by Dr. Packard has to retain polishing action. The high viscosity of etchants containing undissociated inorganic acids promote the polishing action of these mixtures.

R. C. Packard[9]: I have no basic quarrel with Dr. Mironov's thesis that the degree of acid dissociation is a highly important variable. I agree that the etching solution viscosity is important. Dr. Mironov makes the point that the degree of dissociation of inorganic acid, as well as solvent viscosity (alcohol *vs.* glycol, *etc.*), helps determine the final etchant viscosity. This is true. As stated in the cited paper, etches are usually aqueous solutions containing reagents which react with the semiconductor to form soluble reaction products. Dr. Mironov agrees that the chemical nature of the etchant is responsible for the polishing action. However, as I pointed out, the etch rate is dependent on the rate of reactant in-diffusion and product out-diffusion, which is dependent only on solution viscosity, for a given system. Thus, with a normally fast mineral-acid etch, the etching solution viscosity must be a limiting factor.

The Double Layer Capacitance of Silver in Perchlorate Solution

L. Ramaley and C. G. Enke (pp. 947-950, Vol. 112, No. 9)

D. I. Leikis, E. S. Sevastianov, and I. G. Dagaeva[10]: It is suggested in the paper cited that in 1N sodium perchlorate solutions the electric double layer (edl) on silver is similar to edl on mercury, if the potential of zero charge (pzc) of silver is assumed to be equal to —0.7v (NHE), as was shown by one of the authors of the present paper.[11] The authors of the paper under discussion consider, however, that be-

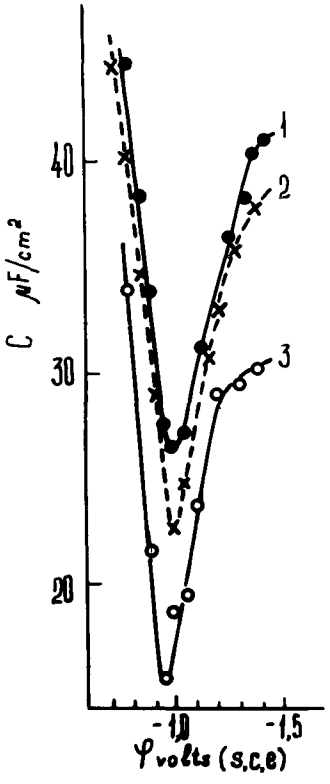

Fig. 1. Dependence of differential capacitance on potential for a silver electrode in Na_2SO_4 solutions of various concentrations: curve 1, 10^{-2}N solution; curve 2, 5×10^{-3}N solution; curve 3, 10^{-3}N solution.

fore drawing final conclusions regarding the problem in question, it would be necessary to have further proofs of the correctness of the value of pzc established. Due to improved experimental technique,[12] we have been able lately to carry out the differential capacitance measurements on silver more carefully, both with respect to accuracy and in solutions of lower concentrations. As can be seen from Fig. 1 the differential capacitance curves on the silver electrode in dilute solutions show a well-pronounced minimum, which becomes deeper with increasing dilution of the solution. The latter fact clearly points to this minimum reflecting the change in the diffusedness of edl with the potential. Hence, $\varphi = -0.7$v (NHE) is really pzc of silver in the solution containing no surface-active ions. This value of pzc agrees with that obtained.[11] A comparison of the differential capacitance curves for silver in 0.01 and 0.001N Na_2SO_4 solutions[13] with those for mercury (taken from [14]) has shown them to coincide almost completely near pzc. This permits us to draw the conclusion that the structures of edl in dilute solutions of electrolytes for the metals being compared are similar. It is shown in[13] that pzc of silver does not depend on pH (in the pH range from 3.4 to 12). This supports the conclusion that the differential capacitance minimum obtained corresponds to pzc of silver.

Another problem—the nature of frequency dispersion—is also considered in the original paper. In particular, in the case of silver this phenomenon is suggested to be due to the surface inhomogeneity of solid metal. Such a suggestion seems to be quite likely. As shown in [11], the difference in the shape of the desorption peak on the capacitance curves in solutions containing a surface-active organic substance in the case of silver and mercury also seems to be due to the inhomogeneity of the silver surface. It should be pointed out, however, that the dispersion data presented in the original paper have been obtained on an electrode which was not sealed into a quartz capillary, *i.e.*, there was still a possibility for a thin electrolyte film to be formed between silver and the capillary. The formation of such a film, as shown in [15,16] may also cause frequency dispersion. The latter may also be caused by some roughness of the surface,[17] which was present, as it follows from the data in the original paper, even in the case of polished silver electrodes.

In our opinion, owing to the above considerations, it is impossible to interpret quantitatively the experimental results for frequency dispersion as being due only to surface inhomogeneity of the metal.

L. Ramaley[18] and **C. G. Enke**[19]: The fine work reported above is noted with great interest by these authors who are pleased to have some of their suggestions concerning the similarity of the double layer structures on Ag and HG supported. However, there is one point concerning the construction and use of the test electrode in our experiments which needs to be clarified. A spherical silver electrode was formed at the end of a fine silver wire. This electrode was immersed in the electrolyte so that the solution surface intersected the silver wire above the sphere but well below the wire-glass seal. Therefore, the observed frequency dispersion could not have been caused by a thin electrolyte film between the silver and the capillary. A similar affect could be caused by creeping of the solution up the wire, but the area involved would be much less significant than in the case of the capillary action which was presumed to exist.

Vapor Phase Deposition and Etching of Silicon

W. H. Shepherd (pp. 988-994, Vol. 112, No. 10)

W. J. Riedl[20]: The contributions in the field of thermodynamic approach to the growth of epitaxial silicon are based on the assumption of the occurrence of chemical reactions either in the gas phase[21] or only on the surface of silicon seed as stated by Dr. Shepherd. Chemical equilibria considered in these two cases are different. Taking into account three reactions

$$SiCl_{4\,gas} + 2H_{2\,gas} = 4HCl_{gas} + Si_{solid} \qquad (i)$$

$$SiCl_{4\,gas} + Si_{solid} = 2SiCl_{2\,gas} \qquad (ii)$$

$$Si_{solid} = Si_{gas} \qquad (iii)$$

Equilibrium concentrations of all components can be computed by solving the following system of equations

$$\frac{(4n_1)^4}{(1-n_1-n_2)\,(w-2n_1)^2(1+w+n_1+n_2+n_3)} = K_1(T) \quad [1]$$

$$\frac{(2n_2)^2}{(1-n_1-n_2)\,(1+w+n_1+n_2+n_3)} = K_2(T) \quad [2]$$

[21] W. Steinmaier, Philips Research Reports, 18, 75 (1963).

$$\frac{n_3}{1+w+n_1+n_2+n_3} = P_{Si}(T) \qquad [3]$$

The constant $K_2(T)$ experimentally determined by Schäfer and Nickl[22]

$$\log K_2(T) = 10.081 - 16427\,T^{-1} \qquad [4]$$

seems to be reliable.

According to Brewer[23], Kubaschevski and Evans[24], and Glassner[25], enthalpy of liquid $SiCl_4$ is $H_{298} = -150.1$ kcal mol^{-1}. Heat of evaporation of this compound in the boiling temperature 330°K is $L_{330} = 6.859$ kcal mol^{-1}.[23] Taking into account the change in the heat capacity within the range 298°-330°K[25] it has been found that $L_{298} = 7.228$ kcal mol^{-1}. Hence, enthalpy of gaseous $SiCl_4$ is $H_{298} = (-150.1 + 7.228)$ kcal mol^{-1}. Using the thermodynamic data given by Wenner[26], Rossini[27], Kubaschevski and Evans[24], listed by Glassner[25], the following equation has been derived

$$\log K_1(T) = -12380\,T^{-1} - 2.51 \log T + 1.2\,10^{-4}\,T + 16.50 \qquad [5]$$

The most reliable values of the saturated vapor pressure over solid silicon seem to be those given by Ceplayeva, Priselkov, and Karelin[28], who applied for measurements the integral variant of the effusion method. Their results have been discussed and compared with those of other authors by Nesmeyanov[29] who represented them by an equation which, expressed in atmospheres, has the form

$$\log P_{Si}(T) = -101.65421 - 11185.64\,T^{-1} + -0.00685812T + 35.81091 \log T \qquad [6]$$

Solving the system of Eq. [1]-[3] gives concentrations of all components at equilibrium states. In higher concentrations of $SiCl_4$ Eq. [3] can be neglected. If, however, equilibria on the boundary gas-silicon surface are considered under assumption of chemical changes occurring on the surface only, the neglect of silicon vapor pressure, which is then higher than partial pressure of $SiCl_2$ especially over 1500°K, probably should not be done. If silicon condensation occurs in the temperature $T < T_s$ at some distance from the seed surface the temperature of which is T_s, this condensation seems to be a consequence of the reverse process given by Eq. [3] rather than by Eq. [2] for the following reason. The decomposition of $SiCl_2$ streaming away from the seed surface, with the formation of solid silicon requires

$$\frac{p^2_{SiCl_2}(T)}{p^2_{SiCl_2}(T_s)} \cdot \frac{p_{SiCl_4}(T_s)}{p_{SiCl_4}(T)} > \frac{K_2(T)}{K_2(T_s)} \qquad [7]$$

If, for example, $T = 1350$°K, $T_s = 1600$°K, the temperature gradient being 450°/cm, the temperature $T = 1350$°K is attained outside of the diffusion layer, where the concentration of $SiCl_4$ equals the initial value. Since, according to the computed values from Eq. [1-3] for the above mentioned conditions, equilibrium pressure of $SiCl_4$ on the surface is very small and that of $SiCl_2$ much smaller in the bulk of the gas than on the surface, then

$$\frac{p^2_{SiCl_2}(1350)}{p^2_{SiCl_2}(1600)} \cdot \frac{p_{SiCl_4}(1600)}{p_{SiCl_4}(1350)} < \frac{K_2(1350)}{K_2(1600)} = \frac{0.82\,10^{-2}}{0.65}$$

As a result, the decomposition of $SiCl_2$ in the gas phase at some distance from the hot silicon surface should not occur.

Details will be given in a more extensive paper.

SYMBOLS

H	molar enthalpy
$K_1(T), K_2(T)$	equilibrium constants of the reactions 1 and 2
L	molar heat of evaporation
n_1, n_2, n_3	extents of reactions 1, 2, and 3
p_i	partial vapor pressure of a component "i"
$P_{Si}(T)$	saturated vapor pressure of silicon
T	absolute temperature
T_s	absolute temperature on the surface of silicon seed
w	number of moles H_2 per mole $SiCl_4$ before any reaction occurs

Reaction of Nickel Carbonyl with Carbon Disulfide

S. H. Pitts, Jr. (pp. 1054-1055, Vol. 112, No. 10)

R. B. Barclay and A. R. Popley[30]: The effect of CS_2 on the decomposition of $Ni(CO)_4$ was investigated at AWRE several years ago and, on the basis of information obtained at that time, we must disagree with Pitts' main conclusion that the breakdown of the $Ni(CO)_4$ under these circumstances is inherently different from straight thermal decomposition.

With reference to the infrared analysis of the residual gases we have always found residual $Ni(CO)_4$ which decomposes often in the form of a fine powder and not on the sides of the container. This was only discovered because attempts to use mass spectographic methods of analysis had produced visible films on the side of the sample tube and when none were found in the initial infrared analysis further investigation led to the discovery of this fine powder. It is suggested that this could, in part, explain the discrepancies in pressure rise found by Pitts. Further evidence that not all $Ni(CO)_4$ was decomposed in the reaction chamber comes from the analysis of the nickel film. If it is assumed that all the nickel in the carbonyl is deposited, then a mass balance calculation on the system shows that almost 50% more S occurs in the plate than is fed into the system. Errors in measuring the system volume or the initial pressure of CS_2 could not be large enough to account for this difference, and the conclusion must be that undecomposed $Ni(CO)_4$ is present. In addition the assumption that all the sulfur from the CS_2 has been incorporated in the plate gives a calculated pressure increase factor of 2.8 which is in agreement with the recorded pressure increases.

Further discrepancies in pressure rise may have been caused by the rapid initial decomposition of the carbonyl during the time which it takes the system to equilibrate, *i.e.*, the "minimum time to admit $Ni(CO)_4$ to the reaction flask to an equilibrium pressure."

On the basis of the data on oxidation obtained by Pitts, calculation shows that the weight gain is consistent with the balance of his analysis being oxygen since it corresponds to that expected if all the Ni were converted to oxide. The high amount of oxygen in the plate is more consistent with oxygen in the system than an extensive breakdown of CO.

We have formulated the following hypothesis based on data from practical plating experiments.

Mechanism of decomposition.—The reaction scheme suggested in the literature[31] is as follows

$$Ni(CO)_4 \rightleftharpoons Ni(CO)_3 + CO \quad [I]$$

$$Ni(CO)_3 \rightarrow Ni + 3CO \quad [II]$$

(*a*) Reaction [I] is rate controlling and leads to the following rate equation

$$-dp/dt = kp/(1 + k'p_{CO}) \quad [1]$$

(*b*) If $Ni(CO)_4$ is weakly adsorbed and CO strongly adsorbed, Eq. [1] reduces to

$$-dp/dt = k''p/p_{CO} \quad [2]$$

(*c*) If $Ni(CO)_4$ were strongly adsorbed the reaction would be simple first order.

This reaction scheme was further developed by Tonosaki[32,33] who showed that Eq. [1] was obeyed in the early stages and Eq. [2] in the later stages of the reaction.

This led to the following results

$$\text{Stage 1.} \quad (1 + 3bp_o)k_m - bv = k_1 \quad [3]$$

$$\text{Stage 2.} \quad 3p_o k_m - v = k_2 \quad [4]$$

where

$$k_m = 2.303\, t^{-1} \log P_o/p$$
$$v = (P_t - P_o)/t$$

b, k_1, and k_2 are positive constants, P_o is the initial pressure of $Ni(CO)_4$, P_t the total pressure at time t. A plot of k_m against v should give two straight lines of slope $(1 + 3\ P_o b)/b$ and $3\ P_o$, respectively.

The above equations were applied to the results obtained by plating brass disks with or without accelerator. In the cases where no accelerator was used two distinct stages were found. However, the later stage did not agree with Tonosaki's Eq. [4] because the gradient of the line was greater than that for the first stage instead of smaller. This might be interpreted as a return to Eq. [3] but when an accelerator was added it was found that the second stage gave a line of negative slope which is completely incompatible with either Eq. [3] or [4].

It therefore seems possible that there may be a third stage to the decomposition of $Ni(CO)_4$ possibly involving an entirely different reaction to that set out in Eq. [I] and [II], and further investigation is being carried out on this point.

It may be that the first stage of decomposition suggested by Tonosaki has been missed in the case of plating the brass disks because few readings were taken early in the run. Thus, the first line obtained by plotting k_m against v could be that represented by Eq. [4]. Two runs without accelerator in fact gave good agreement with the idea that the first line obeyed Eq. [4]. The fact that Eq. [4] is valid over a considerable portion of the run (~30 min) shows that only the rate of breakdown has been effected not the fundamental mechanism.

Effect of temperature and accelerators.—If the rate of desorption controls the reaction, then the addition of an accelerator which was adsorbed in preference to CO would be expected to produce the same effect as raising the temperature, namely, a lowering of the partial pressure of CO at the surface of the plate with a consequent increase in the rate of decomposition. The effect of an accelerator is in fact like that of temperature.

Other evidence can be adduced to support the idea that the accelerator action is a surface phenomenon. It is found that progressive increases in accelerator concentration do not lead to proportional increases in the rate of decomposition: in fact conditions of saturation seem to occur where very little further change in rate is induced by increasing the accelerator concentration. This agrees with the saturation effect found by Pitts. The accelerator is gradually consumed, being incorporated into the plate, and analysis of the surface layer and bulk of the plate has shown that a surface concentration of S exists which is about 50% higher than that in the bulk metal. If the accelerator was acting through the formation of NiS nuclei, this surface concentration would not be expected.

Toward the end of plating the proportion of accelerator to carbonyl will be greater and, since it is well known that large concentrations of S bearing compounds can cause the breakdown of $Ni(CO)_4$, there will be a tendency toward decomposition to NiS and CO: this might be expected to give rise to higher surface S concentrations for plates deposited over a longer time but evidence on this point is still lacking.

S. H. Pitts, Jr.: We appreciate the stimulating comments. While experiments can be urged as supporting a similarity in thermal and CS_2-promoted $Ni(CO)_4$ decomposition theories, proof is lacking. We observed that in nickel plating by induced heat, decomposition of the carbonyl will often occur in the gas phase as well as on the surface. This is independent of CO desorption and does not occur at room temperature.

It is not clear from the discussion by what method the presence of residual $Ni(CO)_4$ was established and if the amount was significant. When 13-15% CS_2 was used, we found no more than 5% $Ni(CO)_4$ in the reacted mixtures by infrared analysis. Tests also were made to decompose any residual carbonyl by heating it in a pressure monitored container. The pressure increase was insignificant. We performed another qualitative test that indicated an absence of $Ni(CO)_4$ in an expended reaction mixture. The addition of more CS_2 gave no further reaction; the addition of more $Ni(CO)_4$ caused another pressure increase. A CS_2 concentration of 13-15% in the initial charge mixture is the optimum to give complete conversion of both CS_2 and $Ni(CO)_4$. At higher concentrations, infrared analysis showed residual CS_2. Lower concentrations gave reacted mixtures that contained unreacted $Ni(CO)_4$.

To produce the mass balance calculations of Barclay and Popley to give 50% more sulfur than was charged and a pressure increase factor of 2.8 requires using 50 mm as the pressure of the $Ni(CO)_4$ in the initial reaction mixture (which was incorrect). The actual $Ni(CO)_4$ pressure in the typical run was only 17.9 mm (21.4-3.5) as described in the fourth paragraph. Also, the reported sulfur and nickel content of the deposited material may have been misleading. The elemental analysis was made on a composite material collected from numerous runs in which the CS_2 pressure was as low as 0.6 mm. It is not necessarily representative of this typical run. If, for example, a CS_2 charge of 2 mm was used instead of 3.5 mm in the mass balance calculations for complete consumption of CS_2 and $Ni(CO)_4$, both the nickel and the sulfur content approximate those found analytically.

It is thought that errors in the initial gas charges are at a minimum. The normal time for charging the system with $Ni(CO)_4$ was 15 sec. The maximum pressure change possible in this period due to the reaction could be only 10% of the total charged as determined from a plot of pressure *vs.* time.

Surface nucleation and growth was a visual observation. The formation of NiS nuclei was not implied.

The extent to which sulfur bearing compounds cause the breakdown of $Ni(CO)_4$ is questionable. In this investigation only H_2S and CS_2 were found to cause it. Sulfur compounds that we found to be ineffective

were sulfur dioxide, methanethiol, carbonyl sulfide, and diethyl sulfide.

A more comprehensive investigation seems necessary to elucidate these reaction mechanisms. We hope Barclay and Popley will publish their work.

An Electrochemical Model for the Oxidation of Zirconium

D. H. Bradhurst, J. E. Draley, and C. J. Van Drunen (pp. 1171-1177, Vol. 112, No. 12)

H. H. Uhlig[34]: It was pointed out in a paper by the undersigned[34a] that thin film oxidation data obeying the cubic equation can often be expressed equally well by the two-stage logarithmic equation. This is the case for data presented in Fig. 9 of the present paper by Bradhurst *et al.*, which are plotted in terms of the cubic equation. The corresponding two-stage logarithmic behavior of the same data are shown in Fig. 1 below. The two heavy lines follow points through the single straight line representing the

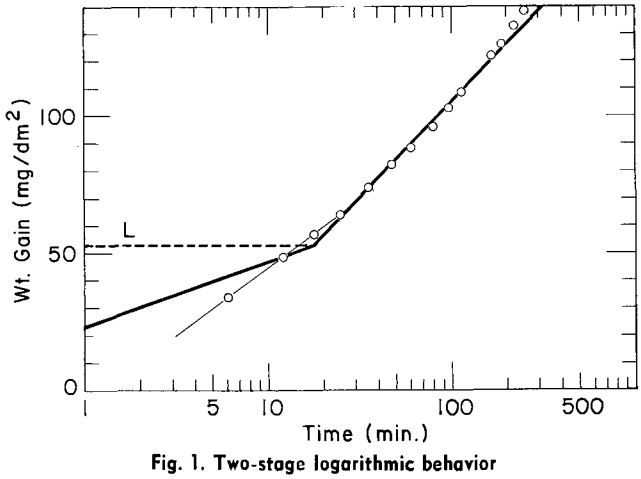

Fig. 1. Two-stage logarithmic behavior

cubic equation as given in Fig. 9; individual points are experimental values supplied by courtesy of J. Draley who also pointed out that the initially obtained points are not as precise as those obtained for longer times. Some correction of weight gain values should be made because of oxygen dissolving in the metal, but such corrections do not affect the present discussion.

The significance of two-stage logarithmic oxidation kinetics has been described in terms of an initial constant density space charge in the growing thin oxide film, with control of oxidation being vested in rate of transfer of electrons from metal to oxide.[35] Beyond a critical thickness L of the oxide, the trapped excess charge dissociates in part, leading to a diffuse space charge and to a higher oxidation rate constant in the usual logarithmic equation $y = k_o \ln (t/\tau + 1)$ where y is the thickness of oxide (or weight of oxygen in the oxide per unit area), k_o is the reaction rate constant, t is time and τ is a constant.

The value of L can be estimated[36] from the work function of the metal, and from the electron affinity v of oxygen adsorbed on the oxide equal to 3.6 ev.

$$L = k_o \left| \frac{e(\phi - v)}{kT} - 1 \right|$$

Taking the thermionic work function of Zr equal to 4.12 ev[37] and the value of k_o from the slope of the first-stage oxidation step in the figure equal to 23/2.3 = 10 mg/dm² the calculated value of L = 52 mg/dm². This compares with the observed value of 53 mg/dm². The observed value of L for lines through the individual points is 68 mg/dm². If the averaged work function of 3.84 ev is substituted [36], the calculated value becomes 19 mg/dm² which is still the right order of magnitude.

The fact that thin film oxidation data for zirconium follow the cubic equation or the two-stage logarithmic equation, combined with the reasonable correspondence of calculated and observed values of L lend support to the view that the oxidation rate is controlled not by diffusion of ions or migration of electric charge through an oxide film, but instead by rate of electron transfer from metal to oxide at the metal-oxide interface.

D. H. Bradhurst[38], **J. E. Draley, and C. Van Drunen:** We have looked at semi-log plots of our oxidation data a number of times. We have never seen good evidence for any straight line portions. Referring to Professor Uhlig's figure, we believe the points best form one continuous curve. Incidentally, the first point (at least 6 min) is plotted a little lower that we have used it. Perhaps we made an error when sending it to him. This small revision, plus additional points from the original recorder trace between 6 and 42 min, confirm to us continuation of the longer time curvature to shorter times. (For this run, reliable data could not be taken at time less than 6 min.)

We appreciate Professor Uhlig's interest in our data. We do not believe that the oxidation of zirconium under our conditions fits his oxidation model. Accordingly, we feel we can offer no evidence to confirm or deny the general validity of his model.

The Valency of Aluminum Ions and the Anodic Disintegration of the Metal

M. E. Straumanis and K. Poush (pp. 1185-1188, Vol. 112, No. 12)

L. Rédey[39]: The authors prove that the black deposit formed on the aluminum anode contains fine aluminum particles, as a result of partial disintegration of electrode. They point out that this phenomenon explains why the apparent valency of aluminum ions leaving the anode is lower than 3. This statement is highly probable in my opinion too.

However there are some circumstances in which metal particles are not observable, but, instead of this, hydrogen evolution occurs during the anodic dissolution of aluminum. Although the apparent valency of aluminum ions entering solution is lower than 3 in this case too, it is unnecessary to assume the formation of Al^+ ions, in spite of the fact that the phenomenon may not be explained by disintegration of anode. Several authors established that, for example in solution of halogen ions, hydrogen gas evolved on aluminum anode and only a small quantity of metal particles were detectable and the apparent valency of aluminum ions was 1.7-2.8 depending on circumstances. A plausible explanation of this phenomena is the mixed electrode behavior of the aluminum anode. At the same time two electrochemical processes take place on its surface

$$Al \rightarrow Al^{3+} + 3e^-$$

and

$$2H^+ + 2e^- \rightarrow H_2$$

The evolution of hydrogen gas is the result of local currents flowing on the anode. Therefore, the quan-

tity of evolved hydrogen is equivalent to the surplus of dissolved aluminum (considering the Faraday law and apart from occasional disintegration of metal). The action of local currents is not identical with so-called self-dissolution; the latter proceeds without external polarizing current. Besides the presence of activating anions also external anodic polarizing current is necessary[40] to get that strong local current observed under some conditions (up to a few hundred ma/cm^2). Namely, the local currents become stronger if the extent of anodic polarization increases.

Under the conditions in question formation of Al^+ ions is improbable because the estimated value of standard redox potential of Al^+/Al^{3+} electrode (in aqueous solution) is -2.76v.[41] That is, the Al^+ ions would be extremely unstable and they could not exist in the solution for a perceptible period.

M. E. Straumanis[42]: I am very much pleased by Professor L. Rédey's statement that Al goes into solution as an Al^{3+} ion, pointing out the extreme instability of Al^+. Nevertheless, there still might be the possibility that the Al^+ just formed returns within a very short period of time to the anode and gives up simultaneously or successively two more electrons. Since it is impossible at present to decide experimentally how the removal of the electrons occurs at the anode, we have the right to assume that Al^{3+} ions are formed at once. A further possibility that the Al^+ ions, if formed, disappear by the self-reduction, and oxidation reaction

$$3Al^+ \rightarrow 2Al + Al^{3+} \qquad [1]$$

is ruled out because of the presence of comparatively large particles (embedded in the oxide layer[43]) which could not be formed in reaction [1][44], and because the coulometric measurements with Al-amalgam as an anode showed the formation of only Al^{3+} ions within the limits of error.[45] The same occurs at an In-amalgam electrode, where only In^{3+} ions are formed, the results falling within an error limit much narrower than in the case of Al.[46] The coulometric measurements are the strongest evidence in favor of Al^{3+} and In^{3+} ion formation in the first step during anodic dissolution[47], although In^+ is much more stable than Al^+. Therefore, intermediate steps[48], may be registered only under specific experimental conditions.

Thus, the deviation from Faraday's law during anodic dissolution of metals is explained by the partial surface disintegration of the metal and by the increase of the self-dissolution rate in case of active metals when under anodic current.[49] Professor Rédey is also correct in stating that anodic dissolution may occur without disintegration. In fact, such a dissolution with no disintegration, or more correctly, with hardly detectable disintegration was also observed in this laboratory.[49] Furthermore, similar observations were made by King *et al.*,[50,51] working with Mg. It depends entirely on experimental conditions whether or not spalling of the oxide or hydroxide films is accompanied by spalling (disintegration) of the anodic metal. If the amounts of the latter are small, they may react quickly with the electrolyte under H_2 evolution, thus escaping microscopic detection.[52]

If the protective oxide layer is partially spalled of an active metal anode (by the impact of cations going into solution), the self-dissolution rate of the bare metal spots increases due to activity of the metal or due to the action of local cathodes now exposed to the electrolyte.[49] So, there is no reason why the action of local elements should be excluded from contributing to the self-dissolution rate.

Anomalously Large Photovoltages in a New Photovoltaic Cell

P. N. Ramachandran and R. E. Salomon (pp. 42-45, Vol. 113, No. 1)

M. Hartl[53]: Ramachandran and Salomon previously have reported on this high voltage photovoltaic effect at low temperatures in anodized zirconium electrodes coated with an evaporated layer of copper or gold.[54] On similar investigations using anodized and sandwich-contacted tantalum electrodes[55] we could find only a small increase (factor 2) of the photovoltage at low temperatures. Measuring the photoeffect also in anodized sandwich-contacted zirconium electrodes[56] we got similar results as in anodized tantalum, *i.e.*, no high voltage photovoltaic effect. According to our investigations we suppose that the difference in the applied measuring methods could explain the different results.

Contrary to Ramachandran and Salomon, who used a high impedance electrometer together with an auxilliary bucking circuit, we compensated the photovoltage in a low impedance circuit (sensitive current instrument for null detection) and this in particular for the following reason:

Using a high impedance electrometer (with or without compensation or bucking circuit) the time constant of the measuring circuit is given by the capacitance and series resistance of the photovoltaic element in the oxide layer. Our measurements show[55,56] that the short-circuit photocurrent and therewith the series resistance of tantalum and zirconium oxide largely increases with decreasing temperature. Together with the relatively high capacitance of the thin oxide layers (nF/cm^2) we got time constants of hours measuring the photovoltage in ZrO_2 layers with an electrometer at -150°C. In this case we also found high but not reproducible values of the photovoltage. But we believe that unintentional charging of the capacitance of the oxide layer may be the reason for this effect, because the high time constant of the measuring circuit does not allow the corresponding discharge. It is possible that the photoemission, as discussed below, together with a bucking circuit produces this charging of the capacitance.

We therefore determined the photovoltage[55,56] by a low impedance compensation circuit. For null detection (photovoltage equal to the compensation voltage) we used a low impedance current measuring instrument, whose sensitivity was sufficient to measure the expected short circuit photocurrent.

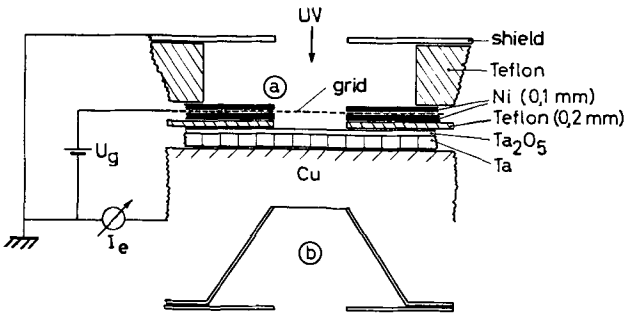

Fig. 1. Schematic set-up of the electrodes used to measure the photoemitted electrons out of an anodized tantalum sheet with a counter electrode in the form of: (a) a fine meshed copper grid mounted between two nickel disks at a small distance (0.3 mm) from the surface of the oxide layer, or (b) a cone made of an anodized tantalum sheet, which could be used instead of the grid. The illuminated area was 3 mm in diameter in both cases.

Therewith the time constant is given by the capacitance of the oxide layer and the input resistance of the current sensitive instrument and was below 0.1 sec in our experiments. It may be mentioned that this compensation circuit (for detail see [56]) seen from the side of the oxide layer, has, in balance ($I = 0$), an "infinitely" high input resistance which is still comparatively infinite, if the sensitivity of the null detecting instrument is high enough to measure the expected short-circuit photocurrent under the given conditions. With this sensitive compensation circuit, we could measure the photocurrent-voltage-characteristic in the proximity of the photovoltage, which was never higher than 2v in gold contacted ZrO_2 layers, produced by an anodization voltage (U_A) up to 60v. Besides the discussed problem of measuring the photovoltage in sandwich-contacted oxide layers with an electrometer, the so far unpublished results of our investigations, concerning the photoeffect in uncontacted oxide layers, may help to explain

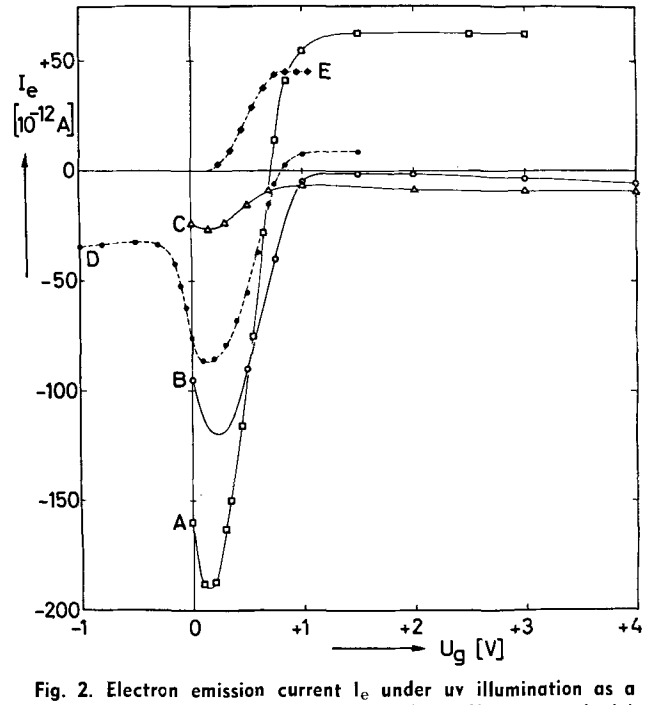

Fig. 2. Electron emission current I_e under uv illumination as a function of the applied grid (or cone) voltage U_g measured: (a) with the grid in Fig. 1a and a tantalum sheet anodized with a formation voltage of 4v: A at + 20°C; B at —10°C; C at —35°C; and D at +25°C at a reduced intensity of light: (b) with the cone in Fig. 1b and a tantalum sheet anodized with a formation voltage of 3v: E at +25°C.

the unusual photoeffect observed by Ramachandran and Salomon. Also in our experiments the conducting path to the surface of the oxide layers was obtained by photoelectron emission. We again used the described low impedance circuit.

Figure 1 shows the mounted electrodes: the chemically polished anodized tantalum sheet (0.1 mm thick) is attached to a copper rod, which was used as electrical lead to the tantalum and also as heat conductor from and to the probe. A fine-meshed copper grid (wire distance 40μ) in a short distance (0.3 mm) above the surface of the oxide layer serves as counter electrode (a in Fig. 1). In this set up, only simultaneous illumination of both electrodes is possible; however the conduction path is defined clearly. To avoid photoemission from the counter electrode while measuring the photoemission from the oxide layer alone, the grid in Fig. 1 was replaced by a cone made of anodized tantalum sheet (b in Fig. 1). The electrode chamber could be evacuated (10^{-5} Torr) by an oil diffusion pump. The light spot (0.25 x 0.25 mm) of an Osram mercury super pressure lamp (HBO 100 W/2) was focused on the probe to get high-intensity photon flux.

Figure 2 shows the current (I_e)-voltage (U_g) characteristics of an anodized tantalum sheet under illumination. Curves A and D in Fig. 2 are measured at room temperature and at different light intensities L_A and L_D ($L_A > L_D$). With sufficient positive grid voltage, current saturation is obtained. The magnitude of this saturation current corresponds to the number of photoemitted electrons out of the oxide layer on the tantalum, and thus is proportional to the intensity of light. Lowering the positive grid voltage, the electron current from the oxide layer to the grid drops to zero at a certain grid voltage U_{go}. This grid voltage U_{go} compensates a photovoltage U_o between the tantalum electrode and the copper grid. It may be mentioned that the photovoltage obtained by this "contactless" measuring method is influenced by the difference in the work functions of the oxide layer and the counter electrode and also by the different number and energy distribution of the photoemitted electrons out of the two electrodes. At lower positive grid voltages than U_{go} the electron flow from the grid to the surface of the oxide layer should also reach a saturation value at sufficient high negative grid voltage. Curve D in Fig. 2 shows that this negative saturation current, which would correspond to the photoelectron emission out of the grid, cannot be obtained. With increasing the negative grid voltage, the negative current decreases from a maximum (between $U_g = U_{go}$ and $U_g = 0$) to a lower value. This specific voltage current characteristic can be explained by the fact that the surface of the oxide layer will be charged to grid potential by the electrons from the grid. Increasing the negative grid potential (and thus increasing the surface potential of the oxide layer to the same values by the assumed charging), an increasing component of the photoemitted electrons from the grid flows to the grounded shield and reduces the measured current from the grid to the oxidized tantalum electrode. Measuring the temperature dependence of the photovoltage U_o with I_e set to zero, we obtained curve A in Fig. 3 for the same oxide coated tantalum electrode as investigated in Fig. 2, and curve C for a chemically polished tantalum electrode without an oxide layer. By comparison curve D in Fig. 3 gives the temperature dependence of the photovoltage in an anodized tantalum electrode coated with an evaporated transparent layer of gold. The similarity of the temperature dependence between the diagrams A and D in Fig. 3 above room temperature (and the difference between A and C) confirms our assumption that the measured photovoltage, identical with U_{go}, is mainly due to the photovoltage in the oxide layer. The large increase of U_o with decreasing temperature below room temperature

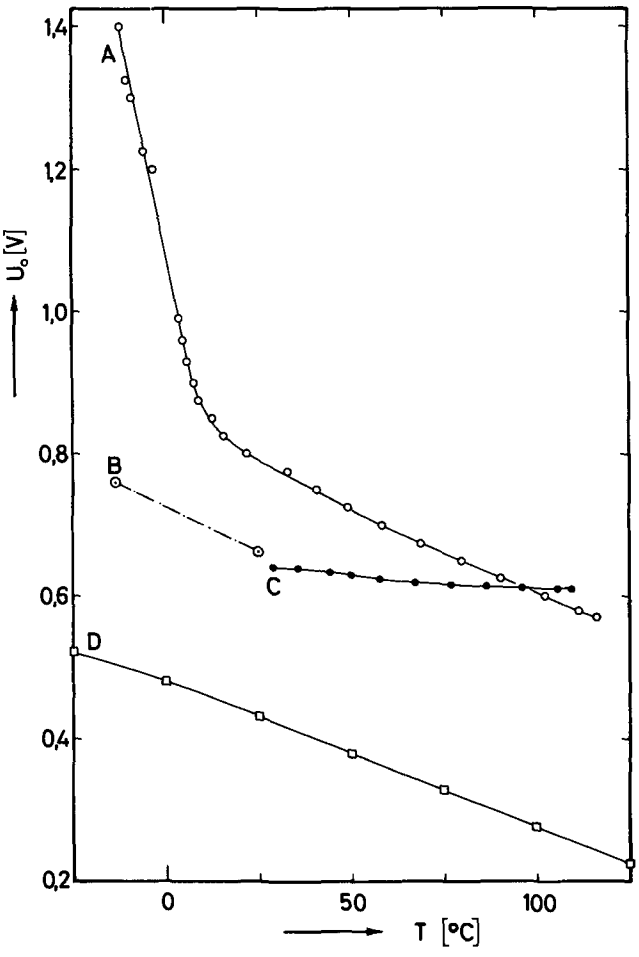

Fig. 3. Photovoltage U_0 as a function of the temperature T measured: A with a low impedance compensation circuit ($I_e = 0$) and B directly with a high impedance electrometer (10^{14} ohm) using the same probe as in Fig. 2a curves A-D. By comparison: C: not anodized tantalum measured as A; D: sandwich contacted anodized tantalum (different intensity of light and oxide thickness corresponding to a formation voltage of 24v.)

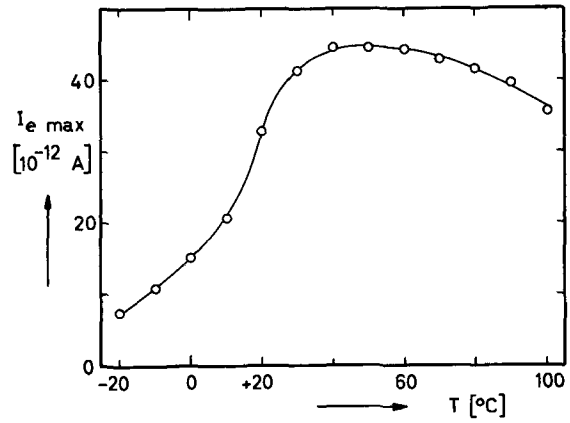

Fig. 4. Maximum electron emission current $I_{e\,max}$ (saturation value of curve E in Fig. 2) out of anodized tantalum (formation voltage 6v) as a function of temperature T.

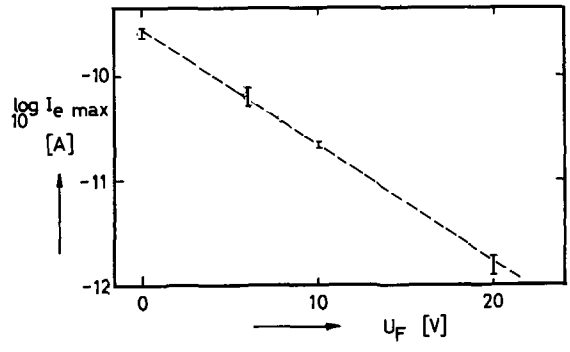

Fig. 5. Maximum electron emission current $I_{e\,max}$ out of anodized tantalum as a function of the oxide thickness corresponding to the given anodization voltage U_A.

is surprising and our curve A seems to lead to the high photovoltages observed by Ramachandran and Salomon. But measuring on the other hand the photovoltage between the grounded grid and the anodized tantalum electrode with a high impedance electrometer directly, without bucking or compensating voltage, we got the two points of curve B in Fig. 3 showing no unusual voltage increase.

To clear this discrepancy we measured the complete current (I_e) voltage (U_g) characteristic also at lower temperatures. Our results are curves B and C in Fig. 2. These curves demonstrate that photoemission out of the anodized tantalum at low temperatures cannot be observed under the given conditions (Fig. 1*a*), and hence a compensation of the photovoltage is not possible with electron current flow only in one direction.

Using the anodized tantalum cone in Fig. 1b instead of the grid (a) it could be shown that the photoemission out of an anodized tantalum electrode is measurable in the investigated lower temperature range. Curve E in Fig. 2 shows the emission current I_e as a function of cone voltage. The saturation current $I_{e\,max}$ at positive cone voltage as a function of temperature is given in Fig. 4. The fact that the saturation point of the emission current as function of the applied voltage (U_g) is nearly independent of temperature, also excludes a larger change of the photovoltage as found in Fig. 3 curve A.

Figure 5 shows the decrease of this saturation current, which also is the maximum photoemission current $I_{e\,max}$, with increasing thickness of the oxide layer. According to the results given in Fig. 4 and 5 it might be supposed that the photoemission out of the relatively thick oxide layers investigated by Ramachandran and Salomon cannot be measured with the used instruments at low temperatures; but without measurable electron emission out of the oxide layer the photovoltage should not be determinable.

However, if the electron emission out of the oxide layer can be neglected against that out of the counter electrode, curve B and C in Fig. 2 should approach zero ($I_e = 0$) with increasing positive grid voltage. The fact that we, however, measured an emission current opposite to the applied field and nearly independent of the positive grid voltage, indicates an additional phenomenon, which could not be explained at present. But according to the shape of curve B and C in Fig. 2 (quite different from A and D) and according to the facts of small electron emission out of the oxide layer and of the directly measured low photovoltage (curve B in Fig. 3), we believe that this negative emission current at positive grid voltage (measured up to + 10v) is not caused by higher photovoltage but more likely by surface charging of the oxide layer, similar to that found with the negative grid voltage even at room temperature (curve D in Fig. 2). The reason for this charging could be any auxiliary voltage (as in our experiments the applied grid voltage, or any other compensating resp. bucking voltage) or perhaps electrons with higher energies emitted by a heated counter electrode.

Although our investigations are not carried out under the same experimental conditions as applied by Ramachandran and Salomon and also were for a different purpose, we hope, however, to have shown some of the problems which should be discussed by Ramachandran and Salomon to clear their measured unusual photoeffect.

Acknowledgment.—The author is indebted to Professor Dr. M. Knoll, the Director of the Institut für Technische Elektronik der Technischen Hochschule München, for encouraging this work and wishes to thank Dipl. Ing. H. Hippmann for some measurements, Dipl. Ings. U. Büktas and Graul for helpful criticisms during the preparation of the manuscript, and the Bundesministerium für wissenschaftliche Forschung for financial support.

Detection of Thermal Reaction in Mixed Oxide Powders by Electrical Resistance Measurements

A. N. Copp, M. Nakahira, and G. W. Brindley (pp. 237-239, Vol. 113, No. 3)

J. Deren and J. Haber[57]: Copp, *et al.*, consider the possibility of employing the measurements of electrical conductivity to the investigation of the solid-state reactions in semiconducting oxide systems. There are several remarks which we would like to mention in connection with this problem.

1. Measurements of the electrical conductivity may be a useful experimental technique mainly in studying first stages of the reaction in the polycrystalline mixtures. A solid-state reaction must begin at the intergranular boundaries, and the first steps of the reaction must comprise the structural changes of surface layers, surface migration, formation of surface compounds, etc. As in many cases the conductivity of polycrystalline material is determined by the conductivity of surface layers and intergranular contacts; these changes will entail the changes of electrical conductivity and its activation energy before any new phase is formed in the amount sufficient to be detected by the x-ray diffraction. The results illustrated in Fig. 1 show that even at comparatively low temperatures irreversible changes of electrical conductivity of the $MgO+Cr_2O_3$ mixture are observed[58] although no formation of new phases could be detected by x-ray technique. These changes are related to surface processes, as shown by the investigation of chemical, microscopic, and adsorptive properties.[59-61]

2. It seems that in many cases additional information may be obtained by measuring the electrical conductivity not only as a function of temperature but also as function of the pressure (pressure of oxygen in case of oxide mixtures). The dependence of conductivity on pressure at constant temperature follows the equation: $\sigma = k \cdot p^{\pm 1/n}$, n being dependent on the nature of the oxide and conditions of the experiment. In the case of the reaction between two oxides characterized by different n, the changes of n may supply some information about the first steps of the reaction.[62]

3. In many solid-state reactions metastable intermediate products are formed in small quantities. Their formation may have a pronounced influence on the electrical conductivity, as these compounds appear mainly at the surface of crystallites.[58-61]

4. Once a new phase of the product is formed, it may determine the over-all electrical conductivity. It seems that the growth of crystallites of this phase influences the electrical conductivity to a smaller degree only. It also seems doubtful whether direct relationship between the changes of electrical conductivity and the conversion can be expected.

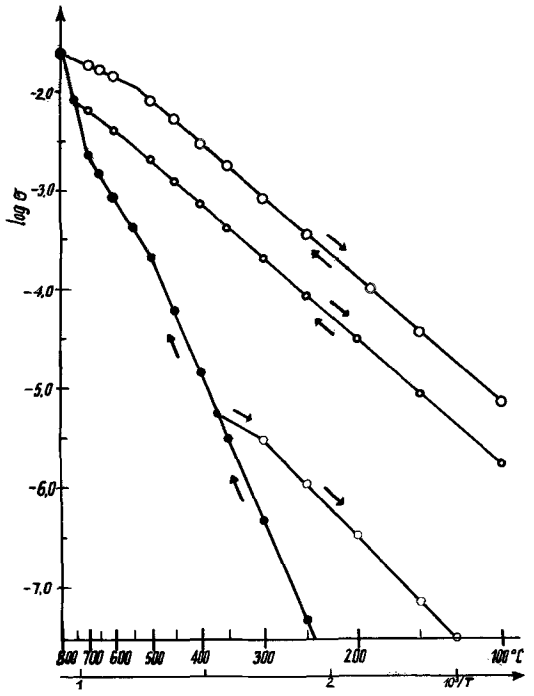

Fig. 1.

5. Measurements of electrical conductivity may also give valuable information concerning the phase diagrams of the oxide systems. In such applications a very critical approach, however, must be adopted since the so-called singular points[63] do not necessarily correspond to a new phase.[59,64]

6. There are two important aspects of the application of conductivity measurements as a method of investigation of the solid-state reactions. As seen from the above discussion the electrical conductivity of an oxide mixture depends on many different factors, and unambiguous conclusions can be drawn only if several various experimental techniques are used simultaneously. In this respect the measurements of electrical conductivity must be considered as a supplementary technique. The second problem refers to the question as to whether electrical conductivity is the most useful property from the point of view of the investigations in this field. It may be suggested that measurements of the work function may give more straightforward information concerning the surface state of the reacting polycrystalline mixture.

A. N. Copp, M. Nakahira, and G. W. Brindley[65]: We are pleased to receive the comments and to have our attention drawn to some recent publications that were overlooked in our own article. We agree entirely with their comment 1 that several different techniques are necessary to avoid unambiguous conclusions; however, we still emphasize that the readily observable breaks in log resistivity (or conductivity) *vs.* $1/T$ curves appear to correspond to the onset of reactions between the components. In their comments 1, 3, and 4, Deren and Haber appear to agree with our general thesis, which we refrained from expressing in as much detail as they supply.

The Growth of Pink Magnesium Aluminate ($MgAl_2O_4$) Single Crystals

C. O. Dugger (pp. 306-307, Vol. 113, No. 3)

L. H. Brixner[66]: The author states in the last paragraph of this paper that the hydrolysis of a fluoride to an oxide might be considered a new technique for growing single crystals. It is probably correct that he was the first to adopt this method specifically for the preparation of single crystalline $MgAl_2O_4$, but as a fundamental technique it is not novel. We used the hydrolysis of both fluoride and chlorides in what we call "flux-reaction technique" for the preparation of transparent single crystalline ferrites of the type $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$ in 1959.

Otherwise Dr. Dugger's paper is a fine piece of experimental work and, if he succeeds in growing larger crystals, he may indeed have a novel host for Cr^{+3}.

C. O. Dugger: I wish to thank Dr. Brixner for calling my attention to his use of chloride and fluoride hydrolysis in the growth of oxide single crystals.[67]

The solid-state chemical equation (solid-phase hydrolysis) to form $BaFe_{12}O_{19}$ from the reactants BaF_2 and Fe_2O_3, as suggested by Dr. Brixner, included one mole of water. The source of water in this reaction was not discussed by Dr. Brixner in his above referenced paper. Also in this paper the source of water was not established in the molten phase hydrolysis of the chlorides. Assuming the mechanism for chloride and fluoride hydrolysis is similar, Dr. Brixner's technique in bringing about the hydrolysis reaction and the temperature at which he added Fe_2O_3 to the molten solution was different from the technique used by the undersigned. The major differences in the two techniques were:

(*A*) Dr. Brixner bubbled oxygen into molten $BaCl_2$ (mp 962°C) while in the preparation of $MgAl_2O_4$ single crystals, extreme care was taken to exclude any oxygen in the carbon furnace chamber in which the starting mixture, BaF_2, MgF_2, and Al_2O_3 was heated.

(*B*) At 1250°C, Dr. Brixner introduced Fe_2O_3 into the molten solution while this author added oxides possessing waters of crystallization to hydrated fluorides at room temperature and then heated the well ground, isostatically pressed mixture to the molten phase.

At present, the exact mechanism for the conversion of MgF_2 to MgO and the chemical formation of $MgAl_2O_4$ from Al_2O_3 is not known. It has been suggested that the chemical reaction MgF_2 and Al_2O_3 to form $MgAl_2O_4$ is a metathetical reaction. Experimental evidence does not support this suggestion. Our laboratory findings indicate that the conversion of MgF_2 to MgO is a hydrolysis reaction.

It appears that the solid and molten phase fluoride hydrolysis-solution technique, for growing high quality stoichiometric oxide single crystals, has the potential of becoming another good method for growing single crystals of some refractory oxides once more is known about the technique.

Adsorption and Oxidation of Butane on Platinum Black in H_2SO_4

J. A. Shropshire and H. H. Horowitz (pp. 490-492, Vol. 113, No. 5)

S. B. Brummer[68]: The authors come to the conclusion that the strong dependence of the initial rate of adsorption of butane on potential in the range 100-300 mv *vs.* the reversible hydrogen electrode (RHE) arises from blockage of butane adsorption sites by adsorbed hydrogen atoms. They conclude, also, that butane adsorbs only in type II (most anodic) H-sites. These conclusions are of great interest and, if confirmed, would be of considerable significance not only in relation to hydrocarbon adsorption on Pt but also in connection with the energetics of H atom adsorption itself. However, some of the authors' experimental techniques appear inappropriate to the study of this system. In addition, the conclusions they draw appear inconsistent with what is generally known about hydrocarbon adsorption on Pt and also with their own data.

Concerning the experimental techniques used by the authors, we would note, as they mentioned, that the early part of the adsorption occurs on a partly oxide covered electrode but, also, as is not mentioned, over a range of potentials.[69] This leads to an intercept of the Q_B *vs.* τ plots of Fig. 5 (Q_B is charge to oxidize adsorbed butane, τ is the time of adsorption). One could hardly agree that the claimed constancy for the intercepts of the Q_B *vs.* τ plots is very convincing (cf. Fig. 5). In any case, when the maximum adsorption is small (*e.g.*, at 0.0v *vs.* SCE) the true initial rate would be concealed by this intercept. One might note also that if the composition of the adsorbed layer varies with potential, which important point the authors completely ignore, the presence of partially oxidized residues adsorbed at high potentials during the return from the "burn off scan" will have profound effects on the kinetics of further adsorption. It would have been considerably better if the authors had really adsorbed at constant potential and if they had measured Q_B in such a way as to avoid readsorption during the "burn off scan."

The major query about the authors' procedures, however, is their assumption that Q_B is a measure of adsorbed butane. The explicit assumption that they make here is that the oxidation state of the adsorbed material is constant, independent of time and potential of adsorption. Further, they assume that the adsorbed material is butane itself. Neither of these assumptions is likely on general grounds and in fact there is a considerable body of evidence to the contrary. Thus, it has been shown for C_3H_8,[70, 71] for C_2H_6,[72] and for various hydrocarbons including C_4H_{10} itself,[73, 74] that the adsorbed material is not the original hydrocarbon and that its oxidation state is a function of time of adsorption and potential. For C_3H_8, this was shown to be true even at 80°C,[70, 71] for C_2H_6 it was shown even as low as 60°C[72] and, in both cases, it would be true at lower temperatures. Recent results[75] show similar behavior for n-C_6H_{14} and there can be little doubt that this is a general effect for the adsorption of saturated hydrocarbons from acid solutions onto Pt electrodes. Thus "adsorption rates" of butane derived from Q_B *vs.* τ plots are unlikely to be correct. Similarly, the reported variation of this "adsorption rate" with potential is of dubious significance.

The authors take no account of this effect. In fact, in their section "additional evidence in support of Type II site adsorption," they explicitly require that the adsorbate be butane itself. This "supporting evidence" based on this asumption cannot then be valid.

It could perhaps be argued that since the authors corrected the "rates" derived from their Q_B *vs.* τ plots for butane oxidation, the reported slopes do represent

[69] "Over a range of potentials," because the potentiostat would take at least 2.5 sec to provide the charge to lower the potential from 1.1v (the end of the "burn off" scan) to the working potential. Much of this charge would be passed over a range of potentials where adsorption of butane would occur.

the true rate of adsorption of butane. However, they used the "steady state" oxidation rate of butane for this purpose and the transient rate of oxidation under the conditions of adsorption onto a clean surface is always much higher. Thus for HCOOH oxidation,[76-79] methanol oxidation,[77] saturated hydrocarbon oxidation[73, 80, 81] and unsaturated hydrocarbon oxidation,[73, 82] the oxidation current always falls rapidly with time during the initial time period. The authors appear to have overlooked this fact in correcting their Q_B *vs.* τ plots. Had they made this correction appropriately they could have obtained the correct adsorption kinetics from their Q_B *vs.* τ plots. However, their overriding assumption which stated simply is that butane either oxidizes to CO_2 or is adsorbed as unchanged butane would not be any more true.[83] One must conclude, then, that the reported "adsorption rates" may be seriously in error.

The important conclusion which the authors say their data point to is that the adsorption rate is first order in free surface (Fig. 7) and occurs only on type II H-sites. Notwithstanding that the "supporting evidence" for this supposition is based on the assumption of 4 sites per adsorbed molecule so that the rate should depend on $(1 - \theta_H)^4$, the evidence is not convincing.[84] Firstly, we note that the data of Fig. 7 refer on the one hand to "adsorption rates" determined at various potentials and on the other to "free surfaces" $[= (1 - \theta_H) = \theta_F]$ determined in absence of C_4H_{10}. The variation in adsorption rate with potential could be due to a number of factors but if the authors' theory were correct then at fixed potential (*e.g.*, in the data of Fig. 5) we expect the observed adsorption rate to decline as butane covers the free surface. Yet, as Fig. 5 of their paper shows, Q_B increases linearly with τ. Indeed this linearity is the basis of the authors' "adsorption rates." The extent of coverage of the electrode by adsorbed C_4H_{10} during the authors' adsorption experiments may be estimated from their results. Thus for the electrode of Fig. 5, Q_B apparently increases at 39 ma at +0.05v *vs.* SCE. Comparing with Fig. 6, and allowing for the steady state oxidation current at +0.05v as given in Table II, shows that this electrode contained 26.5 mg of Pt. From Table I, Q_H^s is 1.265 coul. Adsorption of butane after 40 sec at 0.05v is 2.3 coul and then Q_B/Q_H^s is 1.82. The maximum value, Q_B^s/Q_H^s, is 3.3 and, making the authors' assumptions of 4 sites per molecule, eventual maximum coverage of the relevant sites[85] and adsorption by butane *per se*, this corresponds to coverage by butane of 55% of the electrode surface. Despite this, the Q_B *vs.* τ plots of Fig. 5 show no curvature and, even on a "rate" *vs.* θ_F relation, the rate should have diminished by 55% in 40 sec. If the dependence on θ_F^4 implied by the authors' other assumption were true, the rate should have diminished to ~4% of its original value by this time.

Had the previously mentioned transient oxidation current correction been applied, the initial adsorption rate at low butane coverage would be higher than that at high coverages. There is almost certainly then some dependence on free surface but it is not that claimed by the authors. The only way in which this dependence can be established is to study adsorption *vs.* free surface and time at fixed potential. Figure 7 of the author's article shows merely that a parameter, which is related to the rate of adsorption, changes with the potential of adsorption in a similar way to the way in which H atoms are adsorbed on Pt in the absence of butane. It does not show what the authors claim.[86]

J. A. Shropshire and H. H. Horowitz: The authors would like to thank Dr. Brummer for taking sufficient interest in our paper to offer comments and trust that the following discussion will help to eliminate any misunderstandings that may still exist.

Considerable difficulty would be avoided if it were not immediately assumed that all adsorption-electrooxidation data obtained on active platinum black need be equivalent to that obtained on smooth platinum, often annealed, microelectrodes. It would be very desirable, if it were possible, to study the rate of adsorption of hydrocarbons on smooth platinum electrodes using what have become more or less standard techniques. Unfortunately, diffusion limits the rate of hydrocarbon accumulation on platinum microelectrodes suspended in electrolyte, and true adsorption rates, therefore, cannot be determined. Furthermore, smooth platinum microelectrodes do not behave in the same manner as platinum black electrodes with regard to hydrocarbon adsorption and oxidation, as discussed below. While the use of the porous electrode-flowing electrolyte system required the application of less elegant electrochemical techniques, it nevertheless has demonstrated its merit in showing the existence of an adsorption rate limitation, which correlated with the limiting current observed with actual fuel cell electrodes.

The most stringent requirement of the porous electrode system was that only slow voltage sweeps were possible due to the long charging time of the electrode. An appreciable amount of fuel adsorption, therefore, occurred during the scan and return, giving an apparent intercept of about 10% of maximum coverage. However, most of the coulombs in this intercept reached the electrode during the scan, after the adsorption period and not prior to it. Therefore, the adsorption did occur on an essentially clean surface. In fact, since the intercept was constant, independent of adsorption voltage, it would have been valid for us to subtract it from the raw data of Fig. 5 to obtain curves passing through the origin. A sawtooth rather than triangular voltage form was used to minimize the time available for adsorption after burn-off and prior to the start of the next nominal adsorption period. Since most of the return time is spent in reducing platinum oxides in a potential region where arriving butane is oxidized, the maximum time for fuel adsorption at uncontrolled potential is less than one second, and would have permitted less than 1% coverage to occur.

With the regard to the possible change in composition of the adsorbed butane with potential, we must stress again that desorption of the adsorbed material yielded essentially pure butane identified by gas chromatography. The identification of the adsorbed material is not assumed. Furthermore, this butane is not formed by hydrogenation of fragments since the desorption process consumed no more coulombs than those required to hydrogenate the newly vacated sites. Surely evidence for partial oxidation obtained from kinetic data and adsorption isotherms taken on smooth platinum at lower temperatures must yield to this

[82] J. O'M. Bockris, H. Wroblowa, E. Gileadi, and B. J. Piersma, *Trans. Faraday Soc.*, **61**, 2531 (1965).

[83] And the finally adsorbed material would of course still not be butane itself.

[84] E. J. Cairns [Ref. (6) of June 1965] has reported that for C_3H_8 in HF at 90°C, the adsorption kinetics follow a third order law in free surface.

[85] If we were to accept the conclusion of adsorption only on type II sites, both $Q_B{}^s/Q_H{}^{II}$ and $Q_B{}^{40\ sec}/Q_H{}^{II}$ would be about double these values, but the estimate of coverage would not be altered.

[86] Incidentally, we may note that the authors claim that only ~ 50% of the surface is occupied by C_4H_{10} is certainly not true for C_3H_8[69, 70] and n-C_6H_{14}[75] where coverage by hydrocarbon approaches unity.

Table I.

Electrode form	50 Mg Pt black	1 cm² Smooth Pt
Saturation butane coverage, millicoulombs	8000	0.6
Coverage in 20 sec, millicoulombs (25% of saturation)	2000	0.15
Typical scan time, sec/v	20	0.01
Avg scan current, ma (assuming peak requires 1/3 v)	300	50
Correction for oxidation, millicoulombs (25% of coverage)	500	0.04
Observed oxidation current, ma (assuming 20 sec adsorption)	25	0.002

actual product isolation and analysis. Moreover, data of Niedrach[87] for both ethane and propane adsorption-desorption on high area platinum black completely substantiate this observation. Both these adsorbed paraffins were desorbed substantially unchanged with at most a few per cent of cracked products. It should be noted that only with high surface area porous electrodes is the isolation of desorbed material possible. One hundred mg of platinum black can adsorb and desorb 0.15 cc of butane at STP.

The discussion of the correction for steady-state oxidation during adsorption is very important and needs amplification and clarification for this and other papers. Steady-state oxidation rates in this study were not taken from separate experiments but were measured during the actual adsorption simply by reading the current delivered by the potentiostat. The ability to do this is again a function of the massiveness of the porous electrode system. This is certainly an advantage of the porous electrode over microelectrodes. With low area electrodes and fast scans, the currents are low and the ratio of the current during adsorption to that during the scan is low. These two factors make it virtually impossible to detect anodic oxidation during adsorption on microelectrodes even though it may be quite significant. An example giving order of magnitude numbers will illustrate this important point. Assume that a high area electrode and a microelectrode each reach 25% of saturation coverage with butane after 20 sec adsorption, and during that period each oxidize 25% of what they adsorb. A simple calculation shows that under typical scanning conditions easily detectable scan currents of the order of 10^2 ma are obtained, but the oxidation current is 25 ma in the case of the large electrode and a practically undetectable 0.002 ma in the case of the small one, as shown in Table I.

It was undoubtedly for this reason that a number of authors claimed to measure hydrocarbon adsorption at potentials of 0.5-0.7v *vs.* reversible hydrogen. On porous electrodes, the oxidation currents would be so high at these potentials that it would be obviously impossible to measure saturation coverages. Thus the use of high surface area electrodes has permitted us to verify by actual isolation of the desorbate that butane does not change its composition on the surface under our conditions and has provided an *in situ* method for correcting the adsorption for steady-state oxidation. Both features combine to make a consistent picture.

Much has been made of the fact that one molecule of butane appears to adsorb on four platinum sites. It is appealing to assume one carbon atom per platinum atom at saturation; but no attempt was made to tie this to the kinetics of the adsorption process. In fact, little can be learned about the reaction order since the rate measurements extended to less than 25% coverage of the surface. Maximum coverages were of the order of 6200 millicoulombs. The linear adsorption rate range extended for 500-1500 millicoulombs as shown in Fig. 5 of the paper. Therefore, only an 8-25% change in slope would be expected rather than the 55% calculated by Dr. Brummer on the basis of first order kinetics. We do agree with him that an adsorption rate proportional to the fourth power of the fractional free surface is unlikely on the basis of these data. Perhaps the initial adsorption is virtually irreversible even though it requires four sites. This point should be investigated further.

Explosion of a Chemical Polishing Solution

S. F. Bubar and D. A. Vermilyea (pp. 519, Vol. 113, No. 5)

R. H. Buck[88]: During a period of stay at the Department of Metallurgy, University of Florida, I also had the same experience as the authors but using glycerine (10 parts) as the viscous agent in a nitric acid (5 parts) hydrofluoric acid (5 parts) chemical polishing solution for zirconium. Water was to be added later to control the polishing. A stoppered plastic container in which the fresh solution was stored, ruptured violently about 4 hr after mixing due to reaction occurring within the bottle. On the other hand, a titanium etching solution containing 40 HNO_3/15HF/45H_2O remained stable for months.

Although the exact nature of the chemical reaction causing the explosion is open to speculation it is perhaps pertinent to point out that the presence of concentrated sulfuric acid is usually necessary to bring about the nitration of glycerine to nitroglycerine[89,90] in a reasonable time by promoting anhydrous conditions. A more likely reaction in this case is the oxidation of glycerine in a highly oxidizing medium. Karrer[90], for example, states that strong nitric acid alone will cause oxidation of glycerine, a trihydric alcohol, to glyceric acid. The oxidation may, of course, proceed further and become degradative. The explosion could thus have been caused by a rise in temperature due to the nondissipated heat of reaction, accentuated by the viscosity of the mixture, combined with pressure build-up from the gaseous decomposition products of the reaction. One can visualize a similar reaction occurring in the case of lactic acid (α-hydroxy propionic acid). Lactic acid and glycerine are chosen because they are relatively stable, viscous, and miscible with water in all proportions, properties conferred by the presence of hydroxyl groups. Although these same groups are capable of easy oxidation to corresponding acids, it is difficult to think of less vulnerable organic alternatives having the required physical properties. The role of the viscous agent in chemical polishing is generally thought to be partly physical, but the specificity of some of the reagents used is still not wholly explained. Thus glycerine, glycols, lactic acid, acetic acid, and phosphoric acid[91] have been used.

Inquiries have revealed that the occurrence of such explosions is fairly common. In one case a glycerine/HF/HNO_3 mixture was prepared on the liter-scale and stored in a screw-topped glass bottle—with disastrous consequences. It is not only in the industries concerned with microelectronics or refractory metals that heed should be given: a standard etch for aluminum (Vilella's etch) contains 10 parts HNO_3/20 parts HF/30 parts glycerine. Further in this context, it is relevant to point out the additional hazard recently investigated in connection with perchloric acid/acetic anhydride electropolishing solutions[92] where the reaction between acetic anhydride and water

caused a young metallurgy student to lose the sight of both eyes.

Solutions containing an organic moderator with HNO_3 and HF should certainly not be stored after use. In view of their increasing industrial use in connection with refractory metals and semiconductors, periodic warnings about their hazards such as issued in *This Journal*[89] might serve to reach the worker at the bench.

On the Potential/*p*H Diagrams of the Cu-NH_3-H_2O and Zn-NH_3-H_2O Systems

H. E. Johnson and J. Leja (pp. 630, Vol. 113, No. 6), Discussion Section)

F. Letowski and J. Niemiec[93]: The argument of Messrs. Johnson and Leja, that there are no two substances with alternately reversed acid-basic characteristics, which has been presented in the response to our contribution, is of rather a vague character and seems to be hardly acceptable from our point of view. The point of the matter is that the mathematical equations, called also by us, in abbreviation, equilibria [17] and [15], are, in fact, the two peculiar cases (expressions) describing the same equilibrium between Cu_2O and $Cu(NH_3)_2^+$ at definitely different *p*H conditions.

The general Cu_2O-$Cu(NH_3)_2^+$ equilibrium equation has been derived on the basis of the following data: $\mu^o_{Cu(NH_3)_2^+} = -15{,}510$ cal, $\mu^o_{Cu_2O} = -34{,}980$ cal, $\mu^o_{H_2O} = -56{,}690$ cal, and $K_{NH_3} = 10^{9.22}$, and its mathematical form is as follows

$$pH = -8.43 - \log [Cu(NH_3)_2^+] + 2 \log ([NH_4^+] + [NH_3]) - 2 \log (10^{-9.22} + 10^{-pH}) \quad [1]$$

This has been deduced by using the relationships

$$[NH_4^+] = \frac{[H^+] \cdot C_A}{K_{NH_3} + [H^+]} \text{ and } [NH_3] = \frac{K_{NH_3} \cdot C_A}{K_{NH_3} + [H^+]} \quad [2]$$

where C_A is the total, "analytical" ammonia contents in solution, amounting to the sum

$$C_A = ([NH_4^+] + [NH_3])$$

The general Cu_2O-$Cu(NH_3)_2^+$ equilibrium equation under discussion undergoes simplification to become transformed into Eq. [17], if $pH >> 9.22$. Then $[NH_3] >> [NH_4^+]$ and some simplifications can be made

$$\log ([NH_4^+] + [NH_3]) \approx \log [NH_3],$$
$$\log (10^{-9.22} + 10^{-pH}) \approx \log 10^{-9.22} = -9.22$$
$$\text{and } pH = 10.01 - \log [Cu(NH_3)_2^+] + 2 \log [NH_3] \quad [17]$$

Equation [17], which is a simplified expression of the general equation given above in the case when $[NH_3] >> [NH_4^+]$, loses its practical sense and does not represent the Cu_2O-$Cu(NH_3)_2^+$ equilibrium state when NH_3 and NH_4^+ concentrations become comparable or when $[NH_3] << [NH_4^+]$. In the latter case, the general equation assumes the form of Eq. [15] (according to Mattson) and is valid if $pH << 9.22$. Then

$$\log ([NH_4^+] + [NH_3]) \approx \log [NH_4^+]$$
$$\log (10^{-9.22} + 10^{-pH}) \approx \log 10^{-pH} = -pH, \text{ and}$$
$$pH = 8.43 + \log [Cu(NH_3)_2^+] - 2 \log [NH_4^+] \quad [15]$$

If, on the other hand, the concentrations (activities) of NH_3 and NH_4^+ are comparable, *i.e.*, at *p*H values close to 9.22, the equilibrium may not be described either by Eq. [17] or by [15]. In such a case, the general Cu_2O-$Cu(NH_3)_2^+$ equilibrium equation should be used which would take into account the sum of NH_3 and NH_4^+ concentrations.

H. E. Johnson and **J. Leja**: We wish to thank Messrs. Letowski and Niemiec for their discussion.
