Stress Corrosion in the Grids of the Lead-Acid Storage Battery

A. C. Simon

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

In the lead-acid storage battery, the antimonial-lead grids which support the lead-dioxide active material usually fail by corrosion which occurs in two stages. In the first stage the attack on the lead-antimony alloy was uniform and nonselective. The lead was converted to an adherent layer of PbO_2, and the antimony of the alloy disappeared from the corrosion product. After a certain thickness of this deposit was built up, the attack underwent a change. Corrosion proceeded at a faster rate in the areas of eutectic between individual primary lead dendrites and in particular at grain boundaries. In this second stage the antimony did not disappear from the corrosion product, and the dark material formed did not appear identical to the PbO_2 of the first stage. The examination gave evidence that the greater specific volume of the corrosion product in the second stage introduced sufficient stress to accelerate the attack at grain boundaries and eventually led to cracking. The change from first to second stage appeared to be the result of reduced acidity in the corrosion layer after a sufficient depth of corrosion product had formed.

The active material of the plates used in lead-acid storage batteries is pasted on a metallic grid which is usually a lead-antimony alloy. This grid supports the active material and conducts electricity, and in both functions it is vital to the proper performance of the battery. Corrosion of this grid through the action of the dilute sulfuric acid electrolyte and the electrolytic current during charge and discharge of the battery normally takes place uniformly over the entire metal surface and forms a protective layer of PbO_2. In such circumstances the grid material corrodes at such a slow rate that it might be expected to last for many years under normal conditions of operation. Unfortunately certain areas in the metal surface corrode at a much accelerated rate, so that the actual life of the grid is less than anticipated. When examined, the grid bars are usually found to be separated at numerous points, and as a consequence the pellets of active material are found to be loosened. Conductivity is lost between the active material and the grid as well as between various portions of the grid and the posts for external connection to the battery.

This accelerated corrosion at certain points has been variously attributed to impurity inclusions, casting defects, and design imperfections. In the absence of obvious impurity or casting defects the corrosion is most often attributed to stress. This stress is sometimes considered as developing from the rather heavy load of active material on the grid, which is after all of fairly low creep resistance, or from stresses set up in the corrosion layer itself. Less frequently the stress on the grid has been attributed to actual expansion in the active material. Stress from either the corrosion layer or the active material is a definite possibility as the products of corrosion can be expected to have a greater volume than the original alloy, and it can also be expected that the active material will undergo a considerable change in volume in the conversion from PbO_2 to $PbSO_4$ and the reverse.

The author was fortunate in obtaining from a battery manufacturer several samples of grids that illustrate stress-corrosion cracking and offer an opportunity to study it as it progresses.

The purpose here is to report only some rather unusual features of the microscopic examination of this cracking phenomenon in the lead-antimony alloy when used as a grid in the dilute sulfuric electrolyte. It thus appears unnecessary to refer to the extensive literature either of stress-corrosion cracking or of corrosion in the lead alloys.

Observations

The battery plates examined were all of the same type and had been used on an intermittent cycle type of operation for up to ten years. The samples were mounted for metallographic preparation in such a way that the prepared section would extend across the grid and active material and would be parallel to the plate surface. This gave maximum probability of sectioning the cracks that were known to be present from previously obtained radiographs.

Upon microscopic examination the grids of the ten-year-old batteries were found to contain numerous cracks that extended entirely through the grid member. Although these cracks could be found at practically any location along the grid member, the majority were near the points where vertical and horizontal members intersected. Examination of a number of these cracks established that the cracks were following grain boundaries in almost every case.

A few exceptions were found near the center of a section where a single grain not favorably located for extension of an existing intergranular crack had been fractured. In these rare cases, however, this transverse crack was plainly the result of existing and extensive grain boundary corrosion which extended up to each side of the grain in question.

Examples of the type of intergranular corrosion and cracking which was found are shown in Fig. 1. There was no set pattern to this corrosion mechanism. In one case a corroded grain boundary might extend entirely across the section without a visible crack appearing, as in Fig. 1A. In other cases the outer portions of the interconnecting grain boundaries might show a crack at one or both sides of the section while the remaining side or center of the grid had either not yet corroded or had corroded without visible separation. An example of this is shown in Fig. 1B, where the outer portions of the continuous grain boundary have opened into a visible crack while the center portion, around the misaligned grain, has not yet separated although it has suffered intergranular

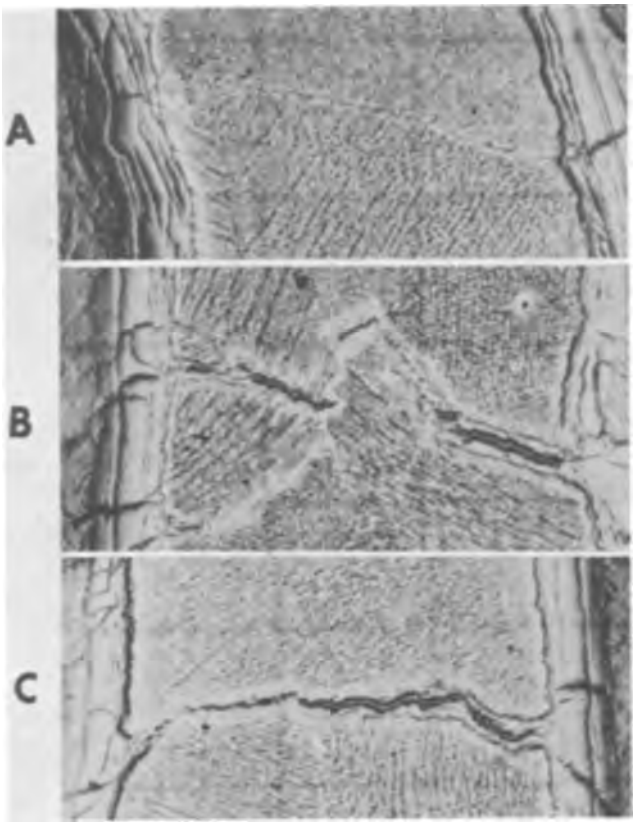

Fig. 1. Examples of the destructive intergranular corrosion that caused failure of the grids: (A) corroded but not yet showing cracking, (B) corroded and cracked but not yet completely separated, and (C) total failure. The side of one square in the dimensional grid measures 528μ. Original magnification 45X.

corrosion. It is believed that the ultimate fate of all examples of intergranular corrosion would be that of complete separation as shown in Fig. 1C.

It should also be remarked at this point that observation of a single cross section at the site of a cracked or corroded boundary leaves much to be inferred. The visible imperfection which so clearly proceeds along the grain boundary in the plane of the photograph or section must also extend above and below this plane. In other planes the grain boundary corrosion or actual cracking may be more or less extensive than in the plane which is visible. Yet the conditions that exist in these other planes or sections will influence the appearance of the visible section and may produce anomalies in the visible section for which there is no apparent reason. Despite this fact it is believed that a sufficient number of sections have been examined to arrive at an approximation of the mechanics of the process.

If this corrosion is stress induced, it is necessary to determine whether this stress is attributable to the active material. The approximately 51% increase in specific volume as PbO_2 is converted to $PbSO_4$ is certainly capable of creating stress in the grid, provided the active material is not free to relieve this stress in other directions. Such stress could be produced either continuously by a slow accumulation of unreactive $PbSO_4$ over an extended period of charge-discharge cycling or intermittently by a repeated conversion of the reactive PbO_2 to reactive $PbSO_4$ on each discharge cycle.

Several factors seemed to indicate that the stress was being exerted by the active material. The active material itself was unusually hard, cohesive, and well retained in the grid even after periods of use of up to 10 years. Examination of this active material from plates supposedly in the fully charged condition showed the presence of a large amount of sulfate.

Since the corrosion product on the grid bars builds up slowly over the period of use and because this product is hard and brittle, one would suppose that any stress that was sufficient to cause intergranular corrosion and actual cracking at the grain boundary would first cause the brittle corrosion product to crack. Moreover, since the corrosion product appears to undergo no visible change between charge and discharge, such a crack would remain visible with no means of repairing itself. For this reason a very careful examination was made of the corrosion product in the vicinity of any visible intergranular corrosion or where there were cases of actual cracking.

It was found that in the majority of cases where intergranular corrosion was just beginning or had not proceeded to a depth exceeding the diameter of the average grain there were no cracks through the corrosion product in a direction perpendicular to the metal surface. In the few cases where cracks did occur under these conditions they did not extend entirely through the corrosion product.

The corrosion product was found to be cracked only in directions either essentially parallel to or perpendicular to the metal surface. Cracks paralleling the metal surface divided the corrosion product into distinct layers. Any cracks that were directed perpendicular to the metal surface at the point where intergranular corrosion had begun had usually only penetrated the inner layer of corrosion product that was next to the metal-corrosion product interface. No perpendicularly directed cracks in other layers were found to lie close enough to be caused by or to influence the spot where intergranular corrosion was beginning. Although all of the outer layers showed cracks perpendicular to the metal-corrosion product interface, these cracks were not aligned with one another in adjacent layers and appeared to have no relation to metal structure defects. They were judged to be the result of internal stresses within the corrosion product itself. Thus there was nothing seen in the case of the slight or moderate intergranular corrosion that would indicate that such corrosion was being initiated by stresses set up in the active material.

In the case of severe intergranular corrosion extending through or nearly through the entire grid member or where actual cracking had occurred at grain boundaries there were still cases where no cracks occurred perpendicular to the surface, but this was the exception. Such cracks in the grid metal were more often accompanied by cracks in the adjacent corrosion product. These cracks in the corrosion product were studied carefully, and it was determined that in the majority of cases cracking did not extend to the outer surface of the corrosion product and also that the end of the crack farthest from the metal surface narrowed out of existence. It is evident that a crack would be wider at its outermost portion if the stress was being applied by the pellets of active material. In those few cases where the cracks did extend through the corrosion product they also extended for a considerable distance into the active material itself, and again the crack narrowed at the end in the active material.

An examination of the contact surface between corrosion product and active material also revealed that there was an actual space between the two in many areas. This would not be expected if the active material was actually applying stress to the grid.

It was therefore decided that the active material had not exerted stress on the grid despite its unusual hardness and undoubted large volume changes.

The next most likely source of stress was in the corrosion product itself. As will be brought out in the subsequent discussion the volume increase that occurs in the conversion of Pb to PbO_2 will vary depending on the amount of antimony in the alloy, but a theoretical maximum of about 20% increase in specific volume is a possibility. A cohesive corrosion product,

firmly attached to the metal surface, might produce a considerable sustained stress.

Continued microscopic examination of the corrosion product revealed first of all that only a small portion of the total thickness of corrosion product would be effective in the promotion of stress. As was previously mentioned cracks parallel to the metal surface divided the total thickness of corrosion product into a number of layers. There were both major and minor cracks. The major cracks were fairly equally spaced and one may imagine that they represent major stress relief as a definite thickness of corrosion product is exceeded. The minor cracks had less definite spacing between them and extended for shorter distances so that they did not divide the material into definite layers. The minor cracks appeared to become more numerous near the metal surface and as the depth of corrosion product increased. These minor cracks extend to within 10μ or less of the metal surface so that the corrosion product was not truly adherent at a greater distance. It thus became obvious that any stress produced by the surface corrosion product would not be increased as the thicknes of corrosion product increased. Only that portion of the corrosion product within about 10μ of the metal surface would be effective in creating stress. As new corrosion took place at the interior of this thin layer, that portion exceeding the 10μ thickness would shed off and thus would no longer be a contributor to the stress of the metal.

There was another factor involved, however, which undoubtedly did contribute to stress. In addition, and unlike the surface corrosion described above which applied a fairly constant stress, this condition became steadily worse as the service life of the battery was extended.

The lead-antimony alloy under consideration and indeed most alloy compositions used in battery grid construction are of a very nonuniform nature. In such material the primary dendrites form first during the freezing process and constitute the skeletons of the individual grains. These primary lead dendrites, which contain only small amounts of antimony in solid solution, usually form an intricate branched structure within which the nearly eutectic proportions of lead and antimony subsequently freeze. This nearly eutectic mixture is itself made up of actual particles of precipitated antimony in a matrix of lead.

Despite this decided lack of homogeneity it was noted that corrosion begins as a remarkably uniform process with no tendency to attack preferentially either grain boundaries or other points of nonuniformity. After a time which may perhaps either depend on length of service or thickness of corrosion product there is a definite shift to a very preferential type of attack. At this time the attack becomes most pronounced at grain boundaries, slightly less pronounced in the interdendritic spaces containing the eutectic type of material and least in those areas occupied by the primary dendritic branches. In addition, where previously the antimony particles were attacked and dissolved from the corrosion product right down to its boundary with the metal, now it is found that the preferentially attacked areas contain all the original segregated and precipitated antimony in unchanged form. In other words attack and dissolution of antimony has apparently ceased, although those areas containing the most antimony are being preferentially attacked.

The black PbO_2 that forms in these areas of most pronounced attack does not appear as dark as that formed at the earlier stage of corrosion when both were viewed by polarized light. When viewed by vertical illumination the hardness and reflectivity of this area of preferential attack was different when compared with the earlier corrosion. (Hardness was judged by the relative elevations of various regions, as the samples had been intentionally relief polished.)

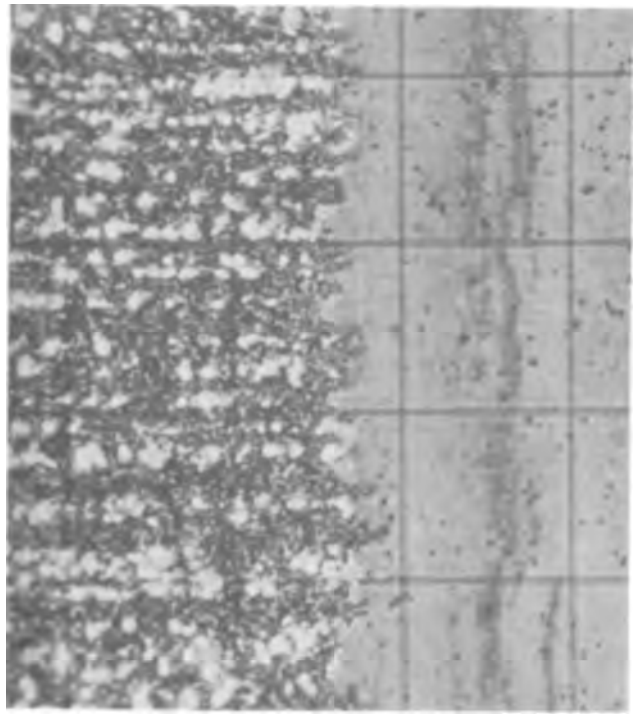

Fig. 2. Pattern of corrosion after 1½ years service. Note that the corrosion-metal interface is fairly smooth and that no antimony appears in the corrosion product; 2μ squares. Original magnification 800X.

As said previously the preferential attack occurred both at grain boundaries and in the spaces between individual arms of the primary dendrite that made up individual grains. This attack on the interdendritic spaces of individual crystals appeared to be at its worst when these spaces between dendritic arms were aligned perpendicular to the surface, but in any case the attack at the grain boundary was always more severe than elsewhere. Once this preferential type of attack began on the grain boundary it became progressively more severe until it had penetrated far beyond the interdendritic penetration. The deeper this attack penetrated into the grain boundary and the further that it proceeded from the surface the greater became the tendency for an interdendritic attack originating from the grain boundary to branch out into the two adjacent grains. This meant that the further the corrosion penetrated into the metal along a grain boundary the greater became the volume of PbO_2 liberated in and adjacent to the boundary and consequently the greater the internal stress that acted as a wedge to force the grain boundary open.

The appearance of the corrosion product after 1½ years of service is shown in Fig. 2. The right-hand part of the photograph shows the corrosion product. To the left is pictured the alloy. The darkly motled bands represent primary lead dendrites and the strings of brightly reflective particles represent antimony in the eutectic areas between primary dendrites. It will be seen that while the interface between metal and corrosion product is not a straight line the variation in rate for the various portions of this grain are slight, so that for all practical purposes the attack may still be considered to be uniform. While not visible in the photograph the same was true at grain boundaries and from one grain to another. It will also be noted that nowhere in the corrosion product are any of the small bright particles of antimony to be found, these having dissolved as the PbO_2 was formed.

Figure 3 shows the condition of the corrosion-metal interface after 7 years of service. This grain is similarly oriented to that shown previously so that the dendritic arms of the primary crystal are perpendicular to the interface. Under these conditions the most

Fig. 3. Same grain structure and orientation as shown in Fig. 2, but here is shown the type of interdendritic attack that was found after 7 years of service. It will be noted that the corrosion-metal interface is no longer smooth and that the particles of antimony originally in the metal now appear in that portion of the corrosion that extends into the metal. Note that no similar material appears in the surface layer of corrosion that does not extend into the metal and appears in right hand portion of the photograph; 28μ squares. Original magnification 800X.

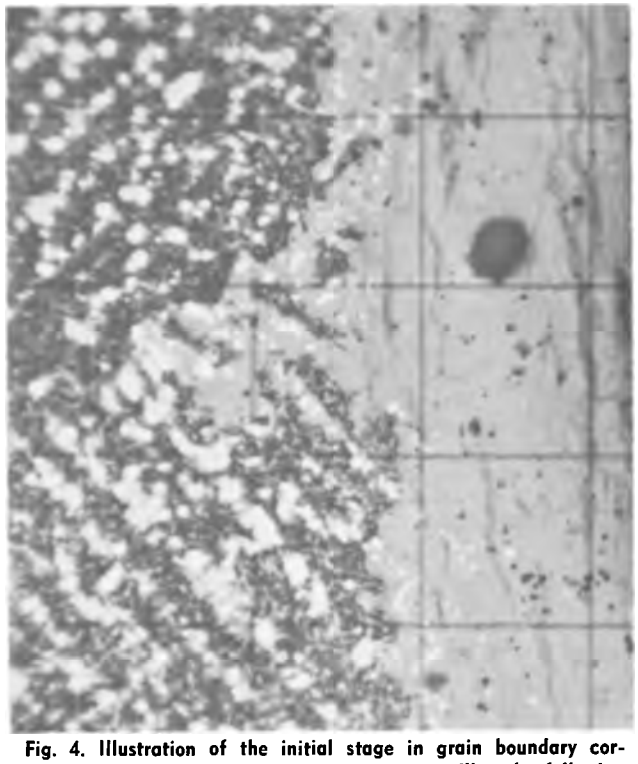

Fig. 4. Illustration of the initial stage in grain boundary corrosion. Note that the actual corrosion appears still to be following interdendritic as well as grain boundaries and that process occurs too extensively to suggest that a microcrack may be responsible; 28μ squares. Original magnification 800X.

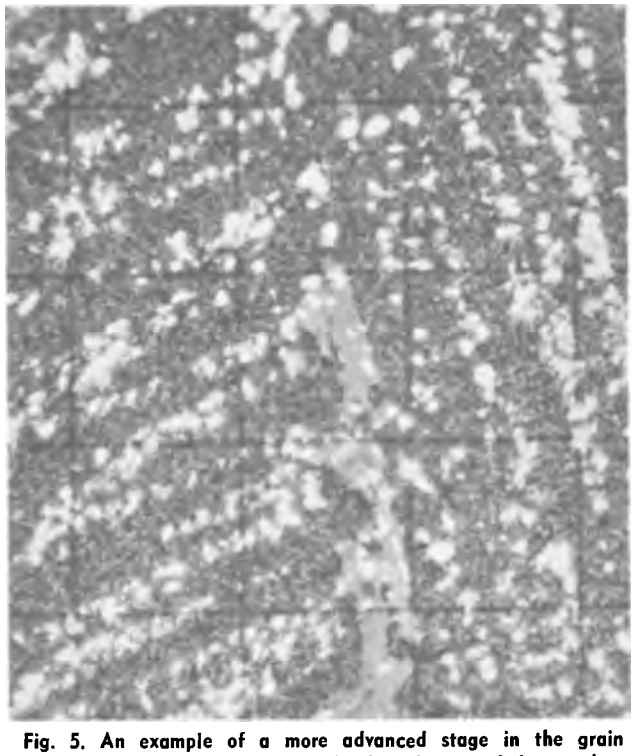

Fig. 5. An example of a more advanced stage in the grain boundary corrosion. Note particularly that the corroded area does not appear to widen with increasing depth and that no actual crack in the metal appears ahead of the corroded portion. Again note the presence of antimony particles in the corroded area; 28μ squares. Original magnification 800X.

severe attack on individual grains occurs. It can be seen that in this case the attack has become very preferential. This can be noted in the center vertical row of squares across which the corrosion product extends. It will be noted that this attack appears to be confined only to the antimony-rich areas (areas containing the bright antimony particles). The lead-rich areas (areas containing dark, mottled material with no bright particles) are much less severely attacked. It will also be noted that in the areas of preferential attack the antimony particles have not been dissolved out. In the actual viewing it was also evident that the reflectivity of the corrosion product in the areas of preferential attack was different from that of the continuous layer of corrosion product that covers the surface and is seen in the right vertical line of squares. Finally the numerous small cracks should be noted that appear in the corrosion product almost up to its interface with the metal.

Figure 4 shows the intersection of a grain boundary with the corrosion interface. The boundary between these two grains in the metal extends to the left through the center horizontal row of squares, and along this boundary corrosion has occurred. It will be noted that in this area and at the interface between metal and corrosion product metallic particles of antimony appear. It will also be seen that the corrosion is not so selective at the grain boundary as to appear to be following a crack nor does any crack appear in the corrosion product.

This can still be considered to be true when the penetration along the grain boundary has proceeded to a considerably greater depth as shown in Fig. 5. This figure also clearly shows the terminus of the corrosion and it will be noted that there is nothing to indicate a crack or defect in the metal ahead of the corrosion. Even the presence of a grain boundary cannot be readily seen, but its presence can be deduced from the different orientations of the primary dendrites to either side of the corroded layer. This becomes a great deal more evident at somewhat lower magnification. It will also be noted in this and other photographs of the series that the random positions of

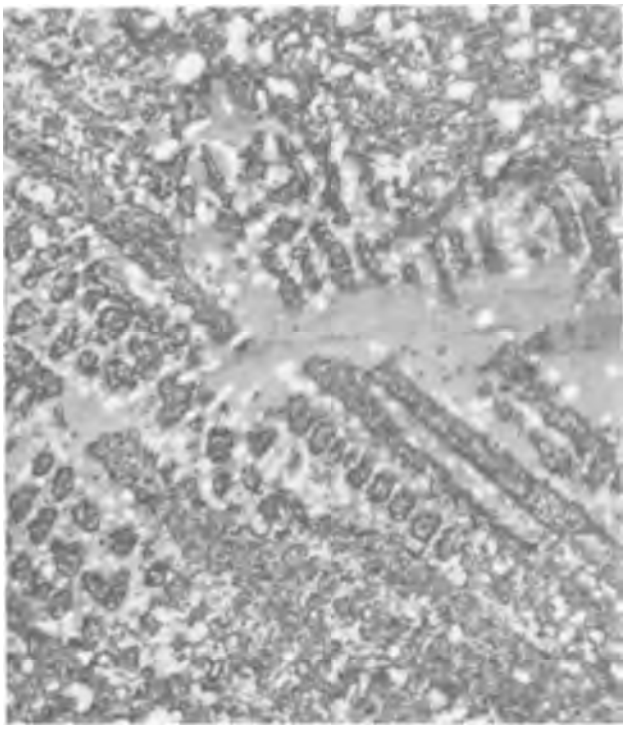

Fig. 6. Illustration of the very intensive interdendritic attack that proceeds outward from each side of the intergranular corrosion when a considerable depth within the metal has been reached. This might be considered as a third stage in the process illustrated by Fig. 4 and 5 and that stage during which actual cracking may occur. Original magnification 800X.

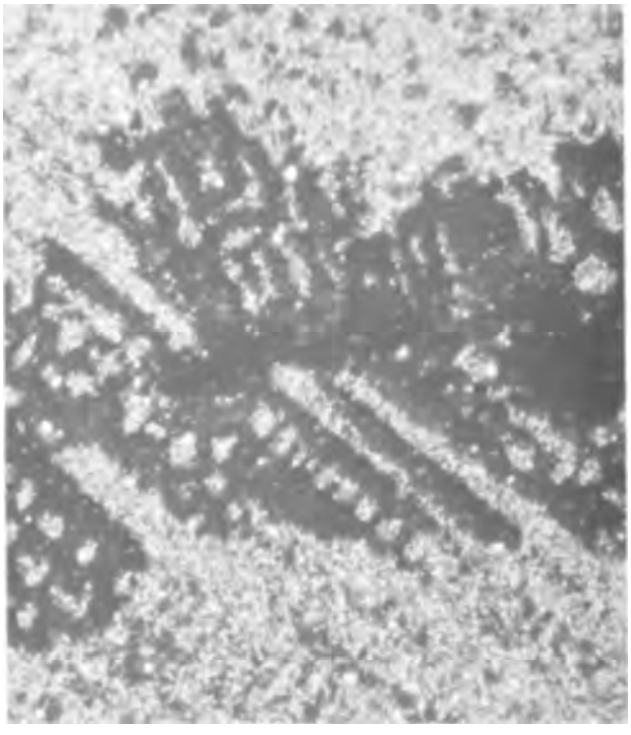

Fig. 7. Some area and magnification as used in Fig. 6 but here illuminated by polarized light to emphasize the extent of the corrosion. The corrosion product is the black area.

the antimony particles throughout the corroded area would also indicate that there was no actual break present during or before corrosion.

As the corrosion proceeds deeper into the grain boundary there is begun a decided preferential corrosion into each adjacent grain provided the orientation of these is suitable. This is shown in Fig. 6 where it can be seen that a very preferential and deep attack has been made into the antimony rich areas at each side of the grain boundary. Again is to be noticed the absence of anything resembling a crack and the antimony particles scattered throughout the corroded area. One does not appreciate the true extent of this corrosion until the same area is seen in polarized light (Fig. 7). While this photograph does not show as much detail as Fig. 6 it serves to illustrate clearly the extent to which corrosion has spread into adjacent grains from the corroded grain boundary and the interdendritic nature of this attack. When compared with Fig. 6 it also serves to identify those areas which represent corrosion. Corroded areas appear black in Fig. 7, a uniform gray in Fig. 6.

Discussion

In a previous report (1) the microstructure and intergranular corrosion of these plates was discussed in greater detail, and additional illustrations representing this phenomenon were presented. Some of the material was reexamined, and the considerably modified present paper is the result.

The mechanism of corrosion for pure lead and for the lead-antimony alloy is different in some physical aspects. Under the conditions existing in the lead-acid storage battery the lead grid becomes covered with a coating of lead dioxide which is formed from the metal. This is usually considered to be a dense and protective covering for the underlying metal, and in the absence of more than trace impurities this is probably true. In the lead-antimony alloy the as-cast surface does not form a continuous homogeneous layer but contains numerous impurities which consist of small particles of antimony and also contains antimony atoms in a solid solution.

It can be demonstrated that the antimony particles are removed from this surface by anodic corrosion even before the lead begins its conversion to lead dioxide. This will naturally result in voids in the protective layer. Since corrosion-product cross sections of considerable thickness reveal no antimony as a solid material and since antimony continues to deposit at the negative plate, it can be assumed that this removal of antimony continues for a considerable time as the lead dioxide builds up from the lead of the alloy.

The most immediate effect of this antimony removal is a reduced volume in the conversion from lead to PbO_2. When antimony is alloyed with lead the resultant alloy will have a specific volume greater than that of lead. As the amount of antimony in the alloy is increased, the specific volume will also increase.

While the corrosion product from pure lead will have a specific volume approximately 20% greater than the lead from which it was formed, that from the lead-antimony alloy will be less than this amount.

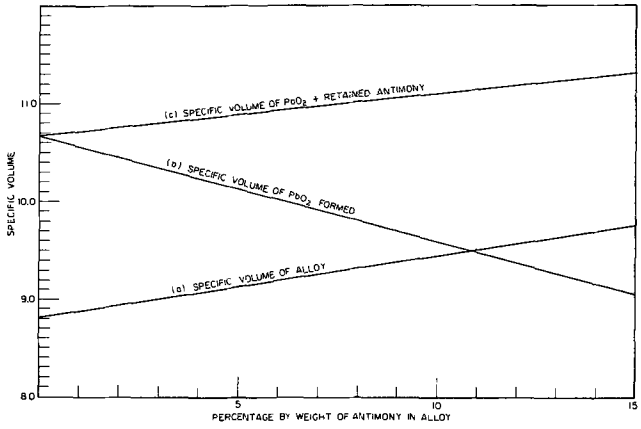

Fig. 8. Illustration of the manner in which specific volume of the alloy and of its corrosion product vary with change in the antimony content of the alloy.

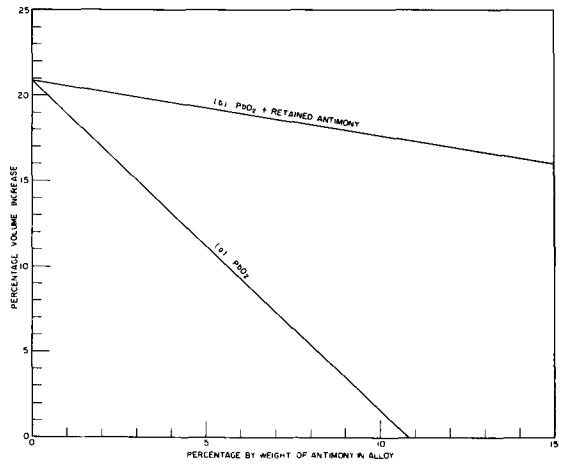

Fig. 9. Relationship between the antimony content of the alloy and the percentage volume increase as the alloy corrodes and is converted to lead dioxide. It will be noted that the volume decreases with increase of antimony in the alloy.

For, if the specific volume of the antimony is not added to that of the corrosion product, the latter will depend entirely on the lead portion of the alloy. As the amount of antimony in the alloy is increased and continues to be removed in the corrosion process, the specific volume of the corrosion product should decrease. A point is then reached where the specific volume of the alloy is greater than that of the corrosion product. This is graphically shown in curves (a) and (b) of Fig. 8. Curve (a) shows the increase in specific volume of the alloy with increase in amount of antimony and curve (b) shows the decrease in specific volume for the corrosion product formed from such alloys when the antimony is removed from consideration.

As has already been seen, a point is reached in the corrosion process when the antimony is no longer removed from the corrosion but remains behind to add to its bulk. In this case the specific volume of the antimony must be added to that of the lead dioxide; the specific volume of the corrosion product does not decrease with increasing antimony content in the alloy, but instead increases at almost the same rate as does the specific volume of the alloy (Fig. 8). This is shown by curve (c). The actual conditions can be expressed perhaps a little more clearly by plotting per cent of antimony in the alloy against the actual percentage volume increase in each case (Fig. 9).

In Fig. 9 curve (a) illustrates the percentage specific volume decrease as the antimony content is increased toward 11%, at which point there is no volume change. This is true provided the type of corrosion process that is taking place removes antimony from the corrosion product. Curve (b) shows the much slower decrease in specific volume that occurs with increasing amounts of antimony in the alloy provided the corrosion process does not remove the antimony from the corrosion product.

It is a well-known fact that lead grids shed corrosion product at an alarming rate whereas lead-antimony alloys retain their products of corrosion much better. It is probable that the entire difference may lie in the above discussed volume changes and not in alloy structure characteristics as some have supposed.

Lead-calcium alloys, unlike pure lead, do not shed corrosion product at such high rates when used as battery grids, and this fact might dispute the above conclusion. Microscopic examination has shown, however, that the entire corrosion process in lead-calcium alloys differs from that discussed here and in particular that the corrosion product appears to be softer and less cohesive than that obtained from lead or its alloys with antimony. Unlike the latter, lead-calcium alloys form a corrosion product that disintegrates and blends with the surrounding active material only a short distance from the metal surface. So definite is this tendency that the true extent of the corrosion layer is impossible to determine. A material so lacking in internal cohesion is able to adjust to large volume changes without visible spalling more easily than is the more brittle and cohesive pure lead corrosion product.

The stress that acts to remove the corrosion product is developed within it and is relieved in two ways. A study of this shedding process revealed that as the volume of corrosion product is increased around the periphery of a grid member, the stress increases in a circumferential direction and is relieved by a breaking away and increase in diameter of a stressed portion. This repeated process results in a series of corrosion layers that appear to be parallel to the metal surface when viewed in a plane section and as concentric layers when viewed in cross section.

At the same time that stress is developing around the periphery of the grid member a similar stress is developing along its length. This cannot be relieved as simply as the circumferential stress, even after breakaway has occurred, because portions of this corrosion product are prevented from longitudinal expansion by the configuration of the grid which is such that a blockage is provided by every grid bar crossing. The result of this restriction is that longitudinal cracks occur and the resultant long strips take a pronounced bow away from the surface to relieve their internal stress. It is unlikely that any great portion of this type of stress is transferred to the grid metal.

The net result of these processes on micrography is that the grid cross section is seen surrounded with a series of concentric layers of corrosion product with each layer containing a number of transverse cracks. When viewing a section cut parallel to the surface a series of nearly parallel layers of corrosion product are seen, but the spacing between two adjacent layers is at a maximum midway between crossing grid bars and is at a minimum near such intersections. As the amount of antimony in the alloy is increased the number of layers decreases and the spacing between adjacent layers also decreases.

Definite series of alloys with up to 11% antimony and various types of operation should be prepared to support this observation, which is based on random sampling of plates with various amounts of antimony and similar but uncontrolled periods of service.

It can be seen from Fig. 9 that even 5% of antimony in an alloy will reduce the specific volume increase by half with a corresponding improvement in the retention of corrosion product and reduced cracking. However the presence of 5% antimony offers hardly any reduction in specific volume when the second stage of corrosion begins and antimony remains in the corrosion product. In this case the volume increase is almost as great as that for pure lead, and the stress developed will be similar. Since a major portion of this stress is developed in the grain boundary, failure is inevitable.

The above may serve to explain the destructive stress developed in the second stage, but it does not explain why this transition in the mechanism of corrosion should take place. It would appear that the corrosion product is initially and for a time sufficiently porous to allow adequate acid penetration for maintaining the original type of corrosion. In this original type of corrosion attack either was not preferential or occurred at such a rate that preferential characteristics were masked. Despite the development of cracks both circumferentially and longitudinally a sufficient thickness of deposit must eventually form to prevent adequate acid being present to maintain the original process. If this is indeed the reason, then once the second stage is initiated it should be self-perpetuating because of its preferential nature and the confined conditions under which it occurs.

The initial penetration at the grain boundary is not believed to be caused by stress on the grid. The weakness at the grain boundary is believed to be caused by microporosity developed during solidification of the alloy.

When primary crystallization of an alloy is completed, a portion of the available metal has already solidified. In the case of the lead-antimony series the amount will depend on the quantity of antimony in the alloy. In the case under discussion it is evident from the well-developed primary branching in each grain and the relatively large amount of primary as compared with eutectic that a major portion of this alloy had solidified during primary crystallization and that a relatively small amount of eutectic melt remained in the channels between the primary dendrites.

Microscopic study of the freezing process in this alloy system during solidification reveals that solidification is arrested when formation of the primary crystals of lead is completed and does not proceed until eutectic crystallization is started by the appearance of antimony crystals. In addition the eutectic freezing does not take place in these alloys as a simultaneous shower of crystals. Instead one or more nuclei are formed within the grain, and the crystallization of the eutectic proceeds from these points by a tortuous route along the various channels left between dendritic branches of the grain. This process also proceeds with relative slowness and can be visually followed.

Eutectic nucleation occurs at more than one place in the grain, and from these points it spreads throughout the remaining channels of the grain. This final freezing causes a reduction in volume, and it is unlikely that sufficient liquid either remains or could reach these areas to fill all voids. As a consequence microporosity in these eutectic areas undoubtedly occurs. Since the nucleation of the eutectic appears to occur within the grain, an even greater porosity must result at the grain boundary from which liquid metal is withdrawn to feed the areas where freezing is occurring.

There is evidence other than the present corrosion to indicate that the grain boundary in these alloys may be microporous. When castings of these alloys were made very thin, on the order of 5 mils (0.127 mm) in thickness, the individual grains could be seen distinctly, as could the primary dendritic structure and the grain boundaries. This sharp demarcation was caused by the pronounced shrinkage of the eutectic portion of the material.

It was discovered that with very careful teasing the film could be separated into individual grains with easy and distinct separation taking place along the grain boundaries. These individual grains were then mounted so that the formerly mating surfaces could be examined; it was found that these showed no evidence of tearing or fracturing. Although there was no evidence of any actual welding at the grain boundary, the foil gave every evidence of being completely normal before separation and could be handled and bent in a normal manner. Microscopic examination of the boundary before separation showed the usual grain boundary structure. The appearance of the grain boundary after separation appeared similar to that seen in the casting defect known as a cold shut.

Burbank (2) has described a process for converting a thin metal film into a chemical replica for the purpose of microscopic examination by transmitted light. The thin cast films described above were converted to a translucent chemical replica by the use of an acetic acid-hydrogen peroxide solution. When examined under the microscope by transmitted light these replicas were found to reproduce the structure of the metal faithfully as seen by metallographic preparation of metal sections but in considerable more detail. These films were reasonably coherent and stable throughout the grain and showed no tendency to be weaker at the junction between primary and secondary structure. However at the grain boundaries there was definite weakness, and as before the film could be easily separated into areas corresponding to the original metal grains (Fig. 10). In addition examination of these grain boundaries at high magnification and with transmitted light produced no evidence that a crack existed before separation.

Fig. 10. Chemical replica of a portion of very thin Pb-Sb alloy cast foil containing 1% Sb illuminated by transmitted light. The dark dots in parallel rows represent segregated antimony concentrated at intersections of primary lead dendritic branches of the crystals. The boundary between the large lower grain and the small grain at center is intact, but separation has occurred cleanly along most of the boundary between lower and upper grain and between upper and center grain. Original magnification 50X.

It is therefore concluded that these boundaries were not in any way welded or soldered together in the freezing process but were merely in very intimate contact and were being held together by atomic forces similar to those which hold a plated coating to the base metal.

Although the conditions encountered at the boundary of a very thin cast grain may not duplicate the conditions at the boundary of a metal in bulk, and

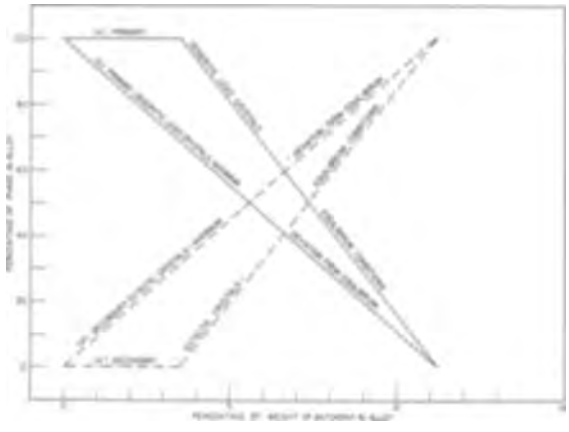

Fig. 11. Illustration of the relative amounts of primary crystallization (in the form of lead-rich dendritic crystals) and of eutectic crystallization present at the final solidification for alloys with various antimony contents.

although eventual diffusion, recrystallization, and resultant grain boundary migration eventually alter this condition, it still seems reasonable to expect considerable microporosity at the grain boundary.

It must be emphasized, however, that the extent of this microporosity and its distribution will change with change in antimony content in the alloy. The effect of changing the alloy composition of the lead-antimony alloys and the manner such changes influence the relative amounts of primary dendritic and secondary eutectic crystallization have been discussed elsewhere (3). It will suffice here to refer to Fig. 11 which shows the relative percentage of the two types of crystallization as the amount of antimony in the alloy is increased. Curves (a) and (a') represent the relative portions when freezing takes place under equilibrium conditions, while curves (b) and (b') show the greatest possible variation that could occur. All actual castings are represented somewhere between these two extremes. It will be realized that when the greater portion of the material freezes as primary dendrites, the remainder and still liquid portion may be confined in narrow passages between primary dendritic arms and as a thin film at the grain boundaries. Under these conditions the freezing of the final eutectic portion will take place with decided porosity at intergranular portions. When the major portion of the material remains liquid after the freezing out of the primary dendrites, the individual and much less complexly grown crystals of primary are separated from one another by large masses of still liquid material and indeed may be floating freely in the latter when final solidification takes place. In such a case final eutectic crystallization probably produces much less microporosity.

Since both volume change in the corrosion product and amount of microporosity in the alloy are reduced as the amount of antimony in the alloy is increased, there may be here the explanation for the lack of success in the numerous attempts to reduce the amount of antimony below that currently used in the industry.

In the process of corrosion that has been described grain boundary corrosion took place without visible cracks being present either in the metal or the original surface corrosion layer. This indicates a fundamental grain boundary weakness rather than corrosion initiated by external strain.

If microporosity is accepted, then its presence may also help to explain another puzzling feature, namely, the change from a uniform to selective mode of attack. With the freezing conditions present at the mold face it is unlikely that microporosity would extend entirely to the surface; the surface would almost certainly be sound. While there are unquestionably other differences in the mode of attack after a definite thickness of corrosion product has been formed, the selective characteristic of this attack might be attributable to penetration beyond the sound surface layer and its encounter with a porous remainder.

The type of corrosion described here is probably much more common than is generally realized. The vast majority of batteries used in such applications as starting, lighting, and ignition, simply do not survive other difficulties long enough for this type of corrosion to become the major problem. It is inherently a problem of the heavier grids used for industrial purposes, and it is suspected that examination of those in long use would reveal many cases of this type of attack.

High Rate Battery Electrodes

Clarence M. Shepherd and Harry C. Langelan

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

It has been shown previously that metal plates of controlled porosities and high surface areas can be produced by the electrolytic reduction of metal compounds subjected to controlled physical pressure during electrolysis. When these plates are discharged as anodes in test batteries their capacities and ampere hour efficiencies are found to increase rapidly as the porosity increases. At porosities of 85-90%, high efficiencies were obtained for extremely high discharge rates over a range of temperatures extending down as low as —60°C. Similar results were obtained with high porosity cathodic active materials. The active materials thus tested included zinc, cadmium lead Ag_2O, and AgO, all of which were highly successful, thus indicating that the technique can be applied to a wide range of batteries and active materials.

Theoretically, there are a very large number of substances that can be used as the active material in battery anodes or cathodes. From a practical viewpoint, this use is not feasible with a majority of these materials since they polarize heavily and can operate only at very low current densities. Since polarization is a monotonic increasing function of the current density, all materials have some limit to the current density at which they may be discharged practically and beyond which limit the drop in the value of the potential is too large to be acceptable for practical purposes. Any physical factor that increases the surface area of the active material decreases the polarization by decreasing the current density expressed in terms of discharge current per unit of surface area and thus makes it feasible for the material to be discharged at much higher rates.

Shepherd and Langelan (1) have shown that metal plates of controlled porosities can be produced by the electrolytic reduction of metal compounds which are subjected to controlled physical pressure during the electrolysis. The porosity of the metal plate is a function of the pressure applied during formation and is also dependent on the particular compound or mixture of compounds being reduced. A wide range of porosities was obtained in this manner from metals of the normal electronegative group such as silver, bismuth, tin, lead, antimony, zinc, cadmium, copper, and mixtures of these including mercury (1). The porosity, P, which is often expressed as a per cent, is defined as that fraction of the total volume of the material that is occupied by pores or void spaces.

Since the surface area of a metal plate increases with increase in porosity, a number of zinc electrodes of various porosities were prepared from ZnO and discharged in a AgO-Zn-KOH cell, in an effort to determine the effect of porosity on cell capacity (1). The results are shown in Fig. 1 where the ampere hour efficiency and the capacity in minutes are plotted as a function of the porosity. The efficiency increases

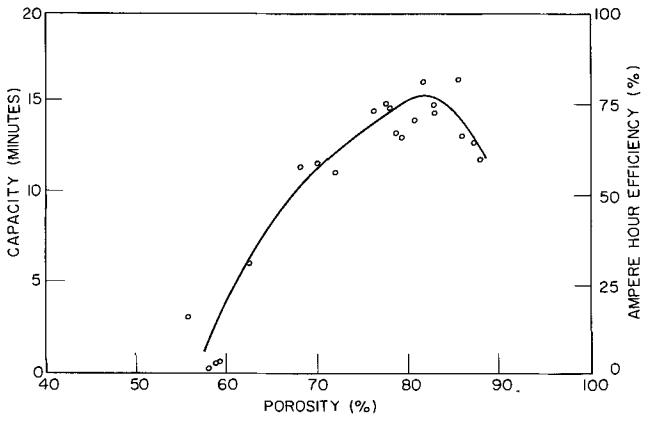

Fig. 1. Effect of zinc electrode porosity on capacity and efficiency, 20°C, 40% KOH, 730 ma/cm².

from close to 0% at 58% porosity up to a maximum of slightly over 75% at 82% porosity. As the porosity is increased beyond this peak value, the metal structure becomes flimsier and anodic dissolution causes high resistance paths and crumbling of the metal. As a result, the capacity and efficiency then decrease as the porosity increases.

On the basis of this information it was felt that an electrode of high porosity could be constructed which could be discharged at much higher rates and still have high ampere hour efficiencies for discharge times considerably less than the 15 min shown in Fig. 1. The information presented here is the result of an exploratory investigation designed to determine if such high rate electrodes could be prepared from zinc and also from other active materials; to determine if porosity was a major factor affecting the capacity of such electrodes; and to determine some of the major factors affecting the design, formation, and operation of high rate electrodes, thus opening the door to future investigations of a more highly detailed and quantitative nature.

High Rate Anodes

A cell or battery consists of components such as an anode, cathode, electrolyte, separators, grids, connectors, etc., all of which must be designed, assembled, and tested under appropriate conditions before the cell can be feasible for consideration in commercial competition with other power sources. The test results shown here are not meant to imply that a commercial cell is now available. However, as soon as a high rate anode and cathode have been tested in a common electrolyte as shown here and found to have suitable characteristics, the major obstacle standing in the path of constructing a high rate cell or battery has been eliminated.

The porous metal anode was suspended in a test cell between cathodes containing an excess of moderately high rate AgO as the active material. Under these conditions the metal anodes were always found to fail first. The effective spacing was 0.075 cm which was large enough to prevent any physical contact between the electrodes and thus eliminated the need for a separator. The presence of a separator tends to decrease the cell potential and also the capacity to a widely varying degree that depends on the physical properties of the separator and the discharge conditions for the cell. Thus, the data taken in the above manner represent an optimum as far as separators are concerned and present a standard against which the use of various separators can be tested in a specific, commercial cell.

A number of porous zinc electrodes of various porosities were formed by the electrolytic reduction of pasted ZnO, $ZnCO_3$, or mixtures of ZnO and $ZnCO_3$ under controlled physical pressures in 15% KOH electrolyte (1). Porosities as high as 92% were obtained

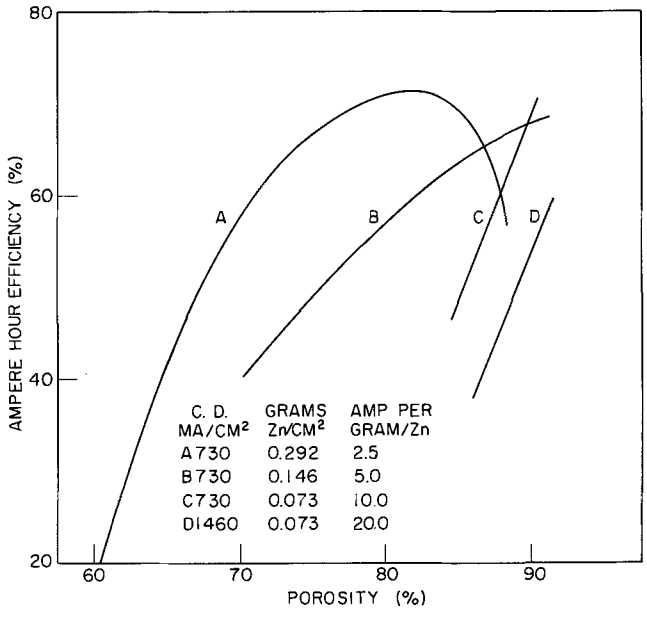

Fig. 2. Effect of porosities on efficiencies of zinc electrodes at 20°C.

by reducing $ZnCO_3$ under the comparatively light pressure of 0.054 kg/cm². A number of discharges were made at constant current covering a range of porosities, current densities, and electrode thicknesses. The results are shown in Fig. 2 where the ampere hour efficiency is plotted as a function of the porosity for various current densities and amounts of zinc. In each case, the efficiency and consequently the cell capacity increases rapidly with increasing porosity. In curve D, discharges are being obtained in slightly over one minute at efficiencies up to 60%. Figure 2 shows, as would be expected, that an increase in current density at a given porosity decreases efficiency. It also shows that a given efficiency can be maintained, within limits, by increasing the porosity as the current density increases. The current density is defined here in amperes per square centimeter, 1 cm² being defined as the area of an electrode 1 cm square. It would seem more logical to define current density as an active material current density measured in amperes per gram of zinc, since this value would be inversely proportional to the theoretical discharge time at 100% efficiency. Consequently the capacity of an electrode, at a given porosity and active material current density should be fairly constant but would tend to decrease as the thickness of the electrode increased.

The fact that ampere hour efficiencies of as much as 60% were obtained on cells discharging in as little as 1 min indicated that a further study should be made in this extremely high rate area. A number of cells were evaluated by means of constant resistance discharges. The average potential and the cutoff poten-

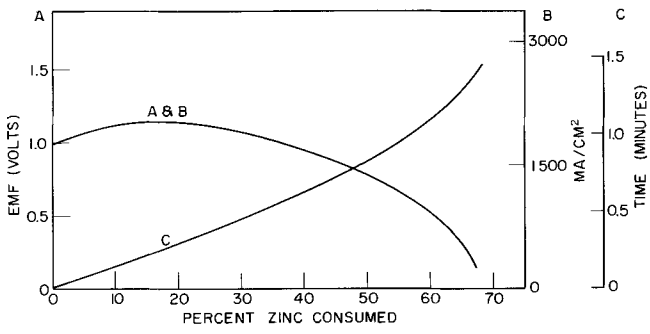

Fig. 3. High rate zinc electrode, constant resistance discharge at 23°C, AgO-Zn-32% KOH, 0.0577 g/cm² of 91.6% porous zinc. A, Potential; B, current density; C, time.

tial as well as the capacity are difficult to evaluate in a constant resistance discharge, since the potential tends to drop slowly with time in the manner shown in Fig. 3, which is in sharp contrast with the constant current discharges of Fig. 7 where the potential is fairly constant throughout most of the discharge and drops off rapidly near the end. However, many uses of a cell approximate constant current discharge conditions.

Occasionally in the past a cell has been observed, particularly at low temperatures, which was incapable of discharging through any type of load. Once started by extraneous means, a cell of this type would sometimes be capable of discharging on its own with satisfactory characteristics. If such a cell were discharged by the usual method of forcing a constant current through the cell and recording the potential, an initial period would be observed where the potential would be less than zero. If this period were too short to be detected by the recording equipment, it would never be known that the cell was incapable of practical operation without being started by an externally applied potential. The constant resistance discharges showed that this problem did not occur with these high porosity electrodes at high rates.

A large number of highly porous zinc electrodes of varying porosity were discharged at various high rates at temperatures varying from 23° to —60°C. A typical discharge is shown in Fig. 3 where the potential, the time, and the current density at 23°C have been plotted as a per cent of the total zinc that has been consumed at any given time. A discharge current equivalent to almost 2000 ma/cm² was maintained for nearly a minute at better than 50% efficiency. To check their durability, one of the cells tested at —60°C was short circuited for 6 sec followed by an immediate discharge through a constant resistance. The results are shown in Fig. 4 and indicate that the short circuit had no apparent effect on the Zn electrode characteristics.

The extremely high rates and efficiencies involved here can best be appreciated by comparison with existing types of electrodes. In Fig. 5, curve A, estimated values of the limiting current densities at various temperatures for the high porosity, high rate electrode are compared with those of a conventional electrode, curve B, recently developed for commercial high rate usage. The high porosity electrode has limiting current densities that are more than ten to thirty times higher than the conventional electrode.

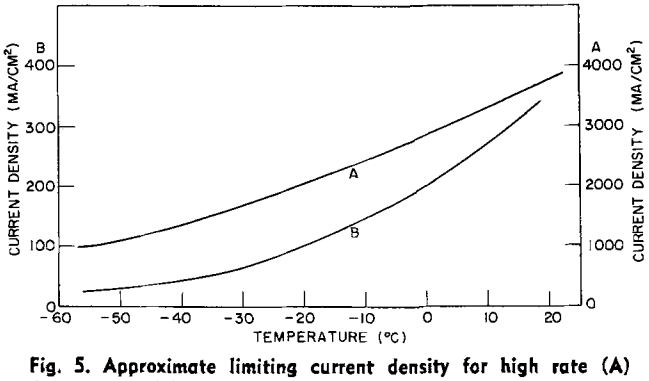

Fig. 5. Approximate limiting current density for high rate (A) and conventional (B) electrodes.

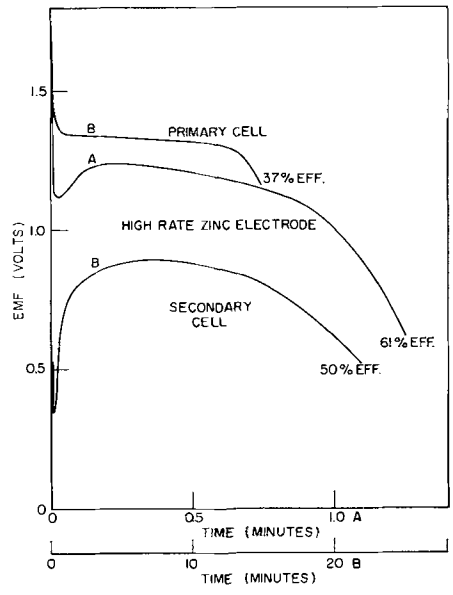

Fig. 6. Comparison of high rate zinc electrode battery with conventional silver zinc batteries.

In Fig. 6, where the potential is a function of the constant current discharge time, a higher efficiency and better characteristics are obtained for the high rate zinc electrode which is discharged in about 1 min, than are obtained for two commercial cells which were discharged in about 20 min. Commercial cells with higher efficiencies than these may be available, but these were the only two in which the weights of the active materials were known.

If the high surface area of the high porosity zinc electrode is the chief reason for its ability to discharge with high efficiencies at high rates and low temperatures then it should be possible to form high rate electrodes from other metals. High porosity cadmium electrodes were prepared by the electrolytic reduction of cadmium oxalate under 0.054 kg/cm² pressure in 15% KOH electrolyte. They were discharged against AgO cathodes in 32% KOH at constant current densities up to 1460 ma/cm². The results are shown in Fig. 7 where the emf is plotted against time throughout the discharge. High efficiencies were obtained, even in discharges that lasted as little as 1 min. Excellent results were also obtained at low temperatures. High porosity lead electrodes were

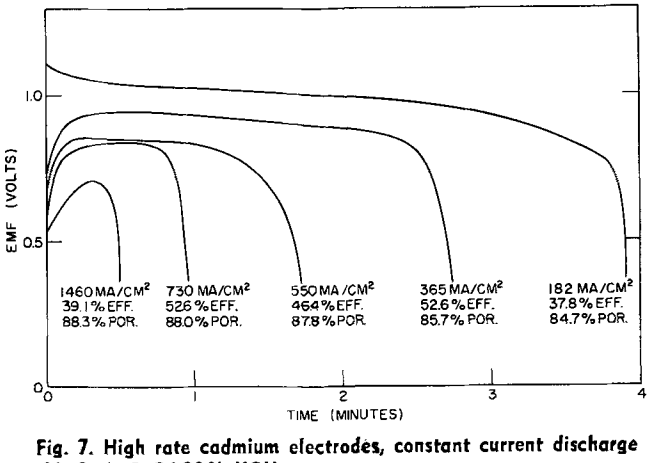

Fig. 7. High rate cadmium electrodes, constant current discharge at 20°C, AgO-Cd-32% KOH.

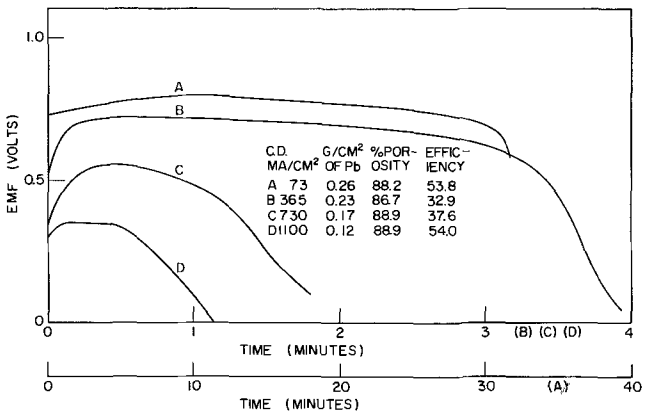

Fig. 8. High rate lead electrodes, constant current discharge at 20°C, AgO-Pb-32% KOH.

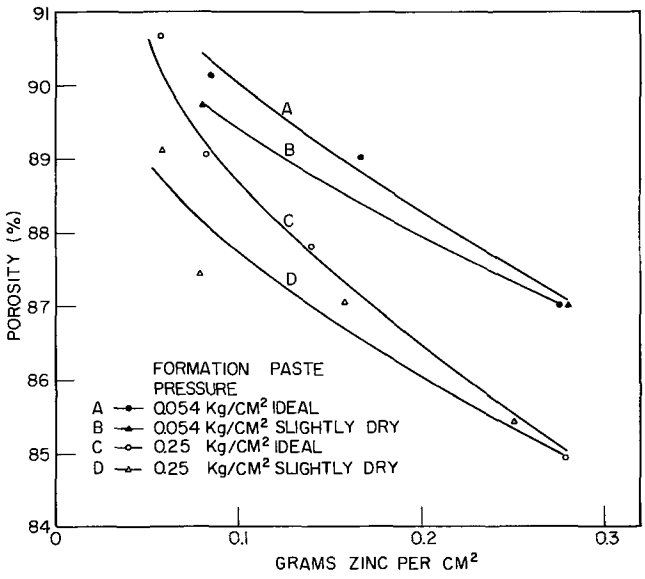

Fig. 9. Variation of porosity with the amount of zinc per unit area.

prepared by the electrolytic reduction of lead cyanamid and lead thiocyanate in 15% KOH electrolyte under 0.054 kg/cm² pressure. These were discharged against AgO cathodes in a 32% KOH electrolyte at constant current densities up to 1100 ma/cm² and discharge times of as little as 1 min. The results are shown in Fig. 8. The high capacities and efficiencies obtained at extremely high rates from the zinc, cadmium, and lead high porosity electrodes indicate that other high porosity, active materials should also make excellent high rate electrodes.

In every case, there was a large increase in temperature during a high rate discharge which would be capable under many conditions of seriously affecting cell capacity and other characteristics, particularly at low, ambient temperatures where the change in capacity with change in temperature is relatively large. This increase in temperature, which measured as much as 30°C, varies widely with changes in cell construction and operating conditions and consequently can have a serious effect on cell design. In the case of a large, closely packed, well insulated cell, containing a minimum of electrolyte, the temperature increase during discharge would be higher. Consequently, the discharge characteristics would be much better at low ambient temperatures than those obtained by the test procedures described here and illustrated in Fig. 4 and 12.

Electrode Pasting

There are a large number of problems involved in the pasting of the grids for the formation of the high porosity electrodes (2). Since the paste is subjected to physical pressure during reduction it cannot be put in the pockets of a commercial grid but must be set on top of a wire screen. Under these conditions the pasted material must be quite stiff in order to avoid flowing. This type of pasting is not particularly easy and is to a certain extent an art (2). An ideal paste gives on reduction a porous metal plate having optimum properties in regard to such characteristics as strength and cohesiveness. This ideal paste is a stiff paste and is almost dry, is slightly flexible and doughy, is not crumbly or sticky, and is cohesive and will flow to a certain extent when placed under pressure. The percentage of liquid present in a particular power-liquid combination is either constant or fixed within narrow limits. There is an extremely wide variation in the pasting properties of various compounds as defined in terms of ease of pasting and quality of paste. It was possible to divide all the compounds tested into five arbitrary groups ranging from "very good" to "very poor." This grouping was found to be a function of particle size and the water content of the ideal paste. The average water content of each group is approximately a linear function of the average geometric mean diameter. In going from the "very poor" to the "very good" paste group, the average water content increases from 32 to 60%, while the average particle size decreases from 1.2 to 0.3μ. Consequently, the finest size of particles make the best pastes and should be used wherever possible (2).

Since the water content of the paste is critical, slight variations in the paste composition might be expected to have an effect on the electrode porosity. The porosity of the metal obtained by electrolytic reduction of a pasted electrode is shown in Fig. 9 to be a function of the amount of zinc per unit area. The porosity decreases as the amount of zinc increases which is equivalent to saying that the porosity decreases as the thickness of the electrode increases. Similar results were obtained with lead. Results are shown in Fig. 9 for two different physical pressures applied throughout the reduction and show, as has been done previously, that the porosity decreases as the formation pressure is increased. A comparison shown here of ideally pasted electrodes with electrodes that were pasted slightly on the dry side indicate that the latter give a slightly lower porosity.

The control of metal porosity by the use of controlled physical pressure during reduction presents a number of problems which are now fairly well understood. This method has been successful in preparing porous metals from the normal electronegative group previously mentioned but has not been successful with the transition metals. It has been shown that the porosity of the metal plate is seriously affected by the choice of metal compound being reduced (1). If it is assumed that the volume of the porous metal plate at the end of the reduction at zero pressure equals the volume of the paste at the start, then the weight of the metal per cubic centimeter is

$$(1-P)\rho = (1-p)\,dP_m \qquad [1]$$

where P is the porosity expressed as a fraction, ρ is the metal density, p is the ratio of the volume of liquid in the paste to the volume of paste, d is the density of the compound being reduced, and P_m is the percentage of metal in this compound. Equation [1] can be rewritten in the form

$$1-P = (1-p)M_c \qquad [2]$$

where $M_c = dP_m/\rho$ = cubic centimeter of metal contained in a cubic centimeter of the compound.

A plot of $1 - P$ *vs.* M_c should give a straight line with the slope $(1 - p)$. Values of the porosity, P, at zero formation pressures were obtained by extrapolation from porosity-pressure curves and were plotted in Fig. 10 against cubic centimeter of metal per cubic

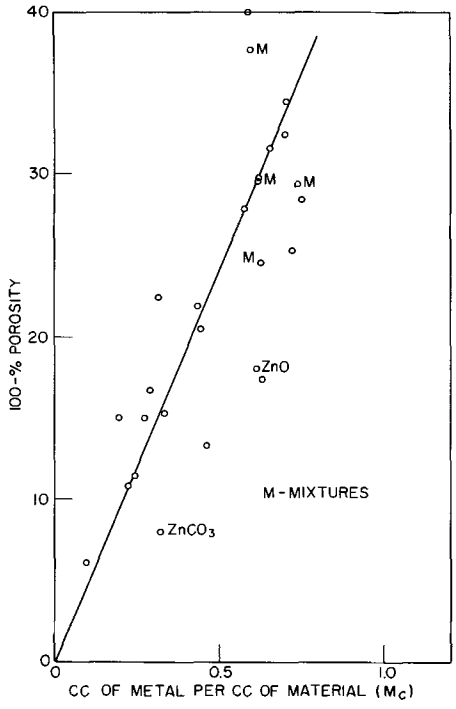

Fig. 10. Effect of cubic centimeter of metal per cubic centimeter of material on porosity.

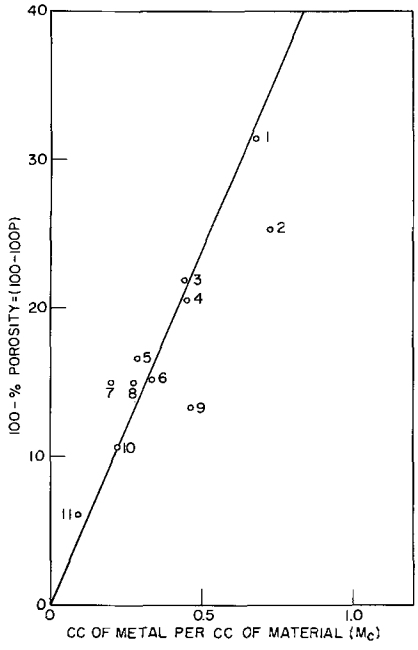

Fig. 11. Effect of cubic centimeter of lead per cubic centimeter of compound on porosity. Lead compounds; 1, oxide (PbO); 2, oxide (Pb_3O_4); 3, maleate (tribasic); 4, carbonate; 5, formate; 6, oxalate; 7, chlorphthalosilicate; 8, cyanate; 9, cyanamid; 10, thiocyanate; 11, stearate.

centimeter of compound for various compounds of zinc, lead, cadmium, silver, tin, copper, antimony, bismuth, and several mixtures of some of these compounds including mercury. The straight line fitted to this data has a slope of 0.48 which corresponds to a liquid content of 52% in the paste, which is about what would be expected (2). There is an appreciable scatter in the data of Fig. 10 due to the fact that each ideally pasted compound has its own particular value of p. In addition, the relationship is probably affected by such factors as the solubility of the compound in the electrolyte and its particle size distribution and shape factor. The two zinc compounds fall well below the line and indicate that the slope may also be dependent on the particular metal being formed. The data for the lead compounds alone have been plotted in Fig. 11 and the scatter, though definite, is much less than in Fig. 10. Porosities of lead from less than 70% up to 94% are shown here and any desired porosity in this range could be obtained by using a single compound or a suitable mixture of two or more of these compounds. All of these compounds were reduced to the porous metal in a 15% KOH electrolyte. The same metal porosity was obtained for Pb formed from PbO in 25% H_2SO_4 as in 15% KOH. It seems likely that the choice of electrolyte will have little effect on the metal porosity as long as the compound will reduce satisfactorily in that electrolyte. The very high porosities are obtained from compounds having a low value of M_c. Organic compounds containing a low percentage of metal tend to have low densities and consequently a low value of M_c. Not all compounds will reduce to the metal by electrolytic reduction under pressure. As a rough rule those compounds that are soluble in the electrolyte or are moderately good conductors of electricity tend to reduce. The best chance of obtaining very high porosities appears to be by the use of a metal salt of a high molecular weight organic acid.

If the use of pressure during the electrolytic reduction could be eliminated, the paste could be applied into the pockets of a conventional grid and thus eliminate most of the problems involved in pasting on top of a wire screen grid to form high porosity electrodes. A careful selection of metal compounds or mixtures thereof obviates the use of pressure to control metal porosity. However, a light pressure during reduction may be necessary in many cases in order to obtain optimum physical properties of the reduced metal electrode. It seems probable that a light pressure could be applied successfully to a pasted conventional grid particularly if a slight excess of paste were used.

If a high rate battery is to be constructed, a high rate cathode is needed in addition to the available high rate metal anodes. The problems involved in preparing high porosity cathodes from such materials as AgO and PbO_2 are similar to those involved in producing high rate metal anodes, but appear to be much more difficult, possibly because they have received less study. The major problem involved is the difficulty of getting good adherence between the active material and the grid. Although an Ag_2O electrode can be easily produced that operates at very high efficiencies at extremely high rates, a study was started on the AgO electrode since it is theoretically capable of producing almost double the capacity of the Ag_2O in terms of ampere hours per unit weight.

AgO electrodes were prepared by oxidation of various silver compounds pasted on a silver screen grid. Cathodes containing up to 87% porous AgO were formed in this manner. A number of cells were discharged under various conditions. A typical result is shown in Fig. 12 where the potential in volts, the current density, and the time are plotted as a func-

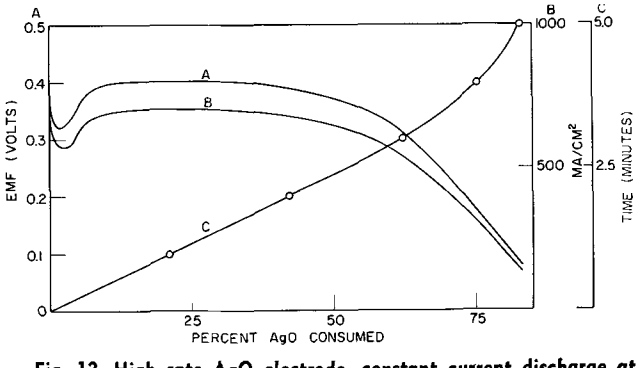

Fig. 12. High rate AgO electrode, constant current discharge at —40°C, AgO-Zn-32% KOH, 0.117 g/cm² of 86.9% porous AgO.

tion of the per cent of AgO consumed throughout a discharge made at —40°C.

A 71% porous PbO_2 electrode was prepared which was capable of discharging at moderately high rates. Both the AgO, the Ag_2O and the PbO_2 electrodes could be recycled.

The data indicated that the maximum efficiency on an efficiency porosity curve may be obtained at about 92% porosity at very high discharge rates as compared to 82% at the much lower rate illustrated in Fig. 1. At 92% porosity there are 11½ cc of electrolyte contained in the electrode for each cubic centimeter of Zn giving a total weight of active material plus electrolyte of about 27.6g. At 84% porosity there are 5¼ cc of electrolyte per cubic centimeter of Zn giving a total of about 14.1g. Thus, a drop in porosity that might be expected to decrease the capacity about 25% gives a decrease in the electrode weight of about 35%. Obviously the porosity that gives a peak capacity does not give a minimum weight. A 92 or 94% porous electrode is fairly flimsy. Rough calculations indicate that the maximum optimum porosity ever needed will be about 85 to 86%. Such an electrode, prepared on top of a wire screen, has fairly good physical strength which would be even better if a conventional grid were used. High porosity metal plates can be produced by other methods such as felt fiber or metallurgical techniques. Whether such electrodes will give the capacities obtained here probably depends on their pore size distribution and surface area. The successful reduction of a metal compound by the methods described here probably depends on the establishment of a network of relatively low resistance electrolytic paths filled with electrolyte and leading to virtually all the available active material. Since they must be there for formation to be possible, they will also be there for the purposes of discharge.

Conclusions

The results of this exploratory investigation show that high rate anodes and cathodes can be prepared that are capable of operating at high ampere hour efficiencies at temperatures down to as low as —60°C, thus pointing the way to the possibility of producing commercial cells capable of discharging with high efficiencies at extremely high rates. What may be of greater importance is the fact that this work shows that the porosity of the active material is a major factor of utmost importance in determining the capacity and other characteristics of many if not all cells which have porous electrodes.

The Formation and Discharge of Copper Chloride in an Organic Electrolyte

M. L. Bhaskara Rao

Laboratory for Physical Science, P. R. Mallory & Co. Inc., Burlington, Massachusetts

ABSTRACT

The electrochemical charge and discharge characteristics of copper electrodes in 1M $LiAlCl_4$ in propylene carbonate have been investigated. Oxidation of copper occurs with 100% efficiency yielding a sparingly soluble CuCl. The discharge efficiency of the precipitated salt is low (~50-75%). Analyses of the electrolyte during discharge have indicated the unusual phenomenon of an increase in the solubility of the salt which accounts for the low utilization efficiencies. An explanation is proposed based on the formation of a copper chloride complex. The significance of the observed results is discussed in relation to the development of organic electrolyte batteries.

It was recognized early that high energy density cell systems operating under room temperature and atmospheric pressure conditions would most probably comprise light transition metal salt cathodes and light alkali metal anodes in nonprotonic electrolytes such as can be obtained with certain organic solvents and inorganic salts. Several investigations have been conducted in recent years aimed at this possibility. It is the purpose of the present investigation to examine the suitability of one of the light transition metal chlorides, copper chloride, for a cathode in such cells.

It has been reported (1-3) that in propylene carbonate solutions of lithium tetrachloroaluminate only silver and nickel form insoluble salts on anodization of the bulk metal. Hence, the investigations conducted hitherto have concentrated on these two metals. It is not clear from the previous work whether the observed high solubility of copper, iron and cobalt chloride salts is due to the inherent solubility of the salt in the solvent, to the presence of impurities like water (4), or to ionic equilibria involving electrolyte salt. Experiments in our laboratory had shown that such processes were not only possible but that they were, indeed, operative in the copper chloride system. Thus it is of interest to consider copper chloride and other cathode salts which have been reported hitherto to be unsatisfactory for solubility reasons.

Previous work on the rechargeability of copper chloride electrodes in chloride ion containing organic electrolytes (1, 2) was limited to lithium chloride solutions in butyrolactone and dimethylformamide, and to lithium tetrachloroaluminate solutions in propylene carbonate. It was possible to charge and discharge copper electrodes reversibly only in the latter electrolyte. Porous copper electrodes operated at an efficiency of 65-75% (2). The causes of the failure to achieve 100% efficiency were not apparent from this work. It is the purpose of this paper to present the results of further work on this system, to interpret the observed behavior, and to indicate areas in which further study is required. Although attention is focused on the copper chloride system, it is apparent that the phenomena are of general relevance to cathode operation in organic electrolyte cells.

Experimental

Solvent.— Propylene carbonate, obtained from Matheson, Coleman, and Bell, was first passed through

a column of Linde 4A molecular sieves to remove part of the water initially present in the solvent. The propylene carbonate was then vacuum distilled at 3-5 mm Hg and the useful fractions collected at 89°-91°C. The water content of the various fractions was analyzed by gas chromatography and found to be between 0.002 and 0.5% by weight, depending on the fraction considered. Solvent fraction containing 0.002 to 0.005% (wt) water was used in the present experiments.

Electrolyte solution.—Various procedures for the preparation of solutions of lithium tetrachloroaluminate have been described (1-3). The most common method involves the controlled addition of stoichiometric quantities of $AlCl_3$ and LiCl to propylene carbonate. Such solutions become discolored and give evidence of extensive side reactions, probably the decomposition of solvent catalyzed by $AlCl_3$. We have adopted another procedure, previously reported (2), involving the direct formation of $LiAlCl_4$ through fusion of solid $AlCl_3$ and LiCl at 200°C. All the operations of premixing the salt, melting, and cooling were carried out in a dry atmosphere to exclude hydrolytic processes. The electrolyte was prepared by dissolving known amounts of this salt in given volumes of distilled solvent. Normally, such electrolytes were more stable than those obtained by other procedures, as evidenced by the very slight discoloration. The specific conductivity of 1M electrolyte solution was 5×10^{-3} ohm^{-1} cm^{-1}.

The cell.—All experiments were carried out in a Pyrex glass H-cell with a sintered glass frit separating the two compartments. Known volumes (25-50 ml) of electrolyte were used in the working electrode compartment. The cell had a cover suitable for holding the electrodes and also had provision for admitting dry, inert gas for deaeration and for maintaining a dry atmosphere over the electrolyte.

Electrodes.—Solid copper foils of 99.99% purity and thickness between 2 and 30 mils were employed to make working electrodes with superficial areas of 2 to 20 sq cm. Porous copper electrodes were also used in the present experiments. They were 2 sq cm in projected area, 0.076 cm thick, and were designated by the manufacturer (Clevite Corporation) to have a porosity of 62%. After the electrodes were cut to the required size, copper leads were attached by spot welding. Solid copper electrodes were cleaned in dilute nitric acid followed by rinsing in distilled water and acetone. Porous copper electrodes were used without any pretreatment. In order to prevent the shedding of products formed during anodization, a layer of Whatman No. 40 filter paper was wrapped around the working electrode.

Measuring set-up.—All measurements were made at a constant current provided by an Electronic Measurements Inc. electronically controlled constant current supply Model 620. The counter electrode was a strip of lithium metal in the counter electrode compartment of the H-cell.

The potentials of the working electrode reported were measured relative to a silver wire situated in the same solution 2-3 mm away from the former. Thus, the reported valves of potential include potential differences due to IR in the electrolyte. The reproducibility of the reference electrode was ±0.05v as evidenced by a series of open-circuit measurements with reference to a lithium electrode in the same solution. The potentials were measured with an electrometer, E-H Research Laboratories Model 230 and were recorded by feeding the output of the electrometer to a potentiometric recorder, Mosley Autograph 680.

Anodic and cathodic measurements were made at currents between 0.5 and 10 ma cm^{-2}, based on the projected electrode area. Most of the measurements were performed in agitated solution, using a magnetic stirrer.

Analytical techniques.—Dropping mercury electrode polarography was used to identify and to estimate the dissolved copper ion species formed in solution during electrolysis. For this purpose, 1-ml aliquots of the electrolyte from the working electrode compartment were added to a thoroughly deaerated, known volume of aqueous 1M HCl contained in the polarographic cell. Such a medium preserves the ratio of copper (I) and copper (II), since copper (I) will not disproportionate (5), and no copper metal is present to reduce copper (II) to copper (I). This procedure for analysis allowed the unequivocal identification and estimation of the copper ion species initially present in the working electrode compartment. In other respects the polarographic measurements were conventional and the results were compared against known solutions of copper (I) and copper (II) in aqueous 1M HCl. A Metrohm Polarecord Model E-261 was used in this work.

Specific experiments.—The following experiments were done: (*A*) Charge-discharge behavior of solid copper electrodes. Solid copper electrodes of known dimensions were submerged in a solution of 1M $LiAlCl_4$ in propylene carbonate in the working electrode compartment of the cell. The electrodes were anodically charged to capacities of 2.5 to 10 ma-hr cm^{-2} at 0.5 to 10 ma cm^{-2}. The charged electrodes were subsequently discharged at various current densities. Both the variation of electrode potential with time and the utilization efficiency were investigated. The utilization efficiency is calculated by dividing the coulombs recovered on cathodization by the coulombs passed during the preceding anodization.

(*B*) Composition of electroformed salt. A 20 cm^2 area electrode was anodized at 10 ma for 15 hr. A large amount of insoluble salt formed on the electrode. The electrode and the adhering salt were repeatedly rinsed in propylene carbonate and then dried. The composition of the salt was determined by x-ray diffraction, using a Phillips Type 422730 x-ray diffraction unit. For the cell constants, copper radiation (no filter) was employed.

(*C*) Maximum possible loading. The maximum anodization that an electrode could sustain was determined by charging anodically a 2-mil thick copper foil of approximately 20 ma-hr theoretical capacity (based on a one-electron oxidation). This electrode could be smoothly charged to capacity of greater than 18 ma-hr. Further charging was limited by the physical discontinuity of the metal due to the exhaustion of the metal rather than to passivation problems.

(*D*) Solubility measurements.—At various intervals of time during the charging and discharging of the electrode, 1 ml aliquots were taken from the working electrode compartment and analyzed to determine the nature and concentration of the dissolved copper species.

(*E*) Open-circuit stability of the charged electrodes. Solid copper electrodes were anodized at 5 ma cm^{-2} in 30 ml of solution to a capacity of 3.25 ma-hr cm^{-2} and were allowed to stand on open circuit in stirred solution for 5½ hr. The solutions were analyzed for dissolved copper species before and after the open-circuit stand.

(*F*) Effect of electrolyte composition on charge-discharge efficiency. The charge-discharge behavior of solid and porous copper electrodes was studied as described above in electrolytes of altered composition. The electrolyte was a propylene carbonate solution, 1M in $LiAlCl_4$ and 0.5M in $AlCl_3$.

Results and Discussion

The Charging Process

The anodic charging of copper metal electrodes in a propylene carbonate solution, 1M in $LiAlCl_4$, produced a partially soluble greenish white salt on the electrode. No change in the color of the solution was ob-

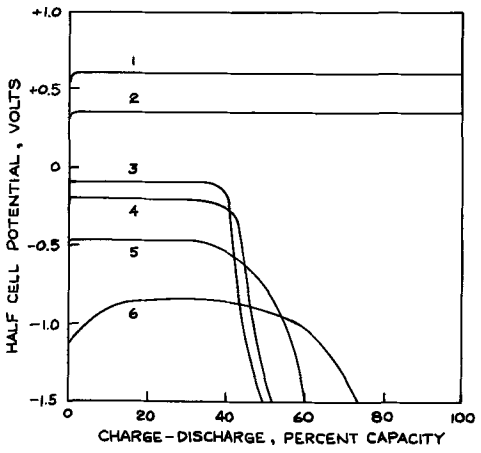

Fig. 1. Charge-discharge behavior of copper electrodes in 1M $LiAlCl_4$. Capacity of charging: 2.5 ma-hr cm^{-2}. Curves 1 and 2 refer to anodic charging at 2.5 and 0.5 ma cm^{-2}; curves 3 to 6 are for discharge at 0.5, 2.5, 5, and 10 ma cm^{-2}, respectively.

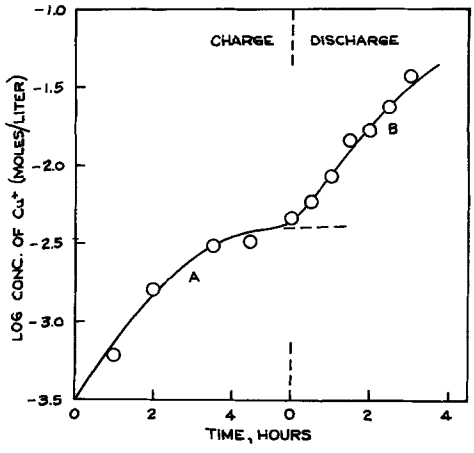

Fig. 2. Build up of copper (I) concentration in the working solution during charge and discharge of 10 cm^2 copper electrodes in 50 cc, 1M $LiAlCl_4$ at 20 ma.

served due to the dissolution of the salt. The charging curves, shown as curves 1 and 2 in Fig. 1, exhibited a single plateau. The salt remaining on the electrode was analyzed by x-ray diffraction as described above. The results are shown in Table I. Only three lines were observed, and these are compared with the ASTM data for CuCl. The data in Table I provide conclusive proof that the bulk of the salt produced on anodic charging was CuCl.

The electrolyte composition was analyzed during anodic charging. The results are shown as curve A of Fig. 2. Only copper (I) was found in solution. The concentration of copper (I) increased initially and then leveled off at a value which is assumed to be the point of saturation. This conclusion is supported by the observation that when an anodically charged copper electrode was allowed to stand on open circuit for as long as 5½ hr, there was no further significant change in the concentration of copper (I) in solution. From these data we may calculate the solubility of copper (I) in this electrolyte to be 4.64×10^{-3} M 1^{-1} at 25°C.

It is concluded that the only product of the anodic charging of copper metal in propylene carbonate, 1M in $LiAlCl_4$, is slighlty soluble CuCl. Since there was no evidence of copper (II) in solution, it must be concluded that, at the saturation concentration of copper (I), disproportionation is negligible.

The Discharge Process

Cathodic discharge curves for the product formed during anodic charging are shown as curves 3 to 6, Fig. 1. These discharge curves were obtained on electrodes which had been anodically charged to a capacity of 2.5 ma-hr cm^{-2}. A single discharge plateau was observed. The utilization efficiencies, calculated as described above, varied with the discharge current density from approximately 50% at 0.5 to 2.5 ma cm^{-2} to 70% at 10 ma cm^{-2}. It was also observed that the color of the solution in contact with the working electrode changed from a light to deeper yellow upon discharge.

Since the utilization efficiencies observed were rather less than 100% it was necessary to analyze the probable causes of the observed inefficiencies. The following phenomena and properties may cause a low efficiency: (*a*) parasitic oxidation and reduction reactions; (*b*) trapping of electroactive material in electrode regions not accessible to electron transfer due to shedding or irregular current density distribution; and (*c*) solubilization of active material in the electrolyte and the diffusion of solubilized species away from the electrode. In the present case, it was possible to ascertain the causes of the low utilization efficiency. During the investigations, the variation of the copper (I) concentration in the solution was also measured as a function of the depth of discharge. Surprisingly, the copper (I) concentration increased during the discharge cycle. The observed buildup is presented in Fig. 2, curve B. It may be seen that the Cu^+ ion concentration increased sharply from 4.64×10^{-3} moles/l at the end of the charge cycle to 2.72×10^{-2} moles/l at the end of the discharge cycle. The observed result was unexpected and seems to have no parallel in electrode processes occurring in aqueous systems.

Table I. Results

dA (Literature, CuK_α radiation)	I/I^o (Literature)	dA (Observed)	I/I^o (Observed)
3.127	100	3.1552	100
1.9148	55	1.9225	54
1.6332	32	1.6407	29

It was possible to account fully for the loss of efficiency from the magnitude of estimated concentrations of the dissolved copper (I) species. In a typical experiment, a coulombic equivalent of 4.1×10^{-3} moles of electricity were used for the charging of the electrode, and an equivalent of 2.46×10^{-3} moles were recovered from discharge. The analysis of the solution for the Cu^+ ion concentration after the discharge cycle indicated the presence of 1.68×10^{-3} mole of Cu^+ ions in the solution which accounted for the low efficiency on discharge. It was interesting to note that the data indicated a current efficiency of 100% for the chloride salt formation process. Obviously some ionic process occurred during the discharge that resulted in the production of a copper species more soluble than CuCl. The following explanation may be offered at this time to explain the observed behavior.

Earlier investigations (2) of copper salt systems in organic electrolyte media had led to the suggestion that there is a strong tendency for copper chloride to form more soluble $CuCl_2^-$ ions in the presence of free chloride ions. The exact experiments in this regard concerned measurement of the conductivity of propylene carbonate suspensions of insoluble CuCl and insoluble LiCl. The conductivity of the equilibrium solution in contact with different proportions of CuCl and LiCl increased linearly till equimolar amounts of CuCl and LiCl were present. Thereafter the conductivity did not increase appreciably with further addition of LiCl. The observed increase in conductivity up to 1:1 mole ratio has been explained on the basis of formation of a more soluble $CuCl_2^-$ complex. This led to the formulation of a reaction mechanism involving the cathodic generation of this complex to account for

the increased solubility observed in the present experiments.

To examine why more copper (I) goes into solution on cathodic discharge than on anodic charge, it is convenient to consider the following equilibria.

$$AlCl_4^- = AlCl_3 + Cl^- \quad [1]$$

and

$$CuCl_2^- = CuCl + Cl^- \quad [2]$$

and the reversible electrode reaction

$$Cu + Cl^- = CuCl + e^- \quad [3]$$

The equilibrium for reaction [1] lies predominately to the left, as is known from the fact that LiCl, which is relatively insoluble in propylene carbonate, does not precipitate in 1M $LiAlCl_4$ solution in propylene carbonate. The equilibrium for reaction [2] lies predominately to the left also, in the presence of a sufficiently large chloride concentration. This is not the case for the $LiAlCl_4$ solution, and there is little tendency for the CuCl to go into solution, as attested by the solubility for copper (I) in this solution of 4.64×10^{-3} M l^{-1}.

At the electrode/solution interface the net reaction during anodization involves the consumption of chloride ions (reaction [3] from left to right), and, hence, there is even less tendency for the dissolution of copper (I) through formation of $CuCl_2^-$. It is reasonable to assume that the aluminum chloride generated in the above reaction may diffuse away from the electrode. Consequently, at the beginning of discharge the concentration of $AlCl_3$ at the electrode/solution interface would be less than needed for reversing the quasi-equilibrium steps involved during charging. As such, part of the Cl^- ions released during discharge (reaction [3] from right to left) become available for combination with undischarged CuCl to form the soluble $CuCl_2^-$ species as in

$$2CuCl + e^- = Cu + CuCl_2^- \quad [4]$$

Thus, the formation and diffusion of $CuCl_2^-$ away from the electrode would account for the observed increase in the Cu^+ ion concentration in solution and the low efficiency on discharge. Whether or not the CuCl is reprecipitated from $CuCl_2^-$ and $AlCl_3$ in the bulk of the solution needs to be investigated.

The following experiments were designed to take advantage of this postulated mechanism to improve the utilization efficiency of the copper electrode.

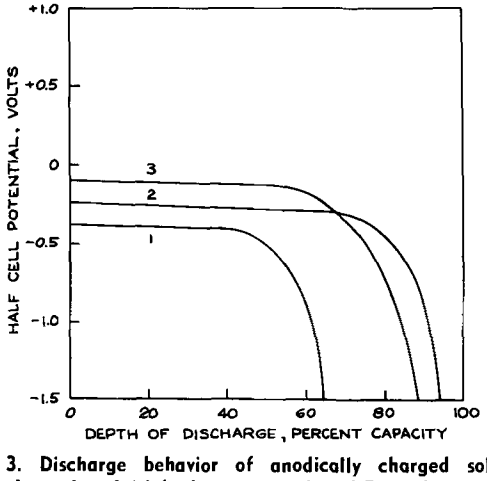

Fig. 3. Discharge behavior of anodically charged solid and porous electrodes. Initial charge capacity: 2.5 ma-hr cm^{-2}; discharge current density: 2.5 ma cm^{-2}. Curve 1 and 2 discharge of electroformed CuCl on solid and porous copper electrode in 1M $LiAlCl_4$ containing 0.5M $AlCl_3$ in propylene carbonate; curve 3 discharge of electroformed CuCl on porous copper electrode in 1M $LiAlCl_4$ in propylene carbonate.

1. Increasing the current density of discharge should increase the utilization efficiency since a larger fraction of the soluble $CuCl_2^-$ species would be reduced before they can leave the domain of reduction, the electrode. The results shown by curves 5 and 6, Fig. 1, demonstrate that this did, indeed, occur.

2. Increasing the porosity of the electrode should increase the utilization efficiency since the tortuous channels of the porous electrode would impede the diffusion of the $CuCl_2^-$ species into the solution, and a larger fraction of the salt should be reduced. This did occur, as is demonstrated by curve 3, Fig. 3, where a cathodic utilization of 85% was realized with the porous electrode under conditions where the solid electrode would have only yielded a utilization efficiency of 50%.

3. Increasing the concentration of $AlCl_3$ should increase the utilization efficiency. This may be seen from an examination of reactions [1] and [2]. The larger the concentration of $AlCl_3$, the more effective will be the competition of $AlCl_3$ for chloride ions, and the smaller will be the degree of complexation of CuCl with chloride ions. This was demonstrated to occur as shown by curves 1 and 2, Fig. 3, and curve 4, Fig. 1. In the 1M $LiAlCl_4$ solution containing 0.5M $AlCl_3$ the utilization efficiency was greater than 90%, whereas, under similar conditions, the utilization efficiency was only 50% when additional $AlCl_3$ was not present.

Conclusions

(*A*) In propylene carbonate, 1M in $LiAlCl_4$, the primary product of the anodic oxidation of copper metal is CuCl. CuCl may be cathodically reduced; the primary problem is the strong tendency of CuCl to form chlorocuprate (I) complexes, which are soluble in this solvent. The tendency toward complexation may be repressed by the appropriate control of the complexation equilibria through the addition of species which preferentially combine with chloride ions.

(*B*) The fraction of copper (I) which, through complexation, escapes into the solution before cathodic reduction may be retarded through the use of high current densities and porous electrodes.

(*C*) Under optimum conditions of current density, electrode porosity, and equilibrium control (through the addition of $AlCl_3$) it has been possible to cycle copper electrodes in propylene carbonate solutions of $LiAlCl_4$ with better than 95% utilization efficiency.

Studies of Hydrocarbon Fuel Cell Anodes by the Multipulse Potentiodynamic Method

III. Behavior of Saturated Hydrocarbons on Conducting Porous Teflon Electrodes with a Phosphoric Acid Electrolyte

L. W. Niedrach and M. Tochner[1]

General Electric Research & Development Center, Schenectady, New York

ABSTRACT

The behavior of methane through butane fuels parallels that previously observed with methane, ethane, and propane with a perchloric acid electrolyte although quantitative differences are observed. A temperature range from 60° to 120° was covered. With both electrolytes all of the hydrocarbons form one class of surface species which is oxidized at relatively low potentials. Hydrocarbons above methane form a second more refractory class of surface species in both cases. As the molecular weight of the fuel increases, greater quantities of the refractory species accumulate on the electrode. These species play a role in determining the maximum current that can be carried by the electrode. They seem connected with the current and voltage oscillations frequently encountered with hydrocarbon fuel cells.

The behavior of ethane and related hydrocarbons on smooth platinum electrodes in the presence of a perchloric acid electrolyte has been previously investigated with the multipulse potentiodynamic (MPP) method in this laboratory (1, 2). More recently the method has been extended to porous fuel cell anodes of more complex structure with which the behavior of methane and ethane was examined in detail, and a few preliminary experiments were performed with propane (3, 4). For this purpose a miniature version of a previously described (5) conducting-porous-Teflon fuel cell electrode (containing platinum black as catalyst) was employed. The electrolyte was again perchloric acid.

The work with porous-Teflon electrodes has now been extended to phosphoric acid systems in the temperature range from 60° to 120°C. Saturated linear hydrocarbons from methane through butane have been included in the new studies which are the subject of the present paper.

As in the previous work, particular attention was given to the behavior of the species that form on the surface of the electrode. In addition data were again obtained to relate this behavior to the over-all polarization curves for the fuel electrodes.

Experimental

The equipment and general procedures utilized in these investigations have been described previously (3). In brief, the 0.2 cm diameter Teflon-bonded, platinum black electrode was mounted in a three compartment, Teflon cell. Platinized platinum flags served as the hydrogen reference and counter electrodes. The former communicated with the working anode through a Luggin capillary. The cell was operated in an air thermostat enabling control of the temperature to within 0.1°C.

The 75% phosphoric acid electrolyte solution used for this work was prepared from reagent grade phosphoric acid and quartz distilled water. Electrolytic grade hydrogen was used in the reference electrode chamber, and Phillips research grade hydrocarbons were used as the fuels. Tank argon, deoxygenated by passage over heated copper turnings, was used as the "fuel" for obtaining solvent blanks. Tank argon was also used for degassing the solution.

The electronic instrumentation and circuit have been described previously (6).

The potential-time sequence applied to the anode for adsorption studies at constant potential is shown in Fig. 1. The significance of the steps is covered below.

(*A*) Pretreatment step (15 sec) to remove oxidizable impurities and to produce a layer of "adsorbed oxygen" which serves to block fuel adsorption. The solution is vigorously stirred and purged with argon to remove molecular oxygen and oxidation products formed.

(*B*) Potential step, during which the oxygen layer formed in (*A*) is maintained, and the solution is purged for an additional minute. The solution is then allowed to become quiescent for 1 min.

(*C*) Reduction step (15 sec) during which the adsorbed oxygen layer is reduced. At this low potential (0.06v) the adsorption of hydrocarbons is blocked. This step was included so that the reduction of the surface and the adsorption of the hydrocarbon would not occur simultaneously. However, omission of this step

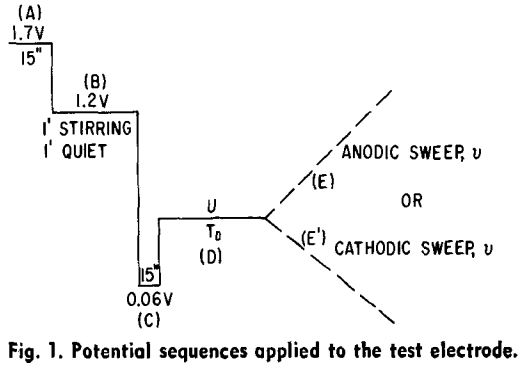

Fig. 1. Potential sequences applied to the test electrode.

[1] Present address: Silicone Products Department, General Electric Company, Waterford, New York.

was found to have no detectable effect on the equilibrations.

(*D*) Adsorption step, during which the hydrogen from (*C*) is rapidly oxidized, exposing a reproducibly clean surface for adsorption. The duration of this step is the adsorption time, T_D.

(*E*) Anodic sweep at 0.1 v/sec. The adsorbed fuel is oxidized and the surface covered with a layer of adsorbed oxygen. Subtraction of the charge due to surface oxidation from the total charge yields the charge required to oxidize the surface species derived from the adsorbed fuel.

(*E'*) Alternative to (*E*), a cathodic sweep at 0.025 v/sec which is used for determination of the "real" surface area of the electrode from the charge $_sQ_H$ corresponding to hydrogen deposition. In this case, argon is substituted for the hydrocarbon fuel.

The rationale behind the various steps has been discussed in detail elsewhere (1-3, 6).

Polarization curves were obtained by application of steps (A)-(D) of Fig. 1 before each measurement of current at a particular potential *U*. At each potential a 10-min equilibration was performed to allow the system to approach steady state before the final current measurement was made.

The work was completed over an interval of three months. During this period the area under the oxygen adsorption wave showed a variation of only ±3%. This is in agreement with a similar small variation in the real surface area of the electrode. It was also found that the blank traces were reproducible over the full range of equilibration periods used, thereby indicating that contamination of the electrode did not occur during the equilibrations.

Results

Each of the four hydrocarbons under study was examined over a range of equilibration times, potentials, and temperatures. As in the earlier work current-potential traces were obtained with a linear anodic sweep to determine the behavior of the adlayer on the electrode towards oxidation. In addition polarization curves were also obtained.

In Fig. 2, a set of current-potential traces is shown for the four fuels after various equilibration times at 0.3v with the 75% phosphoric acid electrolyte at 100°C. The general form of the traces is similar to that previously observed with the perchloric acid electrolyte at 60°C. In particular it is to be noted that only the single wave 1 is again observed with methane. This wave, which occurs at potentials below those at which the surface itself is normally oxidized, is also evident in the case of the higher hydrocarbons, but the latter also show a broad second wave which extends from about 0.8v to oxygen evolution potentials. With the ethane a clear indication is seen of a new, third wave which overlaps wave 2 and has a peak at about 0.9v. It is also to be noted that the charge required to oxidize the adlayer from the higher hydrocarbons is much larger than that required for methane. In addition, the rising portion of wave 1 shifts noticeably to higher potentials as the coverage increases.

The effects of the equilibration potential on the oxidation traces are shown for the four fuels in Fig. 3-6. Here again the temperature was 100°C and standard equilibration times of 10 min were employed. Over the range of temperatures investigated this time was found adequate to establish essentially a steady-state coverage except in the case of methane at low potentials. Again, as in the case of the perchloric acid a marked effect of potential is seen. The maximum charge required for oxidation of the adlayer occurs in the vicinity of 0.2v. This probably also corresponds to maximum surface coverage with adsorbate, but because of the unknown oxidation states of the specific surface species involved, this cannot be stated with certainty. The hypothesis is however supported by the related work of Brummer *et al.* with propane on wire electrodes (7).

It is to be noted that following equilibrations at 0.6v the amount of residual wave 2 increases with the molecular weight of the fuel. The new wave 3 for ethane is conspicuous after equilibrations at 0.2, 0.3, and 0.4v. It cannot be detected in the traces for propane and butane, possibly because of overlapping from a pronounced tail from wave 2.

The observed effects of potential at 100°C are also representative of the trends seen at 60°, 80°, and 120°C. However, there is a general tendency for the

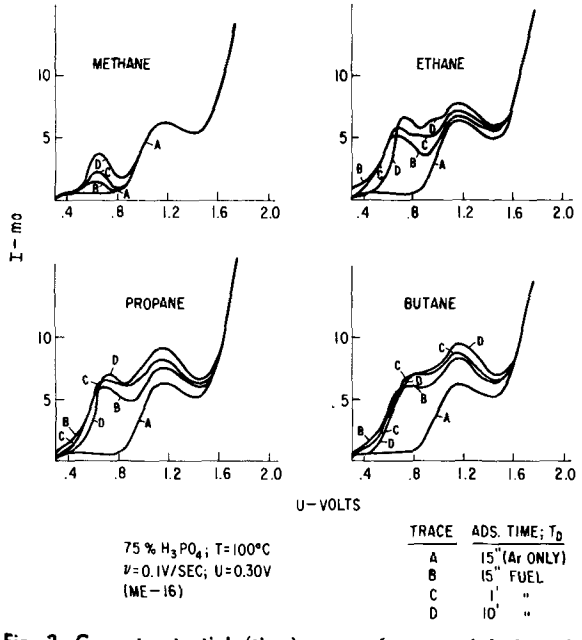

Fig. 2. Current-potential (time) traces for several hydrocarbons after different adsorption times.

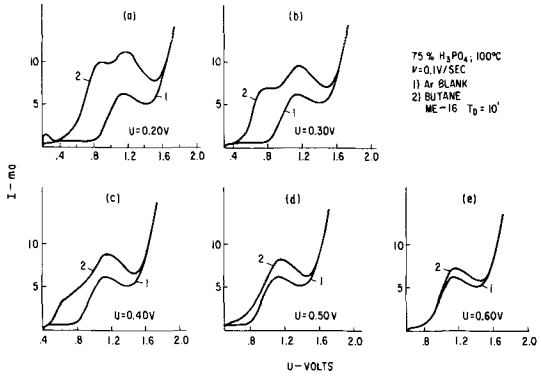

Fig. 6. Current-potential (time) traces for butane adsorbed at several potentials.

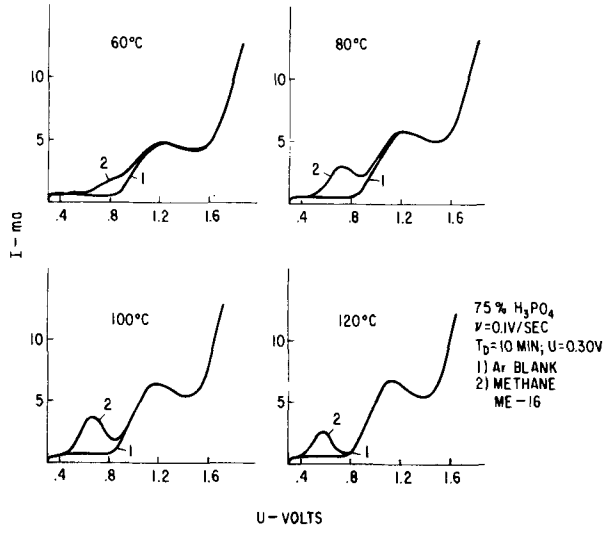

Fig. 7. Current-potential (time) traces for methane adsorbed at several temperatures.

oxidation waves to become more distinct and for wave 1 to grow in at the expense of wave 2 as the temperature is increased. This is illustrated in Fig. 7-10 with data obtained at 0.3v. Similar trends had been observed with the perchloric acid electrolyte over the temperature range from 25° to 80°C (3). The traces obtained with the phosphoric acid electrolyte at 60° and 80°C are, however, somewhat more diffuse than those with perchloric acid at the corresponding temperatures. As in the case of the perchloric acid electrolyte, methane shows only a single wave throughout.

The charge, $Q_{E_{tot}}$, associated with the oxidation of all carbonaceous species in the adlayer was determined at 100°C and 0.3v after different adsorption times, T_D. This was done conventionally by integrating the area enclosed by the solvent blank trace and the fuel trace (1-3, 6). It is to be noted that hydrogen formed by dissociation during the initial adsorption step is not included in these measurements. These data for the four fuels are shown in Fig. 11. The data have been normalized to charge per unit of "real" surface area as determined by cathodic deposition of hydrogen on the electrode. A conversion factor of 0.21 mcoul/cm^2 was employed in calculating the real area (8).

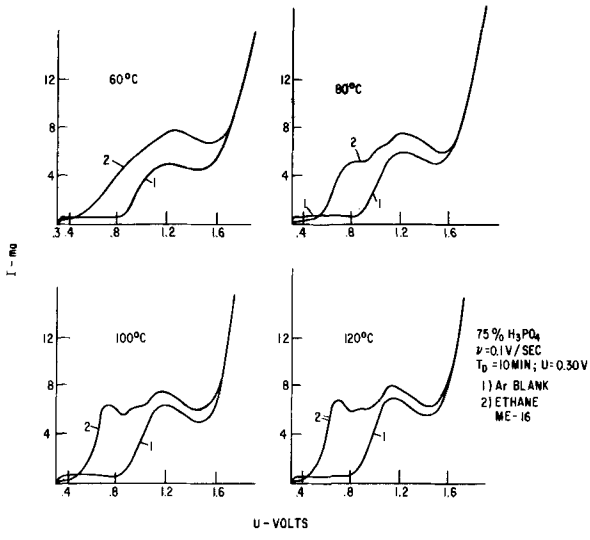

Fig. 8. Current-potential (time) traces for ethane adsorbed at several temperatures.

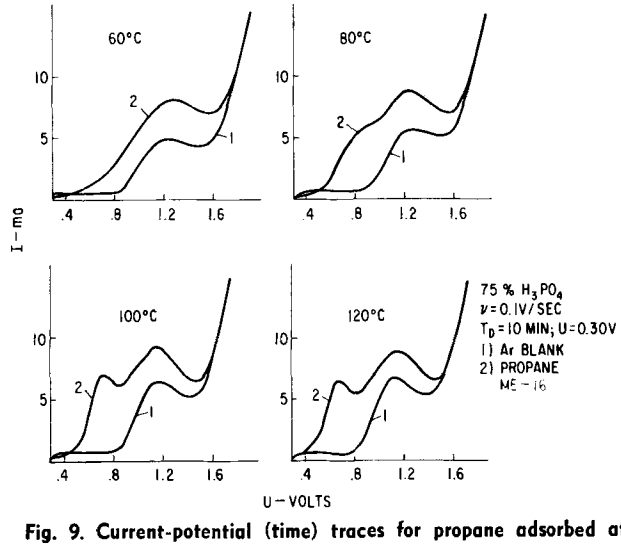

Fig. 9. Current-potential (time) traces for propane adsorbed at several temperatures.

At the temperature of these experiments the rates of accumulation of oxidizable species on the electrode surface are considerably higher than had been encountered in the work at 60°C with perchloric acid. This made it impossible to estimate initial adsorption rates as was reported earlier for the lower temperature work with perchloric acid. For ethane, propane, and butane, even for the shortest equilibrations, $Q_{E_{tot}}$ varies with the logarithm of time as had been observed at intermediate times with the perchloric acid at the lower temperature. In the case of methane a parabolic relationship between $Q_{E_{tot}}$ and time is followed at the shorter equilibration times. This contrasts with the linear relationship previously observed with the perchloric acid. As was noted in the

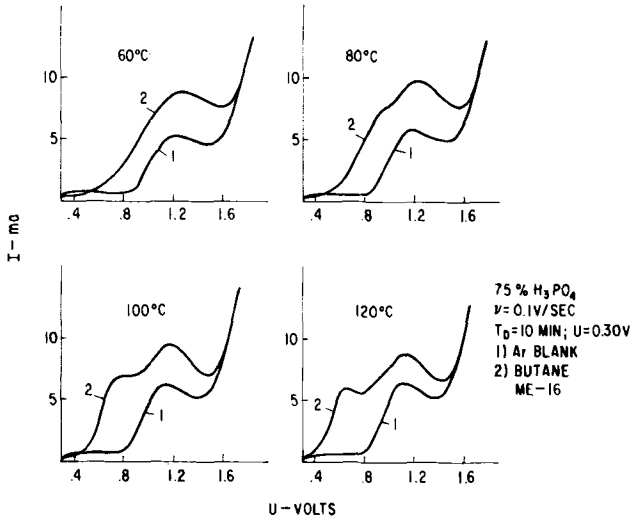

Fig. 10. Current-potential (time) traces for butane adsorbed at several temperatures.

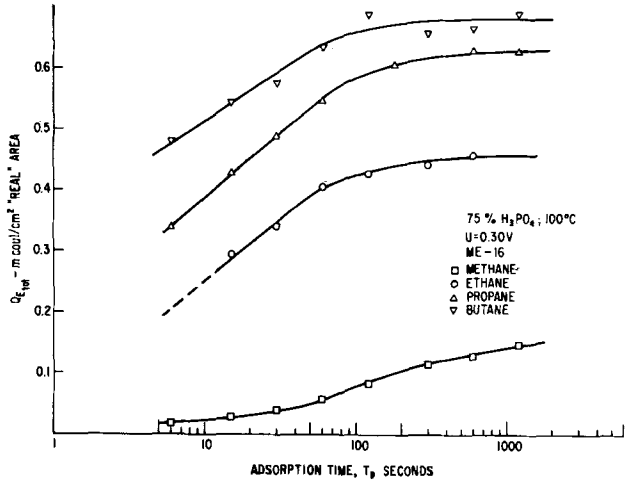

Fig. 11. Variation in surface charge with time for several hydrocarbons.

earlier work, $Q_{E_{tot}}$ eventually levels off to a steady-state value when the rate of adsorption equilibrates with the rate of oxidation. The total surface charge at steady state decreases with decreasing molecular weight of the fuel with the largest increment occurring between ethane and methane.

In addition to the examination of the adlayer, steady-state polarization curves were obtained for the four fuels at 60°, 80°, 100°, and 120°C. The family of polarization curves shown in Fig. 12 for ethane is representative of the effect of temperature on all of the fuels. In this figure the abscissa is expressed in terms of current density per unit geometrical area as well as per unit real area for the electrode. The presence of both scales enables one to relate the polarization curves to the present studies as well as the performance curves of fuel cells. The form of these curves is similar to those previously reported for methane (4) and ethane (3) with the perchloric acid electrolyte.

The polarization curves for the four fuels have been related to the steady-state values of Q_{E_1} and $Q_{E_{tot}}$ at the representative temperature of 100°C in Fig. 13-16. Here Q_{E_1} refers to the charge associated with the oxidation of species of wave 1; the values of Q_{E_1} were obtained by dropping a perpendicular from the minimum on the fuel oxidation trace and integrating

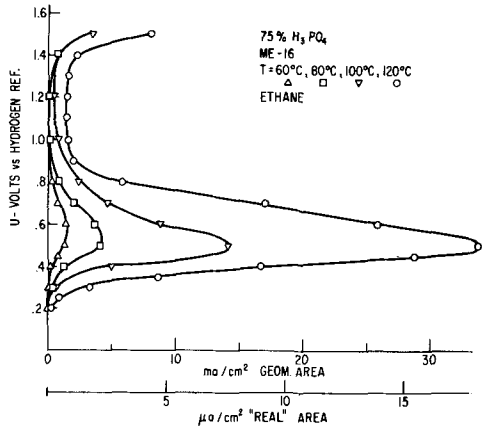

Fig. 12. Polarization curves for ethane at several temperatures

the area between curves 1 and 2 to the left of it in Fig. 3-6. In the case of butane the overlap of the individual waves prevented the determination of Q_{E_1}.

In general the form of the polarization curves is similar to those reported earlier for the perchloric acid system at lower temperatures. A comparison of the curves for ethane at 60°C with the two electrolytes reveals, however, that the maximum current with the phosphoric acid electrolyte is about 33% of that obtained with the perchloric acid. As with the perchloric acid electrolyte, the maximum currents occur at potentials at which there is still adsorbed fuel on the electrode surface.

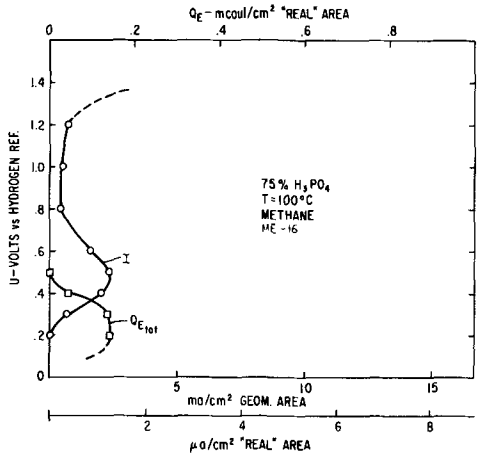

Fig. 13. Polarization and surface charge curves for methane

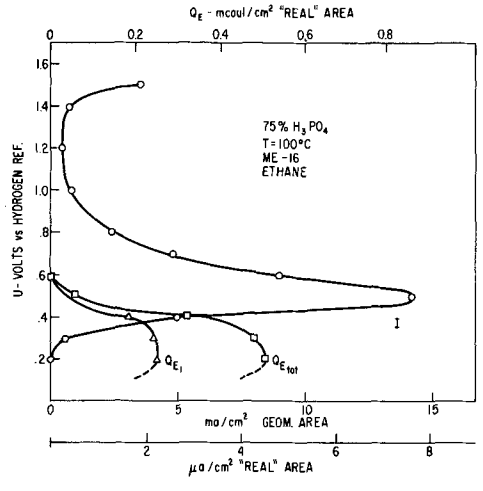

Fig. 14. Polarization and surface charge curves for ethane

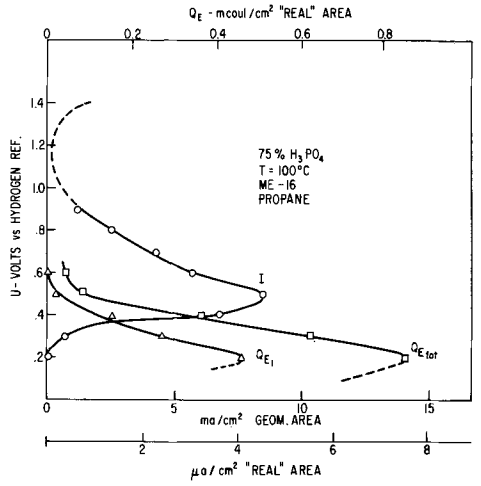

Fig. 15. Polarization and surface charge curves for propane

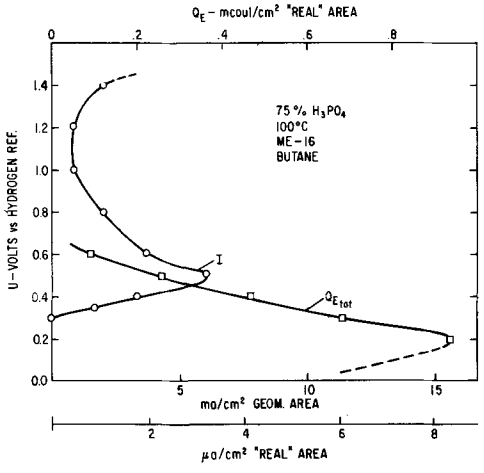

Fig. 16. Polarization and surface charge curves for butane

The maximum current occurred at about 0.5v with all of the fuels. A slight trend of the maximum toward lower voltages was evident as the temperature was increased. Arrhenius plots for the maximum currents for the four fuels indicated similar activation energies in all cases. This is shown by the normalized data plotted in Fig. 17. An average activation energy derived from these data is 14 kcal/mole.

Discussion

All of the results with the phosphoric acid electrolyte show marked similarities to those obtained with the perchloric acid. This includes the single oxidation wave for adsorbed methane, the multiple waves for ethane and propane, the similar effects of increasing the temperature, and the similar relationships between the polarization curves and the charges required for oxidation of the adlayers, *i.e.*, Q_{E1} and $Q_{E\text{tot}}$. These parallels indicate the absence of gross qualitative effects of the ionic double layer on the adsorption and surface behaviors of hydrocarbons on platinum electrodes. However, more subtle effects result in detectable quantitative differences between the two electrolytes. For example, the maximum current observed with ethane at 60°C with a perchloric acid electrolyte was 2.5 μa/cm² of real area and with the phosphoric acid 0.8 μa/cm². This undoubtedly reflects, in part, a stronger anion adsorption from the phosphoric acid electrolyte.

The new and more extensive data that have been obtained with propane and butane also support the earlier suggestion that similar surface reactions and surface intermediates are involved with all of the

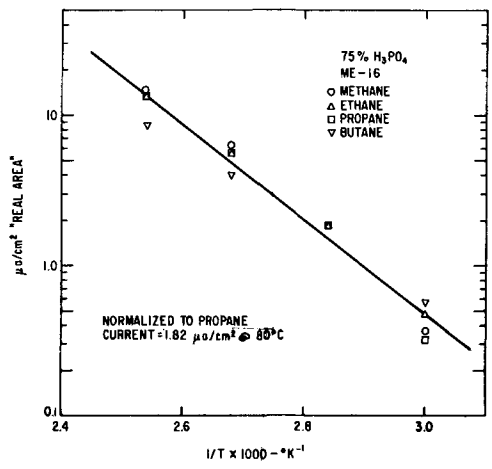

Fig. 17. Arrhenius plots for normalized maximum currents from several hydrocarbons.

saturated hydrocarbons above methane. Thus it appears that following the initial adsorption step two important reaction paths are available (1-4). The desirable path involves cracking to form a partially oxygenated intermediate which is oxidized further to CO_2 at relatively low overvoltages. The second path results in the accumulation of relatively refractory multiple carbon species on the surface. With the higher hydrocarbons it is likely that a variety of such species of different chain length form on the surface since it has been observed that propane produces C_2 species even at 25°C (9).

Increases in the values of Q_{E1} and $Q_{E\text{tot}}$ are also in strong evidence as the molecular weight of the fuel increases; *e.g.*, compare the areas between the blanks and the hydrocarbon traces in Fig. 3-6 as well as the surface charge curves in Fig. 13-16. The increase at 0.5-0.6v in going from methane to butane is of particular interest since it undoubtedly plays an important role in determining the magnitude of the maximum adsorption rate and hence the maximum current that can be drawn from an electrode, although other factors such as anion adsorption, surface oxidation, and bonding of water to the surface can also exert an influence. The accumulation of these refractory species, which can be removed at still higher potentials, is also suspect as an important cause of the current and voltage oscillations frequently encountered with hydrocarbon fuel cells (10, 11). One would expect in view of the trends in surface coverage so far observed that still higher molecular weight hydrocarbons would be more prone toward such oscillations. This has indeed been observed with operating fuel cells (12).

Because of the partial oxidation and cracking reactions, it is not possible to relate Q_{E1} and $Q_{E\text{tot}}$ directly to surface coverage. It is evident, however, from the data in Fig. 11 that the oxidizable species accumulate more rapidly as the molecular weight is increased, with the greatest increment occurring between methane and ethane. A similar trend is evident for the plateau representing steady-state coverage. In part this appears to relate to an increasing proportion of the species of wave 2 as the molecular weight increases. These relatively refractory species are believed to be partially dehydrogenated, but nonoxygenated.

The rate laws in all cases appear to be similar to the extent that a region in which $Q_{E\text{tot}}$ varies with the logarithm of the time precedes the eventual region of equilibrium coverage. The parabolic relationship for methane at low surface coverages (short equilibration times) suggests that mass transport effects may be important under these conditions. Lower solubility of methane in phosphoric acid than perchloric acid may account for the deviation from the initial linear

rate law that had previously been observed with the latter electrolyte. It is possible that similar deviations occur for the higher hydrocarbons at short equilibration times.

In the absence of adsorption rates on the "clean" surface it is not possible to compare these rates directly with the maximum current obtainable on the polarization curve as was done previously. From the data at longer equilibration times, however, it would appear that the initial adsorption rates of the four gases on the clean surfaces are in the order butane > propane > ethane >> methane. With the exception of methane this is the reverse order of the maximum currents as seen by the data of Fig. 13-16. Clearly then the adsorption of butane and propane is more hindered at the maximum than is methane or ethane.

Summary and Conclusions

The behavior of the model saturated hydrocarbons, methane through butane, on platinum-catalyzed electrodes is similar with perchloric acid and phosphoric acid electrolytes. With both electrolytes the adlayer on the electrode contains C_1 species some of which are undoubtedly oxygenated. The adlayers from the higher hydrocarbons also contain relatively refractory multiple carbon species, the coverage with such species increasing with the molecular weight of the fuel. These similarities and trends imply that a corresponding behavior will be followed by all saturated hydrocarbons.

In all cases the anodic performance is strongly influenced by the rate of adsorption and the ability of the catalyst to promote "cracking" of C-C bonds as well as the reaction of C_1 radicals with water. Accumulation of the refractory multiple-carbon species on the surface in turn influences the adsorption rate and results in maximum currents that can be markedly lower than those anticipated on the basis of adsorption rates on clean surfaces. It is also likely that these accumulated species play an important role in connection with the current and voltage oscillations that are frequently encountered with hydrocarbon fuel cells.

The Kinetics of Oxidation of Plutonium Metal and a Plutonium-3.4 a/o Aluminum Alloy at Temperatures from 140° to 550°C

J. G. Schnizlein and D. F. Fischer

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

The kinetics of oxidation of reactor grade plutonium and ultrapure plutonium were studied in oxygen and air at temperatures from 140° through 550°C. Paralinear rate laws apply over the entire range with a change of mechanism between 300° and 400°C. In the low-temperature range (140°-300°C) the process is postulated to be controlled by a compact layer of Pu_2O_3. Simultaneous growth of this layer and linear oxidation to PuO_2 results in paralinear kinetics whose rate constants are

$$k_{\text{parabolic}} = 1.6 \times 10^{15} \left[\exp\left(-27{,}400/RT\right)\right] (\mu g/cm^2)^2/\text{min}$$
$$k_{\text{linear}} = 1.6 \times 10^{8} \left[\exp\left(-16{,}800/RT\right)\right] (\mu g/cm^2)/\text{min}$$

Above 400°C the oxide produced is more protective and is postulated to include a layer of $PuO_{1.6}$ consistent with phase diagram studies. Paralinear kinetics are followed with simultaneous rate constants

$$k_{\text{parabolic}} = 1.8 \times 10^{12} \left[\exp\left(-22{,}500/RT\right)\right] (\mu g/cm^2)^2/\text{min}$$
$$k_{\text{linear}} = 8.8 \times 10^{9} \left[\exp\left(-26{,}400/RT\right)\right] (\mu g/cm^2)/\text{min}$$

The presence of moisture has no effect above 215°C, but causes a marked increase in the oxidation at lower temperatures. As little as 180 ppm moisture caused the linear rate at 190°C to accelerate an order of magnitude.

The presence of 3.4 a/o aluminum in plutonium markedly reduced the oxidation rates at temperatures below 400°C but only slightly reduced oxidation rates at higher temperatures.

The literature on the oxidation of plutonium is understandably limited because of the extreme toxicity and comparatively recent production of plutonium metal (1). Early studies at Los Alamos (2) and in Great Britain (3), conducted in air at temperatures below 100°C, demonstrated a marked increase of oxidation in the presence of moisture. Waber (4, 5) and Sackman (6) have reported that in humid air oxidation rates of plutonium follow logarithmic, parabolic, linear, and accelerating rate laws for extended periods of time. Sackman (7) showed that the oxidation rate at 25°C in moist argon (95% relative humidity, RH) is between 4 and 25 times that in moist air. He concluded, in agreement with Waber, that air oxidation produces a protective film and inhibits the faster reaction with moisture. The observation by Thompson (8) that oxidation is faster at 175°C in 360 mm oxygen with 35-40 ppm moisture than in 760 mm oxygen with 35 ppm moisture is consistent with the competitive reaction. In air at 255°C, with 38 ppm moisture, however, oxidation did not appear to accelerate and the higher pressure (760 mm) resulted in a slightly higher rate than was the case at 360 mm as might be expected for a slight pressure dependence. At the higher temperature no effect of small amounts of moisture was observed.

In dry air at low temperatures, parabolic behavior was usually observed. Sackman (6) observed that oxidation in dry air at 100°C would be represented by a succession of parabolic-shaped curves. The first parabolic rate continued nine days during which period the weight gain was 2.4 mg/cm². This would correspond to a film of plutonium oxide less than 20μ thick. It was thought that the rate of oxidation is limited by diffusion of oxygen ions through a thin film of PuO or Pu_2O_3. The oxide observed after completion of the experiment was PuO_2.

In studies of the oxidation of plutonium at higher temperatures, Waber (5) observed accelerating oxidation in oxygen at 345° and 400°C; Dempsey and Kay (9), using air as the oxidant, observed two-stage linear oxidation at 303°C, parabolic at 416°C, and initially parabolic at 487°C (accelerating to ignition after 300 min). The protective nature of the oxide film at 416°C, when the metal has a delta phase structure, resulted in a lower oxidation rate than at lower temperatures. Notley *et al.* (10) later demonstrated that the oxidation rate passes through a minimum in the vicinity of 416°C. Since the relative amount of adherent oxide to porous oxide increased when the temperature was increased from 400° to 450°C, they proposed that the minimum oxidation rate could be a net result of the increased thickness of adherent oxide and the simultaneous increase of the rate of oxygen diffusion with increased temperature. X-ray diffraction studies showed the readily removable oxide to be PuO_2 and the adherent interfacial oxide to include both cubic and hexagonal Pu_2O_3. Properties and phase relationships of the oxides in the plutonium-oxygen system were reported by Holley *et al.* (11), Chikalla *et al.* (12), and recently by Gardner, Markin, and Street (13). Markin and Rand (14) very recently revised the temperature scale.

The addition of aluminum to plutonium is known to extend the range of stability of the delta phase. The phase diagrams determined by investigators from the Soviet Union (15) and from Los Alamos (16) indicate 3.4 a/o (atom per cent) aluminum stabilized the delta phase from about 290° to 520°C. Without aluminum present the delta phase is stable from 320° to 450°C. Ignition temperatures of the 3.4 a/o aluminum alloy are also higher than for pure plutonium (17). Waber (18) and Sackman (6) have shown that addition of aluminum confers considerable oxidation resistance to plutonium in moist air at temperatures below 100°C.

The present investigation of the oxidation of plutonium at temperatures from 140° to 550°C covers a wider temperature range than any previous study. The objectives have been to provide data on the kinetics of oxidation and information about the rate-controlling mechanisms to aid in understanding the

ignition behavior. The study of preoxidation at high temperature was made to provide insight on the importance of the oxide produced and the understanding of the mechanism of oxidation. The relative effects of the presence of moisture on the oxidation at various temperatures have been evaluated. Isothermal oxidation of a plutonium-3.4 a/o aluminum alloy was studied to aid in understanding the effect of aluminum on the ignition behavior and to evaluate the possible effect of a stabilized delta phase.

Material and Procedure

Plutonium samples of high-purity, reactor grade were obtained from Hanford[1] in the form of 5 and 10 mm cubes. Concentrations of metallic impurities totaled less than 700 ppm. A few samples of ultrapure plutonium were obtained from Metallurgy Division, ANL.[2] The plutonium for these samples was produced by electrolysis of a fused salt mixture and was purer by an order of magnitude than the Hanford material. The electrolytic plutonium was 99.84 a/o pure. Analytical data on impurities in the two supplies of plutonium are presented in Table I. Prior to oxidation the cubes were polished through 600 grit silicon carbide metallographic paper.

Oxygen and air from cylinders were used for most of these studies without further purification. To avoid the use of contaminated gas, each gas cylinder was sampled and analyzed by mass spectrography prior to use. Typical analysis expressed in volume per cent was as follows: oxygen 99.7 O_2, 0.3 N_2, 0.01 Ar, 0.03 H_2O; air 20.7 O_2, 78.5 N_2, 0.92 Ar, 0.1 H_2O.

Because of the extreme toxicity of plutonium, all operations were performed in a glove box. The box atmosphere was dry nitrogen to avoid accidental oxidation during sample preparation and handling. The course of oxidation was followed by the increase in weight of a sample. A recording balance which automatically adds weights (Ainsworth model 1 AU) was equipped with a temperature transducer (19) to permit continuous measurement of the sample temperature without interfering with the operation of the balance.

At about 480°C problems were encountered with self-heating due to the high oxidation rates and minimal heat loss from the sample. Dempsey (7) observed ignition after 300 min in a furnace at 478°C. This self-heating was markedly minimized by clamping two stainless steel plates onto the plutonium sample. These stainless plates served as heat sinks so that during oxidation a sample initially at 541°C was maintained at 557°C after 0.6 min. Control experiments at 350° and 460°C showed no detectible effect of the plates on the oxidation data.

Experimental Results

Reactor grade plutonium.—Oxidation experiments were performed at temperatures from 140° through 550°C in oxygen or air. In general, the observation of somewhat different behavior in the temperature ranges of each of the different phases (see Fig. 1) is consistent with that reported by Dempsey and Kay (7). In the range of the beta phase (120°-220°C), a three-stage oxidation was observed. The third stage showed a linear rate of 20 (μg O_2/cm^2)/min which did not appear to be temperature dependent. This third stage was shown to be caused by very small moisture content in the oxidizing gas (see below). In the range of the gamma phase (220°-320°C), after an initial deviation, an apparently linear rate was observed, ranging from 80 to 200 (μg/cm^2)/min. In the range of the delta phase (320°-450°C) a minimum in the oxidation rate was observed, indicating a change in the mechanism. Above 400°C the oxide becomes more protective so that the extent of oxidation after 15 min is less at 420° than at 283°C. Through the range of the delta prime phase (450°-480°C) and into the epsilon phase (480°-640°C) to the maximum temperature studied at 558°C, the oxidation is initially parabolic followed by a linear rate. The linear rate was 1200 (μg/cm^2)/min at 558°C.

By careful examination of the initial portion of each oxidation run, it was possible to show an initial fit to the parabolic rate law. Figure 2 illustrates the initial parabolic rate law agreement for the same selected experimental data presented in Fig. 1. The value of the parabolic rate constant in (μg O_2/cm^2)^2/min is included with each temperature.

An Arrhenius plot of the parabolic rate constants is presented in Fig. 3. It is apparent that the same initial rate control process is in effect over the temperature range from 140° to 300°C. Application of the method of least squares to all the data in this temperature range provided an apparent activation energy of 29.2 ± 1.4 kcal/mole, and the pre-exponential of 5.5 x 10^{16} (μg O_2/cm^2)^2/min. Above 400°C a somewhat dif-

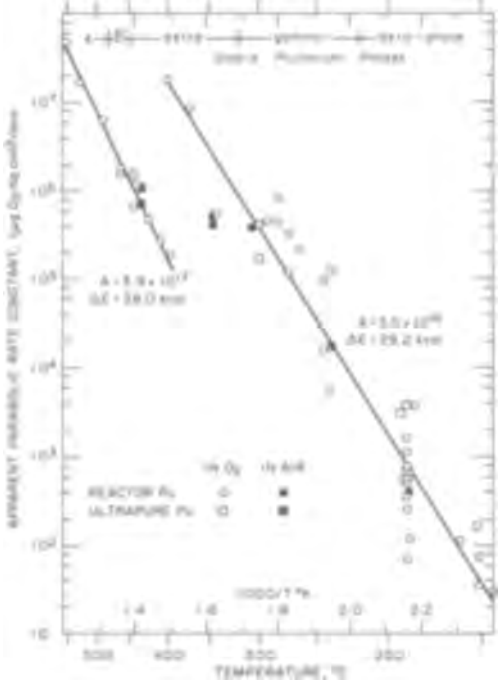

Fig. 3. Initial parabolic oxidation rate data

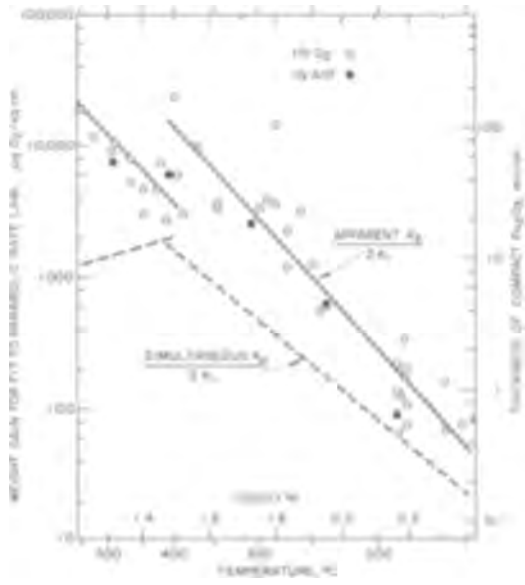

Fig. 4. Compact film thickness based on weight gain at deviation from parabolic rate law and ratio of parabolic-to-linear rate constants.

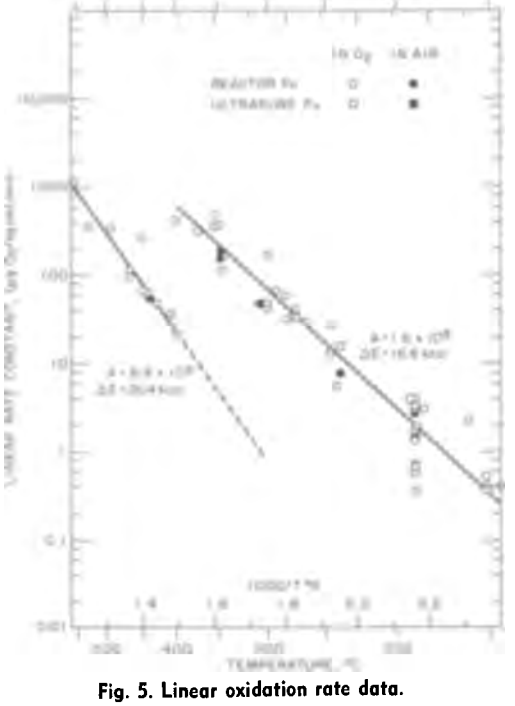

Fig. 5. Linear oxidation rate data.

ferent rate limiting process is indicated by an apparent activation energy of 38.0 ± 2.5 kcal/mole and a preexponential of 3.9 x 10^{17} $(\mu g\ O_2/cm^2)^2/min$. These activation energies are reasonable values for solid-state diffusion of oxygen ions through a thickening oxide film.

Subsequent to the parabolic portion, the adherent layer of compact oxide should remain essentially constant in thickness. Figure 4 illustrates the extent of oxidation at which the oxidation deviates from the fit to a parabolic rate law at various temperatures. Calculated on the basis of densities of plutonium oxides and the extent of oxygen consumed, the thickness varies from approximately 0.5μ at 150°C to 50μ at 350°C. Above 400°C the compact film is more protective, and the apparent thickness increases from about 20μ at 400°C to about 100μ at 550°C.

The linear rate constants for the oxidation subsequent to the parabolic portion are presented in an Arrhenius plot in Fig. 5. The activation energy for the linear process from 140° to 400°C was calculated by least squares method to be 16.8 ± 0.7 kcal/mole. The pre-exponential was 1.6 x 10^8 $(\mu g\ O_2/cm^2)/min$. Above 400°C the more protective underlying film causes the linear process to have an apparent activation energy of 26.4 ± 1.8 kcal/mole and a pre-exponential of 8.8 x 10^9 $(\mu g\ O_2/cm^2)min$.

Electrolytic ultrapure plutonium.—Isothermal oxidations were performed at 151°, 190°, 192°, 240°, 300°, and 438°C with the limited number of samples of ultrapure plutonium which had been prepared by electrolysis from fused salts. The results showed the same characteristic behavior as was observed with reactor grade plutonium obtained from Hanford. All rate constants obtained with the ultrapure plutonium were within the limits of deviations of the other data.

Effect of preoxidation at high temperature.—Two experiments were performed to test whether or not the oxide formed during the high-temperature process (above 400°C) would remain more protective when oxidation was continued at a lower temperature

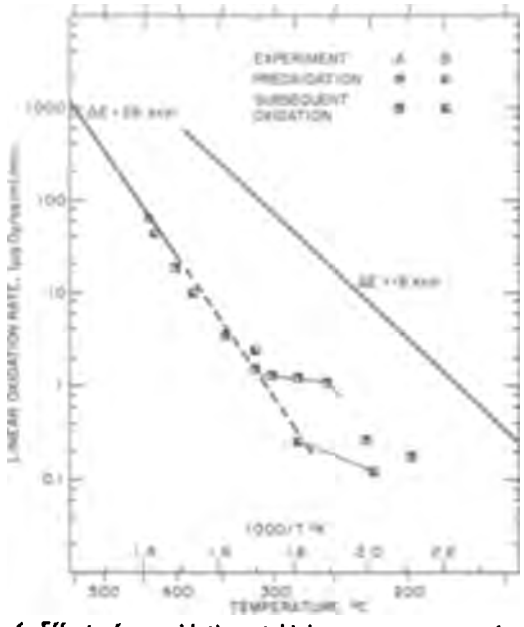

Fig. 6. Effect of preoxidation at high temperature on subsequent oxidation at lower temperature.

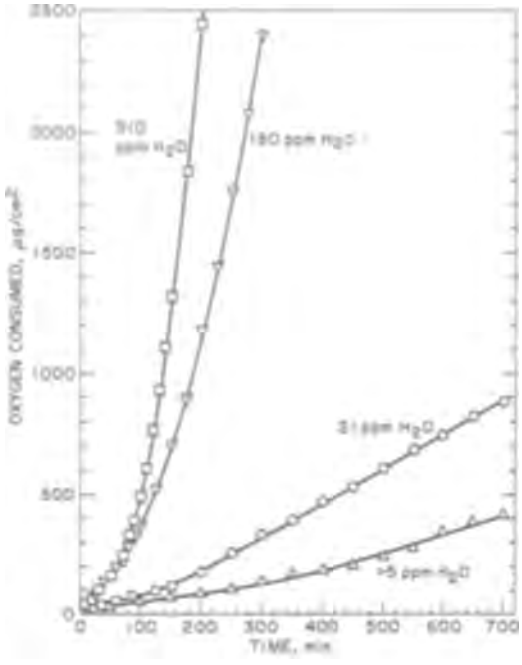

Fig. 7. Effect of moisture on oxidation of plutonium at 190°C in oxygen.

than that normally produced at lower temperatures. Ultrapure plutonium samples were oxidized at 430° and 440°C until 6500 and 11,000 μg O_2/cm^2, respectively, were consumed. The oxidations were proceeding at linear rates of 43 and 63 ($\mu g/cm^2$)/min, respectively. Then, without removal of the oxygen, the temperature was decreased and controlled at a new lower temperature. After a new linear rate was determined, the temperature was reduced again. The linear rate observed at each temperature was markedly lower than the rate expected from the data for low-temperature oxidation. However, when the sample was cooled to room temperature overnight and then reheated, a higher rate was again observed indicating that the reduced oxidation rate below 250°C caused by preoxidation is only temporary.

These data are compared with the previously determined data on the Arrhenius plot in Fig. 6. It is evident from the agreement to an extrapolation (dotted line) of the high-temperature data that the oxide produced at the higher temperature was stable to 318°C in the first experiment and 280°C in the second experiment.

Effect of moisture.—Most of the oxidation experiments were performed in oxygen or air containing a few hundred parts per million moisture. At temperatures below 210°C the oxidation rate would accelerate after a period of time under these conditions. The final rate ranged from 12 to 25 (μg O_2/cm^2)/min at temperatures near 140°C and from 16 to 30 (μg O_2/cm^2)/min near 190°C. This third stage was essentially independent of temperature while the initial parabolic rates and intermediate linear rates varied with temperature consistent with the activation energies deduced from experiments between 215° and 320°C.

The moisture content of the oxidizing gas could be maintained at low values only by exercising extreme care. It was also necessary to eliminate cellulose-type filters used to avoid escape of plutonium from the glove box. Experiments performed with less than five parts per million moisture in the oxygen at 300° and 440°C were, within normal limits, the same as those performed with moisture contents of a few hundred parts per million. Two experiments with 20,000 ppm moisture in air were also performed at 430°C with no evident effect on the oxidation.

In contrast, at 190° and 150°C the third stage was eliminated by the use of extremely dry oxygen (< 5 ppm moisture). The high oxidation rate, 20 ($\mu g/cm^2$)/min, previously called a third stage in the oxidation between 100° and 200°C, is thus attributable to moisture. It is noteworthy that this high rate can be produced by a moisture content as low as 180 ppm and is a similar value to that observed by Dempsey (9) with 10,000 ppm (55% relative humidity) in air at 205°C. In our work, as little as 20 ppm moisture in the oxygen caused some acceleration in the oxidation curve. Figure 7 illustrates the oxidation behavior of plutonium in oxygen at 190°C with four levels of moisture content, 510, 180, 21, and < 5 ppm.

Another experiment illustrated the behavior when the moisture content was changed during the course of an oxidation at 190°C. When the moisture content was increased from 21 to 180 ppm the oxidation rate increased quickly from 1.2 to 1.5 ($\mu g/cm^2$)/min, then further increased to 3.4 with 510 ppm moisture content, and then decreased to 0.71 with 21 ppm moisture content.

Interestingly, extrapolation of the linear rate data obtained above 215°C with or without moisture and the linear data between 200° and 140° under dry conditions agrees within a factor of 2 with the data obtained under dry conditions below 100°C by Kolodney (2), Waber (4), and Sackman (6). They found increases due to moisture to be factors of 100 to 1000.

Effect of aluminum addition to plutonium.—Isothermal oxidation of 5-mm cubes of plutonium-3.4 a/o aluminum alloy have been performed at temperatures from 150° through 588°C on the thermobalance. The results obtained in a few runs in air were not different from those obtained in oxygen. In general, a paralinear behavior was observed which was similar to that of unalloyed plutonium, but at all temperatures the rates for the alloy were lower. Oxidation data for plutonium-3.4 a/o aluminum are compared with data for unalloyed plutonium at a few selected temperatures in Fig. 8. The data for the initial portion of the reaction can be treated as an apparent parabolic or as simultaneous parabolic and linear process as will be explained in the discussion below. The apparent parabolic, simultaneous parabolic, and subsequent linear rate constants obtained are presented in Table II. The parabolic rate constants for the plutonium-3.4 a/o aluminum alloy are compared with those for unalloyed plutonium in Fig. 9, while the linear constants for the alloyed and unalloyed metal are compared in Figure 10.

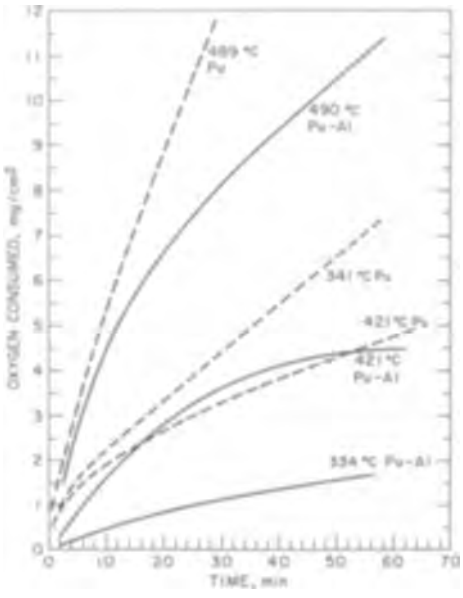

Fig. 8. Oxidation data for plutonium and plutonium-3.4 a/o aluminum alloy in oxygen.

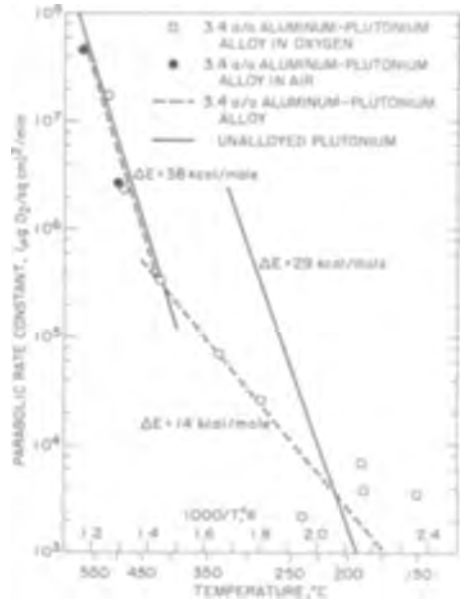

Fig. 9. Parabolic oxidation data for plutonium and plutonium-3.4 a/o aluminum alloy.

In the high-temperature region (above 420°C), the parabolic rate constants for the alloy are very similar to those for unalloyed plutonium. The linear rate constants are about a factor of two lower, but indicate the same activation energy. This is consistent with the observed ignition temperatures which are approximately 70° higher than those for unalloyed plutonium in the high-temperature regime (17).

At lower temperatures (below 420°C), both parabolic and linear rates are very much lower and indicate different activation energies than for unalloyed plutonium. The activation energy for the parabolic process is about 14 kcal/mole and for the linear process about 13 kcal/mole.

Discussion

Previous literature on the oxidation of plutonium has tended to attach considerable importance to the stable phases of the metal. This study indicates consistent activation energies over the temperature ranges of several metal phases. The same process appears to occur through the temperature ranges of the beta and gamma phase and may be extrapolated to include the range of the alpha phase. Another applies over the range of delta, delta prime, and epsilon phases. Thus, it is more appropriate to consider the control process to be attributed to the oxide. The principal features in the kinetics of oxidation reached are the observed

paralinear process and the change of mechanism between 300° and 400°C. Only speculations about the observed effects of moisture and aluminum are possible at this time.

Paralinear kinetics.—Paralinear kinetics have been observed for the oxidation of numerous metals (20). The mechanism to explain this behavior is usually initial growth of a compact adherent oxide film to a limited thickness. The growth process results in a parabolic rate law. When the outer portion becomes porous or is further oxidized to a higher oxide which affords less protection, in a manner that leaves a constant thickness of compact oxide, a linear rate law results. The parabolic rate constants presented in the previous section (Fig. 3) were determined from the original data and would apply to the case of a compact oxide undergoing a change, at some time after a finite thickness was formed, as a consecutive process.

Alternatively, if both compact and porous oxide are formed initially the two processes can be considered to be simultaneous. Simultaneous processes

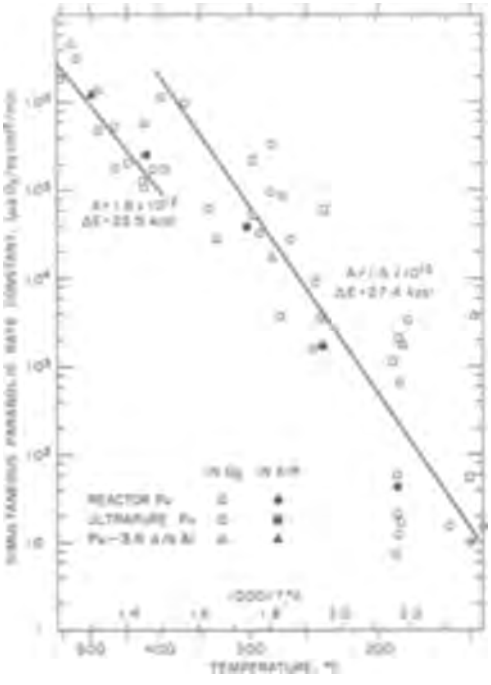

Fig. 11. Simultaneous parabolic rate data

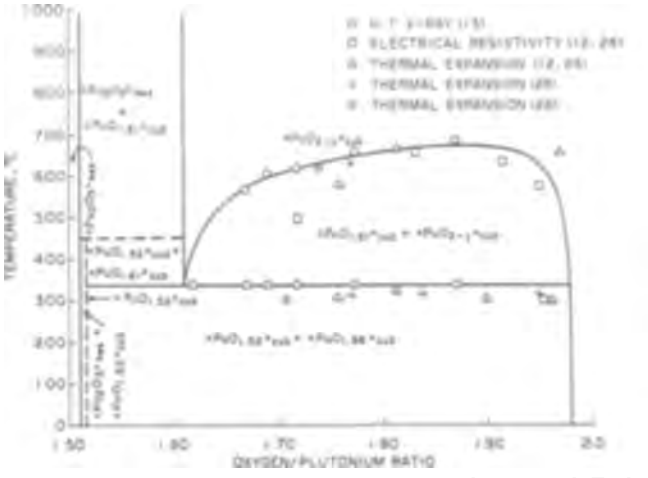

Fig. 12. Plutonium-oxygen phase diagram. Courtesy of T. L. Markin (14).

have been discussed by Haycock (21), Jepson and Aylmore (22), and Wajszel (23). The linear process is assumed constant from the beginning of the oxidation and is predominant after a long time of reaction.

The ease of oxidation of lower oxides to PuO_2 makes it more probable that the reactions occur simultaneously rather than consecutively. Parabolic rate constants for simultaneous reaction were redetermined for each experiment by subtracting the portion of oxygen consumption attributable to the linear process near the end of the experiment. An Arrhenius plot of these parabolic rate constants for a simultaneous process in Fig. 11 indicate an activation energy of 27.4 ± 3.3 kcal/mole and pre-exponential of 1.6 x 10^{15} (μg $O_2/cm^2)^2$/min for the low-temperature region and an activation energy of 22.5 ± 3.9 kcal/mole and pre-exponential of 1.8 x 10^{12} (μg $O_2/cm^2)^2$/min for the high temperatures. The activation energies for initial parabolic oxidation process, whether consecutive or simultaneous with the linear process, are reasonable values for solid-state diffusion of oxygen ions through a compact oxide. No data on oxygen diffusion in plutonium oxides have been found in published literature.

Mechanism change between 300° and 400°C.—The change in kinetics between 300° and 400°C results in a minimum in the over-all oxidation rates at about 400°C. It has been tempting to attribute this behavior to a property of the delta phase metal since early studies (5) had shown ". . . alloying elements that stabilize the delta phase confer substantial corrosion resistance . . .". However, it is more appropriate to attribute the kinetic change to the oxide film. Notley (10) postulated the minimum rate to be the net result of increased film thickness and increase of oxygen diffusion at higher temperature. If the compact film is to become thicker, the extent of oxidation attributable to the parabolic rate law should become greater at 400°C. Consideration of the extent of oxidation for parabolic rate law fit presented in Fig. 4 does not indicate an increase of film thickness between 300° and 400°C.

Haycock (21) deduced the following relationship between compact film thickness and rate constants.

$$\frac{d\mu}{dt} = \frac{k_p}{2\mu} - \frac{bk_l}{a}$$

where μ is the compact film thickness, t is time, k_p is the parabolic rate constant, k_l is the linear rate constant, and b and a are the conversion factors for thickness of porous and compact films, respectively.

As μ approaches a thickness given by $k_p/2\mu = bk_l/a$ then $d\mu/dt$ approaches zero. The inner layer, therefore, approaches a constant thickness $\mu = (a/b)\ k_p/2k_l$. Considered as a consecutive process, the thickness of stable compact film (data points) agree well with this relationship between rate constants and film thickness $\mu = k_p/2k_l$,[3] which is represented by the solid line in Fig. 4. If the linear and parabolic processes are considered to occur simultaneously and the ratio of the new reduced parabolic rate law constant to $2k_l$ is calculated, the dashed line in Fig. 4 is obtained. This relationship indicates thinner compact films at all temperatures and nearly constant film thickness above 400°C. This leads to the conclusions that a change of the compact oxide film occurs between 300° and 400°C and that the diffusion of oxygen through that oxide is reduced.

Chikalla (12) and McNeilly (24) have pointed out discontinuities in thermal expansion and electrical resistivity measurements of plutonium oxides with an oxygen-to-plutonium ratio between 1.64 and 1.98 at approximately 300°C. The plutonium-oxygen phase diagram given by Chikalla and associates (12), Gardner (13), and most recently by Markin and Rand (14) indicates a phase change in the oxide above 300°C. The plutonium-oxygen phase diagram according to Markin and Rand (14) has been reproduced for convenience in Fig. 12. The modification by Gardner (13) in the region of oxygen-to-plutonium ratios between 1.5 and 1.61 makes it reasonable to attribute the decreased oxidation rate above 400°C to the formation of the cubic phase $PuO_{1.61}$ in addition to the partially protective layer of Pu_2O_3. The pre-oxidation experiments demonstrate that when formed at higher temperature the new oxide is stable down to about 300°C. The rapid transformations and inability by Gardner (13) to quench the single phase material to room temperature explains the observation by Notley (10) of hexagonal and cubic Pu_2O_3 in the compact oxide from most experiments.

Effect of moisture.—The presence of moisture during the oxidation of plutonium does not influence the rate at temperatures above 215°C, but even very small amounts cause marked acceleration at temperatures below 200°C. The observation of an even higher

[3] The correction a/b is considered negligibly close to unity since the relationships of weight gain to film thickness for various oxides are very similar. 1 mg O_2/cm^2 is equivalent to 7.2μ hexagonal Pu_2O_3, 8.0μ cubic Pu_2O_3, and 7.4μ PuO_2 thickness.

rate in moist helium than in moist air leads to the conclusion that the presence of moisture causes partial breakdown of the protective layer of oxide formed in oxygen. The near absence of temperature dependence of the high oxidation rate of ~20 (μg O_2/cm^2)/min observed in oxygen or air containing a few hundred parts per million moisture may be the result of a balance between the formation of a protective layer by oxygen reaction and its destruction by reaction with moisture. This may occur by formation of a hydrated oxide or plutonium hydroxide. Sackman (6) reported that weight gains of plutonium on complete oxidation in moist air were greater than calculated for PuO_2 and correspond to $PuO_2 \cdot 0.1\ H_2O$. No information on the stabilities of hydrated oxide or hydroxide under these conditions appear available at this time.

Effect of addition of 3.4 a/o aluminum.—Addition of 3.4 a/o aluminum to plutonium improves the oxidation resistance at all temperatures. The high-temperature process is very similar to that of pure plutonium. Further speculations about the decreased oxidation are heuristic without knowledge of the effects of aluminum oxide on the phase diagram of plutonium oxides. The increase in the simultaneous parabolic rate constants without apparent change of activation energy in the high-temperature region might indicate an increase of oxygen ion diffusion through $PuO_{1.61}$. The linear rate may be lower because of a slightly thicker compact film. In the low-temperature region the presence of aluminum seems to cause a completely different oxidation process than for pure plutonium. In addition, the change of activation energy of the process at about 420°C does not indicate that the decreased oxidation should be attributed to delta phase stabilization. Further study of the effect of varied aluminum content should be informative.

Conclusion

The oxidation of plutonium between 140° and 550°C in air or oxygen follows paralinear kinetics with a change of mechanism between 300° and 400°C. Below 300°C the initial protective oxide is probably hexagonal Pu_2O_3. If this film has a limited thickness of stability and the linear process is a result of subsequent formation of porous oxide on the outside, the apparent parabolic rate constant is defined.

$$k_p = 5.5 \times 10^{16} [\exp(-29{,}200/RT)]\ (\mu g\ O_2/cm^2)^2/min$$

If the linear process occurs simultaneously from the beginning the parabolic rate constant is

$$k_p' = 1.6 \times 10^{15} [\exp(-27{,}400/RT)]\ (\mu g\ O_2/cm^2)^2/min$$

The linear rate constant between 140° and 300°C is

$$k = 1.6 \times 10^{8} [\exp(-16{,}800/RT)]\ (\mu g\ O_2/cm^2)/min$$

Above 400°C additional protectiveness of the oxide is observed which is attributed to the formation of cubic $PuO_{1.61}$ in addition to the hexagonal Pu_2O_3. This is consistent with the most recent phase diagram of the plutonium-oxygen system (14). If the paralinear kinetics is considered to be a consecutive process, the apparent parabolic rate constant is defined

$$k_p = 3.9 \times 10^{17} [\exp(-38{,}000/RT)]\ (\mu g\ O_2/cm^2)^2/min$$

If the linear process occurs simultaneously from the beginning, the parabolic rate constant is

$$k_p' = 1.8 \times 10^{12} [\exp(-22{,}500/RT)]\ (\mu g\ O_2/cm^2)^2/min$$

The linear rate constant above 400°C to the maximum temperature studied of 558°C is

$$k = 8.8 \times 10^{9} [\exp(-26{,}400/RT)]\ (\mu g\ O_2/cm^2)/min$$

If plutonium is preoxidized above 400°C, the linear rate continues to fit the high-temperature equation down to approximately 300°C.

The presence of moisture does not affect the oxidation above 215°C. Below this temperature very small quantities of moisture causes marked acceleration to a linear rate of about 20 (μg O_2/cm^2)/min in the temperature range of 100°-190°C.

The content of 3.4 a/o aluminum in the plutonium alloy causes only small changes in the high-temperature regime but marked differences at lower temperatures.

Manuscript received Dec. 6, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Free Energy of Formation of Cupric Oxide

L. R. Bidwell

Metallurgy and Ceramics Research Laboratory,

Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio

ABSTRACT

The standard molar free energy change for the oxidation of cuprous oxide to cupric oxide was determined over the temperature range 973°-1273°K using galvanic cells employing calcia stabilized zirconia as the electrolyte. The measurements predict a temperature of 1298°K for the decomposition of cupric oxide in air, in good agreement with the generally accepted value of 1299°K. The standard molar free energies of formation of cupric oxide were calculated from the experimental data using previously determined values for $\Delta G^\circ_{Cu_2O}$. The results can be represented by the equation

$$\Delta G^\circ_{CuO} = -35{,}750 + 19.97T \pm 100 \text{ cal mole}^{-1}$$

which is somewhat less negative than values estimated from calorimetric and dissociation pressure measurements.

The best available data for the standard molar free energy of formation of cupric oxide at elevated temperatures have been estimated from calorimetric and dissociation pressure measurements (1-3). The uncertainty in these data is of the order of 4 kcal mole^{-1}. This work was undertaken to obtain more accurate data for use in an investigation of the thermodynamic properties of solid copper-platinum alloys (4) by solid galvanic cell techniques (5).

Experimental

Since excellent data for $\Delta G^\circ_{Cu_2O}$ were available from previous work in this Laboratory (6), ΔG°_{CuO} could be obtained by determining the free energy change for the reaction

$$Cu_2O + \tfrac{1}{2}\, O_2 \rightleftharpoons 2\, CuO \qquad [1]$$

from the open-circuit potential of the following cell

$$Cu_2O, CuO \mid Zr_{0.85}\, Ca_{0.15}\, O_{1.85} \mid O_2\ (air) \qquad [I]$$

Solid galvanic cells employing calcia stabilized zirconia as the electrolyte have been used with considerable success by Kiukkola and Wagner (7, 8) and by many others to determine the standard free energies of formation of oxides at elevated temperatures. The essentially pure ionic conductivity of this electrolyte at high temperatures and at oxygen pressures of 10^{-15} atm and greater has been well established (7-10). Thus, the difference in the chemical potential of oxygen at the anode and at the cathode of the above cell, and hence the change in free energy for [1], is related to the electrical potential of the cell by the relationships

$$\mu_{O_2}{}^a - \mu_{O_2}{}^c = -\Delta G_{[1]} = 2\mathbf{F}E \qquad [2]$$

where **F** is Faraday's constant.

The experimental apparatus used in this work was similar to that employed in a previous investigation (5), with the exception of several important modifications. The cell was enclosed within a gas-tight quartz reaction tube that could be evacuated. The cell holder was modified to permit the use of an air electrode. This was achieved by substituting a closed-end calcia-stabilized zirconia tube containing an internal spring-loaded platinum electrical contact for the mullite push-rod. A gas-tight seal between the zirconia tube and the tapered brass holder was accomplished with a compression O-ring. The mixed copper oxide anode tablet was separated from the zirconia tube by a disk of electrolyte material. This prevented the cathode tube from being contaminated so that it need not be replaced when using different types of anodes. The zirconia tube and the mullite thrust reversal tube were independently spring-loaded to the tapered brass joint in order to keep the cell components in firm electrical contact at all temperatures. A combustion boat containing a 3:1 mixture of CuO and Cu_2O was placed in the hot zone of the furnace to keep the anode environment at the proper oxygen pressure.

The preparation of the electrolyte tablets has been described in an earlier publication (5). The closed-end cathode tube was obtained from the Zirconium Corporation. The mixed oxide anode tablets were prepared from Baker reagent grade Cu_2O and CuO obtained by oxidizing some of the Cu_2O in air. A 1:1 mixture of the two oxides was blended and cold-pressed in a hardened steel die at 50 tsi into tablets 6 mm in diameter by 3 mm thick.

At the beginning of an experiment, the cell apparatus was evacuated to approximately 10^{-3} Torr with a mechanical vacuum pump. The quartz reaction tube was then sealed from the pump and the furnace heated to temperature. The gas pressure within the anode compartment was thus largely dictated by reaction [1]. Cell potentials were measured to 0.1 mv with increasing and decreasing temperature over the temperature range 973°-1273°K with a L&N K-3 potentiometer and a high sensitivity galvanometer. Temperatures were measured with a Pt-13% Rh thermocouple placed within 1 mm of the electrolyte tablet. The thermocouple used for this purpose was calibrated against a second thermocouple that had been calibrated by the National Bureau of Standards. The resulting temperature measurements are therefore believed to be accurate to within ± 1°K.

The observed cell voltages were very stable with time and the cells appeared to be thermodynamically reversible. No tendency for polarization could be detected. After a small current had been passed through a cell by momentarily unbalancing the potentiometer, the potential returned to its initial value almost immediately. Data that were recorded with increasing or decreasing temperatures did not exhibit any systematic differences.

Results

The average values of the cell potentials for four separate experimental runs are listed in Table I. The reproducibility, as indicated, was better than ± 1 mv at all temperatures except 1273°K, where the scatter was somewhat greater (± 1.9 mv). The latter is undoubtedly an indication that the combustion boat of mixed copper oxides had difficulty in establishing the relatively high oxygen pressure required for equilibrium between CuO and Cu_2O at that temperature. The experimental data are well represented by the linear equation

$$E\,(\text{mv}) = 678.7 \pm 1.0 - 0.5228T \qquad [3]$$

Table I. Electromotive force of cell

Cu_2O, CuO | electrolyte | O_2 (air)

Temperature, °K	Number of determinations	E, mv	cal mole^{-1} $\Delta G°_{[1]}$	cal mole^{-1} $\Delta G°_{CuO}$
973	5	170.0 ± 0.7	−9,350	−16,320
1023	5	143.9 ± 0.4	−8,220	−15,320
1073	6	117.7 ± 0.7	−7,090	−14,320
1123	6	91.6 ± 0.9	−5,970	−13,320
1173	6	65.5 ± 0.5	−4,840	−12,330
1223	6	39.3 ± 0.5	−3,710	−11,330
1273	5	13.2 ± 1.9	−2,580	−10,330

calculated by a least squares analysis. This equation predicts a temperature of 1298°K for the decomposition of CuO in air (*i.e.*, E = O and Cu_2O, CuO, and air are in equilibrium), which is in excellent agreement with the generally accepted value of 1299°K (11).

The standard free energy changes, $\Delta G°_{[1]}$, for reaction [1] calculated from the relationship

$$\Delta G°_{[1]} = -2FE + 1/2\ RT \ln p_{O_2}\ (\text{air}) \qquad [4]$$

are listed in Table I. Since at 1 mv uncertainty in the cell potential corresponds to approximately 50 cal mole^{-1} uncertainty in ΔG, the accuracy of $\Delta G°_{[1]}$ should be ±50 cal mole^{-1} or better. The standard states tacitly assumed by this calculation are Cu_2O saturated with oxygen, CuO saturated with copper, and pure oxygen at 1 atm pressure.

Previous solid galvanic cell measurements involving Cu, Cu_2O; Ni, NiO; Fe, Fe_xO; and air electrodes that have been carried out in this Laboratory have yielded reliable, self-consistent free energy data from which the standard molar free energy of formation of Cu_2O over the temperature range 973°-1273°K was determined to be (6)

$$\Delta G°_{Cu_2O} = -40{,}200 + 17.37T \pm 100 \text{ cal mole}^{-1} \qquad [5]$$

Using these values for $\Delta G°_{Cu_2O}$, the standard molar free energies of formation of CuO were calculated from the relationship

$$\Delta G°_{CuO} = 1/2\ (\Delta G°_{Cu_2O} + \Delta G°_{[1]}) \qquad [6]$$

These results are listed in Table I and are well represented by the linear equation

$$\Delta G°_{CuO} = -35{,}750 + 19.97T \pm 100 \text{ cal mole}^{-1} \qquad [7]$$

Discussion

It should be pointed out that the standard state for Cu_2O used in Eq. [5] is Cu_2O saturated with copper, whereas, the standard state employed in this investigation in [4] is Cu_2O saturated with oxygen. The above calculation of $\Delta G°_{CuO}$ therefore assumes that

$$\mu_{Cu_2O(Cu)} = \mu_{Cu_2O(CuO)} \qquad [8]$$

i.e., that the chemical potential of Cu_2O in equilibrium with Cu is equal to the chemical potential of Cu_2O in equilibrium with CuO. This assumption should be valid since Cu_2O is a compound of essentially fixed composition (11). Wagner (12) has shown that the chemical potential of phases whose composition does not deviate greatly from stoichiometry is essentially constant.

Table II. Standard molar free energies of formation of CuO

Temperature, °K	cal mole^{-1} Calculated Eq. [13]	cal mole^{-1} Wicks and Block (2)
1000	−15,780	−16,050
1100	−13,780	−14,100
1200	−11,790	−12,150
1300	−9,790	−10,250

Taking into account both the uncertainties in $\Delta G°_{Cu_2O}$ and in the experimental measurements, the values of $\Delta G°_{CuO}$ calculated from Eq. [7] should be accurate within approximately ± 100 cal mole^{-1} over the 973°-1273°K temperature range of this investigation. Values of $\Delta G°_{CuO}$ calculated at several temperatures are compared, in Table II, with data recently tabulated by Wicks and Block (2). As can be seen, the agreement is reasonably good, however, the differences that exist are much larger than the uncertainties in the present experimental data. Since the methods used to determine $\Delta G°_{CuO}$ in this investigation represent a more direct measurement than the values calculated from dissociation pressure and heat content data, they are to be preferred.

Acknowledgments

The author would like to thank Mr. D. F. Frank for his assistance in the experimental portion of this investigation. He would also like to thank Dr. F. E. Rizzo and Dr. H. A. Lipsitt for their helpful discussion of the work.

The Effects of Crystallographic Orientation and Oxygen Pressure on the Oxidation of Iron

W. E. Boggs, R. H. Kachik, and G. E. Pellissier

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

When clean iron is exposed to oxygen at temperatures of 200°-400°C, a film of Fe_3O_4 forms rapidly on the surface. Soon after this a second phase, α-Fe_2O_3, begins to form in the outer surface of the Fe_3O_4 layer. The rates of nucleation and lateral growth of the second phase depend on the oxygen pressure and on the crystallographic orientation of the Fe_3O_4 matrix which is determined by the crystallographic orientation of the iron substrate. When the oxygen pressure is high and/or when the close-packed oxygen-ion planes in the Fe_3O_4 are parallel to the surface, the rate of formation of the second oxide phase is high, and rapid coverage of the Fe_3O_4 phase occurs. Conversely, when the oxygen pressure is low and/or when the close-packed oxygen-ion planes in the Fe_3O_4 are not parallel to the surface, the rate of formation of the α-Fe_2O_3 phase is lower and the coverage of the Fe_3O_4 by a layer of α-Fe_2O_3 proceeds more slowly. Coverage of the Fe_3O_4 by α-Fe_2O_3 reduces the iron-oxidation rate by reducing the flux of iron ions outward through the Fe_3O_4 layer. Thus, the more rapidly the α-Fe_2O_3 layer forms, the more quickly the rate of oxidation is reduced. The order of oxidation rate with oxygen pressure, 0.01 > 0.1 > 10 Torr, and with iron crystallographic orientation, (001) > (112) > (111) > (011), can be explained by this mechanism.

The effect of oxygen pressure on the oxidation of polycrystalline zone-refined iron has been reported in a recently published paper (1). The rate of oxidation of 99.94% polycrystalline iron increases as the oxygen pressure is decreased from 100 to 0.01 Torr in the temperature range 200°-400°C. The oxidation kinetics are characterized by an initial period of high oxidation rate followed by a period of low oxidation rate. X-ray analyses of the films stripped from the specimens after oxidation for increasing lengths of time indicated that the period of high oxidation rate was associated with the growth of a layer of Fe_3O_4, while the period of low oxidation rate was associated with the growth of α-Fe_2O_3.

Electron microscopic examination of the stripped oxide films revealed that the initial films were extremely fine-grained as though composed of very fine crystallites. The oxide associated with each iron grain formed an individual single-crystal electron diffraction pattern of the cubic oxide, Fe_3O_4, an indication that the orientation of the oxide depended on the orientation of the iron substrate. As the oxidation was allowed to proceed for successively longer times, the oxide films assumed a coarse-grained, herringbone texture suggestive of a Widmanstätten structure. Selected-area electron diffraction analysis revealed that the herringbone texture of the latter films was imparted by crystals of α-Fe_2O_3 grown into the initially formed Fe_3O_4 layer.

At the high oxygen pressures, 10 and 100 Torr, large numbers of acicular α-Fe_2O_3 platelets formed and grew together rapidly into a closely interlocked Widmanstätten structure. At the lower oxygen pressures, 0.1 and 0.01 Torr, the α-Fe_2O_3 platelets were fewer in number and grew together more slowly. Replicas of oxidized and partially stripped specimens revealed that the surfaces of the α-Fe_2O_3 platelets were indented in the oxygen-oxide interface and that the metal surface beneath these crystals was raised above the remainder of the oxide-metal interface (1) so that the Fe_3O_4 layer was thinner under the α-Fe_2O_3 crystals. Replicas of the α-Fe_2O_3-Fe_3O_4 interface obtained after electrometric reduction (2, 3) of the α-Fe_2O_3 crystals revealed that this oxide-oxide interface was rougher than were either the O_2-oxide or the oxide-metal interfaces. Thus, it appeared that the α-Fe_2O_3 platelets grew into the Fe_3O_4 phase from sites of α-Fe_2O_3 nucleation at the Fe_3O_4-gas interface.

These experimental observations suggested the following mechanism to explain the fact that thicker oxide films were formed at the lower oxygen pressures than were formed at the higher oxygen pressures: the p-type semiconductor oxide, Fe_3O_4, forms first on the surface of the metal at these temperatures (200°-400°C) and oxygen pressures (0.01-100 Torr); the film grows thicker as iron ions move outward through lattice defects (cation vacancies) in the oxide; the vacancies are formed at the O_2-Fe_3O_4 interface when oxygen is incorporated into the Fe_3O_4 lattice.

The concentration of vacancies, and consequently the amount of iron moving through the Fe_3O_4 lattice, is dependent on the amount of oxygen available at the outer surface of the Fe_3O_4 layer. Thus, if a film of α-Fe_2O_3 is interposed between the Fe_3O_4 layer and the oxygen atmosphere, the amount of oxygen available to react with the Fe_3O_4 and form the iron-carrying vacancies will be drastically reduced. In consequence, the over-all oxidation rate will be reduced. Because the rates of nucleation and growth of the α-Fe_2O_3 platelets are higher at the higher oxygen pressures than at the lower oxygen pressures, Fe_3O_4 is exposed to gaseous oxygen for a longer time at the low oxygen pressures. This allows the high rate of Fe_3O_4 growth to persist longer at the low oxygen pressures and results in thicker oxide films than are formed at the higher oxygen pressures.

The proposed mechanism appears to explain, qualitatively at least, the observed kinetic and structural aspects of the oxidation of polycrystalline zone-refined iron foils in the temperature range 200°-400°C and over the oxygen-pressure range 0.01-100 Torr. However, the expected typical Widmanstätten pattern of the α-Fe_2O_3 platelets did not develop on all the iron grains in each foil. This suggested that the orientation of the iron substrate has an effect on the nucleation of α-Fe_2O_3 even through the intervening layer of Fe_3O_4. Accordingly, an investigation of the effect of iron substrate orientation on the morphology of the α-Fe_2O_3 platelets and on the rates of oxidation was undertaken.

Materials and Experimental Work

Single crystals of iron, grown by the strain-anneal method, were obtained in the (001), (011), (111), and (112) orientations. The approximately 1 cm square crystals were mechanically ground, spark-machined,

and electropolished into thin wafers of weights suitable for vacuum microbalance experiments. A 30-gauge platinum-20%-iridium wire was spot-welded to one corner of each crystal for support in the microbalance. A disturbed area, only 1 mm in radius, was produced on one surface of each crystal by the spot welding. Laue back-reflection patterns, obtained at this stage in the preparation, demonstrated that the crystals were not otherwise damaged. The surface treatment prior to oxidation was the same as that used on the polycrystalline foils (1). Because the greatest pressure effect was observed at 350°C, all the single-crystal oxidation experiments were carried out at this temperature. Oxygen pressures were 10, 0.1, and 0.01 Torr. Only one crystal suitable for kinetic studies was available in each orientation; consequently, the specimens were cleaned after each experiment and used again.

The oxide films were examined *in situ* by optical microscopy. Stripped oxide films and replicas of the interfaces were examined by electron microscopy. The crystal structure and orientations of the oxides were determined by electron diffraction analysis. Asymmetric specimen-support grids were used in this work so that the orientation relationships between the metal and the oxide could be preserved within a few degrees throughout the examination of the various types of replicas.

Results and Discussion

Kinetic data.—The results of the kinetic experiments at 350°C and at oxygen pressures of 10 and 0.1 Torr are shown in Fig. 1. Each curve, as plotted, is the average of two experiments on each crystal face. The agreement within the sets of data obtained at 10 Torr was quite good. Although the agreement among the data obtained at 0.1 Torr was not as good, there was no overlap among the sets of data for the different conditions, an indication that the effects of iron orientation and oxygen pressure were real.

As was observed in the experiments on polycrystalline iron foils (1), these rate curves consist of a short period of high oxidation rate followed by a period of very low oxidation rate. In each instance, more oxide was formed at 0.1 Torr than was formed at 10 Torr. The order of reaction rates with respect to the crystallographic orientation of the iron was (001) > (112) > (111) > (011), the same as that observed by Wagner, Lawless, and Gwathmey (4).

The curve for polycrystalline iron oxidized at 10 Torr and 350°C lies above the curve for the (112) Fe face and below the curve for the (001) Fe face. This suggests that the polycrystalline iron foils had a preferred orientation approaching (001). This supposition is strengthened by the observation that the oxide microstructures observed on the polycrystalline iron foils were, for the most part, similar to those found on the (001) face of the iron single crystal.

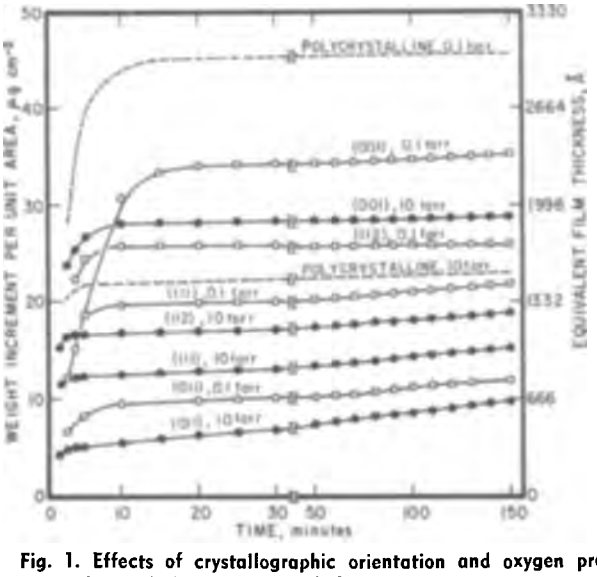

Fig. 1. Effects of crystallographic orientation and oxygen pressure on the oxidation of iron at 350°C.

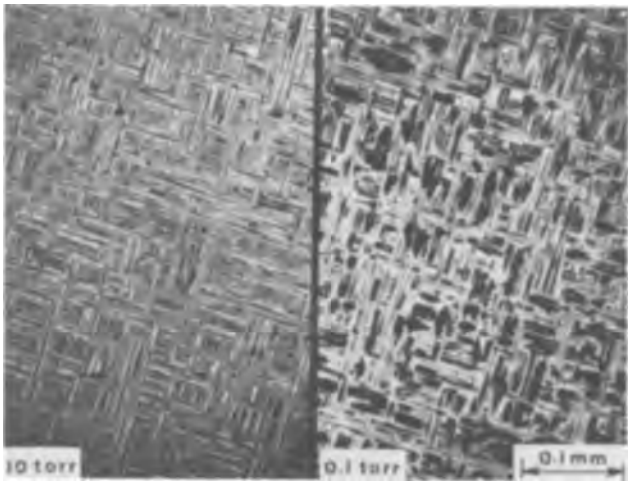

Fig. 2. Optical micrograph of oxide formed on the (001) Fe face in 150 min at 350°C.

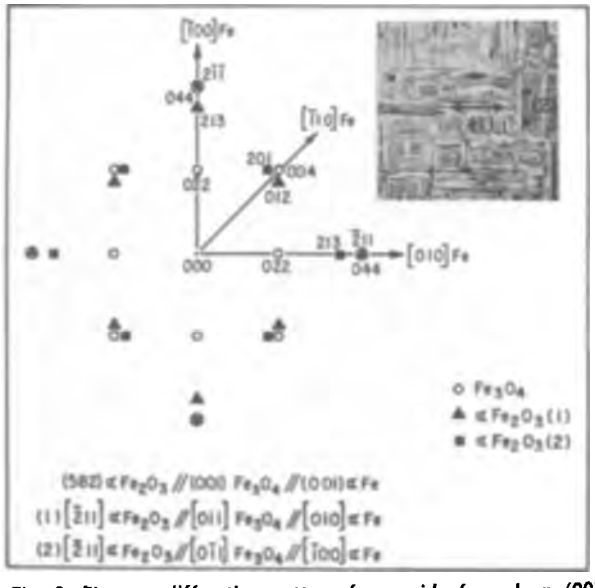

Fig. 3. Electron diffraction pattern from oxide formed on (001) α-Fe face at 350°C.

Morphology and orientation of the oxides.—(001) α-Fe.—The orientation of the cubic oxide Fe_3O_4 films that formed initially on the (001) iron face was the same as that reported in the literature (4, 5): (001) Fe_3O_4 // (001) α-Fe. A layer of acicular α-Fe_2O_3 crystals formed over the initial oxide film in a Widmanstätten pattern such as that shown in the optical micrographs of Fig. 2. The α-Fe_2O_3 layer was composed of two families of parallel crystals. The crystals of one family intersected the crystals of the other at 90°. The electron diffraction pattern obtained from such an α-Fe_2O_3-Fe_3O_4 film is interpreted in Fig. 3. The long axes of one family of α-Fe_2O_3 crystals, labeled 1 in the inset, were parallel to the [010] direction of the iron substrate and the long axes of the other family, labeled 2, were parallel to the [100] iron direction. The crystallographic orientations of α-Fe_2O_3 are given in rhombohedral coordinates that were derived from the electron-diffraction data using matrix algebra (6).

The ridged structure of the α-Fe_2O_3 crystals is evident in electron micrographs of replicas of the oxide-gas interface, Fig. 4. This same type of morphology is

also evident in replicas of the α-Fe_2O_3-Fe_3O_4 interface, obtained after electrometric reduction (2, 3) of the α-Fe_2O_3, Fig. 5. The ridging exhibited by these replicas suggests that the oxide interfaces are composed of microscopic facets.

The effect of oxygen pressure on the size of the α-Fe_2O_3 platelets is illustrated by the optical micrographs of Fig. 2. At the lower oxygen pressure, 0.1 Torr, somewhat fewer platelets were formed, and they became larger than those formed at 10 Torr. The crystals formed at 0.1 Torr were also in higher topographical relief than those formed at 10 Torr as is shown in Fig. 4. The oxide-metal interface was much smoother than the α-Fe_2O_3-Fe_3O_4 interface or the oxygen-α-Fe_2O_3 interface, as is shown in Fig. 6

(112) α-Fe.—Optical micrographs of the oxide formed on the (112) α-Fe face in 150 min at 350°C are shown in Fig. 7. This oxide is characterized by a profusion of small acicular crystals oriented with their long axes parallel to the [111] α-Fe direction. The crystals formed at 0.1 Torr were much larger than those formed at 10 Torr.

The electron diffraction patterns obtained from the oxide formed on the (112) iron face are interpreted in Fig. 8. The (011) Fe_3O_4 plane was parallel to the (112) α-Fe face as has been reported in the literature (5). However, the directional relationship found in this study between the Fe_3O_4 and the iron, $[3\bar{1}\bar{1}]$ Fe_3O_4 // [111] α-Fe, was different from that found by Sewell and Cohen (5). The α-Fe_2O_3 crystals formed over the Fe_3O_4 with the (573) α-Fe_2O_3 plane parallel to the (011) Fe_3O_4 and the (112) α-Fe. Diffraction patterns from two sets of α-Fe_2O_3 crystals are evident in Fig. 8. The two sets of α-Fe_2O_3 crystals are clearly evident in the replica of the oxide-oxygen interface shown in Fig. 9.

Certain reflections from a cubic crystalline phase that are forbidden by diffraction theory for Fe_3O_4 are indicated by diamonds in the electron diffraction pattern of Fig. 8. These reflections are characteristic of the cubic oxide phase γ-Fe_2O_3, and were in the same crystallographic orientation as the cubic Fe_3O_4 crystals

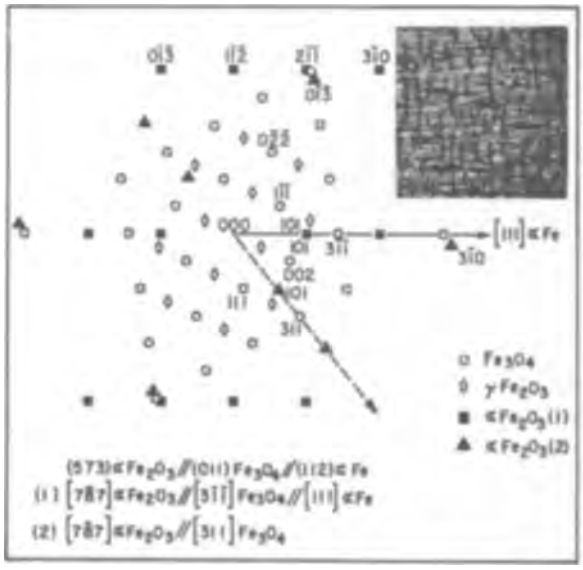

Fig. 8. Electron diffraction pattern from oxide formed on (112) α-Fe face at 350°C.

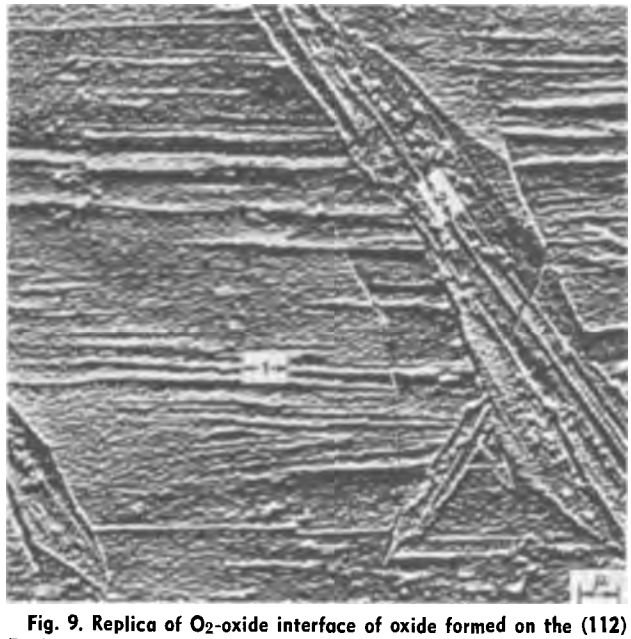

Fig. 9. Replica of O_2-oxide interface of oxide formed on the (112) Fe face in 150 min at 350°C and 0.1 Torr showing major (1) and minor (2) α-Fe_2O_3 orientations

indicated by the open circles. The Fe_3O_4 reflections could also be indexed as γ-Fe_2O_3. However, since no γ-Fe_2O_3 reflections appeared in the third order (that is, there were 011, 022, and 044 reflections but no 033 reflections), it is believed that Fe_3O_4 was the major cubic oxide phase present in these films.

Replicas of the O_2-α-Fe_2O_3, the α-Fe_2O_3-Fe_3O_4, and the Fe_3O_4-α-Fe interfaces are shown in the electron micrographs of Fig. 10. Traces of the α-Fe_2O_3 platelets are evident at all the interfaces. However, the α-Fe_2O_3-Fe_3O_4 interface was in higher topographic relief than was the outer surface of the oxide. This is believed to be evidence of the inward growth of the α-Fe_2O_3 phase from the oxide-gas interface. It is also evident that the planes of contact between the oxide phases were different from those shown to be parallel to the (112) α-Fe face, Fig. 8.

(111) α-Fe.—The effect of oxygen pressure on the size, numbers, and orientation of the α-Fe_2O_3 platelets was most clearly demonstrated in the oxidation of the (111) α-Fe face. The oxide formed at 10 Torr and

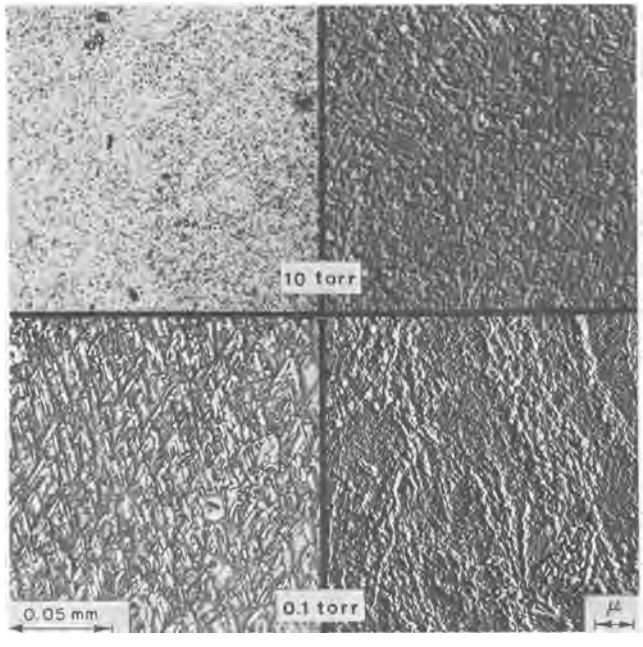

Fig. 11. Optical and electron micrographs of oxide formed on (111) Fe face in 150 min at 350°C.

350°C in 150 min was composed of very fine crystals that exhibited little evidence of morphological or crystallographic orientation in optical and in electron micrographs, Fig. 11, or in electron diffraction patterns. In contrast, Widmanstätten patterns of relatively large acicular crystals were found in the oxide formed at 0.1 Torr and 350°C for 150 min. These crystals were oriented with their long axes nearly parallel to the $[\bar{1}01]$ and $[\bar{1}10]$ directions in the iron crystal, and they intersected each other at an angle of about 50°. The surface of the metal at the oxide-metal interface was smoother than the surface of the oxide at the oxygen-oxide interface (Fig. 12), but was considerably rougher than the original metal surface; traces of the acicular α-Fe_2O_3 crystals were evident in the underlying metal surface.

Two (111) oriented α-Fe crystals were studied. The first crystal (α) was tilted about 2° in the $[2\bar{1}\bar{1}]$ di-

rection and 1° in the $[01\bar{1}]$ direction, whereas the second crystal (β) was tilted <2° in the $[2\bar{1}\bar{1}]$ direction only. Two orientations of Fe_3O_4 were observed; the $(\bar{2}10)$ Fe_3O_4 plane formed parallel to the (111) α-Fe plane on iron crystal (α), as shown in Fig. 13, but the $(1\bar{1}0)$ Fe_3O_4 plane formed parallel to the (111) α-Fe face on iron crystal (β), Fig. 14. However, the same orientations of α-Fe_2O_3 with respect to the orientation of the iron substrate were observed on both crystals.

(011) α-Fe.—No evidence of morphological orientation effects was found in the oxide formed at oxygen pressures of 10 or 0.1 Torr and 350°C for 150 min on the (011) α-Fe face, Fig. 15. As is shown in Fig. 16, the oxide was stripped from this face in irregular patches, and there was little difference between the appearance of the oxygen-oxide interface and that of the metal at the oxide-metal interface. The α-Fe_2O_3-Fe_3O_4 interface was also quite smooth, as is shown in Fig. 17.

Electron diffraction patterns from Fe_3O_4 alone could

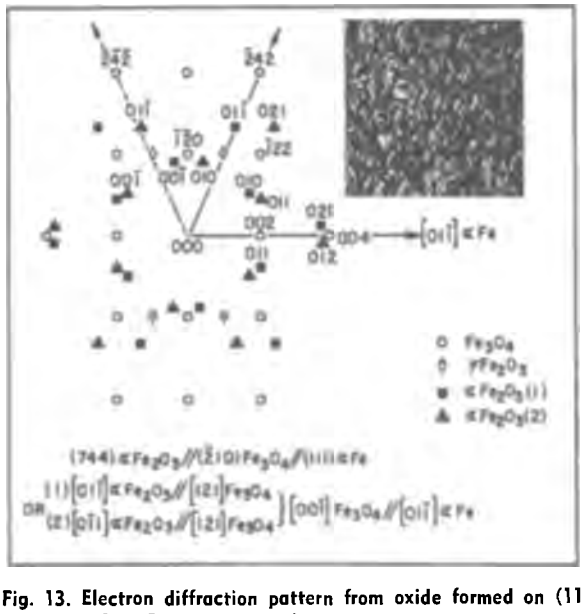

Fig. 13. Electron diffraction pattern from oxide formed on (111) α-Fe face at 350°C (iron crystal α).

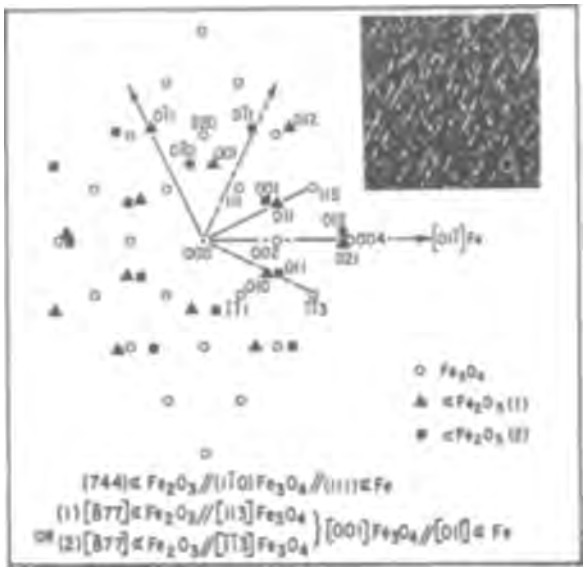

Fig. 14. Electron diffraction pattern from oxide formed on (111) α-Fe face at 350°C (iron crystal β).

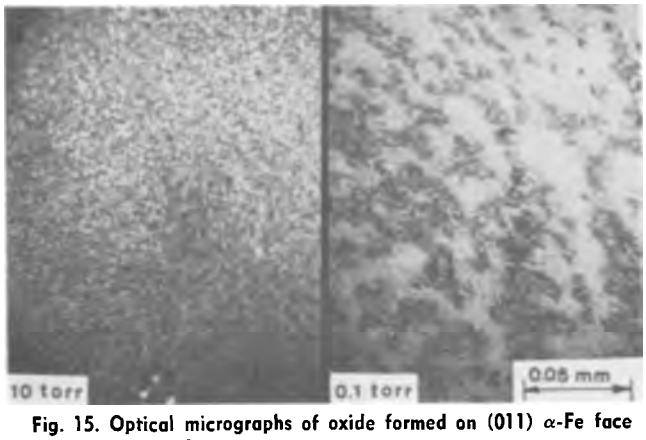

Fig. 15. Optical micrographs of oxide formed on (011) α-Fe face in 150 min at 350°C.

be obtained from oxide formed in short times (2-5 min) at low pressures (0.01 and 0.1 Torr) on the (001), (112), and (111) iron faces. In contrast, the diffraction patterns obtained from the oxide formed on the (011) α-Fe face always demonstrated the presence of both α-Fe_2O_3 and Fe_3O_4 in the single orientation relationship shown in Fig. 18. Apparently, the nucleation and lateral growth of the α-Fe_2O_3 phase over the Fe_3O_4 phase was much more rapid on the (011) α-Fe face than on any of the other iron faces studied.

Moire fringes (7), seldom observed in the transmission electron micrographs of oxide stripped from the other iron faces, were always observed in micrographs of the oxide formed on the (011) α-Fe face, Fig. 19. These fringes, which appear in electron micrographs as parallel black stripes running through a crystal, are a diffraction effect obtained when the electron beam passes through one crystal and then through a second crystal, the lattice spacing or orientation of which is slightly different from that of the first crystal.

The combined evidence of the smooth interfaces, the single diffraction pattern, and the moire fringes suggests that the preferred orientation for α-Fe_2O_3 on Fe_3O_4 is that illustrated by the diffraction pattern, Fig. 18, with the (111) plane of α-Fe_2O_3 parallel to the (111) plane of Fe_3O_4.

Nucleation of α-Fe_2O_3.—The evidence presented in the foregoing sections demonstrates that the nucleation and lateral growth of α-Fe_2O_3 on Fe_3O_4 is influenced not only by the oxygen pressure, but also by the crystallographic orientation of the Fe_3O_4 layer. The early stages in the growth of α-Fe_2O_3 platelets were

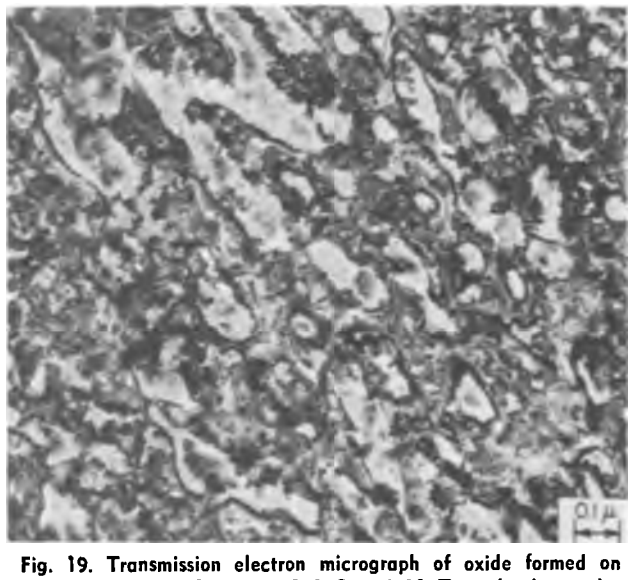

Fig. 19. Transmission electron micrograph of oxide formed on (011) iron face in 60 min at 350°C and 10 Torr showing moire fringes caused by difference in lattice spacing of two parallel layers of oxide crystal phases, α-Fe_2O_3 and Fe_3O_4.

examined in oxide films prepared by oxidizing the four iron single crystals for 2 min at 350°C and oxygen pressures of 0.01, 0.1, and 10 Torr, respectively. The resulting 12 oxide specimens were stripped from the iron substrates, and the α-Fe_2O_3 crystallites were counted in a small area of each film to obtain an estimate of α-Fe_2O_3 nucleation rates. Typical areas of some of these oxide films are shown in the micrographs of Fig. 20. The results of these counts projected to a number of α-Fe_2O_3 crystallites per square centimeter are presented in Table I. The correlation between the number of α-Fe_2O_3 crystallites and the over-all oxidation rate is clearly evident, that is, the smaller the number of α-Fe_2O_3 crystallites, the greater is the over-all oxidation rate. This evidence supports the argument presented in the previous paper (1) that the formation of a continuous layer of α-Fe_2O_3 lowers the rate of oxidation of iron by diminishing the flux of iron ions outward through the Fe_3O_4 layer.

Evidence cited above, in connection with the oxidation of the (011) iron face, suggests that the preferred orientation for the two iron oxide phases is such that the (111) α-Fe_2O_3 plane is formed parallel to the (111) Fe_3O_4 plane. This orientation relationship has been observed by Sewell and Cohen (5) in the oxidation of the (001) and (112) faces of iron, and also by other investigators in mineral specimens of hematite on magnetite (8). The closest-packed oxygen planes in both iron oxide phases are parallel to the respective (111) planes. The arrangement of the oxygen ions parallel to the (111) planes in the two oxide phases is similar, that is, close-packed hexagonal, with an ion spacing (oxygen-to-oxygen) of 2.90Å in α-Fe_2O_3 and 2.97Å in Fe_3O_4 (9). Thus, the transition from Fe_3O_4 to α-Fe_2O_3 is least discontinuous (10) when the (111) planes in each phase are parallel. Furthermore, the boundary between the two phases will be most coherent when these planes are parallel (11). From these considerations, it is inferred that the nucleation and lateral growth rates of α-Fe_2O_3 will be highest when the (111) plane of Fe_3O_4 is parallel to the gross surface, as is the case for the oxidation of the (011) iron face. This hypothesis is supported by the data presented in Table I.

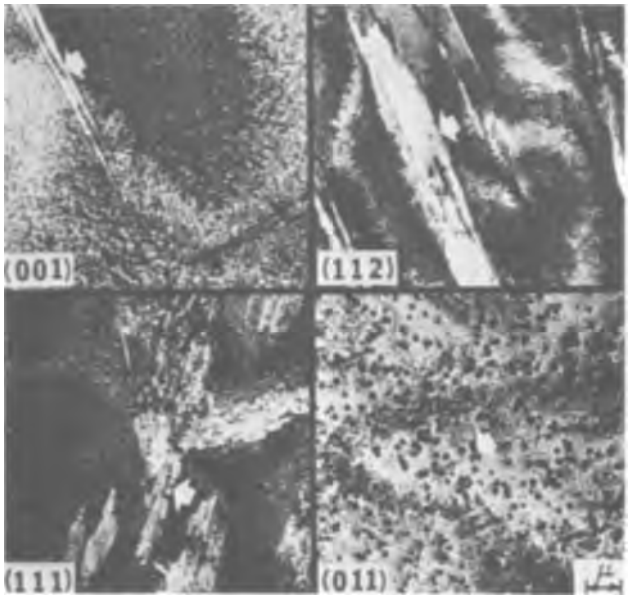

Fig. 20. Transmission electron micrographs of oxides formed on the four iron crystal faces in 2 min at 350°C and 0.1 Torr showing effect of Fe_3O_4 orientation on the number of α-Fe_2O_3 platelets.

The angles between the (111) plane of Fe_3O_4 and the gross surface planes of each of the four iron crystals are shown in Table II. There appears to be a correlation between these angles and the number of α-Fe_2O_3 crystallites, Table I. When the (111) Fe_3O_4 plane is parallel to the gross surface plane, as it is in the case of Fe_3O_4 formed on the (011) iron face, the number of α-Fe_2O_3 crystallites observed is high. Conversely, when the angle between the gross surface plane and the (111) plane of Fe_3O_4 is high, as it is in the case of Fe_3O_4 formed on the (001) face of iron, the number of α-Fe_2O_3 crystallites observed is low.

The roughness shown in electron micrographs of replicas of the α-Fe_2O_3-Fe_3O_4 interfaces of all of the oxide films, except those formed on the (011) face of iron, suggest faceting that is believed to occur parallel to the (111) Fe_3O_4 plane. Thus, the geometry of the interface between the two oxides that form on the four different iron faces is currently believed to be represented approximately by the sketches shown

Table I. Influence of oxygen pressure and iron orientation on the nucleation of α-Fe_2O_3 at 350°C

Orientation of iron crystal	Number of α-Fe_2O_3 platelets formed in 2 min at 10 Torr	0.1 Torr	0.01 Torr
(001)	3.2×10^6 cm^{-2}	1.7×10^4 cm^{-2}	None observed
(112)	9.6×10^7 cm^{-2}	1.0×10^6 cm^{-2}	2.1×10^4 cm^{-2}
(111)	1.2×10^9 cm^{-2}	5.9×10^6 cm^{-2}	3.4×10^5 cm^{-2}

in Fig. 21. Independent electrochemical evidence obtained by Cohen (2, 3, 5) strongly suggests that a thin layer of γ-Fe_2O_3 exists between the α-Fe_2O_3 and the Fe_3O_4. Accordingly, such a layer is indicated in these sketches, although the only experimental evidence of γ-Fe_2O_3 obtained in the present study is that of the extra reflections from cubic crystals shown in Fig. 8 and 13.

Summary and Conclusions

The oxidation of four differently oriented iron single crystals at 350°C and oxygen pressures of 10, 0.1, and 0.01 Torr has been investigated. Kinetic data have been related to morphological data so that a reasonable model for the oxidation process can be deduced. It appears that the mechanism producing the difference in oxidation rates for different iron orientations is similar to that suggested in the previous paper to explain the increase in oxidation rate with decreasing oxygen pressure.

When clean iron is exposed to oxygen at temperatures of 200°-400°C, a film of Fe_3O_4 rapidly covers the surface. It appears that this film is composed of very small crystallites, all in essentially the same orientation, so that single-crystal electron diffraction patterns are obtained from the stripped films. The orientation of this oxide is determined by the orientation of the iron substrate. The formation of the Fe_3O_4 layer is so rapid under the experimental conditions that morphological evidence of the nucleation of the individual Fe_3O_4 crystallites was not obtained.

Soon after the formation of the Fe_3O_4 layer, crystallites of α-Fe_2O_3 begin to form in its outer surface. The number of these α-Fe_2O_3 platelets and the rate with which they spread laterally are dependent not only on the oxygen pressure but also on the crystallographic orientation of the Fe_3O_4 matrix. At high oxygen pressures (10 Torr in these experiments), a large number of α-Fe_2O_3 platelets are formed, and they grow rapidly. At low oxygen pressures (0.1 Torr), fewer platelets are formed, and they grow laterally much more slowly. It also appears that large numbers of α-Fe_2O_3 crystallites are formed, and they grow together rapidly when the close-packed oxygen plane of Fe_3O_4, the (111), is parallel to the gross iron surface [in this instance, the (011) α-Fe face]. These crystallites are fewer in number and grow together more slowly when the (111) Fe_3O_4 plane intersects the gross iron surface. These observations are demonstrated when the crystal counts in Table I are compared with the angles between the (111) Fe_3O_4 planes and the gross surface planes listed in Table II. It is evident that the number of α-Fe_2O_3 platelets

observed decreases, not only as the oxygen pressure decreases, but also as the angles between the (111) Fe_3O_4 planes and the gross surface planes increase from 0° over the (011) α-Fe face to 55° over the (001) α-Fe face. Replicas of the α-Fe_2O_3-Fe_3O_4 interface indicate that the actual interfaces between the two oxide phases are not parallel to the original iron surface except for the oxides formed over the (011) α-Fe face. Thus, it is suspected that the α-Fe_2O_3 phase forms on facets parallel to the (111) planes in the Fe_3O_4 layer, and that the rate of formation of these facets is related to the angle with which they intersect the gross surface plane.

This study tends to confirm the mechanism proposed in the previous paper to explain the effect of oxygen pressure on the rate of oxidation of iron: The formation of an outer layer of α-Fe_2O_3 over the surface of the Fe_3O_4 reduces the area of direct contact between the latter and gaseous oxygen. This reduces the number of cation-carrying vacancies formed at this interface, thereby reducing the flux of iron ions outward through the film. This reduction in iron-ion diffusion through the Fe_3O_4 layer reduces the oxidation rate. Thus, a correlation is observed between the number of α-Fe_2O_3 crystallites and the over-all oxidation rate. When the number is high, the α-Fe_2O_3 forms rapidly and the over-all oxidation rate is low. Conversely, when the number is low, the α-Fe_2O_3 film forms more slowly, and the over-all oxidation rate is high.

Manuscript received June 20, 1966; revised manuscript received Aug. 15, 1966. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Noncathodic Effects of the Permanganate Ion in the Anodic Passivation of Iron[1]

G. H. Cartledge

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Iron actively reduces the permanganate ion at concentrations and pH values at which both chromate and pertechnetate ions inhibit corrosion effectively. The electrostatic polarization hypothesis of inhibition by such ions suggests, however, that the permanganate ion should probably manifest the same noncathodic effects as the inhibiting ions, if its reduction at the interface could be avoided. Anodic passivation of iron in permanganate solutions has therefore been conducted at potentials too noble for the cathodic process to occur. The polarization data showed that passivation was facilitated exactly as was previously found for the chromate and pertechnetate ions. The contrasting behavior of MnO_4^-, TcO_4^-, and ReO_4^- is discussed in relation to different theories of the action of the XO_4^{n-} inhibitors.

The permanganate ion is not generally considered to be an inhibitor of the corrosion of iron and steel, and very little study has been made of its interaction with the metals. In a comparison of the action of several oxyanions with iron, Mirolyubov, Tomaschov, and Zhuk (1) reported the ion to accelerate attack by cathodic stimulation. Hoar and Evans (2) showed that the permanganate ion, having no buffering capacity, differs from the chromate ion in being unable to precipitate ferrous ions completely as a hydrous ferric oxide without addition of alkali. In connection with the hypothesis of inhibition previously proposed (3-5), this failure to inhibit corrosion was ascribed to the strong oxidizing power of the ion, which resulted in its rapid consumption at the interface. Since it is plausible to regard the Mn-O bonds as having a considerable degree of polarity, however, it might be expected that the ion would exhibit the same noncathodic effects as were demonstrated recently for both chromate and pertechnetate ions, provided its reduction were prevented (6). The polarization data of the present study show clearly that MnO_4^- has a noncathodic activity in diminishing the charge and current density required for passivation.

Experimental

Tests for inhibition.—The results of one set of several experiments carried out with 0.1% carbon steel in potassium permanganate of different concentrations and pH values are shown in Table I.

Corrosion was not instantaneously stifled under any of these conditions. Even in the $10^{-1}f$ solution, a

Table I. Tests for inhibition in aerated solutions

$[MnO_4^-]$	pH	Observations
$10^{-3}f$	4.1	Rusting and fading; in 7 hr, almost colorless and much rust
$10^{-3}f$	5.0	Spotting at once; in 14 da, colorless and some loose rust
$10^{-1}f$	3.05	In 1 hr, brassy film 56 da, no visible change, wt = 0.4031g 80 da, no visible change, wt = 0.4029g 103 da, no visible change, wt = 0.4032g 192 da, no visible change, wt = 0.4030g 248 da, no visible change, wt = 0.4031g

heavy, brass-colored film formed quickly, after which no more than a very slow reduction of the anions continued, in agreement with the observed constancy in weight over a period of several months. Subsequent measurements of electrode potentials of iron specimens confirmed the absence of appreciable polarization of the Mn(IV-VII) couple potential when the permanganate concentration was 10^{-1} or $10^{-2}f$ (pH $\geq$ 2.80). In the $10^{-3}f$ solution at pH 4, the couple potential was polarized by 100 mv or more by the corrosion process.

Another experiment was made to determine whether the permanganate ion, with its noble reduction potential, might inhibit attack if admixed with the pertechnetate ion under conditions in which the pertechnetate alone does not inhibit (low pH in the presence of sufficient sulfate ions). The metal was again 0.1% carbon steel (*ca.* 2 cm^2) and the solutions had the following compositions:

(*a*) $KTcO_4$, $10^{-3}f$, $KMnO_4$, $10^{-3}f$, H_2SO_4, $5\times10^{-3}f$; pH 2.16

(*b*) $KTcO_4$, $10^{-3}f$, - - - - - - H_2SO_4, $5\times10^{-3}f$; pH 2.12

The solutions were open to the air. Bubbles formed on the metal in (*b*) within 3 min while the specimen darkened; no bubbles formed in (*a*), but the metal darkened and turbidity developed within 5 min. In 1 hr, the permanganate color in (*a*) was completely bleached, and the metal had a nearly black film which resembled that produced in certain commercial coating processes. After the permanganate color disappeared, evolution of hydrogen was seen on both specimens. At 2.4 hr, the loose corrosion products were brushed away under running water and the specimens were weighed. The loss in weight was 2.6 mg for (*a*) and 1.7 mg for (*b*). It is clear that, under the chosen conditions, the permanganate ion held the potential above that for evolution of hydrogen so long as it lasted, and, at the same time, stimulated the attack on the metal.

Anodic polarization of iron in permanganate solutions.—In order to detect a noncathodic effect of the permanganate ion, if one exists, it is first necessary to ascertain empirically the potential of the permanganate ion and its reduction product under the conditions of concentration and acidity to be used. Then, following the procedure applied in the thorough study of the pertechnetate ion (6), it is necessary only to polarize the iron electrode anodically at a constant potential which is considerably noble to these couple potentials. A noncathodic action will then be seen as a resulting fall of the initial anodic current density to a low value (passivation), without the intervention of the very high current densities requisite for passivation in noninhibiting environments (sulfate, for example).

The Armco iron electrodes were electrocleaned and alternately passivated in HNO_3 and activated in HCl just before being connected to the polarizing circuit and inserted into the electrolyte. A rapid stream of helium swept out oxygen and provided agitation. A 0.1f $KMnO_4$ stock solution was prepared, aged for four days, then siphoned off from the sediment and adjusted to pH 3.60 by Dowex-50 resin that had been freed of substances that reduce permanganate and left in the acid form. Other solutions were prepared by dilution and similarly adjusted to the desired pH values.

The anodic current at a fixed potential was recorded until it fell to an essentially constant value. The cell was then switched quickly to a vibrating reed electrometer and recorder (for following the change of potential on open circuit) by a relay device activated by a multipole switch.[2] The charge passed during passivation was determined by graphical integration of the recorder chart. In order to insure that the potentiostat was set at a potential more noble than that of the Mn(IV-VII) couple under the experimental conditions, this value was determined using a platinum wire coated with the reduction product by cathodic polarization. The details of these measurements are indicated in the following section.

[2] The author is indebted to Mr. M. B. Noggle, of the Instrumentation and Controls Division, for the design and construction of this device.

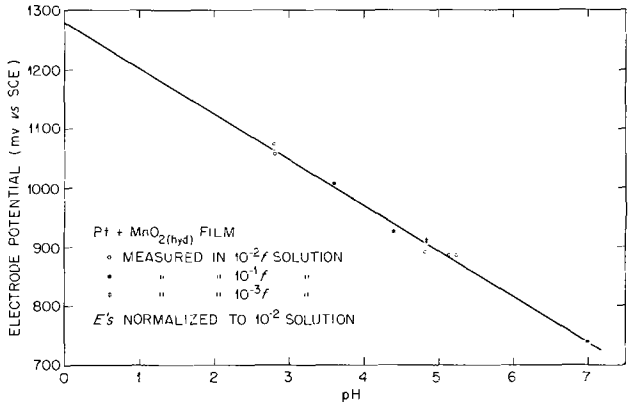

Fig. 1. Variation of the potential of the Mn(IV-VII) couple with pH.

Results

The Couple potential.—The composition of the reduction product from permanganate ion in the pH range 2.8-7.0 and in the presence of an excess of the anion is expected, on chemical grounds, to approximate a hydrous oxide of Mn(IV). Latimer (7) gives an electrode potential for the following couple:

$$MnO_2 \text{ (pyrolusite)} + 2H_2O \rightleftharpoons MnO_4^- + 4H^+ + 3e^-; \quad V_h^\circ = 1.69v$$

It is not known how much this value changes with the probable hydration of the dioxide or whether, indeed, the stoichiometry of the actual cathodic process conforms definitely to the above equation. Measurements were made, therefore, in 10^{-1}, 10^{-2}, and $10^{-3}f$ $KMnO_4$ at pH values ranging from 2.80 to 7.00. Oxygen was excluded by a rapid stream of helium. Although there was evidence of a slight aging effect on the potential of the filmed platinum electrode, the potential responded rather rapidly to changes in pH or concentration.[3] Figure 1 shows that measurements over a considerable range of concentration and pH are in good agreement with the indicated equation, dV/dpH being —78, rather than the theoretical —79 mv/pH. The data for 10^{-1} and $10^{-3}f$ solutions have been normalized to $10^{-2}f$ in accordance with the Nernst equation for the indicated couple. Figure 1 is a least-squares fit of the data and gives V_h° = 1.562 $\pm$ 0.007v.

The manganese couple potential is more noble than the reversible potential for evolution of oxygen in all the solutions used. Hence, the charges computed from the potentiostatic polarization curves are necessarily maximum values for the passivating charge. The data indicate, however, that the overvoltage for discharge of oxygen is large and the contribution of this reaction to the total charge is quite small when the potentiostat is held only 0.1-0.2v above the calculated manganese couple potential, since in such instances the total anodic current density fell to values in the μa/cm^2 region.

Passivation and behavior on open circuit.—Measurements were made at permanganate concentrations of 10^{-1}, 10^{-2}, and $10^{-3}f$, and over the pH range of 2.80-4.82. Results were similar in all cases: a very brief

[3] An example of the rapid equilibration after polarization may be seen in Fig. 3, which shows the ennobling of the oxide-coated platinum cathode from the low potential at which it was held during a passivation experiment.

surge of anodic current was followed by a rapid decrease to an essentially constant value in the microampere per square centimeter range, leaving the metal bright and visually free of any manganese oxide. The potential fell rapidly when the electrode was put on open circuit, but it did not go into the active region below the Flade potential and, at the two higher concentrations, ultimately approximated the stable value shown by a platinum wire coated with the manganese reduction product. The charge passed during passivation increased with the applied potential, owing to evolution of oxygen. Figures 2 and 3 show the temporal sequence of measurements for both the polarizing current density and subsequent change of potential on open circuit for two typical experiments with $10^{-2}f$ $KMnO_4$ at *p*H 2.80. In Fig. 2, the polarizing potential was 180 mv noble to the Mn(IV-VII) couple potential; in this case, the total charge was 16 mc/cm². In Fig. 3, the polarizing potential was 330 mv above the couple potential and the charge was 580 mc/cm². If it is assumed that the constant current density of 310 μa/cm² finally reached represented evolution of oxygen throughout the experiment, the net charge applicable to the passivation process is reduced to 80 mc/cm². Charges observed in the various concentrations were consistently in the range of a few mc/cm² and final current densities were as low as < 1 μa/cm² for the lower polarizing potentials. The very brief initial surge of current varied in the range of a few milliamperes per square centimeter.

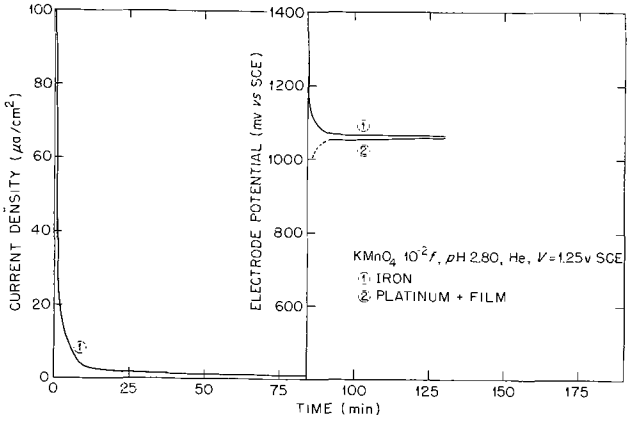

Fig. 2. Passivating current density and open-circuit potential of iron in $10^{-2}f$ $KMnO_4$ at *p*H 2.80; polarization at 1.25v (SCE).

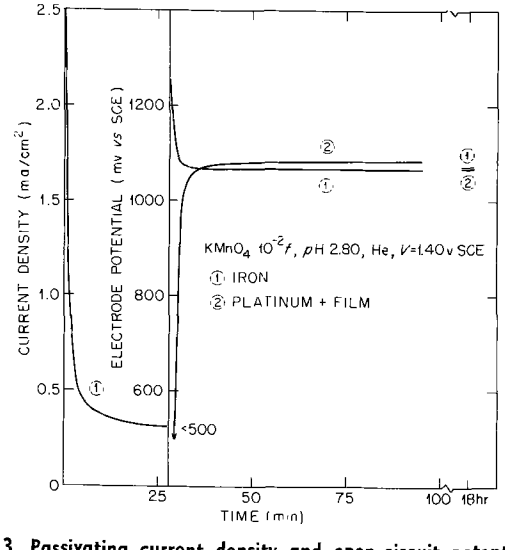

Fig. 3. Passivating current density and open-circuit potential of iron in $10^{-2}f$ $KMnO_4$ at *p*H 2.80; polarization at 1.40v (SCE).

For permanganate concentrations of both 10^{-1} and $10^{-2}f$, the potential of the iron electrode on open circuit exhibited the behavior shown in Fig. 2 and 3. The potential usually went through a very shallow minimum before coming back to a value within a few millivolts of the potential of the Mn(IV-VII) couple. At $10^{-3}f$, the permanganate ion was unable to maintain the passive state produced under anodic polarization after current was discontinued. The potential on open circuit fell 100 mv or more below the potential of the Mn(IV-VII) couple and the electrode corroded visibly. The system came to a mixed potential with the couple potential cathodically polarized by the continuing dissolution of the imperfectly passivated iron electrode. These observations are in agreement with the contrast shown in Table I between $10^{-1}f$ and $10^{-3}f$ solutions, the $10^{-1}f$ solution being able both to produce and to maintain the passive state.[4]

The influence of sulfate ions.—Anodic polarization of the iron electrode was conducted also in mixtures of permanganate and sulfate ions. In $10^{-3}f$ $(K,H)_2SO_4$ at *p*H 4.18, the full voltage of the potentiostat was applied to the cell without passivation.[5] Similarly, in $5 \times 10^{-2}f$ sulfate at *p*H 2.30, with lower cell resistance, the full anodic output of 16.5 ma/cm² failed to passivate the electrode. A mixed solution containing $5 \times 10^{-2}f$ $SO_4^=$ and $5 \times 10^{-2}f$ MnO_4^- at *p*H 3.86 was then used. In two experiments, the potentiostat was set at 1.10 and 1.20v (SCE), respectively. The initial surges of current fell only to 21 and 32 $\mu a/cm^2$. Although the potential of the iron did not fall into the active region on open circuit, considerable attack was evident both in the prompt formation of visible film and in the depression of the potential below the calculated couple potential. In a mixture that was $10^{-2}f$ in MnO_4^- and $10^{-1}f$ in $SO_4^=$ at *p*H 4, a polarizing potential of 1.10v (SCE) gave approximately constant current densities of 390 and 524 μa/cm², in two successive experiments. After the second polarization, the potential fell quickly to —510 mv (SCE) on open circuit. It may be concluded, therefore, that sulfate ions act antagonistically in this case also, although the permanganate ion is more tolerant of their presence than are the pertechnetate and chromate ions.

Cathodic polarization of the Mn(IV-VII) *couple.*—The film-coated platinum electrode used as cathode in the polarization experiments was subjected to cathodic polarization in $10^{-1}f$ $KMnO_4$ at *p*H 3.82. The re-

[4] Corrosion of the iron electrode in the $10^{-3}f$ solution even when the mixed potential is relatively noble is in no way inconsistent with the well-known observation that the metal has a very low corrosion rate at such potentials, if passivated anodically in sulfuric acid. The difference in behavior emphasizes the contrast between the simple surface film produced by passivation in the strongly acidic solution and the composite, nonprotective film resulting from action between the metal and the reducible anion at higher *p*H values.

[5] This means that the resistance of the $10^{-3}f$ sulfate solution held the current at too low a value for passivation, whereas in the permanganate solution of the same concentration and comparable resistance, passivation was readily achieved.

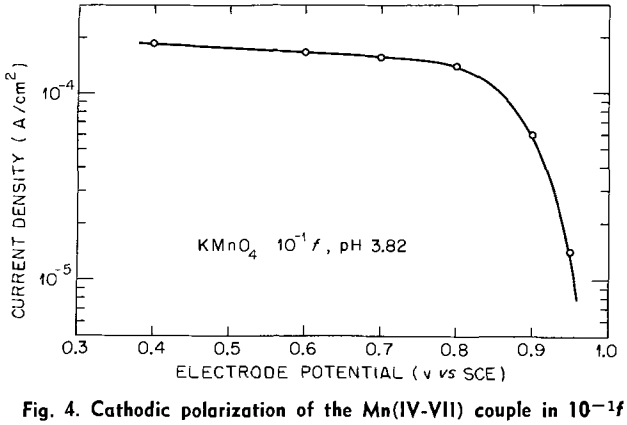

Fig. 4. Cathodic polarization of the Mn(IV-VII) couple in $10^{-1}f$ $KMnO_4$ at *p*H 3.82.

sults (Fig. 4) show that a limiting current density of about 0.2 ma/cm^2 is reached even at the relatively high concentration of permanganate ions. This current density is of the proper magnitude to represent the diffusion current for protons. Reduction of the permanganate ion is thus considerably faster than that of chromate ions at a similar *p*H, as may be seen by comparison of Fig. 4 with Fig. 6 of ref. (6), in which the limiting current density (before evolution of hydrogen) is an order of magnitude smaller.

Discussion

The experiments demonstrate that the permanganate ion is able to passivate iron or low-carbon steel only at concentrations substantially greater than those effective with the pertechnetate and chromate ions. At $10^{-1}f$ and *p*H 3, however, no loss in weight occurred over a long period and the exchange current of the Mn(IV-VII) couple was sufficient to maintain the passive electrode at essentially the reversible potential of the couple. In a $10^{-3}f$ solution at *p*H 5, on the contrary, active corrosion proceeded with reduction of the anions and extensive polarization of the couple potential.

At all three concentrations and over a *p*H range between 2.80 and 4.82, a noncathodic effect was manifest since passivation was observed at current densities which failed to produce passivation in sulfate solutions of comparable concentration and acidity. As in the previous experiments (6), the total charges accumulated during passivation at potentials noble to the anion couple potential were in the range of a few mc/cm^2, in spite of the fact that this charge included whatever amount of oxygen may have been simultaneously evolved. It was shown also that sulfate ions act antagonistically toward the inhibiting action of the permanganate ions, again emphasizing the importance of competing adsorption in the inhibitory process.

A comparison of the XO_4^-'s of the three transition metals of the seventh group of the periodic system shows the subtle character of the property associated with inhibitory action. The permanganate ion has vigorous oxidizing action, yet fails to inhibit corrosion except at relatively high concentrations. The perrhenate ion fails to inhibit at any concentration, even if its solution is artificially made to simulate a pertechnetate solution with respect to radiolytic products and oxidizing power (4). The pertechnetate ion, of intermediate electrode potential, is effective even at very low concentrations at least up to 250°C, although it contributes little to the requisite cathodic current if oxygen, or, still better, hydrogen peroxide is simultaneously present (8). Also, its inhibition is destroyed by noninhibitive anions at moderate concentration. None of the three anions is capable of buffering the interface.

The evidence supports the conclusion that although inhibition by all the XO_4^{n-} ions involves oxidation of iron to a composite film of low dissolution rate, the primary function of the $CrO_4^=$, MnO_4^-, and TcO_4^- ion is their noncathodic action at the interface. In practice, atmospheric oxygen is the chief oxidant (9). The property from which the specific, noncathodic action of these anions derives is therefore not buffering capacity, reducibility, nor formation of an insoluble salt with the cations. The effectiveness of the pertechnetate ion at higher temperatures indicates that the property is not very sensitive to rise of temperature.

As suggested previously (3-5), the difference between inhibiting and noninhibiting XO_4^{n-} ions may be associated with the contrasting polarity of their X-O bonds and the resulting field existing in close proximity to the ions. This field would act precisely in the double layer, across which the reactants in corrosion or passivation, respectively, must pass. Such an electrostatic polarization hypothesis led to the discovery of the remarkable effectiveness of the pertechnetate ion in 1952. Evans (10) used a related concept in 1961, but did not recognize the essential difference between the sulfate and chromate ions with respect to internal polarity and the consequent difference between the short-range fields adjacent to the ions.

The electrocapillary effects of ions in the double layer have been more or less successfully treated for completely polarized electrodes, but the situation becomes more complicated when Faradaic processes are in operation, as in corroding systems. In such cases, a simple treatment in terms of a ψ potential is incomplete, even if possible, since the identity of the rate-determining process can change with the ionic population in the interface, as well as with the potential. That is, the electrochemical rate equation can be altered both in the exponential function containing the net change of potential across the Helmholtz layer and also in the pre-exponential terms which depend on the "chemical" parts of the process. The noncathodic action of the XO_4^{n-} inhibitors is discussed from these points of view in another paper (11).

Manuscript received Jan. 17, 1966; revised manuscript received July 21, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Ellipsometric-Potentiostatic Studies of Iron Passivity

I. Anodic Film Growth in Slightly Basic Solutions

Jerome Kruger and Joan P. Calvert

National Bureau of Standards, Washington, D. C.

ABSTRACT

Cathodically reduced iron was anodically oxidized at potentials in the passive region of the anodic polarization curve in slightly basic sodium borate-boric acid solutions by means of a potentiostat. The kinetics of film growth were studied using an ellipsometer coupled with a fast recording technique, which enabled a determination of the rate of film formation for times less than 1 sec. This study of the kinetics of film growth using a nonelectrochemical technique agreed with kinetic results based on total charge measurements. Three stages of growth were detected: (*i*) First stage—growth limited by a diffusion process in the solution; (*ii*) Second stage—start of limitation of growth by the film involving the combination of several processes difficult to characterize by any rate law; (*iii*) Third stage—growth obeying either a logarithmic or inverse logarithmic rate law. The latter was found to imply that the passive film consisted of an outer layer poorly conductive for electrons.

Earlier ellipsometric studies (1) from our laboratory dealt with the kinetics of growth of passive films on iron in inorganic passivating solutions. As had been found by other techniques (2), that work showed a direct logarithmic growth law of a three-dimensional oxide film was observed. The work to be reported here extends these *in situ* ellipsometric studies on immersed surfaces to the growth of the passive films on iron by means of potentiostatic anodic polarization in slightly basic sodium borate-boric acid solution. This method of passivation has an advantage over both open-circuit passivation in oxidizing solutions and galvanostatic anodic polarization. Potentiostatic anodic polarization enables us to control more carefully the driving force for growth and maintain these conditions throughout the entire growth process, the rate being controlled by the process taking place. Thus, perhaps, we have a better chance to sort out these processes than for the case where the rate is fixed and the driving force changes (galvanostatic oxidation).

There already exists in the recent literature a set of excellent papers by Nagayama and Cohen (3, 4) and Sato and Cohen (5, 6) that deal with the anodic oxidation of iron under the same conditions as those used in this study. Our work complements and extends these studies in two ways: (*A*) By studying film growth using the optical technique of ellipsometry we have a direct nonelectrochemical way of measuring film thickness that does not depend on any possible current producing reactions not involved in film formation. (*B*) We are able to study the early stages ($<$ 10 sec) of the film formation process that are generally neglected in studies of the kinetics of passive film growth.

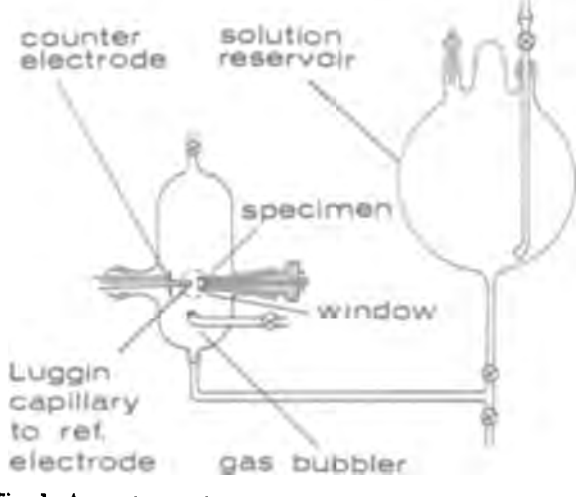

Fig. 1. Apparatus used to study the growth of films by anodic polarization with the ellipsometer. The drawing is not to scale.

This work differs from other *in situ* ellipsometric studies (7-11) on metals exhibiting passivity in one or both of two ways: (*a*) emphasis is placed on the kinetics of film growth and (*b*) the electrolyte is chosen so that little oxide film dissolution occurs. This is important because it leads to metal dissolution and surface roughening. Such an effect would present a complication in the interpretation of the ellipsometric measurements. This is so because the change in the optical parameters measured could be attributed to both film growth and to surface roughening. In this study roughening has been minimized by working in a neutral electrolyte and by growing the passive film rapidly, *i.e.*, by using a fast rise potentiostat to sweep the potential directly from the cathodic region to a potential in the passive region of the potentiostatic anodic polarization curve. The latter minimizes the roughening that would occur in going slowly through the active region before attaining passivity as was recently done in an ellipsometric study of passivity (10). A less ambiguous way of studying the active-passive transition is by going from the passive region to the active one. This will be the concern of the second paper in this series on the decay of passive films.

Cell, Material, and Procedure

Cell.—Figure 1 shows the cell used to observe the iron surface with the ellipsometer, measure its potential, and polarize the surface. The cell consisted of a gas bubbler, two glass windows, a platinum gauze counter electrode 2.25 cm^2 in area, and a Luggin capillary leading through a wetted closed stopcock to the saturated calomel electrode which served as the reference electrode.

The salt bridge was the solution used in the experiments and was drawn directly from the reaction cell through the Luggin capillary. Figure 1 shows also the iron specimen with an exposed area of 1.2 cm^2, mounted in a Teflon holder, and inserted into the cell. Solution was stored in the 2-liter reservoir and introduced into the bottom of the cell as shown in Fig. 1. Around 75 ml of solution were used in a run. This filled about half the cell.

Materials.—Solutions were made up using water of a conductivity of 7×10^{-7} mho or better and analyzed reagent grade H_3BO_3 and $Na_2B_4O_7 \cdot 10H_2O$. The acid

solution used was 0.3*N* and the salt 0.1*N*. Various *p*H's were obtained by mixing these solutions together in the following volume ratios of acid to salt to obtain the *p*H's used in this study: *p*H 7.4, 10/1, *p*H 8.4, 2/1, and *p*H 9.1, 1/4. The solutions were then checked with a *p*H meter. Once the solution was mixed it was placed in the 2-liter solution reservoir and deaerated by prolonged (24 hr) bubbling with purified 99.99% He prior to the introduction of the solution into the cell.

The iron was obtained from the Battelle Memorial Institute and was refined by a floating zone technique. It has less than 10 ppm gaseous impurities and less than 130 ppm metallic impurities.[1]

The specimens were large-grained (average grain size, 3 mm^2). Two specimens were used which had single crystal surfaces exposed to the solution. These were prepared by the strain-anneal technique.

Procedure.—The iron specimen surfaces were first mechanically polished (final polish 1/4 diamond abrasive), then electropolished using the perchloric acid polishing procedures described by Nagayama and Cohen (3), and finally washed in spectrographic grade methanol, dried in a jet of pure oxygen and placed in the cell. Once the iron specimen was placed in the cell and deaerated solution was admitted in the cell, it was possible to reduce any existing oxide film on the iron surface prior to growing a film by polarizing the surface galvanostatically to a cathodic potential. After cathodically reducing the iron surface, the solution was completely replaced by fresh solution with the metal surface maintained at the reduction potential. This step used by Nagayama and Cohen (3) was found to be essential in order to minimize the effect of ferrous ions. Also, oxygen had to be excluded as rigorously as possible in order to obtain reproducible results. When the film was so reduced, optical readings could be made[2] and the surface then brought rapidly by the potentiostat to an anodic potential where films start to form. Film formation was carried out in the potential region −0.4 to +0.8v. All potentials are referred to a saturated calomel electrode. All experiments were carried out at room temperature, 25°±1°C.

Ellipsometric-potentiostatic technique.—Detailed descriptions of ellipsometry in general and the experimental aspects of using ellipsometry in making *in situ* studies of the oxidation and corrosion of metal surfaces are discussed elsewhere (12). Therefore, the discussion here will be confined to the ellipsometric-potentiostatic technique used in this study which allows the kinetics of anodic film growth to be studied during the early stages of film formation at times as short as tenths of a second. The procedure used was an adaption of one recently reported by Reddy and Bockris (13) and consisted of the following: (*i*) After the surface was cathodically cleaned and readings taken, the ellipsometer was set at its extinction point (a minimum of light impinging on the photomultiplier tube). (*ii*) The photomultiplier tube was connected through an amplifier, which was a high impedance electrometer, to a fast two channel recorder of the direct recording galvanometer type with a frequency response as high as 100 Hz. This recorded the photocurrent along with the electrochemical current or potential. (*iii*) The surface was polarized anodically using the potentiostat[3] to potentials where film growth occurs. As soon as the film formed on the metal, the ellipsometer was no longer at the extinction point and the intensity of the light reaching the photomultiplier tube increased. For films <50Å, this was approximately a linear measure of the amount of film formed. This method depends also on the fact that for oxide films on iron Δ, the relative phase retardation, is the optical parameter that is sensitively changing with film growth (< 50Å) while the other optical parameter measured tan ψ, the relative amplitude reduction, is only slightly altered (14). Once the rate of film growth had slowed down (after a minute) more precise readings could be made by hand and the slower parts of the growth process studied. The circuit used to carry out such a technique is given elsewhere (12).

A complex refractive index used for the film formed was 2.5-0.3i (λ = 5461Å). This value was that found for the oxide formed on iron in a gaseous oxidation study (15). For reasons given elsewhere (14) it was reasonable to use in measuring the thickness of the very thin films observed in this study.

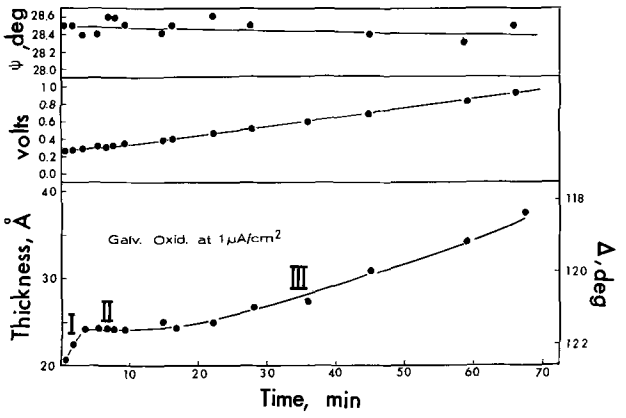

Fig. 2. Optical and electrochemical changes occurring during the galvanostatic oxidation of polycrystalline iron in a solution of pH 8.3. The specimen was pre-oxidized at 0.08v for 1 hr and then oxidized at a constant current density of 1 μa/cm^2.

Results and Discussion

Comparison between ellipsometric and coulometric film thickness measurements.—As a preliminary to the study of film growth kinetics a comparison between optical and coulometric anodic film thickness measurements was made. For this purpose galvanostatic rather than potentiostatic growth was employed. The conditions of growth were essentially the same as those used by Sato and Cohen (5); namely, the iron surface was pre-oxidized at 0.08v for 1 hr and then oxidized at a constant current of 1 μa/cm^2. The optical and coulometric results obtained in a solution of *p*H 8.3 are shown in Fig. 2. All the ellipsometric points shown were measured by the more accurate technique of placing the ellipsometer at extinction rather than the more rapid technique described in the experimental section. The thickness values given in this figure are based on the refractive index value n_2 given for the oxide earlier, 2.5-0.3i. The time is, of course directly proportional to the total charge used in the growth process.

With respect to the ellipsometric measurements, there are three separate regions in the relative phase retardation, Δ *vs.* time plot; before the arrest in Δ-values (called region I), during the arrest (region II), and after the arrest where steady growth occurs (region III). A potential arrest similar to that obtained by Sato and Cohen (5) appears to correspond to the arrest in Δ-values, but this would not be evident from our curve were it not for much more pronounced Δ-value arrest. The relation between the coulometric and the ellipsometric measurements differs in each of these regions and will be considered separately. We will consider only the variations of Δ because, as Fig. 2 shows, the variation of ψ with film growth is slight

[1] Gaseous impurities (ppm): O_2 (vacuum fusion), 2.1; S (colorimetric); 4 ± 3; C (combustion-conductometric), 3 ± 3; N_2 (vacuum fusion), 0.5; H_2 (vacuum fusion), 0.3.
Major metallic impurities (ppm): Al, 15; Cr, 5; Co, 5; Cu, 7; Ni, 20; P, 9; Si, 10.

[2] This cathodic reduction was also used as a check to determine whether roughening had occurred during film growth. Only when the same optical parameters were obtained after reducing a film formed during a given run, was the kinetic data obtained during that run considered valid.

[3] The potentiostat used was a commercial instrument whose rise time as determined under the conditions of these experiments was around 20 msec.

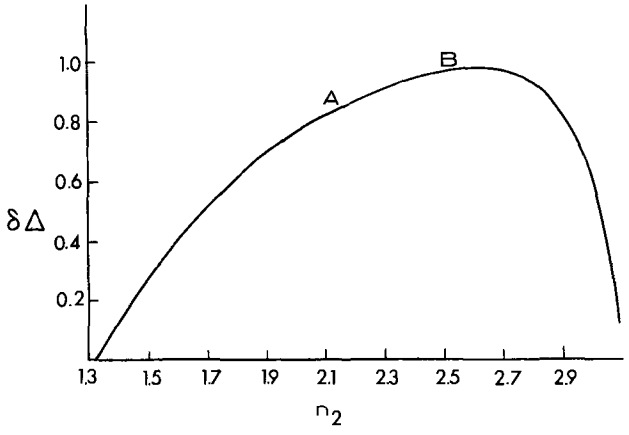

Fig. 3. Theoretically calculated curve showing the effect of varying n_2, the refractive index of the oxide film, on $\delta\Delta$, the change in the phase retardation that occurs on the growth of a 5Å film.

for films whose thickness lies in the range of interest of this study (40Å or less).

Region I.—Before the Δ-value arrest, a film is formed where 0.2 mC/cm^2 are required to cause a change of 1° in Δ as measured ellipsometrically. This compares with a value of 0.9 mC/cm^2 that one would calculate for a film assumed to be Fe_2O_3, density of 5 g/cm^3 and roughness factor of unity having the n_2 given above. This would thus suggest that during the stage before the potential arrest we have a film that has a density lower than 5 and thus probably an n_2 lower than 2.5-0.3i. It is likely that this would mean a film with many empty spaces or perhaps a film made up of discrete separated crystallites of oxide. Such a film probably behaves optically as a continuous film of low refractive index.

Region II.—At the arrest, the empty spaces in the film have filled up sufficiently to shift its n_2 value into a range where a change in n_2 does not appreciably change Δ, as long as the effective thickness is constant. This can be seen from Fig. 3 which shows the result of a calculation of the effect of varying the oxide's refractive index, n_2 on Δ, the change in Δ brought about by the growth of a 5Å film. Between points A and B in Fig. 3 there is only a small change in Δ with n_2. Thus, it would be possible to use up charge without appreciably changing Δ by forming oxide to fill the empty spaces in the film. As long as empty spaces are present and the solution has access to the substrate on which the film is growing, a constant potential would be expected. When the substrate becomes completely covered, the potential then changes and more nearly continuous film grows during the steady growth stage.

Two other explanations may be suggested to explain the Δ-value arrest. It may be related to Sato and Cohen's (6) observation that the outer layer of the passive film has a lower iron content and the process involved is the formation of iron-ion vacancies or excess oxygen ions. Such a process should not produce any observable change in Δ or ψ. Another possibility is that the arrest is associated with the introduction of protons into the Fe_2O_3 lattice, this being necessary for passivation according to some recent ideas of Bloom and Goldenberg (16). Because of the size and mass of the proton, its introduction into the film would probably be even less detectable ellipsometrically than the production of iron-ion vacancies.

Region III.—When the potential and film thickening arrest stage is over, the steady growth stage of a passive film commences. In the steady growth region the attainment of a steady value for the refractive index of the film is a more reasonable assumption than for regions I and II. It is this region that offers the best opportunity to compare the ellipsometrically determined thickness with the coulometrically determined values. A value of 0.242 mC/cm^2 per optically measured angstrom is obtained from Fig. 3. Using the density and composition assumptions described earlier, a thickness ratio of 1.3 can be calculated. Since ellipsometric thickness measurements do not depend on a knowledge of the roughness factor, while electrochemical ones do, the thickness ratio represents the surface roughness factor. A reasonable value for an electropolished surface is 1.3.

Variation of film thickness with potential and pH.—A determination of the variation of film thickness measured at a given time with overpotential[4] is important because it gives us an idea of the fields [or more correctly overfields (17)] involved. Figure 4 shows this variation for three solutions of different pH's used in this study, for a 1 hr polarization at a given potential. At an overpotential of around 0.5v the slope changes for the 7.4 pH solution. This overpotential corresponds to a potential of around —0.2v (SCE) and is near the potential that Nagayama and Cohen (4) call E_a^2, a potential below which Fe^{++} is observed in solution (called by them "region A"), and above which the concentration of Fe^{++} is too low for analysis ("region B"). Very little or no change in slope was observed for the 9.1 and 8.4 pH solutions in the passive region of the polarization curve, roughly between —0.6 to +0.85v (SCE). Our optically determined value for the differential field (dV/dX) [see (17)], for a solution of the same pH, 8.4, as that studied by Nagayama and Cohen (3) agrees with their value to better than 5% for potentials above E_a^2.

The fact that (dV/dX) is greater[5] at the lowest pH (above E_a^2) means phenomenologically that the barrier that the ions must surmount for the film to grow is higher than that existing in the film formed in the pH 9.1 solution.

Below E_a^2 for the 7.4 pH solution, the change in (dV/dX) to a lower value points to a lower barrier. The work of Nagayama and Cohen (4) indicated for the film formed in "region A" has a higher percentage of iron in its outer layer and is less protective because ferrous ions are found in solution. Thus a higher iron content in the film may be related to a lower barrier to the movement of ions.

[4] Our overvoltage values are assumed to be the difference in potential between the potential during film growth, V, as provided by the potentiostat and the open-circuit potential measured after the iron surface has been cathodically reduced. At equilibrium under these circumstances in the pH range used for this study, an oxide film does exist on the metal surface (18). The equilibrium values, E_o, for the solutions shown in Fig. 4 are for pH 7.4, —0.71, for 8.4, —0.75, and for 9.1, —0.78.

[5] It should be noted that since Fig. 4 is a plot of X *vs.* V, the value of (dV/dX) is the reciprocal of the slopes shown in the figure. Also it should be pointed out the current was almost constant when X was measured, $(dV/dX) \approx (\partial V/\partial X)_i$.

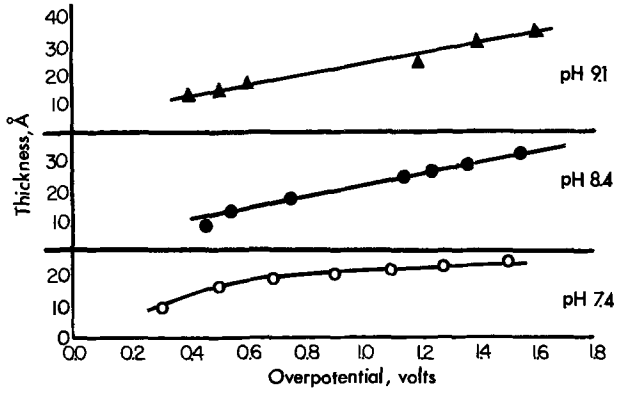

Fig. 4. Comparison of the change in film thickness with overpotential in solutions pH 7.4 (open circles), 8.4 (closed circles), and 9.1 (triangles) used in this study. Specimens were polarized potentiostatically 1 hr at potentials shown.

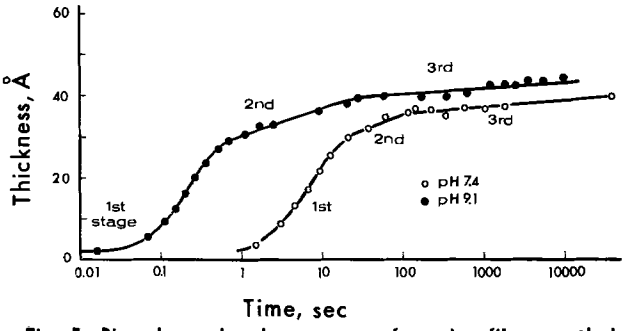

Fig. 5. Plot shows the three stages of passive film growth in solutions of pH 7.4 (open circles) and 9.1 (closed circles) for potentiostatic growth at 0.8v. This also shows that the onset of the three stages is affected by pH. Plot is logarithmic in time.

Stages of film growth.—A rapid recording technique described earlier was used to follow the kinetics of potentiostatic film growth. The growth of the passive film can be followed for times from less than 1 sec to any chosen longer time. Three stages in the growth process can be identified. These three stages are shown in Fig. 5 which also shows the variation in the onset of the stages as affected by *p*H. The division of the growth curve into these three stages is somewhat arbitrary but, except for those times during the growth process when there is a transition between stages, we do not have any difficulty in separating the stages. Strictly speaking, the second stage may not be a true stage in a kinetics sense, because it may be only a transition between the first and third stages. It will be so labeled, however, because there is a possibility, for reasons given in the section where it is discussed, that it may be a true stage.

First stage growth.—Figure 6 shows that the film growth during the first stage in the formation of the passive film follows a square root of time dependence. This was found to give a better fit than either a linear or logarithmic dependence by using a computer programmed for this purpose. Figure 6 also shows that the slope of the straight line plot of thickness *vs.* $\sqrt{t}$, is higher for the solution with the highest *p*H. This linear relationship between the thickness and $\sqrt{t}$ which is obtained by the integration of the diffusion equation (19) suggests that a diffusion process is controlling the rate of film growth during the first stage. Initially, it was thought that OH^- ions were the diffusing species controlling the growth process because the rate increased with an increase in *p*H. However, if the buffering action of a solution is good, the process could not be limited by OH^- diffusion because a well buffered solution would instantaneously supply a given concentration of OH^- ions. Calculations[6] indicate that for the solutions used the buffering action is poor, particularly for the 7.4 *p*H solution. Hence, the situation is complex with diffusion of not only OH^- ions, but also that of borate and boric acid being involved. For this reason the usual diffusion equation (19), which allows one to determine the diffusion coefficient, cannot be used. We can only give an empirical equation

$$x = k_1\sqrt{t} + C \qquad [1]$$

where k_1, the slope of the lines in Fig. 6 is *p*H dependent. This strong *p*H dependence suggests that the most important feature of the first stage is that it is controlled by diffusion through the solution rather than through the film.

To determine if the diffusion of a reacting species, such as oxygen, could be controlling in the first stage, an experiment was carried out using a solution saturated with oxygen. As Fig. 7 shows the concentration of oxidizing species was so high that the first stage $\sqrt{t}$ dependence was over so rapidly that our measuring technique could not detect it. The results obtained could also be due to a change in mechanism that occurs in the oxygen saturated solution.

Second stage growth.—The first stage ends at that point in the growth process at which there is a departure from the linear relationship between thickness and $\sqrt{t}$. When this occurs diffusion through the solution is no longer the rate-controlling step, and we begin to observe a change in the type of rate law governing the process. We call this second stage growth. It appears to be the transition between the solution limited growth of the first stage and the steady-state film limited growth of the third stage. Since the second stage is a transitory one, it is difficult to characterize the type of rate law governing the growth process. Because of this uncertainty, we will not attempt to fit a specific rate law, but will instead just point out the following three qualitative observations:

1. The rate of growth is greater than that in the third stage. This may indicate that the composition of the film formed during the second stage differs from that of the third. It is assumed that a more protective layer, one where ion movement is more difficult, is formed during the latter stage.

2. The possibility of diffusion of Fe^{++} ions in solution being rate controlling is ruled out because current measurements made simultaneously with the optical measurements show that for the coulombs passed all of the Fe^{++} produced have gone into producing the film measured optically at the point of transition between the first and second stages. Film growth during the second stage can therefore not use the Fe^{++} ions present in solution.

[6] The authors are indebted to Dr. William M. Schwarz, Jr., of the Electrochemistry Section of NBS, for making these calculations and pointing out their implications.

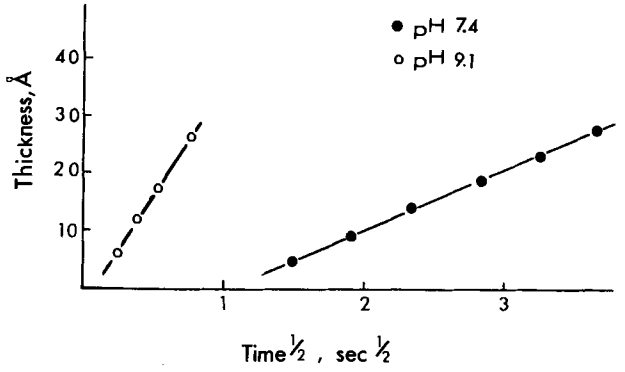

Fig. 6. Plot of film thickness vs. square root of time at pH = 7.4 (closed circles) and pH = 9.1 (open circles) for potentiostatic growth at 0.8v.

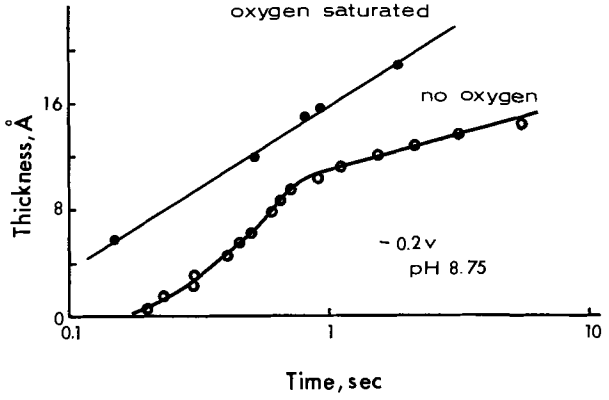

Fig. 7. Plot of film thickness vs. log of time in an oxygen saturated (closed circles) and He saturated solution (open circles). The oxidations were carried out at —0.2v in a solution of pH = 8.75.

Table I. Field, E, existing during the transition from first to second stage kinetics

pH	Potential, v	Overpotential, v	$X^*_{1\to 2}$, Å	(10^6 E v/cm)
9.1	0.8	1.58	27.5	5.8
	0.6	1.38	21.0	6.5
	0.4	1.18	17.9	6.5
7.4	0.8	1.51	22.5	6.8
	0.6	1.31	18.3	7.2
	0.4	1.11	15.4	7.2

* X_{1-2} is the thickness at which there occurs a transition from first to second stage kinetics.

3. When the thickness at which a change from first stage to second stage occurs is divided into the overpotential at which growth is occurring, it is found that this ratio, E, is roughly the same regardless of potential (see Table I). E is the field across the film, assuming that the film is a sufficiently good insulator to support such a field. Thus the first stage may end at that point in time when the field across the film has dropped to a value low enough so that passage of ions through the film becomes rate determining. This assumes that the growth process is field dependent. The results of Table I indicate this may be so.

Third growth stage.—This is the steady-state growth stage and occurs after about the first minute of the growth process. The growth that occurs during this stage is one that has been studied almost exclusively in most other kinetic studies of anodic oxidation. As Fig. 8a and b show this stage fits equally well either the logarithmic (x *vs.* ln t) or inverse logarithmic ($1/x$ *vs.* ln t) rate laws. Figure 9 is for single crystal specimens. A few experiments were carried out using two single crystal surfaces of (110) and (311) orientations. Figure 9 shows that the orientation of the metal surface also affects the rate. This aspect which is of great importance was not gone into in much detail in this study, but will be explored further in later studies. It is interesting to point out, however, that the (110) surface (the closest packed surface in the bcc system) exhibited the higher rate. This fits well with another study (1) that showed that the (110) forms the least protective film.

The logarithmic law implies a number of different mechanisms that are listed by Sato and Cohen (5). None of these require the existence of a large field dependent on film thickness to promote the growth process. Figure 8a shows the direct logarithmic rate is independent of potential (approximately parallel lines for different potentials), but the intercept varies with potential. These results agree with the empirical equation obtained by Sato and Cohen (5) for the same system. They give the expression for current as follows

$$i = k \exp\ (V - Q/B) \qquad [2]$$

where i is the current, V the potential, and Q the total charge accumulated in forming the film; k and B are constants. To compare their coulometric results with our optical ones Equation [2] is integrated and the film thickness, X, introduced in place of charge using the factor determined experimentally (0.242 mC/cm²/Å)

$$x = \frac{B}{0.242} \ln (t + t_o) + \frac{B\beta}{0.242} V + C \qquad [3]$$

The t_o in Eq. [3] is a constant with the unit of time, resulting from the integration, whose value depends on the time scale selected. On the basis of the empirical expression they obtained and because their rate constant B is temperature dependent,[7] they concluded that the various mechanisms leading to direct logarithmic growth do not fit. Instead, they proposed a "place exchange" mechanism for the oxidation of iron. This mechanism involves film grown by the simultaneous exchange of positions between oxygen and iron ions for all layers of these two species forming the film. In this way, oxygen at the solution interface is incorporated into the film while, likewise, iron at the metal-oxide interface is also incorporated.

The average values for a large number of runs obtained for the constants B and β by this ellipsometric study compared with those obtained by Sato and Cohen by electrochemical measurements and are shown in Table II. This agreement is reasonble for the pH 8.4 considering the fact that different iron was used and various assumptions were made with regard to the density and optical constants of the oxide, and the roughness factor of the surfaces. It can be seen from Table II and Fig. 4, however, that this study does indicate that β was found to vary with pH, whereas Sato and Cohen did not find any variation. Whether these variations are real or due to the differences in the two techniques of measurements, *e.g.*, the optical constants of the films formed at different pH's may vary, we cannot say. Possible reasons for the

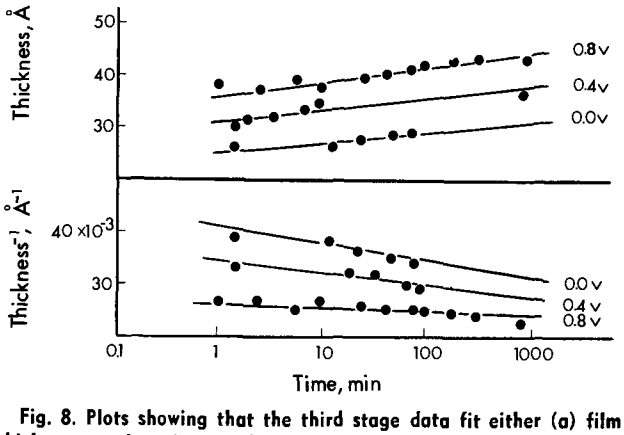

Fig. 8. Plots showing that the third stage data fit either (a) film thickness vs. log time or (b) reciprocal of film thickness vs. log time at potentials shown.

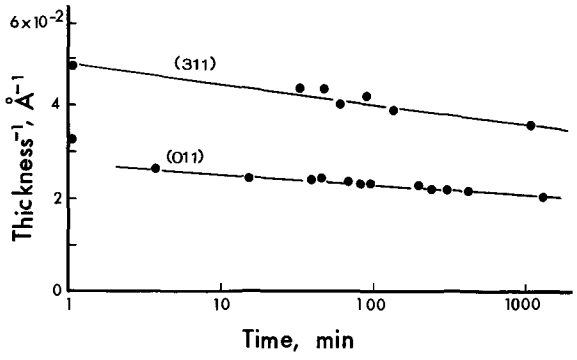

Fig. 9. Plot of reciprocal of film thickness vs. log time for (311) and (110) surfaces.

[7] If B were not as temperature dependent as Sato and Cohen (5) found, electron transport through the film could be rate limiting. Such a process would lead to a logarithmic law.

Table II. Average values of B and β

	pH	B/0.242, Å	β, v^{-1}
Sato and Cohen	8.4	0.77	19.2
Nagayama and Cohen	8.4		20*
This study	9.1	0.76 ± 0.1	28 ± 1*
	8.3	1.08 ± 0.3	18 ± 1*
	7.4	1.04 ± 0.3	12 ± 1*

* These values are based on A *vs.* η or A *vs.* V curves similar to that of Fig. 4, since, as can be seen from Eq. [3], the slope of this curve for a fixed time is $B\beta/0.242$.

variation of β with pH were given in the earlier section on the variation of film thickness with potential and pH.

Empirically, our results can be reasonably related to those obtained by Sato and Cohen and treated in the same way but using optical rather than electrochemical measurements. We will now consider in detail the other way of looking at the data which, as Fig. 8 shows, fit an inverse logarithmic growth equally well. When this type of growth is observed, we can consider the rate to be controlled by the current of Fe^{++} over an activation barrier, W. For such a process a plot of the reciprocal of the film thickness *vs.* the log of time should yield a straight line. Figure 8b shows such a plot for 3 different potentials, all above E_a^2. The rationale behind such a plot is based on the approximate integration of the equation for the ion current (20) neglecting the backward field, whose effect is small at potentials above E_a^2 where virtually no Fe^{++} ions are found in solution. This equation is

$$i = 2a^* n \nu ze \exp - \left[\frac{W - zea^*\eta/X}{kT} \right] \qquad [4]$$

where n is the number of mobile ions per unit volume, ν, the frequency, ze the charge on the mobile ion, η the overvoltage, a^* the activation jump distance, and X is the film thickness. An approximate integration of the equation gives

$$\frac{1}{X} = \text{Const.} - \frac{1}{X_1} \ln t \qquad [5]$$

where

$$\frac{1}{X_1} = \frac{kT}{zea^*\eta}$$

This is the inverse logarithmic rate law derived by Cabrera and Mott (21). From the expression for $1/X_1$ as derived from this theory, we can see that we would expect a plot of X_1 *vs.* η to yield a straight line. Figure 10 is such a plot for the two extreme pH solutions studied. Each point represents the averages of at least three runs. It can be seen that the values for both solutions fit reasonably well a straight line, the 7.4 pH solution showing more scatter.

Since the dependence of X_1 on η, as shown in Fig. 10, is reasonably linear and because an indirect logarithmic rate law is observed, we can consider the mechanism of passive film growth on iron in nearly neutral solutions as being similar to that for aluminum or tantalum, namely, field assisted migration of cations through the film to react with oxygen or OH^- at the solution-oxide interface. This mechanism has indeed been proposed for iron by Vetter (22), Ord (23) more recently, and others. A difficulty, however, arises when comparing the mechanism of passive film growth on iron to that of aluminum or tantalum. The oxides on the latter two metals are very poorly conductive for electrons and can thus support large fields. However, the oxide film on iron is assumed to be a good electronic conductor (22) and would thus not be able to support the 10^6-10^7 v/cm field necessary to pull cations through the film. The assumption that the passive film on iron is a good electronic conductor is probably based mostly on the fact that one gets oxygen evolution when a thin film is still present and at fairly low potentials as compared to aluminum (24). However, as the Pourbaix diagram for iron shows (18) at the oxygen evolution (transpassive) potentials the possibility of a change in the nature of the film exists. Electron diffraction studies from our laboratory (25) have indicated that the γFe_2O_3 found for films formed in the passive region is not found for films formed at potentials in the transpassive region. While still at passive potentials, however, the existence of γFe_2O_3 at the outer part of the film is most probable (3, 25). This oxide is probably a very poor electronic conductor (26) and could support the field required by the theory. As Nagayama and Cohen (3), Vetter (27), and others have pointed out, there exists a strong possibility that the γFe_2O_3 exists as an outer layer of the passive film next to the solution with Fe_3O_4 being next to the metal. Since Fe_3O_4 is a good electronic conductor, the field just postulated would exist only across the poorly conductive γFe_2O_3. In line with this, Vetter (27) has postulated that all of the potential drop in a passive film is across the outer layer. The reasonableness of this concept can be seen if we first calculate a value for the jump distance, a^*, using the slope from Fig. 10 and the expression for X_1 in Eq. [5]. The values in this plot are based on the assumption that the field is across the entire film. Such an assumption leads to a value of around 10Å for a^*, assuming that the mobile ion has a charge of 2. Estimates of a^* for the (110) and (311) surfaces were 8.3 and 4.6Å, respectively. Vetter (22), assuming that the ferric ions are mobile, obtained a value of 5.5Å for films formed in H_2SO_4 solution. Our value as well as Vetter's appears to be abnormally high. However, if the field is only across a poorly conducting outer layer of the passive film, the value of X_1 becomes roughly equal to the product of the fraction of the film that is poorly conducting and the value of X_1 obtained by assuming the field is across the entire film, *i.e.*, the values plotted in Fig. 10. An estimate of this fraction can be obtained from the work of Nagayama and Cohen (3), from the ratio of the charge required to reduce the outer layer to the total charge accumulated in forming the film. The fraction obtained using this assumption and their data is around 1/3. With this assumption the value of a^* becomes 3Å, a most reasonable value. Using this value for a^* or the larger value and either 1/3 the limiting thicknesses shown in Fig. 4 or the whole thickness, the same values for an estimate of W, the activation barrier can be made from the approximate expression for the limiting thickness (22)

$$X_L = \frac{Zea^*\eta}{W - 39kT} \qquad [6]$$

A value of 1.8 ev (41 kcal/mole) was obtained for the pH 9.1 solution and 2.0 ev (46 kcal/mole) for pH 7.4. Values estimated for the single crystal surfaces are about 1.5 ev for both orientations studied. All the values of W are rather high compared to the valve metals (18). This is reasonable in light of the fact that the passive film on iron is much thinner than that on the valve metals such as Al or Ta.

It must be emphasized that the reasonable value of 3Å for a^* is based on the assumption that the field is only across that part of the film that has a low concentration of iron, the part that Nagayama and Cohen concluded contains iron vacancies and Fe^{+6} ions. If the field is across all of the γFe_2O_3 they found to be present, a^* becomes much larger, around 7Å. Therefore, if the field assisted cation migration theory is valid, it

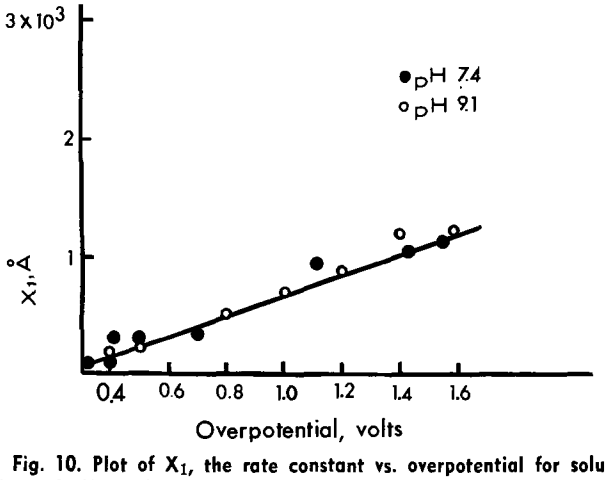

Fig. 10. Plot of X_1, the rate constant vs. overpotential for solutions of pH 7.4 (closed circles) and 9.1 (open circles).

is more reasonable to expect that the field is only across a vacancy rich or, using Bloom and Goldenberg's model (16), a proton rich outer third of the total film. This portion would be expected to be more poorly conducting than a more stoichiometric γFe_2O_3 and would thus be able to support a large field.

Recent work by Ord and DeSmet (28) combining ellipsometric and capacitance measurements on the same system described here indicate that the field is only across the outer part of the film as proposed here. Electrode capacity studies by Wisdom and Hackerman (29) also indicate that the passive film over a wide range of pH has two sorts of material, the last formed being responsible for passivity, and being different from bulk oxides.

Another indication of the importance of the composition of the outer part of the passive film and its bearing on the fields in the film can be obtained by considering film growth at potentials below E_a^2. Here a measurable concentration of Fe^{++} is present in solutions, and thus a more complicated set of conditions exist. Because of this it has been difficult to obtain completely reproducible results. The reason for this lies in the fact that two factors affecting the rate in opposite ways are probably present. The first factor, the increase in importance of a backward field[8] with decrease in overvoltage, tends to decrease the rate and is probably responsible for the appearance of Fe^{++} ions in solution. The second factor, a less protective film which would tend to increase the rate, is probably present on films formed at potentials below E_a^2 as indicated by results of Nagayama and Cohen (3). They found a higher concentration of iron which they ascribed to a lower concentration of defects in the films formed below E_a^2. Loosely expressed, they found the higher the concentration of defects, the more protective the film was.

This model concerned with field assisted movement of cations through a poorly conducting outer layer neglects the movement of cations through the inner layer. Electron diffraction studies (30) give a clue to the manner in which this may occur. These studies indicate that this inner layer is highly oriented, but made up of a very high concentration of grain boundaries or pipes of Fe_3O_4 so that easy diffusion of Fe^{++} is a good possibility. In this manner passage of Fe^{++} through the inner layer would be relatively easy. The second stage growth may thus be a combination of an easy diffusion growth through the inner "porous" Fe_3O_4 and the formation of an outer γFe_2O_3 that becomes more and more nonconductive and less porous with time until it can support a field that assists cation movement until the field becomes too small. Since the second stage is thus a mixture it is difficult to characterize by a simple rate law.

Summary

These studies have shown that by the use of the optical technique of ellipsometry we were able to get reasonable agreement with other studies on the same system using an entirely different way of measuring the amount of film, coulometry. Three growth stages were observed which were interpreted as follows: (*i*) First Stage, growth limited by the rate of diffusion of some species through the solution giving a process where the thickness is proportional to $\sqrt{t}$; (*ii*) second stage, the onset of the limitation of growth by the film but because it is a combination of two or more processes difficult to characterize by any rate law; (*iii*) third stage, described equally well by either a logarithmic or inverse logarithmic rate law. The consequences of the former have been interpreted elsewhere (5). The latter was shown to imply that the passive film involves a film whose outer layer is poorly conductive for electrons allowing a high field to be built up which assists the movement of cations through the film to the solution interface where they are oxidized.

This study has shown that rate studies are not able to decide definitely between the above two mechanisms in a slightly basic solution.

[8] This backward field should be part of Eq. [4], but was left out for simplicity and because it is unimportant until η becomes small (17).

A Study of the Inclusion of a Radioactive Addition Agent in Bright Nickel

Warren R. Doty

Electrochemistry Department, Research Laboratories, General Motors Corporation

and Bernard J. Riley[1]

Physics Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

C-14 allyl and C-14 quinaldine labeled N-allyl quinaldinium bromide (NAQ) were prepared and their inclusion in bright nickel deposits studied. The amount of NAQ inclusion was found to depend on the mass transfer processes, the diffusion layer thickness, and the catalytic state of the nickel deposit.

Previous publications from this laboratory on the mechanism of leveling in bright nickel plating have shown that radioactively labeled addition agents can be used to study the problem (1-3). Work with C-14 and S-35 labeled sodium allyl sulfonate (SAS) demonstrated that slightly more radioactivity was incorporated in the nickel deposit adjacent to peaks rather than valleys of a microprofile surface. These results are in agreement with the general theory of leveling which postulates that a thinner diffusion layer above peaks facilitates transfer of addition agents to these areas, while the relatively thicker diffusion layer above valleys impedes transfer (4, 5). Adsorption of the addition agent or its reduction product leads to localized polarization and partly inhibits deposition of nickel ions. The net effect is the deposition of slightly more metal in the valleys than on the peaks.

In addition to the leveling phenomena the effect of other plating variables, such as *p*H, current density, and concentration of other addition agents on the amount of inclusion of the labeled compound, can also be determined. As is well known, in bright nickel plating, two or more addition agents are necessary to achieve the desired results. Addition agents are categorized as class I and class II brighteners, and a member of each class must be used (6). SAS is a typical class I brightener. The class II brightener used with SAS in the earlier work was N-allyl quinaldinium bromide (NAQ).

The results obtained with C-14 and S-35 labeled SAS in combination with nonradioactive NAQ have been reported (3) and are in agreement with the known behavior of class I brighteners. Recently Edwards also reported similar results with two other S-35 labeled class I brighteners (7, 8).

Relatively little work has been done, however, on the inclusion of class II brighteners.[2] Because of the commercial importance of class II brighteners and the very low concentrations that are normally employed, this problem seemed worthy of study by the radioisotope method.

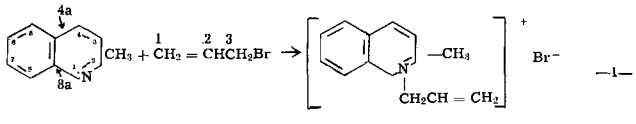
The class II brightener chosen for study was NAQ, primarily because some experimental technique had been developed in its use from the earlier work. Which carbon atom should be labeled was the next decision. In any study involving radioactive compounds, it is necessary to be certain that the labeled portion of the molecule represents the behavior of the whole molecule in all reactions. Purity, availability, and cost of the radioactive intermediates are other factors.

C-14 allyl bromide (3 position) meets all of the latter considerations. Reacting this compound with quinaldine as shown in reaction 1 forms C-14A NAQ. Previous work had shown, however, that some of the NAQ was cleaved during electrolysis at the allyl-to-nitrogen bond and that propene was identified in the gases (mainly hydrogen) which had escaped the cathode (3). The use of C-14A NAQ, therefore, is suspect as correctly representing the behavior of NAQ if only the deposit is to be counted. Nevertheless, C-14A NAQ was prepared because at the time no source for C-14 quinaldine was available.

Later, after the inclusion studies were under way, a supplier of C-14 quinaldine (8a position) was located. A sample of C-14Q NAQ was prepared and the inclusion experiments repeated. With both functional parts of the NAQ molecule labeled, comparison of the relative inclusion of each part could now be made.

Experimental

Synthesis of NAQ.—Quinaldine and allyl bromide react to form the quaternary compound, NAQ.



—1—

As reaction 1 proceeds the liquid reactants are consumed and a solid product formed. In order to moderate the reaction and minimize the occlusion of starting materials in the NAQ, the use of an inert solvent is necessary. Vanderkooi (9) had used isopropanol for this purpose. This same solvent was used in this work before it was discovered that allyl bromide reacts with most of the lower alcohols. One of the products of the solvolysis reaction is HBr which combines with quinaldine and precipitates as quinaldine hydrobromide.

Both radioactive NAQ preparations were contaminated with quinaldine hydrobromide to different degrees and had to be purified. Details of the purification procedure (neutralization and solvent extraction) are omitted in the interest of brevity, but will be supplied on request. Pertinent data of the purified products are summarized in Table I.

Pure nonradioactive NAQ was prepared by refluxing a 1:2 mole ratio of quinaldine and allyl bromide at 70°C for 48 hr with an equal volume of nitrobenzene. Excess allyl bromide was removed by distillation. After cooling to room temperature, the product was filtered and washed with isopropanol. The crude product (mp 225°-228°C) was found by infrared and ultra-

[1] Now with the Military Vehicles Organization, General Motors Corporation, Warren, Michigan.

[2] After this work was completed, a study of class II brighteners was published by J. Edwards and M. J. Levett, *Trans. Inst. Metal Finishing*, 44, 27 1966).

Table I. Radioactive NAQ data

Sample	Volume, ml	Concentration, mg/ml	Activity, cpm/ml	Specific activity, millicuries/millimole
C-14A NAQ	5	13.2	3.5×10^7	0.48
C-14Q NAQ	10	6.15	3.9×10^7	1.15

Table II. Plating solutions and conditions

Bath composition:	300 g/liter $NiSO_4 \cdot 6H_2O$	
	30 g/liter $NiCl_2 \cdot 6H_2O$	
	30 g/liter H_3BO_3	
Plating conditions:	pH	3.0*
	Current density	43 ma/cm²*
	Temperature	60°C
	Agitation	200 rpm
	Addition agents	
	SAS	2000 mg/liter*
	NAQ	4 mg/liter

* Items were studied as individual variables in which case all the other conditions were maintained at the above values.

violet analyses to be free of major contamination. Both spectra were unchanged by recrystallization of the NAQ from isopropanol-water. Melting point of the recrystallized NAQ was 227°-228°C.

Sodium Allyl Sulfonate.—Sodium allyl sulfonate is available as 2-propene-1-sulfonic acid sodium salt.[3] It can be prepared by scaling up a previously described synthesis (1). In this case the procedure is modified to include the dropwise addition of allyl bromide to a well-stirred sodium sulfite solution. The concentration of SAS in the stock solution can be determined by the bromate-bromide method.

Equipment and other conditions.—The plating cell, related equipment, and the method of preparing foil samples for proportional counting are described in earlier reports (1, 2). A circular stainless steel shield was substituted for the previously used lead shield. The area (1 cm²) of the hole remained the same. The change of materials was made because the natural radioisotopes in lead constituted a large background compared to some of the samples. Other conditions are summarized in Table II.

Results

Autoradiography.—The autoradiogram shown in Fig. 1 is representative of a deposit plated in a C-14Q NAQ solution. Deposits from a bath containing C-14A NAQ gave identical autoradiograms.

The cathode from which the foils were removed had a peak-to-valley height of 0.072 cm and a peak-to-peak separation of 0.161 cm. The autoradiogram in Fig. 1 shows a greater darkening occurred on the part of the film next to the peaks as compared to the valleys, indicating more radioactivity was included in the nickel deposited on the peaks. Since the same results were found for C-14A and C-14Q NAQ, it can be concluded that the whole NAQ ion is preferentially incorporated in the deposit on the peaks.

Inclusion of NAQ.—For every data point, at least two and as many as 10 samples were prepared for counting. As is the case with the measurement of low levels of radioactivity, the agreement between replicate samples can sometimes be poor. Therefore, no measurements were discarded unless it was certain that an error had been made in the sample preparation.

From the general shape of the inclusion curve, an equation was selected and the method of least squares used to obtain the best fit to the data. The mathematical procedure was carried out by a computer. The equations used to represent the inclusion curves will be given in subsequent sections.

[3] Eastman Kodak Company.

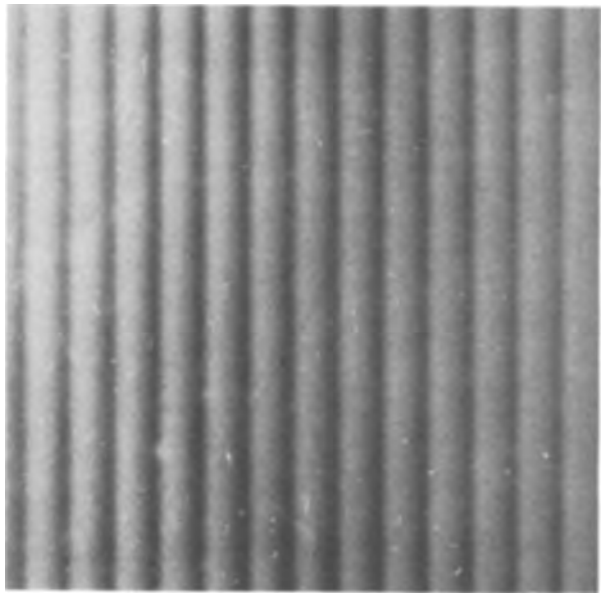


Fig. 1. Autoradiogram of the top of a foil containing C-14Q NAQ

It was convenient to treat and to plot the data in terms of "apparent" inclusion. Apparent inclusion is defined as the observed count rate of the sample without correction for self-absorption. It is known in radioisotope work that the count rate for beta radiation increases as a function of sample thickness until an "infinite" thickness is attained. Above infinite thickness the count rate becomes constant. Since the infinite thickness for C-14 beta radiation in a nickel matrix is 12μ, the sample thickness of 13μ used in this work was infinitely thick. Small variations in sample thickness thus have little effect on the observed or apparent count rate.

The true count rate, N_o, can be calculated from the apparent count rate, N, by correcting for the self-absorption of C-14 beta radiation. The correction is expressed by

$$\frac{N}{N_o} = e^{-\alpha t} \qquad [1]$$

where α is the linear absorption coefficient of nickel and t is the nickel thickness. The major problem in applying Eq. [1] is the difficulty of accurately measuring t. Small errors in t will lead to large errors in N_o.

One of the benefits of fitting a curve to the data is that differences in sample thickness are eliminated, and an average thickness for all samples may be assumed. Eighteen samples were measured, and an average of 1.32×10^{-4} cm was found. Using this value for t, and 2.14×10^3 cm^{-1} for α, Eq. [1] reduces to

$$N_o = 16.9\,N \qquad [2]$$

Any value of "apparent NAQ" inclusion in the following figures can be converted to total NAQ inclusion by Eq. [2].

Effect of NAQ concentration.—Inclusion of C-14A and C-14Q NAQ in nickel deposits as a function of NAQ concentration in the plating bath is shown in Fig. 2. These curves were fitted to the equation

$$y = Ax^1 + Bx^2 + Cx^3 \qquad [3]$$

where y is the apparent NAQ inclusion in the deposit and x the NAQ concentration in the bath in milligrams per liter. A, B, and C are empirically determined constants having the following values:

	A	B	C
C-14Q NAQ	11.05	1.070	—0.0169
C-14A NAQ	10.91	0.067	0.0207

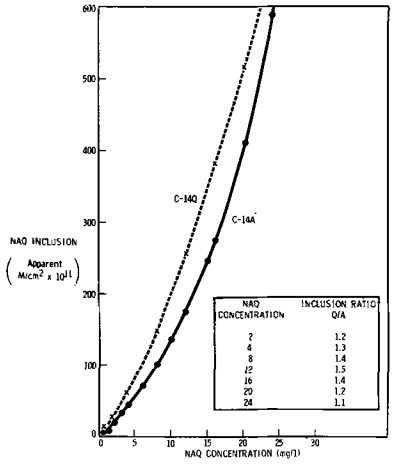

Fig. 2. Inclusion of NAQ vs. NAQ concentration

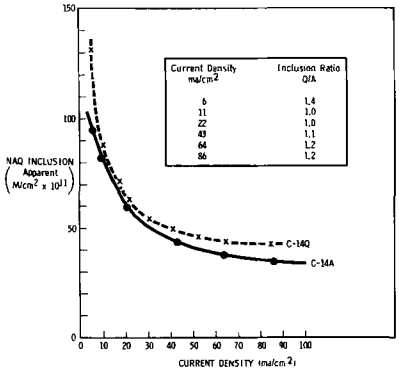

Fig. 3. Inclusion of NAQ vs. current density

According to Eq. [3], inclusion is proportional to NAQ concentration in the bath only at low concentrations of NAQ where the effect of the Bx^2 and Cx^3 terms is small. At higher concentrations of NAQ, the effect of the Bx^2 and Cx^3 terms increases; and, as Fig. 2 shows, both the C-14A and C-14Q inclusion curves bend toward the y axis. Over the concentration range investigated (0-25 mg/liter NAQ), Eq. [3] states that NAQ inclusion increases as a power function of its concentration in the bath, *i.e.*, NAQ increases its own inclusion.

Effect of current density.—Quantities of included C-14A and C-14Q NAQ are shown in Fig. 3 as functions of current density. These curves were fitted to the equation

$$y_i = Aw^{\circ} + Bw^{-1} + Cw^{-2} \qquad [4]$$

where y_i is the apparent NAQ inclusion and w is the current density in milliamperes per square centimeter. A, B, and C are empirically determined constants having the following values:

	A	B	C
C-14Q NAQ	35.83	534.6	— 290.4
C-14A NAQ	25.64	795.4	—2255.0

From Eq. [4] it can be seen that the amount of inclusion will be determined by the Bw^{-1} term at high current densities while it will be dependent on both Bw^{-1} and Cw^{-2} at low current densities.

It has been suggested that inclusion of class II brighteners is diffusion limited at higher plating current densities (5, 7). If this were true, the rate of inclusion, μ_i should level off and become constant after a critical current density is exceeded. The rate of inclusion can be calculated from the apparent inclusion values of Fig. 3 by converting these values to total

Table III. Rate of inclusion of NAQ

Current density, ma/cm²	Plating time, sec	μ_i C-14Q, M/cm²-sec × 10^{12}	μ_i C-14A, M/cm²-sec × 10^{12}
6	12,000	1.84	1.34
11	6,000	2.41	2.34
22	3,000	3.50	3.40
43	1,500	5.53	4.95
64	1,000	7.65	6.42
86	750	9.35	7.92

inclusion using Eq. [2] and dividing by the appropriate plating times. The data are shown in Table III where it can be seen that μ_i increases steadily with current density. No limiting μ_i is reached.

Effect of SAS concentration.—Inclusion of C-14A and C-14Q NAQ as a function of SAS concentration in the plating bath is shown in Fig. 4. From 0 to 400 mg/liter, there is a rapid rise in NAQ inclusion; this portion of the curve is approximated by two straight lines. Above 400 mg/liter, the curve was fitted to the equation

$$y_i = Az^{\circ} + Bz^{-1} + Cz^{-2} \qquad [5]$$

where y_i is the apparent NAQ inclusion and z is the SAS concentration in grams per liter. A, B, and C are empirically determined constants having the following values:

	A	B	C
C-14Q	36.72	27.35	5.44
C-14A	18.27	46.65	—9.12

This equation is the same as the one used to express inclusion as a function of current density and can be interpreted similarly.

The cathode potential as a function of SAS concentration is also shown in Fig. 4. Cathode potentials were measured with a L&N potentiometer using a fiber tip saturated calomel electrode in a Luggin capillary. The salt bridge was filled with saturated NaCl to prevent crystallization of potassium-nickel sulfate in the capillary tip.

An interpretation of Fig. 4 can be given by considering the inclusion curves to be the resultant of two competing phenomena, both of which depend upon SAS concentration.

In the region 0 to 400 mg/liter of SAS, many things occur simultaneously: SAS inclusion in the deposit is rapidly increasing (3); NAQ inclusion is also increasing; cathode potentials shows a smooth increase; the appearance of the deposit changes from dull to bright. It is believed that inclusion of SAS serves to create surface adsorption sites at a rapid rate (8). In support of

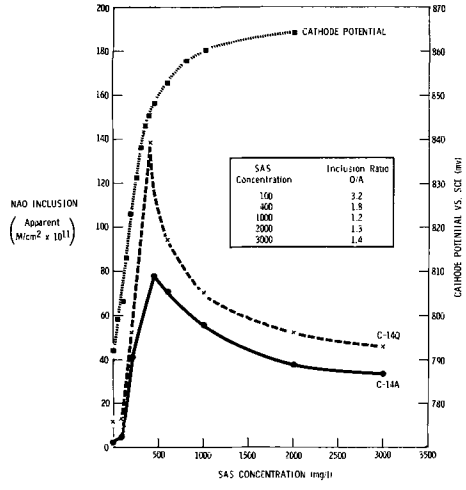

Fig. 4. Inclusion of NAQ vs. SAS concentration

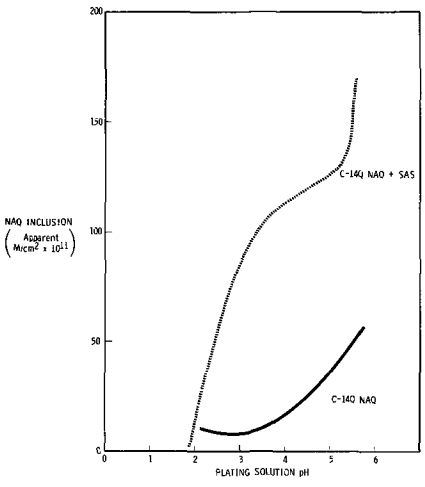

Fig. 5. Inclusion of NAQ vs. pH

this point is the evidence of greatly reduced grain size, even when low concentrations of class I brighteners are employed (10). More sites are created than can be filled by the SAS, and consequently NAQ inclusion rises to a maximum.

In the region above 400 mg/liter of SAS, the regular decrease in NAQ inclusion is due to increasing competition of SAS ions for adsorption sites. From other work (3) it is known that SAS inclusion continues to increase up to approximately 1 g/liter, then levels off and becomes fairly constant. Creation of adsorption sites would probably follow the SAS inclusion curve, but NAQ ions would have to compete with increasingly larger amounts of SAS in order to occupy these sites.

The Effect of pH.—The inclusion of C-14Q NAQ as a function of *p*H in the plating bath is shown in Fig. 5. Only C-14Q NAQ was used for these experiments because it represents better the behavior of the NAQ molecule. As *p*H increases over the range 3.0-5.0, the amount of NAQ included in the deposit increases. With 2 g-liter of SAS in the bath, the same general trend of NAQ inclusion with *p*H is found, but over a much wider range. These results again suggest an effect of plating conditions on the surface density of adsorption sites. Increasing *p*H increases the amount of codeposited colloidal nickel hydroxide which affects the crystallographic structure of the deposit and, hence, the density of adsorption sites. Similar inclusion results were observed by Edwards and Levett (8) for low concentrations of saccharin.

It should be pointed out that these *p*H data were determined in a smaller plating cell and with a slightly different method of sample preparation to obtain more efficient use of the radioactive NAQ. Results are comparable among themselves, but absolute values may differ from data shown in Fig. 2, 3, and 4.

Discussion

All of the inclusion results can be explained by consideration of the principles involved in mass transfer, diffusion layer thickness, and catalytic activity of a surface.

The three modes of mass transfer participate to varying degrees in the movement of addition agent ion, depending on whether the addition agents are in the bulk solution or near the cathode-solution interface. Hydrodynamic flow, caused by agitation and convection currents, is the main mode of transport for all ions in the bulk solution. Diffusion and electrical migration becomes significant at the cathode-solution interface (11). However, the effect of electrical migration usually can be neglected for addition agents because of the large concentrations of nickel and other inorganic ions that are normally present. Thus diffusion is generally concluded to be in the main process by which addition agents move through the cathode-solution interface (5, 7, 8).

The rate of diffusion, μ_d, is given by the well-known equation

$$\mu_d = \frac{D(C_b - C_o)}{\delta} \qquad [6]$$

where c_b and C_o = the bulk and interfacial concentrations, D = diffusion coefficient, δ = diffusion layer thickness.

Since D is a constant at a given temperature and C_b is fixed experimentally, the first approximation of the amount of NAQ inclusion will depend on C_o. However, C_o will depend on the rate of supply, μ_d, and the rate of inclusion, μ_i. Factors affecting the rate of supply are straightforward and are given by the terms of Eq. [6]. Rates of inclusion vary with the concentrations of SAS or hydrogen ions and will be explained later by postulating different numbers of adsorption sites created by addition agent inclusion.

Factors affecting rate of supply of NAQ are C_b and δ, but δ is a function of both the hydrodynamic conditions and the current density. Figure 2 shows that when C_b is increased NAQ inclusion also increases. There appears to be no limit to the amount NAQ that can be included in nickel. Only brittleness of the deposit limited the highest NAQ concentration to 25 mg/liter in this study.

Excluding convection effects the thickness of δ is constant when adjacent to smooth surfaces, but is affected by a microprofile surface (5). The autoradiogram (Fig. 1) shows inclusion of NAQ in the deposit is slightly larger above peaks than in valleys. A δ that is relatively thinner next to peaks and thicker next to valleys can account for the differences in diffusion of NAQ to these areas (12).

Because of the importance of agitation on δ and μ_d, it was attempted to maintain reasonably constant hydrodynamic conditions by using constant stirring speed, temperature, solution composition, cell geometry, and electrode shape. It is believed that δ was reproducible to within 15% for each variable investigated except *p*H. This can be shown by calculating μ_i from the inclusion data in Fig. 2, 3, 4, and 5 at the common point (4 mg/liter NAQ, 43 ma/cm²; 2000 mg/liter SAS; and *p*H 3.0).

Data from	Variable	μ_i C-14Q NAQ	μ_i C-14A NAQ
Fig. 2	NAQ	6.8×10^{-12} M/cm²-sec	5.2×10^{-12} M/cm²-sec
Fig. 3	CD	5.5×10^{-12} M/cm²-sec	5.0×10^{-12} M/cm²-sec
Fig. 4	SAS	5.9×10^{-12} M/cm²-sec	4.4×10^{-12} M/cm²-sec
Fig. 5	*p*H	9.7×10^{-12} M/cm²-sec	—

The average μ_i excluding that of Fig. 5, is $6.1 \pm 0.6 \times 10^{-12}$ M/cm²-sec for C-14Q NAQ and $4.9 \pm 0.5 \times 10^{-12}$ M/cm²-sec for C-14A NAQ. The experiments with *p*H as the variable were done in a smaller sized cell and indicate a smaller δ was probably obtained because of different hydrodynamic conditions.

The amount of NAQ inclusion shown in Fig. 4 and 5 is directly proportional to μ_i. Although the plating conditions should have given a reasonably constant μ_d, it can be seen from the figures that μ_i varies widely. From Fig. 4 the maximum μ_i for C-14Q NAQ is 15.7×10^{-12} M/cm²-sec and occurs at 400 mg/liter of SAS. This is approximately 2.5 times the average μ_i found previously when the SAS concentration was 2000 mg/liter. Similarly, the highest μ_i calculated from the data of Fig. 5 is 18.8×10^{-12} M/cm²-sec or nearly double the rate at *p*H 3.0. Neither the change in SAS concentration nor *p*H would be expected to have affected μ_d or δ. Therefore, changes in μ_i cannot be explained by changes in rate of supply of the NAQ but rather by differences in the catalytic properties of the nickel surface. Adsorption sites, according to Edwards and Levett (8), are created by inclusion of either class I or class II brighteners. The density of sites depends on the relative concentrations of the two brighteners as well as their effectiveness. This hy-

pothesis is applied in more detail in the Results section.

The mechanism of NAQ inclusion is believed to require an initial adsorption step followed by a partial reduction or cleavage of the ion. Possible reduction products were, at first, thought to be propene (3) (collected in the cathode gases) and quinaldine which can be isolated from used baths in large amounts (~25%) by solvent extraction. However, when nickel samples containing C-14A and C-14Q NAQ were dissolved anodically, the Q/A ratio of the anolytes was 1:1 or the same as that contained in the sample. If the C-14A part of NAQ were included as propene, it should have volatilized during dissolution. It was found that the C-14A material was water soluble, not extractable from basic solution, and not distillable up to 110°C. Therefore, it appears that only a small portion of the cleaved NAQ is lost as propene, and the remainder of the allyl part is included in some other chemical form.

The tentative distribution of inclusion products found for C-14Q NAQ is 40% NAQ, 40% quinaldine, 20% reduced NAQ and quinaldine, probably as the corresponding 1, 2, 3, 4-tetrahydro-compounds. The same distribution occurring for C-14A NAQ products can account for 50% of the C-14A activity (NAQ plus reduced NAQ). The rest of the C-14A activity has not been identified.

The above results were obtained from samples plated at 43 ma/cm^2 with 2 g/liter SAS and 10 mg/liter NAQ in the bath. However, the plating cell and current density distribution were different than that used in the earlier work. The ratio of included products will probably change when any of these variables are changed. Some idea of the differences in the included products can be found by comparing the Q/A ratios shown in the inserts of Fig. 2, 3, and 4. Note how large the Q/A ratio is at intermediate NAQ concentrations, low current density or low SAS concentrations. It is believed that the Q/A ratio indicates changes in the catalytic activity of the adsorption sites that are created when different amounts of SAS or NAQ are included.

Manuscript received April 18, 1966; revised manuscript received July 27, 1966. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Surface Roughness Effects in the Electrodeposition of Copper in the Limiting Current Range

N. Ibl and K. Schadegg[1]

Department of Industrial and Engineering Chemistry, Swiss Federal Institute of Technology, Zurich, Switzerland

ABSTRACT

Copper was deposited at high mass transfer rates (rotating disk cathode) in the range of the limiting current of mass transfer. The roughness of the deposit was characterized by impedance measurements. Galvanostatic and potentiostatic experiments, in which the potential, or the current, was measured as a function of time, were also carried out. The various methods used show that a very rough deposit is formed when the limiting current is reached. The results are discussed from the viewpoint of the methodology of electrochemical determination of mass transfer coefficients and from that of the mechanism of metal powder formation at high current densities.

In a previous investigation of the electrodeposition of copper (1) a study was made of the transition from a compact to a powdery deposit[2] which takes place when the current density is increased to a certain value. It was found that this transition occurs when the limiting current of mass transport is reached. The experiments were carried out with nonacidified $CuSO_4$ solutions, under conditions of natural convection, *i.e.*, at rather low mass transfer rates. In the present work copper was deposited from acidified $CuSO_4$ solutions at a rotating disk electrode, which ensured high mass transfer rates under well-defined hydrodynamic conditions. The concentration, speed of rotation, and current density were varied within a wide range. The roughness of the deposit was characterized by impedance measurements. Under otherwise comparable conditions the imaginary component of the vector impedance (reactance) gives a relative measure for the surface area of the deposit. The change in surface area in the limiting current region was also followed by measuring the variation of cathode potential with time at constant current, or the variation of current with time at constant potential.

[1] Present address: Département de Chimie, Université Laval, Quebec, Canada.

[2] A comprehensive review of the literature on electrolytic metal powders has been given in two previous papers (2, 3).

Experimental

The cathode was a rotating stainless steel disk, 1 cm in diameter, embedded in araldite to minimize edge effects. The outer inert annulus of araldite was 2.5 mm wide. The coupling between driving motor and rotating disk assembly was a magnetic one to avoid transmission of vibrations. The anode was a stationary

disk of electrolytic copper, 6 cm in diameter, located 4.5 cm from the rotating disk.

Before each run the deposit from the previous experiment was stripped off the stainless steel cathode, the latter degreased by a treatment with trichloroethylene vapor followed by a cathodic cleaning in an alkaline bath. A copper plate 10μ thick was then deposited on the stainless steel with a current density equal to 5% of the limiting current corresponding to the conditions of the given experiment. Finally, copper was deposited on this plate under the chosen conditions. In Fig. 2, 3, and 6 each point corresponds to a new run, with a freshly prepared surface as indicated above. The same applies to the various curves of Fig. 1, 4, and 5. All reagents used were "pro analysi." The cell was thermostated at 25° ± 0.05°C. The experiments were carried out in deaerated solutions under a N_2 atmosphere.

After switching off the d-c, the cathode was connected with a platinized platinum electrode (ϕ 1 cm), and the impedance of this system was measured with a Wheatstone bridge similar to that employed previously (1). An oscilloscope was used as null detector. The a.c. (250 cycles) applied to the cell had an amplitude of 10 mv. The impedance of the cell was balanced by a resistor and a capacitor in parallel. The reactance R_b was calculated from their resistance R and capacitance C by the relation

$$R_b = \frac{R^2\omega C}{1 + (R\omega C)^2} \qquad [1]$$

where ω is the angular frequency. Both the imaginary and the real part of the impedance decrease with increasing surface area of the metal deposited on the cathode, but the reactance (in contrast to the real component of the impedance) does not include the electrolyte resistance and, therefore, undergoes a much larger relative change when the roughness increases.

A number of impedance measurements were also carried out during the metal deposition by superimposing a.c. on the electrolysis current (Fig. 3). Suitable capacitors prevented the d.c. from flowing through any of the branches of the Wheatstone bridge except through the electrolysis cell.

In general, the metal was deposited under galvanostatic conditions. The current was kept constant by using a large voltage source and a high resistance in series with the electrolysis cell. In a series of typical runs the cathode potential was recorded as function of the electrolysis time. The potential was measured with a Knick high-impedance voltmeter against a copper reference electrode dipping into a solution of the same composition as that being electrolyzed. The reference electrode was connected to the cathode by a fine vertical Luggin capillary reaching to 0.5 mm of the center of the rotating disk.

In addition to the galvanostatic experiments, potentiostatic measurements were also made. The cathode potential was kept constant with an electronic potentiostat (Tacussel PR-2000). The current was measured as voltage drop over a resistor and recorded as function of time by feeding this voltage to a compensating pen and ink recorder.

Results

Figures 1 to 5 present a selection of the results obtained. A more complete account of the results and of the experimental procedure is given in (4). The $CuSO_4$ concentration ranged from 0.05 to 0.7M, the rotation speed of the disk from 300 to 6000 rpm. In general, the curves were of the same shape for all concentrations and speeds employed, so that only one typical curve or family of curves is shown in each case. The theoretical limiting current i_L, as indicated in some of the figures, was calculated from the relation (5)

$$i_L = 0.602\, AzFc_0 D^{2/3} \nu^{-1/6} \omega^{1/2} \qquad [2]$$

where z = charge of cation (for copper, z = 2),

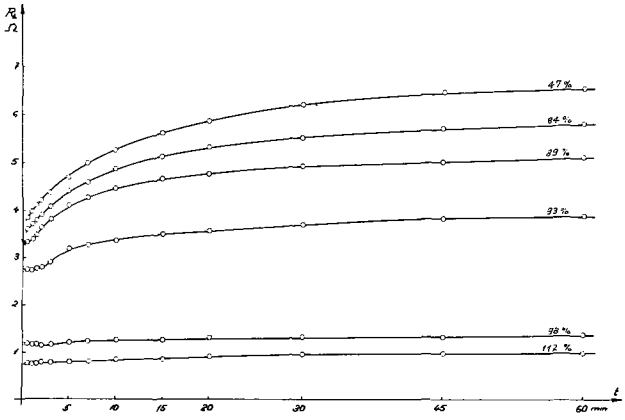

Fig. 1. Variation of reactance with time after switching off the d.c. The copper was deposited from 0.05M $CuSO_4$ + 1.5M H_2SO_4 at 300 rpm with a current indicated on each curve in per cent of the limiting current calculated from Eq. [2]. The metal remained in contact with the solution after switching off the d.c.

F = Faraday's constant (96500 Cb), c_0 = concentration of $CuSO_4$, D = diffusion coefficient, ν = kinematic viscosity, ω = angular velocity of rotation of disk, A = area of disk (0.785 cm^2). The numerical coefficient (0.602) applies for a Schmidt number of 1000, which is approximately the value usually prevailing in aqueous electrolysis. The following average values for ν and D were used (6) for 0.05M $CuSO_4$ + 1.5M H_2SO_4, and 0.7M $CuSO_4$ + 1.5M H_2SO_4, respectively: ν = 1.101 and 1.308 x 10^{-2} cm^2 sec^{-1}, D = 6.50 and 5.14 x 10^{-6} cm^2 sec^{-1}. The values of i_L shown in the figures were calculated for the projected electrode area (0.785 cm^2), *i.e.*, the area of the flat disk, before roughness formation sets in. Migration effects were not taken into account. The reasons are similar to those given by Wilke *et al.* (6), who used acidified $CuSO_4$ solutions of the same concentration range as in the present work. An additional reason why in the present case a more refined treatment would not be justified is that the limiting current was not very accurately defined (see later). In any case, because of the smallness of the effects involved, taking migration into account would not change anything in the conclusions reached.

In Fig. 1 the reactance is plotted against the time which has elapsed after the d.c. has been switched off. On each curve the current at which the metal has been deposited is given in per cent of the limiting current. In all experiments the reactance increased with time during a relatively long period, except when the metal had been deposited at a current close to or larger than the limiting value. This indicates that the surface of freshly deposited metal is unstable. It seems that a smoothing of the surface takes place for several minutes after the electrolysis current has been switched off.[3]

Figure 2 shows the variation of the reactance with the current at which the copper has been deposited. Because of its variation with time the reactance was always measured after the same time interval (30 sec) following switching off the d.c. in order to get comparable results. It is seen that the reactance drops off sharply when the deposition current reaches the limiting value i_L. This indicates a strong increase in surface area at the limiting current. The reactance measured during metal deposition (with a.c. superimposed on the d.c.) goes through a marked maximum at the limiting current (Fig. 3). This can be interpreted as being due to two effects acting in

[3] Alternative interpretations would be (a) the formation of an oxide layer (b) adsorption or desorption effects. However, these explanations appear less likely than a smoothing due to recrystallization processes, because of the fact that no increase of reactance with time occurs when the metal has been deposited at or above the limiting current, *i.e.*, when the deposit is very rough or powdery.

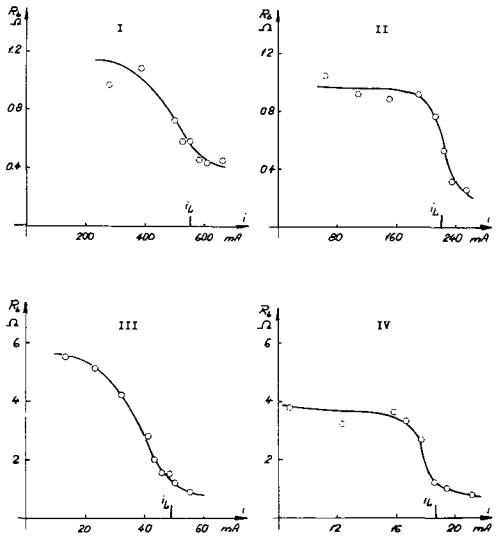

Fig. 2. Variation of the reactance R_b with the current of metal deposition (R_b measured after switching off this current). Deposition conditions: I, 0.7M $CuSO_4$, 1.5M H_2SO_4, 2000 rpm; II, 0.7M $CuSO_4$, 1.5M H_2SO_4, 300 rpm; III, 0.05M $CuSO_4$, 1.5M H_2SO_4, 2000 rpm; IV, 0.05M $CuSO_4$, 1.5M H_2SO_4, 300 rpm.

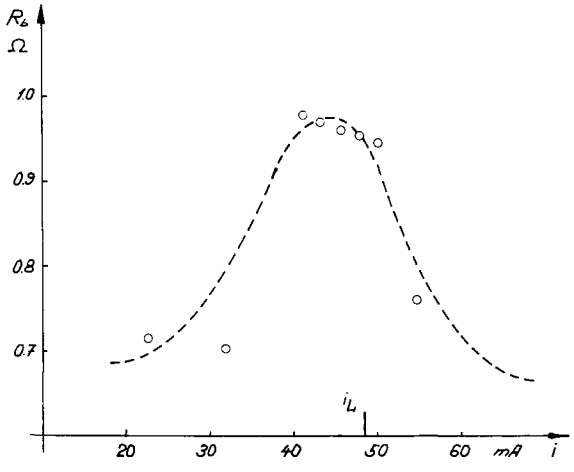

Fig. 3. Variation of reactance R_b with current (R_b measured during metal deposition); 0.05M $CuSO_4$ + 1.5M H_2SO_4, 2000 rpm.

opposite direction. The reactance due to concentration overvoltage, ${}_cR_b{}^*$, increases strongly when the electrolysis current i approaches the limiting current, i_L, according to the equation

$$ {}_cR_b{}^* = \frac{{}_cR_b}{1 - i/i_L} \qquad [3]^4 $$

which has been derived by Gerischer (7). On the other hand, the formation of a rough or powdery deposit in the limiting current range tends to decrease the reactance. When this effect prevails, the over-all reactance decreases again, as is seen on the right branch of the curve of Fig. 3.

In the case of the impedance measurements during metal deposition this decrease of reactance with increasing d.c. is probably not only due to the dependence of the reactance on the surface area as such, but also to an indirect influence of the increase in surface area. For a rough surface (with peaks of a height comparable to the thickness of the diffusion layer), the limiting current is larger than the value calculated for the projected electrode area; therefore, if we calculate i_L from Eq. [2] for the projected electrode area (*i.e.*, without taking the roughness formation into account) and if we electrolyze with a current i which is not much larger than i_L, then, this current i is no longer larger than the limiting current once a rough deposit has started to form and the departure from the limiting current condition causes a decrease of the reactance according to Eq. [3].

A similar influence of an increase of the surface area was observed on the galvanostatic curves, a sample of which is shown in Fig. 4. When the copper is deposited below the limiting current, the overvoltage is virtually independent of electrolysis time. In the limiting current range, however, the overvoltage strongly decreases with time: for instance, for $i = 1.12 i_L$ (i_L being calculated for the projected electrode area) the overvoltage decreases by about 400 mv within 2 min after the beginning of electrolysis.[5] This is due to the onset of the formation of a rough or powdery deposit at the limiting current and to the resulting increase of the limiting current. Figures 5a and 5b show the variation of current with electrolysis time at constant cathode potential. Instead of the decrease of overvoltage observed in the galvanostatic case, we have in the potentiostatic experiments an increase of current with time when a rough deposit is formed. The increase of current occurs only if the potential is more negative than a certain value. As can be seen from a comparison of Fig. 5a and 5b, this potential is less negative with concentrated than with dilute solutions. A similar shift of the potential for the start of the increase of current with time was observed when the speed of rotation was increased. It is not impossible that at very high speeds of rotation and high concentrations the formation of a powdery or very rough deposit would start at potentials less than that corresponding to zero interfacial concentration, *i.e.*, below the limiting current. However, within the range of concentrations and speeds of rotation studied in this work, the strong increase of current with time always occurred within the limiting current range.

It is to be noted, however, that the limiting current was not very well defined in spite of the well-defined hydrodynamics, because the current distri-

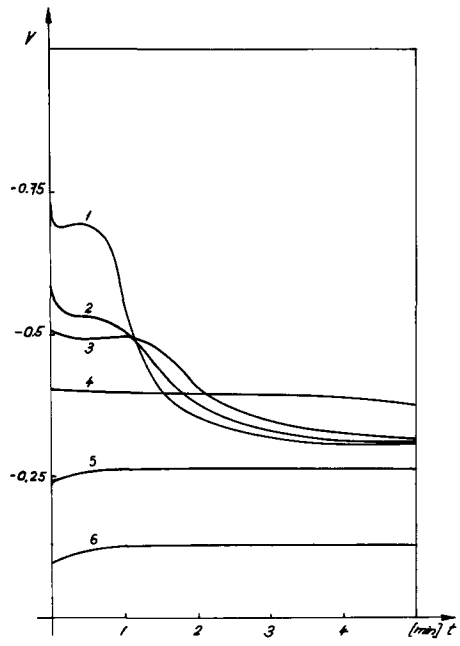

Fig. 4. Variation of overvoltage with time at constant current i (for 0.05M $CuSO_4$, 1.5M H_2SO_4); 1000 rpm: 1, i = 1.12 i_L; 2, i = 0.95 i_L; 3, i = 0.90 i_L; 4, i = 0.84 i_L; 5, i = 0.47 i_L; 6, i = 0.15 i_L.

[4] ${}_cR_b = RT/z^2F^2c_o(2D\omega)^{1/2}$, with ω = angular frequency, R = gas constant, T = abs. temperature. ${}_cR_b$ represents the reactance due to concentration overvoltage in an a-c circuit without superimposed d.c.

[5] A similar decrease of the overvoltage with electrolysis time in the electrodeposition of metal powders has also been reported in other papers (8-10).

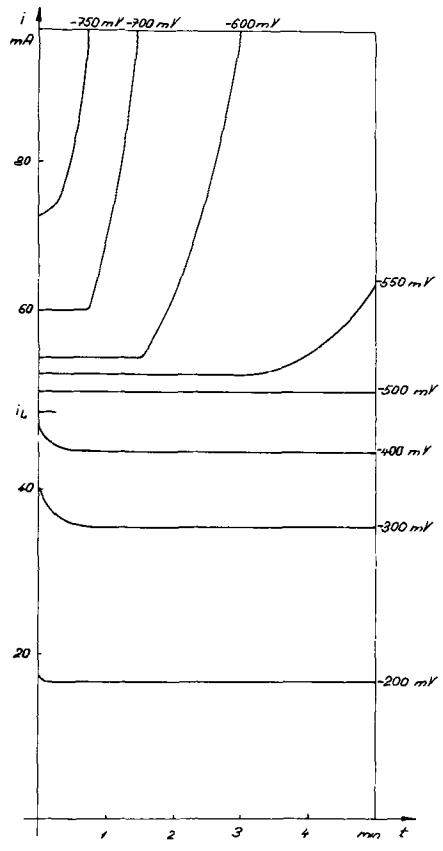

Fig. 5. Variation of current with time under potentiostatic conditions. For each curve the cathode potential was kept constant at the value indicated (which is referred to a copper reference electrode immersed in a solution of the same concentration as that being electrolyzed).

bution at a disk is not uniform below the limiting current. When the current is increased, the limiting current is thus reached first toward the edge of the disk, so that the formation of a rough deposit starts at the edge and successively spreads over the whole electrode area. Owing to the roughness at the edge, the average limiting current for the whole disk can thus be increased before the limiting current condition is reached for the whole electrode area. There is thus a limiting current range rather than a well-defined limiting current. From current voltage measurements the uncertainty in the limiting current was estimated at 5-10% in most cases. The potentiostatic measurements yielded consistently higher limiting currents than the galvanostatic experiments (the current voltage curve being in both cases obtained by plotting the current, or the potential, measured after the same time on the potentiostatic or galvanostatic curves, respectively). Similar observations have been made by Emelyanenko and Baibarova (11).

The appearance of the deposits obtained at the limiting current was more reddish in color, and their adherence to the electrode was better than in the case of our previous study (1).[6] This appears to be due to the fact that strongly acidified solutions were used in the present case, compared to the neutral solutions employed earlier (rather than to the change in the rate of the mass transport owing to the increased stirring). However, the rule, that a deposit with a strongly increased surface is formed at the limiting current, holds true regardless of whether the solution is acid or not.

Discussion

The four methods used (galvanostatic and potentiostatic procedures, impedance measurements with and without d.c.) gave concordant results showing that a very rough deposit is formed when the limiting current is reached. This rule, which has been found previously for unstirred systems (1, 8, 9), is therefore also valid for strongly agitated solutions.

These results are of importance for the methodology of the electrochemical determination of mass transfer coefficients (12), which can be obtained very conveniently from the limiting current as given by the current voltage curve. The deposition of copper from acidified solutions has been repeatedly used as indicator reaction for this purpose in recent years [see for instance (13-16)].

Correct values of the mass transfer coefficient will be obtained only if the effective electrode area does

[6] It could thus well be that it is only the formation of a very rough deposit (rather than the formation of powder itself) which is linked to the limiting current. However, even at rotating disks with acidified solutions a powdery, loose deposit is eventually obtained when one waits long enough, or when the current is sufficiently above the limiting value calculated for the projected area.

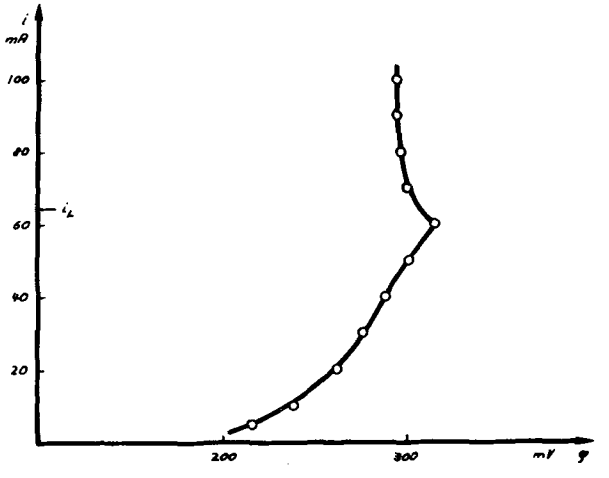

Fig. 6. Current voltage curve (derived from galvanostatic measurements) 0.1M $CuSO_4$, 1.5M H_2SO_4; 1000 rpm.

not change during the measurements for the current voltage curve. The roughness of the deposit, which develops at the limiting current, is thus a great potential source of error.[7] This is illustrated drastically by the current voltage curve of Fig. 6, which exhibits even a negative slope for currents larger than the limiting value. For each current setting the cathode potential was read after 5 min and under these conditions the influence of the increase of surface area becomes predominant. In order to avoid distortions of the current voltage curve the measurements should be made as rapidly as possible. However, one is usually interested in the steady-state mass transfer coefficients, and one must thus wait long enough for the steady state to be established. A compromise with respect to time must therefore be found. Fortunately, the onset of roughness occurs only after some time, as can be seen from Fig. 4 and 5. As long as the current is not much higher than the limiting current, this induction period is substantially longer than the galvanostatic "transition time" (17, 18) elapsing until zero concentration at the cathode surface is reached.[8] This leaves one some "freedom of action" when taking the current voltage curve and makes it more hopeful to find a satisfactory compromise with respect to measurement time. It might well be, however, that the possibility of finding such a compromise, allowing one to obtain reliable mass transfer coefficients, depends on the experimental conditions. From the experiments of this study it would appear, for instance, that dilute solutions are more favorable than concentrated ones. A closer examination of this question would be valuable for the methodology of the electrochemical measurements of mass transfer rates. Of course, the above difficulty does not arise when a redox reaction (such as the reduction of ferricyanide to ferrocyanide) is used as indicator instead of metal deposition. However, the ferricyanide system is not suitable for the study of natural convection and has also some other minor disadvantages.

Let us now briefly discuss the results from the viewpoint of the mechanism of electrolytic powder formation. A number of theories have been proposed. They have been reviewed in an earlier paper (2). An interesting interpretation based on quantum mechanics has been developed by Calusaru and Atanasiu (20). According to this theory, the electrons from the metal are transferred to the cations by the tunnel effect over a distance which substantially increases at the limiting current because the electrode potential becomes very negative and, at the same time, the supply of cations to be discharged is limited. The cations are thus discharged at some distance in front of the interface. When this neutralization distance becomes larger than the lattice parameter, powder is formed. An alternative explanation has been based on mass transfer considerations (2), (21). Below the limiting current the current distribution tends to be uniform because of the activation overvoltage, but at the limiting current the influence of mass transfer becomes predominant, and small peaks present by chance grow faster than the flat parts around them because of the differences in the mass transfer rates of the cations being discharged. There is thus, at the limiting current, a sort of instability with respect to small scale heterogeneities of the surface (21). A rough deposit results and, when the roughness has become very strong, this leads eventually for mechanical reasons to the formation of a loose metal which can easily be stripped off the electrode. The characteristics of such more or less powdery deposits can then much depend on circumstances and be strongly affected by factors such as the adsorption of inhibitors. The present work does not allow clear conclusions regarding these processes, but at least the following can be said with respect to the primary roughness formation. The induction period observed before the onset of roughness (see above and Fig. 4 and 5) as well as the direction in which the potential of the onset of roughness formation shifts when the concentration or the speed of rotation is changed (see above and Fig. 5) are difficult to interpret in terms of the tunnel effect theory and speak for a mass transfer mechanism, at least of the roughness formation.

[7] Although the major roughness increase takes place in the limiting current range, some roughness develops progressively already when one approaches the limiting current and it appears that under certain conditions an appreciable roughness has already formed at 50% of the limiting current, for instance [see Fig. 8 of ref. (1)]. This makes the question of the roughness formation even more important from the viewpoint of the methodology of the electrochemical determination of mass transfer coefficients.

[8] The relationships given in (17) and (18) for the calculation of the transition time apply to the case that there is no convection. This gives a first approximation sufficient for a comparison of the order of magnitude with that of the induction period. A more refined calculation is given in (4). For the potentiostatic case, an accurate calculation taking convection into account can be made on the basis of the Olander theoretical treatment (19): at 300 rpm the mass transfer rate drops in half a second to a value which differs from the figure for the steady state by only 5%. The authors thank Dr. J. R. Selman (University of California, Berkeley) for having drawn their attention to this paper.

Acknowledgment

Thanks are due to the Swiss Aluminium Funds for its support of this research work. We are indebted to Mr. A. M. Frei for his help in the development of the experimental technique.

Manuscript received Jan. 31, 1966; revised manuscript received Sept. 6, 1966. This paper was presented at the Buffalo Meeting Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Kinetics of Nitrogen Transfer through an Iron Surface

E. T. Turkdogan and P. Grieveson[1]

Edgar C. Bain Laboratory for Fundamental Research,
United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

A study has been made of the kinetics of nitrogenization and denitrogenization of γ-iron at 1000°C in the presence of nitrogen, water vapor, and hydrogen in the gas phase. For a given ratio, p_{H_2}/p_{H_2O}, the rate is shown to be directly proportional to the square root of the nitrogen partial pressure. It is shown that under these conditions nitrogen transfer is dominantly controlled by the surface reaction rather than by diffusion. A rate equation is derived for the condition of almost complete coverage of surface sites by adsorbed oxygen atoms. The rate equation derived for this limiting case states that the rate of nitrogen reaction on the surface of iron, for a given nitrogen activity, is inversely proportional to the activity of oxygen in the system. This is in agreement with the experimental observations.

In previous work by the authors (1, 2) on kinetics of solution of nitrogen in purified iron (in α, γ, or δ state), the reaction rate was found to be controlled essentially by the process of diffusion in samples thicker than 0.05 cm. It was shown explicitly that in purified nitrogen the phase boundary reaction with purified iron approached the state of equilibrium in a short reaction time. In unpurified nitrogen, on the other hand, the approach to metal-gas phase boundary equilibrium was found to be much slower. Other investigators (3-7) have also demonstrated that the rate of nitrogen solution in liquid iron is retarded markedly with increasing oxygen content of the iron. Although many rate data have been published, understanding of the nature of this phase boundary reaction with liquid or solid iron containing oxygen remains to be developed.

In an attempt to advance the present knowledge of the kinetics of phase boundary reactions in gas-metal systems at elevated temperature, a study was made of the effect of oxygen on the rate of the reaction of nitrogen with purified γ-iron at 1000°C; the results obtained are presented in this paper.

Experimental

The experimental technique, apparatus, and materials used were the same as those discussed in the previous two papers (1, 2). The material used was vacuum-carbon deoxidized Plastiron rolled to 0.051 cm thick sheet. The impurity contents were: C, Mn < 0.01%; S, P < 0.002%; each of the other usual impurities < 0.004%. The oxygen content of the nitrogen atmosphere was controlled by introducing appropriate mixtures of hydrogen and water vapor into the reacting atmosphere. Depending on the gas composition required, a mixture of hydrogen, argon, and nitrogen was allowed to pass through a long column containing a mixture of oxalic acid dihydrate and 10% anhydrous oxalic acid. The temperature of the oxalic acid dihydrate column was controlled by a thermostatically regulated water bath. Using a total gas flow rate of 200 cc/min at about 0.96 atm, the gas compositions employed in the nitrogenization and denitrogenization experiments were within the following range: 0.0 to 0.92 atm N_2, 0.0 to 0.90 atm Ar and p_{H_2O}/p_{H_2} from 0.03 to 0.3. The ratio p_{H_2O}/p_{H_2} was less than the critical value of 0.67 which is required for the oxidation of iron to wustite at 1000°C.

The temperature dependence of the water vapor pressure of oxalic acid dihydrate, as determined by Baxter and Lansing (8), is given by the following expression

$$\log p_{H_2O} = 18.053 - \frac{9661}{250 + T} \qquad [1]$$

where p_{H_2O} is in mm Hg and T is in °K. This was later confirmed by Bookey and Tombs (9). A series of tests carried out in the present work also gave water vapor pressures in agreement with Eq. [1] within 2% over the temperature range of 20°-50°C.

The iron strips, 3 x 1.5 x 0.051 cm, were cleaned and treated in an atmosphere of purified hydrogen for 17 hr at 1000°C before the reacting gas was introduced. At the end of a specified reaction time, the sample was withdrawn rapidly to the water-cooled end of the reaction tube and analyzed for nitrogen. The reproducibility of chemical analysis was within about 4 ppm.

Results

The results given in Fig. 1 show the retarding effect of oxygen in the atmosphere (as given by p_{H_2O}/p_{H_2}) on the rate of nitrogenization of iron. The dashed curve in Fig. 1 is that calculated for a solid state diffusion-controlled process, using $D = 1.12 \times 10^{-7}$ cm²/sec for the diffusivity (1) of nitrogen in γ-iron at 1000°C. Comparison of the experimental results with the calculated broken curve shows the strong influence of oxygen, or oxygen-bearing gaseous species, on the rate of the nitrogen-iron interfacial reaction.

In one series of experiments, the samples were initially annealed for 17 hr at 1000°C in a hydrogen-water vapor mixture having the ratio $p_{H_2O}/p_{H_2} = 0.064$ (solid triangles in Fig. 1). The rate of nitrogenization of these samples was found to be the same as those in another series (open triangles in Fig. 1) in which the samples were annealed in dry hydrogen prior to the nitrogenization experiment in an atmosphere with $p_{H_2O}/p_{H_2} = 0.064$. This finding indicates that the rate of saturation of the surface of iron with chemisorbed oxygen, in the particular atmosphere employed, is a relatively fast reaction.

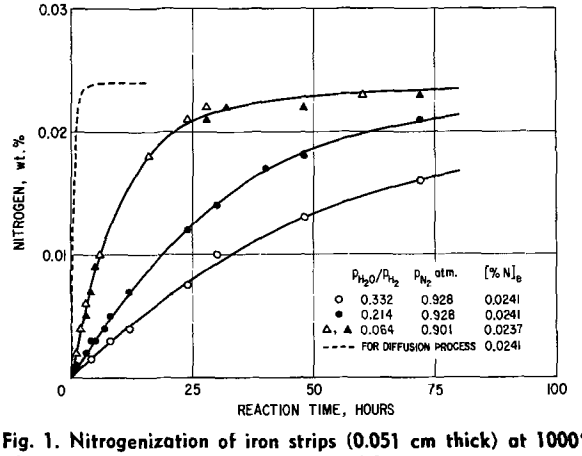

Fig. 1. Nitrogenization of iron strips (0.051 cm thick) at 1000°C in $N_2 + H_2O + H_2$ at total pressure of 0.96 atm.

[1] Present address: University of Newcastle, Newcastle-upon-Tyne, England.

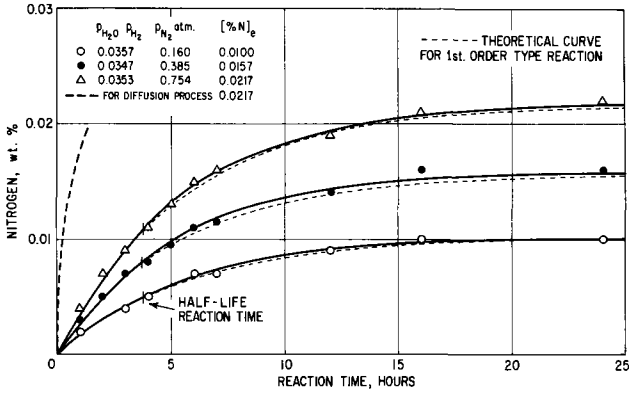

Fig. 2. Nitrogenization of iron strips (0.051 cm thick) at 1000°C in $N_2 + H_2O + H_2$ at total pressure of 0.96 atm.

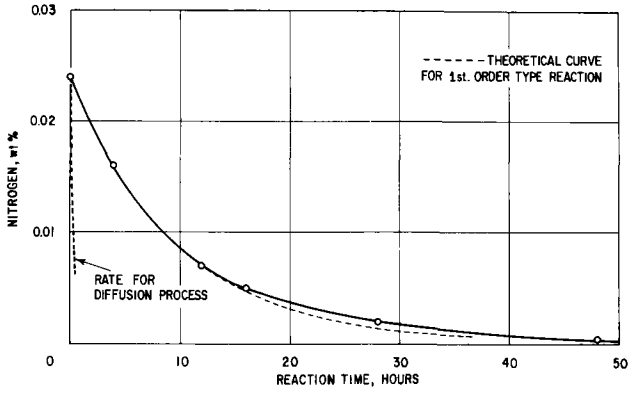

Fig. 3. Denitrogenization of iron strips (0.051 cm thick, containing 0.024% N) at 1000°C in $Ar + H_2O + H_2$ with $p_{H_2O}/p_{H_2} = 0.064$ at total pressure of 0.96 atm.

In another series of experiments, iron was nitrogenized in atmospheres of various nitrogen partial pressures with $p_{H_2O}/p_{H_2} = 0.035$. The results obtained are given in Fig. 2; as would be expected, the rate of nitrogenization decreases with decreasing partial pressure of nitrogen. It should be noted that the half-time of the reaction is independent of nitrogen partial pressure. The dotted curves given in Fig. 2 are calculated from the half-time for a first-order type of reaction. These theoretical rate curves are very close to those drawn through the experimental data.

The values of $[\%N]_e$ given in Fig. 1 and 2 are the calculated equilibrium (1) nitrogen concentrations.

The results in Fig. 3 are for denitrogenization of iron (initial uniform nitrogen content being 0.024% N) at 1000°C in argon with $p_{H_2O}/p_{H_2} = 0.064$. Comparison of the results with the dashed curve for the solid state diffusion-controlled reaction indicates that the presence of oxygen-bearing species in the atmosphere also markedly lowers the rate of denitrogenization. Again, the results compare favorably with the theoretical dotted curve for a first-order type of reaction.

It is apparent from these experimental results that the interstitial diffusion of nitrogen in iron does not play a prominent role in the control of the rate of nitrogenization or denitrogenization of iron strips (0.051 cm thick) when oxygen is present in the reacting gas. In order to verify this indication, a thicker iron strip (0.51 cm thick) was reacted with nitrogen at 1000°C with $p_{N_2} = 0.91$ atm and $p_{H_2O}/p_{H_2} = 0.052$. After a given reaction time, the metal was sectioned parallel to its surface and each layer analyzed for nitrogen. As seen from the results given in Fig. 4, the nitrogen distribution across the sample is essentially uniform. Since in the rate studies much thinner strip was used (0.051 cm thick), the surface nitrogen concentration in solution can in all cases be taken to

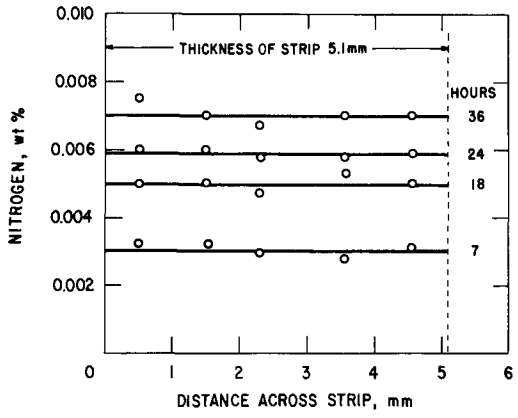

Fig. 4. Nitrogen profiles in iron strip after reaction in 0.914 atm N_2 ($+p_{H_2O}/p_{H_2} = 0.052$) at 1000°C.

be almost the same as those determined by analyzing the entire sample.

Reference should be made here to a recent experimental work of Podgurski (10) of this Laboratory on denitrogenization of iron at 442°C in H_2O-H_2 atmospheres. In this case the reaction product was found to be ammonia, and the rate was observed to be controlled by nitrogen diffusion in the bulk iron phase ($\sim$0.05 cm thick). Since at 1000°C the equilibrium ammonia concentration is very low, the presence of hydrogen in the atmosphere is not expected to enhance the rate of nitrogen reaction at the surface of iron.

For a first-order type of reaction the rate equation has the following form for nitrogenization and denitrogenization

$$\frac{d(\%N)}{dt} = -\frac{2q}{l}[(\%N)_e - (\%N)] \qquad [2]$$

where q = rate parameter for given temperature and p_{H_2}/p_{H_2O} ratio, l = thickness of iron strip, $[\%N]_e$ = nitrogen content of iron in equilibrium with the atmosphere, and $[\%N]$ = uniform nitrogen content of iron at a particular reaction time t.

Upon integration of Eq. [2], the following logarithmic expression is obtained

$$\log \frac{(\%N)_e - (\%N)}{(\%N)_e - (\%N)_o} = -\frac{2q}{2.303\,l}t \qquad [3]$$

where $(\%N)_o$ is the initial nitrogen content of the sample at $t = 0$. In all cases $(\%N)_o$ was about 3 ppm, or less, after hydrogen annealing at 1000°C.

The experimental results on nitrogenization and denitrogenization of iron are plotted in Fig. 5 and 6 in

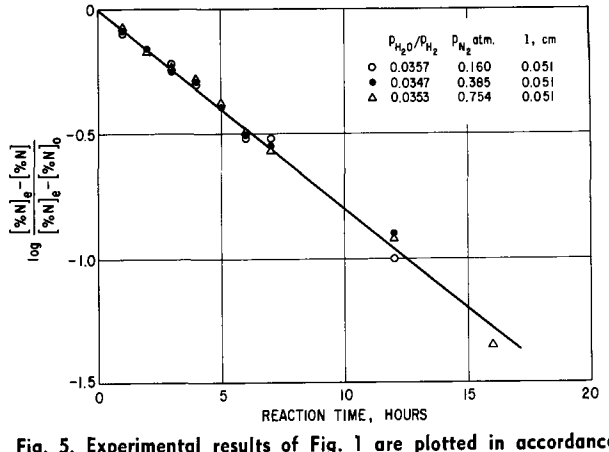

Fig. 5. Experimental results of Fig. 1 are plotted in accordance with the rate Eq. [3] for nitrogenization of iron at 1000°C.

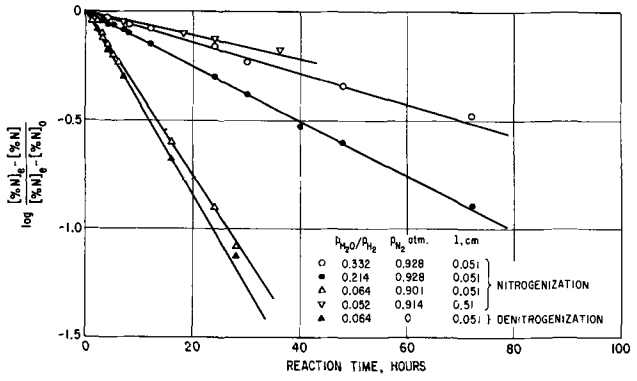

Fig. 6. Experimental results of Fig. 2 and 3 are plotted in accordance with the rate Eq. [3] for nitrogenization and denitrogenization of iron at 1000°C.

accordance with the rate Eq. [3], which appears to be supported reasonably well by the experimental data. The rate parameter q is computed from the slopes of the lines in Fig. 5 and 6 and the thickness of the iron strip, and is plotted against the ratio p_{H_2}/p_{H_2O} in Fig. 7. The line drawn through the points and the origin of the coordinates should of course be terminated at $p_{H_2}/p_{H_2O} = 1.49$ below which iron is oxidized to wustite.

Theoretical

One often refers to retardation of surface reactions on poisoned surfaces without identifying the implications involved in the so-called poisoning effect. There are two effects to be considered. One of them is an increase in the free energy of activation of the surface reaction involving adsorption and desorption of nitrogen. The other is that of retardation of transport of nitrogen through the few available vacant surface sites; that is, if the extent of surface coverage by a contaminant is very high, the fewness of the sites available for nitrogen atoms may create a bottleneck for the passage of nitrogen across the surface layer. The second effect would not appear to be the rate-controlling step for the system considered; however, the rate equation derived for such a transport process in the subsurface region is given in the Appendix.

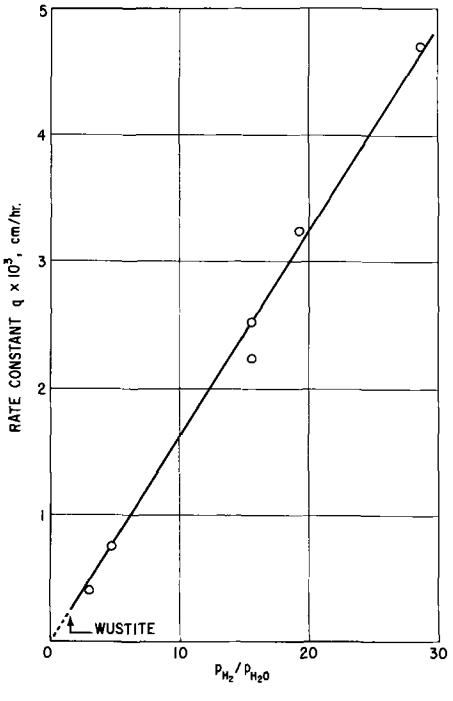

Fig. 7. Rate parameter q for nitrogenization of iron at 1000°C as a function of p_{H_2}/p_{H_2O} in the gas phase.

Thermodynamics of contaminated surface.—In the simple model to be considered, all the sites on the iron surface available for the adsorption of oxygen and nitrogen atoms are taken to be initially of the same kind, the total number being Γ sites/cm²

$$\Gamma = n_O + n_N + n_\ddagger + n_\square \qquad [4]$$

where the subscripts indicate the adsorbed atomic species, ‡ being the activated state of the nitrogen atom and the subscript □ is that for vacant sites.

In the thermodynamic treatment of the surface coverage in a monolayer by the classical statistics, the adsorbed atoms of different species are assumed to be completely interchangeable without affecting the internal energy. Then, the number of ways of distributing Γ elements[2] is given by

$$\frac{\Gamma!}{n_O! n_N! n_\ddagger! n_\square!}$$

The partition function, Q, for such as assemblage becomes

$$Q = \text{const.} \cdot \Gamma! \left[\frac{(g_O)^{n_O}}{n_O!} \cdot \frac{(g_N)^{n_N}}{n_N!} \cdot \frac{(g_\ddagger)^{n_\ddagger}}{n_\ddagger!} \cdot \frac{(g_\square)^{n_\square}}{n_\square!} \right] \qquad [5]$$

where g is the partition function of the element indicated by the subscript. By applying Stirling's approximation

$$\ln Q = \Gamma \ln \Gamma + \sum_i (n_i \ln g_i - n_i \ln n_i) + \text{const.} \qquad [6]$$

where the subscript i indicates terms for a particular element; it is to be remembered also that the summation $\sum_i n_i$ is equal to Γ. Differentiating ln Q with respect to a particular element n_j gives the chemical potential μ_j of that adsorbed species, thus

$$\left(\frac{\partial F}{\partial n_j}\right)_{P,T,\Gamma} = -kT\left(\frac{\partial \ln Q}{\partial n_j}\right)_{T,V,\Gamma} = \mu_j \qquad [7]$$

or

$$-\left(\frac{\partial \ln Q}{\partial n_j}\right)_{T,V,\Gamma} = \frac{\mu_j^o}{kT} + \ln a_j \qquad [8]$$

where μ_j^o is the chemical potential of j in the standard state and a_j its activity. In differentiating Eq. [6], it is to be remembered that $n_\square = \Gamma - \sum_i n_i$; the final form of the equation now becomes

$$a_j = k_j \frac{n_j}{n_\square} \qquad [9]$$

where k_j is a temperature dependent proportionality factor containing all the constant terms.

An important point to be noted is that the proportionality factor k_j for a particular adsorbed species and a given temperature is a constant only when the state of the monolayer satisfies one of the following idealized conditions for which the preceding treatment applies: (*i*) For small coverage in the surface no adjacent sites are occupied, therefore no change in the internal energy of the surface. (*ii*) One of the species occupies most of the surface sites, and that further increase in adsorption in the monolayer hardly affects the energy of the surface. Furthermore, the other species adsorbed on this nearly saturated surface cannot occupy adjacent sites; therefore interaction between them can be neglected. (*iii*) The adsorbed atoms of different species are completely interchangeable without affecting the internal energy of the surface, *i.e.*, an ideal monolayer.

[2] The word, element, is used here in a general sense, including vacant surface sites.

When most of the surface sites on iron are occupied by adsorbed oxygen atoms, condition (*ii*) stated above will apply. For this limiting case, the activities of the adsorbed species may now be given in terms of the fractions of sites occupied, θ, using the general Eq. [9]

$$\theta_O + \theta_N + \theta_\ddagger + \theta_\square = 1.0 \quad [10]$$

$$a_O = k_O \frac{\theta_O}{\theta_\square} \quad [11]$$

$$a_N = k_N \frac{\theta_N}{\theta_\square} \quad [12]$$

$$a_\ddagger = k_\ddagger \frac{\theta_\ddagger}{\theta_\square} \quad [13]$$

where a is the activity of the species indicated by the subscript and k's are temperature-dependent constants. For the limiting case of $\theta_O \rightarrow 1.0$, the fraction of vacant sites may be represented in terms of oxygen activity from Eq. [11]

$$\theta_\square = k_O \frac{1}{a_O} \quad [14]$$

Kinetics of nitrogen reaction.—As shown experimentally, the rate of nitrogenization and denitrogenization of solid iron is directly proportional to nitrogen activity, *i.e.*, to the square root of the corresponding nitrogen partial pressure. The same observation was made by previous workers on the rate of nitrogen reaction with liquid iron containing some oxygen. When most of the surface sites are covered with oxygen atoms, there is little probability for nitrogen atoms to occupy adjacent surface sites, at least for nitrogen activities corresponding to $p_{N_2} \leq 1.0$ atm. Therefore, it would appear reasonable to assume that, whatever may be the nature of the slow surface nitrogen reaction, the activated state for the reaction involves an atom of nitrogen.

There are two possible types of slow reaction steps when most of the surface sites are occupied with chemisorbed oxygen atoms.

(*i*) In the case of nitrogenization, for example, the nitrogen molecules in the gas phase first encounter the upper surface of the adsorbed oxygen monolayer, where equilibrium is assumed to exist between gaseous nitrogen and that adsorbed on the chemisorbed oxygen. The rate-controlling reaction step is considered to be the jump of a nitrogen atom from the outer surface of the oxygen layer to the activated state over a vacant nitrogen site on the surface of iron.

(*ii*) The other possibility is that the nitrogen chemisorption on a few available sites on the surface of iron is in equilibrium with the gaseous nitrogen. The slow reaction step is that due to the jump of the nitrogen atom from the chemisorbed site to the bulk metal phase.

The rate equation derived is identical in form for these two possible reaction steps, and, furthermore, no differentiation can be made between them from the available rate data. The sum of the reactions involved in either case leads to the following over-all reaction equilibrium

$$\tfrac{1}{2}\,N_2\ (\text{gas}) = N_\ddagger\ (\text{activated state}) \quad [15]$$

$$N_\ddagger\ (\text{activated state}) \rightarrow \underline{N}\ \text{dissolved in iron}$$

For the reaction [15] the equilibrium constant $K_\ddagger$ is given by

$$K_\ddagger = \frac{a_\ddagger}{\sqrt{p_{N_2}}} \quad [16]$$

The fraction of sites occupied by the activated nitrogen is obtained from the sum of Eq. [13], [14], and [16] for the limiting case of $\theta_O \rightarrow 1.0$:

$$\theta_\ddagger = \frac{K_\ddagger k_O}{k_\ddagger} \frac{1}{a_O} \sqrt{p_{N_2}} \quad [17]$$

Now, by invoking the theory of absolute reaction rates, a rate equation may be derived from [17]

$$\frac{dn}{dt} = -\frac{kT}{h} \Gamma \theta_\ddagger$$

where dn/dt is the rate in gram-atom N/cm^2 sec, kT/h is the universal rate. Substituting $\theta_\ddagger$ from Eq. [17] gives

$$\frac{dn}{dt} = -k' \frac{1}{a_o} \sqrt{p_{N_2}} \quad [18]$$

where k' is the specific rate constant which is equal to the product of all the other constants for a given temperature, *i.e.*

$$k' = \frac{kT}{h} \frac{K_\ddagger k_O}{k_\ddagger} \Gamma$$

According to the proposed reaction model yielding Eq. [18], when the surface of solid or liquid iron is nearly saturated with chemisorbed oxygen, the rate of nitrogenization is inversely proportional to the activity of oxygen in the system.

In view of the microscopic reversibility of the reaction process, the rate equation for denitrogenization must be based on a similar model. That is, either (*i*) a nitrogen atom adsorbed on the surface of iron, in equilibrium with the bulk phase, goes through an activated state in the process of jumping onto the chemisorbed oxygen layer, or (*ii*) a nitrogen atom in solution in the bulk phase goes through an activated state in the process of jumping into a vacant site on the surface of iron. These are the two possible slow reactions corresponding to the reverse of nitrogenization, and the rate equation is again identical in form.

The net rate equation involving a forward and reverse nitrogen reaction on the surface of iron contaminated with an oxygen monolayer is derived in a manner similar to those given above

$$\frac{dn}{dt} = -k'' \frac{1}{a_O} [(\%N)_e - (\%N)] \quad [19]$$

where k'' is the specific rate constant, $(\%N)_e$ is the nitrogen content of iron when in equilibrium with a given nitrogen partial pressure of the gas phase and (%N) is the nitrogen content of iron at time, t.

Equation [3] for a first-order type of reaction is the integrated form of Eq. [19]. It is seen that the rate parameter q (in Eq. [3]) derived from the slopes of the lines in Fig. 5 and 6 is directly proportional to k''/a_O of Eq. [19]. If the oxygen activity is sufficiently high that the limiting case of $\theta_O \rightarrow 1.0$ is satisfied, then the rate parameter q should be inversely proportional to the oxygen activity.

As seen from the results in Fig. 7, the experimentally determined rate parameter, q, is directly proportional to the ratio p_{H_2}/p_{H_2O} (which is inversely proportional to oxygen activity), at least within the range studied ($p_{H_2}/p_{H_2O} < 30$).

Discussion and Conclusions

In a recent study by Swisher and Turkdogan (11) of the rate of decarburization of liquid iron, the oxygen chemisorption isotherm for liquid iron-oxygen system was derived from the available surface tension data. At oxygen activities corresponding to % O in iron > 0.024%, the oxygen coverage in the monolayer corresponds to $\theta_O > 0.9$ at 1550°C. For the present purpose, the oxygen activity may be defined as $a_O = 1.0$ at oxygen saturation for iron-iron oxide equilibrium. The oxygen solubility limit in liquid iron at 1550°C is 0.17% O, giving $a_O = 0.14$ for 0.024% O content. That is, for liquid iron containing oxygen, chemisorption corresponds to $0.9 < \theta_O < 1.0$ when a_O

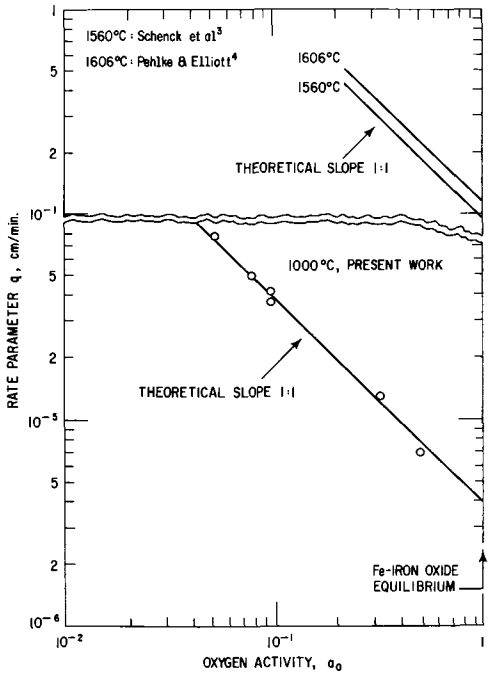

Fig. 8. Logarithmic plot of rate of nitrogen reaction on the surface of solid or liquid iron as a function of oxygen activity for which $\theta_O \rightarrow 1.0$.

> 0.14; for this range, the extent of coverage may be approximated to the limiting case of $\theta_O \rightarrow 1.0$.

At 1000°C, H_2-H_2O mixture corresponding to the iron-wustite equilibrium is given by the ratio $p_{H_2}/p_{H_2O} = 1.49$. The oxygen activity may be defined with respect to this critical ratio, *e.g.*, $a_O = 0.05$ for $p_{H_2}/p_{H_2O} = 30$ at 1000°C. Since the rate of nitrogen reaction with iron at 1000°C is a linear function of p_{H_2}/p_{H_2O} for the range studied, from the foregoing discussion it would follow that $\theta_O \rightarrow 1.0$ when $a_O > 0.05$.

From these observations it may be deduced that monolayer saturation with oxygen on solid iron is approached at oxygen activities (with respect to iron-iron oxide equilibrium) lower than those required for liquid iron surface.

As illustrated elsewhere (1), the rate of nitrogen reaction on liquid iron surface, determined by Schenck *et al.* (5) and Pehlke and Elliott (6), is inversely proportional to the oxygen content of iron for the range % O > 0.04 for which $\theta_O \rightarrow 1.0$. This evidence provides further support to the proposed reaction model.

The rate data on nitrogen reaction on solid and liquid iron surfaces are compared in Fig. 8 where the rate parameter q is plotted against the activity of oxygen in iron on a log-log scale. The results for 1000°C are those reproduced from Fig. 7; the line drawn through the points in Fig. 8 has the theoretical slope of unity. The lines, of course, terminate at $a_O = 1$ at which iron oxide forms.

Neglecting for the present the difference between the surfaces of solid and liquid iron, an estimate may be made of the temperature coefficient of the rate of nitrogen reaction. From the slope of the line of ln (q/T) *vs.* $1/T$ plot, the temperature coefficient of the reaction rate is found to correspond to about 78 kcal/g-atom N. It is to be realized that this is not the true heat of activation of the reaction considered, but it is the sum of all the heat terms associated with the constants contained in the rate equation.

The main conclusion to be drawn from this study is that at 1000°C and oxygen activities $a_O > 0.05$ (relative to iron-wustite equilibrium) the oxygen chemisorption in a monolayer on the surface of iron approaches saturation, *i.e.*, $\theta_O \rightarrow 1.0$. The rate equation derived for this limiting case of oxygen chemisorption states that the rate of nitrogen reaction on the surface of iron, for a given nitrogen activity, is inversely proportional to the activity of oxygen in the system. The experimental results for 1000°C and for liquid iron are found to be consistent with this theoretical analysis. On the basis of the experimental evidence, the activated state of nitrogen in the surface reaction is taken to be that containing an atom of nitrogen. The rate-controlling reaction step on highly contaminated surface may be due either to the jump of a nitrogen atom from the outer surface of the oxygen layer to the activated state over a vacant nitrogen site on the surface of iron, or to the jump of the nitrogen atom from the chemisorbed site to the bulk metal phase. The rate equation for either process is identical in form. Additional rate studies on this system at different temperatures may assist in the clarification of this uncertainty.

APPENDIX

Nitrogen Transport in Subsurface Region

When the extent of surface coverage with chemisorbed oxygen is very high, the paucity of sites available for nitrogen atoms may create a bottleneck for the passage of nitrogen across the surface layer. Although this is not the slow reaction step in the system already considered, it may play an important role in the kinetics of other similar reactions on poisoned surfaces. With this point in view, a particular rate equation applicable for such a transport process in the subsurface region will be given here; for convenience, the nitrogen reaction may again be taken as an example.

If there are a very few sites on the surface of iron available for occupation by nitrogen atoms, there will be radial diffusion of nitrogen atoms to or from these sites in the subsurface region. As an approximation and for mathematical convenience, this subsurface region may be considered to consist of hemispheres of equal size having centers at nitrogen surface sites or at vacant sites. Outside the hemispherical diffusion zone in the bulk phase the nitrogen concentration is taken to be uniform.

The solution of Fick's second law yields the following expression for diffusion in a hemispherical shell at a particular time t

$$F = 2\pi D \frac{c_e - c}{1/r_s - 1/r_o} \quad [20]$$

where F = nitrogen flow per nitrogen site, g-atom N/sec, D = nitrogen diffusivity in the metal, c_e = nitrogen concentration in solution near the surface nitrogen site, g-atom N/cm³, in equilibrium with the gas phase, c = uniform nitrogen concentration in solution in the bulk phase outside the diffusion zone, g-atom N/cm³, r_s = radius of inner hemispherical shell surrounding the surface nitrogen site, and r_o = radius of hemispherical shell which is equivalent to the thickness of the subsurface region.

If there is a total number Γ of sites/cm² at the surface of which θ_N and $\theta_\square$ are fractions of nitrogen covered and of vacant sites, the total number of hemispherical diffusion zones is

$$\chi = (\theta_N + \theta_\square)\Gamma = (1 - \theta_0)\Gamma \text{ per unit area} \quad [21]$$

For a close-packed arrangement of these hemispherical diffusion zones assumed to be uniform in size, the radius r_o is given by

$$r_o = \frac{1}{\sqrt{\pi(1 - \theta_0)\Gamma}} \quad [22]$$

The radius r_s of the inner hemispherical shell around the surface nitrogen atom may be taken to be half of the iron-iron interatomic distance d

$$r_s = \frac{d}{2} \quad [23]$$

By substituting Eq. [21]-[23] in [20], the rate of nitrogen transfer across the unit area of the surface is given by

$$\frac{dn}{dt} = \chi F = 2\pi D(1 - \theta_0)\Gamma \frac{c_e - c}{2/d - \sqrt{\pi(1 - \theta_0)\Gamma}} \quad [24]$$

where dn/dt is the rate of nitrogen transfer in g-atom N/cm² sec.

Since the maximum possible value of Γ is about 10^{15} sites/cm², Eq. [24] may be simplified for small values of $(1 - \theta_0) < 10^{-2}$.

$$\frac{dn}{dt} = q_t(c_e - c) \quad [25]$$

where

$$q_t = \pi d D \Gamma (1 - \theta_0) \quad [26]$$

For the condition that $\theta_0 >> (\theta_N + \theta_\square)$, it is permissible to take $1 - \theta_0 \simeq \theta_\square$ and substituting its equivalence from Eq. [14] in [26] gives

$$q_t = \pi d D \Gamma k_0 \frac{1}{a_0} \quad [27]$$

It is to be noted that the rate Eq. [25]-[27] are similar in form to those given in Eq. [19] for the surface reaction involving monatomic nitrogen in the activated state.

For the ratios p_{H_2}/p_{H_2O} from 3 to 30, the rate parameter q at 1000°C is within the range 1.4 x 10^{-7} to 1.4 x 10^{-6} cm/sec. If the observed rate were that limited by the transport process in the subsurface region, q may be set equal to q_t of Eq. [26]. Taking $\Gamma = 10^{15}$ sites/cm², $d = 3.64 \times 10^{-8}$ cm and $D = 1.1 \times 10^{-7}$ cm²/sec, the value of $(1 - \theta_O)$ would then fall within the range 10^{-8}-10^{-7}. That is, if $(1 - \theta_O)$ were less than 10^{-7} in the experiments considered for $\theta_O \rightarrow 1.0$, diffusion in the subsurface region would become the rate-controlling step. This limiting case is not considered to be reached in the system studied.

Cathode Processes in Molten Nitrates and Nitrites

H. E. Bartlett[1] and K. E. Johnson[2]

Department of Chemistry, Sir John Cass College, London, England

ABSTRACT

Fused $NaNO_3$ is reduced electrolytically first to nitrite and oxide. This process, however, is mixed as exact correspondence is not obtained between the nitrite produced and the coulombs passed. On further reduction of $NaNO_3$ there is an increasing contribution from various other cathodic processes including the production of colored species containing oxidized cathode metal. Reduction of KNO_3 and $NaNO_2$ also gives rise to mixed electrode processes and the formation of colored species in the cathode compartment. Ag^+/Ag is shown to be a suitable reference couple for fused $NaNO_2$.

About 120 years ago, Hittorf (1) attempted the preparation of alkali metals by electrolysis of their fused nitrates and, although his object was not achieved, he observed the formation of brightly colored liquids in the vicinity of gold and platinum cathodes. More recently (2, 3) it has been shown that the $NaNO_3$-KNO_3 eutectic melt is reduced in two discernible stages. In the first stage nitrite and sparingly soluble sodium oxide are produced, and at a more negative potential, with a platinum cathode, an unstable green solution, postulated as being a metastable solution of alkali metal, is said to be formed (3). In conflict with this postulate of the instability of the alkali metals in molten nitrate are the claims of Arvia and co-workers (4, 5) to have measured the standard reversible potential for a Na^+/Na couple in molten sodium nitrate and molten sodium nitrite. In order to resolve this conflict we have studied the current-voltage curves of fused sodium nitrate, fused potassium nitrate, and fused sodium nitrite and have examined the electrolytic reduction products of each of these melts using various metals as cathodes.

Experimental

The starting materials were AnalaR grade chemicals. The sodium nitrite was dried by heating at about 150°C *in vacuo* for 12 hr whereas the sodium and potassium nitrates were dried by bubbling dried nitrogen through their melts. Once molten, the salts were kept under an atmosphere of dried nitrogen.

The cell assembly consisted of a well-lagged 3-necked flask stoppered with silicone bungs, through which passed 1 cm diameter filter tubes cut off below the sintered glass disks (porosity No. 3 or 4) to form the electrode compartments. The flask was heated by a mantle, the power to which was controlled by a simmerstat. With this arrangement the temperature of the melt, as determined by a chromel-alumel thermocouple, could be maintained to ± 1°C.

Ag^+/Ag reference electrodes (6, 7) were made by simple addition or by coulometric generation of Ag^+ ions in compartments containing silver wires.

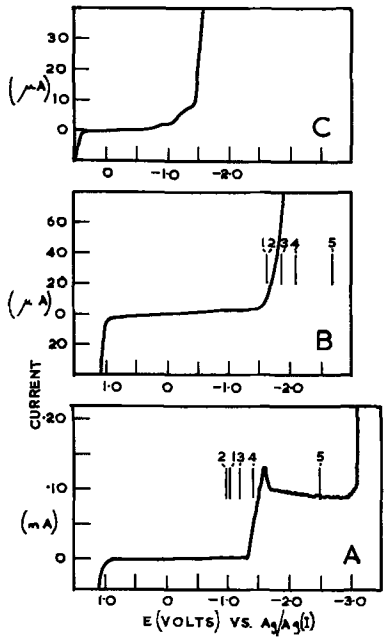

Fig. 1. Current voltage curves with platinum micro-electrodes. A, Sodium nitrate at 340°C; B, Potassium nitrate at 350°C; C, Sodium nitrite at 302°C. The lines numbered 1 to 5 in A and B mark the standard reversible decomposition voltage $E°$ of reactions 1 to 5 in Table measured from the anodic decomposition wave.

The constant current for coulometric generation was supplied by a Metrohm coulometer (ME211) whereas the somewhat larger currents needed for the massive electrolyses were derived either from a Wadsworth potentiostat when experiments were conducted at controlled cathode potentials, or from an Eliminac power supply when it was necessary to apply a large potential difference across the systems.

Platinum microelectrodes, made by sealing platinum wire (0.020 cm in diameter) into Pyrex glass and grinding the ends off flush, and an Ag^+/Ag counter electrode were used to obtain the current voltage curves.

These current voltage curves were recorded either on a Tinsley 13/1 or a Cambridge photographic polarograph.

The reducing power of the catholytes was determined by adding the cold, ground-up compartments and their contents to standard solutions of Ce^{4+} or chloramine T, stirring until all but the glass had dissolved and then back titrating with sodium thiosulfate. (The equivalent of the reducing agent is defined as the number of moles of reducing agent multiplied by the number of electrons involved in its oxidation back to nitrate and is equal to the number of moles of Ce^{4+} or chloramine T used to oxidize the catholyte. Such a definition is required as the reducing agent produced in electrolysis is unknown.)

The rhodium or platinum which went into solution at the cathode was determined as follows:

The catholytes were dissolved in water, any salt still adhering to the electrode being washed off into the solution. Concentrated HCl was then added and the solution evaporated down to dryness. The residue was strongly heated to decompose any nitrate.

When it was cold, more HCl was added and the evaporation and heating repeated to decompose most of the nitrate. The residue v as then dissolved in HCl and stannous chloride solution added. The Pt or Rh were determined colorimetrically (8).

Ag was determined gravimetrically and Co colorimetrically.

Results

Sodium nitrate.—Figure 1A depicts the current-voltage curve obtained for $NaNO_3$ at 340°C, using a platinum microelectrode and an Ag^+/Ag counter-electrode.

This current-voltage curve, which has the same profile as that for a $NaNO_3$-KNO_3 melt (2, 3) may be subdivided conveniently into three distinct regions: the peak, the afterpeak, and the ultimate decomposition wave.

Preparative electrolyses, at controlled potentials, were conducted in separate compartments within the melt, using platinum foil cathodes. Table I gives the results of these experiments.

In addition to the preparative electrolyses at controlled potentials, a number of electrolyses were conducted at high current densities (500 ma cm^{-2}) using various metals as cathodes and, in every case, colored solutions or precipitates were formed in the catholytes (see Table II).

Potassium nitrate.—Figure 1B shows the current-voltage curve obtained for KNO_3 at 350°C using a platinum microelectrode and an Ag^+/Ag counter electrode.

Unlike the corresponding curve for $NaNO_3$, the current-voltage curve for KNO_3 shows only a single cathodic decomposition wave and hence most of the preparative electrolyses were conducted at only the one potential.

During these preparative electrolyses at platinum foil cathodes, it was observed that dark green solutions were formed in the cathode compartments and that only a very small volume of gas was evolved. Neither red catholytes nor sparks could be observed in these experiments.

Further preparative electrolyses were conducted, using other metals as cathodes and in all cases, either colored solutions or precipitates were formed (Table II).

The analyses of the cathode compartments showed that the amount of reducing agent obtained depended on the metal used as cathode. With a platinum cathode there were 1.11 equivalents of reducing agent per Faraday and with a silver cathode 1.52 equivalents per Faraday. It is important to realize that it is impossible to produce more than one equivalent of reducing agent per Faraday unless, in the course of the electrochemical reaction, the metal is oxidized. With these electrolyses in the KNO_3, the metal was in fact oxidized; in the case of the platinum 0.144 mole of platinum per Faraday was found in the catholyte and in the case of silver, silver oxide was isolated from the aqueous extract of the catholyte.

Table I. Results of preparative electrolyses in sodium nitrate

Controlled potential	Observations	Analyses of catholyte (i) Reducing agent	Analyses of catholyte (ii) platinum
Peak potential −1.35v *vs.* Ag/Ag+ reference	Cathode became covered with a white deposit. Catholyte went yellow. Qualitative tests on solidified melt showed that nitrite was present.	0.94 equivalent per Faraday. Expressed as nitrite: −0.47 moles per Faraday (average of 3 determinations)	None
After-peak −2.5v *vs.* Ag/Ag+ reference	Cathode became covered with a dark deposit. Catholyte—red solution. On agitation of electrode green solution formed.	Irreproducible but results ranged from 0.70 to 0.90 equiv. per Faraday	Detected qualitatively
Ultimate decomposition −3.1v *vs.* Ag/Ag+ reference	As for the after-peak potential.	As for the after-peak potential	In green solution approx. 0.03 moles per Faraday. In red solution—detected qualitatively.

Table II. Cathodic corrosion products in fused $NaNO_2$ and KNO_3

Solvent	Cathode	Description of catholyte	Cold catholyte	Action of H_2O
$NaNO_3$	Pt	Orange, turned green on shaking cathode. Sparks observed when orange product formed in quantity without agitation.	Orange unchanged. Green to blue near m.pt. then brown	Decomposed, Pt^{2+} in solution
	Stainless steel	Dark brown precipitate and yellow solution	Dark brown	Fe_2O_3 aq.
$NaNO_2$	Pt	Red, turning green as gas evolved		
	Ag	Yellow precipitate	Yellow	Ag^+ in solution, some $Ag_2N_2O_2$
	Co	Burgundy red	Blue-green	Co^{3+} in solution
KNO_3	Pt	Dark green	Dark green	NO evolved Pt^{2+} in solution
	Rh	Yellow-brown turned green on agitation		Rh^{3+} in solution
	Ag	Dirty-brown	Dirty-brown	Ag_2O

Table III. Cathode processes, over-all cell reactions, and reversible decomposition potentials for $NaNO_3$ and KNO_3

	Cathode process	Over-all cell reaction	$E°_{600°K}$ M = Na	$E°_{625°K}$ M = K
1.	$NO_3^- + 2e^- = NO_2^- + O^{2-}$	$3MNO_3 = MNO_2 + M_2O + 2NO_2 + O_2$	−2.03	−2.64
2.	$NO_3^- + 5e^- = \frac{1}{2}N_2 + 3\,O^{2-}$	$6MNO_3 = \frac{1}{2}N_2 + 3M_2O + 5NO_2 + \frac{5}{2}O_2$	−1.97	−2.63
3.	$2NO_3^- + 8e^- = N_2O + 5\,O^{2-}$	$10MNO_3 = N_2O + 5M_2O + 8NO_2 + 4\,O_2$	−2.18	−2.87
4.	$NO_3^- + 3e^- = NO + 2\,O^{2-}$	$4MNO_3 = NO + 2M_2O + 3NO_2 + \frac{3}{2}O_2$	−2.39	−3.13
5.	$M^+ + e^- = M$	$MNO_3 = M + NO_2 + \frac{1}{2}O_2$	−3.49	−3.73

Sodium nitrite.—In some work on molten $NaNO_2$, Calandra and Arvia (5) have used an Ag^+/Ag electrode in $NaNO_3$-KNO_3 as a reference electrode. This was connected to the nitrite through a Luggin-Haber tip. However, since a reference electrode without the complication of two different solvent systems is preferable, a Ag^+/Ag reference electrode in molten $NaNO_2$ was established.

Figure 2 is a Nernst plot for a concentration cell experiment in molten $NaNO_2$ at 302°C, a line of the slope predicted by the Nernst equation being drawn through the experimental points. The Ag^+ was produced by anodic generation with a current efficiency of 100% (coulombs passed 8.88, weight of silver expected 9.937 mg, weight of silver found 9.94 mg).

Figure 1C is the current-voltage curve obtained for $NaNO_2$ at 302°C, and as with the potassium nitrate there is only a single reduction wave.

Preparative electrolyses were conducted at the potential of this reduction wave, using various metals as cathodes, and in every case the metal was corroded (Table II).

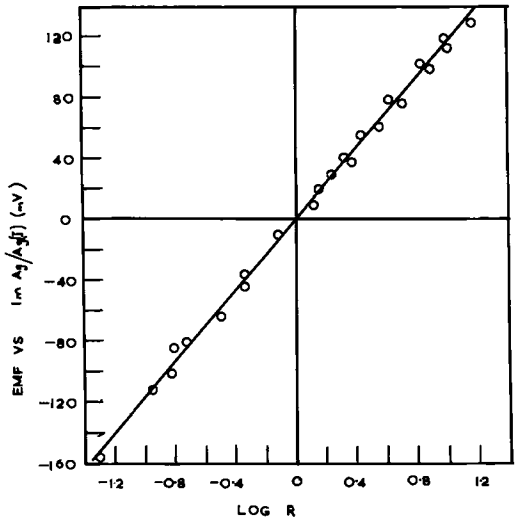

Fig. 2. Nernst plot for Ag/Ag (I) concentration cells in $NaNO_2$ at 302°C. R is the ratio of Ag (I) concentrations in the two compartments.

In contrast to either of the nitrates, the platinum foil anodes used in the sodium nitrite were corroded and, over a period of time, a green coloration developed in the anolyte.

Discussion

Unless otherwise specified this discussion is restricted to the results obtained with platinum electrodes.

At the peak potential in the molten sodium nitrate, the favored electrolytic process appears to be the reduction of the nitrate ion to nitrite and oxide, in accord with the work of Swofford and Laitinen (3). However, the fact that only 0.47 mole of nitrite per Faraday was found analytically indicates that other processes may also occur at, or before the peak potential. Among these processes could be (*a*) nitrogen evolution, (*b*) nitrous oxide evolution, or (c) nitric oxide evolution [cf. the production of nitrite, nitrous oxide, and nitrogen by reduction of nitrate with calcium metal or sodium amalgam (9) and the thermal evolution of nitrogen and nitric oxide from sodium nitrate (10)]. The standard reversible decomposition potentials (11) for each of these evolution reactions, for the production of the alkali metal, and for the formation of the alkali metal nitrite are given in Table III. For the purposes of calculating these standard reversible decompositions, it is assumed that reversible cells of the type

$$Pt, NO_2, O_2 / NaNO_3 // Na_2O, NaNO_3 / N_2, Pt$$

are formed when the melt is electrolytically decomposed. Working on these assumptions, the potentials at which reactions 1 to 5 occur in the sodium nitrate are marked on Fig. 1A: processes 1 to 3 should all occur before a potential of —1.35v *vs.* the Ag^+/Ag reference electrode.

At potentials beyond —1.35v *vs.* the reference electrode there is an increasing contribution from the gaseous evolution reactions and from other reactions, as evidenced by the smaller quantities of reducing agent found, by the appearance of the red and green colorations, and the identification of platinum in the catholytes. These mixed processes occur over a fairly wide potential span, and it is suggested that the sharp rise in current at —3.1v is not due to any one of these processes involving the reduction of the nitrate anion, as the products formed during the after-peak process are substantially the same as formed at —3.1v. The

sharp rise in current at −3.1v is more likely to be due to the breakdown of the sodium oxide film on the cathode. Metallic sodium should be thus produced and would then reduce the nitrate ion. At high current densities, this sodium, produced in fairly large quantities, would be partially shielded from the nitrate by a protective layer of sodium oxide, but when the nitrate does reach the sodium, a violent reaction in the form of sparks is not unexpected as the value for ΔG°_{600} for the reaction

$$5Na + NaNO_3 = 3Na_2O + \tfrac{1}{2}N_2$$

is −173.7 kcal mole^{-1}. Incidentally, this high negative value of ΔG°_{600} and the fact that sparks are observed at the cathode during electrolyses at high current densities would suggest that Arvia, Calandra, and Triaca's (4) claims to have measured the potential of a reversible Na^+/Na electrode are suspect.

The electrolytic reduction processes in potassium nitrate differ in some respects from the corresponding reductions in sodium nitrate, although in both cases it is the nitrate anion that is being reduced. Some of these differences could be explained in terms of the relative insolubility of sodium oxide in nitrate melts and the solubility of potassium oxide in potassium nitrate (3). Thus, there is no peak formed on the current-voltage curve of potassium nitrate as the electrode processes are not inhibited by an insoluble oxide layer. Also, as there is no alkali metal oxide film on the cathode in the KNO_3, there is little chance of forming alkali metal in large concentrations, with the result that no sparks are observed at the cathode on electrolysis of KNO_3 at high current densities.

The preparative electrolyses in molten sodium nitrite showed that the reduction processes in this medium are at least as complicated as those occurring in nitrate. Unfortunately, it is not feasible to analyze a nitrite for reducing agent and the oxide analyses were very unreliable due to the attack of the glass by the oxide. The fact that some silver hyponitrite was found in the catholyte when a silver cathode was used indicates that hyponitrite may be formed as an intermediate.

A reasonable explanation of the appearance of cathode metals in solution may be the attack of the cathode metal by one of the other cathode reduction products. The catholytes formed with platinum cathodes resemble those of aqueous platinum nitrosyl complexes (12, 13), and the brown compound formed in the nitrates when stainless steel cathodes were used is similar in appearance to $Fe(NO)_4$ and the $FeNO^{2+}$ ion which occurs as the "brown ring" compound in tests for the presence of nitrate in aqueous solutions.[3]

Further evidence suggesting that the green complex formed at the platinum cathodes in the nitrates may be a nitrosyl-type complex is that NO is evolved from the catholytes when water is added to them. Also with the sodium nitrite, in contrast of the nitrates, a green color develops in the anode compartment as well as in the cathode compartment. This may indicate that NO is formed as an intermediate in the oxidation of the nitrite and that this NO then chemically reacts with the platinum to form the green platinum nitrosyl type complex.

[3] In this context, it is interesting that the presence of nitrate in aqueous systems can be confirmed by adding a Pt (II) salt to the solution under test (instead of ferrous sulfate as is usually the case) and then adding concentrated sulfuric acid, when a green ring is formed at the sulfuric acid/solution interface.

The Free Energy of Formation of Palladium Oxide

J. Stuart Warner

Henry Krumb School of Mines, Columbia University, New York, New York

ABSTRACT

The equilibrium oxygen pressure for the reaction $2PdO(c) \rightleftarrows 2Pd(c) + O_2(g)$ was accurately measured over the temperature range 910°-1145°K. The following working equation for the oxygen pressure is valid over the experimental range.

$$\log P_{O_2} = 31.905 - 6.29 \log T - \frac{14{,}510}{T} \pm 0.006$$

The following expressions, valid from 298°-1200°K, apply to the formation of one mole of PdO(c)

$$\Delta F^\circ_f = -27{,}013 + 14.0\,T \log T - 6.16 \times 10^{-3} T^2 - 0.1 \times 10^5 T^{-1} - 12.190\,T \pm 100 \text{ cal/mole}$$

$$\Delta H^\circ_f = -27{,}013 - 6.08\,T + 6.16 \times 10^{-3} T^2 - 0.2 \times 10^5 T^{-1} \pm 400 \text{ cal/mole}$$

The heat of formation and entropy of PdO(c) at 298.15°K were found to be −28,345 ± 400 cal/mole and 8.60 ± 0.3 eu, respectively.

In an earlier paper (1), the author pointed out certain advantages that could be realized if the decomposition of a metal sulfate were carried out in the presence of an oxygen-controlling couple. The reaction

$$4CuO(c) \rightleftarrows 2Cu_2O(c) + O_2(g) \qquad (A)$$

was employed to maintain a known partial pressure of oxygen over a sample of $CoSO_4$ and its decomposition products. While the CuO/Cu_2O couple was satisfactory for that particular study, its relatively low equilibrium oxygen pressure and its ability to remove SO_3 from the gas phase, forming the stable compound $CuO \cdot CuSO_4$, restricted its use to the study of the more stable sulfates.

A search of the literature revealed that the PdO/Pd couple produced an oxygen pressure suitable for the study of less stable sulfates and did not itself form sulfates stable at high temperatures. Unfortunately as reported by Coughlin (2), the free energy of formation of PdO was uncertain to ± 2000 cal/mole. This large uncertainty would have seriously affected any thermodynamic properties derived for a sulfate decomposed in the presence of the PdO/Pd couple. It was therefore decided to make an accurate redetermination of the equilibrium oxygen pressure of the following reaction

$$2PdO(c) \rightleftarrows 2Pd(c) + O_2(g) \qquad (B)$$

Experimental Apparatus

An apparatus, suitable for the static determination of a variety of equilibria between gases and condensed phases of fixed composition, was designed and constructed. Since the gas phase was usually produced by some reaction of the condensed phases, it was essential that the apparatus accommodate a substantial quantity of reactants in its isothermal zone while keeping the gas volume to a minimum. This goal was achieved through the use of special furnace control circuitry, a crucible of unusual design, and an electromechanical transducer for pressure measurement.

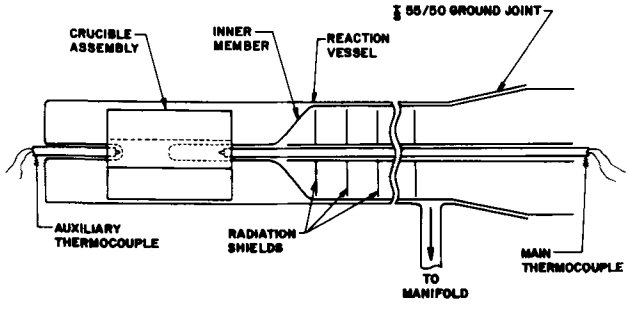

Fig. 1. Reaction vessel and crucible assembly

The reaction vessel, shown schematically in Fig. 1, was a 45 mm ID fused silica tube, 24⅝ in. in length including the Vycor female joint. The inner member, a 41 mm OD fused silica tube, carried the main thermocouple well and permitted the large crucible assembly to be sealed into the reaction vessel without creating much dead volume. The vessel was inserted about 16 in. into a tube furnace so that the crucible assembly rested at the center of the furnace.

The Nichrome heating element was wound evenly on a grooved Alundum core, 2 in. ID and 24 in. long with two taps dividing the winding into three 8-in. sections. The furnace control circuit, patterned after one described by Smith (3), could make as much as an 8 in. length of the 2 in. ID tube isothermal within ±1°C. Such control was particularly important because of the asymmetrical arrangement of the reaction vessel within the furnace. The average difference in temperature at the two thermocouples for the measurements to be reported was only 0.4°C. The furnace element was supplied with heating and cooling currents by a potentiometric controller in parallel with a rheostat. The furnace winding and the controller were supplied electrical power from separate constant voltage transformers. Since the controller had a wide dead band, a small Guoy modulator (4) was placed in series with the control thermocouple whose hot junction was in contact with the furnace winding. This crude form of proportioning control maintained the temperature of the isothermal zone constant within a few tenths of a degree for several hours and within one degree over a day.

The pick-a-back crucible assembly detailed in Fig. 2 was constructed from 0.010 in. platinum sheet. This design reduced the necessary length of the isothermal zone to 3½ in. It could accommodate relatively large volumes of reagents in separate containers, which arrangement was usually necessary in sulfate studies to prevent undesirable side reactions between the sulfate, its decomposition products, and an oxygen-controlling couple. A very important feature of the assembly was that it allowed the main and auxiliary thermocouples (see Fig. 1) to "see" only the interior of the assembly and the surface of the material in the lower crucible. This configuration permitted an accurate measurement of the temperature of the condensed phases.

Temperatures were measured with Pt-Pt/10% Rh thermocouples and an L&N Type K-3 Universal Potentiometer with guarded circuitry. The thermocouples were calibrated in accordance with NBS Circular 950 at the freezing points of zinc, aluminum, silver, and

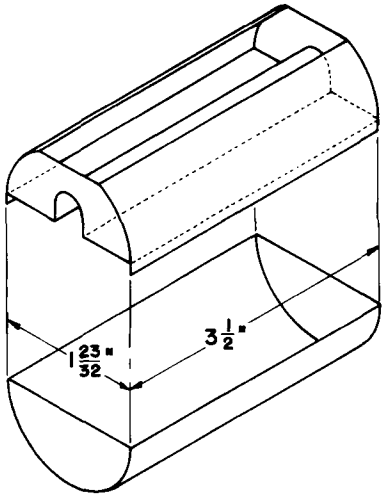

Fig. 2. Crucible assembly

copper. The silver, of 99.999% purity, was obtained commercially, the other metals from NBS. The reported temperatures are probably accurate to at least ±1°C.

The pressure of the system was measured by a miniature electromanometer system (Consolidated Electrodynamics). This device was preferred to a simple manometer because it had a much smaller dead volume and could be treated to resist attack by gaseous SO_3 arising from the decomposition of sulfates. (The author could find no manometric fluid which did not react with SO_3 or absorb significant quantities of gas.) The reaction gases were admitted to a small bellows in the thermostatted pressure balance. The interior of the bellows was gold-flashed for corrosion resistance. An associated servo-amplifier gave a ± 10 vdc output for a ± 15 psi pressure differential between the bellows and the reference cavity of the balance, which was normally evacuated to a pressure of a few microns. The output voltage was divided by a Kelvin-Varley type divider and then measured by the Type K-3 potentiometer or displayed on a potentiometric recorder.

A large-bore (22 mm ID) mercury manometer was constructed and installed in a special housing to insure an accurate determination of the mercury's temperature. Pressures could be measured on this manometer to ± 0.1 mm Hg with a cathetometer. The electromanometer was calibrated at 100 different points by comparing its electrical output with the pressure read on the mercury manometer when both devices were connected in parallel across the same pressure difference. The voltage-pressure data were correlated by a quadratic least squares equation. There was a slight hysteresis effect so different equations were used for increasing and decreasing pressures. By using the quadratic equations, pumping continuously on the reference cavity, maintaining the temperature of the pressure balance constant to within ± ½°C, and correcting for zero drift, one could measure pressures accurately to better than ± 0.1 mm Hg for a few months at a time. The arrangement of the manifold permitted the calibration to be checked at any time during the experiment.

Sample Preparation

Since Hansen (5) reported a continuous series of solid solutions between Pd and Pt, the PdO/Pd couple was contained in a half-cylindrical liner of fused silica which fitted snugly into the lower half of the crucible assembly. The empty upper half of the crucible was set in place to act as a radiation shield. An investigation of the system Pd-Si (6) revealed that, if there were any terminal solubility of Si in Pd, it was less than 0.1 a/o. This fact, together with the great difference in stability of PdO and SiO_2, indicated that no reaction should be expected between the couple and the silica liner. Preliminary experiments lasting several weeks left the liner absolutely clear and unetched.

These early experiments were not very satisfactory because of a slow approach to equilibrium. This was found to be caused by sintering of the Pd, creating a serious reduction in surface area. To prevent this sintering, Pd was mixed with an equal volume of silica which had been crushed to −200 mesh and leached repeatedly until free of iron. The metal was completely oxidized with dry tank oxygen in the reaction vessel at 700°C. The system was cooled, opened, and more Pd added to the mixture of PdO and SiO_2. Two thorough studies were made of this mixture with excellent results. The approach to equilibrium was reasonably fast in both directions, and the equilibrium oxygen pressure did not appear to depend on the amount of oxide present. Finally, x-ray diffraction patterns of the mixture made after the experiment were in excellent agreement with the patterns for PdO, Pd, and SiO_2 given in the ASTM Index.

Experimental Method and Results

The crucible assembly was inserted into the reaction vessel and the inner member sealed in place with Apiezon T grease. The thermocouples were positioned as shown in Fig. 1. The entire system was evacuated to $<5\mu$ then isolated from the mechanical pump and allowed to stand overnight to test for leaks. The system was heated and continuously evacuated for about 1½ hr until its temperature reached 500°C.

The procedure followed in all measurements was to bring the furnace close to the desired temperature, allow it to come to thermal equilibrium, then adjust its controls to minimize the temperature difference across the crucible assembly. Experience proved that subsequent constancy of pressure and both temperatures for ½ hr was sufficient to insure attainment of equilibrium. A small amount of gas was then removed in order to check the zero of the electromanometer and the pressure allowed to re-establish itself. Sometimes the furnace temperature was lowered slightly to approach equilibrium from above. The first experimental point was obtained at a pressure of several Torr, the entire gas phase being removed repeatedly to insure the absence of adsorbed gases. The data in the first two columns of Table I were obtained in this manner.

Correlation of the Data

Implicit in the equation for reaction (B) is the assumption that palladium oxide is a stoichiometric compound. Although the literature offers no evidence to the contrary, it appears that this hypothesis has not been tested. The equilibrium constant for this reaction may be expressed as follows

$$K = \frac{a^2_{Pd} P_{O_2}}{a^2_{PdO}}$$

Schmahl and Minzl (7) reported that the solubility of Pd in the oxide, if any, is very small. Raub and Plate (8) claimed to have found a small solubility of oxygen in Pd that decreased rapidly with decreasing temperature and amounted to only 0.038 a/o at 1173°K. In view of these facts Pd and PdO were assumed to have been pure substances throughout the experiment. The equilibrium constant was simplified accordingly.

$$K = P_{O_2} \qquad [1]$$

Heat capacity equations given by Kelley (9) were employed to derive the following expressions for ΔC°_p and Σ for reaction (B)

$$\Delta C^\circ_p = 12.16 - 24.64 \times 10^{-3} T - 0.4 \times 10^5 T^{-2} \qquad [2]$$

* Equilibrium approached from high oxygen side.

$$\Sigma = -4.5756 \log P_{O_2} + 28.0 \log T - 12.32 \times 10^{-3}T - 0.2 \times 10^{5}T^{-2} \quad [3]$$

The values of Σ calculated from the experimental data are reported in Table I. These were correlated with reciprocal temperature by a linear least squares method, resulting in the following equation.

$$\Sigma = I + \frac{\Delta H^\circ_0}{T} = 24.381 + \frac{54{,}025}{T} \pm 0.029 \text{ cal/mole-°K} \quad [4]$$

The uncertainty quoted for Sigma represents two standard deviations of the data points about the correlating line. This scatter agrees quite well with that predicted from Eq. [3] assuming the errors in measuring temperature and pressure were 1°K and 0.1 Torr, respectively.

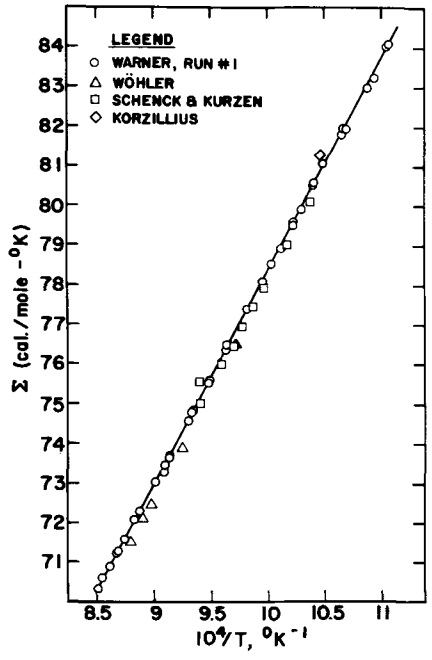

Fig. 3. Σ vs. $10^4/T$ for the reaction $2PdO(c) \rightleftarrows 2Pd(c) + O_2(g)$

Equation [4] has been graphed on Fig. 3 along with values of Sigma calculated from other experimental investigations of reaction (B). The data given in Table I were not plotted because their deviation from the correlating line could scarcely be detected even on a very large graph. When comparing data from various sources in Fig. 3, it is convenient to remember that the difference in Sigma values multiplied by the temperature at which the comparison is made equals the difference in the values of ΔF°_T for reaction (B); *i.e.*, $T(\delta\Sigma)_T = \delta(\Delta F^\circ_T)$ cal/mole. For example, the small scatter in the data of Table I may be expressed as $\delta(\Delta F^\circ_T) = \pm 0.029\ T$. This uncertainty is less than 35 cal/mole over the experimental range of temperature.

The data points labeled "Warner, Run No. 1" resulted from an earlier experiment performed with the dispersed couple in an uncovered silica crucible placed beneath the main thermocouple well. The thermocouple had not been calibrated, but the manufacturer supplied a calibration based on the wire from which it was made. This run covered a temperature range from 903° to 1177°K and developed oxygen pressures up to 1.84 atm. The sixty experimental points were correlated as described above and the resulting equation for Σ was compared with Eq. [4]. In terms of ΔF°_T the data for run No. 1 were 100 cal/mole less positive at the lowest experimental temperature and 10 cal/mole less negative at the highest experimental temperature. When both sets of data were extrapolated to room temperature, run No. 1 was only about 330 cal/mole less positive. Although the earlier experiment generally yielded slightly higher pressures, it was felt that these small differences could be readily explained in terms of the improved temperature measurement in the final experiment.

Since the completion of the author's experiments, another recent study of reaction (*B*) appeared in the literature. Schmahl and Minzl (7) used a thermobalance to determine when a small sample of the couple had come to equilibrium with a controlled oxygen pressure. They reported the following equation, said to describe their 14 data points lying between about 1020° and 1120°K

$$\log P_{O_2} = -\frac{11152}{T} + 9.726 \quad [5]$$

The data appeared to have very little scatter, but no quantitative measure could be obtained as the individual equilibrium points were not reported. In terms of ΔF°_T for reaction (B), their data were found to coincide with the author's at 1120°K and to be about 170 cal/mole less positive at 1020°K. These investigators mentioned that their experiments took a very long time, (experiments No. 1 and No. 2 took over two months), which fact may have been due to sintering of the Pd content of their couple. If this were true, it is not surprising that they found somewhat larger oxygen pressures than the author.

With the exception of one point of Schenck and Kurzen (10) and the sole point of Korzillius (11), all of the older data also lay on the high oxygen pressure side of Eq. [4]. The maximum deviation from the line was 500 cal/mole for Wohler (12), 350 cal/mole for Schenck and Kurzen, and 380 cal/mole for Korzillius.

The data of all five investigators agree extremely well within the experimental temperature range. However, the results of this investigation are preferred for the care taken in measuring temperature and pressure, the precision of the results over a wide range of temperatures, and because, in measurements of this type, the lowest pressures are probably the most accurate, all other things being equal. Equation [4] will be used for all subsequent calculations.

By combining Eq. [3] and [4] the following five-term equation for log P_{O_2} was derived

$$\log P_{O_2} = -\frac{11{,}805}{T} + 6.119 \log T - 2.693 \times 10^{-3}T - 0.044 \times 10^{5}T^{-2} - 5.328 \pm 0.0063 \quad [6]$$

A simple three-term equation was derived for log P_{O_2} which was valid over the actual experimental range of temperatures.

$$\log P_{O_2} = 31.905 - 6.29 \log T - \frac{14{,}510}{T} \quad [7]$$

Equation [7] gives excellent agreement with [6] at 900°, 1000°, and 1100°K, but differs from the preferred values by 0.01 log units at 800°K and by 0.004 log units at 1200°K. However, these deviations are comparable to the uncertainty in Eq. [6].

Thermodynamic Properties of PdO

The following expressions for the change in various thermodynamic properties accompanying reaction (B) were calculated by combining Eq. [2], [3], and [4] with the appropriate thermodynamic relations

$$\Delta F^\circ_T = 54{,}025 - 28.0\,T \log T + 12.32 \times 10^{-3}T^2 + 0.2 \times 10^{5}T^{-1} + 24.381\,T \pm 200 \text{ cal/mole} \quad [8]$$

$$\Delta H^\circ_T = 54{,}025 + 12.16\,T - 12.32 \times 10^{-3}T^2 + 0.4 \times 10^{5}T^{-1} \pm 800 \text{ cal/mole} \quad [9]$$

$$\Delta S^\circ_T = -12.221 + 28.0 \log T - 24.64 \times 10^{-3}T + 0.2 \times 10^{5}T^{-2} \pm 0.5 \text{ eu} \quad [10]$$

Equations [11] and [12] give the standard free energy of formation and the heat of formation of one mole of PdO.

$$\Delta F^\circ_f = -27{,}013 + 14.0\,T \log T - 6.16 \times 10^{-3}T^2 - 0.1 \times 10^{5}T^{-1} - 12.190\,T \pm 100 \text{ cal/mole} \quad [11]$$

$$\Delta H^\circ_f = -27{,}013 - 6.08\,T + 6.16 \times 10^{-3}T^2 - 0.2 \times 10^{5}T^{-1} \pm 400 \text{ cal/mole} \quad [12]$$

The heat of formation of PdO at 298.15°K was calculated to be −28,345 ± 400 cal/mole.

From Eq. [10], $\Delta S^\circ_{298.15}$ was calculated to be 49.94 ± 0.5 eu. This value was combined with the entropies of Pd(c) and O_2(g) given by Kelley (13) to determine $S^\circ_{298.15}$ for PdO(c).

$$49.94 \pm 0.5 = 2[9.06 \pm 0.05] + 49.01 \pm 0.01 - 2S^\circ_{298.15}(\text{PdO}) \quad [13]$$

$$S^\circ_{298.15}(\text{PdO}) = 8.60 \pm 0.3 \text{ eu} \quad [14]$$

Discussion of Results

The second-law correlation of the experimental data indicates that PdO has a smaller entropy at 298.15°K than does Pd. This is unusual, but not rare as CaO, MgO, and SrO also have reported entropies smaller than those of the corresponding metal, within the precision of the measurements.

Kellogg (14) has indicated the value of C_p for PdO at 298.15°K seems low compared with the heat capacity of comparable compounds. The data in Table I were correlated using a modified expression for the heat capacity of PdO, but the calculated value of $S^\circ_{298.15}$ was even smaller than that given in Eq. [14].

From the data given by Coughlin (2) for ΔF°_f and ΔH°_f at 298.15°K, it was apparent that he estimated a value of $S^\circ_{298.15}$ for PdO by Latimer's (15) method. This estimate, 13.2 eu, could not be used in a third-law correlation that honored the experimental points. It was probably for this reason that he assigned such a large uncertainty to ΔF°_f.

It appears that a third-law determination of the entropy of PdO is needed for clarification of these results.

Summary

The equilibrium oxygen pressure of the PdO/Pd couple in the range 800°-1200°K is given by the expression

$$\log P_{O_2} = 31.905 - 6.29 \log T - \frac{14{,}510}{T} \pm 0.006$$

The heat of formation and entropy of PdO at 298.15°K were found to be −28,345 ± 400 cal/mole and 8.60 ± 0.3 eu, respectively.

Acknowledgments

The author wishes to thank Mr. R. J. Slusar for his careful assistance in making many of the measurements and Professor H. H. Kellogg for his helpful suggestions in correlating the data and preparing the manuscript. The National Science Foundation supported this work through its grant G24464.

Manuscript received September 2, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Cation Effects on the Potentials of Zero Charge of Gold, Silver, and Mercury Electrodes

D. D. Bodé, Jr., T. N. Andersen, and H. Eyring

Rate Processes Institute, University of Utah, Salt Lake City, Utah

ABSTRACT

The potentials of zero charge of the mercury, silver, and gold electrodes were measured in aqueous salt solutions containing tetra-alkylammonium and some other cations. The open-circuit scrape method was used in the case of the solid electrodes, and the streaming electrode method was used for mercury. For mercury the potential of zero charge (pzc) shifts either positive or negative with increasing electrolyte concentration, depending on the relative adsorbabilities of the cation and anion. In the case of gold and silver the pzc is more cathodic in tetra-alkylammonium or cesium salt solutions than in solutions containing sodium ions. This difference in trend for mercury from the gold or silver electrode, with cation variation, reflects the variance in metal-anion *vs.* metal-cation interactions on the different metals.

Adsorbable cations markedly affect the kinetics of electrode processes in a manner which is not explicable without a fairly detailed knowledge of the inner double layer (1, 2). Although a knowledge of the potential of zero charge is needed for such studies, this reference point has seldom been directly measured in solutions containing adsorbable cations for electrodes other than mercury.

The present study presents measurements of the pzc on gold and silver electrodes by the "open-circuit scrape" method (3) in solutions containing cesium and tetra-alkylammonium ions. The above method has been tested on gold and silver electrodes in simple aqueous salt solutions (4) and has also recently proven successful in producing pzc values for solid gallium (5), which are in good agreement with the values obtained from the electrocapillary maximum of the liquid metal (6). Since the mobilities of the tetra-alkylammonium ions in water are lower than those of the common inorganic ions (7) it was feared that mass transfer may not be fast enough to insure equilibrium adsorption conditions for the above pzc measurements. Therefore, potentials of a streaming mercury electrode (sme) were measured in tetra-alkylammonium iodide solutions and compared with the electrocapillary maxima available in the literature (8), in order to test the effectiveness of mass transfer at the sme. From these results the applicability of the open-circuit scrape method to these systems could be ascertained, based on the similarity of this method to the sme method for obtaining the pzc. Results of the above tests lead us to believe that kinetic complications do not seriously interfere with the open-circuit scrape experiments, nor with the streaming electrode potentials over a majority of the concentration ranges studied.

Experimental Methods

Streaming mercury electrode.—An air-tight Pyrex glass cell housed the electrolyte. Into the lid was sealed a capillary of approximately 0.04 mm diameter which was joined to an adjustable mercury reservoir. Triply distilled mercury could then be passed from the reservoir into the solution at controlled rates. The saturated calomel reference electrode made ionic contact, through an agar-saturated KCl salt bridge, to a side compartment of the main cell. This compartment contained the solution under investigation and was separated from the main cell compartment by means of a closed stopcock. Solutions were prepared from salts of reagent grade and water which was redistilled from a basic permanganate solution.

After cleaning and assembling the cell, the solution was admitted, and nitrogen of 99.996% purity was bubbled for 30 min. The solution was at room temperature (23.5° + 1.5°C). The potential of the sme *vs.* the reference electrode was measured with a L&N K-3 potentiometer and recorded as V_o *vs.* the normal hydrogen electrode using the I.U.P.A.C.-Stockholm sign convention. The results of Grahame and co-workers (9) with KCl solutions were reproduced within 5 mv, which was satisfactory agreement for the present work considering the degree of care taken in purifying chemicals, maintaining constant temperature and standardization of reference electrodes [besides the fact that direct measurements of the potential of the sme were made, rather than the more accurate methods used by Grahame *et al.* (9)].

The apparatus, materials, and procedure for the open-circuit scrape method were described in a previous paper (4).

Experimental Results

The abbreviation Me, Et, Pr, Bu will be used for the alkyl part of the cation, R_4N^+, where R is the methyl, ethyl, n-propyl, and n-butyl group, respectively.

The pzc obtained with the sme in tetra-alkylammonium iodide solutions are compared with the electrocapillary maxima of mercury in the same solutions (8) in Fig. 1. Considering differences of more than 15 mv as being significant we see that the zero charge potentials measured by the two methods are in agreement for Me_4NI, Et_4NI, and Pr_4NI from the most dilute concentrations studied [0.005, 0.003, and 0.01M, respectively, by ref. (8)] to concentrations of 0.05-0.1M, depending on the solution. In more concentrated solutions it is seen that the electrocapillary results level out and become more positive while the sme values continue to become more negative. Although the pres-

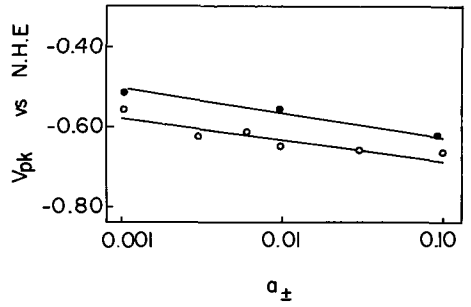

Fig. 4. Peak potential, V_{pk} (in volts), vs. activity (in moles/liter) for the silver electrode: • NaCl, ○ Et_4NCl.

ent results do little to explain the observed differences, it can be seen that slow mass transfer, in the case of the sme, is not the cause of the differences. If this were so, the discrepancies would be consistently present in dilute rather than concentrated solutions. Other investigators have also found that mass transfer need not be considered for tetra-alkylammonium ions at moderate concentrations (2). In the concentrated solutions one might presume that the sme measurements out-run some process involved in double layer formation, such as chemibonding of cations to specifically adsorbed anions (assuming the electrocapillary maximum values to be correct). The convergence of the pzc from the two methods for Bu_4NI, with increasing concentration, does not agree with the trends found for the other solutions and may indicate that experimental errors account for more than 15 mv difference between the two methods.

The potentials of zero charge for the sme in various tetra-alkylammonium solutions are shown in Fig. 2 as a function of concentration. Results shown in Fig. 1 for the iodides indicate that the sme in Fig. 2 should agree closely with the electrocapillary maximum results at least up to 0.1M, and even when there is some divergence it is by no means certain which procedure is most accurate. No results are available in the literature to compare with values given in Fig. 2 for the bromides, chlorides, and hydroxides.

From comparing the sme and electrocapillary results, one may safely assume that mass transfer considerations can be neglected in the open-circuit scrape experiments (in which the solution is in a state of rapid movement), and thus the transient peak potential, V_{pk}, is expected to yield the potential of zero charge. Figures 3 and 4 show peak potentials for silver in chloride solutions containing Na^+, Cs^+, and Et_4N^+ cations. From previous pH and anion work (4) we may interpret, as the pzc, all the V_{pk} values in Fig. 4 and those in the linear V_{pk} *vs.* pH region in Fig.

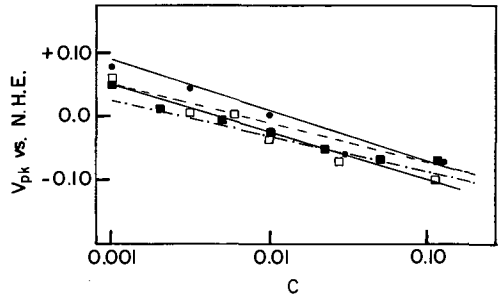

Fig. 5. Peak potential (in volts) vs. concentration (in moles/liter) for the gold electrode: ■ Me_4NOH, □ Et_4NCl, • Me_4NCl (---, NaCl; —.—.—, NaOH).

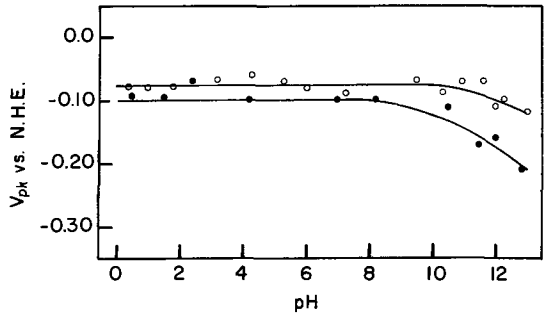

Fig. 6. Peak potential (in volts) vs. pH for the gold electrode: • 0.1N Et_4NCl + (HCl or NaOH), ○ 0.1N Me_4NCl + (HCl or Me_4NOH).

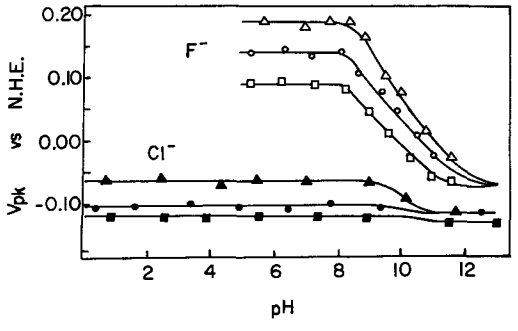

Fig. 7. Peak potential (in volts) vs. pH for the gold electrode in 0.1N fluoride (F^-) and chloride (Cl^-) solutions of Na^+ (triangles), Rb^+ (circles), and Cs^+ (squares).

3. For pH < 3, the hydrogen evolution reaction occurs so rapidly that charge is transferred to the electrode before the potential is measured. Figures 5, 6, and 7 show the V_{pk} for gold electrodes in solutions containing various large cations. In these figures all V_{pk} values are considered to be the pzc (4), and the deviations of the V_{pk} potentials from the horizontal at high pH arise from preferential adsorption of hydroxyl over the chloride or fluoride ions (4) in the alkaline region.

Discussion

When there is no electronic charge on the metal (*i.e.*, at the pzc) the change in potential brought about by the electrolyte is due to several causes. We write for this, ΔV, change in potential

$$\Delta V = \Delta V_{ad} + \Delta V_{dif} + \Delta V_{dip} + \Delta W \quad [1]$$

Here ΔW is the change in the work function of the electron which is added in charging the electrode with the change of the electrolyte. We consider ΔW to be negligible in our experiments. ΔV_{dip} arises from the orientation of dipoles at the interface. ΔV_{dif} is the potential arising from the diffuse double layer, and ΔV_{ads} is due to the closer approach to the surface of ions of one charge over that of the counter ions. We now write

$$\Delta V_{ad} = \sum_i \frac{4\pi q_i \gamma_i}{\epsilon_i} \quad [2]$$

Here q_i is the surface density of the adsorbed ions, i; γ_i is the difference in distance from the electrode to an adsorbed ion and its counter ion (10), *i.e.*, the distance between the inner and outer Helmholtz layer for this pair of ions; ϵ_i is the effective dielectric constant for the ith kind of ions.

If one plots data for various sources (11-13) for ΔV_{ad} against q_i either changing concentration or the kind of ion at a fixed concentration, nearly straight lines are obtained. This is understandable if ΔV_{ad} is the large term in ΔV and if γ_i is roughly constant for different ions. We accordingly neglect all terms in ΔV except ΔV_{ad} in our subsequent discussion.

When only one ion is adsorbed we therefore write

$$\Delta V = \frac{4\pi q_i \gamma_i}{\epsilon_i} \quad [3]$$

In this case ΔV measures the amount of adsorbed ions q_i providing γ_i/ϵ_i is known. The anodic shift, ΔV, has been observed for mercury in sodium sulfate or sulfuric acid to which tetra-alkylammonium ions have been added (14, 15). It is assumed that the OH^- ion is only slightly adsorbed on Hg, since the potential of zero charge for a 0.1*N* KOH solution is near to that for KF (9), and the KF is known to show negligible specific adsorption (11). Thus the pzc for Me_4NOH and Pr_4NOH in Fig. 2 should indicate the extent of cation adsorption.

Assuming that a simple competitive adsorption exists between anions and cations, the relative positions of the pzc in Fig. 2 may be explained assuming that the adsorbability decreases in the order $I^- > Bu_4N^+ > Br^- > Et_4N^+ > Cl^- > Me_4N^+ > OH^-$. Pr_4N^+ lies immediately to the left or right of Br^-. A minimum or maximum in the pzc *vs.* log c plot appears for the electrocapillary curves in the case of Et_4NI and Pr_4NI (cf. Fig 1) and for the streaming electrode in the case of Bu_4NCl and Bu_4NBr (cf. Fig. 2). This indicates that the sign of the preferentially adsorbed ion changes with progressive adsorption.

When both the cations and anions adsorb as in the case of most of the salts in Fig. 2, the interpretation of the pzc becomes more complicated, since the potential shift due to either ion may be compensated by that due to the opposite ion. When two ions are competitively adsorbed we write

$$\Delta V = \frac{4\pi q_1 \gamma_1}{\epsilon_1} + \frac{4\pi q_2 \gamma_2}{\epsilon_2} \quad [4]$$

Devanathan and Fernando (8) used their measurements to estimate the amount of adsorbed cation and anion. Actually they could only measure the sums of the concentrations in the adsorbed and diffuse layer for each ion. They then estimated the amount of adsorbed iodide ion. Using this value they calculated q_{ad} for the cation. In this way they arrived at stronger adsorption of the tetra-alkylammonium than of the iodide ions. This seems inconsistent with the fact that the zero charge potential of tetra-alkylammonium iodides are markedly negative with respect to KF for which neither ion is adsorbed. This explains the discrepancy between their order and ours for ion adsorption.

The potentials of zero charge for gold and silver (Fig. 3-7) show a surprising anomaly with respect to mercury. Thus the pzc for gold and silver shifts negatively for tetra-alkylammonium ions over the values for the comparatively small H^+, Li^+, or Na^+ ions. Such results require that the negative charge be nearer to the metal than the positive charge. This requires that there be some metal-anion interaction which is stronger than the metal-cesium or tetra-alkylammonium interaction. To understand these results we must suppose that the preferential adsorption of anions is enhanced by large cations. This would be explained if ion pairs are adsorbed with the negative ion next to the metal. Analogous "bridges" have been discussed by Frumkin (1). If the adsorbed ion pairs decrease the dielectric constants in Eq. [4], we see that ΔV will be enhanced in such cases. With mercury there is no evidence of preferential orientation of the negative end of such ion pairs as may exist toward the metal. Selective orientation of ion pairs depending on the metal is consistent with the known differences in tendencies to form coordination compounds as exemplified by the difference of gold and mercury in complexing with the cyanide ion.

The enhancement of anion adsorption by tetra-alkylammonium ions is an already familiar phenomenon in certain kinetic processes (1, 17). The formation of metal-anion-cation bridges has also been invoked in explaining corrosion inhibition by organic cations (17) and in a variety of other reaction rates (1).

Technical Note

The Anodic Oxidation of Yttrium Thin Films

J. R. Rairden

General Electric Company, Research and Development Center, Schenectady, New York

As part of a study of the properties of vacuum deposited thin films of yttrium, it has been observed that these films can be anodized to form thin, apparently dense, oxide films on the surface.

The yttrium was deposited onto 1 x 3 in. microscope slides from a water-cooled, electron-beam heated source using equipment that has been described previously (1). The evaporation source was a 100g ingot of 99.9% yttrium metal heated with a beam power of 250 ma at 14 kv. Prior to deposition, the slides located 10 in. from the source, were heated to about 300°C; then the yttrium was deposited in a vacuum of 1 x 10^{-5} mm Hg at a rate of approximately 30-40 Å/sec. X-ray diffraction analyses indicated that only very fine grained elemental yttrium is deposited with a slight amount of preferred orientation of (001)-type reflections.

During evaporation, the yttrium was deposited through a stencil mask so that the film coated an area 1.8 x 7.0 cm on the glass.

Electroplaters masking tape was used to define a film area on the slide approximately 1.8 x 4.5 cm, and this area of the film was completely immersed in the solution during anodization.

Several anodizing solutions were tried; the best one found, based on low-leakage current and high scintillation voltage, was a solution consisting of: 156g ammonium pentaborate, 1124g ethylene glycol, and 720 ml water.

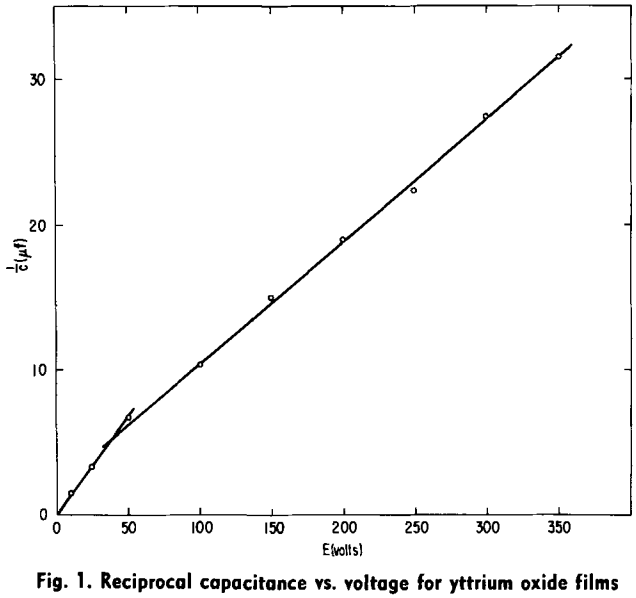

Fig. 1. Reciprocal capacitance vs. voltage for yttrium oxide films

A platinum foil cathode was used for all experiments. Using a constant voltage power supply, the anodic voltage was increased manually at a rate so that the current density was about 5-8 ma/cm². When the terminal voltage was reached, the current was allowed to decrease to, typically, 10-20 μa. For instance, using these conditions, it took about 1 min to anodize to 300v and about 3 min at voltage for the current to decrease to the minimum value.

The oxide films formed showed strong interference colors similar to those observed when tantalum or niobium is anodized. X-ray diffractometer traces taken of anodized films yielded patterns characteristic of yttrium; the oxide being too thin and/or of too small particle size to yield a pattern. Electron diffraction patterns showed three broad, diffuse halos at "d" values of 3.07, 1.98, and 1.16Å. These diffraction data indicate that the surface oxide is "amorphous" or of very small particle size which is similar to the structure of the anodic oxide formed on tantalum.

Capacitance values for the oxide films were measured at 1 kc in the anodizing electrolyte using a General Radio Company Type 650-A bridge. The reciprocal capacitance *vs.* voltage is shown in Fig. 1. It is interesting to note that this curve appears to have two linear regions; one from 0 to about 50v, and another above 50v. Scintillation occurs in the region of 375-400v. No quantitative measurements of capacitance reproducibility were made; however, it was observed that films anodized to a given voltage show identical interference colors.

Samples of several different thicknesses of yttrium were deposited; then the metal film was completely converted to oxide by anodization. These experiments indicate that for anodization above 50v, the "oxide build" is (14.8 Å/v + 300Å) ± 0.5 Å/v. By calculation, the dielectric constant of the anodic yttrium oxide is 16.5 ± 0.5. By comparing the thickness of the oxide to the thickness of the original yttrium film, it was determined that the volume ratio of oxide to metal is 1.36 ± 0.03 for the films examined. All film thickness measurements were made using a Sloan Instrument Corporation Model M-100 Angstrometer.

Acknowledgments

Helpful discussions with Dr. D. A. Vermilyea are gratefully acknowledged. R. L. Cormia kindly performed the film thickness measurements.

SOLID STATE SCIENCE

The Growth and Crystallographic Properties of Calcium Fluor- and Chlorapatite Crystals

J. S. Prener

General Electric Company, Research and Development Center, Schenectady, New York

ABSTRACT

Stoichiometric crystals of $Ca_5(PO_4)_3F$ and $Ca_5(PO_4)_3Cl$ were grown by slowly cooling solutions of the polycrystalline apatites in fused $CaCl_2$ or CaF_2. While fluorapatite is hexagonal, optical and x-ray observations indicate that $Ca_5(PO_4)_3Cl$ has a monoclinic $P2_1/b$ space group. All crystals of this compound are highly twinned. At about 200°C a transition to a hexagonal phase ($P6_3/m$) occurs. Loss of $CaCl_2$ from the crystals leads to a stabilization of the hexagonal phase whereas at low concentrations F ion impurities have the opposite effect. Some previous observations on the luminescence of $Ca_5(PO_4)_{3-x}(MnO_4)_xCl$ can now be understood in terms of the lower symmetry structure.

The calcium apatites [$Ca_5(PO_4)_3X$; X = F, Cl, OH] form an important class of natural and synthetic compounds. Fluorapatite is the major ore of phosphorous, hydroxyapatite makes up the mineral portion of bones and teeth in all animals, and the mixed fluorchlorapatites constitute the base for the major phosphor component in fluorescent lamps. Structural, optical, and other significant properties of these compounds can best be determined and studied using single crystals of good quality. The first part of this paper describes the solution growth methods used for obtaining fairly large, stoichiometric crystals of both fluor- and chlorapatite. Recently Young and Elliott (1) in some preliminary experiments have found it possible, by heating in steam, to convert the crystals of chlorapatite grown by us from solution (but not natural mineral chlorapatite) into single crystals of hydroxyapatite. These contained only 6% of the original Cl. Thus for the first time, large crystals of this biologically important material may become available for study. The fluorapatite crystals grown from solution have been used in optical and EPR studies of color center formation on x-ray irradiation (2).

In the latter part of this paper some optical and crystallographic properties of the solution grown crystals are described. In particular the availability of chlorapatite of sufficiently high purity and good stoichiometry has revealed that at room temperature the structure is monoclinic, not hexagonal as previously reported (3). Preliminary x-ray diffraction studies on these crystals have already been reported by Young and Elliott (1). We describe here some optical studies on the twinning and birefringence of chlorapatite which reveal its lower symmetry. The observation of a transition at about 200°C from a monoclinic to hexagonal form is described, and the effects of stoichiometry and fluoride content on the transition temperature are discussed. Even though the present evidence therefore clearly indicates that stoichiometric, pure, $Ca_5(PO_4)_3Cl$ does not have a true apatite structure at room temperature, we shall for convenience refer to this compound as calcium chlorapatite in this paper.

Solution Growth of Apatite Crystals

Single crystals of fluorapatite have been grown previously by the Kyropoulus method, but stoichiometric chlorapatite could not be grown by this method due to the rapid loss of $CaCl_2$ by vaporization at the high temperatures required for fusion (*ca.* 1650°C) (4, 5). No chemical analysis was reported for the fluorapatite crystals, but these too may be off stoichiometry for the same reason. Furthermore, crystals grown from the melt at such high temperatures tend to be severely strained due to the large temperature gradients present during growth. In contrast, crystal growth from solution takes place at much lower temperatures under almost isothermal conditions.

In the methods to be described below, the formation of apatites that are halide deficient is averted through the use of CaF_2 or $CaCl_2$ as the solvents. These solvents provide a halide-rich surround for the growing crystals.

The phase diagrams of the pseudobinary systems CaF_2-$Ca_5(PO_4)_3F$ (calcium fluorapatite) and $CaCl_2$-$Ca_5(PO_4)_3Cl$ (calcium chlorapatite) were determined by Nacken (6), and his results are reproduced in Fig. 1. In the fluoride system there is a simple eutectic at 1205°C. In the chloride system there is one intermediate solid phase. Besides chlorapatite, $Ca_5(PO_4)_3Cl$, there exists the incongruently melting compound Ca_2PO_4Cl corresponding to the mineral spodiosite. The eutectic temperature is 770°C and the incongruent melting point occurs at 1040°C. In growing chlorapatite crystals from a $CaCl_2$ solution, therefore, growth must take place above 1040°C. It is not of course possible to grow Ca_2PO_4Cl from a melt of the same composition, but rather large (0.4 cm) well-formed crystals of this material have been obtained from solutions of $Ca_5(PO_4)_3Cl$ in $CaCl_2$ at temperatures below 1040°C (7).

The solutions, from which crystals of the apatites were grown, were made up by fusing mixtures of microcrystalline $Ca_5(PO_4)_3F$ [1] or $Ca_5(PO_4)_3Cl$ [1] and either CaF_2 of $CaCl_2$. The CaF_2 used consisted of small

[1] The apatites were made by solid phase reactions and kindly supplied by the Chemical Products Plant of the General Electric Company, Cleveland, Ohio.

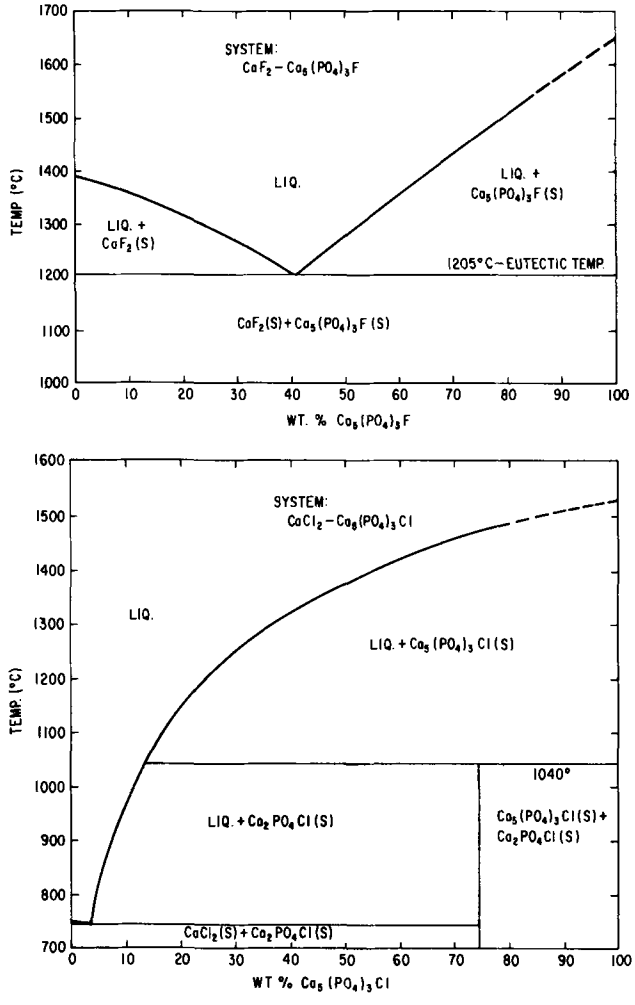

Fig. 1. Phase diagrams of the pseudobinary systems CaF_2-$Ca_3(PO_4)_2$ (top) and $CaCl_2$-$Ca_3(PO_4)_2$ (bottom) (6).

crystalline chips obtained from the Harshaw Chemical Company. The $CaCl_2$ was prepared by dehydrating AR $CaCl_2 \cdot 2H_2O$ in a stream of anhydrous HCl at 500°C. Typical compositions of the mixtures suitable for crystal growth are given in Table I.

The mixtures were contained in 100 ml platinum crucibles having a ⅛ in. lip around the top. For the chlorapatite, the crucibles were tightly covered by crimping 20 mil Pt foil around the lip and placed in the central, isothermal region of a wire wound furnace. For the fluorapatite, it was necessary to use the arrangement shown in Fig. 2. Whereas chlorapatite crystals could be separated very easily from the $CaCl_2$ matrix by leaching with hot water, fluorapatite crystals could not be separated from the solidified CaF_2. It was therefore necessary to effect a separation of the liquid and solid crystalline phases at a temperature above the 1205°C eutectic. The high-temperature separation was accomplished by inverting the furnace for several hours at the end of the crystal growing run (temperature about 1220°C). The liquid phase passed through the Pt gauze which retained the fluorapatite crystals. After cooling to room temperature,

Table I. Typical compositions used for growth of apatites from solution in fused salts

Compound	Wt. halide, g	Wt. apatite, g	Liquidus temp, °C	Temp of growth, °C
$Ca_5(PO_4)_3F$	45.0	55.0	1325	1375-1220
$Ca_5(PO_4)_3Cl$	60.0	23.5	1230	1280-1060

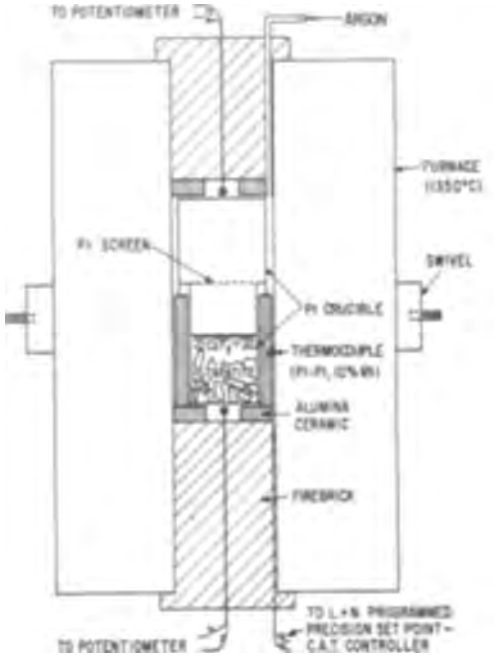

Fig. 2. Furnace and crucible used to grow crystals of $Ca_5(PO_4)_3F$ from fused CaF_2 solutions.

the crystals could be washed free of any adhering CaF_2 by boiling in an aqueous 20% solution of $Al(NO_3)_3 \cdot 9H_2O$.

Crystal growth runs were carried out as follows. The mixture of apatite powder and halide was soaked at temperatures some 50°C above the liquidus temperature for 10 to 20 hr in order to insure complete solution and then cooled at linear rates of 2-4°C/hr. Uniform cooling rates and precise temperature control (better than ±0.2°C) could be attained by driving the set-point potentiometer of a L&N Precision Set Point C.A.T. controller with a synchronous motor and suitable gear train. During cooling, when the temperature of the melt dropped below the liquidus temperature, crystallites of the apatites spontaneously nucleated in the melt or on the walls of the Pt crucible. Many crystals grew under these conditions, usually resulting in a large number of small crystals in addition to some larger ones. In the growth of fluorapatite, we cycled the temperature several times up and down some 20°C below the liquidus temperature. In this way the smallest of crystallites were redissolved leaving a fewer number of the larger crystallites which then acted as a sink for further growth. We were able to obtain many large crystals of fluorapatite (Fig. 3). The largest chlorapatite crystals obtained were 3-4 mm. The apatite crystals generally grew in the form of hexagonal prisms bounded by the faces of the $\{10\bar{1}0\}$ form. In many cases inclusions of the flux in thin rods parallel to the hexagonal axis were seen by microscopic examination, but it was always possible to find a large number of flux free crystals. The chlorapatites cleaved extremely easily perpendicular to the hexagonal axis, but no easy cleavage was observed in the fluorapatite crystals.

A number of mixed fluor- and chlorapatite crystals were grown by the use of mixtures of CaF_2 and $CaCl_2$ as the solvent and $Ca_5(PO_4)_3Cl$ powder as the source of apatite. In Table II we list the composition of the charges and the atomic ratio, $F/(Cl + F)$, in the charge as well as in the crystals. No attempt was made to determine the uniformity of the composition among the many crystals grown or within a single crystal.

It can be seen that the crystals are richer in F than the melt from which they grow. The ratio of the atomic fraction of F in the crystals to that in the charge is 2.0 ± 0.5 from the data shown in Table II.

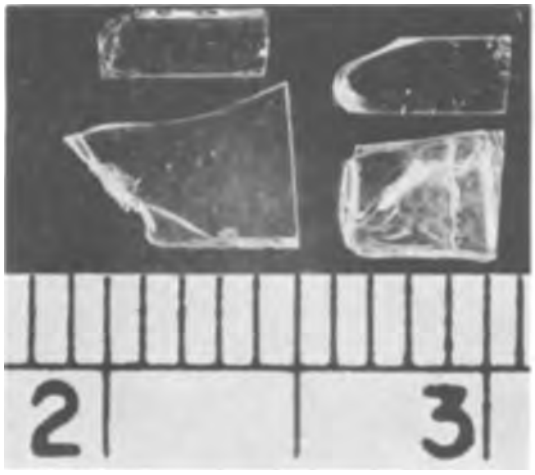

Fig. 3. Some fluorapatite crystals grown from fused CaF_2 solutions by slow cooling. The three transparent crystals have been cut and polished on the $10\bar{1}0$ faces. The scale is in centimeters.

Properties of the Apatite Crystals

Samples of both fluor- and chlorapatite crystals were analyzed for Ca, PO_4, and halide and the results are given in Table III.[2]

Since the accuracy of the chemical analyses was probably of the order of 0.1 w/o, the results given in Table II indicate that the apatite crystals were very near the stoichiometric composition.

The optical absorption of thin polished slabs of apatite crystals was measured at room temperature. A Cary Model 14 spectrophotometer was used down to 2000Å and a 1M normal incidence grating vacuum monochromator (8) was used for measurements at shorter wavelengths. The absorption coefficients of fluor- and chlorapatite are given in Fig. 4 and 5. Fluorapatite has essentially no strong absorption down to 1600Å (7.75 ev). The onset of strong absorption at this wavelength is probably intrinsic in origin [see also ref. (4)]. By way of comparison, fluorapatite crystals grown from the melt have a strong absorption band (200 cm^{-1}) peaking at 1900Å (4). This band is not intrinsic, but is due either to impurities or to a departure from stoichiometry for the melt-grown crystals since the absorption coefficient in this region

[2] The analyses were performed by the Quality Control and Testing Laboratory of the Chemical Products Plant, General Electric Company, Cleveland, Ohio.

Table II. Composition of charges and the F/(Cl + F) atomic ratios in crystals of mixed fluor- and chlorapatite

Wt. $Ca_5(PO_4)_3Cl$, g	Wt. $CaCl_2$, g	Wt. CaF_2, g	F/(Cl + F) in charge	F/(Cl + F) in crystals
11.7	29.7	0.3	0.014	0.03
11.7	28.5	1.5	0.067	0.09
11.7	27.9	2.1	0.093	0.16
11.7	27.0	3.0	0.13	0.36

Table III. Analysis of fluor- and chlorapatite

	Wt % halogen		Wt % Ca		Wt % PO_4	
	Found	Calc.	Found	Calc.	Found	Calc.
$Ca_5(PO_4)_3F$[a]	3.73	3.77	39.7	39.7	56.5	56.5
$Ca_5(PO_4)_3Cl$[b]	6.72	6.81	38.5	38.5	54.2	54.7

[a] It was necessary to correct analytical results for 0.17 wt % occluded CaF_2 solvent which could not be removed by washing the powdered charge with a hot concentrated $Al(NO_3)_3$ solution.
[b] Analytical sample analyzed for 1.5% $Ca_2P_2O_7$ as a separate phase. This again may have been an occluded phase.

for the solution grown crystals is only about 30 cm^{-1}. Strong optical absorption in chlorapatite also starts at about 1600Å, and again this probably represents an intrinsic edge. Solution-grown chlorapatite crystals have an absorption band (65 cm^{-1}) at 2000Å. It is again probably not intrinsic and has also been seen as a very strong optical absorption in diffuse reflectance spectra of chlorapatite powders (4). The origin of these impurity or defect absorption bands is being investigated.

Lattice constants of both fluor- and chlorapatite were obtained from single crystal c-axis rotation photographs. Based on a hexagonal unit cell (see, however, the next section) the measured lattice constants are given in Table IV and compared with previous determinations. The agreement of our results on single crystals with previous values determined using polycrystalline material is seen to be very good.

Microscopic examination under crossed polaroids using a quartz wedge showed fluorapatite to be uniaxial negative. For white light, the difference between the two principal refractive indices ($n_\omega - n_\epsilon$) was found to be 0.0019. The space group of fluorapatite as determined from x-ray precession photographs was

hexagonal $P6_3/m$, and the intensities of the various observed reflections were in agreement with those of previous studies of natural and synthetic fluorapatite. In contrast to fluorapatite, sections of solution grown chlorapatite crystals cut perpendicular to the apparent hexagonal c-axis appeared very weakly birefringent under crossed polaroids. The difference between the two principal refractive indices in this plane, $n_\gamma - n_\beta$, was found to be about 0.0002. Calcium chlorapatite is biaxial, and the true symmetry must therefore be lower than hexagonal. Young and Elliott (1) have already found from x-ray diffraction studies on some of these crystals that the true symmetry of chlorapatite was monoclinic $P2_1/b$, the monoclinic unit cell arising from a doubling of one of the a axes of a hexagonal cell. We were able to confirm their observations using x-ray precision camera techniques. The strong reflections indicated a hexagonal lattice. However, along one direction of the reciprocal lattice (which we take as b*) weak reflections were found half-way between the main reflections, thus indicating a doubled b-axis. The absence of odd k-indices in hko reflections and of odd l-indices in 001 reflections limit the space group to monoclinic $P2_1/b$. For monoclinic $Ca_5(PO_4)_3Cl$, Fig. 6 shows the relationship between the unit cell directions a, b, and c and the directions of the principal refractive indices (*i.e.*, the orientation of the indicatrix).

All crystals of chlorapatite when examined under crossed polaroids were found to be multiply twinned. In Fig. 7a, b, and c are shown microphotographs of a thin crystal slab cut perpendicular to the c-axis (taken as the unique axis of the monoclinic cell to coincide with the pseudo-hexagonal c-axis) as seen by transmitted light between crossed polaroids. The crystal was rotated 120° between each photograph. This crystal (as well as all other crystals examined) consists of three interpenetrating twins each having a common c-axis but oriented 120° to each other in the a-b plane. The 120° angle between the a and b axes and the fact that $b_0 = 2a_0$ results in the growth of mimetic twins having apparent hexagonal symmetry. The twinning planes are 120 and $1\bar{2}0$ and Fig. 8 shows the relationship between adjacent twins and the observed twinning planes.

Phase Transition in Chlorapatite

A large number of crystals of $Ca_5(PO_4)_3Cl$, cut perpendicular to the c-axis, were observed between

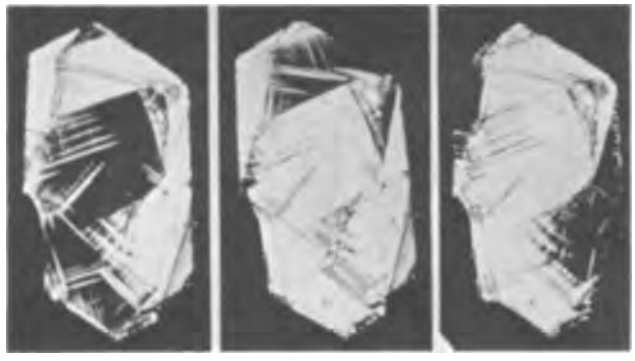

Fig. 7a, b, c (left, center, right). Microphotographs of a $Ca_5(PO_4)_3Cl$ crystal slab cut perpendicular to the c-axis (pseudohexagonal axis) and viewed through crossed polaroids. In each successive picture, the crystal is rotated 120°. The long dimension of the crystal was 4 mm.

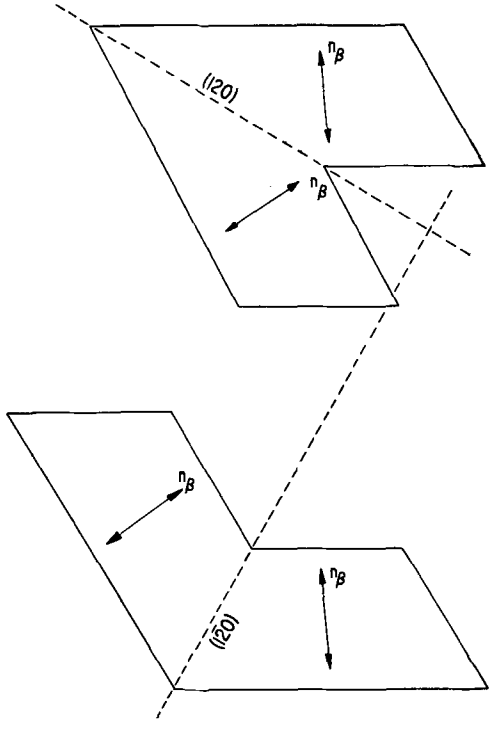

Fig. 8. Orientation of adjacent twins in $Ca_5(PO_4)_3Cl$ and the observed twinning planes. The two other adjacent sets of twins are obtained by two 120° rotations.

crossed polaroids while being heated on a microscope hot stage. At temperatures varying between 185° to 210°, for different crystals, the birefringence disappeared, the crystals becoming optically isotropic in this plane but not in a perpendicular plane. Because of the low birefringence of monoclinic apatite, observations were greatly aided by the use of a gypsum unit retardation plate. Below the transition temperature, at a suitable orientation of the crystal, the three twins show up as second order bright blue, first order bright orange and red-violet, whereas above the transition temperature, the entire crystal appears red-violet. The transition was found to be a perfectly reversible one. With each temperature cycle, however, the twinning patterns in many areas of the crystals changed drastically. For example, Fig. 9 shows the same crystal and orientation as in Fig. 7a, after one temperature cycle through the transition point. The change in the twinning pattern is obvious from the photograph. This transition was also studied by x-ray diffraction. Below the transition temperature, as already described, the space group is monoclinic $P2_1/b$, but above the transition temperature the observed re-

Fig. 9. Same crystal and orientation as one in Fig. 7a after one temperature cycle through the phase transition point.

flections are consistent with the hexagonal space group $P6_3/m$. The only obvious changes in the x-ray diffraction pattern as one goes through the transition is the disappearance of the odd k reflections in hkl ($l \neq 0$) resulting from the doubling of the hexagonal cell.

The real differences in the transition temperature observed in different crystals suggested that either deviations from stoichiometry, impurities, or both could effect this transition. To study the effect of stoichiometric deviations we heated chlorapatite crystals in vacuum at various temperatures and for various lengths of time. The results on two typical crystals are summarized in Table V. X-ray diffraction patterns taken of these heated crystals after they had become optically isotropic in the a-b plane again showed that their symmetry was hexagonal $P6_3/m$ with an apatite structure. We attributed the continuous lowering of the transition temperature and the final stabilization of the hexagonal form to a loss of $CaCl_2$ from the structure since it has been shown that there is a loss of $CaCl_2$ when chlorapatite powders are heated at temperatures of 900°-1000°C (10). Furthermore, we were able to restore the monoclinic form by reheating the hexagonal crystals in $CaCl_2$ vapor at 900°C for about 15 hr. Microscopic examination revealed that these crystals were now extremely highly twinned on a microscopic scale. These results on the effect of stoichiometry explain why $Ca_5(PO_4)_3Cl$ grown from the melt at about 1650°C are optically uniaxial (5).

Table V. Effect of heating chlorapatite in vacuum on the transition temperature

Heating temperature, °C	Time, hr	Transition temperature, °C
	Crystal I

800	85	Optically isotropic down to 6°K

Table VI. Monoclinic-to-hexagonal transition temperatures of $Ca_5(PO_4)_3$ (F,Cl) crystals

Atomic ratio, F/(Cl + F)	Transition temperature, °C
0.0	200
0.03	223
0.09	315
0.16	310
0.36	Optically isotropic down to 6°K

Natural mineral chlorapatite is also apparently always optically uniaxial. Since mineral chlorapatite always appears to contain considerable amounts of F(11), we also studied the effect of the F content in chlorapatite on the transition temperature. The composition of the crystals of $Ca_5(PO_4)_3(F, Cl)$ used are given in Table II. In Table VI are listed the observed monoclinic-to-hexagonal transition temperatures as measured optically. It is quite apparent from the results on Table VI that small amounts of F in the chlorapatite lattice tend to stabilize the monoclinic form, but that somewhere between an atomic ratio of F/(Cl + F) of 0.16-0.36, the hexagonal form becomes the stable one. Presumably other impurities can act in a similar manner in stabilizing the hexagonal form of chlorapatite when present in sufficient concentrations. Young and Elliott (1) for example state that OH groups replacing Cl stabilize the hexagonal form.

Discussion

The structure of $Ca_5(PO_4)_3F$ (hexagonal space group $P6_3/m$) has been investigated many times (1, 3, 12). In the fluorapatite structure the two F^- ions per unit cell lie in the twofold positions (a) at 00¼ and 00¾. They are thus located in columns parallel to the hexagonal c-axis; each F^- ion lying on the mirror planes at $z = ¼$ and ¾ and in the center of a Ca^{2+} triangle. All six PO_4 tetrahedra per unit cell are crystallographically equivalent.

The location of the F^- ions and the surrounding Ca^{2+} ions are shown in Fig. 10a. Previous x-ray diffraction studies of chlorapatite have indicated that its space group symmetry was the same as that of fluorapatite (3). Because of the larger size of the Cl^- ions, however, it seemed most probable that they were in the twofold positions (a) at 000 and 00½, halfway between the mirror planes. However, as we have pointed out, x-ray diffraction and optical studies on single crystals of stoichiometric $Ca_5(PO_4)_3Cl$ have shown that the true symmetry at temperatures below 200°C is monoclinic $P2_1/b$. The monoclinic unit cell can be derived from a hexagonal cell by doubling one of the hexagonal a axes. In this lower symmetry struc-

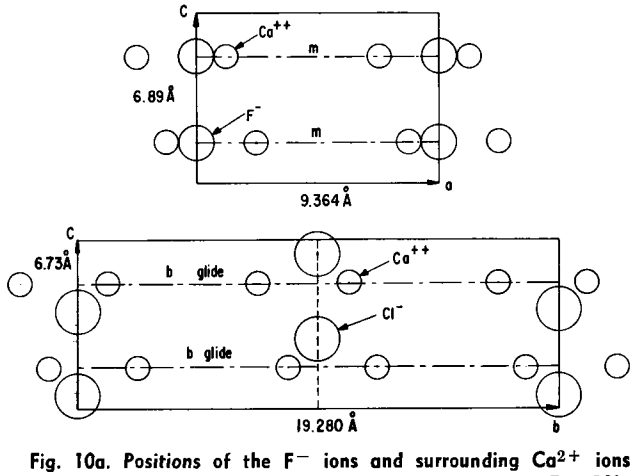

Fig. 10a. Positions of the F^- ions and surrounding Ca^{2+} ions projected on an a-c plane in the fluorapatite structure; Fig. 10b, possible positions of the Cl^- ions projected on the b-c plane in the monoclinic form of the $Ca_5(PO_4)_3Cl$ structure. The ionic sizes are drawn ½ scale for clarity.

ture all the atoms most probably lie on the fourfold general positions (e). As a consequence of this, the twelve P atoms per unit monoclinic cell will lie on three crystallographically inequivalent sets of positions (e). By a suitable choice of parameters, the general equivalent position of the $P2_1/b$ space group can be made close to or even the same as those of $P6_3/m$. The similarity in the strong reflections of $Ca_5(PO_4)_3Cl$ above and below the monoclinic-hexagonal transition indicates that the atomic positions in the monoclinic and hexagonal forms of chlorapatite are indeed not very different. Hence the term pseudo-hexagonal symmetry used to describe the low-temperature form. That there are, however, slight but measurable differences in the surroundings of the three sets of P atoms is shown by the fluorescence studies in fluor- and chlorapatites and spodiosite (Ca_2PO_4Cl) doped with small amounts of MnO_4^{-3} (7). The MnO_4^{-3} ion substitutes for the PO_4^{-3} ion in these materials. At 78°K in fluorapatite and spodiosite a strong, sharp fluorescent emission line is observed at 8640 and 8410 cm^{-1}, respectively. In chlorapatite three lines, of about equal intensity and separated by 5 cm^{-1}, are observed near 8600 cm^{-1}. These lines are due to electronic transitions between the excited ^1E and ground $^3A_2$ states of the e^2 configuration of the tetrahedral MnO_4^{-3} ion. Crystal field splittings of the ^1E state due to deviations from perfect T_d symmetry are also observed and vary from about 110 cm^{-1} in fluorapatite and 166 cm^{-1} in chlorapatite to 293 cm^{-1} in spodiosite. The origin of the 5 cm^{-1} splitting of the fluorescent line observed only in chlorapatite was attributed to a splitting of the threefold spin degenerate $^3A_2$ state. It was not understood why a similar splitting was not observed in fluorapatite or spodiosite. In view of the structural considerations discussed above, it seems most probable now that the three closely spaced equally intense lines observed in chlorapatite are in fact due to the presence of equal numbers of Mn^{5+} on the three different sets of P positions. The small value of the splitting indicates again that the three sets of P positions are structurally not very different from each other. Incidentally, the much larger crystal field splitting (arising from deviations from T_d symmetry mentioned above) in spodiosite as compared to the apatites is also reflected in the large distortion of the PO_4 tetrahedra found from x-ray diffraction studies of Ca_2PO_4Cl (13).

At temperatures near 200°C, we have found that monoclinic $Ca_5(PO_4)_3Cl$ undergoes a reversible transition to a hexagonal form and that the x-ray diffraction patterns of the high-temperature form are consistent with the hexagonal space group $P6_3/m$ and an apatite structure. Young and Elliott (1) have suggested that the lower symmetry of chlorapatite compared to fluorapatite arises primarily from the positions of the halide ions. They indicated that the four Cl^- ions per unit monoclinic cell could lie on the fourfold (e) positions (with $x = 0$ and $y = \frac{1}{4}$ and the origin on the twofold screw axis) $00z$; $0, \frac{1}{2}z$; $0, 0, \frac{1}{2}+z$; $0, \frac{1}{2}-z$ of the $P2_1/b$ space group. From considerations of ionic size and typical Ca-Cl bond distances they further suggest a possible value of 0.413 for the z parameter. The effect of moving the Cl^- ions away from positions halfway between the mirror planes of the apatite structure ($z = 0, \frac{1}{2}$) is to lower the symmetry to $P2_1/b$ and to replace the mirror planes by b glide planes. These proposed geometrical features of the monoclinic structure are illustrated in Fig. 10b. Considering only the Cl^- ions, the observed monoclinic-to-hexagonal transition can occur in two ways. Above the transition temperature the Cl^- ions may be shifted to mean positions at $z = 0$ and $\frac{1}{2}$, thus raising the symmetry to hexagonal. These shifts would be accompanied of course by corresponding small displacements of the other atoms to positions consistent with the hexagonal space group. On the other hand, the higher symmetry above the transition temperature can be achieved by a statistical disordering, within each column of Cl^- ions, of the sign of the z parameter. We have no experimental evidence as to which mechanism operates in the reversible transition at about 200°C. We do, however, have evidence that the hexagonal off-stoichiometric chlorapatite which results from the loss of $CaCl_2$ when $Ca_5(PO_4)_3Cl$ is heated in vacuum is a disordered phase. We have measured the fluorescence spectrum of MnO_4^{-3} ions in this hexagonal phase, and find that at 6°K the three closely spaced lines are still observed but much broadened when compared to those in the monoclinic form. At 77°K only one broad line was observed. We may conclude therefore that there exist small coherent regions (containing a small number of unit cells) with the monoclinic structure having the three inequivalent P sites. Between neighboring regions, however, there is no structural coherence. If the structurally coherent regions are small enough, the symmetry would appear to be hexagonal as far as the birefringence or x-ray diffraction effects are concerned. The line broadening may be due to lattice strains introduced by the disordering. This type of disordering as well as the stabilization of the hexagonal structure by Cl vacancies can be made plausible when we consider again the suggested Cl^- ion positions. In the monoclinic form the Cl-Cl distance along a column is given by $c_0/2 = 3.39$Å. Keeping any one Cl^- ion fixed and changing the sign of the z parameter of a neighboring Cl in the chain would put the two Cl ions a distance $c_0(2z-\frac{1}{2})$Å apart. Taking $z = 0.413$, we get a value of 2.20Å, a distance considerably smaller than twice the ionic radius of Cl^-, 3.62Å. Complete statistical disordering in the Cl^- ion positions does not therefore seem reasonable from size considerations. Such a shift in a Cl^- ion position could, however, take place adjacent to a Cl^- vacancy. In fact, a Cl^- vacancy would constitute locally an effective positive charge and would tend to attract a neighboring Cl^- ion. We might imagine therefore, that the presence of Cl^- vacancies destroys the structural coherence between neighboring coherent regions. A schematic diagram of such a possible effect of vacancies on the Cl^- ion positions in a Cl column is shown in Fig. 11 (a) and (b). The coherent regions

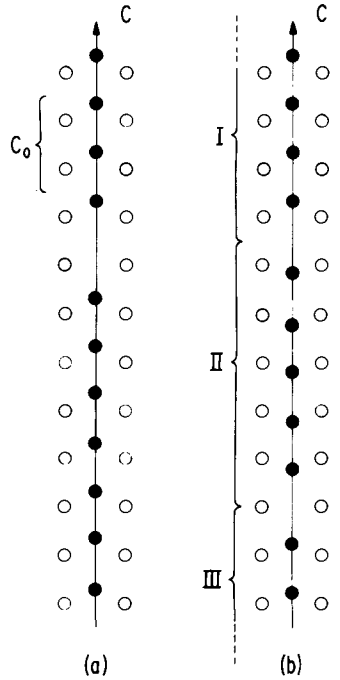

Fig. 11. Schematic representation of the possible disorder in the Cl^- positions produced by a vacancy. The open circles represent Ca^{2+} ions and the closed circles are Cl^- ions. In (a) the monoclinic arrangement of Cl^- ions is shown together with one vacancy. In (b) the movement of the Cl^- ions in region II has produced small structurally coherent regions marked by the brackets.

along the c-axis are bracketed. The structure shown in (b) is obtained by a change in the sign of the z parameter of the Cl^- ions in region II. This role of vacancies in $Ca_5(PO_4)_3Cl$ bears a certain resemblance to the role of F^- ion impurities in promoting one-dimensional disorder in the orientation of OH groups in hydroxyapatite (14).

The role of small concentrations of F^- ion impurity in stabilizing the monoclinic form of chlorapatite is uncertain. It may only be that the mixed fluor- chlorapatite crystals are more stoichiometric. On the other hand the F^- ions, presumably residing in the center of the Ca^{2+} triangles at $z = \frac{1}{4}$ and $\frac{3}{4}$, would provide a fixed negative charge in the halide column. If effectively positively charged vacancies lower the transition temperature and finally stabilize the hexagonal form by providing space for the nearby Cl^- ions to move, then any fixed negative charge in the halide column might have the opposite effect. At this time it seems fruitless to try to speculate further on this point. At a sufficiently high F content, the fixed F^- ions at positions consistent with the hexagonal space group would lead to the hexagonal apatite structure. This we have observed to occur at an atomic ratio of $F/(F + Cl)$ somewhere between 0.16 and 0.36.

The marked twinning observed in crystals of $Ca_5(PO_4)_3Cl$ is also understandable. In the high-temperature hexagonal phase there are three equivalent directions, 120° apart in the plane perpendicular to the c-axis. As the crystal cools through the transition temperature any one of these directions can give rise to the doubled axis of the monoclinic structure. A nucleus of the monoclinic cell once formed with a particular orientation will tend to grow with this orientation until it meets a twin with another orientation. Hence, the formation of the highly twinned crystals and the change in the twinning pattern with each temperature cycle through the transition point can be understood.

Acknowledgments

The author would like to thank A. M. LaTorre for his technical assistance, Dr. W. Roth for his help with the x-ray work, and Dr. P. D. Johnson for taking the absorption data in the vacuum ultraviolet.

Emission Spectra of Impurity Activated (Zn,Cd) (S,Se,Te) Phosphors

III. Self-Activated Phosphors

W. Lehmann

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

ABSTRACT

The blue SA-emission of self-activated ZnS phosphors, due to the sole incorporation of a donor impurity, shifts monotonically toward red if Zn is gradually replaced by Cd. In contrast, gradual replacement of S in ZnS by Se causes little or no shift but replacement of the blue band of ZnS by an orange band in ZnSe. Again, the latter shifts monotonically into the infrared if Zn is replaced by Cd but is replaced by another band, also in the infrared, if Se is replaced by Te. The dependences are demonstrated in recombination term schemes assuming predominantly ionic crystal bonding and validity of the Schön-Klasens model of luminescence.

Emission spectra due to copper and silver, respectively, in (Zn,Cd) (S,Se,Te) phosphors as functions of the composition of the binary or ternary host material were reported in two earlier papers (1, 2). This present paper deals with a similar investigation on self-activated phosphors whose emission is due to the incorporation of a donor impurity (*e.g.*, Cl or Al). The ordinarily observed emission of self-activated ZnS consists of a single, although rather broad, band (SA-emission band) in the blue region of the visible spectrum and is frequently described in the literature (3-12). Relatively little is published on the SA-emission of (Zn,Cd)S (3, 13) and of Zn(S,Se) (3, 14), and practically nothing of the other II-VI compounds.

Our investigations were limited to powder phosphors prepared, excited (by ultraviolet radiation at 77°K), and measured as described in ref. (1). The evaluation of the measured emission spectra was the most problematic part of the investigation since the blue SA-emission band in ZnS, and the corresponding band in the other II-VI compounds, is only one of several which can be observed, especially at low tem-

peratures. The additional emission bands are not necessarily due to contaminations of the materials with undesired impurities, *e.g.*, copper, but some are probably due to native lattice defects with or without participation of the added donor impurity. Particularly troublesome were the following additional emission bands:

(*a*) A very broad and featureless emission extending from the blue over the whole visible range into the infrared, and with a peak position in the neighborhood of 2.0 ev appears in ZnS prepared with Ga or In. This emission sometimes dominates so much (especially in case of indium) that no other emission can be observed. Examples are shown in Fig. 1. It is probably related to an essentially similar emission reported by Apple and Williams (15) in ZnS:Cu and ZnS:Ag containing Ga or In. Its intensity decreases fairly rapidly with gradual replacement of ZnS by CdS and somewhat slower if ZnS is replaced by ZnSe.

(*b*) A band of moderate width appears in phosphors containing Al, Ga, or In (but ordinarily not in phosphors made with Cl, Br, or I) at about 0.3 ev higher quantum energy than the SA-emission. Its peak position in ZnS is about 2.95 ev (λ = 420 nm, violet). Details on this emission will be described in a separate publication. Examples are shown in Fig. 1.

(*c*) The SAL-emission (16) which is observed at about 0.6 ev higher quantum energy than the SA-emission. Its peak position is about 3.2 ev (λ = 397 nm, near-ultraviolet).

(*d*) Near-edge emission (at about 3.6 ev in ZnS) of a more or less complex spectral distribution appears in many self-activated phosphors. It is usually readily distinguished from the other emission bands.

This rather complex situation observed already in binary II-VI compounds (*e.g.*, ZnS or ZnSe) becomes still more complicated within some ternary mixtures [*e.g.*, Zn(S,Se)] where new emission bands may appear as a function of the host crystal composition. Close overlap of the generally rather broad and structureless bands is then unavoidable so that a clear identification frequently cannot be made.

All concentrations in this paper are given in terms of mole per cent based on 100% of the combined host material. The indicated impurity concentrations are those added before firing and not necessarily identical (especially in cases of the volatile halides) with the concentrations retained in the phosphors after firing.

Zinc Sulfide

The peak position and the width of the blue emission band (SA-emission) of self-activated ZnS phosphors are slightly uncertain and vary from sample to sample within small limits [similar to what is observed in cases of activation by copper (1) and by silver (2)]. Typical widths (measured at 50% of peak) are about 0.50 ev at room temperature and 0.30-0.35 ev at 77°K. A dependence of the peak position on the crystal structure (cubic or hexagonal) and on the donor impurity used seems to exist but is small and almost lost in the general uncertainty. In particular, we are not able to confirm a significant difference between ZnS phosphors prepared either with halides (Cl, Br, or I) or with group III-B elements (Al or Ga) as reported by Prener and Weil (8). The following peak positions were measured within these investigations as averages over many samples, all excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K:

cubic	ZnS: (Cl, Br, or I)	2.61 ev
cubic	ZnS: (Al or Ga)	2.65 ev
hexagonal	ZnS: (Cl, Br, or I)	2.64 ev
hexagonal	ZnS:Al	2.62 ev

The peak position of the blue SA-emission depends to a small but measurable extent on the quantum energy (*i.e.*, on the wavelength) of the exciting ultraviolet radiation, quite in contrast to the luminescence of Cu- or Ag-activated ZnS phosphors where no such dependence was detected. Generally, excitation "across the band gap" (~3.8 ev in ZnS at 77°K) gives a peak position at slightly higher quantum energy than excitation with lower quantum energy. Some actual emission spectra, all measured on the same phosphor sample under different excitation conditions, are shown in Fig. 2.

Hexagonal Zinc-Cadmium Sulfide

The blue emission band of hexagonal ZnS prepared with the aid of a halide (Cl, Br, or I) shifts gradually toward red as Zn is replaced by Cd (3, 13) without significant change in band width and shape. Examples are shown in Fig. 3. In our work, the SA-emission dominated over all others only in the spectra of (Zn,Cd)S:halide phosphors containing low Cd concentrations but it could be followed up to 100% CdS

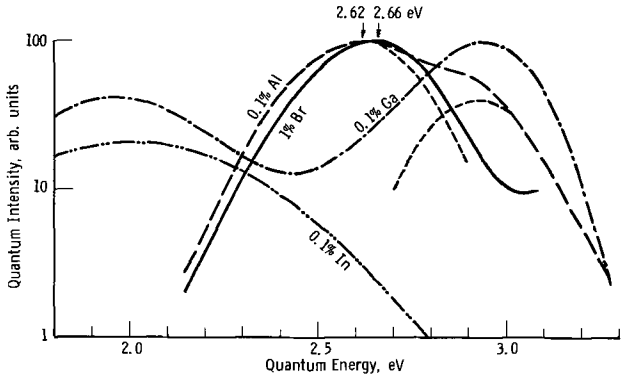

Fig. 1. Emission spectra of four different samples of hexagonal, self-activated ZnS excited by ultraviolet of 3.95 ev (λ = 313 nm) at 77°K.

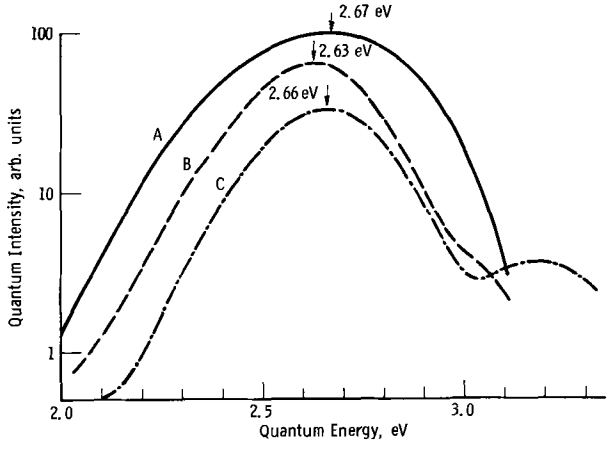

Fig. 2. Emission spectra measured on a single sample of hexagonal, self-activated ZnS:Br(1%). A, excited by 3.40 ev (λ = 365 nm) at room temperature; B, excited by 3.40 ev (λ = 365 nm) at 77°K; C, excited by 3.95 ev (λ = 313 nm) at 77°K.

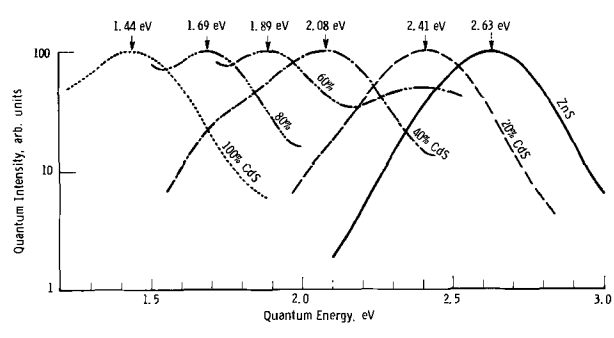

Fig. 3. Emission spectra of hexagonal (Zn,Cd)S:Br(1%) excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

where the peak position is near 1.45 ev (λ = 855 nm).

Emission spectra of self-activated (Zn,Cd)S prepared with Ga or In differ somewhat from those made with the help of a halide. The peak position of the SA-band is at roughly 0.05-0.08 ev lower quantum energy (in contrast to ZnS phosphors where this difference is smaller).

The II-VI compounds can approximately be considered to be ionic compounds where the conduction band belongs to the cation (Zn or Cd) and the valence band to the anion (S, Se, or Te). Hence, a variation of the Zn/Cd ratio in (Zn,Cd)S phosphors means mainly a variation of the conduction band while, in a first approximation, the valence band remains unchanged. This approach is shown in Fig. 4 where the edge of the valence band is represented as a horizontal straight line while the edge of the conduction band is curved according to the dependence of the band gap on the Zn/Cd ratio.

The electron transition responsible for the emissions of copper or silver activated ZnS phosphors is generally ascribed to be from the edge (or from a level very near to the edge) of the conduction band into empty acceptor levels somewhat above the top of the valence band (Schön-Klasens model). The nature of the electron transition responsible for the SA-emission of self-activated phosphors is not as well known but the Schön-Klasens model may, somewhat empirically, be applied here also. The result is shown in Fig. 4 where the quantum energies corresponding to the peak positions of the measured emission bands are plotted downward from the curved edge of the conduction band. The so-determined term positions are connected by two separate curves. Curve A corresponds to the SA-emission of two separate phosphor series, (Zn,Cd)S:Cl and (Zn,Cd)S:Br, both of which gave practically identical results. Curve B corresponds to the SA-emission of a series of (Zn, Cd)S:Ga phosphors; it is obtained so far only with gallium. Attempts to replace Ga by Al failed (probably because of the too high reactivity of Al with traces of oxygen), and indium did not produce well-developed SA-emission bands. Curve B is very closely a horizontal straight line, but Curve A deviates somewhat from the horizontal in the direction of the variation of the conduction band edge although to a far lesser degree than the latter.

Cubic Zinc Sulfo-Selenide

The blue emission band of self-activated ZnS is reported to be gradually replaced by a green band if the sulfur is gradually replaced by selenium (3, 14). This is essentially confirmed in our measurements on cubic Zn(S,Se):halide phosphors. All three halides Cl, Br, and I give similar results. Some emission spectra of self-activated Zn(S,Se):Br phosphors are shown in Fig. 5 and 6. It is seen that replacement of only 1% of sulfur by selenium causes the green band (peak ~2.3 ev) to appear, and both bands, the green and the blue, are of comparable intensity at about 5% of ZnSe (Fig. 5). The bands are rather broad so that their peak positions can only be estimated because of strong overlap. Both bands shift slowly toward lower quantum energies as more ZnS is replaced by ZnSe (Fig. 6). Simultaneously, the "blue" band decreases in intensity until the SA-emission of ZnSe consists only of the "green" band which by then is shifted to orange (peak ~2.0 ev). Hence, the SA-emission of ZnSe:halide consists only of one band just as that of ZnS although there is no direct connection between the bands.

A variation of the host crystal composition from ZnS to ZnSe means a variation of the valence band, while the conduction band remains constant, if the II-VI compounds are considered to be ionic compounds.The Schön-Klasens model of electron recombination can be assumed here also. Hence, the quantum energies corresponding to the peaks of the measured emission bands are plotted downward from the horizontal edge of the conduction band. The points so obtained in Fig. 7 are connected by two separate curves corresponding to the two SA-bands of Zn(S, Se):Br. The curves deviate only slightly from the horizontal, much less than the edge of the valence band varies over the same range. A discontinuity near 100% of ZnS [as observed in cases of activation by copper (1) and by silver (2)] cannot be detected.

Cubic Zinc Seleno-Telluride

Emission spectra of self-activated Zn(Se,Te) phosphors do not seem to be reported elsewhere. Our work on this system was confined to phosphors prepared

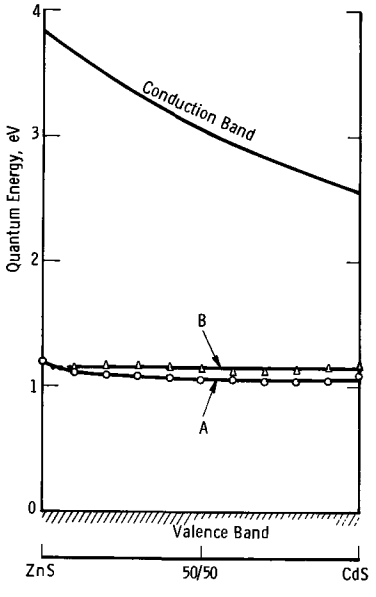

Fig. 4. Recombination term scheme of hexagonal, self-activated (Zn,Cd)S at 77°K. Curve A, 1% Cl or Br added. Curve B, 0.1% Ga added before friing.

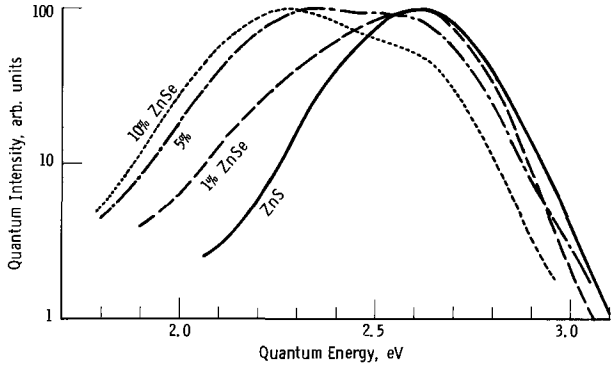

Fig. 5. Emission spectra of cubic, self-activated Zn(S,Se):Br excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

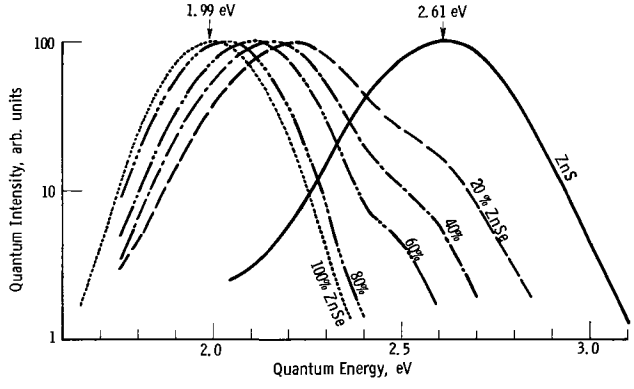

Fig. 6. Emission spectra of cubic, self-activated Zn(S,Se):Br excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

with the addition of 1% of Br (added as $ZnBr_2$) and fired at 800°C.

The orange emission band of self-activated ZnSe:Br (peak ~2.0 ev) can be followed up to roughly 10% of ZnTe after which it disappears. Instead of it, another emission band builds up at about 1.58 ev (Fig. 8). It is strong for a ZnTe concentration as low as 1%, can be followed up to roughly 20 to 30% of ZnTe and, apparently, shows up again in 100% of ZnTe at 1.51 ev (Fig. 9). The writer considers this latter emission band to be the analog of similar bands observed in cases of activation by Cu (1.7-1.75 ev) (1) and by Ag (~1.8 ev) (2).

A third emission band appears at about 1.29 ev in Zn(Se,Te):Br containing 10% of ZnTe (Fig. 8). In striking contrast to all others, its position is not nearly constant but shifts steadily with increasing ZnTe concentration toward higher quantum energy until it reaches 1.89 ev in ZnTe:Br (Fig. 9). The band may be identical with an emission in ZnTe reported by Dietz, Thomas, and Hopfield (17). It does not seem to be in any way related to the SA-emission bands of these phosphors but details are still unknown, and it is included in Fig. 8-10 only out of curiosity.

A fourth emission band is observed in Zn(Se,Te) phosphors containing high ZnTe concentrations. It appears in appreciable intensity in the neighborhood of 1 ev[1] (Fig. 9). It seems to be independent of any particular impurity and not related to the SA-emission, but details are still unknown.

[1] The spectral limit of the phototube used in these investigations.

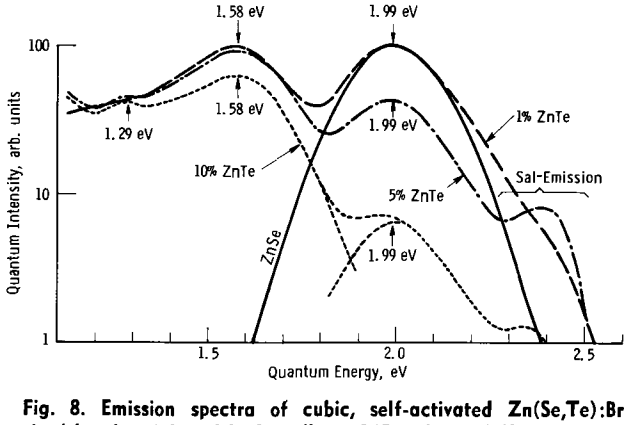

Fig. 8. Emission spectra of cubic, self-activated Zn(Se,Te):Br excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

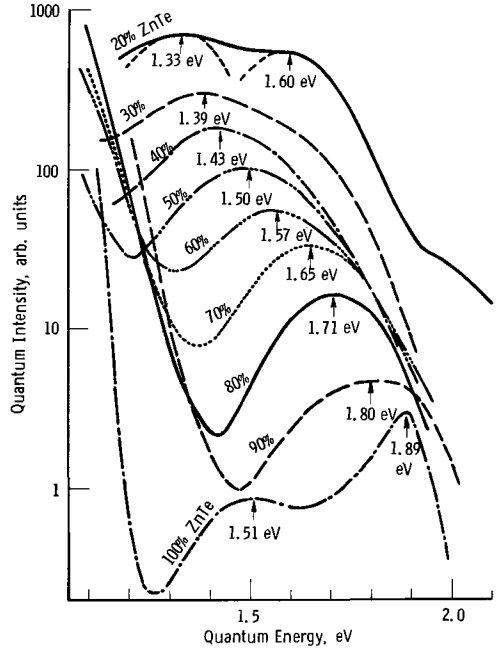

Fig. 9. Emission spectra of cubic, self-activated Zn(Se,Te):Br excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

Assumption of ionic crystal binding and of the Schön-Klasens model of luminescence permits one to plot the quantum energies corresponding to the peaks of the emission bands downward from the horizontal edge of the conduction band to determine the energy position of the center responsible for the emission as a function of the Se/Te ratio. This gives the term scheme of Fig. 10 where the obtained points are connected by three curves. Curves A and B correspond to the SA-emission of Zn(Se,Te) phosphors and resemble very similar curves obtained in the case of Zn(S,Se) (Fig. 7). Both curves are very nearly horizontal straight lines. Curve C, corresponding to the unknown emission band of variable position, is also very nearly straight but not horizontal. This emission band may possibly be a close superposition of several narrower sub-bands.[2]

Zinc-Cadmium Selenides

The SA-emission of cubic ZnSe consists essentially, or only, of a single band with the peak at about 2.0

[2] Suggested by the referent.

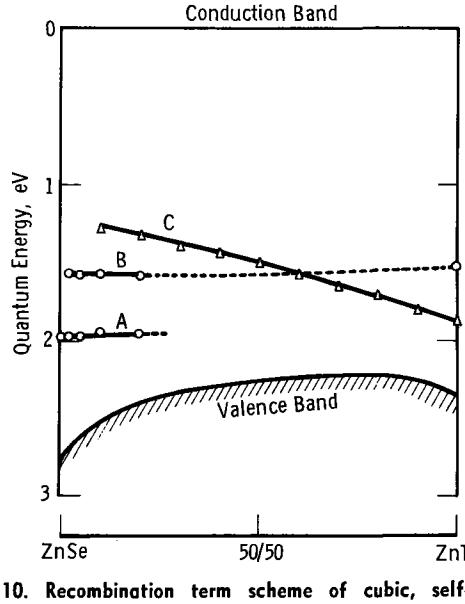

Fig. 10. Recombination term scheme of cubic, self-activated Zn(Se,Te):Br at 77°K.

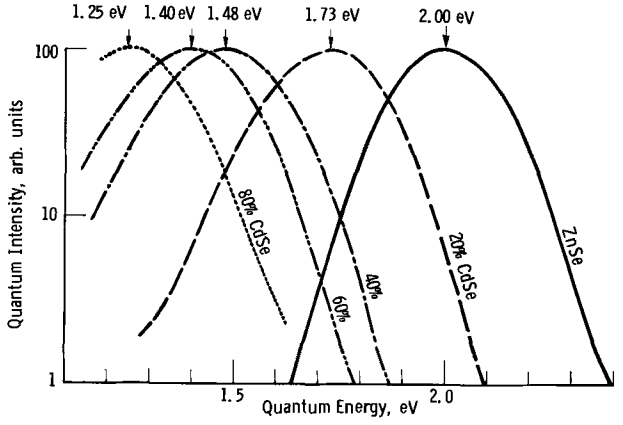

Fig. 11. Emission spectra of self-activated (Zn,Cd)Se:Br excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

ev. Gradual replacement of ZnSe by CdSe causes a gradual shift of the emission band toward lower quantum energies (*i.e.*, into the infrared) without any significant change of band width and shape, all analogous to what is observed in corresponding sulfide phosphors. Some measured spectra are shown in Fig. 11.[3] If the Schön-Klasens model of luminescence is used and the quantum energies corresponding to the peaks of the emission bands are plotted downward from the curved edge of the conduction band, one obtains the recombination term scheme of Fig. 12 where all points scatter closely about a curve approaching a horizontal straight line. A slight curvature near 100% ZnSe seems to be present (analogous to curve A, Fig. 4, for corresponding sulfide phosphors) but is rather weak. The slight discontinuity near 40% of CdSe is reproducible and seems to be correlated to the phase transition from cubic to hexagonal. Extrapolation of the curve toward 100% CdSe indicates a probable peak position of the SA-emission of self-activated CdSe:Br, at 77°K, near 1.07 ev (λ = 1160 nm).

Discussion

No emission spectra of Zn(S,Se) containing Al, Ga, or In nor any spectrum of Cd(S,Se) phosphors are presented here. These phosphors were made but their emission spectra were very confusing and did not permit clear distinction between the various bands and their dependences on the S/Se ratio. Obviously, there is too much overlap of too many and too broad bands. Nevertheless, the dependence of the SA-emission on the host crystal composition can fairly unambiguously be deduced even from those spectra which are given in the figures of this paper. The main observations can be summarized as follows:

The SA-emission of self-activated binary compounds ZnS, ZnSe, CdS, and (probably) CdSe containing halide ions as donors consists essentially of one rather broad band. Gradual replacement of the zinc by cadmium either in the sulfides or in the selenides causes a steady shift of the emission band toward lower quantum energy. By contrast, gradual replacement of sulfur in ZnS by Se causes little shift of the emission but gradual replacement of the one emission band by another. The same behavior is expected also within Cd(S,Se):halide phosphors. The situation within the Zn(Se,Te) system is somewhat confused by an emission band with the peculiar shift toward higher quantum energy with increasing ZnTe-concentration. Although this band is, so far, observed only in self-activated Zn(Se,Te), chances are that it is not related to the SA-emission. If its presence is neglected, the emission spectrum of self-activated Zn(Se,Te):halide follows the general pattern, *i.e.*, the single SA-band in ZnSe is gradually replaced by another one in ZnTe.

This behavior of the SA-emission in the entire (Zn,Cd)(S,Se,Te) system resembles very much what is observed in the case of silver activation, *i.e.*, the SA-emission in the whole system consists of three bands. One band requires the presence of sulfur, another the presence of selenium, and the third that of tellurium. It is admittedly tempting to assume that each one of the three bands belongs to a particular recombination center which, besides others, contains either one sulfur or one selenium or one tellurium ion, but arguments presented in the case of silver activation (2) speak against this simple assumption.

[3] The emission spectrum of self-activated, 100% CdSe could not be measured because of instrumental limitations.

Peroxide Etching of Germanium

W. Primak and R. Kampwirth

Argonne National Laboratory, Argonne, Illinois

and Y. Dayal[1]

Argonne National Laboratory, Argonne, Illinois, and Illinois Institute of Technology, Chicago, Illinois

ABSTRACT

Etching with 3% hydrogen peroxide is useful for removing fractional micron layers of germanium. The etching rate is insensitive to concentration, but it is sensitive to pH, showing a minimum of about 0.021 μ/min at pH 4, a region recommended for controlled etching experiments; to temperature, showing a change of a factor 2 from 20° to 30°C; and to some foreign ions, *e.g.*, about twice as great for sulfate ions present in solutions as when phosphate ions are present. The etching rate is different for different orientations; among those tested, slowest for the [111], fastest for [201] in acid solution and [100] in alkaline solution. Mechanically polished surfaces possess an enhanced etching rate. The enhancement is removed by heavy ion bombardment, but not by light ion bombardment. The etching rate of normal germanium surfaces is not affected appreciably by heavy ion bombardment, but the etch pit density is greatly increased. Photomicrographs of the etched surfaces are given.

Etching by 3% aqueous hydrogen peroxide was used by Bredov and co-workers (1) to remove thin (fractional micron) layers of germanium for the purpose of determining the depth of penetration of alkali metal ions. The method was adopted by Davies, McIntyre, and Sims (2) who repeated these experiments and reported a variability in the peroxide etching rate. They reported a large increase in etching rate with increase in peroxide concentration and a decrease in etching rate on bombardment with cesium ions. We adopted the peroxide etching technique to determine the depth of the electrical conductivity change produced by ion bombardment. Since we could not determine weight losses because of attached metal leads, it was necessary to know the etching rate of normal and ion-bombarded germanium. The present investigation was begun when an irregularity in our results indicated a considerable alteration in etching rate during a set of successive etchings.

There are detailed reports of investigations of the etching rates of peroxide solutions containing hydrofluoric acid (3), but these solutions etch far too rapidly to be used for removing fractional micron layers. Camp (3) reports one experiment in which ". . . it was found that a [111] surface is etched by 1 part 30% H_2O_2 in 5 parts water at 26°C at a rate of 0.0275 μ/min."

Procedure

Most of the germanium used in these studies was purchased under the specification n-type, single crystal, lineage free, highest resistivity, nearly intrinsic, high purity, <111>, from the Eagle-Pitcher Company. One piece used for [100] orientation studies was a Kyropoulos grown crystal of very high purity. Plates of desired orientation were cut with a diamond saw. They were then lapped successively with 19 and 9.5μ alumina abrasive. Final surface treatments used for various studies were (*a*) CP4 etched, (*b*) mechanically polished with Linde A on silk cloth followed by Linde A on Microcloth followed by a 1-min etching in hydrogen peroxide, (c) etch polished with a sodium hypochlorite solution on Pellan Pan-W cloth (4) followed by a brief (1-10 sec) etching with CP4.

Irradiations were performed in a Cockcroft-Walton machine operated at energies from 20 to 140 kev. The ions used for the various studies were H^+, D^+, He^+, Ne^+, and A^+. For all the studies described here, one of two masks were used. The first shielded half the specimen and provided a sharp boundary. The second had six small rectangular openings which could be covered or uncovered individually or successively to prepare as many differently irradiated areas on the specimen. The specimens were irradiated in a clean mercury pumped (liquid nitrogen trapped) chamber maintained below 10^{-6} Torr.

The original etching studies were performed with reagent grade 3% aqueous hydrogen peroxide from several different manufacturers. Later studies were performed with 30% aqueous hydrogen peroxide diluted with distilled water to the desired concentration.

Hydrogen peroxide concentrations were determined by permanganate titration after addition of sulfuric acid as described in the U. S. Pharmacopoeia XII (5).

Germanium content of the etching solutions both before and after etching was determined as described by Hillebrant and Hoste (6) by forming the colored complex ion with phenylfluorone (2, 6, 7-trihydroxy-9-phenyl-isoxanthene-3-one D in 0.5*N* hydrochloric acid). The complex compound was extracted with benzyl alcohol, diluted to volume and measured spectrophotometrically at 505 mμ. The determination was made on an aliquot in which the peroxide was destroyed by hydroxylamine.

The pH was determined with a glass electrode and the PHM4C instrument made by Radiometer (Copenhagen).

Peroxide etching was performed in vessels 3-6 in. in diameter with 100-200 ml of solution. Specimens were grasped by the edges with a stainless steel forceps and held in a horizontal plane while the solution was stirred by means of a magnetic stirrer. After the desired etching time elapsed, the specimen was rinsed with distilled water, washed in distilled water for 2 min in a vessel like the one used for etching, and then blown dry with clean air or nitrogen. Drying in a desiccator before weighing was found to be unnecessary. The specimens were weighed on a Mettler microbalance to within 10 μg. The etching rates were computed from the weight changes and the area (calculated from the dimensions determined with a comparator), known density, measured weight, and etching times measured with a stop watch.

The differential etching rate for irradiated and unirradiated areas was determined by measuring the

[1] Ph.D. thesis student at Argonne National Laboratory from Illinois Institute of Technology; present address, General Electric Company, Atomic Products Division, San Jose, California. Part of the material presented here is taken from a dissertation submitted by Y. Dayal in partial fulfillment of Ph.D. requirements.

height of the step formed at the boundary of the irradiated area with a Zeiss interference microscope.

Results

Effect of concentration, pH, temperature, orientation.—When evidence of a variation in etching rate appeared during the course of a series of etchings of a set of specimens, the variation was at first attributed to peroxide concentration because hydrogen peroxide is considered a labile chemical, and the age of our reagents was unknown. Accordingly, the etching rates were determined for 2% and 4% peroxide. The two etching rates were found to be about the same.

The *p*H of the hydrogen peroxide from our stockrooms was then determined and was found to vary widely. According to the analyses given on the labels, sulfuric acid is an additive, presumably to control decomposition and its concentration employed by different manufacturers differs considerably. Accordingly, the effect of *p*H on the etching rate was determined, first by using 3% peroxide from different sources, then diluted 30% peroxide made up variously with sulfuric acid, saturated with carbon dioxide, and buffered with KH_2PO_4, NaOH, and H_3PO_4. Results for plates whose faces were perpendicular to the direction stated are given in Fig. 1.

It is seen that the etching rate is greatly dependent on *p*H and possesses a minimum in the neighborhood of *p*H 4.5. For the results given in Fig. 1, no effort was made to control H_2O_2 concentrations closely. Further experiments at controlled *p*H confirmed the etching rate to be independent of peroxide concentration at these concentrations. The etching rate for CO_2 saturated solutions was found to be the same at 1.8% and 6% H_2O_2 used to etch the [111] face. For KH_2PO_4-NaOH solutions buffered at *p*H 6, the etching rates remained within ±7% over the range of peroxide concentrations 1-4.8% for the four orientations given in Fig. 1. The variations found here were typical of those found for the conditioning of a clean (CP4 etched) surface; an abnormally high (by 7-15%) etching rate gradually falls during half an hour of etching to the stable value reported in Fig. 1.

To confirm that the weight losses are a correct measure of the etching rate, germanium assays were made of several peroxide baths after etching. The assays agreed with the weight losses to within 5% when the not insignificant germanium content of the reagents (apparently arising largely by leaching germanium from the glass reagent bottles and chemical glassware) was corrected for. This proves that in the

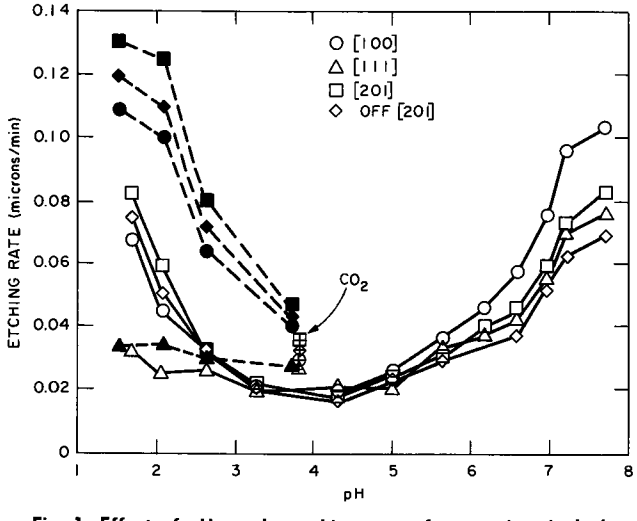

Fig. 1. Effect of *p*H on the etching rate of germanium in hydrogen peroxide, concentrations between 1.5 and 3%. Unshaded points are for H_3PO_4-KH_2PO_4-NaOH buffers, shaded points are for sulfuric acid addition to peroxide, and the crossed points are for CO_2 saturated solutions. Etching temperature is 24°C.

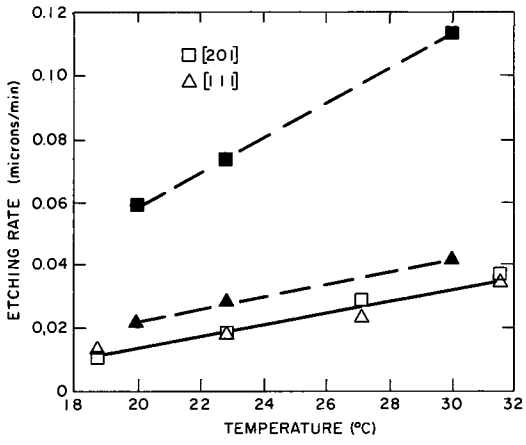

Fig. 2. Effect of temperature on the etching rate of germanium with peroxide (~3%) at *p*H 3.8; open points for phosphate buffered, shaded points for sulfuric acid addition.

etching the germanium goes into solution in the etching bath.

The temperature dependence was determined over a range of temperatures near room temperature; the results are shown in Fig. 2. It is seen that there is an increase of about a factor of 2 in etching rate for a 10°C temperature rise.

Effects of ion bombardment and mechanical polishing.—The original experiments for determining the effect of ion bombardment on the etching rate were performed with mechanically polished plates because it was thought necessary to have optically flat surfaces for the interferometric observations. These experiments were performed with H^+, Ne^+, and A^+ in the 100 kev region, as described above, with half the specimen masked. No effect was seen with H^+. From the fact that a step of 1/20 fringe height is easily visible, the etching rates must have been the same within a few per cent. With Ne^+ 140 kev, and A^+ 100 kev, definite steps were seen. Some examples of these steps taken from our collection of photographs are shown in Fig. 3. In all cases the bombarded area etched more slowly. The etching seems to progress in a manner described fully by a number of writers (7) for the etching of polished glass surfaces; namely, that as the etching progresses, the character of the lapping is revealed and scratches become more prominent. In these specimens the etching rate of the irradiated areas was the slower. The behavior of a typical case is shown in Fig. 4. The maximum differences in etching rates calculated from such curves was 20-30%. A direct comparison of the etching rates of the mechanically polished and CP4 etched surfaces prior to bombardment was made before the factors affecting the etching rate were known. The average values for several determinations were 0.024 μ/min for CP4 etched surfaces and 0.030 μ/min for mechanically polished surfaces. While these values are not reliable, they do afford some direct evidence that on unbombarded surfaces the etching rate is faster for the mechanically polished than for CP4 etched specimens.

When these experiments were repeated with chemically polished surfaces which had been lightly etched with CP4, again no effect was seen for H^+ or He^+ bombarded surfaces. For the Ne^+ bombarded surface an increase in etch pit density was found. Two examples are shown in Fig. 5. Although the etching rate for the bombarded area appears to be about the same as for the unbombarded area, there is a marked variation in etching rate at the boundary of the bombarded area. Passing from the unbombarded area, there is a sharp ridge of about the depth of the major radiation effect, and beyond it a broader shallow depression.

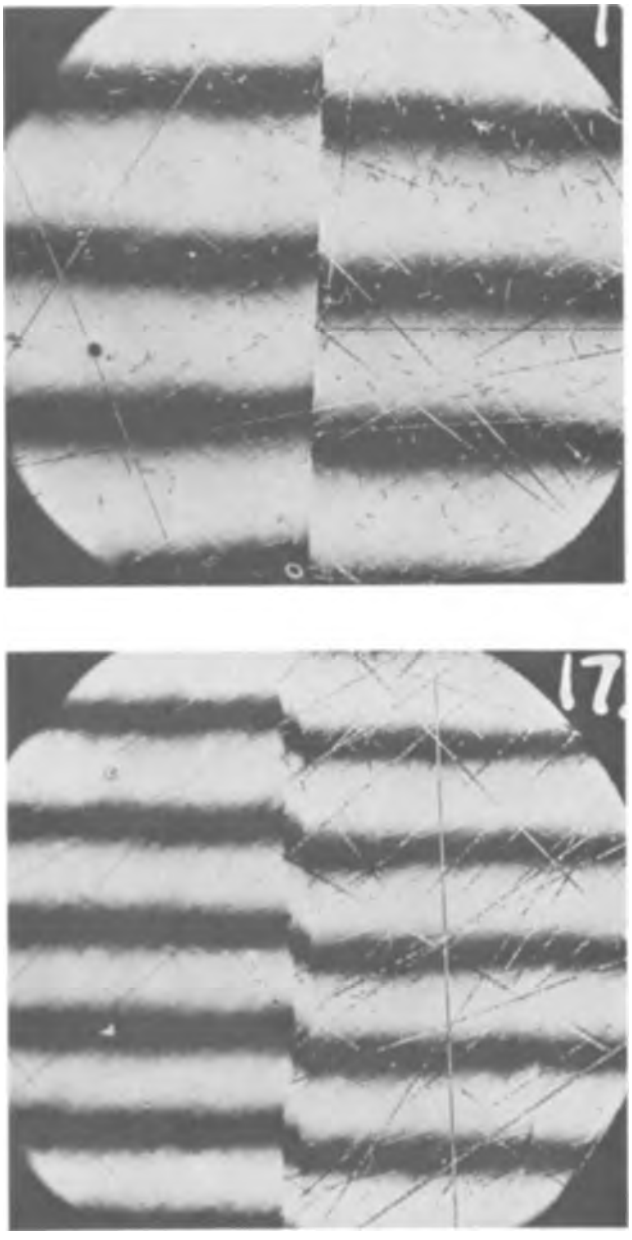

Fig. 3. Appearance of a [111] mechanically polished surface, left side bombarded and the whole plate etched. The contour interval indicated by the fringes is 0.27μ. A, 100 kev A^+ bombardment 300 $\mu C/cm^2$ after 12 min etching. The fringes are spaced at 157μ across the specimen; B, 140 kev Ne^+ bombardment 300 $\mu C/cm^2$ after 10 min of etching. The fringes are spaced 106μ across the specimen. It is not known whether the complex boundary was caused by the ion beam shifting or was the depletion layer effect described in the Discussion. (A, top; B, bottom)

Discussion

The large pH effect found for the peroxide etching rate of germanium indicates the etching is largely controlled by the solubility of the amphoteric oxide surface layer.

The ridge which is formed at the boundary of the bombarded layer, we suppose, is evidence of the effect of the depletion layer on the electrochemical reaction involved in the oxidation of the germanium. It provides evidence for one of the possible mechanisms for the oxidation; namely: that the oxidation occurs by electrons passing through the germanium dioxide film from the solution to the germanium. The unbombarded germanium is n-type. The bombarded area is strongly p-type. Thus in the field of the p-n junction, the electrons move toward the bombarded material preventing oxidation at the p-n junction where a

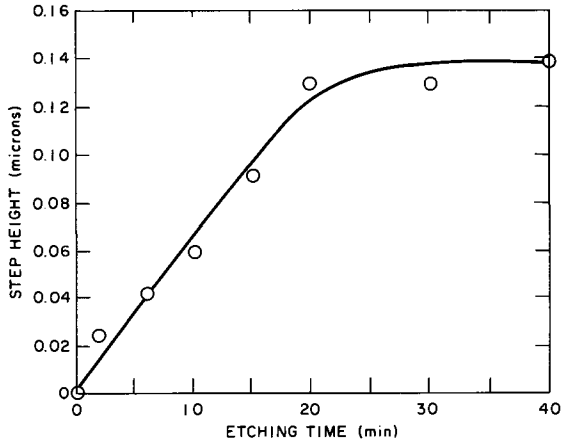

Fig. 4. Development of the step in etching a mechanically polished specimen bombarded with 140 kev Ne^+, 300 $\mu C/cm^2$. The etching rate was about 0.024 μ/min.

ridge develops, and causes an enhanced solution rate just beyond where a valley develops. We suppose these effects do not appear when etching in depth (*i.e.*, at the boundary parallel to the surface) because the p-region here merges very gradually into the n-region below and as the etching proceeds the strongly p-type material is removed before the boundary is approached.

Since the etching rates for bombarded and unbombarded chemically polished surfaces are the same, the slower etching rate found for the bombarded half of the mechanically polished surfaces is attributed to a release of the strain of mechanical polishing in bombardment. This is suggested also by the appearance of the surfaces on etching as described above. This confirms the earlier result that the etching rate of a mechanically polished surface is greater than the

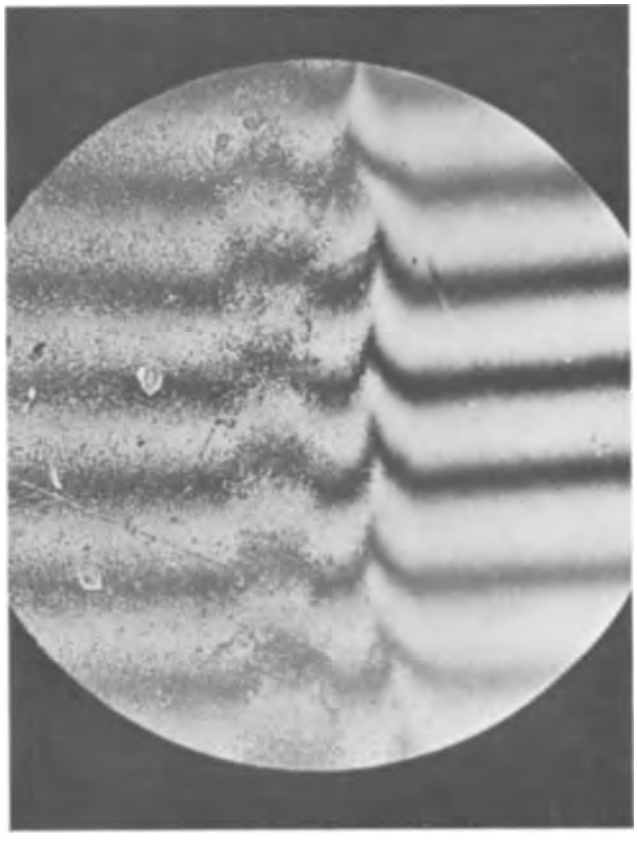

Fig. 5A. Appearance of a [111] surface bombarded with 140 kev ions after 17 min etching. Fringes mark a contour interval of 0.28μ. The fringes are spaced about 40μ along the surface.

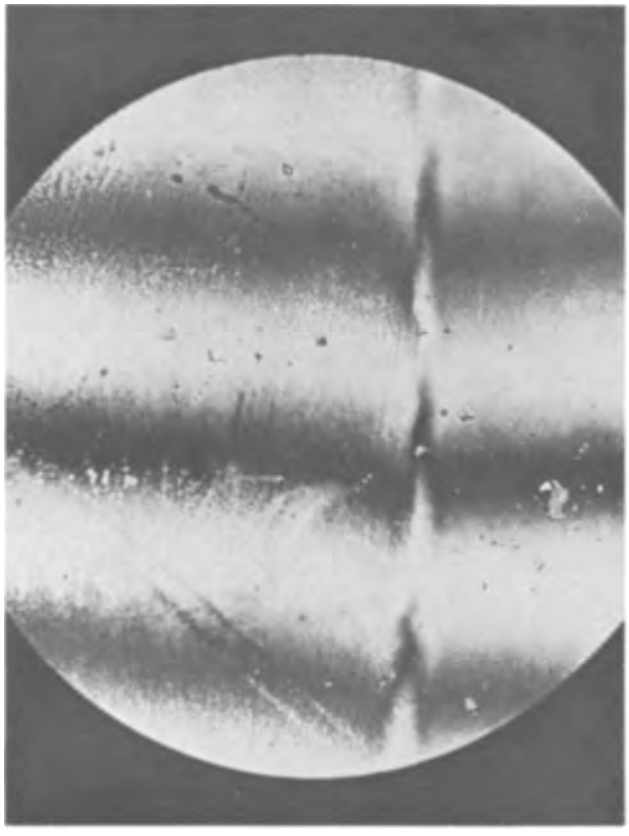

Fig. 5B. Appearance of a [111] surface bombarded with 80 kev Ne^+ ions. The fringes mark a contour interval of 0.28μ and are spaced about 84μ along the surface.

etching rate of a chemically polished surface. The strain of mechanical polishing is released by Ne^+ and A^+ bombardment, but not by the light ions, a point which is of significance in the theory of the radiation damage.

Davies *et al.* (2) report a decrease of a factor of 3 in the etching rate caused by 5 kev Cs^+ ion bombardment. We have not had the opportunity to confirm this result. Since ion bombardment alone did not affect our etching rates and since the Cs would be expected to raise the *p*H, hence increasing the peroxide etching rate, we speculate some other chemical or physical effect may be involved; *e.g.*, scavenging of the peroxide ion by the Cs in the lattice, a gas barrier produced from Cs reacting with water, or the formation of a protective film of greater integrity or with lower diffusion constants than in the absence of Cs.

Recommendations for Etching

For some time CO_2 saturated solutions made from diluted 30% peroxide (Superoxol) were employed in this laboratory. However, in our vessels loss of CO_2 was found to be substantial in 10-min etching periods causing a change from *p*H 3.8 to *p*H 4.2-5.2. The etching solution currently in use is made by taking 175 ml of 3-4% hydrogen peroxide (made by diluting 30% hydrogen peroxide) and 25 ml of 0.2M KH_2PO_4 containing 12 ml/l of 1*N* phosphoric acid. This gives a 2.7-3% H_2O_2 solution of *p*H 3.8. Temperature is controlled to $\pm\frac{1}{2}$°C which insures etching rates constant to a few per cent. Such batches have been used for etching as much as 8 cm^2 for as long as 10 min. Specimens are suspended in the etching solution at mid-depth and the solution is stirred with Teflon-coated magnetic stirring bars at a speed well below that causing splashing or air entrainment.

The Ternary Condensed Phase Diagram of the Ga-As-Te System

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The condensed phase diagram for the Ga-As-Te system has been partially constructed on the basis of data obtained from DTA, electron beam microprobe, and x-ray studies. No regions of extensive solid solubility of Te in GaAs were observed. DTA data indicate that a region of ternary solid solution based on the Ga_2Te_3 structure exists in the Ga_2Te_3 region of the diagram. There is some evidence for a ternary compound in the arsenic rich region.

Interest in the Ga-As-Te system stems mainly from the growing usefulness of Te doped GaAs as a semiconductor for solid-state laser and electroluminescent diode applications. In this paper are presented the results of the first part of a study of the Ga-As-Te system which will include determination of both the liquidus isotherms in the GaAs primary phase field and the solidus isotherms representing the equilibrium

concentrations of Te in crystals which are in equilibrium with liquidus compositions along the liquidus isotherms.

The primary object of this present work is to present the ternary liquidus isotherms in the GaAs primary phase field and to establish whether there are regions in this phase field where there is extensive solid solubility of Te in GaAs.

Most work with III-V-VI systems has been done for the $A^{III}B^{V}$-$A_2^{III}C_3^{VI}$ binary systems (1) where there is particular interest in the $A_2^{III}C_3^{VI}$ compounds, which crystallize in a tetrahedral lattice with built-in vacancies. These compounds might therefore be expected to have extensive solid solubility with the $A^{III}B^{V}$ compounds. In addition to solid solution formation, III-V-VI systems are likely to be complicated by ternary compound formation such as has been suggested by Hahn and Thiele (2) for In_2AsSe and demonstrated for $InAs_3Se_3$ by Luzhnaya *et al.* (3). Liquid immiscibility has been observed in the InSb-InSe system by O'Kane and Stemple (4).

Experimental

Semiconductor grade arsenic and tellurium with purities better than 99.999% were used in this work. Reclaimed gallium with purity better than 99.99% was used, and for many of the runs semiconductor grade GaAs was used instead of the elements. The use of GaAs was necessary when the relative amounts of Ga and As were high in order to prevent explosions resulting from the exothermic reaction of the elements. For several samples in the high arsenic part of the phase diagram, GaAs, As_2Te_3, and As were used as starting materials. As_2Te_3 was prepared from the elements.

Fused silica capsules with a volume of about 13 cc which were about 2/3 filled with melt were used for the differential thermal analysis experiments. Experimental details are very similar to those which have already been described for the study of the Ga-As-Zn ternary (5, 6) and several other systems (7, 8). The precision to which thermal effect temperatures are reported is ±3°C except where otherwise indicated.

X-ray analysis of the DTA (differential thermal analysis) samples was done by standard powder techniques and electron beam microprobe analyses were obtained for several of the samples.

Binary Phase Systems

Ga-As.—Gallium and arsenic form a single congruently melting compound, GaAs, with a reported melting point of 1238°C (9). Thurmond (10) has utilized the solubility measurements of Köster and Thoma (9) and Hall (11), along with an adaptation of the regular solution treatment of Vieland (12) to construct the binary GaAs liquidus curves. The melting point of GaAs was recently measured by this author (6) and a value of 1237° ± 2°C was obtained.

Ga-Te.—Gallium and tellurium form two congruently melting compounds, GaTe and Ga_2Te_3. The melting point of Ga_2Te_3 has been reported as 792° (13) and 790°C (14), and that of GaTe as 835° (13) and 824°C (14). In this work the melting points of Ga_2Te_3 and GaTe were found to be 789° ± 3° and 827° ± 3°C, respectively. Two other tellurides, Ga_3Te_2 and $GaTe_3$, have been suggested on the basis of thermal analysis studies (13). These compounds were reported to decompose below their melting points. A phase corresponding to $GaTe_3$ has been identified in a metallographic study (15), but in the same study Ga_3Te_2 was not identified. A region of liquid immiscibility on the gallium rich side of the binary phase diagram has been reported but not confirmed (13).

A thermal effect which could be attributed to a peritectic formation of Ga_3Te_2 was noted in the work reported here; however, this thermal effect could equally well be attributed to the formation of a two liquid region. X-ray analysis did not reveal Ga_3Te_2 in any of the cooled DTA samples. No compositions which would yield information about $GaTe_3$ were studied.

As-Te.— There is very little information available about the arsenic-tellurium system. Only one compound, As_2Te_3, has been reported (16). The melting point of 362°C is in agreement with that of 362° ± 3°C obtained in this work. Hansen (16) gives a tentative phase diagram based on the work of Pelahon (17) in which As_2Te_3 is assumed to melt congruently and in which a region of liquid immiscibility is shown in the arsenic rich region.

Results

The temperatures at which thermal effects were observed when melts of various compositions were cooled are given in Table I. Most of the experimental data were obtained from samples with over-all compositions on the GaAs-GaTe, GaAs-Ga_2Te_3, GaAs-Te, and GaAs-As_2Te_3 binary cuts of the ternary phase diagram.

In each case T_1 represents the temperature at which the surface of primary crystallization was reached. For those cuts in which a thermal effect has been interpreted below as the temperature at which the cooling mixture reaches a peritectic boundary between two primary phase fields the thermal effect has been referred to as T_2. For those cuts in which a thermal effect has been interpreted below as the temperature at which the cooling mixture reaches a eutectic boundary between two primary phases, the thermal effect has been referred to as T_3. Thermal effects which appear to result from ternary eutectic or peritectic points are referred to as T_4, and those which are presumed to result from the formation of a second liquid phase are referred to as T_5.

Construction of the Ternary Phase Diagram

The ternary phase diagram (Fig. 1) is drawn in such a manner as to be consistent with the DTA and x-ray data for the various binary cuts discussed below and with the experimental data obtained for other points in the ternary system. Most of the experimental data were obtained for compositions in the GaAs primary phase field.

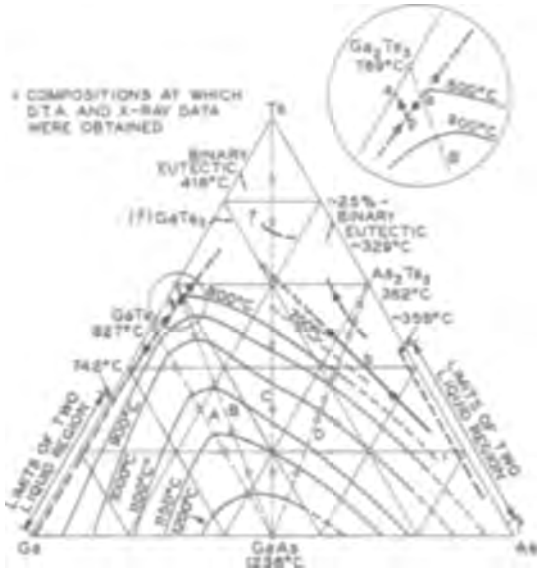

Fig. 1. The Ga-As-Te ternary phase diagram; Units are atom per cent.

Other regions of the phase diagram have not been studied in detail. As will be discussed below, there seem to be several ternary peritectic or eutectic points near 340°C. The location of these points on the phase diagram has not been determined in this work.

There is some evidence for a ternary compound which forms peritectically over a wide range of ternary liquidus compositions in the gallium poor regions of the phase diagram. This compound, if it does exist, is apparently consumed in a ternary peritectic reaction and is not observed in powder x-ray photographs.

The GaAs-GaTe *cut.*—The thermal effect data for the GaAs-GaTe binary cut, which are tabulated in Table I are plotted in Fig. 2. The primary phase separating at T_1 is GaAs. The concentration of Te in solid solution with the GaAs is apparently below the limit of detection of the x-ray powder photographs, and no line smearing or shifting was observed.

The secondary phase GaTe precipitates at T_3 along with GaAs. Although the GaAs-GaTe cut appears on the basis of Fig. 2 to be simple eutectic, the thermal effect noted as T_5 corresponds to approximately the temperature at which two liquids are found in the Ga-Te binary. In order for some of the liquid to reach the two liquid region near the binary, the GaTe phase precipitating must be somewhat richer in Te than the stoichiometric compound. The possibility that the peritectic formation of Ga_3Te_2 gives rise to T_5 and that

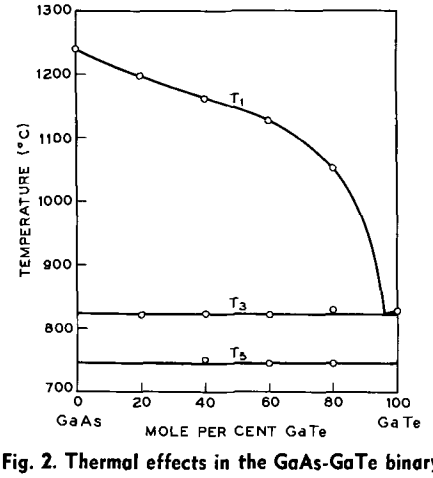

Fig. 2. Thermal effects in the GaAs-GaTe binary.

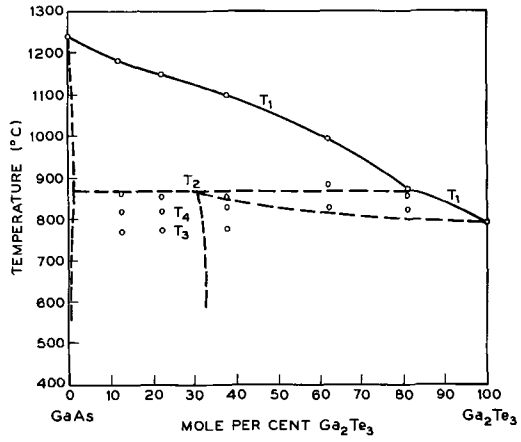

Fig. 3. Thermal effects and illustrative phase boundaries for the GaAs-Ga_2Te_3 binary. The dashed curves are intended to indicate only the shape of the phase boundaries in this cut.

the thermal effect due to the formation of the two liquids either does not occur at all or is hidden in the T_5 effect cannot be discounted.

No evidence for ternary compound formation such as that reported for the InAs-InSe system (3) was obtained.

The GaAs-Ga_2Te_3 *cut.*—The most complicated differential thermal analysis cooling curves obtained in the Ga-As-Te system were found with melts with over-all composition in the GaAs-Ga_2Te_3 cut. The T_1 liquidus is plotted as a solid curve in Fig. 3. Other thermal effects were noted which are interpreted here to indicate that the GaAs-Ga_2Te_3 system is not a true binary since the crystallization paths must be out of the plane of that system.

To illustrate the nonbinary behavior of this system, the DTA cooling curves are shown schematically in Fig. 4. For each cooling curve in Fig. 4, T_1 is the temperature at which the first solid appears, and each of the T_1 points is representative of a liquid with a composition on the GaAs-Ga_2Te_3 binary cut. If the GaAs precipitates with a small amount of Te in solid solution, the crystallization path will deviate only slightly from the GaAs-Ga_2Te_3 cut. The second thermal effect, T_2, will be observed when the liquidus composition reaches the boundary of the Ga_2Te_3 primary phase field between points a and p on Fig. 1. If the system remains in equilibrium as the mixture is cooled still further, the liquid composition will move along the two phase boundary a-p to a ternary pertectic (p), if the second solid is relatively rich in Te, at which time

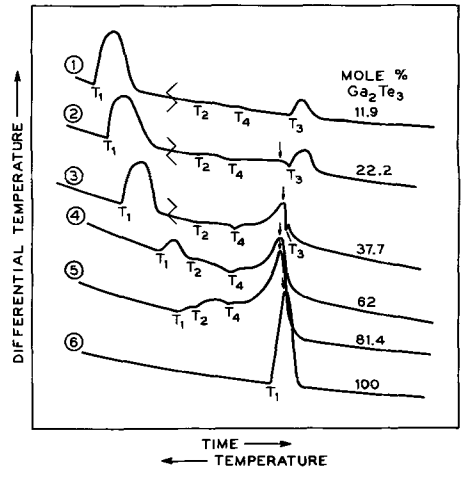

Fig. 4. Schematic DTA curves for samples with compositions on the GaAs-Ga_2Te_3 binary.

the thermal effect T_4 will be noted. At the ternary peritectic the reaction

$$\text{liquid} + \text{GaAs} \rightarrow \text{GaTe}$$

occurs, and with further cooling the liquidus composition will move along p-e (Fig. 1) until the binary eutectic is reached at e (thermal effect T_3).

The curve a-p is assumed here to represent the intersection of primary phase boundaries of a solid solution based on the Ga_2Te_3 structure but with variable ternary composition, and Te doped GaAs. Woolley and Smith (18) have shown that extensive solid solutions of Ga_2Te_3 and GaAs exist and that equilibrium in the solid solution region occurs very slowly. It is not expected, therefore, that the cooling curves of Fig. 4 represent equilibrium systems. Although the thermal effects T_2, T_3, and T_4 are observed for most of the curves obtained by cooling liquid mixtures with over-all compositions in the GaAs primary phase field of the GaAs-Ga_2Te_3 cut a different type of thermal effect (indicated in Fig. 4 by an arrow) rapidly gains in importance as the starting composition becomes closer to pure Ga_2Te_3. This thermal effect may be interpreted as being due to the nonequilibrium precipitation of the above mentioned solid solution with coring as the temperature overshoots T_4 and the peritectic reaction cannot be completed.

The analysis presented above is consistent with a binary section such as is illustrated approximately by the dashed and full curves of Fig. 3. A miscibility gap exists in the solid between GaAs-Te solid solutions and solid solutions based on Ga_2Te_3. The above analysis is also consistent with the studies of Woolley and Smith (18) who used long annealing procedures in an attempt to produce equilibrium phases in the GaAs-Ga_2Te_3 binary. They were not able to produce single phase behavior on the GaAs side of the system; however, on the Ga_2Te_3 rich side, extensive solid solubility of GaAs in Ga_2Te_3 was demonstrated.

Woolley and Smith noted that it was possible that they did not attain equilibrium and that the two-phase condition observed was due only to the fact that the diffusion rates were too low. If this were the case, and at equilibrium there were a complete series of solid solutions, the T_2, T_3, and T_4 thermal effects noted in this work would not have been observed. In such a situation T_1 would have been observed, and the GaAs-Ga_2Te_3 solid solution would precipitate with severe coring. As a result of the coring Ga_2Te_3 would precipitate as a separate phase when the temperature had approximately reached the melting point of the pure compound, and a large thermal effect would have been noted at that temperature.

X-ray powder photographs of the cooled DTA samples in this section do not show coring in the case of GaAs. Since the solid solubility of Te in GaAs is apparently quite small and probably below the limits of detection in the powder photographs this is not surprising. The Ga_2Te_3 powder diffraction lines showed evidence of severe coring for all of the samples on this cut. A lattice constant variation of from 5.88 to 5.77Å was noted.

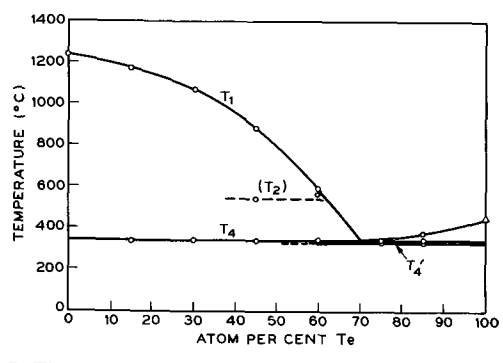

Fig. 5. Thermal effects in the GaAs-Te binary; Units are atom per cent for all components.

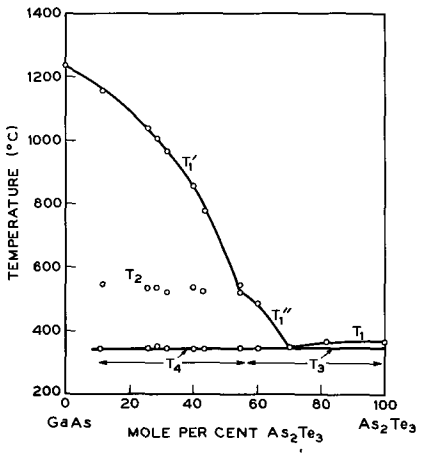

Fig. 6. Thermal effects in the GaAs-As_2Te_3 binary

The GaAs-Te *cut.*—The thermal effect data for this cut are plotted in Fig. 5. The shape of the T_1 liquidus curve is that of a simple eutectic system with the GaAs primary phase field occupying the major portion of the diagram. A very slight thermal effect was noted on two of the cooling curves, and this has been designated T_2 because it appears to be the same effect designated T_2 on the GaAs-As_2Te_3 cut and on several other cooling curves in the high arsenic region of the phase diagram. If, as discussed below, this represents the peritectic formation of a ternary compound, the system is obviously not a simple eutectic type and is not binary in nature. Two other thermal effects, designated T_4 and T_4', were noted in the DTA curves. These may result from a ternary peritectic and eutectic near 340°C. No attempt has been made to study the high Te region of this phase diagram and the composition at which these points occur has not been determined. The x-ray data for all samples on this cut are discussed below with the data for the GaAs-As_2Te_3 cut.

The GaAs-As_2Te_3 *cut.*—The thermal effect data obtained when solutions with over-all compositions along this cut were cooled are shown in Fig. 6. The T_1 liquidus curve resembles that for a binary system with a peritectic point. A small thermal effect (T_2) was noted for all cooling curves where T_1 was greater than T_2. A large thermal effect was observed in almost all the cooling curves at about 340°C.

If T_2 represents the peritectic formation of the compound GaAs-As_2Te_3 [by analogy to the In-As-Se system discussed by Luzhnaya *et al.* (3)], it would be expected that DTA curves obtained for compositions on the GaAs-As_2Te_3 cut would show a greater thermal effect at T_2 than nearby compositions in the ternary system. Actually greater T_2 thermal effects were noted for several compositions at higher As concentrations on the 1000° isotherm. The ternary compound is therefore not GaAs-As_2Te_3, and its actual composition has not been determined in this work.

The thermal effect at 340°C (T_4) may be ascribed to the intersection of curve b (Fig. 1) with a ternary peritectic point involving the peritectic formation of the Ga_2Te_3 based solid solution when the starting composition of the mixture is less than 55 mole % As_2Te_3. For mixtures with starting compositions greater than 55 mole % As_2Te_3, the thermal effect (T_3) at about the same temperature appears to result from the intersection of the liquidus crystallization path with the As_2Te_3 primary phase field. The x-ray powder photographs of cooled DTA samples with over-all compositions along the GaAs-Te and GaAs-As_2Te_3 cuts are quite interesting. The compounds identified by their x-ray patterns in each

** Very small amount.

sample are given in Table II. These x-ray patterns are consistent with the interpretation that the T_2 thermal effect in Fig. 5 and 6 is due to the peritectic formation of a ternary compound if we assume that the compound formed decomposes at a ternary peritectic point on further cooling to yield the Ga_2Te_3 based solid solution. The presence of As in all samples with starting compositions on the GaAs-As_2Te_3 cut and several samples with higher As starting compositions may indicate that there is a second unidentified ternary peritectic which permits the liquidus to reach the reported two liquid region on the Te-As binary. Details in this region of the phase diagram cannot be drawn on the basis of the data presented here.

Electron beam microprobe studies of several DTA samples along the GaAs-As_2Te_3 cut are consistent with the room temperature powder x-ray studies. GaAs, As_2Te_3, and As were observed where expected from the powder photographs. The Ga_2Te_3 phase had a variable composition and was difficult to study because it appeared to react under the impact of the electron beam.

Conclusion

A major part of the condensed ternary phase diagram for the gallium-arsenic-tellurium system has been constructed on the basis of data obtained from differential thermal analysis and x-ray studies. Unlike several other III-V-VI systems (18-22), no regions of extensive solid solubility of tellurium in GaAs were observed. The GaAs-GaTe cut shows essentially pseudobinary eutectic characteristics although it appears that the GaTe phase may be Te rich. The GaAs-Ga_2Te_3 cut is not a true pseudobinary and has a considerable region in which the liquid is in equilibrium with a ternary solid solution with a structure based on Ga_2Te_3. The GaAs-Te cut resembles, on the basis of the DTA studies, a binary eutectic, but a consideration of the x-ray data and the DTA data of the GaAs-As_2Te_3 cut reveals the possibility that a peritectic boundary may intersect the cut at about 62.5 atom % Te. DTA and x-ray studies of the GaAs-Te cut and the GaAs-As_2Te_3 cut have provided information which suggests the existence of a ternary compound which reacts at one or more ternary peritectics to yield a solid solution of GaAs and Ga_2Te_3. The composition of this compound is not known.

It is interesting to note that the shapes of the isotherms in the GaAs primary phase field are very similar to those in the In-As-Se system (3).

Acknowledgments

The author would like to thank P. Schmidt for some of the x-ray analyses and for a number of useful discussions of their interpretation. Other x-ray analyses were done by Mrs. V. Compton and Mrs. A. M. Hunt. H. Schreiber performed the electron beam microprobe analysis and aided in their interpretation. S. Sumski prepared the DTA samples. Discussions with C. D. Thurmond were very helpful.

Manuscript received May 27, 1966; revised manuscript received Aug. 19, 1966. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Printable Insulated-Gate Field-Effect Transistors

Y. T. Sihvonen, S. G. Parker, and D. R. Boyd

Corporate Research and Engineering, Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Graphic means for fabricating active circuit elements have been examined in an exploratory program. Compatible and complementary semiconductor-, dielectric-, and metal-inks have been developed and tested. Their use in various juxtaposed and overlayed configurations has produced operational insulated-gate field-effect transistors. The ultimate goal is to establish processes compatible with existing processes for silk-screened resistors and capacitors and produce high-volume, low-cost active circuits. Four types of graphically produced transistors typically exhibit two characteristic modes of behavior; high transconductance ($\leq$2000 μmhos) coupled with poor frequency response ($<$100 cps); and low transconductance ($\leq$20 μmhos) coupled with better frequency response ($>$100 cps). These behaviors correlate with gate-dielectric parameters. Various organic and inorganic gate-dielectric materials have been tested; best results to date have been obtained with nitrocellulose, silicate cement, glyceryl monostearate, or barium titanate in association with CdS:CdSe. Sintering of the semiconductor layer and post-processing of the inks after each printing deposition have been found necessary to enhance device performance. The times involved with these operations are comparable to conventional screened conductor, resistor and capacitor processing periods.

Printing processes as applied to the manufacture of film-type electronic circuitry hitherto have been limited to combinations of passive elements, *i.e.*, resistors and capacitors connected by conductive paths to which active elements, i.e., diodes and transistors, are annexed in "chip" or package form. Partially negating the economic advantages of such printing operations are processing costs associated with fabricating and inserting the active elements.

The possibility of printing active elements as well as passive ones has received impetus from recent achievements with evaporated polycrystalline semiconductor films. Inasmuch as diodes and transistors can be readily fabricated from such films, it is not unreasonable to expect that active devices should be realizable by the deposition and processing of special "inks" either wet or dry in appropriate configurations on suitable substrates. The envisioned payoff for such a successful coalescence of printing disciplines with semiconductor concepts would be high volume production of components and networks attractively competitive costwise with components and networks manufactured by other means. The accuracy and speed with which modern printing presses produce meaningful patterns and designs are well exemplified by the high-quality color designs seen in the better magazines and books. Intricate overlayed and juxtaposed dot or dash configurations produced by multiprint operations are common practice, and to rapidly generate a million complex designs or pictures indistinguishable from each other to the n^{th} dot is generally taken for granted by artisans of the trade.

The purpose of this paper is to summarize results of an investigation into problems associated with printing active devices by means compatible with existing silk-screen processes for depositing resistors and capacitors. Effort has been expended in developing and testing various semiconductor-, dielectric-, and metal-inks, using these to print operational insulated-gate field-effect transistors, and evaluating their performance. Transistor components have received most study to date because they are considered vital for complete success of the over-all concept. Our studies involving printed diodes and wholly printed circuits are incomplete and will not be included in this paper.

Fabrication Considerations and Materials

Device types.—The Graphic Active Devices (GAD's) successfully printed are fundamentally similar to the evaporated insulated-gate field effect transistor developed by Wiemer (1). In such a device, the majority carrier concentration in the semiconductor film is controlled by an electric field applied to a dielectric overlay. Four variations of the structure are shown in Fig. 1: (a) and (b) are coplanar types having all layers on the same side of the semiconductor layer, and (c) and (d) are staggered types having the gate layer and source-drain layers on opposing sides of the semiconductor layer.

Substrates.—The choice of an appropriate substrate to receive the ink layers for GAD types (a) and (d) has been dictated by mechanical considerations and by the necessity to minimize undesirable reactions between the semiconductor and the substrate during post deposition heat treatments. For a variety of experimental inks, high-purity alumina has been especially useful as a passive substrate for it has good film adherence qualities and is nonreactive under a wide variety of fabrication processes. These alumina substrates, for convenience in measuring device parameters, were shaped to fit a standard four-lead TO-5 header. Protection against open-environment influences was afforded by polystyrene plastic coatings or by canning units in dry nitrogen.

Type (c) GAD's, wherein the gate insulator serves both as the substrate and the printing surface, require strong rigid materials that have both good in-

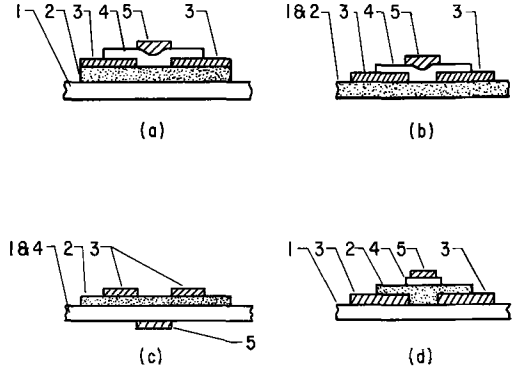

Fig. 1. Four types of GAD's in cross section: (a) planar structure on passive substrate; (b) planar structure on semiconductor substrate; (c) staggered structure on dielectric substrate; (d) staggered structure on passive substrate. 1, Substrate; 2, semiconductor; 3, source and drain electrodes; 4, insulator-dielectric; 5, gate.

sulating properties and relatively high dielectric coefficients. The advantages in printing this kind of device are that one material (an auxiliary substrate) is eliminated and that printing operations proceed on both broad areas simultaneously, thereby reducing the number of serial processing steps.

Type (b) GAD's utilize a pressed and sintered wafer of the semiconductor material that serves as both the substrate and active material. This approach is attractive because a separate substrate is not required, and it achieves the ultimate simplicity envisioned for printing and processing complete circuits of R's, C's, and active devices on the same wafer. To form these substrates, powder (typically CdS:CdSe powder of 99.999% purity) is compressed to 1 mm thick in a die at 20,000 psi and then fired at 550°C in air for 1 hr to recrystallize and bond the particles. Surface resistance approximates 10^3 ohms/sq and the pellet withstands relatively rough handling. Source and drain contacts, the gate insulator, and the gate are applied directly to the surface by one of several procedures to be described. Insulation of elements is achieved by diffusing appropriate dopants to create high-resistance boundaries.

Semiconducting layer.—Deposition and treatment. Various satisfactory inks which could be screen-deposited and processed into semiconducting layers were empirically developed by first concocting a screenable mix, and then adjusting the semiconducting and doping constituents for best device performance. A very useful ink and one employed for most GAD development work has been prepared by the following procedure: (*A*) A mixed compound of CdS:CdSe is made by mixing equal portions (by weight) of 99.999% purity CdS and CdSe and sintering at 950°C for 4 hr in a H_2S ambient of 1 atm. After cooling, the conglomeration is ground to 80 mesh with a porcelain mortar and pestle. (*B*) A slurry is made by the addition of distilled H_2O and $CdCl_2$ solution so that the $CdCl_2 \cdot 2\frac{1}{2} H_2O$ to CdS:CdSe weight ratio is 1:10. This slurry is dried on a hot plate at 100°C. (*C*) The final ink is prepared by mixing 10g of the dried CdS:CdSe material with 40 cc of a carrier solution of 5% (by weight) ethylcellulose in butyl cellusolve, and then ball milling for 16 hr. Inks stored for more than 24 hr required only simple stirring to properly resuspend the semiconducting particles.

In use, the CdS:CdSe ink is transferred to substrates in controlled thicknesses ranging from 2 to 25μ by screening through a 100 mesh silk-screen and is then predried to remove the carrier solvent. The resulting raw film exhibits high electrical resistance (> 1 Mohm), adheres well to most types of substrates and withstands considerable abuse before showing physical damage.

Sintering is required to activate the raw film. The $CdCl_2$ present serves as a flux that promotes particle fusion and granule regrowth at temperatures well below the normal CdS:CdSe sublimation point, and it also dopes the CdS:CdSe particles with Cl donors, bringing the resistance of the film into the desired range of 10^3 to 10^5 ohm/sq. The sintering operation is typically carried out at 570°C under conditions of limited air. Poor bonding strength and film homogeneity would result with insufficient $CdCl_2$ while excess $CdCl_2$ unfavorably affected device stability and frequency response. In the latter case, unreacted $CdCl_2$ could be satisfactorily removed by leaching.

Post treatment.—The application of surface activating agents (surfactants) to the sintered semiconductor layer prior to printing the gate insulator dielectric has been found to have beneficial effects on device performance. The surfactants used most extensively have been Lewis-type bases such as triethanol amine lauryl sulfate (TALS), glyceryl monostearate (GMS), sodium lauryl sulfate (SLS), dimethyl glyceryl stearate (DGS), ethanol amine (EA), and NH_3 gas. Best results were consistently achieved with NH_3 gas which was able to penetrate better into the inked film and envelop the CdS:CdSe granules. The liquid surfactants were applied as aqueous coatings over the semiconductor films and dried under a heat lamp. Ammonia was added to the films by passing NH_3 gas over units in an ice bath at about 0°C. Comparative performances of surface-treated GAD's are shown in Table I.

Source and drain electrodes.—A necessary condition for best GAD performance is unhindered electron flow through the source-semiconductor and drain-semiconductor interfaces. In addition to being "ohmic," the deposited electrodes need to be highly conducting, nonreactive with the other layers, and stable with time and temperature.

The many conducting silver and carbon preparations commercially available proved to be nonohmic with the CdS:CdSe layer. Several metals, *viz.* indium, tin, and aluminum, were empirically found to have suitable electrical properties, but simple air-drying inks based on these gave poor registry and line definition and were not particularly useful.

One means for obtaining satisfactory source-drain electrodes on the CdS:CdSe layer made use of a 90% Hg-10% In amalgam. After printing this paste-like mix, the Hg content was lessened by heating in a vacuum at 120°C. The resulting film made good ohmic contact and had solid metallic characteristics. Another

means for printing source-drain electrodes utilized an alloy of Sn-Ga (5-10% Sn) which remains fluid and has excellent wetability. Good line definition was readily obtained as well as good ohmic contact. The composition of this alloy can be varied to control the fluidity of contact. Though the resulting film remains "wet" it does not tend to flow and can be "locked" in place with the gate-insulator material. A third means for making source-drain electrodes used metallic powders of Sn or In, either sprinkled on or conveyed from transfer tapes onto the CdS:CdSe layer, then rolled to promote intimate contact, and finally sintered near the melting point. Fair to good ohmic contact was achieved, but results were often erratic.

Gold normally makes rectifying contacts to CdS:CdSe, but it was found that if the CdS:CdSe ink was fired onto predeposited Au layers, the resulting electrodes were electrically and mechanically very satisfactory for GAD use. A gold-resinate solution, Hanovia Liquid Brite Gold 7621, would first be deposited onto the alumina substrates and decomposed thermally at 750°C in air to give a metallic film. The source-drain electrodes were formed by diametrically scribing a 1-2 mil wide gap after which the CdS:CdSe ink was screened onto the substrate and fired. This method of making contacts restricted devices to the staggered-structure type since the gold ink could not be fired satisfactorily onto a predeposited CdS:CdSe ink layer.

Table I summarizes performances of various GAD devices prepared with the better source-drain materials that were applied by different means. No systematic superiority of any one contact material and method of application has been evident including evaporated indium electrodes which were used as a control, and it is our conclusion that major limitations to GAD performance are not a consequence of contact phenomena. While at least two or three of the methods described have been adequate and useful, further development work will be required before a simple printable contact ink is realized.

Gate insulator-dielectrics.—The insulating material separating the semiconductor layer and the gate electrode is ideally required to have stable dielectric properties, and its processing must be compatible with the remainder of the device. The number of carriers induced into or removed from the source-to-drain electrical path is a direct function of the capacitance existing between the gate electrode and a pseudo-capacitor plate located somewhere at or near the semiconductor surface. While it is desirable to have large current changes in response to gate voltage fluctuations, a compromise becomes necessary since long charging-times and low input impedance are inherent with large capacitances. Furthermore, any nonconstant properties present in the insulator, such as temperature instability or frequency or voltage dependent polarization, can be expected to appear directly as variances in GAD transconductance. Evidence for this dependence will be discussed later.

Organic dielectrics.—Some 25 solvent-, polymer-, and molten-type organic films were tested with various degrees of success. Most successful to date for routinely printing operational GAD's has been nitrocellulose in the form of Duco (DuPont) or flexible collodion, each producing layers having large relative dielectric coefficients ($> 10^5$). Unfortunately, the magnitude of this coefficient is highly frequency dependent, and the frequency performance of typical GAD's would diminish rapidly at frequencies above 1 cps. Furthermore, these films tended to "dry out" if left unencapsulated. GAD performance would correspondingly cease with this drying but could be restored by exposure to the solvent vapors.

The low-frequency dielectric coefficient in nitrocellulose is surprisingly large. It may be a consequence of molecular polarization either between the many polar groups such as —OH, —NO_2, and —O— or between these groups and the surface states on the CdS:CdSe layer. Alternatively, it is possible that the electric potential across the dielectric causes mobile ions to migrate. Movement of these ions would result in a dipole buildup. Evidence for ionic migration and perhaps some electrochemical action was demonstrated by electrolysis experiments with collodion solutions in which ions were tagged with neutral red indicator. Ions were observed to accumulate at and around both electrodes with H_2 gas being released at the negative platinum electrode.

Glyceryl monostearate (GMS), an animal fat derivative, was the best molten-type gate dielectric material found for GAD use. It is an ester formed between glycerol and stearic acid with numerous polar groups,

—OH and —C—O, present in each molecule. GAD units made with the GMS (which is also a surfactant) showed less frequency falloff than nitrocellulose dielectrics and the other organic materials tested. One major disadvantage of GMS is its low melting point of 60°C, a temperature often reached in a GAD under heavy operating loads. Other useful molten films have been made using triethanol amine lauryl sulfate (TALS) and vinyl polymers (*e.g.*, Tygon).

The major disadvantage of the more promising organic gate insulators in conjunction with the CdS:CdSe ink layer is their rapidly decreasing dielectric coefficient with frequency. Although the organic dielectrics cited would ultimately be unsuitable for printing devices meeting reasonable stability and frequency requirements, much knowledge as to what is needed in a good gate insulator was gained from their use.

Inorganic dielectrics.—The numerous difficulties with organic dielectrics prompted a look at inorganic dielectrics which could be expected to be more stable with respect to temperature and frequency. A problem confronted in their projected use was finding a suitable method of application. Inorganic dielectrics such as mica, $BaTiO_3$ and glasses are normally formed at high temperatures which could not be tolerated directly in GAD fabrication. Thus the search for inorganic gate dielectrics was narrowed to materials and processes involving low-melting temperatures, flame spraying, or chemical curing.

Cements were the most fruitful inorganic dielectrics to be applied by a print-on method. Several types were tested, *viz.*, lime, gypsum, phosphate, and silicate, but only the silicate cements (Sauereisen Cement Company) produced devices with adequate transconductances. However, as with the organic dielectrics, the current modulated decreased rapidly in magnitude at frequencies greater than 1-10 cps. The Sauereisen cements successfully used were No. P-1, No. 78, and No. 63 each containing 85-95% SiO_2 with the remainder being Al and Fe oxides and water of hydration. Water was added to make the cement "spreadable" and it was deposited in a straightforward manner onto the CdS:CdSe layer. The units were then stored in a sealed container for 24 to 48 hr to allow silicate, hydroxide, and hydrate reactions to proceed. When cured at room temperature these cements underwent continuous change lasting many weeks which is attributed to chemical processes proceeding to completion. As a consequence, GAD's would show continuing improvements in transconductances and speeds of response as the cements aged. More rapid stabilization could be instigated by heating canned units to 200°C for 48 hr. Some improvements in transconductance and frequency response in cement-dielectric GAD's were obtained when $BaTiO_3$ powder was added to the cement in a ratio of 1:3 by weight.

Dielectric substrate.—The use of the substrate itself as the gate insulator necessitated that the staggered-type structure, Fig. 1(c), be employed. The semicon-

ductor ink would be first screened over one surface of the substrate and processed, then the source and drain electrodes were applied over the semiconductor layer, and finally the gate electrode was printed and dried on the opposing face of the substrate. Since the substrate has to be relatively thick (in order to withstand both handling during processing and flexing that could cause component fractures), the dielectric coefficient needs to be very large in order to provide sufficient charge-change in the semiconductor layer. Few materials are known to have the required dielectric coefficient, and those that do are inherently inconstant in their properties.

$BaTiO_3$ substrates were superior to all materials tested producing GAD's with stable characteristics to over 1000 cps. The attendant problems with $BaTiO_3$ involved undesired reactions during sintering between the CdS:CdSe layer and the $BaTiO_3$. One effect was a doping of the CdS:CdSe layer making it higher in resistivity and another was poor adhesion caused partly by outgassing. Moderation and/or virtual elimination of these effects was affected by presintering the $BaTiO_3$ blank at 1000°-1250°C in air for 16 hr and increasing the amount of $CdCl_2$ in the CdS:CdSe ink. Either of these two corrective measures alone improved device transconductance and together the results were most impressive as seen in Table I.

Gate electrodes.—The gate electrode material and method of application were determined by the dielectric to which it was applied. Major requirements were that the electrode material be highly conducting and that it not react detrimentally with the dielectric. For organic dielectrics, an aqueous ink was developed containing by weight 5 parts Ag + 2 parts Zein + 4.1 parts 2-methyl 2,4 Pentanediol + 4.1 parts H_2O. The Ag (300 mesh powder) was suspended by ball milling and after application was allowed to dry at 25°C. For cement, ceramic, or inorganic dielectric materials, DuPont's Ag Paint No. 5584 was used. This paint is readily applied and quickly dries with only modest heating in air. It was also used to make conducting paths and connections to the header wires.

Electrical Performances and Interpretation

Devices fabricated in the manners described in this paper are composed entirely of disordered materials and obviously can give rise to extremely complicated behaviors not entirely interpretable by modern carrier transport theory as developed with single crystalline materials. The semiconductor layer, being a conglomeration of fused macroscopic particles, is highly inhomogeneous and contains a very high density of surface and bulk traps which strongly influence free carrier responses to electric fields. The insulator dielectric in contact with the semiconductor layer gives rise to further complications since ionic and polarization effects can and do manifest themselves. In spite of these serious problems, however, it is encouraging that with reasonable control over the materials and their processing, GAD's can be reproducibly printed to exhibit certain basic characteristics in their performances. The following section discusses results observed with literally dozens of GAD variations and several thousand devices. Table I summarizes typical performances of representative units at frequency decades ranging from 0.1 to 1000 cps.

Transconductance and drain current.—Transconductance, g_m, in an active device may be taken as a figure-of-merit of device performance. Two kinds of general transconductance-behavior have been encountered: one wherein g_m diminishes with frequency, and the other wherein g_m is relatively invariant with frequency (up to 1000 cps). The former behavior is found in GAD's processed with gate-insulators of deposited layers while the latter behavior is shown by the $BaTiO_3$ dielectric substrate structure devices. Typical transconductance data for two units, each

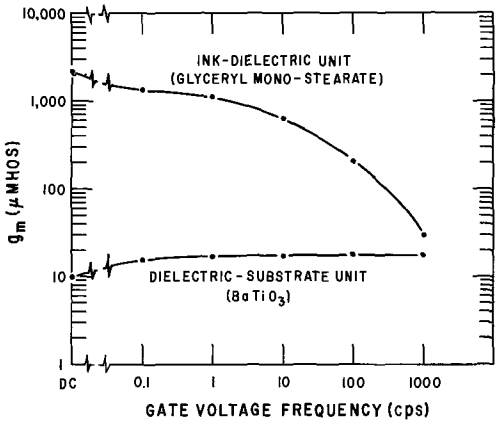

Fig. 2. Mutual transconductance vs. frequency of two representative GAD's.

representative of the behavior noted, are shown in Fig. 2.

The differences observed in g_m magnitude and the variations of g_m with frequency can be in the most part explained by considerations of capacitance data shown in Fig. 3, and simple field effect transistor theory. From Borkan *et al.* (2) the drain current expression is

$$I_d = \frac{\mu C_g}{L^2}\left[(V_g + V_o) - \frac{V_d}{2} \right] V_d \qquad [1]$$

where μ = carrier mobility, C_g = gate capacitance, L = source-to-drain separation, V_g = gate-to-source voltage, V_o = threshold voltage, and V_d = source-to-drain voltage.

It is important to distinguish between total gate capacitance, C_{gm}, as it is measured, and that part of the gate capacitance, C_g, which is effective in adding or subtracting charge carriers in the semiconductor layers. For the two representative devices considered, $C_g \approx C_{gm}/6$, where the factor 6 is calculated from simple area considerations. It follows that transconductance

$$g_m = \left.\frac{\partial I_d}{\partial V_g}\right|_{V_d = \text{constant}} = \mu C_g V_d / L^2 \qquad [2]$$

can be expected to vary directly with C_g, and qualitatively this is what is observed.

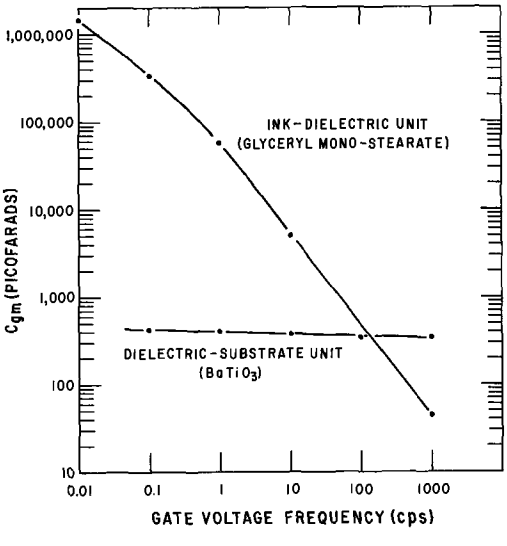

Fig. 3. Measured gate-to-channel capacitance vs. frequency of two representative GAD's. The apparent relative dielectric coefficient is obtained by multiplying the ordinate by 10. The approximate capacitance, C_g, directly interacting with the source-to-drain material can be calculated by dividing the ordinate by 6.

Quantitatively, reasonable agreement between calculated and observed g_m's is obtained for $BaTiO_3$-dielectric substrate units but not for any of the GAD's with film gate-insulators. In the latter type devices, not only does g_m not follow exactly the nearly 1/f proportionality measured for gate capacitance, but the effective relative dielectric coefficient of the dielectrics used turns out to be amazingly large, typically 3×10^6 at 0.1 cps. These data imply the existence of an unusual polarization which is relatively slow in responsiveness. As mentioned earlier, this mechanism very likely involves electric field separation of some type of mobile ionic species and further has associated with it a phenomenon which affects the capacitance as measured but not the capacitance which induces carriers into the semiconductor layer. Two possibilities are: simple battery action, or a combination of electrolysis and polarization. Both of these processes can be expected to absorb electrical energy during part of the dielectric charging cycle and then return some of it during the discharge cycle in a capacitor-like manner. The amount of energy-transfer involved would be strongly dependent upon the inverse of frequency thereby displaying a 1/f capacitance behavior. Furthermore, the charge displacement caused by these processes would not result in equivalent semiconductor carrier-increases because some of the induced carriers would be required to neutralize electrochemical reactions at the interface. The major difficulty with this explanation is accepting that the same kind of polarization-like effect is common to each of the chemically different dielectric species, *viz.*, nitrocellulose, glyceryl monostearate, and silicate cement.

Striking differences observed between GAD performance and that of normal insulated-gate field-effect transistors (IGFET's) is shown in Fig. 4. In a typical IGFET, I_d has a linear or less-than-linear proportionality to V_d, and at some V_d pinchoff (current saturation with increasing V_d) takes place. In the GAD, I_d response is everywhere superlinear with V_d and no pinchoff manifests itself. These differences in device behavior are interpreted as follows.

Pinchoff occurs in normal IGFET's because, as drain voltage increases, an effective voltage is induced across the gate capacitance, C_g, that removes carriers from the conducting channel. In Eq. [1], the terms in the square bracket are proportional to the conducting channel carrier density. The V_o term is proportional to the free carrier density of the semiconductor material itself. The V_g term is directly proportional to the carrier density induced or removed from the channel by gate voltage acting through the dielectric capacitance, C_g. Similarly, the $V_d/2$ term is directly proportional to the carrier density removed from the channel by drain voltage also acting through the gate capacitance. It is the carrier removal represented by the $V_d/2$ term that causes pinchoff in IGFET's. Pinchoff is defined as the point where the slope of the I_d *vs.* V_d curves become ideally zero, *i.e.*, where

$$\frac{\partial I_d}{\partial V_d} = 0 = \frac{\mu C_g}{L^2}\left[(V_g + V_o) - V_d\right] \qquad [3]$$

Pinchoff will not occur when V_d is prevented in some way from influencing the channel carrier density so that the condition of Eq. [3] is not met. The common property suspected to be preventing ink-dielectric GAD's from approaching this condition is the strong frequency dependence of C_g. Equations [1] and [3] do not reveal how this dependency acts to prevent pinchoff because their derivation tacitly assumes no variation of C_g with frequency.

A linear steady-state zero-order analytical accounting for the frequency dependence of gate capacitance can be incorporated into Eq. [1] as follows

$$I_d(\omega_g,\omega_d) = \frac{\mu C_g}{L^2}\left[\left(\frac{V_g}{1 + j\omega_g T_c} + V_o\right) - \frac{V_d}{2(1 + j\omega_d T_c)}\right] V_d \qquad [4]$$

where a gate capacitance time constant, T_c, is defined as the inverse of the angular frequency at which the I_d (or g_m) response to a sinusoidal gate voltage is 0.707 of its d-c value, and ω_g and ω_d are the angular frequencies of applied gate and drain voltages, respectively. The pertinent consequences of Eq. [4] are that not only the transconductances of ink-dielectric GAD's will be frequency dependent but that their pinchoff, as well, will be just as strongly frequency dependent. Pinchoff, of course, will depend on the frequency of applied drain voltage used for measurement rather than the gate voltage frequency. Equation [4] indicates the pinchoff can not occur for $\omega_d >> 1/T_c$. But, as ω_d is reduced, a pinchoff condition will ultimately manifest itself and, furthermore, the pinchoff point will occur at lower and lower drain voltages and currents.

The validity of the foregoing statements in GAD's having different ink-type dielectrics was tested by

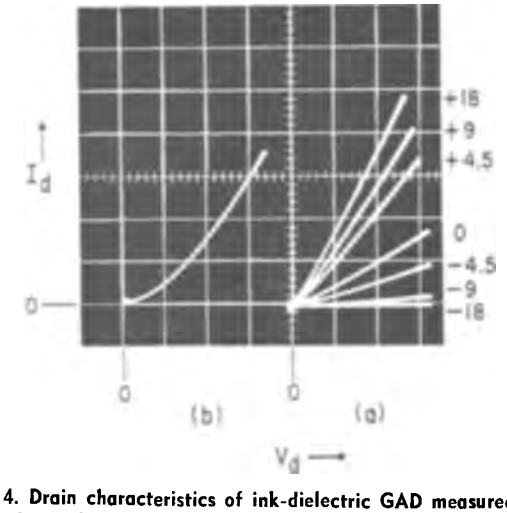

Fig. 4. Drain characteristics of ink-dielectric GAD measured at a drain voltage frequency of 100 cps. (a) Family of characteristics for gate voltages indicated. All curves are somewhat superlinear and pinchoff is not in evidence. Vertical scale = 2 ma/major div; horizontal scale = 5 v/major div. (b) Amplified V_g = — 18v curve showing drain current superlinearity in more detail. Vertical scale = 10 μa/major div; horizontal scale = 5 v/major div.

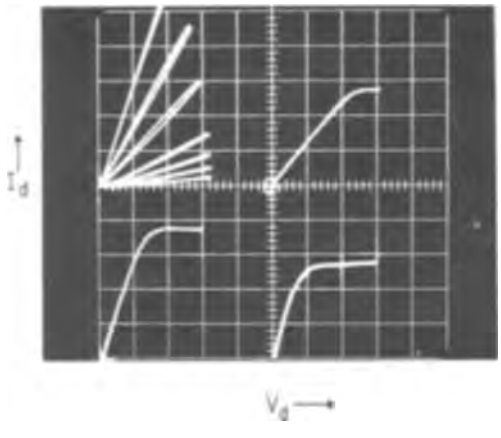

Fig. 5. Drain characteristics of a typical ink-dielectric GAD as a function of frequency showing the frequency dependence of pinchoff. Traces in the upper-left quadrant are a family of characteristics for V_g = 18, 9, 4.5, 0, —4.5, —9, and —18v at a drain voltage frequency of 100 cps. The other quadrants display the V_g = +4.5v curve at lower frequencies: upper right at 10 cps; lower left at 1 cps; and lower right at 0.1 cps. Vertical scales: upper left and right, I = 2 ma/major div; lower left and right, I = 1 ma/major div. Horizontal scales = 5 v/major div. Retraces have been blanked out for purposes of clarity.

varying drain voltage frequency with results from a typical unit pictured in Fig. 5. As drain frequency is decreased a rather well-defined pinchoff appears, thus qualitatively, at least, substantiating the preceding hypothesis. Our normal $BaTiO_3$ dielectric GAD's would not be expected to pinch off for V_d's within their power dissipation limits because V_o, Eq. [1], is too large. However, two specially made units having V_o's of approximately 18v that should have been able to satisfy Eq. [3] for $V_g \leq 0$ were tested and found not to pinch off.

Drain characteristics of one unit are shown in Fig. 6. Lack of pinchoff in conventional IGFET's has been attributed (3) to un-ionized surface donors in the semiconductor at the dielectric interface. Whether this explanation is pertinent to substrate-dielectric GAD's that should pinch off but did not has not been investigated further.

Superlinear volt-ampere characteristics (*i.e.*, $I_d \propto V_d^a$, where $a > 1.0$) are associated with the polycrystalline semiconductor used as channel material. The cause of superlinear characteristics is not completely understood, but it is thought that voltage sensitive intercrystalline boundaries are primarily involved. It is unlikely that superlinearity is due to one-carrier or two-carrier space-charge-limited currents (4, 5) because trap densities are sufficiently high to preclude the trap-filled condition necessary (6). All polycrystalline materials tested (including CdS pressed pellets, CdS vapor deposited films, and CdS:CdSe sintered inks) exhibited superlinearity with the magnitude of the coefficient ranging between $1 < a < 3$. Higher resistivity materials generally were found to have larger coefficients than lower resistivity materials as long as material deposition and processing remained the same. Contact barrier effects as possible sources of superlinear V-I characteristics were examined, but all contact material diffusion and electrical pulse treatments that are known to reduce superlinearity to ohmic behavior in single crystal specimens were of no avail in polycrystalline samples.

Stability.—Storage tests with $BaTiO_3$-substrate GAD's protected from atmospheric environments have shown only minimal changes in g_m while those exposed to ambients have shown varied but no more than 50% degradation over a period of 12 months. When longevity-tested at power dissipation levels of approximately 150 mw or less, no change in performance has been noted with canned units. However, when operated at higher power levels that caused device heating, permanent reduction of g_m would occur.

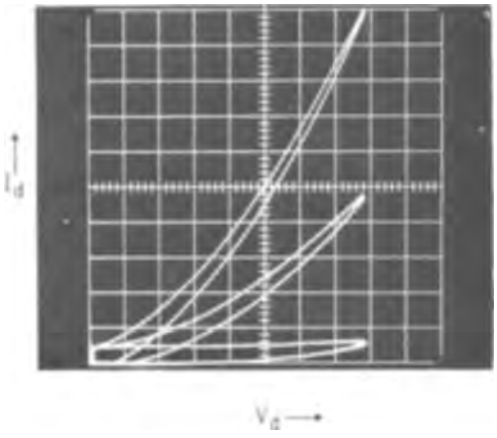

Fig. 6. Drain characteristics of a $BaTiO_3$ dielectric-substrate GAD showing the lack of pinchoff in a device that should meet pinchoff conditions. Vertical scale = 0.5 μa/major div. Horizontal scale = 2 v/major div. Upper, mid, and lower curves were obtained at V_g = +18, 0, and −18v, respectively. Drain voltage frequency = 100 cps. Area in curves due to capacitance of measuring circuit.

Permanent changes invariably would be accompanied by semiconductor conductivity reductions whereas no permanent deterioration in substrate capacitance was ever evidenced.

The $BaTiO_3$ dielectrics used in dielectric-substrate GAD's (Alsimag T-183-A and T-176-A) were moderately temperature sensitive and units would exhibit g_m degradation at elevated temperatures (~60°C) that corresponded with the dielectric coefficient change. This means that use of even higher permittivity materials to achieve greater g_m response has temperature-performance implications for, as far as is known, high permittivity materials have the greatest temperature coefficients. High-permittivity dielectrics are also voltage sensitive; however, the low-voltages employed in normal GAD operation would produce only minimal variations in substrate capacitance.

The shelf-life behavior of GAD's with organic and inorganic ink-dielectric films are qualitatively similar but, in general, exhibit greater instabilities than dielectric-substrate units. Some units of each species more than one year old still operate. Several that were longevity tested under load have been relatively stable at room temperature from one longevity measurement to another but the majority have exhibited varying g_m's that involve the dielectric primarily. Semiconductor material property changes, except for temperature-caused variations, have been found insignificant relative to dielectric changes.

Observed gate-capacitance decreases with time are attributed to solvent evaporation or hydrolysis and the consequent loss of ions from the polarization process. This conclusion is based on observations that canned units invariably had much longer shelf-lives than uncanned units, and on the evidence that replacement of lost solvents would restore C_{gm} and g_m in defunct devices. In some cases these parameters, after solvent additions, were greater than those originally measured. Nonsolvent ink-dielectric GAD's have shown virtually no capacitance changes with time as they contain no time-dependent constituents or lingering chemical reactions.

As might be expected, GAD's printed with any of the successfully deposited dielectrics are sensitive to changes in ambient temperature. Typically, a 100 times increase in g_m occurs as device temperature is raised from 0° to 50°C. This change is attributed mainly to increase in density and mobility of the ion species associated with the polarization (gate capacitance correspondingly increases) and partly to increases in semiconductor conductance.

Concluding Remarks

Producing active devices, having power gain, by serial deposition of particulate "inks" has been demonstrated. Four basic types of insulated-gate field-effect transistors have been processed without recourse to vacuum evaporation, and these have been examined for characteristic performance. Device behavior is largely determined and limited by the properties of the gate dielectric and the dielectric-semiconductor interface. Best stability has been achieved with $BaTiO_3$-substrate GAD's but lack of drain-current pinchoff remains an interesting anomaly.

In this feasibility study, we do not consider the materials and processes that have been developed as anything more than preliminary solutions to a variety of problems involving compatibilities of inks and their interactions with each other. At this time a more systematic evaluation of better materials and printing processes is in order and needs to be carried out. Ideally, it would be desirable to produce entire circuitry at speeds approaching modern newsprint rates in order to achieve the ultimate in low cost manufacturing. Our ink processing times presently preclude achieving this ideal objective. However, the processing times and printing surfaces employed are comparable to those now used in producing thick-film resistor and capacitor combinations. Finally, printed active devices

in their present state of development, are limited in both performance and stability, but improvements are likely to evolve with better understanding of the basic chemical, physical, and electrical processes involved.

Growth Mechanism of Vapor Deposited Germanium Films

M. S. Seltzer, N. Albon[1], B. Paris, and R. C. Himes

Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Direct microscopic observation of the movement of growth steps during chemical vapor deposition of epitaxial layers of germanium on germanium substrates, in an open tube reactor, has been employed to study growth mechanisms operative in this system. The reaction studied was the disproportionation of germanium diiodide: $2GeI_2(g) = Ge(s) + GeI_4(g)$. Rate of step movement has been measured as a function of step height, substrate temperature, iodide pressure, gas flow rate, and other growth variables. In addition, transpiration measurements have been made to determine the actual partial pressures for gaseous species produced at various sites in the open-tube flow system. The predominant stepped growth features observed on (111) planes were triangular pyramids. They are shown to be quite minor deviations from the (111) plane, the slope of the side for a typical pyramid being at most 1 in 30. A maximum in rate of step movement has been found with the germanium seed near 360°C, and observable step movement was detected in a narrow temperature range about this optimum temperature. From the observed influence of step height and iodide pressure on rate of step movement it is suggested that growth depends on processes occurring directly at step sites. At high iodide pressure two-dimensional nucleation of germanium on terrace portions may occur, resulting in an increased concentration of crystalline defects.

In recent years the use of epitaxially grown, single-crystal films in the fabrication of semiconductor devices has become widespread. Among the more attractive methods for preparation of epitaxial deposits are those involving formation of films by chemical reaction, either dissociation or reduction. The utilization of chemical vapor deposition (cvd) techniques for the purpose of obtaining epitaxial semiconductor films has been hampered, however, by a lack of fundamental information concerning the influence of the several variables involved on the growth and perfection of the films formed. In particular there have been few attempts to arrive at a basic understanding of the mechanisms for epitaxial growth of these covalently bonded materials in a cvd system. For many cases, growth of imperfect crystals containing spiral dislocations can be adequately described in terms of the mechanism proposed by Burton, Cabrera, and Frank (1), which consists of surface diffusion of adsorbed species to ledges on low-index terraces, and movement along the ledge to kinks where incorporation of the species into the deposit occurs. This model, although very general, was derived mainly for growth by a process of physical vapor deposition or condensation of monomers at low supersaturation. It was the objective of this investigation to study the process of growth of semiconductor materials by chemical vapor deposition and to determine the degree of applicability of current crystal-growth theory to these rather complex systems. The principal experimental method chosen to attain this objective was direct microscopic observation of the behavior of growth steps in a deposition cell. In order to obtain a satisfactory understanding of crystal growth it is necessary to establish the manner in which growth steps move and the kinetics of this process. Thus, rate of step movement has been measured as a function of step height, substrate temperature, and other growth variables in order to identify rate-controlling processes. Although the movement of growth steps on semiconductor crystals had not been measured previously, the sensitivity of procedures involved in such measurements makes step-movement determination an extremely useful tool for study of crystal growth. The weight of material deposited during an observation on step movement may be many orders of magnitude less than that required when studying growth by more conventional means.

The growth of germanium films on germanium substrates by dissociation of the diiodide in an open-tube flow system was chosen for study in this investigation. There are considerable data available on this system, and precise control of growth conditions, purity, and substrate perfection is possible. Furthermore, the low deposition temperature (350°-400°C) facilitates microscopic observations and measurement of step movement. This low deposition temperature is one of the most significant of the possible advantages to be gained from the use of cvd methods since higher purity deposits may be achievable, with lower point-defect concentrations than are found in material prepared at elevated temperatures.

The design and operation of the apparatus used to study crystal growth in this investigation have been described previously (2). The equipment consists of a

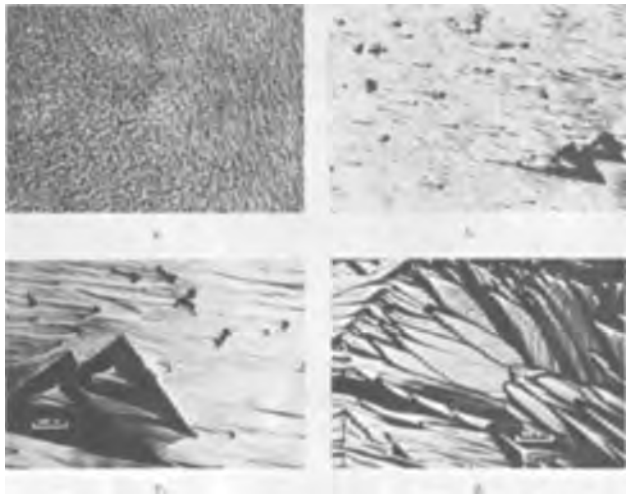

Fig. 1. Various surface features during deposition on the germanium (111) face.

system for carrier gas-flow control and purification, a multistage furnace where formation of gaseous GeI_2 occurs, a deposition cell, and a microscope for observation of growth features. In the following sections we present the experimental observations and results, discussion of step movement data, and conclusions.

The partial pressures for gaseous species produced at various sites in the open-tube reactor employed in this study could not generally be calculated on the basis of equilibrium conditions; instead, a series of transpiration measurements was required to determine the conditions under which equilibrium is achieved at these critical sites. The results of this auxiliary work are discussed in some detail in the Appendix.

Experimental Observations

Various features found during deposition on a (111)-type surface are shown in Fig. 1. A typical surface before deposition is shown in Fig. 1a. When growth commenced, numerous features became visible. Later, these became more pronounced and most of the surface had the appearance shown in Fig. 1b. Still later, two triangular growth hillocks were formed as shown in Fig. 1c. These are similar to features observed by other investigators (3-7) who have studied growth of germanium by the disproportionation reaction. One small area of the deposit displayed a somewhat different appearance as shown in Fig. 1d, which reveals well-defined growth steps on a planar area. It was the movement of such growth steps,

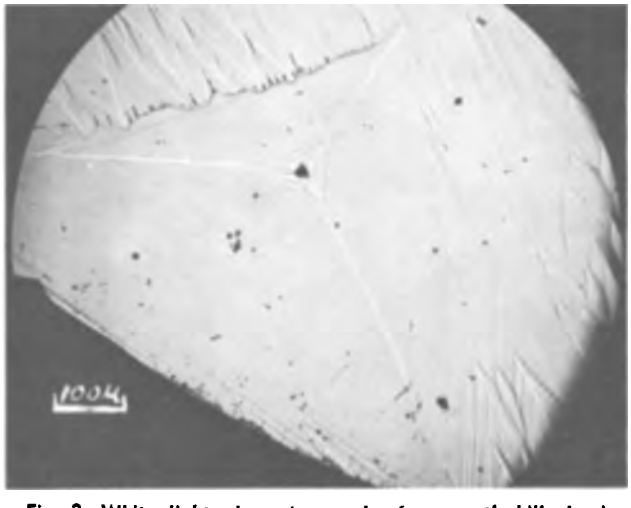

Fig. 2. White light photomicrograph of a growth hill showing many small steps.

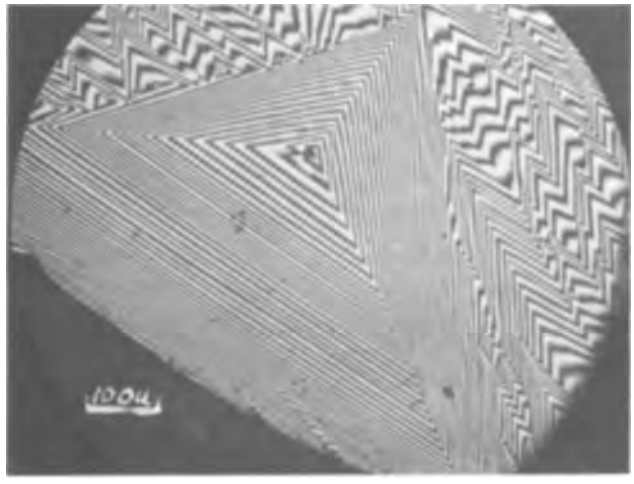

Fig. 3. Same growth hill as shown in Fig. 2 observed under interference lighting.

either on growth pyramids or on planar regions, that was measured during crystal growth. Measurements on planar surfaces were preferred because steps of various heights could be observed better than on hillocks, and their comparative movements measured. In addition, a particular step could be observed for a relatively long period of time. This permitted measurements on the same step under different growth conditions.

The topography of selected growth hillocks was established by utilization of interference microscopy, as exemplified in Fig. 2 and 3. A growth hill is shown under white light in Fig. 2 and under interference lighting in Fig. 3. Many steps can be seen in Fig. 2. As the fringes in Fig. 3 represent a vertical distance of 0.27μ, the height of the hills can be determined. In this example the profile obtained indicated a height of 6.2μ, and the length of each side is 200μ. A rate of step movement of 4 μ/min represents a rate of film thickening at the hillock of 7.5 μ/hr. Although these hills appear prominent, they are quite minor deviations from the (111) plane, the slope of the side being at most 1 in 30. [Seed orientation is such that the exposed surface is, to good approximation, a (111) plane.]

The influence of impurity contamination during deposition has been observed in two ways. First, it has been found that steps often appear to become complex in form, with oxide patches visible on the germanium seed, when undiluted helium is used as the carrier gas. This is probably due to deficiencies in removal of oxygen and water vapor from the helium and source materials.

Second, the problem of incipient doping of the gas stream with moisture has been observed even with hydrogen present, if the experimental procedure did not include preoutgassing of the iodine source. This effect of doping on step movement was observed qualitatively; after the iodine source temperature was increased, the steps moved at a lower rate than expected for the corresponding I_2 pressure. After sufficient time, about 20-30 min, normal step rate was generally resumed. The amount of H_2O in I_2 was small, for no oxide was visible on the seed. No evidence of oxide was observed on the source germanium at 500°C.

Experimental Results

Measurements of rate of step movement were made as a function of seed temperature, step height, GeI_2 pressure, carrier-gas flow rate, and gas composition.

The influence of step height on the rate of step movement was investigated under a variety of conditions. It was determined that at low iodide pressures steps of various heights (greater than 100Å) moved at the same rate, while under higher iodide pressures,

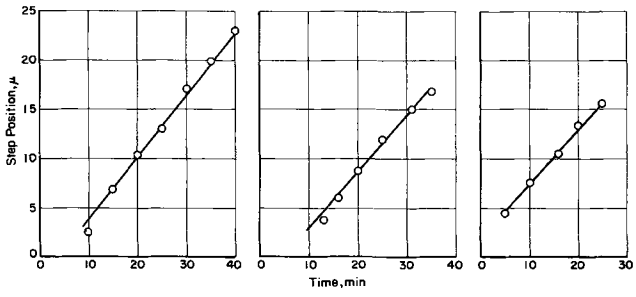

Fig. 4. Step movement for steps of varying height: hydrogen flow 1½ l/min; iodine source temperature 54°C; seed temperature 349°C.

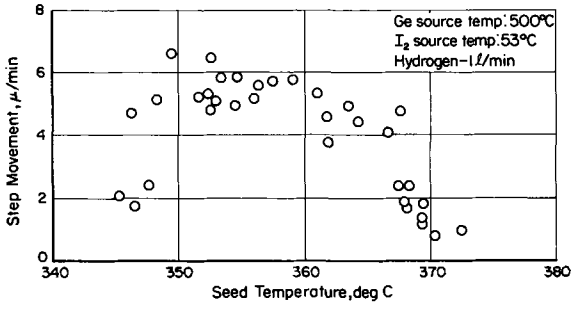

Fig. 5. Rate of step movement with seed temperature

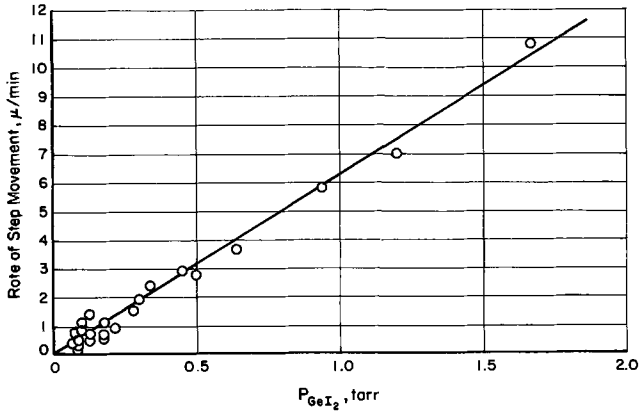

Fig. 6. Rate of step movement plotted as a function of experimentally obtained pressures of GeI_2. Germanium source at 500°C, germanium seed at 354°C, and hydrogen flow rate of 1 l/min.

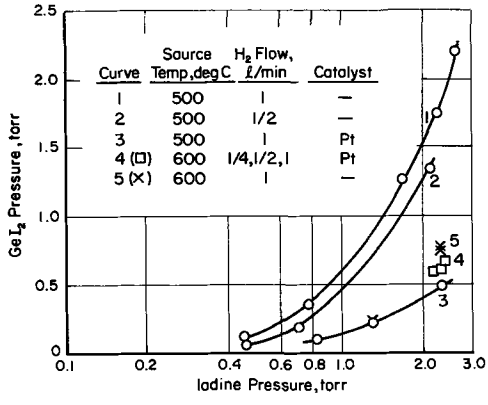

Fig. 7. Vapor pressures of GeI_2 obtained from the weight-loss experiments.

above 2 Torr, larger steps were measured to move at a rate as much as 50% faster than the small steps.

Figure 4 shows step position plotted against time, for three steps of different heights measured during one experiment, where the GeI_2 partial pressure was about 1.8 Torr. The differences in height as determined from contouring of the growth hills with interference fringes were estimated to be at least a factor of ten. The rate of step movement for the three steps is seen to be essentially independent of step height, the slopes varying from 3.0 to 3.1 μ/min, which is within the acceptable range of accuracy, 10%, for these measurements.

An extensive series of measurements was made of the variation of the rate of step movement as a function of seed temperature. These measurements were made at selected iodine pressures and with hydrogen and a mixture of hydrogen and helium as carrier gases. The results presented in Fig. 5, showing the rate of step movement *vs.* germanium seed temperature under the conditions given in the figure, are typical for this series of experiments. Measurable rates of step movement are seen to occur over a narrow temperature range. Changing the iodide pressure or the H_2/He ratio serves to alter the rate of step movement but does not influence the range of seed temperatures over which measurable step movement occurs.

An attempt was made to correlate step movement with the partial pressure of GeI_2, leaving the germanium source, by calculating the equilibrium pressure of GeI_2 under experimental conditions. However, when the results of the transpiration study (Appendix) were obtained, it became apparent that the partial pressures for the various gaseous species could not generally be calculated on the basis of equilibrium conditions, but rather the experimental pressures determined from weight-loss measurements were required. By selecting values for the experimentally determined GeI_2 pressure from curve 1 of Fig. 7, it was possible to replot step velocity (μ/min) *vs.* p_{GeI_2} (Torr), as shown in Fig. 6. The step rates had been determined with germanium source at 500°C, hydrogen flow rate of 1 l/min, seed temperature of 354°C, and with germanium and I_2 source beds equivalent to those used in the weight-loss study. The step velocity in Fig. 6 is seen to be a linearly increasing function of the GeI_2 pressure over the entire range of pressures studied, with possible small deviations at low pressures. Although these deviations at low pressure may be attributed to impurity effects, more likely causes are the variations in experimental conditions which occur during the long periods of time required to obtain step-movement data under low supersaturation.[2]

A cursory investigation of step movement as a function of hydrogen gas flow rate indicated that the rate of step movement increased with gas flow rates up to approximately 1 l/min. Above this flow rate, little increase in step rate was observed. This behavior is compatible with the transpiration results presented in Fig. 8, which showed that the GeI_2 pressure increased with increasing flow rate in the range 250-1000 cm³/min. Possible reasons for this effect are discussed in the Appendix.

Step movement studies complementary to the weight-loss work were performed by measuring step velocity under conditions which assured complete conversion to HI of all iodine entering the germanium source bed. This was accomplished by placing a quantity of platinum wool between the iodine and germanium source beds at a temperature in excess of 300°C. It was apparent from initial experiments in which the platinum catalyst was utilized that considerably less GeI_2 was produced than in similar experiments which did not include use of a catalytic agent. Step velocities were substantially depressed as compared with rates obtained under similar conditions (germanium source at 500°C, iodine source at

[2] Another possibility, suggested by the reviewer, is that the growth rate at seed is diffusion and/or mass transport controlled in the gas phase which can be minimized by increasing the flow rate.

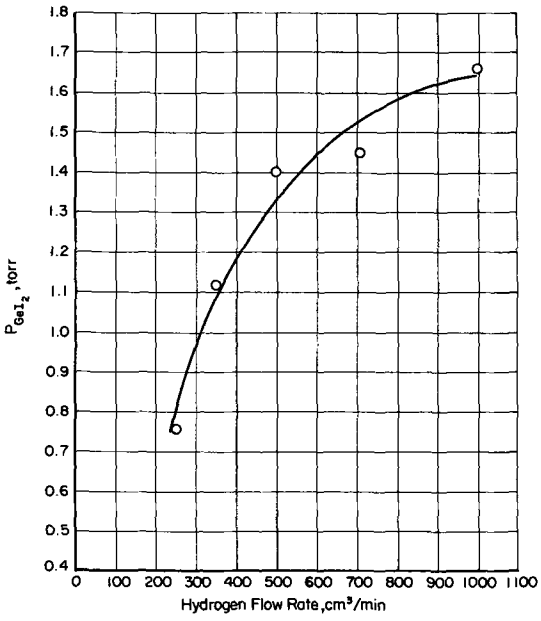

Fig. 8. Partial pressure of GeI_2 as a function of hydrogen flow rate.

50°C, hydrogen flow rate of 1 l/min, and seed at 354°C) but without a catalytic agent placed in the system. This result would be predicted from the data obtained in the weight loss-experiments. Comparison of curves 1 and 3 in Fig. 7 shows that the presence of platinum catalyst reduces the available GeI_2 concentration by a factor of four at iodine pressure corresponding to a source temperature of 50°C.

Discussion of Step-Movement Data

It was shown above that, under the conditions of these experiments, step velocity was independent of step height with low gas pressure and increased slightly with increasing height at high GeI_2 partial pressure. These results suggest that surface diffusion of adsorbed species to kink sites is not the rate-controlling process for growth since they are contrary to the behavior expected according to the BCF surface-diffusion-limited theory of crystal growth. It is suggested, rather, that in this study, the growth of germanium by dissociation of the diiodide is controlled by processes occurring directly at the step.

Calculation of the rate of impingement of GeI_2 molecules directly onto the growth step, based on typical conditions of $p_{GeI_2} = 1.0$ Torr with seed temperature of 354°C and step velocity of 6.2 μ/min shows that the rate of step movement can easily be accounted for by dissociation of those molecules which impinge directly on the step.

This suggestion is similar to that proposed for certain examples of whisker growth (8), in which case reaction is assumed to occur only at ledges on the tip where a spiral dislocation emerges. In the case of growth of copper whiskers by hydrogen reduction of CuI, it was assumed that reduction did not occur in the vapor phase, but that catalytic reduction of absorbed iodide occurred at the whisker tip. For the case of germanium growth, it may be supposed that the reaction at the growth step involves reduction

$$H_2(g) + GeI_2(g) \rightarrow Ge(s) + 2HI(g) \qquad [1]$$

or disproportionation

$$2GeI_2(g) \rightarrow GeI_4(g) + Ge(s) \qquad [2]$$

The step velocity has been shown to be directly proportional to the GeI_2 concentration (Fig. 6) as would be expected either from reaction [1] or [2], where, for example, the rate-controlling step may involve association of a GeI_2 molecule with one previously adsorbed on the step to yield germanium and the tetraiodide. It should be possible to distinguish between the predominance of reactions [1] or [2] by determination of rate of step movement at fixed GeI_2 pressure under varying hydrogen flow rates.

A number of factors may have contributed to limit the temperature range over which appreciable germanium deposition occurred. The results of some thermodynamic calculations (9) based on an assumed model for the experiment indicate that in the disproportionation reaction the pressure of GeI_2 becomes equal to its saturation pressure between 300° and 350°C, resulting in the formation of solid GeI_2. Therefore the inability to produce observable germanium growth below 345°C may have been due to a lack of available germanium in the gas phase at the lower temperatures. Furthermore, it was shown that under equilibrium conditions the amount of germanium (all species) in the gas phase for the system Ge-I_2-H_2 increases as the temperature is lowered from 500° to 323°C. This increase would have to be at the expense of the seed crystal. Of course, growth has been observed above 345°C, indicating that equilibrium is not achieved at the seed under the experimental conditions, but a tendency toward limited or negative growth at low temperature is suggested from the thermodynamic analysis.

Figure 5 shows that the rate of step movement approaches a pronounced maximum near 360°C, leveling off to gradually decreasing values above 370°C. This behavior may be explained in terms of the amount of germanium available for deposition, as determined in the thermodynamic analysis. Under equilibrium conditions the Ge/I_2 ratio at the seed temperature slowly approaches the value obtained at the source temperature (500° to 600°C) with increasing seed temperature. This might lead to the results obtained for seed temperatures above 370°C.

Although not explicitly discussed in the previous sections presenting details of the research, some attention should be given to the changes in appearance of growth features with increasing GeI_2 pressure. As the partial pressure of diiodide is raised, the small, straight steps are seen to become ragged, with large steps overtaking smaller ones. A possible explanation of this effect is that the steps become unstable because the concentration of unreacted GeI_2 on the surfaces is high enough for projections to be stable. Thus two-dimensional nucleation may be possible between the steps, leading to the formation of germanium crystallites and ragged growth. This observation of fundamental change in the growth mechanism is particularly significant in relation to the perfection of deposits. It is anticipated that films grown under conditions where nucleation occurs would have increased concentrations of crystalline defects such as stacking faults.

Summary and Conclusions

The low-temperature vapor deposition of germanium was studied by microscopic measurement of step movement as a function of iodide pressure, gas flow rate and composition, seed temperature, and growth-step height. In conjunction with the information obtained from a thermodynamic analysis and the source weight-loss study, these results obtained for rate of step movement were considered, and the following conclusions were reached.

1. The predominant stepped growth features observed on (111) planes were triangular pyramids. The hillocks were shown to be quite minor deviations from the (111) plane, the slope of the side for a typical pyramid being at most 1 in 30.

2. Generally, rate of step movement appears to be nearly independent of step height. Under high partial pressures of GeI_2 step velocity may increase with increasing step height. It is suggested that the rate of step movement depends on processes occurring directly at step sites rather than on surface diffusion of adsorbed species to the steps.

3. Step velocity has been shown to be directly proportional to $GeI_2(g)$ pressure, as would be expected from consideration of the reactions by which deposition might occur. From measurements of GeI_2 pressure *vs.* rate of step movement an estimate of the relation between impinging GeI_2 and rate of addition of germanium atoms could be made. It was found that the rate of step movement could be accounted for by dissociation of these molecules which are adsorbed directly on the step.

4. A maximum in rate of step movement has been found with the germanium seed temperature near 360°C, and observable step movement was detected in a narrow temperature range about this optimum temperature. This behavior was obtained for several different iodine pressures and carrier-gas compositions.

5. With increasing $GeI_2(g)$ pressure, small, straight growth steps were observed to change in appearance, first to dark bands, and then into ragged, nonlinear arrays. A possible explanation of this effect is that two-dimensional nucleation occurs on the epitaxial surface as the concentration of unreacted GeI_2 on the surfaces is increased.

APPENDIX

Transpiration Studies

In order to determine the operating conditions under which equilibrium is achieved in the open-tube flow system used in this work a transpiration study was initiated whereby weight-loss measurements were employed to determine the pressures of various gaseous species formed at the iodine and germanium sources for the system $Ge\text{-}I_2\text{-}H_2$. A number of studies of systems including $Ge\text{-}I_2\text{-}H_2\text{-}He\text{-}HI$ have been made (10-14), but the results of these studies are not necessarily applicable to the physical system employed in the present investigation. Measurements were made as a function of iodine and germanium source temperatures and gas flow rate.

Experimental Procedure

A technique for easy disassembly of the reaction train was required for an extensive program of weight-loss determinations. At the same time, it was desirable to maintain in the germanium and iodine source chambers the physical dimensions of the beds used in the step-movement study. The following arrangement proved satisfactory and was of sufficient simplicity to ensure a maximum number of transpiration experiments.

A U-shaped iodine source chamber was designed which could be immersed in a constant-temperature water bath containing a mechanical stirrer. Teflon stopcocks, placed on either side of the U-shaped chamber, could be fixed so that the incoming hydrogen, purified by the palladium-diffusion process, flushed the germanium source and bypassed the iodine charge during heatup. The problem of channeling in the iodine was minimized by the vertical position of the source and by vigorous shaking of the entire chamber after each run.

The container for the germanium source was a Vycor test tube, 2.6 cm in ID and 17.5 cm long. Gas flow through the bed was provided for by perforations in the closed end of the tube. The charge itself consisted of a uniform distribution of irregularly shaped particles whose weight varied from 0.2 to 2.0g. The packed chamber was placed, open end toward the iodine supply, within a close-fitting 30-mm quartz tube and pushed against a tapered section to form a seal. For some runs, to ensure complete conversion of I_2 to HI, platinum wool (fibers 0.001-0.004 in. in diameter) in the form of a plug 1.8 cm in diameter and 8.7 cm long was positioned between the iodine and germanium source beds and maintained at a temperature greater than 300°C.

A run consisted of bringing the source beds to the desired temperatures and allowing a known flow of purified hydrogen to pass through the system for a predetermined time. At the end of a run the hydrogen was allowed to bypass the iodine chamber, and the entire system was brought to room temperature. Both source beds were then weighed on a balance accurate to 1 mg with a 5-kg capacity.

Experimental Results and Discussion

The following assumptions were made in interpretation of results obtained from weight-loss measurements.

1. The formation of GeI_4 may be neglected for germanium source temperatures above 500°C, and therefore all germanium consumed at the source bed is in the form of GeI_2.
2. All iodine not associated with germanium reacts with hydrogen gas and leaves the germanium source as HI.
3. Partial pressures of GeI_2 and HI can be determined from the ideal gas equation.

The experimental variables include time, gas flow rate, germanium- and iodine-source temperatures, and the absence or presence of a platinum catalyst. It was found that in all cases the sum of the p_{GeI_2} and $\frac{1}{2}\, p_{HI}$ was approximately equal to the equilibrium vapor pressure of I_2 at various iodine source temperatures employed. This suggests that the equilibrium iodine concentration was removed from the iodine source bed for the various hydrogen flow rates used.

In Fig. 7, the partial pressure of the volatile halide, GeI_2, is plotted as a function of the iodine pressure for a series of experiments in which other variables were maintained at the values given in the figure. Curve 1 is drawn through points which represent data obtained with a germanium source at 500°C and a hydrogen flow rate of 1 l/min. The GeI_2 pressure is seen to be a rapidly increasing function of the iodine pressure under these conditions. A similar pressure dependence is observed when the hydrogen flow rate is reduced to ½ l/min as can be seen from examination of curve 2. It is noted, however, that when the flow rate is reduced to one-half of the previous value, lower GeI_2 pressures are obtained. Comparison of curves 1 and 3 reveals a dramatic decrease in GeI_2 formation (especially for high iodine pressures), when a platinum catalyst is placed in the reaction system. The number 4 represents data indicated by the squares. These were obtained with the germanium source at 600°C, a platinum catalyst in the system, and hydrogen flow rates of 1, ½, and ¼ l/min. Flow rate seems to have little influence on GeI_2 pressure

under these conditions. The points (x) designated by 5 are those resulting from data obtained with a source temperature of 600°C, flow rate of 1 l/min and no platinum catalyst in the system. The excellent agreement obtained for p_{GeI_2} from these two runs, and the lack of deviation of experimental points from curves 1, 2, and 3 of Fig. 7 are a measure of the reproducibility of the weight-loss measurements.

The following observations can be made from examination of the experimental data presented in Fig. 7.

1. It is evident that H_2-I_2-HI equilibrium is not achieved under the conditions represented by curves 1 and 2 when compared with curve 3, which represents the case where an active catalyst is known to convert all of the I_2 to HI. Thus, for cases 1 and 2, a large amount of free iodine vapor is allowed to enter the germanium source chamber and react to form GeI_2.

2. From comparison of curves 1 and 2 it would appear that germanium is a poor catalyst for the reaction $H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$ at 500°C. Lowering the flow rate to increase the residence time of the gaseous species over the germanium bed has little effect on the amount of GeI_2 formed.

3. The formation of GeI_2 is critically dependent on iodine pressure for the conditions represented by curves 1 and 2. For an iodine pressure of 2 Torr, the pressure of GeI_2 formed changes by 0.1 Torr for a 2°-change in iodine source temperature. This factor may be an important cause of fluctuations in step-movement measurements, although inconstancy of supply of iodine vapor due to channeling in the iodine bed may also be a significant factor here.

4. From examination of curve 3, it is seen that formation of GeI_2 is less sensitive to variations in iodine pressure when a platinum catalyst is employed in the system. However, the transport efficiency, in terms of GeI_2 formed, is considerably reduced when complete conversion of free iodine to HI is accomplished. Thus, for a system using hydrogen as a carrier gas, transport of germanium is increased with increasing free-iodine concentration, but the more rapid step movement which results may be obtained at the expense of reproducible crystal growth rates.

5. Weight-loss measurements from runs with the germanium source at 600°C and a platinum catalyst present show that a higher yield of GeI_2 is obtained as compared with that obtained in similar experiments in which a lower germanium source temperature was employed (compare 3 and 4 in Fig. 7). This result is attributed to an increase in reaction rate with increasing temperature for

$$2HI(g) + Ge(g) \rightleftharpoons H_2(g) + GeI_2(g) \qquad (A)$$

It has already been mentioned that flow rate has little effect on GeI_2 formation at 600°C. Furthermore, comparison of 4 and 5 in Fig. 7 indicates that presence of a platinum catalyst has little influence on GeI_2 formation at 600°C. Thus it may be tentatively concluded that for hydrogen flow rates less than 1 l/min and iodine pressures below 2.5 Torr, equilibrium is achieved at 600°C for the system Ge-I_2-H_2-HI.

In Fig. 8, the partial pressure of the volatile halide, GeI_2, is plotted as a function of hydrogen flow rate for a series of experiments in which the germanium source was held at 500°C while the iodine source was maintained at 50°C. It is seen that the GeI_2 pressure is strongly dependent on gas flow rate over the range 250-1000 cm^3/min and that the experimental partial pressure of GeI_2 tends to level off as the flow rate is increased.

It is believed that these results may be explained in terms of the equilibrium or lack of attainment of equilibrium in the open-tube flow system employed in this study. At the lowest carrier-gas flow rates (lower than those employed in this study), it is presumed that the reaction of hydrogen with iodine to form hydrogen iodide goes nearly to completion. Then the reaction controlling the formation of GeI_2 at the germanium source is given by

$$2HI(g) + Ge(s) \rightleftharpoons GeI_2(g) + H_2(g) \qquad (B)$$

as discussed above. Thus, for some range of low carrier-gas velocities it is expected that the partial pressure of GeI_2 formed will be independent of flow rate.

Increasing the hydrogen flow rate decreases the residence time for the carrier gas over the sources with the result that the reaction

$$H_2(g) + I_2(g) \rightleftharpoons 2HI(g) \qquad (C)$$

does not go to completion. In this case a quantity of free iodine is available for direct reaction with germanium to form GeI_2 according to

$$Ge(s) + I_2(g) \rightleftharpoons GeI_2(g) \qquad (D)$$

Thus the partial pressure of GeI_2 is found to increase with increasing flow rate in some intermediate range of hydrogen flow rates, which includes those given in Fig. 8.

Finally, at very high flow rates (somewhat above 1 l/min), the hydrogen acts simply as an inert carrier in the system and the partial pressure of GeI_2 formed might approach that of the elemental iodine formed at the iodine source, 2.18 Torr. Complications may be introduced at high carrier-gas flows, however, if the equilibrium concentration of iodine is not removed from the iodine source, or if some germanium leaves the germanium source as GeI_4.

Technical Notes

Segregation Coefficients of the Rare Earth Niobates in $CaMoO_4$

L. H. Brixner

Pigments Department, Experimental Station,

E. I. du Pont de Nemours & Company, Inc., Wilmington, Delaware

In an earlier paper (1), the segregation coefficients of the $LnNbO_4$-type rare earth niobates have been reported for the $SrMoO_4$ host. Because of the deviation of the ionic radii of the smaller rare earths from that of Sr^{+2}, only a limited number of single crystals could be grown. Since none of the rare earth ion radii (except Sc^{+3}) deviates more than 15% from that of Ca^{+2}, all rare earths should fit substitutionally in the calcium site in $CaMoO_4$; therefore a more complete study of their distribution characteristics can be done in this host. Nassau (2) has already incorporated the rare earths in $CaWO_4$, using both $LnNa(WO_4)_2$ as well as $Ln_2(WO_4)_3$ as dopants, and a limited list of segregation coefficients for some $LnNbO_4$ compositions in $CaMoO_4$ has been reported (3).

This note reports the distribution coefficients of all rare earth niobates in $CaMoO_4$ and points out some relationships of these parameters as a function of the ion size deviation from that of the host. In addition, some previously unreported absorption spectra and structural parameters are presented.

All crystals were grown by the Czochralski technique. Particular care was taken to keep the pulling speed (½ in./hr), the rotation rate (20 rpm), and the shape of the crystal (½ in. diameter, c-axis) as identical as possible from run to run. Generally, 50 ± 5% of a 100g charge was grown into single crystalline material. The rare earth niobates were charged in the form of their constituent components according to

$$0.99CaMoO_4 + 0.005Ln_2O_3 + 0.005Nb_2O_5 \rightarrow$$

$$Ca_{0.99}Ln_{0.01}Mo_{0.99}Nb_{0.01}O_4$$

Since the segregation coefficient for all rare earth niobates in $CaMoO_4$ is greater than 1, this resulted in an actual rare earth concentration of slightly more than 1 mole % in the growth crystal.

All analytical information was obtained by x-ray fluorescence techniques. The analytically determined ratio of Ln_2O_3:Nb_2O_5 in no case fell below 1:0.95 or exceeded 1:1.15. No particular trend or shift of this ratio as a function of growth rate could be detected (it went up in 6 cases, down in 8, and stayed the same in 1); therefore, the stoichiometry of the rare earth niobates in $CaMoO_4$ fluctuates only slightly around the theoretical 1:1.00 ratio. The computed segregation coefficients, together with the ion size deviation and the color of the crystals, are summarized in Table I. We can see that Sc^{+3} is the only element which deviated in size more than 15% from Ca^{+2}, and repeated attempts to grow a single crystal with Sc^{+3} invariably failed. The only crystal in this series differing in color from those of the $SrMoO_4$ group was that containing Ce, which had a much more intense color. Although it is not reflected in the value of the segregation coefficient, it is suspected that in the $CaMoO_4$ host an even higher concentration of Ce^{+4} is present than in $SrMoO_4$. Due to the fact that the Ce^{+4}/Ca^{+2} difference (0.05Å) is smaller than the Ce^{+3}/Ca^{+2} (0.08Å) difference, it could be understood how some Ce^{+4} is stabilized in the Ca^{+2} site. The best qualitative colorimetric technique (4) failed, however, to show the presence of Ce^{+4}. In an ESR experiment, the crystal did exhibit strong paramagnetic absorption, indicating the presence of a predominant amount of Ce^{+3}. In the europium case, the crystal again grew deep red, but was readily oxidized to the colorless trivalent state of Eu^{+3}. This in sharp contrast to the $SrMoO_4$ case where such an oxidation was impossible. The $EuNbO_4$ segregation coefficient deviates significantly in the direction of larger ions (because of Eu^{+2} content) as can be seen in Fig. 1. All other rare earth niobates fall on the curve in Fig. 1 within the analytical error of the determination of k. This error was taken as the maximum deviation experienced in many repeated analyses on the same as well as on different crystals grown under the same conditions. It corresponds to ±0.02 points of k or roughly ±2%. Basically, the top part of the curve corresponds to the plot presented earlier (1) for the $SrMoO_4$ case. However,

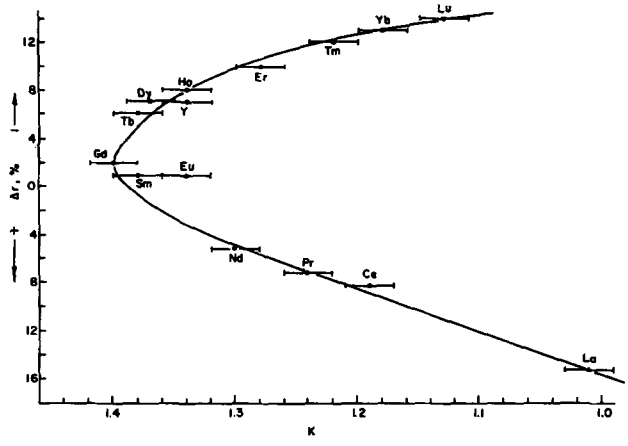

Fig. 1. Segregation coefficients, k for $LnNbO_4$ in $CaMoO_4$ as a function of differential cation radii.

since in the $CaMoO_4$ case we have an almost equal number of rare earths deviating on the positive side of Ca^{+2}, the lower part of the curve is new. Fundamentally, this plot reflects the fact that the rare earths with the best fit (near 0 deviation in the curve) exhibit the largest segregation coefficient,[1] $k = c_s/c_l$, since the solubility in the solid, c_s, is greatest. Deviation to either side decreases the solubility in the solid and results in a smaller k. Although this relationship was by no means evident from the few segregation coefficients reported in (3), the agreement with those earlier data is fairly good. If one examines Nassau's (l.c.) data in view of this relationship, one can also detect the same curve, although on first glance the data seem to reflect only scatter around a basic number. The three key points, Lu, Sm, and La, are in good agreement and show the same spread of k on a different scale (0.23, 0.50, 0.22 as compared to 1.13, 1.38, 1.01).

The greatest difference compared with the $SrMoO_4$ series is the fact that all segregation coefficients in $CaMoO_4$ are greater than 1. This prompted us to study some mixed Ca-Sr molybdates as hosts for Nd^{+3} only. Four crystals were grown with the host composition $Ca_{0.99-x}Sr_xMo_{0.99}Nd_{0.01}Nb_{0.01}O_4$, where x varied from 0.195, 0.09, 0.04 to 0.01. In the first case, the crystal melted 50°C under the normal melting point of 1490°C, indicating the formation of a eutectic. It also cracked repeatedly. The segregation coefficient for $NdNbO_4$ was 0.68. The second crystal also cracked and gave a segregation coefficient of 1.31. The third and fourth grew without cracking and gave segregation coefficients of 1.35 and 1.27, respectively. Since the segregation of Sr^{+2} in these mixed hosts is opposite to that

[1] The segregation (or distribution) coefficient k is defined as the ratio of the concentrations of the active (or impurity) element in the solid (c_s) over the concentration in the liquid (c_l).

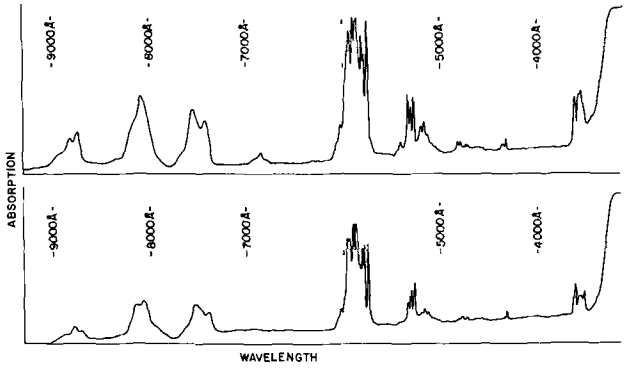

Fig. 2. Absorption spectra of $Sr_{0.01}Ca_{0.98}Nd_{0.01}Mo_{0.99}Nb_{0.01}O_4$ (top) and $Ca_{0.99}Nd_{0.01}Mo_{0.99}Nb_{0.01}O_4$ (bottom).

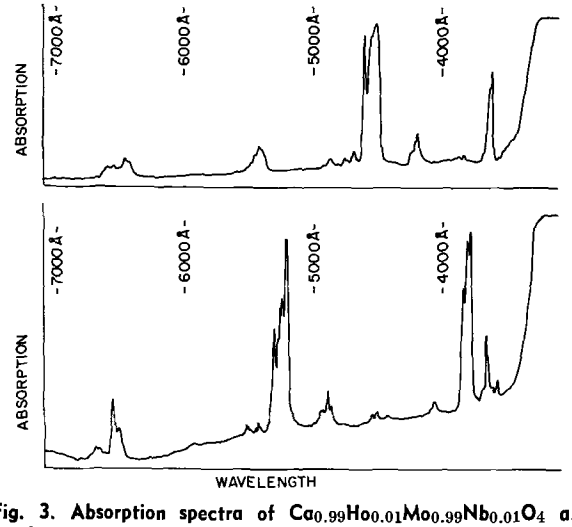

Fig. 3. Absorption spectra of $Ca_{0.99}Ho_{0.01}Mo_{0.99}Nb_{0.01}O_4$ and $Ca_{0.99}Er_{0.01}Mo_{0.99}Nb_{0.01}O_4$.

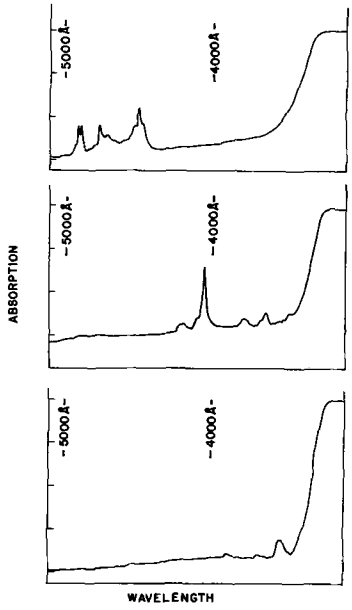

Fig. 4. Absorption spectra of $Ca_{0.99}Pr_{0.01}Mo_{0.99}Nb_{0.01}O_4$, $Ca_{0.99}Sm_{0.01}Mo_{0.99}Nb_{0.01}O_4$, and $Ca_{0.99}Dy_{0.01}Mo_{0.99}Nb_{0.01}O_4$.

of both Nd^{+3} and Nb^{+5}, the only advantage we can see is in a more perfect valence compensation throughout the length of the crystal as indicated by a Nd_2O_3:Nb_2O_5 ratio of 1:0.98 on top and 1:1.04 on the bottom of a 3-in. crystal. It is also interesting to note that despite the small concentration of Sr^{+2} in $Ca_{0.98}Sr_{0.01}Nd_{0.01}Mo_{0.99}$-$Nb_{0.01}O_4$ the crystal had the more reddish-blue color typical of the pure $SrMoO_4$ host. This difference can easily be seen in a comparison of the absorption spectra in Fig. 2. All spectra were determined at room temperature on single crystal slices, 0.25-0.50 mm thick. A CARY Model 14 spectrograph was used with a standard scanning speed of 25 Å/sec. Figures 3 and 4 represent the absorption spectra of the other colored rare earths. The rest of the crystals were colorless with a u.v. cut-off at 0.33μ, except the cerium sample which cut-off at 0.43μ. All spectra were run up to 2.1μ in the infrared and the noteworthy absorption characteristics are summarized in Table II.

In a structural characterization, we determined the lattice parameters of the top portions of an undoped $CaMoO_4$, a $LaNbO_4$, and a $LuNbO_4$ doped crystal. These data are summarized in Table III. The small parameter and cell volume differences reflect the size changes due to the two rare earths differing most from Ca^{+2} toward each extreme.

In summary, we can state that the Ca^{+2} site in $CaMoO_4$ afforded a unique opportunity to study the substitution characteristics of all rare earths whose ion radii deviate just about up to ±15% to either side of the calcium ion radius. The segregation coefficient for

the $LnNbO_4$ compounds in $CaMoO_4$ does not show a direct dependence as a function of the Ln^{+3} ion size, but rather goes to a maximum at the point of least deviation from the host ion's size and decreases again as the deviation proceeds in the opposite direction. Knowledge of this behavior and the establishment of the dependence in a graphical plot will permit predicting segregation coefficients of any one Ln^{+3} ion in the Ca^{+2} site of the $CaMoO_4$ host. In other hosts, the determination of k for 2 or 3 key compositions should therefore also permit the prediction of the segregation coefficient of all the other rare earths.

Carrier-Concentration Profiles of N-Type Sn and Te Doped Epitaxial GaAs Films

R. R. Moest and D. T. Lassota

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Carrier concentration profiles of n-type doped epitaxial GaAs films grown by the HCl/H_2 transfer technique have been studied. The growth system is the same as reported earlier for the growth of undoped films (1). Because of the anomalous results obtained on {111} oriented substrates with undoped epitaxial films, the substrates used in this study were almost exclusively (100) oriented. The GaAs substrates had net carrier concentrations of 2 x 10^{18} and 6 x 10^{18} as determined by Hall measurements and were Te- or Se-doped, respectively. Only readily available Te- or Sn-doped GaAs source material was used with the net carrier concentration ranging from 2 x 10^{16} to 5 x 10^{18}. The carrier concentration profiles in the films were determined by the differential capacitance-voltage method on gold surface barrier diodes (1, 2).

Results

The surfaces of the epitaxial films were microscopically smooth and free of growth patterns and were obviously not affected by the high impurity concentration of the films. The net carrier concentrations of the doped films depend on the concentration as well as on the kind of dopants in the source material: tin or tellurium.

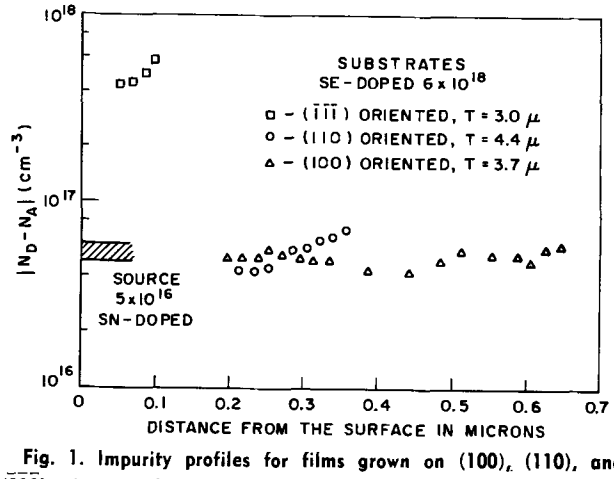

Fig. 1. Impurity profiles for films grown on (100), (110), and (1̄1̄1) oriented substrates from 5x10^{16} Sn-doped source.

Sn-*doped* GaAs *source*.—The Sn-doped GaAs source materials used in these experiments had net carrier concentrations of 5 x 10^{16}, 2 x 10^{17}, 3 x 10^{18}, and 5 x 10^{18}. Initially some epitaxial films were grown on n^+-type substrates of (1̄1̄1) and (110) orientations from 5 x 10^{16} Sn-doped source material. Results are shown in Fig. 1. The impurity profile for the (100) film at approximately 5 x 10^{16} is essentially flat over the thickness measured. The impurity concentration of the (1̄1̄1) films is well above the level of the dopant concentrations of the source material and is identical with the anomalous profiles obtained from undoped source material, observed in a previous study (1). Figures 2B, 3A and 2A show impurity profiles of (100) films grown from different source materials: tin doped 2 x 10^{17}, 3 x 10^{18}, and 5 x 10^{18}, respectively. The data scattering on films with impurity concentrations above 2 x 10^{18}, as indicated in Fig. 2A and 3A, are due to the rather poor quality of the surface barrier diodes on such highly doped material. Figures 3A and 3B show

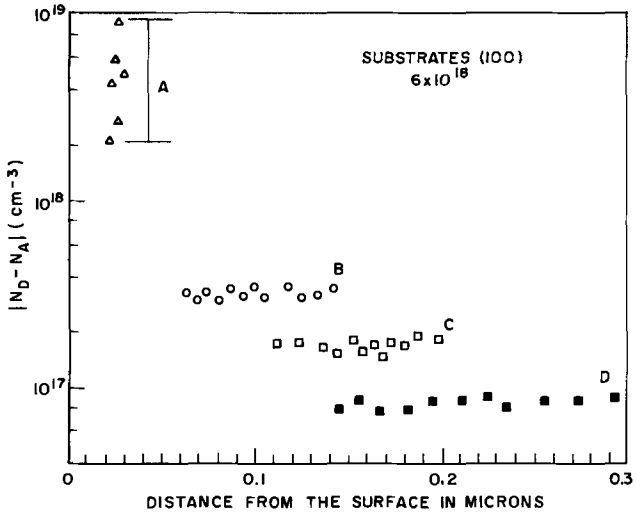

Fig. 2. Impurity profiles for films grown on (100) Se- or Te-doped substrates from different sources: A, GaAs, Sn-doped 5x10^{18}; B, GaAs, Sn-doped 2x10^{17}; C and D, GaAs, Te-doped 2x10^{18}. C = upstream, D = downstream sample.

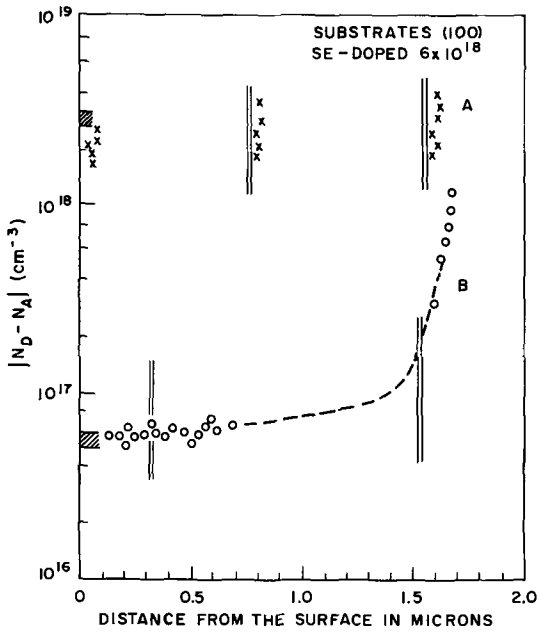

Fig. 3. Impurity profiles for films grown on (100) oriented substrates from A, GaAs, Sn-doped $3x10^{18}$; B, GaAs, Sn-doped $5x10^{16}$.

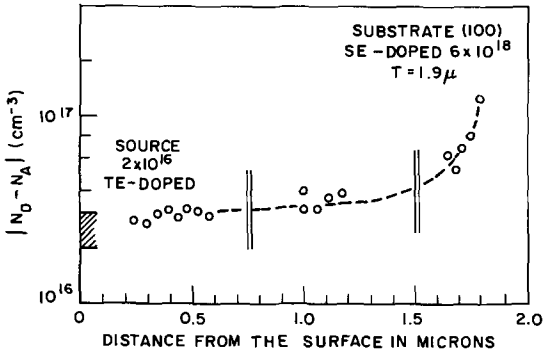

Fig. 4. Impurity profile for step etched (100) film grown from $2x10^{16}$ Te-doped source.

the impurity profiles of Sn-doped films after step etching. Several terraces had been etched in the epitaxial films prior to the evaporation of 10 mil gold dots. The results in Fig. 3A indicate that, within the accuracy of the measurements, the doping concentration remains fairly constant throughout the thickness of the epitaxial films. For all tin-doped source material studied with carrier concentrations from 5 x 10^{16} to 5 x 10^{18}, the experimental results indicate a net carrier transfer ratio of 1:1.

The reverse bias breakdown voltages for 10 mil diameter surface barrier diodes varied with the doping level of the film; 10v for 5 x 10^{16}, 3-4v for 2 x 10^{17}, and 0.7-1.5v for 5 x 10^{18} were measured on 2-3μ thick (100) films.

Te-*doped* GaAs *source*.—The Te-doped GaAs source materials had net carrier concentrations of 2 x 10^{16}, 5 x 10^{16}, 2 x 10^{17}, 4 x 10^{17}, and 2 x 10^{18}. Only (100) oriented substrates were used and the results of these experiments are shown in Fig. 2C, 2D, 4, 5, 6, and 7. Figures 4 and 5 depict the doping profiles of films grown from 2 x 10^{16} and 5 x 10^{16} Te-doped source materials, respectively. Within this doping range, an impurity transfer ratio of approximately 1:1 is observed. However, a downstream impurity depletion in the GaAs deposition zone becomes noticeable. This effect is also observed with Sn-doped source material although not to such an extent.

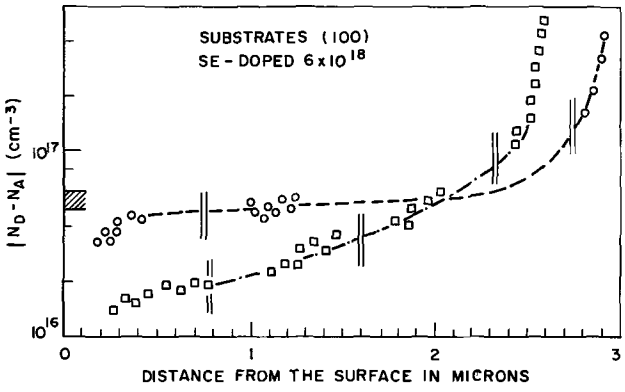

Fig. 5. Impurity profiles for step etched (100) films grown from $5x10^{16}$ Te-doped source.

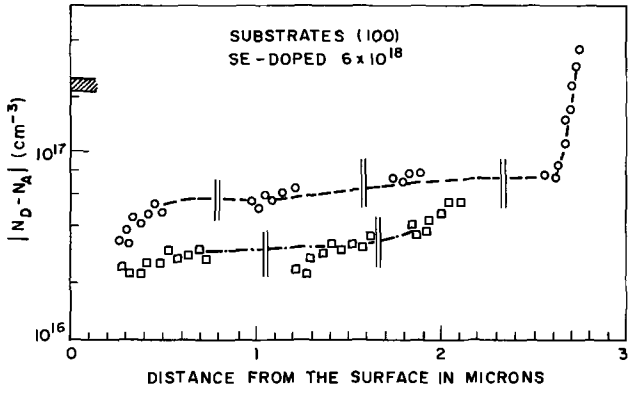

Fig. 6. Impurity profiles for step etched (100) films grown from $2x10^{17}$ Te-doped source.

Figures 5, 6, 2C and 2D show the respective impurity profiles for pairs of substrates positioned less than 1 cm apart from each other and at a uniform temperature of 750° ± 3°C. The impurity profiles of the upstream substrates appear generally flat whereas the downstream samples seem to have more graded doping profiles. The film-substrate interfaces are abrupt and approach an infinite slope, even on downstream samples. The downstream dopant depletion effect becomes noticeable even on single, large wafers exceeding the usual substrate size of approximately 1 cm^2. In these cases, it has been observed that the film doping level was higher on the upstream and lower on the downstream portion of one wafer. This effect is again much more pronounced with Te- than with Sn-doped source material.

The Te-doped films were step-etched as described earlier; in Fig. 4, 5, 6, and 7 these terraces are indicated by double bars intersecting the impurity profiles. If the Te-doping concentration of the source material exceeds approximately 1 x 10^{17}, the apparent impurity transfer ratio changes and less tellurium seems to be transferred to the substrates. This effect is demon-

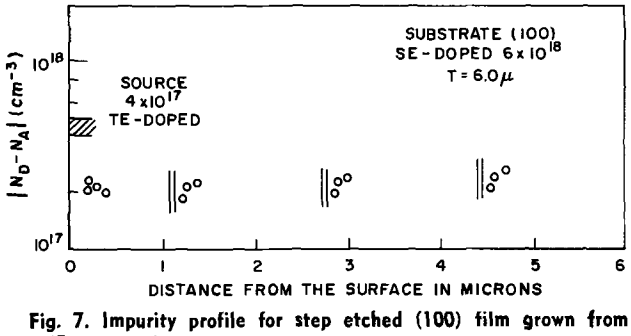

Fig. 7. Impurity profile for step etched (100) film grown from $4x10^{17}$ Te-doped source.

strated by the profiles in Fig. 6, 7, 2C and 2D. It appears that a maximum doping transfer of tellurium is approached at approximately 2 x 10^{17}, even if the Te concentration of the source material is as high as 2 x 10^{18}. This result is vastly different from the one observed with Sn-doped source material where the apparent transfer ratio of 1:1 is maintained up to a carrier concentration of approximately 5 x 10^{18}.

The maximum net carrier concentration for Sn-, or Te-doped, pulled, or boat grown GaAs is approximately 5 x 10^{18} (3). This imposes an upper limit for the impurity concentration of the epitaxial films grown from Sn-doped GaAs source material. Williams (3) reported, however, that net carrier concentrations of 1 to 2 x 10^{19} can be obtained in epitaxial films by using elemental Sn, Te, or Se as dopants in a stream of HCl at elevated temperatures. For films with carrier concentrations higher than those reported in this paper, the use of additional dopants is necessary.

ELECTROCHEMICAL SCIENCE

A Coulogravimetric Study of the Sintered Silver Electrode in 1 Molar Potassium Hydroxide

A. Langer and J. T. Patton

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Weighing of a sintered silver electrode while immersed in electrolyte during cathodic and anodic reaction reveals breaks in the weight change-coulomb curves. The different slopes can be explained by the volume change during phase transformation, affecting the buoyancy of the electrode. These breaks coincide with the potential changes of the plate, measured against a reference electrode.

The silver electrode in alkali electrolyte has gained considerable prominence in the construction of batteries offering high discharge rates and high energy densities per unit weight and volume. The outstanding properties of this electrode have long been recognized (1-4), but a complete understanding of its behavior is still lacking (5,6). Moreover, since efficient electrodes are usually of the porous type, an exhaustive interpretation of their behavior requires an understanding of the many factors affecting this type of electrode. Among these are the expansion and contraction of the active mass.

This volume change affecting the buoyancy is studied by weighing continuously the porous silver electrode in 1.0M potassium hydroxide as electrolyte during the complete cathodic and anodic cycle. Simultaneously, the corresponding number of coulombs involved is determined, and the potential of the electrode is recorded against a suitable reference electrode and correlated with the change in weight. A similar procedure was used by Schoop (7) at the turn of the century, but it has not been practiced frequently since (8, 9).

Theory

If a silver plate suspended in the electrolyte is oxidized anodically to silver oxide, the change in the weight of the immersed electrode is the algebraic sum of several related effects, principally (*i*) a weight increase due to the added mass of reacted oxygen, and (*ii*) an altered buoyancy lift due to the volume change of the electrode by the newly formed compound. There is still another factor affecting the buoyancy of the sample considered to be minor. The density of the electrolyte around the electrode is changing, due to the consumption of ions at the interface and the heat that is generated by the passage of the current.

In the following discussion we assume that minor effects can be neglected, provided low current densities are used, so that concentration differences in the electrolyte are small since equalized by diffusion. Additionally, for these conditions, the density gradients are not large enough to produce convection of the electrolyte which may still further influence the weight of the sample. The reaction must be carried out at potentials where no gas evolution will occur since small bubbles formed in or adhering to the electrode will alter its true weight. We also assume that the reaction products are only sparingly soluble in the electrolyte.

Under these conditions we can derive an equation for the weight change of the electrode in the electrolyte. Let a mass of silver m_{Ag} and density d_{Ag} be immersed in a liquid electrolyte of density d_s. The weight of the silver in the solution $m_{Ag}{}^s$ will be

$$m_{Ag}{}^s = m_{Ag}\left(1 - \frac{d_s}{d_{Ag}}\right) \quad [1]$$

If the silver is converted to an oxide, for example AgO, the weight of the oxide in the electrolyte will be

$$m_{AgO}{}^s = m_{AgO}\left(1 - \frac{d_s}{d_{AgO}}\right) \quad [2]$$

If the metal were oxidized and weighed in air, the weight increase would be

$$m_{AgO} - m_{Ag} = m_O \quad [3]$$

or simply the mass of oxygen reacted with the specimen. In the electrolyte we will register a change m^s due to both mass increase and volume change, given by the equation

$$m^s = m_{AgO}\left(1 - \frac{d_s}{d_{AgO}}\right) - m_{Ag}\left(1 - \frac{d_s}{d_{Ag}}\right) \quad [4]$$

In an electrochemical process without any side reaction, the mass of the reaction products produced by a current I in a time t is given by Faraday's law

$$m = \frac{It\,M}{nF} = Eq \cdot Q \quad [5]$$

Here $Q = It$ is the number of coulombs passed, $Eq = (M/nF)$ is the electrochemical equivalent of the species of molecular weight M, F is the Faraday, and n is the number of electrons per molecule taking part in the reaction. A line should result if the weight change m^s of the electrode in the electrolyte is plotted against the number of coulombs used. The slope of this line can be expressed by substituting [5] into [4]

$$\frac{m^s}{Q} = Eq_{AgO}\left(1 - \frac{d_s}{d_{AgO}}\right) - Eq_{Ag}\left(1 - \frac{d_s}{d_{Ag}}\right) \quad [6]$$

If a constant reaction rate is maintained by charging (or discharging) the electrode with a constant current, then Q is calculated by measuring the elapsed time.

In cases where the density of the electrolyte is not altered, a change in the slope of m^s *vs.* Q represents a variation in the density of the active mass formed. Information can be obtained concerning the density of the products by utilizing Eq. [6] and the experimentally determined value of the slope.

Electrode Reactions

Ever since the earliest investigations on the silver electrode, it has been apparent that charging and discharging processes in an alkaline solution proceed in steps that have been associated with the formation of the oxides Ag_2O and AgO.

The formation of these oxides seems to be well established and verified by x-ray diffraction (10-13)

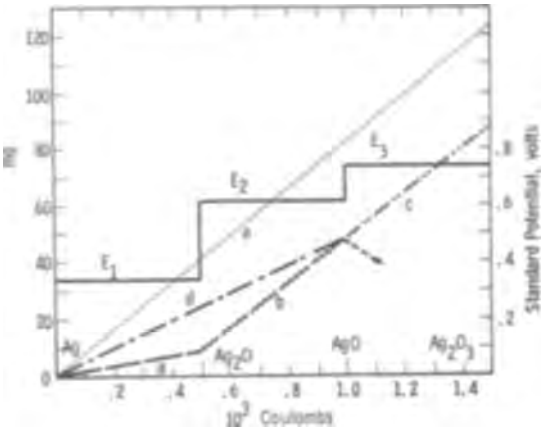

Fig. 1. Ideal weight change-coulomb relations, silver electrode of 10^3 coulomb total capacity.

Reaction	Weighing in electrolyte $d_s = 1.050$ line	slope mg/kQ	Weighing in air line	slope mg/kQ
$2Ag + ½ O_2 \rightarrow Ag_2O$	a	18.4	e	82.9
$Ag_2O + ½ O_2 \rightarrow 2AgO$	b	78.2	e	82.9
$Ag + ½ O_2 \rightarrow AgO$	d	48.0	e	82.9
$2AgO + ½ O_2 \rightarrow Ag_2O_3$	c	—	e	82.9

although the true nature of the AgO is still disputed (14). It has been shown that AgO can take up additional oxygen electrochemically (15). However, in the charging process, oxygen gas is liberated on the electrode after the AgO level has been reached. Other reactions of the silver electrode have been advanced (16, 17), especially the direct conversion of silver to AgO, but their importance is not well established. The main reactions are accompanied by definite potential plateaus.

Using the density of the involved species, $d_{Ag} = 10.5$, $d_{Ag_2O} = 7.14$, and $d_{AgO} = 7.44$ g/cm^3 (18), in Eq. [6], and assuming that silver will convert first completely to the Ag_2O oxide of bulk density and then completely again to AgO, we can calculate the weight change curves. Figure 1 represents the idealized theoretical behavior of a silver plate of 10^3 coulombs (1 kQ) total capacity up to the AgO level. The plate is immersed in approximately 1.0M KOH electrolyte of density $d_s = 1.050$ at room temperature.

Line a represents the weight increase of the electrode for formation of Ag_2O. Because of the large difference in density between silver and this oxide, there is a considerable buoyancy correction, causing the slope m^s/Q to be 18.4 mg/kQ, rather than the 82.9 mg/kQ slope that would be obtained if the weighing were performed in air. The weight change curve in air is represented by line e. As the oxidation proceeds from Ag_2O to AgO, the change in density should be relatively small, resulting in only a minor buoyancy influence. The calculated slope of 78.2 mg/kQ, as represented by line b, is therefore almost parallel to the line representing the weighing in air. The possible weight change curve for formation of Ag_2O_3 cannot be predicted with any certainty since the density of the compound is unknown. In case silver is directly converted to the AgO, the weight increase should follow line d with a slope of 48 mg/kQ.

The potential-coulomb curve should follow lines E_1-E_3, representing the standard potentials of the reactions. In actual charging E_c and discharging E_d, the effect of overvoltage for the particular current density must be considered.

How an actual sintered electrode follows this predicted scheme was tested on the following experimental arrangement.

Experimental

The apparatus used is shown schematically in Fig. 2. It consists of an analytical balance, with small mercury-filled cups attached to the balance support and to one of the pans. Platinum wires, fastened to the middle and end of the balance beam, were bent to dip very slightly into the mercury. In this way, electrical connection could be maintained through the balance arm without impairing its free movement. The automatic weighing was done with a permanent magnet and solenoid restoring element, balanced by a dual photocell (19). The weight change was recorded on a pen recorder. The speed of the recording paper (1 in. in 10 min) gave the time base for the reactions studied. The sensitivity was adjusted so that 1 mg gave ½ in. on the chart. Weight fluctuations due to amplifier noise were about 0.2 mg.

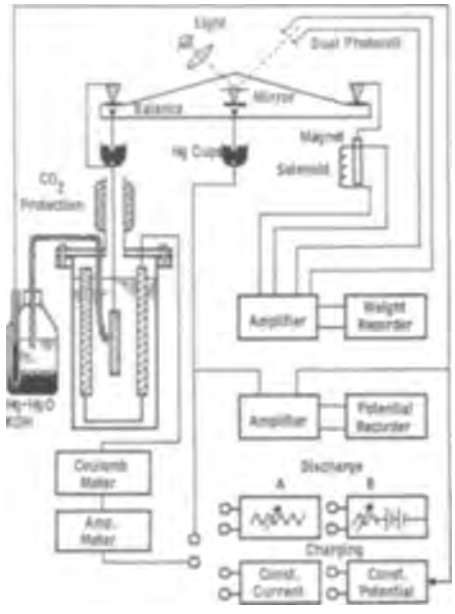

Fig. 2. Continuous coulogravimetric arrangement

The electrodes were enclosed in a plastic box with a small opening for the wire suspending the working electrode. The wire was also passed through an attached perforated tube surrounded by solid KOH. It was hoped to minimize in this way the influence of atmospheric CO_2 on the electrolyte, as carbon dioxide seems to affect adversely the extended operation of silver electrodes. As the negative electrodes, two commercial sintered cadmium plates were used; each was about 5 times the physical size of the silver electrode. The cadmium electrodes were wrapped in two layers of wettable cellophane of the type used to wrap silver electrodes. This was done to retard the possible deposition of silver on these plates. An external 1.0M KOH mercury-mercury oxide electrode was used as reference. The capillary was made of polyethylene tubing filled with a purified asbestos string. The potential was recorded by a high impedance chart recorder driven synchronously with the weight recorder.

The current passed through the cell was registered on a calibrated multirange ampere meter. An ampere-hour meter (Danubia-Wien, Austria), accurate to 0.001 amp-hr, was used as a check, to record the total number of coulombs. Reversing switches were used to operate these instruments during charge and discharge cycles.

The electronically regulated, constant-current power supply allowed charging currents up to 400 ma. The constant current discharges were made by manually regulating the current with a decade resistance box. To obtain very deep discharge, or to help stabilize the discharge current, a 12v storage battery was sometimes used in series with the test cell.

The working electrode consisted of a piece of sintered silver plate, cut to about 3.1 x 3.1 cm and 0.05 cm thick, and attached to the balance by a silver wire. As an electrolyte, a 1M solution was prepared from

chemically pure KOH and boiled water that had been cooled under N_2. Although the solution was handled as little as possible in air, it could have absorbed unknown amounts of CO_2. All experiments were performed at about 25°C with some shielding against light.

Results

Before proceeding with the experiments, the validity of Eq. [1] was tested by electroplating copper from a copper sulfate solution onto a copper strip. The corrected weight in the electrolyte, the weight in air after washing and drying, and the weight calculated from the number of coulombs all agreed within 2%.

The assumption that the electrolyte in the pores and around the electrode interchanges rapidly with the bulk of the solution was tested in the following way. An approximately 4 x 4 cm, 0.05 cm thick, sintered and previously cycled silver plate was first fully charged and then drained at the Ag_2O voltage plateau, using discharge rates ranging from 20 to 200 ma for the whole plate. Figure 3 shows straight sections of different slopes in the weight loss-time coordinate system. For the same number of coulombs passed, the weight loss was equal for all of the current densities used. This result indicates that no appreciable concentration polarization could occur at these current densities, and that there was no deficiency in transport of the proper ions to sustain the reaction. This conclusion was also substantiated by the observation that the different rates were established without any noticeable time delay on the graphs.

To verify that the Faradic efficiency of the reactions was close to 100% under the prevailing conditions, direct weighings of the electrode were performed in air at different stages in the charge and discharge cycle (11). The electrode was removed from the electrolyte and soaked in fresh water four times for a period of at least 1 hr each. After rinsing with alcohol, the electrode was dried to a constant weight in a desiccator. The weighings were made in the region where the potential plateaus changed. The results are shown in Fig. 4. These points coincide quite well with the calculated values for m_O. We conclude, in addition, that the compounds formed in the reaction are stable enough to withstand this analytical procedure.

The actual weighings of the electrode during the charge-and-discharge cycle has indicated that the silver electrode behaves similarly to predictions from the theoretical equation. Typical experimental results are plotted on Fig. 5.

When an unused, sintered silver electrode is charged at constant current, the measured potential settles down to an almost constant value E_1 after an initial potential rise in the first few seconds. This steady potential is designated as the Ag-Ag_2O level. With the 10 cm^2, 0.05 cm thick electrode charged at a 100 ma total current rate, the measured weight-change/coulomb slope was 36 mg/kQ as shown in dashed line

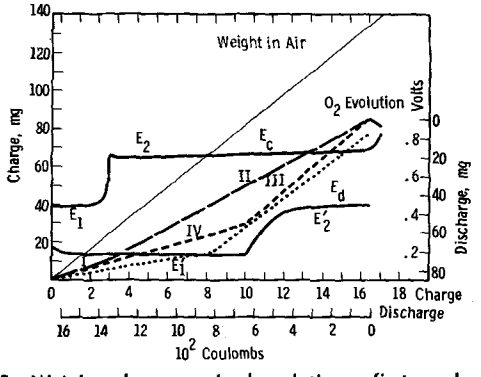

Fig. 5. Weight change-coulomb relations, first cycle; porous silver electrode 3.1 x 3.1 cm, 0.5 mm thick, in KOH electrolyte of d_s = 1.050 g/cm^3 at 25°C; charge and discharge current 100 ma; slope of segments in mg/kQ. Charging I = 36, II = 56, discharge III = 83, IV = 29.

segment I. This slope is almost twice as large as the predicted 18.4 mg/kQ (dotted line), but it is much lower than would be expected if no volume change had taken place. One can conclude that the density of the compound formed in the experiment must be around 8 g/cm^3.

At a later stage, the potential-coulomb curve starts to rise, slowly at first and then suddenly, until a new higher level E_2 is reached. This level is assigned to the formation of AgO. Figure 5 shows that more silver is oxidized on this level than on the previous one. It is interesting to observe that the point of sudden increase in potential coincided with a change in the slope of the weight-change/coulomb curve, the new slope being close to 56 mg/kQ as shown by dashed line segment II. This value is not as high as the predicted 78.2 mg/kQ for the conversion of Ag_2O to AgO and indicates that the active mass is expanding more than expected, so that a larger buoyancy correction is still in play. Actually, the slope of 56 mg/kQ is closer to the value of 48 mg/kQ that would indicate the direct conversion of silver to AgO.

Whether these data represent a gradual expansion of the existing lattice, or the formation of new distinct crystals as revealed by some x-ray diffraction studies (19) cannot be decided.

After a lengthy plateau region, during which the potential rises only slightly, there is a sudden increase with a corresponding change in the weight-change curve. The curve becomes erratic, levels for a short period, and then decreases quite rapidly. An inspection of the electrode at this point reveals that the gassing stage has been reached and the decrease in weight is caused by gas bubbles clinging to the surface of the electrode.

Several minutes are allowed for the gas to be dispelled before starting the discharge process. At the same current density of 100 ma/plate, one finds that

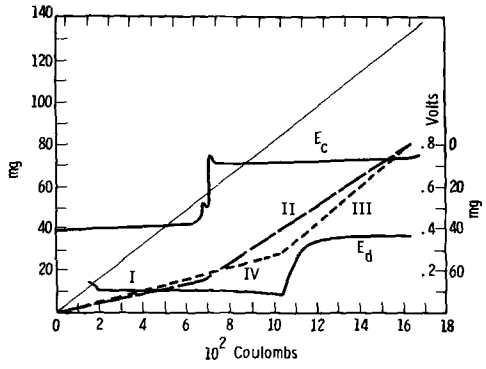

Fig. 6. Weight change-coulomb relations, second cycle; slope of segments in mg/kQ. Charging I = 23, II = 68, discharge III = 83, IV = 29.

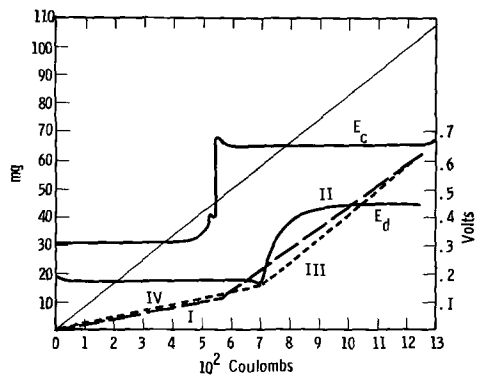

Fig. 7. Weight change-coulomb relations, fourth cycle; slope of segments in mg/kQ. Charging I = 20, II = 74, discharge III = 82, IV = 22.

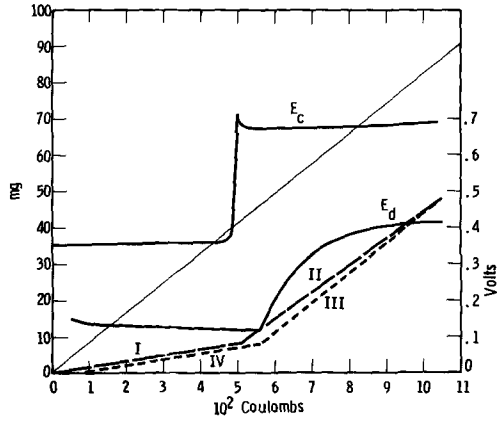

Fig. 8. Weight change-coulomb relations, sixth cycle; slope of segments in mg/kQ. Charging I = 16, II = 72, discharge III = 80, IV = 17.

the discharge proceeds at a potential E_2'. This potential decreases slowly at first, then gradually faster, but never is the change as rapid as during the charging process. The weight decreases rather fast at a rate of 83 mg/kQ, as shown by shortly dashed line III. (The discharge curves on all the graphs are plotted backwards from the charge curves. The new origin for the weight-change and number of coulombs is the maximum value reached during charging as indicated by the double scale in Fig. 5 but omitted in succeeding graphs.) This rapid change in weight is nearly what the plate would suffer if the weighings were made in air. This may mean that the volume of the electrode remains unchanged during the higher potential plateau of the discharge cycle. The slight contraction that should occur in this region should give a slope of 78.2 mg/kQ.

After the potential reaches the second discharge plateau, E_1', the potential remains almost constant until the silver oxide is close to exhaustion. In a self-sustained discharge, the potential begins to rise with the rapidly falling current output. In most cases tested, the current sank so low, even with the resistance box shorted, that a complete exhaustive discharge was not achieved. Shorting of the cell for many hours was not attempted. In this region, the weight curve followed the line IV with a slope of 29 mg/kQ, as compared to a slope of 36 mg/kQ in the charging portion, but not as low as the expected slope of 18.4 mg/kQ.

The data clearly show the large "hysteresis loop" created by the weight-change, coulomb charge and discharge curves. The rather short charging branch on the Ag_2O level represents only 18% of the total charge taken up, while the corresponding branch on discharge amounts to about 60% of the total charge released.

As early as the second cycle, Fig. 6, the Ag_2O charging branch becomes considerably extended. The slope was now 23 mg/kQ. Assuming a start from the silver level, this slope would represent the formation of an oxide of 7.3 g/cm^3 density. This density is very close to 7.25, the x-ray density of Ag_2O.[1] The weight change for the AgO plateau was 78 mg/kQ on charging, and again 83 mg/kQ during discharge. Figure 6 also shows that a slope of 29 mg/kQ was obtained during discharge at the Ag_2O level. The difference between the charge and discharge behavior became less pronounced.

A potential overshoot is usually noticed on charging during the transition from the Ag_2O to the AgO level. This overshoot has been the subject of several investigations, and different causes have been assigned for its appearance (16, 21). It can be seen in Fig. 6 that an additional small peak preceded the main one. In other runs, such peaks sometimes followed the main one.

Figures 7 and 8 represent the response of the same electrode in the fourth and sixth cycle. The cathodic and anodic behavior become even more similar, with weight change per coulomb values approaching the predicted values, and both plateaus in the charging and discharging cycle of almost the same length. But another factor became more apparent, namely, the total capacity of the plate decreased progressively during cycling. The first cycle gave 1650 coulombs, and the sixth only about 1050 coulombs. Taking into account the weight of the active silver in the electrode, by subtracting the weight of the reinforcing grid, the electrode was about 50% efficient in the first cycle, considering the conversion to AgO. The departure from higher efficiencies obtained in actual batteries might be attributed to the difference in electrolyte concentration. The decrease in capacity represents a calculated loss of 335 mg of active silver.

These experiments were repeated with new electrodes and electrolyte several times. The behavior was not completely identical although the general features were the same. One factor became disturbing during cycling. The electrolyte acquired a dark brown color, and some sediment appeared at the bottom of the cell, indicating considerable solubility of the active compounds in the electrolyte. Taking the solubility of the silver oxides in 1M KOH as 2.10^{-4}M Ag (22, 23), the silver in the 200 ml of electrolyte amounts to only 4.3 mg. The residue formed in cycling which settled at the bottom of the cell was less than 50 mg. The combined weight loss and solubility alone cannot account for the large loss in capacity of the silver electrode.

Conclusions

The coulogravimetric experiments confirm the proposition that the silver electrode undergoes a large volume change, mainly during the transition from Ag to Ag_2O phase. This change occurs in both the

[1] Data of x-ray density were kindly indicated by one of the reviewers.

cathodic and anodic reaction. Changes in the weight-coulomb relation coincide with the changes in potential-coulomb curves. Differences in coulombic efficiencies of the two potential-coulomb plateaus were found mainly during the first few charging and discharging cycles. More silver was being oxidized on the second AgO plateau than the amount converted in the initial step. On the contrary more oxide was reduced on the Ag_2O level than at the higher oxide one. These differences became less pronounced during repeated cycling.

The loss of electrode capacity during cycling cannot be explained solely by the dissolution of the silver oxides in the electrolyte or shedding of the active mass. The loss in capacity might be due to sealing up of capillary passages in the sintered electrode, reducing the available active area in the next cycle or the influence of increasing carbonate concentration.

Manuscript received March 30, 1966; revised manuscript received Nov. 10, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

A Kinetic Study of the Heterogeneous Reactions of Metallic Sodium with Chlorine and Bromine

M. J. Dignam and D. A. Huggins[1]

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

Data on the chlorination and bromination of sodium in the temperature range of 238°-323°K have beeen obtained for evaporated sodium films by following the change in optical density of the metal films. The chlorination data corresponding to the first few minutes of reaction have been found to be in accord with an equation of the form of that predicted by Mott and Cabrera for the growth of very thin oxide films on metals, while the bromination data for 273°K and below are in accord with a direct logarithmic law. Following longer reaction periods for chlorination, and above 273°K for bromination, the behavior is complex, being influenced in the case of bromination, for example, by illumination with light.

Stimulated by the practical problems of corrosion, fundamental research in the field of anodic and air oxidation of metals has gained increasing attention in recent years. Whereas early studies were concerned primarily with the formation of thick films (>1000Å) recent studies have examined more closely the kinetics and morphology of thin film formation. The material reported herein falls into this latter category.

Many metals, perhaps all which oxidize readily, show very similar behavior when exposed to oxygen at sufficiently low temperatures. The oxidation rate is initially very rapid, but drops off to a low or negligible value, a stable film of the order of 20-200Å being formed (1). Theories which have been applied to these low-temperature, thin film conditions have been based on a model involving a continuous adherent and homogeneous film. The rate-controlling process has been assumed variously to be electron transport (1-5); ion transport under the influence of the high electrostatic field produced by equilibration of electrons between the metal and surface levels at the film-oxidant interface (6, 7); chemisorption or incorporation of the oxidant at the film oxidant interface (8); combinations of some of the above allowing for space charge in the film; and finally film recrystallization and related phenomena (9, 10).

Differentiation between some of these theoretical approaches from experimental data is difficult, since many of them lead to the same or a similar form for the rate law. It is for this reason that we chose to investigate the halogenation of the alkali metals, which apart from providing a unique series of reactions, involves reactants and products which are sufficiently simple to make possible calculations of the rate constants from other data. In this manner, an unequivocal choice between alternate theories should be possible. At present one cannot say what information, if any, gained in the study of these systems may be readily related to more conventional metal oxidation reactions. It appears almost certain, however, that a thorough experimental and theoretical investigation of these systems will provide considerable insight into conventional oxidation studies. In addition, the investigation has intrinsic interest.

The present paper presents data on the reactions of metallic sodium with chlorine and bromine in the temperature range 230°-320°K. The chlorination reaction appears to be in accord with the Mott-Cabrera (7)

[1] Present address: J. Roy Gordon Research Laboratories, Sheridan Park, Clarkson, Ontario, Canada.

mechanism for film growth in the very thin film region. Good agreement between the data and the theoretical equation has been obtained over five decades of time and for up to a sevenfold increase in the film thickness.

The bromination data show some very interesting effects. The rate law is not that obeyed for the chlorination reaction, but instead takes the form

$$X = K \log t + K'^{2}$$

where for the lower temperatures, K is independent of temperature. Limitations of the data prevented the temperature coefficient of K' from being ascertained. It appears, however, to be fairly small or zero. At higher temperatures the value of K is smaller, the change in K' being once again uncertain. Irradiation with light of wavelength 5461Å has no effect on the rate at low temperatures, but at the higher temperatures it increases K to the value observed at low temperatures.

Experimental

As the apparatus employed for the present investigation is now being replaced, the description of it will be kept to a minimum. An outline of the experimental procedure follows, with further details given in subsequent sections.

Distilled sodium metal was evaporated in a stainless steel system at a rate of about 4 Å/sec, to form a film approximately 1000Å thick on a quartz slide cooled to near liquid nitrogen temperatures. The evaporation process was stopped by introducing purified argon to a pressure of about 1 atm.

The quartz slide was mounted on the end of a stainless steel tube which could be manipulated through a double "o" ring vacuum seal. Following film deposition the sample was transferred into the reaction chamber, which was then isolated from the evaporation unit.

The film was annealed at 60°C, the argon pumped out of the reaction chamber, and a predetermined pressure of halogen introduced through a pneumatically operated valve. The rate of the reaction was then followed by measuring the change in the intensity of the beam of monochromatic light (Hg 5461Å line) transmitted through the film. This change arises from the decrease in optical density of the film, since the metal with a high extinction coefficient reacts to give an essentially transparent halide layer. The output from the photocell unit, to be described later, was connected to an oscilloscope with camera and to a recording potentiometer.

The switch that controlled the pneumatic valve also triggered the oscilloscope, and thus the course of the reaction could be followed from times as short as a few milliseconds up to many hours or even days. It is primarily the speed of measurement which recommends this optical method for the study of thin film formation.

Evaporation unit and reaction vessel.—Figure 1 is a scale drawing, somewhat simplified, of the apparatus labelled to indicate the function of the various components. It was constructed entirely from stainless steel, the vacuum seals being formed with "o" rings of compound number 17507, Precision Rubber Products (a fluorocarbon polymer of high chemical inertness and stable to temperatures in excess of 150°C). As the diagram is largely self-explanatory, little will be added except to point out the various functions of the sample support tube which supports at one end the quartz slide on which the metallic sodium was deposited. Its principal function was to transport the slide from the sodium evaporation chamber to the reaction chamber while maintaining high vacuum or controlled atmosphere conditions. At the same time, however, a flange on this tube sealed the evaporation chamber from the reaction chamber when the slide

[2] By log y shall be meant $\log_{10} y$.

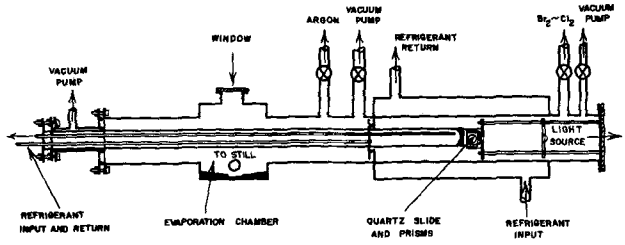

Fig. 1. Evaporation unit and reaction vessel

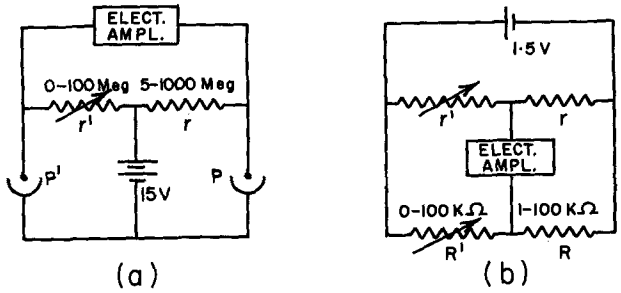

Fig. 2. Photometer circuit diagram and related circuit

was positioned in the latter, thus preventing contamination of the sodium in the evaporation chamber during the reaction. Within the main sample support tube were smaller tubes through which thermostated fluids or liquid nitrogen could be circulated to control the temperature of the quartz slide. The window in the evaporation chamber was used to observe the sodium film during deposition.

Following bakeout at about 150°C, the apparatus could be evacuated to a pressure of better than 3 x 10^{-7} Torr.

Photometric measurements.—A mercury arc lamp (General Electric AH100A) in conjunction with filters to isolate the 5461Å line (Kodak interference filter 540 and gelatin filter number 77), collimating lenses, first surface mirrors, and prisms made up the optical part of the photometric equipment. A beam splitter was used, and the intensity of the beam transmitted through the metal film was compared to that of the reference beam using circuits (Fig. 2) similar to those described by Dignam, Forbes, and Le Roy (11). Figure 2a consists of a Wheatstone bridge in which two adjacent resistance elements are replaced by 1 P37 vacuum photocells (P and P') whereas Fig. 2b is a simple Wheatstone bridge used to obtain the value of the resistance ratio r/r' in terms of the precision resistors R and R'. The electrometer amplifier was a Keithley Model 603 instrument (input impedance 10^{15} ohms), the output for which was connected to a recording potentiometer and to an oscilloscope with camera.

In addition to the circuits illustrated in Fig. 2, two other circuits could be selected which enabled the voltages across the resistors r' and r to be measured independently. Under experimental conditions the photocell dark currents were about 2 x 10^{-11} amp, with the lowest value for the light current being about 5 x 10^{-10} amp. In some runs, therefore, correction for the dark current was required.

Changes in the optical density of the metal film were measured as follows. The experimentally determined quantities are the voltages across the resistors r and r' and the ratio R/R' when circuit b is in balance. Associating P' with the reference beam, and P with the transmitted beam, the following symbols are defined in connection with the transmitted beam: V, voltage across r; i, total photocurrent; i_d, dark current; i_L, $i - i_d$; I, light intensity incident on photocell P. An identical set of primed symbols are defined in connection with the reference beam.

From Fig. 2a, $i = V/r$ and $i' = V'/r'$, and from Fig. 2b, at balance, $r/r' = R/R'$ so that

$$i/i' = (R'/R)(V/V')$$

or

$$\frac{i}{i'} = \frac{R'}{R}\left[1 + \frac{\Delta V}{V'}\right] \qquad [1]$$

where $\Delta V = V - V'$.

The dark current could always be neglected in connection with the reference beam, but not always in connection with the transmitted beam. Therefore $i = i_L + i_d$ and $i' = i'_L + i'_d \simeq i'_L$ so that [1] becomes

$$\frac{i_L}{i'_L} = \rho - \rho_d \qquad [2]$$

where

$$\rho = \frac{R'}{R}\left[1 + \frac{\Delta V}{V'}\right] \qquad [3]$$

and ρ_d is the value of ρ when $i = i_d$ (*i.e.*, the value of ρ measured with $I = 0$). Since $I \propto i_L$ and $I' \propto i'_L$[3] we may write

$$I/I' \propto (\rho - \rho_d)$$

The change in optical density from time zero to time t

$$\Delta\alpha = \log \frac{I(t=0)}{I(t)} \qquad [4]$$

is therefore given by

$$-\Delta\alpha = \log\left(\frac{\rho(t) - \rho_d}{\rho(t=0) - \rho_d}\right) \qquad [5]$$

During any given run, the value of r was held constant, as was the intensity of the lamp, so that I' remained constant. Thus $V' \propto I'r' = I'r(R'/R)$ so that we may set $V' = v(R'/R)$ where v is a constant for any given run.

The equation for ρ now becomes

$$\rho = \frac{R'}{R} + \frac{\Delta V}{v} \qquad [6]$$

Prior to beginning a run, r and r' were adjusted to make ΔV close to zero, and v was determined. ΔV was then recorded continuously during the run, with r' (and hence the ratio R'/R) adjusted from time to time to keep ΔV within the recorder scale. In Eq. [6], the second term, $\Delta V/v$, arises from the off-balance of the bridge circuit (Fig. 2a). By maintaining $\Delta V/v$ small compared with R'/R, fluctuations in the lamp intensity have only a small effect on the values of ρ determined. With this circuit it was possible to detect changes in the transmitted light intensity as small as 1 part in 3000, although such sensitivity was rarely required.

The thickness of the halide film may now be related to the change in optical density, $\Delta\alpha$, in the following way. If we let I_o be the light intensity incident on an element of area, dA, of the metal film system, then on neglecting multiple reflections within the films the element of transmited light, dI, is given by

$$dI = dA\, I_o\, 10^{-\epsilon X_m} \qquad [7]$$

where ϵ and X_m are the decadic extinction coefficient and thickness of the metal film. We shall assume that I_o and X_m are in general dependent on the position on the surface, but that ϵ and the halide film thickness, or thickness of metal consumed, ΔX_m, are independent of position. Substituting $X_m = X^o_m - \Delta X_m$ in the above equation, where X^o_m is the metal film thickness before reaction, and integrating over the entire illuminated surface, we obtain the following expression

$$I = \int_{\text{Area}} dA\, I_o\, 10^{-\epsilon(X^o_m - \Delta X_m)} \qquad [8]$$

[3] In the intensity range employed, 1P37 vacuum photocells have a linear response according to tube specifications.

Since ΔX_m is constant at any given time, and is zero at time zero, it follows immediately from [8] that

$$\frac{I(t)}{I(t=0)} = 10^{\epsilon\Delta X_m} \qquad [9]$$

and hence from [4], [5], and [9]

$$\Delta X_m = \frac{1}{\epsilon}\log\frac{\rho(t) - \rho_d}{\rho(t=0) - \rho_d} \qquad [10]$$

The thickness of the halide film, X, can be calculated from [10] and the relation

$$X = (\Omega/\Omega_m)\Delta X_m \qquad [11]$$

where Ω and Ω_m are the volumes per metal atom in the halide and metal, respectively.

The extinction coefficient, ϵ, was calculated from the optical constants[4] for evaporated sodium films measured by Ives and Briggs (12), the value for 5461Å radiation being given by $\epsilon = 2.32 \times 10^{-3}$ Å^{-1}.

The effect of neglecting multiple internal reflections within the metal and halide films will now be examined. Multiple reflections within the metal film can, of course, be entirely neglected because of the extremely high rate of attenuation of amplitude in this medium. Interference effects arising from multiple reflections within the halide film are, however, significant. Thus, a NaBr film (refractive index 1.62) 500Å thick, will cause a reduction in the transmitted intensity of about 6%, which in turn corresponds to an error in the halide film thickness determination of about 10Å. For thinner films, the error is less, going to zero at zero film thickness. The errors for NaCl films are somewhat less for the same thickness owing to the smaller value for the refractive index (1.50). In both cases, the errors introduced by neglecting multiple reflections, although not insignificant, are of the same order or smaller than random errors arising from other sources, principally light scattering, a phenomenon which is discussed later.

As the properties of thin metal film are known to depend appreciably on film thickness for sufficiently thin films, care was taken to make sure that the metal film thickness never fell below about 300Å during the run.

Materials.—Analar grade sodium was melted in a Pyrex vessel under vacuum, filtered, then outgassed, and finally transferred in an argon atmosphere to a stainless steel still connected to the sodium evaporation chamber. It was further outgassed here under high vacuum conditions and finally distilled at about 375°C into the evaporation chamber, the background pressure being never higher than 10^{-5} Torr. According to Horsley (13) this should produce sodium of 99.9995% purity, apart from gas content.

Argon was purified as required by bubbling it through a column of liquid sodium.

Commercial tank chlorine was condensed into a Pyrex trap and subjected to ten trap-to-trap distillations while pumping. On the final distillation, the background pressure did not rise above 2×10^{-6} Torr.

Bromine was treated in a similar manner.

Results

Chlorination.—Chlorination results obtained for metal films deposited under conditions where the background pressure during deposition was much in excess of 10^{-6} Torr were irreproducible. Only results obtained for films deposited at background pressures of 7×10^{-7} Torr or less are reported herein. The apparatus is being replaced by an ultrahigh vacuum system, capable of sustaining vacuums of the order of 10^{-10} Torr, in order to overcome the above difficulty.

For a number of runs, the expected behavior of the transmitted light intensity with time was not ob-

[4] The familiar chemical extinction coefficient is related to the fundamental optical extinction coefficient k' (which is the imaginary part of the complex refractive index) by the equation $\epsilon = 4\pi k'/\lambda_o$ 2.303, where λ_o is the wavelength of the light *in vacuo*.

served. Instead, the transmitted light first appeared to decrease in intensity, followed ultimately by the expected increase with time. The anomalous behavior arose almost certainly as a result of the scattering of the light beam at the sodium-halide-halogen interfaces, brought about presumably by the roughening of the surface during the initial period of reaction. This extremely undesirable effect was reduced very substantially by having the light beam incident on the bare surface of the quartz slide rather than on the halide surface. The effect appeared to be entirely absent for several runs, suggesting that the initial roughening of the surface probably took place as a result of surface contamination prior to introducing the halogen gas. However, no reaction could be detected prior to introducing the halogen, despite the fact that reaction of about 1/10 of the sodium atoms on the surface should produce a detectable change in optical transmission.

The above problem constitutes the major limitation of the data and the principal incentive to abandon the apparatus in favor of one which overcomes this difficulty. Nevertheless, the present data, despite this limitation, provide some interesting information concerning the kinetics of halogenation of sodium.

The chlorination data, plotted as chloride film thickness *vs.* the logarithm of the reaction period, are presented in Fig. 3 to 6, the circles representing the experimental values. The runs at 237° and 255°K (Fig. 3) were the only ones which showed no evidence of the light scattering effect mentioned above. The points for these two runs were calculated using Eq. [10] and [11], no correction for scattering being applied. Five further runs, (Fig. 4-6) although they showed a light scattering effect, were otherwise acceptable in that the background pressure during film deposition was less than 7×10^{-7} Torr. Of these five, all but one (curve a, Fig. 5) gave results reasonably consistent with the above two for reaction periods greater than 10 sec on applying an additive correction, X_0, to the film thickness calculated from [10] and [11]. If the fraction of light scattered remained constant after about 10 sec of reaction, such an additive correction should indeed apply. The method of choosing the values for the correction thickness, X_0, will be dealt with shortly.

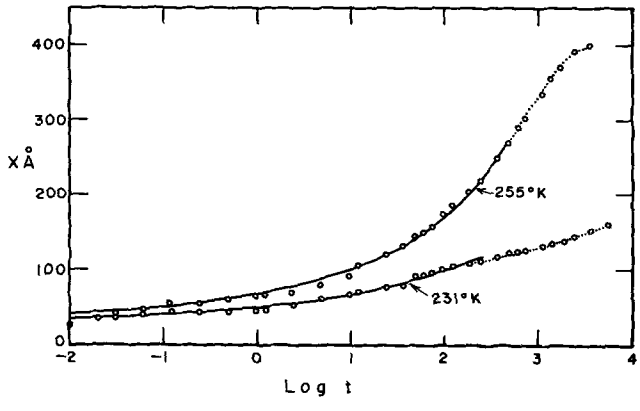

Fig. 3. Results for the chlorination runs which showed no evidence of the light scattering effect. Time in sec; chlorine pressure 3.86 Torr at 331°K, 3.90 Torr at 255°K.

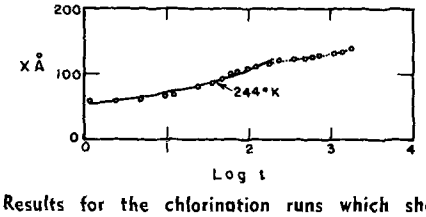

Fig. 4. Results for the chlorination runs which showed light scattering, corrected for light scattering as discussed in paper. Time in sec; chlorine pressure 4.60 Torr.

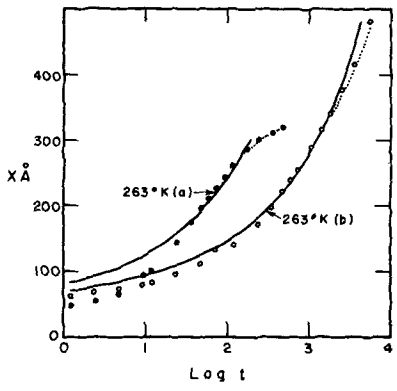

Fig. 5. Results for the chlorination runs which showed light scattering, corrected for light scattering as discussed in paper. Time in sec; chlorine pressure 5.48 Torr curve a, 6.90 Torr curve b.

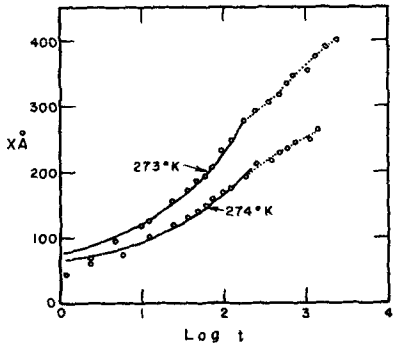

Fig. 6. Results for the chlorination runs which showed light scattering, corrected for light scattering as discussed in paper. Time in sec; chlorine pressure 4.61 Torr at 273°K, 4.90 Torr at 274°K.

An experiment to determine the pressure dependence of the reaction rate, although not entirely conclusive, indicated that the rate was proportional to the chlorine pressure to the power of approximately 0.3 (see Fig. 7).

Bromination.—As the data for the bromination of sodium were found under certain conditions to be affected by the 5461Å radiation used in the optical transmission measurements, the majority of these runs were carried out under conditions of intermittent illumination, the sample being illuminated only long enough to make the individual measurements (about 1 sec).

As was the case for the chlorination, only results for metal films deposited at background pressures of 7×10^{-7} Torr or less are reported. Furthermore, all

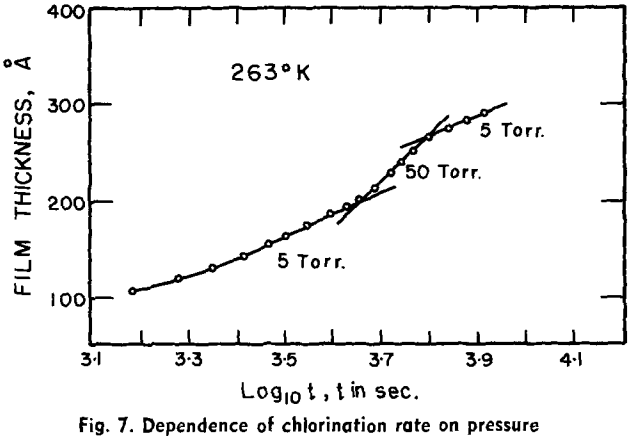

Fig. 7. Dependence of chlorination rate on pressure

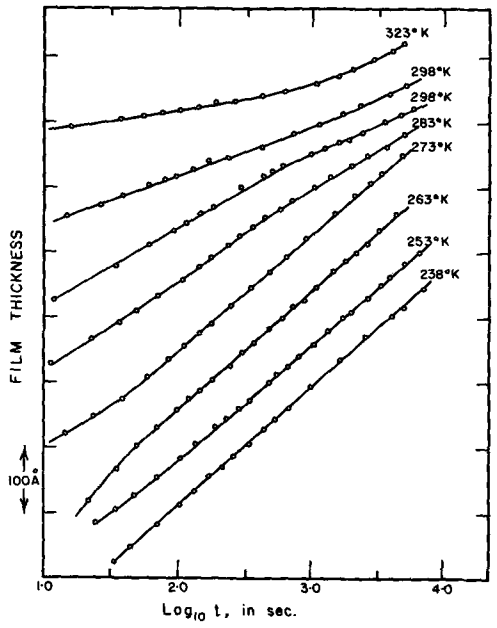

Fig. 8. Bromination results

the runs showed the light scattering effect, making it impossible to determine the absolute thicknesses of the bromide films. The change in thickness following the first few seconds of reaction could be determined as before, however, provided the fraction of scattered light remained independent of film thickness and time (*i.e.*, provided the degree of roughness of the halide-halogen interface remained essentially constant).

The data are presented in Fig. 8, the positioning of the curves with respect to translation along the "Film Thickness" axis being arbitrary. As far as could be determined, however, there appeared to be no systematic change in intercept with temperature for the temperature range 238°-273°K. indicating only a small or zero temperature coefficient for the reaction rate in this temperature range. It is clear from Fig. 8 that above 273°K, the behavior is somewhat different.

Illumination with 5461Å radiation was found to have an effect on the rate only for runs at the higher temperatures (*i.e.*, above 273°K). The influence of continuous irradiation on the rate is illustrated in Fig. 9.

Combined bromination, chlorination runs.—A few runs were carried out under conditions of intermittent illumination in which the sodium film was first reacted with bromine, then the bromine removed and chlorine

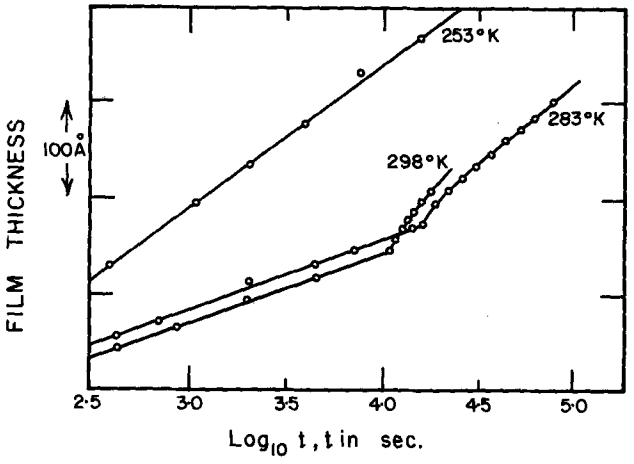

Fig. 9. Effect of illumination with 5461Å radiation on bromination rate.

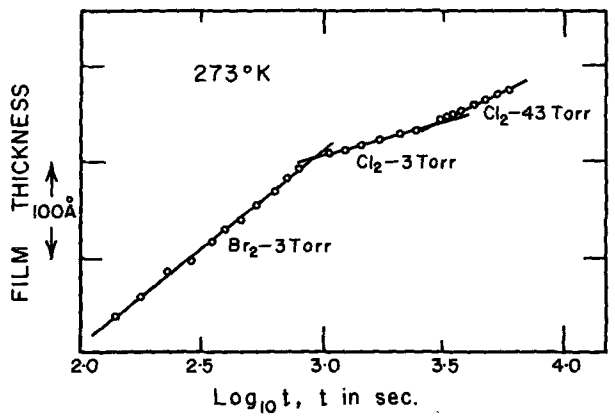

Fig. 10. Effect on rate of metal consumption of replacing bromine with chlorine following bromination.

introduced. The results for one such run are presented in Fig. 10.

Discussion

Chlorination results.—The data for the chlorination of sodium were fitted to a slightly modified form of the Mott-Cabrera theory (10) for the growth of thin and very thin films. The equation, which is discussed in some detail by Dignam, Fawcett, and Böhni (14), is given below

$$dX/dt = 2A \sinh (B/X) \qquad [12]$$

$$A = \Omega\nu\, an \exp (-U/kT) = A_o \exp (-Q/kT) \qquad [13]$$

$$B = \mu^* V/kT \qquad [14]$$

where the symbols are defined as follows: n, volume concentration of mobile species, in general a function of temperature; U, zero field activation energy associated with movement of the species; ν, usual frequency term associated with the movement of the species; a, distance travelled per activation, or the jump distance; Ω, volume of product per cation or anion (depending on whether transport is cationic or anionic); μ^*, charge-activation distance produced (activation dipole) associated with movement of the species; V, potential drop across the product film arising from equilibration of electrons in the metal with those in surface states at the film-gas interface. Equation [12] may be re-written in the following integrated form

$$\int_{B/X}^{\infty} \frac{(1/2)\ \mathrm{csch}\ u}{u^2}\, du = \frac{A}{B} t \qquad [15]$$

where the boundary condition $X = 0$ at $t = 0$ has been used. The data in Fig. 3 where fitted to Eq. [15] using a 7094 IBM computer and a procedure outlined previously. The solid curves shown were calculated for values of B and A which minimized the variance in each case. From the values of B, μ^*V was calculated to be $7.2_2 \pm 0.3_3$ and $7.7_7 \pm 0.2_6$ eÅv for the runs at 231° and 255°K, respectively. Since the two values agree within their combined standard deviations, μ^*V was taken to be temperature independent, the weighted mean value and the standard deviation of the mean being given by: $\mu^*V = 7.5_7 \pm 0.2_1$.

As the remaining data (Fig. 4-6) involve light scattering effects, as mentioned previously, they were analyzed in a slightly different manner. In Eq. [15], X was replaced by $X' + X_o$ where X' is the apparent film thickness calculated from [10] and [11], and X_o the correction term to allow for the attenuation of light arising from scattering. If the fraction of light scattered remains constant after a short period of time, then X_o will be constant following this transition period. For these runs, therefore, B was assumed to be given by [14], using the above value for μ^*V, and

A and X_o chosen to minimize the variance. The computed curves for these runs are also shown as solid lines in Fig. 4-6.

It is clear from the data that following chlorination for a period in the neighborhood of 100-1000 sec, a more or less abrupt break occurs in the plot of film thickness *vs.* log (time), the direction of the break suggesting a fairly sudden decrease in the reaction rate. Apart from this effect, however, which will be discussed later, fairly good agreement between the data and calculated curves is obtained.

Thus, the only two fully reliable chlorination runs (Fig. 3) fit Eq. [12] or [15] over about 4 decades in the chlorination period, and in the case of the run at 255°K, over a factor of 7 in the chloride film thickness. Furthermore, the fit is obtained for essentially the same value of μ^*V. Of the remaining five runs which may be considered, all of which involve light scattering, two (Fig. 4 and 5b) are brought into excellent accord, and two (Fig. 6) into fair accord with [12] or [15] after correcting for scattering on the assumption of a constant fraction of light scattered. Furthermore, the accord is achieved for the same value of μ^*V as above. Again, the values of A determined for the seven runs show the expected temperature dependence (Fig. 11) within experimental scatter. It therefore appears that the chlorination of sodium in the temperature range 231°-273°K takes place initially in accord with [12] (*i.e.*, essentially the Mott-Cabrera theory), a "break-away" occurring to lower rates after a certain period.

Before the Mott-Cabrera theory or any minor modification of it can be accepted even tentatively, however, other common rate laws must be examined. To this end, the data of Fig. 3 (255°K), which do not involve light scattering, and furthermore are the most extensive, were fitted to the most general form of the parabolic and direct logarithmic equations (*i.e.*, $X = K_p(t + t_o)^{1/2}$ and $X = K \log (t + t_o) + K'$, respectively). The results are summarized in Table I, in which the standard deviation of X, σ_X, from the most probable curve is given for the three rate laws. In order that the statistical significance of differences in σ_X can be ascertained, the standard deviation of σ_X, σ_σ, is also given.[5] From these values one can conclude that the chances against the improved fit for the Mott-Cabrera law being accidental are about 20 to 1 on comparison with the logarithmic law and 100 to 1 for the parabolic law. An even more pronounced decision in favor of the Mott-Cabrera law is obtained for run b, Fig. 5. As this run involved light scattering, however, the result is perhaps less convincing than the above. For the remaining runs, the total per cent change in film thickness is insufficient to provide a basis for distinguishing between the three rate laws. On the present evidence we conclude, therefore, that the chlorination data for the initial reaction period are in accord with the Mott-Cabrera law, rather than either the direct logarithmic or parabolic law.

[5] σ_σ was calculated from the relationship $\sigma_\sigma = \sigma_X/[2(n - i)]^{1/2}$ where n is the number of experimental points and i the number of disposable constants in the equation being fitted.

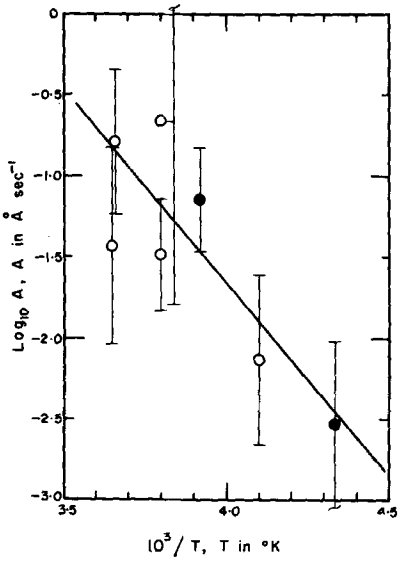

Fig. 11. Temperature dependence of the factor A for chlorination of sodium. The vertical lines represent 95% confidence limits, the diagonal line being the weighted least squares regression line for A. The solid circles represent the results for the runs which did not involve light scattering.

Table I. Comparison of the fit of the data of Fig. 3 (255°K) to the Mott-Cabrera, direct logarithmic and parabolic rate laws

	Mott-Cabrera	Logarithmic	Parabolic
σ_X, Å	6.0	10.6	13.4
σ_σ, Å	0.9	1.6	2.0

From Fig. 11, the temperature dependence of A is given by [13] with log (A_o in Å/sec) = 7.9 ± 2.4, Q = 0.48 ± 0.12 ev where the limits represent one standard deviation. We note that Q is smaller than the activation energy for migration of a cation vacancy in sodium chloride (about 0.8 ev) suggesting that the concentration of cation vacancies in the present case has a negative temperature coefficient. Although a detailed mechanism can support such a proposition, the difference in the activation energies is not sufficiently large compared with the standard deviation in Q, to rule out chance disagreement.

Any explanation of the "break-away" phenomena offered at this stage must be regarded as highly speculative. Bearing this in mind, the accumulation, as the film thickens, of the space charge due to the mobile ionic species would have the effect of reducing the rate below that predicted by [12]. Although this postulate has been tested quantitatively and successfully, further development of the thesis will be delayed until more extensive data are available.

Bromination results.—From Fig. 8 it is clear that for runs at temperatures of 273°K and below, the data are in accord with a direct logarithmic law (*i.e.*, film thickness linear in log time). This is in contrast with the chlorination results which appear to fit the Mott-Cabrera theory of metal oxidation, an approximate integrated form of which is sometimes referred to as the inverse logarithmic law. That reactions which are so very similar in nature should follow different kinetic rate laws is somewhat surprising. We note, however, that the chlorination data fit the Mott-Cabrera theory only for sufficiently short time periods. It is possible that the bromination data for sufficiently short time periods would also fit this law. The light scattering effect mentioned previously thwarted attempts to obtain such data.

A further interesting result is that the decadic rate constant is temperature-independent below 273°K (although it cannot be said with any degree of certainty that the intercept on a thickness *vs.* log t graph is likewise temperature-independent) and decreases as one proceeds to higher temperatures (see Fig. 8). Furthermore, illumination with 5461Å radiation, while having no measurable effect on the decadic rate below 273°K, above this temperature it causes the decadic rate to increase to the value found below 273°K (see Fig. 9). A tentative explanation for these observations follows.

It is possible that for sufficiently thin films the rate is controlled by ion transport through the film. In the absence of space charge effects this will lead to data in accord with the Mott-Cabrera theory (*i.e.*, inverse logarithmic law). If space charge effects are important, however, then a kinetic law approximating to a direct logarithmic law might perhaps be expected (15). As the film thickens, the rate might become controlled by

electron transport through the film rather than ion transport. Assuming the mechanism of electron transport to involve Schottky emission, this mechanism will also lead to a kinetic rate law approximating to a direct logarithmic law (16). Illumination of the brominating sample with light would be expected to have little if any effect on the rate of ion transport through the film, but would alter very substantially the rate of emission of electrons. Thus, at the higher temperatures where the electron transport mechanism is presumably operative, illumination with 5461Å radiation could stimulate electron transport through the film to such an extent that the rate-controlling process becomes ion transport once more. No such effect is expected at the lower temperatures where the rate-controlling process is presumably already ion transport. These considerations must be regarded at present as highly speculative.

Results for combined bromination chlorination runs. —The significance of these results (Fig. 10) concerns the fact that most of the reaction conditions remain unaltered as one proceeds from a point just before that at which the bromine was removed to a point immediately after the reaction was recommenced with chlorine present. In particular, the temperature, metal, and film materials are the same in both cases as well as the film thickness. The only change in the system, therefore, concerns the nature of the film-gas interface. We note that the rate of reaction on replacing the bromine with chlorine is reduced very substantially despite the fact that the free energy decrease for the reaction of sodium with chlorine is greater than that with an equivalent pressure of bromine at the same temperature. We must conclude, therefore, that the detailed structure of the film-gas interface is extremely important in the over-all kinetic process. Presumably the reduction in rate arises from the fact that chlorine atoms can be less readily chemisorbed on sodium bromide than can bromine atoms. Further investigation along these lines should provide interesting results.

Summary and Conclusions

Preliminary data on the chlorination and bromination of sodium have been obtained in the temperature range 238°-323°K. The results may be summarized as follows.

The initial chlorination data are in accord with an equation of the form

$$dX/dt = p^m \gamma \sinh (B/X)$$

where

$$m \approx 0.3,\ \gamma \simeq 2 \times 10^8 \exp (0.5/kT \text{ (ev)})$$

$$B = \mu^* V/kT,\ \mu^* V = 7.6 \text{ eÅv}$$

After a few minutes reaction time, however, the rates fall below those predicted by this equation. At 255°K, the results adhered to this equation over a range corresponding to more than 4 decades in the time and to an increase in the film thickness of more than a factor of 7. The film thicknesses achieved after about 1 hr reaction time range from about 150 to 420Å over the temperature range 231°-273°K.

For temperatures of 273°K and below, the data which correspond to bromination periods of 10 sec or more are in accord with an equation of the form

$$X = K \log t + K'$$

where K, the decadic rate constant, is independent of temperature in this region and has a value of 180Å per decade of time. The temperature dependence of the intercept, K' is uncertain, but appears to be small. Above 273°K, the decadic rate constant decreases with increasing temperature, however on illumination with 5461Å radiation, the decadic rate is increased to match that found below 273°K.

On interrupting a bromination run by replacing the bromine with chlorine at the same pressure, the rate is found to decrease very substantially, indicating that the processes occurring at the film oxidant interface play an important role in the over-all kinetic behavior.

The present data, though preliminary in nature, already show promise in providing information for the critical evaluation of mechanisms of growth of thin continuous films on metals. Further calculations will be postponed, however, until more extensive and more precise data are available.

Acknowledgments

The authors are grateful to the National Research Council of Canada for supporting this research and for a scholarship (D.A.H.). They also wish to express their thanks to Miss W. Y. Shiu and Mr. D. Goad for assistance in carrying out the calculations.

Oxide Growth and Capacitance on Preirradiated Zircaloy-2 and Zirconium

R. J. Davis

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Previous work has demonstrated a large enhancement of corrosion of Zircaloy-2 by oxygenated aqueous solution during bombardment by fast neutrons. Measurements of oxide growth and of film impedance were made on specimens preirradiated with fast neutrons in order to determine whether the irradiation damage important to corrosion occurs in the oxide film or in the metal substrate. A small enhancement of corrosion was observed with some specimen pretreatments. The results indicate that some corrosion enhancement results from irradiation of the substrate metal and that dissolved oxygen is required for the effect.

It has been demonstrated that corrosion of Zircaloy-2 in oxygenated aqueous media under heavy particle irradiation occurs at constant rates. If the heavy particles are fission fragments, the corrosion rate R (mils per year) depends on the fission power density in solution, P (watts per ml). At high power densities (greater than several w/ml) the rates also depend on temperature according to (1-3)

$$1/R = 2.3/P + 2.25 \times 10^{-11} \exp^{11,500/T} \quad [1]$$

If the heavy particles are fast neutrons and the flux, ϕ is 10^{13} (n/cm^2/sec $>$ 1 Mev) or less, the rate increases with fast neutron flux according to (4)

$$R = 4.3 \times 10^{-13} \phi \quad [2]$$

It was hypothesized that the radiation damage which affected corrosion, with both types of heavy particles, was the production of interstitials and vacancies (4). The rate equations were roughly correlated (*i.e.*, as well as the uncertainty of the estimation of the number of defects per fission would allow). This indicated that in terms of the rates of atom displacement D (no/cm^3/sec)

$$R \cong 10^{-15} D$$

These efforts did not establish the mechanism of the radiation effect. It is the purpose of this study to determine one feature of the mechanism, namely, where the important damage occurs.

Experimental

In outline the experimental proposal was to prepare pairs of specimens with and without oxide film, to irradiate one specimen of each pair and retain the other for a control and to corrode both specimens in an oxygen-steam environment and compare rates of weight gain and film impedance. The weight gain data were to provide a measure of corrosion rates and the film impedances an empirical indication (5) of the protective quality of the film. It can be shown that such data would in principle distinguish between three conceivable situations: (*i*) the primary radiation damage is in the oxide; (*ii*) the primary damage is in the metal which results in inferior oxide; or, (*iii*) the damage is in the metal, but the oxide is not changed.

Table I. Preirradiation treatments

Prefilmed:	Pickle in HF-HNO_3; oxidized in 300°C H_2O-O_2 (50-50 volume % mixture at 1 atm); seal in He-filled Zr-2 autoclave.
Film free:	Pickle in HF-HNO_3; seal in He-filled Zr-2 autoclave;[1] heat at 500°C 16 hr.
Film-free, fluoride-free:	Pickle in HF-HNO_3, vacuum anneal at 700°C 4 hr; oxidize in 300°C H_2O-O_2 (50-50 volume % mixture at 1 atm) for 1 hr; seal in He-filled Zr-2 autoclave; heat at 500°C 16 hr.
Low oxygen content:	Pickle in HF-HNO_3; seal in He-filled Zr-2 autoclave; heat at 800°C 16 hr.

[1] In one experiment the interior of the autoclave was pickled. (In all other experiments the autoclave surfaces were as machined.)

Two sets of prefilmed specimens were prepared as indicated in Table I; one set was preoxidized for 1 hr and the other set for four days. Two sets of film-free Zr-2 specimens were also prepared (Table I); the 500°C heating in helium was employed to dissolve into the metal (6) the small amount of oxide left by pickling. (In the film-free specimen experiment, number 2, the interior of the autoclave was pickled; in all other experiments the autoclave interiors were as machined.)

The results of the first experiments led to other specimen preparations as indicated below. There was some indication of an effect due to fluoride left in pickling; also the possibility was raised that the effect found was due to the additive elements in Zircaloy-2. For these reasons a set of crystal-bar zirconium specimens was prepared to be film-free and fluoride-free but in a manner to provide some dissolved oxygen in the substrate metal. This is the film-free, fluoride-free preparation in Table I. The 700°C vacuum anneal was done in a large, zirconium foil-lined, quartz furnace. Any fluoride was expected to be volatilized as ZrF_4 by the treatment.

A set of specimens was prepared, as indicated in Table I, in a way to provide not only a film-free surface but a surface with a low dissolved oxygen content in the substrate metal. The low oxygen content was achieved by heating in helium at 800°C which is expected to dissolve into the metal the small amount of oxide left by pickling and disperse it almost uniformly through the metal (6).

The irradiations were made with the specimens still in the autoclaves which were canned as shown in Fig. 1, with a layer of boron-10 around them to reduce the thermal neutron flux and hence the activation of the zirconium. The irradiations were done at 100°C at a fast flux (>1 Mev) of 10^{13} for ten days. The control specimens were held at 100°C in an oven for a similar period.

The postirradiation oxidations were made in a furnace which provides a stream of a 50-50 mixture of oxygen and steam at 300°C and 1 atm. This environment was chosen for two reasons: (*i*) it contains water and oxygen, the chemical constituents of the media in which irradiation enhancement of corrosion has been seen (1, 2), and (*ii*) it is a convenient system. The notable feature of this furnace is the rapid heat-up device. By appropriate manual interchanges of the two portable furnaces shown on the left (Fig. 2), specimens were heated to 300°C in 30 sec and

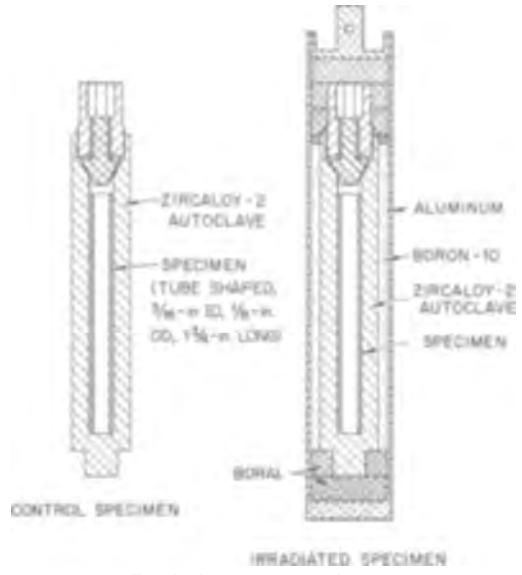

Fig. 1. Specimen autoclaves

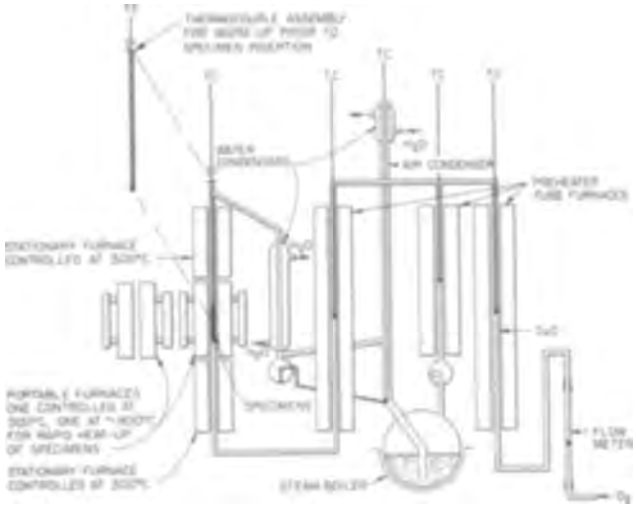

Fig. 2. Steam-oxygen furnace

meaningful exposures of as short as 5 min were made. Periodic rapid heat-ups were shown not to affect subsequent corrosion.

The impedance measuring devices are shown in Fig. 3. All but the cell are conventional equipment. The electrolyte was 1M NH_4NO_3. NH_4NO_3 was chosen because it decomposes at 210°C to volatile products; therefore traces of the electrolyte should not affect subsequent corrosion.

The measured impedances include the impedance of the platinized platinum surface, the electrolyte, and the ZrO_2 film. The impedance of the platinum surface is negligible, the electrolyte resistance is small and is known both by observation and calculation and can therefore be subtracted out. The impedance of the ZrO_2 film can therefore be measured (9).

The novel feature of this cell is the use of Teflon sleeves to demark the area over which the impedance is observed. Previous workers have used various sealing waxes (10). The important advantage of Teflon is that the impedance measurements do not affect the specimen weight or subsequent corrosion.

Several measurements were made to demonstrate the reliability of the impedance measurements. Reported film capacities on anodized films (10) have been reproduced. It was demonstrated that the same impedance is measured using Teflon as using Apiezon

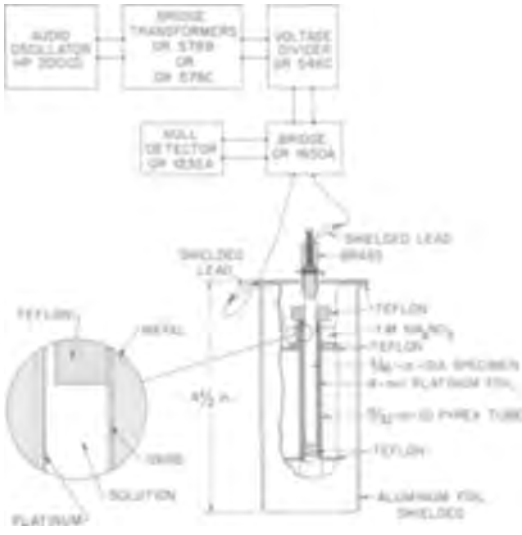

Fig. 3. Capacitance cell

W sealing wax. It was also shown that a γ-field of intensity similar to that from induced radioactivity in an irradiated specimen does not affect the measured impedance. The impedances reported were all measured at 1 kc. Weight gains were measured on a microbalance with a precision of about 0.3 $\mu g/cm^2$.

Results

The weight-gain *vs.* time data for the film-free specimens (Fig. 4) show that a small increase (x 1.5-2 in corrosion rates occurred due to the irradiation. (The film-free specimen which was pretreated and irradiated in the autoclave which had been pickled showed a smaller radiation effect.) The corrosion of the irradiated specimen was continuously faster than the controls from essentially the start to the end of the postirradiation exposures. The crystal-bar specimen with the minimized surface fluoride showed the same behavior as the others.

The weight-gain data for the prefilmed specimens (Fig. 5) show no acceleration of corrosion due to irradiation; in fact the data suggest a small and temporary retardation of corrosion. [The prefilmed control specimens corroded more rapidly than the film-free controls. This is attributed to the 100°C treatment in He for 10 days. Others (7, 8) have found that heating a corrosion film in an inert environment at as low as 150°C (8) enhances subsequent corrosion.]

The low-oxygen specimen (Fig. 6) showed no effect as a result of irradiation.

The impedance data are given in Fig. 7-9. The data taken from the impedance bridge were equivalent series capacitance and loss tangent (tan δ) across the cell for about 0.5 cm^2 areas. The observed values were corrected for the solution resistance (~1 ohm-cm) and

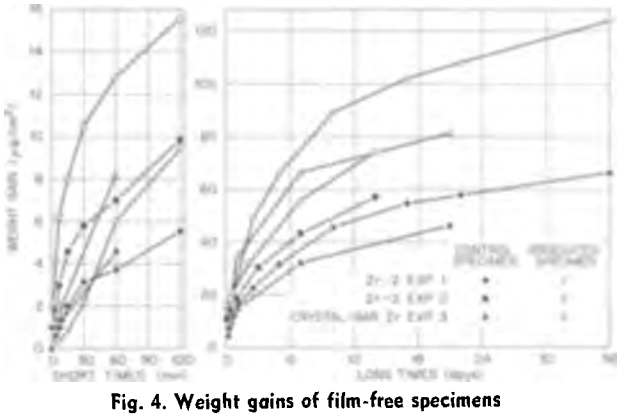

Fig. 4. Weight gains of film-free specimens

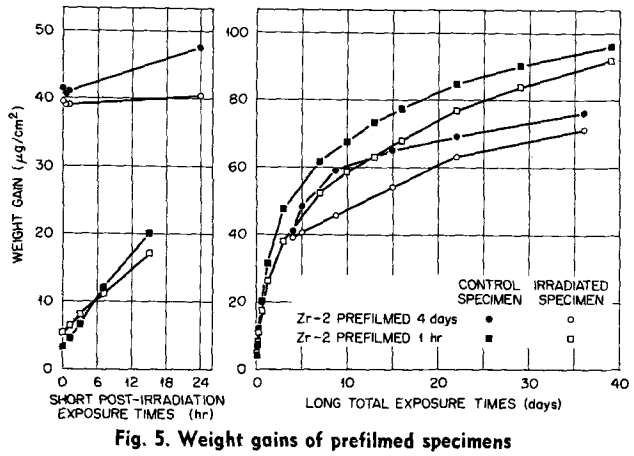

Fig. 5. Weight gains of prefilmed specimens

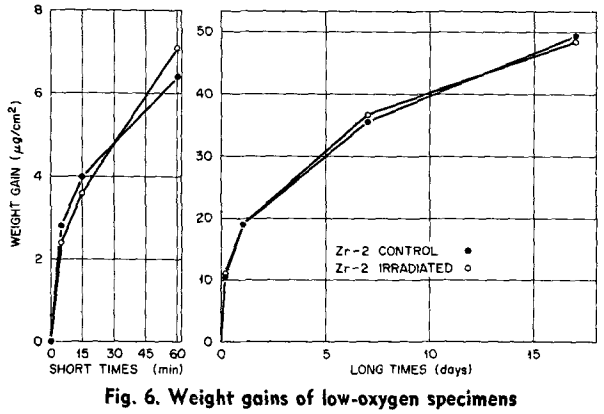

Fig. 6. Weight gains of low-oxygen specimens

the capacitances were converted to equivalent parallel capacitances per unit area. Both corrections are small. The data are plotted as reciprocal of capacitance per unit area and tan δ, both as a function of weight gain. For uniform growth of a homogeneous oxide film, reciprocal capacitance *vs.* weight gain should plot as a straight line through the origin. The slope of the line is inversely proportional to the dielectric constant of the oxide. Tan δ, for a homogeneous insulating material, is a property of the material, independent of thickness.

The impedance data (Fig. 7-9) generally show two deviations from the simple behavior expected for uniform growth of homogeneous material. In some cases the reciprocal capacitance (Fig. 7) remained very low up to weight gains as high as 20 μg/cm². In most cases (Fig. 7, 8, and 9), tan δ was lower (in one case higher) during the first 20 μg/cm² of weight gain than the approximately constant value observed thereafter. Neither of these effects were peculiar to irradiated specimens.

The impedance data for film grown on film-free specimens (Fig. 7) show no significant effect due to irradiation on either tan δ or reciprocal capacitance. (A possible exception is the reciprocal capacitance of the crystal-bar specimen, however neglecting the first 20 μg/cm² weight gain) the slopes of these two plots on Fig. 7, are similar.)

The impedances of the prefilmed specimen, after postirradiation oxidation are given in Fig. 8. Here we find no significant effect on tan δ but the reciprocal capacitances were less (or the dielectric constant greater) for the irradiated specimens. The differences were about 15% for the four day prefilmed specimens and almost 30% for the 1-hr prefilmed specimen.

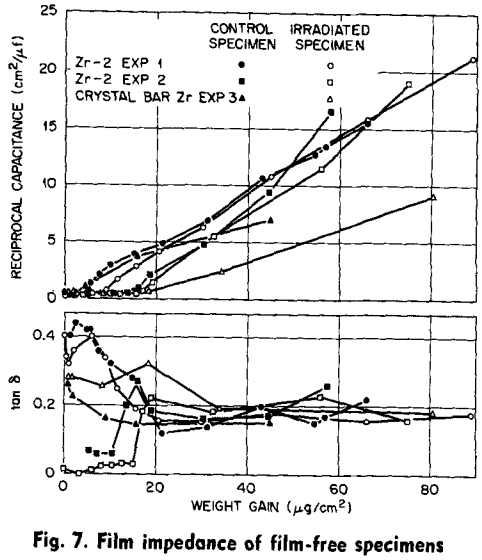

Fig. 7. Film impedance of film-free specimens

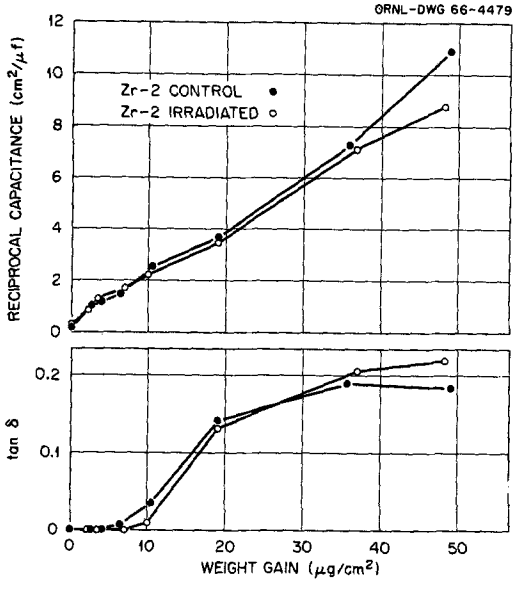

Fig. 9. Film impedances of low-oxygen specimens

The low oxygen specimen (Fig. 9) showed no effects due to irradiation.

Discussion

A small and continuing enhancement of postirradiation corrosion due to irradiation was found with certain pretreatments and not with others. Corrosion enhancement due to irradiation was observed with specimens pretreated to be free of oxide film, showing that the irradiation damage was in the metal. The pretreatments which would provide an oxygen-rich layer of metal at the surface resulted in irradiation enhancement of corrosion. These pretreatments included: (*i*) the Zr-2 pickled then heated in helium at 500°C and (*ii*) the X-bar Zr pickled, annealed, briefly prefilmed, then heated in helium at 500°C. The pretreatments which would lead to a nearly oxygen-free metal layer at the surface resulted in no enhancement of corrosion by irradiation. These include the pickle followed by heating in helium at 800°C, and prefilming at 300°C. These results indicate that the irradiation damage in the metal, which affects corrosion, is associated with dissolved oxygen although other interpretations, related to effects in the metal as a result of the various heat treatments, may be possible. The small irradiation enhancement was observed with the fluoride-free X-bar Zr, which is taken to indicate that neither fluoride nor the additive elements in Zr-2 are required for the irradiation effect.

The film impedances were measured to provide an empirical indication of protective quality. It was presumed that oxide of lower apparent dielectric constant would be more protective. (In terms of the weight gain, w, and reciprocal capacitances, 1/c, and where K is an appropriate constant, the apparent dielectric constant is given by: $\epsilon = K\frac{d(w)}{d(1/c)}$. In the case of an irradiation effect in the metal, it was anticiated that film impedances would distinguish between two possibilities: first, that the damaged metal was more chemically reactive, and second, the metal damage resulted in poor quality oxide.

The apparent dielectric constants of film grown on those specimens which show the small corrosion enhancement, was not significantly different from the controls. However, it is not clear how the apparent dielectric constant relates to protective quality. In the case of the prefilmed specimens, the slight retardation of corrosion was accompanied by a significant increase in apparent dielectric constant, which is opposite to the relation expected (5). The film impedances therefore do not distinguish between the possibility that poor oxide grows on irradiated metal from the possibility that the damaged metal is more chemically reactive.

As indicated in the introduction, simultaneous exposure of Zircaloy-2 to oxygenated aqueous media at 300°C with irradiation to a fast neutron flux of 10^{13} n/cm^2/sec results in linear corrosion at a rate of 4.3 mils/year (metal consumption) or about 3 μg/cm^2/hr (weight gain). The question of whether this phenomenon and the enhancement of postirradiation corrosion reported in this paper are indeed ramifications of the same kind of irradiation damage cannot be completely resolved.

Although not related to irradiation effects, it is of incidental interest to take note of the two phenomena regarding the impedances of thin films. Up to 20 μg/cm^2 weight gain, very low reciprocal capacitances were observed for several specimens, perhaps due to short circuits through the film. Also low (and in one case high) tan δ values were observed for thin films on Zr-2 specimens; this indicates a change in the nature of the material at about 20 μg/cm^2 weight gain.

It is concluded that a small enhancement of corrosion of Zircaloy-2 results from prior irradiation of film-free surfaces prepared in certain ways. The data indicate that the damage occurs in the metal and is probably related to dissolved oxygen.

Cox (11) has found that Zircaloy-2 corrosion in steam is accelerated by inhomogeneously distributed oxygen in the metal surface, and particularly in the limiting case where oxygen is present as particles of ZrO_2 in the metal. Fast neutron irradiation has been found to precipitate carbon (12) and nitrogen (13) in iron as the carbide and nitride, respectively. A possible mechanism of the irradiation effect on corrosion is therefore suggested: during the process of corrosion the outermost layers of metal are supersaturated with dissolved oxygen. Fast neutrons cause the precipitation of this dissolved oxygen as zirconium oxide particles, and these precipitated particles enhance corrosion.

Electrodeposition of Tc^{99} from Aqueous Solution

Roger E. Voltz[1] and M. L. Holt

Chemistry Department, University of Wisconsin, Madison, Wisconsin

ABSTRACT

A study has been made to determine the optimum conditions necessary for the electrodeposition of macro amounts of technetium (Tc^{99}) from an aqueous bath containing about 0.018 mole of NH_4TcO_4 and 1 mole of $(NH_4)_2SO_4$ per liter of solution with H_2SO_4 added to *p*H about 1. Electrolysis of this solution at 1 to 2 amp/dm^2 and room temperature gives a bright, metallic appearing deposit of Tc with a cathode current efficiency of up to 30%. Included in this study are the effects on CCE of such factors as current density, bath *p*H, concentrations of the various reagents, temperature, and the colored cathode reduction product. Tests made to determine the nature of the deposit showed it to be essentially metallic; however, annealing is necessary to produce metallic crystals. During electrolysis a light pink reduction product forms in the bath; as electrolysis continues this reduction product becomes darker and appears to poison the bath. Addition of small amounts of H_2O_2 to the bath during electrolysis can prevent the colored reduction products from forming.

Technetium, the first artificial element to be synthesized (1), can be purchased from Oak Ridge National Laboratory as the salt NH_4TcO_4 for about $90 per gram of activity. This availability suggested to the authors that a study of the electrodeposition of technetium on a macro scale from aqueous solution would be a worthwhile addition to the already extensive literature dealing with the electrochemistry of the element and its compounds. An excellent review article by Boyd (2) and a book by Colton (3) gives information about the production and properties of Tc so detailed information will not be repeated here.

Tc^{99} has a half life of about 2.12×10^5 years and emits weak beta rays with a maximum energy of 0.32 Mev (4); thus the walls of ordinary laboratory glassware give sufficient radiation protection when Tc and its compounds are being used. Since information about the physiological effects of Tc is still incomplete, great care should be taken to protect the worker as well as the laboratory from contamination. Several sources of information describing the handling of Tc and its salts (3, 5) are available. Use of rubber gloves, protective clothing, a "film badge," a well-ventilated hood [$HTcO_4$ is fairly volatile (6)], and a covered plating cell are mandatory protections for the laboratory worker.

A number of reports of the electrodeposition of technetium from aqueous solutions have appeared in the literature, but most of them necessarily deal with dilute baths in the order of 10^{-12} to 10^{-5} m/l (mole per liter). The discoverers of Tc, Perrier and Segré, reported the deposition of a thin layer on a platinum wire from a very dilute acid solution (7). Other investigators (8) obtained bright cathode deposits from solutions of NH_4TcO_4 in 2*N* H_2SO_4 and NH_4HF_2. Black or brown cathode deposits were obtained when various pertechnetate salts in H_2SO_4 were electrolyzed (9, 10). Lietzke and Stoughton (11) obtained semi-quantitative data on the electrodeposition of Tc on Pt and Hg cathodes indicating that up to 97% of the Tc could be removed from an acid bath but not necessarily as the pure metal. An alkaline bath containing a Tc salt in 2*N* NaOH produced dark deposits (12). Polarographic studies have indicated the reduction of TcO_4^- to the metal or even to the hydride (13-15).

A survey of the literature suggested that two plating baths producing macro electrodeposits of Tc should be tried before further work was undertaken. The first was the bath reported by Eakins and Humphries (16) which contained NH_4TcO_4 in 2*N* H_2SO_4 with H_2O_2 added to prevent formation of a colored reduction product. We found that electrolysis of this bath at the conditions recommended by the authors gave a metallic appearing plate with a CCE of about 10%. The second macro bath developed by Box (17) uses various minimum amounts of H_2SO_4 (depending on the metal used as a cathode) with ammonium pertechnetate in 0.7M ammonium oxalate and a specially designed electrolysis cell. Plates up to 18 mg/cm^2 were reportedly obtained from this bath at a current density of 130 amp/dm^2, and no H_2O_2 was needed. We were not able to duplicate exactly these results in our electrolysis set-up which consisted of small (1 cm^2) cathodes and anodes in 50-100 ml of plating solution contained in a 150 ml beaker. We found that a light green reduction product formed when the NH_4TcO_4 concentration was about 1 g/l although the bath continued to plate at a low efficiency (about 2%). The extremely high C.D. makes it necessary to take special precautions, and apparently it is necessary to use the plating cell described in the article in order to operate this bath effectively.

Both of these reports indicate that virtually 100% of the Tc can be removed from the plating solutions as what appears to be metallic Tc. Neither of these baths was studied in detail. The first seemed unsuitable for our purpose because of the variation in CCE with each addition of H_2O_2 and the rapidity with which the bath darkened if H_2O_2 was not added. The second was unsuitable for our purpose because of the low CCE and because we were unable to obtain consistent results in our electrolysis set-up. For example, five different baths containing 1-2 g/l of NH_4TcO_4, made according to directions (17), were electrolyzed using both gold and copper cathodes. The deposits on the gold were very loose but metallic gray in appearance whereas those on copper were dark and obviously heavily oxided. All of these baths containing 1-2 g/l of NH_4TcO_4 turned light green after 15 min of electrolysis.

Experimental Methods

The source of Tc in all plating solutions was NH_4TcO_4. Boiled, distilled water was used for making the solutions. One hundred ml of bath was used for each plating run. The electrolysis cell, a 150 ml beaker, was fitted with two 3 x 3 cm Pt anodes and either a gold, copper, or stainless steel cathode of the same size. Direct current was supplied by a variable voltage rectifier. Cells were covered during electrolysis by specially fitted hard plastic plates, and all runs were made in a well ventilated hood. All *p*H determinations were made with a Beckman, battery operated *p*H meter. When semi-quantitative results were required a copper coulometer was used in series with the plating cell. The bus bars were arranged so that the coulometer electrodes and the plating cell elec-

[1] Chemistry teacher, East High School, Wauwatosa, Wisconsin. National Science Foundation Fellow.

trodes could be removed simultaneously from their respective cells. In cathode current efficiency calculations, the equivalent weight of Tc was assumed to be 14.4g (99/7). Shielding and possible spillage or spattering were monitored with a model 107C Professional Geiger Counter.

Preliminary observations.—A number of different plating solutions each containing 0.006 mole of NH_4TcO_4 per liter of solution were electrolyzed at room temperature for about 15 min with a cathode current density (CCD) of about 4 amp/dm^2, and the results are given in Table I.

The results given in Table I indicated that the sulfuric acid bath containing $(NH_4)_2SO_4$ was quite promising. Hull cell tests showed a plating range of approximately 0.6 to 15 amp/dm^2 for a pH 1.0 solution of this bath compared to about 0.1 to 4.0 amp/dm^2 for the acid solutions without $(NH_4)_2SO_4$. Also, this bath had a higher CCE (about 18%) than a comparable bath containing NH_4HF_2 (about 12%). Both the K_2SO_4 and Na_2SO_4 baths gave CCE's (16 and 17%, respectively) comparable to the ammonium sulfate bath, but the solubilities of these salts limited a study of their concentration effects. Thus all additional experimental results were obtained using the NH_4TcO_4-$(NH_4)_2SO_4$-sulfuric acid bath.

Experimental Results

The bath used to obtain the following experimental results contained (unless otherwise stated) 1 mole of $(NH_4)_2SO_4$ and 0.006 mole of NH_4TcO_4 per liter of solution with H_2SO_4 added to give the desired pH. Electrolysis resulted in a pink or brown solution; this was shown to be a cathode reduction product when the cathode was placed in a porous cup during electrolysis runs. The solution in the cup became black and heavy with precipitate while the solution outside the cup remained clear and colorless. The effect of this precipitate on the electrolysis is indicated by the low CCE of these runs (about 3%). Addition of small amounts of H_2O_2 removed the color and dissolved the precipitate. If the bath was to be restored to its former plating efficiency, it was necessary to decompose the excess H_2O_2 by heating with Pt black. Failure to do so resulted in a plating solution that gave a lower CCE.

Cathode current density and CCE.—The results of this study are given in Table II and show that CCE decreased as CCD increased and that a CCD of about 1-2 amp/dm^2 was satisfactory.

Bath pH and CCE.—H_2SO_4 was used to vary the pH. The results given in Table III indicate that a pH range of 0.5-1.5 is satisfactory for producing metallic appearing plates, and thus a bath pH of 1.0 was used for additional work.

Bath temperature and CCE.—Although most electrolyses were made at room temperature, the results given in Table IV show that a higher CCE is obtained at elevated temperatures.

It was noted that the plate taken from the bath at 90°C was much duller and darker than those from lower temperature baths, probably indicating deposit of some oxide and accounting for the apparently much higher CCE. It was also noted that the baths darkened much faster at elevated temperatures than they did at room temperature.

NH_4TcO_4 *concentration and CCE.*—A series of runs were made with baths containing larger amounts of NH_4TcO_4. Table V shows that at about 0.018M NH_4TcO_4 the CCE begins to level off.

All plates were bright and metallic in appearance. Two further runs were later made on fresh baths at 0.030 and 0.036M NH_4TcO_4 concentration. They produced CCE's of 32 and 33%, respectively, again showing the tendency for the CCE to level off at a maximum near 30%.

$(NH_4)_2SO_4$ *concentration and CCE.*—The results, shown in Table VI, indicate that any concentration of $(NH_4)_2SO_4$ above 1 m/l produces a darker plate. For all subsequent studies, the concentration of $(NH_4)_2SO_4$ was 1 m/l.

Table I. Electrolysis of 0.006M NH_4TcO_4 solutions; room temperature; 15-min runs at 4 amp/dm^2

Solution	pH	Appearance of cathode deposit	Remarks
NH_4TcO_4 aqueous	6.0	Shiny, metallic	Poor conductivity
NH_4TcO_4 + H_2SO_4	2.0	Dark, loose	Bath darkened
NH_4TcO_4 + H_2SO_4	1.0	Shiny, metallic	Bath darkened
NH_4TcO_4 + 1M H_2SO_4	—	Shiny, metallic	Bath darkened
NH_4TcO_4 + 2M H_2SO_4	—	Shiny, metallic	Bath darkened
NH_4TcO_4 + H_2SO_4 + NH_4HF_2	1.0	Shiny, metallic	Bath darkened
NH_4TcO_4 + citric acid + H_2SO_4 or NH_4OH	2 to 9	All black	Bath darkened
NH_4TcO_4 + $(NH_4)_2SO_4$ + H_2SO_4	0.5 to 1.5	Shiny, metallic	Bath turned light pink
NH_4TcO_4 + Na_2SO_4 + H_2SO_4	1.0	Shiny, metallic	Light pink
NH_4TcO_4 + K_2SO_4 + H_2SO_4	1.0	Shiny, metallic	Light pink
NH_4TcO_4 + NaOH	12.0	Black	Bath dark

Continued electrolysis and CCE.—A plating solution originally containing 0.012 m/l of NH_4TcO_4 was used in a series of 15-min runs with no treatment between consecutive runs. A dark precipitate gradually formed in the bath and, as shown in Table VII, the CCE decreased. All plates, however, remained shiny and metallic in appearance.

After this series of runs, a small amount of H_2O_2 was added to the solution to oxidize the black reduction product back to the colorless TcO_4^-. The solution was then warmed with Pt black to decompose the excess H_2O_2. The resulting solution, made up to 100 ml and pH 1.0, on electrolysis gave a CCE only slightly (2%) less than the original solution. A bath originally containing 0.03 m/l of NH_4TcO_4 gave similar results with 12 consecutive 15-min runs, and H_2O_2 treatment also restored this bath so that on electrolysis it gave almost its original CCE (29 instead of 32%).

Nature of the Cathode Deposit

The cathode deposit obtained from the ammonium pertechnetate-ammonium sulfate-sulfuric acid bath at pH 0.5-1.5 appeared very metallic. It was not attacked by HCl and only slowly by concentrated H_2SO_4. It was attacked readily by HNO_3 of various concentrations and also by H_2O_2 in either sulfuric acid or ammonium hydroxide, as others have reported (18). When the bath pH was 2.0 or higher, the deposit became dark and quite loose. Accordingly, the possibility that the deposit was an oxide of technetium existed. Three series of tests were developed to explore this possibility. These were hydrogen reduction studies, precipitation studies, and x-ray diffraction studies. Other methods for quantitative determination of Tc are summarized by Colton (3).

Cathode deposits for these studies were obtained from 100 ml of the $(NH_4)_2SO_4$-H_2SO_4 bath containing 0.012 mole of NH_4TcO_4 per liter (pH 1.0, C.D. 2 amp/dm^2) on gold, platinum, and stainless steel cathodes. Before electrolysis, cathodes were rinsed with distilled water and then alcohol and dried to constant weight in an evacuated dessicator and after the plating run was completed, the plated cathodes were treated in the same manner.

Hydrogen reduction.—Ten plated cathodes, along with the control plates (unused stainless steel cathodes), were heated in a hydrogen atmosphere at 350°-400°C (10, 15) for 2 hr. They were then allowed to cool to room temperature, with the hydrogen still passing over them, before reweighing. Calculations, based on the stoichiometry: $Tc + TcO_2 \cdot 2H_2O + 2H_2 \rightarrow 2Tc + 4H_2O$, showed the deposit to be 92 ± 5% metallic Tc. Allowance was made for standard weighing deviations and control plate weight loss (average 0.0001g), but there was no way to measure the weight loss involved in the mere handling of this deposit that was not very adherent. Hence the evidence from this study can only be interpreted as indicating that the plate is essentially Tc metal.

Precipitation studies.—Three cathode deposits, whose weights had been previously determined, were dissolved in HNO_3 to remove the deposit from the gold cathodes and the solution adjusted to pH 8.0 with NH_4OH. Tetraphenylarsonium chloride was then used as the precipitating agent using the procedure described in the literature (19). Preliminary tests on this procedure had indicated a recovery of Tc was 98-100% which was in accord with the results of other investigators (20) and well within our standard weighing deviations. After drying the tetraphenylarsonium pertechnetate to constant weight, calculations were made based on the stoichiometry: $Tc + TcO_2 \cdot 2H_2O + 10\ HNO_3 + 2NH_4OH + 2(C_6H_5)_4AsCl \rightarrow 2(C_6H_5)_4AsTcO_4 + 2NH_4Cl + 10\ NO_2 + 8H_2O$. The results obtained showed the deposit to be 100 ± 2% Tc metal.

X-ray diffraction studies.—It was felt that three comparison values were needed in order to pursue this investigation: (*i*) A diffraction study of pure Tc metal. The Tc metal was prepared by electrodepositing Tc on stainless steel cathodes and subjecting these deposits to hydrogen reduction at 400°C until no further weight loss was noted. The deposits were then scraped (with great difficulty) from the stainless steel. (*ii*) A diffraction study of technetium dioxide. The oxide was deposited from a high pH (9.0) bath and dried to constant weight at 100°C. (*iii*) A diffraction study of the cathode deposit taken from the bath being studied. The cathode deposit taken from the bath described above was dried and easily scraped from the stainless steel cathode. Each of these prepared samples was then submitted for an x-ray diffraction study. The pure Tc metal prepared as above, showed only the lines of Tc, as reported in the literature (21), and no other lines; but neither the oxide nor the cathode deposit scrapings showed any lines capable of evaluation. Both were judged as being amorphous. A search of the literature revealed that others had experienced the same difficulty in evaluating a plate taken from a slightly acid ammonium sulfate-ammonium pertechnetate bath (22) and found that further annealing was necessary to develop the crystalline nature of the plate. Their study showed that from their higher pH bath, both Tc and Tc in an oxidation state of 4 were present.

We obtained several more cathode plates and collected more oxide and annealed both in an argon atmosphere for 2 hr. It was found that a temperature in excess of 200°C was needed to bring out the lines in the oxide while a temperature of 350°-400°C was required to anneal the plate material.

Seven fresh cathode plates were then prepared from the bath and the weights determined as described previously. The plates, along with control plates, were then annealed in an argon atmosphere for 2 hr at 400°C and the weight loss noted. In all cases, the weight losses were well within the standard weighing deviation. Annealing made the deposit extremely adherent and difficult to remove from the basis metal.

The scrapings from the plates were submitted to x-ray and in all cases showed only the lines of Tc and no other lines. At the annealing temperature we would expect any hydrated technetium oxide to have released its water of hydration with the stoichiometry:

$$Tc + TcO_2 \cdot 2H_2O \xrightarrow{400°C} Tc + TcO_2 + 2H_2O \quad (23).$$

Since the weight losses were well within the standard weighing deviations and since no lines other than pure Tc metal were discernible in the x-ray diffraction pattern, it appears that the amorphous plates, produced under the bath conditions described, were metallic within the limits of our investigation. Thus, all three studies tend to support the conclusion that the plate is certainly not oxide and is probably about 100% metallic.

Alloys

Attempts to electrodeposit a Ni-Tc (TcO_4^- added to a Watts bath) and a W-Tc alloy ($TcO_4^- + Na_2WO_4$ solution) were not successful. There was some evidence, however, that it might be possible to codeposit Re and Tc from a solution containing ReO_4^- and TcO_4^-.

Conclusions

The results presented show that Tc can be deposited in macro amounts as the bright metal from various

aqueous solutions. The $(NH_4)_2SO_4$-NH_4TcO_4-H_2SO_4 bath described here gives good CCE, is reasonably stable, can be readily rejuvenated by H_2O_2, and with reasonable precautions can be used safely in ordinary laboratory equipment. A bath containing 1M $(NH_4)_2SO_4$ and from 0.006 to 0.024M NH_4TcO_4 with H_2SO_4 added to give a *p*H of about 1.0, can be electrolyzed at 1-2 amp/dm^2 to produce a metallic cathodic deposit of Tc with a CCE range of 18-30%.

Electrodeposited Tc metal has few uses at the present time outside of medicine (24). However, its superconductivity at low temperatures as a metal (25) and as an alloy may find value in the rocket guidance systems and computer systems at a future time (26). Certainly, the possibility of plating an alloy of Tc deserves consideration.

Acknowledgment

The authors express their thanks to Dr. Chin-Hsuan Wei, of this department, who gathered and interpreted the x-ray diffraction data. One of us (REV) is grateful to NSF for financial support that made this work possible.

Determination of the Composition of Complexes and Their Instability Constant by Calorimetry

II. The Complex in Fused Potassium Chloride and Cadmium Chloride

William H. Metzger, Jr., Abner Brenner, and Harry I. Salmon

National Bureau of Standards, Washington, D. C.

ABSTRACT

A new method of determining the composition of complexes in solution and their equilibrium constant has been developed which is based on the determination of the partial molal heat effect developed when a small increment of each salt is added in turn to a series of mixtures covering the range of composition from 0 to 100%. The method was applied to the molten KCl-$CdCl_2$ system. The data show that the system contains the 1:1 complex with an instability constant of 0.32 at temperatures of 600° and 780°C. A calorimeter is described which permits the addition of the increments of salt to the molten mixture while the latter is stirred continually.

In a previous publication (1) a general method was described for determining the composition of complexes and their instability constant by calorimetric measurements. The experimental procedure consisted in adding a small amount of one reactant to a mixture of the reactants and determining the heat effect. From the latter the partial molal heat effect was obtained. The purpose of adding only a small amount of reactant was to determine the resultant heat effect without changing the composition of the mixture by more than a per cent. Thus, the heat effect is a function of the composition of the mixture. This procedure was repeated with one or preferably with both reactants over the range of composition of mixtures from 0 to 100%. In the aforementioned paper the method was applied to the determination of the composition and instability constant of two of the copper cyanide complexes. These measurements involved the addition of about 1g of sodium cyanide to solutions of cuprocyanide covering a range of composition.

The partial molal heat effect can be considered as the heat effect resulting from the addition of one mole of reactant to an infinite amount of mixture. It can be seen qualitatively that the heat effect is a function of the composition of the mixture by the following example: Let the complex formed from the two reactants A and B be AB_2. If small increments of A are added to a series of mixtures, starting with pure B

and then proceeding through intermediate steps to the composition AB_2 and beyond to pure A, it would be found that the maximum heat effect would occur when the addition of A is made to pure B. If the instability constant is small (less than 10^{-2}), the molal heat effect would be approximately equal to the heat of formation of the compound AB_2. The heat effect would diminish only slightly with succeeding mixtures until the composition AB_2 is approached. At the stoichiometric point the partial molal heat effect would rapidly decrease and beyond this point would have a small value. The partial molal heat effect of adding pure B to an infinite amount of pure A would be only half of that obtained by adding A to an infinite amount of B because only ½ mole of complex is formed per mole of B.

Assume that almost complete reaction occurs when a small amount of A is added to an infinite amount of B, and let this maximum heat effect (which is approximately the heat of reaction) be designated by θ_A per mole of A. Then the ratio of the partial molal heat effect $\Delta\overline{H}$ (obtained by adding a mole of A to an infinite amount of a mixture of A and B) to θ_A represents the fraction of a mole of AB_2 formed. For example, if θ_A is 10 kcal and $\Delta\overline{H}$ for a mixture just beyond the stoichiometric point is 0.5 kcal, this would mean that the addition of one-mole of A to an infinite amount of mixture of that composition results in the formation of only 1/20 mole of complex. This ratio, which is the fraction of a mole formed in the reaction, will be called the "fraction of reaction."

The fraction of reaction is the quantity which is experimentally determined. It can vary from zero to unity. This fraction is a partial derivative and is related to the mass action expression. If dy is the increment of A added to a mixture of any composition and $d\bar{a}$ is the amount of the product AB_2 formed, then the fraction of reaction is $\partial\bar{a}/\partial y$. Similarly, if dx denotes the increment of B that is added to a mixture, then $\partial\bar{a}/\partial x$ also is the fraction of reaction, and it cannot be larger than ½.

The two partial derivatives will be denoted by $\bar{a}'_x$ and $\bar{a}'_y$ or simply $\bar{a}'$ when only one independent variable is used throughout the discussion. They are derived mathematically from the expression for the mass action law by differentiation. If the reaction is $rA + sB \rightarrow A_rB_s$, the general expression for the mass action law for fused salts written in terms of mole fraction is

$$\frac{\left[\frac{y-r\bar{a}}{f}\right]^r\left[\frac{x-s\bar{a}}{f}\right]^s}{\frac{\bar{a}}{f}} = k \qquad [1]$$

where y and x represent the initial moles of A and B, respectively, used in making up the mixture, $\bar{a}$ represents the moles of A_rB_s formed at equilibrium. r and s are the coefficients of A and B in the chemical reaction, and f is the total number of moles present, $f = x + y + \bar{a}(1-r-s)$.

The formulas and the methods of determining the composition and the instability constant of a complex were derived in a former publication (1).

The cadmium chloride-potassium chloride system was chosen for study mainly to explore the applicability of the partial molal heat method to a fused salt system. This system had received extensive investigation (3-17) but the complexes present in the molten mixture had not been determined with certainty. We studied the system at a temperature of about 780°C so that it would be above the melting point of the highest melting component, potassium chloride (mp 772°C). This permits the introduction of increments of either salt in the molten form, hence there is no complication owing to heat of fusion of a solid. This temperature was higher than that used by most of the previous workers.

Apparatus

The determination of the heats of reaction in the fused salt bath requires the construction of a calorimeter which is operable at temperatures up to 900°C. The literature contains descriptions of several high temperature calorimeters, but experience with them has been so limited that no one design has emerged as the best. A description of the various high temperature calorimeters which have been constructed would be too much of a digression here. However, none of them have the two features which we consider essential for the success of the measurements. The two features are (*i*) continuous stirring of the reaction mixture while an increment of a reactant is added, and (*ii*) the complete submersion of the ampoule containing the increment below the surface of the fused salts, so that it is exactly at the temperature of the reaction mixture at the time that the ampoule is broken. Otherwise the construction of the furnace and calorimeter is conventional.

The construction of the calorimeter is shown in Fig. 1. It consists of a stainless steel jacket about 40 cm in diameter and 75 cm high, surrounded by a 5 cm thick layer of thermal insulation. Internally, the loss of heat is diminished by seven radiation shields made of stainless steel. The heating system consists of two wire wound concentric heaters and a third flat heater placed horizontally on the bottom below the other two. The outer and the bottom heaters are operated at a con-

stant current, such that a temperature slightly below the desired temperature is maintained in the center of the furnace. The inner heater is controlled by an automatic device which obtains its input signal from two chromel alumel thermocouples connected in series and located in the heart of the furnace near the reaction vessel. Most of the emf of these thermocouples is annulled by a potentiometer as the controller can handle a maximum input of only 7 mv. This method of obtaining the emf-change only as a difference increases the sensitivity of the control system. Over a period of 10 min the temperature of the inner vessel holds constant to about 0.01°C, but over a period of a day the temperature varies about 0.5°C. However, since the reaction is complete in about 15 to 30 sec, constancy for only a short time is adequate. The heaters have a total maximum power capacity of 5 kva.

To improve the uniformity of temperature, the furnace is provided with two concentric cylinders of silver about 1 cm thick, having a total weight of about 30 kg.

The inner vessel consists of a mullite tube, 8 cm in diameter and 60 cm long which is closed at the lower end. The upper end carries a brass flange which is cemented to the tube by an air cured silicone plastic material. The end projects sufficiently above the furnace so as not to be heated higher than 200°C. Another reason for having the open end of the tube project above the level of the furnace is to prevent corrosive halide vapors from damaging the heating elements.

The fused salt is contained in a platinum-rhodium vessel measuring 6.5 cm in diameter and 14 cm high. About 600 to 800g of salt are used for an experiment and the liquid level generally comes to within 5 cm of the top of the vessel. It is essential to construct the vessel of a platinum alloy as ceramic vessels frequently break when the fused salts solidify in them.

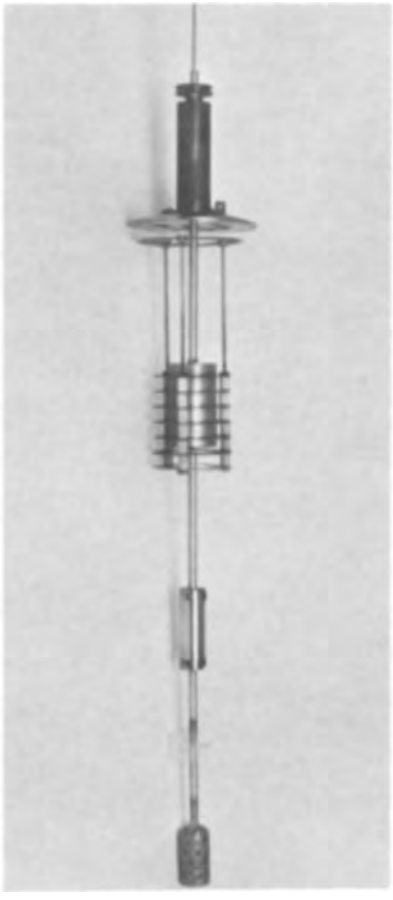

Fig. 2. Dispenser-stirrer unit, fully assembled with bearings and removable radiation shields.

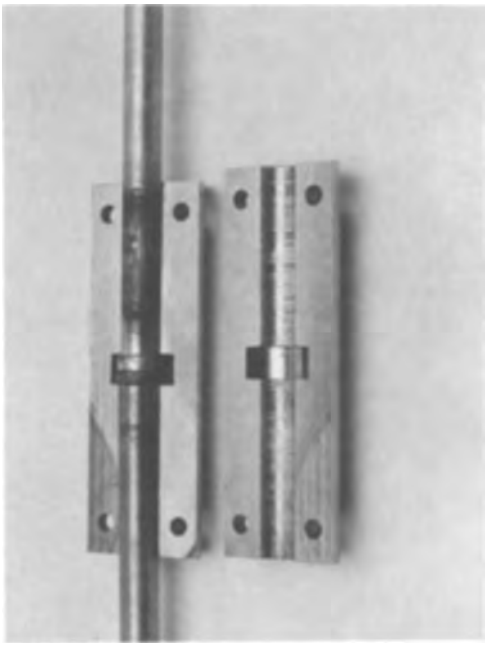

Fig. 3. Shaft coupling of the dispenser-stirrer; open view.

Fig. 4. Dispenser-stirrer: exploded view of the dispenser with loaded ampoule.

The most time-consuming part of the investigation was the development of a satisfactory device hereafter referred to as "dispenser-stirrer" for stirring the molten salt and for adding the increment. This part of the apparatus is shown in Fig. 2-4 in both an assembled and exploded photographic view. The dispenser-stirrer body is constructed of a platinum-iridium alloy, as ceramic vessels which were tried were not rugged enough and caused the loss of many experiments through breakage. The platinum alloy basket holds the ampoule, retains the broken fragments of the ampoule, and prevents them from catching in the thermocouples or the heater used for calibration. The notched platinum alloy bar with tabs holds the basket and ampoule in place and in addition acts as an anvil for breaking the ampoule. The pointed tungsten rod located inside of the shaft is used for breaking the ampoule containing the increment of salt. The stirring shaft is a nickel tube connected to the

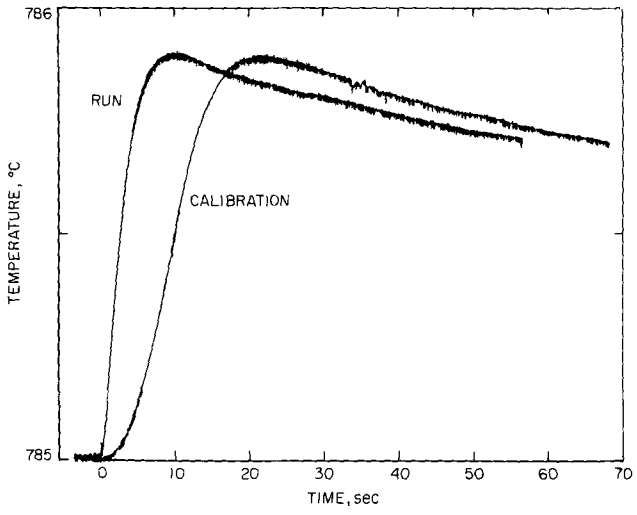

Fig. 5. Typical curves of temperature vs. time obtained with the recording potentiometer.

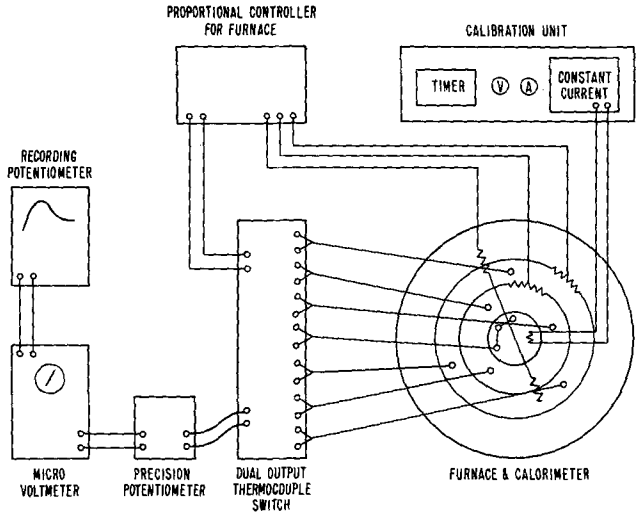

Fig. 6. Block diagram of apparatus

upper tubular part of the dispenser-stirrer by the coupling shown in Fig. 3. This construction allows for interchange of parts and permits the tungsten rod to move freely up and down in the shaft while the assembly is rotating.

The ampoules are made of fused silica. They are thin-walled and about 2 cm in diameter. They are easily broken by punching with the tungsten rod while stirring is in progress. The end of the neck of the ampoule is either bent or enlarged with a piece of fused silica to prevent the neck from protruding through the holes in the dispenser and snagging a thermocouple.

The temperature rise in the reaction vessel is measured by three commercial chromel alumel thermocouples connected in series. These are only 1.5 mm in diameter and require very little space. Furthermore, because of their small size they react to the temperature changes in a second. A temperature change of 0.01°C gives an indication slightly more than 1 μv. The average temperature rise in the experiments is about 1°C and the largest temperature rise is about 3°C.

The temperature increase during an experiment is measured by a microvoltmeter in series with an output voltage from a microvolt potentiometer. This arrangement made it posible to balance the thermocouple emf with the potentiometer immediately prior to the breaking of the ampoule and thus read the emf change on the microvoltmeter. The temperature rise is measured on the microvoltmeter, usually on the 100 μv scale. The voltage *vs.* time trace is recorded on a recording potentiometer connected to the microvoltmeter shown in Fig. 5. Readings are made to 1 μv.

For purposes of accurate temperature measurement and stability, the thermocouples used in the body of the furnace consist of platinum, platinum-10% rhodium alloy. These thermocouples are placed in tubes of pure aluminum oxide. At a temperature of 800°C the resistance between a thermocouple and ground is about 20 megohms. The proper insulation of the thermocouples is a matter of considerable importance.

In our first experiments the thermocouples were placed in mullite tubes, and they operated satisfactorily up to a temperature of about 600°C. But at 800°C the mullite tubes became too conductive and the thermocouples picked up stray voltages which prevented accurate readings being taken with the microvoltmeter. The block diagram for the thermocouples and associated measuring instruments is shown in Fig. 6.

Procedure

The furnace is allowed to come almost to temperature by being left on at a steady current over night. The furnace is put on automatic temperature control in the morning. The salt mixture is placed in the platinum-rhodium reaction vessel and melted in a pot furnace. It is then quickly transferred to the calorimeter furnace. The preliminary heating of the mixture reduces the time required for the setup to come to thermal equilibrium, and in so doing also reduces the loss of cadmium chloride by volatilization.

Next, the dispenser-stirring device is loaded with an ampoule of salt, the latter weighing usually from 1 to 3g (usually about 0.02 mole of salt is added to about 4 moles of salt mixture). The entire unit shown in Fig. 2 is locked into place with a split ring-clamp at the top of the ceramic tube. Stirring is started and after about ½ hr thermal equilibrium attained. This is considered to be the case when the temperature does not change more than 0.01°C/min. On breaking the ampoule, the reaction is completed in about 15 sec, as indicated by the maximum in the temperature rise.

The calibration of the calorimeter is performed at least twice for each determination, usually before and after the introduction of the increment of salt. An electric current of about 4 amp at 14v is passed through the platinum alloy heater coil (the latter being enclosed in a fused silica tube) for 10 to 20 sec. The high current and short period of heating is necessitated by the need to duplicate the heating rate of the chemical reaction. This is not achieved exactly, as the time of heating would have to be too short and the current too large for convenience in measuring. Although the interval of calibration may vary from 10 to 20 sec, it is accurately read on an electric timer accurate to 0.01 sec. The current is delivered by a constant current device, consequently, only one reading of current needs to be made during the calibration. The voltage, however, varies from about 13 to 14v during the calibration. Readings are therefore taken at intervals of about 2 or 3 sec on a voltmeter accurate to 0.5% and averaged. The heat capacity of the calorimeter, including the fused salt, is about 1 cal/μv or about 120 cal/degree.

In calculating the heats of reaction, no correction is made for the heat leak. The temperature rise is taken as the peak of the curve. This probably does not represent the true equilibrium temperature, but since the calibration is made in the same manner, most of the error is annulled. Since the heat leak is mostly a result of radiation, a simple correction cannot be made, as in calorimetry which is done at room temperature. This is because the rate of heat leak is not directly proportional to the temperature head. A graphical method of correcting for heat leak, which is based on the cooling curve, is given in the appendix. This correction for heat leak was not considered to be practicable in our work, because the calorimeter did not maintain a sufficiently constant temperature over

the period of 10-30 min that would be required to establish the cooling curve.

The filling of the ampoule presented a special problem, because the presence of a trace of moisture in the salt caused some of them to explode in the furnace. The following procedure is successful. After the required amount of salt is placed in the ampoule, it is placed in a furnace at 650°C for an hour to remove moisture. Then after cooling in a desiccator the ampoule is evacuated and sealed.

To expedite the measurements, two complete dispenser-stirring units are used. This permits another run to be made as soon as one unit is removed from the calorimeter. Four complete runs can be made in one day, including the necessary number of calibrations. The largest amount of time is spent in waiting for the system to come to thermal equilibrium.

Results

Although the precision of measuring the temperature rise in most of the experiments was about 1%, the precision of the measurements of the heat capacity of the system was about 3%. The over-all precision of the measurement of the partial molal heat effects was about 5% or 200 cal, whichever was the larger.

As an over-all check on the accuracy of the measurements, the heat of fusion of potassium chloride was measured. This was done by adding about 3g of potassium chloride to 450g of a melt consisting of about 95 mole % potassium chloride and 5 mole % cadmium chloride. Additions of solid potassium chloride were made at about 8° below its melting point. We found that the heat of solution (cooling) of the solid potassium chloride was 6380 cal/mole (1 cal = 4.18 Joules). The heat of mixing of the molten potassium chloride, determined at 780°C in the same melt, was small and positive, about 180 cal/mole. The heat of fusion of potassium chloride was 6560 ± 160 cal/mole. This result is about 5% higher than the value of 6274 cal/mole obtained by the drop method of calorimetry (2).

The experimental results for the $CdCl_2$-KCl system were obtained in the form of a heat effect for the increment of potassium chloride or cadmium chloride added to the melt. From this effect was computed the heat effect per mole of added salt, that is, the partial

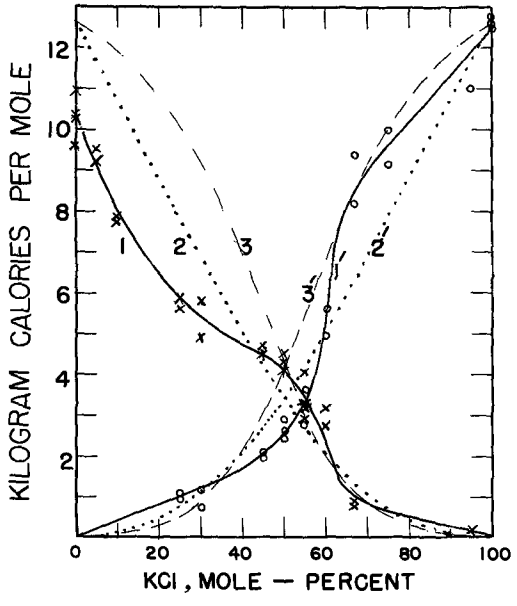

Fig. 7. Partial molal heat effects obtained at 780°C. by adding either potassium chloride (curve 1) or cadmium chloride (curve 1') in the molten state to molten mixtures of potassium and cadmium chloride. Curves 2 and 3 represent theoretical curves for the addition of potassium chloride and curves 2' and 3' represent the corresponding curves for cadmium chloride.

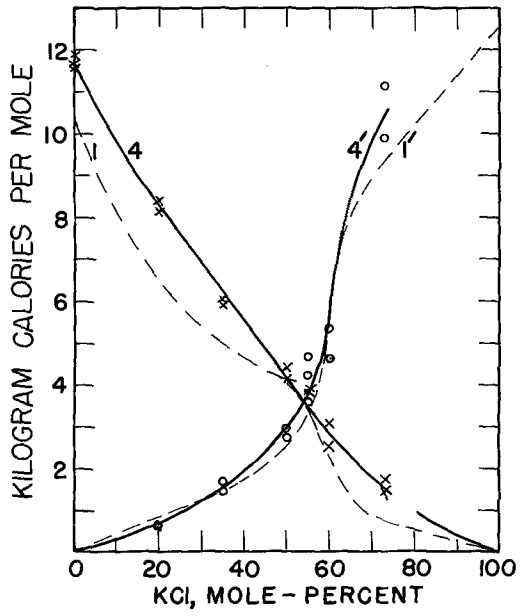

Fig. 8. Partial molal heat effects obtained by adding either potassium chloride (curves 1 and 4) or cadmium chloride (curves 1' and 4') to molten mixtures of potassium chloride and cadmium chloride. Curves 1 and 1' are the same as the like-numbered curves in Fig. 7 and refer to a temperature of 780°C. Curves 4 and 4' represent the data obtained at 600°C with cadmium chloride and potassium chloride.

molal heat effect, $\Delta\bar{H}$. These data are graphed in Fig. 7 and 8 against mole per cent of potassium chloride in the melt.

Even without any mathematical analysis, the data show that the complex consists of equal moles of $CdCl_2$ and KCl. This follows from the approximately equal heat of reaction for an increment of KCl added to pure $CdCl_2$ and an increment of $CdCl_2$ added to pure KCl. Further evidence is that the curves cross at 55 mole % which is close to the stoichiometric 50 mole % point. No other complex appears to exist at the temperature of 780°C.

The mass action expression, in terms of the mole fraction, is

$$(x-\bar{a})(y-\bar{a}) = \bar{a}k(x+y-\bar{a}) \qquad [2]$$

where x and y are the initial number of moles of reactants, $\bar{a}$ is the moles of complex formed, and $(x + y - \bar{a})$ is the total number of moles present at equilibrium.

The instability constant may be calculated either from the fraction of reaction $\bar{a}'$, or from the slope of the curves at their intersection. The former method is less satisfactory than the latter if the instability constant is small, but in the present case it is equally satisfactory. The value of $\bar{a}'$ is obtained for the point of intersection of the two curves, where $\Delta\bar{H}$ = 3400 cal/mole. Hence, $\bar{a}'$ = 3400/12,600 = 0.27. (The value of 12,600 cal/mole is the heat of reaction derived from our experiment of adding an increment of molten cadmium chloride to molten potassium chloride, as shown in Fig. 7 for the abscissa: KCl, 100%.) This value is substituted into the following equation [see Eq. 33 of ref. (1)]

$$k = \frac{(1-2\bar{a}')^2}{4\bar{a}'(1-\bar{a}')} = \frac{(1-0.54)^2}{4(0.27)(0.73)} = 0.27 \qquad [3]$$

To use the second method, $\bar{a}''$ is found at the point of the intersection of the curves, from the slope of the curves. Since the intersection should have occurred at the stoichiometric point, consider $x = y = 1$ at the point of intersection.

$$\bar{a}'' = \frac{\partial \bar{a}'}{\partial x} = \frac{1}{\theta} \cdot \frac{\partial \Delta \bar{H}}{\partial x} \quad [4]$$

Since the abscissa represent the mole per cent, $\frac{x}{x+y} \times 100$, of the components weighed out, that is the initial composition of the melt, the slope of the curve at the stoichiometric point is with respect to the mole per cent (or mole fraction) and must be converted to a function of x as follows

$$\frac{\partial \Delta \bar{H}}{\partial x} = \frac{y}{(x+y)^2} \cdot (\text{Slope}) \quad [5]$$

$$\bar{a}'' = \frac{1}{\theta} \cdot \frac{y}{(x+y)^2} \cdot (\text{Slope})$$

$$= \frac{1}{12{,}600} \cdot \frac{1}{4} (-18{,}500) = -0.367 \quad [6]$$

if $x = y = 1$

The instability constant is calculated from the following equation [see Eq. 37 and 38 in Ref. (1)]

$$k = \left[\frac{\bar{a}'}{2\bar{a}''y}\right]^2 \cdot \left[\frac{1-\bar{a}'}{\bar{a}'}\right]$$

$$= \left[\frac{0.27}{2(-0.367)}\right]^2 \cdot \frac{(1-0.27)}{0.27} = 0.137 \times 2.7 = 0.37 \quad [7]$$

This result of 0.37 calculated from the slope of the curves agrees fairly well with value of 0.27 calculated from the ordinate of the curve. The average value of 0.32 will be used in following discussions.

Another possibility for the composition of the complex presents itself for consideration on the basis that the curves cross at 55 mole per cent potassium chloride. This composition represents a compound having the formula $6KCl \cdot 5CdCl_2$ which has a mole percentage of KCl of 6/11 x 100 = 54.5% or a mole ratio of cadmium chloride to potassium chloride of 0.83. This possibility seems to derive support from the differing values of the partial molal heat effects for the addition of $CdCl_2$ to pure KCl ($\Delta\bar{H}$ = 12,600 cal) and KCl to pure $CdCl_2$ ($\Delta\bar{H}$ = 10,300 cal) which give a ratio of 0.82, a result very close to the ratio obtained from the point of intersection of the curves. However, this possibility has been discounted because the calculation of the instability constants from the ordinate, a', of the curve [see formula 33 of reference (1)] gives a value of $k = 1.0 \times 10^{-3}$, whereas the calculation from the slope of the curve, via $\bar{a}''$, [see formula 37 of reference (1)] gives the greatly different value of $1.0 \times 10^{+3}$.

Returning now to a consideration of the simple complex, $KCl \cdot CdCl_2$, since it has a relatively large instability constant, this means that the complex is moderately dissociated. At the stoichiometric point the melt contains about 50% of the constituents in the form of complex. (This follows from the relation that the amount of complex formed by adding 1 mole of A and then 1 mole of B to an infinite amount of 1:1 mixture is $(1 \times \bar{a}'_x) + (1 \times \bar{a}'_y) = 0.27 + 0.27 = 0.54$.) It is rather surprising that the complex is dissociated even in the presence of a large excess of either one of its components. This follows from the mass action law which shows that on adding an increment of salt to an infinite amount of the other constituent, the whole increment is not converted into complex, that is to say, the fraction of reaction, $\bar{a}'$, is appreciably less than unity

$$a'_x = \frac{\bar{a}(1+k) - y}{(1+k)(2a - x - y)} \quad [8]$$

As the content of y in the melt becomes infinite with respect to both the increment x and the complex $\bar{a}$, the value of $\bar{a}'_x$ approaches the limit

$$\bar{a}'_x = \frac{1}{1+k} = \frac{1}{1+0.32} = 0.76$$

On this basis the true heat of reaction of potassium chloride and cadmium chloride to form a mole of complex must be larger than the observed value of 12,600 cal and have the value of 12,600/0.76 = 16,600 cal. With this derived value for the heat of reaction and with the value of k = 0.32 two curves were drawn, 3 and 3′ (see Fig. 7) for comparison with the two experimentally determined curves. The agreement is fair. It will be noted, however, that the derived curves cross at a value of $\Delta\bar{H}$ = 4300 cal instead of the experimentally determined value of 3400 cal, because of the higher value of the heat of reaction used in the computation.

Probably the best fit of derived curves with the experimental data is obtained if the curves are chosen so as to intersect at 3400 cal and to have the value of 12,600 cal at the right and left sides of the graph. Calculation yielded the result that the value of k would be 2.7 and the value of the true heat of reaction would be 46,620 cal. These derived curves are shown in Fig. 7 as dotted lines 2 and 2′. These fit the experimental data better, but it is doubtful that such a large extrapolation is meaningful in view of the probable experimental error of the data, hence, we reject this interpretation. A value of k = 2.7 leads to the result that the reaction mixture contains only about 15% of complex at the stoichiometric point and that only about 27% of an increment is converted into complex when added to the pure salts.

The feature of the experimental data for which we have no explanation at present is the intersection of the curves at a mole fraction of about 55 mole per cent instead of the stoichiometric value of 50%. With a melt of stoichiometric composition, an increment of either salt should yield the same partial molal heat effect. A difference in activity coefficients is not an acceptable explanation, since the same reaction mixture (hence, the same activities) is used for both increments. Perhaps the discrepancy can be explained on the basis of the formation of another complex which is too dissociated to yield a definite inflection in the curves.

The heat of reaction (12,600 cal) resulting from the addition of $CdCl_2$ to KCl is larger than that (10,300 cal) obtained by adding KCl to molten $CdCl_2$, whereas on the basis of simple considerations they are expected to be equal. The difference might be due either to a lower activity of cadmium chloride in the mixture in comparison with potassium chloride, or to the formation of a small amount of a higher complex, for

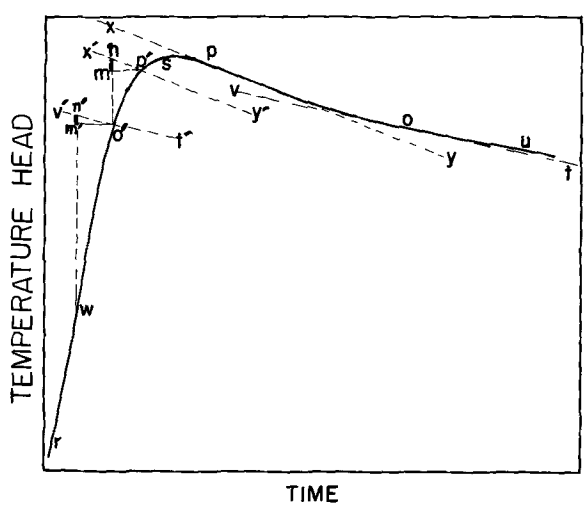

Fig. 9. Method of using the cooling curve, sou, for correcting the heat lost during the period of temperature rise, rws.

example, $2KCl \cdot CdCl_2$, when $CdCl_2$ is added to molten KCl.

The cadmium chloride-potassium chloride system was also investigated at a temperature of 600°C. At this temperature potassium chloride is solid, and consequently all the experiments with increments of KCl had to be corrected by the heat of fusion of KCl, for which purpose we took the round number of 6500 kcal. The melt becomes solid at about 75 mole % potassium chloride, hence, our data was extended only to a melt of 73 mole % KCl. In Fig. 8 the curves 4 and 4′ for the 600°C determination are compared with the curves 1 and 1′ obtained at 780°C. The data for the 600°C determinations yielded about the same instability constant as the data for 780°C. This follows because the curves 4 and 4′ cross at about the same point as curves 1 and 1′ and the slopes are not very different for these two pairs of curves at the points of intersection.

Discussion of the Literature

There are a number of publications in the literature dealing with the nature of the molten cadmium chloride-potassium chloride system. The constitutional diagram of the system, first investigated by Brandt (3) shows the existence of the congruently melting compound $KCl \cdot CdCl_2$ and the incongruently melting compound, $4KCl \cdot CdCl_2$. However, the existence of a solid compound does not prove its existence in a melt.

Attempts have been made to determine the composition of the complex in the molten system by means of various physical measurements. The rationale behind these studies is that the deviation of a physical property from an additive or ideal value based on the properties of the parent compounds would be greatest at the stoichiometric point. However, since both positive and negative deviations from ideal behavior occur for mixtures of fused salts that are known not to form complexes, these measurements do not generally lead to an unequivocal conclusion.

The physical property of the system that has been investigated most is electrical conductivity. This was first measured by Sandonnini (4) whose data on specific conductivity showed a slight minimum at 40 mole % potassium chloride. Mulcahy and Heymann (5) computed the equivalent conductivities from Sandonnini's data. Finding the greatest departure from additivity at 65 mole % potassium chloride, they suggested the formula, $2KCl \cdot CdCl_2$. Bloom and Heymann (6) found that the equivalent conductivity of the mixture was at a minimum between 55 and 60 mole % potassium chloride (their specific conductivities did not show a definite minimum) and that the temperature coefficient of the conductivity was a minimum at 50 mole %. The electrical conductivity of the system was also investigated by Sakai (7).

Several other physical properties of the system have been investigated. Harrap and Heymann (8) found that the viscosity of the system at 650°C was at a minimum between 50 and 60 mole % potassium chloride. Measurement of the densities and molar volumes of the system by Boardman, Dorman, and Heymann (9) showed that the system had large positive deviations from additivity. The measurement of surface tension by Boardman, Palmer, and Heymann (10) showed a negative deviation from ideal behavior, but no well defined minimum that would unambiguously define a compound. Barton and Bloom (11) measured the vapor pressure of the system and calculated activity coefficients for 900°C. Their discussions of the composition of the complex were speculative. Bloom, Davis, and James (12) investigated the surface tension and surface heat of the system and had this to say: "This method, in common with results of electrical conductivity, viscosity, molar volume, etc., do not lead unequivocally to the stoichiometric composition of such complex ions, although there is general acceptance of their presence in certain systems."

The Raman spectra of the system have also been investigated. Bues (13) favored the $CdCl_3^-$ complex ion on the basis of his measurements, but Bredig and Van Artsdalen (14) claim that Bues' data could better be interpreted to prove the existence of the $CdCl_4^{2-}$ complex. Bredig (15) backed up his assertion in a subsequent publication dealing with Raman spectra and electrical conductivity, and in a paper published the following year (16) claimed that the measurement of activity coefficients that had been published by Russian investigators supported his view.

Bockris and co-workers also entered the discussion. On the basis of the measurement of the self-diffusion of Cd^{++} ion in the molten mixture, Bockris and Angell (17) found the maximum rate to occur at the composition corresponding to $KCl \cdot CdCl_2$. Tanaka, Balasubramanyam, and Bockris (18) also measured the Raman spectra of the system and considered that the data indicated that the complex ion was $CdCl_3^{-1}$ and thus supported Bues instead of Bredig. However, they differed from the former in finding that the complex was pyramidal, whereas Bues had found it to be a planar triangle. The arguments of Tanaka, Balasubramanyam, and Bockris were somewhat tenuous as they were not based entirely on experimental findings, and some of the Raman lines were very weak.

Summary

The foregoing discussion indicates that measurements of the physical properties of the system did not lead to a decisive determination of the composition of the complex ion in the melt and none of the methods led to a value for the instability constant. The method of partial molal heat effect, in contrast, has led to an unambiguous determination of the composition of the complex, as well as to an approximate value of the instability constant. The fundamental reason that the calorimetric method has been more successful is that it involves measurements on the chemical reaction itself, and in this way it is unique. It leads to a determination of the "fraction of reaction." It requires no prior knowledge of the physical constants of the components or of the complex, whereas the other methods depend on deducing the existence or the concentration of a complex by comparing physical properties of static systems.

APPENDIX

Graphical Method of Correcting for Heat Leakage in Calorimetry

In Fig. 9, rws is the temperature-time curve resulting from the reaction and st is the cooling curve.—The graphical correction involves no assumption other than that the rate of heat leakage is a function of temperature head. Thus, for any given temperature head while the temperature of the reaction vessel is rising (point p', for example) the rate of loss of heat is the same as that noted at the same temperature (point p, for example) while the reaction vessel is cooling. Thus p and p' (and O and O') are characterized by the same temperature head and, therefore, by the same rate of heat loss. The heating effect of stirring is neglected.

Divide the curve rs into a number of segments, such as wo' and o'p'. The correction is applied to each segment, then summed. The segments need not be of the same length.

Example of graphical method: Draw tangent xy at p and with triangle and straight edge reproduce same slope x'y' at p'. Draw line nmo'. The length of mn is the correction. Repeat performance for each segment, such as wo'. The correction is the sum of the lines such as mn and m'n'. These can be summed up by marking off the lengths on the edge of a sheet of paper.

The reason that mn is the temperature correction, ΔT, for the segment between o' and p' is that the slope of xy gives the rate of temperature change, dT/dt for that temperature head. mp' represents the time, dt, that the system was at that approximate temperature head during the heating period.

$mn = dT/dt \times dt = \Delta T$.

Phenomena at an Electrode Covered with an Electrolyte Film

F. G. Will

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The anodic oxidation of hydrogen is studied on a large horizontal electrode covered with an electrolyte film of millimeter thickness. Polarization curves and the potential distribution in the film are obtained for various film thicknesses and electrolyte concentrations. Concentration gradients in the film electrolyte are measured and found to be very small. Convection in the film and water transport above the film are shown to exist. Both phenomena appear to be significant factors in keeping the concentration gradients small. Theoretical considerations suggest that the convection is induced by surface tension gradients. The convection is formally taken into account in an analysis of the rate-controlling transport of the reacting gas through the film. This involves the introduction of a diffusion layer thickness as parameter. Excellent agreement is found between experimental and calculated polarization curves and potential distribution. The phenomena occurring at the model electrode are believed to represent similar phenomena occurring at actual gas diffusion electrodes. Certain ramifications also exist with regard to wet corrosion.

The transport of reacting gases through thin films of electrolyte covering a metal surface plays an important role in many fuel cell and battery electrodes and in metal corrosion. In the case of fuel cell electrodes operating on gases like hydrogen, hydrocarbons, and oxygen, it is very likely (1-9) that the reacting gas passes through a thin electrolyte film covering the pore walls or the catalyst particles prior to reacting at the electrode surface. Likewise, in hermetically sealed batteries, oxygen and hydrogen that are evolved especially during overcharge are expected to diffuse through thin electrolyte films before reacting on one of the battery plates or an auxiliary electrode (10-12). "Wet" metal corrosion often involves the simultaneous anodic dissolution of the metal and cathodic reduction of oxygen from the air. The rate at which oxygen diffuses through the liquid layer covering the metal surface (13) often controls the rate of corrosion.

A previous experimental study (2) of the oxidation of hydrogen on a platinum electrode partially immersed in sulfuric acid had strongly suggested gas transport through a thin electrolyte film as rate-controlling reaction step. This mechanism was further supported by the good agreement between experimental polarization curves and curves resulting from a mathematical analysis (3). The analysis was made under the assumptions of diffusion control without convection in the film and of constant electrolyte concentration throughout the length of the film. Furthermore, the analysis contained the film thickness as an adjustable parameter.

However, we might expect a substantial increase of the electrolyte concentration in the film due to the formation of hydrogen ions and the migration of anions in the film (14, 15). If, on the other hand, concentration gradients exist, we expect convection in the film electrolyte, caused either by evaporation and condensation of water vapor, or by gradients in surface tension (13, 16-19).

It is the aim of this paper to test the assumptions of the previous analysis experimentally and to verify the predicted potential and current distribution in the film. This information cannot be obtained by direct measurements on porous electrodes or partially immersed electrodes, owing to the small thickness of the electrolyte film (20) and the short length of the reaction zone. Hence, measurements were carried out on a scale-up model of an electrode covered with a thin film of electrolyte.

The results obtained on such an experimental model have important ramifications regarding a better understanding of the gas transport phenomena occurring in many porous electrodes and in corrosion. To which extent information obtained on the model can be transferred to actual systems depends on the extent of hydrodynamic similarity (19) between model and system and has to be decided from case to case.

Experimental

The scale-up model used in the following study consists of a horizontal platinum foil, 40 cm long, 2.42 cm wide, and 50μ thick that has been cemented to a plane-

parallel glass bar of equal length and width. Acid-resistant, high-temperature cure epoxy resin was used for cementing. The cemented foil proved to be flat within $\pm 10\mu$. The glass bar with foil is tightly fitted on three sides into the rectangular depression of a Teflon bar. A small rectangular reservoir for the electrolyte borders on the fourth side of the glass bar. The top edges of the Teflon vessel rise 1 mm above the top of the platinum foil. The Teflon vessel with glass bar and foil is contained in a glass cell. A platinum foil counter electrode and a platinum screen reference electrode are introduced into the reservoir through a glass joint. This part also has provisions for introducing gas and electrolyte. The gas leaves the cell through a water trap. Platinum wire probes of 0.5 mm diameter are introduced through glass joints in the top of the glass cell. The probes are located in the center line of the foil and spaced 2 cm apart from each other. Their flat ends are spaced at an accurate height of 0.25 mm above the foil. Counter electrode, reference electrode, and the tips of all probes are platinized. The electrolyte, contained in the reservoir, spreads over the platinum foil, forming a film of uniform thickness. A steady stream of hydrogen was blown over the electrolyte film at a rate of about 10 cm^3/min. To minimize evaporation of the film, the hydrogen, before entering the cell, was blown through two gas wash bottles containing sulfuric acid of the same concentration as used in the experiment. These concentrations were 8*N*, 1*N*, 0.4*N*, 0.1*N*, and 0.02*N*. All experiments were carried out at a controlled room temperature of 25° ± 1°C.

Electrolyte films of thicknesses 2, 1, and 0.5 mm were applied. The film thicknesses were measured mechanically to a precision of $\pm 25\mu$. A platinum tube with a flat end, rigidly mounted on a precision cathetometer, was lowered through a glass joint after removing the respective probe. An ohm-meter was connected between the platinum tube and the platinum foil. The moments that the platinum rod first touched the electrolyte surface and then the platinum foil could be precisely determined by the changes in the deflection on the ohm-meter.[1]

A block diagram of the electrical setup is shown in Fig. 1. The lower part of the diagram contains a schematic of the electrolytic cell with the grounded test electrode (platinum foil) T, counter electrode C, reference electrode R, and probes P1 to P20. Potentials E_a' between 0 and 0.8v are applied between R and T by means of a potentiostat, and the cell current I through C and T is measured as a function of E_a'. In all plots and equations, the corrected applied potential E_a occurs instead of E_a'. E_a is identical to the potential measured between probe 1 and test electrode T and is related to E_a' by

$$E_a = E_a' - E_{1R} \qquad [1]$$

where E_{1R} is the ohmic voltage drop between probe 1 and reference electrode R. The local electrode potentials $E(x)$, *i.e.*, the potential distribution, are measured as the potentials between the various probes P1 to P20 and T. The impedances between the various probes and T were measured at frequencies of 1 and 10 kHz using an impedance bridge. A 1 μF capacitor effectively prevented the bridge circuit from interfering with the d-c measurements. Thus, the impedances could be measured while different d-c potentials E_a' were being applied. At 10 kHz, the ohmic component of the measured impedance is essentially identical to the electrolyte resistance between the particular probe and the test electrode. After calibration with known electrolyte concentrations, the magnitude of this resistance is an accurate measure for the concentration of the electrolyte in the vicinity of that particular probe.

[1] The suggestion of this simple and precise method by J. D. Livingston of our laboratory is gratefully acknowledged.

Results

Current-potential curves.—Polarization curves for different concentrations of sulfuric acid and different film thicknesses are shown in Fig. 2. The cell current per centimeter width of the electrode, I/W, is plotted against a square root expression containing the applied potential E_a and an exponential of E_a. The reasons for plotting the polarization curves in this particular way will become apparent in the Discussion section.

The following features of the polarization curves are noted: (*i*) The effect of the film thickness on the slope of the polarization curves is relatively small. (*ii*) Decreasing the concentration of the sulfuric acid decreases the slope of the curves drastically, *i.e.*, increases the polarization for fixed current drastically. (*iii*) A limiting current is obtained for 8*N* H_2SO_4. The limiting current is considerably larger for 1 mm than for 2 mm film thickness.

Potential distribution.—Figure 3 shows a linear plot of the local electrode potentials against the distance

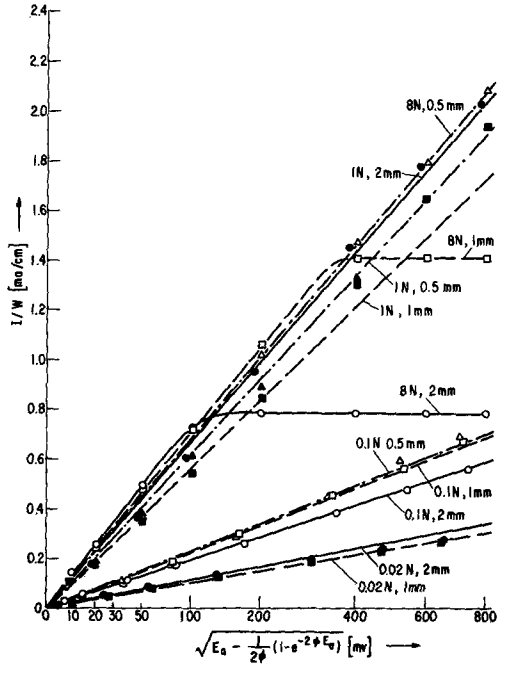

Fig. 2. Polarization curves for various acid concentrations and film thicknesses: I/W, cell current per unit width of electrode; E_a, applied potential; Ψ, F/RT.

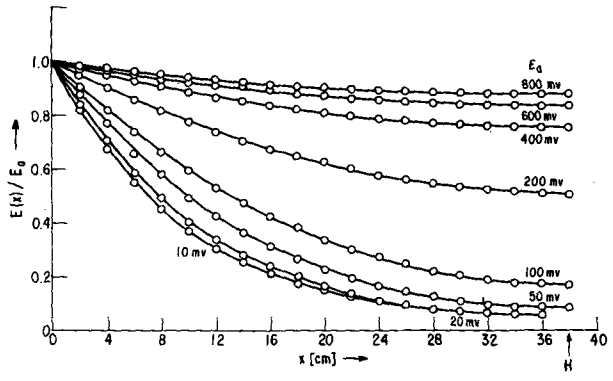

Fig. 3. Potential decay for 8N H_2SO_4 and 2 mm film thickness with applied potential E_a as parameter.

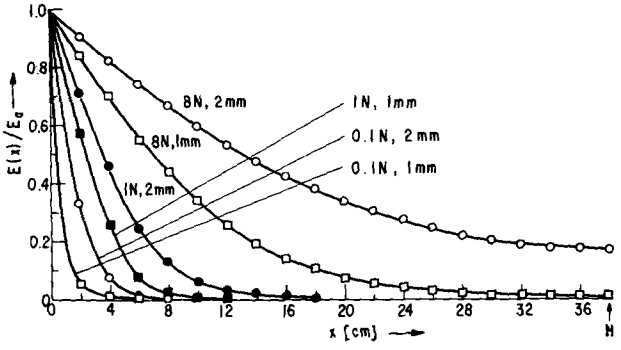

Fig. 4. Potential decay for fixed applied potential E_a = 100 mv with the concentration and film thickness as parameters.

x for 8N H_2SO_4 and 2 mm film thickness with the applied potential E_a as a parameter. $E(x)$ is plotted in dimensionless units as ratio $E(x)/E_a$. The distance x along the film is counted from the beginning of the film at probe 1. We find that the potential decay is quite small for the larger applied potential and that the rate of decay is substantially increased as the applied potential is decreased. This finding applies to all acid concentrations and film thicknesses.

The effect of the acid concentration and the film thickness on the potential decay for a fixed applied potential of 0.1v is shown in Fig. 4. As expected, the potential decays much more rapidly as the acid concentration or the film thickness are decreased. In 0.02N H_2SO_4, and for δ = 2 mm the potential decays to 2% of the applied value between probe 1 and 2 and to less than 1% for δ = 1 mm.

Concentration changes.—The impedances between the various probes and the test electrode were measured in 0.4N H_2SO_4 at a film thickness of 1 mm. The flow rate of hydrogen was decreased to about 1 cm^3/min to minimize evaporation of the film. For a fixed applied potential of 100 ± 0.5 mv, the current, the potential distribution, and the impedances were measured as a function of time over a period of 240 hr.

During this period, the film thickness decreased from 1.0 to 0.9 mm and the current from 0.84 to 0.82 ma. Concurrently, the potential decay became slightly larger, as shown in Fig. 5. The maximum change amounted to less than 5%.

The electrolyte resistances at t = 0 between the various probes and the test electrode fell in the range 18.7-24.4 ohms. The spread in resistance values is caused by the nonuniformity of the vertical spacing of the probes above the test electrode. After 240 hr, the resistances varied from 18.4 to 25.4 ohms. The changes of the resistances, ΔR, at the various probes, in per cent deviation from their original values, are plotted in Fig. 5. We note that the resistances have become slightly larger near the reservoir, at probe 1 and 2, and near the film end. Between probes 3 and 13, on the other hand, the resistances have become

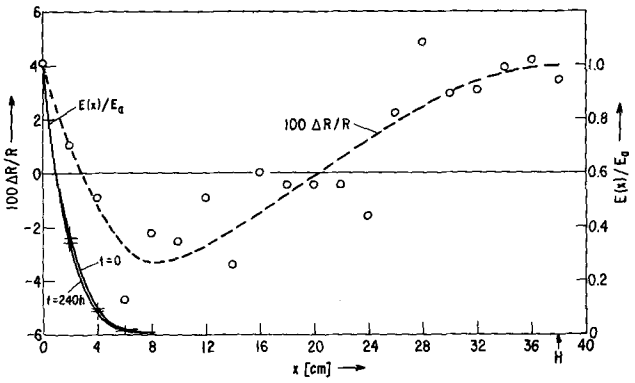

Fig. 5. Resistance changes in per cent deviation from original values after 240-hr polarization at 100 mv in 0.4N H_2SO_4. Also potential distribution at t = 0 and t = 240 hr.

slightly smaller. This reflects a tendency of the acid concentration to become slightly smaller in the reservoir and near the film end and slightly larger in the regions of the film where the oxidation of the hydrogen occurs. However, the effect is quite small, the changes of the acid concentration amounting to less than ±5% along the whole length of the film.

Water vapor transport.—Water vapor may be transported above the film from areas of the film with low electrolyte concentration to those with higher concentration. The rate of vapor transport would then be expected to have an effect on the magnitude of the concentration changes and, hence, the electrolyte resistance.

The possible effect of vapor transport was studied by decreasing the rate of vapor transport perpendicular to the film relative to the rate of hydrogen transport. This was effectively done by floating a Teflon membrane of 3μ thickness on the 1 mm thick film of 0.4N H_2SO_4. Hydrogen permeates through Teflon membranes roughly 30 times faster than water vapor.[2] The probes were inserted through small holes in the Teflon membrane. The current for E_a = 100 mv was 15% smaller (0.71 ma) than without the Teflon membrane (0.84 ma) due to the limited rate of permeation of hydrogen through the membrane. The electrolyte resistances between x = 0 and 20 cm changed in a manner similar to that shown in Fig. 5 which applies to the case without membrane. However, the relative changes were approximately double as large as without the membrane. Hence, the concentration gradients between x = 2 and 20 cm were about double as large as without membrane. For x > 20 cm, the concentration changes amounted to less than 1%.

Convection of film electrolyte.—Possible convection of the film electrolyte was tested for by adding a small amount of red pigment to the electrolyte. The electrode was covered with a 1 mm film of 1N H_2SO_4. A potential of 800 mv was applied. The current of 4.6 ma did not change on addition of the pigment through the glass joints in the top of the cell. The pigment quickly conglomerated to form particles of a few tenths of a millimeter diameter which floated in the film electrolyte. Within a few minutes, these particles moved from near the center of the film to the vicinity of the film edges. This motion proved to be independent of any applied potential. The cell was then left standing for 12 hr without a potential applied. The particles remained essentially motionless during this time. A potential of 800 mv was now applied and the motion of several particles monitored with markers. The particles in the film between probe No. 1 (x = 0) and probe No. 6 (x = 10 cm) showed a distinct motion in the direction of the reservoir while the particles closer to the film end (x > 20 cm)

[2] Private communication by W. L. Robb of the General Electric Research and Development Center.

remained essentially motionless. As soon as the applied potential was turned off ($E_a = 0$), the particles stopped moving. With a potential applied again, the particles started moving again. The velocity of the particles near probe No. 4 ($x = 6$ cm) was determined in repeated runs as $1.3 \cdot 10^{-3}$ cm/sec $\mp$ 10%.

Discussion

Concentration changes and convection.—If there were no convection in the film electrolyte, we would expect an exponential increase of the electrolyte concentration in the film over that in the reservoir (14, 15). In this case, the steady-state current would be due to migration and diffusion of hydrogen ions.

The finding that the electrolyte concentration changes very little indicates the presence of convection in the film electrolyte. Indeed, convection was proved to exist by observing the motion of particles added to the film electrolyte.

We suggest two effects that are likely to cause the observed convection: (*i*) motion induced by gradients of the surface tension in the electrolyte and (*ii*) motion induced by water vapor transport above the electrolyte.

Motion induced by surface tension.—The formation of hydrogen ions at the electrode surface is expected to give rise to concentration gradients in the film parallel to the surface and also perpendicular to the surface. The concentration gradients, in turn, cause gradients of the surface tension in the electrolyte which are known to set the liquid in motion if certain instability criteria are fulfilled.

A number of papers have dealt with convection cells or Bénard cells (21) driven by surface tension gradients (18) and established the criteria for convective instability in liquid films (22-26). Pearson (22) derived a characteristic dimensionless constant B, whose value determines the onset of convective instability. If the driving forces are concentration gradients in the film rather than temperature gradients, one obtains

$$B = (\delta^2/\mu D_+)\ (\partial\sigma/\partial c_+)\ (\partial c_+/\partial y) \qquad [2]$$

δ = film thickness, μ = viscosity, c_+ = concentration, D_+ = diffusivity of electrolyte, σ = surface tension, y = coordinate perpendicular to the film. For the case of constant flux at the bottom of the film ($y = 0$), Pearson calculates a critical value $B_{crit} = 48$. $B > B_{crit}$ characterizes the onset of convective instability. Using Eq. [2] we find that for a 1 mm thick film of $1N$ H_2SO_4 a concentration gradient of only 10^{-3} mole/l/cm is required to cause convective instability.

It is important to note that convective instability caused by density gradients is governed by a dimensionless constant, called Rayleigh number (27), which is proportional to δ^4 and that the critical Rayleigh number is more than an order of magnitude larger than B_{crit}. Thus, in films of 1 mm thickness and thinner, convective instability can confidently be attributed to the surface tension rather than the buoyancy mechanism (22).

In contrast to cellular motion, Levich (19) treated gross motion of the film electrolyte parallel to the surface induced by surface tension gradients which are caused by temperature or concentration gradients in the x-direction. He derived a parabolic velocity distribution

$$v_x = (3/4\delta\mu)\ [(y-\delta/3)^2 - (\delta/3)^2]\ \partial\sigma/\partial x \qquad [3]$$

where v_x = x-component of the velocity of the liquid. Equation [3] predicts a motion of the electrolyte in the direction of the surface tension gradient near the electrode surface (lower 2/3 of film thickness) and in the opposite direction near the film surface (upper 1/3 of film thickness). The surface tension of sulfuric acid increases with increasing concentration in the range of 0-50% by weight (28). The change amounts to about 1 dyn/cm/mole/l. The observed change of the electrolyte resistance in $0.2M$ H_2SO_4 for $0 < x < 8$ cm (see Fig. 5) corresponds to a concentration gradient of $2.5 \cdot 10^{-3}$ mole/l/cm. Using this value, we calculate from Eq. [3] an average velocity in the lower 2/3 of the film of $0.7 \cdot 10^{-3}$ cm/sec. This is about one half the observed velocity of the suspended particles ($1.3 \cdot 10^{-3}$ cm/sec) and suggests that surface tension gradients are likely to be a significant factor in causing convection in the film electrolyte and thereby reducing concentration gradients.

Water vapor transport.—A rough calculation of convective transport of water vapor above the film shows that a flow velocity of only $2 \cdot 10^{-2}$ cm/sec is sufficient to keep the concentration gradient of the electrolyte near the film surface at the low observed value. The fact that the concentration gradient is roughly doubled when a Teflon membrane is used also suggests that water vapor transport is significant in reducing concentration gradients. The evaporation and condensation of water vapor are expected to cause convection in the film electrolyte due to capillary and gravity forces.[3]

Diffusion layer thickness.—Since the film electrolyte is in motion, the reacting gas (hydrogen) is carried to the electrode surface by convective diffusion. The gas flux and, hence, the current density is larger than for pure diffusion through the electrolyte film. Mathematically, the treatment of this problem is very complicated because it involves the introduction of the velocity of the electrolyte as a function of x and y into the convective diffusion equation. A specific case of this general problem was treated by Levich (19), but is not applicable to the present problem. In general, the flux in a convective diffusion regime can be expressed in terms of Fick's law of diffusion by introducing a diffusion layer which is a function of the coordinate x and contains various material constants (19).

Lacking a theory that would allow us to express the diffusion layer thickness in this way, we introduce a diffusion layer thickness δ' formally as an adjustable parameter.

The previous analysis (3) of electrochemical reactions involving the slow diffusion of a reacting gas through the electrolyte film was made under the assumption of no convection and constant concentration in the film electrolyte. The analysis will now be modified in terms of a diffusion layer thickness δ', which, due to convection, is only some fraction of the actual film thickness δ.

Current-potential curves.—For penetrations of the electric field small compared to the length of the film, *i.e.*, if the potential at the film end, E_H, is essentially zero, the expression

$$I/W = 2\sqrt{\delta/\delta'}\ \sqrt{FDc_0\kappa}\ \sqrt{E_a - (1-e^{-2\Phi E_a})/2\Phi} \qquad [4]$$

results for the current-potential curve. W is the width of the electrolyte film, D and c_0 the diffusion coefficient and the solubility of hydrogen in sulfuric acid, respectively; κ is the conductivity of the electrolyte, and $\Phi = F/RT$. It is interesting to note that the current in the original expression (3) is independent of δ.

For $E_a >> RT/F$ and penetrations of the electric field large compared to the length of the film, *i.e.*, for $E_H \lessapprox 50$ mv, the concentration of molecular hydrogen at the surface of the test electrode approaches zero along the whole length of the film. Under these conditions, a maximum diffusion current

$$I_m/W = 2\ (\delta/\delta')\ FDc_0/\delta \qquad [5]$$

should be obtained.

The value of the applied potential, E_m, for which the maximum diffusion current at any given value of $(H/\delta)_m$ is obtained, can be calculated from

[3] The possible significance of vapor transport was also suggested by Bennion and Tobias (29).

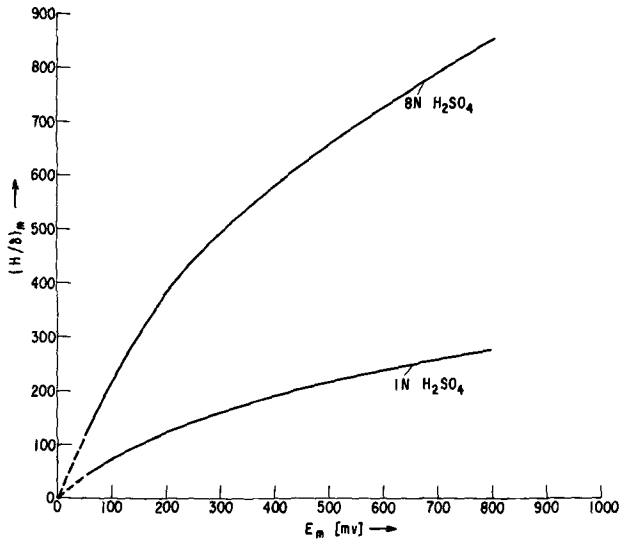

Fig. 6. Values of the ratio film length H to film thickness δ for which the applied potentials E_m produce the maximum diffusion current in 8N and 1N H_2SO_4.

$$E_m - E_H = (FDc_0\,\delta/\delta'\kappa)\ (H/\delta)^2_m \qquad [6]$$

where $E_H = 0.05$v. An increase of H/δ beyond $(H/\delta)_m$ produces essentially no increase of the current. Figure 6 correlates values of $(H/\delta)_m$ and E_m over a wide range of potentials for 8*N* and 1*N* H_2SO_4.

According to Eq. [4], straight lines should result in a plot of I/W against $\sqrt{E_a - [1 - \exp(-2\Phi E_a)]/2\Phi}$. Equation [5] predicts a maximum diffusion current for 8*N* H_2SO_4 whose magnitude is inversely proportional to δ. According to Eq. [6] and Fig. 6, the maximum diffusion current should start at lower potentials for the larger film thicknesses. It is seen from Fig. 2 that the experimental curves follow the predicted behavior. A good quantitative fit between experimental and theoretical curves is obtained for the values of δ/δ′ shown in Table I. Also tabulated are the experimental values for the slopes of the curves in Fig. 2, the maximum diffusion currents and the values for E_m. For all acid concentrations, the values of δ/δ′ lie between 1.8 and 2.9, *i.e.*, the diffusion layer thickness is only about 1/2 to 1/3 of the film thickness.

Potential distribution.—For small values of the applied potential, *i.e.*, $E_a << RT/F$, the local electrode potential can be written as

$$E(x)/E_a = \exp\left(-2\sqrt{F^2Dc_0/\kappa RT}\,\sqrt{\delta/\delta'}\,x/\delta\right) \qquad [7]$$

Figure 7 shows a plot of the logarithm of $E(x)/E_a$ against x/δ for $E_a = 10$ mv and different acid concentrations and film thicknesses. As predicted by Eq. [7], the experimental points lie on straight lines. Their slopes can be matched with the theoretical slopes

$$2\sqrt{F^2Dc_0/\kappa RT}\,\sqrt{\delta/\delta'}$$

for the values of δ/δ′ given in Table II. While two of these values (2.30 and 1.90) agree well with the values given in Table I, the other three values are by some 25 to 35% smaller than those in Table I.

Table II. Values of δ/δ′

	8*N*		1*N*		0.1*N*
	2 mm	1 mm	2 mm	1 mm	2 mm
δ/δ′	2.30	1.50	2.20	1.40	1.90

For large values of the applied potential, *i.e.*, $E_a >> RT/F$, and large penetrations of the electric field, *i.e.*, $E_H \gtrapprox 50$ mv, one obtains

$$\psi(x) = E_a - E(x) = (FDc_0\,\delta/\delta'\kappa)\ \{(H/\delta)^2 - [(H-x)/\delta]^2\} \qquad [8]$$

The potential decays less rapidly than the exponential decay given by Eq. [7]. We expect straight lines in a plot of the ohmic potential drop $\psi(x)$ in the electrolyte film against $(H/\delta)^2 - [(H-x)/\delta]^2$. Their slopes are given by $FDc_0\,\delta/\delta'\kappa$ and should depend on the film thickness δ only insofar as δ enters through the correction factor δ/δ′ with values between 2 and 3. Figure 8 shows that these predictions are fulfilled very well for 8*N* H_2SO_4 and $\delta = 2$ and 1 mm. The four top curves, shown in Fig. 3 for $E_a = 200$, 400, 600, and 800 mv, all fall on one straight line when plotted as in Fig. 8. The same is true for all potentials between $E_a = 400$ and 800 mv in the case of $\delta = 1$ mm. For the other concentrations and film thicknesses, the condition $E_H \gtrapprox 50$ mv is not fulfilled. Hence, Eq. [8] cannot be applied. A quantitative fit between the

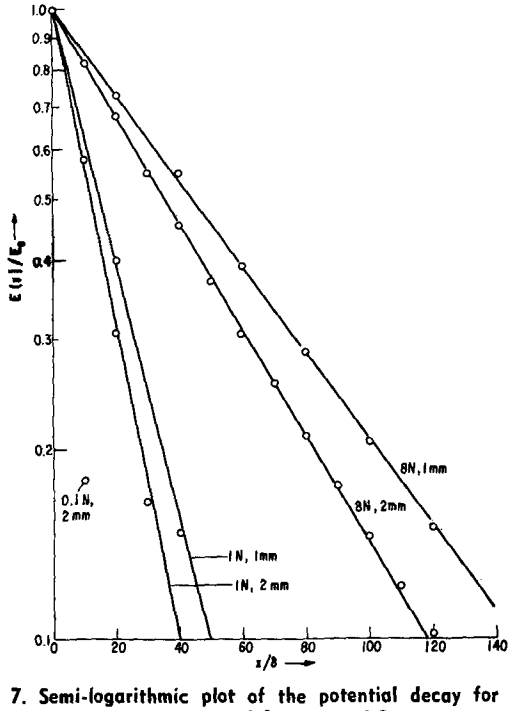

Fig. 7. Semi-logarithmic plot of the potential decay for E_a = 10 mv at various normalities, and δ = 1 and 2 mm.

slopes of the straight lines in Fig. 8 and the slopes calculated from Eq. [8] is obtained with $\delta/\delta' = 2.63$ for $\delta = 2$ mm and $\delta/\delta' = 2.18$ for $\delta = 1$ mm. These values agree moderately well with those given in Table I.

Hydrodynamic similarity between model and gas electrodes.—The degree of hydrodynamic similarity between the model electrode and actual gas electrodes can strictly be obtained only by a rigorous analysis with dimensionless quantities. Such an analysis leads to a system of second order partial differential equations. These can be solved only in special cases and with approximations which are often so stringent that the case treated no longer represents the original problem. Levich (19) treated a special case of convective diffusion of a gas through a liquid film with surface tension-induced motion. However, he did not concern himself with concentration gradients in the liquid and ionic motion due to migration, diffusion and convection. He derived a Reynolds number for the film which is

$$Re = (\delta^2\rho/4\mu^2)\ (\partial\sigma/\partial c_+)\ (\partial c_+/\partial x) \qquad [9]$$

when written in terms of a concentration gradient as driving force. The dependence of Re on δ^2 and on the concentration gradient is the same as that of Pearson's dimensionless constant B in Eq. [2]. Own unpublished calculations show that $\partial c_+/\partial x$ is, to a first approximation, inversely proportional to δ^2. This means that the film Reynolds number and Pearson's constant B are independent of the film thickness and would indicate hydrodynamic similarity between model and actual gas electrode. We stress that this conclusion is based on an approximate solution of the problem and not the result of a rigorous analysis.

Before we can establish similar arguments with regard to the significance of water vapor transport in gas electrodes we have to obtain knowledge about the thickness of films as a function of the pore radius. A rough calculation shows, however, that vapor transport in pores of 4μ diameter with 0.1μ thick films is a feasible mechanism.

Experimental results show that good hydrodynamic similarity must exist between the millimeter thick films on the model electrode and the micron thick films (2, 3, 20) on partially immersed electrodes under diffusion control. The current-potential curves in both cases are essentially identical and follow the behavior predicted for electrodes under diffusion control in the absence of concentration gradients in the film electrolyte. For the case of the large concentration gradients expected (14, 15) in the absence of convection and vapor transport, the predicted current-potential curves are quite different (30) from the experimental curves.

Several experimental facts also suggest that fair hydrodynamic similarity exists between the model electrode and actual gas electrodes under diffusion control. Polarization curves obtained on actual hydrogen (4) and oxygen diffusion electrodes (4, 5), the latter at higher current densities, show the same typical behavior as those obtained on the model electrode and as predicted by Eq. [4].

Conclusions

Polarization curves obtained on the model electrode, which is completely covered with an electrolyte film of precisely known thickness, display a dependence of the current on the square root of the potential and an exponential of the potential. This dependence is predicted by an analysis of rate-controlling diffusion of the reacting gas through the film under the assumption of constant concentration of the film electrolyte. Experimental evidence for convection in the film and transport of water vapor above the film is presented, and both phenomena are made responsible for the observed lack of substantial concentration gradients in the film electrolyte. Theoretical considerations suggest that the motion of the film electrolyte is induced by surface tension gradients. A diffusion layer thickness δ' is formally introduced in the analysis which, due to the convection, is only a fraction of the film thickness δ. For values of δ'/δ between 1/3 and 1/2 a quantitative fit between observed and calculated polarization curves is obtained. The measured potential distribution also follows closely the predicted behavior, namely, the potential decays exponentially for small polarizations and less steeply, as the square of the distance x, for large polarizations.

Polarization curves obtained on partially immersed electrodes and on actual gas electrodes often display the same typical behavior as the curves obtained on the model electrode. We conclude from this fact that a good degree of hydrodynamic similarity exists between these different systems. This conclusion is also borne out by theoretical considerations. Hence, we expect the phenomena observed on the model electrode to be fairly representative for similar phenomena occurring on actual gas electrodes.

Technical Notes

Fuel Cell Performance as a Function of Catalyst Surface Area

Harold I. Zeliger[1]

Union College, Schenectady, New York

In order to study the relationship between specific platinum surface area and fuel cell performance, it is necessary to have electrodes which are prepared similarly and which contain catalysts that are similar but with varying platinum content and specific platinum surface area. In the work described below the dependence of fuel cell performance on the surface area of the catalyst was demonstrated.

Platinized asbestos samples with varying platinum content were prepared by repeated (6 cycle) platinization (1) of a single starting batch of asbestos as follows.

Asbestos (5g) was impregnated with a 3% solution of chloroplatinic acid and the excess solution was filtered off. The moist impregnated asbestos was dried and reduction was carried out with hydrogen at 100°C. The platinization was repeated 5 more times, with samples taken at the end of each cycle. Platinized asbestos samples with 1, 2, 3, 4, 5, and 6% platinum were prepared in this manner from a single starting batch of asbestos. A 3% solution was used because it was found empirically that this added 1% of platinum per cycle.

The electrodes used in this study were modified Neidrach-Alford (2) electrodes. They consisted of a mixture of catalyst, Teflon binder, and conducting graphite diluent (which was required in these electrodes because of the small quantities of platinum present) pressed into a supporting platinum screen which also served as a current collector. A porous Teflon film on the gas side of the electrode provided for proper electrode wetting so that both the electrolyte and reacting gas had satisfactory access to the catalyst incorporated into the structure. This electrode structure provided for high electronic conductivity and rapid input and removal of reactants and products.

All the electrodes prepared were evaluated as oxygen cathodes in standard test fuel cells. The test cells contained the test electrode, a Teflon-bonded (2) hydrogen counter electrode with 34 mg platinum per cm^2, and 5*N* sulfuric acid electrolyte.

Fuel cell performance data were obtained under the condition of steady d-c drain. The cells tested were discharged through a resistive load. IR free potentials were obtained by interrupting the flow of current (sweep speeds of 100 μsec/division were adequate) and monitoring the voltage change on an oscilloscope.

Specific platinum surface areas were determined by measuring the dissociative chemisorption of hydrogen on platinum (3), using the apparatus of McKee (4).

Platinum contents and specific platinum surface areas of the six samples of platinized asbestos prepared are given in Table I.

Table I. Properties of catalysts prepared through stepwise platinization

Catalyst	% Pt	Specific Pt surface area in m^2/g
A	1.0	46
B	2.0	42
C	3.0	37
D	4.0	32

Table II. Data for comparison of current density obtained per unit area of platinum

Electrode No. and catalyst	Mg Pt per electrode	Specific Pt surface area in m^2 per g	Total Pt area in m^2	Current density at 0.7v IR free in ma/cm^2	Current density per unit area at 0.7v IR free, in $ma/cm^2/m^2$
1-A	3.0	46	0.139	7.9	57.0
2-B	6.0	42	0.252	14.9	59.0
3-D	12.0	32	0.392	22.8	58.0
4-F	18.0	23	0.414	25.0	61.0

Electrodes 1, 2, 3, and 4 were prepared incorporating catalysts A, B, D, and F, respectively, and containing 0.17, 0.33, 0.66, and 1.0 mg Pt/cm^2. The electrodes were evaluated as cathodes in fuel cells. Oxygen rather than hydrogen was used for the evaluation, because hydrogen is such a good fuel that it gives excellent performance with very small amounts of platinum catalyst. IR-free polarization curves for the four electrodes are given in Fig. 1.

Comparison of fuel cell performance with specific platinum surface area was made by measuring the current density produced per unit area of platinum at a 0.7v potential for each of the test electrodes. Table II summarizes the data. As can be seen from the data in Table II, there is an excellent correlation between surface area and performance. All four electrodes, each with a different platinum content, gave between 0.057 and 0.061 $ma/cm^2/m^2$ of platinum area at 0.7v.

It is believed that the interior of a metal catalyst does not contribute to the catalytic process. The above described work supports the conclusion that this is indeed the case for the electrocatalytic reduction of oxygen in fuel cells.

Acknowledgments

The author is indebted to Professor K. V. Nahabedian of Union College and L. W. Niedrach of the General Electric Research and Development Center for their guidance and assistance in this work. The author also wishes to gratefully acknowledge the assistance of D. W. McKee of the G. E. R&D Center for his assistance in determining surface areas. H. A. Liebhafsky, Manager Electrochemistry Branch of General Electric R&D Center, is sincerely thanked for making available the facilities with which the experimental work was carried out.

Manuscript received Sept. 1, 1966; revised manuscript received Oct. 12, 1966. The information reported in this paper is part of an M.S. thesis submitted to Union College.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

The Anodic Oxidation of Alloys

G. C. Wood, C. Pearson, A. J. Brock, and S. W. Khoo

Corrosion Science Division, Department of Chemical Engineering,

The University of Manchester Institute of Science and Technology, Manchester, England

Surprisingly little previous work on anodic film growth on alloys, either of a fundamental or practical nature, has appeared in the open literature. This is true even for dilute alloys but is particularly so for compositions far removed from those of the pure "valve" metals. Investigations are in progress to elaborate the theory of film growth on binary alloys between valve metals, and between valve metals and metals which do not themselves form this type of film, and to pursue possible applications of such films in the fields of corrosion-resistant materials, capacitors, and catalysts. The present communication presents results and theories principally for niobium-base alloys, but certain concepts introduced are considered of much more general significance.

Experimental

Specimens cut from sheet or spark-machined as slices from rod were prepared from zone-refined niobium, electron-beam-melted niobium, and from binary alloys of niobium containing, respectively, nominally 5, 20 and 50 a/o (atomic per cent) zirconium, titanium, tungsten, vanadium, or molybdenum. Additional experiments were conducted on Nb-V, Ti-V, Nb-Mo, and Ti-Mo alloys containing 70, 85, or 95 a/o of vanadium or molybdenum. The alloys were generally made from electron-beam-melted or comparable purity metals. After chemical polishing, followed by a 10-sec etch in 40% HF, the samples containing up to 50 a/o alloying element were anodized at 10 ma/cm^2 or at 100 $\mu a/cm^2$ to an appropriate cell voltage, followed by current decay, in 3% W/V ammonium tartrate solution (*p*H adjusted to 7) at 25°C. The alloys richer in vanadium or molybdenum were prepared only at 10 ma/cm^2 with current decay in this electrolyte or alternatively in the nonaqueous electrolyte of 20% W/V ammonium pentaborate in ethylene glycol.

After visual examination for adhesion, compactness, and color, the frequency dispersions of balancing series capacitance and dissipation factor of films were measured in 1M sodium chromate solution (*p*H adjusted to 7.2) at 25°C using a General Radio capacitance measuring assembly type 1610-B with a 50-mv p-p signal. These data also permitted the calculation of average a-c resistivities, on the assumption of the validity of a simple electrical analogue for the film of a resistor in parallel with a capacitor at any one frequency. It was also assumed that the Å/V ratio of 23 and dielectric constant of 41.4, which refer to Nb_2O_5 films on pure niobium, held. Although this is not strictly true, any errors involved in the assumption do not greatly affect the subsequent argument. It should be noted that resistivities measured in chromate solution cannot be compared directly with those measured for films on pure metals in tartrate solution (1). This is because of the influence of the double layer impedance on the measured film impedance, for reasons (2) that will be explained elsewhere.

Results

Thick, relatively good quality films were readily produced on niobium and the alloys containing up to 50 a/o additions, with approximate current efficiencies of 100% at 10 ma/cm^2 and 64-72% at 100 $\mu a/cm^2$. Current decay performed at the end of the main anodizing run had little effect on the film properties, but enabled reproducible film thicknesses to be obtained. These were 230, 1150, and 2300Å, respectively, for pure niobium, but films on the alloys were ap-

parently a little thicker except for tungsten alloys where they were a little thinner. Deviations from the above thicknesses for 50 a/o alloys were never greater than 20-30% from capacitance measurements and were generally less than this when compared with an optical step gauge constructed with Nb_2O_5 films on niobium, and from considerations of the charge required to form films to a given cell voltage. Thus, although there was undoubtedly some error in defining the film thicknesses and consequently in calculating resistivities, this was not sufficient to invalidate the comparisons of alloy behavior seriously. It is very important to note that all these films appeared of comparable quality, although it is likely that there were minor differences in compactness, solubility, etc. This contrasts strongly with experiments on pure metals in tartrate electrolyte where it was found (1, 2) that only niobium and zirconium gave good films. Film formation on titanium was limited by extensive oxygen evolution and on tungsten by film solubility, and it was impossible to anodize vanadium or molybdenum. It is the authors' experience that even films formed on vanadium or molybdenum in nonaqueous electrolytes are nonadherent and of poor quality. All the present films were insoluble in tartrate or chromate solutions, even after several days. Clearly their solubilities in more severe electrolytes will vary and further work is progressing to pursue this aspect.

Figures 1a and 1b, giving the frequency dispersions of dissipation factor for films formed to 10 and 100v, respectively, on niobium and its alloys, show that in general alloying increased the dielectric loss of the films. Additionally, it tended to increase the slopes of plots of series capacitance against frequency (which have been omitted in the interests of brevity).

Figures 2a and 2b illustrate the frequency dispersions of average a-c resistivity for films approximately 230 and 2300Å thick on niobium and the 50 a/o alloys, derived from Fig. 1a and 1b as mentioned earlier. The values were largely independent of whether the initial current density of formation was 10 ma/cm² or 100 μa/cm². The results were identical, within experimental error, for films on the two purities of niobium. The average resistivities and frequency dispersions of resistivity were greater for the oxide on niobium than on any of the alloys. The various curves

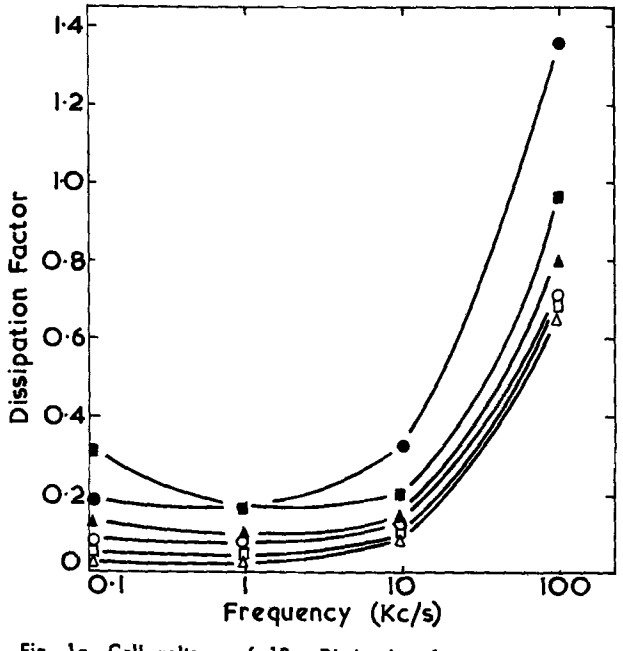

Fig. 1a. Cell voltage of 10v. Dissipation factor vs. frequency (kc/s) for films formed on niobium and Nb-50 a/o alloys. △, Niobium; □, Nb-Zr; ○, Nb-Ti; ▲, Nb-Mo; ■, Nb-V; ●, Nb-W. The symbols are the same for Fig. 1 and 2.

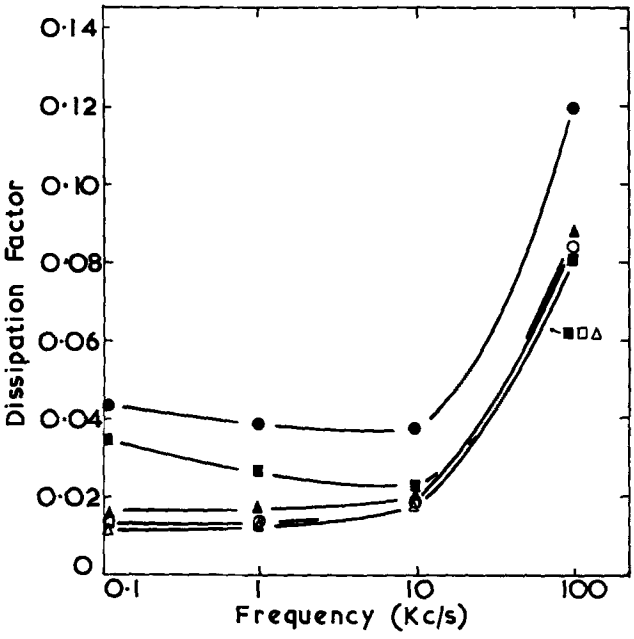

Fig. 1b. Cell voltage of 100v.

almost converge at 100 kc/s with the exception of those for Nb-50 a/o W, probably because the latter were somewhat thinner. At lower frequencies the resistivity was always lower with alloy addition, the effect generally increasing in the order zirconium, titanium, molybdenum, vanadium, and tungsten. This

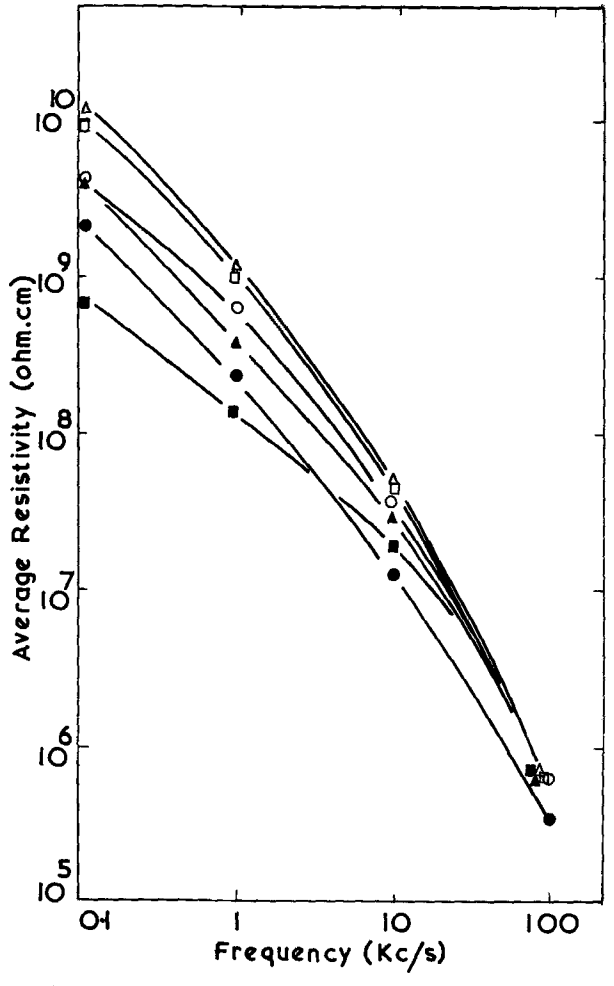

Fig. 2a. Approximately 230Å films; average resistivity (ohm cm) vs. frequency (kc/s) for films on niobium and Nb-50 a/o alloys.

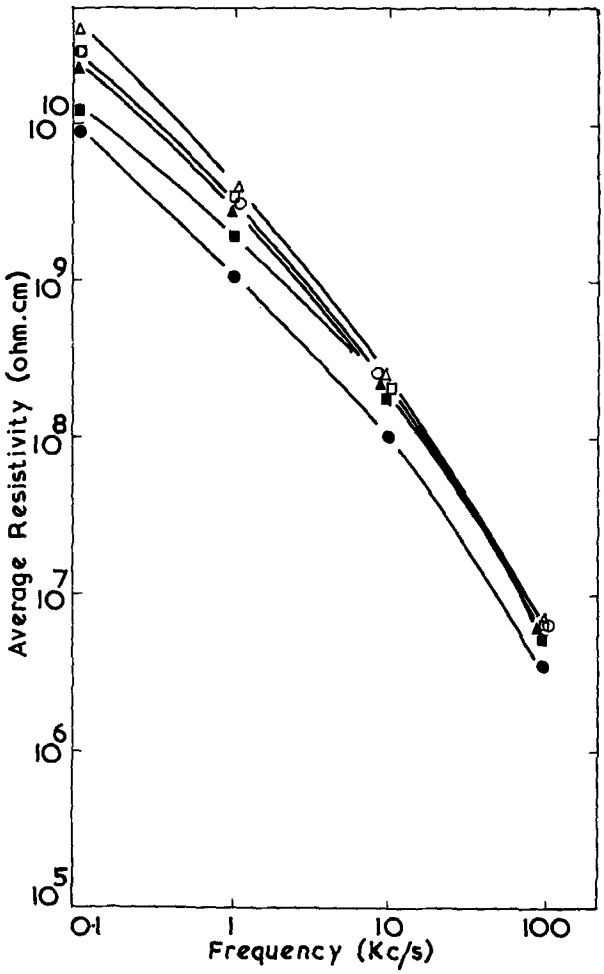

Fig. 2b. Approximately 2300Å films

result appears to be a general one with all the alloy systems that the authors have studied. Curves for films on the more dilute alloys lay in the anticipated order between those for the pure metal and the 50 a/o alloys.

Thus, with the apparent exception of tungsten, the addition of a valve metal to niobium led to higher resistance films than did the addition of vanadium or molybdenum, which do not themselves normally develop typical thick anodic films. An important observation was that the effect of the alloying additions studied in reducing the resistivity of films on niobium was most pronounced for the thinner films. The film capacitances were also relatively larger and showed a greater frequency dispersion. Particularly with Nb-50 a/o V and Nb-50 a/o Mo the thicker films appeared of much better quality; indeed for 2300Å films it is remarkable to observe that the curve for the film on Nb-50 a/o Mo alloy is little lower than that for the film on pure niobium. The reason for this consistent result will be evident later. By analogy with previous results for films on the niobium and zirconium (1), it might have been expected that the curve for Nb-50 a/o Zr would lie above that for pure niobium. Presumably this is not so because the alloy is two-phase and oxide above the niobium-rich regions, which predominates, will produce the dominant dielectric loss. It should also be noted that for all alloys the trend of the thicker the film the higher its average resistivity held at all frequencies. The spaces between curves increased as alloying element was added in the order zirconium, titanium, molybdenum, and vanadium because the improvement of film quality with increased thickness increased in this order.

Electron probe microanalysis at low kilovoltages of stripped and attached films examined in plan proved that tungsten and titanium were incorporated into 2300Å films on 50 a/o alloys in their alloy proportions, and the slight apparent enrichment of vanadium and depletion of molybdenum in the appropriate films were probably insignificant. Similar conclusions were recently reached for copper and zinc entry into films on aluminum alloys (3).

With progressive alloying additions greater than 50 a/o vanadium or molybdenum to niobium or titanium there was a gradual transition from films with good properties to insignificant film formation. On Nb-70 a/o V and Nb-70 a/o Mo films were formed, at rather lower current efficiencies than those given earlier, to voltages of 10, 50, or 100v (corresponding to 230, 1150, and 2300Å films, respectively, on pure niobium). They may in fact have been somewhat thicker than these figures indicate, with a porous outer layer and most of the voltage concentrated across an inner barrier layer, but this remains to be determined. The films were of the usual visual appearance, displaying interference colors and were insoluble or dissolved only very slowly in tartrate, chromate, or distilled water. Films of 10v (nominally 230Å) gave very high capacitances, close to values expected for the double layer capacitance, probably indicating a high degree of microporosity. As the film thickness was increased the impedance characteristics progressively improved until at 100v (nominally 2300Å) the capacitances were relatively low and the frequency dispersion of capacitance was only slightly greater than that expected for a top quality anodic film. The resistivities of these films were sufficiently high to suggest that they may be useful practically, but were several times lower than for the 50 a/o alloys or pure niobium. On Nb-85 a/o V and Nb-85 a/o Mo films could also be formed to high voltages at an even lower current efficiency, but viscous dissolution products could be seen streaming away from the anode, reminiscent of electropolishing. These films, especially when only formed at 10 or 50v, continued to dissolve in the forming electrolyte, in chromate solution, or in distilled water. Films formed at 100v tended to persist in an adherent form for long periods, but showed low impedances which fell with time, indicative of continued dissolution. Nb-95 a/o V and Nb-95 a/o Mo could not be anodized in the aqueous tartrate but films could be formed on the former alloy in the almost "nonaqueous" borate electrolyte (as indeed they could on the other alloys). However, these were soluble in water or in aqueous solutions. The same general pattern was true of Ti-V and Ti-Mo alloys except there was a greater tendency to poorer and more soluble films, as would be expected from the poorer film-forming properties of titanium itself.

Discussion

In attempting to explain the above results it is worthwhile initially demonstrating briefly that analogous concepts developed for the thermal oxidation of alloys appear inapplicable.

1. There is little, if any, preferential oxidation effect, as in thermal film growth, during which one alloying constituent is preferentially incorporated into the film. Thus, a mixed oxide must be considered, although it is not yet known how alloying elements are distributed through the film. From the ability to form films on alloys containing only small concentrations of niobium, it might have been postulated that this element would be expected toward the exterior of the film. Work on the analogous case of InSb, using a sensitive chemical analysis method (4) however, indicated that this is perhaps unlikely because the film contained a uniform distribution of both elements through its thickness, except for the outer 100Å where the concentration of the soluble component, antimony, fell almost to zero.

2. Since all the added ions, whether of higher or lower valency than five, reduce the a-c resistivity of the film, it is apparent that Hauffe's valency rules are of little application to anodic films, whether the a-c

conduction process occurring during impedance measurements be related to d-c electronic conductivity, electronic relaxation processes due to anion vacancies and their associated electrons, or to ionic relaxation processes associated with anion vacancies or interstitial cations. It is possible that all additions to the cation lattice make a more disordered structure, promote ionic relaxation effects, and thus reduce the low frequency resistivity.

3. Consideration of the effect of the addition element on the Pilling-Bedworth ratio in altering the degree of compactness of the oxide has proved useful in thermal oxidation, but the criterion does not apply here, if ionic sizes are considered.

The most useful approach is to compare the properties of these mixed anodic alloy oxide films, such as their solubilities, with those of metallic alloys interacting with electrolytes. Thus the "theory of parting limits" indicates that a noble metal will tend to prevent the selective dissolution of a base metal with which it is alloyed, even when present in only relatively low concentrations. The precise parting limit, often in the range 50-70 a/o of the soluble element, may be sharp or diffuse depending on the alloy and the solution. In certain alloys the base metal is leached out leaving a skeleton rich in the more noble metal. This concept is of course much related to electrochemical processes and does not specifically refer to oxides. In the analogous situation with anodic films, ions of the valve metal, such as Nb^{5+}, effectively play the part of the noble metal and tend to suppress the dissolution of V^{5+}, W^{6+}, or Mo^{6+} ions and their associated oxygen ions from the film.

The experiments described earlier suggest that there is a diffuse transition between solubility and insolubility of anodic films. The "useful" parting limit will depend on the alloy, the electrolyte, and the application. Thus, for the V-Nb system it would be in the range 70-80 a/o V for exposure to certain neutral electrolytes, but less vanadium in the alloy would be permissible in certain severe environments and more if forming were conducted in a nonaqueous electrolyte and the film kept dry subsequently. Similar considerations apply to the other alloy systems.

A film model may be envisaged in which there is an outer porous layer and an inner more compact layer. The precise nature of the "pores" cannot yet be stated, although preliminary electron microscopial examination confirms their existence; they will probably be extremely fine for the more dilute alloys and coarser in alloys rich in soluble component. The degree of this porosity will fall progressively from the oxide/electrolyte interface to the alloy/oxide interface. In certain cases, *e.g.*, in the 50 a/o alloy, it appears that it terminates after only a short distance into the film (perhaps about 100Å), when there is no longer a feasible continuous path of soluble material connecting with the electrolyte. This penetration would be approximately constant for all greater film thicknesses. In other alloys, such as the Nb-85 a/o V and Nb-85 a/o Mo alloys it is more extensive, as witnessed by the continuous stream of soluble material leaving the anode. Such a model is in agreement with the observation that thicker films have generally better properties and superior impedance characteristics. This would be expected because the thicker films would possess much thicker compact regions adjacent to the alloy protected from dissolution.

In view of the above considerations, it is tempting to suggest that the dielectric properties, particularly at low frequencies, of even good quality films on certain valve metals may be modified by hydrated or electrolyte anion-rich regions between the film crystallites. There are instances where impedances of films, *e.g.*, on aluminum, are modified by the anion type and *p*H of the electrolyte, and the authors will return to these matters elsewhere.

The general conclusion is therefore that metals such as molybdenum and vanadium, which cannot themselves normally be anodized, can be made to produce films by alloying with relatively low proportions of valve metals such as niobium and titanium. Zirconium, aluminum, and possibly tungsten would probably afford similar protection. Also the properties of films on metals such as titanium and tungsten, which are relatively poor, can be improved by alloying with metals giving superior films.

SOLID STATE SCIENCE

Analysis of N-Type GaAs with Electron-Beam-Excited Radiative Recombination

H. C. Casey, Jr., and R. H. Kaiser

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The study of spontaneous emission for n-type GaAs has shown that the spectral shape and peak position may be utilized to determine the free electron concentration within ±15% near concentrations of 5 x 10^{17} cm^{-3} and ±7% at 5 x 10^{18} cm^{-3}. Excitation of the sample with a 1μ diameter electron beam gives such sensitivity with a 3-6μ spatial resolution. This sensitivity and spatial resolution are sufficient for investigating sample inhomogeneities that are related to the spatial variations in the quantum efficiency.

Several investigations (1, 2) of radiative recombination in heavily doped GaAs have shown that the photoluminescent peak shifts to higher energy as the donor concentration is increased above 5 x 10^{17} cm^{-3}. Cusano (3) has reported data demonstrating the dependence of the cathodoluminescent (electron-beam excitation) peak energy and the spectral half-width on the donor concentration. For n-type GaAs, the average distance between impurity atoms is close to the diameter of the Bohr orbit of a donor electron in the crystal for concentrations in excess of 5 x 10^{17} cm^{-3}, and the density of states becomes a function of the substitutional impurity concentration (4). Since the spontaneous emission is given by an integral containing the conduction and valence band density of states and their corresponding occupation probabilities (5), the spectral shape will depend on the impurity concentration. Therefore, the observed dependence of the spectral shape on free electron concentration is also suggested by fundamental theoretical arguments. This paper explains how the dependence of the spectral shape on the free electron concentration may be used to determine the donor concentration in micron-sized regions. No attempt will be made to calculate the density of states and then the spectral shape to demonstrate explicitly the dependence of spectral shape on impurity concentration. However, the spectral shapes presented here may permit comparison of the various models for the density of states and indicate which approach best describes n-type GaAs in the 0.5 to 5 x 10^{18} cm^{-3} impurity range.

There are many nondestructive techniques for determining the electrically active impurity concentration; however, only electron-beam excitation offers micron-sized resolution. Hall measurements are the most sensitive and accurate, but give an average value for the entire sample and cannot be used on layered structures of the same conductivity type. Optical methods [photoluminescence or Reststrahlen-band minimum (6)] normally require excitation of a thin layer of a large cross section, and therefore spatial variations will not be resolved. Schottky barrier diodes (7) can be used for thin layers with 50-100μ diameter spots, but at donor concentrations in excess of 5 x 10^{17} cm^{-3} the high conductance makes the capacitance measurements difficult. Most applications for electroluminescent GaAs devices require free electron concentrations in the decade of 5 x 10^{17} to 5 x 10^{18} cm^{-3}, and it is in this concentration range where the spectral shape may be utilized to determine the substitutional donor concentration. This concentration determination is confined to a hemispherical volume whose radius can be approximated by the sum of the electron-beam radius, the depth of electron penetration, and the diffusion length for holes. A total radius on the order of 4-6μ would be expected for a 40-kev beam voltage in n-type GaAs. At lower beam energies, features as small as 3μ have been resolved in the cathodoluminescence.

The quantum efficiency η_q of n-type GaAs for electron-beam excitation has a strong dependence on free electron concentration n_o (3, 8). The quantum efficiency initially increases as n_o increases, and then η_q decreases rapidly when n_o exceeds about 5 x 10^{18} cm^{-3}. Also, the quantum efficiency for a given wafer can vary greatly over a distance of only a few microns (9, 10). Therefore, it is extremely useful to have an analytical tool with a spatial resolution of the same order of magnitude as the macroscopic crystal variations. By procedures discussed in this paper, it is possible to investigate the variations in quantum efficiency and consider the possibility that these variations correspond to free electron variations or compensation.

Experimental Procedure

The samples used in this study were single-crystal, <100> oriented, Te-doped, floating-zone wafers prepared at Bell Telephone Laboratories. The electron concentrations, 0.2 to 8 x 10^{18} cm^{-3}, were measured on each wafer investigated. The wafers were polished to provide a damage-free surface with a bromine-methanol etch described by Sullivan and Kolb (11). In fact, the usual preparation of a wafer for device fabrication, one which gives a planar damage-free surface, satisfies all the requirements of sample preparation for cathodoluminescence.

The electron-beam-excitation system is an electron probe microanalyzer, the Cambridge Microscan, in which a light pipe has been inserted to transmit the recombination radiation through the specimen chamber exit port. This excitation system is shown schematically in Fig. 1. The finely focused electron beam at A is deflected synchronously with the display cathode-ray tube. The electron beam strikes the GaAs wafer at B and creates one hole-electron pair for each 4.5 ev of beam energy (12). A small fraction of these generated carriers produces infrared radiation by recombining radiatively. This radiation is

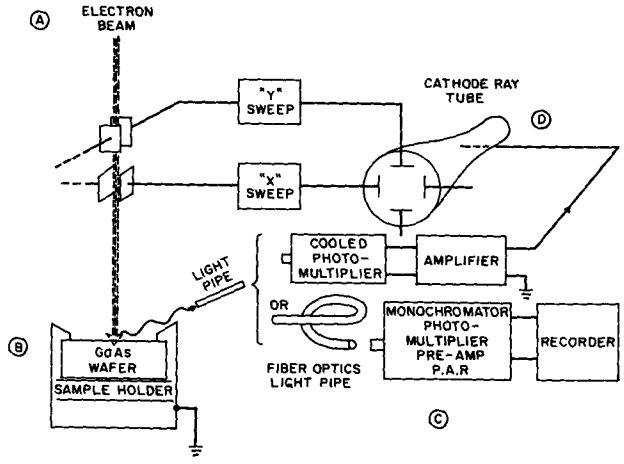

Fig. 1. Schematic representation of the electron-beam excitation system and the infrared detection systems.

transmitted outside the specimen chamber by the light pipe that views the sample at 70° from the surface normal with a solid angle of approximately 3 x 10^{-2} steradians. For display of spatial variations in the radiative-recombination intensity, a dry-ice cooled Amperex 150 CVP (S-1 response) photomultiplier detects the radiation transmitted through the light pipe as shown at C; after amplification this photomultiplier signal serves to intensity-modulate the cathode-ray tube D. In this manner recombination radiation intensity variations over approximately 300 x 300μ areas may be observed at magnifications of several hundred times in the television-type picture that appears on the cathode-ray tube. Wittry and Kyser (9, 10) have described some features of the spatial variations; further elaboration on the features in the scanning-infrared images, especially precipitation and dislocations, is given in the next paper (13).

In the place of the photomultiplier, a fiber optics light pipe may be used to transmit the radiation to a Leiss double-prism monochromator (resolution = 4 mev) in order to resolve the spectral shape. The infrared radiation, chopped at 37.5 Hz, is detected at the exit of the monochromator by the cooled photomultiplier, and the resulting signal amplified by a Princeton Applied Research lock-in amplifier which drives a recorder. The electron-beam accelerating voltage was generally 40 kev, and the beam current could be varied from 2.0 to as low as 0.07 μa with a beam diameter of 2μ or less and obtain resolvable spectra. During measurements of spectral shape the beam current was held constant at 0.5 μa or less, and the beam was generally stationary rather than scanning a line or area. The temperature of the excited region (14) was approximately (30 + 80I_B) °C where I_B is the beam current in microamperes.

Experimental Spectra

A typical cathodoluminescent spectrum is shown in Fig. 2 for a sample containing 1.75 x 10^{18} electrons/cm^3. The electron-beam voltage was 40 kev and the beam current was 0.3 μa. The low-energy side of the spectrum appears exponential and can be represented by $I = I_0 \exp(\beta h\nu)$, where I is the intensity, β the low-energy tail slope, and $h\nu$ the emission energy. At lower intensities the emission is dominated by a deep level as shown. In more lightly doped material and at temperatures below room temperature, this deep level becomes more dominant and can prevent an accurate determination of the low-energy tail slope. The width of the spectrum at one-half the maximum intensity and the energy of the maximum intensity $h\nu_p$ are also shown.

The spectral shapes for a series of samples containing 0.2 to 5 x 10^{18} electrons/cm^3 have been summarized in Fig. 3, 4, and 5 by plotting the low-energy tail slope, the energy of the maximum intensity $h\nu_p$, and the half-width as a function of the free electron concentration. (The technique described here still applies above 5 x 10^{18} cm^{-3}, but the drastic decrease in quantum efficiency made it difficult to resolve the spectral shape.) The thermal equilibrium free electron concentration is used rather than the donor concentration because n_o is the quantity determined by

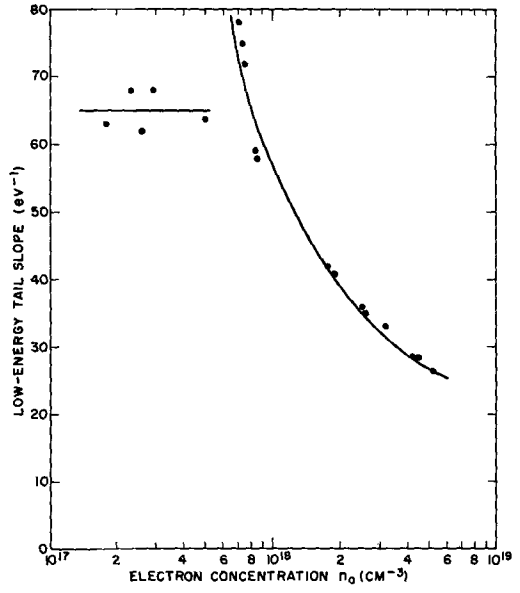

Fig. 3. Low-energy tail slope as a function of the free electron concentration.

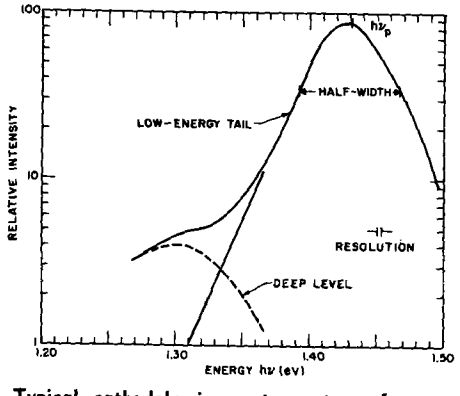

Fig. 2. Typical cathodoluminescent spectrum for n-type GaAs containing 1.75×10^{18} electrons/cm^3. The electron beam voltage was 40 kv and the beam current was 0.3 μa.

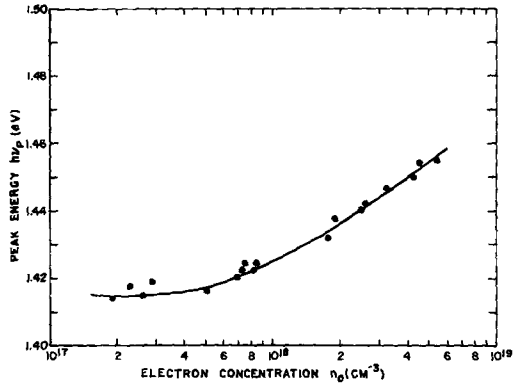

Fig. 4. Peak energy as a function of the free electron concentration.

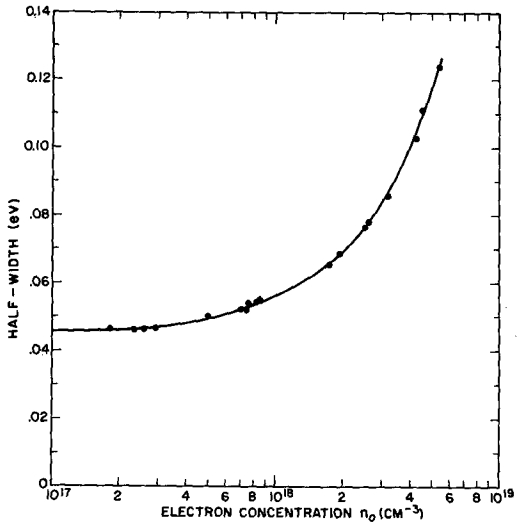

Fig. 5. Half-width as a function of the free electron concentration.

Hall measurements [see Discussion, ref. (13)]. In Fig. 3 the slope of the low-energy tail appears to be constant until a concentration of about 5 x 10^{17} cm^{-3} is reached, then a discontinuity occurs which is followed by a smooth decrease in slope as the electron concentration becomes larger. The slopes at the lower concentrations are influenced by emission from the deep level and are subject to increasing uncertainties. Therefore, without additional study no significance should be placed in the discontinuity shown near a concentration of 5 x 10^{17} cm^{-3}. The peak energy is shown by Fig. 4 to shift to higher energies as the electron concentration exceeds 5 x 10^{17} cm^{-3}. The half-widths summarized in Fig. 5 show a change of 2.5 times over the decade of concentration from 5 x 10^{17} to 5 x 10^{18} cm^{-3}, and the experimental data show very little scatter. From these three figures it should now be obvious that from the spontaneous emission spectral shape it is possible to determine if a sample contains more or less than 5 x 10^{17} electrons/cm^3, and if more, the concentration value.

Since the emission intensity was observed to vary across the sample (9, 10), it was necessary to resolve the spectra in regions that differ in total emission intensity. No variations in spectral shape between regions of differing quantum efficiency were observed for any floating-zone sample. This lack of variation in spectral shape between regions of varying emission intensity suggests two possibilities: either the free electron concentration does not vary between regions, or the sensitivity of spectral shape to variations in n_o is insufficient to resolve possible differences in n_o. To separate these possibilities it is necessary to determine the sensitivity of this technique, the dependence of quantum efficiency on n_o, and the variations in Te concentration between regions differing in emission intensity. The sensitivity of this technique is considered in the next section, while the dependence of quantum efficiency on n_o and the magnitude of the Te concentration variations that could lead to variations in n_o are considered in the following paper (13) on inhomogeneities in GaAs.

Discussion

Figures 3, 4, and 5 show that the spectral shape depends on n_o only above about 5 x 10^{17} cm^{-3}. Of the three spectral shape properties, the low-energy tail slope is the least reliable. This difficulty results from the distortion of the low-energy tail that can occur because of the deep level shown in Fig. 2, as previously discussed. Also, for the lightly doped samples the slopes are quite steep, and any slow responses in the detection and recording system can introduce sizable errors. The build-up of a carbon contamination spot[1] on the sample due to the electron beam was found to reduce the emission intensity. This effect was minimized by using only as large a beam current as necessary to detect the spectral shape and by using a cold finger cooled by liquid nitrogen. At heavier doping levels the emission peak tends to flatten out, and the exact value of $h\nu_p$ can be difficult to determine. Even though the exact energy of the peak intensity is difficult to measure, the value of the peak intensity is rather obvious. Therefore, the spectral width at half the maximum intensity is an accurate and easy quantity to determine. The lack of data scatter in Fig. 5 as compared with Fig. 3 and 4 demonstrates the greater inherent ease in determining the half-width. For these reasons, the half-width will be used as the primary means of determining n_o, and the low-energy tail slope and peak energy will be considered as supplementary data. Taking ±0.005 ev as the resolvable difference in half-width results in a sensitivity of ±0.3 x 10^{18} cm^{-3} for the concentration range covered in Fig. 5.

The sensitivity of ±0.005 ev is a very conservative quantity. For example, the ±0.3 x 10^{18} cm^{-3} sensitivity would suggest that at 7 x 10^{17} cm^{-3} it would not be possible to tell the difference between 5 and 7 x 10^{17} cm^{-3}, while Fig. 5 shows that this distinction is readily made. Therefore, a sensitivity of ±15% at the lower concentrations and ±7% at the higher concentrations might be more reasonable. As mentioned in the introduction, the spatial resolution for this sensitivity depends on the beam voltage and is typically 3-6μ.

Several experimental factors can influence the spectral shape. If the steady-state minority carrier density becomes large enough, a superlinear peak will emerge on the low-energy side of the peak (15). For excitation densities below this level, the spontaneous emission at these impurity concentrations has a linear dependence on the beam current. Also, the effect of self-absorption on the spectral shape must be considered. A detailed analytical treatment of self-absorption cannot be made for the case of a finely focused beam for two basic reasons: (*a*) presently available models for the energy loss of energetic electrons are not adequate for properly describing the carrier generation rate in two independent spatial coordinates, and (*b*) the experimental absorption coefficients for heavily doped GaAs have not been measured for absorption coefficients above 10^3 cm^{-1}, the range where self-absorption might be significant. By making certain reasonable approximations it is possible to consider qualitatively what quantities contribute to self-absorption and their effect on spectral shape.

For description of the variation of electron penetration with beam voltage, the carrier generation rate may be approximated by neglecting the lateral scattering and representing the energy loss by Lenard's law (16)

$$I/I_o = \exp(-\alpha_e x) \qquad [1]$$

where I/I_o is the fraction of the electron flux transmitted, α_e the electron linear absorption coefficient, and x the distance measured from the sample surface. The advantage of using Lenard's law is that it is simple mathematically and analogous to the more familiar expression for optical absorption. The disadvantage is that it does not completely fit the experimental results. The absorption coefficient in Lenard's law depends on beam voltage and can be represented by (17)

$$\alpha_e = 1.9 \times 10^{11} \rho Z^{1/2} E_o^{-2} \qquad [2]$$

where ρ is the sample density, Z the atomic number, and E_o the beam voltage. For a density of 5.32 g-cm^{-3}

[1] A representative presentation of carbon contamination which also occurs in electron microscopes: Hans Gunther Heide, "*Electron Microscopy*," Vol. 1, p. A-4, Sydney S. Breese, Jr., Editor, Academic Press, New York (1962).

and Z of 32, α_e decreases from 1.4 x 10^4 cm^{-1} at 20 kv to 3.6 x 10^3 cm^{-1} at 40 kv. Therefore, the carrier generation rate will vary exponentially in depth as given in Eq. [1], and generation of carriers deeper in the sample will occur as the beam voltage increases.

The distribution in depth of the steady-state minority carrier density depends not only on the generation rate, but also on the diffusion length for holes L_p. This dependence is shown by solution of the continuity equation (neglecting lateral scattering) with suitable boundary conditions. For surface recombination velocities equal to the thermal velocity, an approximate expression for the minority carrier density may be written as

$$p(x) = KE_o[\alpha_e\tau_{nr}/(\alpha_e^2L_p^2 - 1)] [\exp(-x/L_p) - \exp(-\alpha_e x)] \quad [3]$$

where K is a spatially independent factor and τ_{nr} the over-all lifetime which is dominated by the nonradiative lifetime. The generated spectral shape will be uniform in depth and have an intensity proportional to $p(x)$. [Wittry recently presented a more complex analysis for the steady-state minority carrier density. The distribution in depth depends on L_p and the penetration of the beam into the sample, but not as simple exponentials (18)]. At 40 kv and for an L_p of 1.25μ, about 50% of the emission occurs within 3μ of the surface and 95% within 10μ. Emission from a given depth x will be observed after being attenuated by a factor of exp $[-\alpha(h\nu)x_1]$ where $\alpha(h\nu)$ is the optical absorption coefficient at the energy $h\nu$, and x_1 the distance traversed in the solid ($x_1 = x/\cos 70°$). When the $\alpha(h\nu)x_1$ product is the order of unity or larger, significant self-absorption will occur.

The effect of self-absorption on spectral shape really becomes the question of what effect changes in L_p for samples of the same free electron concentration will have on the spectral shape. Reference to the available absorption coefficient data reveals that significant self-absorption is to be expected only above the peak energy. Studies of absorption and photoluminescence by Lucovsky *et al.* (19) have shown that the spontaneous emission peak occurs where the logarithmic slope of the absorption coefficient is $(kT)^{-1}$, where k is Boltzmann's constant and T the temperature. From Fig. 4 and Hill's absorption data (2) the emission peak is found to occur at an absorption coefficient of approximately 10^3 cm^{-1}. Above the peak energy the absorption coefficient will approach a value slightly greater than 10^4 cm^{-1}. For the nominal values of α_e and L_p previously considered in Eq. [3], the emission will occur within less than 10μ of the surface so that the self-absorption, as represented by the $\alpha(h\nu)x_1$ product approaching or exceeding unity, will occur only for emission on the high-energy side of the peak. It is certainly not readily possible to demonstrate experimentally at a given n_o the variation of spectral shape with L_p, but a change in electron penetration can have a similar effect to variations in L_p. Therefore, the dependence of spectral shape on the steady-state hole distribution in depth may be illustrated by varying the beam voltage.

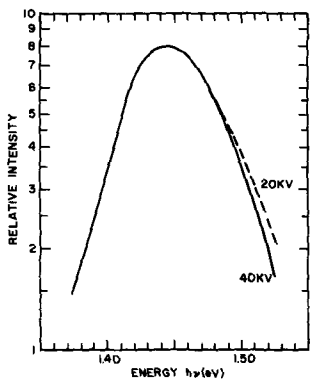

Fig. 6. Demonstration of the effects of self-absorption in a sample of $n_o = 3.2\times10^{18}$ electrons/cm^3. The deeper penetration of electrons at 40 kv may be seen to result in greater self-absorption only at energies above the peak energy.

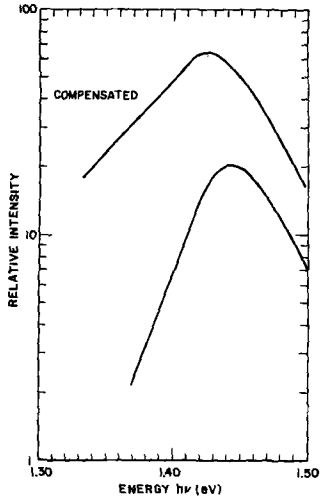

Fig. 7. Comparison of the spectrum for compensated (upper curve) and uncompensated (lower curve) samples with the same n_o of 2.6×10^{18} electrons/cm^3. The relative quantum efficiencies of the uncompensated and compensated samples do not significantly differ. They are displaced in intensity only to clearly illustrate their spectral shapes.

Figure 6 shows the spectra at 40 and 20 kv for a sample containing 3.2 x 10^{18} electrons/cm^3. The spectrum at 20 kv was normalized to the 40 kv spectrum by setting the intensities equal at 1.400 ev. The two spectral shapes diverge only well above the peak intensity. The difference in penetration, as represented by a change in α_e by a factor of 4, leads to no change of the low-energy tail slope or peak position, but changes the half-width by 0.005 ev. Because changes in the electron penetration and L_p have a similar effect on the steady-state minority carrier density, Fig. 6 suggests that variations in L_p by a factor of 2 or more at a given n_o would be necessary to change the half-width an observable amount. Fortunately, significant optical absorption coefficients occur at emission energies greater than the peak energy, and the effect of self-absorption is minimized.

By use of the calibration curves, it is possible to identify compensated samples. The spectrum for a compensated sample with a net free electron concentration of 2.6 x 10^{18} cm^{-3} is shown in Fig. 7 along with the spectrum of an uncompensated sample of the same n_o (see figure caption). Reference to Fig. 3, 4, and 5 shows that the half-width of the compensated sample corresponds to an n_o larger than 2.6 x 10^{18} cm^{-3}, while the peak position corresponds to a smaller concentration. In addition, the low-energy tail slope corresponds to a larger n_o by an order of magnitude. Thus, a compensated sample is characterized by a peak position that is too low for the n_o indicated by the half-width, and also a low-energy tail slope much less than expected for its half-width. By considering the effect of compensation on the edge absorption coefficient and the resulting spontaneous emission in the manner described by Lucovsky *et al.* (19), it can be seen that the decreased slope and peak energy are consistent with compensation effects. Comparison of Fig. 6 and 7 illustrates the manner in which self-absorption and compensation influence the spectral shape and shows the variation in L_p at a given n_o cannot lead to spectra representative of compensation.

Conclusions

The spontaneous emission spectral shape, characterized by half-width, peak energy, and logarithmic slope of the low-energy tail, depends uniquely on the

free electron concentration above concentrations of about 5 x 10^{17} cm^{-3}. A sensitivity of ±15% may be expected near 5 x 10^{17} cm^{-3} and ±7% at 5 x 10^{18} cm^{-3} with a spatial resolution of 3-6μ. The spectral shape also readily identifies compensated samples. This technique of measuring the free electron concentration from the spectral shape may also be applied to photoluminescence which is generally simpler experimentally; however, most bulk or layered samples are often inhomogeneous, and the small spatial resolution of electron-beam excitation is necessary for investigation of these features. The technique presented here should be applicable to p-type GaAs, but the concentration at which the spectral shape begins to depend on the acceptor concentration will probably be about a factor of 10 higher because of the larger effective mass of holes.

Investigation of Inhomogeneities in GaAs by Electron-Beam Excitation

H. C. Casey, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Striations concentric with the growth axis, which are usually considered as impurity fluctuations, represent the inhomogeneity most frequently encountered in GaAs. Images of such striations were obtained by scanning-electron-beam-excited recombination radiation (SEBERR) and displayed on a cathode-ray tube. The samples investigated were Te-doped, floating-zone GaAs containing 2 x 10^{17} to 8 x 10^{18} free electrons-cm^{-3}. The spectral shape of recombination radiation demonstrated that any variation in free electron concentration within a cross section normal to the growth axis must be less than about 10%. In addition, the spectral shape showed that compensation is not the reason for the difference in the Te concentration and the free electron concentration. Precipitation of a Te-rich ternary solid solution with a crystal structure other than GaAs may be the most consistent explanation for the striation inhomogeneity and also may account for the cathodoluminescent features associated with dislocations.

In GaAs many techniques have shown the presence of concentric striations normal to the crystal growth axis. These striations represent fluctuations or inhomogeneities in several properties of the semiconductor crystal. Since the striations are readily revealed by etching (1), they obviously affect the rate of many etches. They also have been reported to cause variations in the infrared transmission (2). Schlieren imaging (3, 4) shows that the striations give fluctuations in the index of refraction and that no significant strains are associated with the striations (4). In the images produced by scanning-electron-beam-excited recombination radiation (SEBERR) and displayed on a cathode-ray tube, bands of decreased intensity were observed (5, 6); these bands will be shown to be the striations which can be revealed by etching. This variation in emission intensity indicates that the striations affect the radiative recombination. Striations have been observed also by x-ray diffraction microscopy in silicon (7) and by resistivity probing in germanium (8). Light emission from reverse-biased GaP p-n junctions clearly reveals striations and their effect on reverse breakdown (9). Because of striations, it is necessary, when preparing wafers for epitaxial growth, to use etching techniques that are not sensitive to these inhomogeneities (10); it is also necessary to consider the effect of these inhomogeneities on diffusion and p-n junction lasers (2, 3, 11,12).

Such an effect which causes variations in so many semiconductor properties has stimulated numerous investigations of both the origin and the nature of striations. Recent studies of InSb single crystals have shown that the formation of striations is the result of temperature fluctuations at the solid-liquid interface due to sharp temperature gradients in the growing crystal near the interface (13). For Te in GaAs, striations were shown by autoradiograms (14) and

electron probe microanalysis (15) to be Te concentration variations. These measurements of Te concentration also revealed that the average Te concentration exceeds the free carrier concentration as determined by Hall measurements. A transmission electron microscope study showed the striations in the particular crystals studied to contain bands of very fine precipitates (16). The result of using the Schlieren technique suggests the striations are variations in the index of refraction due to free electron concentration variations or band-gap changes (4). A number of reasons for the variations in the crystal properties and the difference in the total Te and free electron concentration have been proposed: (*a*) un-ionized Te, (*b*) fluctuations in free electron concentration, (*c*) compensation, (*d*) band-gap changes, and (*e*) precipitation.

Of the many techniques just described for observing the striations, none discriminates entirely between the proposed reasons for the variations. For example, the transmission electron microscope shows precipitation, but does not rule out other possibilities such as variations in free electron concentration. This paper explains how electron-beam excitation may be utilized to observe and investigate the striations and also to discriminate between the proposed reasons for the variations. Another benefit of SEBERR is that the range of magnification and resolution permits observation of such interesting features as dislocations and the discrete nature of some striations. The other techniques, although very useful, are generally limited to low magnifications where the fine features are not resolved or to such extremely high magnifications that the large-scale variations are lost and do not directly demonstrate the effect of the inhomogeneities on radiative recombination.

As previously reported (17), the spontaneous emission spectral shape and peak position may be used to determine the free electron concentration within $\pm 15\%$ near concentrations of 5×10^{17} cm^{-3} and $\pm 7\%$ at 5×10^{18} cm^{-3}, or to determine if a sample is compensated. These concentrations cover the range where the striations are most pronounced and also the range most useful for electroluminescent devices. In addition, the characteristic x-rays generated by the electron beam permit quantitative measurement of the impurity concentration if the spectrometer system has sufficient sensitivity. A Cambridge Microscan can detect Te concentrations only above about 10^{20} cm^{-3}, but by using a fully focusing spectrometer Wittry (15) was able to achieve a sensitivity in the low 10^{18} cm^{-3} concentration range. The spatial resolution for cathodoluminescence (CL) is 3-6μ and 2-3μ for x-rays. This paper is concerned only with CL, but Wittry's x-ray results (15) for Te variations will be discussed in order to describe the striations properly.

Relationship between Cathodoluminescent and Etching Features

It is beneficial first to consider the factors that contribute to the observed contrast in SEBERR images. For a sample scanned by a constant-current beam at a fixed-beam voltage, the measured intensity of the recombination radiation is proportional to the quantum efficiency η_q in a material of uniform generation rate times a factor which accounts for nonradiative surface recombination. This factor F_s will depend on surface-recombination velocity, minority carrier diffusion length, and beam voltage. At a fixed-beam voltage and a constant surface-recombination velocity, the principal effect of F_s on the observed intensity will be due to the diffusion length L_p or the over-all lifetime τ, since $L_p = \sqrt{D\tau}$ where D is the diffusion constant for holes. Wittry's results (18) indicate that τ becomes smaller at the higher impurity concentrations, and thus the factor due to nonradiative surface recombination F_s has a functional dependence on the free electron concentration n_o, $F_s \propto f(n_o)$. The quantum efficiency is simply the ratio of the hole-electron pairs that recombine radiatively to the total that recombine. This relationship is expressed as (19)

$$\eta_q = \frac{C}{n_i^2} \tau_{nr} n_o \int_0^\infty \alpha(h\nu) \exp(-h\nu/kT)\, d(h\nu) \quad [1]$$

where C is a collective constant, n_i^2 the thermal equilibrium electron-hole density product, τ_{nr} the over-all lifetime which is dominated by the nonradiative lifetime, and $\alpha(h\nu)$ the absorption coefficient at the energy $h\nu$. The absorption coefficient has a strong dependence on n_o at the concentrations being considered (20) and will cause the integral in Eq. [1] to decrease above concentrations of 10^{18} cm^{-3}. No data are now available to describe the concentration dependence of n_i^2, but some preliminary calculations based on a model by Halperin and Lax (21) suggest that the dependence will be small. The dependence of τ_{nr} on n_o has not been established, but τ_{nr} can depend on both the concentration of other impurities serving as traps and also on the lattice imperfections. For the present argument, the surface recombination factor F_s will be neglected and the observed intensity taken as η_q. Therefore, contrast in CL shows variations in the minority carrier generation rate, or for a uniform generation rate it measures variations in free electron concentration, unknown impurities, and/or lattice defects.

For comparison of the CL and the preferentially etched surface features over a reasonable portion of a wafer, an area was defined on a <111> oriented wafer containing 2.2×10^{18} cm^{-3} electrically active Te atoms. A smooth surface was obtained by chemically polishing by a procedure using a bromine-methanol etch and intensive stirring (22). Then a "home-plate" shaped mesa with a 0.060 in. base was produced by masking and etching the surrounding material to a depth of 10μ. Areas on this mesa of approximately $300 \times 300\mu$ were scanned by a 40-kv, 0.05-μa electron beam, and the SEBERR pictures were obtained from the cathode-ray tube as previously reported (17). The only optically observable surface irregularities were scratches that occurred during processing. The cathodoluminescent picture of the mesa, made by joining the many pictures of the scanned areas, is shown in the left half of Fig. 1. The sample was then etched with a solution known to reveal dislocations (23); the resulting optical photomicrograph is shown in the right half of Fig. 1. The cathodoluminescent and optical pictures are shown as mirror images so that features found at a certain distance to the right of the center line may be compared with the features at the same distance to the left.

There are a number of features with a unique correspondence between the etched and cathodoluminescent pictures. The irregular, roadlike lines are surface scratches obtained in processing the sample and are actually necessary to align and join the many pictures properly in the composite picture. The dark spots in the cathodoluminescence surrounded by bright regions about 100μ in size correspond uniquely to pits surrounded by smooth regions in the etch portion of the figure. Increased magnification readily identifies the pits as dislocation etch pits. The slightly curved vertical bands of decreased infrared emission spots appear as striations or bands of irregular, overlapping pits. A careful comparison of the left and rights sides of Fig. 1 conclusively demonstrates that the features of dislocations and striations seen by etching are completely reproduced in cathodoluminescence.

General Cathodoluminescent Characteristics of Striations and Dislocations

Examination of SEBERR pictures of samples taken from several Te-doped, floating-zone GaAs ingots reveals typical properties of striations and dislocations which are described in this section. This information

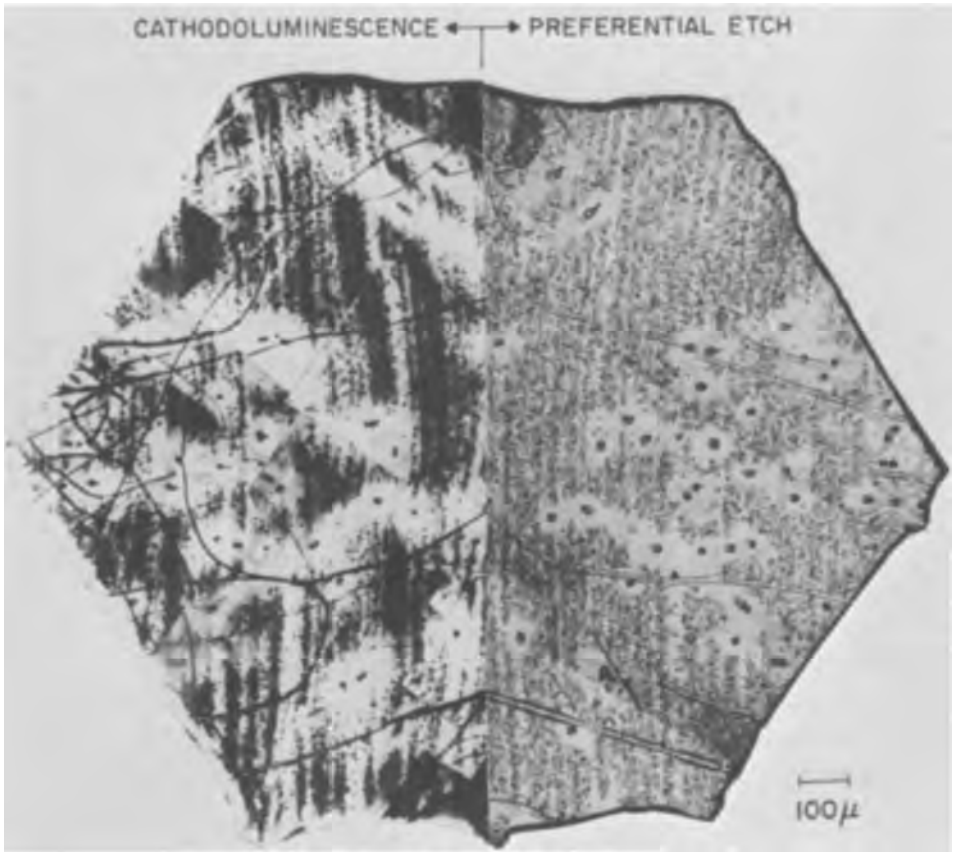

Fig. 1. Comparison of the cathodoluminescent and preferential etch features in GaAs. The free electron concentration is 2.2×10^{18} cm^{-3}.

will be utilized in the next section to infer the nature of the inhomogeneities.

The wafers in Fig. 2 cover a decade in free electron concentration, and for this figure as well as Fig. 3 the wafers were cut normal to the growth axis resulting in <100> orientation. In parts (a) and (b) of Fig. 2, the concentric, circular nature of the striations may be seen. The sample in Fig. 2(c) has a very large dislocation density, and the concentric nature of the striations is not recognizable in a picture of an area this small. The free electron concentrations of the samples in Fig. 1 and Fig. 2(c) are about the same; however, the striation regions of decreased recombination radiation in Fig. 1 are discrete, small, overlapping spots, while in the other wafer these regions appear continuous. Three samples from the same ingot are shown in Fig. 3 to further illustrate this property. Figure 2(b) is representative of most samples up to free electron concentrations of 6×10^{18} cm^{-3}. At higher concentrations the quantum efficiency rapidly decreases, and variations, if present, would be lost in the detector and amplifier system noise.

The dark spots at dislocations have the unique feature of usually being surrounded by a radially symmetrical region of increased emission intensity even in the dark band of the striations. In Fig. 1, 2, and 3 these regions have a radius of approximately 10-50μ. Often, as in Fig. 1, this high-intensity region surrounding a dislocation has the same quantum efficiency as the bright bands between the dark striations. The size of the dark spot at the dislocation is usually at least twice as large as the resolution of this technique (about 3-6μ), and therefore the contrast must be caused by more than just the line associated with the extra plane of atoms.

The three pictures in Fig. 3 show that an interesting and consistent relationship exists between the occurrence and size of discrete spots in striations, and the size of the dislocation spot and its surrounding bright region. Samples shown in Fig. 3 are from the same ingot and have free electron concentrations of 1.7, 2.5, and 3.2×10^{18} cm^{-3}, respectively. The approximate diameters of a dislocation and a bright region, and the size of the striation spot in Fig. 3 are summarized in Table I. This table shows that the larger striation spots occur with the larger dislocation spots and bright regions.

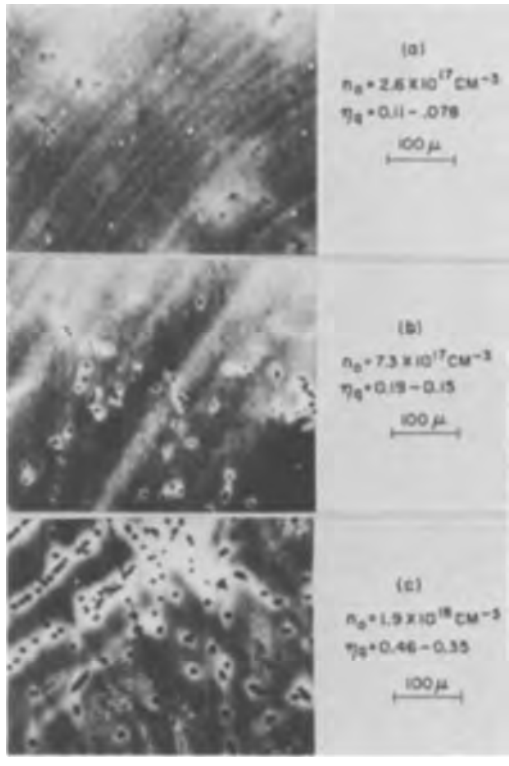

Fig. 2. Typical properties of the inhomogeneities in GaAs as illustrated by SEBERR pictures. The relative quantum efficiency η_Q is given for the bright region surrounding the dislocation (dark spots) and the dark bands in the striations.

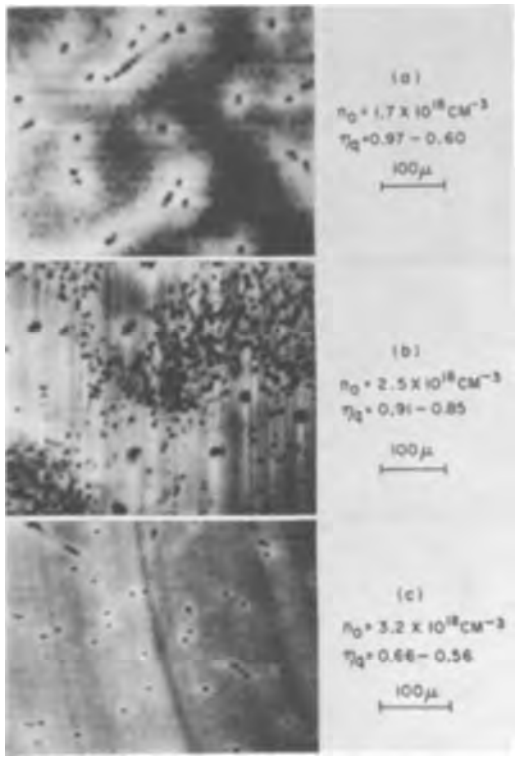

Fig. 3. SEBERR pictures demonstrating the size relationships of the dark spots at the dislocation, the radially symmetric bright region surrounding the dislocation, and the discrete nature of striations.

Since the contrast displayed on a cathode-ray tube can be deceptive, it is necessary to obtain the magnitude of the relative quantum efficiency variations by measuring the relative output voltage of the photomultiplier. The resulting efficiencies for bright regions near dislocations and the dark striation bands are plotted as open and closed circles respectively in Fig. 4. The efficiency limits for these wafers show the same general dependence on free electron concentration as the average values given by Cusano (24) and Kyser and Wittry (6). The rapid decrease in quantum efficiency above about 5 x 10^{18} electrons-cm^{-3} may be attributed partly to movement of the absorption edge to higher energies as described by the Burstein (25) shift which reduces the integral in Eq. [1] (19).

The spontaneous emission spectral shapes were resolved for the samples summarized in Fig. 4. Both the bright areas near dislocations and the dark striations were considered, but no differences in spectral shape were found on any wafer. This result means that the free electron concentration fluctuations must be less than ±15% near 5 x 10^{17} cm^{-3} and ±7% near 5 x 10^{18} cm^{-3} (17). These limits of uncertainty are rather conservative, and with extreme care the uncertainty will be half the above values. Also, spectral shapes which are characteristic of compensation (17) were not observed in the striations.

Discussion of Results

Initially, it is necessary to examine the relationship between the free electron concentration and the donor concentration. At Te concentrations above 10^{17} cm^{-3},

Table I. Size relationships of cathodoluminescent features

Figure	Diameter of dislocation spot, μ	Diameter of bright region, μ	Striation spot size, μ
3(a)	12	60	4-6
3(b)	20	100	10-12
3(c)	6	25	Continuous

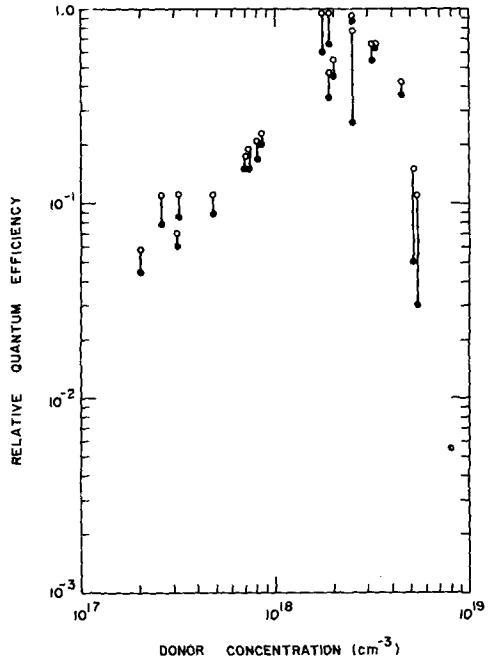

Fig. 4. Relative quantum efficiency as a function of free electron concentration. The open circles represent the efficiency in the bright regions near dislocations and the solid circles represent the efficiency in the dark bands of the striations.

the average distance between impurity atoms is close to the diameter of the Bohr orbit of a donor electron in a crystal, and Hall measurements reveal conduction by carriers in impurity bands or band tails (26). Under these conditions the free electron concentration no longer has any temperature dependence. This result indicates that for concentrations above 10^{17} cm^{-3} each donor atom located substitutionally in an As site contributes one free electron, and substitutional donors do not exist in a neutral or un-ionized state which would demand a temperature dependence of the free electron concentration. The possibility of the compensation as an explanation for the differences between n_o and the Te concentration or for the CL contrast can readily be eliminated since none of the spectral properties related to compensation (17) was observed.

The striations have been shown to be Te fluctuations by Wittry's (15) electron probe microanalysis and autoradiograms by Cronin *et al.* (14). Bands of increased Te concentration showed a decrease in CL intensity (15), which means the dark bands (and presumably the dark spots at the dislocations) in Fig. 1, 2, and 3 are the regions of greater Te concentration. Not only are Te fluctuations present, but the average Te concentration was significantly greater than n_o (14, 15). For example, in a sample containing 5.2 x 10^{18} electrons-cm^{-3}, the average Te concentration was approximately 7 x 10^{18} cm^{-3} (15), and chemical analysis of one of our samples with n_o = 8 x 10^{18} cm^{-3} showed it contained 1.5 x 10^{19} Te atoms-cm^{-3}. This discrepancy between the impurity concentration and the free electron concentration was also observed for Se (27) (results of numerous other papers suggest this is a general effect), but the differences are larger at a given Se concentration than observed for Te. Clearly, Te must be present in a form other than as a substitutional donor on an As site.

A variation of the free electron concentration would be expected because the striations are Te concentration fluctuations. However, the lack of any observable variations in spectral shape between bright and dark bands in the striations limits the possible range of variation to approximately 10%. With 30% Te fluctuations, Wittry (15) was also unable to find any spectral shape variations. In general, at high concentrations n_o does not follow the Te concentration;

in fact, Vieland and Kudman (27) found that n_o varied as $(Se)^{1/3}$ above concentrations of 4×10^{18} cm^{-3}. This dependence of n_o on the Te concentration suggests that the bands of greater Te concentration would not be accompanied by a comparable n_o change. The spectral shape technique does limit the possible variation in n_o, but cannot demonstrate a complete absence of n_o variation.

Equation [1] can be used for showing that differences in quantum efficiency between the bright regions and the dark bands of the striations, if attributed to differences in free electron concentration alone, will lead to an inconsistent result. Since the SEBERR pictures show dislocations as dark spots surrounded by bright regions of the same intensity as the bright striation bands throughout the n_o concentration range studied, it will be assumed that the dark bands in low concentration samples are bands of greater Te concentration as found for the more heavily doped samples. Below concentrations of 10^{18} cm^{-3}, the absorption coefficient is constant at a given $h\nu$, and with a constant τ_{nr} and n_i^2 Eq. [1] becomes

$$\eta_q = C_1 n_o \qquad [2]$$

where C_1 is a constant containing the various constant factors. From the data in Fig. 4, the dark striations would be predicted to contain a smaller concentration than the bright regions: $n_o(\text{dark}) < n_o(\text{bright})$. At higher concentrations, α at a given $h\nu$ decreases rapidly, and small changes in n_o cause a larger change in the integral in Eq. [1] than the linear dependence on n_o. In this case Eq. [1] becomes

$$\eta_q = C_2 \int_0^\infty \alpha(h\nu) \exp(-h\nu/kT)\, d(h\nu) \qquad [3]$$

with the various constants represented by C_2. At concentrations above 10^{18} cm^{-3} the dark regions in Fig. 4 would be due to a smaller α at a given energy, and hence $n_o(\text{dark}) > n_o(\text{bright})$, which is inconsistent with the previous inequality. Inclusion of the nonradiative surface recombination will lead to more complex expressions than Eq. [2] and [3], but will not change the above inequalities between concentrations in the bright and dark regions. Thus, any possible variation in the free electron concentration, which has been limited to about 10%, will not be the principal source of contrast or inhomogeneity seen in cathodoluminescence.

From the above discussion, the most probable source of contrast seen in the SEBERR pictures is the nonuniform distribution of the precipitated Te-rich phase or complex associated with the difference between Te concentration and n_o. Whether the inhomogeneities are band-gap variations will depend entirely on the nature of the precipitation. The contrast would be interpreted in terms of Eq. [1] as τ_{nr} variations. The spatial characteristics are more fully described in Table I by comparing the diameter of the dark spots at dislocations and the surrounding bright regions along with the size of the spots in the striations for the samples shown in Fig. 3. In general, this difference in Te concentration and n_o can be described as a Te-rich ternary solid solution with a crystal structure other than GaAs, but a more explicit description would only be speculation. For example, a solid solution of GaAs-Ga_2Te_3 can form as the crystal cools below 827°C (28). However, to explain the size of the bright regions around the dislocations requires diffusion of Te (at 827°C or lower) from the dark bands to the "dislocation" at very much larger diffusion rates than observed for donors in GaAs (29). Therefore, the Te-rich phase or complex must either be grown into the crystal or be formed by a species which is capable of extremely rapid diffusion.

Vacancies diffuse rapidly, and Vieland and Kudman (27) have suggested a complex involving a Ga vacancy and three Se atoms to describe the cube root dependence of n_o on the Se concentration. Mass action relations were written to describe the cube root dependence; however, mass action relations only mathematically describe equilibrium reactions and do not necessarily prove the existence of the assumed reactants. Acceptors also diffuse rapidly, but there is no evidence of any significant amount of compensation in these highly doped crystals.

The experimental observation that the free electron concentration is consistently less than the chemical donor concentration seems to be a general relationship for GaP (30) as well as GaAs. A fundamental understanding of this phenomenon is lacking at the present time.[1] Electron-beam excitation may be useful as a quantitative measurement technique in experiments intended to study this effect. This technique of studying inhomogeneities in bulk crystals should be applicable to many other compounds, especially the III-V mixed crystals. The only requirements are that the energy of the radiative recombination must exceed about 1.2 ev to permit detection with photomultipliers, and the quantum efficiency be not less than about 10^{-5}.

Conclusions

The features in SEBERR pictures were found to have a complete correspondence to those seen in photomicrographs of preferentially etched surfaces. These features included both dislocations and striations. Dislocations are characterized by 6-12μ dark spots that are usually surrounded by 25-100μ bright regions. The striations appear as either continuous bands or bands of discrete spots of decreased radiative recombination. In previously published results, the striations were found to contain Te concentrations in excess of the free electron concentration. Hall measurements and theoretical considerations show that Te atoms located substitutionally in the lattice cannot exist at these concentrations in an un-ionized form. Other techniques readily demonstrate the presence of inhomogeneities, but do not discriminate between the various reasons suggested for the variations in crystal properties. The infrared emission spectral shape demonstrates that compensation is not present in the striations, nor can very large free carrier variations be present. The contrast in cathodoluminescence and the difference between the total Te concentration and the free electron concentration are therefore accounted for by precipitation of a Te-rich solid solution or complex.

Acknowledgments

The author is indebted to several people for contributions to this paper. The floating-zone crystals were grown by R. G. Sobers, and the Hall measurements were made by F. Ermanis. R. H. Kaiser assisted in the spectral shape measurements, K. L. Lawley aided in the etching studies, and M. B. Panish provided information on the Ga-As-Te phase diagram.

Manuscript received July 18, 1966. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Textural and Electrical Properties of Vacuum-Deposited Germanium Films

J. D. Williams and L. E. Terry[1]

Solid State and Thin Film Devices Division, Sandia Corporation, Albuquerque, New Mexico

ABSTRACT

An investigation has been conducted to determine the effect of condensation rate and substrate temperature on the textural and electrical properties of germanium films vacuum-deposited on amorphous substrates. All films deposited were either amorphous or polycrystalline. Regions in the condensation rate-substrate temperature plane exist which exhibit very high degrees of preferred orientation of the polycrystalline films. It was confirmed that substrate temperature influences the textural properties of the films. Also, for large variations in condensation rate, different preferred orientations were obtained for a constant substrate temperature. This demonstrates that film structure is a function of both the substrate temperature and the deposition rate.

Thin-film semiconductor research activity has been greatly stimulated by the need for improvement in one or more of the aspects of lower cost, smaller size, greater reliability and radiation resistance in electronic components and circuits. The electrical properties of semiconducting films are intimately related to their textural properties; therefore, this investigation of germanium films has been conducted to determine the effect of condensation rate and substrate temperature on the textural and electrical properties of the films. Two papers reporting textural properties of vacuum-deposited germanium films on heated amorphous substrates produced seemingly contradictory results. Davey (1) working with condensation rates on the order of 1 Å/sec, reported [110] texture for substrate temperatures in the 175°-350°C range. He found that a competition for growth occurs in the 350°-575°C range and that the texture varies principally between being powder, [110] and [111]. Above 575°C he found that the [111] texture became dominant. Via and Thun (2), working at 80 Å/sec, reported practically amorphous films at substrate temperatures up to 400°C. In the 400°-500°C range, they found mixed orientation of [110] and [100]. At approximately 500°C, the [100] orientation disappears and a mixture of [110] and [111] is found. At temperatures above 600°C, they found that the preferred [110] is by far predominant.

Sloope and Tiller (3), investigating vacuum-deposited germanium films on heated single-crystal substrates, found that the tendency of a film to exhibit epitaxy increases with increasing substrate temperature. Krikorian and Sneed (4) reported a similar observation in their investigation of sputtered germanium films deposited on heated single-crystal substrates. These observations, plus our own preliminary findings, led us to expect that a given preferred orientation obtained on heated amorphous substrates at low condensation rates and low temperatures could also be obtained at higher substrate temperatures and condensation rates.

During the course of our work, Davey *et al.* (5), published another paper which stated that, for thicknesses of germanium films greater than 500Å, the [110] texture was independent of all the other deposition parameters. A careful examination of Davey's data revealed that, for a constant substrate temperature, 240°C, the deposition rate was varied between 1 and 100 Å/sec. Likewise, for a constant deposition rate of 8.25 Å/sec, the substrate temperature was varied between 225° and 600°C. Therefore, we have chosen to investigate the textural properties of germanium films formed in an extended portion of the rate-temperature range.

Experimental Procedure and Equipment

Two hundred germanium films were vacuum-evaporated onto glazed alumina ceramic and Corning No. 7059 glass substrates with the following range of deposition parameters: (*a*) substrate temperature 25° to 700°C, (*b*) condensation rate 0.5 to 380 Å/sec, (*c*) deposition pressure 10^{-8} to 5 x 10^{-6} Torr, and (*d*) thickness 800 to 50,000Å. The vacuum evaporations were performed with the fixtures and bakeable ion-pumped system shown in Fig. 1. The molybdenum and 304 stainless steel fixture permitted seven samples to be prepared in one pumpdown cycle. Magnetic rotary motion feedthroughs allowed a selection of groups of 2-3-2 substrates for a choice of temperature and condensation rates. The 0.1-ohm centimeter n-type germanium source material was heated to evaporation temperatures with a Varian electron gun. Open cylindrical alumina and quartz crucibles, resistance-

[1] Present address: Motorola Inc., Phoenix, Arizona.

Fig. 1. Substrate holder and heater

heated by helical tungsten baskets and heavy tungsten coils with no inserts, were used as evaporation sources to obtain condensation rates above 100 Å/sec. Substrate heating was accomplished by two methods: (*i*) A molybdenum or stainless steel block, with heater wire imbedded in it, was placed in intimate contact with the substrate; (*ii*) The substrates were placed in a cylindrical oven. The contact heater was capable of raising the substrate temperature to approximately 600°C, and the oven was capable of producing substrate temperatures up to at least 800°C. Construction details of the contact heater are shown in Fig. 2.[2] Substrate temperatures were monitored by chromel-alumel thermocouples in contact with the back of the substrates. A considerable temperature differential is created between the front and back surfaces of the substrates when they were heated by the contact heater. In some cases this temperature difference is as much as 250°C. These differences were carefully correlated with the back surface temperatures by attaching thermocouples to both front and back surfaces and simulating the evaporating conditions. All temperatures in this report refer to the front surface of the substrate.

[2] The imbedded heater wire was Thermocoax manufactured by the Amperex Corporation, Hicksville, New York.

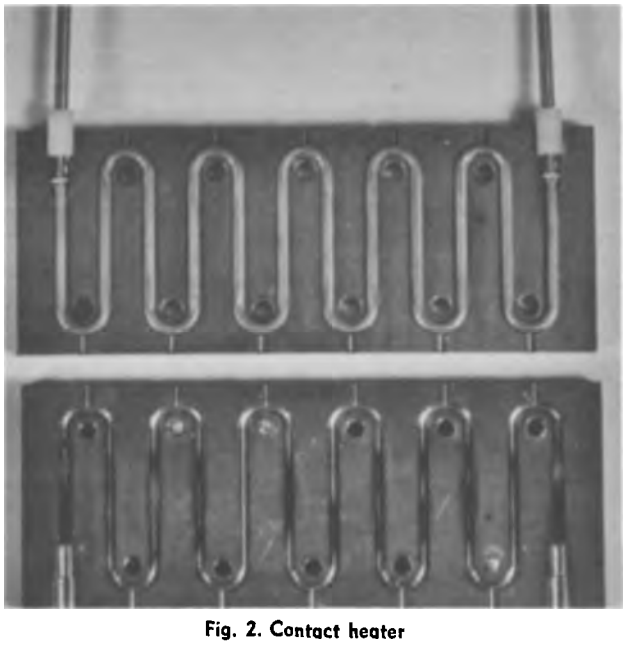

Fig. 2. Contact heater

The substrates were cleaned by the following procedure[3]: (*i*) 15-min ultrasonic bath in Alconox (3 g/liter distilled H_2O), (*ii*) 15-min ultrasonic rinse in room temperature distilled water, (*iii*) 10-min immersion in a boiling 10% solution of H_2O_2, (*iv*) boiling in ultrasonic rinse in distilled water, (*v*) drying in ethanol vapor, and (*vi*) storing in jars with ground glass seals.

The deposition parameters were varied by controlling the electron-gun beam current, the power delivered to the tungsten coil, and/or the deposition time. The source dimple of the electron gun was always filled with approximately 2*g* of germanium. The source material was slowly outgassed and the evaporation conditions allowed to reach equilibrium before the shutter was opened. Since the source material was never depleted by more than a few per cent during any evaporation, the effective source area and volume remained nearly constant, resulting in uniform condensation rates. Films were measured for thickness on a Zeiss interference microscope with the exception of a few of the very high substrate temperature films which exhibited rather rough surfaces. A beta-ray backscattering instrument was used to measure the average thickness of these films.

All samples were analyzed by x-ray diffraction on a General Electric XRD-6 diffractometer unit. The Bragg reflection peaks from the (111), (220), (311), and (400) planes were scanned at 4° and 0.4°/min. The method of determining the degree of preferred orientation of the films and a description of the crystallographic notation is given in Appendix A.

Results and Discussion

Crystallite orientation.—All films deposited on amorphous substrates were either amorphous or polycrystalline. Films deposited in the 1-100 Å/sec condensation rate and 25°-150°C substrate temperature range were all amorphous. Polycrystallinity was observed between 150° to 200°C but consistent, repeatable results were not obtained until the substrates were heated to above 200°C. A composite plot showing regions of preferred orientation in the substrate temperature-condensation rate plane is given in Fig. 3. Additional information pertinent to the data pre-

[3] This is cleaning procedure No. 1 reported in "A Comparison of Substrate Cleaning Procedures," J. D. Williams and J. N. Shafer, presented at the San Francisco Meeting of the Electrochemical Society, May 1965, Abstract No. 115.

sented there is given in Table I. In Fig. 4 the three regions of the substrate temperature condensation rate plane previously investigated by Davey and Via and Thun are outlined. Three broader regions designated A, B, and C are also labeled to aid in the discussion of the figure.

Davey's first results are shown in the lower portion of Fig. 4. He found [110] texture[4] for low substrate temperatures (175°-350°C) and [111] texture for high substrate temperatures (525°-650°C) with the indicated mixed orientations in between. Via and Thun's results are shown near the top of the figure. Their films were all deposited at a condensation rate of 80 Å/sec. Polycrystallinity was first observed at 350°C. Mixed orientation was found up to 600°C, and the [110] texture was by far predominant above 600°C. The results of the present work extend into both regions and clearly indicate that a continuous range exists which connects the two regions of [110] texture. This is shown as region B in Fig. 4. In these polycrystalline films, a certain crystallographic plane of each crystallite is arranged parallel to the substrate surface, but we expect that the orientation is random in the other two directions. Two possible factors which influence the texture are: (*i*) that a larger binding energy exists between the condensing atoms than between the film atoms and the substrate surface, and (*ii*) the surface mobility of the atoms is an increasing function of the substrate temperature. According to a generalization of Bravais, the bounding planes which develop in growth are likely to be those which are parallel to the crystallographic planes of densest packing. There are many exceptions to this, but in the diamond structure the [110] is the most dense plane. In order to maintain similar conditions on the sub-

[4] The word texture is used to denote preferred orientation of crystallite faces parallel to the plane designated by the smallest integer Miller indices. For germanium the x-ray peaks are actually from the (111), (220), (311), and (400) reflections.

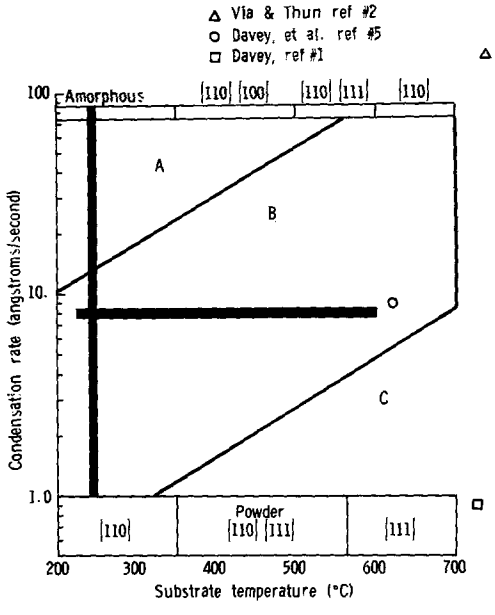

Fig. 4. Regions of special interest of the composite plot

strate surface, the surface mobility of atoms must be increased as the deposition rates increase, to keep successively arriving atoms from burying the preceding atoms which have not had time to form an appropriate lattice.

In general, the textures other than [110] reported by Davey, Via, and Thun are also confirmed by our investigation. The differences found probably result from different definitions of preferred orientation. For example, we actually classed as [100] the region designated by Davey as [111]. But if only the first three reflection planes were used for comparison, then we also would have obtained the [111] texture there. All condensation rates in the range 100-380 Å/sec in the substrate temperature range 250°-600°C caused the random powder orientation which probably results from the burying effect mentioned earlier. For substrate temperatures greater than 650°C and condensation rates of 10 Å/sec or less, the films are very granular. All of these films exhibit either the random powder orientation or a mixed orientation, probably because the evaporant atoms are not arriving fast enough to permit any orderly bonding arrangement.

Table I also contains values of R_{111}, R_{220}, R_{311}, and R_{400} calculated by the method outlined in Appendix A. In the left center portion of region B, values of R_{220} as high as 250 were obtained, indicating very strong [110] texture. For some specially selected rates and temperatures outside region B, [110] texture can also be obtained; but, in general, in regions near the indicated borders, the competition for growth results in a mixed texture.

The theory of nucleation on amorphous substrates is not well understood. Many and widely different theories and models have been proposed even when the experiments performed have been conducted on cleaved or ultraclean single-crystal substrates. For example, lattice constants of the parent crystal and the growth film were once expected to be within 15% for epitaxy to occur (6). A new concept, pseudomorphism, has been developed to explain the fact that oriented overgrowth has been observed for even greater differences in lattice constants. Such variables as substrate temperature and condensation rate are often of greater significance than the amount of lattice misfit (7, 8). The glass substrates used in our experiments, even though ultraclean, do not exhibit the ordered surface of a single-crystal substrate. Therefore, they do not lend themselves readily to conventional epitaxial theories.

The diamond structures of germanium can be considered as two interpenetrating face-centered cubic lattices. Because of the complicated covalent bonding of the diamond-type semiconductor structure, a rigorous treatment of the dependence of crystallographic formation on the substrate temperature is not given. However, a heuristic argument, following a development of Rhodin and Walton (9), is presented to offer a qualitative understanding of the changes in orientation with temperature and rate.

Rhodin and Walton considered the formation of a deposit of a face-centered cubic metal as a function of substrate temperature at a constant incident rate. At the low-temperature limit, the critical nucleus is a single atom, and the nucleation rate, I, can be expressed as

$$I_1 = R\left(\frac{R}{\nu N_0}\right)\exp\left[\frac{(2Q_{ad}-Q_D)}{kT}\right] \quad [1]$$

which is obtained from a general expression

$$I_n = R\left(\frac{R}{\nu N_0}\right)^n \exp\left[\frac{(n+1)Q_{ad}+E_n-Q_D}{kT}\right] \quad [2]$$

where n = number of atoms in the critical nucleus, E_n = dissociation energy of the critical nucleus ($E_1 = 0$), R = rate of incidence of vapor atoms, N_0 = density of adsorption sites, ν = a frequency term of the order of 10^{12}/sec, Q_{ad} = heat of adsorption of adsorbed atom, Q_D = activation energy for surface diffusion, k = Boltzmann constant, and T = absolute temperature.

At the low-temperature limit, the critical nucleus should be a single atom. Therefore, each time that a pair is formed it will usually grow, rather than decay into two single atoms. As the supersaturation is decreased, either by increasing substrate temperature or by decreasing incidence rate, a supersaturation point is reached where the probability of a pair decaying is equal to the probability of its growing. Below this point of supersaturation, a pair will be a critical nucleus until supersaturation is reached where the stable configuration formed by adding a single atom to the pair becomes unstable. Then the three-atom cluster becomes the stable nucleus.

As the substrate temperature is increased, a temperature is reached at which the pair is no longer stable (Eq. [2]). The next smallest cluster (three-atom) is one that has a minimum of two bonds per atom. One way of achieving a minimum of two bonds per atom is to have three atoms arranged in a triangle. The critical nucleus is the pair and the nucleation rate is

$$I_2 = R\left(\frac{R}{\nu N_0}\right)^2 \exp\left[\frac{(3Q_{ad}+E_2-Q_D)}{kT}\right] \quad [3]$$

where E_2 is the dissociation energy of the pair.

Another way of achieving a minimum of two bonds per atom is to have four atoms arranged in a square. The critical nucleus for this arrangement can be taken as three atoms in a capital L arrangement, and the nucleation rate is

$$I_3 = R\left(\frac{R}{\nu N_0}\right)^3 \exp\left[\frac{(4Q_{ad}+E_3-Q_D)}{kT}\right] \quad [4]$$

where E_3 is the dissociation energy of the three atoms in the critical nucleus.

The three-atom smallest stable cluster leads to an orientation in which the [111] plane is parallel to the substrate. The four-atom configuration leads to the [100] orientation. Therefore, Eq. [4] applies where the [100] is the first orientation to be observed, and Eq. [3] when the [111] orientation is first observed. Similarly, other orientations can also be observed. To obtain the temperature, T_1, at which the smallest stable cluster of one bond per atom changes to the two bond per atom (a triangular arrangement), one need only to equate Eq. [1] and [3] to obtain

$$T_1 = \frac{-(Q_{ad}+E_2)}{k\ln\left(\frac{R}{\nu N_0}\right)} \quad [5]$$

Likewise, the temperature, T_2, at which the smallest stable cluster of one bond per atom changes to the two bond per atom (a square arrangement), is obtained by equating Eq. [1] and [4]. This yields the following expression for T_2

$$T_2 = \frac{-(Q_{ad}+E_3/2)}{k\ln\left(\frac{R}{\nu N_0}\right)} \quad [6]$$

The preceding discussion, for the simple faced-center cubic metal, illustrates, at least for the initial stages of growth, that the type of orientation obtained for a given deposit is a function of substrate temperature. Since the nucleation rate is also dependent on the incidence rate of vapor atoms, the number of atoms in a critical nucleus is dependent on the condensation rate as well as the substrate temperature.

The preceding development would be more plausible if the complete films were formed as successive complete monolayers. The experimentally observed orientation rate and temperature dependence could then be

described by heterogeneous nucleation rate theory. However, monolayer formation does not seem to be the normal mode of growth for alkali halides and various metals previously studied (10). Since it is more likely that the germanium nuclei are experiencing three-dimensional growth, it therefore appears that a combination of heterogeneous and homogeneous nucleation is occurring.

Crystallite sizes.—When the size of the individual crystal is approximately 2000Å or less, one may use information obtained from diffractometer line broadening in estimating crystallite sizes. The extent of line broadening is given by the Scherrer formula

$$t = \frac{K\lambda}{(B_M^2 - B_S^2)^{1/2} \cos\theta} \qquad [10]$$

where B_M = width of diffraction line measured at half its maximum intensity, B_S = width from standard of crystallite size larger than about 2000Å, t = diameter of the crystal particle, K is a constant taken to be equal to 0.9, θ the Bragg angle, and λ is the wavelength of characteristic x-ray target material. All diffraction lines have a measurable breadth because of divergence of the incident beam and width of the x-ray source in diffractometers. The expression $B_M^2 - B_S^2$ assumes a Gaussian distribution of the counts and is essentially zero whenever the particle size exceeds approximately 2000Å. A standard half-width B_S was obtained for the XRD-6 unit by scanning the peaks from 40μ germanium powder samples. Six calibration samples of 40μ powder yielded an 8.8-min resolution width for the (111) peak and 11.6-min for the (220) peak.

Half widths for the (111) and (220) peaks were measured and are presented in Fig. 5 as a function of the substrate temperature. The data represented here covers deposition rates from 0.2 to 80 Å/sec and thicknesses from 2500 to 15,000Å. The data were grouped in temperature increments of 25°C, and the peak widths averaged within this temperature increment. Thus, each point represents approximately eight samples whose peak widths normally varied less than 2 min. The (111) and (220) crystallite size increases with temperature and, in agreement with Davey (5), the (220) crystallite sizes are larger than the (111) crystallites over the whole temperature range. Crystallite sizes calculated from the peak half-width data are also presented in Fig. 5. Some individual films from region B over the complete temperature range were also checked for crystallite size. It was found that the crystallite sizes of individual films followed the average data of Fig. 5 very closely. Thus, even though R_{220} peaks in the 250°-350°C range, the crystallite sizes are increasing functions of temperature. The [110] crystallite films in the 275°-280°C temperature range were also investigated for changes in crystallite size as a function of deposition rate. It was found that at a substrate temperature of 280°C when the condensation rate was increased from 1-8 Å/sec the [110] crystallites increased from 800 to 1200Å in average size.

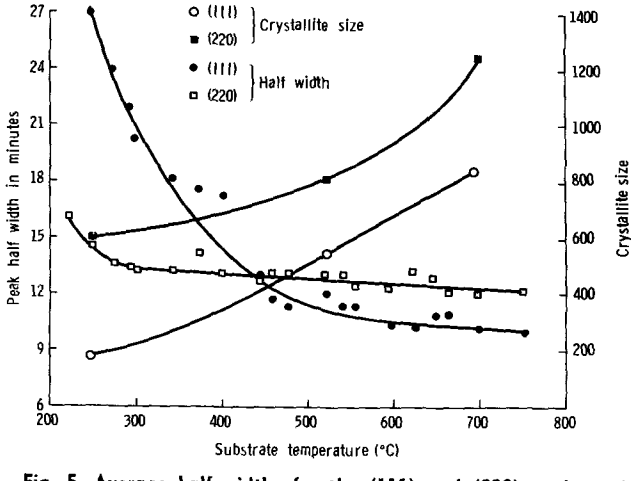

Fig. 5. Average half widths for the (111) and (220) peaks and crystallite size vs. substrate temperature.

Electrical properties.—In single-crystal semiconductor technology the most important parameters are resistivity, conductivity type, carrier mobility, carrier concentration, and lifetime of injected carriers. Because most single-crystal devices are minority carrier devices, the quantities mentioned above are those most pertinent to minority carrier devices. Vacuum-deposited semiconductor films presently produced on amorphous substrates are no more than polycrystalline films with large (>1000Å) diameter crystallites which may or may not exhibit a preferred crystallographic orientation. The most successful use of these semiconductor films has been in majority carrier devices. In polycrystalline films, the parameters mentioned are not always as meaningful as they are in single-crystal materials; however, they do form a basis of comparison and are widely used in thin-film research. The electrical parameters measured for these films are the conductivity type, the resistivity, and the Hall coefficient. All measurements were made at room temperature.

Lattice defects, grain boundaries, and other film imperfections found in polycrystalline films exhibit acceptor-type characteristics. Therefore, in these films the apparent doping level is shifted, in general, from source to film in the direction of higher p-values. All of the films deposited exhibited p-type conductivity, although the source material was n-type.[5]

Figure 6 shows the resistivity of the films *vs.* substrate temperature as measured with a four-point probe.[6] The data was also grouped in temperature increments and averaged. A few values of mobility are shown at key points in Fig. 6. Although the resistivity again increases slightly at temperatures above 400°C, the mobility of crystallite sizes continue to increase. Rectifying grain boundaries in polycrystalline material will cause fluctuation in the electric field intensity. Therefore, the resistivity will register higher values than in similarly doped single-crystal material.

[5] The film conductivity type was checked by a thermoelectric probe and by observing the sign of the Hall voltage. The film conductivity type was checked immediately after the films were removed from the vacuum chamber.

[6] For films less than 10^5Å thick $\rho = 4.532 \times 10^{-8}\ V/I\ W$, where V is in volts, I in amperes, and W in angstroms.

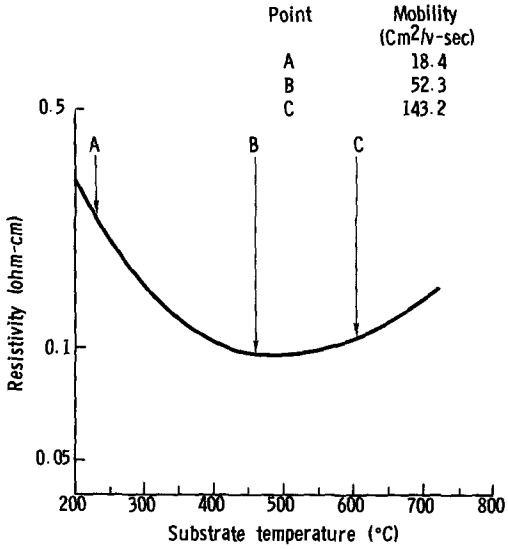

Fig. 6. Resistivity vs. substrate temperature

Conclusions

For large variations in condensation rate, different preferred orientations can be obtained for a constant substrate temperature. This fact, combined with the well-known variations in textural properties with changes of substrate temperature, suggests that film structure is a function of both the substrate temperature and the deposition rate. The [110] textural characteristics produced at low-substrate temperatures and low-condensation rates can be extended through higher substrate temperatures if the condensation rate is increased. Thus, since the results of Davey and Via and Thun fall at opposite ends of a continuous substrate temperature condensation rate region they are basically in agreement rather than contradictory.

From x-ray diffraction line broadening, the crystallite sizes increase with substrate temperature. The crystallites of [110] texture are always larger than the [111] oriented crystallites. The ratio R_{220}, which gives a quantitative measure of the degree of preferred orientation, peaks in the 250°-350°C, 2-7 Å/sec portion of region B. Crystallite sizes were also observed to increase with condensation rate. A 50% increase in crystallite size could be observed by increasing the temperature or by increasing the condensation rate across the ranges of region B.

The resistivity and Hall mobility of the films are dependent on the substrate temperature during deposition. The resistivity varies down to a minimum of approximately 0.1 ohm-cm near a substrate temperature of 500°C. The Hall mobility increases with substrate temperature. Values from 1 to 150 cm^2/sec were obtained. The resistivity values seem to depend on the number of crystallites oriented, since they pass through a minimum soon after the degree of preferred orientation peaks. The mobility continues to increase and therefore must depend on the average crystallite size.

Manuscript received May 10, 1965; revised manuscript received Aug. 29, 1966. This paper was presented at the Toronto Meeting, May 3-7, 1964. This work was supported by the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX A

Determination of Preferred Orientation

A standard definition of what is meant by "preferred orientation" of polycrystalline films does not exist. The following definition was developed and used in this paper. A ratio that provides a quantitative measure of the relative amount of preferred orientation is defined as follows

$$R_{ijk} = \frac{h_{ijk}^{s}}{h_{111}^{s}} \frac{h_{111}^{Ps}}{h_{ijk}^{Ps}}$$

where h_{ijk}^{s} = height of (ijk) plane reflection peak, above noise, for sample being measured; h_{ijk}^{Ps} = height of (ijk) plane reflection peak, above noise, for powder standard (for germanium $h_{111}^{Ps} = 1$, $h_{220}^{Ps} = 0.57$, $h_{311}^{Ps} = 0.39$, $h_{400}^{Ps} = 0.07$); h_{111}^{s} = height of (111) plane reflection peak, above noise, for sample being measured; and h_{111}^{Ps} = height of (111) plane reflection peak, above noise, for powder standard.

Thus, for example, we have

$$R_{220} = \frac{h_{220}^{s}}{h_{111}^{s}} \cdot \frac{h_{111}^{Ps}}{h_{220}^{Ps}}$$

and

$$R_{400} = \frac{h_{400}^{s}}{h_{111}^{s}} \cdot \frac{h_{111}^{Ps}}{h_{400}^{Ps}}$$

It is apparent then that if

$$R_{220} = 1$$

then the height of the (220) plane reflection peak in the sample and the height of the (111) reflection peak in the sample are in the same ratio as these two peaks in the powder standard. However, if

$$R_{220} > 1$$

then the ratio of the height of the (220) plane reflection peak to that of the (111) plane reflection peak for the sample is larger than the corresponding ratio for the powder standard. Thus we have preferred orientation of (220) over the (111) in the sample.

Similarly, if

$$R_{220} < 1$$

then the (111) is preferred over the (220).

It is apparent that all the ratios are normalized to the (111) plane. Therefore, if we have $R_{400} > R_{220}$ then the (400) plane is preferred over the (220) plane.

If a particular plane exhibited a relative ratio of at least one greater than the next highest ratio, the sample was considered to exhibit preferred orientation in that direction. If no more than three of the peaks exhibited ratios within one of each other, the preferred orientation of the sample was considered mixed between the two highest ratios; and if all four ratios were within one of each other, the sample was considered to exhibit the random powder orientation. The above criterion can be used for all evaluations except those in which the (111) reflections are predominant. In these cases, all ratios are one or less; therefore the criterion becomes one-half below rather than one above: *i.e.*, the (111) direction is preferred if $R_{111} = 1$ and all other R_{ijk}'s are below one-half; mixed orientation between the two highest reflections is obtained if no more than three of the peaks exhibit ratios within one-half of each other; and if all four ratios were within one-half of each other, the sample was considered to exhibit the random powder orientation. If no peaks were observed, the sample was considered to be amorphous. The notation used throughout this paper is as follows: [111] =preferred orientation or texture; $M\begin{pmatrix}111\\110\end{pmatrix}$ = mixed orientation with $R_{111} > R_{220}$; and P[111] = powder orientation with $R_{111} >$ the other R_{ijk}.

Preparation of Epitaxial $Ga_xIn_{1-x}As$

R. W. Conrad, P. L. Hoyt, and D. D. Martin

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Single-crystal, epitaxial $Ga_xIn_{1-x}As$ alloys have been prepared on (100), semi-insulating GaAs substrates, using an open-tube, vapor phase deposition system. High-purity elemental gallium, indium, and arsenic were used as source materials. Severe distortion of substrate and deposit was observed when thin substrates (less than *ca.* 11 mils) were used. This was attributed to the large lattice mismatch between deposit and substrate. The electron Hall mobility showed a pronounced minimum for alloys in the middle of the composition range, in agreement with earlier results.

In contrast to the $GaAs_xP_{1-x}$ alloy system, relatively few studies of the preparation and properties of $Ga_xIn_{1-x}As$ alloys have been reported. Abrahams *et al.* (1) prepared polycrystalline $Ga_xIn_{1-x}As$ alloys by gradient freeze and zone-leveling techniques. The variations of lattice thermal conductivity, electron mobility, and band gap were determined as a function of alloy composition. Woolley *et al.* (2) apparently prepared more homogeneous polycrystalline alloys by directional freezing. The variation of energy gap with composition was found to be linear up to about 80 mole % GaAs. At higher GaAs contents, a more rapid increase in energy gap was observed. Hall measurements of these alloys gave mobilities lower than obtained by Abrahams *et al.* when single-carrier treatment of the data was used. This was attributed to mixed conduction. Homogeneous polycrystalline alloys were recently prepared by Hockings *et al.* (3) by zone-leveling. Thermal conductivity, Seebeck coefficient, and electrical resistivity were measured as functions of temperature, impurity concentration, and alloy composition. Electron mobilities were reported for several samples with $x = 0.3$ and 0.7. However, these samples were very highly doped with selenium (from 7×10^{17} to $4 \times 10^{18}/cm^3$). Sirrine (4) briefly described the nonseeded growth of several single crystals of $Ga_xIn_{1-x}As$ using halogen vapor transport in a closed system. Minden (5) reported on the preparation of single-crystal $Ga_xIn_{1-x}As$ alloys, both unseeded by a closed tube method, and epitaxial on GaAs substrates using an open-tube system. Minden's open-tube system employed sources of elemental arsenic and gallium-indium solutions. Considerable fractionation of the gallium-indium source occurred, making control of composition difficult. Electrical properties were not reported.

The present investigation further deals with the open-tube preparation and properties of epitaxial $Ga_xIn_{1-x}As$ alloys on GaAs substrates. Instead of mixed gallium-indium solutions as a source material, separate reservoirs of gallium and indium are used.

Experimental

Materials preparation.—Initially, a deposition system employing separate reservoirs of crushed GaAs and InAs was tried. Transport of the gallium- and indium-halides and introduction of arsenic were accomplished by passing $AsCl_3/H_2$ mixtures over the heated source materials. Control of alloy composition in this system however was not straightforward in that InAs and alloys with greater than about 50 mole % InAs were difficult to prepare. For this reason and for reasons of economy, flexibility, and purity, a different type of system was devised.

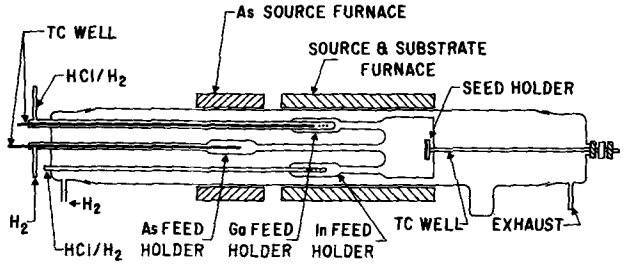

Fig. 1. Open-tube vapor deposition system for epitaxial $Ga_xIn_{1-x}As$ alloy preparation.

The open-tube deposition system used in this work is shown schematically in Fig. 1, and is constructed of fused quartz. Purified H_2 was passed over heated elemental arsenic[1] to transport arsenic vapor to the deposition zone. Mixtures of purified H_2 and HCl (prepared by H_2 reduction of $AsCl_3$) were passed through the heated gallium[1] and indium[1] reservoirs to transport the volatile gallium and indium chlorides to the deposition zone. (The concentration of HCl in the gas mixture is fixed at about 6 v/o by the vapor pressure of $AsCl_3$, which is maintained at 25°C.) The compositions of the deposited alloys were primarily controlled by the relative flow rates of the gas mixture through the gallium and indium reservoirs. These could be varied continuously from 0 to about 70 cc/min. An additional flow of H_2 of about 30 cc/min was introduced into the outer reactor tube to prevent back-diffusion and to aid in sweeping out the reaction products.

A two-zone resistance furnace was used to provide temperature control of the arsenic, gallium, indium, and substrate. One zone controlled the arsenic temperature (typically 440°C). The second zone controlled the gallium and indium reservoirs simultaneously (at 865°-870°C) since they are side-by-side. Control of the substrate temperature (745°-750°C) was accomplished by placing the substrate on a movable holder and positioning it at the proper location in the temperature gradient at the end of the gallium-indium source zone. The substrate had to be held in a vertical position because of the steepness of the temperature gradient. With care, all temperatures were maintained at ± 2°C.

Substrates used in this investigation were (100)-oriented wafers cut (30 mils thick) from chromium-doped GaAs pulled crystals. Room temperature resistivities of such crystals were about 10^8 ohm-cm. The wafers were chemically polished using the method of Reisman and Rohr (6), and etched in 5:1:1 $H_2SO_4:H_2O_2:H_2O$ immediately prior to use.

Materials evaluation.—The alloy layers were shown to be epitaxial by x-ray diffraction. Epitaxial layer thicknesses were determined by bevel-lap and stain techniques. A good stain for delineating the junction in GaAs and GaAs-rich alloys was the $Fe\text{-}HNO_3\text{-}H_2O$ stain (7). For InAs and InAs-rich alloys, a brief treatment with 1.5% NaOCl in H_2O provided sharp contrast between substrate and layer (8).

Compositions were determined by x-ray diffraction techniques, assuming a linear variation of lattice

[1] 99.9999% pure.

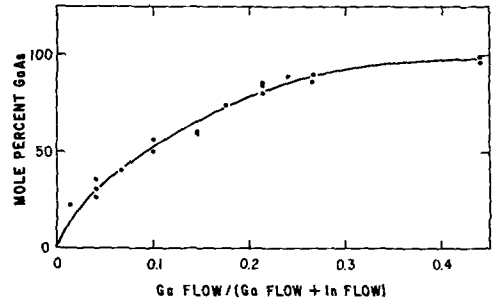

Fig. 2. Variation of composition of epitaxial $Ga_xIn_{1-x}As$ alloys with change in fractional $HCl-H_2$ mixture flow through gallium reservoir.

constant with alloy composition. The sharpness of the alloy diffraction peaks also provided a qualitative measure of deposit homogeneity.

Hall and resistivity measurements were made on ultrasonically cut six-armed specimens with indium solder contacts, using either a-c or d-c techniques, depending on whether the sample resistance was low or high.

Results and Discussion

Physical properties.—Deposition rates obtained with this system ranged from 20 to 35 μ/hr, essentially independent of substrate temperature over the range 720°-760°C, and also independent of alloy composition. These results are in contrast with the observation (5) that InAs deposition occurs efficiently only at temperatures below 700°C.

Alloy composition could be varied in a straightforward fashion by changing flow rates over the gallium and indium sources. This relation is shown in Fig. 2. The abscissa is the ratio of the flow rate of the $HCl-H_2$ mixture over the gallium source to the total flow rate of the $HCl-H_2$ mixture over both gallium and indium sources. This is similar to the variation of alloy composition with source composition found by Minden (5). In contrast, however, we have experienced no difficulty in fabricating alloys with less than 10 mole % InAs. The relationship shown in Fig. 2 is unusual in view of the fact that deposition rate is essentially independent of alloy composition even though GaAs appears to deposit preferentially. We have no explanation for this at present.

The homogeneity of alloys produced in the deposition system using compound source materials has been described previously (9). Material produced in the present system was similarly examined using reflectivity and absorption methods and found to be homogeneous within the limits of resolution of the analytical methods (about ± 3% absolute).

Often the alloy layers had macroscopically smooth, shiny surfaces and sharp substrate-deposit interfaces. Occasionally, for reasons not yet clear, physical defects of the "hillock" type were obtained in the more GaAs-rich alloys. These generally were protrusions with apparently (100) facets. For InAs-rich alloys, defects took the form of short line imperfections oriented along <110> directions. These line imperfections appear to be (100) analogs of the (111) stacking faults in epitaxial GaAs described by Gabor (10).

The hillock imperfections appeared to be connected with substrate quality, since some substrate crystals yielded higher hillock densities than others. The line imperfections, however, did not appear to be closely connected with the substrates. Since such line imperfections were only observed in InAs-rich alloys, they may be related to the large lattice mismatch (InAs, 6.06Å; GaAs, 5.65Å).

When alloys were deposited on very thin GaAs substrates (less than about 11 mils thick), the samples were severely plastically distorted. Figure 3 shows a

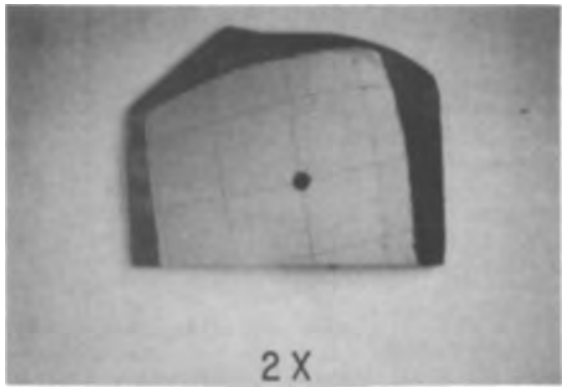

Fig. 3. Distorted epitaxial $Ga_{0.75}In_{0.25}As$ sample obtained by deposition on a 10 mil thick (100) GaAs substrate.

39μ thick layer of $Ga_{0.75}In_{0.25}As$ on a substrate 10 mils thick. (The sample was photographed through a hole in a piece of graph paper to illustrate the curvature.) Surface contour measurements showed this sample to be symmetrically curved about its center point with a radius of curvature of 12 cm. A detailed study of this phenomenon was not performed. However, we did ascertain that (*i*) the effect was caused by alloy deposition since heat-treatment of a thin substrate under conditions similar to those used during a deposition did not produce bending, and (*ii*) qualitatively the effect appears to become more severe as the InAs content of the alloy is increased. Since the thermal expansion coefficients of InAs and GaAs are not very different over the temperature range 50°-700°C (11), the distortion is attributed to the considerable mismatch of lattice constants.

Electrical properties.—The initial investigations of the electrical properties of the $Ga_xIn_{1-x}As$ system were at the end points of the alloy range, *i.e.*, GaAs and InAs. Table I shows the electrical properties of the better deposits. Next, alloys of various compositions were prepared and evaluated. Generally, deposits were n-type with excess carrier concentrations in the 10^{15}-10^{16} cm^{-3} range. However, we observed that use of low arsenic reservoir temperatures (<*ca.*400°C) invariably produced p-type, high-resistivity layers (10^4-10^5 ohm-cm at 300°K) for GaAs and alloys with less than about 70 mole % InAs. The resistivities of such deposits were essentially independent of alloy composition. The nature of the impurity or defect causing such behavior is not known; however, the invariance of resistivity with composition implies an acceptor level which stays approximately a fixed distance from the valence band through the alloy range. This has been partially confirmed by conductivity measurements as a function of temperature for several such samples. The activation energy of con-

duction (ΔE) as a function of alloy composition is shown in Fig. 4. The ΔE values shown are uncorrected for variations of mobility and densities of states with temperature. However, in all cases the variation of the logarithm of conductivity with reciprocal absolute temperature was linear over a large temperature range (from 100° to 300°K). The energy level of the unknown acceptor appears to become deeper than $E_g/2$ at about 70 mole % InAs. This is consistent with our observation that p-type high resistivity alloys with more than 70 mole % InAs could not be obtained. The electrical properties (at 300°K) of alloys with more than 70 mole % InAs prepared at excessively low arsenic temperatures (less than about 400°C) were typically < about 10^{15} electrons/cm^3 with very low mobilities (< about 2000 cm^2/volt-sec). This is consistent with an acceptor deeper than $E_g/2$.

The reason for the change from p-type high resistivity to n-type, low resistivity with increasing arsenic temperature is not clear. Three likely explanations of such behavior however are (*i*) a strong dependence of an impurity vapor-solid segregation coefficient on arsenic pressure, (*ii*) increased shallow donor impurity contamination from the arsenic at the higher temperatures, (*iii*) a physical defect whose concentration is dependent on the arsenic pressure. Unfortunately very little is known about the influences of items (*i*) and (*iii*) on epitaxial film growth, and we cannot definitely eliminate the possibility of (*ii*).

The variation of electron Hall mobility (at 300°K) of our best samples with alloy composition is shown in Fig. 5. (The excess electron concentrations of these samples, determined from Hall measurements, are all in the range 1-8 × 10^{15}/cm^3, except for the GaAs sample, which was 8 × 10^{14}/cm^3.) These mobilities are similar to those observed by Abrahams *et al.* (1) for polycrystalline alloys with higher excess electron concentrations. Invariably, the mobilities of the alloys decreased with decreasing temperature, in contrast to the temperature variation of mobility of GaAs and InAs. This implies scattering from a charged center of some type. Since the mobilities of the GaAs and InAs samples prepared in this system compare favorably with published values, we suspect that alloy formation *per se* may be responsible in part for the low mobilities. However, alloy scattering of the kind described by Brooks (12) does not appear to be applicable in this case, since a negative temperature dependence of mobility is predicted.

Conclusion

An open-tube system employing separate reservoirs of gallium, indium, and arsenic is a satisfactory method for fabricating epitaxial layers of $Ga_xIn_{1-x}As$ alloys on GaAs substrates with good physical properties. There appears to be considerable strain associated with lattice mismatch. However, InAs, for which lattice mismatch is greatest, can be prepared with electrical properties comparable to bulk material.

The electrical properties (primarily electron mobility) of the alloys prepared in such a system are not improved over polycrystalline alloys prepared by gradient freeze and zone-leveling techniques. However, the versatility of the open-tube system permits fabrication of material suitable for device fabrication and investigation.

Transport Processes in the Thermal Growth of Metal and Semiconductor Oxide Films

F. C. Collins and T. Nakayama

Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The transport problems involved in the thermal growth of thick oxide films are reexamined on the basis of a semiconductor model of the oxide film, in which the electron and hole concentrations are assumed to be in local thermodynamic equilibrium. The coupled transports of ions and of electrons or holes required in the Wagner electrochemical model of film growth are related separately to the electrostatic and Fermi potential gradients in the oxide film. The electrostatic potential difference across the oxide film is shown to be fixed by the free energy of formation of the oxide and by the transport coefficients of the several migrating species. The effect of externally applied fields on the thermal growth process is discussed. Anomalies pointed out by Raleigh are shown not to be inconsistent with the electrochemical model of film growth. The question of local electroneutrality in the film relative to the parabolic growth law is also examined.

Interest in the theoretical aspects of the thermal growth of oxide films has been greatly stimulated by recent experimental studies particularly by the intensive investigations of the growth of amorphous silicon dioxide films on single crystals of silicon (1). The work of Jorgensen (2) in this connection is of special interest particularly his finding that the thermal growth rate can be altered by the application of an external electric potential. This indicates that film growth involves ionic migration in agreement with the electrochemical model of film growth of Wagner (3), Mott (4), and Cabrera and Mott (5).

The electrochemical model assumes the transport of charged species, rather than neutral molecules, across the growing oxide film with counterflow of electrons and holes to maintain electrical neutrality. Whether the growth of a particular oxide film is supported by the transport of a metal cation or an oxygen anion may be established by a marker experiment. In the case of most metal oxides, the metal cation is the dominant species transported. However several investigators (6) have found that an oxygen anion is the species transported in the case of the growth of silicon dioxide films.

In the interests of an explicit presentation, the electrochemical model will be discussed within the framework of the case of the silicon dioxide thermal growth, which is selected because of the relatively large amount of published experimental data for this system. The general concepts outlined may be extended to other thermal oxides without difficulty. The possible species transported and the corresponding electrode reactions at the opposite interfaces of the silicon dioxide film are shown in Fig. 1. The nonelectrochemical case of the diffusion of neutral oxygen molecules which react at the silicon-silicon dioxide surface is also illustrated. It will be treated later in the discussion of alternatives to the electrochemical model.

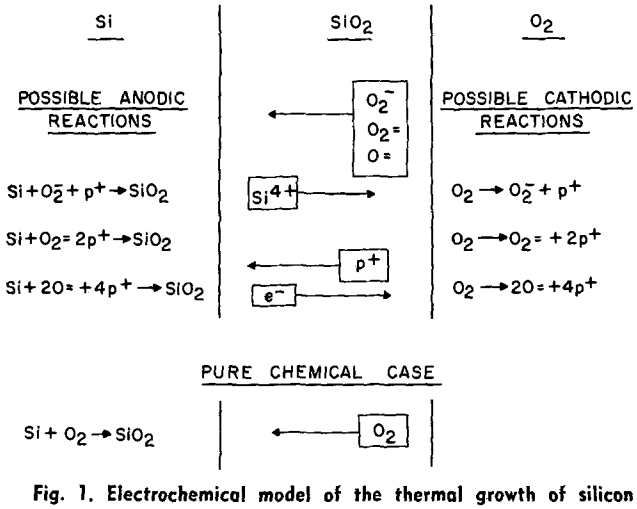

Fig. 1. Electrochemical model of the thermal growth of silicon dioxide films in a pure oxygen ambient.

It is clear that the transport of an ionic species must be balanced by the transport of an equivalent number of electrons or holes in order to prevent build-up of charge on the opposite sides of the film. However the counterflows of ions and of electrons and holes do not necessarily bring about local electroneutrality in the oxide film.

In most ionic crystals, first-order electroneutrality is provided for in that the current-carrying ionic defects are generally present as oppositely charged pairs. Thus in SiO_2, anionic conduction could occur by anti-Frenkel defects (equal concentrations of oxygen interstitials and vacancies) or by oxygen anionic defects compensated by cations of some impurity. Electroneutrality then requires that the electronic carrier concentration compensate the difference in the concentration of the two kinds of ionic defects at every point in the oxide film. This condition will not necessarily be established by balance of the ionic and electronic currents.

Fromhold (7) has shown that the generally observed parabolic law of growth requires local neutrality throughout the bulk of the film. Thus the transport processes must be subject to some additional constraint in order to provide local electroneutrality.

Raleigh (8) has recently cast some doubt on the interpretation of the Jorgensen experiments in terms of the simple variation of the drift rate of diffusing ions under the externally applied potential. He points out that the application of an external field in the direction which accelerates growth will retard the flux of holes and electrons while promoting the migration of ions. He explains the Jorgensen results on the basis of an electrolysis superposed on the normal diffusion-controlled oxide film growth.

The present paper attempts the resolution of these questions on the basis of the electrochemical model of film growth.

Semiconductor Model of Oxide Films

The substrate in oxide film thermal growth problems may be generally treated as metallic. This is true even in the case of semiconductor substrates such as

silicon, which will be degenerate at the temperatures encountered in thermal growth. On the other hand, even those oxide films which have wide band gaps and are insulators at room temperature will behave as semiconductors at the temperatures at which thermal growth occurs. For example, amorphous intrinsic silicon dioxide with an optical absorption edge of about 1900Å has a carrier density at 1000°C at least equal to that of an intrinsic semiconductor with a band gap of 1.5 ev at room temperature.

It is to be expected that the electron and hole densities in oxide films undergoing thermal growth will correspond to conditions of thermal equilibrium except for some slight perturbation due to the small flux of holes and electrons involved in the growth process. The presence of ionic species and structural disorders may cause the oxide film to behave as an extrinsic semiconductor, apart from the question of the effect of the space charge of ionized impurities on local electron and hole densities. However in any case the electron and hole densities are fixed by thermodynamic considerations other than satisfaction of an electroneutrality condition. The semiconductor model of the oxide film requires that the Fermi or electrochemical potential for holes and electrons be explicitly distinguished from the electrostatic field acting on all charged species. This distinction appears not to have been brought out in previous treatments. The transport of holes and electrons is most conveniently formulated in terms of the gradient of the Fermi potential, but the latter is largely irrelevant to the transport of ions which drift under the gradient of the electrostatic potential. In the next section of this paper, it will be shown that the requirement of conservation of charge in the transport process leads to a formulation of the Fermi potential difference across the film in terms of the free energy change involved in the oxidation reaction and of the transport coefficients. In the present section, the principles of transport of holes and electrons will be reviewed for later reference.

The equilibrium concentrations of holes p and that of electrons n in a semiconductor are given by the well-known equations

$$\mathrm{p} = \mathrm{n_i}\, e^{q(\phi - V)/kT} \qquad [1]$$

$$\mathrm{n} = \mathrm{n_i}\, e^{q(V - \phi)/kT} \qquad [2]$$

where $\mathrm{n_i}$ is the concentration of electrons in the intrinsic material, ϕ is the Fermi potential, V is the electrostatic potential, and the other symbols have their usual significance. The fluxes of holes J_P and that of electrons J_n are given by the generalized Fick's first laws

$$J_p = -\frac{kT}{q}\mu_p \frac{dp}{dx} - \mu_p \mathrm{p}\frac{dV}{dx} \qquad [3]$$

$$J_n = -\frac{kT}{q}\mu_n \frac{dn}{dx} + \mu_n \mathrm{n}\frac{dV}{dx} \qquad [4]$$

where μ_p and μ_n are the respective mobilities, x is the position coordinate in the film, and Einstein's relation $D = \mu q/kT$ has been used. On differentiating Eq. [1] and [2] and inserting the results into Eq. [3] and [4] we obtain

$$J_p = -\mu_p \mathrm{p}\frac{d\phi}{dx} \qquad [5]$$

$$J_n = \mu_n \mathrm{n}\frac{d\phi}{dx} \qquad [6]$$

where the fluxes are formally proportional to the gradient of the Fermi potential. The total electronic current is given as usual by

$$I = q\,(J_p - J_n) = -\,q\,(\mu_p \mathrm{p} + \mu_n \mathrm{n})\frac{d\phi}{dx} \qquad [7]$$

$$= -\,\sigma_e \frac{d\phi}{dx}$$

where σ_e is the electronic conductivity as ordinarily defined.

The flux J_i of the i_{th} ionic species across the growing oxide film is given by

$$J_i = -D_i\frac{dc_i}{dx} - D_i\frac{\alpha_i q}{kT}c_i\frac{dV}{dx} \qquad [8]$$

where D_i is the diffusion coefficient of the i^{th} species, c_i its concentration, and α_i the number of electronic charges on it, taken with due regard to sign. A steady value of electrostatic potential across the film requires that

$$I + \sum_i \alpha_i q J_i = 0 \qquad [9]$$

The growth rate of the film is proportional to the sum of the flux terms where all migrating species are assumed to contribute to growth and may be represented as

$$\frac{dX}{dt} = S\sum_i |\alpha_i| J_i \qquad [10]$$

Here, if J_i is given in terms of number flux

$$S = \frac{M/\beta}{\rho N_o} \qquad [11]$$

where M is the molecular weight of the oxide, β is twice the number of oxide ions in the molecular formula of the oxide, ρ is the density, and N_o is Avogadro's number.

The growth rate is then related to the electronic current by

$$\frac{dX}{dt} = -\frac{SI}{q} \qquad [12]$$

The Fermi Potential Profile

The further development of the problem requires the calculation of the Fermi potential as a function of position within the oxide film. The standard cell potential E^o corresponding to the oxidation process is given by the thermodynamic equation

$$E^o = -\Delta G^o/\alpha q \qquad [13]$$

where ΔG^o is the free energy change of the redox reaction expressed in electron-volts and α is the number of electrons involved in the oxidation. The Fermi potential difference $\Delta\phi$ across the film at infinite electronic impedance is given by

$$\Delta\phi = \phi(\mathrm{X}) - \phi(\mathrm{O}) = E^o \qquad [14]$$

where the metal-oxide interface has been selected as the origin of the coordinate system, and X is the outer surface of the film. Under the condition of infinite electronic impedance, there is no electrostatic potential difference across the film, the charges balancing separately in each of the electrical double layers at the surfaces of the oxide film.

If electric current is transported across the film by electron and hole conduction at a finite rate, the Fermi potential is lowered accordingly and is given by

$$\Delta\phi = E^o + \Delta V \qquad [15]$$

In the limit of very small electronic impedance, $\Delta\phi$ approaches zero[1] and

$$\Delta V = -E^o \qquad [16]$$

This is analogous to the well-known situation in a semiconductor p-n junction.

In the further development of this discussion, the mathematical handling of the general case of several

[1] Cabrera and Mott (5) present a detailed discussion of the background of Eq. [14] and [16].

ionic diffusing species with arbitrary charges and the transport of both holes and electrons becomes unwieldy. We shall therefore restrict the present treatment to that of the migration of a univalent anion in a p-type oxide. The treatment may be extended to other specific situations by analogy.

We shall also simplify matters by assuming electroneutrality throughout the oxide film. This could be brought about by complete compensation of the anions by immobile cationic defects. The maximum deviations from electroneutrality consistent with a parabolic law of growth will be presented in a subsequent section of this paper, together with an exploration of the considerations tending to produce electroneutrality.

Let us first examine the situation with respect to electronic transport. By combining Eq. [1] and [5] and making use of $V(x) = x\ \Delta V/X$, where the latter is a consequence of electroneutrality, we obtain

$$J_p e^{qx\Delta V/kTX} dx = \mu_p n_i\, e^{q\phi/kT} d\phi \qquad [17]$$

which may be integrated between the points $x = 0$ and $x = x$ to yield

$$J_p = \frac{\Delta V}{X} \mu_p n_i \frac{(e^{q\phi_o/kT} - e^{q\phi/kT})}{(e^{qx\Delta V/kTX} - 1)} \qquad [18]$$

where ϕ_o is the Fermi potential at the point $x = 0$. Because of the large excess of electrons in the metal compared to the semiconductor oxide film and its adsorbed oxygen layer it may be presumed that the Fermi level in the semiconductor is pinned to that of the metal at the metal interface. Equation [18] then gives the profile of the Fermi potential $\phi(x)$ in terms of the electrostatic potential difference across the oxide film and the hole concentration

$$p(O) = n_i e^{q\phi_o/kT} \qquad [19]$$

in the semiconductor at its interface with the metal.

Equation [8] for the flux J of univalent anions may be put into the form

$$J e^{-qx\Delta V/kTX} = -D \frac{d}{dx} (c e^{-qx\Delta V/kTX}) \qquad [20]$$

which may be integrated to yield[2]

$$J = \frac{Dq\Delta V}{kTX} \frac{[c(O)\, e^{q\Delta V/kT} - c(X)]}{(e^{q\Delta V/kT} - 1)} \qquad [21]$$

For the special case of holes and univalent anions, Eq. [9] simplifies to

$$J_p = J \qquad [22]$$

If now Eq. [18] is evaluated at the point $x = X$ and combined with Eq. [19], [21], and [22], we obtain

$$\frac{Dq}{kT} [c(O)\, e^{q\Delta V/kT} - c(X)] = \mu_p p\ (O)\ (1 - e^{q\Delta\phi/kT}) \qquad [23]$$

The Fermi level difference $\Delta\phi$ may be obtained explicitly by introducing Eq. [15]

$$e^{q\Delta\phi/kT} = \frac{\mu_p p\ (O) + \frac{Dc}{kT} c(X)}{\mu_p p\ (O) + \frac{Dq}{kT} c(O) e^{-qE_o/kT}} \qquad [24]$$

The unknowns in Eq. [23] and [24] may be taken as the electrostatic potential difference ΔV and the boundary concentrations $c(O)$ and $c(X)$, if we assume that the transport coefficients $\sigma_p = q\,\mu_p p_o$ and D are available in principle. It may be readily confirmed that the boundary concentrations in the growing oxide film are not those corresponding to the equilibrium concentrations of the Nernst equation

$$\Delta\phi = E^o - \frac{kT}{q} \ln \frac{c(O)}{c(X)} \qquad [25]$$

as in this case Eq. [21] yields a value of $J = 0$. Possible experiments would be the measurement of the Fermi level difference $\Delta\phi$ by an electrometer. With this information, Eq. [23] and [24] may be solved for the ratio of the unknown boundary concentrations $c(O)$ and $c(X)$. Measurement of the growth rate enables the two boundary concentrations to be determined separately by use of Eq. [10] and [21].

Deviations of the Oxide Film from Electroneutrality

Here we shall investigate quantitatively the magnitude of the maximum space charge in the oxide film which is consistent with a parabolic growth law within the ordinary experimental errors encountered in this type of measurement. Let us commence with some arbitrary distribution of space charges $C(x)$ which will be taken to be positive and univalent for the sake of convenience. The potential distribution is then obtained from Poisson's equation

$$\frac{d^2V}{dx^2} = -\frac{qC(x)}{\epsilon} \qquad [26]$$

where ϵ is the permittivity of the oxide.

A single integration with the boundary condition $(dV/dx)_o = -\mathcal{E}_o$ yields

$$\frac{dV}{dx} = -\mathcal{E}_o - \frac{q}{\epsilon} \int_o^x C(x')\, dx' \qquad [27]$$

A second integration with the boundary condition, $V(O) = 0$, leads to

$$V = -\mathcal{E}_o\, x - \frac{q}{\epsilon} \int_o^x \int_o^{x'} C(x'')\, dx''dx' \qquad [28]$$

The ionic flux is then obtained in terms of a differential equation by rearranging Eq. [8]

$$J e^{qV(x)/kT} = -D \frac{d}{dx} [c(x) e^{qV(x)/kT}] \qquad [29]$$

Particular note is to be taken that the concentration of the diffusing species c is not necessarily equal to the net concentration C of the defects responsible for space charge in Eq. [26]. Integration using the boundary conditions $V(O) = 0$ and $V(x) = \Delta V$ yields

$$J = -\frac{D\,[c(X) e^{q\Delta V/kT} - c(O)]}{\int_o^x e^{-[E_o x + w(x)]q/kT}\, dx} \qquad [30]$$

where

$$w(x) = \frac{q}{\epsilon} \int_o^x \int_o^{x'} C(x'')\, dx''dx' \qquad [31]$$

Further progress cannot be made without introducing assumptions concerning the magnitude and nature of the distribution $C(x)$. Let us determine the effect of a small arbitrary space charge on the ionic flux J. Expanding the exponential in the denominator of Eq. [30] we obtain

$$\int_o^x e^{-qE_o x/kT} \left[1 - \frac{qw(x)}{kT}\right] dx = \frac{kT}{q\mathcal{E}_o} [1 - e^{-qE_o X/kT}] - W(X) \qquad [32]$$

where

$$W(X) = \frac{q}{kT} \int_o^X w(x) e^{-qE_o x/kT}\, dx \qquad [33]$$

Introducing Eq. [32] into [30], we obtain

$$J = -\frac{D[c(X) e^{q\Delta V/kT} - c(O)]}{\frac{kT}{q\mathcal{E}_o} [1 - e^{-qE_o X/kT}] - W(X)} \qquad [34]$$

[2] Equation [18] is equivalent to one previously derived by Fromhold (9).

It may be expected that the term $W(X)$ will cause the growth behavior to deviate from the parabolic law.

Under the condition of a uniform charge density so that $C(x) = C$, Eq. [32] is readily integrated and yields

$$w(x) = \frac{qC}{2\epsilon} x^2 \qquad [35]$$

Equation [33] may likewise be now integrated

$$W(X) = \frac{-q^2C}{2kT_\epsilon}\left\{e^{-qE_0\,X/kT}\left[\frac{kT}{q\mathcal{E}_0}X^2 + 2\left(\frac{kT}{q\mathcal{E}_0}\right)^2 X + 2\left(\frac{kT}{q\mathcal{E}_0}\right)^3\right] - 2\left(\frac{kT}{q\mathcal{E}_0}\right)^3\right\} \qquad [36]$$

The boundary field $\mathcal{E}_0$ may be evaluated from Eq. [28] and is

$$-\mathcal{E}_0 = \frac{\Delta V}{X} + \frac{qCX}{2\epsilon} = \frac{\Delta V}{X}\left(1 + \frac{qCX^2}{2\epsilon\Delta V}\right) \qquad [37]$$

In the field migration case, $(q\Delta V/kT) >> 1$, enabling considerable simplification of the problem. The ratio $q\Delta V/kT$ will ordinarily be of the order of 10. The expansion of the denomination of Eq. [30] places an upper limit on $w(x)$ of the order of 0.01V. Further for the case of relatively small space charge density C, we may approximate

$$-\frac{1}{\mathcal{E}_0} = \frac{X}{\Delta V}\left(1 - \frac{qCX^2}{2\epsilon\Delta V}\right) \qquad [38]$$

With the use of the above, together with Eq. [36], Eq. [34] takes the following limiting form with neglect of terms higher than first order in $qCX^2/2\epsilon\Delta V$ and $kT/q\Delta V$

$$J\left\{\frac{kTX}{q\Delta V} - \frac{qCX^3}{2\epsilon\Delta V}\right\} = Dc(X) \qquad [39]$$

Upon making use of Eq. [10] formulated for a single univalent anionic diffusing species and rearranging, we have

$$\frac{dX}{dt}\left(X - \frac{q^2CX^3}{2kT\epsilon}\right) = SD\frac{q}{kT\epsilon}c(X) \qquad [40]$$

Integration yields

$$\frac{X^2}{2} - \frac{q^2CX^4}{8kT\epsilon} = k_2 t \qquad [41]$$

The coefficient $q^2C/8kT\epsilon$ could be determined experimentally from a plot of t/X^2 *vs.* X^2. Alternatively, the space charge density C corresponding to a stated deviation δ, say 2%, from the parabolic growth law may be evaluated. For the interesting case of a silicon dioxide film of 5000Å thickness, and dielectric constant of 4, thermally grown at 1000°C, we obtain

$$C = \frac{4kT\epsilon\delta}{q^2X^2} = 1.25 \times 10^{13}\ \text{cm}^{-3} \qquad [42]$$

with

$$\sum = \int_0^x C\,dx = 1.25 \times 10^8\ \text{cm}^{-2}$$

This order-of-magnitude value of the space charge density indicates that charge compensation of the diffusing ions in the case of the silicon dioxide film need not be fully complete in order to yield an apparent parabolic growth law from the experimental point of view.

Partial or complete compensation of diffusing anions may be brought about by holes, if the oxide is p-type, or by immobile cations. Let us examine the situation of complete compensation via the first of these cases. This corresponds to the introduction of the additional condition that

$$p(x) = c(x) \qquad o \leq x \leq X \qquad [43]$$

in addition to the balance of the hole and anionic fluxes previously considered, Eq. [9].

The boundary concentrations are then immediately given by

$$c(X) = c(O)\ e^{qE_0/kT}$$

with the aid of Eq. [1] and [15]. The electrostatic potential difference ΔV following rearrangement of Eq. [23] is given by

$$e^{q\Delta V/kT} = \frac{R + e^{qE_0/kT}}{Re^{qE_0/kT+1}} \qquad [44]$$

where

$$R = \frac{\mu_p}{Dq/kT}$$

The transport coefficients may be individually evaluated from experiment by the use of Eq. [21], [43], and [44]. The validity of the assumed condition of Eq. [43] may then be tested by comparing the transport coefficients above calculated with those obtained by independent measurement.

Compensation of the diffusing anions by immobile cations implies the condition that

$$c_-(x) = c_+(x) \qquad [45]$$

where c_- and c_+ are the concentrations of anions and cations, respectively. From Eq. [20] and [21] we obtain

$$c_-(x) = c_-(O)\,e^{qx\Delta V/kTX} - J\frac{kTX}{Dq\Delta V}\left(e^{qx\Delta V/kTX} - 1\right) \qquad [46]$$

where the final term represents the perturbation of the Boltzmann distribution by the transport process. It is now easily established that the cation distribution corresponding to Eq. [46] is such that if the cations were mobile, the free diffusion term of Eq. [8] would be of a direction to oppose the growth of the oxide film while the field term will contribute to the growth. Thus it would appear that complete compensation of diffusing anions by diffusing cations is generally inconsistent, with the following exception: where $q\Delta V/kT >> 1$, then Eq. [21] assumes the limiting form

$$J_- = \frac{Dq}{kT}c(x)\frac{\Delta V}{X} \qquad [47]$$

with the concentrations of anions and cations uniform throughout the film.

Raleigh Electrolysis Theory

Raleigh (8) has suggested that in consequence of the conservation Eq. [9] an externally applied electric field of itself should have no effect upon the growth rate because, if the field promotes the migration of the ions supporting the growth of the film, it must hinder the migration of the electrons or holes, the transport of which is required to maintain over-all electrical neutrality. He proposes that the effect of the applied potential in the Jorgensen experiments in accelerating or retarding the thermal growth of the silicon dioxide film is due to an electrolytic cell process superposed on the normal thermal growth. It is the purpose of this section to formulate this proposal in more detailed terms and to show that it is consistent with the Wagner electrochemical model of film growth.

In terms of the diffusion of neutral molecules, the oxidation of silicon may be represented as in Fig. 1 with the chemical reaction $Si + O_2 \rightarrow SiO_2$ occurring at the silicon-silicon dioxide interface. If no ionization of the oxygen occurs, its transport in the film occurs solely by free diffusion, thus

$$J = -D\frac{dc}{dx} \qquad [47]$$

where c here refers to the effective concentration of the species O_2 in the film. In the steady state J is constant implying that

$$\frac{dc}{dx} = \frac{c(X) - c(O)}{X} \quad [48]$$

which leads to the parabolic growth law as earlier noted.

As pointed out by Raleigh, the neutral species O_2 may be in thermodynamic equilibrium with ionized forms. Examples of possible equilibria for the case of silicon dioxide growing in a perfectly dry oxygen ambient are shown in Fig. 1. For the sake of simplicity, let us consider just the first of these equilibria which may be formulated in terms of the equilibrium constant

$$K = \frac{[O_2^-]p}{[O_2]} \quad [49]$$

on introducing Eq. [49] into Eq. [47], we obtain

$$J = -D\frac{p}{K}\frac{d[O_2^-]}{dx} + \frac{Dq}{kT}\frac{p}{K}[O_2^-]\frac{\Delta V}{X} - \frac{Dq}{kT}\frac{[O_2^-]}{K}p\frac{d\phi}{dx} \quad [50]$$

where Eq. [1] had been specialized to the case of electroneutrality. The last term of Eq. [50] represents the contribution of hole flux to the net transport of the oxygen molecules. Upon again making use of Eq. [49], Eq. [50] takes the form

$$J = -D\frac{[O_2]}{[O_2^-]}\frac{d[O_2^-]}{dx} - \frac{Dq}{kT}[O_2]\left[\frac{d\phi}{dx} - \frac{\Delta V}{X}\right] \quad [51]$$

Let us now consider the case that an external field E is applied across the oxide film by insulated electrodes so that no transport of holes takes place externally. The electrostatic potential gradient and the Fermi potential gradient are each increased by the amount E. It is clear from Eq. [51] that no increase of the flux J will occur, in complete agreement with the discussion of Raleigh.

The situation is completely altered if the field is applied by means of electrodes which are in ohmic contact with the oxide film. Here hole transport through the external circuit takes place, and the Fermi potential differences across the film is fixed by the potential ΔU applied by the external source. The treatment developed in this paper remains applicable with $\Delta\phi$ replaced by $\Delta\phi + \Delta U$ throughout. The application of an anodic potential is then tantamount to the situation which would exist in an oxidation reaction with a higher free energy change but with all other physical variables remaining the same.

Acknowledgment

The authors are indebted to Dr. Raleigh for kindly furnishing them with a preprint of his paper and for helpful discussion. They are also grateful to Dr. R. N. Hall for useful discussion of the problem.

Manuscript received Feb. 21, 1966; revised manuscript received Sept. 9, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Studies of the Defect Structure of Nonstoichiometric Rutile, TiO_{2-x}

R. N. Blumenthal, J. Baukus, and W. M. Hirthe

Metallurgy and Materials Science, Department of Mechanical Engineering, College of Engineering, Marquette University, Milwaukee, Wisconsin

ABSTRACT

The electrical conductivity of single crystals of rutile was measured in the "c" and "a" directions over the temperature range 1000°-1500°C and from 1 to 10^{-15} atm of oxygen. Based on the excellent fit observed between the theoretically derived relation

$$\sigma^5 = (A\sigma + B)P_{O_2}{}^{-1} + I'\sigma^3$$

and the experimental conductivity data, the nonstoichiometric defect structure of rutile was rationalized in terms of quasi-free electrons and both triply and quadruply ionized titanium interstitials. In addition, this equation satisfies a contribution due to impurity conduction where I' is proportional to a temperature dependent concentration of ionized impurities or a contribution due to intrinsic conduction where I' is proportional to a temperature dependent concentration of holes in the valance band.

The standard enthalpy of formation for the following defect reactions in rutile

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i}^{+3} + 3e; \qquad \Delta H_a{}^o = 9.6 \pm 0.2 \text{ ev} \qquad (a)$$

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i}^{+4} + 4e; \qquad \Delta H_b{}^o = 10.8 \pm 0.2 \text{ ev} \qquad (b)$$

$$\mathrm{Ti_i}^{+3} = \mathrm{Ti_i}^{+4} + e; \qquad \Delta H_c{}^o = 1.2 \pm 0.4 \text{ ev} \qquad (c)$$

$$I = I^{+} + e; \qquad \Delta H_d{}^o = 3.7 \pm 0.2 \text{ ev} \qquad (d)$$

were determined from the temperature dependence of A, B, and I' obtained from the above relation and from the experimental expression for the temperature dependence of electron mobility. The values of $\Delta H_a{}^o$, $\Delta H_b{}^o$, and $\Delta H_c{}^o$ are in agreement, within experimental error, with those obtained in an earlier investigation based on conductivity measurements in the c direction only. If impurity conduction is involved, $\Delta H_d{}^o$ is equal to the standard enthalpy of formation for the ionization of an impurity. If intrinsic conduction is involved, $\Delta H_d{}^o$ is equal to the band gap energy which is thought to be between 3 and 4 ev for rutile. The ratio of electrical conductivities for the c and a direction is essentially independent of oxygen pressure above 1100°C; but at the lower temperatures, 1000° and 1100°C, the ratio is dependent on pressure in contradiction to the initial assumption that mobility is a function of temperature only.

Nonstoichiometric rutile may be classified as a metal-excess, n-type semiconductor on the basis of experimental observations (1, 2). Recent investigations (3-5) have favored a defect model consisting of quasi-free electrons and titanium interstitials in one or more states of ionization. In an earlier investigation in this laboratory (5) the nonstoichiometric defect structure of rutile was rationalized in terms of a defect model involving quasi-free electrons and both triply and quadruply ionized titanium interstitials.

The investigation reported here was initiated to obtain additional conductivity data for the *c* direction, particularly in the oxygen pressure range 10^{-2} to 10^{-9} atm, in order to account for the marked temperature dependence of the term in the electroneutrality equation attributed to the concentration of ionized impurities revealed in subsequent analyses of the experimental data and to refine calculations of the parameters in the theoretically derived relation. In addition, the conductivity was measured in the a direction over the same range of temperature and oxygen partial pressure in order to determine the validity of this type of relation and the dependence of conductivity on crystallographic direction.

Experimental Procedure

Single crystal specimens of dimensions 0.15 x 0.25 x 1 in. with the longitudinal axis parallel to the c or a direction were cut from a boule obtained from the National Lead Company. The apparatus and techniques employed were essentially the same as those described in the earlier investigation (5). The electrical conductivity was measured over the range 1000°-1500°C and from 1 to 10^{-15} atm of oxygen. This range of oxygen pressure effectively covers the stability limit of rutile (6, 7), TiO_{2-x}, at 1500°C, and includes the major portion of the phase field at 1000°C where the pressure corresponding to the stability limit is about 7×10^{-19} atm.

Results and Discussion

Isobaric plots of the logarithm of electrical conductivity *vs.* the reciprocal of absolute temperature for oxygen partial pressures from 1 to 10^{-3} atm are shown in Fig. 1 and 2 for the c and a direction, respectively. The experimental technique utilized in this investigation was substantiated by the excellent agreement between the conductivity measured in both c and a directions from 1000° to 1500°C in 1 atm of air and the data of Cronemeyer (8).

In order to analyze the data, experimental plots of log σ *vs.* log P_{O_2} were obtained in the following manner. Values of the conductivity were selected at 100°C intervals between 1000° and 1500°C from the plots of log σ *vs.* $1/T$. For the isobaric plots, Fig. 1 and 2, the values of conductivity at 1000° and 1100°C were taken from the straight line extrapolated from higher temperatures rather than the measured conductivity data for a few of the points. Justification for this treatment lies in the fact that the previous investigation (5) revealed that the appearance of a two-slope behavior in this range of temperature is the result of contamination of the specimens *in situ* during the period of time the measurements are being taken. The partial pressure of oxygen corresponding to the above values of conductivity for various atmospheres was

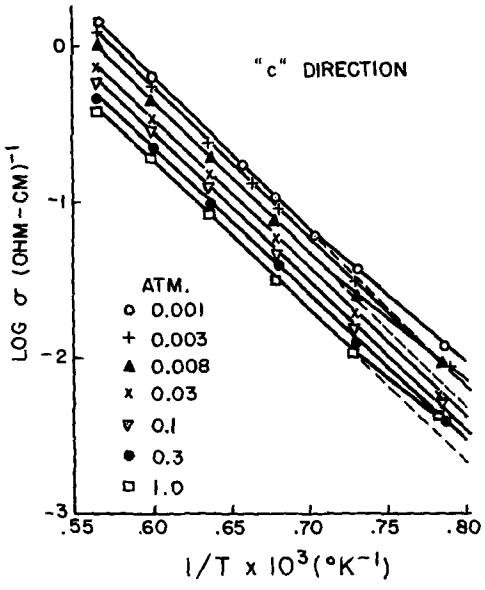

Fig. 1. Logarithm of electrical conductivity of rutile single crystal in the c direction vs. the reciprocal of absolute temperature for oxygen partial pressures from 1 to 10^{-3} atm.

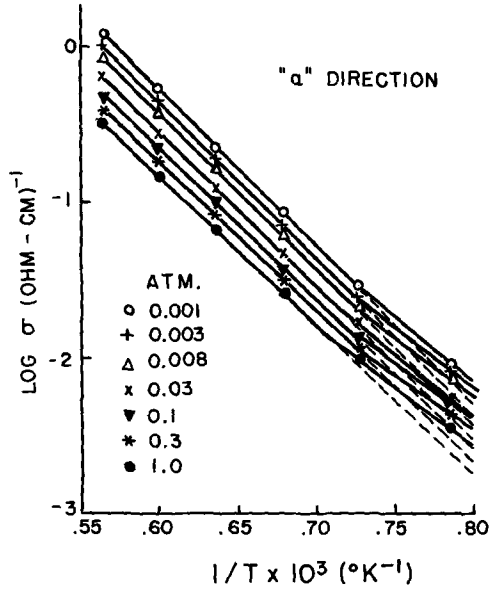

Fig. 2. Logarithm of electrical conductivity of rutile single crystal in the a direction vs. the reciprocal of absolute temperature for oxygen partial pressures from 1 to 10^{-3} atm.

calculated and combined with the respective conductivity to obtain the isothermal plots at 100°C intervals between 1000° and 1500°C of log σ *vs.* log P_{O_2} shown in Fig. 3 and 4 for the c and a directions, respectively. The curvature of the 1000°C isotherms at the low pressure end of the plots was verified experimentally by subjecting the specimen to partial pressure less than 10^{-15} atm followed by a return to 10^{-15} atm. The conductivity values before the further reduction and after the increase to 10^{-15} atm were the same indicating that the curvature is representative of the equilibrium situation.

The objection to the analysis presented in the earlier investigation lies in the fact that it does not account for the temperature dependence of the third term in the electroneutrality equation revealed in subsequent analyses of the experimental conductivity data. Therefore, an electroneutrality expression of the following type

$$n = 3(\mathrm{Ti}_i^{+3}) + 4(\mathrm{Ti}_i^{+4}) + I^+ \qquad [1]$$

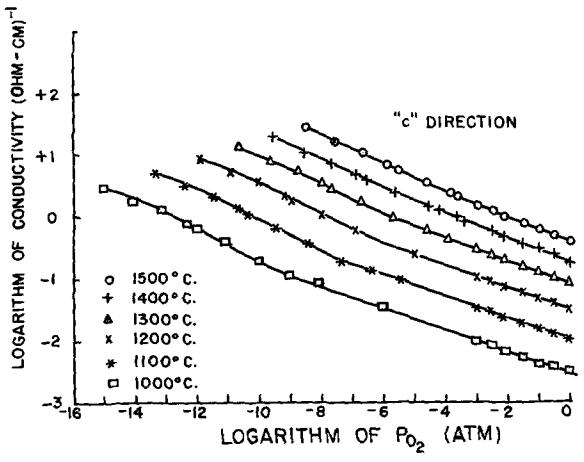

Fig. 3. Isothermal relation between the logarithm of electrical conductivity in the c direction and the logarithm of partial pressure of oxygen in the range 1000°-1500°C.

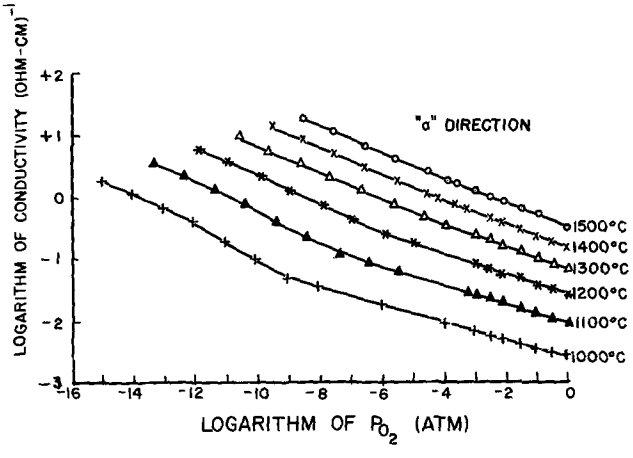

Fig. 4. Isothermal relation between the logarithm of electrical conductivity in the a direction and the logarithm of partial pressure of oxygen in the range 1000°-1500°C.

where (Ti_i^{+3}) is the concentration of triply ionized titanium interstitials, (Ti_i^{+4}) is the concentration of quadruply ionized titanium interstitials, and I^+ is the temperature dependent concentration of ionized impurities which act as donors, was employed to obtain a quantitative relation between σ and P_{O_2}. The relation for the ionization of the impurity is

$$I = I^+ + e \qquad [2]$$

and from the law of mass action the equilibrium constant can be written as

$$K_6 = \frac{I^+ n}{I} \qquad [3]$$

If the assumption is made that $I >> I^+$, the expression for the conductivity as a function of oxygen partial pressure may be obtained by combining Eq. [1], the mass action equations for defect equilibrium, and the equation for extrinsic electron conduction

$$\sigma^5 = (A\sigma + B)P_{O_2}{}^{-1} + I'\sigma^3 \qquad [4]$$

where

$$A = 3K_4'C^4; \quad B = 4K_5'C^5; \quad I' = IK_6C^2 \qquad [5]$$

It should be pointed out at this time that Eq. [4] will also apply for the case of intrinsic conduction where I^+ is the temperature dependent concentration of holes in the valence band. The corresponding equation for conduction involving holes and electrons is

Table I. Calculated values of the parameters A, B, and I' in the expression $\sigma^5 = (A\sigma + B) P_{O_2}^{-1} + I' \sigma^3$ and the standard error (95% confidence limit) in the calculation of these parameters at 100°C intervals from 1000° to 1500°C:

Temperature, °C	A	Standard error of A (±)	B	Standard error of B (±)	I'	Standard error of I' (±)
			c Direction			
1000	8.64×10^{-14}	7.68×10^{-15}	4.82×10^{-14}	6.53×10^{-15}	9.41×10^{-6}	1.27×10^{-6}
1100	4.20×10^{-11}	3.54×10^{-12}	3.22×10^{-11}	5.64×10^{-12}	1.22×10^{-4}	2.04×10^{-5}

$$\sigma = nq\mu + pq\mu' \quad [6]$$

where p is the concentration of holes and μ' is the hole mobility. However, previous investigations (2, 9, 10) of the thermoelectric power of rutile have suggested that

$$\mu >> \mu' \quad [7]$$

Consequently, Eq. [6] reduces to the relation for extrinsic electron conduction, and Eq. [4] also represents the conductivity as a function of the partial pressure of oxygen for a defect model based on both triply and quadruply ionized titanium interstitials and intrinsic conduction.

A computer program was written for Eq. [4], and the calculated values of the parameters in this equation and their standard errors are tabulated in Table I. It is apparent from the values of the standard error as the parameter shown in Table I that Eq. [4] represents an acceptable fit of the experimental data for both the c and a directions. Thus the excellent agreement between Eq. [4] and the experimental data for the electrical conductivity in both the c and a direction provides a quantitative confirmation of a defect model involving both triply and quadruply ionized titanium interstitials and a third term in the electroneutrality equation which is dependent on temperature.

Plots of the logarithm of the parameters A, B, and I' *vs.* the reciprocal of absolute temperature yield straight lines for both c and a directions. The standard enthalpies of formation for the reactions

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i^{+3}} + 3e; \quad \Delta H_a^\circ \quad [8]$$

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i^{+4}} + 4e; \quad \Delta H_b^\circ \quad [9]$$

$$I = I^+ + e; \quad \Delta H_d^\circ \quad [2]$$

can be calculated from the slopes of these lines by assuming (2) that the electron mobility is proportional to the exp (0.1 (ev)/kT). In addition, the standard enthalpy of formation for the ionization reaction

$$\mathrm{Ti_i^{+3}} = \mathrm{Ti_i^{+4}} + e; \quad \Delta H_c^\circ \quad [10]$$

can be calculated from the equation

$$\Delta H_c^\circ = \Delta H_b^\circ - \Delta H_a^\circ \quad [11]$$

The results of these calculations for both c and a direction data are shown in Table II and compared with data of the previous investigation. The good agreement in ΔH_a°, ΔH_b°, and ΔH_c° between these investigations based on c direction data indicates that the interpretation of the nonstoichiometric defect structure is independent of the physical significance given to the third term on the right-hand side of the electroneutrality equations. The agreement in these values of enthalpies based on c and a direction conductivity further substantiates the validity of the proposed nonstoichiometric defect structure since these thermodynamic quantities should be independent of crystallographic direction. The values of ΔH_d° based on c and a direction data are independent of direction, and this is consistent with the concept of an impurity ionization energy or intrinsic conduction. However, the magnitude of ΔH_d°, 3.7 ev, suggests intrinsic conduction because the intrinsic band gap energy is thought to be between 3 and 4 ev as the result of numerous optical and thermal measurements (1).

In order to substantiate further the validity of Eq. [4], the parameters A, B, and I' were extrapolated to 600°C, and the conductivity was calculated as a function of temperature in the range 1500° to 600°C for 1 atm of air. A comparison of the temperature dependence of the conductivity as calculated from Eq. [4] with the data of Cronemeyer over the same range of temperature in air is shown in Fig. 5 and 6 for the c and a directions, respectively. It is significant to note that Eq. [4] yields the well-known two-slope behavior for a plot of log σ *vs.* $1/T$. The agreement in the magnitude of the conductivity is good in the high-temperature regions, but there is some discrepancy in the low-temperature regions. This discrepancy can be accounted for in Eq. [4] if I' is assumed to be proportional to the number of impurities which act as donors when ionized. For this case, the magnitude of the conductivity and the experimental activation energy will depend on the nature and concentration of impurities present in the crystal employed in the particular investigation.

Since only conductivity data was taken in this investigation, the electron mobility could not be determined. However, the ratio of electron mobility in the c to the mobility in the a direction was determined by

plotting the ratio of the conductivities as a function of the logarithm of partial pressure of oxygen at 100° intervals between 1000° and 1500°C as shown in Fig. 7. From Fig. 7 it can be seen that the mobility is essen-

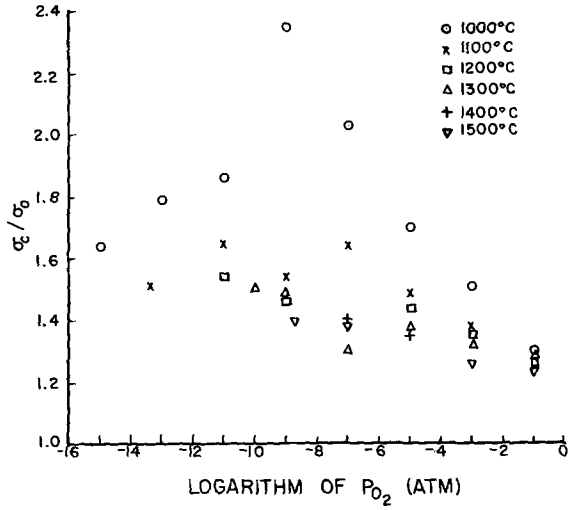

Fig. 7. Isothermal relation between the ratio of electrical conductivity and the logarithm of partial pressure of oxygen in the range 1000°-1500°C.

tially independent of pressure at the higher temperatures within the limits of experimental error. At the lower temperatures, 1000° and 1100°C, the ratio of the mobilitites is dependent on pressures in contradiction to the initial assumption that the mobility was dependent on temperature only. In general, the ratio of the mobilities decreases with increasing temperature in the range of this investigation. This plot clearly indicates the limitation of the technique employed in this investigation and the need for electron mobility data in order to understand the nature of the transport mechanisms in rutile below 1000°C.

As a check on the internal consistency of the data, the ratios of the experimental conductivities are compared with the ratios of the calculated parameters of Eq. [4] raised to the appropriate power in Table III. The corresponding values of conductivity ratio and parameter were selected in the oxygen pressure range where the particular defect was the major contributor to the concentration of conduction electrons, n, in the electroneutrality equation. The variation in these values with temperature can be explained in terms of the temperature dependence of the mobilities in the c and a direction. If these dependencies are not the same, some variation with temperature is reasonable.

Conclusions

The nonstoichiometric defect structure of rutile is rationalized in terms of quasi-free electrons and both triply and quadruply ionized titanium interstitials. In addition, there is a contribution to the electrical conductivity due to impurity conduction or intrinsic conduction. The experimental confirmation of this model is based on the excellent agreement between the theoretical relation

$$\sigma^5 = (A\sigma + B)\, P_{O_2}{}^{-1} + I'\sigma^3$$

and the c and a direction conductivity data measured over the temperature range 1000° to 1500°C over the oxygen partial pressure range 1 to 10^{-15} atm.

The standard enthalpy of formation for the following defect reactions in rutile

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i^{+3}} + 3e; \quad \Delta H_a^\circ = 9.6 \pm 0.2\text{ev} \text{ (a)}$$

$$\mathrm{Ti} + 2\,\mathrm{O} = \mathrm{O_2(g)} + \mathrm{Ti_i^{+4}} + 4e; \quad \Delta H_b^\circ = 10.8 \pm 0.2\text{ev} \text{ (b)}$$

$$\mathrm{Ti_i^{+3}} = \mathrm{Ti_i^{+4}} + e; \quad \Delta H_c^\circ = 1.2 \pm 0.4\text{ev} \text{ (c)}$$

$$I = I^+ + e; \quad \Delta H_d^\circ = 3.7 \pm 0.2\text{ev} \text{ (d)}$$

where determined from the temperature dependence

of A, B, and I' obtained from the above relation and from the experimental expression for the temperature dependence of electron mobility. The values of ΔH_a°, ΔH_b°, and ΔH_c° are in agreement, within experimental error, with those obtained in the previous investigation based on conductivity measurements in the c direction only. If impurity conduction is involved, ΔH_d° is equal to the standard enthalpy of formation for the ionization of an impurity. If intrinsic conduction is involved, ΔH_d° is equal to the band gap energy which is thought to be between 3 and 4ev for rutile.

Values of the electrical conductivity calculated from the above equation yield the well-known two slope behavior on a plot of logarithm of electrical conductivity vs. reciprocal of absolute temperature. The calculated values agree in magnitude with the data of Cronemeyer for the same range of temperature, 600°-1500°C, and a pressure of 1 atm of air. The ratio of electrical conductivities in the c and a direction is essentially independent of oxygen partial pressure above 1100°C; but at the lower temperatures, 1000° and 1100°C, the ratio is dependent on pressure in contradiction to the initial assumption that mobility is a function of temperature only. In general, the ratio of conductivities, *i.e.*, mobilities, decreases with increasing temperature in the range of this investigation.

Germanium Oxidation in Nitric Acid

Ernest W. Valyocsik

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

The oxidation in nitric acid of single crystal Ge (100) surfaces and of polycrystalline Ge (111) surfaces has been studied at 27.5°C over the concentration range 7.0-15.6N HNO_3. The surface oxide growth rate decreases smoothly with time and is not described by simple film growth laws. The average oxide nuclei size at saturation thickness decreases with increasing acid concentration, and more rapid surface saturation occurs with increasing acid concentration. No induction period for surface oxide growth was observed over the range of concentrations studied. The oxide films which grew on the Ge surfaces had saturation thicknesses inversely dependent on acid concentration, and the saturation thickness was also observed to be dependent on the crystallographic orientation of the Ge surface. Structural studies of the oxide layers by infrared, x-ray, and electron diffraction techniques indicate that the surface oxide grown under these conditions is crystalline hexagonal germanium dioxide.

Etching solutions in practice contain strong oxidizing agents which attack a semiconductor surface with subsequent dissolution of the products in the bulk solution. One such commonly employed oxidizing agent is nitric acid. Even after etching in dilute solutions, Ge surfaces still retain a thin oxide layer. At higher concentrations the removal of the reaction products from the solid-liquid interface into the bulk liquid is restricted to such an extent that the growth of thick oxide films is promoted on the semiconductor surface (1-4).

The object of the present work was to study the kinetics of oxide growth and the nature and structure of the oxide layers grown on Ge surfaces over an extended range of nitric acid concentrations. Measurements were made on the oxide films by several techniques in an effort to determine the crystallographic structure of the films grown under these conditions. It is the purpose of this paper to report the results of a study of Ge surface oxidation in concentrated nitric acid solutions.

Experimental Method

Materials.—Samples of Ge for oxidation were in the form of rectangular slabs. The Ge was obtained from two sources: (*A*) Polycrystalline samples (n-type, resistivity 2.5 ohm-cm) of size 1.4 x 9.0 x 15.8 mm were cut from Ge crystals grown in our laboratory by the Czochrolski method. Many of the samples possessed low-angle grain boundaries. The principal orientation of the largest faces of the rectangular slabs was parallel to the (111) planes to within 10° as determined by x-ray techniques. (*B*) Single crystal samples (n-type, arsenic doped; resistivity range 13-24 ohm-cm) of size 0.43 x 4.9 x 15.0 mm were cut from a boule of zone-refined Ge. The orientation of the largest faces was parallel to the (100) planes.

All chemicals used in this study were of reagent grade quality. Normalities of the nitric acid solutions were determined by standard titrimetric methods and ranged from 7.0 to 15.6N. It has been shown by Cretella and Gatos (1) that the dissolution rate of Ge in HNO_3 reaches a maximum at 6N. Ge oxidation was not studied in solutions of concentration less than 7.0N.

Surface treatment.—The rectangular Ge slabs were attached to the faces of glass plates with low-melting wax and lapped with a water slurry of 800 mesh silicon carbide. This was followed by lapping the surfaces to a shiny finish with ~1μ alumina. The samples were then removed from the glass plates and washed free of wax with boiling methanol.

Prior to reaction the Ge slabs were etched for 2 min at room temperature in 30% H_2O_2 (one part by volume) 49% HF (one part by volume) and de-ionized water (one part by volume). After etching, the

surfaces were visibly bright and shiny although they are known not to be "oxide free."

Apparatus.—Reactions were carried out in a thermostat controlled at 27.50° ± 0.05°C. All weighings were made to an accuracy of ± 4 μg.

Procedure.—Before reaction the samples were weighed, and all exposed areas of the rectangular Ge slabs were measured.

Nitrogen gas was bubbled through the solution for about 1 hr prior to placing the Ge into the solution in order to sweep the solution free of dissolved oxygen gas. The solutions were covered but not stirred during reaction. Samples were removed at given time intervals, placed in methanol, and boiled for 15 min. After removal from the methanol, the samples were rinsed several times with fresh methanol and dried before reweighing. The weight change of each sample was the net difference between the weight lost by Ge dissolution and the weight gained by surface oxide growth during the reaction time interval.

In the first few experiments the oxide thickness was determined by dissolution of the oxide in 49% HF at room temperature. There was no additional detectable weight loss of the sample after 5 min in 49% HF at room temperature. Ge is not soluble in HF at these conditions. Thus, it is assumed that the HF treatment removed the oxide only.

Following oxide removal, the samples were reweighed, and the oxide thickness was calculated. Since this method of thickness determination destroyed the sample for further studies, a technique was developed (5) whereby infrared absorption (6) was used to measure oxide film thickness *in situ*.

Lippincott and co-workers (6) have observed a strong fundamental absorption at 11.5μ (attributed to the Ge-O stretching mode) and a somewhat weaker set of fundamental absorption bands at about 17, 18, and 19μ. Combination or overtone bands due to the lattice vibration at about 7.50, 6.90, and 6.55μ, which are much weaker in strength relative to Lippincott's set at 17-19μ, have also been observed in our laboratory (5). Depending on the oxide thickness range, one or other of these bands can be used to measure the oxide thickness. The weaker bands are more appropriate for the thicker oxide layers. Film thickness measurements were made on a Perkin-Elmer Model 21 Infrared Spectrometer equipped with a scale expansion accessory. A weighed, oxidized sample was placed in one beam of the spectrometer with an unoxidized Ge sample in the reference beam and the spectrum scanned. The oxidized sample was then placed in water and part of the surface oxide dissolved. The sample was dried, then carefully reweighed, and the infrared absorption measurement repeated. This procedure was continued until all detectable oxide was removed. The integrated intensities corresponded to the peak heights so that after calibration the peak heights were measured to determine the oxide thickness of the samples. A calibration curve for oxide thickness *vs.* infrared absorption of the 18μ band is reproduced in Fig. 1.

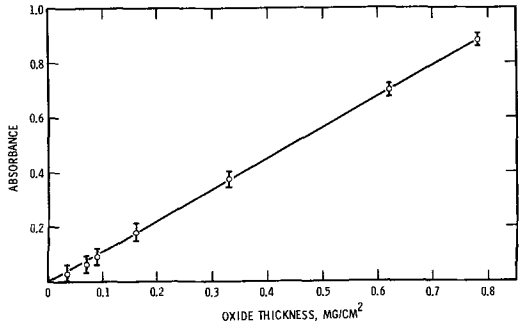

Fig. 1. Infrared absorption measurement of oxide film thickness

Results and Discussion

Nucleation of surface oxides.—On immersion of a Ge sample in nitric acid the surface is rapidly oxidized with some dissolution of the oxidized Ge. Dissolution decreases with continuing reaction presumably because of local saturation at the solid-liquid interface. Cretella and Gatos (1) had observed that in stirred concentrated HNO_3 solutions the behavior of Ge is similar to that in nonstirred solutions except that higher concentrations or longer times were required to achieve saturation of the surface by the oxide. Due to the rapid decrease in solubility of germanium oxide (7) with increasing nitric acid concentration, supersaturation of the interface takes place more rapidly at the higher acid concentrations. As the solubility limit is approached, the oxide can nucleate to produce crystalline particles on the Ge surface. The effect of an oxide-saturated interface on Ge dissolution was tested by preparing HNO_3 solutions containing dissolved hexagonal GeO_2 powder. These solutions were prepared by vigorously stirring the HNO_3 with excess GeO_2 powder over night at the temperature of the bath. After stirring was terminated, the excess GeO_2 powder settled to the bottom of the beaker. The solutions were ready for reaction after bubbling N_2 through them. A comparison run was conducted for Ge reaction in pure 7.5*N* HNO_3 and in 7.5*N* HNO_3 saturated with GeO_2. Referring to Fig. 4, one sees that the maximum Ge weight loss in 7.5*N* HNO_3 occurs at approximately 1.5 hr after reaction starts. Single crystal Ge (100) samples were removed from solution after 1.7 hr of reaction time. This was done to check the effect of solution saturation at the maximum weight loss point. The results showed that the Ge sample in pure 7.5*N* HNO_3 lost 3.18 mg/cm² while the sample in 7.5*N* HNO_3 saturated with GeO_2 lost 2.69 mg/cm² of weight. The oxide thicknesses at these times were 1.78 mg/cm² for reaction in pure acid as compared to 2.61 mg/cm² for the oxide saturated acid. These values are the averages for three Ge samples in each solution. There was a definite decrease in the dissolution of the Ge sample and an increase in the surface oxide thickness with the GeO_2 present in solution prior to reaction. The magnitude of the dissolution did not approach that characteristic of 10.2*N* HNO_3 (Fig. 4). Two alternatives can be considered: (*a*) the solution was not equilibrated with the GeO_2 prior to reaction, or (*b*) saturation of the interface may not be the controlling factor in Ge dissolution or surface oxide growth. In their work Brauer and Müller (7) found that solutions of 2-5*N* HNO_3 had equilibrated with GeO_2 within 10 hr at 25°C. Solutions far from equilibrium could not easily account for the magnitude of the effect on the dissolution of the Ge sample. The oxide layers grown in the 7.5*N* HNO_3 containing GeO_2 did appear more uniform than those grown in the pure acid. The fact that dissolution of the Ge in the oxide saturated acid was not entirely eliminated may be related to factors other than interface saturation which are important in controlling the sample dissolution and oxide nucleation rate. Reactions of single crystal Ge (100) surfaces with pure 15.6*N* HNO_3 and GeO_2 saturated 15.6*N* HNO_3 after 1.7 hr showed sample weight gains of 0.204 mg/cm² and 0.221 mg/cm² for the pure and oxide saturated acid, respectively.

Figure 2 shows photomicrographs of Ge (111) surfaces oxidized in 7.0*N* HNO_3 for 1 and 3 hr. The oxide nuclei are seen to have a definite crystalline structure and appear to have a random surface orientation. Konorov and Romanov (4) have also observed the growth of definite hexahedral crystals of ~10μ dimensions on the Ge surface in 7*N* HNO_3. The growth of these oxide nuclei on Ge surfaces is similar to the growth of As_2O_3 nuclei that takes place on GaAs surfaces oxidized in concentrated nitric acid solutions (8, 9). In the early stages of oxidation at the lower

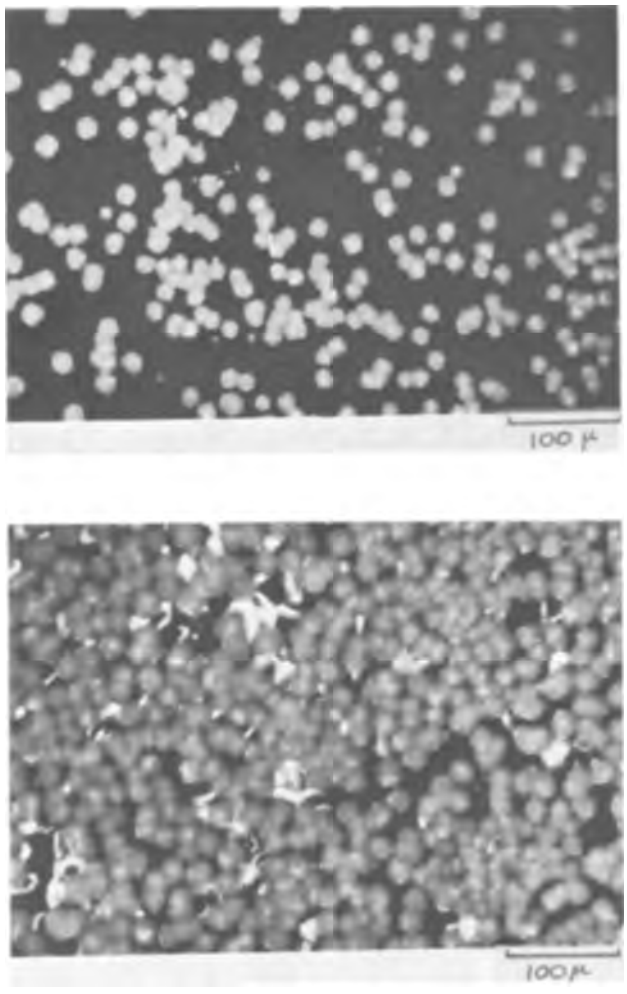

Fig. 2. Ge (111) surfaces oxidized in 7.0N HNO_3 for (a) (top) 1 hr and (b) (bottom) 3 hr.

acid concentrations the oxide nucleates and grows in patches on the surface, accompanied by severe surface etching. With continued oxidation the nuclei grow, with additional nucleation occurring, presumably at points of high local saturation, until the surface is completely covered. Thus, a protective oxide layer forms; that is, the oxide layer grows to a limiting thickness and then stops, with no further reaction taking place. These oxide nuclei adhere strongly to the surface, but for Ge samples left for long times in the less concentrated solutions the chemical attack may be so severe that, on occasion, spalling of the oxide film takes place.

At the higher acid concentrations (greater than 11*N*) nucleation occurs very rapidly at many random sites, and the surface density of nuclei is very large. This observation is in agreement with the results of Faust (3). The nucleation rate of the oxide particles on the surface is so high and the surface density so great that the nuclei do not grow to large sizes. The protective effect of the oxide layer was also noted by Cretella and Gatos (1) and Miuller and co-workers (2).

Figure 3 is a photomicrograph of a Ge (111) surface oxidized for 30.2 hr in 11.9*N* HNO_3 at 27.5°C. This surface can be compared with those oxidized in 7.0*N* HNO_3 as shown in Fig. 2. The oxide nuclei sizes are noticeably smaller than those grown at lower acid concentrations.

Oxide film growth.—In Fig. 4 are plotted the data at 27.5°C for the weight change, in mg/cm^2, of polycrystalline Ge samples (each point a separate sample) as a function of time in solution with no stirring. For solutions with concentration 10.2*N* and less we observed an initial net sample weight loss since the weight lost by Ge dissolution exceeds the weight gained by surface oxide growth. After a time interval, the sample weight gain from oxide film growth overtakes the weight lost by dissolution. For concentrations greater than 10.2*N*, a net sample weight gain is noted from the beginning. All of the weight change curves approach limiting values.

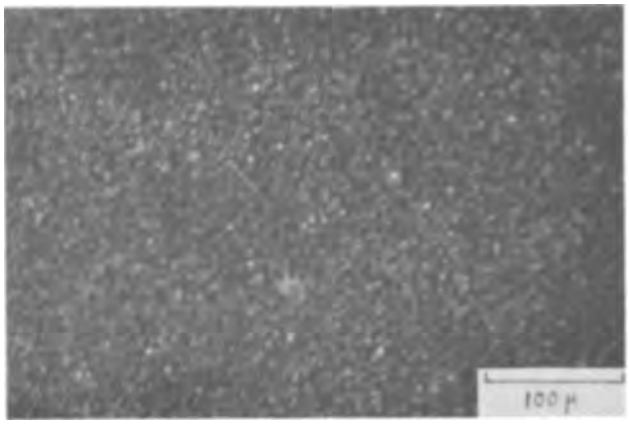

Fig. 3. Ge (100) surface oxidized for 30.2 hr in 11.9N HNO_3 at 27.5°C. Oxide nuclei sizes are notably smaller than those grown in 7.0N HNO_3.

The data for oxide film growth on Ge (111) surfaces at 27.5°C in varying HNO_3 concentration are given in Fig. 5. No induction period for oxide growth was observed at any acid concentration in the range studied although Cretella and Gatos (1) report an induction period to oxide growth at 7.5*N* HNO_3. This is probably due to differences in the preparation of the samples. The initial growth rate of the film is high, but, as the protective oxide film builds up on the Ge surfaces, the growth rate decreases, and the film thickness approaches a maximum value. This saturation value for films grown in 7.0*N* HNO_3 (Fig. 5) is seen to be on the order of five times the value for films grown in 15.6*N* HNO_3 solutions. As was discussed above, the high nucleation rate of surface oxides at the high acid concentration produces rapid saturation of the Ge surface with a protective layer. A similar trend was noted by Cretella and Gatos (1). The average oxide thickness, in microns, was calculated by assuming that the density of the surface oxide was that of the bulk hexagonal GeO_2, 4.228 g/cm^3 (10). The basis for this assumption is discussed in the next section.

The surface oxide layer was observed to improve in uniformity with increasing acid concentration. Figure 6 is a comparison of single crystal Ge (100) surfaces oxidized for 12 hr in 7.5, 10.2, 11.9, and 15.6*N* HNO_3. At 7.5*N* HNO_3 the oxide layer is "patchy" while the

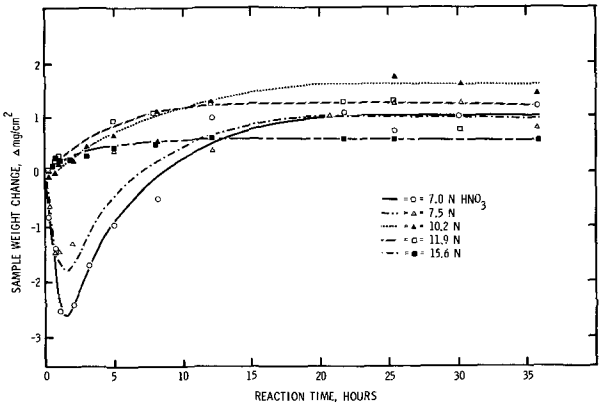

Fig. 4. Weight change of polycrystalline Ge samples with time at 27.5°C. At lower HNO_3 concentrations a net sample weight loss occurs initially.

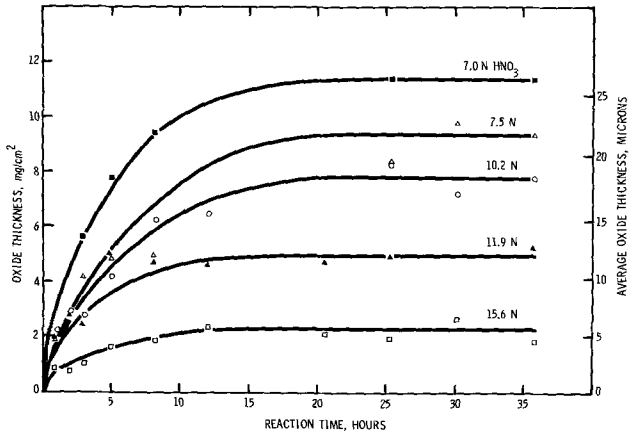

Fig. 5. Oxide growth on polycrystalline Ge (111) surfaces at 27.5°C. Film thicknesses approach saturation values.

most uniform layers are grown in 15.6*N* HNO_3. The variation in the appearance of the samples from dark to white results from the variation in visible light reflection from the surfaces with change in oxide thickness. An electronmicrograph of a Ge (100) surface oxidized for 2 hr in 15.6*N* HNO_3 at 27.5°C is reproduced in Fig. 7. The oxide nuclei density for layers grown in 15.6*N* HNO_3 is seen to be much greater than that for layers grown in 7.0*N* HNO_3 (Fig. 2).

Temperature dependence studies were not pursued to any extent since the contiguity of the oxide layers showed no marked improvements in a preliminary study. Hot nitric acid produced a layer with a higher density of fine-grained oxide nuclei than the layers grown at room temperature (9a). Faust (3) also had noted this. For long reaction times at high temperatures the acid concentration became less certain as a result of loss of nitrogen oxides. A fine-grained oxide layer was observed to grow at lower temperatures when the Ge surface was oxidized in contact with an inert surface such as polyethylene (9a).

Surface oxide characterization.—Germanium dioxide is known to exist in at least three polymorphic forms (10, 11): (*a*) hexagonal crystalline, (*b*) tetragonal crystalline, and (c) amorphous GeO_2. At ordinary temperatures tetragonal GeO_2 is the thermodynamically stable modification (12), but, when Ge is oxidized, the normally occurring forms are the hexagonal or amorphous GeO_2, depending on conditions. Tetragonal GeO_2 can be formed by conversion from hexagonal GeO_2 by using a fluxing agent (13). The phase diagram of the Ge-GeO_2 system has been determined (14, 15), and the transition temperature for the tetragonal to hexagonal crystalline modification has been measured to be 1033°C (12).

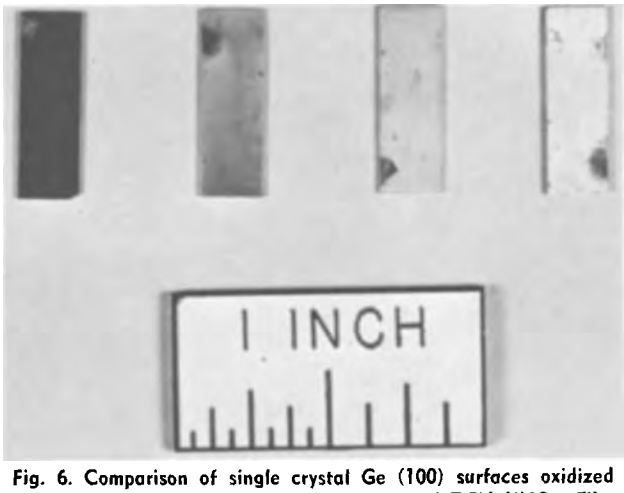

Fig. 6. Comparison of single crystal Ge (100) surfaces oxidized for 12 hr in (l. to r.) 15.6N, 11.9N, 10.2N, and 7.5N HNO_3. Film uniformity improves with increasing acid concentration.

Fig. 7. Electronmicrograph of a Ge (100) surface oxidized for 2 hr in 15.6N HNO_3 at 27.5°C. The oxide layer is seen to be composed of densely packed crystalline oxide nuclei.

In order to determine the form assumed by the oxide in the nitric acid oxidation studies, structural studies were performed on the surface oxide layers by three techniques: (*a*) infrared absorption, (*b*) x-ray diffraction, and (c) electron diffraction. The method used for infrared absorption measurements has already been described. The spectra were compared to those published (6) on the polymorphs of GeO_2. The results indicated that the oxide layers grown in 7.0-15.6*N* HNO_3 on Ge surfaces are composed of hexagonal GeO_2. Infrared spectra characteristic of amorphous (16) and tetragonal GeO_2 were not detected.

X-ray diffraction studies were undertaken to characterize the surface oxide further. Oxidized samples were mounted in a General Electric XRD-5 unit, and diffraction patterns of the surface oxide were obtained using chromium Kα radiation. Measured d-values for the surface GeO_2 were compared to published values (17, 18). Only hexagonal GeO_2 lines were identified. No lines characteristic of tetragonal GeO_2 were detected.

Thin layers of surface oxide, grown for short periods in HNO_3, were prepared for electron diffraction studies in a Siemens Elmiskop I in an effort to determine the nature of the oxide at the Ge-GeO_2 interface. 100 kev electrons were diffracted from the thin oxide layers at low angles (1°-2°) of incidence, and measured patterns were compared with published results for GeO_2 (19). Hexagonal GeO_2 was identified, but, again, no tetragonal GeO_2 was detected in the surface oxide layers. The results of these structural studies indicate that the surface oxide layers grown on Ge surfaces in concentrated HNO_3 are crystalline hexagonal GeO_2..

Orientation effect.—The growth of oxide layers on Ge surfaces in concentrated HNO_3 appears to be affected by the crystallographic orientation of the Ge surface. Figure 8 is a photomicrograph of a grain boundary on a polycrystalline Ge (111) surface oxidized for 30.2 hr in 11.9*N* HNO_3. Faust (3) also noted a dependence of oxide film growth on the Ge surface

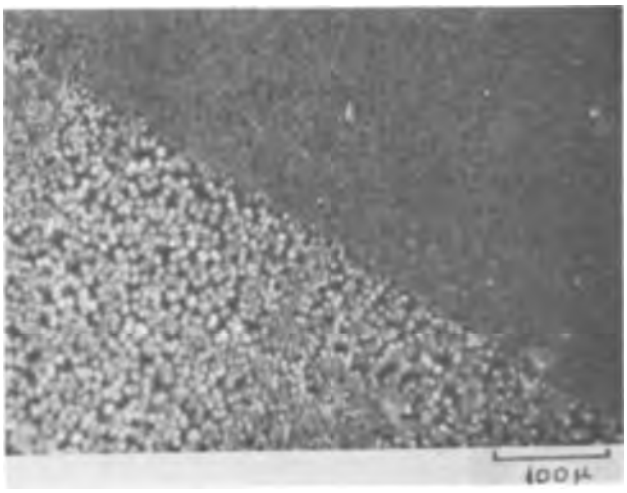

Fig. 8. Oxidation of a grain boundary on a polycrystalline Ge (111) surface after 30.2 hr in 11.9N HNO_3 at 27.5°C. An orientation effect on oxide film growth is visible.

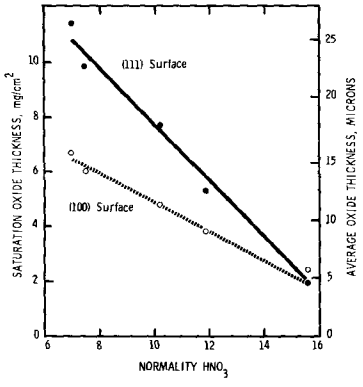

Fig. 9. Dependence of saturation oxide film thickness on HNO_3 concentration at 27.5°C. The surface orientation becomes less important with increasing acid concentration.

orientation, but quantitative data were lacking. Our study considered film growth on Ge (111) and Ge (100) surfaces. Saturation oxide layer thickness, measured by infrared absorption, is compared in Fig. 9. Two interesting features are readily apparent from the data of Fig. 9: (*a*) saturation oxide film thickness is inversely dependent on HNO_3 concentration, and (*b*) oxide film thickness is orientation dependent. The difference in film thickness with Ge surface orientation is seen to decrease with increasing acid concentration. It is interesting to note that the etching rate decreases with increasing acid concentration (1, 2), while the oxide nucleation rate increases with increasing acid concentration. An orientation effect on the etching rate of Ge in solution has been detected by others (20-22). Harvey and Gatos (21) observed that the dissolution rates were (100) > (110) > (111) for the three principal crystallographic orientations at 30°C while Camp (20) found that the order of (100) and (111) was reversed below 25°C. Schwartz and Robbins (22) studied the etching rates of Ge in HNO_3 solutions containing low concentrations of HF. Their results show that the rate dependence on orientation is (110) > (111) > (100). Miuller and co-workers (2) also noted a reduced etching rate for (100) and (110) compared to (111) surfaces. These data indicate that at the lower HNO_3 concentration the etching rate of the Ge surface may be the rate-controlling factor, while at the higher acid concentrations the nucleation rate may be the dominant factor so that the orientation of the surface becomes less important (Fig. 9). As a result, it is difficult to apply a simple diffusion model, proposed for silicon (23), to the oxidation behavior of Ge in solution.

The dissolution of Ge is evidently a complex heterogeneous reaction with simultaneous oxidation of Ge surface atoms and hydration of oxidation products followed by their transfer into solution. Nitric acid as the oxidizing agent complicates the interpretation because of the complex kinetic relationship of nitric acid with its various reaction products (24, 25). Briner and co-workers (26, 27) have shown that the oxidizing power of HNO_3 in concentrated solutions depends on the undissociated species. Cretella and Gatos find that the rate of oxidation of Ge is proportional to the product of HNO_2 and undissociated HNO_3. Their reasoning is based on the mechanism proposed by Vetter (24)

$$HNO_2 + HNO_3 = N_2O_4 + H_2O \quad \text{slow} \quad [1]$$

$$N_2O_4 = 2NO_2 \quad \text{fast} \quad [2]$$

$$NO_2 + e^- = NO_2^- \quad \text{fast} \quad [3]$$

Miuller and co-workers (2) also consider the active species to be NO_2. The apparent over-all rate of oxidation, as deduced from the observed weight changes, is related to the exposed Ge surface area. As this area decreases with the build up of a protective oxide layer, the apparent growth rate of the surface oxide decreases, and the oxide thickness approaches a saturation value. A lack of detailed knowledge of the oxidizing agent and of the exact nature of the possible oxidation products (H_2GeO_3, $HGeO_3^-$, GeO_2, . . .) that are diffusing through the surface-liquid interface, precludes a quantitative model of the oxide growth process at the present time.

Some qualitative remarks can be made however. The rate limiting process cannot be purely a diffusion process as evidenced by the orientation dependence and the way the dissolution kinetics are affected by saturating the HNO_3 with GeO_2 prior to sample oxidation. Miuller and co-workers (2) propose a chemical oxidizing-hydrating mechanism of Ge atom transfer into solution where the rate of the process is limited by the chemical heterogeneous reaction and the accompanying diffusion into solution. Their proposed mechanism follows several steps: (*i*) the exposed Ge surface atom, with an individual pair of electrons, bonds with the oxygen atom from NO_2; (*ii*) a surface dipole is formed; (*iii*) coordination bonds can be formed between protons and the oxygen atom in acid solution, Ge retains a positive charge; (*iv*) the molecule $GeO(OH)_2$ is separated from the surface as a result of hydrolysis and can react with a second NO_2 molecule; (*v*) a new surface of Ge atoms with unshared electron pairs is exposed after the oxide has gone into solution, and the cycle starts anew. The relative importance of each of these steps (plus others, perhaps) in limiting the oxide growth rate is, for the moment, speculative. Additional work on the kinetics of oxide growth will be necessary in order to establish, with any certainty, the chemical mechanism which dominates the oxidation process. Presumably, the temperature dependence studies, under consideration in our laboratory, may provide a more complete view of the reaction mechanism involved. The higher acid concentrations used in our study did not reveal any gross differences from the results published for Ge oxidation at lower acid concentrations (1, 2, 4).

Summary and Conclusions

The study of Ge oxidation in HNO_3 has been extended to high acid concentrations. Thick oxide layers can be grown on Ge surfaces in the concentration range 7.0-15.6*N* HNO_3. Film uniformity improves with increasing acid concentration. No induction period for oxide growth was observed over the acid concentration range studied. The oxide growth rate decreases smoothly with time and is not described by simple film growth laws. Saturation film thickness was observed to be inversely dependent on acid concentration. The oxide nuclei sizes at saturation film thickness decrease markedly with increasing acid concen-

tration. The saturation film thickness was found to be dependent on the crystallographic orientation of the Ge surface. This result indicates that the rate limiting step in oxide growth is probably not purely diffusion controlled. Structural studies, by infrared, x-ray and electron diffraction techniques, of the oxide layers grown on Ge surfaces in concentrated HNO_3 solutions indicate, unambiguously, that the surface oxide is crystalline hexagonal GeO_2.

Acknowledgments

The author would like to express his gratitude to D. E. Swets for the polycrystalline Ge crystals and P. A. Gudaitis for technical assistance. T. R. McKinney performed electron diffraction analyses, and Miss A. Forster performed x-ray analyses on oxidized samples. Discussions with W. A. Albers, Jr., C. E. Bleil, R. N. Hollyer, Jr., and P. V. Mohan were of much benefit to the author.

Manuscript received June 17, 1966; revised manuscript received Sept. 1, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Precipitates Induced in GaAs by the In-Diffusion of Zinc

J. F. Black and E. D. Jungbluth

The Bayside Laboratory, research center of

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Imperfections in GaAs due to the in-diffusion of zinc at temperatures in the range of 700°-1100°C have been investigated by means of x-ray diffraction topography, optical microscopy, and infrared transmission microscopy. The imperfections, which were generated in the diffused layer, were identified as submicroscopic precipitates. Precipitation was almost unavoidable when metallic zinc was used as the diffusant source. Although precipitation could be prevented when $ZnAs_2$ was used as a source, prolonged diffusion always resulted in precipitation. It was concluded that diffusion-induced dislocations plus precipitation, or diffusion-induced precipitation alone, was occurring in our samples.

The study of defects generated in semiconductors by the in-diffusion of p- or n-type impurities has achieved considerable impetus in recent years. In particular, the generation of dislocations due to the diffusion of phosphorus or boron into silicon has been extensively investigated (1). The documentation of diffusion-induced defects in silicon is in contrast to the small amount of published information on these effects in the compound semiconductor GaAs. Recent work (2-4) has shown that surface layers with a high content of structural defects can be produced in GaAs by the vapor phase in-diffusion of zinc. Zinc is widely employed as a p-diffusant in GaAs; therefore it is imperative to define the conditions that give rise to these defects so that their occurrence may be controlled.

This paper presents some results of an investigation of zinc-diffusion-induced imperfections in GaAs. Diffused samples were examined by x-ray anomalous transmission, by infrared transmission microscopy, and by optical microscopy of etch structures. Previous indications (2) of severe lattice damage by diffusion of zinc into GaAs were confirmed, and it was established that this damage was largely due to submicroscopic precipitation in the diffused layer. It was further established that precipitation and its consequent lattice damage in the diffused GaAs could be avoided by proper control of diffusion conditions.

Experimental Techniques

Sample preparation.—The starting material was commercially available single crystal GaAs, boat-grown by the gradient freeze technique. The single crystals displayed dislocation densities ranging from about $10^2/cm^2$ to $10^5/cm^2$, as determined by etch pit counts. Wafers 0.5-1.5 mm thick were cut from these crystals and were then chemically etched or chemically polished to remove all traces of damage resulting from cutting and grinding operations. All diffusions were made by a standard technique; the GaAs samples were contained along with 1g of GaAs powder

and 10 mg of pure zinc (or in some cases with only 10 mg $ZnAs_2$) in evacuated quartz ampoules of 50 cm^3 volume. Each diffusion was carried out with one or more low dislocation density samples in the capsule in addition to other samples of high dislocation density and of differing n-doping level. The low-dislocation-density samples were required for x-ray anomalous transmission topographs, while the high-dislocation-density samples allowed evaluation of the effects of initial crystal perfection. The samples of differing n-doping level made it possible to estimate the zinc penetration profile (p-n junction depth *vs.* n-doping level) for each diffusion run. Diffusion was carried out at temperatures ranging from 700° to 1100°C for a period of 2 hr with GaAs powder and pure zinc in the capsule, unless otherwise noted. All diffusions were carried out so that the end of the capsule containing the diffusant source was maintained at a temperature 10°C below the diffusion temperature. After diffusion the ampoule was cooled by gradually withdrawing it from the furnace over a period of 2 min and then immersing it in water. In this way the contents of the capsule were cooled to room temperature within 3 min. A few diffusion runs were terminated by rapid quenching and a few by slow cooling in the furnace. Rapid quenching was accomplished by withdrawing the capsule from the furnace, plunging it into a bucket of water and crushing with a long-handled pliers. It is estimated that in this way samples were cooled to room temperature within 5 sec.

Examination of samples.—Large-area x-ray diffraction topographs of starting material with low dislocation densities were recorded by the anomalous transmission method (5). This method is highly sensitive to the perfection of the material. Highly imperfect crystals strongly attenuate the x-ray transmission, especially in the immediate vicinity of imperfections. Thus crystal imperfections are revealed as areas of reduced x-ray intensity within the x-ray topographs.

GaAs wafers studied with this x-ray method were oriented in <111> directions. The diffused junctions on the As face were always removed by chemical etching prior to recording x-ray topographs. Since defects confined to shallow surface layers, such as occur in diffused junctions, appear sharpest where the x-ray beam leaves the crystal, the wafers were always positioned so that the Ga face corresponded to the exit surface of the beam on the crystal (6). This allowed etch pit studies, which were carried out on the Ga face, to be correlated with defects shown in x-ray topographs. In many of the samples studied, the diffusions resulted in very strong x-ray absorption by the crystal, and crystal wafers were defined as being opaque to x-rays when no diffracted image could be obtained. Pictures of the diffraction topographs are photographic negatives; consequently, highly imperfect regions appear dark.

In addition to anomalous transmission studies, etch structures were also examined to reveal the presence of crystalline defects. The etch structures were developed on a Ga (111) surface by swabbing the surface with a freshly prepared mixture of one part 30% H_2O_2 and five parts 2% NaOH for 2 to 5 min. This etchant was selective to surface orientations near a (111) Ga surface and developed small pits with a well-defined triangular shape. The pits could be developed over a range of orientations, although with distortion in symmetry, as much as 10° from <111> Ga direction, thus obviating preparation of accurately oriented samples. At sample orientations more than a few degrees from <111>, however, the number of pits produced in a given sample was reduced, so all etching was carried out on surfaces within 2° of an (111) Ga surface. Etch pit counts obtained on a well-oriented wafer were in substantial agreement with etch pit counts obtained with a known GaAs dislocation etch (1 conc. $NHO_3 - 2H_2O$ solution).

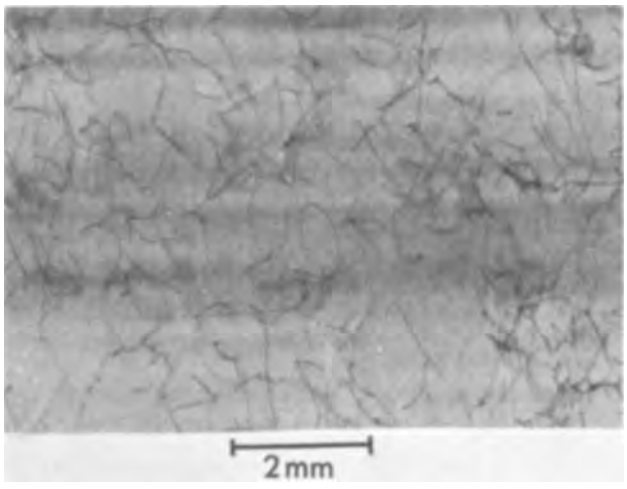

Fig. 1. X-ray topograph of low dislocation density GaAs

Infrared transmission microscopy was accomplished by means of a commercially available image converter adapted to the occular of an inverted stage microscope. Infrared photomicrographs were recorded on Eastman Kodak Type I-M 4 x 5-in. spectrographic plates.

Results

Description of the defect structure.—The dislocation density of the samples used for most of the x-ray anomalous transmission studies was no more than 200/cm^2 (by etch pit count). Figure 1 shows an x-ray topograph typical of this material. After standard diffusions at 700° and 725°C such material showed a slight reduction in the anomalous transmission intensity, but no change in the appearance or in the number of the dislocations occurred. Furthermore, no additional defects, such as misfit dislocation networks, could be detected in the x-ray topographs. At 750°C the intensity due to anomalous transmission was reduced about 20% by the in-diffusion of zinc, and there was still no change in the dislocation structure. Standard diffusions at temperatures higher than 750°C resulted in complete x-ray absorption by the sample, indicating that a high degree of crystal lattice imperfection had been produced. The fact that the transmitted x-ray intensity was reduced (resulting in ultimately opaque samples), while the original dislocation structure was preserved indicates that the diffusion process has produced a substantially uniform microscopic strain in the crystals. Patel and Batterman (7) have reported a similar kind of reduction in anomalous x-ray transmission through silicon, caused by annealing single crystals contaminated with oxygen. These authors established the presence of microscopic strains resulting from the formation of Si-O clusters in the early stages of the precipitation of silicon oxides. This connection of microscopic strain with precipitation is significant because in the present work other evidence of precipitation, *i.e.* high densities of etch pits, appeared in the diffused layer, concomitant with the reduction in anomalous x-ray transmission.

Figure 2 shows three photomicrographs of etched cross sections of diffused samples mounted and polished to produce a (111) Ga plane of section. In an investigation of the precipitation of Cu_2O in copper single crystals Young (8) has described etch structures strikingly similar to those of Fig. 2a. Young observed triangular pit etch structures in oxygen-doped copper single crystals annealed to cause small Cu_2O particles to form. Each particle, even when submicroscopic in size, gave rise to a surrounding cluster of densely packed etch pits, which was interpreted to be due to dislocations produced by plastic deformation which accompanied the formation and growth of the precipitate particles. The dense pitting that is observed throughout the surface layer of the

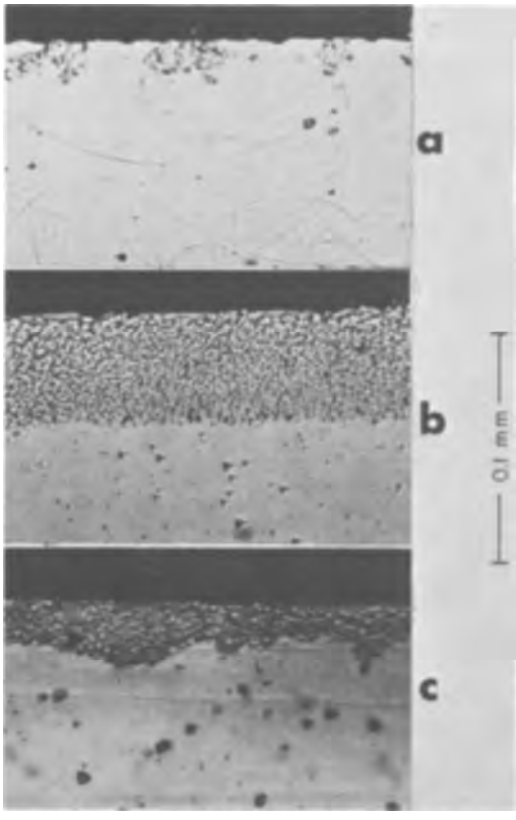

Fig. 2. Etched cross sections of GaAs wafers diffused from a pure zinc source: a, 2 hr at 750°C; b, 2 hr at 800°C; c, 24 hr at 700°C.

sample diffused at 800°C is therefore consistent with the complete x-ray opacity of the GaAs slices that were subjected to standard diffusions at temperatures greater than 750°C. Additional data and pertinent comments for diffusions performed with pure zinc as a source are contained in Table I.

The etched cross sections of samples diffused at a temperature of 700°C showed no evidence of imperfections in the diffused layer even though there had been appreciable diffusion of zinc into these samples (attested by the development of a p-n junction 8μ deep in samples of $n = 5.9 \times 10^{18}/cm^3$). There was, nevertheless, a defect structure layer present that was so thin (1 or 2μ) that it was difficult to develop a clearly defined etch structure in cross section. This layer was detected by carefully etching the diffused surface of the samples. The fact that such a layer, however thin, was detected is again consistent with the reduction in transmitted x-ray intensity noted for these samples. These results suggest a pre-precipitation

Table I. Data on diffusions for 2 hr from a pure zinc-powdered GaAs source

Temp, °C	Depth of p+p junction, μ	Comments
700	7	Slight reduction in x-ray transmission, no change in etch structure
725	10	Slight reduction in x-ray transmission, no change in etch structure
750	20	20% reduction in x-ray transmission, scattered etch pit clusters in p+ layer, sample still transparent to IR
775	35	Completely opaque to x-rays, high etch pit density in p+ layer
800	50	Completely opaque to x-rays, nearly opaque to IR, high etch pit density in p+ layer
900	110	Completely opaque to x-rays, completely opaque to IR, high etch pit density in p+ layer
1000	125	Completely opaque to x-rays, completely opaque to IR-high etch pit density in p+ layer
1100	125	Completely opaque to x-rays, completely opaque to IR, high etch pit density in p+ layer

incubation period of about 2-hr duration in 700°C standard diffusions. At diffusion times longer than two hours at low temperatures, *e.g.*, 24 hr at 700°C, deep zinc penetration was achieved, and the diffused layers were again so highly defective as to be opaque to x-rays. Such a layer is shown in cross section in Fig. 2c.

The infrared absorption increased along with the x-ray absorption, but was not nearly as sensitive a measure of diffusion-induced damage. For instance, the sample of Fig. 2c, though completely opaque to x-rays was still somewhat transparent to IR radiation; the sample of Fig. 2b was opaque to x-rays and very nearly opaque to IR; while a sample with structure like that of Fig. 2b but diffused at 900°C was opaque to both x-rays and IR. In no instances were structures such as decorated dislocations revealed by IR transmission microscopy. Note that the starting dislocation density (etch pit density) is preserved in the region below the diffused layer of Fig. 2c. The only difference apparent between damaged layers produced at low diffusion temperatures (700°C) and those produced at higher temperatures (800°C) was that the boundaries of the layers produced at the lower temperatures were more irregular. This probably is related to the fact that the diffusion-induced damage begins in isolated regions of these samples (see Fig. 2a). These regions, indicated by the etch pit clusters, spread out and penetrate more deeply with time. Until the diffusion depth is large compared with the mean distance between clusters, however, we continue to see evidence of the heterogeneous beginnings of the diffusion-induced damage in the uneven boundary of the defect structure layer.

The samples shown in Fig. 2 had initial dislocation densities of $10^3/cm^2$ to $10^4/cm^2$ by etch pit count. The starting dislocation density did not have a strong effect on the occurrence of highly defective layer structures; the defect structure could be equally well developed in samples with starting dislocation densities of $200/cm^2$ and $100{,}000/cm^2$. This indicates that the diffusion-induced damage was not critically dependent on the presence of existing dislocations, as would have been the case, for example, if the damage were due to decoration of existing dislocations. Clustering of etch pits such as is seen in the sample diffused at 750°C in Fig. 2a was specially prevalent in the early stages of diffusion at temperatures in the range 700°-750°C. Again, if the production of diffusion induced damage was heterogeneous, it would be most apparent in the early stages of its occurrence.

When $ZnAs_2$ was used as the source of zinc, it was possible to preserve the crystal perfection in the diffused layers if the diffusions were not too deep and were not made at too high a temperature. For example, samples diffused for ½ hr at 800°C from a pure zinc-powdered GaAs source developed 25μ deep layers that were opaque to x-rays, while samples diffused for eight hours at 800°C from a $ZnAs_2$ source developed 25μ deep layers with no measurable reduction in anomalous transmission. This was most interesting because of the experience that some workers have reported in fabricating efficient light-emitting diodes (9). Diffusions from a $ZnAs_2$ source were found to yield better GaAs electroluminescent and laser diodes than diffusion from a pure zinc source. It would appear that these results can partly be explained by the differences in defect structure between p-layers prepared from pure zinc source and p-layers produced from $ZnAs_2$.

At diffusion temperatures higher than 800°C or for long diffusion times at 800°C (24 hr), diffusion from a $ZnAs_2$ source ultimately developed highly imperfect layers. One of the effects of using $ZnAs_2$ as a diffusant source is a lengthening of the incubation period before the onset of diffusion damage. The distribution of etch pits in the defect layer was found to be quite different from that observed for pure zinc diffusions. A good example of the structure produced by a $ZnAs_2$ diffu-

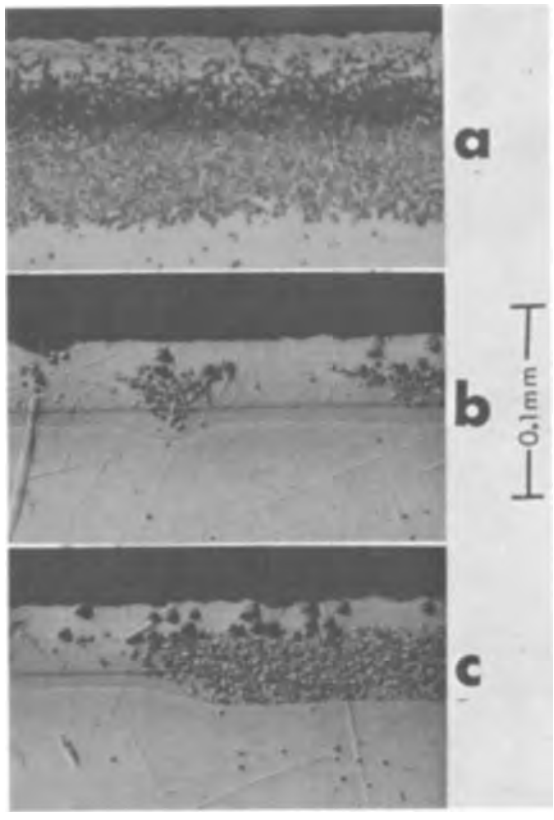

Fig. 3. Etched cross sections of GaAs diffused from $ZnAs_2$ source: a, 8 hr at 900°C; b and c, 24 hr at 800°C.

sion is shown in Fig. 3a. Although a detailed explanation of why the etch pit distribution is so different for $ZnAs_2$ cannot be given at this time, it is probably a result of the much less steep penetration profile produced by diffusion from $ZnAs_2$ (9).

A particularly good example of clustering of defects was observed in a sample diffused from $ZnAs_2$ and is shown in Fig. 3b and 3c. This sample has been etched with a p-n junction etch as well as with the hydroxide-peroxide defect structure etch. It can be clearly seen in Fig. 3b that clustering of etch pits is closely associated with a deeper penetration of the p-n junction. The heavy dark line just above the p-n junction was seen in p-type samples as well as in n-type samples and was identified as a p^+-p boundary by previous studies (10). By comparison with companion samples doped with tellurium to various levels of free electron concentration, the zinc concentration at the p^+-p boundary in the samples of Fig. 3b and 3c was estimated to be $6 \times 10^{18}/cm^3$, and at the p-n junction $3.0 \times 10^{17}/cm^3$. The deeper penetration of the p-n junction in regions of etch pit clusters suggest that the diffusion process induces defects to appear first in regions where there is already some kind of lattice disturbance in the crystal. This is also in line with our observation that clustering was more prevalent in samples of initial high imperfection. However, the kind of defect assumed to be inherent in the host matrix was not evident by x-ray contrast methods before the diffusion cycle. It would be expected that regions of imperfect lattice structures would show enhanced mobility of a diffusant (deeper penetration of p-n junction). Pilkuhn and Rupprecht (9) have shown similar evidence of enhancement in p-n junction depth in regions of crystal defects in GaAs. Evidence that these diffusion-induced defects can seriously affect device properties is shown in Fig. 3c, where the defects extend all the way to the p-n junction.

Optical micrographs of etch structures of a diffused sample are correlated with x-ray topographs in Fig. 4. Dense clustering of defects which occurred in this

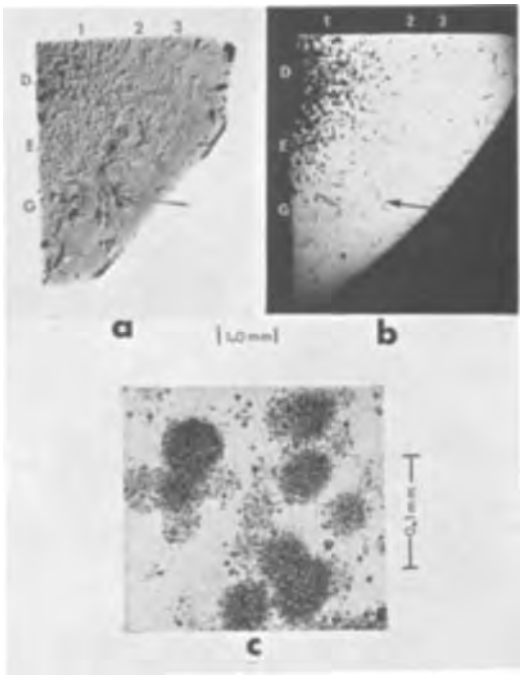

Fig. 4. a, X-ray topograph of clustered defect structure; b, corresponding etch structure; c, details of etch pit clusters.

sample, diffused at 750°C, is evident in Fig. 4a and b within region D1. More clustered defects are seen in the x-ray topograph than the etched surface, which is the plane of diffusion, because only the clusters that intersect the surface are seen by etching, while all of the clusters are seen by x-ray transmission. The clusters were also areas of reduced IR transmission, but the optical contrast was so slight that it could not be clearly registered on our IR sensitive plates. An enlarged view (Fig. 4c) shows that the defect clusters are composed of triangular type pits. These clusters of etch pits have the same structure as those shown in cross-section in Fig. 2a. The dark broad images in the diffraction topograph, such as are indicated by the arrows, are scratches introduced after the diffusion.

Figure 5 shows x-ray topographs of a sample before and after an 800°C diffusion. The sample was initially 1.0 mm thick and was diffused to a depth of 50μ. Because the diffused layers were opaque to x-rays, it was necessary to remove the diffused layer from the B side (the As side) and then angle lap and etch away nearly the entire layer on the A side to obtain the topograph shown in Fig. 5b. Notice that where the diffused layer has been completely removed, Fig. 5c, and region C in Fig. 5b, the original dislocation structure has been preserved. The original structure is still reflection dependent; hence no precipitation along dislocations has occurred in the bulk of the wafer. A clear line of demarcation separates what remains of the defective diffused layer on the A side from the underlying undisturbed material. The diffraction contrast at this boundary resembles the contrast seen in the clusters of Fig. 4. By means of control runs, *i.e.*, runs in which the treatment of samples was identical except that there was no zinc (or $ZnAs_2$) present in the capsule, it was established that only when zinc was indiffused did defect structures appear. This confirmed that these effects were due to zinc and not to thermal stresses, or the precipitation of impurities independent of the presence of zinc.

There was good reason to believe that these defects were due to precipitation, presumably a zinc-complex. A detailed argument and analysis of the data to justify this belief will be presented in the Discussion section, but we mention it at this point because the experiments to be described in the next three paragraphs were performed to confirm whether pre-

The dark spots are due to deep damage.

cipitation was responsible for the defect structures we had observed.

Experiments with zinc (melt) doped GaAs.—Electron probe analysis of several standard diffused samples established that the concentration of zinc at the boundary of the layer of high etch pit density was about 5 x 10^{18}/cm^3. This agreed with the observation that the boundary of this layer usually coincided with the p^+-p junction (Zn = 6 x 10^{18}/cm^3) in standard samples.

On samples melt-doped with zinc up to 3.7 x 10^{19} atoms/cm^3 (free hole concentration equal to zinc concentration within 10%) no trace of defects besides grown in dislocation tangles (about 5 x 10^3/cm^2) could be observed either by etching or by x-ray analysis. Even when the melt-doped samples were additionally annealed (in the presence of their own powder) under conditions of time and temperature where defects consistently occurred by diffusion into undoped GaAs, the zinc-melt-doped samples remained unaffected. However, when the zinc-melt-doped samples were subjected to a standard zinc diffusion at 1000°C the samples developed a defect layer structure and became opaque to x-rays and IR radiation.

The attenuation of optical transmissions was far stronger in diffused samples than in melt-doped samples for material of equal thickness, even though the concentration of zinc in the diffused samples was less than that in the melt-doped samples. For example, for a 100μ thick diffused layer with a zinc concentration ranging from 4 x 10^{19} atoms/cm^3 to 5 x 10^{18} atoms/cm^3(p^+-p boundary), optical transmissions over the range of wavelengths from 0.9 to 1.2μ (s-1 image convertor) were nil, while a 100μ thick wafer of the zinc-melt-doped GaAs was transparent in the same spectral region. If the diffusion-induced damage were largely a result of precipitation, this result might be expected except that the intensity of the IR attenuation implies a rather large amount of precipitate ($>>$ 10^{18} atoms/cm^3).

To ascertain whether the defects were due to some impurity unknowingly introduced during the preparation and diffusion processes, samples were analyzed by emission spectroscopy both before and after diffusion. Only three impurities were detected Cu 3-6 ppm, Mg 5-15 ppm, and Si 10-50 ppm, and their concentrations were unchanged by the diffusion process. It is possible that the residual impurities or that undetected impurities, such as oxygen, are responsible for the diffusion damage, but whatever the nature of the defect structures, they occurred only when zinc was indiffused.

Quenching experiments.—We found that the defect structure that appeared in zinc-diffused GaAs was identical whether samples were quenched from the diffusion temperature to room temperature in a matter of seconds or whether they were slowly cooled in the diffusion furnace over a period of many hours. The character of the defect structure was inspected by etching within 15 min of quenching, and by x-ray anomalous transmission within 30 min after quenching. In both instances the defect structure was fully developed. It was therefore concluded that the defects were occurring during the in-diffusion of zinc or were occurring extremely rapidly during cooling.

In a study of zinc diffused GaP, Gershenzon and Mikulyak (16) observed precipitate structures which they tentatively identified as zinc-rich. They likewise were not able to quench their samples fast enough to prevent the occurrence of these precipitates. It was concluded that the precipitation was occurring during the diffusion period and, furthermore, thermodynamic considerations then implied that the precipitate phase could not be pure zinc. These considerations apply in the present circumstances as well.

Free carrier concentration vs. zinc concentration.—The reduction in the free carrier concentration is a frequently used measure of the progress of precipitation in semiconductors (11). Thus the free carrier concentration was compared with the zinc concentration (average zinc concentration $\geq$ 5 x 10^{18} atoms/cm^3) in diffused samples known to contain well-developed defect (precipitate) structures. These samples were opaque to IR radiations as well as to x-rays. We did find samples which exhibited a free carrier (hole) concentration less than the zinc concentration, but we also found samples which showed agreement (within $\pm$30% spectroscopic analysis accuracy) between the free hole concentration and the zinc concentration. The ratio of free charge carriers to zinc depended in a systematic way on the exact diffusion conditions for each sample. These results are, however, the subject of a separate investigation (12) and they will not be described further in this paper.

The occurrence of these defects did not depend critically on the purity of the GaAs or on the particular method of crystal growth. It was induced in many different crystals, p-doped to 4 x 10^{19}/cm^3, n-doped to 6 x 10^{18}/cm^3 and undoped n = 1.2 x 10^{16}/cm^3, μ = 5,000 cm^2/v-sec, grown by the gradient freeze method in quartz boats, in crystals taken from ingots zone refined in graphite boats, and in crystals pulled from graphite, alumina, or boron nitride crucibles.

Discussion

The introduction of an impurity atom into a crystal by vapor phase diffusion can have two distinct but not necessarily separate effects on the lattice perfection: (*i*) the diffusion can cause dislocations to be introduced to accommodate lattice deformation effects of the solute atom; (*ii*) the diffusion can cause precipitates to appear. Solute atom deformation of the host lattice usually results in highly regular networks of dislocation lines. Diffusion induced precipitation

can be of several kinds and can occur (*a*) during cooling, because of reduced solubility of the diffusant at low temperatures; (*b*) during diffusion because of formation of stable compounds between the diffusant and the constituents of the host lattice; (*c*) during diffusion because of exolution of residual impurities, similar to the "common ion effect" which is well known in solution chemistry. We believe that the clusters and layers of high etch pit density produced in our samples by the in-diffusion of zinc are areas in which submicroscopic precipitation has occurred. No individual precipitate particles could be observed at magnifications up to 1000X. Although it seemed very likely that the diffusion induced precipitate was zinc, or some substance containing zinc as a major constituent, the experimental data were not sufficient to permit us to describe the precipitate in any detail.

The appearance of diffusion-induced dislocations will not automatically cause the appearance of precipitate structures, but if there are species present which are liable to precipitate, diffusion-induced dislocations will hasten their appearance. If precipitation occurs during in-diffusion or during a slow cool, dislocations of a type other than solute deformation dislocations will occur. These dislocations will be due to differences in the specific volume of the precipitate phase and the matrix phase and will be more localized and more intense than diffusion-induced dislocations.

In the following sections our data will be analyzed to show that both diffusion-induced dislocations with precipitation or precipitation alone are occurring. None of our results indicate the production of diffusion-induced dislocations alone.

The case for precipitation alone.—In samples diffused from pure zinc at temperatures below 775°C ($ZnAs_2$ source at temperatures below 850°C) there was no evidence of the regular networks of dislocation traces that are so characteristic of solute-induced lattice deformation. The x-ray topographs do, however, show that for diffusions from pure zinc the crystal perfection is being uniformly degraded (x-ray absorption is being increased). Such behavior is characteristic of the early stages of precipitation in highly perfect crystals (7). The heterogeneous nature of the defect structures observed in the early stages of their formation is characteristic of precipitation but not necessarily of diffusion induced dislocations. Also the distinct incubation period that is observed before damage to the crystal structure appears and the fact that this period is inversely proportional to both the temperature and the partial pressure of zinc (concentration of zinc), is consistent with a precipitation reaction. Furthermore the strong IR absorption which was observed in the defect structures is to be expected if precipitation is occurring but not if dislocations alone are present.

For those samples subjected to standard diffusions from a pure zinc source at 800°C or above, it was not possible to quench the precipitation. If the precipitation were supposed to have occurred during the diffusion period, this result is understandable. If the precipitation were supposed to have occurred after the diffusion, *i.e.*, during the cooling period, it is difficult to argue for a pure precipitation reaction unless the samples had initial high dislocation densities. The fact is that these samples had initial dislocation densities as low as 100/cm^2. For the moment we shall defer the question of precipitation during diffusion to pursue the argument for diffusion-induced dislocations with precipitation.

The case for diffusion-induced dislocations with precipitation.— If dislocations were generated during standard diffusions from pure zinc at 800°C and higher we could, at least qualitatively, explain the failure to quench the precipitation by citing the strong effects that dislocations are known to have in accelerating solid-state precipitation reactions (13, 14). The important question of whether or not dislocations are actually generated in GaAs by the in-diffusion of zinc has been answered by the recent work of Schwuttke and Rupprecht (4). They showed that under certain conditions the diffusion of zinc into GaAs can cause the regular arrays of dislocations characteristic of lattice solute deformation. For prolonged diffusion, however, a layer of intense crystal damage was produced. Although this may have been a layer of submicroscopic precipitation similar to the layers we have observed, it would be necessary to verify this by other techniques. For those samples of the current investigation in which we could have observed dilatational dislocations, had they occurred, the diffusion conditions were sufficiently different from those of Schwuttke and Rupprecht to explain the absence of dislocations. In those samples in which solute dilation dislocations should have been observed we are prevented from confirming their occurrence because of the high density of microprecipitation.

It must be emphasized that at high defect concentrations it is not possible to distinguish between crystal imperfections due to lattice solute deformation, *i.e.*, misfit dislocations, and crystal damage due to precipitation. The rather dramatic onset of the defect structure between 725° and 775°C (see Table I) is, nevertheless, consistent with the introduction of dislocations during the diffusion process. It has long been known that, at a temperature close to 2/3 T_m (15), where T_m is the absolute melting temperature, many of the so-called intermetallic compounds, including the III-V zinc blend type semiconductors, undergo a change in mechanical properties from brittle to ductile behavior. For GaAs 2/3 T_m is equal to 738°C, which is within the temperature range where our experiments suggest that dislocations are introduced. Whether precipitation occurred during in-diffusion or during cooling, diffusion-induced dislocations would be expected to enhance the rate of precipitation.

There are cases known, especially involving high dislocation densities ($> 10^6$/cm^2) (13) where precipitation reactions occur with time constants of a second or so, *i.e.*, fast enough to make quenching very difficult. However, the amount of precipitant exsolved within this second or so is only a few parts per million. There are no cases extant of nearly instantaneous precipitation of relatively large amounts of material (> 100 ppm) in the solid state. Although precipitation of a few parts per million of an impurity is sufficient to explain the strong attenuation of x-rays (7) it does not seem to be nearly enough to account for the strong IR absorption and scattering in our samples.

For example, the precipitation in the zinc-diffused regions of the crystals was sufficient to render these regions (only several thousandths of an inch thick) quite opaque to optical transmission as viewed through an IR image convertor (0.9 to 1.2μ wavelength). The average absorption coefficient of such a diffused layer containing between 4 x 10^{19} and 5 x 10^{18} zinc atoms/cm^3 (800-100 ppm, respectively) was greater than 500 cm^{-1}. The average free-carrier concentration p = 2.0 x 10^{19}/cm^3 agreed with the average zinc concentration within 30% which means that no more than about 6 x 10^{18} zinc atoms/cm^3 could have been precipitated. The average free-carrier absorption coefficient for p-type GaAs in the 0.9-1.2μ spectral interval for a carrier concentration range from 5 x 10^{18}/cm^3 to 4 x 10^{19}/cm^3 is only about 200 cm^{-1} (20). Thus we must account for an excess "absorption" amounting to more than 300 cm^{-1}, apparently with a precipitate structure involving no more than 6 x 10^{18} zinc atoms/cm^3 (120 ppm). Gershenzon and Mikulyak (16) have published optical measurements of zinc diffused GaP which indicate an excess absorption of 20 cm^{-1} in a sample containing precipitates and in which $\bar{p}$ = 2 x 10^{18} holes/cm^3. No information was provided on the actual zinc concentration present in these samples, but the conditions of diffusion indicates an average zinc content of at least 5 x 10^{18} atoms/cm^3. Therefore the excess absorption of 20 cm^{-1} appears to be due

to more than 3 x 10^{18} atoms/cm^3 of precipitated zinc. These measurements of zinc diffused GaP suggest that we need considerably more than 6 x 10^{18} zinc atoms/cm^3 (precipitated) to explain an excess IR attenuation of 300 cm^{-1} in GaAs. Nevertheless, we cannot be certain that 6 x 10^{18}/cm^3 or even 1 x 10^{18} atoms/cm^3 of precipitated zinc is not enough to explain the observed effects. A firm description of the sizes, distribution, and composition of the precipitate particles necessary to explain a given degree of particulate attenuation is required to calculate the corresponding zinc concentration. The authors could find no experimental papers in the literature that could provide an unqualified answer to this problem. The pursuit of a solution to this problem can be conducted on theoretical grounds, but this is not within the scope of this paper.

Let us return, now, to discussion of the case for precipitation during the diffusion period with or without help from diffusion-induced dislocations. The results of several investigations (17) of zinc doped GaAs have shown that the solubility of zinc in solid GaAs is greater than 7 x 10^{19} atoms/cm^3 at temperatures in the range of 700°-1100°C. How, then, can we explain the occurrence of precipitates in GaAs diffused with much less than 7 x 10^{19} atoms/cm^3 of zinc at these temperatures. The exsolution of residual impurities or the undetected introduction of other impurities during the diffusion offers a ready explanation. The question of the exsolution of residual impurities is a difficult one to answer experimentally, but the question of the introduction of impurities during diffusion is one that can be answered by experiment. Because the quartz capsules that we used were not of the highest purity, it was possible that undetected impurities had been leached out of the quartz to contaminate our samples during the diffusion period. For example, impurities such as Li, Na, and Ca, which are difficult to detect by the usual emission spectroscopy techniques, are known to be present in the range of 5-10 ppm in ordinary quartz. To check the possibility that impurities were being leached from the quartz, several GaAs wafers were diffused in Spectrasil capsules. Spectrasil is a highly pure grade of quartz, but nevertheless the zinc diffused samples still developed the usual precipitate structures. The fact that the free-carrier concentration was substantially equal to the zinc concentration in many samples with well-developed precipitate structures supports the premise that the precipitates are composed of an element other than zinc. On the other hand the fact that some samples do show much less free carriers than zinc is evidence that zinc eventually does precipitate. It must be remembered, too, that because of problems in attaining a better degree of accuracy in the zinc analysis, *i.e.*, better than 30% accuracy, those samples which showed agreement of zinc analysis and free carrier concentration, still could have had, at the very least, 1.5 x 10^{18} zinc atoms/cm^3 tied up in the precipitate structure.

Although, the occurrence of crystal damage due to precipitation does not depend critically on the identity of the precipitating species, the identification of the species is critical, if we wish to understand the precipitation processes.

Conclusions

None of the recent experimental-theoretical investigations (18, 19) of the diffusion of zinc into GaAs take account of the possibility of diffusion induced damage, especially precipitation. Clearly, the current investigation shows that one must qualify such investigations: (*i*) by establishing the absence of such precipitation; (*ii*) by demonstrating that precipitation is of no consequence to the diffusion processes; or (*iii*) by modifying the transport equations to take account of precipitation. In particular it would be interesting to determine if the isoconcentration diffusion studies of Chang and Pearson (19) were conducted in the presence of diffusion-induced defects since these investigators employed vapor phase in-diffusion of zinc to prepare zinc-doped GaAs wafers for subsequent isoconcentration diffusion with radioactive zinc.

Acknowledgments

The authors wish to express their thanks to R. J. Modena, J. Daly, and J. Hurley for their technical assistance in various phases of the experimental work. They also wish to acknowledge the support and encouragement of Dr. B. Smith and Mr. D. J. Bracco in carrying out this investigation.

Decorated Dislocations and Sub-Surface Defects Induced in GaAs by the In-Diffusion of Zinc

J. F. Black and E. D. Jungbluth

The Bayside Laboratory, Research Center of

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

The diffusion of zinc into GaAs can, under certain conditions, cause defects to appear in the diffused crystal. These diffusion-induced crystal imperfections have been investigated by means of x-ray anomalous transmission topography, optical microscopy, and infrared transmission microscopy. There were three kinds of defects observed: submicroscopic precipitation in the diffused surface layer, decorated dislocations below the diffused surface, and an unidentified defect structure which extended throughout the undiffused region of the wafers. Diffusion-induced decoration of dislocations initially present in samples was observed in crystals previously melt doped with zinc, but not in undoped or in n-doped crystals. The unidentified deep-lying imperfections occurred only in wafers with very intense precipitation in the diffused surface layer.

In a recent publication (1) the authors showed that the diffusion of zinc into GaAs could induce submicroscopic precipitation in the diffused layer. This precipitation was always accompanied by severe crystal damage in the diffused layer and in many cases there was sufficient precipitation to cause strong attenuation of optical transmissions. This paper presents the results of further investigations of zinc-diffused GaAs in which visible precipitate structures and damage to the underlying crystal were observed in addition to submicroscopic precipitation in the diffused surface. The visible precipitates, which were composed of submicroscopic particles condensed onto curvilinear dislocations initially present in the crystals, caused high attenuation of x-ray anomalous transmission and high attenuation of infrared (IR) transmissions. Zinc-diffusion-induced damage to the underlying crystal caused high attenuation of x-rays, but had little effect on transmission of optical radiations.

Experimental Techniques

Sample preparation.—The starting material was single crystal GaAs grown in quartz boats by the gradient freeze technique. Dislocation densities, by etch pit count, ranged from 50/cm^2 to 50,000/cm^2. Wafers cut from the crystals were ground flat and parallel and were then chemically polished in a Br_2-methanol solution to remove the crystal damage resulting from cutting and grinding operations. The final thickness of the wafers ranged from 0.5 to 1.5 mm. Unless otherwise indicated, the diffusions were carried out according to the following conditions: 10 mg of pure zinc 1g of GaAs powder in evacuated quartz capsules of 50 cm^3 volume (ordinary grade quartz); the diffusion time was 2 hr at a fixed temperature ranging from 800° to 1000°C. These diffusions are referred to as standard diffusions. Each diffusion included several samples of differing n-doping level in addition to the samples used for study of diffusion-induced defects. The purpose of the n-doped samples was to allow an estimate of the zinc penetration profile for each diffusion run, by measurements of p-n junction depth *vs.* n-doping level. At no time during the diffusion cycle was the temperature of the end of the capsule initially containing the diffusant source allowed to rise above that of the region containing the GaAs powder and the samples. The samples, which were laid flat in the boat with the Ga face up, were separated from the powder by a quartz partition. All diffusions were terminated by gradually withdrawing the ampoule from the furnace over a period of 2 min and then immersing it in water. It is estimated that by this procedure the contents of the capsule were cooled to room temperature within 3 min.

Examination of samples.—X-ray diffraction topographs were recorded by the anomalous transmission method (2) using Cu radiation. Highly imperfect regions of crystals strongly attenuate the x-ray transmission, especially in the immediate vicinity of the imperfections. Such regions show up as dark areas in the topographs of Fig. 2, 4, and 6. The GaAs wafers studied by the x-ray anomalous transmission technique were oriented in <111> directions. The diffused layers on the As face were always removed by chemical etching prior to examination by x-rays, and the wafers were positioned so that the Ga face corresponded to the exit surface of the x-ray beam. Because defects in shallow surface layers, such as occur in diffused samples, appear sharpest where the x-ray beam leaves the crystal (3), this procedure allowed etch structures produced on the Ga face to be correlated with defects shown in x-ray topographs.

Etch structures were developed on the Ga (111) surface by swabbing the surface with a freshly prepared mixture of one part 30% H_2O_2 and five parts 2% NaOH solution for several minutes. This etchant was selective to surface orientations within 10° of a (111) Ga surface and developed small pits with a well-defined triangular shape. Etch pit counts on a <111> Ga oriented wafer were in agreement with counts of etch pits developed by 1 part concentrated HNO_3 — 2 parts H_2O, a well-known dislocation etchant for GaAs. All etching with the NaOH-H_2O_2 defect etch was carried out on surfaces within 2° of a (111) Ga surface.

Infrared transmission microscopy was accomplished by means of a commercially available image convertor adapted to the ocular of an inverted stage microscope. Infrared photomicrographs were recorded on Eastman Kodak Type I-M 4x5 in. Spectrographic Plates.

Experimental Results and Discussion

Unless the diffusion of zinc into GaAs is properly controlled, intense submicroscopic precipitation will occur in the diffused layer. This precipitation will cause the appearance of an etch structure like that shown in Fig. 1b. In addition, such precipitation causes strong attenuation of x-ray anomalous transmission wavelengths and strong absorption (in excess of that corresponding to the free carrier absorption) of near-infrared radiation. A detailed description and discussion of these structures can be found elsewhere (1).

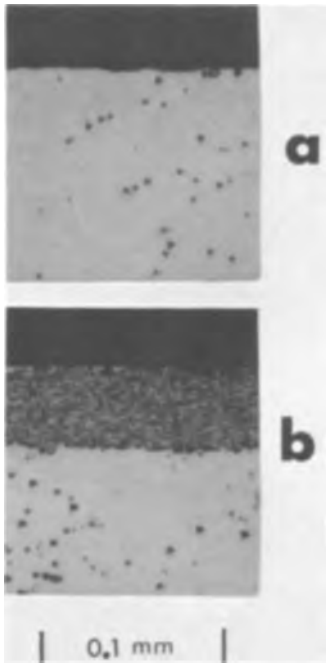

Fig. 1. Etch structure of GaAs sample: (a) initial etch structure, (b) after sample was subjected to a standard diffusion (see text) at 800°C. The plane of section is a (111) Ga plane normal to the surface of the sample. The layer of high etch pit density is a region containing submicroscopic precipitation.

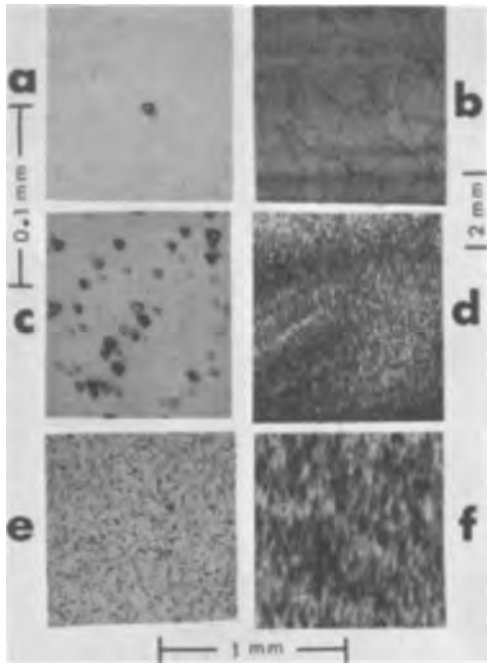

Fig. 2. Etch structures (on the left) and x-ray topographs (on the right) of a GaAs sample. Note the difference in scale between (a), (c) and (b), (d). (a) Initial etch structure, (b) initial x-ray structure, (c), (e) and (d), (f) etch structure and x-ray structure, respectively, of the crystal after it was subjected to a standard diffusion and after removing the damaged precipitate containing layer.

It is important to note here, however, that in samples in which submicroscopic precipitation had occurred it was found that the concentration of zinc along the sub-surface boundary of the precipitate containing layer was usually close to 1×10^{19} atom/cm^3. In crystals diffused under standard conditions at temperatures of 800°C or lower in which such precipitation had occurred, the careful removal of the damaged precipitate-containing layer was found to yield the underlying crystal essentially in its original state of crystal perfection (1). In standard diffusions performed at temperatures of 900°C or higher the crystal damage was not confined to the diffused layer but extended throughout the bulk of the wafer. The character of this subsurface damage was, however, different from the damage induced in the diffused surface layer.

An example of damage below the diffused layer is seen in the photographs of Fig. 2. A 1-mm thick wafer whose initial etch pattern is shown in Fig. 2a, and whose x-ray topograph is shown in Fig. 2b was diffused with zinc to a measured depth of 120μ. The initial etch pit count was 150/cm^2. After diffusion, 320μ were removed from each face, and the etch structure and x-ray topograph of the zinc-free substrate was recorded, Fig. 2c and 2d. The etch pit count after diffusion was $\sim$ 250,000/cm^2. Figure 2e and 2f compare the x-ray topograph and the etch structure of the zinc-free substrate on the same scale. As expected from the high etch pit count, the sample is nearly opaque to x-rays. A crystal which is opaque to x-rays is defined as a crystal whose anomalous transmission properties are so much reduced due to regions of imperfect lattice structure that no diffracted image can be obtained. Examination of the sample under IR transmission (0.9 to 1.2μ wavelength) showed little change in the IR transmissivity and no IR absorption structure like that suggested by the x-ray topograph. It is clear that diffusion has caused an increase of more than three orders of magnitude in the defect concentration of the crystal lattice below the diffused layer.

Because these defects occurred in a region that was essentially free of zinc ($<$ 5 ppm), and because the defects did not show up under IR microscopy, they cannot be submicroscopic precipitates of the type found in the diffused layer. This raises the question of the nature and the origin of these subsurface defects. One possibility is that we are observing precipitation, but in such an early stage of development that it is detectable by x-ray topography but not by IR transmission microscopy. The concentration of these subsurface defects was, however, too high to determine whether they were dislocations or precipitates by observation of the reflection dependence of individual defects in the x-ray topograph of Fig. 2d. If we suppose that these defects are due to precipitation, then we must explain how the presence of high concentrations of zinc and/or the presence of precipitates in the surface layer can cause precipitation deep in the interior of the crystal. For example, to what impurity can we attribute such precipitation? Spectroscopic analysis before and after diffusion showed no increase in residual impurities nor any (spectroscopically detectable) additional impurities. Though the nature of these deep-lying defects was not clearly established, the occurrence of dislocations in crystal material underlying a severely damaged surface layer is not inconsistent with the formation of such a layer. The existence of precipitation in the zinc-diffused layer is concomittant with the presence of high internal stresses in this layer. The more intense the precipitation the stronger the surface layer becomes and the higher the surface stresses become. Eventually these surface layer stresses exceed the yield strength of the interior GaAs crystal and dislocations are introduced. This would explain why interior defects were not produced by all diffusion runs; they only occur when the precipitation is sufficiently intense to cause stresses in the interior crystal lattice exceeding the yield strength. In this respect it is significant that in most of the crystals with interior crystal damage the precipitation in the surface layer was great enough to render this layer completely opaque to IR transmissions.

Further evidence that considerable stresses can be produced by the diffusion of zinc into GaAs is shown in Fig. 3. These are photomicrographs of diffused GaAs crystals that were cleaved normal to the diffused layer

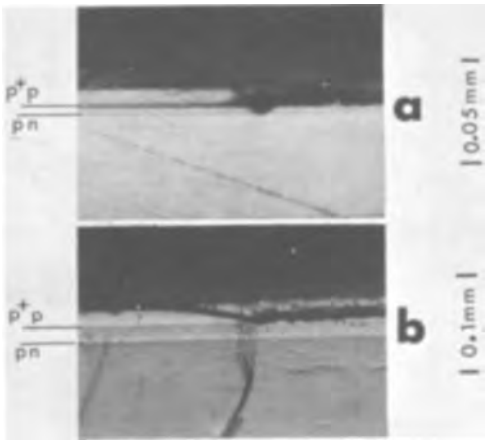

Fig. 3. Etched cross-sections of diffused and cleaved GaAs. (a) 800°C pure zinc source for 10 min, n(Te) = 3.1 x 10^{17}/cm^3, sample has been mounted and polished after cleaving, (b) $ZnAs_2$ source 800°C for 1 hr, n(Te) = 1.1 x 10^{18}/cm^3, curved lines are cleavage steps.

in the process of fabricating injection electroluminescence devices. The material, which was <111> oriented, showed a tendency to fracture parallel to the plane of diffusion along the p$^+$-p boundary, indicating the presence of residual stress at this boundary. Such behavior would be expected of diffused zinc-blende-type crystals in which stresses were built up by the diffusion process. Diffusion-induced stresses become locked-in along the diffusion boundary when the sample is cooled from the diffusion temperature. This occurs because the yield strength of zinc-blende-type semiconductor crystals increases rapidly as the temperature is lowered and eventually exceeds the diffusion stresses. The diffusion stresses can then no longer be relieved by slip in the crystal and become locked-in. X-ray extinction contrast topographs of profile sections of zinc-diffused samples, published recently by Schwuttke and Rupprecht (4), also show regions of high residual stress immediately beneath a heavily damaged surface layer.

To determine whether precipitation could be made to occur in samples already doped with more than 5 x 10^{18}/cm^3 zinc, some melt-doped samples were subjected to annealing treatments. The samples were annealed in the presence of their own powder to prevent both out-diffusion of zinc and the decomposition of the sample. Figure 4 shows an x-ray topograph of a zinc-doped wafer before the annealing treatment. The dislocation density is about 5000/cm^2 by etch pit

count and consists of individually resolved and tangled curvilinear dislocations. Although the zinc content of the melt doped samples was 3.7 x 10^{19} atoms/cm^3 (which was considerably more than the zinc concentration at which precipitation occurred in standard diffused samples), annealing of the samples for 2 hr at 1000°C had no effect on the crystal perfection. Contrary to expectations, there was no reduction in x-ray anomalous transmission nor in IR transmissivity; neither was there any change in the x-ray topograph (dislocation contrast), etch structure, or IR transmission structure. However, when a melt-doped sample was zinc diffused at 1000°C for 2 hr, it became opaque to x-rays and a precipitate structure was developed. This structure is shown in cross section in the photomicrograph of Fig. 5. In addition to the layer of submicroscopic precipitation and high etch pit density (region I), usually generated in GaAs by such a diffusion treatment, there was a region (II) about 200μ thick just ahead of this layer in which other more distinctive types of etch structures were seen. These etch structures were best correlated with x-ray anomalous transmission topographs and with infrared transmission microscopy in a sample sectioned parallel to the diffused layers. Thus the structures seen in Fig. 6a, 6b, and 6c were recorded after the diffused layers had been removed from both the A and B faces of a sample and after the sample had been further lapped and polished down to 100μ thickness in the region designated II in Fig. 5. To obtain good infrared transmission photomicrographs it was necessary to make the sample thin in order to minimize the optical absorption due to the high background zinc level. Notice that the dislocation structure in Fig. 6a is no longer visible as fine lines (compare with Fig. 4), but in place of the individual curvilinear dislocations and tangles, broad diffraction contrast images now appear. The very strong infrared absorption of these structures indicates that they too are precipitates of some kind. Examination of carefully polished samples as well as lightly etched samples at magnifications of 1000X failed to show any trace of sharp boundaries around these structures such as would have been present if a precipitate phase of microscopic dimensions had formed. This is the result expected if these structures have been formed by the decoration of dislocations, since this process leads to condensation of particles of submicroscopic size onto the dislocation line.

In Fig. 7 an area of the sample is shown at higher magnification to resolve details of the precipitates by

Fig. 6. Defects in region II, (see Fig. 5) sample preparation described in text. (a) X-ray topograph, (b) IR transmission photomicrograph, (c) etch structure of the area shown in (b).

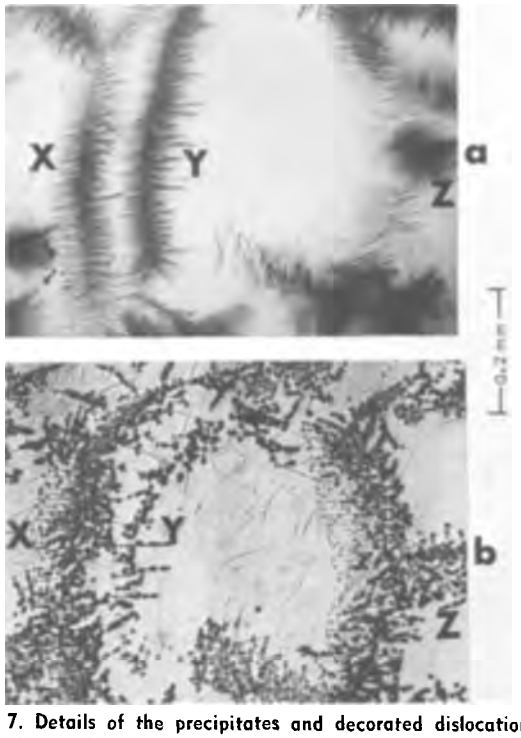

Fig. 7. Details of the precipitates and decorated dislocations in region II. (a) IR transmission structure, (b) etch structure of the area shown in (a).

infrared transmission and visible reflection microscopy. Figure 7a is the infrared transmission photomicrograph of the sample before etching, and Fig. 7b is the photomicrograph of the etch structure of the same region. The curved centipede-like configurations are the broad images seen at low magnification in Fig. 6a and are very similar to decorated dislocations that are revealed in silicon by the Dash method of Cu precipitation (5). The dislocation marked Y in the infrared photo is only partially visible in the etched sample because it is not as close to the plane of section, as for example, the dislocation at X. Infrared absorption not associated with decorated dislocation lines but associated with clusters of etch pits (microprecipitation) can be seen at locations such as Z in the figure. A very close correspondence exists between the infrared transmission structure and the etched structure.

There are several features of the defect structures in Fig. 6 and 7 that merit further discussion. The direction of the dislocations is more or less random, but the direction of the decorating spikes is quite regular and in fact lies almost normal to the direction of the dislocation. Most of the spikes lie along two of three directions the projections of which are 120° apart on the (111) plane, which is the plane of polish as well as the plane of diffusion. On a given dislocation practically all of the decorating spikes lie along the same direction. Also, in curvilinear dislocations long enough to show changes in direction greater than 10° or 15°, such as X and Y in Fig. 7a, the decoration becomes less intense as the direction of the dislocation line approaches the direction of the spikes. This is in agreement with observations of dislocations in GaP decorated by indiffusion of zinc (6). Very similar effects are observed in Cu decorated silicon (5, 7) where it has also been established that precipitate needles are oriented in <110> directions perpendicular to the Burgers vector of the particular dislocation or dislocation segment they decorate. This could also be the case in the present instance, though more detailed data are necessary to make definite conclusions. Abrahams and Buiocchi (8) have recently described etch structures in GaAs essentially the same as those associated with the precipitate spikes in Fig. 7. They identified their etch structures as decorated dislocations from etching behavior alone. Our observations, while confirming the conclusions of Abrahams and Buiocchi, provide more convincing evidence that these etch structures are due to decorated dislocations.

The appearance of a decorated dislocation structure, such as shown in Fig. 6 and 7, was unique to the diffused zinc-melt-doped GaAs samples. Despite diligent examination of many other zinc diffused samples, which were initially undoped or n-doped not a trace of similar structures was found. A comparison of spectroscopic analysis of the zinc-doped material before and after diffusion showed no new (spectroscopically detectable) impurities after the diffusion and no increase in the impurities initially present. There were only three impurities detected; Cu (4 ppm), Mg (5 ppm), and Si (30 ppm).

To determine if the regions containing precipitates were of significantly different composition than the surrounding crystal, electron probe microanalysis was conducted in region I and along the backbone of the centipede-like structures in region II. Since precipitation was observed only after the indiffusion of zinc, it was expected that more zinc would be found in the precipitates than elsewhere in the diffused crystal. However, zinc content in regions of precipitation was found to be no higher than in the surrounding precipitate-free material (where Zn = 4.0×10^{19} atoms/cm^3). Only near the surface of the diffused layer (about 50μ below the surface in region I) did the zinc concentration rise above that of the initial zinc doping level. This, in fact, was the only evidence that zinc had actually been diffused into the crystal.

Residual impurities were the next most likely precipitants. The Cu content was also determined to be no higher at the precipitates than in the surrounding regions. The limit of detection for Cu in GaAs was estimated to be the same as that for Zn in GaAs which is about 100 ppm. Electron probe microanalysis for Si and Mg, the other (known) residual impurities,

failed to show concentration of these elements at precipitates either. The Si and Mg analysis are not too meaningful though, since the limits of detection for these elements in GaAs were quite high (> 1000 ppm).

It has recently been shown (9) that submicroscopic precipitation in zinc-diffused GaAs is definitely zinc rich. Moreover, it has been established (1) that the critical concentration of diffused zinc necessary for the appearance of these precipitates is about 5 x 10^{18} atoms/cm^3. Thus the failure to observe a zinc concentration in excess of the background (initial) zinc concentration in the precipitates of regions I and II can be explained as follows. Since we need only 5 x 10^{18} zinc atoms/cm^3 (diffused) to form precipitates, the total zinc concentration at precipitates in the diffused melt-doped crystal need only be 4.5 x 10^{19} atoms/cm^3, not much different from the background zinc doping (4.0 x 10^{19} atoms/cm^3) in the crystal. Such a difference could not have been clearly distinguished by the electron probe since this was just about the limit of the analytical precision for zinc in this concentration range. If there had been much more than 5 x 10^{18} atoms/cm^3 excess zinc, say at least 1 x 10^{19} atoms/cm^3, it would have shown up in the probe analysis. It appears that only indiffused zinc is capable of decorating these dislocations initially present in the zinc-doped GaAs.

Acknowledgments

The authors wish to express their thanks to R. J. Modena, J. Daly, and J. Hurley for assistance in various phases of the experimental work. They also wish to acknowledge the support and encouragement of Dr. B. Smith and Mr. D. J. Bracco in carrying out this investigation.

Manuscript received Aug. 23, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Preparation and Properties of Epitaxial Gallium Phosphide

G. S. Kamath and D. Bowman

Xerox Corporation, Webster, New York

ABSTRACT

Gallium phosphide has been grown epitaxially by open tube vapor transport using Ga and PCl_3 as starting materials. The over-all reaction for the process can be represented by $5Ga + 2PCl_3 \rightarrow 2GaP + 3GaCl_2$. The undoped GaP obtained is p-type with carrier concentration ~10^{14} cm^{-3} and mobilities up to 150 cm^2 v^{-1} sec^{-1} at 300°K. The transport properties as well as the mass spectroscopic analysis are presented and demonstrate the high purity of the GaP. The addition of water vapor to the hydrogen carrier gas progressively raises the resistivity of the p-type epitaxial layer. Semi-insulating GaP has been produced by this method with resistivities over 10^{10} ohm cm.

Gallium phosphide has been grown by many variations of the vapor transport process starting from the presynthesized polycrystalline form (1) as well as from the elements, Ga and P, themselves (2). In the present investigation Ga and PCl_3 were used as starting materials.

The two major objectives were to ascertain the over-all mechanism of the process and to study the influence of water vapor in the carrier gas on the nature of the epitaxial deposit.

Experimental Procedure

The apparatus used is shown schematically in Fig. 1 and is similar to the one reported by Oldham (3). Some innovations of special significance are the use of an Engelhard palladium diffusion purifier for the hydrogen carrier gas and the fully glass-enclosed solenoid-operated valves which eliminate all greased joints and valves for controlling gas flow. Low flow rates of hydrogen (30-80 cm^3 min^{-1}) plus the use of a bubbler in the gallium boat ensure thorough mixing of PCl_3 and Ga at the source temperature. The temperature profile was optimized to grow pure gallium phosphide. The source and substrate temperatures were comparatively low and gave GaP with minimum contamination from the GaAs substrate and the quartz reaction tube. The graded junction normally formed between GaAs and GaP was held to a minimum even though this resulted in some strain in the epitaxial layer. The minimum temperature for epitaxy at a practical growth rate (~10 μ/hr) was found to be about 780°C. The flow rates used were about 35 cm^3/min. H_2 through PCl_3 kept at 0°C. The ice point was chosen because the vapor pressure of PCl_3 is a rapidly varying function of the temperature and accurate control of this parameter is essential to maintain steady growth conditions at the substrate. The (111) A face of n-type GaAs was used for deposition as it proved to be the best suited for rapid growth of a

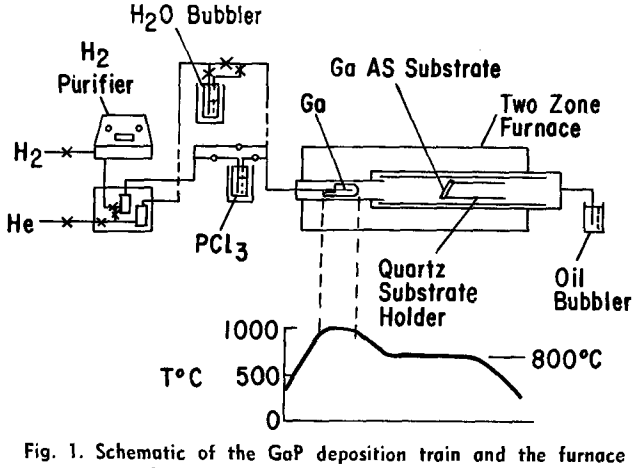

Fig. 1. Schematic of the GaP deposition train and the furnace temperature profile.

homogeneous epitaxial layer. The deposition rates were about 40 μ/hr and layers grown varied from 200μ to a few millimeters in thickness.

After deposition, the GaAs was removed with aqua regia and the side of the epitaxial layer adjacent to the GaAs lapped to remove any graded junction. This procedure yielded single crystals of GaP with arsenic contamination of only a few hundred ppm. Previous studies report an arsenic impurity in the per cent range (4, 9). Another important observation singular to the present work is that p-type GaP was invariably obtained in the normal undoped runs. Comparable experiments in the literature report low resistivity n-type deposits (3, 4), presumably due to sulfur or other impurities.

X-ray Laue patterns as well as etching and polishing studies confirm the epitaxy of the GaP, and optical absorption measurements from 0.4-10μ indicate the material to be pure with no detectable GaAs contamination. The purity of the samples is further confirmed by mass spectroscopic analysis, the results of which are given in Table III.

A slight modification of the apparatus was made to study the effect of water vapor on the deposit. Figure 1 shows the side arm with the water bubbler at a controlled temperature. It permits the addition of known amounts of water vapor into the carrier gas.

Electrical resistivity and the Hall coefficients were measured on several representative samples as a function of temperature. The contacts used were mainly pressure type to gallium dots ultrasonically applied to the clean GaP surface. When properly prepared, these contacts were found quite satisfactory for p-type material, i.e., ohmic and low resistance.

Results and Discussion

The over-all reaction.—The three possible reactions that should be considered are the following.

$$2Ga + PCl_3 \rightarrow GaP + GaCl_3 \quad [1]$$

$$5Ga + 2PCl_3 \rightarrow 2GaP + 3GaCl_2 \quad [2]$$

$$4Ga + PCl_3 \rightarrow GaP + 3GaCl \quad [3]$$

It must be emphasized that only the over-all reaction is being considered in its simplest form. The data now available does not warrant a discussion of the many complex intermediate steps.

Even the actual reaction probably involves more than one of these, but it was hoped one would be dominant. It has been assumed in the literature (5) that [1] is the most probable from analogy with the comparable GaAs reaction and because $GaCl_3$ is the most stable chloride. Preliminary results from the present investigation were inconsistent with this postulate, and this led to a systematic study of the over-all reaction mechanism. The pertinent data given in Table I covers over 50 deposition runs.

Column 3 shows the agreement between calculated and observed values for the amount of PCl_3 used to transport 50g of gallium. This quantity can be measured accurately by difference in volume before and after the run. On the contrary, the amount of gallium phosphide formed (column 4) is difficult to determine since it is in large part deposited on the quartz tube and cannot be removed completely. Both values are

10	1	10^8	10^{-13}
4	10	10^{10}	10^{-12}

seen to be in good agreement with those predicted by reaction [2]. Further, the grayish halide deposited at the cool exit side of the reaction tube can be shown to be $GaCl_2$, with properties (such as the melting point) described by Laubengayer and Schirmer (6). The dichloride invariably shows some dissociation into Ga + $GaCl_3$. These results suggest that [2] is the dominant over-all reaction under the conditions of transport.

Water vapor experiments.—The addition of small amounts of water vapor to the carrier gas affects the properties of the epitaxial layer drastically as can be seen from Table II.

The resistivity of the layer rises with increasing partial pressure of water vapor in the carrier gas. The role of oxygen in raising the resistivity of III-V compounds in general is well known (7). As the effect here is quite similar, it was assumed that the water vapor acts as a source of oxygen in the reaction zone. This led to the rough estimate of the oxygen present in the gas as follows. The concentration of water vapor in the carrier gas was determined from the flow rate of hydrogen through the water bubbler. Using the dissociation constant of water (18), the equivalent partial pressure of oxygen was calculated for the highest temperature in the reaction zone. This was used for making a qualitative comparative estimate of the amount of oxygen in the reaction zone. The complicated nature of the various reactions in the total process precludes any refined quantitative approach. The point of interest is that the use of water vapor allows the addition of oxygen to the hydrogen in concentrations less than 1 ppm. The values obtained appear in column 4, Table II.

Over thirty runs were made with controlled addition of water vapor into the hydrogen carrier gas. The results show that, with increasing water vapor concentration, the epitaxial layer stays p-type until extensive gallium oxide formation takes place. There is a systematic and reproducible variation in the resistivity of the GaP epitaxial layer as a function of the partial pressure of water vapor (p_{H2O}). In electrical characteristics, the acceptor level changes from 0.4 to 0.9 ev with increased p_{H2O}. The result is in agreement with the observations of D'Yakanov and coworkers (9).

The exact role of oxygen is not clear, and several possibilities suggest themselves. Oxygen may interact with the 0.4 ev level p-type impurity in two ways. (*i*) It may react with the impurity in the gas phase and prevent it from reaching the GaAs substrate or, (*ii*) it may be incorporated in the epitaxial layer and interact with the 0.4 ev level.

Mass spectroscopic analysis results show that if (*i*) is the mechanism, the variation in resistivity is not due to interaction of oxygen with Si as has been suggested for GaAs (10), since Table III shows that similar amounts of Si are present in both high and low resistivity samples. It can also be seen from the data that there is no systematic variation of any detectable impurity with the resistivity of the layer. The possibility remains that the impurity concerned may be one below detection limits.

The alternative (*ii*) is more complicated. As a donor, oxygen could act as a compensating n-type impurity. Gershenzon and co-workers (8) indicate a 0.47 ev donor level for oxygen. Such a level should give rise to n-type conductivity when the oxygen concen-

* All values for impurity concentrations are in parts per million. Detection limits for most impurities 0.01-0.1 ppm.

tration is progressively increased. No such change has been observed which might indicate that the oxygen level, if present, is much deeper. If the oxygen level were deeper than the 0.9 ev acceptor level, it could compensate the 0.4 ev acceptor level, but never achieve high enough electron concentration to yield n-type samples. Alternatively the solubility of the oxygen may be governed by the concentration of the acceptor impurity at the 0.4 ev level. Identification of, and controlled doping experiments with, the acceptor and oxygen are necessary to determine which of these alternatives is the controlling factor in producing high resistivity GaP layers. Until such studies are available, the above models will have to be tentative suggestions only.

Several samples were analyzed by mass spectroscopic methods, and the results appear in Table III. The classic impurities in III-V compounds like groups II and VI and copper are below detection limits. The absence of several of these with shallow levels in the forbidden band, especially the group VI, is further confirmed by the transport properties given in the next section. The group III and V impurities present should be electrically neutral. The main impurity detected, silicon, does not seem to play the role generally allocated to it. Previous results (11, 12) report it to be a net shallow donor. At least at concentrations below $10^{17}/cm^3$ this is in disagreement with the present data. In this region silicon would have to be either self compensating or a net acceptor. Recent results on electroluminescence (13) in gallium phosphide infer the possibility of Si having a p-type level in GaP. Only a much more detailed study can lead to an unequivocal solution to this problem.

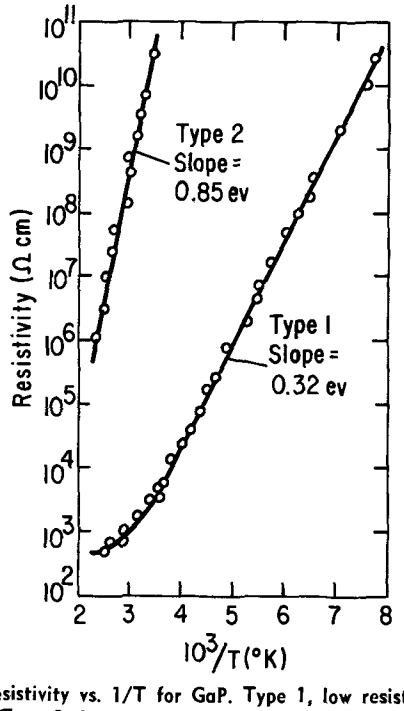

Fig. 2. Resistivity vs. 1/T for GaP. Type 1, low resistivity p-type (undoped); Type 2, high resistivity p-type (doped).

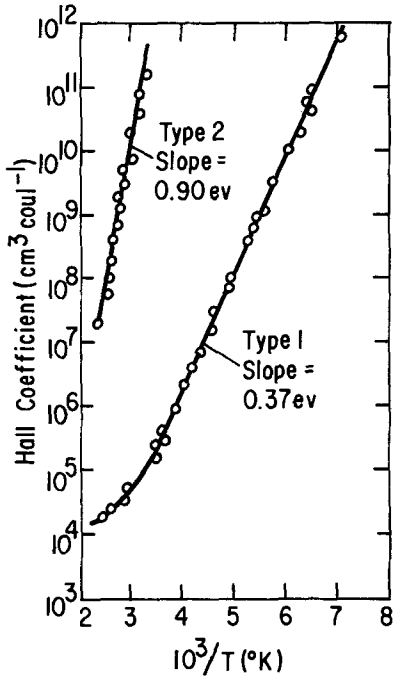

Fig. 3. Hall coefficient vs. 1/T for GaP, type 1* and type 2* (* see Fig. 2).

Transport properties.—Figure 2 shows the resistivity as a function of temperature for two types of samples; type 1, undoped low-resistivity p-type; and type 2, high-resistivity material grown at $P_{H_2O} > 0.1$ mm Hg (vide Table II). Type 1 ranged up to 10^6 ohm cm (300°K) in resistivity whereas type 2 exceeded 10^7 ohm (300°K).

Figure 3 gives the Hall coefficient as a function of temperature for the same samples. Since the Hall coefficient has a linear variation over six orders of magnitude a one-carrier system is assumed and the Hall mobility is then given by $R_H\sigma$.

Figure 4 represents the Hall mobility as a function of temperature for the two sets of samples. All type 1 samples show a similar variation in resistivity and Hall coefficient over a wide range of temperature. Type 2 samples could only be studied over a small

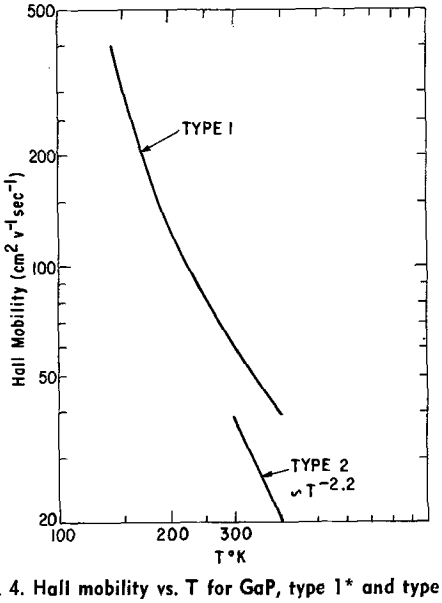

Fig. 4. Hall mobility vs. T for GaP, type 1* and type 2*

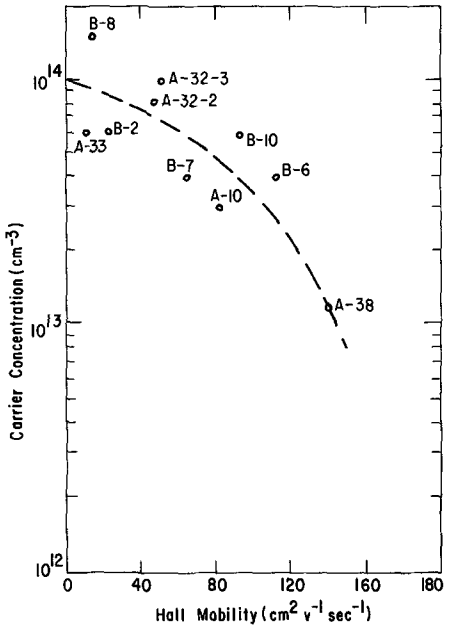

Fig. 5. Carrier concentration vs. Hall mobility at 300°K

range of temperature due to their high resistivity. The $T^{-2.2}$ dependence observed, consequently, has limited significance.

It is instructive to compare the results on type 1 samples with those in the literature. Alfrey and Wiggens (14) reported some results on p-type material with a carrier concentration $\sim 10^{17}$ cm^3 and mobility $\mu \sim 70$ $cm^2\ v^{-1}\ sec^{-1}$. They found that μ varied as $T^{-3/2}$ above 100°K and attributed this to acoustic mode scattering. Below 100°K their data indicated a dominance of impurity scattering. Their acceptor impurity was a shallow one at 0.04 ev and was not identified. Essentially similar results were reported by Nasledov and Slobodchikov (15) and Allen and Cherry (16) for p-type material. Using a largely empirical and semi-qualitative approach Allen and Cherry also postulated a limiting mobility of ~ 250 $cm^2\ v^{-1}\ sec^{-1}$ and an effective mass ratio for holes ~ 0.5.

The present data for type 1 samples gives an exponential μ *vs.* T dependence below room temperature. Such a behavior indicates screened polar scattering following Ehrenreich's (17) calculations for III-V compounds, although the magnitude of the mobilities can be explained fully only by assuming some other form of scattering also to be present.

Figure 5 shows the carrier concentration as a function of Hall mobility at 300°K for a number of type 1 samples. Although the scatter is quite large, and only one high mobility, low carrier concentration point is shown, it is felt that the dashed line shows a general trend indicating a limiting Hall mobility of the order of 180 $cm^2\ v^{-1}\ sec^{-1}$. Therefore, using arguments similar to those advanced by Allen and Cherry, a hole effective mass ratio somewhat less than their value of 0.5 is likely. This lower value would be in agreement with a greater predominance of optical polar scattering which has been observed.

In summary, the present study has helped establish the over-all reaction for the open tube transport process for the synthesis of GaP from Ga and PCl_3. It also provides a method for growing epitaxial layers of GaP with controllable resistivities in the range 10^2-10^{11} ohm cm by incorporating known levels of water vapor into the carrier gas. Results on the electrical and transport properties of single crystal epitaxial GaP obtained are reported.

Tracer Evaluation of Hydrogen in Steam-Grown SiO_2 Films

P. J. Burkhardt

Components Division, International Business Machines Corporation,

East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Silicon wafers were oxidized in capsules at 1000°C with 1 atm of tritium-tagged steam. The oxide films formed were investigated by conventional tritium counting techniques. The hydrogen profile suggested a complementary error function type in-diffusion of water, giving a C_o of 4 x 10^{19} molecules of H_2O per cm^3. The profile had a minimum value at around 600Å oxide thickness. The location of this value was independent of original oxide thickness. Following this minimum, the concentration again increased as the Si/SiO_2 interface was approached. The concentration of hydrogen near this interface was greater for the thinner oxide films. This observation led to the conclusion that either a hydrogen-containing intermediate is formed by the reaction between water and silicon and that the concentration of this intermediate is dependent on the oxidation rate or that a transition region exists in the oxide film which permits segregation of the diffusant near the Si/SiO_2 interface. Thermal biasing experiments followed by surface charge measurements and autoradiograms showed that mobile positive charge was present in the oxide near the Si/SiO_2 interface. However, this mobile charge was not hydrogen or a hydrogen-containing species. Out-diffusion experiments yielded an activation energy of 15.7 kcal/mole for the tritium species.

The rapid development of planar transistor and surface field effect transistor technology has brought with it an increasing demand for a better understanding of the insulator films that are used for diffusion masks and surface passivation, as well as for electrical insulators. In silicon technology, a film of thermally grown silicon dioxide has proven to be both effective and convenient. These films, originally suggested by Atalla *et al.* (1) are normally grown at temperatures of 1000°-1200°C in ambients of dry oxygen, pure steam, or oxygen-containing water vapor. Steam oxidation is the faster method and is therefore quite popular. The steam cycle is usually preceded by a period in either oxygen or inert gas to allow the silicon to come to temperature. Following the steam cycle, a final period in a dry ambient is sometimes used to "dry out" the oxide.

Kuper and Nicollian (2) have made a study of steam-grown oxides formed on ring-dot diodes and have noted that an n-channel is formed after steam oxidation. Treatment of these devices in a dry ambient at elevated temperatures tended to reduce the channel. Olmstead *et al.* (3) studied surface inversion under an oxide film by measuring channel resistance and found that annealing in forming gas produced an n-channel. Subsequent etching experiments showed that the region of oxide responsible for the channel was within 400Å of the Si/SiO_2 interface.

Balk (4) has found by electron spin resonance (ESR) studies of thermal oxides that an ESR peak occurs only when the final preparatory step does not include a hydrogen-containing species. Thus, steam oxides have no unpaired spins while steam oxides subjected to a period in dry oxygen do. Recently, Nishi (5) reported ESR studies which appeared to contradict Balk's findings. He reports resonance absorption centers produced by hydrogen annealing which can be removed by subsequent annealing in dry oxygen. Balk (6) also found that annealing of dry-oxygen-grown oxides in hydrogen increased the field effect mobility of electrons at the silicon surface. The field effect mobility of devices made using steam-grown oxides was higher than that for dry-oxygen-grown oxides. He further concluded that the primary effect of hydrogen was the annihilation of fast surface states. The fixed charge in the oxide played only a secondary role. The degree of reduction of the fast surface state density depended on the amount of hydrogen in the film, and, consequently, the field effect mobility of devices annealed in pure hydrogen was greater than that of devices annealed in forming gas or unannealed steam-grown oxides. These surface states are probably singly occupied nonbonding orbitals on silicon atoms which also give rise to the ESR peak and can be removed easily by the formation of highly covalent bonds with hydrogen atoms.

This study using oxides grown with tritium-tagged steam was undertaken to observe the disposition of hydrogen and perhaps to shed more light on the mechanism of steam oxidation.

Experimental

Sample preparation.—The oxidations were carried out in fused silica capsules. Each capsule contained several vapor-polished 2-10 ohm-cm p-type silicon wafers that were spaced apart by small indentations in the capsule wall. Each capsule also contained an amount of T_2O-enriched water which would produce 1 atm of vapor when the capsule was placed into a 1000°C furnace. The capsules, of course, were large enough so that the consumption of water vapor by the wafers and walls did not significantly reduce the partial pressure of water vapor in the ambient.

The loading of the capsules with a controlled amount of water was done with the apparatus shown in Fig. 1. The source water, obtained from the New England Nuclear Corporation, contained a T_2O enrichment of 0.5 Curie/g. The ampoule in which it was received was placed in liquid nitrogen to freeze the water, and then scored, opened, and dropped into the

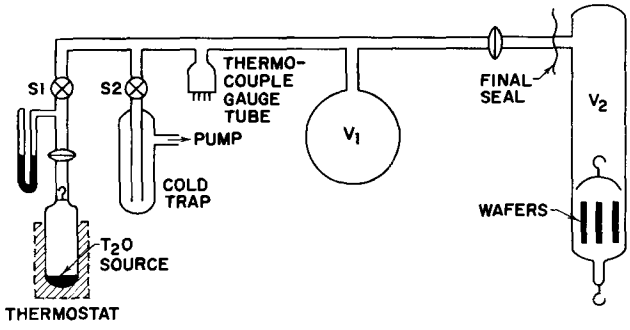

Fig. 1. Apparatus for loading fused silica capsules with tritium-tagged water.

source flask which was immediately connected to the rest of the apparatus. The water was again frozen in the source flask with liquid nitrogen, and the entire system was evacuated with an oil pump to a pressure of about 10μ. Next the source flask was thermostated slightly below room temperature (to avoid condensation in the rest of the system) and the source water vapor expanded into the entire apparatus until the equilibrium vapor pressure, determined by the thermostat temperature, was reached. Volume V_1 was chosen so that the amount of water in the entire system at the vapor pressure was the correct amount for subsequent condensation into the oxidation capsule.

The oxide thicknesses obtained by these capsule oxidations were within 5% of those obtained in a conventional flow system using 1 atm of steam.

Each capsule contained some 10 microcuries and had to be handled with care. The individual wafers however had less than 0.01 microcuries and could be handled conveniently. For the profiling and diffusion experiments, square sections having areas of about 0.6 cm^2 were cut. The oxide on the unpolished side was etched off with HF. Counting was done with a Nuclear-Chicago Model 6810 scintillation counter using a napthalene-dioxane base scintillant. Two counting methods were used in this investigation. The first involved counting the oxide directly on the wafer. For this method, a small aluminum pedestal was fastened to the base of the scintillant vial. The wafer section was placed on this pedestal, which located it near the middle of the vial. A guide edge was provided on the pedestal top so that the wafer section could be located precisely with respect to the counting phototubes. Finally, the vial was filled with scintillant and counted. Next, the wafer section was removed, rinsed in methanol, and placed in an etchant known as p-etch (7). This etchant, prepared by adding 15 ml of 49% hydrofluoric acid and 10 ml of 70% nitric acid to 300 ml of distilled water, removed SiO_2 at the rate of 2Å/sec at 24.7°C. To insure accurate etch rates, the etchant was thermostated in a water bath at 24.7° ±0.2°C. Following the etching, the thickness of the remaining oxide was checked with an SiO_2 step gauge calibrated by the VAMFO technique (8). Finally, the wafer section was again counted as before, and the process was repeated until the oxide had been completely removed. Below 1000Å, where the gauge was ineffective, the etch rate alone was used as the thickness criterion. In some instances where greater accuracy was required, the VAMFO technique was used. Steps ranging in thickness from 100 to 500Å were used, depending on the initial thickness of the oxide. This counting method produced smooth and relatively scatter-free curves, but was greatly affected by attenuation of the low energy betas in thick oxide films. This problem will be discussed later.

The second method involved counting of the etchant. Fifteen 3-cm-long polypropylene tubes 1 cm in diameter fastened onto a metal base with epoxy cement were used to contain 2 ml of the etchant. This entire assembly was thermostated, and etching proceeded by dipping the wafer section into a vial for a predetermined length of time. Between etches, the section was rinsed and, if possible, the remaining thickness was measured. In some instances, the section was also counted between etches. When etching was complete, a 1-ml aliquot was pipetted from each etchant vial into 15 ml of scintillant and counted. Because the counting sensitivity was extremely low, particularly when small steps were used, it was necessary to use this small volume of etchant to reduce the dilution factor.

Calibration of the scintillation counter for the etchant counting was done by comparison of the experimental count rates with that of a tritium water standard. Because small quantities of water in the scintillant tended to quench the light produced by the betas, calibration curves were prepared with varying amounts of added water and etchant. Quenching produced by the etchant was much more severe than that produced by water alone.

For the profiling of the SiO_2 films, both counting methods were used and interpreted according to their relative merits.

In another set of experiments, the rate of out-diffusion of the protonic species was investigated by baking wafer sections at constant temperature and observing the decrease of count rate with time. For these measurements, the wafer counting technique alone was used. Baking was done in a conventional tube furnace with a dry nitrogen flow of 250 cm^3/min.

Finally, the response of the protonic species to an electric field was observed by evaporating an array of 20-mil-diameter aluminum electrodes on the oxide surface. The MOS devices thus formed were thermally biased at 200°C with a d-c field of 2 x 10^5 v/cm for ½ hr. Both positive and negative biases were used. Capacitance-voltage curves were measured before and after biasing. [For a more detailed description of these techniques see ref. (9) and (10).] Following the thermal-bias treatments, the electrodes were removed with a nitric acid aluminum etch, and the oxide was etched down to 1000Å or less with p-etch. Kodak KK x-ray film was then applied, and autoradiograms were made. The exposure times of these autoradiograms ranged from two weeks to one month.

Results and Discussion

For the profiling experiments, the greatest precision was obtained by the wafer counting technique. This method provided smooth scatter-free curves, as shown in Fig. 2 and 3. Because the tritium betas are of such low energies, attenuation becomes a serious problem in films thicker than 1000Å.

When the oxide is sufficiently thin, betas from the entire oxide contribute to the count and, consequently,

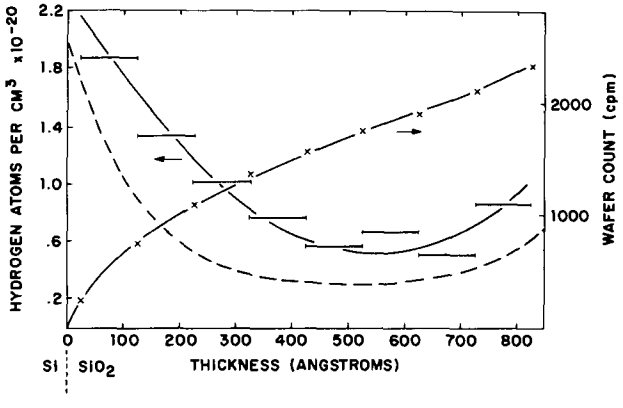

Fig. 2. Wafer count rate vs. thickness and etchant count profile for an 820Å SiO_2 film. The dashed line represents the derivative of the wafer count curve on an arbitrary scale.

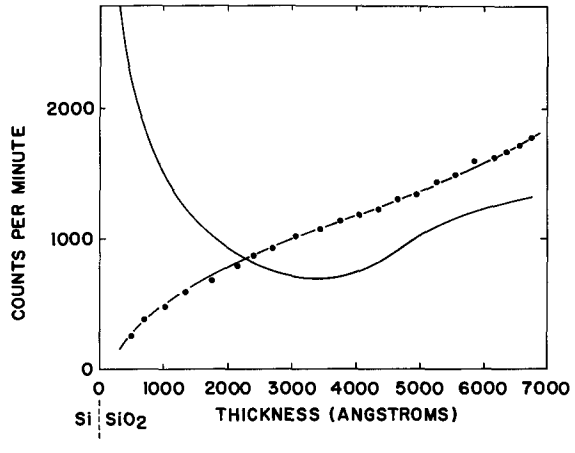

Fig. 3. Wafer count rate of a 6750Å SiO_2 film. The solid line represents the derivative of the count rate curve.

the derivative of the wafer count curve is proportional to the proton concentration in the removed section. To determine the maximum thickness of oxide in which attenuation effects are negligible, it was necessary to calibrate carefully the scintillation counter in terms of beta particle energies and to determine what portion of the beta energy spectrum the counter was capable of measuring. This was done by counting a solution of tritium-tagged water in scintillant at progressively widening energy windows. The lower limit of the energy window remained fixed. The count intensity difference between adjacent windows was taken to be representative of the density of betas having energies equal to those just above the energy maximum of the smaller window. As the window was gradually opened, the count rate increased with decreasing rapidity until finally further expansion of the window produced no more increase in count rate. At this width, betas of all energies were counted, including the highest energy, which was used as a reference calibration. This maximum energy is 18.6 kev (11). Figure 4 shows the beta energy spectrum as determined by this method. The voltage scale represents the counter discriminator voltages that are proportional to the beta energies by a constant determined from the maximum energy of 18.6 kev, which was taken to be at the position shown in Fig. 4. From this calibration, it was found that the lower cut-off limit of the counter was about 1.5 kev. An effort to locate the maximum energy by counting from a low voltage to infinity and continually raising the lower limit of the energies counted was unsuccessful because, as the lower limit was increased, it was necessary to use higher and higher concentrations of tritium in order to maintain a measurable counting rate. This increase, in turn, led to interference from coincidence counting.

It is obvious from Fig. 4 that an accurate energy calibration point for the scintillation counter could not be obtained by using the maximum beta energy of tritium alone. To verify the calibration, a sample of $_{27}Co^{57}$ was used to give another calibration point. This isotope decays to $_{26}Fe^{57}$ by electron capture and gamma emission. The electron capture results in the emission of a 6.4 kev x-ray (12). The three gammas released to relieve the nucleus from its excited state

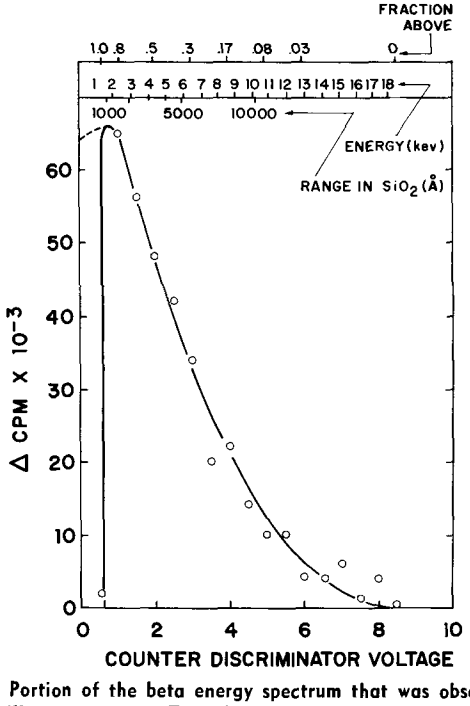

Fig. 4. Portion of the beta energy spectrum that was observed by the scintillation counter. The three scales at the top represent, respectively, the fraction of betas having energies above a certain point, the actual beta energy, and the effective range in SiO_2.

have energies of 14.4, 121.9, and 136.3 kev (13). By examining the spectrum of this isotope in the region of interest, peaks from the 6.4-kev x-ray and the 14.4-kev gamma could produce calibration points. The 14.4-kev gamma peak was found to yield a threshold energy of 1.7 kev for the tritium betas, which is in good agreement with the previous estimate.

The fraction scale in Fig. 4 represents that portion of the total observed tritium betas which have energies greater than that indicated by the same point on the energy scale. This was obtained by integrating the area under the curve. Thus, for example, about 50% of the observed betas have energies greater than 4 kev.

The next problem to be considered is that of the effective range of monoenergetic electrons in silicon dioxide films. For this we refer to the work of Holliday and Sternglass (14), who have made range measurements and who also present data from other authors. In their Fig. 5 they show a nearly linear relationship of the logarithm of effective range (in mg/cm^2) and the logarithm of the primary electron energy from about 1 to 10 kev. Assuming this linear relationship and using a density of 2.2 g/cm^3 for silicon dioxide (15), one obtains a relationship between range in SiO_2 and initial electron energy of

$$d = 5 \times 10^{-6} E^{1.29} \quad [1]$$

where d is the range in cm and E the energy in kev. Recent measurements of effective range of monoenergetic electrons in SiO_2 films by the back-scatter technique indicate that the constant 5×10^{-6} in [1] is slightly low (16). The range in SiO_2 for various energies obtained by using [1] is shown by the range scale in Fig. 4. This scale takes into account the fact that a beta coming out of the SiO_2 film must have an energy of at least 1.5 kev to be counted. Examination of these scales indicates that about 90% of all the tritium betas are capable of penetrating a SiO_2 film 1000Å thick and being counted. Thus, the count rate profile for the 820Å film shown in Fig. 2 may be translated directly into concentration units by plotting the derivative of the curve. This derivative is shown in arbitrary units by the dashed line in the figure. What is immediately apparent from this figure is that the concentration of protonic species increases markedly very near the Si/SiO_2 interface.

The profile for this oxide, obtained by etchant counting, is also shown in Fig. 2. The thicknesses of the etch steps taken here were determined by the etch rate alone. For very thin oxide films, the etch rate is reputed to be somewhat faster than for thicker films (17). This factor was taken into account in determining the thicknesses of the very thin films. The appearance of hydrophobicity also served as an indication of oxide removal. Again, by etchant counting, it was found that the concentration of hydrogen increased near the Si/SiO_2 interface.

The wafer counting data for a thick oxide film (6750Å) is shown in Fig. 3. Also included in the figure is the derivative of the count curve which, of course, does not represent the concentration profile accurately. The increase of this curve toward the Si/SiO_2 interface does not represent an increase in tritium content in this direction but rather represents a decrease in attenuation effects. The etch count profile for this particular oxide is shown in Fig. 5 along with the corresponding profiles for 820 and 4400Å oxides. Note that in all cases we find what appears to be a normal in-diffusion profile over the bulk of the oxide. Assuming a complementary error-function diffusion profile, one may compute a diffusion coefficient. This coefficient, however, turns out to be much smaller than that obtained for water diffusion in SiO_2 (18). This may be due to the distortion of the profile during the cooling of the wafers following oxidation. Note that the hydrogen atom concentration near the outer surface of the oxides is about 8×10^{19} atoms/cm^3, which corresponds to 4×10^{19} water molecules/cm^3. This value is in good agreement with the value of 3.0×10^{19}

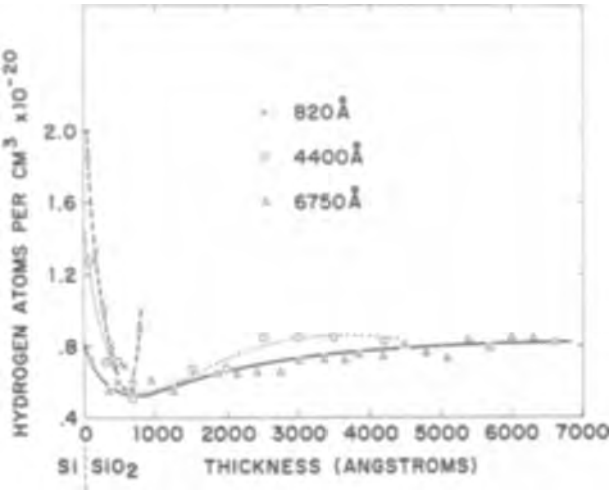

Fig. 5. Etchant count profiles for SiO_2 films of varying thickness

molecules/cm³ obtained for the solubility of steam oxidizing species in SiO_2 at 1000°C by Deal and Grove (19). Moulson and Roberts' (18) infrared value, also given by Deal and Grove, is 3.4 x 10^{19} molecules/cm³.

The data in Fig. 5 represent typical etch count profiles of oxides of various thicknesses. In all cases, the proton concentration began to rise again as the Si/SiO_2 interface was approached. The minimum always occurred in the neighborhood of 600Å no matter how thick the oxide was, indicating that the protonic species in this region was associated with the interface and not the diffusion. It is interesting to note here that the charged species observed by Olmstead *et al.* (3), which was responsible for producing n-channels in the silicon, was located in the region below 400Å. Possibly, it is an intermediate in the reaction between water and silicon. It thus remains near the reaction front until the reaction goes to completion and the product hydrogen then diffuses out rapidly. A potential gradient may also assist in confining the material in this region. This could also be affected by the doping. The steady-state amount of this intermediate behind the reaction front will depend on the rate at which the diffusant reacts with the silicon at the interface, which for practical purposes should be the same as the oxide growth rate. During the early stages of oxidation, the growth rate is very large and is determined by the concentration of oxidant in the gas phase. As the film thickens, the growth rate decreases parabolically. The amount of intermediate will then be greater in the thinner films, which were quenched when the growth rate was the greatest. Comparison of the three curves in Fig. 5 shows that this is indeed the case. The presence of a transition layer in the oxide at the Si/SiO_2 interface could also cause the segregation of the diffusant species in the region below 600Å as well as result in a greater concentration of hydrogen in this region for the thinner oxides. If this transition layer exists, other species could be made to segregate in this region.

A 5-min bake at 1000°C of a 4400Å oxide in a nitrogen ambient was sufficient to reduce the beta count to background level. To make sure that the protonic species near the Si/SiO_2 interface had been removed by this treatment, half of the oxide was etched off and the wafer recounted. No activity was detected. The lower limit of detection for these experiments was estimated to be about 10^{17} hydrogen/cm³. To obtain some rate data on the removal of hydrogen containing species from the oxide film, a number of baking experiments were done in the temperature range of 500°-650°C. In this range, the wafer activity decayed at a conveniently measurable rate. The simplest physical process relating to this situation is the out-diffusion of material from a slab of thickness d into a large, well-stirred, ambient. The solution to this problem (20), where the initial concentration is uniform and one side of the slab is impermeable, is given by

$$M_t/M_o = 8/\pi^2 \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp - \left[\frac{(2n+1)^2 \pi^2 Dt}{4d^2} \right] \quad [2]$$

where M_t is the amount of material remaining in the slab at time t, M_o the initial amount, and D the diffusion coefficient. For sufficiently long times, this series may be approximated by its first term, leading to an exponential decay of M_t/M_o with time.

The slope should yield the diffusion coefficient if the thickness is known. The situation which we encounter here deviates from the ideal case in two respects: (*i*) the concentration is not uniform, although it does not vary greatly, and (*ii*) the wafer counting method that had to be used does not measure all of the material in a thick film because of attenuation.

The data obtained by baking out oxides of various thicknesses did indeed follow the pattern suggested by [2]. If we consider only the first term in [2], we have

$$M_t/M_o = (8/\pi^2) e^{-t/\tau} \quad [3]$$

where

$$\tau \equiv (4d^2)/(\pi^2 D) \quad [4]$$

Figure 6 illustrates the data for a number of runs on different oxides plotted against t/τ. Normalizing the data to $1/\tau$ has the effect of eliminating dependence on D and d. However, from [3] it is expected that the intercept of the line in Fig. 6 should be at log $8/\pi^2$ = log 0.812, which is not the case. Instead the intercept occurs at the lower value of log 0.59. One explanation for this would be the presence of another protonic species which was in the oxide at time zero, but diffused out very rapidly during the first bake. This situation would lead to an anomalously high value for M_o. If this were the case, the fast species concerned could not be the species located near the Si/SiO_2 interface. The reason for this is that this species could not contribute significantly to M_o, particularly in the thicker oxides, because of attenuation. Efforts to remove any fast species by prebaking at 200°C for ½ hr had no significant effect on the intercept. Consequently, a second fast species must be ruled out as the cause of the intercept deviation. The fact that the distribution of protons is nonuniform will alter the boundary conditions of the diffusion problem, which might lead to a different intercept.

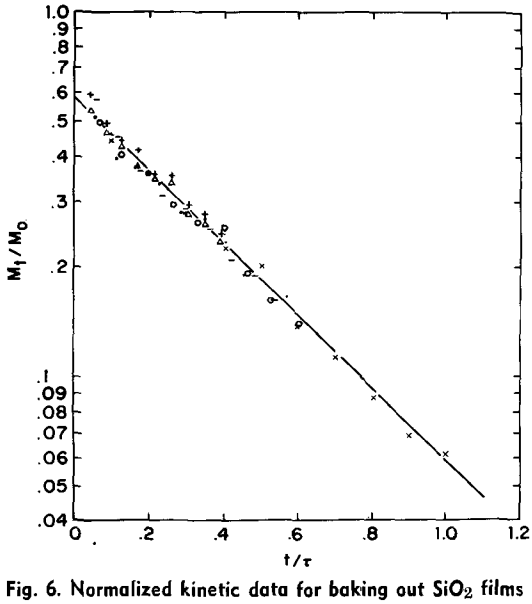

Fig. 6. Normalized kinetic data for baking out SiO_2 films

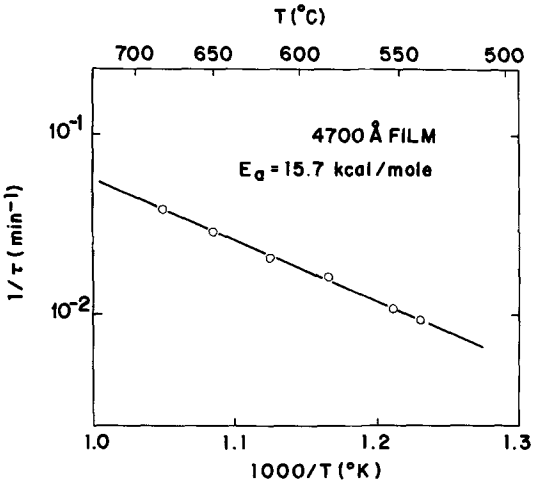

Fig. 7. Activation energy plot for a 4700Å SiO_2 film

From [4], one would expect an exponential temperature dependence of $1/\tau$ by virtue of the diffusion coefficient. The values of $1/\tau$ for a 4700Å oxide at various temperatures are presented in Fig. 7. The activation energy obtained from the slope of this line is 15.7 kcal/mole, which agrees well with that obtained by other authors. Table I gives the values of the activation energy and the pre-exponential of the diffusion coefficient obtained by several methods. The pre-exponential obtained by this work is some two orders of magnitude too low. This may be due in part to an isotope effect, especially if tritons are involved in the diffusion process.

The oxides which were electroded showed a large negative flat-band voltage from the C(V) trace corresponding to a negative surface charge in the silicon of 5×10^{12} charges/cm^2. Normally, oxides grown in a flow system with steam or by the dry-wet-dry method have surface charges of about 3×10^{11} per cm^2. We found that this initial large C(V) offset was characteristic of a capsule-grown steam oxide. Thermal biasing at 200°C for ½ hr showed a reduction of surface charge to about 1×10^{12} charges/cm^2 with negative bias on the aluminum electrode and only a very slight increase with positive bias. This indicates that a large amount of positive charge initially resides in the oxide near the Si/SiO_2 interface. During negative bias, this charge migrates away from the silicon. Positive bias has no significant effect.

It was expected that, if the migrating charge were associated with a hydrogen-containing species, the autoradiograms on the etched oxides would show the outlines of the electrodes for the negatively biased devices. However, the film appeared to be uniformly exposed, with no discernible electrode circles. This result suggests either that the positive charge initially in the oxide was not hydrogen associated or that it was initially on a proton, hydronium ion or some reaction intermediate and subsequently transferred to a silicon atom as follows

$$(\equiv Si - O - Si \equiv) + [RH]^+ \rightarrow (\equiv Si - OH) + [\equiv Si]^+ + R \quad [5]$$

Table I. Diffusion coefficient of water in silicon dioxide

Method	Author	E_a, kcal	D_o, cm^2/sec
Steam oxidation	Pliskin (21)	16.0	2×10^{-7}
Steam oxidation	Edagawa *et al.* (22)	23.0	1×10^{-6}
Wet oxygen oxidation	Deal (19)	16.3	2×10^{-7}
In-diffusion of H_2O	Moulson and Roberts (18)	18.3	1×10^{-6}
Out-diffusion of H_2O	Moulson and Roberts (18)	17.3	2.7×10^{-7}
Out-diffusion of T_2O	This work	15.7	2×10^{-9}

The formation and migration of the charged defect $[\equiv Si]^+$ is discussed in another paper (23).

Another method of charge transfer could be the replacement of a bound sodium ion by a proton, thereby rendering the sodium ion mobile. Such a possibility has been suggested (24) and can be described by

$$(\equiv Si - O - Na) + H^+ \rightarrow (\equiv Si - OH) + Na^+ \quad [6]$$

The presence of significant quantities of sodium in thermally grown SiO_2 films has been observed by neutron activation analysis (25).

Conclusions

The profiling experiments on steam-grown oxides of various thicknesses have suggested the possible existence of a reaction intermediate located in the oxide directly behind the reaction front. The concentration of this intermediate depends on the oxidation rate. Thus, the concentration is greater near the Si/SiO_2 interface in thinner films. Thermal biasing experiments suggest a positively charged species located near the Si/SiO_2 interface. Balk (4) has found that thinner oxides have greater surface charge than thicker ones, thus correlating the positively charged species with the hydrogen-associated species. Our autoradiograms suggested that the charged species which migrates at 200°C is not hydrogen associated. This could only be possible if (*i*) the positively charge species and the hydrogen associated species occur concurrently, as would be the case where a transition phase caused segregation of two species or (*ii*) the positively charged species and the hydrogen-associated species are initially one and the same and a charge transfer like that described by [5] or [6] takes place.

Burgess and Fowkes (26) have recently reported similar experiments using oxides grown with tritium-tagged steam in a flow system. They, too, have found that the hydrogen does not respond to an electric field. The results which are reported here for capsule-grown steam oxides are for the most part compatible with those of Burgess and Fowkes (26) for flow system oxides. There is a marked difference, however, with respect to the out-diffusion of hydrogen. Whereas we found an activation energy of 15.7 kcal/mole using the model described by [2], Burgess and Fowkes obtained an energy about twice as large from a first-order decay law.

Acknowledgment

The author wishes to express his gratitude to Dr. B. J. Masters for his assistance with the radiochemical techniques and to Mr. E. F. Roginsky for much of the experimental work.

Chemical Vapor Deposition of Mo onto Si

J. J. Casey, R. R. Verderber,[1] and R. R. Garnache[2]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Molybdenum has been deposited on single crystal silicon substrates by the vapor phase decomposition of molybdenum chlorides. The thickness, alloy phase, and crystalline nature of the films were studied as functions of substrate temperature, substrate orientation, and source material, using electron microscopy and reflection electron diffraction.

The present study, which originated from work on the deposition of thin film metal layers for the base region of hot electron devices (1), describes the composition and structure of thin layers of molybdenum and molybdenum-silicon phases formed by chemical vapor deposition on single crystal silicon. The fabrication parameters investigated were source material, substrate temperature, and crystal orientation of the substrate.

Previous studies of the molybdenum-silicon system have been mostly concerned with the forming of the disilicide to obtain high temperature corrosion resistant coatings. A monograph (2) on the binary silicides is available which describes the uses, properties, and formation of molybdenum-silicon phases and includes an extensive literature survey.

Experimental

Three series of depositions were made at various substrate temperatures in the range from 600° to 1350°C. Two of these series used molybdenum pentachloride as the source for the molybdenum deposition on (111) and (100) oriented silicon single crystals. The other series utilized a molybdenum oxychloride (MoO_2Cl_2) source on a (100) oriented silicon substrate. The system used to deposit the films is shown in Fig. 1.

A lapped, mechanically polished, and cleaned silicon wafer was placed on the pedestal in the reaction chamber and the system was purged with nitrogen. The wafer was then heated 10 min at 1250°C in a purified hydrogen flow of 1.5 l/min to remove oxides. An epitaxial layer of silicon was then deposited at 1200°C by the hydrogen reduction of silicon tetrachloride. This presented a fresh silicon surface to the molybdenum deposit. The molybdenum was then deposited by the decomposition of the molybdenum pentachloride or oxychloride for 20 min at the various substrate temperatures. The source material was heated in the reservoir chamber to 35°C and transported to the reaction chamber by the purified hydrogen flowing at 1.5 l/min.

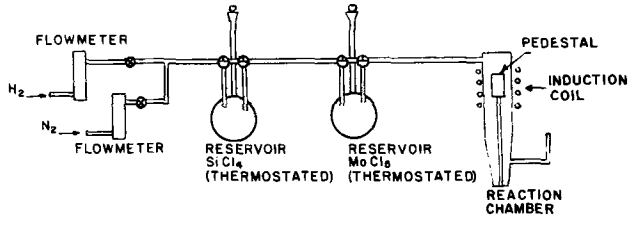

Fig. 1. Deposition system

Measurements

The crystal orientation of the substrates was known and the alloy phases and crystalline nature of each deposit were determined from the reflection electron diffraction data. For deposits that were single crystals, several diffraction patterns were taken at different azimuth angles to obtain the necessary data. Shadowed replicas were made of the surfaces to examine the morphology by electron microscopy.

The effective molybdenum thickness of the deposited molybdenum or molybdenum-silicon alloy was determined by the electron microprobe. The thickness was calculated from the ratio of intensities of MoL_α radiation measured for the film and for bulk molybdenum. The intensity ratio was corrected for x-ray absorption, the nonlinear trajectory of the primary exciting electrons, and the excitation by electrons backscattered from the substrate as described by Hutchins (3). The calibration factor was determined empirically by measurements of films of known thickness and also by interpolation of data for other elements.

For film thicknesses less than 10% of the total electron penetration depth, the corrections are small and the x-ray intensity is a nearly linear function of film thickness. The electron penetration may be controlled by adjusting the beam voltage. At 20 kv the MoL_α intensity is nearly linear up to a thickness of 1000Å of molybdenum.

The excellent sensitivity of the method is most easily demonstrated with an example of representative data (Table I). Relative accuracy depends primarily on counting statistics; absolute error depends primarily on the error in the calibration factor which may be as large as 10%. The measurement gives mass thick-

Results

$MoCl_5$ *Source and (100)* Si *Substrate.*—Table II lists the alloy composition, thickness, and crystalline nature of the layers deposited at the designated temperatures. At 800°C molybdenum-silicon alloys are formed which are molybdenum rich; at more elevated temperatures the deposited layers become more silicon rich until, at 1000°C, molybdenum disilicide is formed.

Deposits below 1000°C are all polycrystalline and have, at most, a small degree of orientation similar to a fiber aggregate (4). At 600°C the orientation is $(100)_{Mo} \parallel (100)_{Si}$ and at 700°C it is $(110)_{Mo} \parallel (100)_{Si}$. All other polycrystalline phases are randomly oriented. A single crystal phase appears at 1000°C and becomes highly developed at 1100°C, Fig. 2. The alloy phase of the 1100°C layer is molybdenum disilicide, and its orientation with respect to the silicon substrate can be described as $(001)_{MoSi_2} \parallel (100)_{Si}$ with $(110)_{MoSi_2} \parallel (010)_{Si}$. At 1200°C the film consists of large unoriented crystallites as evidenced by the occurrence of the diffraction spots on the diffraction rings of a molybdenum disilicide pattern, Fig. 2. These diffraction patterns also show Kikuchi lines typical of the silicon substrate.

The surfaces of the films are initially smooth and become rougher at higher substrate temperatures. From 1100° to 1350°C one observes cylindrically shaped growths protruding from a very smooth surface (Fig. 2). From the micrographs one can estimate the average size of the growths and the number per unit area can be counted. If one assumes that these growths represent the total $MoSi_2$ present, the average film thickness can be calculated and compared with the measured thickness. Pertinent data are presented in Table III.

The thickness data from the microprobe measurements are based on the assumption that all of the molybdenum determined by the probe is present as molybdenum disilicide, the equivalent thickness of which can be then calculated. Since the measured thickness values are several factors larger than the calculated ones, it must be assumed that either the growths do not represent all of the disilicide, or that some molybdenum has diffused into a thin surface layer of the bulk silicon, or that some other molybdenum-silicon phase is present, which does not contribute to the electron diffraction pattern under the experimental conditions. Insufficient data are available to allow unequivocal choice among these possibilities.

$MoCl_5$ *source and (111)* Si *substrate.*—The results from the experiments for the deposition on the (111) silicon substrate are listed in Table IV.

Molybdenum-silicon alloys initially form at 800°C. The alloys formed are metastable phases and have been tentatively identified as $MoSi_5$ and $MoSi_{12}$ by isomorphism (5) with the molybdenum-aluminum system (6). The structure of the phase tentatively identified as $MoSi_5$ has been determined from the diffraction pattern to be bcc with a_o equal to 7.6Å. The alloys formed become more molybdenum rich at higher substrate temperatures, finally becoming Mo_3Si. Above 1000°C the diffraction patterns (Fig. 3) become rather complex, and the corresponding alloy phases have not yet been identified.

The films deposited below 900°C are polycrystalline and randomly oriented. At 900°C epitaxial growth occurs and well-ordered single crystals are obtained at 950° and 1000°C (Fig. 3). However, a polycrystalline Mo_3Si phase is also present. The orientation of the single crystal phase with respect to the substrate can be described as $(110)_{Mo_3Si} \parallel (111)_{Si}$ with $[335]_{Mo_3Si} \parallel$

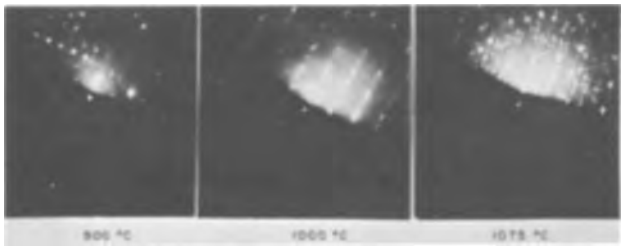

Fig. 3. Electron diffraction patterns of molybdenum deposited on (111) silicon substrate.

$[10\bar{1}]_{Si}$. At higher temperatures, the film consists of large crystals sufficiently disordered to result in a complex diffraction pattern (Fig. 3), and the alloy phase could not be determined.

The electron micrographs of these layers showed no peculiar growths as seen on the (100) silicon substrate and the layers could be described as having slightly rough surfaces.

MoO_2Cl_2 *source on (100) Si substrate.*—Table V lists the results for the series of depositions using the molybdenum oxychloride source material.

The deposits at 650° and 750°C were shown to contain molybdenum by microprobe analysis. Since they are amorphous, however, they cannot be positively identified. By analogy with the results in Table I, which show no silicide formation on (100) silicon at 600° and 700°C, it seems likely that these deposits are molybdenum, but this is not certain.

Discussion

The different alloy phases which are formed on the (100)- and (111)-oriented silicon substrates under similar experimental conditions indicate that the mechanism for alloy formation is different for the two orientations. At 850°C, a stable, molybdenum-rich alloy, Mo_3Si, is formed on the (100) surface, while unstable, silicon-rich alloys along with excess molybdenum are formed on the (111) surface. This difference can be accounted for by the different reactivities of the silicon surfaces which arise from the difference in atom densities. It is well known, for example, that the densely populated (111) silicon surface offers more resistance to chemical etching agents than the less populated (100) surface. A slow rate of reaction on the (111) surface could account for the initial formation of alloys deficient in molybdenum and for the presence of unreacted molybdenum in the deposited layer. In most cases 200Å films of molybdenum deposited at 800°C were found to be metallic, as determined by the attenuation of microwaves through the sample. These films, however, showed a 4-probe resistivity comparable to the silicon substrate. Furthermore, the line widths for the electron diffraction pattern for this specimen indicate that the molybdenum crystallite size is much less than 100Å. It is suggested that the phase tentatively identified as $MoSi_{12}$, unlike $MoSi_2$, Mo_3Si, and Mo_5Si_3, is nonmetallic, and that the whole layer consists of very small molybdenum crystallites in a $MoSi_{12}$ matrix. Further alloys are then formed with an excess of molybdenum available and become more molybdenum rich at the elevated temperatures. This explains the formation of Mo_3Si instead of the disilicide observed in the case of the (100) substrate. Studies of the kinetics of the formation of molybdenum silicides (7) show that Mo_3Si can be formed in a molybdenum-silicon system with excess molybdenum available by annealing at suitable times and temperatures.

Table V. Properties of phases deposited on (100) Si substrate by H_2 reduction of MoO_2Cl_2

Substrate temperature, °C	Alloy phase	Structure	Thickness, Å, Microprobe
650	Unidentified	Amorphous	85 (as Mo)
750	Unidentified	Amorphous	80 (as Mo)
850	Mo_3Si	Polycrystalline	77 (as Mo)
900	Mo_3Si	Polycrystalline	41 (as Mo)
1100	$MoSi_2$	Polycrystalline	10 (as $MoSi_2$)
1200	$MoSi_2$	Monocrystalline	21 (as $MoSi_2$)

The results show that the epitaxial growth is dependent on the substrate temperature, substrate orientation, and source material. As for any type of oriented overgrowth, a minimum temperature must be exceeded to obtain single crystal layers. The temperature is 1000°C for the $MoSi_2$-(100) silicon deposit-substrate pair and 900°C for the Mo_3Si-(111) silicon deposit-substrate pair. However, after a temperature is reached at which the films become well oriented, the orientation of films deposited at still higher temperatures deteriorates, and in the case of the (100) substrate the orientations are random. This indicates other factors are affecting the oriented growth.

The thickness data indicate a limiting deposit thickness at high substrate temperatures. Some clarification of this phenomenon was obtained when attempts were made to deposit molybdenum disilicides at 1200°C on the surface of silicon areas exposed by photoresist techniques on a thermally oxidized silicon surface.

Figure 4 is a photograph of a section of the surface polished on a bevel of 3°. The edge of the beveled section intersects two circular silicon areas on the otherwise oxidized surface. The surface of these areas, having a very thin layer of $MoSi_2$ after the reaction, is seen to lie below the level of the original silicon surface. It can be concluded that the silicon is slowly etched away by the hydrogen chloride and other chlorine-containing species in the reaction ambient. [The reaction of silicon with hydrogen chloride at elevated temperatures has been studied by many authors, among them Lang and Stavish (8).] The thin layer of disilicide deposited may be the result of a steady-state reaction, or it is possible that it is not deposited at all at the high temperature, but only during the cooling period as a result of the desorption of some molybdenum-containing species from the walls of the reaction chamber and subsequent reaction with the exposed silicon surface.

The occurrence of the cylindrical growths on the top (100) silicon surface and their variations in characteristics with temperature are interesting. The formation of a lower density of nuclei on the (100) surface than on the (111) surface is indicated, implying a high mobility of molybdenum atoms on the (100) surface compared to that on the (111) surface. This is particularly true at the higher temperatures, where the growths are larger and less numerous. These

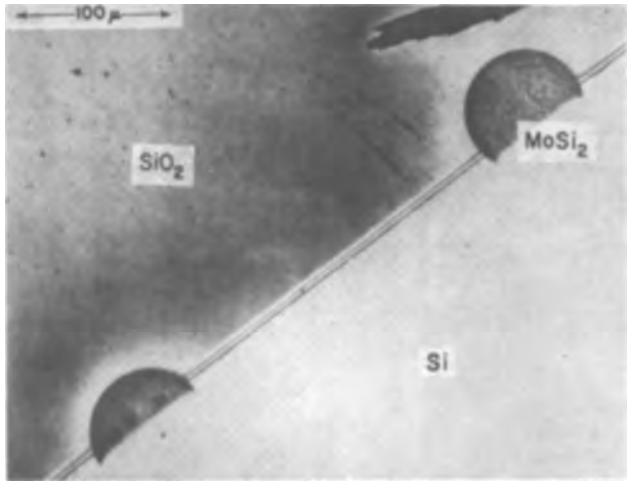

Fig. 4. Beveled section of molybdenum deposited on a masked silicon wafer showing the metal deposit below the initial silicon surface.

phenomena appear to be consistent with Haneman's (9) concepts of the atom arrangements and bonding characteristics on clean surfaces of semiconductors with the diamond structure, arrived at through interpretation of low energy diffraction studies of such surfaces after ion bombardment and vacuum anneal. Freshly formed epitaxial silicon surfaces such as those used as substrates in the present experiments can approach a high degree of perfection and cleanliness and might, therefore, be similar in character to the surfaces studied by Haneman, particularly at high temperatures, where a minimum of gaseous ambient would be adsorbed to the surface. Haneman's model of the (111) surfaces gives s-type bond character to the dangling bond on every other silicon atom in every other row of atoms, and also raises it slightly above the surface, while the dangling bonds on the remainder of the silicon atoms have p-character. Maximum overlap with the orbitals of approaching molybdenum atoms would be offered by the dangling s-bonds, providing a high uniform density of energy minima, which could tend to initiate a high density of nuclei and would result in a very smooth surface, as observed experimentally. The structural model proposed by Haneman for the (100) surface can be interpreted as resulting in dangling bonds which are mostly p-type in character, offering little overlap for the orbitals of approaching molybdenum atoms. The mobility of the molybdenum atoms would be unimpeded, and a smaller number of nuclei would be formed resulting in the type of growth observed in the (100) surface. The nucleation on these surfaces could arise more at the sites of impurity centers and micro-irregularities, which are generally accepted requirements for the initiation of epitaxial growth nuclei, and the high mobility would account for the growth of larger deposits at the higher temperatures. This model is in accord with concepts expressed by Pashley in his reviews on epitaxial growth (10, 11).

The effect of oxides on the crystalline growth is readily seen from the results using the molybdenum oxychloride source. The crystalline nature of the film is considerably poorer over the entire range of substrate temperatures, indicating that oxide contaminants inhibit the formation of a single crystal thin film.

Summary

This study shows that molybdenum can be deposited on a silicon substrate by the decomposition of $MoCl_5$ or MoO_2Cl_2. Under suitable conditions of temperature and source purity, highly oriented thin films can be grown. The process of alloy formation is critically dependent on the orientation of the substrate, and the thickness of the deposit is limited by an etching process occurring at high substrate temperatures.

Acknowledgments

The authors gratefully acknowledge the efforts of A. Harvin for her contribution in supplying the electron diffraction and electron microscopy data and determining the alloy phases, and Mrs. G. Hutchins for microprobe determination of film thicknesses.

Technical Note

Gas Phase Etching of Sapphire with Sulfur Fluorides

H. M. Manasevit and F. L. Morritz

Autonetics, A Division of North American Aviation, Inc., Anaheim, California

The quality of epitaxial films of silicon grown on sapphire is greatly affected by the quality of the substrate surface (1-3). Processing with diamond has been, generally, a practical requirement for cutting and polishing sapphire substrates. Unless, however, stringent care is taken to polish the surface properly, various size scratches will remain. These scratches affect the nucleation mechanism and, consequently, the silicon overgrowth. Some success in "fine scratch" removal can be effected by a final alumina buff, but the fine powder frequently fills deep scratches and leaves a surface that appears optically to be scratch-free. The usual high-temperature etching prior to deposition can remove this material and expose a rather poor surface for the epitaxial growth of silicon.

Attempts at scratch removal using "wet" chemical techniques appear to have been only partially successful (3, 4). The usual etchants for sapphire (orthophosphoric acid, sodium borate, potassium carbonate, sodium hydroxide, potassium hydrogen sulfate, lead (II) fluoride, and potassium tetrafluoroaluminate) tend to be quite sensitive to orientation and temperature. Usually, polishing can be effected by these agents, but rates cannot be controlled sufficiently to provide the smooth, flat surfaces desired for epitaxial growth.

In addition, any residual surface contamination due to the etchants, even if not optically visible after polishing, can affect the epitaxial process. Furthermore, other wafers in the same system can be contaminated by transfer of residual material. For these reasons, it was thought advisable to study the feasibility of gas phase etchants for sapphire removal. Hydrogen gas has been used (1, 3, 5, 6) to treat sapphire in the reactor prior to deposition, but the etch rate is very low below 1500°C. Its "cleaning" capability is probably due, for the most part, to removal of the polycrystalline alumina residue remaining after optical polishing of the sapphire. Hydrogen chloride (HCl) reacts with sapphire (7) and was found to be a polishing etchant for sapphire at pedestal temperatures exceeding about 1400°-1450°C (8), but the low attendant etch rate of 0.1 μ/min may not be considered practical for removal of considerable surface work damage (or deep scratches).

This paper reports on the successful use of sulfur fluorides as polishing etchants for sapphire. Reactivity of the sulfur fluorides with other oxides had been established at room temperature and below (9, 10), but their use as etchants for aluminum oxide and other oxides at high temperatures has not been reported previously.

Experimental

Apparatus.—A vertical-reactor system similar to that used in our research laboratories for epitaxial growth (11) was used in performing the etching studies. Palladium-diffused hydrogen and a commercial grade helium were used in the studies. Sulfur tetrafluoride (nominally 90-94% pure) and sulfur hexafluoride (nominally 99.99% pure) were used without further purification.

The experiments were usually performed on 0.5-in. diameter sapphire windows, 0.010-in. thick, with $(1\bar{1}02)$ and $(11\bar{2}3)$ orientations. Substrates were heated indirectly while resting on a 3-mm thick alumina spacer which rested on an inductively heated carbon pedestal (except where indicated). The spacer minimized interaction between the substrate and pedestal and provided an even heat distribution. The etching gases were monitored on No. 600 Matheson flowmeters (a sapphire float for SF_4; a Pyrex float for SF_6), and the gases were introduced directly into the flowing H_2 or He ambient at approximately 1 atm total pressure. Carrier gas flow rates were arbitrarily set at 2.5 l/min. Pedestal temperatures were measured with an optical pyrometer, and uncorrected values are reported. They are estimated to be 50°-100° higher than the actual substrate temperature.

Results and Discussion

With SF_4.—Small amounts of SF_4 (less than 1 mole %), diluted with H_2 or He, effectively etched sapphire. After etching at silicon pedestal temperatures of about 1150°C (observed), fluorine compounds were detected on the sapphire surface by electron microprobe induced x-ray fluorescence. AlF_3 formation [presumably epitaxial because of its oriented nature on $(1\bar{1}02)$ sapphire] was suggested by the two-dimensional distribution of aluminum and fluoride which were obtained by electron microprobe techniques (Fig. 1). However, this growth was not observed when gas-phase etching was performed at about 1300°C. Presumably at this temperature the vapor pressure of the material was high enough so as not to interfere with the etching process. Etch rates of about 2 μ/min at carbon pedestal temperatures of 1450°C left highly polished scratch-free surfaces on good quality substrates. Major grain boundaries in sapphire were accentuated by the etching process (see Fig. 2).

With SF_6.—Since pyrolysis of the SF_4 produces sulfur and sulfur hexafluoride (10), the use of the latter was investigated to determine if, indeed, its *in situ* formation might be an important factor. It was found that SF_6 etched sapphire considerably when helium was the diluent gas and almost not at all when hydrogen was used as the carrier under otherwise comparable conditions. Representative removal rates with SF_6 are presented in Fig. 3 through 5 for different temperatures and concentrations. Figure 6 shows the effect of etch-polishing sapphire at 1350°C (ped. temp.) with different SF_6 concentrations so that equivalent amounts of sapphire were removed. The lower concentration produced a smoother sapphire surface.

Success in etching sapphire at reasonable rates by the above processes enhanced the possibility of applying the sulfur fluoride etch process to lapped sapphire surfaces as well as to diamond polished surfaces. The successful gas-phase polishing of lapped surfaces would minimize work damage attributed to mechanical polishing. Experience has indicated that a 10-min exposure of a polished sapphire to SF_6 at 0.22 mole %

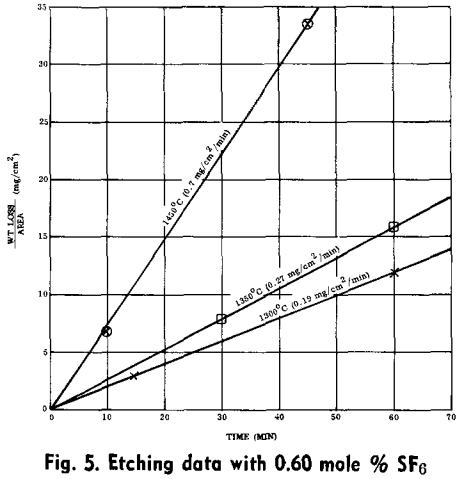

Fig. 5. Etching data with 0.60 mole % SF_6

in He flowing at 2.5 l/min at 1550°C (ped. temp.) will suffice to remove essentially all the surface scratches present due to normal optical polishing techniques. After a 30-min etch under the above flow and temperature conditions, a lapped ($1\bar{1}02$) sapphire slice had a reasonably smooth surface, as indicated in Fig. 7a. Figure 7b shows the surface of a sequential slice (from the boule) which was cut, mechanically polished and processed in the reactor simultaneously with the slice shown in Fig. 7a. The same grain boundary is depicted.

During preliminary experiments in which substrates rested directly on the heated pedestal, it was observed that the carbon pedestal was attacked by the sulfur fluorides. Examination of the substrate surface showed pitting of the type shown in Fig. 8, especially when low carrier gas flow conditions were used. The pits appear to have a definite orientation. Similar patterns are obtained after carbon particles were deliberately rubbed onto the sapphire surface which then was etch-polished. Molybdenum and silicon were also used as pedestal materials; however, a substantial amount of reaction occurred with the etching gases, producing deposits of undesirable byproducts throughout the reactor.

The results of the etching study with SF_6 indicate that it is selective in its etch-polishing capability for different orientations of sapphire. Under identical conditions, at relatively high SF_6 concentrations, optically polished ($1\bar{1}02$) sapphire will usually etch and roughen while ($11\bar{2}3$) sapphire will polish further. At very low concentrations of SF_6 (less than 0.2 mole %) ($1\bar{1}02$) sapphire seems to polish rather than etch at rather appreciable removal rates. Reasonably polished ($1\bar{1}02$) surfaces have been obtained on good quality

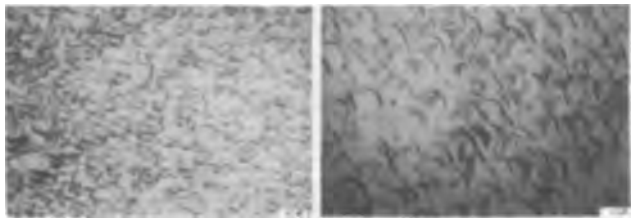

Fig. 6. Surface characteristics ($1\bar{1}02$) sapphire after SF_6 etching: (a) (left) for 30 min at 1350°C with 0.60 mole % SF_6; (b) (right) for 60 min at 1350°C with 0.22 mole % SF_6.

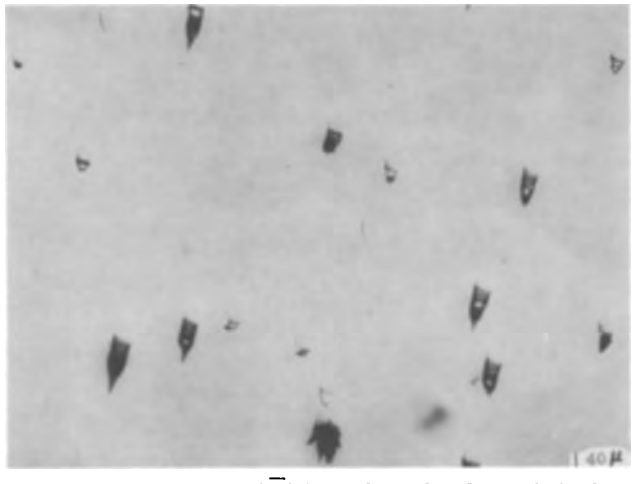

Fig. 8. Pits observed on ($1\bar{1}02$) sapphire after SF_6 etch (carbon pedestal used).

sapphire at removal rates of up to 0.4 mg/cm²/min at 1550°C (obs. ped. temp.) while optically polished surfaces oriented to the ($11\bar{2}3$) have retained a polish at etch rates of 0.7 mg/cm²/min at 1450°C. Single crystal silicon deposits were obtained on SF_4 or SF_6 polished sapphire surfaces.

Conclusion

The polishing of sapphire by the sulfur fluorides seems to offer a distinct advantage over the wet chemical techniques now available. Experience will dictate if the process is to be preferred over HCl polishing, which is considerably slower at comparable temperatures. Since it has been shown that SF_6 (or SF_4) will etch-polish a lapped (or ground) sapphire substrate, its potential as a means for eliminating optical polishing of sapphire is worth consideration.

Acknowledgments

The authors wish to express their appreciation to W. I. Simpson and J. E. Coker for their valuable as-

sistance in the etching studies, to C. C. Nealey and C. W. Laakso for the electron microprobe work, and to the Linde Company for their cooperation in supplying the Czochralski wafers used in the etching study.

Brief Communication

Travelling Solvent Defects on Silicon Wafers

E. Biedermann

IBM Laboratories, Boeblingen, Germany

In the usual planar silicon technology, the growth of an epitaxial Si layer on a single crystalline substrate wafer at a temperature of 1100°-1200°C is a basic process step. A variety of perturbations and defects can occasionally be observed on these epitaxial surfaces.

In Fig. 1, we show a special type of surface defect which occurs now and then, and which to our knowledge has not yet found its proper explanation. From its optical appearance in Fig. 1, we called it the "nail defect." These nails, achieving sometimes a length of a millimeter and more, can, under proper illumination, easily be observed even with the naked eye. The most obvious characteristic properties of these nails can be summarized as follows:

1. The distribution of the nails over the wafers is completely statistical.
2. Neighboring nails have almost identical length, shape, and orientation, without correlation to the crystal structure of the Si wafer, the orientation of the gas stream, or the direction of the gravitational force. (The exception of unusually short "incomplete" nails will be treated below.)
3. Length, shape, and orientation of the nails can vary strongly from one region of a wafer to another.
4. Under higher magnification (500X), head and shaft of the nails lose all their contrast, indicating that the nails consist of nothing but a slight profiling in the wafer surface (Fig. 2, 3)
5. Only in the uttermost tip of most of the nails, a sharp defect is found under high magnification. (Fig. 3)

These defects have been identified as small impurity pellets which, liquid at the temperature of the epitaxial process, travel over the wafer surface under the influence of the incidental temperature gradients thereon, just as does the liquid zone in the well-known travelling solvent processes (1). Thus the shafts of the "nails" are nothing but the traces of these traveling pellets. The small kinks in these traces can clearly be correlated to the change from preheating cycle to epitaxial growth period to postheating and cooling cycle. The behavior of the travelling pellets is apparently not much influenced by the epitaxial growth process itself, and the growth of a 10μ epitaxial layer

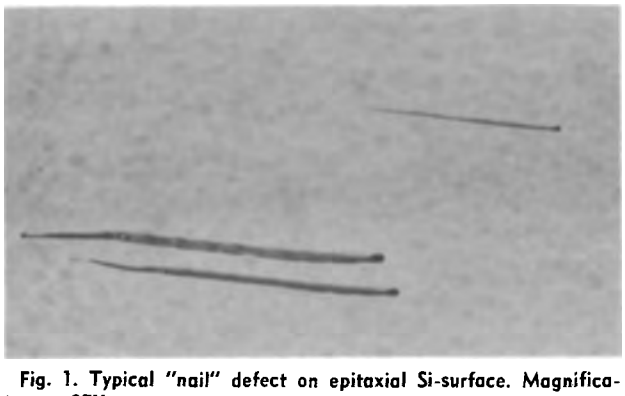

Fig. 1. Typical "nail" defect on epitaxial Si-surface. Magnification ca. 37X.

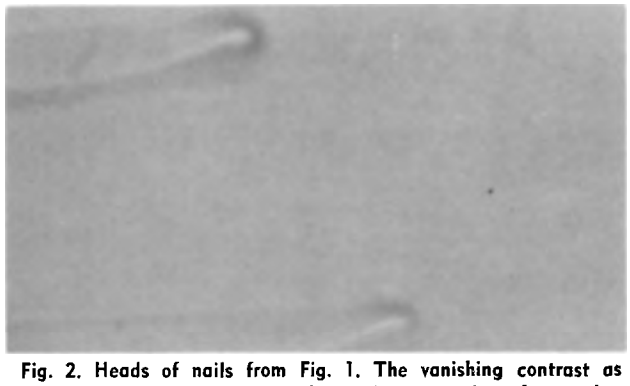

Fig. 2. Heads of nails from Fig. 1. The vanishing contrast as compared to Fig. 1 indicates the nails to consist of a rather smooth surface profiling. Magnification ca. 365X.

does not effect a noticeable levelling out of these traces.

The occurrence of unusually short nails in the neighborhood of longer ones (like the one in Fig. 1) is also easily explained. They never contain a pellet in their tip. Here the impurity material has been used up before the end of the heating cycle by solution in the silicon wafer, respectively by evaporation.

By observation in a high-temperature microscope under pure H_2-atmosphere, the melting point of the pellets has been determined to be about 1000°C and the travelling direction and speed could qualitatively be correlated to the temperature gradient on the wafers.

Electron microprobe analysis showed the pellets to contain the elements Fe, Cr, and Ni in a ratio corresponding approximately to the composition of stainless steel: 70 pt Fe, 20 pt Cr, and 8 pt Ni. Besides these metals an appreciable content of Si was found in the pellets, as is to be expected from the formation of essentially the Fe-Si eutectic with about 25% Si.

Evidently, the vapor pressure of these metals over the eutectic melt and their solubility in the solid silicon are low enough to guarantee the astonishingly long lifetime of these pellets on the silicon surface even in the chlorine-containing ambient of the epitaxial process.

Quite similar nails are easily produced in a pure hydrogen atmosphere on a silicon surface by seeding it with small pellets of other metals such as Cu, Ag, Cr, Ni, Pd, Pt, and heating it in an inert atmosphere like hydrogen to a temperature somewhat above the respective eutectic point. All these metals also have a low solubility in solid silicon at the temperature of their eutectic melt with Si.

From these findings the nails on the Si wafers appear as one example of a quite basic process which may just as well be observed on any other solid surface under appropriate conditions.

ELECTROCHEMICAL SCIENCE

Fused-Organic Electrolytes for Thermal Cells

Richard A. Wallace[1] and Paul F. Bruins

Department of Chemical Engineering, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The low-melting (<200°C) fused electrolytes tested were salts of organic acids, substituted pyridinium halides, and acetamide salt solutions. Methylpyridinium bromide and several alkali acetates were found to be thermally stable and good conductors, but they entered into spontaneous reactions with cathodic oxidants. Salts in molten acetamide, however, made suitable low-melting electrolytes for organic thermal cells. Potentials of some fused-acetamide cells were measured as a function of temperature, and the behavior on discharge was observed.

An organic fused-salt cell is a reserve-type thermal cell which produces electrical energy of long duration on application of a requisite amount of heat. The organic electrolyte of this cell is solid and nonconducting at ordinary temperatures, but, on activation, the heat rapidly applied to the cell causes the electrolyte to melt and become conducting.

Organic thermal cells have not been studied thoroughly in the past, chiefly because of a lack of reliable data of the physical and electrochemical behavior of suitable low melting salts. The literature on fused-salt thermal cells relates chiefly to inorganic ones of the type reported by Hamer and Schrodt (1) and Goodrich and Evans (2). Special inorganic types have been treated by Rubin and Malmberg (3), McKee (4), Doan (5), Selis (6), and Jennings (7). Panzer (8) carried out exploratory test surveys on a wide variety of organic and inorganic salts for possible application as suitable electrolytes in fused-salt thermal cells. Unfortunately, most fused-salt cell studies are largely qualitative in nature.

The three most important disadvantages of current inorganic thermal cells are (*a*) high operating temperatures (400°-600°C), (*b*) cell life limited to 5-10 min, and (c) marked cathodic polarization.

Organic electrolytes can be divided into two classes. The first is organic salts that conduct electrolytically in the molten state, *e.g.*, the sulfonates, formates, acetates, and substituted pyridinium salts. The second class includes solutions of salts in organic solvents, *e.g.*, molten acetamide salt solutions (9).

Experimental

Reagents.—Methylpyridinium chloride was prepared by the method of Rozhdestvenskii (10). The hygroscopic crystalline solid melted at 138°C, in agreement with that reported in the literature. On melting, the salt forms a clear, water-white melt that did not decompose up to 200°C for 2 hr. This chloride salt was extremely hygroscopic and difficult to obtain in high yields. On the other hand, the corresponding bromide pyridinium salt was appreciably less hygroscopic and was obtainable in yields greater than 80%.

Methylpyridinium bromide was prepared by passing excess methyl bromide into a mixture of equal volumes of pyridine and benzene at room temperature. After about 4 min, the exothermic addition reaction between pyridine and methyl bromide occurred. At this time the addition reaction was stopped, and the resulting white slurry removed and washed with large volumes of benzene to ensure removal of trace amounts of pyridine adsorbed on the salt. The salt was purified further by crystallization from anhydrous ethyl alcohol at —40°C. This purification procedure was repeated three times. The salt was vacuum-dried for two days; its melting point is 150°-151°C. The bromide salt forms a clear, water-white melt that did not char or otherwise decompose up to 200°C for several hours.

Acetamide crystals (Mallinckrodt analytical reagent) were further purified by recrystallization from pure benzene and then vacuum-dried for two days. The salts $MgCl_2$, $AlCl_3$, $ZnCl_2$, and $CdCl_2$ (Baker and Adamson reagents) were used without further purification; they were dried at about 200°C and kept in a desiccator.

Metal rod electrodes (Fisher Scientific) were at least 99.5% pure. Silver-silver chloride electrode was prepared electrolytically. Cathodic oxidants such as $CaCrO_4$ and K_2CrO_4 were supplied by Eagle-Picher. All electrode materials were washed with acetone and dried at 120°C prior to use in cells.

Electrolytic cell.—Figure 1 depicts the electrolytic cell used to measure the potentials of organic fused-salt cells as a function of temperature. The cells were constructed of Pyrex glass unless noted otherwise. All

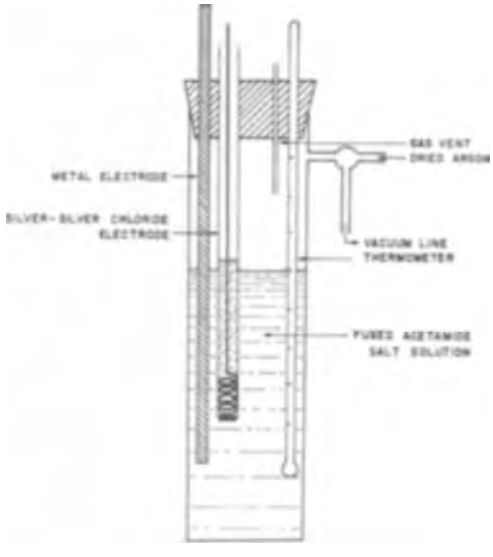

Fig. 1. Fused-acetamide salt cell

negative electrodes were ⅛-in. commercially pure metal rods. The positive electrode was nickel mesh with $CaCrO_4$ or K_2CrO_4 oxidants for fused acetate and pyridinium cells. For fused acetamide salt cells, a 1/16-in. Ag/AgCl rod immersed in 0.10M KCl-Acetamide and contained in a fritted glass tube, shown in Fig. 1. A positive liquid head was maintained in the tube compartment of this Ag/AgCl electrode to prevent contamination of the acetamide salt solution. Interelectrode distance was about 1.0 cm. Approximately 100g of a tenth molal metal chloride solution was placed in the cell, immersed in a thermonitor-controlled oil bath by Sargent.

Upon fusion of the organic salt mixture, the cell was vacuum-pumped for 2 hr through the side arm to remove water vapor from the electrolyte. Then dry argon gas was allowed to enter, bringing the system to atmospheric pressure. Argon was continuously maintained above the organic melt and allowed to escape via a small exit tube in the stopper. Once constant temperature was attained, the emf of the system was measured with an L&N K-3 potentiometer.

Results and Discussion

Potassium methylsulfonate and the sodium salts of benzene and p-toluene sulfonic acids all failed to melt. Molten sodium formate did not decompose for several hours at 270°C, but readily reduced AgCl, $CaCrO_4$, and K_2CrO_4 cathodic reactants.

A eutectic mixture (11) of sodium, potassium, and lithium acetates (37.5/11.9/50.6 w/o) melted at 157°C and remained thermally stable and conductive at 200°C for 5 hr. The fused acetate eutectic also reacted spontaneously with $CaCrO_4$ and K_2CrO_4. The cell Mg/alkali acetate eutectic/$CaCrO_4$,Ni failed to deliver useful amounts of current at 250°C.

Substituted pyridinium halides have better thermal and conductive properties than unsubstituted pyridinium halides (12). Methylpyridinium chloride and bromide were thus synthesized and evaluated as molten electrolytes for organic thermal cells. Figure 2 presents the electrical conductivity of molten methylpyridinium bromide. Clearly, this salt conducts very well in the molten state.

The organic salt cell, Mg/methylpyridinium bromide/$CaCrO_4$,Ni gave an open-circuit potential of 1.15v at 200°C. Appreciable currents, however, were not obtained when this cell was under load. At the magnesium electrode, two reactions took place during discharge: the electrochemical cell reaction and the redox reaction between magnesium and methylpyridinium bromide.

Potential-temperature data of several fused acetamide salt systems were measured in our experimental

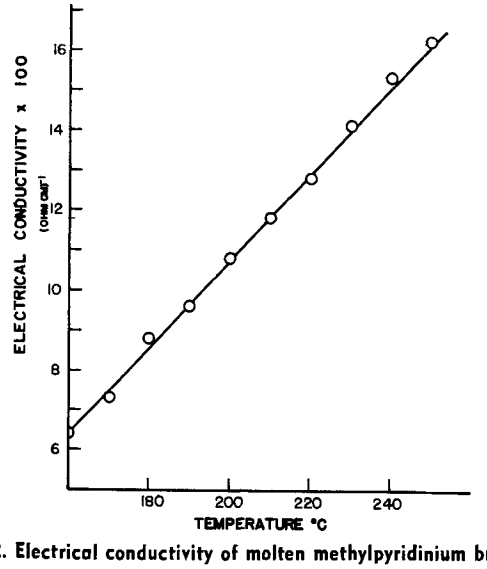

Fig. 2. Electrical conductivity of molten methylpyridinium bromide

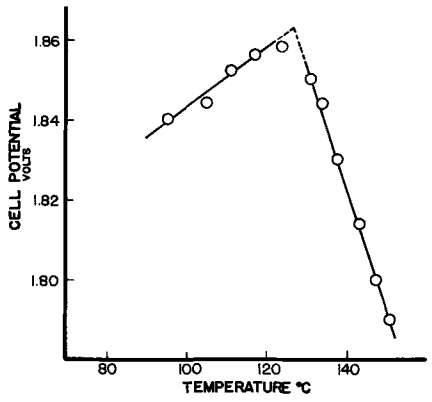

Fig. 3. Cell potential of Mg/0.10M $MgCl_2$-acetamide/AgCl,Ag. Hydrogen was evolved above 125°C.

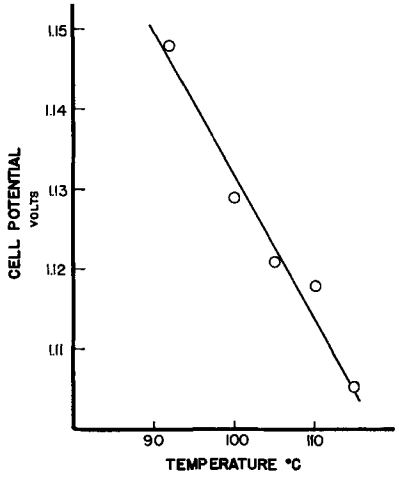

Fig. 4. Cell potential of Al/0.10M $AlCl_3$-acetamide/AgCl,Ag. Hydrogen was evolved both on open circuit and discharge.

cell. Calcium is not included here because of its vigorous reaction with fused acetamide to generate hydrogen. Conductance data for several alkali and alkaline earth chlorides in molten acetamide are given by Wallace (9) and Winkler (13).

Magnesium.—The open-circuit potential of Mg/0.10*M* $MgCl_2$-acetamide/AgCl,Ag cell is shown in Fig. 3 as a function of temperature. The potential (1.835v at 90°C) increased with temperature up to about 125°C (1.860v) where hydrogen evolution began. Above 125°C the cell potential rapidly decreased. The extent of magnesium corrosion with molten acetamide increased slowly up to 125°C and then accelerated in an exponential-like manner with rising temperature.

Much hydrogen gassing occurred in these cells when placed on discharge. On replacing chloride solutions with bromide salt solutions in magnesium-acetamide thermal cells, however, hydrogen evolution was reduced markedly.

Aluminum.—The open-circuit potential of Al/0.10*M* $AlCl_3$-acetamide/AgCl,Ag cell was measured as a function of temperature. Figure 4 shows the cell potentially (1.150v at 90°C) falling sharply with increasing temperature. Hydrogen evolution occurred rapidly with aluminum due chiefly to the high acidity of molten $AlCl_3$-acetamide. When aluminum-acetamide cells were placed on discharge, very vigorous hydrogen evolution was noted.

Zinc.—The equilibrium voltage of Zn/0.10*M* $ZnCl_2$-acetamide/AgCl,Ag decreases linearly with increasing temperature, as shown in Fig. 5. The potential of the cell reaction: $Zn + 2AgCl = ZnCl_2$ (0.10*M*) $+ 2Ag$ with a zinc chloride concentration of 0.10*M* in molten

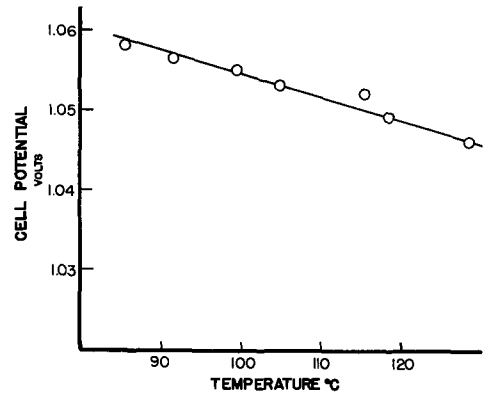

Fig. 5. Cell potential of Zn/0.10M $ZnCl_2$-acetamide/AgCl,Ag

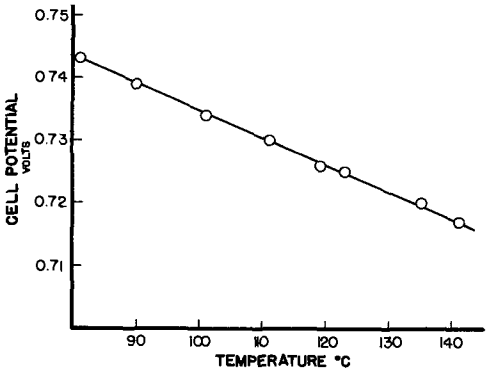

Fig. 6. Cell potential of Cd/0.10M $CdCl_2$-acetamide/AgCl,Ag

acetamide is 1.058v at 90°C. By use of the Gibbs-Helmholtz relation, the heat of reaction is calculated to be —56.3 kcal/mole and entropy change, —25.3 e.u. For comparison, ΔH of —55.6 kcal/mole and ΔS of —34.5 e.u. are recorded at 25°C for the aqueous cell reaction: Zn + 2AgCl = $ZnCl_2$ (a = 1) + 2Ag with unit zinc chloride activity in water (14).

The discharge behavior of this galvanic cell system was determined at 90° and 130°C. Several silver chloride-zinc cells were held at these temperatures for 8 hr before discharging. No harmful effects or cell deterioration was observed. Even under maximum current drains, the zinc electrode did not gas. The initial maximum current output from these cells were largely limited by the resistance offered by the molten electrolyte. Values for the conductivity of molten 0.10*M* $ZnCl_2$-acetamide were 0.5 x 10^{-3} ohms-cm^{-1} at 90°C and 0.9 x 10^{-3} ohms-cm^{-1} at 130°C. Discharge cell performance and limitations for silver chloride-zinc cells are presented in another paper (15).

Cadmium.—In Fig. 6 is given the equilibrium cell potential of Cd/0.10*M* $CdCl_2$-acetamide/AgCl,Ag cell as a function of temperature. The potential of the cell reaction: Cd + 2AgCl = $CdCl_2$ (0.10*M*) + 2Ag with a cadmium chloride concentration of 0.10*M* in molten acetamide is 0.739v at 90°C. The heat of reaction is calculated to be —42.3 kcal/mole and entropy change, —23.0 e.u. For comparison, ΔH of —36.5 kcal/mole and ΔS of —26.1 e.u. are recorded at 25°C for the aqueous cell reaction: Cd + 2AgCl = $CdCl_2$ (a = 1) + 2Ag with unit cadmium chloride activity in water (14).

The discharge behavior of this galvanic cell system was also determined at 90° and 130°C. No cell deterioration or gassing was noted on discharge. Likewise, maximum current output from these silver chloride-cadmium thermal cells were initially limited by the conductivity of 0.10*M* $CdCl_2$-acetamide melt, 0.3 x 10^{-3} ohms-cm^{-1} at 90°C, and 0.7 x 10^{-3} ohms-cm^{-1} at 130°C. Discharge behavior of these cells was similar to silver chloride-zinc thermal cells.

Fused-Acetamide Thermal Cells

Richard A. Wallace[1] and Paul F. Bruins

Department of Chemical Engineering, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Low-temperature (<200°C) fused-acetamide thermal cells, using highly porous cathodes, furnish appreciable electrical energy on discharge. The cell, Zn/2.5% KCl-acetamide/AgCl,Ag had an average discharge voltage of 0.970v (at 2.0 ma/cm^2 and 100°C) for 360 min. Cathodic polarization was principally responsible for termination. Voltage regulation and uniform discharge depended to a very large degree on silver chloride electrode. Effects of charge rate and addition of small amounts of water on cell discharge were also measured.

In the previous paper (1) we reported that low-temperature (<200°C) organic thermal cells generated appreciable electrical energy on discharge and molten acetamide salt solutions made good cell electrolytes. In this paper, the fused acetamide cell, Zn/2.5% KCl-acetamide/AgCl,Ag has been studied.

Existing information on the physical and chemical properties of solid and molten acetamide has been reviewed by Winkler (2) and Wallace (3). In 1957 Jander and Winkler (4) made careful potentiometric and conductometric titrations of a relatively large number of acid-base neutralization reactions in molten acetamide. Early in 1960, Wallace (3) measured several physical and electrochemical properties of molten KCl-acetamide and KBr-acetamide systems over their full solubility and temperature ranges and reported their use as low-temperature thermal cell electrolytes. We found that molten saturated KCl-acetamide meets most of the basic criteria set down for a suitable electrolyte for organic fused-salt cell usage (1). Its effective liquid range, and hence the temperature range of the cells, lies between 77°C (melting point) and 180°C (200 mm Hg vapor pressure).

Acidic (H_2SO_4) and basic (KOH) solutes are not suitable for cell usage because they decompose acetamide. A nonhygroscopic, neutral salt having good solubility and conductance in molten acetamide is needed and KCl was found suitable. The molten acetamide salt solution (see Fig. 1) should be nearly saturated (2.5g KCl/100g acetamide or 0.33*M*). Such a KCl-acetamide solution is preferred because it provides maximum conductance while still assuring complete solution of KCl at any temperature.

Silver chloride was selected as the cathodic reactant. Preliminary experiments showed that it provides excellent voltage stability and an unusually flat discharge curve in working acetamide cells. Also, it is slightly soluble in saturated KCl-acetamide solutions.

Zinc was the most convenient working anode for a study of fused-acetamide salt cells under discharge for long periods (hours) at moderately high current drains. Zinc did not gas in the organic thermal cell, Zn/KCl-acetamide/AgCl,Ag on dicsharge. It has a high electrochemical capacity (49.2 amp-min/g), and $ZnCl_2$ is highly soluble in molten acetamide.

Experimental

Reagents.—Acetamide crystals (Mallinckrodt analytical reagent grade) were further purified by recrystallization from pure benzene. Recrystallized acetamide was vacuum-dried for two days and then kept in a desiccator. The salts KCl and $ZnCl_2$ (Baker and Adamson reagents) were used without further purification; the salts were dried at about 150°C and the dried salts kept in a desiccator. Dry argon gas was used to minimize dissolved oxygen in fused acetamide. Zinc sheet (N. J. Zinc) was 99.95% containing less than 0.005% Cu, 0.005% Fe, 0.005% Cd, the major impurity being Pb. Rectangular sheets of high-purity, fused AgCl electrodes with a surface skin of Ag to make electronic contact were supplied by Eagle-Picher. Our analysis showed these electrodes contained 99.5% AgCl and 0.5% Ag.

Reference electrode.—The Ag/AgCl/Cl^- reference electrode has been used successfully in both aqueous and molten salt electrochemistry and found by Wallace (3) to be a stable and reproducible reference electrode in molten acetamide systems. The Ag/AgCl/Cl^- reference electrode is described in Fig. 2. The glass container for this reference electrode (Fig. 2) was a small glass tube of about ½-in. diameter with a fritted glass bottom (medium porosity) that acted as a salt bridge between the reference electrode and test cell electrodes. The electrode proper was prepared by chloridizing a 1.6 mm silver wire in 1*N* HCl at 25°C for 2 hr at 10 ma/cm^2 current density. The lower portion of the electrode was wound spirally to provide not only greater electrolytic contact area, but also a snug fit with the inside of the tube, thereby fixing the position of the electrode. Excess solid KCl was added to the tube compartment in order to keep the chloride activity constant.

Conductometric measurements.—Conductances of molten electrolytes were measured with an industrial instrument (model RC-16B2) conductivity bridge using a dip-type cell with a 0.630 cell constant. The measurements were made at a frequency of 1000 Hz; preliminary runs showed that electrolyte resistances were independent of frequency.

Temperatures of molten acetamide solutions were controlled to 0.3°C by a forced-draft electric furnace. A period of 20 min was allowed after each salt addition before a resistance reading was taken. During this period the melt was shaken to ensure complete solution of the added salt and to hasten equilibrium.

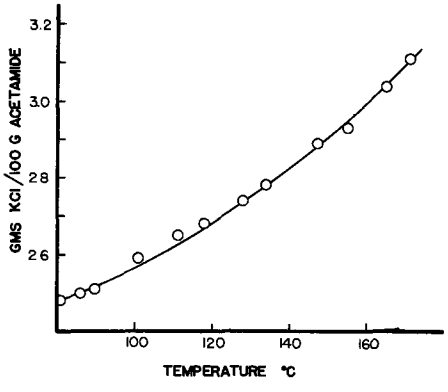

Fig. 1. Solubility of KCl in molten acetamide

[1] Present address: Department of Chemical Engineering, University of California, Berkeley, California.

Cell design and testing.—Experimental acetamide cells consisted of a Ag-AgCl rectangular cathode (3.3 x 3.3 x 0.091 cm) sandwiched between two parallel zinc anodes (3.3 x 3.3 x 0.059 cm). Electrode separation was effected by four tiny glass strips (0.80 cm long and 0.40 cm wide) cemented to the top and bottom edges of each electrode with a high-temperature epoxy adhesive. The parallel-electrode arrangement (Fig. 2) was used because it was simple in geometrical design, provided as nearly uniform current density as possible over the surfaces of the plane electrodes, and allowed the acetamide melt to circulate freely between working electrodes. Electrical contact was made by soldering a thin Zn tab to the two outside Zn sheets and by silver-soldering a thin Ag wire to the silver-coated AgCl electrode, or in the case of electroformed Ag-AgCl, to the Ag mesh screen itself. This sandwich cell was sturdy and did not buckle under thermal stresses produced during testing.

More porous Ag-AgCl cathodes were also prepared by chloridizing spongy silver sheets, incorporated on silver grids of about 50 by 50 mesh supplied by Eagle-Picher. Silver was electrolytically converted into active AgCl by chloridizing in a 1*N* HCl at 25°C and a current density of 10 ma/cm². Formation was continued until the remaining silver was reduced to about one-half its original thickness.

All cells were immersed in a 400 ml Pyrex beaker containing 2.5% KCl-acetamide solution maintained at a constant temperature in an electric oven. Cell voltages were measured with a Sargent (Model MR) multirange potentiometric recorder, calibrated periodically against a Weston standard cell whose emf was 1.0193v. These cells were discharged at a constant current by manually adjusting the load. Charging of the cells was done either on an automatic constant current charger supplied by Ray-O-Vac, Division of Electric Storage Battery Company, or manually.

Electrode polarization.—Polarization potential of the working electrodes were measured at 100°C by means of the reference electrode in the same acetamide electrolyte. Included in these polarization potentials was the ohmic drop in the electrolyte between the reference electrode and the surface of the working electrode. To minimize this voltage drop, the reference electrode was placed in close proximity to the outer edge of both working electrodes, a region where the current flux is minimal.

Results and Discussion

A systematic conductometric analysis of the role and influence of $ZnCl_2$ in molten $KCl_{(sat.)}$-acetamide was made by Wallace (3). In Fig. 3 is presented the specific electrical conductance of $ZnCl_2$-$KCl_{(sat.)}$-acetamide solutions, as a function of zinc salt concentration and temperature. When added in small amounts, $ZnCl_2$ markedly diminished the conductivity of the molten KCl-acetamide electrolyte. On further additions, the conductivity reached a minimum and then increased fairly rapidly thereafter until it attained a maximum value occurring in the 1-3*M* zinc salt region.

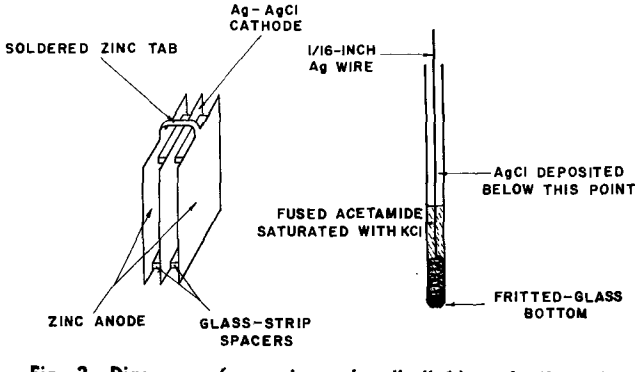

Fig. 2. Diagrams of experimental cell (left) and silver-silver chloride reference electrode (right).

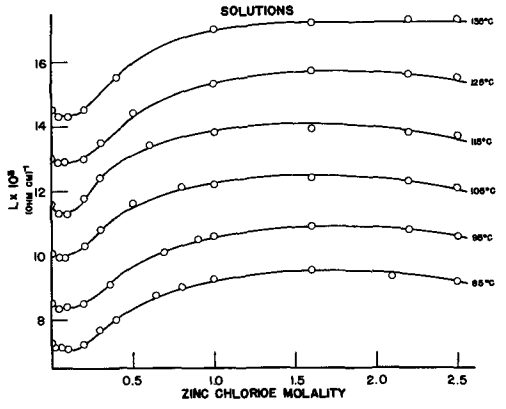

Fig. 3. Specific conductance of molten $ZnCl_2$-$KCl_{(sat.)}$-acetamide solutions.

These conductance deviations were attributed to the formation of chlorozinc complex and coordination molecules in the saturated KCl-acetamide melt; these effects resulted in minimum-maximum curves. The precise location of the minima and maxima points depend upon the temperature and amount of KCl in acetamide. In Fig. 3 it is of interest to point out that the large temperature coefficient of conductance may be due to two factors: (*i*) less stability of chlorozinc complexes with increasing temperature, putting more chloride ions in solution, and (*ii*) increased KCl solubility with temperature, putting more potassium and chloride ions in solution.

Cell performance.—The performance characteristics of experimental Zn/2.5% KCl-acetamide/AgCl,Ag cells were measured with temperature, electrode spacing, and discharge current density as parameters. Typical performance curves for cells using fused Ag/AgCl cathodes are shown in Fig. 4. On applying a load, the cell voltage falls almost instantaneously to a steady value and remains fairly constant throughout discharge.

The magnitude of the maximum current drains increased with an increase in operating temperature and, to a lesser extent, with a decrease in electrode spacing. Discharge current densities exceeding 30 ma/cm² could not be obtained from these experimental cells, although it is likely that higher current densities could be attained in cells using more porous cathodes, operating at higher temperatures with closer electrode spacings.

Temperature effect.—In all experimental cells, the cell voltage and maximum current output increased

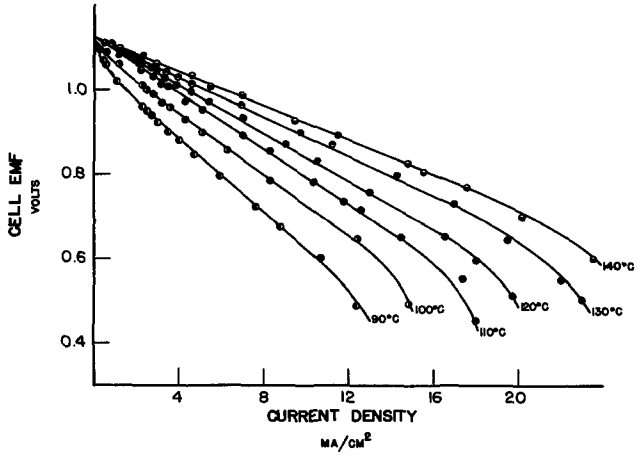

Fig. 4. Performance of Zn/KCl-acetamide/AgCl,Ag cells (0.312 cm electrode spacing) at various temperatures.

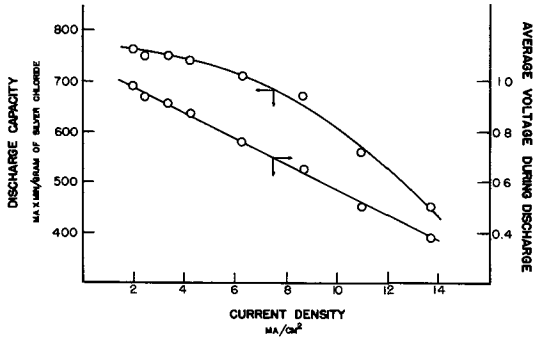

Fig. 5. Discharge capacity and average voltage of acetamide cells on discharge at 100°C.

materially with temperature. Figure 4 illustrates the large temperature effect on cell output.

Discharge capacity.—The discharge capacity, in milliamps-minutes per gram of fused AgCl, was calculated from cell performance curves and given in Fig. 5 as a function of current density. Also included in Fig. 5 is the variation of the average cell voltage with current density. Figure 5 points out that Zn/2.5% KCl-acetamide/AgCl,Ag cells do not furnish as great a capacity when discharging at high current densities as when discharging at low densities.

A more porous, electroformed silver chloride cathode was fabricated and tested. Approximately 1.40g of AgCl was electrolytically formed on the silver mesh grid (22 cm^2 exposed geometric surface area). Several Zn/2.5% KCl-acetamide/AgCl,Ag cells, with this electroformed AgCl were discharged at 100°C at a current density of 2 ma/cm^2. These cells had a 0.970 average discharge voltage and a 360-min cell life, which is equivalent to 1.3g of converted AgCl. In comparing cells using fused AgCl electrodes with an average cell capacity of only 0.762 amp-min/g AgCl with electroformed AgCl electrodes with a cell capacity 11.1 amp-min/g AgCl, a striking increase in cell capacity is revealed. It should be pointed out that this higher cell capacity is close to the theoretical capacity of 11.2 amp-min/g. AgCl. Longer discharge times were also obtained by electroforming even greater amounts of AgCl on silver grids.

Individual electrode behavior.—For the purpose of pinpointing the cause of cell termination and improving performance, individual electrode polarizations were measured at 100°C at a variety of discharge rates. Generally, the current drain had much more effect on cathodic than on anodic polarization. Cathodic polarization increased with time much more rapidly under high current drains and was principally responsible for discharge termination.

Anodic polarization, on the other hand, was comparatively small and did not significantly alter cell performance. The magnitude of anodic polarization was in the 5-15 mv range and increased with an increase in current drain, and only slightly with length

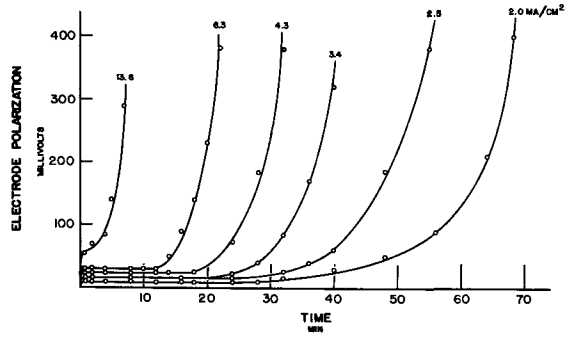

Fig. 6. Fused AgCl cathodic polarization in discharging acetamide cells at 100°C.

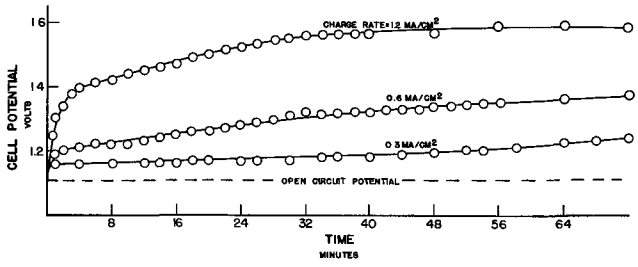

Fig. 7. Performance of Zn/KCl-acetamide/AgCl,Ag cells (0.12 cm electrode spacing) on charging at 100°C.

of discharge. This was attributed entirely to concentration polarization effects.

Cathodic polarization results in Fig. 6, clearly point out that the silver chloride cathode contributes most to cell termination. The polarizations remain fairly constant over much of the discharge until, at the inverted knee of the curve, there is a sudden large increase.

At the end of cell discharge, the AgCl on the cathode surface was observed to be reduced to spongy silver. Chloride ions must diffuse from within this dense, fused AgCl electrode. As a result, severe polarization took place. At current drains greater than 15 ma/cm^2, cell output was virtually dependent on the amount of KCl in immediate contact with active layers of AgCl. These polarization results accentuate the need to use a cathode of high porosity for usage in fused-acetamide thermal cells.

Charge rate.—Figure 7 shows the effect of charge rate on cell performance at low current densities at 100°C. These cells consisted of a zinc sheet (17.0 cm^2 exposed surface area) and a silver grid of the same area. On charge, their terminal cell voltage increased sharply. This abrupt rise in charge voltage was caused by the sudden drop in KCl concentration at the silver electrode and by hydrogen evolution coming from the zinc electrode. All cells were arbitrarily charged for 72 min and then discharged at 4.0 ma/cm^2 current density; on the average, about 60-70% charge was recovered. These experiments demonstrate that Zn/KCl-acetamide/AgCl,Ag molten acetamide cells are capable of being recharged.

Water addition.—Water is completely miscible with molten acetamide and allows the slightly aqueous acetamide to dissolve greater amounts of salt. The effect of water on melting point of solid 2.5% KCl-acetamide solution is recorded in Fig. 8.

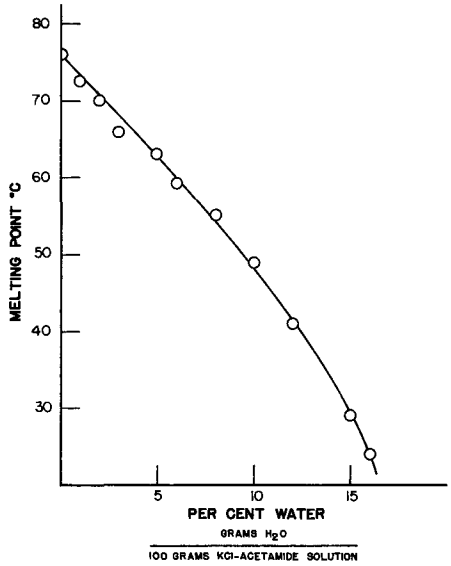

Fig. 8. Effect of water on melting point of solid 2.5% KCl-acetamide solution.

Addition of small amounts of water permitted the operating temperatures of acetamide thermal cells to be extended downwards. For example, three acetamide cells were discharged at 80°C in saturated KCl-2% H_2O-acetamide, melting point 70°C. The discharge performance of these cells at 80°C were similar to anhydrous cells at 100°C.

Infrared Spectroscopic Investigation of Charged Nickel Hydroxide Electrodes

Frederick P. Kober

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Through the use of deuterated samples of $Ni(OH)_2$ electrodes at various stages of charge, it has been possible to make definitive band assignments for the structures of the active material. The relative intensity of the band due to hydrogen bonding in the charged state is shown to be a measure of the electrochemical capacity of the system. The charging reaction gives rise to the formation of active oxygen sites (as defined by Aia) through a site alteration mechanism in addition to the formation of hydrogen bonded sites within the charged phase. The mechanistic and structural implications of these spectral data are discussed in detail.

In a previous publication (1), the characteristic structural changes which occur in the hydrated nickel-oxide electrode during charge-discharge were examined. It was shown that the discharged state is characterized by nonhydrogen bonded hydroxyl groups whereas the charged state is a hydrogen bonded structure. In addition, Labat (2) and more recently Aia (3) have demonstrated the role of active oxygen[1] in the electrochemical capacity of the charged state. In fact, there is quantitative agreement between the equivalents of active oxygen "stored" in the higher oxide structure and the observed electrochemical capacity (3).

The nickel hydroxide electrode reaction, particularly the charged state, has been re-examined using high resolution infrared spectroscopy. By means of deuterium substitution, more definitive band assignments are made for the structure of the active materials. The formation of active oxygen which accompanies the charging reaction is shown to be closely associated with the formation of hydrogen bonding within the solid phase. The relative intensity of the absorption band due to hydrogen bonded groups is found to be proportional to the electrochemical activity of the higher oxide and, hence, its active oxygen content.

Experimental Procedure

Preparation of sintered electrode samples for infrared analysis is given in detail elsewhere (1). For this particular study, Nujol mulls were employed throughout. In the region from 4000 to 2500 cm^{-1} both CaF_2 and Irtran II windows were used, whereas polyethylene windows were used for the far infrared measurements (600-280 cm^{-1}). All measurements were made using a Beckman IR-7 double-beam instrument equipped with CsBr optics.

[1] The concept of active oxygen formation resulting from the anodic polarization of $Ni(OH)_2$ is discussed by Labat (2) and by Aia (3).

Deuteration of the discharged electrode material was accomplished by washing ground samples several times with D_2O (99.99%) using the method of Cabannes-Ott (4). This method takes advantage of the rapid exchange of hydrogen with deuterium in the $Ni(OH)_2$ system (5). When applied to the charged electrode material, this method of deuteration proved unsuccessful. Deuteration was achieved by immersing the discharged electrode in 31% KOD (D_2O), cycling several times, and subsequently washing the charged electrode in D_2O. This result indicates that protons are considerably more tightly bound in the higher oxide thus limiting exchange with D_2O.

The spectra of deuterium-free samples were measured against pure Nujol placed in the reference beam. In order to clearly discern spectral shifts due to deuteration, it was necessary to place undeuterated samples in the reference beam. The necessity of this differential technique was a consequence of the fact that the deuteration procedures employed yielded only partial exchange with hydrogen.

Results and Discussion

4000-2500 cm^{-1} Region.—Deuteration of the discharged electrode caused the sharp intense band observed at 3650 cm^{-1} to shift to 2705 cm^{-1}. This result is in agreement with that of Cabannes-Ott (4) and is illustrated in Fig. 1. These frequencies are in the ratio 1.35 substantiating the assumption that this absorption is the stretching fundamental of the nonhydrogen bonded hydroxyl groups.[2] During charging, the stretching fundamental is replaced by a broad diffuse absorption having a center at approximately 3450 cm^{-1} and attributed to hydrogen bond forma-

[2] To a first approximation, the frequency in wave numbers of a classical harmonic oscillator is given by $\gamma\ (cm^{-1}) = (1/2\pi C)\ (k/\mu)^{1/2}$ where k is the Hook's law force constant and μ is the reduced mass. Consequently, the ratio of frequencies will be inversely proportional to the square-root of the ratios of reduced masses. The theoretical ratio $(\mu_{OD}/\mu_{OH})^{1/2}$ is found to be 1.36.

tion (1). Examination of this band under high resolution (greater than 1 cm^{-1}) reveals that, in fact, two or perhaps three bands are superimposed. These bands are shown in Fig. 2. Due to the nature of the samples, it was not possible to achieve better resolution of these absorptions even with deuterium substitution.

The broad diffuse nature of these bands suggests that they arise from lattice modes of the hydrogen bonded hydroxyl layers. Similar spectral features in the three micron region are observed for the minerals boehmite (γ-AlOOH) (6) and lepidocrocite (γ-FeOOH). These minerals are hydrogen bonded layer structures in which the central cations are surrounded by distorted octahedra of oxygens, the over-all symmetry being orthorhombic. Although the spectrum of the charged nickel-oxide electrode is not truly definitive with regard to structure, there is indication that similarities exist between the structure of the higher nickel oxides and that of boehmite (or lepedocrocite).

650-250 cm^{-1} Region.—The spectra, in this region, of both discharged and charged electrodes have been reported previously (1). Upon deuterium substitution, several frequency shifts are observed. These shifts are illustrated in Fig. 3. The band at 325 cm^{-1} in the deuterated sample is associated with the librational mode at 350 cm^{-1}.[3] In addition to the absorption at 325 cm^{-1}, there are bands observed at 415 and 525 cm^{-1}. Since the absorption at 450 cm^{-1} in the undeuterated sample is due to the nickel-oxygen lattice mode and does not involve proton vibration (1), the two vibrations observed for deuterated electrodes must be associated with shifts in the band having a center at 540 cm^{-1}. Consequently, this absorption is actually the superposition of two vibrations. From group theoretical considerations (7), the band at 540 cm^{-1} appears to arise from the singly degenerate lattice vibration associated with the motion of hydroxyl groups along the 001 direction relative to the nickel ion sites. The shift from 550-540 to 525 cm^{-1} is a manifestation of this assignment. Superimposed on this lattice mode is the torsional mode of the weakly bound lattice water also having a band center at 550-540 cm^{-1} (1). Upon deuteration, a shift to 415 cm^{-1} is observed.

The spectral changes which result from charging of the electrode have also been discussed in ref. (1). The broad but intense band having a center at 575-580 cm^{-1} was shown to arise from hydrogen bonding of the hydroxyl groups. For deuterated samples, this band shifts to 540-550 cm^{-1} with the appearance of a shoulder at approximately 520 cm^{-1}. These shifts are illustrated in Fig. 4. The ratios of these frequencies indicate that the 580 cm^{-1} absorption is a lattice mode(s) caused by the motion of hydrogen bonded linkages, *i.e.*, ---H–O–H––, relative to the nickel sites. This band is discussed in greater detail below. All frequencies together with possible assignments are listed in Table I.

580 cm^{-1} Band.—This band, which arises from the motion of hydrogen bonded linkages, appears to be characteristic of the charged state. As was shown by Aia (3), the charging reaction is accompanied by the continuous formation of active oxygen, the equivalents being in quantitative agreement with the electrochemical capacity. Thus, it is not unlikely that hydrogen bond formation is a consequence of structural changes brought about by the formation of active oxygen sites during the charging reaction. This suppo-

[3] The assignment in ref. (1) for the band at 350 cm^{-1} as a combination band arising from an interaction of the nickel-oxygen lattice mode with a low frequency librational mode (<100 cm^{-1}) now appears to be incorrect. Reconsideration of the data leads to the conclusion that the band at 350 cm^{-1} is, in fact, the true librational mode of the free OH groups. For a theoretical discussion of the OH librational mode in nonhydrogen bonded hydroxides see: C. K. Coogan, *J. Chem. Phys.*, 43, 823 (1965).

sition is supported by the fact that the formation of hydrogen bonding is also found to be a continuous function of charge (1). Consequently, any change in active oxygen content should manifest itself as a change in intensity of the band at 580 cm^{-1}.

Thermal decomposition of charged electrodes at various temperatures is accompanied by a loss of active oxygen, leading to a loss in electrochemical capacity (3). This loss of active oxygen does indeed result in a decrease in relative intensity of the absorption due to hydrogen bonded linkages at 580 cm^{-1} (Fig. 5). In fact, this decrease in relative intensity is a direct measure of the remaining electrochemical activity of the electrode.

If we assume that the intensity of the 580 cm^{-1} band for an electrode dried at 25°C represents 100% capacity, the relative intensity of this band as a function of drying temperature is then a measure of the remaining capacity (active oxygen content) after thermal treatment. These data are plotted in Fig. 6 together with actual capacity measurements of charged electrodes thermally treated at various temperatures. The excellent agreement between the capacity values predicted from infrared data with those measured experimentally strongly indicates that the formation of active oxygen is associated with the formation of hydrogen bonding. This conclusion is further supported by the thermal and stoichiometric results of Aia (3).

Mechanistic Implications

It has been demonstrated that the local site of electrochemical activity in the $Ni(OH)_2$ structure is at adjacent nonhydrogen bonded hydroxyl groups (8). Also, from the above results we see that the formation of active oxygen sites (electrochemical capacity) during charging of the electrode causes hydrogen bonding to occur within the solid phase. These data imply the following mechanistic steps.

The charging reaction involves the interaction of a "free" hydroxyl group with the electrolyte, resulting in an alteration of the electron density (electronic structure) at that given hydroxyl site. Since the reaction is initiated at the hydroxyl sites any change in the electronic structure of the nickel ion sites must be the result of electron transfer across the nickel-to-oxygen bonds. The change in the d^8 electronic configuration of the nickel sites brought about in this manner results in the formation of a hydrogen bonded structure possessing an over-all symmetry lower than D_{3d}. Thus, the appearance of active oxygen is a manifestation of a change in electronic structure at a hydroxyl site. A theoretical treatment of the changes in electronic structure which occur at the hydroxyl and nickel ion sites as a result of the interaction of a free hydroxyl site with the electrolyte will be presented in a subsequent paper.

The magnetic susceptibility data of Labat (2) clearly demonstrates that the charging reaction causes a decrease in electron-spin density about the nickel ion sites, thus effecting a change in electronic structure. Since the charging reaction alters the electronic structure of both the hydroxyl and nickel ion sites, a resulting change in crystal structure is anticipated. This over-all change in symmetry of the OH groups about the nickel ion sites has been discussed by Aia (3). Infrared data observed for the charged state in the 3μ region suggests that similarities exist between the structure of the higher oxide and that of boehmite (or lepidocrocite). This possibility is indeed compatible with the mechanistic implications discussed above. The beohmite structure is a hydrogen bonded layer lattice comprising brucite-type subunits linked through the sharing of oxygen atoms at the corners

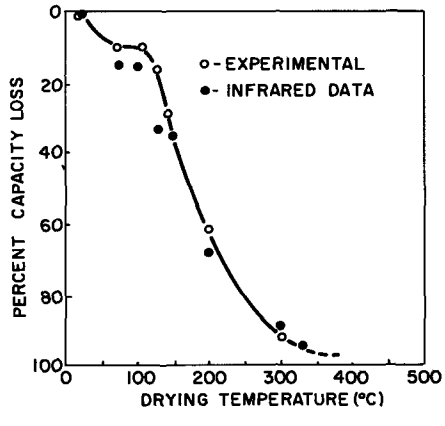

Fig. 6. Predicted and experimental electrochemical capacity remaining after thermal treatment at various temperatures.

of MO_6 octahedra (9). The fact that the nickel-to-oxygen coordination remains essentially octahedral upon charging has been previously shown (1, 8). It is not difficult to envision the conversion of the $Ni(OH)_2$ brucite-type structure into the orthorhombic boehmite-type structure via a change in symmetry at the hydroxyl sites.

Kinetics of the Fluorination of Iron

Patricia M. O'Donnell

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

ABSTRACT

The effect of temperature and pressure on the reaction of fluorine gas on solid iron samples was studied at various pressures up to 200 Torr over the temperature range of 225° to 525°C. The reaction was found to follow the logarithmic rate law, and logarithmic rate constants are reported. The probable mechanism of film growth is movement of fluorine through defects in the fluoride film to the iron surface.

The purposes of this report are (*i*) to present the results of a kinetic study of the fluorination of iron in the temperature range of 225°-525°C and (*ii*) to propose a mechanism for this reaction. The kinetics of this reaction are interesting since the only data available in the literature are the corrosion type where the reaction of fluorine on iron has been observed by taking a few measurements at long incremental time periods and linearly extrapolating them to give results reported as inches of penetration per month or per year at varying temperatures (1). A linear extrapolation of this type does not give a detailed picture of the reaction but merely defines maximum gross effects. This kinetic study was, therefore, undertaken in order to observe the details of the reaction of fluorine on iron. A few detailed studies of the reaction of fluorine gas with other metals have been reported. By studying the reaction between copper powder and fluorine gas from room temperature up to 250°C and at pressures up to 60 Torr, Brown, Crabtree, and Duncan (2) found that the reaction obeys a logarithmic rate law and is not pressure dependent. This law is widely applicable to corrosion kinetics (3) and relates the amount of reaction y with time t by

$$y = K \log (at + 1) \qquad [1]$$

and where K and a are constants for a given system and temperature. In a study of the reaction of fluorine on plate copper (4, 5), it was found that the reaction followed a logarithmic law above 538°C, but that below that temperature a simple power law was applicable. The reaction was observed to be pressure dependent. Other studies have been made of the reaction kinetics of fluorine with copper (6), nickel (7), and zirconium compounds (8) under various conditions. Although there have been extensive kinetic studies of the rates of oxidation of iron, there are no similar studies on the rates of the fluorination of iron.

Experimental

The vacuum apparatus used to measure the rate of fluorination of iron has been described previously (5).

The general experimental method used to determine the rate of fluorine consumption by iron was to measure the pressure decrease in a vessel of known volume containing the iron sample. In order to maintain approximately constant fluorine pressure, the pressure was allowed to drop only about 2 Torr, whereupon additional fluorine was admitted to return the pressure to its initial value. The perfect gas law was used to calculate the amount of fluorine consumed after each of these steps, from the incremental pressure drop, the vessel volume, and the temperature. Fluorine consumed was expressed in milliliters at standard temperature and pressure. Standard volumetric procedures were used to calibrate the volume of the furnace, storage vessel, and connecting lines. The glass system was passivated by introducing fluorine at increasing pressures and temperatures until further reaction of fluorine with the system was insignificant. The blank after passivation represented a correction of less than 1%.

To determine the temperature gradient along the iron strip, a special strip was made with eight Chromel-Alumel thermocouples attached along it. The leads came through a special end plug to a recording system. The temperature profile along the strip varied ±0.5°C at the low temperatures and ±3° for the 525°C temperature in a nitrogen atmosphere.

The iron samples were machined from spectrographically pure iron having the following impurities in parts per million: manganese, 2; silicon, 2; magnesium, 1; nickel, 1; silver, 1; and copper, 1. The samples were 1.27 x 15.24 x 0.012 cm with a 0.5-cm hole drilled in one end to facilitate handling. All samples were degreased in trichloroethylene, cleaned in 20% hydrochloric acid for 3 min, and washed in distilled

water, acetone, and alcohol. Samples were immediately inserted into the furnace under flowing argon and were positioned the same for each run. The system was sealed and pumped down to about 0.1μ pressure. All samples were preheated 0.5 hr at 525°C under vacuum before running. After the pretreatment, the temperature was adjusted to the operating temperature, and fluorine was introduced to the desired pressure. The recorder plotted the amount of fluorine consumed on a continuous time trace. Some experimental points from the traces are shown on Fig. 1 and 2. When the consumption of fluorine had decreased to a negligible value, the heaters were turned off, the system was allowed to cool to 25°C, and the fluorine was pumped out of the system through the soda lime traps. The test sample was removed to a glass tube holder, which was attached to the end of the reaction section, and was sealed under flowing argon for later visual and instrumental analysis. Some of the films scraped from the strips were analyzed by x-ray diffraction.

For cross-sectional analysis, samples were embedded in plastic, cut, and polished. They were then examined on a metallograph and photographed. The cross section was etched and dyed in order to determine if there was any grain boundary attack. Microscopic analysis was performed to reveal the topology of the samples.

Results and Discussion

The fluorine consumption by the iron samples was measured at several temperatures and pressures (Table I). Figures 1 and 2 illustrate the results; the milliliters of fluorine consumed per square centimeter of iron surface are plotted against the time in minutes. Some duplicate runs (solid symbols) have been plotted in order to show the reproducibility of the data. The effect of temperature on the reaction is shown in Fig. 1 where the data are plotted at temperatures from 225° to 525°C at a constant pressure of 60 Torr. Figures 2(a) and (b) show the effect of pressure on the reaction. In Fig. 2(a) the pressure effect is plotted at a constant temperature of 225°C and in Fig. 2(b) at a constant temperature of 525°C. In Fig. 1 the runs at 375° and 425°C cross at t = 90 min. Similar behavior is noted in Fig. 2 where the runs at 60 and 100 Torr at 525°C cross at t = 70 min. This type of crossover phenomena has also been observed in the oxidation of iron (9). In the 525°C 15-Torr run [Fig. 2(b)], the fluorine was pumped out after 125 min while the sample was kept at 525°C in order to determine the effect of heat and vacuum on the reaction. New fluorine was introduced to 15 Torr (point B), and the reaction appeared to start again. Copper plate and fluorine showed similar behavior (5); however, the reaction between copper powder and fluorine did not start again under similar conditions (2).

525	60	0.064
525	100	0.089

Product identification and volume ratio.—X-ray diffraction patterns were run on both the low and high temperature films and the product was identified as ferric fluoride (FeF_3); no ferrous fluoride (FeF_2) was detected. The over-all reaction may be described by

$$2Fe + 3F_2 \rightarrow 2FeF_3 \qquad [2]$$

In this reaction, the fluoride occupies a larger volume than the metal destroyed. The volume ratio (10) is defined as $\Phi = Wd/wD$ where W is the molecular weight of the film formed, w the formula weight of the metal, D the density of the film formed, and d the density of the metal. The volume ratio Φ for this reaction has a value of 4.9 at 25°C.

Logarithmic equation.—The data from Fig. 1 and 2 are replotted in Fig. 3 and 4 on a log time as a function of fluorine consumed basis. The straight lines shown on Fig. 3 and 4 fit a logarithmic equation that is similar to Eq. [1]. This equation is

$$y = K(\log at) + c \qquad [3]$$

where y is the fluorine consumed (at STP), ml/cm²; t time, min; K the logarithmic rate constant; a the constant with dimensions of reciprocal min; and c the intercept. The constant a is unity for the lines drawn on Fig. 3 and 4. Figure 3 shows the data at constant pressure of 60 Torr for various temperatures. In Fig. 4(a) the 225°C data are plotted at 20, 60, and 200 Torr, and in Fig. 4(b) the 525°C data are plotted at 15, 60, and 100 Torr showing the effect of pressure at constant temperature. It can be seen that the logarithmic equation fits all the data within the experimental error except at short times. Figure 2 indicates that heat and vacuum have an effect on the passivity of the metal strip. At point B the metal strip had reached a point

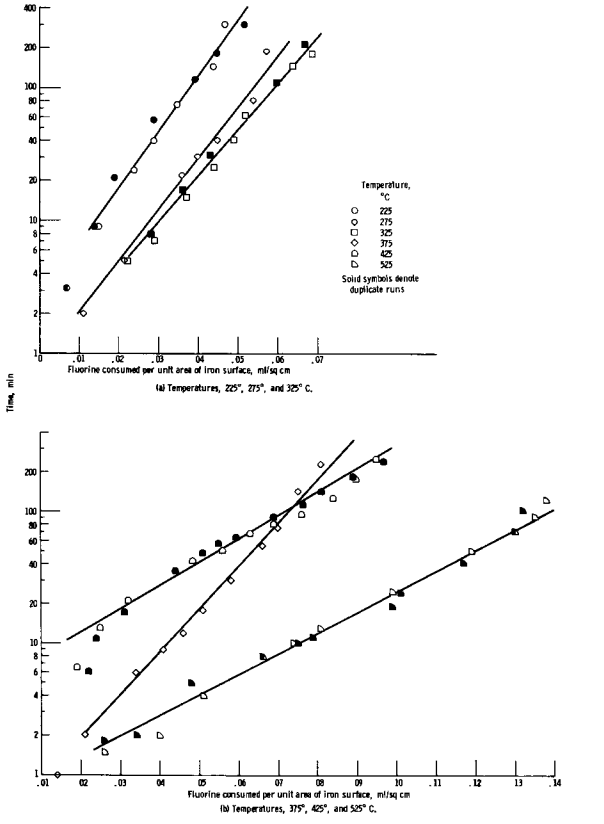

Fig. 3. Temperature effect at 60 Torr

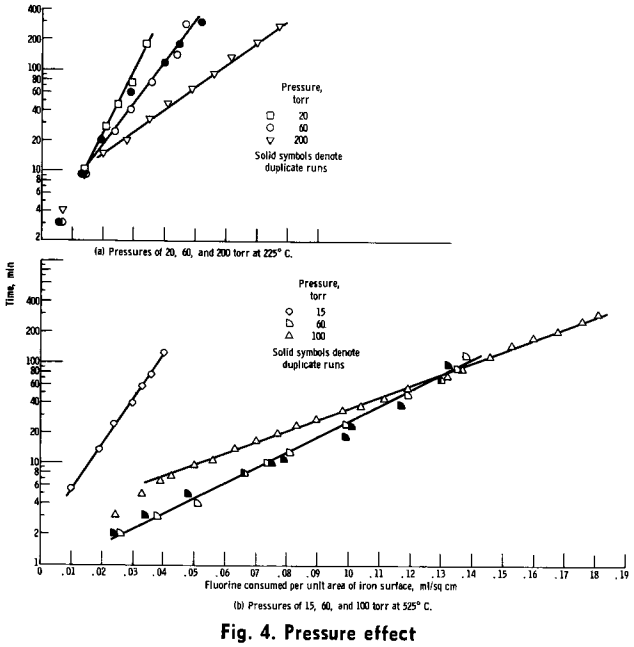

Fig. 4. Pressure effect

of negligible reactivity (passivation), however, when subjecting it to heat and vacuum for a period of approximately ten minutes and then to fluorine again it appears to lose some of its passivation. Figure 5 shows both parts of the 525°C run at 15 Torr plotted according to the logarithmic equation. The two lines on Fig. 5 were obtained by plotting the fluorine consumption against log time from point B on by considering the fluorine consumption for this second part of the reaction as the difference between reaction 1 (dashed line) and reaction [2] and B as the zero time point for reaction [2]. The rate for this second reaction is, however, lower than the original rate. The values of K for these reactions are 0.022 and 0.013 ml/cm^2, respectively, and are listed in Table I along with the values of the other rate constants.

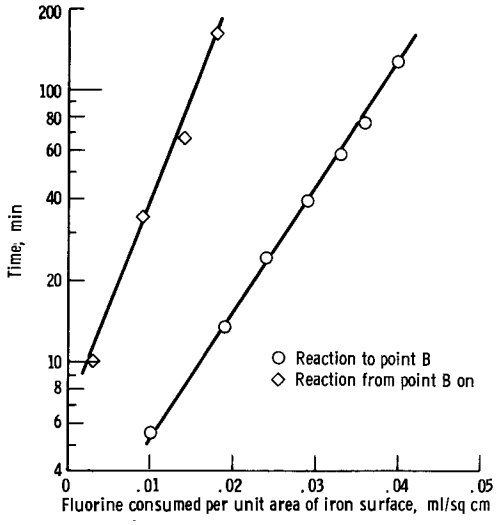

Fig 5. Interrupted fluorination of iron at 525°C and 15 Torr

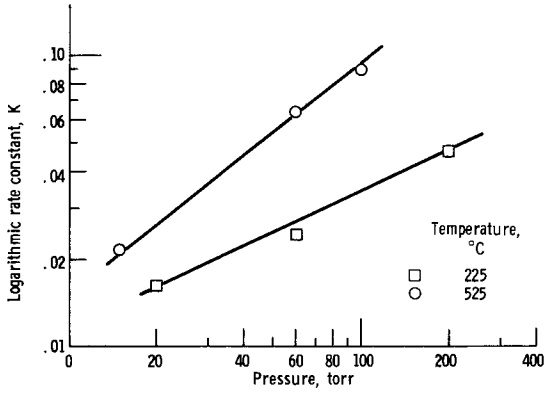

Fig. 6. Effect of pressure on rate constant

From the data of Fig. 1 and 2, the reaction between iron and fluorine is seen to be both temperature and pressure dependent. The effect of pressure on the logarithmic rate constant is shown in Fig. 6 where the log of this constant is plotted as a function of pressure at constant temperature according to the equation $\log K = m \log P + B$. The slope m is the order of the reaction with respect to the fluorine pressure. At 225°C, m has a value of 0.87, and at 525°C m is 0.48.

Metallographic studies.—Cross sections of the fluorine-corroded iron strips were prepared by standard metallographic techniques. Photomicrographs of typical cross sections are shown in Fig. 7. These photographs show that the boundary between the fluoride and the iron is very sharply defined. The fluoride film does not grow preferentially along grain boundaries in the iron. This was confirmed by etching and staining of polished cross sections. Near the iron-fluoride interface, the fluoride appears to be uniformly dense. Near the surface of the fluoride film, the fluoride appears somewhat broken and imperfect. This is to be expected, since the fluoride film occupies a volume 4.9 times larger than the iron from which it is formed, and this volume expansion must result in stresses which can fracture the film when it is thick enough.

Mechanism of fluorine attack.—The rate-determining process in growth of corrosion films on metals can be deduced by consideration of the growth law of the film. For example, if the film grows by diffusion of lattice vacancies through the film, the film thickness will increase with the square root of time. In the experiments reported here, the fluorine uptake, and hence the film thickness, varied directly with the logarithm of time except at short times, where the

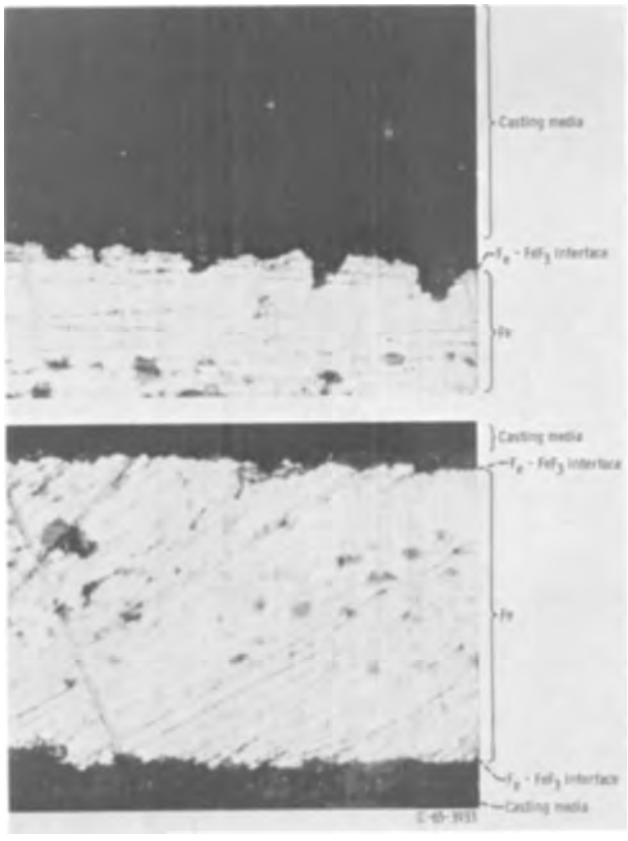

Fig. 7. Cross-section views (Fe + F_2 at 500°C). X500

film thickness is less than about 350Å. Theoretical analyses (3) have shown that such a direct logarithmic dependence can arise from either of two mechanisms: (*i*) when the growth rate is controlled by tunneling of electrons through the film, or (*ii*) when the growth rate is controlled by passage of gas through pores or other defects in the film to the metal surface. Tunneling is important only for films thinner than a few hundred angstroms. The film thicknesses in this research were much larger, so that this mechanism can be discarded. The second mechanism, that of passage of gas through pores in the film, is the most likely process. The pores through which the gas moves may be the intersection of three grains, the intersection of two slip-planes, screw, and edge dislocations, or simply fractures in the film. When the compressional stress in one pore exerts a pressure on neighboring pores, some of these will be blocked as the film grows. This is the case of mutually blocking pores and leads to the direct logarithmic growth law as found in this research. At low temperatures, the logarithmic law is found to be obeyed for the oxidation of iron and copper, where the expansion which occurs when metal is transformed to oxide tends to close up neighboring pores. In this research, the fluoride occupies a volume 4.9 times that of the metal from which it is formed, so that mutual blockage by compression can be expected. It is concluded that above a film thickness of about 350Å the fluoride film on the iron grows by passage of fluorine through pores in the film, and that these pores tend to block one another as the film thickness increases.

Electrochemical Aspects of the Interaction Between Materials and Blood

Dennis B. Matthews and Avery Catlin

Department of Materials Science, School of Engineering and Applied Science, University of Virginia, Charlottesville, Virginia

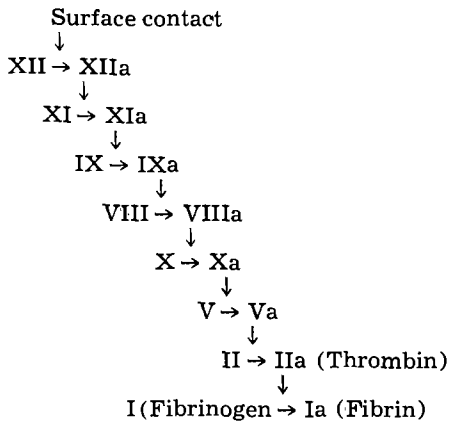
ABSTRACT

Electrolysis of human plasma, collected under various conditions, and of bovine fibrinogen (a protein normally present in blood) was carried out in order to verify conclusions made by earlier investigators. Electrolysis of recalcified plasma, ACD-plasma (plasma to which an acid solution of dextrose and sodium citrate has been added), citrated-plasma (plasma to which sodium citrate has been added), and heparinized plasma (plasma containing heparin anticoagulant) in glass, plastic, and silvered tubes did not support the conclusion that electrolysis produced inhibitors of, or catalysts for, the enzymatic blood coagulation reaction. The results were interpreted in terms of the effect of *p*H on the rate of coagulation.

Blood, withdrawn from a human and placed in contact with various materials, clots at a rate dependent on the material with which it is in contact. The rate of clotting is a maximum for such materials as glass, kaolin, celite (diatomaceous silica), and barium carbonate; it is a minimum for such materials as the normal vascular endothelium (the inside lining of blood vessels), paraffin, plastics including cellophane, and siliconized glass. For use as vascular prostheses such as artificial arteries, heart valves, and hearts, a

material must, besides other requirements, not initiate blood coagulation.

The intrinsic enzyme mechanism of blood coagulation, initiated by contact with a foreign surface, is fairly well documented, and the mechanism currently accepted by a large number of the workers in this area is shown below.



This enzyme cascade (1, 2) sequence or bioamplifier (3, 4) system is believed to be initiated by adsorption of factor XII (Hageman factor). The adsorbed factor XII is in an active state, designated as XIIa and capable of activating factor XI to give XIa which in turn activates factor IX, and so on, until the enzyme IIa (thrombin) attacks factor I (fibrinogen), converting it to fibrin which polymerizes, both end-to-end polymerization and crosslinking occurring, forming a net which enmeshes blood cells and serum.

There exists at present in the literature sufficient evidence to be able to conclude that electrical and possibly electrochemical factors play a role in the interaction between materials and blood, both "*in vitro*" and "*in vivo*" (21, 25).

This paper is concerned with the analysis of existing data in the light of some new results reported herein.

Despite the fact that the dependence of blood coagulation on electrolysis was observed as early as 1824, the first significant and systematic work on this subject was not carried out until 1953. In 1953, Sawyer, Pate, and Weldon (5, 7) observed that the potential difference across the canine artery wall changed sign upon injury being −3 to −15 mv (inside negative with respect to the outside) before injury and +1 to +10 mv after injury. The current flowing across the artery wall was also observed to change its sign and magnitude upon injury. The reversal of sign of the potential difference and the appearance of an "injury current" was accompanied by the formation of a thrombus, or blood clot, within the injured artery. A similar result was reported by Sawyer and Pate (6, 7) for the canine aorta.

Electrolysis of heparinized or citrated canine blood between platinum electrodes in a glass tube at 0.2-10 ma for 30 min resulted in the formation of a precipitate at the anode (8). The precipitate contained platelets, red blood cells (erythrocytes), and white blood cells (leukocytes). In the case of heparinized blood, fibrin strands were also reported to be part of the precipitate. No precipitate was formed at the cathode. It was demonstrated by Sawyer and Pate (8) that this precipitate was not caused by gross changes in *p*H. As the anode and cathode were situated in the same vessel separated only by 1 cm of solution it is not surprising that no gross changes of *p*H were observed.

The results of Sawyer and Pate (8) have been repeated by Lamb *et al.* (14) who used platinum wires 5 mm apart in the electrolysis of heparinized whole blood and plasma. The nature and amount of deposit formed on the anode was noted for various potentials between the anode and cathode and for various quantities of charge passed.

Passage of current across a blood vessel wall or across the blood vessel *in vivo* was also found to produce a deposit, or thrombus, on the vessel wall nearest the anode. On the basis of these experiments it was postulated by Sawyer, Deutch, and Pate (9) in 1955 that reversal of the normal potential difference across the canine blood vessel wall results in an electrophoretic migration of platelets, other cellular elements, and negatively charged proteins to the injured vascular wall thus precipitating a thrombus (blood clot). In later years, however, Sawyer (15) has concluded that electrolysis interferes with the intrinsic enzyme mechanism of blood coagulation.

In 1956 the investigations proceeded one step further when it was found by Sawyer and Deutch (10) that thrombosis (blood clot formation) was delayed at the cathode during electrolysis. Currents greater than 30 μa, when passed between a platinum cathode, placed around crushed canine arteries and veins, and an anode located at a distant position in the dog, were able to delay thrombosis compared to a control experiment where no current was passed.

These results were confirmed in 1959 by Schwartz (11) who observed *in vivo* thrombosis at the anode during electrolysis and who found that cathodic polarization was able to delay thrombin-induced thrombosis. Several other workers (12, 13, 16, 17) have since been able to produce *in vivo* thrombi by anodic polarization.

The experiments of Sawyer and Pate (8) were repeated by Sawyer, Dennis, and Wesolowski (15) with platinum electrodes in separate glass tubes connected by a salt bridge. Currents of 0.1-1.0 μa were found to produce a deposit on the anode in heparinized or citrated blood. A solution of fibrinogen in sodium chloride was also electrolyzed, and a deposit was observed at the anode. This deposit was thought to be fibrin produced from fibrinogen by electrolysis. It was conjectured that electrolysis can cause blood coagulation by bypassing all but the final steps in the intrinsic enzyme clotting mechanism.

In all the above *in vitro* experiments the blood was heparinized or citrated. The intrinsic blood coagulation mechanism was thus checked; in particular, the activation of factor IX is inhibited under these conditions.

In 1964 Naumovski and Dejanov (21) reported some results on the effect of electrolysis on *in vitro* clotting. Currents of 1.6 ma were passed through citrated plasma for 1 hr. At the cathode the plasma was found to have a markedly prolonged recalcification time, more than 80 times the average spread. The plasma *p*H was 9.6-9.8. Diluting the cathode plasma by imadazole buffer (*p*H 7.4) did not change the anticoagulant effect. Plasma at the anode changed negligibly, and the *p*H was 6.6-6.8.

On the other hand, Lavelle (21) concluded that direct electric current does not appear to initiate, or accelerate, the enzymatic coagulation system in circulating native blood. Lavelle's work, however, suffered from the disadvantage that the anode and cathode were not in separate chambers. Any material oxidized at the anode may well have been reduced at the cathode. In 1964 Sawyer, Brattain, and Boddy (18) observed that erythrocytes and leukocytes in Krebs solution (an electrolyte of ionic composition similar to that of blood) at *p*H 7.4 migrate and adhere to a platinum electrode at potentials greater than or equal to +0.33v (against NHE). Decrease of this potential led to desorption of the blood cells.

A similar behavior was observed with platelet suspensions (19) except that the adsorption of platelets was irreversible, the platelets visibly disintegrating at the electrode. Fibrinogen in buffer solution, however, was not found to deposit under these conditions (20).

The above results obtained by Sawyer and his coworkers and by others have led Sawyer to believe (21) that electrolysis is capable of interfering with the in-

trinsic enzyme mechanism of blood coagulation, the rate of blood coagulation being catalyzed at an anode and an inhibitor being produced at the cathode.

It was the aim of the present work to substantiate if possible the above viewpoint by repeating the *in vitro* experiments of Sawyer and co-workers under conditions where the intrinsic enzyme mechanism of coagulation is operative.

Experimental

Blood was collected in 450 ml quantities from healthy male donors. The blood was withdrawn under vacuum into a double plastic pack containing acid citrate-dextrose (ACD) anticoagulant. In some experiments sodium citrate or heparin anticoagulant was used in the place of ACD. The blood was centrifuged at either 1000g (platelet poor plasma, p.p.p.) or 300g (platelet rich plasma, p.r.p.) for 30 min to remove red cells and white cells. The plasma was squeezed off from the packed cells into the second plastic pack. Aliquots of about 4 ml were gravity fed from the pack into siliconized glass or polystyrene tubes, sealed and stored at either 4° or −20°C. Immediately prior to an experiment a plasma aliquot was thermostatted in a water bath at 37°C. In the case of plasma stored at −20°C, this procedure disrupts the platelets, producing lysed plasma.

To initiate clotting, 0.20 ml of 0.25M $CaCl_2$ was added to 2 ml of plasma. The rate of coagulation was followed with a photometric system (23). Light from a voltage regulated 0.25 amp 6-volt lamp was passed through the sample, contained in a block of aluminum thermostated at 37° ± 0.5°C, and the transmitted light was monitored with a CdS photocell. The resistance of the photocell was measured with a Wheatstone bridge, and the change of resistance with time was continuously recorded with a potentiometric recorder. The measuring system is shown in Fig. 1. The type of recording obtained is idealized in Fig. 2. The times t_0 and t_1 mark the onset and completion of fibrin polymerization, respectively. The shape of the curve obtained depended on the experimental conditions. In the case of a simple sigmoidal curve the time $t_{1/2}$ was used as a measure of the rate of coagulation. For more

complex curves. *e.g.*, double sigmoidal, linear + sigmoidal, the times t_0 and t_1 were tabulated.

Electrodes used were, except where otherwise indicated, platinum wire spirals approximately 1 cm^2 in area. The cathode and anode were placed in separate tubes connected by a saturated KCl-gelatin salt bridge. The salt bridge was constructed either of siliconized glass tubing or of polyethylene tubing. The platinum electrodes were cleaned in 1:1 mixture of concentrated HCl-concentrated H_2SO_4, rinsed with distilled water, and heated to red heat in a flame.

Bovine fibrinogen obtained from Warner-Chilcott was dissolved by standing at 37°C with distilled water.

All pipettes and other glassware used in handling plasma were siliconized with Clay-Adams Siliclad. Test tubes were discarded after use, fresh tubes being used in each test.

Polystyrene tubes were silver coated according to a well-known procedure (22) and dried at 60°C for 5 hr or more.

Results

The effect of electrolysis, after recalcification, of various types of plasma, collected and stored under various conditions, is summarized in Table I and Fig. 3. The tests were carried out in glass tubes at 37°C. In these experiments the plasma was in contact with both glass and an electrode.

In order to eliminate uncertainties brought about by contact with glass, a polystyrene tube coated internally with electrically conducting silver was used both as container and cathode. The effect of cathodic electrolysis was tested in these tubes by electrolyzing citrated plasma for a given time, t_a, and then transferring the plasma to a polystyrene tube containing $CaCl_2$. The experiments were carried out at 37°C with

platelet poor plasma (lysed) collected in ACD. Results are given in Table II.

The experiment of Sawyer, Dennis, and Wesolowski (15) on the electrolysis of fibrinogen was repeated. Purified bovine fibrinogen (2.0 ml) was electrolyzed with platinum electrodes in separate glass tubes connected by a salt bridge. At 1 ma a deposit formed on the anode within 25 sec. The deposit consisted of a white precipitate mixed with bubbles of O_2 causing the precipitate to adhere to the anode. No reason was seen for believing the deposit to be fibrin rather than fibrinogen. Addition of sodium citrate to fibrinogen was found to inhibit the formation of a deposit. Only after 15 min of electrolysis at 1 ma did a very fine precipitate form, and this tended to remain in suspension. Electrolysis of citrated plasma itself, which contained the same concentration of fibrinogen as in the above experiments, resulted in the formation of a very fine precipitate only after 15 min of electrolysis at 1 ma. The possibility of fibrinogen being precipitated by a decrease in pH of the solution in the anode compartment was checked both by calculation and actual measurement of the pH change. In the absence of buffer the pH changed from 6.00 to 3.61 after 1 min of electrolysis at 1 ma, while in the presence of sodium citrate the pH change was from 8.16 to 7.58.

The experiments of Naumovski and Dejanov on the electrolysis of citrated plasma were repeated using platelet poor plasma. Electrolysis was carried out at 1.6 ma with 10 ml of plasma in polystyrene tubes using Pt electrodes. After 60 min electrolysis the plasma was thermostatted at 37°C and 2 ml recalcified in glass tubes at 37°C. Results obtained are shown in Table III. Both cooled and lysed plasma were tested.

The above experiments were repeated with heparinized platelet poor plasma. Electrolysis was conducted in polystyrene tubes at 3.2 ma for 30 min using 10 ml of fresh plasma. After electrolysis 2 ml of the sample was contacted for 10 min in glass tubes at 37°C, 0.20 ml of protamine sulfate was then added to neutralize the heparin. This experiment was repeated with a 1:1 sample of fresh plasma and veronal buffer (pH = 7.5),

Table III. Effect of prolonged electrolysis on the rate of clotting of citrated platelet-poor plasma at 37°C

in order to inhibit the pH changes brought about by electrolysis. The results of the experiments with heparinized plasma are given in Table IV.

Discussion

Table I shows that for plasma collected in either ACD or sodium citrate there is little effect of electrolysis either on t_0 or t_1. This result is independent of whether the plasma was platelet rich or platelet poor and whether or not the platelets were lysed by freezing and thawing. The variations in clotting time as a function of platelet concentration and platelet condition are not meaningful since each set of results refers to a different batch of plasma. Variations in plasma obtained from different donors or from the same donor on different days are such as to allow comparison only between results obtained within a given batch of plasma. Such experiments yield the result that the clotting time t_0 is less for platelet rich than for platelet poor plasma. With platelet rich plasma clot retraction was very pronounced and prevented determination of t_1. Platelet lysis led to a decrease in clotting times t_0 and t_1, but the decrease in t_0 was almost independent of the original platelet concentration indicating the release of an enzyme from the platelets. The decrease in t_1 was dependent on the original platelet concentration, but when the platelet fragments were removed by centrifugation at 2500g then lysis caused no change in $t_1 - t_0$.

A small increase in the rate of clotting was produced by cathodic electrolysis, but this effect is much smaller and of opposite sign to that previously reported for plasma and whole blood containing anticoagulant. Moreover, in the presence of anticoagulant (ACD), Table II shows that electrolysis in silvered tubes did not inhibit the formation of contact factor (factor XIa) nor did it produce an inhibitor to clotting, rather, a small increase in coagulatibility was observed.

Electrolysis of fibrinogen in unbuffered solutions was shown to produce a rapid and large decrease of pH in the anode compartment with the resultant precipitation of fibrinogen.

Prolonged electrolysis of plasma in polystyrene tubes with Pt electrodes did not produce an inhibitor in the plasma. The recalcification time was not greatly increased by cathodic electrolysis contrary to the observation of Naumovski and Dejanov, rather, the clotting time for ACD-plasma was slightly decreased by cathodic electrolysis. Anodic electrolysis caused an increase in clotting time compared to unelectrolyzed ACD-plasma. These results may be attributed to the pH changes produced in the plasma by electrolysis. It is well known (24) that the clotting time for blood is a minimum at pH = 7.5 and increases rapidly with either increase or decrease of pH. Inspection of Table III for lysed plasma shows that cathode plasma with pH 7.35 has the smallest clotting time. Unelectrolyzed plasma of pH 7.01 (due to presence of ACD) has a slightly larger clotting time and anode plasma with pH 6.47 has a much larger clotting time. Similar effects were noted on electrolysis of heparinized plasma.

The present results on the electrolysis of human plasma and bovine fibrinogen indicate no interference with the intrinsic enzyme mechanism of blood coagulation, and it is concluded that the results of Sawyer and others on the electrolysis of blood were caused by an electrophoresis mechanism, negatively charged erythrocytes, leukocytes and platelets migrating in the field between the anode and the cathode.

The results do not exclude the possibility of electrochemically influencing the intrinsic enzyme mechanism of blood coagulation. One might reasonably hope to influence the adsorption of Hageman factor (factor XII) on a given material by altering the charge on the material. However, the conditions under which specific proteins are adsorbed and desorbed are by no means obvious and information is required on factors which influence protein adsorption at the solid-liquid interface. Such information would be of great value not only to the study of blood-materials interaction but to the general area of compatability of prosthetic materials and the human body.

Surface Tensions of Co-Ce and Pu-Co-Ce Alloys as Determined from Frozen Menisci

John C. Biery

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

The surface tensions of three Pu-Co-Ce and three Co-Ce alloys at their freezing point were determined from their frozen menisci. A new calculational procedure was used in which calculated menisci were compared with the experimental menisci. The meniscus shapes were calculated by numerically integrating the Laplace-Young equation. The best surface tension for a given meniscus was found by comparing the computed and experimental menisci at 25 points across the meniscus and by varying the surface tension and contact angle at the outside of the meniscus section until various restraints were satisfied. The meniscus comparing techniques satisfactorily detected and discarded distorted menisci. Of the 28 menisci studied, 15 were found to be acceptable.

Molten plutonium alloys with cobalt and cerium were tested as possible fast nuclear reactor fuels. These studies indicated that unusual phenomena occur at and above the liquid/gas interface of the molten fuel when it is contained in tantalum capsules. Since some of these phenomena may be associated with the energy in the interface, the surface tensions of these alloys should be known to understand the systems better. The usual methods of determining surface tension such as capillary rise, pendant drop, sessile drop, and bubble pressure require expensive and time-consuming experiments when plutonium is involved. Therefore, a technique was developed to generate surface tensions from photographs of menisci since in many cases well-formed menisci are observed in sectioned capsules containing the Pu-Co-Ce alloys. The initial mathematical and numerical techniques for making these determinations from menisci and the test of the method with mercury and water are reported elsewhere (1). Here, the results from analyzing frozen menisci of Co-Ce, Pu-Co-Ce, and Ni-Ce/NaK are presented.

The previously published geometrical and computational methods (1) were tested experimentally with liquid menisci. An important objective of this paper is to test the applicability of the methods as applied to frozen menisci. The tests of the methods were made by (*i*) processing many capsules and comparing the

acceptable results from capsules with similar radii, (*ii*) comparing results from menisci formed in capsules with significantly different radii, and (*iii*) comparing results for Pu-Co-Ce with one value obtained from a capillary rise experiment.

Experimental and Calculational Procedure

The frozen menisci were analyzed by an experimental and calculational procedure that has been previously described in detail (1). Below are summarized the important features of the analysis.

Experimental procedure.—The capsule containing the frozen alloy is sectioned longitudinally and is then polished to the centerline position.[1] For best results the void space above the alloy should be filled with epoxy resin. The meniscus is then photographed, and the photograph is enlarged to 25 cm across the diameter of the tube. Meniscus heights at 25[2] positions across the radius are read from a graph onto which the meniscus curve had been traced. These heights are replotted on a graph of expanded scale, and a smooth curve is drawn through the points. Values from this curve are read into the computer for comparison with the computed curves.

Also, from the experimental heights, the sine of the tangent angle at the outside of each radial increment is calculated. A smooth curve is drawn through these points. This "adjusted" sine curve is positioned after calculations have been made to produce a constant surface tension when these sines are used as boundary conditions in the calculations.

Calculational procedure.—The analysis as developed includes a mathematical procedure for calculating the meniscus curve and a method for comparing the computed and experimental curves. The comparison is made in such a manner as to produce the best surface tension value and to throw out the distorted menisci. The meniscus curve is generated by numerically solving a modified form of the Laplace-Young equation shown below.[3]

$$z = \frac{\gamma}{rg(\rho_1 - \rho_2)} \frac{\partial}{\partial r} (r \sin \theta) \qquad [1]$$

The determination of the surface tension and the testing of the distortion of the meniscus involves the selection of γ and ϕ to produce a best fit between the computed and experimental meniscus curves. The procedure involves the following steps:

1. A $\gamma_{optimum}$ *vs.* $\sin\phi$ curve is calculated for portions of the meniscus out to radial increments 21 through 25.[4] The range of $\sin\phi$ for each sized meniscus is determined by a ± 0.015 range about the smoothed experimental $\sin\theta$ curve. For each $\sin\phi$, $\gamma_{optimum}$ is found by satisfying the "sum of mass restraint." A series of menisci are calculated with various surface tension values, γ_{as}, for each $\sin\phi$. The capillary rise, z_o, calculated at the center of the capsule for each γ_{as}, when combined with the experimental meniscus curve, allows a γ_{cal} to be calculated by equating the net weight of fluid between the meniscus and the datum plane to the peripheral surface tension force. When the γ_{as} and γ_{cal} agree, this common value is the desired surface tension which satisfies the "sum of mass restraint" for the chosen $\sin\phi$.

2. An "adjusted" experimental $\sin\theta$ curve is drawn to fit the experimental $\sin\theta$ points best and to give the same value of surface tension for the calculations at increments 21 through 25. The $\gamma_{optimum}$ *vs.* $\sin\phi$ curves calculated in 1 above are used to determine the surface tension at each radial position.

3. For each calculation, standard deviations, s and s_7, between the calculated and experimental meniscus heights are calculated. For an undistorted meniscus at the correct values of γ and ϕ, these standard deviations should be a minimum and should have a value less than 0.0015 cm. If such a minimum occurs with $\sin\phi$ within a ± 0.015 range of the "adjusted" experimental sine curve, then this surface tension is allowed as an acceptable value.

Thus, the primary test as to whether or not a meniscus is undistorted and the surface tension value is acceptable is that the s and s_7 standard deviation values calculated at the conditions where the "sum of mass restraint" is satisfied have minima which are less than some arbitrarily chosen value. Also, the $\sin\phi$ values at these minima in s and s_7 must be within ± 0.015 range of the "adjusted" experimental sine curve. Averaging methods 1, 2, 3 as listed below are versions of this set of requirements with increasing limits on the maximum allowable values of s and s_7 at the minima. In the original formulation of the averaging methods, additional less stringent requirements were proposed as methods 4 through 9. These methods were tested in the present study but are not listed below. Their requirements can be formed elsewhere (1).

Method 1.[5] Average of all surface tension values as determined by the "sum of mass restraint" and a minimum in s or s_7 where $|(\sin\phi_{min} - \sin\phi_{adj})| < 0.015$ and s and $s_7 < 15 \times 10^{-4}$ cm.

Method 2.[5] Same as method 1 except s and $s_7 < 25 \times 10^{-4}$ cm.

Method 3. Same as method 1 except s and $s_7 < 35 \times 10^{-4}$ cm.

The above restricting procedures were designed to separate the undistorted from the distorted menisci. The possible sources of distortion in both liquid and frozen menisci that require detection are as follows: (*a*) optical distortion when meniscus is viewed through a cylindrical surface; (*b*) distortion produced by local wetting such that the meniscus is not a surface of revolution; (c) variation of the surface with time where wetting conditions or temperature conditions are not stabilized to produce an equilibrium meniscus; and (*d*) errors introduced by sectioning of a frozen meniscus where the cut may be off center or not parallel to the axis of the cylinder.

Specific tests in the initial paper (1) or in this paper have not been performed to determine specifically the limits of distortion which the various restricting techniques detect. In both cases the applicability of the methods is inferred by the comparison of numerical results from a number of menisci and the comparison of surface tensions with known values as determined by other methods.

[1] Most of the capsules utilized in this study were not carefully polished to the centerline position since the sectioning was done for metallographic purposes in conjunction with another project.

[2] The value of N, the number of increments across the radius of the tube, is arbitrary and should be chosen small enough to limit computation time but large enough to allow accurate reproduction of the highly curved section of the meniscus near the wall. For the present system with surface tensions in the 600 to 1000 d/cm range, densities near 10 g/cc, and tube radii between 0.45 and 1.2 cm, the choice of N equal to 25 was found to give good results. However, with larger capsules N should be increased to insure that the highly curved section near the wall is divided into at least 5 and preferably 10 increments. Also, with a smaller ratio of $\gamma/(\rho_1 - \rho_2)$ and a resulting flatter meniscus, more increments may have to be used.

[3] See Nomenclature at end of paper.

[4] In all of the calculations and comparisons, the section of the meniscus used was that portion from the centerline out to some arbitrary radial position less than or equal to the radius of the tube. The effect of utilizing successively smaller portions of the meniscus was studied by discarding increments of the meniscus at the outside perimeter. As each increment was discarded and the comparison between computed and experimental data was made, a better or worse value of surface tension was obtained. The change depended on whether or not the discarded increment was more or less distorted than the remaining inside portion of the meniscus. Many calculations were run with 21, 22, 23, 24, and 25 increments retained when the radius was divided into 25 increments. The results indicated that the 25th increment, which was next to the tube wall, was many times distorted and that the most consistent data were obtained when the calculations were made for 24/25 or 23/25 of the total meniscus. Because of the increased curvature near the wall, the most readily detectable surface tension data were contained in the outside 10/25th of the meniscus. Therefore, the quality of the surface tension results deteriorated when as many as 4 increments were discarded.

[5] The limits on methods 1 and 2 were revised somewhat as compared to those used in the Hg, water calculations (1). The changes were made to make methods 1, 2, and 3 consistent. In these three methods the limit on the sines is held constant while the restraint on s and s_7 is progressively relaxed.

Surface Tensions of Co-Ce Alloys from Frozen Menisci

The surface tensions of 6, 12, and 18 w/o Co in Co-Ce alloys were determined from their frozen menisci. A total of 12 menisci were analyzed, and of this number 7 produced minima in the s and s_7 curves that met the demands of methods 1, 2, or 3. The best data came from the 12 w/o Co-Ce melts. For this composition, 6 samples were run, and four of them gave acceptable s and s_7 minima.

In Tables VII and VIII in the Appendix,[6] are compiled the physical properties and chemical analyses of the alloys, characteristics of the menisci, and the computation data for the three alloys. The densities at melting of the alloys were obtained from a paper by Perkins *et al.* (2). These density studies show the 12 and 18 w/o Co-Ce alloys to be near eutectics and to melt at nearly constant temperatures of 425° and 440°C. The 6 w/o alloy is not a eutectic and melts over a range from 420° to 625°C. Therefore, the surface tension for the 6 w/o material does not accurately represent the surface tension of the alloy, but probably shows the properties of a melt near 12 w/o Co which is the last material to solidify at 420°C.

All of these alloys expand on freezing. Thus, the shape of the meniscus is quite well preserved since a crust tends to form first over the meniscus and excess liquid is squeezed upward by the freezing action and usually escapes up on the meniscus crust through cracks. The upward pressure of the unsolidified melt does not seem to distort the meniscus unduly. The characteristics of each alloy and its surface tension determination are discussed below.

6 w/o Co-Ce alloy.—The surface tensions for the 6 w/o alloy are shown in Table I. Because of a large s value greater than 0.0025, only those methods that did not include or relaxed the s and s_7 size restrictions gave any useful results. Acceptable minima in s were obtained when s was allowed to be as large as 0.0035 cm in method 3, and the average surface tension, 685 ± 38.2 dynes/cm, obtained with these restrictions had the smallest 95% confidence intervals. Methods 8 and 9 gave comparable results, 677 dynes/cm, but with a larger confidence interval of ±96.8 dynes/cm.

In these determinations the radius of the capsule ranged from 0.47 to 0.57 cm. The meniscus in this sized capsule had maximum heights above the meniscus bottom of 0.32 cm, and the calculated capillary depression varied between 0.23 and 0.29 cm for the two acceptable menisci. In Table X in the Appendix, is tabulated a summary of the computation results for the three menisci.

12 w/o Co-Ce alloy.—The analyses of the 12 w/o Co-Ce menisci gave the best and most consistent results. Six menisci were studied, and these were formed in three different size tubes of 0.46, 0.57, and 1.2 cm radii. Acceptable minima in the s and s_7 curves were obtained from all three sizes of menisci. These menisci produced surface tensions with an average value of 644.5 dynes/cm with a 95% confidence interval of ±7.7 dynes/cm. The menisci with the largest radius were most easily analyzed. The minima in s and s_7 were much sharper, and the surface tension was much more insensitive to changes in $\sin\phi$. Also, in the larger radius capsules the value of z_0 was smaller, and its influence on the total calculation was less.

The results from the 12 w/o Co-Ce menisci gave the best indication that distortion was not significant when the criteria of method 1 were satisfied. Menisci from three different radii tubes were analyzed, and the results from all three agreed very satisfactorily. Since the cooling histories of the melts in the capsules were considerably different, the probability of all menisci distorting in such a manner to meet the demands of method 1 and still give the same value of surface tension is quite small. In Fig. 1 and 2 are shown the menisci for capsule 3 (1.21 cm radius) and capsule 277 (0.459 cm radius), both of which produced surface tensions which met the requirements of method 1. The large diameter capsule exhibited distortion in the center. However, the outside portions of the meniscus were undistorted and produced acceptable values of surface tension. Capsule 277 meniscus appears visually to be undistorted, and the computations supported

this contention. In Fig. 3 and 4 are shown the s and s_7 curves for these two capsules.[7] The "adjusted" and experimental sine curves for these two capsules are shown in Fig. 5 and 6. Visual comparison of Fig. 3 *vs.* 4 and of Fig. 5 *vs.* 6 indicates that the methods used to treat the data permit satisfactory results to be obtained from both symmetric and distorted menisci provided only that the region of obvious distortion is not in the curved section near the outside perimeter of the meniscus.

In Table X in the Appendix are summarized the computational results for the 12 w/o Co-Ce alloys.

18 w/o Co-Ce *alloy.*—The surface tension results for the 18 w/o Co-Ce melts are summarized in Table I. Only one of the three menisci gave acceptable minima in the s and s_7 curves. However, the limitation of method 6 allowed two results from two capsules to be averaged and gave a result of 876 ± 51 dynes/cm. The two acceptable menisci for method 6 had significantly different radii of 0.57 and 1.21 cm. The computational

and comparison results for the 18 w/o Co-Ce alloys are presented in Table XI in the Appendix.

Surface Tensions of Pu-Co-Ce Alloys

The Pu-Co-Ce system forms a series of low melting alloys in which the plutonium concentration can be varied over a wide range of concentrations without significantly changing the melting temperature. These alloys are of interest in a liquid metal nuclear reactor because of the possibility of changing the plutonium concentration and the power density without changing the temperature requirements of the coolant system. Alloys from this system have been extensively tested as to their corrosion characteristics in tantalum containers, and some usable menisci were observed when photomicrographs were made from the sectioned capsules. The three alloys of interest are the 3, 5, and 8g Pu/cc concentrations. The nominal weight per cent compositions for the three alloys are listed in Table II. Also, listed are the melting ranges of these materials. These alloys are not true ternary eutectics, but their compositions do reside near the bottom of a temperature trough running through the ternary diagram. Therefore, the 3 and 5g Pu/cc materials do melt over a very narrow range of 10°C while the 8 g/cc melts over a 25°C range.

The data reported here were obtained from various capsules that were run for other purposes. As a result, many menisci were asymmetrical and distorted from not being in an exact vertical position on freezing. Also, no great care was taken to section the capsule exactly in the center. However, the number of undistorted menisci was sufficiently large to give reasonable estimates of the surface tension of the melts on freezing. In Tables XII and XIII, in the Appendix, are listed the chemical analyses for many of the melts tested. Also, the physical properties of the menisci and the computation requirements for the three alloys are tabulated in Table XIV of the Appendix.

3 g/cc Pu-Co-Ce *alloy.*—Five menisci were analyzed for the 3 g/cc alloy; the results are shown in Table III. Two of the menisci produced acceptable minima in the s and s_7 curves as required by method 1, with a resulting average surface tension of 653.6 ± 14.9 dynes/cm. For this alloy only methods 1, 2, and 3 produced averages with small enough confidence intervals to be meaningful.

One of the 5 menisci was obtained by radiographing a sealed capsule in which the meniscus was frozen. Added uncertainty was produced by the fuzzy nature of the radiograph, and the resulting s and s_7 values were excessively large. However, the average γ from the "adjusted" sine curve was 598 dynes/cm which compares surprisingly well with the 654 dynes/cm value from the two acceptable mensici. A summary of the computational and comparison results for the 3 g/cc alloy is presented in Table XV of the Appendix.

5 g/cc Pu-Co-Ce *alloy.*—Five menisci from the 5 g/cc alloy were studied, and two of the menisci produced minima acceptable by method 2. However, in this case the range of the surface tensions from these minima was very large, 927 to 1340 dynes/cm. The average surface tension from method 2 was 1125 ± 151 dynes/cm. Method 7 actually produced an average with a smaller confidence interval, 1079.8 ± 116 dynes/cm. This wide confidence interval indicates that some distortion was being allowed in method 2 and that more menisci should be studied as they become available. The tabulation of comparison results is given in Table XVI in the Appendix.

The radiographed meniscus again had very large s values. The average value from the adjusted sine curve was 629 dynes/cm which does not compare favorably with the above averages.

8 g/cc Pu-Co-Ce *alloy.*—The average surface tensions found for the 8 g/cc alloy are presented in Table III. Of the 5 menisci tested none met the requirements of methods 1 and 2. However, the minima in s and s_7 were acceptable from three of the menisci when the size restriction of s and s_7 was relaxed to

35 x 10^{-4} cm in method 3. This result of 1019 ± 118 dynes/cm had the smallest 95% confidence interval for all of the 9 averaging methods. All other restricting methods had confidence limits of ±164 dynes/cm or greater. Table XVII in the Appendix contains the computational and comparison results for the various menisci.

The radiographed capsule had very large s and s_7 values and gave an average surface tension of 740 dynes/cm. The fuzziness of the radiograph produced some of the distortion indicated by the size of the s and s_7.

Capillary rise surface tension determination.—The surface tensions of these alloys have not been determined by other methods in experiments designed for such determinations. However, one independent calculation of the surface tension of 6.2g Pu/cc Pu-Co-Ce (57.7 w/o Pu-9.4 w/o Co-32.8 w/o Ce) was made possible from a radiograph of the fluid contained in an electromagnetic pump experimental apparatus (3). The reservoir and manometer legs provided a system in which capillary rise in the legs could be measured. At 530°C the rise in the manometer tube along with the assumption of 0° contact angle gave a surface tension of 1050 dynes/cm. This value compares very favorably with the values of 1125 ± 151 and 1019 ± 118 dynes/cm for the 5 and 8g Pu/cc Pu-Co-Ce alloys.

Interfacial Tension of a Co-Ni Alloy Covered with NaK

In density studies made with a NaK volumeter (2) the density specimen is held in direct contact with the indicating NaK fluid. Many of the specimens formed well-shaped concave menisci between the alloy and the NaK. At this time one of these menisci from an 18 w/o Ni-Ce alloy has been analyzed. The results presented in Table IV indicate that the meniscus was relatively undistorted since acceptable minima in s and s_7 at three of the four radial increments tested were obtained. The best result came from method 3 where a tension of 421.3 ± 16.1 dynes/cm was produced. Since only one sample was run, most of the analyzing methods could not give a 95% confidence interval. The physical data for the mensicus and the computation times are given in Table XIX in the Appendix. The computation results for each radial increment are included as Table XX in the Appendix. As indicated in Table XVIII the Ni-Ce alloy melted over a temperature range of 450°-490°C and is not a true eutectic. A complete tabulation of the experimental meniscus heights for all of the menisci studied are presented in Table XX in the Appendix.

Results and Conclusions

Surface tensions of 6, 12, and 18 w/o Co-Ce, 3, 5, and 8g Pu/cc Pu-Co-Ce alloys, and the interfacial tension of 18 w/o Ni-Ce/NaK were determined from frozen menisci of the alloys. A total of 28 menisci were analyzed and, of this number, 15 produced minima in the standard deviations, s and s_7, that met the limitation of size of s and s_7 and of deviation in $\sin\phi$, as required by averaging methods 1, 2, and 3. Nine methods of testing the surface tension data for distortion were tested on the menisci, and methods 1, 2, and 3 which require acceptable minima in s and s_7 were consistently the best. Of the more liberal restricting techniques, methods 7, 8, and 9 most consistently produced results that agreed with methods 1, 2, and 3. These last restrictive methods invariably had 95% confidence intervals that were from 1½ to 10 times as large as those from methods 1, 2, and 3. In one case, for 18 w/o Co-Ce, method 6 which only requires that experimental and adjusted sine curves be nearly parallel gave the most acceptable results with the smallest 95% confidence interval. The surface tensions obtained from the analyses are summarized in Table V.

The surface tension calculation and restriction procedure was designed such that if averaging method 1 was satisfied the meniscus could be assumed to have no significant distortion from freezing. Averaging methods 2 and 3 also should minimize the possibility of distortion, but because of the larger allowable standard deviation in meniscus differential heights, more distortion is permitted. The analysis of the 28 menisci in this study indicate that the restrictions of method 1 are sufficient to eliminate distorted menisci. Methods 2 and 3 with their relaxation on the size of the standard deviation also give good results in general. Three tests of the restricting procedures were possible from the computations. Comparisons of surface tensions from capsules of similar size could be made. Also, surface tension comparisons from capsules with significantly different radii were possible. And finally, one independent surface tension determination was available for comparison.

In the first test, the surface tension of a given alloy was determined from a number of capsules of approximately the same diameter, and these values were compared. Since the cooling histories of the capsules were probably dissimilar, the surface tension values from the capsules could be significantly different if distortion were allowed to influence the results. Also, the values from the various capsules could vary from asymmetries resulting from nonvertical freezing and noncenterline cutting. The minima methods were designed to detect and discard nonmeniscus type of shapes. Thus, if the methods are operating satisfactorily, the remaining acceptable menisci should produce comparable values of surface tension. In Table VI are summarized the data obtained from capsules of comparable size for the alloys tested. The surface tensions of the capsules accepted and from those rejected are noted. Also, the type of minima method used is listed. Three sets of capsule pairs from two alloys met the requirements of method 1. The range of the dual values was for each set within ±1.8, ± 1.2, and ± 0.23% of the average for the two capsules. As the magnitude of the standard deviations, s and s_7, was relaxed in methods 2 and 3, the spread in surface tensions became greater. For the 5g Pu/cc Pu-Co-Ce with method 2, the range was ± 13.4%. Method 3 gave very good results for 6 w/o Co-Ce with a range of ± 0.43%. However, the range with method 3 for 8g Pu/cc Pu-Co-Ce was ± 10.5%. These results tend to indicate that method 1 is sufficiently stringent to insure that the shape being studied was formed by surface tension forces. However, some dis-

tortion in the meniscus can be expected if methods 2 or 3 are used.

A second test of averaging method 1 was made available by the data from the 12 w/o Co-Ce menisci. Here two sets of capsules with significantly different radii met the requirements of method 1. The shapes of these menisci were quite different as indicated in Fig. 1 and 2, and their thermal cooling histories had to be very different because of the different radii. As shown in Table VI, the average values for these two sets of capsules were 643 and 645 dynes/cm.

Finally, a surface tension value was obtained by a capillary rise experiment for the 6.2g Pu/cc Pu-Co-Ce fuel. This value was 1050 dynes/cm which falls right between the values obtained for the 5 and 8g Pu/cc fuels as determined by methods 2 and 3.

These calculational and experimental results show that good surface tension values can be obtained from frozen menisci with the comparison and restricting procedures utilized. However, the less stringent averaging procedures, methods 4 through 9, should be used with care and should be utilized only to indicate the general range of the surface tension for a given liquid metal.

γ_{optimum}	surface tension calculated with sum of mass restraint where $\gamma_{\text{as}} = \gamma_{\text{cal}}$, dynes/cm

Technical Notes

The Application of Ultraviolet Analytical Techniques to Lead Acid Systems

Thomas F. Sharpe

Research Laboratories, General Motors Corporation, Warren, Michigan

The use of ultraviolet (uv) spectrophotometric techniques to clarify the role of organic additives in electrolytic systems has been restricted to some extent because portions of the spectra of the organic materials have been obscured. In studies of adsorption at copper, nickel, and silver electrodes, Barradas and Conway reported (1) that traces of metal ions and/or complexes formed between the metal ion and the organic compounds tended to distort the uv absorption bands of the organic adsorbate. To minimize these effects, the study was confined to alkaline and weakly acidic solutions at electrode potentials near the reversible hydrogen potential for the given solution.

Similarly, the application of uv methods for studying the reactions of conjugated organic compounds in experimental lead-acid battery systems is limited because of inorganic uv-absorbing materials in the electrolyte.

This paper reports on attempts to characterize the various inorganic uv-absorbing constituents in lead-acid cells to find ways to minimize their interference with the evaluation of concentration and structural changes of the organic materials. The experimental approach was to measure the uv absorbance of sulfuric acid solutions exposed to lead surfaces on open circuit and during polarization, and then to compare these results with the absorbance exhibited by lead and lead-antimony corrosion products added to the acid as the reagent grade chemicals. Absorbance measurements were made with a dual beam spectrophotometer[1] using distilled water as a reference. The sulfuric acid solutions were prepared by diluting the reagent grade acid to the desired specific gravity with distilled water. The absorbance exhibited by these solutions was negligible throughout the range 350-210 mμ.

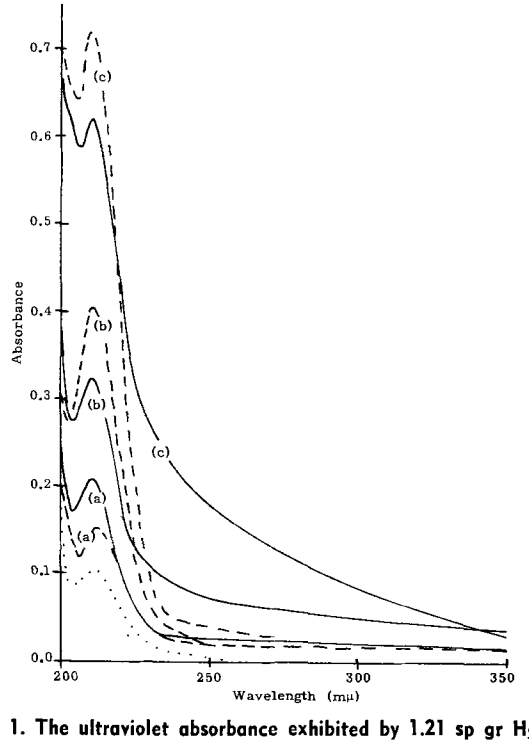

Fig. 1. The ultraviolet absorbance exhibited by 1.21 sp gr H_2SO_4 solutions containing: ——— lead power, (a) 10 g/liter, (b) 100 g/liter, and (c) 500 g/liter; — — — PbO_2, (a) 1 g/liter, (b) 10 g/liter, and (c) 100 g/liter; and . . . . $PbSO_4$ (saturated).

The absorption spectra presented in Fig. 1 were obtained following the additions of pure lead powder, lead sulfate ($PbSO_4$), or lead dioxide (PbO_2) to 1.21 sp gr H_2SO_4. To insure equilibrium, the solutions were stirred thoroughly for several hours; then the excess solid material was allowed to settle before making the absorbance measurements.

The magnitude of absorbance exhibited by the $PbSO_4$ is attributed to the sparingly soluble Pb^{2+} ion, since quantities of $PbSO_4$ greater than those required for saturation did not affect the absorbance. Increasing the amount of excess PbO_2, however, caused an increase in absorbance. Since PbO_2 can oxidize the water in the solution, the absorbance may be caused by Pb^{2+} ion present in greater quantity than normal saturation, or by the formation of an oxygen-containing complex, such as $PbO \cdot PbSO_4$. The absorbance of the acid exposed to the pure lead powder reached its maximum in 18 hr and is similar to that resulting from additions of PbO_2.

Since the increase in absorbance of H_2SO_4 solutions exposed to the lead may be caused by the reaction of lead with oxygen, some experiments were conducted in nitrogen stirred solutions to determine whether the absorbance was minimized. Electrodes (3.0 x 4.0-cm portions of a lead-3% antimony gauze) were polarized in an H-type cell whose two electrode compartments were separated by a glass frit. Figure 2 shows the effect of both anodic and cathodic polarization on absorbance of the acid determined by sampling the appropriate compartment of the H-cell for spectrophotometric analysis.

No increase in absorbance was found after an 18-hr open-circuit exposure of the electrodes in nitrogen stirred solution. However, anodic polarization in nitrogen stirred solution, even at very low current densities, gave measurable increases in absorbance.

Prolonged cathodic polarization in nitrogen stirred solution at low current density gave no increase in absorbance. However, when nitrogen stirring was replaced by air stirring (without interrupting the current), the absorbance increased in a manner similar to that found in the solution from the anode compartment. In the presence of air, the absorption con-

[1] Cary Model 15, Applied Physics Corporation, Monrovia, California.

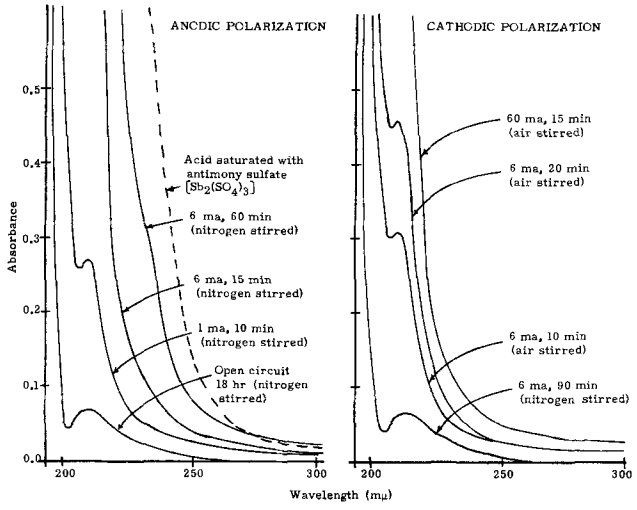

Fig. 2. Effect of anodic and cathodic polarizations of lead-3% antimony electrodes on the absorbance of 1.30 sp gr H_2SO_4. (Acid saturated with $PbSO_4$ before test.)

tinued to increase even at much higher cathodic current densities.

The spectrum (broken line in Fig. 2) resulting from the addition of antimony sulfate [$Sb_2(SO_4)_3$] to the acid suggests that a substantial portion of the absorbance shown in Fig. 2 was because of dissolution of the antimony. It appears that in nitrogen stirred solutions the electrode potential is sufficiently noble so that there is no metal dissolution. However, in the presence of oxygen (air), even when applying a low cathodic current, the potential is sufficiently active to allow metal dissolution to take place.

It has been suggested that an additional cause for absorption is the possible formation of hydrogen peroxide (H_2O_2) by reduction of oxygen (2) at the cathode. Small quantities of H_2O_2 in H_2SO_4 give uv absorbance patterns similar to those shown by the acid exposed to the lead surfaces. The minimum quantity of H_2O_2 detectable by the uv method is 0.001%, which was established by measuring the absorbance of H_2SO_4 solutions containing known quantities of H_2O_2. During the experiment represented in Fig. 2, quantities of solution in the cathode compartment were checked periodically for H_2O_2. Using the standard peroxytitanic acid test (3), the presence of H_2O_2 was not indicated. Since this test is sensitive to $< 0.001\%$ H_2O_2, it appears that H_2O_2 is not a contributor to absorption in these experiments. The absence of H_2O_2 in lead-acid systems is not surprising, however, since lead surfaces are reported (4) to be excellent peroxide decomposers.

To summarize, these experiments indicate that when ultraviolet techniques are applied to lead-acid systems, conditions should be maintained to minimize buildup of corrosion products of lead and lead-antimony alloys. Therefore, the reactions of conjugated organic compounds at lead surfaces should be studied in nitrogen stirred solutions at potentials more cathodic than the corrosion potential of the lead surface.

Studies of Hydrocarbon Fuel Cell Anodes by the Multipulse Potentiodynamic Method

IV. Effect of Various Electrolytes on the Behavior of Hydrocarbons on Conducting Porous Teflon Electrodes

L. W. Niedrach and M. Tochner[1]

General Electric Research & Development Center, Schenectady, New York

Important variables in fuel cell studies are the electrocatalyst, electrode structure, electrolyte, and fuel structure. A systematic study of these variables using the multipulse potentiodynamic (MPP) method has been under way in this Laboratory (1-5). Previous papers in the present series have dealt with the behavior of methane, ethane, and propane on Teflon bonded platinum black electrodes with a perchloric acid electrolyte (3, 4) and with methane through butane with a phosphoric acid electrolyte (5).

Recent observations in fuel cell studies that higher current densities can be sustained by hydrocarbons with a hydrofluoric acid azeotrope electrolyte than a concentrated phosphoric acid electrolyte (6) initiated the present examination of the effects of various electrolytes. Of particular interest was any difference in behavior that could account for the higher, steady-state current densities that can be supported in hydrofluoric acid cells without the appearance of voltage decay and oscillations. The electrolytes that were compared in this study were H_3PO_4, $HClO_4$, and HF at 60°C. Ethane served as the model hydrocarbon for the comparison.

Experimental

A three-compartment Teflon cell described elsewhere (3) was used in these experiments. A miniature version (0.2 cm diameter) of a previously described (7) conducting-porous "Teflon" fuel cell electrode containing platinum black as the catalyst was employed. That used in this work was designated as ME-16.

Both the hydrogen reference and counter electrodes were platinized platinum flags. The hydrogen reference communicated with the working electrode by a Luggin capillary. All potentials are referred to this electrode. The cell was operated in an air thermostat enabling control of the temperature to within 0.1°C.

The acids employed in the study were 4.3*N* perchloric acid, 5*N* phosphoric acid, 36*N* (75%) phosphoric acid, and 22*N* (azeotrope) hydrofluoric acid. All were prepared by diluting reagent grade acids with quartz distilled water. Electrolytic grade hydrogen was used in the reference electrode chamber, and

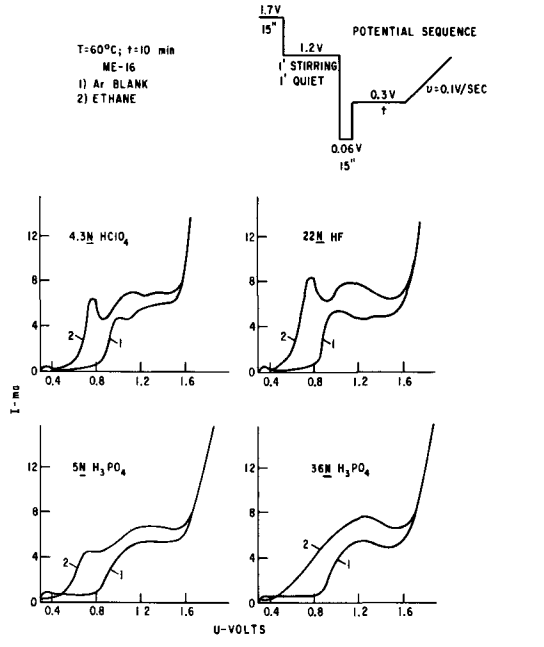

Fig. 1. Current-potential (time) traces for adsorbed ethane with various electrolytes.

Phillips research grade ethane was used as the fuel. Tank argon deoxygenated by passage over heated copper turnings was substituted for the fuel for obtaining solvent blanks. Tank argon was also used for degassing the electrolyte.

As in the earlier work linear anodic sweeps were applied to the electrode to determine the behavior of the ad-layer as well as the amount of fuel adsorbed after equilibrations at various potentials for varying times. Prior to each equilibration the electrode was pretreated with a series of potential steps which have previously been found to result in reproducible conditions. The sequence of steps is shown in Fig. 1 and the details are discussed elsewhere (3).

Briefly, oxidizable impurities are removed from the electrode during the period at 1.7v. During the step at 1.2v, oxygen evolution ceases, and free oxygen is removed from the vicinity of the electrode. Adsorption of fuel is blocked at this time by "adsorbed oxygen" on the electrode. The brief excursion to 0.06v results in reduction of the "adsorbed oxygen" layer at a potential at which hydrocarbons are themselves not adsorbed. The potential is then stepped to that at which adsorption and performance data are required. After the desired equilibration time a linear anodic sweep is applied in order to determine the number of coulombs associated with oxidation of the carbonaceous ad-layer. This information is obtained by integrating the area between the trace for the equilibrated electrode and that obtained when argon is substituted for the fuel. In the latter case the wave starting at about 0.8v corresponds to the formation of the adsorbed oxygen layer. When fuel is present on the electrode some ad-species may be oxidized prior to the formation of the oxygen ad-layer while others may be oxidized concurrently over the same potential range. In the latter case, the wave obtained over the potential range 0.8-1.6v is enhanced over that obtained during an argon blank. The final sharp rise in all of the traces marks the onset of oxygen evolution.

Polarization curves were obtained by measuring the currents during the longer equilibrations just prior to application of the linear anodic sweeps. These curves, of course, differ in form from the current-voltage traces obtained during linear anodic sweeps. The former reflect quasi steady-state performance while the latter are associated with complete oxidation of all of the ad-species on the surface. It is to be noted that the steady-state currents are much smaller than those flowing during the linear anodic sweeps. They therefore introduce a negligible error in the determination of the charge associated with oxidation of the ad-layer.

Results and Discussion

The general form of the current-voltage traces obtained with linear anodic sweeps for adsorbed ethane in the presence of the four electrolytes is shown in Fig. 1 after 10-min equilibrations at 0.3v. Traces obtained after shorter and longer equilibrations were of the same form. In all cases the ad-layer is oxidized over a range of potentials. With the perchloric and hydrofluoric acid electrolytes two distinct waves can be detected. The first occurs at potentials below those (approximately 0.8v) at which the surface itself is normally oxidized. The second wave exhibits a flat maximum which extends from 0.8v to oxygen evolution potentials. In the case of the perchloric acid electrolyte the first wave has been attributed to the oxidation of C_1 species and the second to C_2 species (1-4).

With the phosphoric acid electrolytes oxidation of the ad-layer is again initiated at potentials below those required for platinum surface oxidation, but the resolution of two discrete waves is less pronounced than with the other electrolytes. It has been noted, however, that at higher temperatures resolution of the two waves occurs (5).

As the equilibration potential is increased from about 0.2v the magnitudes of both waves decline, indicating that the surface coverage with the assorted species decreases (3, 5). This occurs in order that the rate of adsorption may keep pace with the increasing steady-state currents being drawn from the electrode as the potential increases (1-5). The change in coverages with equilibration potential, as reflected by changes in Q_{E1} and Q_{Etot}, the charges required for oxidation of the species of wave 1 and the entire ad-layer, respectively, are illustrated in Fig. 2 through 5. Because of the incomplete identification of the precise oxidation states of the species involved, it is not possible to relate these data to the actual number of surface sites obscured. The values of Q_{Etot} were obtained from linear anodic sweeps by integrating the area between the ethane trace and that of the argon blank as described above. Q_{E1} was obtained by a similar integration to the left of a perpendicular at about 0.85v. In the cases of the perchloric and hydrofluoric acid electrolytes this potential corresponded to the minimum on the fuel oxidation trace.

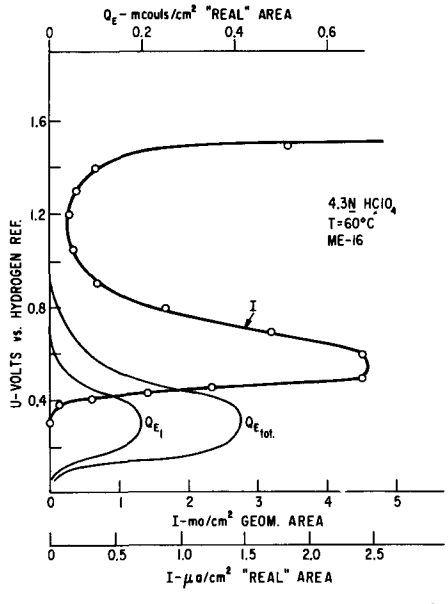

Fig. 2. Polarization and surface charge curves for ethane with a perchloric acid electrolyte.

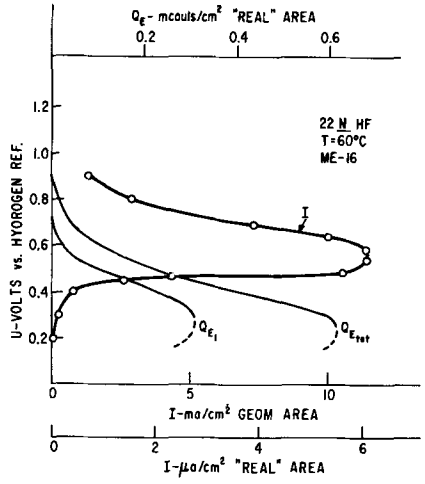

Fig. 3. Polarization and surface charge curves for ethane with a hydrofluoric acid electrolyte.

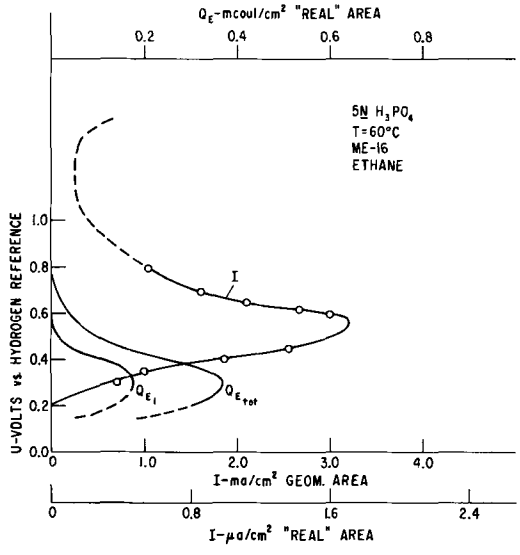

Fig. 4. Polarization and surface charge curves for ethane with a 5*N* phosphoric acid electrolyte.

Also shown in Fig. 2 through 5 are polarization curves for the four electrolytes. The form of the polarization curves is similar for the four electrolytes. However the maximum currents vary strongly among them as shown by the data in Table I. In all cases the maximum currents occur at potentials at which there is still adsorbed fuel on the electrode surface. Maximum surface coverage of the electrode occurs at 0.2-0.3v in all cases.

Table I. Effect of electrolyte on maximum current

Electrolyte	Maximum current density	
	ma/cm² (geom.)	Relative
4*N* $HClO_4$	4.6	1.0
22*N* HF	11.4	2.5
5*N* H_3PO_4	3.2	0.7
36*N* H_3PO_4	1.5	0.3

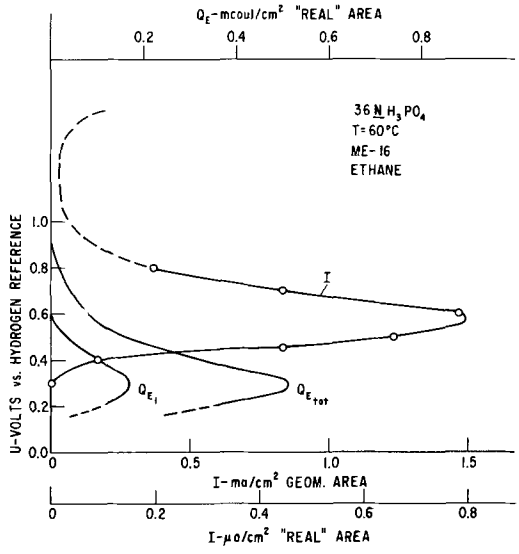

Fig. 5. Polarization and surface charge curves for ethane with a 36*N* phosphoric acid electrolyte.

Summary and Conclusions

Linear anodic sweep data obtained with ethane as a model hydrocarbon with perchloric acid, hydrofluoric acid, and phosphoric acid electrolytes indicate that in a qualitative sense the behavior is similar with all of the electrolytes. In view of the similarities of the behaviors of ethane, propane, and butane in previous studies (3,5) it is anticipated that the present observations with ethane will extend to higher hydrocarbons as well. Quantitative effects therefore appear to account for the differences in performance of hydrocarbons in fuel cells employing different acidic electrolytes. These are probably associated with changes in the double layer structure and may also reflect differences in the solubility of the hydrocarbons in the various electrolytes.

A New Air Electrode for Fuel Cells

Harold I. Zeliger[1]

General Electric Research & Development Center, Schenectady, New York

It is believed that a porous structure will allow better mass transport of reactant gases to the active sites of fuel cell electrodes and thereby give higher performances. With the thought that the incorporation of high surface area inert material would yield a highly porous structure, electrodes containing silica were prepared and evaluated in fuel cells.

Standard Teflon bonded electrodes (1) (pressed at 350°C) were prepared incorporating silica. These electrodes were extremely hydrophobic, showed no porosity when placed in fuel cells, and would not perform on hydrogen. They apparently were impervious to hydrogen. Leaching them with sodium hydroxide or hydrofluoric acid for periods of up to 3 days improved their fuel cell performances only slightly. (Apparently the Teflon protected the silica from the leaching media.)

If, however, the electrodes were pressed cold (room temperature) the resulting structures were highly porous and readily wetable, and the electrodes showed moderate fuel cell performance. Further experimentation led to an electrode fabrication procedure which gave very high performance electrodes. It is as follows:

A mix was prepared consisting of 0.15g John Cabot Cab-O-Sil silica (surface area: 175-200 m^2/g), 0.15g graphite,[2] 0.12cc Dupont T-30 Teflon suspension (0.108g Teflon), 5 drops Rohm and Haas Triton X-100 wetting agent, the appropriate quantity of chloroplatinic acid (from Engelhardt Industries, 40% platinum), and sufficient water to give a free flowing slurry. The slurry was applied on alternate sides of a 17.7 cm^2 (1⅞ in. diameter) 45 mesh platinum screen (woven from 8 mil wire) with a single quill camel's hair brush or medicine dropper and dried above a 350°C hot plate after each application. Four or five applications were required on each side to get all the material onto the screen. After each application the material was pressed into the screen by rolling a glass rod over it with a firm hand. Drying was carried out at 350°C so that it could be accomplished quickly thereby preventing the Teflon from settling out of the mix.

A 1.6 mg/cm^2 waterproofing Teflon film was sprayed onto one side of the electrode (1). Finally, the chloroplatinic acid was reduced under a stream of hydrogen at room temperature for 2 hr.

By initially incorporating chloroplatinic acid rather than platinum black into the electrode, the catalyst was not subjected to high temperatures which could cause sintering. A second advantage of adding the platinum in solution is that more uniform distribution of catalyst in the final electrode structure is assured than if materials of varying densities were mixed together.

Electrodes with varying platinum content[3] were prepared and evaluated on hydrogen, oxygen, and air in ambient temperature, 5*N* sulfuric acid electrolyte fuel cells. A Kordesch-Marko (2) interrupter bridge was employed to monitor performance.

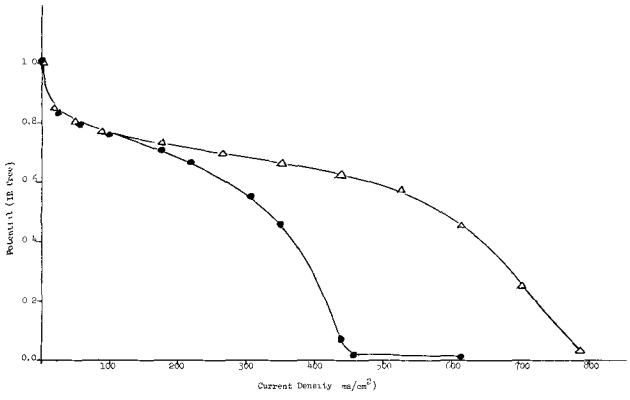

Fig. 1. IR free performance curves for standard and new silica containing electrodes on air at ambient temperature. Anodes, standard electrodes with 34 mg Pt/cm^2; cathodes, △ = new silica containing electrode with 10 mg Pt/cm^2, • = standard electrode with 34 mg/cm^2; electrolyte: 5*N* H_2SO_4.

Excellent performances (0.8v IR free at 350 ma/cm^2) were obtained on hydrogen with platinum loadings of 1.0 mg/cm^2, and on oxygen with platinum loadings of 4.0 mg/cm^2. It was, however, as air electrodes that these new electrodes showed superiority. Figure 1 shows the IR free polarization curves for a test electrode with 10 mg platinum/cm^2 (also containing 0.15g silica, 0.15g graphite, and 0.12 cc T-30) and for a representative standard electrode (1) containing 34 mg platinum/cm^2. At low current densities (up to 100 ma/cm^2) performance of the test electrode paralleled those of standard electrodes, while at higher current densities the performance of this electrode, was significantly better. This electrode had a limiting current density of 800 ma/cm^2.

At current densities where standard electrodes show major polarization attributed to mass transport limitations, this new electrode, with less than one third the catalyst content, showed very little polarization. At 450 ma/cm^2 the IR free difference in potential between the two electrodes was 0.6v.

This improved performance is most probably attributable to a very highly porous electrode structure which allows for rapid mass transport of air to the catalytically active sites. Incorporation of a high surface area material such as silica into a fuel cell electrode makes the attainment of such a structure possible.

[2] The graphite served the dual purpose of imparting structural stability and conducting current in electrodes with low platinum contents.

[3] With lower platinum loadings (<6 mg/cm^2) more graphite was used, *e.g.*, electrodes with 1.0 mg Pt/cm^2 contained 0.3 g graphite.

Further Observations on the Oxidation of Zirconium in Dry Oxygen

E. Hillner

Bettis Atomic Power Laboratory, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

In a previous investigation on the high-temperature oxidation performance of pure zirconium, it was demonstrated that crystal bar (iodide process) zirconium will exhibit a transition in rate kinetics from cubic to parabolic behavior after extended exposure periods whereas high-grade sponge material undergoes a cubic-to-linear change under these same conditions (1). Both materials were found to behave in almost an identical manner in all other aspects of the oxidation reaction. Further investigations were undertaken at this laboratory in an attempt to substantiate the previously observed variance in posttransition behavior between sponge and crystal bar zirconium, and to initiate a limited parametric study involving the possible origins of this deviation.

Experimental

The primary concern associated with the initial study (1) involved the choice of specimen geometry (0.05 cm diameter wire). The present investigation employed platelet specimens of both materials, ~2.5 x 1.25 x 0.38 cm. Due to the size and weight of these coupons, the constant modulus helical spring balance employed in the first study could not be used; instead, the new specimens were placed in a molybdenum boat, in the center of a tubular zircon vacuum chamber, which in turn was externally heated with the aid of a horizontally mounted, split-tube, resistance-wound furnace. The loading and weighing of specimens was performed by two different schedules. In the first scheme, four specimens (two sponge and two crystal bar zirconium) were loaded into the boat, evacuated to below 10^{-5} Torr, heated in 400 Torr predried oxygen for a specified length of time, cooled to room temperature, weighed on a Mettler semi-automatic microbalance, and returned to the vacuum chamber for additional exposure. Thus, this method of collecting kinetic data involved the repeated heating, cooling, and weighing of the same specimens after various exposure times. Specimens handled in this manner are henceforth designated as having undergone "discontinuous weight determinations." In the second schedule, the specimens were exposed for only one time cycle, cooled, weighed and then discarded. A freshly prepared group of platelets was then employed for the next exposure time, etc. Data from this latter group are indicated by the term "continuous weight determinations." In order to expedite the comparison of the current information with that presented in (1), all test results generated in this study have been obtained at the highest test temperature of the referenced experiments, *i.e.*, 850°C. Oxygen pressure was maintained at 400 Torr for each exposure, and at least two experimental runs were carried out for each test condition. Detailed chemical analyses of the two zirconium materials are presented in (1).

Results

The kinetics of oxidation can be described by the empirical equation

$$(\Delta W)^n = kt$$

where ΔW is the weight gain per unit area of original surface, t is the time, n and k are constants for a given temperature. To determine the applicable rate equation from weight gain data, the empirical equation is more conveniently used in its logarithmic form

$$\log \Delta W = 1/n \log k + 1/n \log t$$

in which case, a plot of ΔW against t on logarithmic coordinates yields a straight line having a slope of $1/n$. The average results for each test condition are plotted in this manner in Fig. 1. The open symbols represent specimens that were chemically polished in

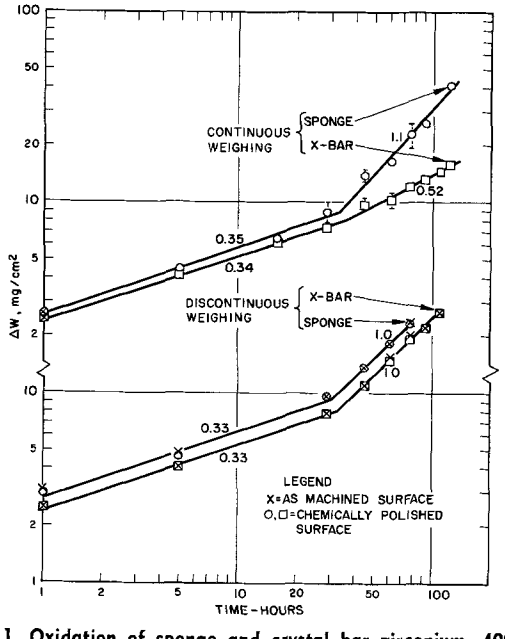

Fig. 1. Oxidation of sponge and crystal bar zirconium, 400 Torr O_2, 850°C, 0.38 cm thick specimens.

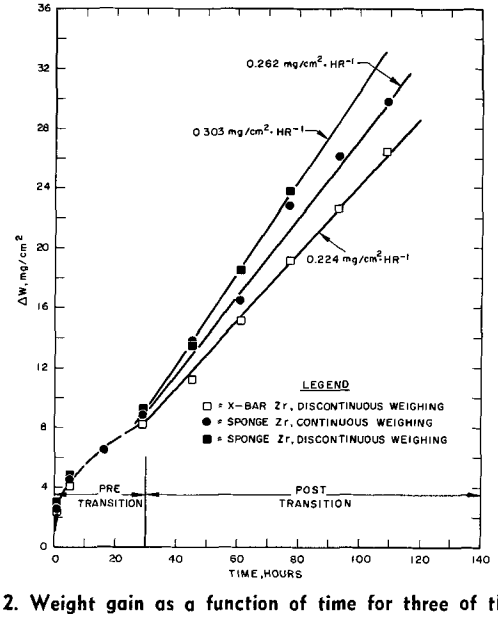

Fig. 2. Weight gain as a function of time for three of the four curves depicted in Fig. 1.

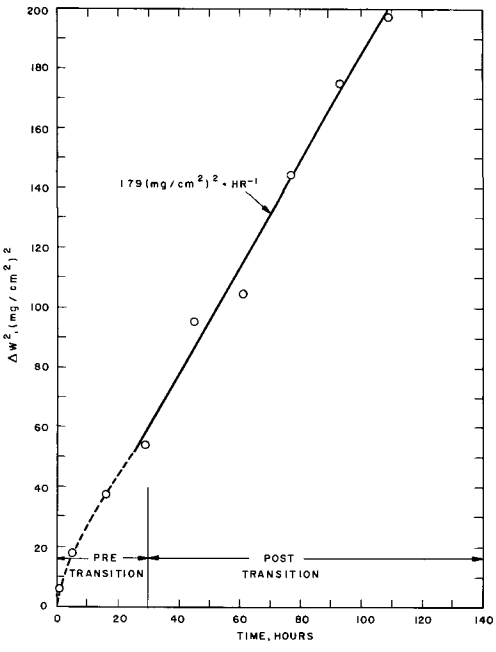

Fig. 3. Square of the weight gain as a function of time; continuously weighed X-bar specimens.

solutions of 45 v/o HNO_3 + 5 v/o HF + 50 v/o H_2O prior to exposure whereas the "X"'s indicate the data generated with specimens whose surfaces were machined to a 64 rms finish, degreased and rinsed in ethyl alcohol before each test. The numerical values indicate the calculated slopes on the log-log plot. Values for n in the pretransition kinetic region were obtained directly from Fig. 1; k_c was determined from a plot of the cube of the weight gain against time. The corresponding values for posttransition oxidation performance were obtained by replotting the data on linear coordinates (Fig. 2, 3). (One group of data, X-bar under continuous weighing conditions, required a replot of the square of the weight gain against time.) Table I compares the results generated in this limited study with those of the parent investigation.

Discussion and Conclusions

The data shown in Table I appear to indicate no significant alteration in the oxidation characteristics of the two materials as a consequence of the change in specimen geometry. At first glance it may appear that the pretransition rate constants (k_c) cluster into two groups; one group with an average value of 0.28, the other at approximately 0.47. It should be recalled, however, that the cubic rate constant is obtained from the cube of the weight change ($\Delta W^3 = k_c t$); a variation in the weight gain data of ~12% can account for the differences noted in the pretransition rate constants. Thus, the observed values are within the uncertainty band associated with data acquisition since it has been established previously (1) that the reproducibility in weight gain data in this series of experiments was no better than 10-15%. The same discussion can be applied to the apparent variations noted in the two posttransition parabolic rate constants (k_p) determined from the square of the weight gain. A weighing bias of ~14% can account for the observed differences in the latter values.

Once again, it has been demonstrated that for the method of continuous weight gain determination, the pretransition oxidation performances of high-grade sponge zirconium and crystal bar zirconium are alike in all respects. It has also been substantiated that, for continuously weighed specimens, the posttransition kinetics of sponge zirconium will follow a linear rate equation whereas crystal bar zirconium exhibits parabolic rate behavior. It has been postulated previously that this disparity in posttransition oxidation behavior may be related to the initial oxygen level of the two materials (1). Since the data generated in ref. (1) were obtained in 50 Torr oxygen pressure and those of the present study in 400 Torr oxygen, the oxidation performance of either grade of zirconium appears insensitive to oxygen pressure in the range 50-400 Torr. These results confirm the work of other investigators who found no pressure effect on zirconium oxidation (2, 3).

The major conclusion drawn from this limited study involves the sensitivity of crystal bar zirconium in the posttransition kinetic region to the method of obtaining weight change information. Thus, the information presented in Table I and Fig. 1 clearly shows that crystal bar zirconium will oxidize in accordance with a posttransition parabolic rate equation when weight gain information is obtained by either continuous measurements at test temperature (1) or by employing different specimens for each datum point. When a fixed group of identical specimens was used to obtain the entire kinetic curve by means of interrupted weight determinations on the same samples, linear posttransition behavior was observed. The crystal bar pretransition region and the entire kinetic behavior of sponge zirconium appears unaffected by the mode of weight change measurement. A possible explanation for this behavior may involve the enhanced susceptibility to oxide film breakdown due to the thermal cycling imposed on those specimens subjected to repeated heating and cooling during interrupted weight gain determinations.

Table I. Comparison of the oxidation behavior of high-grade sponge and crystal bar (iodide) zirconium at 850°C

		Discontinuous	—	N/A	—	N/A

* For pretransition: $\Delta W^n = k_c t$.
For posttransition, $\Delta W^{n'} = k_L t$ (when $n' = 1$) or $\Delta W^{n'} = k_p t$ (when $n' = 2$).
** All chemically etched surfaces.
‡ Trans—at transition.
N/A = not applicable.

As a final observation, it can be seen from Fig. 1 and Table I that the quantity of residual fluorides or other contaminants that may be associated with the chemical polishing of zirconium surfaces does not affect the subsequent long-term oxidation behavior of the metal to any significant degree.

Brief Communications

The Diffusion Layer on a Rotating Disk Electrode

John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

In a recently published work (1), the author treated the current distribution on a rotating disk under conditions where ohmic potential drop, surface overpotential, and concentration variations near the electrode must all be taken into account. The diffusion layer, which is then characterized by a nonuniform current density and concentration at the surface, was handled by a power-series expansion in r, the radial distance from the axis of rotation

$$c = c_\infty \left[1 + \sum_{m=0}^{\infty} A_m (r/r_o)^{2m} \theta_m(\zeta) \right] \qquad [1]$$

where c is the concentration of the reactant, c_∞ is the bulk concentration, r_o is the radius of the electrode, and θ_m represents functions of $\zeta = y(a\nu/3D)^{1/3}\sqrt{\Omega/\nu}$, where y is the normal distance from the disk, $a = 0.51023$, ν is the kinematic viscosity, D is the diffusion coefficient, and Ω is the rotation speed of the disk.

The functions θ_m and, in particular, the derivatives $\theta_m'(0)$ at the surface were obtained by a finite-difference solution of the differential equations

$$\theta_m'' + 3\zeta^2\theta_m' - 6m\zeta\theta_m = 0 \qquad [2]$$

subject to the boundary conditions

$$\theta_m = 1 \text{ at } \zeta = 0 \text{ and } \theta_m = 0 \text{ at } \zeta = \infty$$

Subsequent numerical difficulties were encountered which required accurate values of the derivatives $\theta_m'(0)$.

As suggested by the work of Rosner (2), one can use the equations in section 58 of Levich's book (3) to obtain the concentration at the surface in terms of an integral over the concentration derivative at the surface

$$c(r,o) = c_o(r) = \frac{1}{\Gamma(2/3)} \int_o^r \frac{J(r')r'\,dr'}{(r^3 - r'^3)^{2/3}} \qquad [3]$$

where $J(r) = -\partial c/\partial\zeta$ at $\zeta = 0$. Substitution of a power-series expansion for c into Eq. [3] yields an expression for $\theta_m'(0)$

$$\theta_m'(0) = -\frac{3\Gamma\left(\frac{5}{3}\right)\Gamma\left(\frac{2m+3}{3}\right)}{2\Gamma\left(\frac{4}{3}\right)\Gamma\left(\frac{2m+2}{3}\right)} \qquad [4]$$

The gamma functions necessary to evaluate $\theta_m'(0)$ from Eq. [4] are given (4) to 15 significant figures. Values of $\theta_m'(0)$ are in satisfactory agreement with those tabulated in Table I of ref. (1). At the same time direct use of Eq. [3] or its inverse (2) provides a possibility of avoiding the numerical difficulties encountered in the earlier work (1).

Large Amplitude A-C Polarography of Aqueous Cd(II)

J. D. McLean and Andrew Timnick

Department of Chemistry, Michigan State University, East Lansing, Michigan

Theoretical treatment of a-c polarographic data has been limited to the condition that the amplitude of the applied a-c voltage, $\Delta E_{p\text{-}p}$, be no larger than $16/n$ mv peak to peak, n being the number of electrons transferred in the reduction process (1). Several formulas have been derived for large amplitudes for the special case of very small frequencies ($k_h >> \omega D$), but these are of very limited use (2). Here, k_h is the heterogeneous rate constant for electron transfer, ω is the angular frequency of the applied alternating

potential, and D is the diffusion coefficient. Recently, Smith extended the theoretical treatment to $70/n$ mv p-p and derived an expression by which currents and phase angles could be calculated (3). No experimental verification was presented.

The work reported in this note was in progress when the most recent information appeared (3). Even though this work does not directly test Smith's equations it was undertaken to test the extent of applicability of existing equations developed for low amplitudes, by determining the effect of large amplitudes on experimentally determined k_h values for aqueous solutions of Cd(II).

All data were obtained at $E_{1/2}{}^R$, the reversible d-c half-wave potential, since maximum deviation in quantities measured to evaluate k_h would be expected at this d-c potential. Several supporting electrolytes were employed, to obtain a variation in the value of k_h.

The solutions used were prepared from A.C.S. reagent grade chemicals without further purification. A 0.0100M Cd(II) stock solution was prepared from $Cd(NO_3)_2 \cdot 4H_2O$ and standardized by EDTA titration (4).

Current and phase-angle measurements were obtained at maximum drop size, with an a-c polarograph constructed in this laboratory using the circuits of Smith (5) with modifications in the phase-angle detecting circuit (6). A Hewlett-Packard Model 202A signal generator provided all a-c potentials. A Sargent S-30260 potentiometer was employed to measure all d-c potentials applied to the cell. A Tektronix Model 502 oscilloscope was employed to measure the amplitude of the alternating potential applied to the cell. A Sargent Model S.R. recorder was employed to measure the d-c currents, rectified a-c currents, and signals proportional to the phase angle.

Phase angles were corrected for the uncompensated solution resistance and double-layer charging current of the supporting electrolytes according to the method of Bauer and Elving (7).

The polarographic cell was constructed so that prepurified nitrogen, which had been further purified by bubbling through an acid vanadous column, could be either bubbled through the solution by way of a coarse frit at the cell bottom or blown over the top of the solution. The cell was equipped with three electrodes: dropping mercury electrode, saturated calomel electrode, and a platinum wire auxiliary electrode. The side arm of the reference electrode was separated from the polarographic solution by an isolation compartment with a fine frit. The auxiliary electrode was also separated from the polarographic solution with a similar isolation compartment. The isolation compartments contained the supporting electrolyte.

All measurements were made in a constant temperature room which had an ambient temperature of 24 ± 1°.

Instrument performance was tested at large amplitudes through the frequency range 30-1200 Hz by determining the resistance and capacitance values for known value components of a dummy cell. Tests were run at 10, 50, and 100 mv peak to peak, and all results were within an experimental error of the order of 3%. The double-layer capacity, C_{dl}, and uncompensated solution resistance, R_t, for the supporting electrolytes 1.0M Na_2SO_4, 1.0M H_2SO_4, and 1.0M KNO_3 were determined at both 10 and 100 mv. The resistances and double-layer capacitances measured at 10 mv for the individual supporting electrolytes did not vary by more than 3% from those measured at 100 mv over the frequency range investigated. The values measured at 10 and 100 mv are listed in Table I, as well as the half-wave potentials at which they were measured. The $E_{1/2}{}^R$ for Cd(II) in each supporting electrolyte was determined from the log = 0 intercept of a log $(i_d - i)/i$ *vs.* $E_{d\text{-}c}$ plot. The diffusion coefficients listed in Table I were determined in this laboratory during a previous study (6) and were calculated by the Lingane-Loveridge equation (9).

The dependence of the heterogeneous rate constant on the applied a-c potential is tabulated in Table II, for various supporting electrolytes. The heterogeneous rate constants were obtained by use of the expression

$$\cot \Phi = 1 + \frac{1}{k_h} (D\omega/2)^{1/2} \qquad [1]$$

where Φ is the corrected phase angle (8). This is the correct expression for the special case when $E_{d\text{-}c} = E_{1/2}{}^R$ and under the restriction that the amplitude of the applied alternating voltage be less than $16/n$ mv p-p. By plotting cot Φ *vs.* $\omega^{1/2}$ (see Fig. 1 and 2), one can readily calculate k_h from the slope of the linear

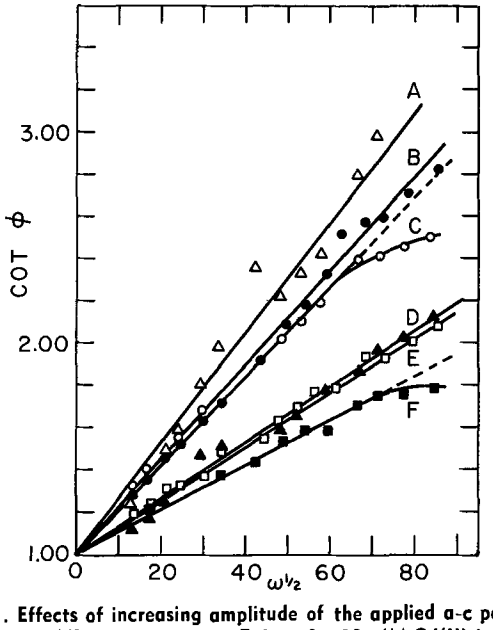

Fig 1. Effects of increasing amplitude of the applied a-c potential on cot Φ vs. $\omega^{1/2}$ evaluated at $E_{1/2}{}^R$ for 5.0 x 10^{-4}M Cd(II) in sulfate media. Curves A, B, and C are for 1.0M Na_2SO_4: A, $\Delta E_{p\text{-}p}$ = 10 mv; B, $\Delta E_{p\text{-}p}$ = 60 mv; C, $\Delta E_{p\text{-}p}$ = 100 mv. Curves D, E, and F are for 1.0M H_2SO_4: D, $\Delta E_{p\text{-}p}$ = 10 mv; E, $\Delta E_{p\text{-}p}$ = 60 mv; F, $\Delta E_{p\text{-}p}$ = 100 mv.

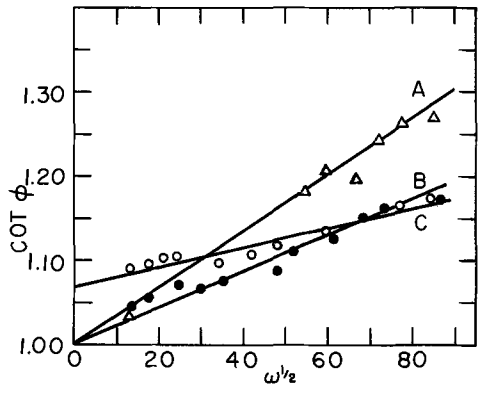

Fig. 2. Effects of increasing amplitude of the applied a-c potential on plots of cot Φ *vs.* $\omega^{1/2}$ evaluated at $E_{1/2}{}^{R}$ for 5.0 x 10^{-4}M Cd(II) in 1.0M KNO_3. A, $\Delta E_{p\text{-}p}$ = 10 mv; B, $\Delta E_{p\text{-}p}$ = 60 mv; C, $\Delta E_{p\text{-}p}$ = 100 mv.

portion of the plot, if a value for $D^{1/2}$ is known. The values used for the plots were obtained by making phase-angle measurements on 5.0 x 10^{-4} M Cd(II) in various supporting electrolytes at fourteen different frequencies between 30 to 1200 Hz and at the d-c potential equal to $E_{1/2}{}^{R}$.

From Table II it can be seen that, if k_h is between 0.05 and 0.20 cm/sec, its value, as determined by the low amplitude equation, does not vary markedly to the limit of amplitudes tested up to a frequency of 800 Hz. Although the k_h values show good agreement, some deviations in the data become apparent above 60 mv as is shown in Fig. 1. These deviations occur as a distinct falling off from linearity of the cot Φ *vs.* $\omega^{1/2}$ plots at frequencies above 800 Hz, with the magnitude of the error increasing directly with the frequency. In all of these plots, the intercept is cot Φ = 1 at 0 frequency, as is predicted by Eq. [1].

In a recent monograph (3), Smith presents theoretical a-c polarograms and a-c polarographic phase angles for a specific hypothetical system for $\Delta E_{p\text{-}p}$ of 10, 40, 60, and 80 mv. He demonstrates that cot Φ should decrease with increasing values of $\Delta E_{p\text{-}p}$ at the d-c potential equal to $E_{1/2}{}^{R}$. Although the magnitudes of these changes cannot be compared directly with our experimental values due to differences in constant parameters involved, one can see that the changes follow the same pattern. Smith's theoretical figures as well as our experimental data indicate that the changes are relatively small if the heterogeneous rate constant is in the range 0.01 to 0.20 cm/sec as is the case for Cd(II) in sulfate media.

Heterogeneous rate constants for Cd(II) in 1.0M KNO_3 calculated from slopes obtained from Fig. 2 show much greater variation than the values obtained in sulfate media. This is primarily due to the fact that the heterogeneous rate constant in this medium is considerably faster, and thus changes in the slope produce a much greater change in the value of k_h. Rate constants of the order of 1.0 cm/sec or faster are difficult to determine accurately by the a-c method we employ. Figure 2 data were included to demonstrate what might be expected if large amplitudes are employed on these systems. Although the values of k_h show deviation as $\Delta E_{p\text{-}p}$ increases, no deviation from theoretical behavior, that is linearity of the plot of cot Φ *vs.* $\omega^{1/2}$ and intercept of cot Φ = 1 as $\omega \rightarrow 0$, is observed until $\Delta E_{p\text{-}p}$ exceeds 60 mv. At this point, the cot Φ intercept at $\omega \rightarrow 0$ becomes greater than 1.00 in violation of theory. Again, the error becomes increasingly large as $\Delta E_{p\text{-}p}$ increases.

The results obtained for the aqueous Cd(II) system indicate that if the heterogeneous rate constant for the electron transfer is between 0.05 and 0.20 cm/sec, low amplitude equations can be used to calculate k_h values for $\Delta E_{p\text{-}p}$ up to 70 mv, which is considerably beyond the previously predicted limit of $\Delta E_{p\text{-}p} = 16/n$ mv, which would be 8 mv for Cd(II).

Recrystallization of Supported Platinum

J. F. Connolly, R. J. Flannery, and B. L. Meyers

Research and Development, American Oil Company, Whiting, Indiana

Measurements of surface areas electrochemically (1) and by x-ray diffraction show that supported platinum crystallites grow rapidly when in contact with a conducting solution. This effect indicates that the type of dispersion necessary to make platinum an economic direct-hydrocarbon-fuel-cell catalyst may be difficult to maintain.

The crystallite growth was first observed during attempts to extend the conditions for electrochemical platinum-area measurements (1) to higher temperatures. Results are summarized in Table I. Platinum area losses range from 5 to 90% of the initial area depending on such factors as initial crystallite size, temperature, and type of support.

Area losses are not due to poisoning because they are detected in roughly the same measure by both x-rays and the electrochemical method. Furthermore, they cannot be attributed to permanent platinum dissolution because: platinum determinations made before and after treatment usually agreed within the reproducibility of the method (2%); analyses of the soaking liquids after the highest temperature runs showed a pickup of only 0.1% of the platinum originally in the samples; integrated x-ray diffraction intensities increased in all cases where they were measured.

There are no detectable area losses due to heating in air or argon at these temperatures, or even 100°C

higher. Thus, the rate of area loss is orders of magnitude higher than that of the losses experienced in "sintering." A possible mechanism would be "electrorecrystallization," *i.e.*, local cells may be formed between large and small platinum crystallites, with the smaller crystallites acting as anodes because of their higher surface energies. Complex platinum ions would then be transported through the solution while electrons pass through platinum-platinum contacts, or through a conducting support, or through both. The transport of platinum complexes through the solution with no necessity for electron flow between crystallites would also be conceivable.

Experimental

The technique for making electrochemical measurements of the surface area of carbon-supported platinum (1) has been simplified by using powdered rather than Teflon-bonded samples, and by substituting a charge measurement in the "double layer" region for the oxide arrest as a measure of the support effect.

Teflon bonding of powders, in addition to being tedious, requires that they be subsequently anodized extensively (1) to reactivate the platinum surface. We have found that tightly confining a powdered sample between porous tantalum plates (Kennametal) in a tantalum holder gives reproducible results for samples with supports like NC60[1] and ACG.[1] Hard supports like PC62[1] and B_4C may be used in the same way, so long as a three- or fourfold dilution with a low-surface-area graphite like NC60 is used to promote electrical contact. The NC60 has practically no effect on the measurement. Because the holder exposes only 0.8 cm^2 of the porous tantalum plates (Fig. 1) the currents

[1] See Table I footnote j.

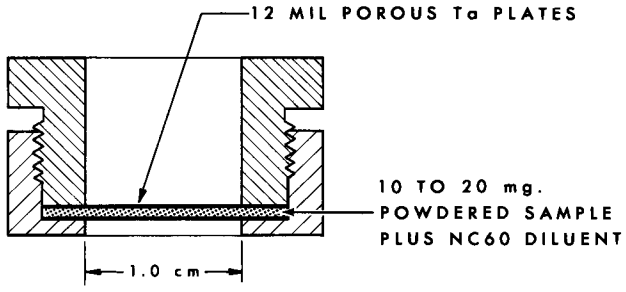

Fig. 1. Tantalum holder for powdered samples

must be held below 20 ma to avoid excessive IR drops. IR drops are further minimized by drawing 0.1-0.2 cc of electrolyte through the holder after assembly to thoroughly wet the sample and porous tantalum plates.

The change from Teflon-bonded to powdered electrodes resulted in the higher area carbons giving somewhat more O_2 evolution activity at 1.3-1.4v (*vs.* a reversible hydrogen electrode in the same solution) than is desirable. Therefore, as a measure of the support contribution, the charge consumption from 0.55 to 0.35v was substituted for the charge consumption in the oxygen arrest.[2] We then obtain equations for platinum surface area analogous to Eq. [5] and [6] of ref. (1), *i.e.*,

$$r' = Q_{C,D}/Q_{C,H} \quad [1]$$

$$A_{Pt} = (r'Q_{T,H} - Q_{T,D})/(r'k_H - k_D) \quad [2]$$

where A_{Pt} is the platinum area in contact with solution, $Q_{C,D}$ and $Q_{C,H}$ are charges consumed on the carbon support from 0.55 to 0.35v and 0.05 to 0.30v, $Q_{T,D}$ and $Q_{T,H}$ are the total charges consumed on the electrode from 0.55 to 0.35v and 0.05 to 0.30v, and k_D and k_H are constants which give the charge consumption on platinum per square centimeter of platinum from 0.55 to 0.35v and 0.05 to 0.30v. The quantities $Q_{C,D}$ and $Q_{C,H}$ are measured at the same dv/dt (usually 10 to 20 mv/sec) on the nonplatinized carbon support while $Q_{T,D}$ and $Q_{T,H}$ are similarly measured on the platinized electrode; k_D and k_H are measured on bright platinum of known roughness.

For the supports listed in Table I, $r' = 1.00 \pm 0.05$. Using this value for r' and $k_H = 0.19$ mc/cm^2 and $k_D = 0.005$ mc/cm^2 reduces Eq. [2] to

$$A_{Pt} \cong 5.4(Q_{T,H} - Q_{T,D}) \quad [3]$$

Equation [3] was used to calculate the electrochemical areas in Table I. The potential-time sequence for each measurement is shown in Fig. 2.

There is a misprint in ref. (1). The equations for calculating the fractions of the total charge consumptions which are due to the carbon support should be

[2] Of course, in those cases where oxide stripping is suitable and the hydrogen arrest is unuseable (*e.g.*, palladium area measurements on moderate area carbons), then a charge measurement in the double layer region can correct for the support contribution in the oxide reduction arrest.

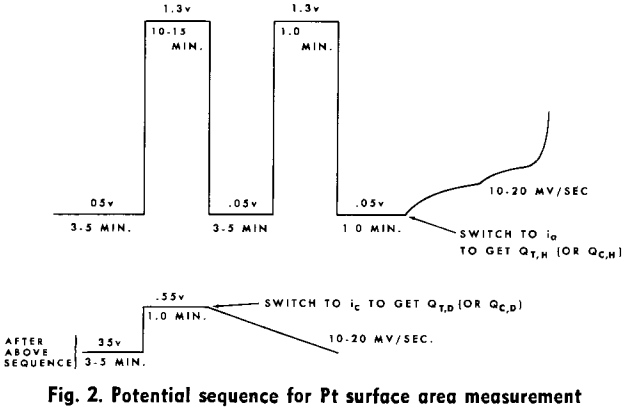

Fig. 2. Potential sequence for Pt surface area measurement

$$\frac{Q_{C,O}}{Q_{T,O}} = r\left(1 - \frac{k_0}{k_H}\frac{Q_{T,H}}{Q_{T,O}}\right) \Big/ \left(r - \frac{k_0}{k_H}\right) \quad [4]$$

$$\frac{Q_{C,H}}{Q_{T,H}} = \left(\frac{Q_{T,O}}{Q_{T,H}} - \frac{k_0}{k_H}\right) \Big/ \left(r - \frac{k_0}{k_H}\right) \quad [5]$$

For the simplified procedure used in this note Eq. [4] has little meaning, while Eq. [5] reduces to

$$\frac{Q_{C,H}}{Q_{T,H}} \cong \frac{Q_{T,D}}{Q_{T,H}}$$

Reference (1) also contains the doubtful claim: "there should be no lower limit on the size of the platinum crystallites which can be detected." However, very small crystallites probably grow at rates large enough to interfere with electrochemical surface-area measurements made at room temperature.

ABSTRACT

Manganese-activated phosphors were prepared by solid state reactions throughout the spinel crystalline solution region in the $MgO-Al_2O_3-Ga_2O_3$ system. The best ultraviolet-excited phosphor examined, $(Mg_{0.90},Mn_{0.01})Ga_{2.06}O_4$, is characterized by a peak emission wavelength at 512 nm, a 50% peak intensity band width of 36 nm, and a quantum efficiency equivalent to that of Zn_2SiO_4:Mn. Al^{3+} for Ga^{3+} substitutions in $MgGa_2O_4$ lead to phosphors with improved cathodoluminescence, decreased photoluminescence, longer peak emission wavelength, and longer cathodoluminescence decay characteristics. These data are discussed in view of temperature, crystal structure, and related literature.

The mineral spinel, $MgAl_2O_4$, is only one of a large class of isostructural AB_2O_4 compounds that have become known as spinels. Ideally the spinel structure consists of a face-centered cubic close-packed array of oxygen anions with metal cations filling the interstices. The unit cell contains 32 oxygen ions or eight AB_2O_4 molecules. This gives rise to 96 interstices per unit cell of which 32 are octahedral (B) sites and 64 tetrahedral (A) sites. Normally only 16 of the B and 8 of the A sites are filled with cations. There are three general classifications of spinels, the normal spinel in which the A ions are in tetrahedral sites and the B in octahedral, the random or intermediate spinel in which the A and B ions are randomly distributed in the 8 tetrahedral and 16 octahedral sites, and the inverse spinel in which the 8 tetrahedral sites are occupied by B ions and the 16 octahedral sites occupied randomly by A and B ions. It is well established that the equilibrium cation distribution in spinels is dependent on temperature and pressure as well as composition.

Originally it was the purpose of this investigation to attempt to incorporate Mn^{2+} selectively in octahedral and tetrahedral sites in basically the same spinel compound. A logical choice for this study was the crystalline solution series between the compounds $MgGa_2O_4$ and $MgAl_2O_4$ in the $MgO-Al_2O_3-Ga_2O_3$ ternary system since Mn^{2+} has an octahedral site preference larger than Ga^{3+} but smaller than either Mg^{2+} or Al^{3+}. However, when the intense uv-excited green luminescence of $MgGa_2O_4$:Mn was observed, major emphasis was shifted to the empirical optimization of formulation variables and characterization of spectral properties of phosphors throughout the ternary system.

Literature

Moller and King (1) prepared various gallate compounds, including $MgGa_2O_4$ spinel, and presented characteristic x-ray diffraction data. More recently Schmalzried (2) established the phase relationships in the $MgO-Ga_2O_3$ system. Twenty mole % Ga_2O_3 and 2 mole % MgO were found to be soluble in $MgGa_2O_4$ at 1200°C. At 1000°C, the solubility of Ga_2O_3 decreased to 10% and of MgO to about 1%. The population of Mg^{2+} in octahedral sites in $MgGa_2O_4$ was found to vary from 0.90 at 900°C to 0.84 at 1400°C, indicating the influence of temperature on cation distribution in this spinel compound. More recently Weidenborner *et al.* (3) determined the detailed structure of magnesium gallate from single crystals grown from a molten lead-oxygen-fluoride melt. Their results confirmed the partially inverted nature of $MgGa_2O_4$, that it belongs to the space group Fd3m with $a_o = 8.286 \pm 0.003$Å, and that 16 ± 2% of the Mg^{2+} are in tetrahedral sites and 81 ± 1% in octahedral. Since the single crystals used in this study were annealed slowly from 1200° to 850°C, the data must be assumed to correspond to a temperature of 850°C or slightly higher.

The $MgO-Al_2O_3$ phase relations have been studied by several people (4-7). This system resembles the $MgO-Ga_2O_3$ system in that considerable Al_2O_3 is soluble in $MgAl_2O_4$ spinel, but only trace amounts of MgO. Datta and Roy (8,18) have reported that the cation distribution in $MgAl_2O_4$ is a function of temperature and pressure and becomes more normal at high temperatures. Saalfeld (9) has found that the vacancies associated with the $MgAl_2O_4$ crystalline solution series in the $MgO-Al_2O_3$ system prefer to locate on octahedral cation sites. Hummel and Sarver (10) prepared cathodoluminescent phosphors by activating $MgAl_2O_4$ by Mn^{2+} and isoelectronic Fe^{3+}.

Hill *et al.* (11) established the phase relationships in the $Ga_2O_3-Al_2O_3$ system which showed extensive crystalline solution at high temperatures and the formation of an intermediate solid solution series below 800°C. Katz and Roy (12) studied the phase relationships in the $MgAl_2O_4-Ga_2O_3$ binary join and found extensive crystalline solution of Ga_2O_3 in $MgAl_2O_4$. These data were used to estimate the extent of crystalline solution within the ternary system.

Based on the above references, the probable phase relationships in the $MgO-Al_2O_3-Ga_2O_3$ system were constructed as shown in Fig. 1.

Green-emitting $ZnGa_2O_4$:Mn is the only gallate compound reported by Leverenz (13) in his extensive treatment of luminescent materials.

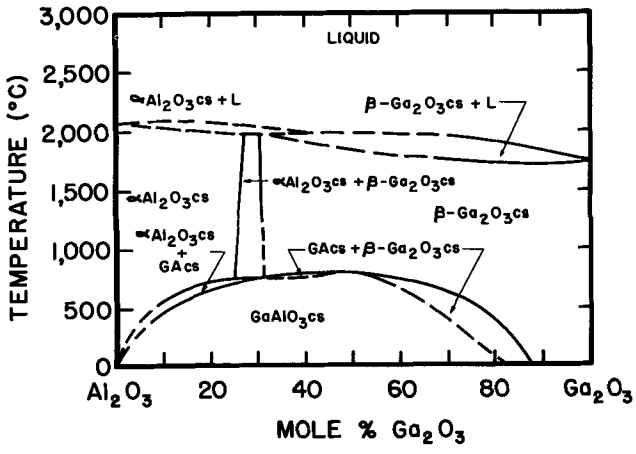
Experimental Procedure

Sample preparation.—The raw materials used in this investigation consisted of luminescent grade basic magnesium carbonate, $MgCO_3 \cdot Mg(OH)_2$, and manganese carbonate, $MnCO_3$, aluminum hydroxide, $Al_2O_3 \cdot nH_2O$, and 99.999% pure gallium oxide, Ga_2O_3. Weight loss measurements were conducted on the magnesium



d

and aluminum compounds in order to compensate batch calculations for sorbed water. Appropriate proportions of the raw materials were weighed to an accuracy of ±0.1 mg on an analytical balance. Each preparation was hand mixed under acetone in a glass mortar and pestle for 10 to 20 min and allowed to air dry. Samples to be used for subsolidus equilibria studies were heat treated twice in air at the desired temperature for 17 hr each, with an intermediate light mixing. This procedure was necessary to insure complete reaction and homogeneity. Preparations used for luminescence studies were heat-treated only once in air at the desired temperature for 8 to 17 hr, then reheated at a slightly lower temperature for 1 hr in a very mildly reducing atmosphere. In all cases, fused silica or sintered alumina crucibles were used. Noble metal containers were unsatisfactory because the gallium tended to amalgamate with the crucible metal.

Compositions were periodically analyzed quantitatively by atomic absorption and wet chemical methods in order to confirm the formulated compositions. A typical result is shown in Table I.

A Norelco x-ray diffractometer employing nickel-filtered CuKα radiation, operating at 40 kv and 15 ma was used with a scanning rate of 1°-2θ/min for routine phase identification and 1/8°-2θ/min for more precise lattice parameter measurements.

Luminescence.—All fluorescence excitation and emission spectra and peak height measurements were obtained with a Perkin-Elmer spectrofluorimeter as previously described (14).

Cathodoluminescence spectra were obtained using a demountable cathode-ray tube operating at 12 kv anode potential and 6 μa beam current over a standard scan TV raster of 1 in.^{2} area. Brightness under these conditions were measured with an eye-corrected Weston foot-Lambert meter.

Experimental Results

The MgO-Ga_2O_3 *system.*—Table II lists the compositions, x-ray diffraction, and luminescence data for preparations throughout the MgO-Ga_2O_3 system. In all cases the samples were heat-treated in two steps. The first heat-treatment at 1400°C/17 hr in air formed the host lattice with manganese incorporation. Qualitative data indicated that the highest practical

reaction temperature eventually provided the brightest phosphors. Typical preparations at this point had a pink body color and very weak green and red emission bands when excited by 253.7 nm radiation.

The second heat-treatment, carried out at 1200°C/1 hr in a 2% H_2 — 98% N_2 by volume gas mixture, provided preparations with a white body color and bright blue-green luminescence. For maximum phosphor brightness, it was found necessary to cool the samples to below 500°C in the protective atmosphere. Brightness was found to be dependent on the time, temperature, and atmosphere of the second heat-treatment, with the conditions specified above being optimum for 25g samples.

It is evident from Table II that magnesium gallate crystalline solution is the phase responsible for the luminescence in the MgO-Ga_2O_3 system. Manganese-activated MgO and β-Ga_2O_3 are nonluminescent under these conditions of preparation. It is also evident from Fig. 2 and Table II that these phosphors are efficiently excited only by 253.7 nm radiation. Cathodoluminescence measurements indicated typical light outputs of about 7.0 ft-L and color coordinates of $x \cong 0.110$ and $y \cong 0.670$.

The excitation and emission spectral energy distribution curves for $MgGa_2O_4$:Mn are shown in Fig. 2. It can be noted that the excitation spectrum peaks near 253.7 nm making this phosphor especially suited for application in fluorescent lamps. The emission peaks sharply at 512 nm with a half width of 36 nm. Following the method of Palumbo and Wisnieski (16), the fluorescence quantum efficiency of $MgGa_2O_4$:Mn was found to be equivalent to that of NBS 1028 zinc orthosilicate (with high manganese concentration) as shown in Table III. Also shown in Fig. 2, for sake of comparison, are the emission bands present prior to the second heat-treatment. The green emission is increased about 50 times by mild reduction, whereas the red band completely disappears.

Figure 3 shows the variation of the spinel a_o lattice parameter and fluorescence peak height with composition. The abrupt breaks in both curves near 48 and 62 mole % Ga_2O_3 signify the limits of $MgGa_2O_4$ crystalline solution. These are in good agreement with Schmalzried's (2) data when one realizes that the preparations of the present study contain 1 mole % manganese activator. Optimum fluorescence is obtained within the crystalline solution region at approximately 53 mole % Ga_2O_3. Crystalline solution of MgO in $MgGa_2O_4$ decreases the fluorescence more markedly than Ga_2O_3 substitutions. The brightness curves outside of the crystalline solution region approximates linearity because of dilution effects from the second phase.

Table IV and Fig. 4 show the effect of manganese concentration on phosphor brightness and peak emis-

sion wavelength. Compositions were adjusted for manganese additions so that the Mn^{2+} could substitute for Mg^{2+} (or Ga^{3+}) and maintain the same approximate vacancy concentration. The top curve in Fig. 4 shows the variation of peak wavelength with increasing manganese additions. The apparent linear relationship is not surprising in view of the isomorphous $MgGa_2O_4$ and $MnGa_2O_4$ structures. The bottom curve shows the variation of peak intensity with manganese content. Concentration quenching, common to many Mn^{2+}-activated phosphors can be observed. Optimum fluorescence brightness is obtained at approximately 0.01 moles MnO.

The extreme right-hand column of Table IV shows the per cent peak height decrease observed between 25° and 100°C. This property was obtained by mounting a small furnace in the sample chamber of the spectroradiometer. These data confirm the general knowledge that low Mn^{2+} levels usually improve the temperature dependence of a phosphor. A very slight emission broadening and peak wavelength shift (towards shorter wavelengths) was observed, especially at high manganese levels.

Figure 5 shows the temperature dependence of $MgGa_2O_4$:Mn (sample 4, Table IV) measured up to 400°C with a HPMV plaque tester (17). The curve was found to be completely reversible up to at least 250°C, eliminating the possibility of the brightness decrease being caused by a chemical reaction.

These high-temperature data are important because they indicate that this phosphor, correctly formulated, can be used in fluorescent lamps (which generally operate below 100°C) without significant changes in brightness or other spectral characteristics.

The MgO-Al_2O_3 *binary system.*—Phosphors prepared throughout the spinel crystalline solution region of this system were excited only by cathode rays. The results of samples prepared at 1400°C are shown in Table V. Brightness appears to be maximum at approximately $(Mg_{0.90},Mn_{0.01})Al_{2.06}O_4$, and there is little change in color coordinates throughout the series. In general, these data are in agreement with those of Hummel and Sarver (10).

The Al_2O_3-Ga_2O_3 *binary system.*—Manganese-activated phosphors were prepared throughout the Al_2O_3-Ga_2O_3 system at 1400°C. Significant luminescence was not observed. X-ray diffraction powder data agreed essentially with the phase diagram of Hill *et al.* (11). Compositions in the intermediate crystalline solution region were not prepared because of their low-temperature stability range.

The MgO-Al_2O_3-Ga_2O_3 *ternary system.*—The compositions, lattice parameters, fluorescence, and cathodoluminescence data for preparations throughout the

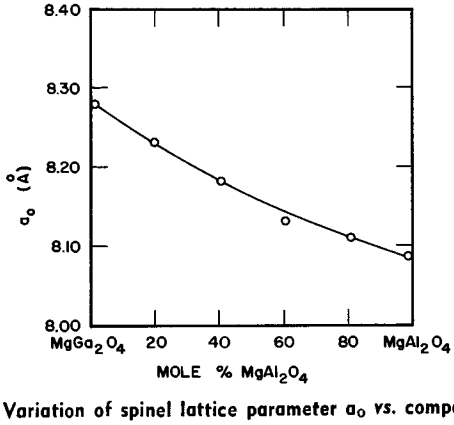

Fig. 6. Variation of spinel lattice parameter a_o vs. composition on the $MgGa_2O_4$-$MgAl_2O_4$ join.

spinel crystalline solution region in the MgO-Al_2O_3-Ga_2O_3 ternary system are listed in Table V. All compositions were heat-treated at 1400°C/17 hr in air and second fired at 1200°C/1 hr in a 2% H_2-98% N_2 atmosphere. The data plotted in Fig. 6 illustrate the variation of the a-axis of the spinel unit cell with composition throughout the $MgGa_2O_4$-$MgAl_2O_4$ join. The continuous variation of this parameter confirms the existence of a crystalline solution series. The decrease of a_o from 8.279Å for $MgGa_2O_4$ to 8.083Å for $MgAl_2O_4$ reflects the relative sizes of the trivalent cations, *e.g.*, the Goldschmidt radius of Ga^{3+} is 0.62Å and Al^{3+} is 0.57Å. The following luminescence results were obtained:

1. Photoluminescence.—As Al^{3+} replaces Ga^{3+} in the spinel structure, the manganese-activated ultraviolet excited peak wavelength increases and brightness decreases (Fig. 7). Magnesium aluminate is practically inert.

2. Cathodoluminescence.—The general trend of peak wavelength observed for ultraviolet excitation is also evident for cathode-ray excitation. (Brightness data are too erratic for a trend to be observed.)

Figure 8 illustrates the variation of brightness (ft-L) and chromaticity coordinates (x,y) throughout the ternary crystalline solution region. These results indicate (*i*) brightness is maximum near the center of the region (*e.g.*, near 40MgO, $30Ga_2O_3$, $30Al_2O_3$), and (*ii*) x and y increase as the Al^{3+} content increases.

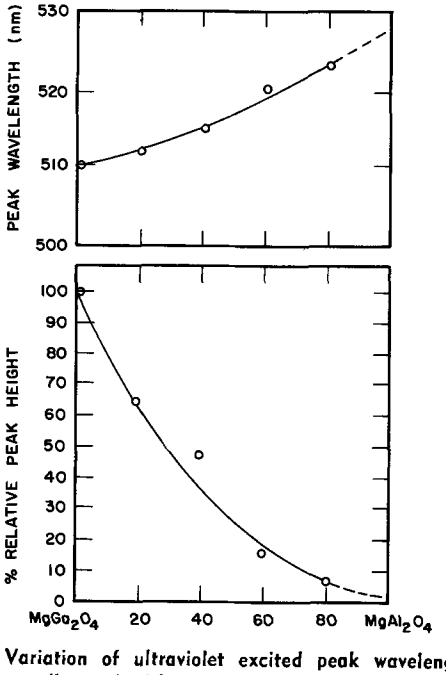

Fig. 7. Variation of ultraviolet excited peak wavelength (top) and brightness (bottom) with composition on the $MgGa_2O_4$-$MgAl_2O_4$ join.

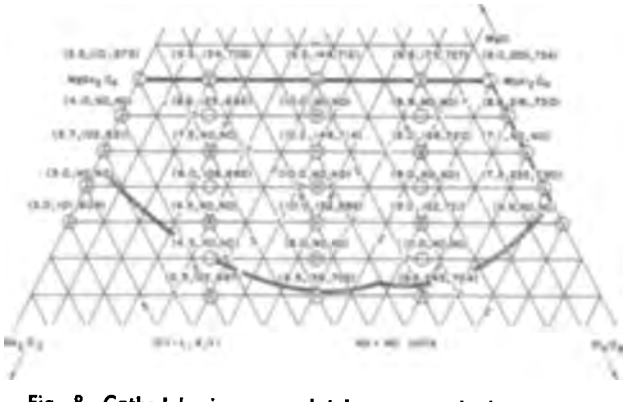

Fig. 8. Cathodoluminescence brightnesses and chromaticity coordinates of phosphors prepared throughout the spinel crystalline solution region in the MgO-Al_2O_3-Ga_2O_3 system.

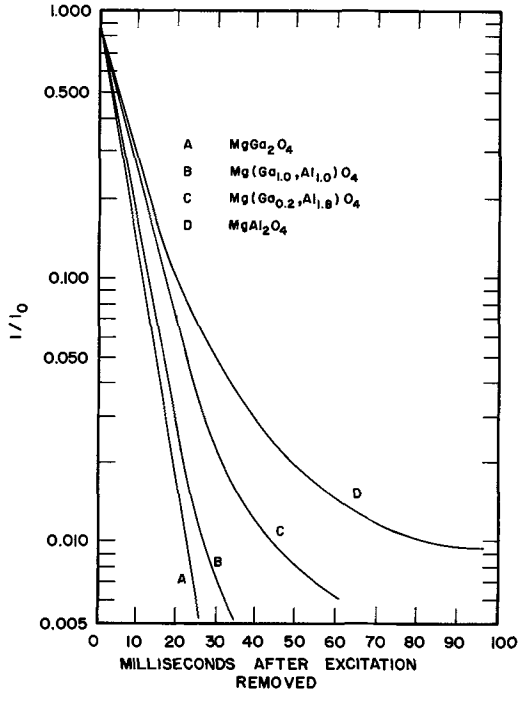

Fig. 9. Cathodoluminescence decay of phosphors throughout the $MgGa_2O_4$-$MgAl_2O_4$ join.

Figure 9 illustrates the effect of increasing $MgAl_2O_4$ concentrations on the decay characteristics of this phosphor. A persistent "tail" develops at about 50% $MgAl_2O_4$ and becomes progressively longer at higher $MgAl_2O_4$ concentrations. These decay curves were found to vary somewhat depending on the composition of the atmosphere of the second heat-treatment.

Discussion

Although both $MgGa_2O_4$ and $MgAl_2O_4$ crystallize with the spinel structure, they differ in their cation distributions as previously pointed out. The green emission of manganese in both of these compounds suggest tetrahedral oxygen coordination of Mn^{2+}. Furthermore, the pink body color and absence of luminescence after only air heat-treatments of $MgGa_2O_4$ suggest the possibility of manganese entering the structure as Mn^{3+}. The presence of Mn^{3+} after air heat-treatment is strengthened by the reflectance spectra of $MgGa_2O_4$:Mn measured before and after reduction as shown in Fig. 10. The broad absorption band in the blue-green region of the spectrum present only in the air-fired sample appears to be similar to

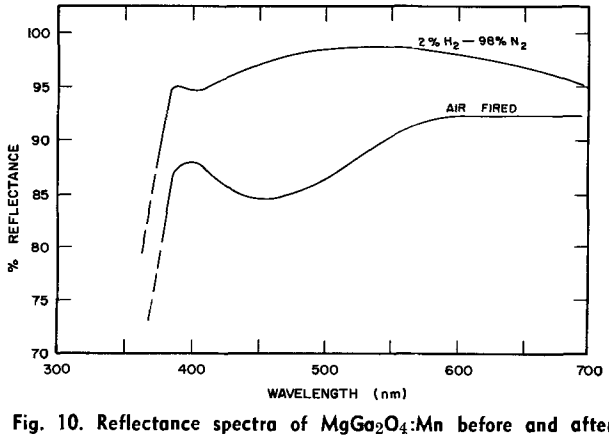

Fig. 10. Reflectance spectra of $MgGa_2O_4$:Mn before and after reduction.

that shown by Rabatin and Gillooly (15) to be characteristic of Mn^{3+}. Another qualitative indication of this mechanism was the significant green fluorescence developed after only air heat-treatments in preparations where small amounts of Si^{4+} or Ge^{4+} were substituted for Ga^{3+}. This probably resulted from the tetravalent cations forcing more of the manganese into the divalent state in order to balance the electrostatic charges.

Jagodzinski and Saalfeld (4) have shown that vacancies are distributed only over octahedral sites in $MgAl_2O_4$. If it is assumed that this is also the case for $MgGa_2O_4$, and that the population of Mg^{2+} ions in octahedral sites is about 0.84 at 1400°C (2), then the optimum phosphor composition can be approximated as follows

$$(Mg^{2+}_{0.06},Ga^{3+}_{0.93},Mn_{0.01})^{IV}\ (Mg^{2+}_{0.84},\square_{0.03},Ga^{3+}_{1.13})^{VI}\ O_4$$

Summary

1. Magnesium gallate activated by divalent manganese has been found to be an efficient ultraviolet excited phosphor with a peak emission wavelength at 512 nm. The optimum phosphor composition was determined to be $(Mg_{0.90},Mn_{0.01})(Ga_{2.06})O_4$.

2. Al^{3+} for Ga^{3+} substitutions in the spinel lattice rapidly decrease the fluorescence brightness, but increase the cathodoluminescence light output. The peak emission shifts from 512 to 525 nm and the decay characteristics become increasingly longer with Al^{3+} substitutions.

Acknowledgments

The author wishes to thank Mr. D. T. Palumbo and Dr. R. W. Mooney for many stimulating discussions during the course of this investigation. X-ray diffraction data were obtained by Dr. C. W. W. Hoffman. Procedures for the quantitative analyses of Mg, Ga, and Mn in magnesium gallate by wet chemistry methods were developed by Mrs. A. R. Mikus and by atomic absorption methods by Mr. J. L. Seeley. Sample preparations were carried out with the assistance of Messrs. J. D. Deysher and O. B. Bullock.

Manuscript received Aug. 25, 1966; revised manuscript received Oct. 14, 1966. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Fluorescence of Eu^{3+}-Activated Garnets Containing Pentavalent Vanadium

G. Blasse and A. Bril

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

ABSTRACT

$NaCa_2Mg_2V_3O_{12}$ has garnet structure and shows a broad emission band with a maximum at about 500 nm under short-wave uv excitation. Eu^{3+} is introduced according to the substitution $Ca^{2+} + Mg^{2+} \rightarrow Eu^{3+} + Li^+$. Unlike the emission of the usual Eu^{3+}-activated garnets (like YAG) the Eu^{3+} emission shows strong $^5D_0$-$^7F_2$ transitions in this case. The energy transfer from the vanadate group to the Eu^{3+} ion is not very efficient. This is ascribed to the small value of the overlap of the Eu^{3+} and V^{5+} orbitals, the V-O-Eu angles being 90° and 120°.

Rare earth activated garnets have been studied extensively. Usually the composition of the host lattice is $A_3B_5O_{12}$ (A = Y,Gd; B = Al, Ga). The formula $\{Y_3\}[Al_2](Al_3)O_{12}$ gives more insight into the crystal chemistry of the garnets: { } represents a dodecahedral site, [ ] an octahedral site, and ( ) a tetrahedral site. Recently Bayer (1) described garnets containing pentavalent vanadium, *e.g.*, $\{Na\,Ca_2\}[Mg_2](V_3)O_{12}$. Since a number of vanadates [*e.g.*, YVO_4 (2) and $Ca_3(VO_4)_2$ (3)] appear to be suitable host lattices for rare earth activated phosphors, we studied the fluorescence of unactivated and Eu^{3+}-activated $NaCa_2Mg_2V_3O_{12}$.

Experimental

Materials with composition $\{NaCa_{2-\delta}Eu_\delta\}[Li_\delta Mg_{2-\delta}](V_3)O_{12}$ were prepared by firing intimate mixtures of Na_2CO_3, $CaCO_3$, Eu_2O_3, Li_2CO_3, $MgCO_3$, and NH_4VO_3 at 750°C in O_2 several times. X-ray powder diagrams were obtained using CuKα radiation.

The performance of the optical measurements has been described in detail elsewhere (4).

Results

Compositions $\{NaCa_{2-\delta}Eu_\delta\}[Li_\delta Mg_{2-\delta}](V_3)O_{12}$ proved to be single-phased garnets up to $\delta = 0.4$. For higher values of δ a second phase with zircon structure was found in the x-ray diagrams. These materials were not studied further. The lattice parameter of the garnet phase did not change more than 0.01Å going from $\delta = 0$ to $\delta = 0.4$ and amounted to a = 12.45Å for $\delta = 0$, in good agreement with Bayer's results (1).

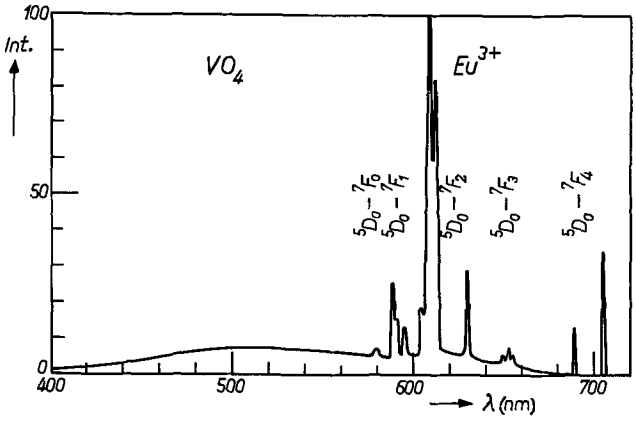

Fig. 1. Spectral emission under short wavelength u.v. excitation of $NaCa_{1.9}Eu_{0.1}Li_{0.1}Mg_{1.9}V_3O_{12}$.

Under short-wave u.v. excitation $NaCa_2Mg_2V_3O_{12}$ shows a white emission at room temperature (quantum efficiency about 30%; this value may be a lower bound due to the low reaction temperature). Even at the highest Eu^{3+} concentration ($\delta = 0.40$), we observed this host lattice emission in addition to the characteristic Eu^{3+} emission. Figure 1 presents the emission for the composition with $\delta = 0.10$. Table I gives the ratio of Eu^{3+} emission to total emission for several values of δ. The excitation spectrum of the fluorescence and the diffuse reflection spectrum for the material with $\delta = 0.10$ are given in Fig. 2. These spectra do not change with the activator concentration.

Discussion

Emission.—Figure 1 shows the host lattice emission as well as the activator emission. The former consists of a very broad band extending from approximately 400 to 700 nm with a maximum at roughly 500 nm, which must be due to transitions in the vanadate group. Vanadate emission at room temperature has been reported earlier for compounds of the type $M_2V_2O_7$ (M = Mg, Zn, Cd, Ca, Sr, Ba) (5).

The emission of the Eu^{3+} ion consists of the well-known transitions from $^5D_0$ down to the ^7F manifold. It is interesting to note that in the vanadium garnet the red lines ($^5D_0 - {}^7F_2$) have the strongest intensity. In the aluminum and gallium garnets (*e.g.*, YAG), however, the red and orange lines ($^5D_0 - {}^7F_1$) have comparable intensity (6), which is not surprising, because the Eu^{3+} ion occupies a site which has an approximate center of symmetry, if only the nearest neighbors, *viz.*, the eight O^{2-} anions are considered. For a strict center of symmetry the red fluorescence due to the $^5D_0 - {}^7F_2$ transition is forbidden. Blasse, Bril, and Nieuwpoort (7) have noticed that the intensity ratio of the red and orange lines can be drastically changed by chemical variations of the next-nearest neighbors of the Eu^{3+} ion. The present results are another example of this effect. Contrary to the situation with the anions, the cation neighbors of the dodecahedral site in the garnet structure of $Y_3Al_5O_{12}$ lack inversion symmetry. In $NaCa_2Mg_2V_3O_{12}$, where the tetrahedral Al^{3+} ions are replaced by V^{5+} ions and the octahedral Al^{3+} ions by Mg^{2+} ions, this lack of inversion symmetry seems to be of more importance.

Table I. Ratio of the quantum efficiency of the Eu^{3+} emission to the total quantum efficiency for materials $NaCa_2Mg_2V_3O_{12}$: Eu, Li

Composition	Ratio
$NaCa_2Mg_2V_3O_{12}$	0
$NaCa_{1.96}Eu_{0.04}Li_{0.04}Mg_{1.96}V_3O_{12}$	0.1
$NaCa_{1.9}Eu_{0.1}Li_{0.1}Mg_{1.9}V_3O_{12}$	0.2
$NaCa_{1.8}Eu_{0.2}Li_{0.2}Mg_{1.8}V_3O_{12}$	0.4
$NaCa_{1.6}Eu_{0.4}Li_{0.4}Mg_{1.6}V_3O_{12}$	0.6

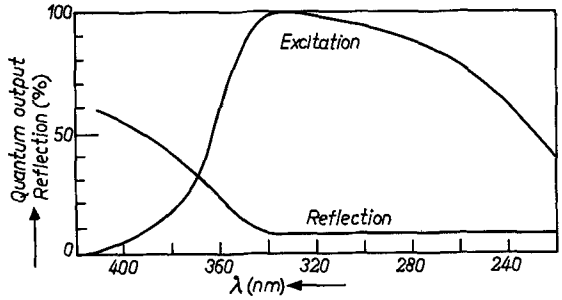

Fig. 2. Relative excitation spectrum of the fluorescence and diffuse reflection spectrum of $NaCa_{1.9}Eu_{0.1}Mg_{1.9}V_3O_{12}$.

This is an indication again that the intensity alterations seem to be dependent on the state of polarization of the oxygen ions, as noted earlier (7): in $NaCa_2Mg_2V_3O_{12}$ the anions are much more strongly polarized than in YAG because in $NaCa_2Mg_2V_3O_{12}$ each O^{2-} ion has one highly charged and small V^{5+} ion as one of its neighbors. The crystal field splittings are not strongly influenced by this effect, as follows from a comparison of the Eu^{3+} emission of YAG : Eu (6) and $NaCa_2Mg_2V_3O_{12}$: Eu, Li. The $^5D_0 - {}^7F_1$ transition contains three lines and the $^5D_0 - {}^7F_2$ transition four lines in both cases. The splittings are of the same order of magnitude.

In this connection we note that the anomalous behavior of the Curie temperature of V^{5+}-substituted yttrium iron garnet (the Curie temperature does not change if the paramagnetic ions are replaced by diamagnetic ions) has also been ascribed to an influence of the V^{5+} ions on the chemical bonding (8).

Excitation and reflection.—Since the reflection spectra do not change very much in the investigated region of δ(0-0.4), the absorption in the u.v. region is ascribed to the vanadate groups of the host lattice. The excitation is most efficient at the wavelength of the absorption edge (see Fig. 2). From Table I it is seen that the energy transfer from vanadate group to Eu^{3+} activator is not very efficient. This is contrary to the energy transfer from vanadate group to Eu^{3+} ion in Eu^{3+}-activated YVO_4 and $Ca_3(VO_4)_2$, where the transfer is very efficient (2, 3). Elsewhere we have argued that transfer of this type is exchange-regulated and therefore strongly dependent on the crystal structure, the O^{2-} ions playing a role (9). Unfortunately the structure of $Ca_3(VO_4)_2$ is not known. In YVO_4 : Eu the V-O-Eu angle is 170°, whereas in $NaCa_2Mg_2V_3O_{12}$: Eu,Li the V-O-Eu angle is 90° or 120° (10). This means that the wave function overlap of the vanadium and europium ions is larger in YVO_4 than in $NaCa_2Mg_2V_3O_{12}$, σ-bonding being involved in the 180° case and π-bonding in the 90° case. Therefore the vanadate → Eu^{3+} ion transfer should be more efficient in YVO_4 than in $NaCa_2Mg_2V_3O_{12}$, in agreement with the experimental results. That there is still considerable energy transfer from vanadate group to Eu^{3+} ion in the garnet may be due to direct overlap of the orbitals of the V^{5+} and Eu^{3+} ion. Each V^{5+} ion is surrounded by six dodecahedral ions, of which two are at a distance equal to one quarter of the cell edge, *i.e.*, only 3.1Å in the present case. Direct overlap is a well-known phenomenon in magnetic exchange theories as is the angle-dependence of the overlap of wave functions of cations separated by anions (11). The strong magnetic interaction between Cr^{3+} ions in $ZnCr_2O_4$, for instance, is ascribed to direct overlap of t_{2g} wave functions of the Cr^{3+} ions ($Cr^{3+} - Cr^{3+}$ distance 2.9Å).

Fluorescence and Cathodoluminescence of Eu^{+3} in Some Alkali and Alkaline Earths-Yttrates and Gadolinates as Hosts

L. H. Brixner

Pigments Department, Experimental Station,

E. I. du Pont de Nemours & Company, Wilmington, Delaware

ABSTRACT

Efficient fluorescence of Eu^{+3} was measured in alkali yttrate and gadolinate hosts of the type ABO_2, where A is Li or Na; B, Y or Gd, under both ultraviolet and electron excitation. The optimum Eu^{+3} concentration was determined for each host; the concentration *vs.* fluorescent intensity curves are presented, as well as some fluorescent emission spectra. Some alkaline earth compounds were also studied as hosts.

Although the fluorescence of Eu^{+3} in such hosts as Gd_2O_3 and $CaWO_4$ was studied as early as 1909 by Urbain (1), it was not until the advent of the laser concept that europium has been more extensively investigated in all conceivable solid hosts as well as in liquid systems. Stimulated emission was first observed from Eu^{+3} in a chelate (2) and later also in Y_2O_3 (3) as a solid state host. In some of our own experiments (4), we failed to observe laser action from Eu^{+3} in $Ca_3(VO_4)_2$, despite the fact that energy exchange between the host lattice and Eu^{+3} was demonstrated. Van Uitert (5) showed that energy exchange also occurs in the host $GdVO_4$. This composition, or rather the isostructural YVO_4, became of interest recently when Levine *et al.* (6) found that europium in this type of host also shows very efficient cathodoluminescence. It was probably this finding which initiated a renewed search for other novel host structures for Eu.

Most previous work was either done with compositions where the rare earths (Y or Gd for instance) have a cationic function (vanadates, molybdates, tungstates, etc.) or with the rare earth oxide itself. A number of rare earth compounds where the rare earth constitutes the anionic portion, such as SrY_2O_4 (7) or $LiYO_2$ (8), have been described recently, and it was the purpose of this study to investigate these compounds as hosts for Eu^{+3}.

Experimental

The constituent components were generally of the best commercially available purity and were given no further purification treatment. The preparation techniques were essentially identical to those described in detail in (9). Occasional analytical checks were carried out for compositions after complete reaction employing x-ray fluorescence techniques. X-ray powder patterns were taken to confirm the structures obtained with those well documented in the literature; only minor lattice parameter deviations could be observed when appreciable portions of Y^{+3} were substituted by Eu^{+3}. For the Gd hosts, the parameters were essentially unchanged when Eu was introduced. The procedures for obtaining the spectra upon optical excitation have already been described (9). To study the emission characteristics under electron excitation we used an available electron microprobe analyzer. The advantage here was the fact that as many as 11 samples could be excited and studied under absolutely identical conditions. These were generally an excitation current of 0.002 μA, a voltage of 20 kv, using a S-11 response-type detector tube (No. 6199) together with a red filter. The samples were powder compacts pressed into 1/8 diameter holes of a 1 in. diameter brass support plate. The inspection area was approximately 540 μ^2.

The first system which was studied in detail was $LiY_{1-x}Eu_xO_2$. As can be seen from Fig. 1, the optimum fluorescent emission occurred around 6 mol % Eu^{+3} for both ultraviolet and electron excitation. Although different in gradients, the two curves show

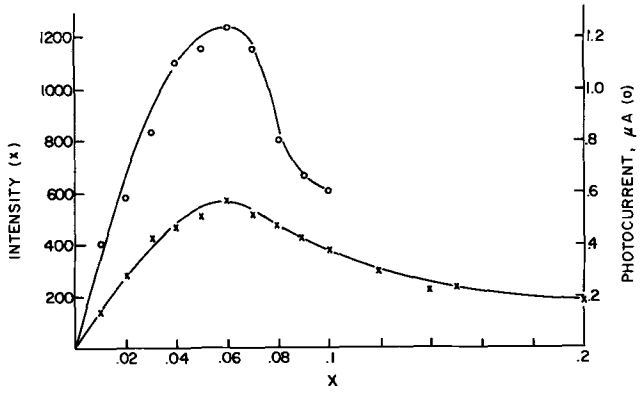

Fig. 1. Intensity of fluorescent emission on electron excitation (o) and on u.v. excitation (x) as a function of X for the $LiEu_xY_{1-x}O_2$ system.

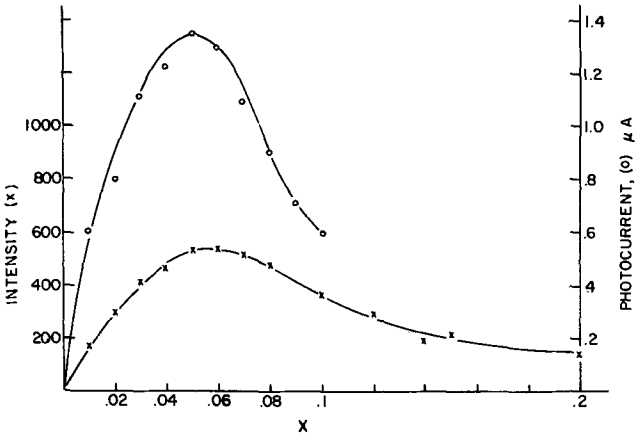

Fig. 2. Intensity of fluorescent emission on electron excitation (o) and on u.v. excitation (x) as a function of X for the $LiEu_xGd_{1-x}O_2$ system.

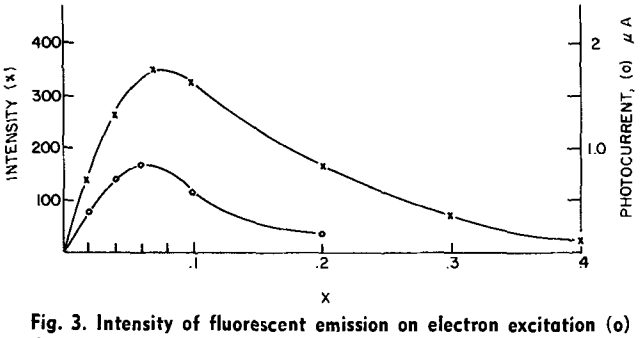

Fig. 3. Intensity of fluorescent emission on electron excitation (o) and on u.v. excitation (x) as a function of X for the $Eu_xY_{1-x}NaO_2$ system.

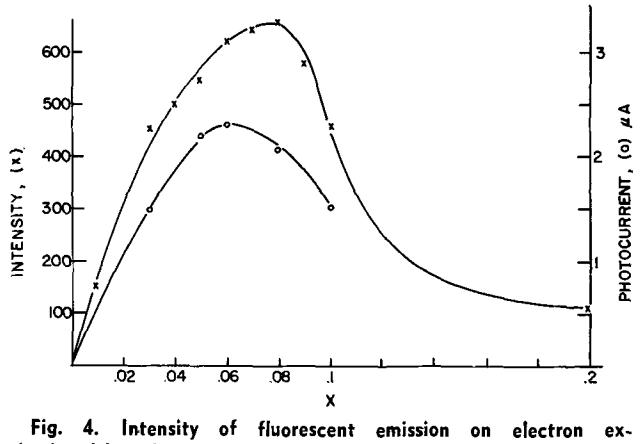

Fig. 4. Intensity of fluorescent emission on electron excitation (o) and on u.v. excitation (x) as a function of X for the $NaEu_xGd_{1-x}O_2$ system.

fundamentally the same characteristics of a steep rise to the optimum emission point and then gradual drop of emission intensity until eventually complete concentration quenching occurs. Figures 2, 3, and 4 show the same results for the corresponding systems: $LiGd_{1-x}Eu_xO_2$, $NaY_{1-x}Eu_xO_2$, and $NaGd_{1-x}Eu_xO_2$. All attempts to prepare any compositions between both Y_2O_3 and Gd_2O_3 and the alkali oxides of K, Rb, and Cs failed completely.

For the purpose of a comparison, the peak intensities of the investigated compositions are summarized in Table I. In the last column marked Lum/o, we have something of a "Figure of Merit," giving the efficiency based on the equivalent Eu concentration. The term is derived from the over-all intensity divided by the % Eu present in this composition. The

Table I. Comparison of peak emission for some Li and Na yttrates and gadolinates

Composition	Opt. inten. under uv excitation (2537Å)	Opt. inten. under electron excitation	% Eu	Lum/o
$LiEu_{0.06}Y_{0.94}O_2$	570	1.24	6.93	82.25
$LiEu_{0.05}Gd_{0.95}O_2$	540	1.35	3.88	139.20
$NaEu_{0.07}Y_{0.93}O_2$	350	0.85	7.17	48.81
$NaEu_{0.08}Gd_{0.92}O_2$	660	2.30	5.74	115.00

location of the peak emission of all compounds is at about 613 mμ as specifically demonstrated for $LiEu_{0.07}Y_{0.93}O_2$ in Fig. 5. The halfwidth of the predominant 613 mμ line narrowed to 3Å at 77°K.

Concerning ternary compositions between the alkaline earth oxides and Y_2O_3 and Gd_2O_3, Schwarz (7) had already demonstrated that only SrO and BaO formed compounds of the types AB_2O_4 (A = Sr^{+2}, Ba^{+2}; B = Y^{+3}, Ln^{+3}). In our own experiments, we also failed to form compounds with CaO or with MgO, ZnO, and CdO. For these reasons, we studied only SrY_2O_4 and BaY_2O_4 as host compositions for Eu^{+3}.

Although the substitutional elements are the same as in the previously discussed compounds, due to the different environmental symmetry as well as the different crystal field influence on the Stark splitting, the fluorescent emission spectra for Eu^{+3} in these hosts could be expected to be different and therefore it seemed of interest to study it. The most striking difference becomes apparent in Fig. 6, where a complete reversal of the intensity in the 590 and 610 mμ region can be observed. Such shifts of the bulk of the emission intensity are, of course, associated with the corresponding change of symmetry. Unfortunately the structures of neither host are well enough known to establish from group theory the number of possible components which each transition would be allowed to have. Under monoclinic symmetry the $^5D_0 \rightarrow {}^7F_1$

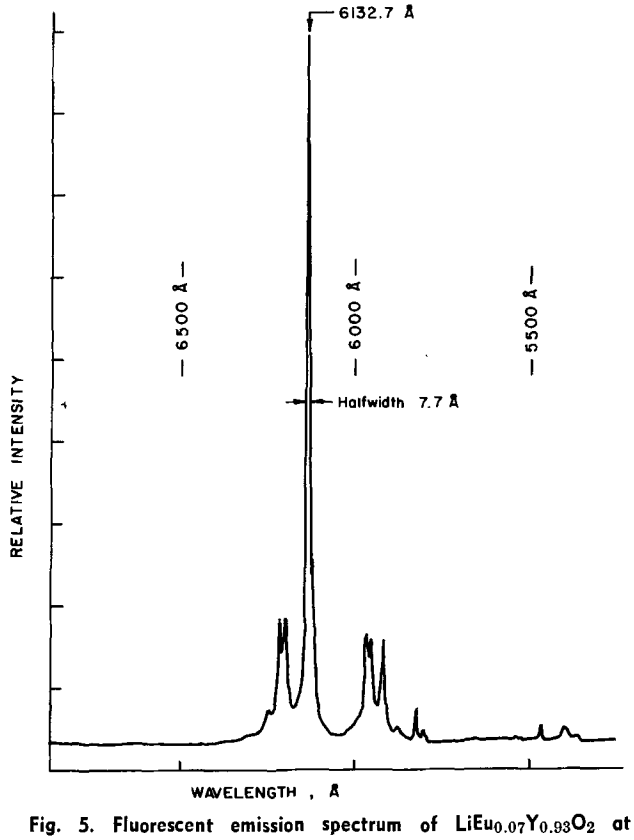

Fig. 5. Fluorescent emission spectrum of $LiEu_{0.07}Y_{0.93}O_2$ at 300°K.

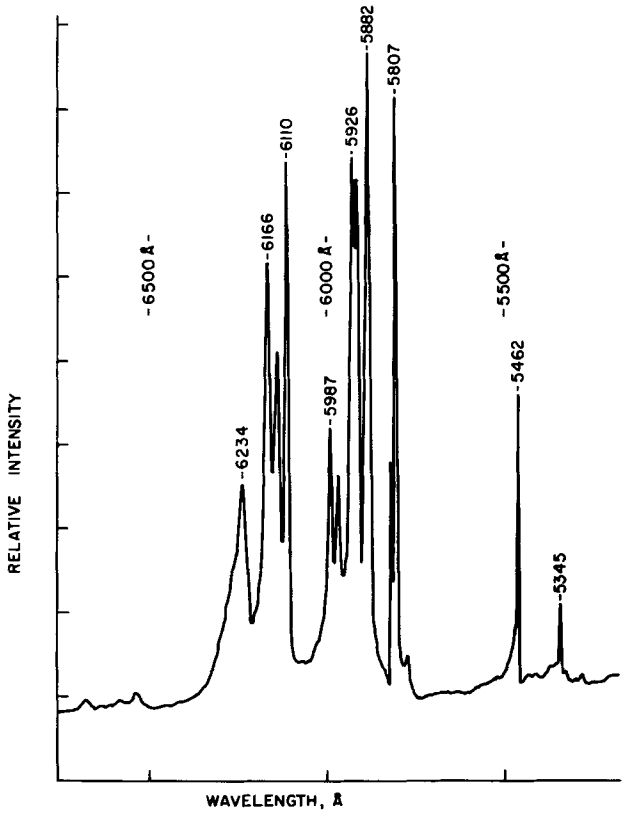

Fig. 6. Fluorescent emission spectrum of $SrEu_{0.20}Y_{1.80}O_4$ at 300°K.

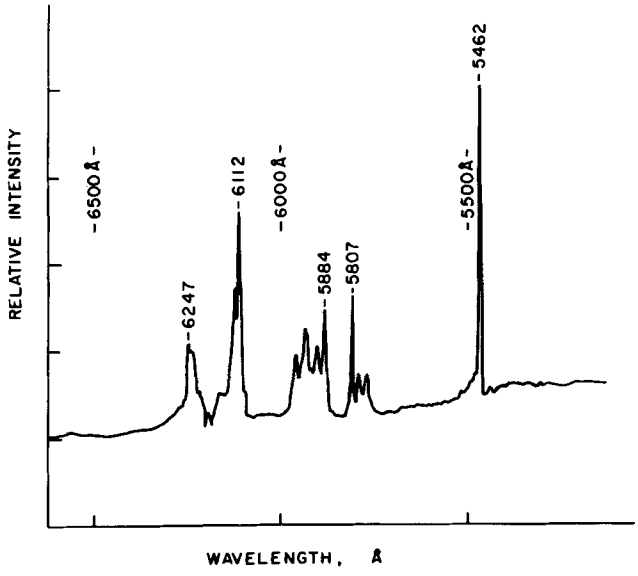

Fig. 7. Fluorescent emission spectrum of $BaEu_{0.14}Y_{1.86}O_4$ at 300°K.

transition can, for instance, exhibit a maximum of three components, all of which are clearly resolved in the spectrum of $Gd_{0.5}Eu_{0.5}NbO_4$ (10). For this case, the bulk of the emission also shifts from the $^5D_0 \rightarrow {}^7F_2$ transition to the $^5D_0 \rightarrow {}^7F_1$ transition in going to the more symmetrical $Ba_2La_{0.9}Eu_{0.1}NbO_6$. Similar observations have also been made for organic Eu compounds (11). Figure 7 shows the corresponding spectrum for $BaEu_{0.14}Y_{1.86}O_4$ where the same type of reversal can be seen. The over-all intensities were also much weaker than in the alkali-rare earth oxide hosts. For the purpose of a comparison we did determine the complete fluorescent emission characteristics as a function of the Eu concentration in both hosts. In $BaEu_xY_{2-x}O_4$, the optimum occurred at $x = 0.14$, and in $SrEu_xY_{2-x}O_4$, at $x = 0.20$. The observed intensities of emission at the optimum x were 78 for the Ba and 52 for the Sr compounds, compared with 570 for $LiEu_{0.06}Y_{0.94}O_2$.

In summary, we can state that the Li and Na rare earth oxides of Y_2O_3 and Gd_2O_3 make interesting and efficient hosts for Eu^{+3}, but the location of the emission prevents them from being useful as good red phosphors. The alkaline earth compounds SrY_2O_4 and BaY_2O_4 showed completely different fluorescent emission characteristics and were furthermore substantially less efficient as hosts for Eu^{+3}.

Resistivity Inhomogeneities in Silicon Crystals

R. G. Mazur

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The extent of small-scale radial resistivity inhomogeneity in several n-type silicon crystals has been quantitatively determined with high spatial resolution by the spreading resistance resistivity measurement technique. Typical results for Czochralski, float-zone refined, crucible-less, web-grown and vapor-deposited epitaxial silicon are given, showing that appreciable nonuniformity in local resistivity exists in many crystals. The usefulness of the spreading resistance technique in rapid evaluation of the degree of resistivity inhomogeneity of individual silicon samples is illustrated.

In the last few years a number of publications have dealt with a variety of microdefects and inhomogeneities in silicon single crystals. This work has recently been reviewed by John, Faust, and Stickler (1). The various crystallographic defects have been extensively studied with high spatial resolution by several techniques. Optical and infrared microscopy, scanning electron microscopy, and x-ray diffraction microscopy have given a linear spatial resolution on the order of 10^{-4} cm, while transmission electron microscopy has utilized a much higher spatial resolution capability of about 10^{-7} cm.

Resistivity or impurity concentration inhomogeneities have also been observed qualitatively with 10^{-4} cm linear resolution using several preferential etching and plating techniques. However, quantitative measurements on electrically active inhomogeneities have been limited by the spatial resolution of the standard potential probe resistivity measurement techniques. While certain situations allow a high linear spatial resolution through a one-dimensional approach, *e.g.*, the study of diffusion profiles by incremental etch and four-point probe (2), the general case is strongly affected by the fact that resistivity is a volume property. Standard potential probe limitations are most obvious when minimum volumes sampled are compared with those of the "visual" techniques mentioned above. Light microscopy, scanning electron microscopy, and x-ray diffraction microscopy all provide a volume resolution of ca. 10^{-12} cm^3 and transmission electron microscopy utilizes a volume resolution of 10^{-18} cm^3 or better. In contrast, the incremental anodic oxidation, etch and four-point probe technique involves a minimum volume of about 5×10^{-8} cm^3. The one- or two-point potential probe technique requiring a bar-sample of at least $5.0 \times 10^{-2} \times 10^{-2}$ cm^2 cross-sectional area gives an average resistivity over a volume of 5×10^{-7} cm^3, if the probes are moved in 1×10^{-3} cm increments along the length of the bar. There is obviously a difference of several orders of magnitude in the spatial resolution of resistivity fluctuations by the standard methods as opposed to the essentially visual techniques. Recent developments in the spreading resistance resistivity measurement technique (3) have enabled us to begin a study of fine-scale resistivity fluctuations in silicon with a sampling volume of 10^{-10} cm^3 or less. This paper provides preliminary data on fine-scale resistivity inhomogeneities observed in typical Czochralski, float-zone refined, crucible-less, web-grown and vapor-deposited epitaxial silicon, showing that significant variations do exist in many crystals. The data also suggest a tentative procedure for assessing the microscale quality of silicon by the spreading resistance technique.

The data reported are not considered extensive enough for a judgment of the relative worth of material produced by the various growth processes as the total number of samples examined to date is small and the degree of correlation between raw material fine-scale resistivity homogeneity and final device performance is not accurately established.

Experimental

All of the material examined to date has been n-type silicon. The samples used were not especially selected in any way so that, aside from their limited number, they represent a good cross section of single crystal silicon commonly available. Sample resistivities ranged from a few tenths of an ohm-centimeter to several hundred ohm-centimeters. This initial study has been limited to radial resistivity variation as much as it is possible to do so on the scale involved.

Spreading resistance resistivity measurements can be made by measuring the resistance between a pair of probe-contacts (obviating the need for any other contacts to the sample) or with a single spreading resistance probe and some form of relatively large-area contact to the sample for current return. This latter mode provides maximum spatial resolution, and all data reported here were obtained with a single probe. The base contact used was ultrasonically soldered tin-indium (50:50). Base contact resistance was separately checked for each sample to insure that it was negligibly small compared to the spreading resistance on that sample.

Each sample was polished with 0.3μ alumina in a water slurry on a rough glass plate to produce the surface finish for which the calibration curve relating spreading resistance and sample resistivity had been previously established. Certain samples were also checked after several minutes etching in CP4A.[1]

After preparation each sample was probed radially at intervals of 0.1 mm over a span of 5.0 mm located approximately midway between the center and edge of the crystal. A second set of measurements was then made, covering a 0.5 mm interval midway in the first 5 mm span in steps of 0.01 mm. The raw values of measured spreading resistance were then computer processed to

(*i*) convert the local spreading resistance values to local resistivities (ρ_i), using a predetermined calibration curve;

(*ii*) calculate the average resistivity of each set of measurements ($\bar{\rho}_i$);

(*iii*) calculate the standard deviation ($s = \sqrt{\Sigma^n_{i=1}(\bar{\rho}_i - \rho_i)^2/n-1}$) of the n individual values of resistivity ρ_i about the average $\bar{\rho}_i$;

(*iv*) tabulate the individual deviations of the ρ_i from $\bar{\rho}_i$;

(*v*) reject any raw data which led to a deviation ($\bar{\rho}_i - \rho_i$) greater than 4s;

(*vi*) if such rejection of "spurious" data was necessary, the amended data was reprocessed through steps (*i*) to (*iv*);

[1] 120 cc 40% HF, 120 cc acetic acid, 200 cc HNO_3.

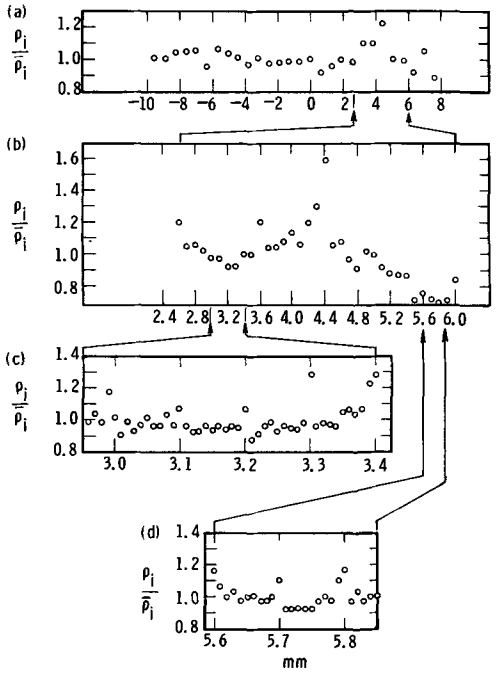

Fig. 1. Typical radial resistivity inhomogeneity in float-zone silicon, plotted as $\rho_i/\bar{\rho}_i$ vs. relative radial position, where $\bar{\rho}_i$ is in each case the local average resistivity. (a) Standard potential probe profile; (b), (c), (d), spreading resistance probe profiles; (b) 0.1 mm scale; (c) and (d) 0.01 mm scale.

(*vii*) calculate values of the ratio of local resistivity, ρ_i, to the average resistivity, $\bar{\rho}_i$, for each point probed (in order to allow direct comparison of resistivity fluctuations in samples of varying nominal resistivity); (*viii*) plot these values of ρ_i/ρ_i *vs.* the radial position (*ix*) calculate $s/\bar{\rho}_i$ for each sample, in an attempt to characterize the various materials checked by a single quantitative parameter as well as by the pictorial results produced by the digital plotter.

Results and Discussion

Figure 1 is an illustration of some results obtained with the procedure described above. The sample is a rather typical float-zone crystal of 1 ohm-cm average resistivity. Figure 1a is a radial resistivity profile obtained by a standard one-point traveling potential probe technique covering a span of 18 mm more or less centered on the crystal. The potential probe was moved in 0.5 mm increments. The average resistivity of these 0.5 mm sections is seen to vary from about 0.9 to 1.2 times the over-all average resistivity of the crystal. Figure 1b gives a spreading resistance-derived resistivity profile on the same sample as in Fig. 1a. The arrows indicate the section of the 1a sample examined. The spreading resistance probe measurement was made at intervals of 0.1 mm. The resulting values of $\rho_i/\bar{\rho}_i$ show that the resistivity fluctuations in this material are more extreme than was indicated by the standard traveling probe potential profile, with local resistivities ranging from 0.7 to > 1.3 times the average resistivity of the material probed in Fig. 1b. Figure 1c and 1d are plots of $\rho_i/\bar{\rho}_i$ of two separate sections of the material covered in Fig. 1b, now at intervals of 0.01 mm.

Figure 2a is a plot of $\rho_i/\bar{\rho}_i$ for a 10 ohm-cm Czochralski crystal, probed at 0.1 mm intervals over a span of 5 mm. It can be seen that the local resistivity varies from about 0.85 to about 1.15 times the average resistivity of this 5 mm section of the crystal. For the data in Fig. 2a, $s/\bar{\rho}_i = 0.067$. Thus, local resistivities 6.7% greater or less than the average resistivity in this 5 mm section of silicon have a probability of occurrence of 0.32; with 1% of the volumes sampled then having a probable resistivity 2.5 ($s/\bar{\rho}_i$) or about

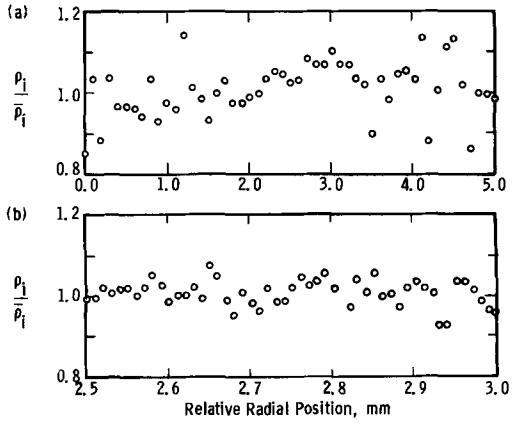

Fig. 2. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 10 ohm-cm Czochralski crystal. (a) 0.1 mm scale, $s/\bar{\rho}_i = 0.067$; (b) 0.01 mm scale, $s/\bar{\rho}_i = 0.031$.

17% greater or less than the sample's average resistivity.

Figure 2b gives the values of $\rho_i/\bar{\rho}_i$ measured in the central region of the 2a sample with a 0.01 mm spacing. The local resistivity variation on this finer scale is seen to be less than that observed on the 0.1 mm scale. The lesser range of local resistivity values on the 0.01 mm scale is reflected in a smaller value of fractional standard deviation of 0.031 for the data in Fig. 2b.

Another Czochralski crystal, a 14 ohm-cm (average resistivity) sample, clearly illustrates in Fig. 3 several features of this type of measurement. While the fine-scale data of Fig. 3b, as well as the point-to-point variation of $\rho_i/\bar{\rho}_i$ in Fig. 3a, show the material to be relatively uniform on the fine-scale, a long-period and very large variation in resistivity is apparent from the data of Fig. 3a, which shows a variation of almost a factor of two in resistivity over a 4 mm span of this crystal. This type of profile is also indicated nonpictorially by the relative values of fractional standard deviation, these being 0.024 for the 0.01 mm scale data of Fig. 3b and 0.185 for the 0.1 mm data in Fig. 3a, a ratio of $s/\bar{\rho}_i$ (0.1 mm) to $s/\bar{\rho}_i$ (0.01 mm) of about 8.

An interesting point illustrated by the sample depicted in Fig. 3 is that, while the fractional standard deviation obviously fails to characterize accurately the material in detail completely, it fails safe; that is,

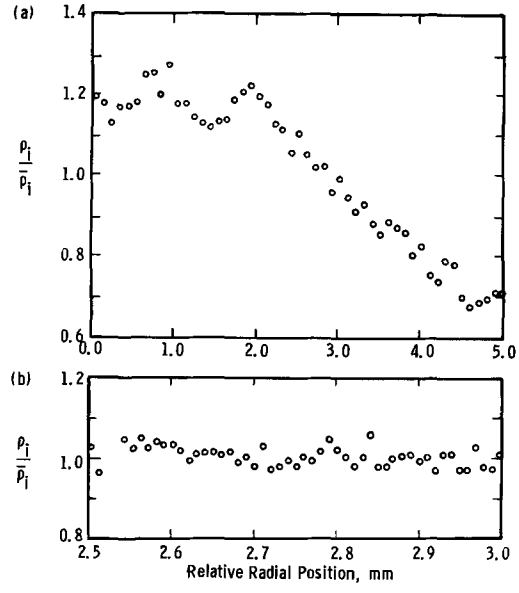

Fig. 3. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 14 ohm-cm Czochralski crystal with a long-term resistivity gradient. (a) 0.1 mm scale, $s/\bar{\rho}_i = 0.185$; (b) 0.01 mm scale, $s/\bar{\rho}_i = 0.024$.

the material is clearly indicated to be defective or questionable in some way by a high value of $s/\bar{\rho}_i$ on any scale.

Figure 4 is a plot of fine-scale (0.01 mm probe intervals) made on a sample of 175 ohm-cm Czochralski crystal before and after etching the sample for several minutes in CP4A. The purpose of this experiment was to determine how much of the fine-scale, point-to-point spreading resistance variation was due to inherent fluctuations in resistivity in the material and how much was the result of scratches or other polishing artifacts on the alumina-polished surface. Figure 4a (the polished surface) apparently has the same scatter as that of the etched sample (Fig. 4b). The quantitative measure of homogeneity, the fractional standard deviation, bears out the qualitative picture: values of $s/\bar{\rho}_i$ of 0.038 (for the polished surface) and 0.032 (for the etched surface) are not significantly different. Thus, the observed fine-scale fluctuations in resistivity are not due to the surface finish.

Figure 5 shows some results obtained on a 0.7 ohm-cm float-zone crystal. Figure 5a is the 0.1 mm scale

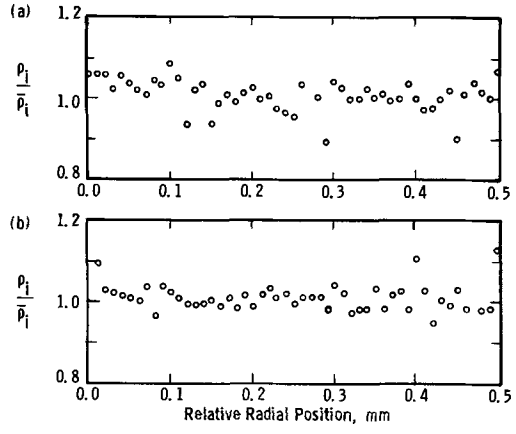

Fig. 4. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 175 ohm-cm Czochralski crystal as a function of surface finish. (a) alumina-polished surface, 0.01 mm scale, $s/\bar{\rho}_i = 0.038$; (b) chemically polished surface, 0.01 mm scale, $s/\bar{\rho}_i = 0.032$.

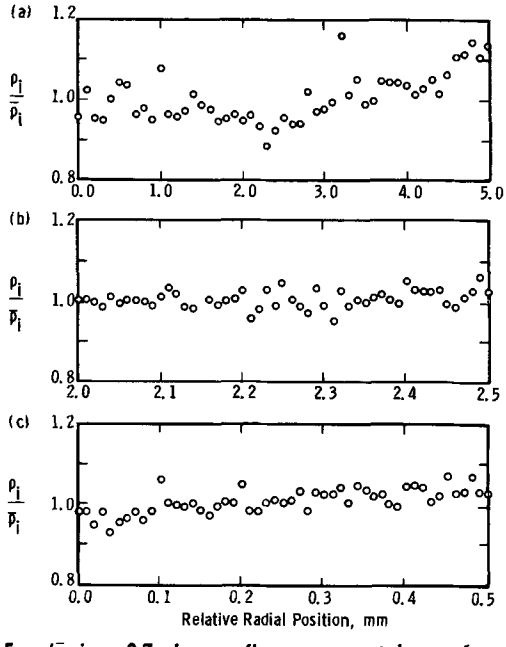

Fig. 5. $\rho_i/\bar{\rho}_i$ in a 0.7 ohm-cm float-zone crystal as a function of relative radial position and surface finish. (a) 0.1 mm scale, alumina-polished surface, $s/\bar{\rho}_i = 0.060$; (b) 0.01 mm scale, alumina-polished surface, $s/\bar{\rho}_i = 0.022$; (c) 0.01 mm scale, chemically polished surface, $s/\bar{\rho}_i = 0.029$.

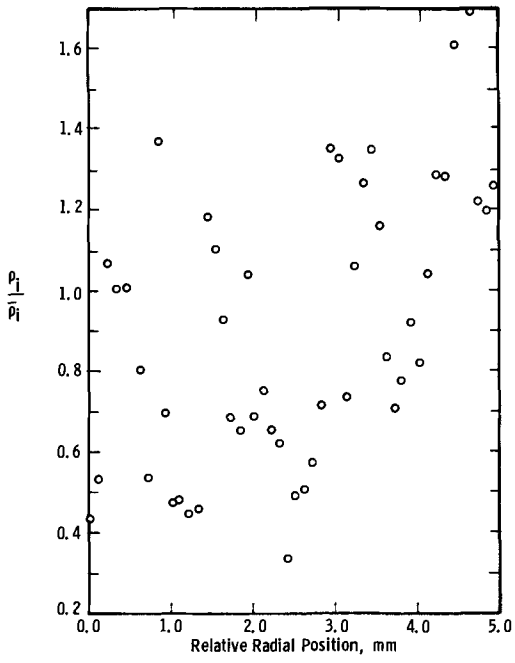

Fig. 6. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 250 ohm-cm float-zone crystal, 0.1 mm scale, $s/\bar{\rho}_i = 0.37$.

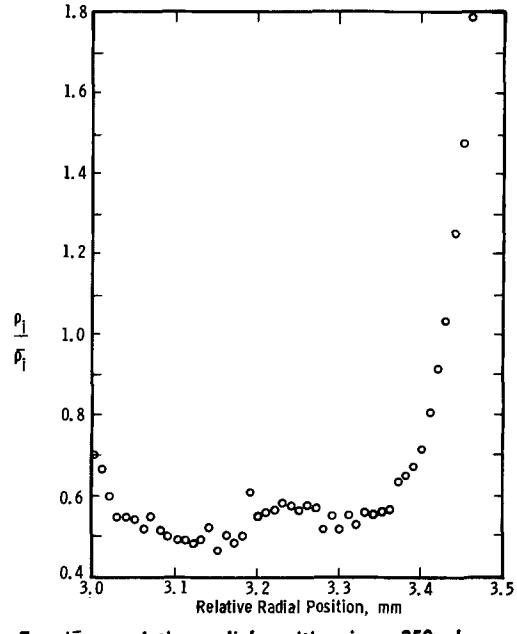

Fig. 7. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 250 ohm-cm float-zone crystal, 0.01 mm scale, $s/\bar{\rho}_i = 0.42$.

data, with $s/\bar{\rho}_i = 0.06$; Fig. 5b gives the 0.01 mm scale data on the center section of the polished sample shown in Fig. 5a, with $s/\bar{\rho}_i = 0.022$; Fig. 5c shows 0.01 mm scale data on a sample of this same material etched for several minutes in CP4A. The value of $s/\bar{\rho}_i = 0.029$ for the etched sample of Fig. 5b again demonstrates that the variations in resistivity observed in this work are real and do not reflect a variable surface finish.

Figure 6 illustrates an extreme situation. This is a 250 ohm-cm float-zone crystal which has a 0.1 mm scale fractional standard deviation of 0.37; with a corresponding range of local resistivities varying by a factor of about 6. Figure 7 shows a small section of this material on the 0.01 mm scale. While the resistivity fluctuation over distances of a few tenths of a millimeter is quite small, the beginning of a high ρ region at the end of the section shown leads to an over-all value of $s/\bar{\rho}_i = 0.42$. As before, it is apparent

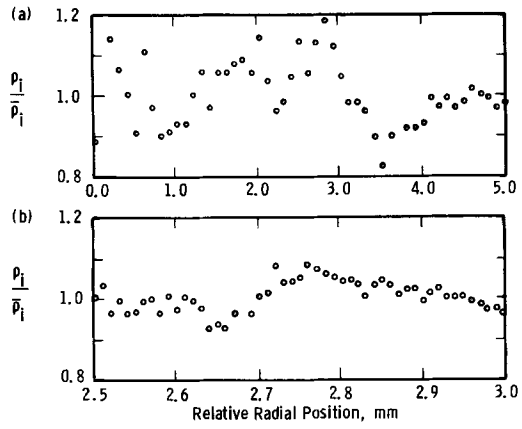

Fig. 8. $\rho_i/\bar{\rho}_i$ vs. relative radial position in a 44 ohm-cm crucible-less pulled silicon crystal. (a) 0.1 mm scale, $s/\bar{\rho}_i = 0.079$; (b) 0.01 mm scale, $s/\bar{\rho}_i = 0.037$.

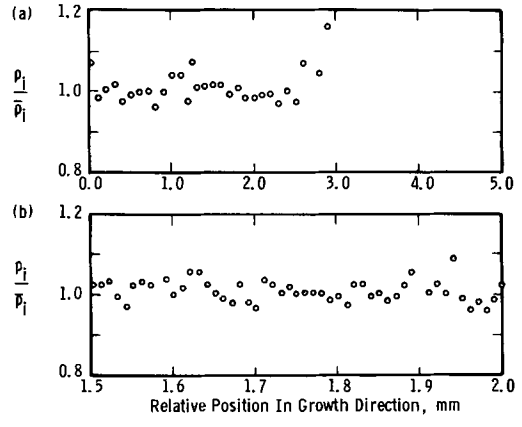

Fig. 9. $\rho_i/\bar{\rho}_i$ vs. relative position in growth direction in a 0.31 ohm-cm silicon web: (a) 0.1 mm scale, $s/\bar{\rho}_i = 0.039$; (b) 0.01 mm scale, $s/\bar{\rho}_i = 0.027$.

that the value of the fractional standard deviation of ρ_i is a "fail-safe" parameter in evaluating crystal quality in that it is necessary for the material to be uniform on both the macroscopic and microscopic scale to satisfy the condition $s/\bar{\rho}_i << 1$.

Figure 8 shows a sample of crucible-less silicon with a resistivity of 44 ohm-cm. Here the fractional standard deviation of the 0.1 mm scale data is 0.079. The fractional standard deviation of the 0.01 mm scale data (Fig. 8b) is 0.037. From this and other specimens, it is apparent that the crucible-less silicon, in this respect, as in many others, is often midway between the float-zone and Czochralski crystals.

Figure 9 shows a web sample with a resistivity of 0.31 ohm-cm. Figure 9a shows a 3 mm section of the material probed at 0.1 mm intervals, with a fractional standard deviation in the resistivity values of 0.039. Figure 9b shows the fine-scale data taken at 0.01 mm intervals with a fractional standard deviation of 0.027. These data indicate that this web material is at least

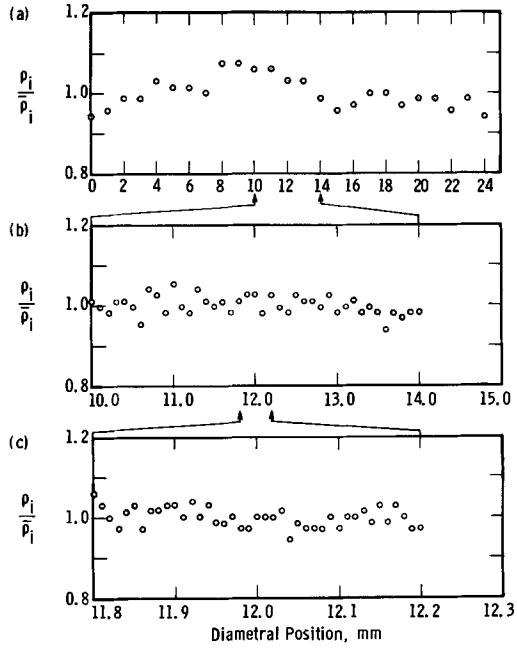

Fig. 10. $\rho_i/\bar{\rho}_i$ vs. diametral position coordinate in a 28 ohm-cm vapor-deposited epitaxial crystal: (a) 1.0 mm scale, $s/\bar{\rho}_i = 0.039$; (b) 0.1 mm scale, $s/\bar{\rho}_i = 0.023$; (c) 0.01 mm scale, $s/\bar{\rho}_i = 0.025$.

as uniform as the float-zone material on the coarse scale and is as uniform or more uniform than either float-zone or Czochralski material on the fine-scale. Note also the near unity value of the ratio $s/\bar{\rho}_i$ (coarse) to $s/\bar{\rho}_i$ (fine-scale).

Figure 10 shows a sample of 28 ohm-cm, n-type epitaxial silicon produced in our laboratories. It may be seen that the epitaxial sample, at least produced under the conditions used here, is very uniform in resistivity, both across the whole of the diameter of a 25 mm slice, and on the fine-scale as well, with the total scatter of all of the resistivity values lying in the range of plus or minus 7%.

Where a comparison may be made, these results agree with those of Benson (4) relating to radial resistivity variations in Czochralski crystals. They also provide experimental support for a model involving convection currents in the liquid as the primary cause of resistivity inhomogeneities in melt-grown silicon (5). If this model is indeed an accurate one, the greater resistivity homogeneity of silicon web and epitaxial silicon may be then understood as the result of the rapid growth rate of web from its supercooled melt and, in the case of the vapor-grown epitaxial material, as due to the complete absence of a liquid phase.

Summary and Conclusions

The quantitative results of these measurements are summarized in Table I. Note especially the values given for the ratio s (0.1 mm scale) to s(0.01 mm scale). The tabulated data suggest that two parameters

Table I. Quantitative results of measurements

Growth process	Over-all average resistivity, $\bar{\rho}$ (ohm-cm)	s/ρ_i, 0.1 mm scale	s/ρ_i, 0.01 mm scale	Surface finish	s, 0.1 mm scale / s, 0.01 mm scale

may be conveniently used to establish crystal quality insofar as resistivity inhomogeneity is concerned. These are the fine-scale (0.01 mm scale) fractional standard deviation of resistivity and the ratio of the coarse-scale value of fractional standard deviation to the fine-scale value. With these parameters determined in accordance with the procedures used in this work, a low value of $s/\bar{\rho}_i$ (0.01 mm scale) and a near-unity value of the ratio of $s/\bar{\rho}_i$ (0.1 mm) to $s/\bar{\rho}_i$ (0.01 mm) indicates uniform resistivity silicon. It is essential to note that both criteria must be met to rate material as truly homogeneous.

In conclusion, while this work cannot support a final judgment of the relative worth of material produced by the various growth processes, it does show that significant variations in local resistivity do exist in at least some silicon samples and that the spreading resistance technique may be used to advantage in investigating the problem of resistivity inhomogeneity in silicon. Further work must be done, especially in comparing device yields to crystal "quality" as defined above, to determine the real importance of these measurements.

The Solidification of Bi_2Te_3 and Its Solid Solutions with Bi_2Se_3 and Sb_2Te_3 under the Influence of Ultrasonic Agitation

H. E. Bates and Martin Weinstein

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

The effect of ultrasonic agitation during solidification was studied for three systems: Bi_2Te_3, 0.8 Bi_2Te_3-0.2 Bi_2Se_3, and 0.25 Bi_2Te_3-0.75 Sb_2Te_3. Reduction in grain size was most pronounced in 0.8 Bi_2Te_3-0.2 Bi_2Se_3; the other compositions showed relatively little refinement. A definite tendency for alignment of acicular grains with low intensities of ultrasonic irradiation was noted in all three systems. Compressive fracture stress was increased by agitation for all three systems with considerable anisotropy of strength, relative to the growth direction, occurring in agitated and unagitated material. Highest fracture strength was found in 0.8 Bi_2Te_3-0.2 Bi_2Se_3, 7000 *vs.* 5000 psi for unagitated material. Reduction in length was about equal at 3%. Seebeck coefficient and resistivity were measured as functions of temperature and found to exhibit a difference between agitated and unagitated material which correlated with the amount of grain refinement observed. This is a result of the crystallographic anisotropy of electrical properties in Bi_2Te_3 alloys, reflected by the degree of misorientation caused by ultrasonic agitation.

During the course of investigating the effects of ultrasonic energy on the solidification of thermoelectric materials (1, 2), experiments were carried out with Bi_2Te_3 and some of its technologically interesting alloys. It was of specific interest to observe the effect of ultrasonic agitation on the solidification behavior of these materials because of their highly anisotropic nature.

Other investigators (3-5) have observed coarsening of acicular crystallites in solidified eutectic structures with sonic and ultrasonic vibrations. These are the only instances of the effects of vibration on the solidification of crystals having strong acicular growth habits. In addition Bi_2Te_3 alloys are susceptible to segregation during freezing, requiring either elaborate zone-leveling techniques to produce homogeneous ingots or preparation of thermoelements by powder metallurgical techniques which introduce a number of difficulties with contamination (6) and sintering and grain size effects (7, 8). The results of our investigations with PbTe materials indicated the possibility of considerably enhancing the mechanical properties and improving the homogeneity of cast ingots of Bi_2Te_3 and related alloys.

Thus, the purpose of the present work was to explore the effect of ultrasonic agitation during solidification of a class of alloys exhibiting highly anisotropic growth and to observe the consequences of this method of preparation on the mechanical and electrical properties of these alloys.

Experimental

The experimental procedures and apparatus have been described in detail previously (1, 2). The assembly used to solidify the melts with ultrasonic agitation is shown in Fig. 1.

A charge of 50-75g was sealed under vacuum in the quartz tube. A resistance furnace was lowered over the tube and heated until the charge had melted, as indicated by a thermocouple attached at the base of the tube. After a short period at a temperature 30°-40° above the melting point, the piezoelectric transducer, epoxied to the base of the quartz pedestal, was energized. The furnace was then raised by a motorized hoist so that solidification proceeded upward from the bottom of the ingot at a rate defined by the rate of removal of the furnace. As the freezing interface moved upward, the input frequency to the piezoelectric crystal was varied slightly to maintain a resonant condition. The input power was also increased gradually to compensate for increasing attenuation of the ultrasonic energy in the solidified portion of the

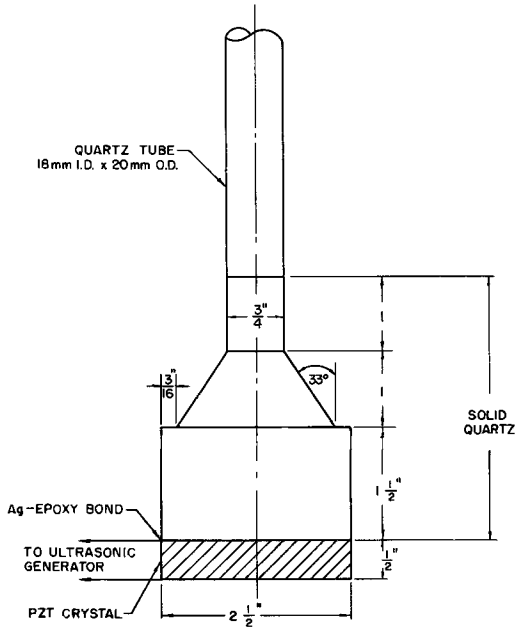

Fig. 1. Piezoelectric transducer, quartz concentrator, and crucible assembly.

melt. Energy intensities varied from 1-9 w/cm^2 at frequencies of approximately 21 and 33-35 kc. Solidification rates were varied from 6.3 x 10^{-3} to 14.1 x 10^{-3} mm/sec.

Results

The effect of ultrasonic agitation during solidification was to cause some reduction in grain size in all three materials. The most interesting result was the varying responses to agitation of three materials of identical structure. Bismuth telluride is rhombohedral with atoms arranged in a sequence Te-Bi-Te-Bi-Te . . . Te with adjacent Te atoms probably bonded only by van der Wall's forces (9). This structure accounts for the anisotropic transport processes and easy cleavage of Bi_2Te_3. Bismuth selenide and antimony telluride form complete isomorphous pseudobinary solid solutions with Bi_2Te_3.

Macrophotographs (Fig. 2) show the gross structure of two ingots of 0.8 Bi_2Te_3-0.2 Bi_2Se_3, the one on the left directionally solidified, the one on the right directionally solidified with 8 watts/cm^2 of ultrasonic agitation for approximately two-thirds of its length. Both were grown at the same rate of 1.1 iphr. The coarse acicular grain structure of the unagitated ingot is plainly visible, while in the lower half of the

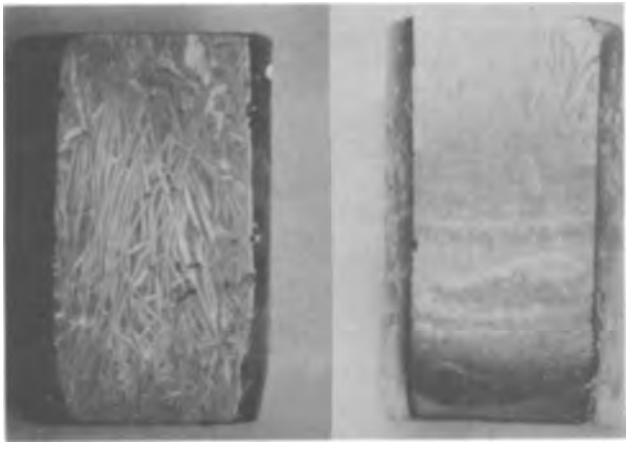

Fig. 2. Macrostructure of 0.8 Bi_2Te_3-0.2 Bi_2Se_3 ingots: (a) directionally solidified; (b) directionally solidified with ultrasonic agitation. Magnification 1½X.

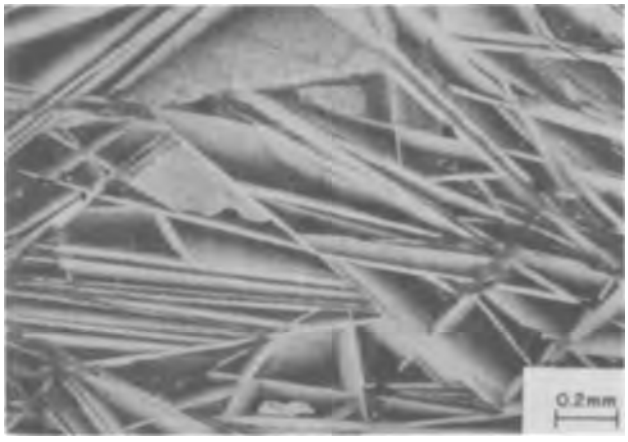

Fig. 3. Microstructure of directionally solidified 0.8 Bi_2Te_3-0.2 Bi_2Se_3. Magnification *ca.* 35X.

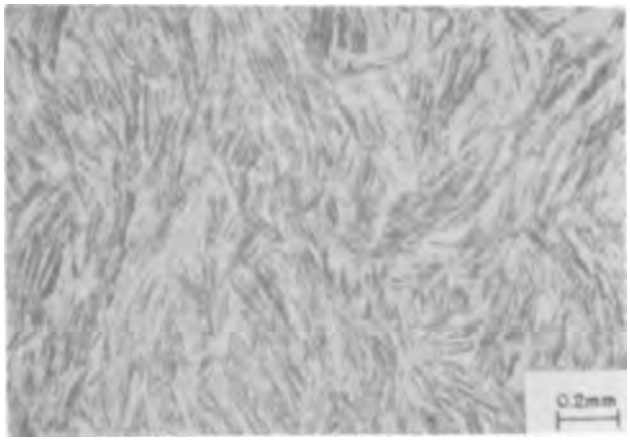

Fig. 4. Ultrasonically agitated 0.8 Bi_2Te_3-0.2 Bi_2Se_3. Magnification *ca.* 35X.

agitated ingot the grains cannot be resolved. The various bands in the agitated ingot are the result of changes in the frequency of the ultrasound to maintain resonance and of turning off the ultrasonic input for a short period at one point. The microstructures of these ingots are shown in Fig. 3 and 4. It is interesting to note here that the very finest grains found in the agitated material were still basically acicular. Figure 3 is not truly representative of the structure of the unagitated material since none of the very large grains are shown. The bismuth telluride-bismuth selenide showed the greatest reduction in grain size of all three systems. The average grain size (length) in the agitated material was approximately 30 times less than that of the unagitated, directionally solidified material.

The structure of the unagitated Bi_2Te_3 was virtually identical to that of the Bi_2Te_3-Bi_2Se_3 shown in Fig. 3. A transverse section at the bottom of an agitated ingot of Bi_2Te_3 is shown in Fig. 5. The ultrasonic energy intensity was approximately 6 w/cm^2 and growth rate 1.1 iphr. It is obvious that while the grains here are fairly long, they are considerably more "blocky" than those in the Bi_2Te_3-Bi_2Se_3. The top of an ingot similarly prepared is shown in Fig. 6; the grains are very needle-like here. The top ends of the ingots, which were 1.5 to 1.75 in. long, received substantially less agitation than the bottom portions because of increased attenuation in the solidified portion of the ingot. The intensity applied to the top section may have been about 1w/cm^2 or less. This is a clear example of the application of increasing ultrasonic energy tending to promote an increasingly equiaxed structure. Grain size reduction in the lower portions of agitated ingots was of the order of 10 or 12:1. An

Fig. 5. Microstructure of Bi_2Te_3 solidified with ultrasonic agitation; bottom section of ingot. Magnification *ca.* 35X.

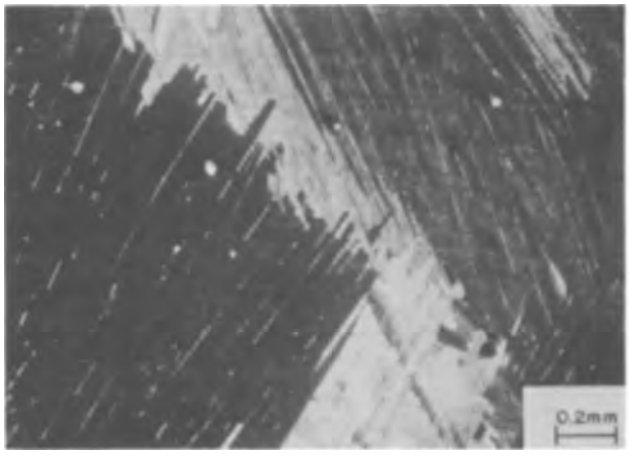

Fig. 6. Microstructure of top section of Bi_2Te_3 of Fig. 5, transverse section. Magnification *ca.* 35X.

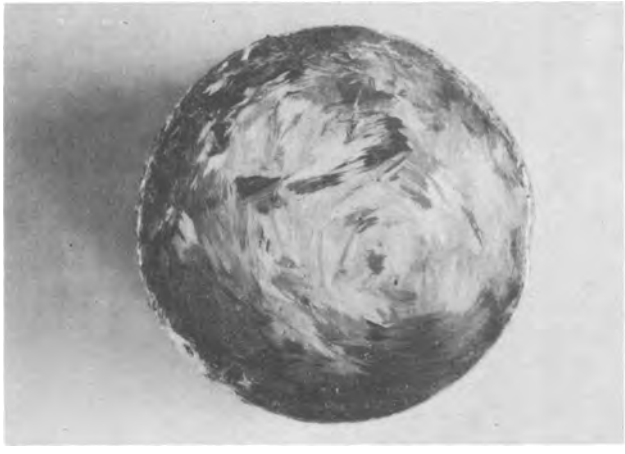

Fig. 7. Macrostructure of Bi_2Te_3 ingot showing crystallite alignment by low intensity vibrations in top section. Magnification 1½X.

interesting phenomenon was observed in the top sections of agitated ingots of all three materials. particularly bismuth telluride and bismuth-antimony telluride. An example from Bi_2Te_3 is shown in Fig. 7. The grains in this case tend to line up with their long axes roughly parallel to the circumference thus giving the somewhat spiral appearance to the gross structure. This was apparently the result of low intensity radial vibrations of the system. Such an effect of low intensity vibrations could be of benefit in producing an oriented structure in the materials so as to take advantage of the anisotropic thermoelectric properties.

Bismuth-antimony telluride, when solidified quickly, grows in acicular grains which are severely segregated

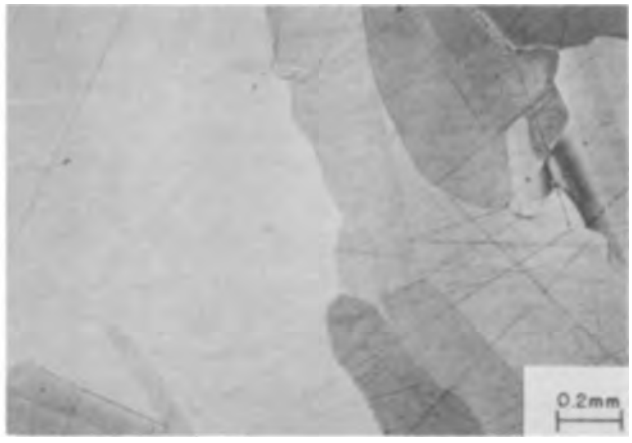

Fig. 8. Microstructure of directionally solidified 0.25 Bi_2Te_3-0.75 Sb_2Te_3. Magnification *ca.* 35X.

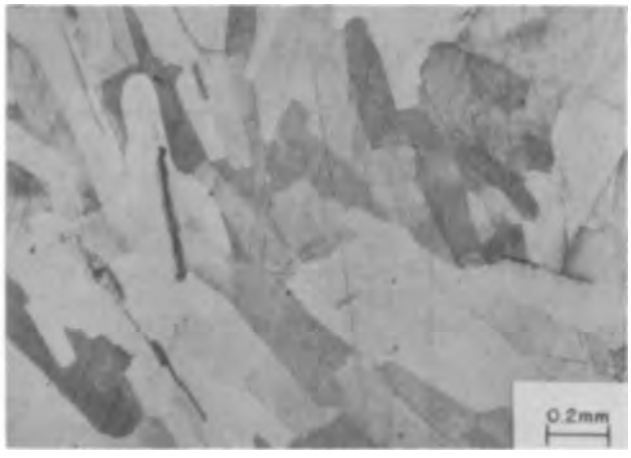

Fig. 9. Ultrasonically agitated 0.25 Bi_2Te_3-0.75 Sb_2Te_3. Magnification 35X.

on a microscale. We found this in water-quenched material and to some extent in ingots grown at more than two inches/hr. Solidification at 0.9 iphr produced the microstructure of Fig. 8. This unagitated ingot exhibited a wide range of grain sizes, the majority tending to a length/diameter (l/d) ratio of about three. Significant grain refinement was difficult to achieve in this system. Figure 9 shows the microstructure of the agitated material. (Ultrasonic energy intensity was 8-9 w/cm^2.) The grains retain approximately the same l/d ratio, while a reduction in average size of about 6-8:1 has occurred. A tendency to greater ratios of length to width in the grains of the top section was found in both agitated and unagitated ingots. The grains of the agitated ingots showed an alignment with the side of the crucible similar to that in Bi_2Te_3.

Compressive strength.—The compressive fracture strengths were measured on samples cut parallel and perpendicular to the growth direction of the ingots as shown in Table I. Samples were mainly in the shape of rectangular blocks about 0.25 in. on a side by 0.4-0.5 in. long. A Hounsfield Type W Tensometer was used for the tests. The agitated material showed

Table I. Compressive fracture strength parallel to growth direction

Material	Compressive fracture strength, psi	Total strain at fracture, in/in
Bi_2Te_3 (agitated)	3,500	0.03
Bi_2Te_3 (unagitated)	2,500	0.02
0.8 Bi_2Te-0.2 Bi_2Se_3 (agitated)	7,000	0.030
0.8 Bi_2Te_3-0.2 Bi_2Se_3 (unagitated)	5,000	0.026
0.25 Bi_2Te_3-0.75 Sb_2Te_3 (agitated)	6,500	0.016
0.25 Bi_2Te_3-0.75 Sb_2Te_3 (unagitated)	2,300	0.08

a definite increase in strength over the unagitated for all three materials.

Considerable anisotropy of strength was found in all the materials. Fracture strength perpendicular to the growth direction was 50-60% of that parallel to the growth direction in unagitated samples. In the agitated samples strength perpendicular to the growth direction was 70-80% of that parallel. Grains grow in these materials as a rule with their cleavage planes parallel to the heat flow. In the unagitated, directionally solidified ingots the grains were generally aligned with the growth direction. Thus, compression parallel to the growth direction was also parallel to the cleavage plane.

Compression perpendicular to the growth direction is averaged over all angular orientations of the cleavage plane with respect to the compression direction. Thus in compressing perpendicular to the growth direction some favorably oriented grains reach the critical shear stress for slip or cleavage in the basal plane at a fairly low over-all stress level. In compressing parallel to the growth direction, where the cleavage planes are essentially all parallel to the stress axis, the over-all stress level must approach the critical shear stress for slip and/or cleavage. The samples of agitated material, however, with decreased orientation of the grains with the growth direction, exhibit strengths more nearly equal in the two directions. That the agitated materials showed generally higher strengths may be attributed to their finer grain sizes. A fine grain size increases the strength by limiting the propagation of slip or cleavage in any given grain through the interference of the more numerous grain boundaries.

Electrical properties.—Measurements of the Seebeck coefficient and resistivity as functions of temperature were made parallel to the growth direction on all ingots. The results of these measurements are shown as α^2/ρ (volt^2/°C — ohm cm) in Fig. 10-12 for 0.8 Bi_2Te_3 — 0.2 Bi_2Se_3 + 0.04% CuBr (n-type), Bi_2Te_3 + 0.04% Pb (p-type), and 0.25 Bi_2Te_3 — 0.75 Sb_2Te_3 + 0.05% Pb + 0.03% Cd (p-type). The values shown are in generally good agreement with those reported by most other authors for these materials.

The curves reflect the effect of the ultrasonic agitation in disturbing the orientation of the grains with the growth direction. With the cleavage planes generally oriented in the growth direction, the unagitated materials exhibit higher electrical efficiency factors. Madigan (10) predicted a reduction of 28% in the figure of merit of randomly oriented polycrystalline rods of Bi_2Te_3 *vs.* oriented single crystals, while Piwkowski (8) finds differences of 25-60% in

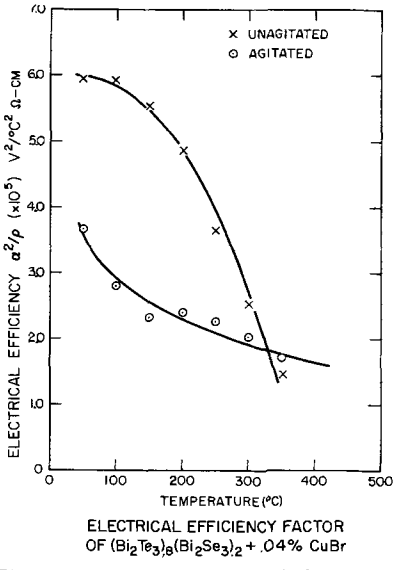

Fig. 10. Electrical efficiency factor of 0.8 Bi_2Te_3-0.2 Bi_2Se_3 measured parallel to growth direction.

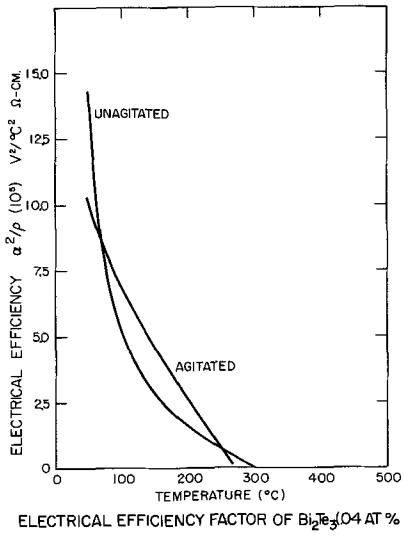

Fig. 11. Electrical efficiency factor of Bi_2Te_3 (0.04 a/o Pb) measured parallel to growth direction.

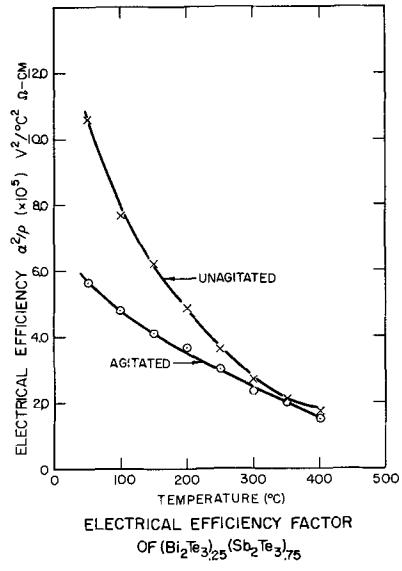

Fig. 12. Electrical efficiency factor of 0.25 Bi_2Te_3-0.75 Sb_2Te_3 measured parallel to growth direction.

the figure of merit of single crystal compared with pressed and sintered Bi_2Te_3.

The sharper decrease of α^2/ρ with increasing temperature for the unagitated Bi_2Te_3 — Bi_2Se_3 and Bi_2Te_3 —Sb_2Te_3 can be attributed to somewhat poorer chemical homogeneity than the agitated material. This is ultimately reflected in a less regular behavior than that exhibited by the agitated material.

Conclusions

1. Significant grain refinement was obtained in the Bi_2Te_3 — Bi_2Se_3 system by ultrasonic agitation of the melt during solidification. Little refinement was observed in the Bi_2Te_3 and Bi_2Te_3 — Sb_2Te_3 systems.
2. A tendency for alignment of acicular grains parallel to the crucible wall was noted at low ultrasonic intensities.
3. The Seebeck coefficient and resistivity as a function of temperature exhibit a difference between agitated and unagitated material which correlates with the amount of grain refinement. This is a result of the crystallographic anisotropy of electrical properties in Bi_2Te_3 alloys, reflected by the degree of misorientation caused by ultrasonic agitation.

Nucleation and Growth of Crystals in Gels

J. Dennis and H. K. Henisch

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Because the crystals in any one-growth system grow competitively, nucleation control is one of the keys to the practical exploitation of the gel-growth technique. The paper discusses some of the principal factors on which nucleation in gels depends and shows how nucleation can be controlled by programming of the reagent concentrations, by trace impurities, and by varying the gel structure. Multiple reseeding procedures are described which permit the growth of larger crystals than can be obtained with single growth stages.

Studies of nucleation have in the past been hampered by the lack of sufficiently simple systems on which meaningful experiments could be performed and by the general difficulty of controlling the processes involved. For such studies, the gel method (1, 2) offers new opportunities. The crystals grow within the gel, in the same localities in which they nucleate and in chemical environments which can be locally analyzed. Once nucleation has taken place, the growth has been shown to be diffusion controlled (2). This paper describes the results of nucleation experiments and shows how they can be at least qualitatively understood in terms of critical radius theory. It also provides an explanation for the photonucleation phenomena previously reported (1) and describes procedures which promote orderly growth through nucleation control.

The growth procedures are simple, even though the associated chemical and diffusion processes are not. Gels of 1.06 g/cm^3 density are made from solutions of sodium metasilicate, in the presence of varying acid concentrations. The acid in question may be one of the reagents participating in the formation of the crystal material. The other reagent is placed as a solution on top of the gel and allowed to diffuse. Alternatively, a nonacid reagent may be added to the sodium silicate solution before gelling, in addition to an acid which then serves only to adjust the pH. There are various possibilities, as the following examples will make clear:

(*a*) Growth of calcium tartrate crystals:
Present in the gel: tartaric acid, (initially pH 2.7), Diffusing into the gel: calcium chloride (initially 1*N*).

(*b*) Growth of lead iodide crystals, PbI_2:
Present in the gel: lead acetate and acetic acid, (initially pH 4.0), Diffusing into the gel: potassium iodide (initially 0.1*N*, increasing to 0.5*N*).

(c) Growth (3) of lead hydroxy iodide crystals, PbI(OH):
Present in the gel: acetic acid and potassium iodide (initially pH 8.5), Diffusing into the gel: lead acetate (initially 0.2*N*).

It has already been shown that a variety of crystals suitable for solid-state experimentation can be produced in similar ways. The method is especially useful for substances which, because of their low solubilities or low dissociation temperatures (or both) cannot readily be grown by other methods. Since the crystals in any one growth system grow competitively, control of the nucleation process is in many cases a key to the practical utility of the method.

Heterogeneous and Homogeneous Nucleation

The most readily accountable form of nucleation is "heterogeneous," in the sense that it depends on the presence of foreign substrates. It is easy to demonstrate (*e.g.*, by dispersing inert crystalline powders) that it can take place in a gel. There is no reason for expecting heterogeneous nucleation in a gel to be generically different from corresponding process in simple solution, but the frequency of its occurrence is not the same. Thus, most of the accidentally present dust grains which would ordinarily be eligible as nuclei in solution are immobilized by the presence of the gel, perhaps because they are embedded in small cells. In such circumstances, very thin layers of crystal may grow on them, but insufficient material would be available to permit growth beyond submicroscopic size. Alternatively, since the gelling process itself is believed to depend on the presence of foreign nucleation centers, most of the available substrates may be used up by the time gelling is complete. What ever the mechanism, the immobilization of unwanted nucleation centers is believed to be one of the important factors governing the success of the gel method.

Heterogeneous nucleation can be utilized for epitaxial growth and may become important in connection with the growing interest in heterojunctions. In passing, heterojunctions of PbI_2/PbI(OH) and $CaC_4H_4O_6/CuC_4H_4O_6$ have been gel-grown in this way.

There are, however, reasons for believing that much and sometimes most of the nucleation observed in reasonably low dust content gel media is "homogeneous," *i.e.*, that it depends on the formation of critical

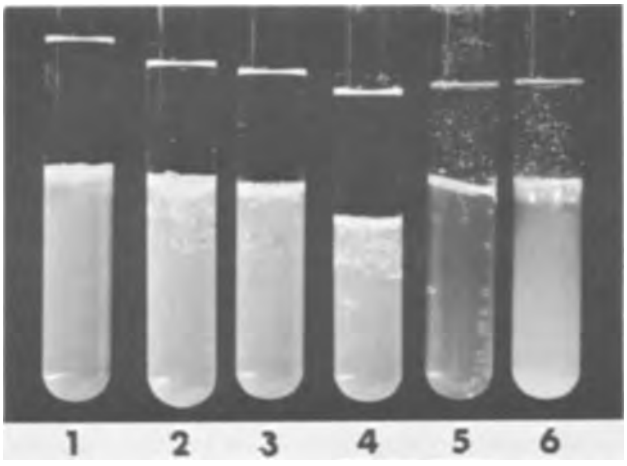

Fig. 1. Experiments on nucleation control: 1, 2, 3, 4, calcium tartrate, 5, 6, lead iodide; 1, 2, pH 3.5; 3, pH 2.5; 4, pH 2.8; 5, 6, pH 4.1. Artificial nuclei present in tubes 2, 3, 4 and 6; the round objects in tube 5 are bubbles.

nuclei. This follows in part from the enormous supersaturations which prevail in the gel, from the distribution of crystals in any given growth system, and from the time-sequence of their appearance. If nucleation were heterogeneous, the final distribution should in the normal way be uniform, corresponding to a uniform dust-distribution, but this is not in fact observed. There is, in principle, the possibility (4) that the diffusing reagent may create its own foreign substrates by reacting with impurities in the resident reagent, thereby creating a nonuniform distribution of nuclei. However, this would involve rather specialized conditions and, as a general mode of operation, seems unlikely. Epitaxial growth on a foreign substrate generally calls for lower supersaturations than homogeneous nucleation, and a corresponding demonstration is shown on Fig. 1. Tubes 1 and 2 contain, above the gel, the same solution of $CaCl_2$. The gel in tube 1 is free of deliberately added foreign nuclei and is seen not to support any crystal formation because the $CaCl_2$ concentration is too low. Some accidental unwanted dust grains are undoubtedly present but are evidently immobilized by the gel. Tube 2 contains heterogeneous nuclei in the form of fine titanium dioxide dust and supports copious nucleation. The number of crystals formed is still much smaller than the total number of TiO_2 grains present, showing that, in the presence of very high dust concentrations, the gel cannot immobilize all the potential nucleation centers. Tubes 5 and 6 provide the same demonstration for PbI_2. A similar difference can be observed by varying the pH in the gel. One would expect the homogeneous nucleation of calcium tartrate to be sensitive to the acidity of the gel, considering that the material is appreciably soluble in tartaric acid. In fact, crystal formation in a clean system is rare below pH 3. In the presence of artificial nuclei, pH is still an important factor but crystals appear in gels which are considerably more acidic. Tubes 3 and 4 on Fig. 1 show this, the acidities being 2.5 and 2.8, respectively.

Nucleation Control through Concentration Programming

The above considerations lead (in low dust-content gel media) to a simple method of nucleation control. The concentration of the diffusing reagent is initially kept below the level at which nucleation is known to occur. It is then increased in a series of small steps, which can be optimized for any system as regards magnitude and timing. At some stage, a few nuclei begin to form. As the concentration of the diffusant increases, these nuclei act as sinks, and the resulting establishment of radial diffusion patterns reduces concentrations and appears thus to inhibit the formation of additional nuclei. Subsequent increases of reagent concentration lead to faster growth but not, in general, to new nucleation. The existing crystals are thus able to grow noncompetitively and their quality is correspondingly good. It has been found empirically that frequent small steps are more beneficial than a few large concentration increases. The method has been successfully applied to the control of nucleation in several systems (Table I), and has yielded crystals of larger size and a higher degree of perfection than those produced without programming. The size increase amounts to approximately a factor of 3, except for calcium tartrate for which nucleation is rare enough even without programming to reduce the importance of the competitive growth limitation.

Table I. Effect of concentration programming on crystal size

Crystal	Typical sizes: largest linear dimensions, mm	
	Without programming	With programming
Calcium tartrate	~12	~12
Cuprous tartrate	1	3
Lead iodide	3	15
Thallium iodide	0.5	1.5
Calcium carbonate (aragonite spherulites)	0.5	1.5
Cadmium oxalate	2	5

It remains to be shown that the method can be more generally applied, the present indications being that it can.

Effect of Trace Impurities and Molecular Volume

The theory of homogeneous nucleation via critical nucleus formation in solution is still only imperfectly understood (5, 6). Under the simplifying assumptions envisaged by the Kelvin equation and the Gibbs-Duhem relationship, the radius r_c of the critical nucleus forming in a solution would be given by

$$r_c = \frac{2\sigma V_s}{kTS}$$

where V_s is the molecular volume of the solute, S the supersaturation, and σ the surface energy per unit area (closely related to the surface tension and identical with it under simplest conditions). By analogy with other interface parameters, σ is expected to be selectively sensitive to the presence of contaminants, especially since the free energy of nucleus formation (7) depends on σ^3. It is certainly true that solution processes can be affected sensitively by the presence of contaminants in the low ppm range (8). For the calcium tartrate system, the most potent contaminant

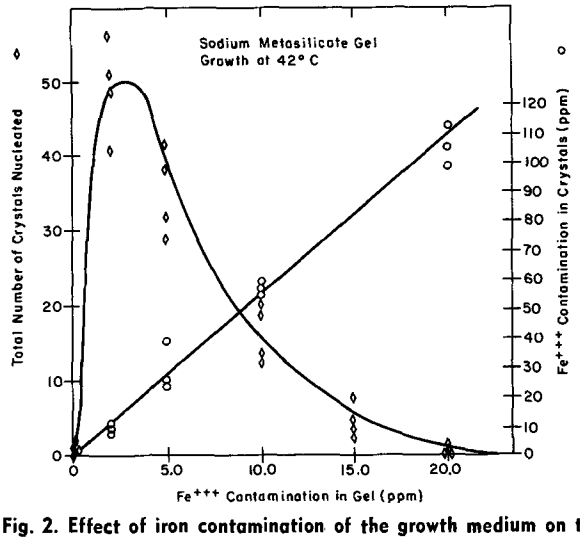

Fig. 2. Effect of iron contamination of the growth medium on the nucleation and composition of calcium tartrate crystals.

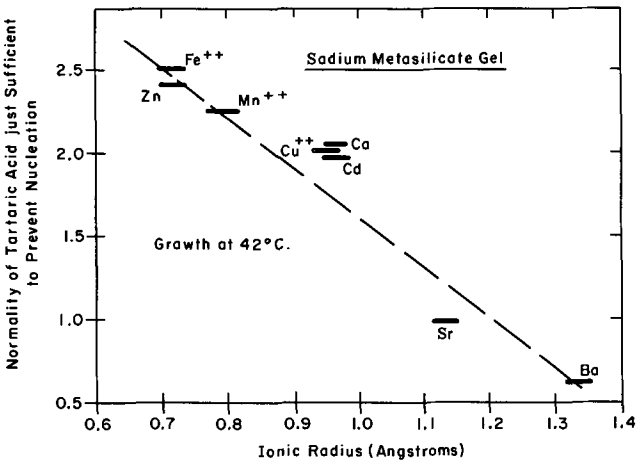

Fig. 3. Effect of molecular volume on critical nucleus formation of tartrates.

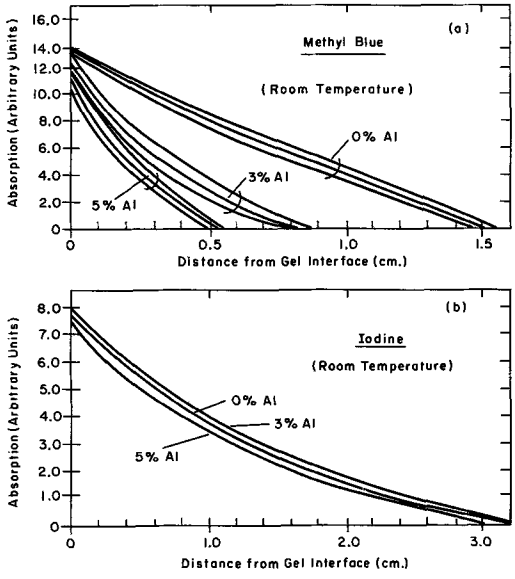

Fig. 4. Effect of alumina content on the diffusion of methyl blue and iodine in sodium metasilicate aluminate gels, assessed by optical absorption measurements.

was found to be iron. Results which show its effect are given in Fig. 2 and the relationship is evidently not simple. A very small concentration of ferric ions promotes nucleation; larger concentrations inhibit it, whereas the uptake of iron by the crystal itself (spectroscopically determined) increases uniformly as expected. That the growing crystals become enriched in contaminant appears to be a peculiarity associated with iron. There is, of course, infinite scope for investigations of this kind, using different combinations of crystals and potential contaminants. General predictions cannot as yet be made.

The previously reported observations of photonucleation can, in all likelihood, be understood in similar terms, *i.e.*, as an indirect effect of light on σ. It has long been known (9) that light (especially uv) dissociates tartaric acid with the production of CO_2, which can easily be shown to enhance the nucleation of calcium tartrate crystals. This can be demonstrated convincingly by comparing a series of growth systems, maintained in darkness, but with different amount of CO_2 additive in the gel.

In a manner similar to that demonstrated above, a correlation can be established between nucleation frequency and the molecular volume of the solute, as suggested by the approximate calculation of the critical radius. For this purpose it is actually convenient to use, as an index of comparison, not the probability of nucleation as such, but the normality of the acid on the gel which is just sufficient to suppress nucleation. Its correlation with the ionic radius of the metal is shown in Fig. 3 for a series of tartrates grown under otherwise identical conditions. The radius may be taken as a relative measure of molecular volume.

Effect of Gel Structure

If the views expressed above are correct, then one would expect nucleation to be more difficult in gels of smaller cell size. In order to test this, it is necessary to have some method whereby gels can be compared from this point of view, at least in a semiquantitative manner. Quantitative work on hydrogels is, of course, hampered by their complicated structure and, in particular, by the fact that not only the mean cell dimensions but also the size distribution about this mean can vary. However, by allowing a compound of large molecular volume to diffuse, an empirical relative measure of effective cell size can be obtained. In the present case, this was done by observing the diffusion of methyl-blue in gels of varying Si:Al ratio. The diffusion process is monitored by making light absorption measurements as a function of distance from the gel surface. As Fig. 4 shows, diffusion becomes more difficult as the amount of Al increases, and it is reasonable to conclude that this is due to progressively diminishing cell sizes. Al certainly has this effect on the cell dimensions of dehydrated gels, as Plank and Drake (10) have demonstrated.

Table II shows how, under a standard set of conditions, the number of crystals nucleated depends on gel composition and thus evidently on the cell size. The expected correlation is observed and Table II, incidentally, gives an impression of the extent to which the results vary between growth tubes of the same composition and thermal history. It is, however, necessary to check that the various gels used do not present different diffusion conditions to the reagents involved in crystal formation. When the diffusants are very small compared with the cell size, the cell size should have no material effect on the diffusion process. Figure 4 shows that (for iodine) this is indeed correct, and the comparison implied by Table II is therefore valid.

Reseeding Procedures

Once nucleated, the crystals grow until they reach a constant size. It has already been shown that this size is determined by the progressive exhaustion of the reagents (1). Replenishment of at least one (the diffusing) reagent is a simple matter, but the removal of the waste products of the reaction is not. If, therefore, a crystal of larger size is required, it must be reseeded into another gel. This is done first by gelling a small amount of sodium metasilicate in a tube, resting the seed on the gel surface thus formed, and covering it first with additional sodium metasilicate solution and, after second gelling, with the diffusing reagent. In the course of transferring the crystal from one growth system to another, its surfaces are generally damaged and possibly contaminated, resulting in polycrystalline growth. To prevent this, the temperature is

Table II. Standard set of conditions.

Crystal	0% Al	3% Al	5% Al	6% Al	8% Al

	18.4	30.2	66.0	81.7	103.4

raised immediately after reseeding in order to dissolve a portion of the seed, as is usual in all seeding procedures. When the temperature is subsequently lowered, growth proceeds in the normal way until the reagents are once again exhausted. The process can then be repeated. In a series of steps it is thus possible to grow considerably larger crystals than can ordinarily be obtained in a single growth system. The method has not yet been widely applied, but the principle is illustrated below on the basis of calcium and copper tartrate. Table III shows the weights of particular crystals after successive reseeding stages. With care, their high degree of optical perfection can be fully maintained throughout this procedure.

Characteristics of the Surface-State Charge (Q_{ss}) of Thermally Oxidized Silicon

B. E. Deal, M. Sklar, A. S. Grove, and E. H. Snow

Research and Development Laboratories, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

The nature of the surface-state charge (Q_{ss}) associated with thermally oxidized silicon has been studied experimentally using MOS structures. The effects of oxidation conditions, silicon orientation, annealing treatments, oxide thickness, and electric field were examined, as well as the physical location of the surface-state charge. The results indicate that the surface-state charge can be reproducibly controlled over a range 10^{10}-10^{12} cm^{-2}, and that it is an intrinsic property of the silicon dioxide-silicon system. It appears to be due to an excess silicon species introduced into the oxide layer near the silicon during the oxidation process.

In much of the early work on the properties of semiconductor surfaces, experimental results were interpreted within the framework of two quantities: fast and slow surface states (1). "Fast surface states" are electronic states within the forbidden gap of the semiconductor, located at the surface, which are in good electrical communication with the semiconductor bulk. Because of this, they can act as surface recombination centers. Their density per unit area for both clean germanium and silicon surfaces has been generally found to be of the same order as the surface atom density. If the semiconductor is covered by an adsorbed layer, or an oxide, the density of fast states has been found to decrease to 10^{11}-10^{12} cm^{-2}. "Slow states," in contrast, have been attributed to ionic contamination within an oxide covering the semiconductor surface. Because of their relatively large distance from the semiconductor, they are in poor electrical communication with it. Their density is a strong function of the ambient and surface treatment of the sample, but generally ranges in the neighborhood of 10^{12}-10^{13} cm^{-2}.

In the past several years, the thermally oxidized silicon surface has been investigated very intensively, partly due to its extreme technological importance and partly to the ease with which its characteristics can be studied (2). As a result of these investigations, a detailed picture of this system has emerged which is not explainable strictly within the framework of fast and slow surface states.

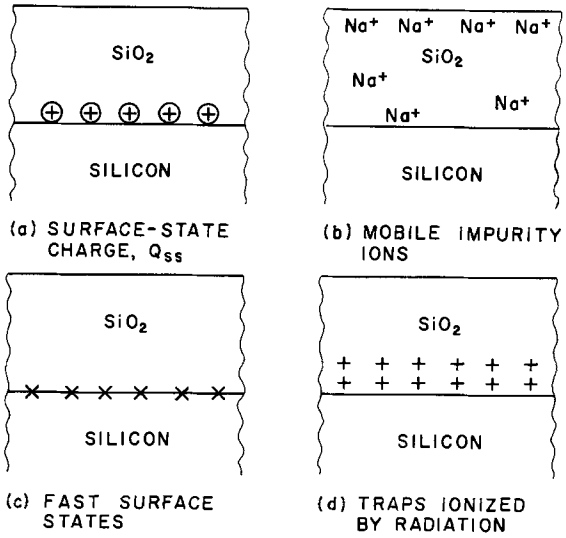

Fig. 1. Charges or states associated with the silicon dioxide-silicon system.

An idealized representation of the current picture of the thermally oxidized silicon system is depicted in Fig. 1. Fast surface states have been identified, but in many cases their density has been found to be less than 5 x 10^{10} cm^{-2} (3), considerably lower than in other systems, thus leading to the low surface recombination velocity of passivated silicon devices (4). While slow surface states, in the customary sense, have not been evident, ionic space charges within the oxide have been observed. These were found to result from either contamination by relatively mobile ions such as sodium (5, 6), or from exposure to ionizing radiation (7). They are evidently in poor electrical contact with the underlying silicon even when located very near the oxide-silicon interface.

These charges within the oxide, which have generally been found to be positive, induce a negative charge in the silicon, and thereby lead to the tendency of thermally oxidized silicon surfaces to be n-type, as observed already in the earliest experiments (8). On the other hand, it has been shown (3) that even oxides grown in such a manner that ionic contamination was precluded are characterized by a positive charge, apparently located in the oxide, near the oxide-silicon interface. This charge, which has been designated the surface-state charge, and whose density per unit area is denoted by Q_{ss} (3), is the subject of the present paper.

The characteristics of the surface-state charge as established in the earlier study, were the following: (*i*) Its density Q_{ss} is reproducible. For one particular set of conditions [oxidation at 1200°C, in dry O_2; (111) silicon orientation] its density is ~2 x 10^{11} cm^{-2}. (*ii*) Its density is independent of the impurity concentration in the silicon, and of the oxide thickness over a wide range. (*iii*) Its density is independent of the band bending or surface potential in the silicon over at least the middle 0.7 ev of the energy gap. (*iv*) Its density is stable under elevated temperature—bias test conditions of the kind that would lead to rearrangement of sodium contamination in the oxide, or to annealing of radiation-induced space charges.

These characteristics are difficult to reconcile with the conventional picture of slow and fast states at a semiconductor surface. Therefore, a study was undertaken to examine in detail the nature of the surface-state charge. The present paper contains a summary of an extensive experimental investigation dealing with the effect of oxidation conditions, silicon orientation, annealing treatments, oxide thickness, and electric fields on Q_{ss} and with its spatial distribution in the oxide. The primary means of evaluation was the capacitance-voltage method of analysis using metal-oxide-semiconductor (MOS) structures.

Experimental

Materials.—Silicon used in these studies was single crystal Czochralski type. It was obtained from the Kollstan Semiconductor Elements Company of Westbury, New York, in the form of circular slices approximately 2 cm in diameter and lapped on both sides to a thickness of 250μ. Dislocation count was specified to be less than 100 cm^{-2}. Both p- and n-type dopants (boron and phosphorus) were included, the concentrations being ~10^{16} cm^{-3} for most of the experiments. Various surface orientations were studied, including (111), (110), and (100).

Aluminum used for field plates and back contacts was obtained from Cominco Products, Inc., Spokane, Washington, and was specified as 99.9999% pure. A separate analysis indicated the sodium content was 1 ppm or less. Gases used for oxidation and annealing (O_2, N_2, and argon) were obtained in a liquid form from Air Reduction Company, Richmond, California. Total water content was less than 5 ppm in each gas. Special tests indicated other impurities such as hydrocarbons or hydrogen were extremely low, *i.e.*, less than 2 ppm. A molecular sieve trap was used to remove any excess water or hydrocarbons in all gases. Deionized water used for rinsing samples and for wet oxidations had a resistivity at 25°C of 16 megohm-cm and an initial sodium content of less than 0.002 ppm. Although this latter value increased upon storage in the Pyrex or quartz bubbling flask, the analysis of the distillate from the exit end of the oxidation tube indicated 0.030 ppm Na or less.

Procedure.—Immediately prior to oxidation, the silicon slices used for MOS device fabrication were cleaned in both organic and inorganic solvents using ultrasonic agitation. They were then chemically polished in a 4HF: 10HNO_3 solution followed by a quench in acetic acid. Approximately 50μ per side were removed during this operation. Appropriate deionized water rinses were used between the various cleaning and polishing steps. Samples used for thickness measurements were mechanically polished resulting in the removal of 30μ per side. The same cleaning as mentioned above was carried out following mechanical polishing.

The oxidation procedure was essentially the same as described earlier (9). Slices were placed flat on a thin quartz boat and inserted in a tube furnace with separate systems being used for n- and p-type samples. Either dry oxygen or wet oxygen (oxygen bubbled through 95°C H_2O) was used as the oxidizing ambient, with the time and temperature of oxidation depending on the specific experiment. Various pulling rates were employed, the standard one being very rapid (less than 3 sec through the 50 cm from the center of the furnace to the end of the tube).

In certain cases, the samples were annealed in either nitrogen or argon following oxidation. Each oxidation contained a slice for thickness evaluation in addition to those samples used for MOS device fabrication and evaluation. Oxide thicknesses were determined on the special test slices using multiple beam interferometry (10). Accuracy of this method was found to be ±40Å for oxides greater than 2000Å and ±20Å for thicknesses less than 2000Å. After oxidation or annealing, the back oxide was removed from selected samples and MOS capacitance-voltage plots obtained using a gold pressure contact probe. The other samples were metallized with aluminum on the top surface after first removing 50-100Å of oxide in a 10:1 H_2O:HF solution to eliminate contamination. The thickness of the aluminum field plate was 2000-5000Å. The back oxide was then removed and aluminum evaporated on the bare silicon. Top field plates 375μ in diameter on 1250μ centers were then prepared by photoresist operations. Finally, the slices were heat treated at 550°C for 2-5 min in dry nitrogen. Most electrical measurements were made on the slice but in certain cases the slices were scribed and broken into individual dice 1250μ square.

Evaluation.—The majority of the electrical evaluations in this investigation involved the determination of the surface-state charge density Q_{ss}. This measurement was accomplished by determining the shift of an experimental MOS capacitance-voltage curve along the voltage axis from the ideal theoretical curve calculated on the basis of assuming no fast surface states or oxide charges and no work function difference between metal and semiconductor. The resulting voltage shift ΔV is related to Q_{ss} by the expression (3)

$$\Delta V = Q_{ss}\frac{x_o}{K_o\epsilon_o} - \Phi_{MS}$$

where Q_{ss} is the surface-state charge density per unit area, $K_o\epsilon_o/x_o$ is the oxide capacitance per unit area, and Φ_{MS} is the metal-semiconductor work function or barrier energy difference. The latter value for aluminum/SiO_2/n-type silicon (10^{16} cm^{-3}) is —0.25v, while for aluminum/SiO_2/p-type silicon (10^{16} cm^{-3}) it is —0.95v (11). In the majority of the experiments, the experimental C-V curve was identical in shape to the theoretical curve so that the shift along the voltage axis was parallel within experimental error.

In general, C-V plots were obtained on a number of units from each slice. The measurements were made by automatically plotting capacitance *vs.* voltage on an X-Y recorder. Capacitance measurement frequency was about 100 kc and measurements were at 25°C. Reproducibility of Q_{ss}/q values was always better than 5 x 10^{10} cm^{-2} for a particular condition of sample preparation.

Results

Oxidation conditions.—The temperature of oxidation in dry oxygen was found to affect the value of Q_{ss} significantly. A certain reproducible value of Q_{ss} was obtained at any given temperature. This was the case whether the oxide was prepared at that particular temperature, e.g., 1000°C, or prepared at another temperature and then given a final treatment in dry oxygen at 1000°C. This effect was observed with both n-type and p-type silicon.

Typical MOS C-V plots for samples prepared by dry O_2 oxidation of n-type silicon at four different temperatures are shown in Fig. 2. The effect of oxidation temperature on Q_{ss} is clearly demonstrated by the displacements of the different plots from the theoretical curve. More complete data showing the effect of temperature on Q_{ss} are shown in Fig. 3. Both n-type and p-type values are included for temperatures ranging from 550° to 1250°C. All oxide thicknesses for this particular graph are 0.20μ. Above 920°C, the oxides were prepared at the temperature indicated. Below 920°C, the oxides were first prepared at 1200°C and

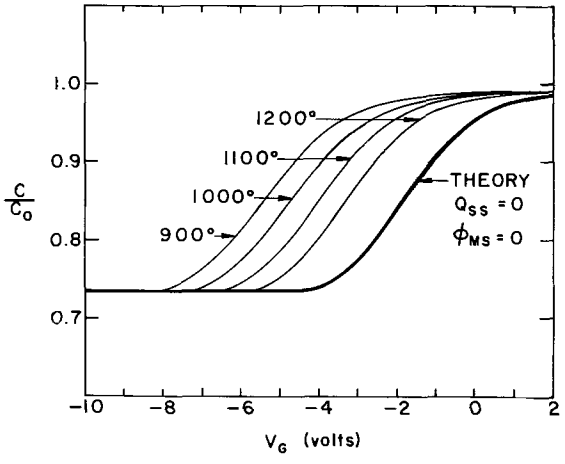

Fig. 2. Capacitance-voltage characteristics of MOS structures prepared by oxidation in dry oxygen at various temperatures [x_o = 0.20μ; N_D = 1.4 x 10^{16} cm^{-3}; (111) orientation].

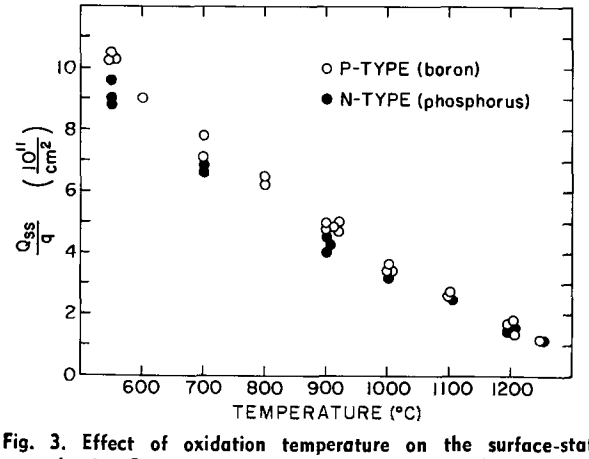

Fig. 3. Effect of oxidation temperature on the surface-state charge density Q_{ss}—dry oxygen [x_o = 0.20μ; N_A, N_D = 1.4 x $10^{16}$$cm^{-3}$; (111) orientation].

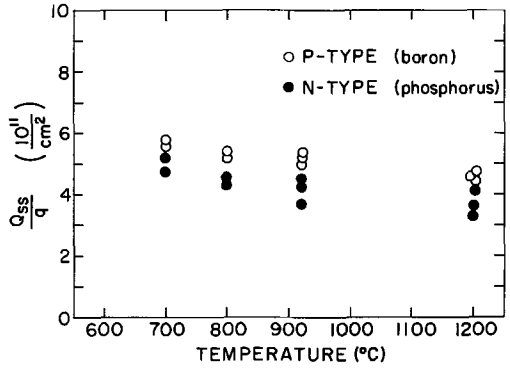

Fig. 4. Effect of oxidation temperature on the surface-state charge density Q_{ss}—wet oxygen (95°C H_2O) [x_o = 0.20μ; N_A, N_D = 1.4 x 10^{16} cm^{-3}; (111) orientation].

then immediately subjected to the lower temperature for a sufficiently long time (previously determined) that the steady state value of Q_{ss} was reached. This time varied from less than 10 min at 900°C to nearly 1 hr at 550°C. It should be re-emphasized that the values presented in Fig. 3 were obtained by quenching the oxidized silicon slice from the oxidation temperature as described previously.

The effect of oxidation temperature on Q_{ss} for the case of oxides prepared in wet oxygen (95°C H_2O) was not nearly so pronounced: Q_{ss} was found to be nearly unchanged between 700° and 1200°C, increasing only slightly with decreasing temperature. Typical data are shown in Fig. 4. Note that at the higher temperatures the Q_{ss} values for wet O_2 are considerably higher than those for dry O_2 oxides, but dry O_2 values are higher below 900°C. Results identical to those shown in Fig. 4 were obtained by oxidation in wet argon (95°C H_2O). By oxidizing under bias in order to exclude contamination, Goetzberger (12) found $Q_{ss}/q = 4$ x 10^{11} cm^{-2} for 1000°C, steam oxidation, in agreement with these data.

The increased values of Q_{ss} at lower oxidation temperatures (for dry O_2 oxidation) are directly related to another effect, namely, the dependence of Q_{ss} on pull rate from the oxidation furnace. Typical data are given in Table I for various pull rates from a 1200°C oxidation in dry oxygen. It is evident that the slower the rate of pull, the higher the Q_{ss} value. These observations are easily explained by the fact that the slower the rate of pull, the more time the sample is exposed to oxygen in the lower temperature range, which results in increased Q_{ss} values. The rapid pull (t < 3 sec) evidently does not permit sufficient exposure of the samples to oxygen in this temperature range and therefore results in the Q_{ss} value corresponding to the oxidation temperature.

Silicon orientation.—It has been shown (13-15) that silicon orientation affects the surface-state charge density Q_{ss} of MOS devices, *i.e.*, the value of Q_{ss} decreases in the order (111)>(110)>(100). Results obtained in the present study, which are in agreement

Table I. Dependence of surface-state charge density (Q_{ss}) on pull rate in dry O_2 following thermal oxidation

(Samples were oxidized at 1200°C for 60 min. x_o = 0.2μ. Silicon was p-type, boron doped, C_B = 1.4 x 10^{16} cm^{-3}, (111) orientation. Distance from center to end of tube was 54 cm.)

Pulling time (min)	Pulling rate (cm/min)	Q_{ss}/q (cm^{-2})
<0.05	>1065	1.9 x 10^{11}
0.167	319	2.8

		(110)	1.7	12.0
		(100)	1.2	7.2
Wet O_2 (95°C H_2O)	920	(111)	5.6	0.406
		(110)	3.6	0.37
		(100)	3.4	0.21

with those of ref. (13-15), are summarized in Table II, for both dry and wet O_2 oxidation at 1200° and 920°C.

A similar effect of orientation on oxidation kinetics was noted in earlier investigations (9, 16). In particular, it is now known (17) that the silicon orientation influences the linear rate constant B/A, which is proportional to the chemical reaction rate constant at the oxide-silicon interface (17-19). This effect is also indicated in Table II. It is evident that the values of B/A and of Q_{ss} for the three orientations follow similar trends.

Annealing treatments.—A wide variety of annealing effects on the surface condition of thermally oxidized silicon has been reported (20-25).

The effect on Q_{ss} due to annealing in oxygen at temperatures other than that of initial oxidation was already described above. This effect is summarized in Part A of Table III. Here, values of Q_{ss} are listed for three conditions of oxygen anneal after 1200°C oxidation: slow pull in O_2, anneal at 900° and at 550°C. These results are compared with the 1200°C standard. Both (111) and (100) orientations are included. It can be inferred from earlier work (21, 24) that the higher Q_{ss} values resulting after certain oxidation conditions can be significantly reduced by annealing in an inert ambient. The inert ambient effect is shown in Part B of Table III. Data are presented for both wet and dry oxygen oxidations followed by inert ambient anneals for two silicon orientations. It can be noted that regardless of the original oxidizing ambient, the final Q_{ss} value will be approximately that of 1200°C dry O_2 if the sample is subsequently annealed in dry argon or nitrogen.

Part C of Table III also demonstrates the fact that the final oxidation or annealing treatment determines the Q_{ss} value. In this case samples have been given combination oxidation treatments, *i.e.*, first dry O_2 followed by wet O_2 or conversely wet O_2 and then dry O_2. Standard dry O_2 and wet O_2 data are also included for comparison. In each case the value of Q_{ss} was characteristic of the final oxidizing ambient.

These results are best summarized by reference to the "dry oxygen triangle" illustrated in Fig. 5. Here

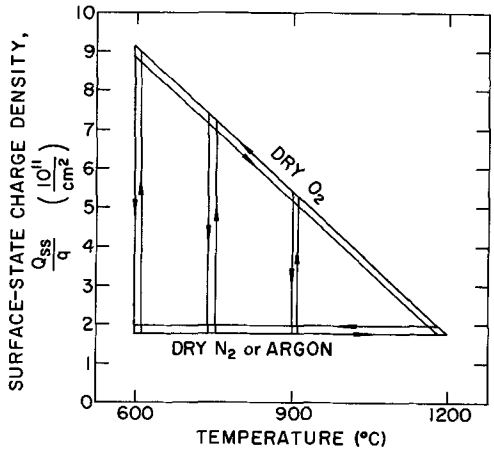

Fig. 5. Illustration of the reversibility of heat treatment effects on the surface-state charge density Q_{ss}.

Q_{ss} is plotted against oxidation temperature. As temperature decreases, Q_{ss} increases and we may move in either direction along the diagonal line labeled "dry O_2." Thus, an oxidized sample may be prepared at any temperature and then subjected to dry oxygen at any other temperature, with the resulting value of Q_{ss} being that associated with the final temperature. The time required for attaining steady state increases with decreasing temperature, being less than 5 min at 1200°C and approximately 1 hr at 550°C.

Another characteristic of the "dry oxygen triangle" is that associated with annealing in an inert ambient. As is indicated in the figure by the lower plot marked "N_2 or Argon", any Q_{ss} value resulting from a previous oxidation at a given temperature can be reduced to a constant value approximating that af 1200°C dry oxygen. This is accomplished by subsequently annealing the structure in dry high purity nitrogen or argon for times characteristic of the particular temperature. These times are similar to those mentioned above for oxygen. Both of these effects are reversible.

The lines shown in Fig. 5 are based on data for (111) p-type silicon; the effect with n-type silicon is approximately the same. A similar relationship exists for (100) silicon, where the Q_{ss} values are reduced by a factor of 2-3 from that of an MOS structure prepared from (111) silicon under identical conditions.

The purity of the gases used in the annealing experiments was found to be extremely critical, especially in the case of the inert ambients argon or nitrogen. For instance, gaseous sources of argon gave nonreproducible increases of Q_{ss} values at the lower temperatures. This was believed to be due to contamination of the gas, although the impurities involved were not identified. Only by use of freshly evaporated liquid argon were reproducible results obtained.

Table III. Dependence of surface-state charge density on annealing treatments and silicon orientation

	Oxide type	Oxidation temperature (°C)	Annealing ambient	Annealing temperature (°C)	Annealing time	Q_{ss}/q (cm^{-2}) (111)	(100)
(A)	Dry O_2	1200	—	—	Std. fast pull (<3 sec)	1.7×10^{11}	0.2×10^{11}
	Dry O_2	1200	O_2	—	Slow pull (2 min)	7.4	2.0
	Dry O_2	1200	O_2	900	10 min	4.6	1.7
	Dry O_2	1200	O_2	550	90 min	10.0	4.2

		0.550	6.6	0.415	3.5
n-type	1200	0.200	3.3×10^{11}	0.190	0.6×10^{11}
n-type	920	0.185	3.7	0.127	1.7×10^{11}

Oxide thickness.—Measurements of the effect of oxide thickness on Q_{ss} were extended to include samples prepared in both dry and wet oxygen at 1200° and 920°C, and for (111) and (100) oriented p- and n-type silicon. Oxide thicknesses ranged from less than 0.01μ to over 0.6μ. The resulting Q_{ss} values are given in Tables IV and V. It can be noted that the values of Q_{ss} are relatively constant over the entire thickness range.

The orientation effect is again quite evident from the data in Tables IV and V, with the Q_{ss} ratio between (111) and (100) samples being approximately 2-3:1 for any given condition.

It should be emphasized that unless the correction for work function difference Φ_{MS} is made, an erroneous dependence of Q_{ss} on thickness would be obtained. That this correction is necessary is evident from Fig. 6 where the voltage shift ΔV is plotted as a function of oxide thickness for four different oxidation conditions. It is evident that conditions (A), (B) and (D) have widely different slopes reflecting the different Q_{ss} values, but that they have identical intercepts, *i.e.*, Φ_{MS} values. Conditions (B) and (C) have identical slopes, *i.e.*, Q_{ss} values, but different intercepts, reflecting the difference in Φ_{MS} for p- and n-type silicon (11). These results are in close agreement with data presented by Ko and Locher (26) who demonstrated the constancy of Q_{ss} with oxide thickness and the effect of metal work function in a similar manner.

Electric field[1].—It has been shown that ionic contamination within the SiO_2 layer can be rearranged in minutes at 150°C (5). On the other hand, the characteristics of MOS structures prepared as described above have been demonstrated to be stable at 150°C, under applied fields of ± 75 v/μ for 3600 hr (3), and also under various other test conditions (27). Recently, an apparent increase in Q_{ss} has been reported (28, 29) due to application of negative fields (metal negative) at higher temperatures. This effect was investigated in further detail.

[1] The phenomenon discussed in this section has locally been referred to as Drift VI.

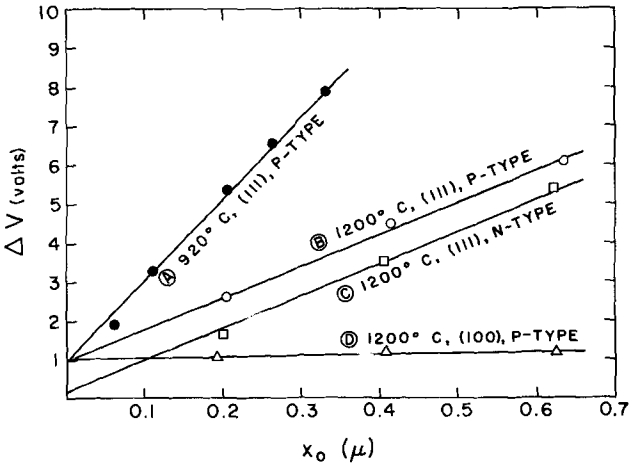

Fig. 6. Displacement ΔV between experimental and theoretical capacitance-voltage characteristics as a function of oxide thickness x_o. In each case the slope is proportional to Q_{ss} while the intercept equals $-\Phi_{MS}$.

Negative fields of 50 to 275 v/μ were applied across the oxide at temperatures of 300°-450°C for times of 2 min or more. Typical results are shown in Fig. 7, where the plots in Fig. 7(a) are for a 0.2μ dry oxide on p-type silicon, while Fig. 7(b) is for the same type of oxide on n-type silicon. In each case, the theoretical curve is labeled (A), the original experimental curve is labeled (B) while the curve resulting after application of the negative field is labeled (C). It can be noted that for each conductivity type the resulting curve displays a sharp break near the intrinsic point. Other experiments using current-voltage measurements on gate-controlled p-n junction diodes (4) have definitely related this phenomenon to an increase in fast surface state density N_{st}. The approximate N_{st} values can be estimated as indicated in Fig. 7 to be about 5×10^{11} cm^{-2}, while the resulting increase in Q_{ss} values are about $5\text{-}7 \times 10^{11}$ cm^{-2}. If no fast states were observed after application of the negative field, the resulting curves (due only to a change in Q_{ss}) would be represented by the dotted lines in Fig. 7, labeled (D).

Several interesting observations were made concerning the effect of negative fields on the C-V characteristics of MOS structures. These effects were similar for p- or n-type silicon with (111) or (100) orientations, and for wet or dry oxides prepared at high or low temperatures. First, an increase in Q_{ss} was generally accompanied by an increase in N_{st} of about equal magnitude. Second, the total change of C-V characteristics would saturate in 1 to 3 min at 400°C for a given applied field. At 300°C, the time required to reach the same saturated or steady-state value was about 8 hr. These times are about four orders of magnitude longer than those required for the rearrangement of sodium contamination. Third, the total change in C-V characteristics at a given field was proportional to the initial Q_{ss} value. Finally, the results obtained with different oxide thicknesses show the effect to be proportional to the applied field rather than the applied voltage.

Examples of some of the above observations are indicated in Fig. 8 and 9. In Fig. 8, the steady state values of $Q_{ss}/q + N_{st}$, corresponding to the total displacement of the midpoints of the C-V plots from the

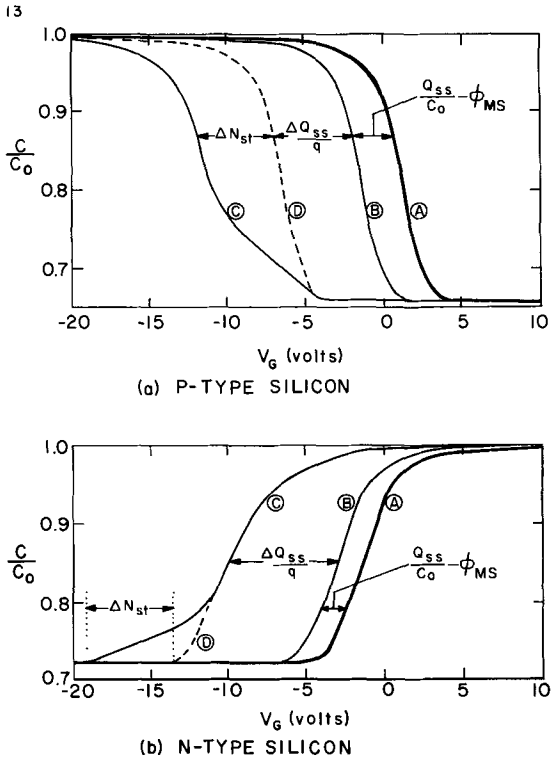

Fig. 7. Illustration of the effect of heat-treatment under negative gate bias on the capacitance-voltage characteristics [—200 v/μ for 2 min at 400°C].

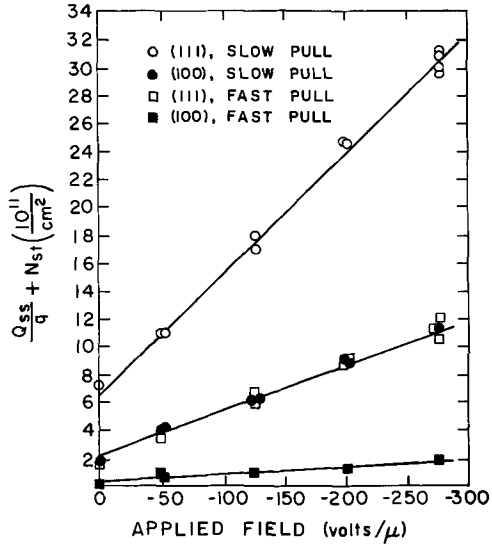

Fig. 8. Steady-state values of $Q_{ss}/q + N_{st}$ as a function of applied field for four different MOS structures with various initial Q_{ss} values [1200°C dry O_2 oxidation; $x_o = 0.20\mu$; p-type, $N_A = 1.4 \times 10^{16}$ cm^{-3}].

theoretical value [see Fig. 7 (a)] are shown for four structures as a function of applied field. The linear dependence of change in the C-V curve with applied field is readily seen, as well as the dependence on the initial Q_{ss} value. In Fig. 9, similar plots are shown for oxides of three different thicknesses on n-type silicon. Here the total change in C-V characteristics reflects only ΔQ_{ss}, but the ΔN_{st} term would just double the change. It is obvious from this plot that the change is dependent on field, not voltage, across the oxide.

An attempt was made to move the charge in the opposite direction by application of a positive field. Small decreases in Q_{ss} were indeed noted, even on structures with low initial Q_{ss} values. It was also noted that in cases where the C-V characteristics had

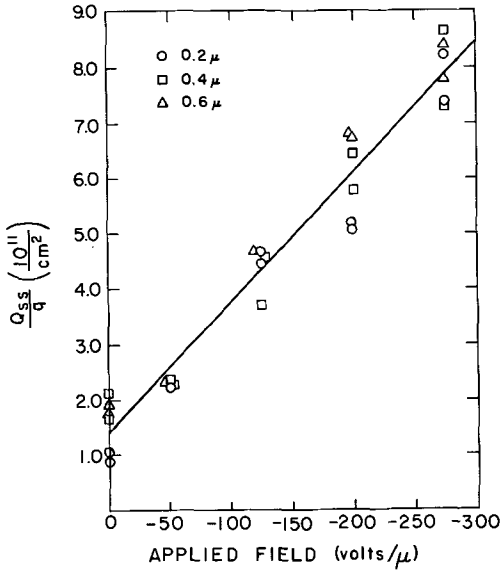

Fig. 9. Steady-state values of Q_{ss}/q as a function of applied field for MOS structures with various oxide thicknesses [1200°C dry O_2 oxidation; (111) orientation; n-type, $N_D = 1.4 \times 10^{16}$ cm^{-3}].

been shifted by a negative field, they could be partially recovered toward the original value by the application of a positive voltage or by shorting the field plate to the silicon at 400°C.

Spatial distribution of Q_{ss}.—The spatial distribution of Q_{ss} within the oxide can be inferred from etching experiments in which the conductance of an inverted surface is measured as a function of the amount of oxide removed.[2] However, one must use great care in the interpretation of these experiments. In particular, it should be noted that the inversion layer conductance will decrease as the oxide is removed even if Q_{ss} is located entirely at the oxide-silicon interface. The reason for this is that, because of the finite width of the surface depletion region in the silicon, Q_{ss} will induce part of its image charge on the outer surface of the oxide and only part in the silicon. As the oxide becomes thinner compared to the depletion region width, more and more of the image charge will be induced on the outer surface and correspondingly less in the silicon. This is clearly true in the case of a metallized surface where the charge at the outer surface is in the form of electrons in the metal. In the case of a bare oxide, it is reasonable to assume that the charge at the outer surface is in the form of ions adsorbed onto the surface from the etch solution.

If we assume Q_{ss} to be uniformly distributed over some finite width d near the oxide-silicon interface, then the charge distribution in an oxidized, high resistivity p-type silicon surface will be as shown in Fig. 10 where Q_G is the charge per unit area induced on the outer surface of the oxide, Q_n is the charge per unit area in the inversion layer,[3] Q_B is the charge per unit area in the surface depletion region and $x_{d\,max}$ is the depletion region width. The condition of charge neutrality requires that

$$Q_G + Q_{ss} + Q_n + Q_B = 0$$

and the condition of zero voltage drop across the system requires that

$$\frac{Q_G x_o}{K_o} + \frac{Q_{ss} d}{2K_o} - \frac{Q_B x_{d\,max}}{2K_s} = 0$$

[2] Similar experiments have been used to determine the spatial distribution of sodium ions (5) and of radiation-induced space-charge (30).

[3] Most of the inversion layer charge will be within a distance from the Si-SiO_2 interface of the order of $(^\circ KT/q)E_s$ where $E_s = Q_s/K_s\epsilon_o$ is the surface field. For the case considered, this distance is about 30Å and is therefore negligible.

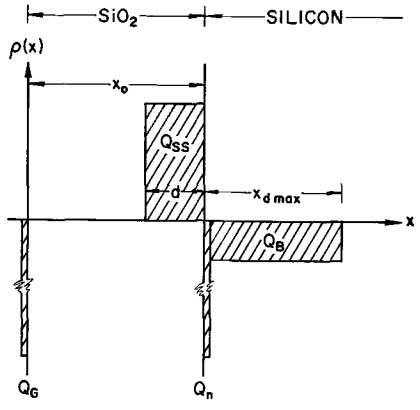

Fig. 10. Charge distribution due to Q_{ss} in a thermally oxidized, p-type silicon structure.

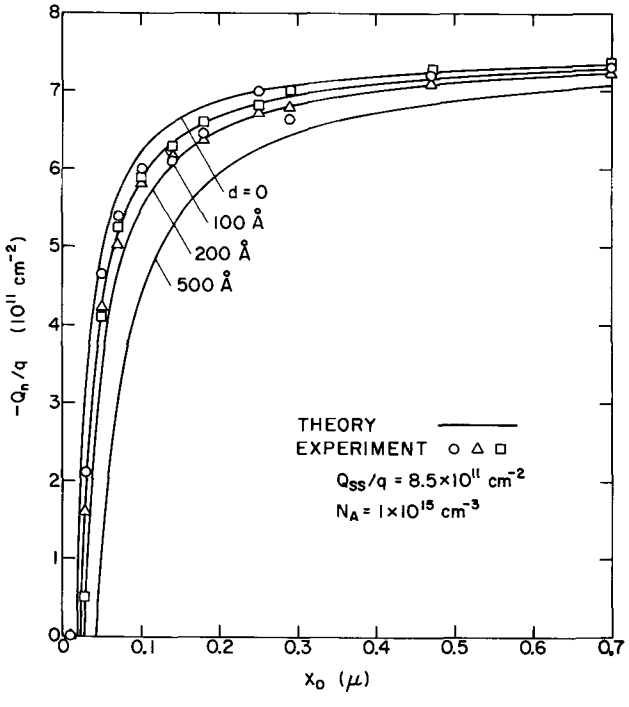

Fig. 11. Inversion layer charge density as a function of remaining oxide thickness. Theory is based on various assumed spatial distributions of Q_{ss}; experimental points are based on channel conductance measurements.

If Q_G is eliminated between these two equations, we obtain for the charge in the inversion layer

$$-Q_n = Q_{ss}\left(1 - \frac{d}{2x_o}\right) + Q_B\left(1 + \frac{K_o x_{d\,max}}{2K_s x_o}\right)$$

Since Q_B and $x_{d\,max}$ can be calculated for any given doping level (3), one can plot a family of theoretical curves of $-Q_n$ *vs.* x_o with d as a parameter. This is done in Fig. 11 for the case of $Q_{ss}/q = 8.5 \times 10^{11}$ cm^{-2} and $N_A = 10^{15}$ cm^{-3}.

Experimentally, Q_n can be determined directly by measuring the small-signal source-drain conductance of an MOS transistor which is given by $g = -\mu_{eff} Q_n Z/L$, where Z/L is a known geometrical factor and μ_{eff} is the effective inversion layer mobility which has been previously determined (31). Experiments have been performed in which Q_n was measured as the oxide was etched away in steps. Some typical results are plotted in Fig. 11 along with the corresponding theoretical curves. By comparing experiment and theory it can be concluded that d lies between 0 and 200Å, although the method is not sufficiently sensitive to allow a more precise determination.

Similar results were obtained on other samples with Q_{ss}/q values ranging between 2 x 10^{11} and 1 x 10^{12} cm^{-2}. These findings are not in agreement with the results of a similar experiment by Lindmayer (25). The discrepancy appears to be due to his neglecting the factors discussed above.

Discussion

On the basis of the above experimental results, it is possible to enumerate certain characteristics of the surface-state charge.

Its density Q_{ss} is independent of the band bending or surface potential over at least the middle 0.7 ev of the energy gap. This can be concluded from the fact that experimentally observed capacitance-voltage characteristics are displaced in a parallel manner from the ideal theoretical characteristics (3).

Its density is stable under moderate temperature-bias tests (3).

Its density is practically independent of the impurity type and concentration in the silicon in the range 10^{14} to 10^{17} cm^{-3} (3), although n-type Si shows a slightly lower density than p-type (see Fig. 3 and 4).

Its density is independent of the oxide thickness for a given preparation condition (see Tables IV and V and Fig. 6).

Most of the charge is located within not more than 200Å of the oxide-silicon interface as demonstrated by etching experiments (see Fig. 11).

Its density can be significantly, reproducibly, and reversibly varied by changing the ambient (*i.e.*, dry oxygen or water vapor) and temperature of oxidation. The surface-state charge density is dependent only on the final oxidation step (see Fig. 5).

Heat treatment in inert ambients reduces Q_{ss} to approximately its lowest value, that found after oxidation in dry oxygen at 1200°C (see Fig. 5).

The orientation of the silicon influences Q_{ss} significantly (13-15). The variation follows approximately the variation of the surface reaction rate constant for oxidation (see Table II).

Under negative fields applied at temperatures well in excess of that required to move sodium contamination in the oxide, Q_{ss} can be increased (28-29). This increase saturates at a value proportional to both the initial Q_{ss} and the applied field (see Fig. 8 and 9); and it is also accompanied by an apparent increase in the density of fast surface states (see Fig. 7).

The most important conclusion that can be made on the basis of these facts is that the surface-state charge is not an extraneous contamination, such as sodium ions, but is a phenomenon intrinsically connected with the silicon dioxide-silicon interface. This is supported by the relative immobility of the surface-state charge, and more importantly, by its high degree of reproducibility.

The lack of variation of this charge with surface potential taken together with the observation that the charge is located within 200Å of the interface indicates that this charge must be related to energy levels which are outside of the middle 0.7 ev of the silicon energy gap. It is quite possible, in fact, that the energy levels are outside of the entire silicon energy gap, but are located within the forbidden gap of the silicon dioxide as illustrated in Fig. 12.

The fact that the charge is practically independent of doping type and concentration rules out the possibility that it is due to doping impurities from the silicon being incorporated into the oxide during its formation. On the contrary, the silicon orientation dependence strongly suggests that it is a silicon species in the oxide that is responsible for the surface-state charge.[4]

[4] For the purposes of this discussion, we make no attempt to distinguish between an excess of silicon and a deficit of oxygen. It should be noted that oxygen vacancies generated as a result of reaction between the metal gate electrode of an MOS structure and the silicon dioxide layer have been proposed in an entirely different context as an explanation for the low temperature instability (32).

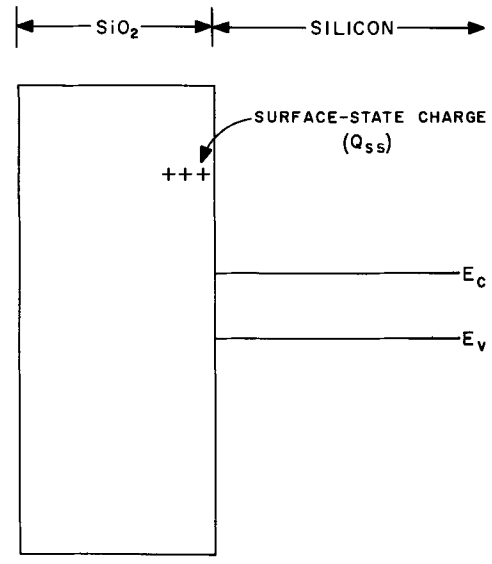

Fig. 12. Energy band structure of the Si-SiO_2 system, in flat-band condition, showing proposed energy levels associated with the surface-state charge.

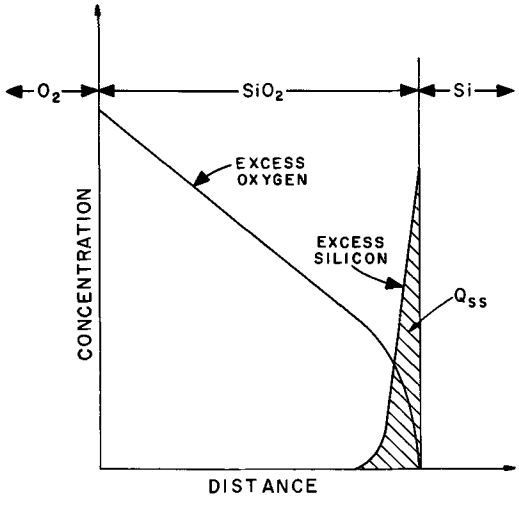

Fig. 13. Schematic illustration of the proposed distribution of excess species in an oxide film during formation.

This possibility is further supported by the fact that the strongest effect on Q_{ss} is due to variations in the oxidation conditions. Although it is well known that thermal oxidation of silicon proceeds by the inward motion of an excess of the oxidizing species, there must be an excess of silicon present near the oxide-silicon interface in order to react with the oxidant. Should this excess silicon be ionic,[5] it could indeed lead to a positive charge near the interface with many of the observed characteristics.

This possibility makes the variation of Q_{ss} with oxidation conditions plausible. It is also consistent with the observed increase in surface-state charge density on application of a negative field at high temperatures: it is known (35) that during anodic oxidation it is the silicon species that moves, under the influence of negative fields, toward the outer oxide surface. It might be then that in this case also, the negative field near the interface aids the entry of excess silicon into the oxide. This would be consistent also with the resulting increase in fast surface state density: vacancies in bulk silicon are known to act as recombination centers. Thus, should silicon be injected from the interface into the oxide, an enhanced concentration of vacancy-like irregularities would result which might lead to increases in surface recombination rates and in fast surface state densities.

It is interesting to note that a similar hypothesis has been advanced by Brody and Handy (36) in order to resolve discrepancies in measurements on tunnel sandwiches involving the Al-Al_2O_3 interface. Also, Heine and Sperry (37) have shown evidence for the existence of excess ionic aluminum incorporated into the aluminum oxide near the oxide-metal interface.

Thus, in summary, it appears that the surface-state charge (Q_{ss}) can best be explained as being due to excess silicon ions in a narrow region next to the silicon, which are introduced into the oxide, as illustrated schematically in Fig. 13, during the process of oxidation.

[5] Ionized silicon was one of several possibilities suggested in this context by Donovan (2) and by Revesz (33). Without specifying the species leading to the surface-state charge, Lindmayer (34) developed a model which treats the interface between oxide and silicon as a heterojunction. This model, although appealing, seems inconsistent with the experimental results; the heterojunction picture leads to the conclusion that the charge transfer from oxide to silicon should be a function of the impurity concentration and type in the silicon much as is the case in an ordinary p-n junction. This, however, is in contradiction to the experimental observations.

Acknowledgment

The authors wish to thank P. J. Fleming for his assistance with the measurements and G. E. Moore for his continued suggestions and encouragement throughout this investigation.

Manuscript received Aug. 19, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

A Nitric Oxide Process for the Deposition of Silica Films

Myron J. Rand

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

ABSTRACT

A new process for vapor depositing thin films of silica on a heated substrate is described. The reagents are hydrogen (≧95%), nitric oxide (1-4%), and silicon tetrachloride or tetrabromide (0.1-1%). The chloride system is useful at 950°-1200°C and the bromide at 775°-950°C, so that the latter may serve to coat Ge as well as Si. The over-all reaction is believed to be $2NO + 2H_2 + SiX_4 \rightarrow SiO_2 + N_2 + 4HX$ and is probably mostly homogeneous. For the more commonly used film thicknesses the nitric oxide process is three to five times more rapid than either the steam or carbon dioxide reactions. Rate curves are presented for various temperatures and concentrations. The apparent temperature coefficient of deposition rate decreases markedly in the upper part of the temperature range for both the Cl and Br systems. Improved film thickness uniformity may be obtained as a practical result. The films produced are transparent, vitreous, smooth, and tightly adherent. Physical tests indicate they are amorphous silica with less short-range order than in thermal oxides. Films from the chloride system regularly produce Si surface charges of 3-6 x $10^{11}/cm^2$ in MOS capacitor tests. Breakdown voltages equal those of steam oxides. Limited bias-aging experiments have shown shifts similar to those of steam oxides. The films are satisfactory masks for boron and phosphorus diffusions; Kodak Photoresist adheres very well.

In principle, deposition of silicon dioxide films from the vapor phase has several advantages in planar semiconductor device processing over the more conventional thermal oxide formation by reaction of a silicon substrate surface with steam or wet oxygen. Since no silicon is consumed, junction movement is minimized, as is pileup or depletion of dopants at the substrate-oxide interface. It is easier to produce thick films by vapor deposition, since the rate is not diffusion-limited. The process is also more practical for producing doped films for diffusion sources. Finally, materials other than silicon may be coated; an example is the deposition of silica for an etching mask with nonfluoride-containing etches.

Nevertheless, deposited oxide film processes are uncommon in device production, with the exception of low-temperature pyrolytic oxides from organosilanes used by necessity for germanium coating. Recently there has been experimental-scale interest in oxides from the hydrogen-carbon dioxide-silicon tetrahalide system (1-4). The slow acceptance of deposited oxides from this (and other) systems appears to arise from the difficulties of producing uniform thicknesses, the fact that growth rates are not significantly faster than for thermal oxides for the more useful film thicknesses, the possibility of introducing carbon into the film or substrate, the evidence for some substrate etching reaction occurring, and unfamiliarity with film quality.

This paper presents a novel system for silica film deposition from mixtures of hydrogen, nitric oxide, and silicon tetrachloride or tetrabromide. It was originally devised to improve two of the five conditions mentioned above, those of growth rate and possible carbon contamination. As it happens, the other three are affected favorably also. This report summarizes some sixty runs in apparatus ranging from a single-slice vertical-flow tube to a ten-slice machine with provision for continuous rotation of each substrate independently. Films up to 1.5μ thick have been deposited.

The $NO-H_2$ *System*

Silica vapor deposition employing oxides of nitrogen was investigated primarily because of the large free energy change available to drive the reaction. In addition, any trace codeposition of silicon nitride which may occur should be tolerable, since it is a good insulator and diffusion barrier also. Nitric oxide, rather than N_2O or NO_2, was chosen for superior thermal stability to confine the reaction to a zone very close to the heated substrate and thus avoid deposition of particulate silica both on the slice and in the cooler parts of the system. NO has an additional advantage: it is a good intermediate in chain reaction mechanisms because it is readily either oxidized or reduced. As an example, it is known that NO may transform the chain initiation or termination steps in the H_2-Cl_2 reaction from heterogeneous to homogeneous (5).

The standard free energy change for the NO process is shown in Fig. 1, with the corresponding reactions for the CO_2 process included. At all temperatures the NO process has much greater driving energy. The reaction as written assumes that the ultimate reduction product of the NO is nitrogen. Other possibilities are N_2O, hydroxylamine, ammonia, and hydrazine; in ≧95% hydrogen ambient at the 800°-1200°C used in this work only ammonia is considered a rea-

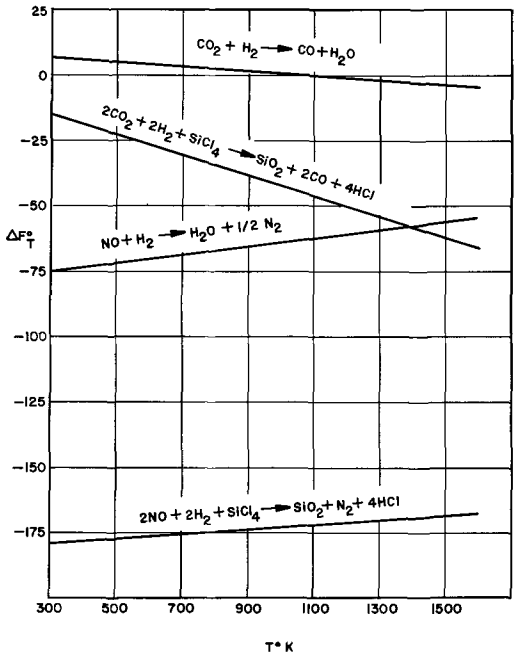

Fig. 1. Standard free energies of nitric oxide and carbon dioxide process reactions at various temperatures.

sonable alternative to nitrogen, and even ammonia is extensively dissociated at equilibrium at these temperatures.

The NO-H_2 reaction has been investigated at temperatures below 500°C (6, 7), where it must be catalyzed and where substantial amounts of ammonia may be formed. At the other extreme it has been studied extensively under conditions providing an abundance of atomic hydrogen, in flames (>1500°C) or with mercury photosensitization; here the reaction is homogeneous. The only recent study of the intermediate zone is that of Graven (8) in the range 850°-1060°C. The reaction was predominantly homogeneous; a complex rate expression was proposed, but the reaction mechanism could not be determined unequivocally.

The multislice deposition apparatus used for much of the work reported here employed an r.f.-heated molybdenum susceptor as the major hot surface. By monitoring the moisture content of the exhaust gases, the reaction between hydrogen and 2% NO in this apparatus was observed to begin at 400°-500°C and increase steadily as the temperature was raised. At 1000°C, at a flow rate which would displace the reactor volume about once a minute, the moisture content of the exhaust was 5000 ppm, or a reaction "efficiency" of 25%. By scrubbing the exhaust gas with dilute HCl and back-titrating it was established that less than 2% of the NO present was reduced to ammonia.

At present we believe that in excess hydrogen NO reacts at 800°-1200°C to produce nitrogen and water; that the reaction is mostly homogeneous, with some surface catalysis possible in the lower part of the range; and that it is a chain reaction of unknown mechanism, proceeding by unstable intermediates probably including atomic hydrogen, N_2O, nitroxyl (HNO), and perhaps HO_2. Needless to say, the addition of the silicon tetrahalide multiplies the complexity. The nitric oxide process for silica film deposition may be regarded as

$$2\left[NO + H_2 \rightarrow \frac{1}{2}N_2 + H_2O\right] \qquad [1]$$

$$2H_2O + SiX_4 \rightarrow SiO_2 + 4HX \qquad [2]$$

only if it is borne in mind that there are many possible routes to SiO_2 other than reaction [2]

Nothing in the foregoing discussion should limit the process to silicon halides; it should be adaptable to oxide deposition in any system with volatile metal halides. To date only silica deposition has been attempted.

Experimental

The deposition area of the apparatus most frequently used has already been described (4); in any event, the reactor design is not important to the success of the process. Each apparatus geometry has different gas dynamics and should be calibrated for the effect of total flow rate. Nitric oxide (Matheson Company) contained ~0.1% each of N_2, N_2O, and NO_2. When passage through Ascarite (which removes NO_2) and a −78° trap did not influence deposition rates the gas was thereafter used without purification. Reactant concentrations ranged from 0.25% NO-0.05% SiX_4 to 4.2% NO-1.0% SiX_4. Total flow rates were such as to displace the reactor volume about once a minute. The bromide system was studied over the range 790°-950°C, the chloride system 950°-1200°C. Substrates coated include Si and Ge of various resistivities, Mo, Ta, and fused silica.

Instead of bringing the substrates to temperature in hydrogen and then introducing the other reactants, it was found advantageous to adjust the gas ambient first and then heat the substrate. Using this method the substrate etching which often plagues the carbon dioxide process was not observed. There are several possible etching reactions, but at temperatures at which their rates become significant the nitric oxide process has already sealed the surface with a continuous silica film. With any method of ambient adjustment, however, the NO process definitely gives less trouble with etching than the CO_2 process.

Deposition Rates

Figures 2 and 3 are Arrhenius plots showing rates of silica film deposition for typical reactant concentrations for the chloride and bromide systems. Rates for the CO_2 process from ref. (1, 2, 4) are included also. Activation energy for the Cl system is 65 kcal (2.8 ev)/mole, and for the Br system 55 kcal (2.4 ev)/mole. Since activation energies for the NO-Cl and CO_2-Cl processes are about the same, it is possible that the rate-determining slow step for the two is the same. If so, this could only be the gas-phase hydrolysis of $SiCl_4$. It would then be a mistake to assume that this reaction, at elevated temperature, is very rapid simply because it is rapid in the liquid phase at room temperature.

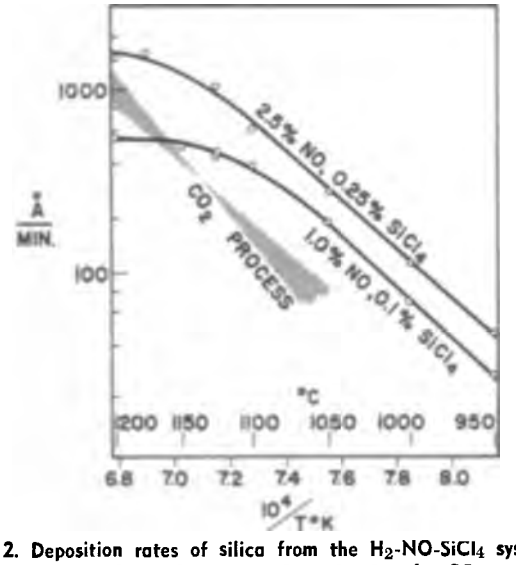

Fig. 2. Deposition rates of silica from the H_2-NO-$SiCl_4$ system. The shaded area shows the range of results for the CO_2 process from ref. (1), (2).

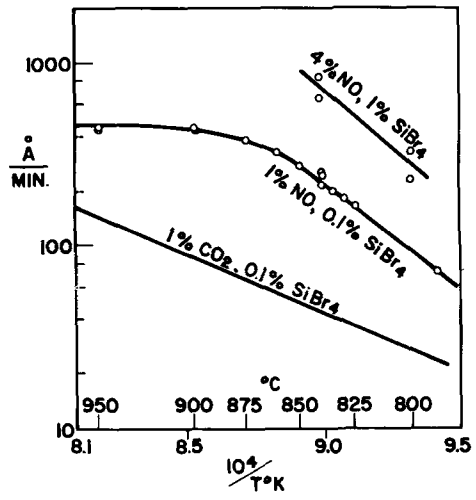

Fig. 3. Deposition rates of silica from the H_2-NO-$SiBr_4$ system

Table I compares the time required to grow a 5000Å film by steam, CO_2, and NO processes at various temperatures. The NO process has a speed advantage of 3 to 5 times over competing processes under usual operating conditions.

The shape of the Arrhenius plots requires comment. In the lower parts of the temperature ranges studied the expected linear dependence of log rate *vs.* $1/T$ is found. Results are little affected by transport rate, *i.e.*, total flow rate, and should thus be close to true kinetic rates. However, at higher temperatures the deposition rate levels off to an extent which is influenced by concentration. Here there is evidently serious depletion of silicon halide in the reaction zone, and the reaction is becoming diffusion-controlled. At still higher temperatures the apparent rate actually decreases, and particulate silica is embedded in the deposited films. The interpretation is that now the reaction zone has moved out far enough from the substrate to allow some of the silica formed to escape deposition and instead be carried away by the gas flow.

The tendency of the deposition rates to level off may be used to advantage in improving the thickness uniformity of oxides from the NO system. If nonuniformity is due to temperature inhomogeneity of the substrate, it may be minimized by operating under conditions where the apparent temperature coefficient of deposition rate is low. An oxide thickness variation of only ±5% across a 1 in. diameter slice may be obtained, for example, at 950° in the bromide system. The same equipment, used for the CO_2 process under identical conditions, produced ±17% variation in oxide thickness. The deposition of particulate silica imposes an upper temperature limit to the use of this expedient. Film uniformity is also aided by high total flow rate and by low reactant concentrations.

Film Properties

The nitric oxide process reliably produces clear, vitreous, tightly adherent silica films which are amorphous by electron diffraction. Electron microscopy shows fewer surface features than with any other process yet examined; the NO-Br system film appears particularly smooth.

Table I. Time (minutes) required for a 5000Å SiO_2 film

Temperature, °C	Steam	CO_2-$SiCl_4$	2.5% NO - 0.25% $SiCl_4$	1% CO_2-0.1% $SiBr_4$	1% NO-0.1% $SiBr_4$
825	—	—	—	143	30
900	—	—	—	58	12
950	112	>350	114	38	11
1050	44	83	17	—	—
1100	35	28	7	—	—
1200	19	5	3.2	—	—

Some other film properties are given in Table II. The etch rate and residual halogen content are of the same order as those of CO_2 process oxides. The slightly high refractive index, considered along with the absorption spectrum, opens the possibility that the films are slightly oxygen-deficient. (The high refractive index of the NO-Br system film can be accounted for by its Br content, however.) The SiO stretching vibration appears at a frequency lower than in thermal oxides, and the absorption band is considerably broadened. The NO oxide is evidently more truly amorphous, *i.e.*, has less short-range order. Instead of oxygen deficiency, an alternative explanation is that the films contain small amounts of codeposited silicon nitride. The absorption maximum of the nitride is ~850 cm^{-1}, and its refractive index near 2.0.

No hydroxyl has been detected in the Cl system films; small amounts are sometimes seen in the Br system films, but this is common in films made at 850° by any deposition process where water is a possible product.

Kodak KPR Photoresist adheres very well to NO process oxides. Patterns etched in the silica and examined at 500X have shown no evidence of resist-film lifting at the edges.

The electrical properties given in Table II have been measured on three MOS capacitors on each of 16 slices, these made in ten separate runs. The NO-Cl oxides, as made, produce a lower Si surface charge than does routinely produced steam oxide. NO-Br oxides run about twice as high as steam; these have not yet been subject to experiments on treatments to reduce the charge. Both systems produce films with acceptable insulating properties. Breakdown voltage is not polarity-dependent, and is usually sharp. A few capacitors showed "channels" (current limiting) which did not then break down further up to 2 x 10^7 v/cm.

Tests as masks against boron and phosphorus diffusion have been made with patterns etched in 0.4-0.5μ thick films made with 1% NO-0.1% $SiCl_4$ at 1100°. Conditions for the B diffusion were: B_2O_3 predeposition 18 min, 870° in N_2, later followed by 135 min drive-in at 1200° in 90% N_2-10% O_2. For phosphorus P_2O_5 in O_2 for 45 min at 1040° was used. Junctions were delineated by angle-lapping and staining. There was no instance of dopant leaking through the film, or of any mechanical film failure.

Planar transistors made with the NO process film as the first oxide were indistinguishable from those with

conventional processing in such tests as breakdown voltages, leakage currents, gain, capacitance, frequency cutoff, and saturation voltage. Extended aging tests are not yet available. A limited study of drift in films 1700-2100Å thick was made using MOS structures. After 1 hr at 100°C with a field of 10^6 v/cm (field plate positive), the surface charge density was increased by 2-4 x 10^{11}/cm^2. Freshly grown 1050° steam oxides with field plates deposited in the same evaporation equipment showed increases of 3-4 x 10^{11}/cm^2 under the same drift conditions.

Acknowledgment

The aid of J. Drobek and H. E. Nigh in the physical evaluation of the films is acknowledged with thanks.

Manuscript received Aug. 1, 1966; revised manuscript received Oct. 17, 1966. This paper was presented at the Philadelphia Meeting Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Physical Description of the Anisotropic Stress Effect in the Silicon P-N Junction Cantilever Transducer

Lewis K. Russell and Wilhelm H. Legat

Components Division, Semiconductor Operation, Raytheon Company, Mountain View, California

ABSTRACT

A silicon p-n junction device using the anisotropic stress effect has been constructed. The device exhibits a change in reverse leakage current on application of a bending force. The device consists of a narrow bar of silicon into which a sharp notch is cut electrolytically. On the opposite surface, a shallow p-n junction is produced by diffusion. Sensitivity to bending is achieved when mechanical damage is produced at the surface of the shallow junction in a controlled fashion. The corresponding change in the forward and reverse characteristics of the device after scribing is described. Methods of testing the device and changes in operating characteristics are discussed.

A theory of device operation is proposed. This theory presents a model of generation of dislocation loops from Frank-Read sources produced during the plastic deformation phase. The dislocation loops, on application of stress, enter the depletion region of the junction creating a generation current according to the Sah-Noyce-Shockley generation-recombination theory. A mathematical model of the device is developed. Operating characteristics are then compared with the mathematical model. The sensitizing operation produces noise sources within the device. The spectrum of these sources is described and the intensity is compared to device sensitivity during the scribing operation. Device noise is reduced by a decrease in the emitter perimeter. Operating characteristics of the device are discussed. These include linearity of the stress-leakage current curve, change of sensitivity with voltage, deflection with applied force, a-c impedance, junction capacity, mechanical stiffness, effective minority carrier lifetime, and fundamental vibration frequency.

In 1962, Wilhelm Rindner reported extreme changes in the electrical characteristics of p-n junctions when they were anisotropically stressed by a diamond stylus (1). He called the effect "the anisotropic stress effect" (ASE). Similar stress on the emitter-base junction of transistors will drastically modify the collector characteristics causing a large decrease in current gain (2). Indeed, any solid-state device wherein a shallow junction is anisotropically stressed will show changes in operating characteristics. Besides transistors, the devices which have been investigated include: 4-layer diodes (3) and avalanche transistors which showed changes in their negative resistance regions, field-effect transistors (3) where large impedance and transconductance changes were seen, and tunnel diodes (4) where large excess current changes were observed.

A distinct and separate stress effect was reported by Goetzberger and Finch (5) who observed a reversible change in diode breakdown voltage when the shallow junction was stressed by a stylus of material softer than silicon. Like Rindner, Goetzberger and Finch used a stylus to apply force to the junction.

Description of the Device

Figure 1 shows a sketch of a stress transducer that does not require the use of a stylus but depends entirely on the stress created at the junction by bending the device about a sharp notch running beneath the

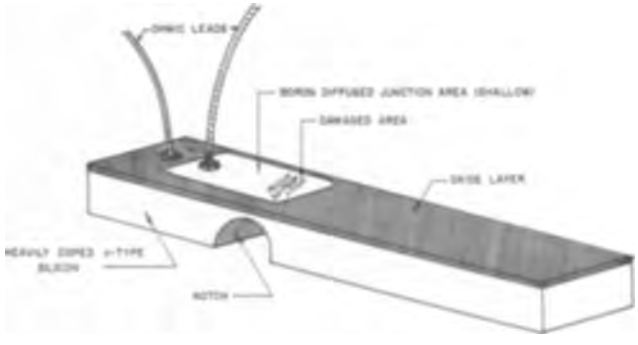

Fig. 1. Structure of the silicon p-n junction stress transducer

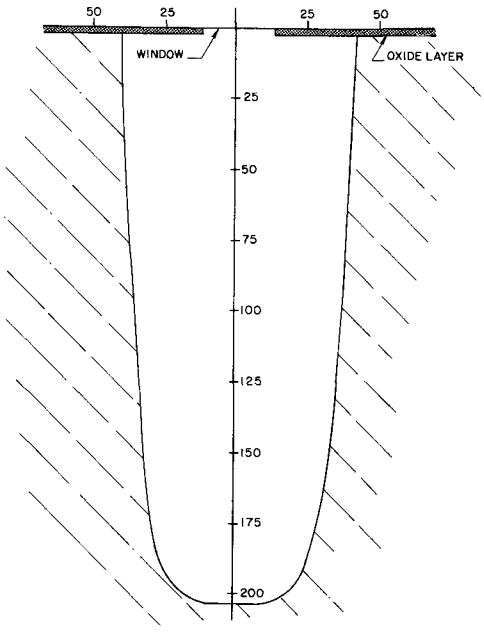

Fig. 2. Typical notch profile, in microns.

junction area. When one fastens one end of the device and bends the free end down, tension will be created at the shallow junction, ($\lesssim 0.5\mu$ deep). Bending in the opposite direction will create compression at the junction. Experimentally, it was seen that the bending occurred only in the vicinity of the notch. The high stress necessary for the anisotropic stress effect is thus produced. The range of reverse-bias operation of the device is controlled completely by the choice of starting material resistivity. If a low voltage device is desired which has voltage variations about a reference level of 1-2v, a material resistivity of about 0.01 ohm-cm is necessary as indicated in Fig. 1. Other devices were made having material resistivities as high as 50 ohm-cm. These devices were better suited for study of the effect whereas the low resistivity devices have better noise properties and are better suited for practical applications. A complex relationship exists between device sensitivity (current change per unit bending moment), applied voltage, and substrate resistivity; it has been determined empirically from measurement of many samples to be $S = 2.4V^{155}\ \rho^{-0.8}$ where S is sensitivity in μa/gcm, V is in volts, and ρ is resistivity in ohm-cm.

The junction was formed by diffusing phosphorus into n-type silicon or boron into p-type silicon to a depth of roughly $\frac{1}{2}\mu$. Suitable metallic contacts were sintered into the n- and p-regions to form ohmic contacts. Gold wires of roughly 1 mil diameter were ball-bonded onto the metal contacts leaving enough lead-length to permit easy testing.

The bridge of silicon running above the apex of the notch is typically 25μ thick. This thickness and even the notch shape may be varied to meet the demands of sensitivity and mechanical stiffness. A typical notch shape is shown in Fig. 2. Depth to width ratios of 2.5 are easily obtained by electrolytic etching. One can see in the figure the presence of a thin oxide layer with a 25μ window. Etching occurs through this window which acts as a virtual cathode in that all ionized particles must pass through this window. By varying the electrical field intensity one may vary the notch shape. The notch shape may also be varied by changing the window size and the length of time of etching.

Sensitization

Early in our work to develop the intrinsic stress transducer, we discovered that no measurable anisotropic stress effect could be produced by stress concentration alone (6). At about the same time it was discovered that physical damage occurred to the surface of p-n junctions that were stressed by diamond stylii. It thus seemed reasonable that some method of sensitization was required to produce the desired effect. Various methods of treating the surface of the junction were attempted, including damage by high-speed electrons, damage by sandblasting, damage by ultrasonic scribing, and damage by scribing with a diamond stylus under a controlled pressure. Of these four methods the last was most satisfactory and most controllable.

The damaged area shown in Fig. 1 is produced by scribing with a diamond stylus under a controlled pressure while displaying the characteristics of the diode on a Tektronix 575 curve-tracer. Scribing is continued until a given degradation of the reverse characteristic of the diode is obtained. Figure 3 shows a drawing of the reverse characteristic of a typical diode with a high resistivity before and after

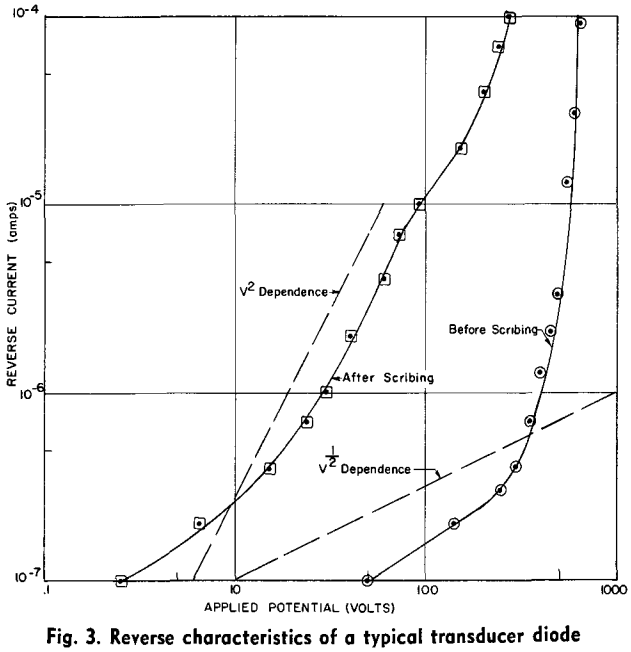

Fig. 3. Reverse characteristics of a typical transducer diode

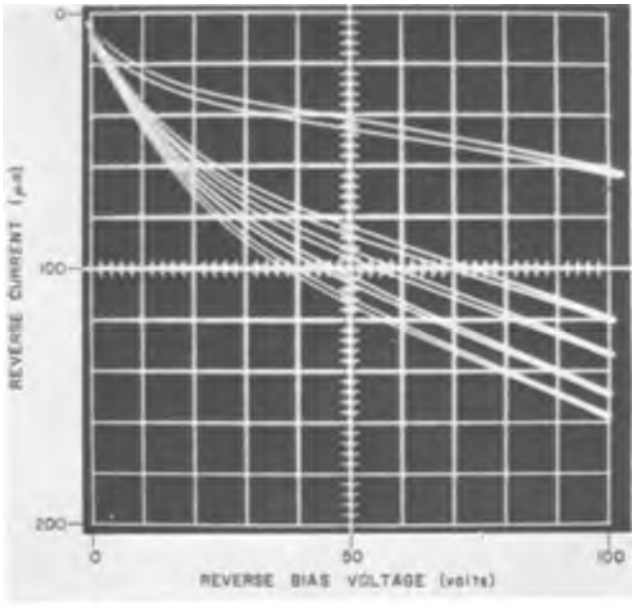

Fig. 5. Multiple exposure oscillograph of the reverse characteristics of a transducer diode under forward loads of 0, 9,000, 12,000, 14,500, and 17,000 dynes at a distance of 2 mm from the notch.

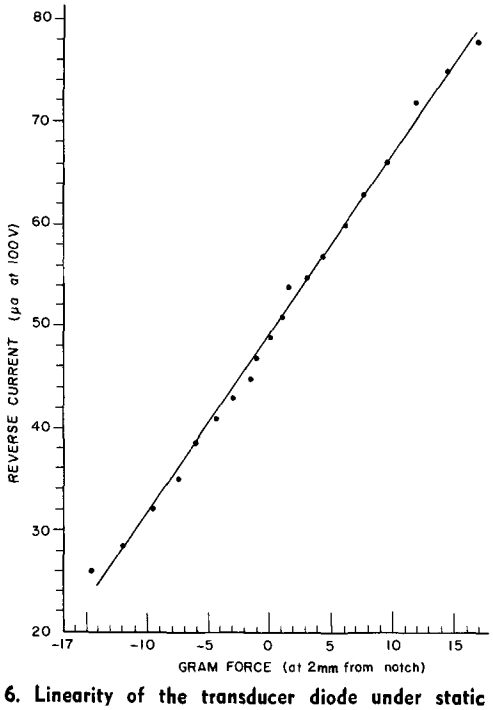

Fig. 6. Linearity of the transducer diode under static test.

scribing. Before scribing the leakage current is very small; after scribing a large leakage current is seen. We have deliberately destroyed some of the rectifying properties of the diode, principally, the high impedance in the reverse bias condition. Figure 4 shows that the forward current increased by about an order of magnitude up to an applied forward potential of about 15 ev/kT. In both forward and reverse bias conditions, the amount of change is proportional to the amount of damage sustained by the junction. With little damage, there would be little change in the operating characteristics.

Response

Figure 5 shows a multiple exposure oscillograph of a typical transducer under forward loads of from 9,000 to 17,000 dynes. The top curve is the zero load curve. Forward load refers to the fact that bending occurs in such a way as to produce compression at the junction. Under reverse load, tension would be created at the junction, and the characteristics of the device under load would fall above the zero load line. Thus, forward load produces an increase in reverse current and reverse load produces a decrease in reverse current. Figure 6 best illustrates the difference. Here, reverse current is plotted against gram force at a distance of 2 mm from the notch. One notices that a reverse current of 50 μa at 100v bias is obtained when the device is unstressed. At a forward load of 9800 dynes, reverse current has risen to 67 μa. The corresponding reverse load produces a reverse current of 32 μa.

In the earliest devices made, we could obtain an initial sensitivity of about 2 μa/dyne-cm. Under testing and high current heating, this sensitivity dropped to about 0.86 nanoamp/dyne-cm. This represents a factor of 2000 change. At this final sensitivity little further sensitivity degradation of the device was seen. More recent devices have not shown this much decrease of sensitivity, but some annealing is observed after the sensitizing process. We have also seen experimentally that temperatures on the order of 500°C will accelerate this annealing process. Complete annealing, however, is not possible even at temperatures up to 800°C, and usually 0.17% of the initial sensitivity remains at this temperature.

Figure 7 shows a typical graph of the reduction of reverse leakage current over a period of continuous testing at high dissipation levels. The device was reverse biased at 100v. The top curve shows the initial current-force characteristic. The slope of this curve from 1 to 3½g force shows a 25 μa/g sensitivity. The 40 mw dissipation is shown by the arrow. After 2 hr of testing, the sensitivity dropped to 16 μa/g. The 20 mw power dissipation point is shown by the arrow on this curve. After 6 hr of continuous testing, the sensitivity had dropped to 5 μa/g. After 10 hr, the sensitivity was 2 μa/g, and further reduction of device stress sensitivity was slight. The 5 mw point is shown on the diagram.

This sensitivity degradation or annealing of the anisotropic stress effect was at first considered to be a serious flaw in the device design. However, after the initial annealing is accomplished, the characteristics remain stable over long periods of time. This type of Joule heat annealing has also been shown to exist in germanium tunnel diodes which were degraded by indentation with a stylus and by 2 Mev

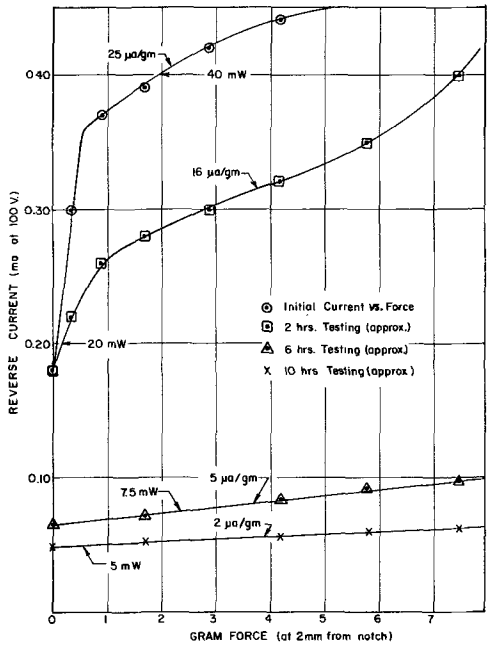

Fig. 7. Decrease of reverse current sensitivity over a period of continuous testing at high dissipation levels (100v reverse bias).

electrons (7). Stability was tested by bending the device in forward and reverse directions continuously at 120 Hz for a period of 11 months. During this time further degradation of the device characteristics was not observed. This test was performed at room temperature. Temperatures up to 100°C did not seem to cause further deterioration of the device characteristics, *i.e.*, sensitivity.

Theory of Device Operation

Several models of the anisotropic stress effect have been proposed up to this time (4, 8, 9). These models include piezoresistance, internal field emission, band bending, and generation-recombination. These models have all been examined in detail by Rindner (3, 10). The piezoresistance and internal field emission models predict a reverse current change with applied force having the wrong temperature dependence, whereas band bending has been shown (9) to produce a smaller effect in the reverse bias condition of silicon (111) diodes than is seen experimentally. As stated earlier, no stress sensitivity was detected by using the notch alone; sensitivity was seen only after the sensitization was accomplished. The fact that ASE sensitivity can be annealed out strongly suggests that the major mechanism contributing to the effect is one that is also affected by high temperature. The best model having the correct temperature dependence and strong stress sensitivity is the generation-recombination model. This model was first proposed by Rindner in 1963 (8) and is the model which best describes the results obtained with the present transducer.

In the early work using the diamond stylus visible damage was seen on the surface of the semiconductor even at very low forces. Rindner, in his discussion of stylus type anisotropic effect, also indicates a limit to complete reversibility of the effect, *i.e.*, when a certain load on the stylus was exceeded, the zero stress curve had shifted in the direction of increasing current. Thus the junction and the electrical characteristics of the junction show permanent deterioration. Surface damage of this type is very likely to produce dislocations which extend deep into the body of the semiconductor material. These dislocations have been postulated to be loops which are pinned to the damage at the surface or to internal defects. Annealing of the damaged surface at the plastic flow temperature and subsequent etching with CP4 shows the typical rosette pattern of dislocation loops attaching to pinning points at the surface (11). These rosette patterns have long been known to exist in lithium fluoride crystals which have been indented by small particles (12).

Pariiski, Landau, and Startsev investigated the jumping of dislocation loops in LiF single crystals when the pinning points were etched away (13). They found that energy was stored in the dislocation loops, and when the pinning points were removed the loops would reduce in size, collapsing toward the center, until the loop intersection with the surface encounters another pinning point or blocking point which retards further jumping. Jumping occurs with subsequent etchings until the dislocation loop completely annihilates itself. These specimens were etched at room temperature without application of any external load to the crystal. These researchers determined a lower limit of the dislocation velocity during the jump. This minimum velocity was given as about 500 μ/sec. They conclude that the velocity might be much higher than this.

Chaudhuri *et al.* (14) have investigated the velocity of dislocations in semiconductors. They propose an activation energy for dislocations in silicon of 2.17 ev which appears to be independent of stress level and temperature. Using the equation for the velocity of a dislocation held by pinning points (locks) proposed by van Bueren (15) and reasonable stress values, one would predict velocities of from 3 to 3000 cm/sec at room temperature. For example, a loop 1000Å in length and a stress level of 1.075×10^8 dynes/cm^2 (less than two orders of magnitude below the theoretical yield strength of silicon) would produce a velocity of 250 cm/sec. Detailed calculation of dislocation velocity using van Beuren's equation may be found in the appendix.

Direct experimental measurement of these velocities are made extremely difficult because the loops are, first of all, quite small, and second, they encounter obstacles in the form of other loops and flaws which again pin the moving loop and retard or stop its forward motion. Celli *et al.* (16) have proposed a model of dislocation motion which considers the effect of dragging points. With reasonable assignment of parameters the theory is able to agree with experimental values of dislocation velocity. Although dislocation velocities of the magnitude proposed here have not been observed by direct experiment, some indirect evidence does exist that very high dislocation velocities are achieved in crystals at room temperature, *e.g.*, in LiF. The experimental difficulties of growing sufficiently pure dislocation free silicon crystals have restricted all experiments to crystals having a high density of dragging points and hence quite low dislocation velocities. Since we have been unable to detect any significant ASE due to bending stress alone, we have been forced to conclude that damage, and hence dislocations, have a key role in the effect. To our knowledge we know of no other experiments wherein anisotropic stress has been applied to a shallow p-n junction in the absence of damage and where the ASE has been demonstrated. If one now assumes the existence of such dislocation loops pinned to the surface at the damaged region created by the scribe line (the results of Rindner seem to indicate this is possible), one may extend or diminish the loop size by compressing or extending the material between the pinning points as shown in Fig. 8. Kabler (17) has indicated that the loop is probably a half-hexagon where loop growth is accomplished by motion parallel to the surface of the 60° segments and motion perpendicular to the surface of the bottom segment. In Fig. 8, 9, and 10 the depletion layer is shown as roughly symmetrical about the junction. This corresponds to the low-voltage transducer design wherein a shallow diffusion is made into an already heavily doped crystal. The dimensions are not accurate since the figures are intended to illustrate the dislocation motion only.

Another mechanism by which dislocations may enter the depletion region is as follows. Deformation

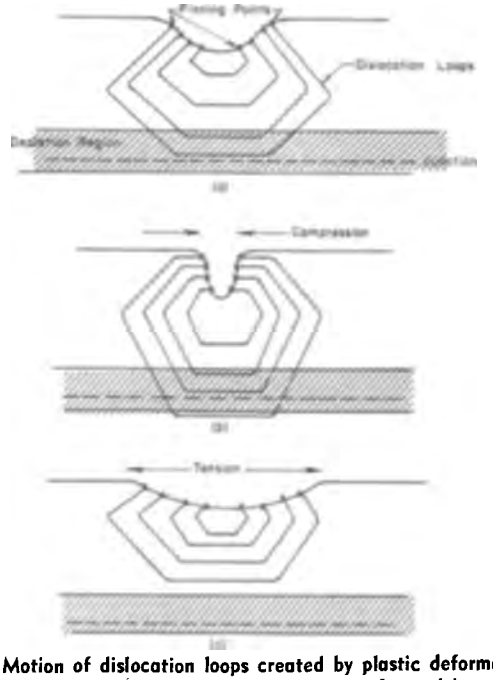

Fig. 8. Motion of dislocation loops created by plastic deformation (scribing): (a) no stress; (b) compression at surface; (c) tension at surface.

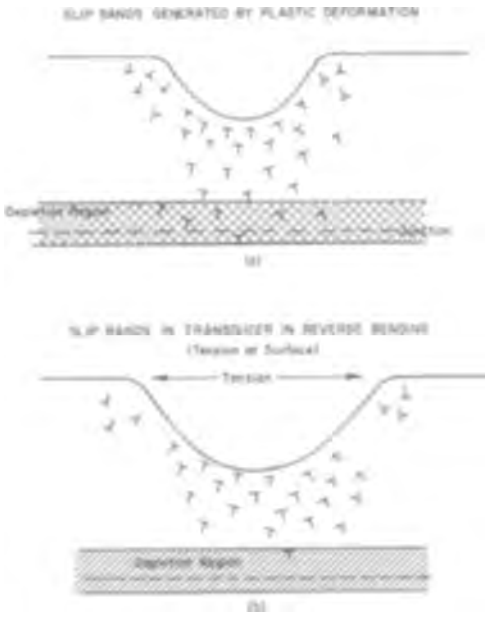

Fig. 9. Motion of slip bands created by plastic deformation: (a) no stress; (b) tension at surface.

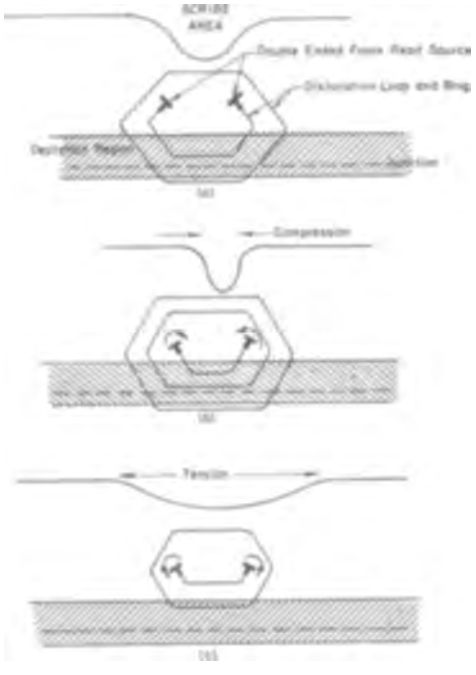

Fig. 10. Motion of dislocation loops and rings emanating from a double-ended Frank-Read source: (a) no stress; (b) compression at surface; (c) tension at surface.

bands are known to be generated by plastic deformation. These bands are formed mostly in crystals by compression or tension rather than in bending or twisting. Slip bands are formed across the deformation bands without interruption apart from bending to follow the curvature of the lattice as shown diagramatically in Fig. 9. On forward bending, compression is created at the surface, and the slip bands, under compression, migrate deeper into the body of the material. Thus more dislocations enter the depletion region of the p-n junction. Reverse bending causes tension at the junction as shown. The slip bands migrate toward the surface pulling the dislocation lines out of the depletion region. As seen in Fig. 9, the number of dislocations at any point is proportional to the radius of curvature at that point. An increase in the radius of curvature at the surface will cause the dislocations to pull in toward the scribe line.

The two theories of reversible movement of dislocations in and out of the depletion region may not be the only ones possible. In creating the anisotropic stress effect, both theories of dislocation movement may apply. The movement of dislocation lines and loops is further complicated by Frankel defects and foreign atoms lying inside the crystal bulk. Thus the theories presented here are not complete answers but merely steps toward solving a complicated phenomenon. A third theory involves a merging of the two previous theories. In Fig. 9 the parallel dislocation lines may, under stress, rotate forming dislocation loops. Pairs of dislocation lines may act as double-ended Frank-Read sources (18). After plastic deformation, dislocation loops may already have been generated by the dislocation line pairs. Many of these loops enter the depletion region causing the degraded reverse characteristic. Figure 10 shows a diagram illustrating the process. Under compression the loops radiate further outward and more loops are formed by the line pairs. When the compression is relieved, the dislocation loops collapse toward the Frank-Read sources as in the diagram. Tension causes further collapse of the loops and even the collapse of rings that have been formed. This pulls more loops and rings out of the depletion region. This effect is known as the Bauschinger effect (19). When the device is under forward pressure, compression is applied to the scribed area and an increase in reverse leakage current is observed. This corresponds to an increase in the number of dislocation loops in the depletion region. In Fig. 10 only one double-ended Frank-Read source is shown. In reality, there may be many Frank-Read sources packed close together under the scribe line, the density of sources being proportional to the amount of plastic damage sustained by the crystal during the sensitizing process. One must recognize that this theory is very incomplete and has not been proven by an extensive program of metallurgical experiments.

We have endeavored, using x-ray diffraction studies, to determine whether room temperature scribing with a diamond stylus would produce any dislocations in silicon. The silicon slices were cut from an ingot doped with antimony to a resistivity of roughly 0.01 ohm-cm. They were lapped to 15 mils thickness and chemically polished to a final thickness of 11 mils. Scribing was performed in the $(1\bar{1}0)$ direction and perpendicular to the $(1\bar{1}0)$ direction with forces of 2000, 4000, and 8000 dynes. X-ray micrographs were taken following scribing with the diffracting plane lying in the $(1\bar{0}1)$, $(1\bar{1}0)$, and the $(0\bar{1}1)$ planes of the slice. If the Burgers vector of a generated dislocation lies in the diffracting plane it will almost disappear from the micrographs, whereas if it is perpendicular to the dif-

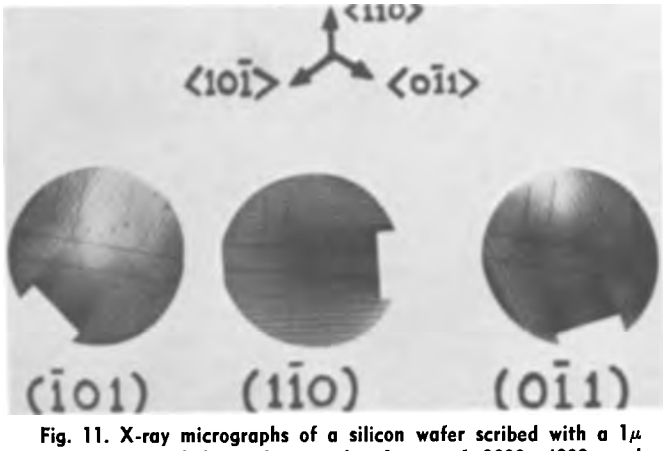

Fig. 11. X-ray micrographs of a silicon wafer scribed with a 1μ diameter diamond hemisphere under forces of 2000, 4000, and 8000 dynes along the <111> direction and perpendicular to the <111> direction. Diffractiongraphs were taken with the plane of diffraction parallel to the $(\bar{1}01)$, $(1\bar{1}0)$, and $(0\bar{1}1)$ planes of the crystal.

fraction plane it will exhibit maximum contrast. Figure 11 shows the existence of dislocations due to room temperature scribing. In the center micrograph the short 2000 dyne/cm^2 line has all but disappeared. The diffraction plane is here almost parallel to the dislocation Burgers vector. In the two side micrographs the diffraction plane lies at 30° to the Burgers vector of the long lines. Here the 2000 dyne/cm^2 line shows much reduced contrast. Further diffraction experiments have been completed and will be reported in the near future (20).

It is known that dislocations act as acceptors in silicon producing trapping levels in the forbidden region between the valence band and the conduction band. Depending on the position of the Fermi level, the acceptor sites are filled to some degree, and the dislocation line is negatively charged. This negative line charge is neutralized by a cylindrical space charge of fixed donors around the dislocation. It has been confirmed (21) that dislocations produce recombination centers in germanium and that the minority carrier lifetime is drastically decreased by the existence of these recombination centers. Indeed, at room temperature, p-type germanium has a lifetime of $\tau=0.7/N_d$. In n-type, the lifetime is $\tau=2.5/N_d$ where N_d is the dislocation density. One would expect similar relationships to exist for silicon.

Up to now the argument has been to link the reversible motion of dislocation loops with reversible changes in the leakage current of the back biased diode. Justification for this linkage can be made by using the Sah-Noyce-Shockley model of carrier generation and recombination in p-n junctions and its effect on p-n junction characteristics (22). for medium to large reverse bias ($V > kT/q$) the generation current is given by Eq. [1].

$$J_{gr} = \frac{qn_i W}{2\sqrt{\tau_{no}\tau_{po}}} \left[\cosh\left\{\left(\frac{E_t - E_i}{kT}\right) + \ln\sqrt{\frac{\tau_{po}}{\tau_{no}}}\right\}\right]^{-1} \quad [1]$$

where W is the space charge layer width, τ equals minority carrier lifetime, E_t the energy level of the traps, and E_i the energy of the intrinsic Fermi level. τ_{no} and τ_{po} are the electron and hole minority carrier lifetimes. When the trap levels lie at mid-band the first term in the hyperbolic cosine is 0 and the term in square brackets is given by expression [2].

$$\cosh\left\{\ln\sqrt{\frac{\tau_{po}}{\tau_{no}}}\right\} = 1/2\left(\exp\left[\ln\sqrt{\frac{\tau_{po}}{\tau_{no}}}\right] + \exp\left[-\ln\sqrt{\frac{\tau_{po}}{\tau_{no}}}\right]\right) = 1/2\left(\sqrt{\frac{\tau_{po}}{\tau_{no}}} + \sqrt{\frac{\tau_{no}}{\tau_{po}}}\right) \quad [2]$$

As a simplifying assumption, let us consider this to be true (Rindner has found the effective trapping level in germanium to be 0.09 ev from the intrinsic Fermi level). Using this simplifying assumption, Eq. [1] now becomes

$$J_{gr} = +\frac{qn_i W}{4}\left(\frac{1}{\tau_{po}} + \frac{1}{\tau_{no}}\right) \quad [3]$$

We see that the generation recombination current is dependent upon depletion layer width and lifetime. Investigators of ASE in Japan have been successful in demonstrating up to a 30% decrease in minority carrier lifetime under both uniaxial and anisotropic stress for both germanium and silicon (23, 24). They attributed the reduction in lifetime to strain fields and expressed total lifetime as a function of two components, the stress independent and the stress dependent lifetimes, in the following fashion:

$$\frac{1}{\tau_n} = \frac{1}{\tau_{no}} + \frac{1}{\tau_\sigma}$$

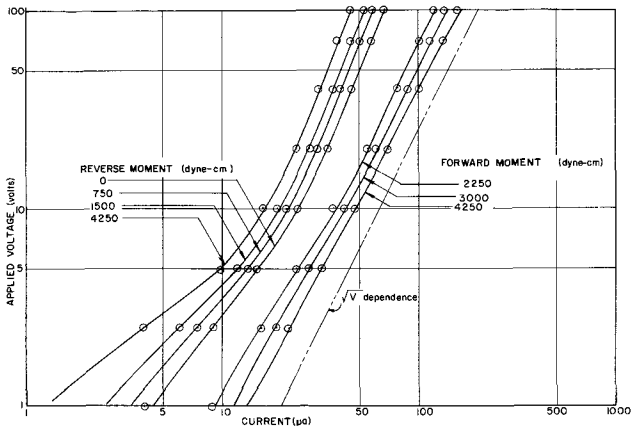

Fig. 12. Reverse characteristics of a typical transducer diode under stress.

where τ_σ has the following dependence

$$\tau_\sigma = \frac{1}{vAN}$$

where v is the thermal velocity of minority carriers, cm/sec^{-1}, A the capture cross section for minority carriers, cm^2, and N the number of recombination centers, cm^{-3}.

Assuming v and A constant throughout our measurements we may obtain J_{gr} as a function of N. Thus for an N-type substrate with a p-type diffusion the lifetime of minority carriers in the surface layer will be

$$\tau = \left[\frac{1}{\tau_{no}} + vAN\right]^{-1}$$

Since the p-n junction is formed by using a constant impurity source high-temperature diffusion for a very short time, it will closely approximate a step junction, especially at the higher voltages and for shallow junctions. For a 0.5μ junction the voltage at which the cube root dependance becomes a square root dependance is about 2v (26). Using the step-function equation for depletion layer width given by Eq. [4]

$$W = \left[\frac{2\kappa\epsilon_0 V'}{q(N_D - N_A)}\right]^{1/2} \quad [4]$$

and considering only the effect of the change of minority carrier lifetime given by the equation above we have

$$J_{gr} = \frac{qn_i}{4}\left[\frac{2\,\kappa\epsilon_0 V'}{q(N_D - N_A)}\right]^{1/2}\left(\frac{l}{\tau_{no}} + vAN\right) \quad [5]$$

where V' is the applied voltage plus the built-in voltage.

Thus, for reverse voltages greater than kT/q the generation-recombination current is proportional to the density of recombination centers in the depletion region and proportional to the square root of the applied voltage. Figure 12 shows the square root voltage dependence for our device under various forward and reverse load conditions and for reverse bias. Figure 6 shows clearly that the current-force relationship was quite linear which would suggest that recombination center density is linearly proportional to the applied bending moment. Note that an approxi-

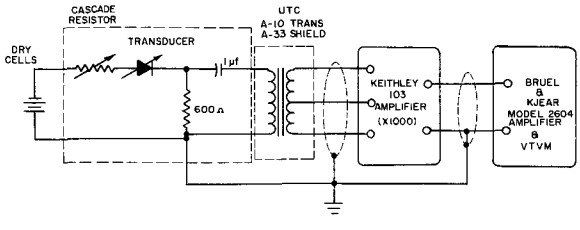

Fig. 13. Transducer noise measurement set-up

mate square-root voltage dependence is maintained for both forward and reverse bending moment for voltages above 5v. Below this voltage the slope changes somewhat for the reverse moment curves in the direction of lower resistance approaching an inverse cube-root dependence.

For the moment it is not clear whether the change in τ_σ is due to a change in A or a change in N. Certainly a strain field would change A, but on the other hand dislocation loops have been shown to exist in silicon, they have been shown to move rapidly as a function of the motion of the pinning points in LiF, and we show here that ASE is seen in the bending mode only when damage is present. With this assemblage of facts it does not seem too unreasonable to postulate that the change in $1/\tau_\sigma$ is due to N, and that the change in N is due to the reversible movement of dislocation loops into the depletion region as previously discussed.

Noise

Electrical noise generated at the junction was investigated using the apparatus shown in Fig. 13. The transducer diode was biased at its normal operating voltage (around 1.0v for the low-voltage variety and 45.0v for the high-voltage type). Using this set-up the noise current-frequency spectrum was found to be approximately (1/f) from 1 to 100 kHz both before and after the sensitizing operation although scribing increased the noise current over the entire range by roughly a factor of 10 as shown in Fig. 14. Indeed, scribing changes the noise current from about 6 na to about 60 na on typical units as may be seen from Fig. 15. The oxide layer offers some protection as can be seen by the increase of noise after oxide removal. Much of the noise eliminated by the oxide layer is below 100 Hz and is due to slow states in the thin air grown oxide present after the removal of the thermal oxide. The noise current generated by scribing is (1/f) flicker noise due to reverse leakage current. As was mentioned earlier, scribing degrades the reverse characteristic lowering the resistance, and increasing the leakage. Fonger (27) has shown that this type of noise current is directly proportional to leakage current. We have observed this type of behavior as may be seen from Fig. 16.

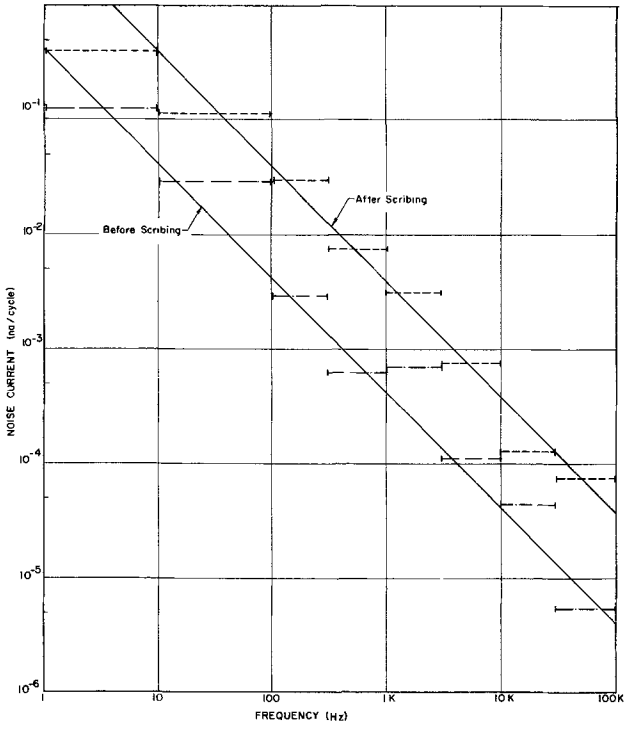

Fig. 14. Noise current spectrum of a typical transducer diode

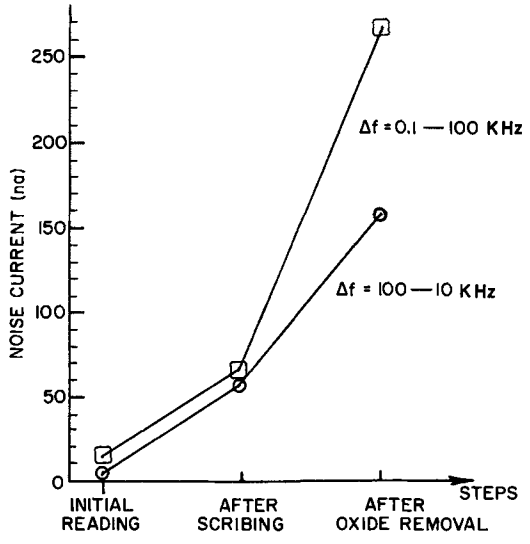

Fig. 15. Noise current increase in the transducer diode after scribing and oxide removal.

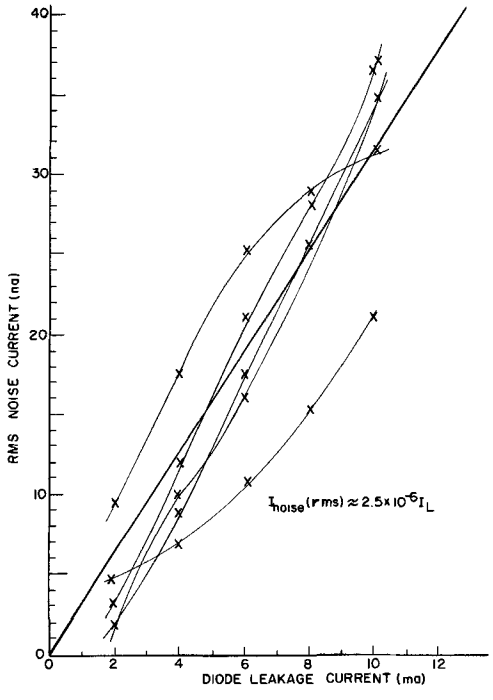

Fig. 16. Variation of diode noise current with reverse leakage current.

With the protective oxide present the transducer is insensitive to gaseous ambients. Gas cycles using dry N_2, wet N_2, O_2, and air were applied to the surface without a change in noise current. CCl_4 was also tried as an atmosphere, but it did not change the (1/f) spectrum or intensity. Contact noise has been shown to be responsible for flicker noise by Montgomery (28).

An experiment involving four ohmic contacts on the diode showed that contact noise was responsible for only 20% of the total (1/f) noise. About half of the total noise is located at the perimeter of the junction where it intersects the oxide layer. Reduction of this perimeter correspondingly reduced the (1/f) noise. This noise is also leakage noise generated by channeling under reverse bias.

Since the sensitivity of the transducer increases with scribing as well as the noise it was at first thought that the signal-to-noise-current ratio might remain

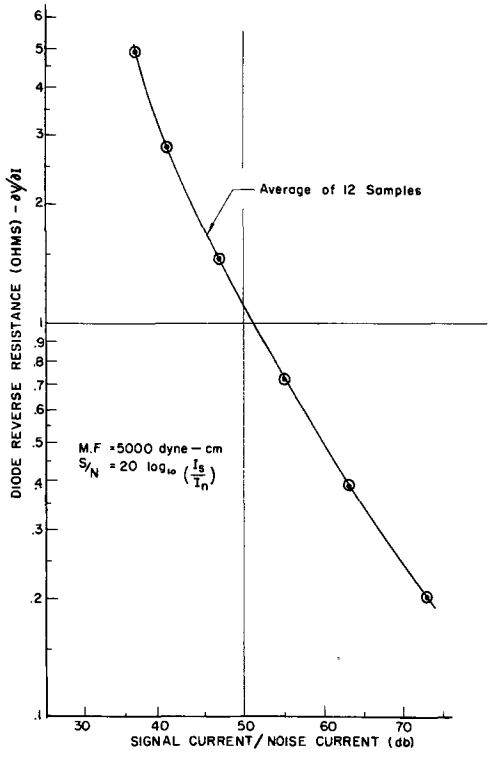

Fig. 17. Change in signal-to-noise ratio as a function of diode reverse resistance.

constant during the process. However, an experiment revealed that the signal-to-noise ratio actually slowly increased with scribing as shown in Fig. 17. In the figure the reverse resistance is the slope of the reverse-biased current-voltage trace taken at the operating voltage. The increase in S/N ratio is perhaps due to the relative decrease in importance of nonscribe-related noise sources. A device with 75db signal-to-noise ratio was obtained under a 5000 dyne-cm variation.

An analysis of stress created at the junction in a direction parallel to the surface and perpendicular to the notch indicates a stress maximum of 3.6×10^9 dynes/cm^2 for a bending moment of 5000 dyne-cm. Beyond this stress the more fragile units would fracture. The pressure and shape of the notch seriously complicates an analysis of the stresses at the junction itself although methods of analysis exist (29). A typical notch had a mechanical stiffness of 3.3×10^5 dynes/cm.

A recent analysis of dislocation velocity (14) in silicon indicates a room temperature velocity for these stress levels above 100 cm/sec. For a movement of 0.1μ a frequency of 10 MHz is theoretically possible. The maximum frequency of vibration of the free end of the transducer is however related to the geometry of the device. Typical units had a 10 kHz self-resonance, and no attempt was made to increase this value. Mechanical stiffness for the 10 kHz resonance was about 3×10^5 dynes/cm.

Effective junction lifetime using the method of Lederhandler and Giacolleto (30) was found to be in the range of 1 μsec before stress was applied. One must remember here that this already represents the lifetime of a seriously degraded junction. This lifetime corresponds to that obtained by Matsuo (31) using a stylus pressure of almost 30g. A simple equivalent circuit of the diode under reverse bias is a variable resistor with a zero-stress resistance of 500 ohms in parallel with a capacitor of about 200 pf capacity. Impedances calculated using this model are in close agreement to measurements taken on a typical transducer diode from d.c. to 1 MHz.

Manuscript received Nov. 22, 1965; revised manuscript received Oct. 14, 1966. This paper was presented at the San Francisco Meeting, May 9-15, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX

Calculation of dislocation velocities at room temperature under high stress.—Van Bueren has derived an expression for the velocity of a dislocation line pinned between two points in a crystalline lattice (15). The resulting expression is given below.

$$v = \nu_0 b \exp(-E/kT) \sinh(\tau b^2 l/kT)$$

where ν_0 is the lattice vibrational frequency, b the distance of line travel (minimum of one lattice constant), τ stress level, l length of dislocation line between pinning points, and E activation energy for the motion of a dislocation; k and T have their usual meaning.

When $b^2 l >> kT$ we have $\sinh(\tau b^2 l/kT) \approx \frac{1}{2} \exp(\tau b^2 l/kT)$ and our equation becomes

$$v = \frac{\nu_0 b}{2} \exp\left(\frac{\tau b^2 l}{kT} - \frac{E}{kT}\right)$$

Consider a dislocation loop 1000Å long between the two pinning points. If we subject the loop to a stress of 10^8 dynes/cm^2 the resulting dislocation velocity should be found as shown below:

for $b = 5.4 \times 10^{-8}$ cm; $b^2 = 2.916 \times 10^{-15}$ cm^2
$\nu_0 = k\theta_0/h = 1.376 \times 10^{13}$ (sec)$^{-1}$ (θ_0 = Debye temperature)
$k = 1.38 \times 10^{-16}$ ergs/°K $= 8.625 \times 10^{-5}$ ev/°K
$T = 300$°K; $kT = 4.14 \times 10^{-14}$ dyne-cm $= 0.0258$ ev
$E = 2.17$ ev (14)

Since $\tau b^2 l/kT = 70.42$ and $E/kT = 83.86$, the exponential term equals 8.23×10^{-5}.

Also $\nu_0 b/2 = 3.72 \times 10^5$ which yields $v = 3.06$ cm/sec.

If we increase the stress level slightly (say by only 1%) a large increase in dislocation velocity results.

We now have

$$\tau = 1.01 \times 10^8 \text{ dynes/cm}$$
$$\tau b^2 l/kT = 71.121$$

and the exponential term becomes 8.83×10^{-6}. This gives a resultant $v = 3.28$ cm/sec, *i.e.*, almost a 10% increase in velocity. Calculations of 5, 7.5, and 10% increases in stress yield velocities as shown below:

% Increase	Velocity, cm/sec
1.0	3.28
5.0	18.0
7.5	250.0
10.0	3.120.0

Since τ and l exhibit the same behavior in the equation, a slight change in the length of the dislocation loop would produce the same effect on the dislocation velocity. We also observe that the distance of travel of the loop (b) profoundly affects the dislocation velocity. The distance of travel will of course be limited by crystalline imperfections preventing its forward travel. When such an imperfection is encountered by a loop, a great deal more energy is needed to overcome this barrier than is necessary for simple unhindered forward travel.

The velocity calculated above is instantaneous velocity between imperfections as opposed to average velocity taken over large distances and times. Average velocity is the quantity reported in experiments on various materials. Chaudhuri *et al.* (14) report that the distances over which the dislocations accelerate before encountering imperfections are small compared to the distances necessarily involved in making an experimental measurement of dislocation velocity.

Chemical Etching of Germanium in the System HF-H_2O_2-H_2O

B. Schwartz[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The etching of germanium in the system HF-H_2O_2-H_2O has been studied, and comparisons are made with results obtained from the HF-HNO_3-H_2O system. Strong crystal-orientation influences and relatively high apparent activation energies are observed; surface reactivity and subsequent removal of reaction products are consequently proposed as rate limiting in the etching reaction. On the basis of equilibrium in the adsorption-dissociation steps, an equation is derived which describes the rate data obtained over the entire concentration and temperature ranges studied. Evidence is presented to show that divalent germanium is the prime oxidation state leaving the (100) and (111) surfaces. $GeOF_2$ is postulated as one of the reaction products leaving the (110) surface.

The use of semiconductor materials in the fabrication of active electronic devices has resulted in much work on the chemistry of these materials. Most of the effort has been spent on the problems of impurity content, stoichiometry, and thermodynamics in the formation of single crystals of these materials (1-3). Another important aspect is the etching of the single crystals to obtain the desired electrical and geometrical characteristics (4).

When an elemental semiconductor is etched in an aqueous system, somewhere in the process oxidation of the element must occur in order to produce a removable product. For that reason, an oxidizing agent is always present in the solution[2] when either silicon (6, 7) or germanium (8-11) is etched. In most cases nitric acid is used as the oxidizing agent and hydrofluoric acid is added as the means of forming a soluble or gaseous reaction product (6, 8, 11). However, the etching of germanium in the system HF-HNO_3-H_2O is beset with many difficulties, such as uncontrollable induction periods and passivating films (9, 11). Another etching system for germanium that has found practical application is HF-H_2O_2-H_2O (10). This paper reports the results of a study of the etch rate of single-crystal germanium in aqueous solutions of HF and H_2O_2 as a function of the composition and temperature of the etchant. The influence of crystallographic orientation and conductivity type of the germanium specimens on the etch rate is discussed. A kinetic model is developed, based on adsorption-dissociation isotherms, which describes mathematically the etch-rate data obtained. A comparison is made of equilibrium constants for both peroxide and fluoride adsorption and dissociation reactions. From the order of the reaction, relative to H_2O_2 and HF concentrations, postulations of the desorbing species are made.

Experimental Procedure

The etch rates were determined by measuring the decrement in thickness of both n- and p-type germanium dice of approximately 3 ohm-cm resistivity after subjecting them to the etchant under the chosen conditions of time and temperature. The thickness of each die was measured at its center with a double-pointed micrometer that could be read to ±0.0001 in., and the reading was estimated to the next decimal place. Three dice were etched simultaneously in each

[1] The data used in this paper were obtained while the author was employed at Hughes Aircraft Company.

[2] Although it has been observed that water will dissolve germanium, Harvey and Gatos (5) determined that it was necessary to have dissolved oxygen in the water or the etching would not proceed.

experiment; all three were of the same conductivity type, but the major faces of each displayed only one of the three low-index planes. All of the dice were approximately 0.025 in. thick, but the surface areas were 1.25×10^{-2}, 1×10^{-2}, and 1.6×10^{-2} in.^{2} for the (111)-, (110)-, and (100)-oriented samples, respectively. All dice were pre-etched in a solution of HF-HNO_3-H_2O-$HC_2H_3O_2$ to produce a specular surface free of work damage.

The etching solutions were prepared by weighing out the required amounts of the reagents in polyethylene bottles. Although it has been found that solutions so made and stored are stable (8), no solutions were allowed to stand overnight, and all solutions were used within ½ hr to 4 hr after preparation. In order to ensure an adequate supply of reagents of constant concentration, several 1-lb bottles of the specific reagent (HF or H_2O_2) were thoroughly mixed in a large container. The concentrations of these master batches were determined, and the original bottles were then refilled from these master batches.

Since H_2O_2 is catalytically decomposed by many metals and metallic ions, it was considered necessary to take precautions to exclude these from contact with the etching solutions. Thus neither platinum nor stainless-steel equipment could be used, and all experiments were conducted in polyethylene ware. The etchant was allowed to equilibrate thermally in a constant temperature bath before any samples were introduced. The quoted temperature was the initial temperature of the solution and, unless otherwise stated, was 25°C. Because of the poor heat-transfer characteristics of polyethylene beakers, the experiments were run under essentially adiabatic conditions.

All of the samples were contained in a small, perforated basket, which was agitated violently while immersed in the etching solution. Quenching was achieved by rapidly transferring the basket to a large beaker containing 250 ml of water. Approximately 20 ml of etchant was used for each measurement and was discarded immediately afterward; fresh solution was used for each determination. The conditions of etching were chosen such that the concentrations of reagents in the etching solution were depleted to a negligible extent.

Experimental Results

Figure 1, a plot of thickness change as a function of time, using differently oriented specimens, shows that there are no apparent induction periods in this system; thus, explicit etch-rate numbers can be quoted. In general, the rate numbers obtained in this work were comparable, to within ±5%, to the numbers obtained by Bloem and van Vessem (10).

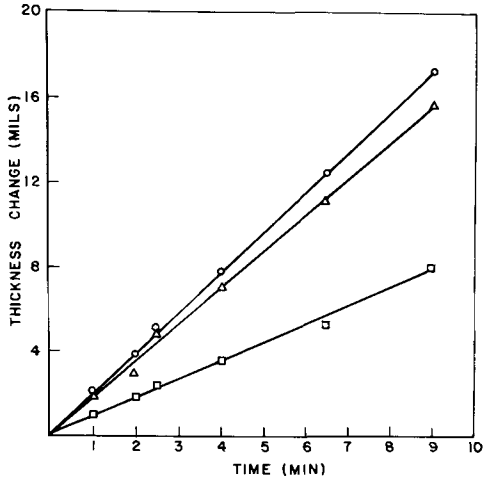

Fig. 1. Thickness change as a function of time, using a solution of 50% HF, 50% H_2O_2. The samples were n-type and were □ (100), ○ (110), and △ (111)-oriented, respectively. The solutions were made using 49.05% HF and 29.0% H_2O_2.

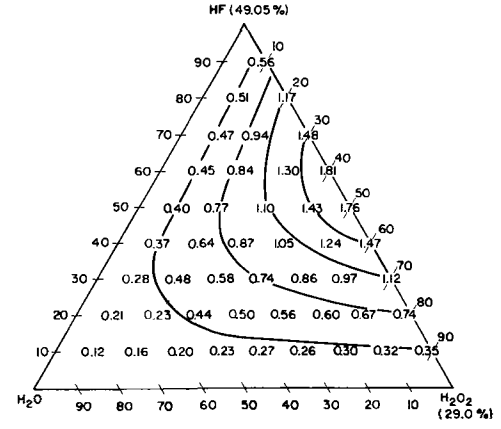

Fig. 2. Etch rate, in mils/min, as a function of etch composition. Samples were n-type, (111)-oriented, and the initial temperature was 25°C.

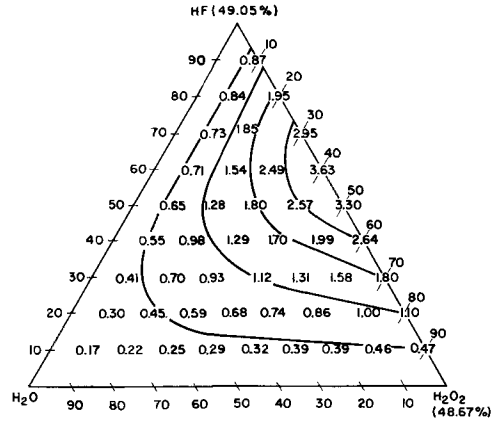

Fig. 3. Etch rate, in mils/min, as a function of etch composition. Samples were n-type, (111)-oriented, and the initial temperature was 25°C.

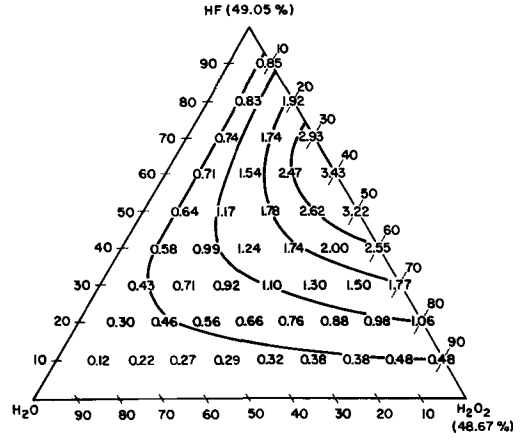

Fig. 4. Etch rate, in mils/min, as a function of etch composition. Samples were p-type, (111)-oriented, and the initial temperature was 25°C.

Figures 2, 3, and 4 are triaxial plots of etch rates at 25°C as a function of etchant composition, using (111)-oriented specimens. For ease in displaying the data,[3] the axes were left in weight-per cent units and normalized to 100% of the concentrated solutions used. The H_2O axis represents added water, not total water in the system. Also it should be noted that both standard-concentrated H_2O_2 (29.0% in Fig. 2) and

[3] Conversion of the scales to mol fraction units compresses the region of representation considerably but yields basically the same isoetch-rate contours.

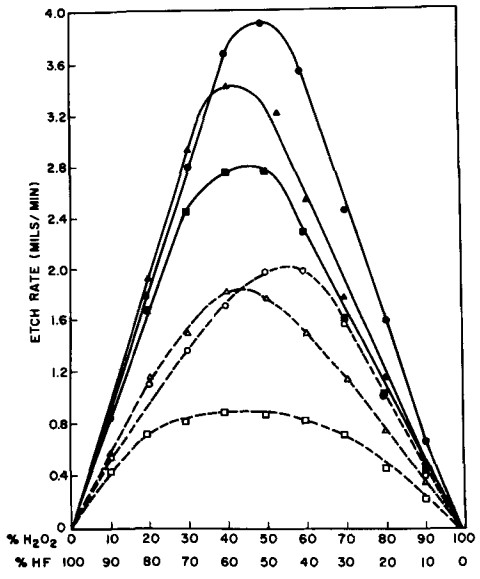

Fig. 5. Etch rates *vs.* normalized etch composition, using only the zero-added-water data. The solid curves were obtained using 49.05% HF, 48.67% H_2O_2 solutions, and the dashed curves were obtained with 49.05% HF, 29.0% H_2O_2 solutions. Orientations were ○ (110), □ (100), △ (111), and all samples were p-type.

special high-concentration H_2O_2 (48.67% in Fig. 3 and 4) were used as reagents for this study. Figures 2 and 3 show that a change from 29 to 49% H_2O_2 had practically no effect on the isoetch-rate contour but changed only the magnitude of the etch rates. A comparison of the data in Fig. 3 and 4 shows that, within experimental error, n- and p-type germanium of the same crystallographic orientation etched at the same rate in comparable etching solutions.

When all of the triaxial plots are examined, it is seen that in the regions of high H_2O_2 concentrations the isoetch-rate curves are essentially parallel to constant HF lines. Conversely, in regions of high HF concentrations the isoetch-rate curves indicate that the H_2O_2 concentration is the important rate-controlling factor.

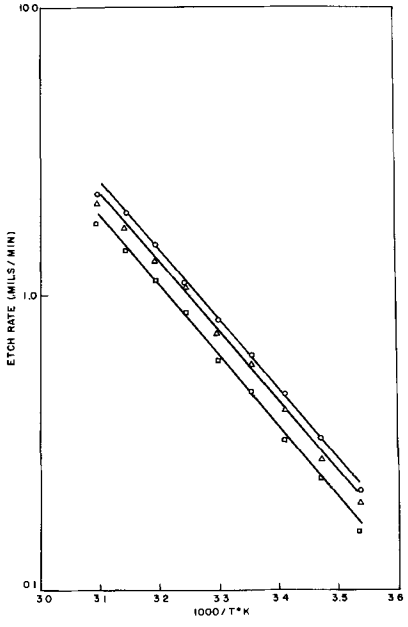

Fig. 6. Influence of temperature on the etch rate of n-type samples. The curves were obtained using 10% HF, 90% H_2O_2. The solution was made from 49.05% HF and 48.67% H_2O_2. Orientations were ○ (110), □ (100), and △ (111).

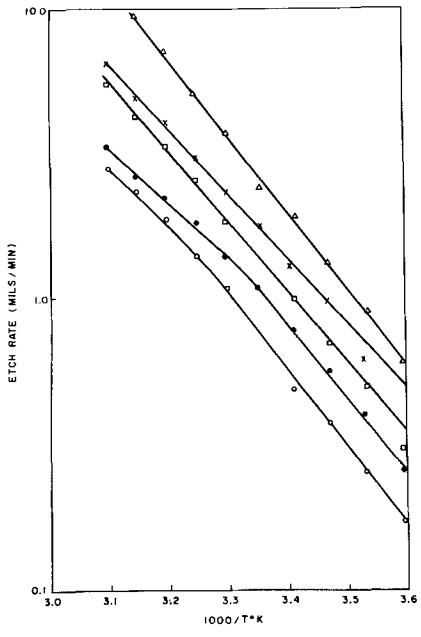

Fig. 7. Influence of temperature on the etch rate of (100)-oriented, n-type samples. Solution concentrations were: ○, 15% HF-55% H_2O_2-30% H_2O; ●, 55% HF-15% H_2O_2-30% H_2O; □, 20% HF-80% H_2O_2; X, 80%HF-20% H_2O_2; △, 35% HF-65% H_2O_2. Solutions were made using 49.05% HF and 48.67% H_2O_2.

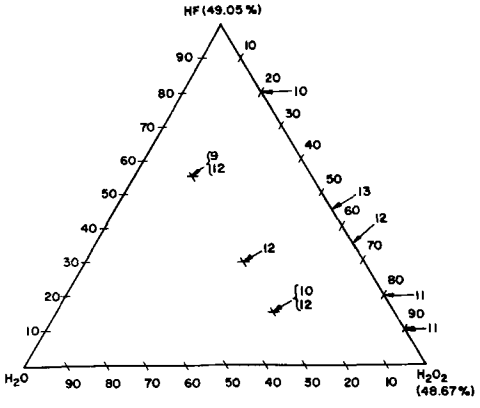

Fig. 8. Temperature dependences, in kcal/mol, as a function of solution composition.

Whereas Fig. 3 and 4 show that conductivity type had no apparent effect on the etch rate, Fig. 5 shows that orientation influences the etch rate strongly in both the 49 and the 29% H_2O_2 systems.

A study of the influence of temperature on the etch rate yielded curves shown in Fig. 6 and 7. Although the different orientations etch at different rates, the slopes of the lines drawn through the points in Fig. 6 are essentially the same. The breaking curves of Fig. 7 are typical of data obtained when there appears to be a shift in the rate-controlling step. A summary of the "apparent" activation energies as a function of etch composition is given in Fig. 8. The magnitude of the temperature dependences (9-13 kcal/mol) and the effect of orientation on the etch rates, together with the fact that etch rates in this system are much lower than in the HNO_3 system (11), suggest that over the entire composition region the etching reaction is surface controlled and not diffusion controlled.

Figure 9 is a plot of the effect of dilution with water on the etch rate of (110)-oriented dice; it is a two-dimensional representation of the three-dimensional etch-rate surface obtained with these reagents. The line drawn is the curve of 2:1 mol ratio of HF to

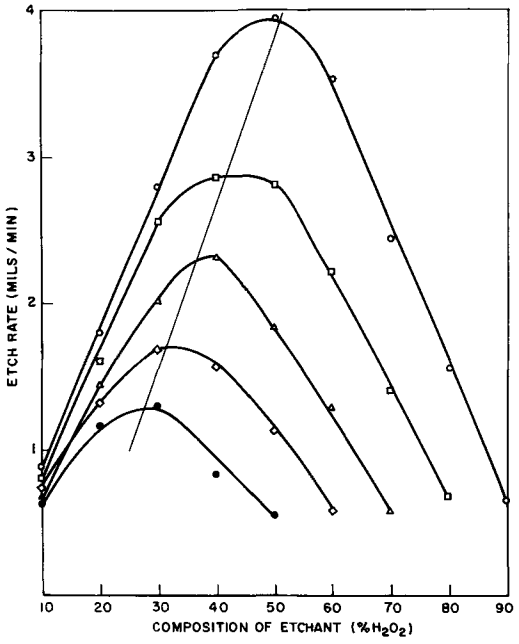

Fig. 9. Influence of added water on the etch rate of p-type, (110)-oriented germanium. Dilutions were ○, zero; □, 10%; △, 20%; ◇, 30%; and ●, 40% added water. Reagent concentrations were 49.05% HF and 48.67% H_2O_2.

H_2O_2, and it appears to agree very well with the etch-rate maxima. This might indicate the following stoichiometry

$$Ge + 2HF + H_2O_2 \rightarrow GeF_2 + 2H_2O \quad [1]$$

or

$$Ge + 4HF + 2H_2O_2 \rightarrow GeF_4 + 4H_2O \quad [2]$$

as the over-all reaction equation. However, as can be inferred from Fig. 5, the line that could be drawn through the maxima of the (111) and (100) etch rates would be displaced to mol ratios greater than 2:1. An analysis of the raw data showed that the ratios could be as high as 3:1, as indicated by Bloem and van Vessem (10). This ratio would then suggest the stoichiometry

$$Ge + 6HF + 2H_2O_2 \rightarrow H_2GeF_6 + 4H_2O \quad [3]$$

Miuller and his co-workers (12), studying the dissolution of germanium in acidic and basic solutions of hydrogen peroxide, found that the etching rate increased with increasing acid or base concentration. The dissolution rate passed through a maximum and then decreased as more additive was put in the etching solution. In fact, if enough acid or base was added to the solution, the etching action would cease. Supin (13) has also studied the dissolution of germanium in hydrogen peroxides of various *p*H and found similar effects.

In order that the influence of an acid diluent on the etch rate in this system might be seen, a comparison was made between the etching rates of n-type (110)-oriented germanium in solutions that were diluted with pure water, glacial acetic acid, or concentrated sulfuric acid. Figure 10 shows the results of these experiments: curve I resulted when 20% acetic acid was added; curve II shows the effect when 20% sulfuric acid was added; and curve III indicates the effect of 20% added water; curve IV shows the effect of adding only 10% water, and curve V is the etching rate with no added diluent. Note the similarity of curves II and V; the etch rate appears to remain the same whether the solution was diluted with H_2SO_4 or not. However, dilution with acetic acid results in a definite increase in the etch rate. In both cases of dilution in acid, though, more etching was achieved than with an equivalent water-diluted system. It appears

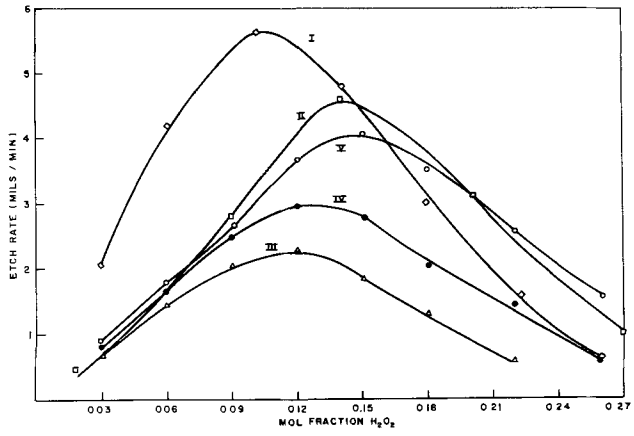

Fig. 10. Influence of acid diluent on the etch rate of (110)-oriented, n-type samples. Curve I, 20% added glacial $HC_2H_3O_2$; II, 20% added concentrated H_2SO_4; III, 20% added H_2O; IV, 10% added H_2O; V, zero added H_2O. Reagent concentrations were 49.05% HF and 48.67% H_2O_2.

that the etch-rate surface generated by the composition-rate plot for acid-diluted HF-H_2O_2 etches would probably have less of a gradient in the direction of the diluent until critical added-acid concentrations were reached. Then a very marked decrease in etch rates would occur owing to the presence of large concentrations of diluent in the system.

Discussion of the Kinetics Model

In the introduction it was noted that dissolution of an elemental semiconductor proceeds in stepwise fashion: oxidation of the element followed by complexing of the oxidized form. Laidler (14) points out that a heterogeneous reaction occurring on a solid surface involves five consecutive steps:

1. Diffusion of the reacting molecules to the surface.
2. Adsorption of the reactants on the surface.
3. Reaction on the surface.
4. Desorption of the products.
5. Diffusion of the desorbed products into the main body of the surrounding medium.

Since the present study deals with the dissolution of a solid in a liquid, these five steps must be considered. In the system Si-HF-HNO_3-H_2O it was shown (6, 7) that, in a specific etchant-composition region, diffusion was the dominant kinetic factor in the dissolution. In the system Ge-HF-HNO_3-H_2O it was observed (11) that control by diffusion was only of secondary importance, and it was postulated that step 4 was the most important part of the sequence. In the system Ge-HF-H_2O_2-H_2O the high-temperature dependence and strong crystallographic orientation effects clearly indicate that, over the entire composition region studied, the rate-controlling factors are involved in one or more of steps 2, 3, and 4, while steps 1 and 5 play only minor roles.

Camp (8) considered the system of r-sequential steps involved with rate control at a Ge-HF + H_2O_2 solution interface and derived a relationship which fitted his temperature data quite well

$$R = \frac{1}{\sum_{1}^{r} \frac{e^{E_i/kT}}{a_i C_i^{p_i}}} \quad [4]$$

where R = etch rate, E_i = activation energy of i^{th} step, C_i = concentration of reagent involved in i^{th} step, p_i = power to which C_i enters i^{th} reaction, a_i = constant associated with i^{th} reaction, k = Boltzmann constant, T = absolute temperature. For his derivation Camp used the expression

$$R_j = \theta_j a_j C_j^{p_j} \exp(-E_j/kT) \quad [5]$$

where θ_j was the fraction of the surface on which the j^{th} or rate-limiting reaction took place; he assumed rate control by only one reagent at a time.

It was found that Eq. [4] qualitatively fitted the temperature data shown in Fig. 6 and 7 and also the data displayed in Fig. 5, which were obtained by varying the reagent concentrations and holding the temperature constant. However, if the data of Fig. 2, 3, and 4 are converted to mol fraction or molality units and replotted as a function of varying only one reagent at a time (Fig. 11 and 12), then Eq. [4] no longer describes the shapes of the curves obtained.

Laidler (14) has considered the case where a diatomic molecule is first adsorbed and then dissociated on a surface

$$A_2 + 2S \rightleftharpoons 2(S-A) \qquad [6]$$

He found that at equilibrium the fraction of surface sites covered, θ, was

$$\theta = \frac{a_\theta C_{A_2}{}^{1/2}}{1 + a_\theta C_{A_2}{}^{1/2}} \qquad [7]$$

where a_θ = constant of proportionality. His analysis can be extended so that if there are two diatomic molecules simultaneously in equilibrium with activated surface sites, *i.e.*

$$X_2 + 2S \overset{K_X}{\rightleftharpoons} 2(S-X) \qquad [8]$$

$$Y_2 + 2S \overset{K_Y}{\rightleftharpoons} 2(S-Y) \qquad [9]$$

then the fractions of the surface covered by each activated species would be

$$\theta_X = \frac{K_X{}^{1/2} C_{X_2}{}^{1/2}}{1 + K_X{}^{1/2} C_{X_2}{}^{1/2} + K_Y{}^{1/2} C_{Y_2}{}^{1/2}} \qquad [10]$$

$$\theta_Y = \frac{K_Y{}^{1/2} C_{Y_2}{}^{1/2}}{1 + K_X{}^{1/2} C_{X_2}{}^{1/2} + K_Y{}^{1/2} C_{Y_2}{}^{1/2}} \qquad [11]$$

and the fraction of unoccupied sites would be

$$(1 - \theta_X - \theta_Y) = \frac{1}{1 + K_X{}^{1/2} C_{X_2}{}^{1/2} + K_Y{}^{1/2} C_{Y_2}{}^{1/2}} \qquad [12]$$

Laidler (14) also considered the generalized bimolecular surface-catalyzed gas-phase reaction

$$A + B + S_2 \rightleftharpoons ABS_2 \rightarrow \text{reaction products} \qquad [13]$$

and he arrived at the expression

$$R = k' C_A C_B C_{S_2} \qquad [14]$$

where k' = rate constant, C_A = concentration of reagent A, C_B = concentration of reagent B, C_{S_2} = concentration of bare dual sites at adsorption-desorption equilibrium.

The following is an attempt to apply the surface adsorption-dissociation concepts to the aqueous system under study here. If we assume an n-component system in steady state with the surface reaction or desorption step as rate limiting, then an equation analogous to Laidler's expression for the j^{th}, or rate-controlling, step can be written as

$$R_j = a_j e^{-E_j/kT} C_{S_m} \prod_1^n C_i{}^{p_i} \ [4] \qquad [15]$$

where C_i = concentration of each of the reagents in solution, p_i = stoichiometry with which each of the reagents is involved in the rate-limiting step, C_{S_m} = a surface-concentration function that describes the nature of the surface on which the j^{th} reaction takes place (the adsorption and dissociation steps on the surface are assumed to be in equilibrium with the reagents in solution).

For the system Ge-HF-H_2O_2-H_2O, Eq. [15] becomes

$$R = a'[H_2O_2]^{p_1}[HF]^{p_2} C_{S_m} \qquad [16]$$

where a' contains the water and the activation terms, which are assumed to be constant factors at constant temperature. Note that Eq. [15] reduces to Camp's original expression, Eq. [5], if indeed the reaction steps are sequential and the rate-controlling step involves only one reagent. Therefore Laidler's surface-concentration function should be Camp's fraction of the surface on which the rate-limiting reaction can proceed and

$$R = \theta a'[H_2O_2]^{p_1}[HF]^{p_2} \qquad [17]$$

Let us assume that X_2 and Y_2 in Eq. [8] and [9] represent the peroxide and fluoride reagents, respectively; the pair of adsorption and dissociation steps might then be

$$H_2O_2 + 2Ge \overset{K_1}{\rightleftharpoons} 2(Ge-OH) \qquad [18]$$

and

$$HF_2^- + 2Ge \overset{K_2}{\rightleftharpoons} (2Ge \cdot HF_2)^- \ [5] \qquad [19]$$

For constant [HF], and if we assume that H_2O_2, the rate-limiting reagent, acts only on the unoccupied surface sites, then Eq. [17] becomes

$$R = (1 - \theta_1 - \theta_2)\, a''[H_2O_2]^{p_1}[HF]^{p_2} \qquad [20]$$

Substitution of corrected Eq. [12] into Eq. [20] results in

$$R = \frac{a''[H_2O_2]^{p_1}[HF]^{p_2}}{1 + K_1{}^{1/2}[H_2O_2]^{1/2} + K_2{}^{1/2}[HF]^{1/2}} \ [6] \qquad [21]$$

For constant [H_2O_2] and if we assume that HF, the rate-limiting reagent, acts only on the oxidized surface sites, then Eq. [17] becomes

$$R = \theta_1 a'''[H_2O_2]^{p_1}[HF]^{p_2} \ [7] \qquad [22]$$

Substitution of corrected Eq. [10] into [22] results in

$$R = \frac{a'''K_1{}^{1/2}[HF]^{p_2}[H_2O_2]^{p_1+1/2}}{1 + K_1{}^{1/2}[H_2O_2]^{1/2} + K_2{}^{1/2}[HF]^{1/2}} \qquad [23]$$

Although Eq. [15] is the general rate expression governing the over-all system, the assumption that there are two different rate-limiting situations results in two specific rate equations. In that part of the etchant composition region where [H_2O_2] is rate limiting, it is the oxidation of bare germanium that is assumed to be the important step and Eq. [21] is believed to be the rate expression describing the situation. When [HF] is rate determining, Eq. [23] is believed to be the appropriate rate expression. One approach to the generation of a single relationship which describes the entire system is to use the mathematical technique of linear combination of the component parts. This results in

$$R = \frac{b[H_2O_2]^{p_1}[HF]^{p_2}}{1 + K_1{}^{1/2}[H_2O_2]^{1/2} + K_2{}^{1/2}[HF]^{1/2}} + \frac{b'K_1{}^{1/2}[H_2O_2]^{p_2+1/2}[HF]^{p_2}}{1 + K_1{}^{1/2}[H_2O_2]^{1/2} + K_2{}^{1/2}[HF]^{1/2}} \qquad [24]$$

or

$$R = (b + b'K_1{}^{1/2}[H_2O_2]^{1/2}) \frac{[H_2O_2]^{p_1}[HF]^{p_2}}{1 + K_1{}^{1/2}[H_2O_2]^{1/2} + K_2{}^{1/2}[HF]^{1/2}} \qquad [25]$$

[4] It should be noted that $a_j \exp(-E_j/kT)$ is equivalent to k' of Eq. [14] by the Arrhenius equation.

[5] According to Sidgwick (16), the predominating anionic species in hydrofluoric acid solutions is HF_2^-. The symbol $(_2Ge \cdot HF_2)^-$ is to be regarded as an abbreviation for a possible bridged structure of the form Ge·F-H-F·Ge⁻.

[6] Note that [HF] has been used in the denominator in order to simplify the analysis. The fluoride species of importance is not really known. A more rigorous derivation might require use of $[HF_2^-]$ or $[H_2F_2]$, but this would merely be a correction of K_2 by a factor of 20 or 2, respectively. The former number comes from the fact that the concentration of the bifluoride ion is approximately 5% of the total hydrogen fluoride in solution.

[7] The reason a'' and a''' are used and are to be distinguished from the generalized a' is that now two different rate-controlling reagents are being considered separately and the specific rate constants for these reactions do not necessarily have to be equal.

Let us now consider the results of applying some specific sets of conditions to Eq. [25].

Case I.—If [HF] is held constant at different parametric values and $[H_2O_2]$ is considered to be the independent variable, then

(*A*) when

$$1 + K_1^{1/2}[H_2O_2]^{1/2} << K_2^{1/2}[HF]^{1/2} \quad [26]$$

and if $b'\sqrt{K_1[H_2O_2]}$ is also small then

$$R \propto [H_2O_2]^{p_1} \quad [27]$$

(*B*) when

$$1 + K_2^{1/2}[HF]^{1/2} << K_1^{1/2}[H_2O_2]^{1/2} \quad [28]$$

and if b' is small then

$$R \propto [H_2O_2]^{p_1 - 1/2} \quad [29]$$

Case II.—If $[H_2O_2]$ is held constant at different parametric values and [HF] is considered to be the independent variable, then

(*A*) when

$$1 + K_2^{1/2}[HF]^{1/2} << K_1^{1/2}[H_2O_2]^{1/2} \quad [30]$$

then

$$R \propto [HF]^{p_2} \quad [31]$$

(*B*) when

$$1 + K_1^{1/2}[H_2O_2]^{1/2} << K_2^{1/2}[HF]^{1/2} \quad [32]$$

then

$$R \propto [HF]^{p_2 - 1/2} \quad [33]$$

Application of the Kinetics Model

It is readily seen that the curves in Fig. 11 can be expressed by the relationships shown in Eq. [26] through [29] if p_1 is unity. Similarly, the curves of Fig. 12 can be expressed by the relationships shown in Eq. [30] through [33] if p_2 is greater than unity but less than 2.[8] And finally, the data in Fig. 5 can be described by Eq. [25] since, when the concentration of either of the reagents is zero, the rate is zero.

Consideration of the appropriate data on all three orientations studied made possible an evaluation of p_1 and p_2 as a function of orientation; the results are shown in Table I.

[8] When the data in curves IV, V, and VI of Fig. 12 are used, p_2 appears to be about 1.3.

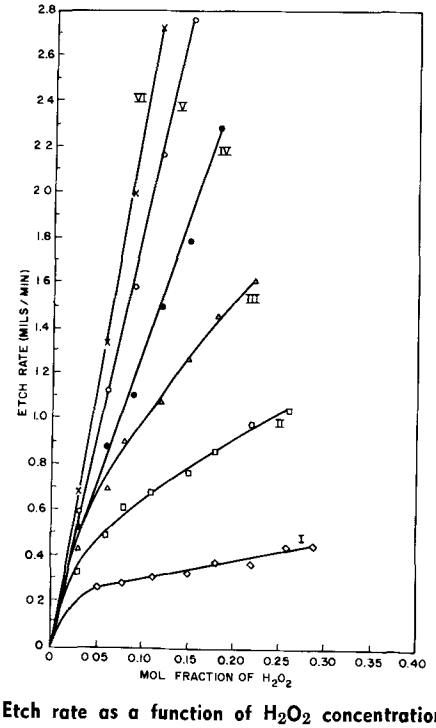

Fig. 11. Etch rate as a function of H_2O_2 concentration at constant HF concentration. The HF mol fractions were: I, 0.05; II, 0.09-0.11; III, 0.14-0.16; IV, 0.18-0.21; V, 0.23-0.26; and VI, 0.28-0.31. Samples were p-type, (100)-oriented.

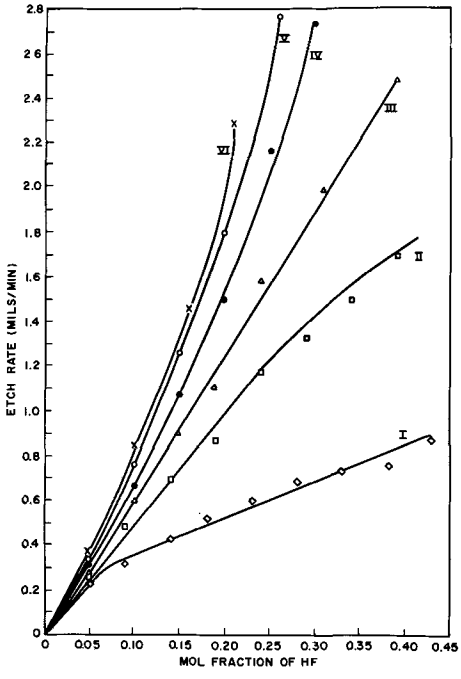

Fig. 12. Etch rate as a function of HF concentration at constant H_2O_2 concentration. The H_2O_2 mol fractions were: I, 0.03; II, 0.06; III, 0.08-0.09; IV, 0.11-0.12; V, 0.15; and VI, 0.18. Samples were p-type, (100)-oriented.

Equation [29] and the data from Table I lead to the prediction that at low [HF] and relatively high $[H_2O_2]$ the etch rate for the (100) surface should vary as the square root of the peroxide concentration. When the data from curves I and II of Fig. 11, which are an approximation to these reagent concentration conditions, are used, the predicted square-root dependence is indeed obtained. In a similar manner, Eq. [33] predicts a $(p_2 - 1/2)$ dependence of the etch rate on [HF] at low $[H_2O_2]$. From curve I of Fig. 12, the etch rate is found to be dependent on [HF] to the 0.7 power, in excellent agreement with the value predicted using the (100)-data in Table I.

Although Eq. [25] appears to express the over-all etching situation, it contains at least four parameters that can be manipulated in any attempt at a detailed quantitative evaluation. Since the raw data are limited in quantity and precision, it is simpler to take Eq. [21] and [23] and attempt order-of-magnitude calculations to determine if the assumptions made in the analysis are reasonable. With each of the two equations considered separately as the working relationship, the etch-rate data for all three orientations of the p-type series were analyzed using an IBM 7094 computer[10] to determine the best values for a, K_1, and K_2. The computer analysis consisted of determining the root-mean-squared deviation of calculated from measured etch rates for each of the experimental con-

Table I. Results of evaluation[9]

Orientation	p_1	p_2
(100)	1	>1
(111)	1	>1
(110)	>1	>1

[9] In most cases the value for p_2 was approximately 1.2 – 1.3. For the (110) orientation p_1 is identical to p_2. When both HF and H_2O_2 concentrations were simultaneously high, it was observed that p_2 could go as high as 1.9.

[10] The entire computer program and analysis were developed by M. Yamin.

Table II. Summary of results

Orientation	From use of Eq. [21] a''	From use of Eq. [21] K_1/K_2	From use of Eq. [23] a'''	From use of Eq. [23] K_1/K_2
(100)	2×10^4	3	1×10^2	10
(111)	2×10^4	3	1×10^2	10
(110)	2×10^4	3	2×10^2	5

ditions. This computation was performed for 1000 combinations of a, K_1, and K_2, covering a predetermined range for each constant. The particular combination of a, K_1, and K_2 which minimized the root-mean-square deviation was selected. The parameter ranges were determined initially by a hand calculation where the data from two experimental points were used in solving a pair of simultaneous equations. Table II summarizes the results of the computer analysis. These results show that in all cases the peroxide adsorption reaction is favored over the fluoride adsorption reaction. It is also seen that $a'' >> a'''$ by two orders of magnitude, and this is consistent with the assumption that $b >> b'$.

The agreement between experiment and theory can be seen in Fig. 13 and 14, which are computer-generated plots of calculated *vs.* measured etch rates for the (111)-oriented specimens using Eq. [21] and [23], respectively. On the basis of any normal standards for predicting rates in heterogeneous kinetics, this is a surprisingly good correlation, considering that all 45 points covering the entire composition region studied are being examined in each case. The predicted rate is less than a factor of two away from the experimentally measured value at any given point.

The data of Table I indicate that for the (100) and (111) orientations the etch rate is first order with respect to the hydrogen peroxide concentration. This means that the rate-controlling step involves formation or removal of divalent germanium on or from the surface, as described, for example, in Eq. [1]. For the (110) orientation, the superlinearity, evidenced by the higher value of p_1, indicates that some tetravalent germanium is also being formed. However, the fact that for the (110) orientation p_1 and p_2 were equal and greater than 1 but less than 2 leads to the postulation of the reaction stoichiometry

$$Ge + 2HF + 2H_2O_2 \rightarrow GeOF_2 + 3H_2O \qquad [34]$$

GeF_2 as a chemical entity has been isolated and identified (16, 17), but the existence of $GeOF_2$ has never been demonstrated; the analogous $GeOCl_2$ has been obtained (17). In all cases it is believed that once the reaction product leaves the surface of the solid and diffuses into the bulk of the solution, continued fluoridation to the GeF_4 or H_2GeF_6 form takes place.

Earlier in this paper, in discussion of Fig. 9, comments were made about reaction stoichiometry based on the maximum etch rate and solution concentration. Although at first it would appear that these results were being contradicted by the stoichiometries resulting from the kinetics analysis, in reality they are two different situations. The former relationship is the efficiency of the system as a function of concentration. The latter relationship is the rate-limiting process taking place only on the surface and therefore should be considered as truly kinetics limiting.

It has been shown that Eq. [15] can be reduced to Camp's original expression, Eq. [5]. Using an analysis similar to his, it is possible to obtain a temperature-dependence relationship of the form

$$R = \frac{1}{\sum_{1}^{r} \frac{e^{E_i/kT}}{a_i \prod_{1}^{n} C_h^{p_h}}} \qquad [35]$$

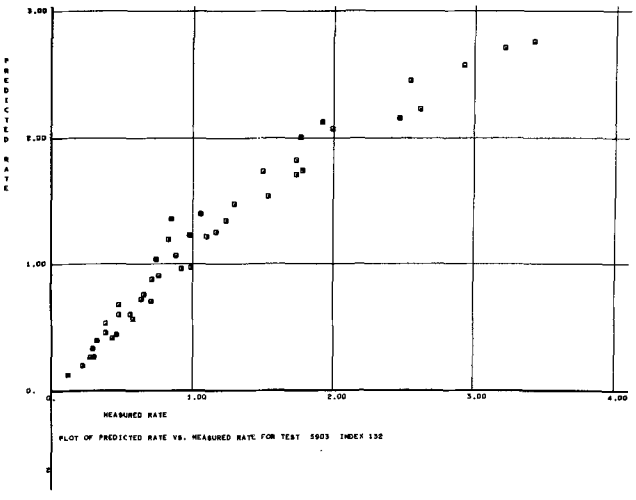

Fig. 13. Computer-generated plot of calculated etch rate *vs.* measured etch rate for (111)-oriented, p-type specimens with Eq. [21] as the generating function. Both coordinates are in units of mils/min.

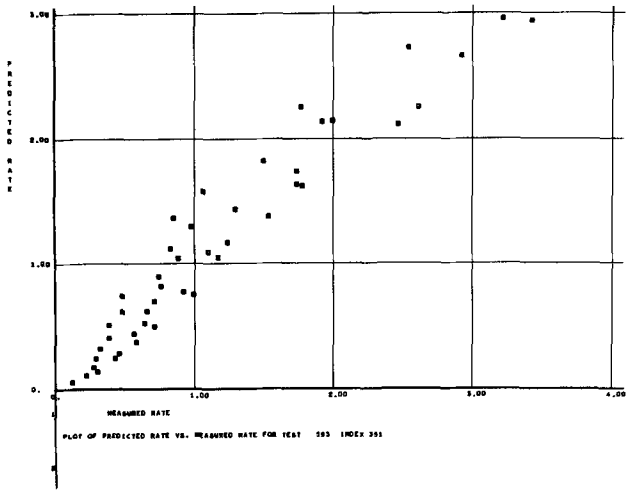

Fig. 14. Computer-generated plot of calculated etch rate *vs.* measured etch rate for (111)-oriented, p-type specimens with Eq. [23] as the generating function. Both coordinates are in units of mils/min.

Although the j^{th} reaction may be the rate-limiting step at a given temperature, it does not necessarily hold that this step is rate limiting at all temperatures. In fact, another step in the sequence could become the slow step at an elevated temperature and the rate limitation would shift from the j^{th} to the k^{th} step. In order for this to occur there would have to be a higher activation energy[11] associated with the k^{th} step than with the j^{th} step, and breaking curves of the form observed by Camp and also seen in Fig. 7 would then result.

Reaction Mechanism

The question naturally arises as to what is the actual mechanism by which the above-described surface reactions take place. Unfortunately, no answers can be provided at this time. In fact, the existence of the intermediate reaction products hypothesized above still needs to be verified experimentally. It is interesting to speculate, however, about certain aspects of the mechanism implied by the kinetics postulated. Why is the "adsorbed fluoride" not the final form of

[11] It is interesting to note the relationship between rate and activation energy in Eq. [35]. Because of the inverse-sum effect, the temperature dependence of the rate becomes low when the activation energy is high. This is a good example of how dangerous it is to attempt to get a true activation energy from a semi-logarithmic plot of rate *vs.* reciprocal of temperature.

the intermediate? A suggested answer (18) might be that ultimately at least two fluorine atoms are needed on each germanium atom and the adsorption of the charged anionic form of the fluoride reduces the possibility that a second fluorine may come to that site. If this is so, then it is possible that the acid-dilution effects seen in Fig. 10 are in reality merely influencing the concentration of HF_2^- ions, which in turn influence the concentration of "inactive" sites on the surface. However, this approach to the possible reaction mechanism still does not give any understanding of why the particular orientations act the way they do.

Conclusions

The major conclusion reached in this study is that the Ge-HF-H_2O_2-H_2O etching system is etch-rate limited by a surface-reaction or product desorption step. The application of Laidler's gas-phase adsorption-dissociation isotherm concepts to this liquid system yields results qualitatively in agreement with the experimental data, and consistent with the relationships previously obtained by Camp.

Evidence has been presented which shows that divalent germanium is the major reaction product leaving the surface. There is also strong kinetic evidence for postulating the formation of $GeOF_2$ as a reaction product leaving the (110) surface. However, it is believed that the ultimate reaction product found in solution would probably be GeF_4 or H_2GeF_6.

A comparison of the equilibrium constants for the peroxide and bifluoride adsorption-dissociation reactions shows that the peroxide reaction is favored over the bifluoride reaction.

Although different orientations appear to have different reaction stoichiometries, no firm mechanism explaining these results can be presented at this time.

Acknowledgments

The author would like to express his appreciation to Mr. J. Estlick and Miss J. Werner, of the Hughes Aircraft Company, for their assistance in obtaining the rate data; and his deep indebtedness to Mr. H. Robbins, of the Bell and Howell Company, for the time and effort which he spent on this problem. Also, stimulating discussions with many of his colleagues, D. L. Klein, M. Yamin, P. C. Milner, B. G. Cohen, J. Klerer, K. L. Lawley, and I. Amron, to name only a few, were of invaluable assistance.

After this paper was accepted for publication, one of the reviewers questioned the legitimacy of using the technique of linear combinations in going from Eq. [21] and [23] to Eq. [24]. Since we have assumed that the system is in steady state, by definition

$$R = R_1 = R_2 = R_3 = \ldots = R_r \quad (a)$$

Therefore, also by definition

$$R = \frac{1}{r}\sum_{1}^{r} R_i \quad (b)$$

which is a linear combination of the component reactions. For Eq. [24] I have chosen to use only two terms of the sum and the $1/r$ factor is included in the constants b and b^1.

Manuscript received May 31, 1966; revised manuscript received Nov. 2, 1966. This paper was presented in part at the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Reflection X-Ray Topography of GaAs Deposited on Ge

Eugene S. Meieran

Fairchild Semiconductor, Division of Fairchild Camera & Instrument Corporation, Palo Alto, California

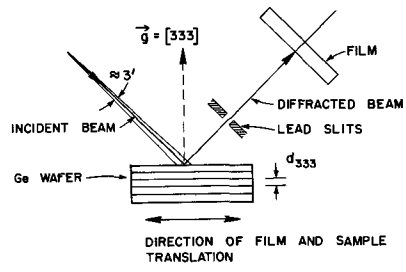
ABSTRACT

Reflection x-ray topography is well suited to the study of defects in epitaxial films deposited on single crystal substrates. In particular, since GaAs and Ge have lattice parameters that are almost, but not quite equal, certain reflecting planes can be used with suitable radiation to allow separate topographs of the GaAs epitaxial film and Ge substrate to be taken. In this way, the various types of defects appearing in the epitaxial film can be analyzed to show whether or not they were influenced by growth conditions or by substrate preparation. During our investigation, growth pyramids due to imperfections or contamination in the substrate, and dislocation networks, probably due to mismatch between film and substrate lattice parameters, were observed. The latter were observed in both the film and substrate, but occurred only for films more than about 2μ thick.

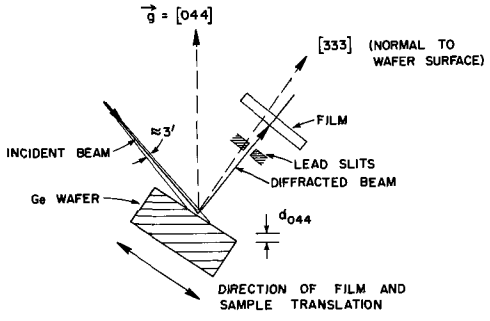
Germanium is structurally an ideal substrate material for the epitaxial deposition of GaAs, since single crystal Ge is relatively inexpensive, the technology of wafer preparation is well known, and the lattice parameter is within 0.1% of that of GaAs. Several types of epitaxial reactors for such deposition have been described in the literature (1, 2). In addition, studies by means of optical microscopy of the perfection of the GaAs layer have been conducted (3). It is the purpose of this paper to describe how x-ray topography, using reflection Berg-Barrett geometry (4), can be used to characterize, separately and nondestructively, both the substrate Ge and the epitaxial GaAs film. The comparison of topographs of the film and substrate can aid in understanding the propagation of defects into the film from the substrate, or the formation of defects in the film or substrate separately.

Experimental

Sample preparation.—The GaAs films were grown by the water transport method (5) on chemically polished (111) Ge wafers, doped with As to a carrier



a) (333) reflection, Cu $K\alpha_1$ radiation



b) (044) reflection, Cu $K\alpha_1$ radiation

Fig. 1. Crystal alignment for taking (333) and (044) topographs

concentration of about 1 x 10^{19}/cc. All films described in this paper were doped to about 1 x 10^{18} carriers/cc and ranged between 1 and 15μ thick. The surface of the wafer after deposition consists of a central region covered with single crystal GaAs deposition, a narrow surrounding region covered with polycrystalline GaAs, and pure Ge on which no deposition took place.

X-ray technique.—The difference in lattice parameters a_o between GaAs and Ge, 5.6576 *vs.* 5.6534Å, is the important parameter in the x-ray technique. According to Bragg's law

$$\lambda = 2d \sin\theta$$

so

$$\frac{\Delta\theta}{\tan\theta} = \frac{\Delta d}{d} = \frac{\Delta a}{a_o}$$

and transposing

$$\Delta\theta = \frac{\Delta a}{a_o}\tan\theta = \frac{0.0042}{5.65}\tan\theta = 7.42 \times 10^{-4}\tan\theta$$

where d is the interplanar spacing of the crystal and 2θ the angle between incident and diffracted beams. Consequently, for any particular set of reflecting planes, in order to take separate topographs of Ge and GaAs, $\Delta\theta$ should be as large as possible. For this reason, and because surface defects only rather than bulk defects are to be studied, Cu$K_{\alpha 1}$ radiation is used with reflection geometry. For convenience in comparing the topographs to normal optical micrographs, the topographs should be as undistorted as possible, while for maximum resolution, the diffracted beam should be normal to the recording film. For all these reasons, (333) symmetric and {044} asymmetric reflections are useful. All the pertinent data for these two reflections are given in Table I, and the geometries involved for (111) wafers are shown in Fig. 1. The geometries necessary for other wafer orientations, such as {100} or {110}, can be derived similarly. For intensity purposes, the (333) reflection is more useful and allows faster topographs to be taken, while from the point of distortion, the {044} is more useful.

It is seen from Table I that a beam divergence of less than 5 min of arc is needed to resolve the four peaks due to the $K_{\alpha 1}$ $K_{\alpha 2}$ doublets from both GaAs and Ge. Therefore, the divergence slits were set to 3 min of arc. Then, in order to examine large regions of the sample, both the sample and recording film (film firmly attached to the sample) were translated through the direct beam, in a manner similar to Lang scanning (6).

The actual apparatus used was a Lang camera, modified for taking reflection topographs. Since the counter window used for aligning the sample is wide, the 2θ setting of the counter arm need only be approximate. However, the actual sample setting is critical and must be set to within a few seconds of arc. The alignment of the wafer for (333) reflections does not depend on the rotation of the wafer about its normal, since the reflecting planes are parallel to the wafer surface. However, for asymmetric reflections, where the reflection planes must be rotated to the vertical position, a Laue photograph is useful. For the purposes described here, a 100μ spot focus and Cu target of a Jarrell Ash Microfocus x-ray unit was used, operating at 35 kv and 6.5 ma. The beam divergence slits were set to 0.5 mm wide, and were placed 50 cm from the focal spot of the x-ray tube. Ilford nuclear plates emulsion L-4, 50μ thick, were used and required an exposure time of about 1 hr for 1-cm scan.

Results

The optical micrograph of a thick film chosen to illustrate some of the defects observed is seen in Fig. 2a. Pyramidal defects and "fish scale" are seen, as is the polycrystalline boundary between the single crystal film and the film free region. The film-free area at the bottom of the micrograph is almost defect free. Figure 2b shows the (333) reflection topograph using only the beam diffracted from the Ge, while Fig. 2c shows the (333) reflection topograph using only the GaAs. The polycrystalline boundary region between the single crystal GaAs and the undeposited region is clearly seen in both Fig. 2b and 2c, as are the pyramidal defects which appear as white dots. As reported elsewhere for Si (7, 8), it appears that the pyramids nucleate at the epitaxial film-substrate interface and grow larger as the film grows thicker. Also seen in both topographs is evidence of slip in the Ge and GaAs along the three <110> directions in the (111) surface plane. (The <110> directions do not seem to meet at 60° due to distortion in angles, as seen in Fig. 1a.) None of this slip corresponds to the "fish scale" of Fig. 2a. The region of Ge free from film appears defect free, in agreement with Fig. 2a.

For comparison purposes, Fig. 2d is an (044) topograph of the same region of the sample. For this topograph, the divergence slits were opened slightly so that both the GaAs and Ge peaks record simultaneously. Again, the various types of defects mentioned above are visible. As schematically shown in Fig. 1b, there is very little angular distortion in this topograph.

The question of whether the strain field in the Ge is plastic, due to slip in the Ge, or elastic, due to the slip in the GaAs and the adherence of the GaAs to the Ge, can be answered by Fig. 3. Figure 3a shows the surface of a Ge wafer from which the deposited GaAs film was etched away in a small region. Again, numerous pyramidal type defects can be seen both

in the remaining film and on the Ge. Figure 3b shows an (044) topograph which records both GaAs and Ge peaks. The strain in the Ge remains even though the GaAs has been removed, and is therefore plastic strain. This is in agreement with the work of Amick (3), who by optical techniques saw strain patterns in the Ge substrate which resembled those seen in Fig. 2 and 3.

The depth of strain field in the Ge was estimated by taking a wafer, removing the GaAs film, and then etching steps about 8μ deep into the Ge itself, as shown in the optical micrograph Fig. 4a. The Ge topograph, Fig. 4b, shows that the strain lines disappear after about 15μ of Ge is removed, so that the depth of the strain in Ge corresponds roughly to the thickness of the epitaxial film, about 15μ thick in this example.

It is apparent that the strain is due to large amounts of plastic deformation or slip that occurs during either film growth or sample cooling from the deposition temperature. The slip is probably due to mismatch in lattice parameters between substrate and film. This was indirectly confirmed by taking x-ray topographs of GaAs deposited on GaAs, where the film and substrate resistivities corresponded roughly to the GaAs on Ge case. No evidence of large-scale slip was observed. Unfortunately, a comparison of theoretical values of dislocation density necessary to accommodate mismatched lattices (10) with experimental observations is not possible. This is due to the lack of resolution of the x-ray technique ($\approx 2\mu$) in comparison to the required theoretical dislocation spacing of less than 0.1μ. However, it can be stated that the dislocations forming the networks observed in Fig. 2, 3, and 4 are spaced much closer than 2μ apart, since individual dislocations cannot be resolved. These latter observations were confirmed by transmission electron microscopy. A sample with a thick GaAs film was etched to remove the film and chemically thinned from the backside to enable transmission samples to be made which showed the strained surface. The electron micrographs showed dislocation clusters in which the dislocations were spaced $\approx 0.1\mu$ apart. The dislocations ran in the <110> directions.

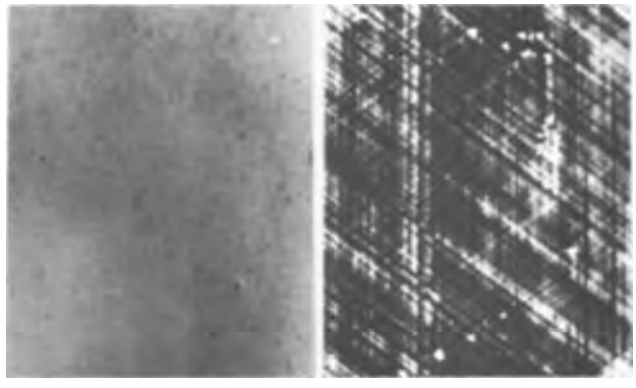

Fig. 5. GaAs deposited on (111) Ge substrate by HCl transport. (333) Ge + GaAs topographs: a (left) 1μ thick film; b (right) 15μ thick film. Magnification *ca.* 10X.

No dislocation networks were observed in films less than about 2μ thick, in agreement with theoretical considerations proposed by Van der Merwe (10). For example, Figs. 5a and 5b are topographs of the GaAs layer deposited on two identical Ge substrates. Figure 5a shows a film about 1μ thick, while Fig. 5b shows a 15μ thick film, made under identical deposition conditions except for duration of deposition. No slip is seen in Fig. 5a while slip similar to Fig. 2, 3, and 4 is seen in Fig. 5b. These two films were deposited by HCl transport rather than H_2O transport, but no structural differences in films have been observed to depend on the transporting medium.

Conclusions

1. Reflection x-ray topography can be used to image separately and nondestructively the GaAs films and the Ge substrates on which they have been deposited.
2. For films thicker than a few microns both the substrate and film contain dislocation networks, probably due to the mismatch between lattice parameters.

3. In cases where slip occurs, the depth of the strain in the Ge is of the same order of magnitude as the thickness of the epitaxial film, about 15μ.

Acknowledgments

The author wishes to thank Dr. Bruce Cairns for growing the epitaxial films; R. Warncke and R. Jiminez for assistance in the laboratory; and Doctors I. Blech and H. Sello for many valuable and interesting discussions.

Technical Notes

Chemical Polishing of Cadmium Sulfide

M. V. Sullivan and W. R. Bracht

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The usual crystal form of CdS is the wurtzite structure which is in the hexagonal crystal system. When crystal faces, which are perpendicular to the c axis, are examined one notices striking differences in some of the physical, electrical, and chemical properties. These differences may be attributed to the fact that on one face the surface Cd atoms have only three S atoms as nearest neighbors, whereas the S atoms have four Cd atoms as nearest neighbors. On the opposite face the order is reversed. Thus, one face appears to be rich in Cd, whereas the other appears to be rich in S. The Cd-rich face (00.1) is commonly referred to as the A face. The opposite face (00.$\bar{1}$) appears to be rich in S and is referred to as the B face. The difference in etching characteristics of these two faces has been noted many times (1-4). Although several etchants for CdS are described in the literature, none produces a high polish on the B face.

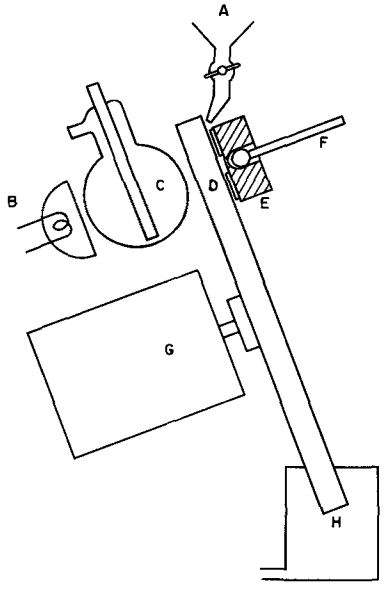

Fig. 1. Schematic arrangement of electropolishing equipment: A, dropping funnel containing etchant; B, light; C, heat absorber; D, rotating disk; E, polishing block holding 3 or more specimens; F, support rod for polishing block; G, motor drive; H, drip pan.

It is well known that stirring of the etchant often influences etching rates. Advantage has been taken of this effect in order to improve the flatness and smoothness of polished semiconductor surfaces (5, 6). A known etchant is selected and fed between the semiconductor being polished and a large flat surface moving parallel to the semiconductor. The result is a stirring action which accelerates the etching on elevated areas of the surface being polished and thus produces a relatively flat, smooth surface. The present work describes the application of this polishing technique to CdS.

Experimental

A schematic drawing of the equipment is shown in Fig. 1. It is similar to that developed for polishing other semiconductors (5, 6). Undoped CdS in the range of 1-10 ohm-cm with a Hall mobility of 300-380 cm^2/v-sec was cut perpendicular to the c axis, producing A (00.1) and B (00.$\bar{1}$) faces, and perpendicular to the a axes producing the six equivalent sides of the hexagonal unit prism. The A and B faces can be distinguished from each other by a 60-sec etch in 50% HCl.[1] This produces a mat finish on the B face and a bright finish on the A face. The slices were mounted on block E as shown in Fig. 1 and lapped with 5μ Al_2O_3. Disk D is 12 in. in diameter and covered with PAN-W Pellon cloth. The HCl etchant is fed at the rate of about 15 cc/min from supply A to the region between the driven disk (rotating about 50 rpm) and the free-running polishing block E. Light, if required, is supplied by a Sylvania Sun Gun, B, and the majority of the radiant heat is removed in the water-filled flask C.

Results and Discussion

The etching rate as a function of concentration is shown in Fig. 2. In the lower range (10-20%) the removal rate was inconveniently slow, and near the upper limit (40-50%) the intensive stirring could not control the rapid etching rate and preferential etch-

[1] All concentrations of HCl are expressed as a volume per cent of the standard 37-38% assay HCl.

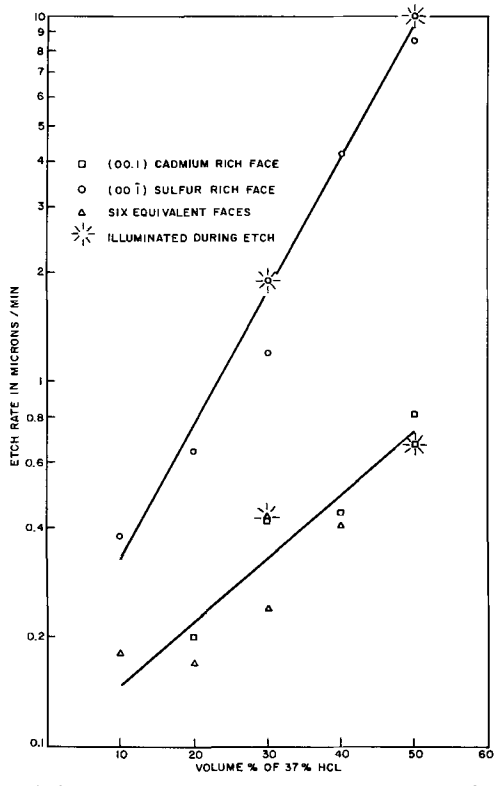

Fig. 2. Etch rate for CdS in various concentrations of concentrated (37-39%) HCl and H_2O.

ing appeared. This preferential etching occurred on the A-face (00.1) at a slightly lower HCl concentration than on the B-face (00.$\bar{1}$) or on any of the six equivalent faces of the hexagonal unit prism. A practical concentration limit for routine work seems to be 30% HCl since this composition can be used on all of the principal faces with excellent results. Figure 3A illustrates an A-face polished in a high concentration of HCl while Fig. 3B is typical of any face polished in the 30% composition.

Figures 4A and 4B are interference photographs of the A and the B face, respectively, of a slice of CdS polished in 30% HCl. A major portion of the surfaces is flat to within ±0.1 mil (±2.5μ). Figures 5A and 5B are profiles of the same surfaces taken on at Talysurf, model 3. Irregularities in the surface of the A-face are consistently less than 500Å and on the B-face less than

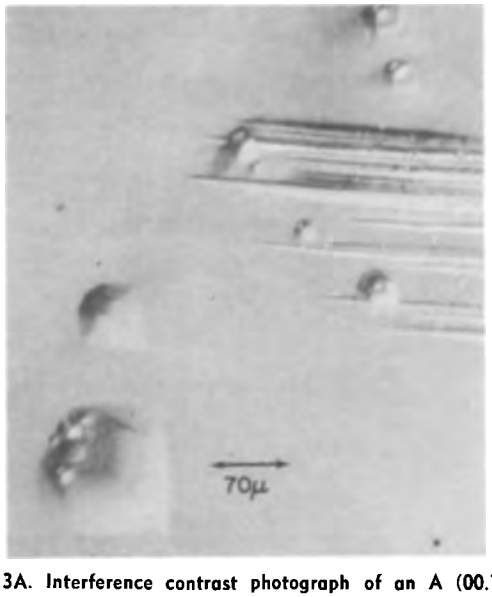

Fig. 3A. Interference contrast photograph of an A (00.1) face polished in 50% HCl. Preferential etching results in poor polishing at this concentration of HCl.

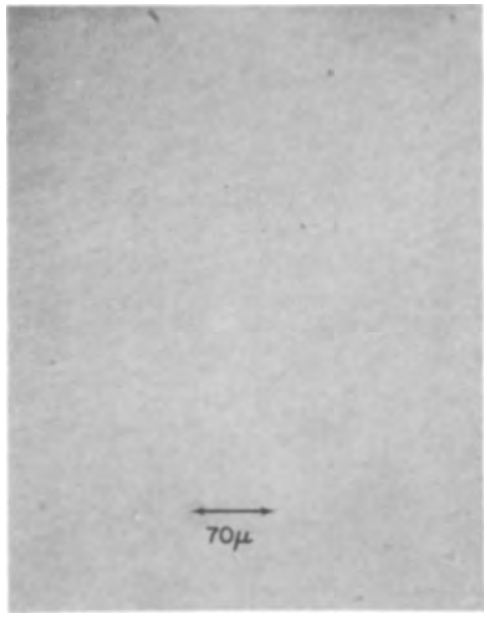

Fig. 3B. The A (00.1) face polished in 30% HCl. The B (00.$\bar{1}$) face and the six equivalent faces of the hexagonal unit prism appear similar to the A (00.1) face when polished in 30% HCl. The field of view in Fig. 3A and 3B is about 0.017 x 0.019 in.

250Å. Occasionally it is more difficult to polish the A-face of a particular crystal of CdS, but only rarely is any difficulty encountered on any other crystal face.

The data in Fig. 2 indicate that there may be a slight effect of light on the etch rate as calculated from thickness measurements. On two faces there was an increase in rate and on the third face a slight decrease. Illumination on the A face appeared to produce a slight beveling effect indicating a greater etch rate at the edges of the slice.

In the chemical polishing of GaAs (6) it was found that the etch rate varied directly with pressure. Since polishing is usually a slow process, this acceleration due to pressure was very desirable. In the case of CdS, any significant increase in pressure over that required to maintain the polishing block close to the wheel

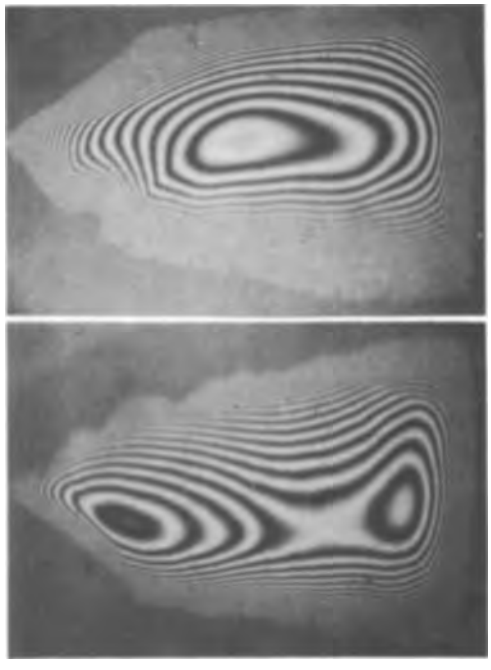

Fig. 4A (top) Interference photograph using thallium light of a polished A (00.1) face. Each fringe represents 2700Å difference in elevation and the field of view is about 0.25 x 0.36 in. Fig. 4B (bottom) Same for the B (00.$\bar{1}$) face.

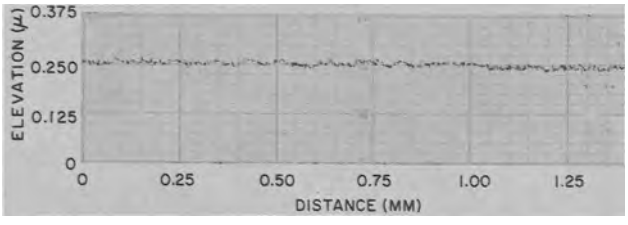

Fig. 5B. Profile of the specimen from Fig. 4B as taken on Talysurf Model 3.

(about 50 g/cm^2) caused scratching of the surface.

The epitaxial films which have been grown on CdS polished in this manner are more perfect than those which have been grown on mechanically polished or chemically polished (HCl without "planar intensive stirring") CdS.

Summary

The chemical polishing of CdS with HCl ordinarily gives a bright surface on the A face and a satin finish on the B face, but neither surface has the "polished" finish which is most desirable for device applications. The addition of planar intensive stirring to the chemical polishing has resulted in smooth, flat damage-free surfaces on all of the principal faces including both the A and the B faces. The recommended polishing solution is 30% concentrated (37-38%) HCl in water.

Addendum to Precipitates Induced in GaAs by the In-Diffusion of Zinc

J. F. Black and E. D. Jungbluth

General Telephone & Electronics Laboratories, Bayside, New York

(Vol. 114, No. 2, pp. 181-187)

The purpose of this communication is to clarify some of the procedures and qualify several of the results described in this recently published paper (1).

The infrared (IR) absorption (more accurately called IR attenuation) of diffused samples was frequently referred to in terms such as "strong IR absorption," or "reduced IR transmission," or "opaque to IR." These phrases were intended to denote IR attenuation over and above that which could be attributed to free carrier absorption.

A progressive increase in (excess) *IR* attenuation was described for several samples listed in Table I of the paper. This increase in IR attenuation was ascribed to increasing degrees of precipitation. Under illumination normal to the plane of diffusion the different thickness of the diffused layers in these samples would, alone, have caused strong differences in IR attenuation. Therefore, in this work comparisons of the IR attenuation were conducted on polished profile sections of equal thickness (75μ) cut from each sample. These comparisons were made with the aid of slotted masks, positioned and fixed under the microscope, over each profile section so that only the diffused layer was exposed to the IR illumination. When these masks were not used, or when they were not properly positioned, the IR radiation passing through the relatively transparent undiffused portion of the section interfered with the observations of IR transmission through the diffused layer. Recent measurements have shown, however, that the concentration of zinc at the boundary of the precipitate containing layers varied significantly from sample to sample (these measurements are described below). Consequently, the variation in IR attenuation through the diffused layers can only be approximately equated with variations in the degree of precipitation in each sample.

Diffused samples were sectioned normal to the diffusion plane for junction delineation by etching. Since etching did not generally produce a sharp line at the p+ p junction (for 600 X magnification), it was usually difficult to resolve a separation as small as 1μ between p+ p and p-n junctions. This meant that even though a p+ p junction occurred at a zinc concentration greater than 1 x 10^{19} atoms/cm^3 in an n-doped sample, if the p+ p junction was no more than 1μ away from the p-n junction it would appear that only one junction was present. In such a case, for example in our 5.9 x 10^{18} n-doped samples, the p+ p junction would be judged to occur at the same concentration as the p-n junction; 5.9 x 10^{18} atoms/cm^3. This amplification of our previous comments shows that our data are consistent with other recent measurements (2) of etched profile sections of p+ p and p-n junctions in zinc diffused GaAs. Extrapolation of these other junction measurements suggests that the p+ p junction in zinc diffused GaAs occurs at a zinc concentration of about 2 x 10^{19} atoms/cm^3.

Additional determinations of diffusion profiles performed with the electron beam microprobe showed somewhat higher zinc values at the p+ p boundary than before. On three additional samples the zinc concentration at the boundary of the layer of high etch pit density was 8 x 10^{18} atoms/cm^3 (24 hr at 700°C), 1.2 x 10^{19} atoms/cm^3, (2 hr at 800°C), and 1.0 x 10^{19} atoms/cm^3 (2 hr at 900°C). On each analysis the instrument "noise" level was equivalent to ± 5 x 10^{18} zinc atoms/cm^3. These analyses were obtained with a Philips Model AMR-3 Electron Probe Microanalyzer using a flexible mica crystal to achieve optimum focussing of characteristic x-rays and a 30 kv beam, at a sample current of 0.18 μa and counting over a period of 100 sec.

The discussion (1) of the excess IR attenuation in the diffused layers led to the conclusion that, for a zinc concentration of 5 x 10^{18} atoms/cm^3 at the boundary of the layer, the excess IR attenuation amounted to more than 300 cm^{-1}. This excess was proposed to be due to the presence of the submicroscopic precipitation. It would appear that the magnitude of this excess absorption must now be revised downward because the boundary zinc concentration may in general be higher than 5 x 10^{18} atoms/cm^3. However, even if the zinc concentration were as high as 2 x 10^{19} atoms/cm^3, which seems possible according to recent measurements, we must still account for excess IR attenuation amounting to about 200 cm^{-1}.

Acknowledgment

The authors wish to express their gratitude to W. J. Sutkowski for the electron probe analysis.

Brief Communication

Study of Impurity Heterogeneities in InSb by Means of a Permanganate Etchant

A. F. Witt

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

Heterogeneities of the impurity distribution in semiconductors (coring and striations) can be revealed by several different techniques like autoradiography, resistivity measurements, and etching. Of these, etching is the method most frequently used because of its relative simplicity and the good resolution that can be obtained.

In InSb impurity striations are commonly investigated with dilute or modified CP-4 etchants. This reagent gives good resolution if the semiconductor surface is properly prepared and adequate optical facilities are available. Like most etchants it suffers from a major disadvantage: the etching process is accompanied by gas evolution which frequently leads to severe pitting and demands careful control if optimum resolution is to be obtained. The background of the etched surface is not very smooth and thus requires relatively long exposure times for microphotography with a resulting deterioration of the photographic resolution.

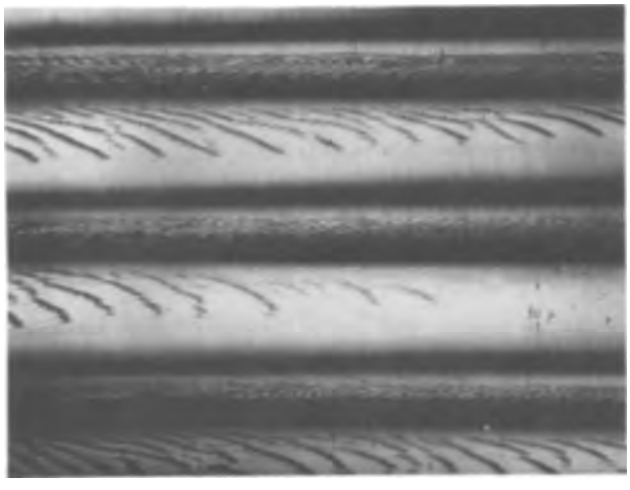

Fig. 1. Vibrational tellurium striations in InSb

A permanganate nongas-evolving etchant was developed (1 HF, 1 CH_3COOH, 1 $KMnO_4$ 0.05M) which has striking advantages over modified CP-4 etchants. For optimum results the semiconductor surface to be investigated is either immersed into the etchant or alternately the etchant is applied with a cotton applicator for a period of 4 to 6 min. (Heating or agitation is not required.) Since the oxidation process with $KMnO_4$ is not accompanied by any gas evolution the etching time is not critical and pitting is completely absent. This particular etching solution leads to a very smooth background and reveals striations with extremely high resolution. From our investigations we conclude that the ultimate resolution of striations is limited by the resolution of the optical system (about 0.2μ) rather than by that of the etchant. As a consequence of the increased reflectivity of the specimen (smoothness) it is possible to decrease the exposure times for microphotography from several minutes to fractional seconds and thus to preserve optimum resolution.

Fig. 2. Impurity striations in InSb as revealed with permanganate etch on a (211) plane.

Figures 1 and 2 show two typical instances of InSb surfaces etched with the new nongas-evolving etchant. Resolution of this magnitude could not be achieved with the standard etchants. It is most likely that the same etchant or some modified composition could be used for other materials.

ELECTROCHEMICAL SCIENCE

On the Electrolytic Conductivity of Electrolytes Simulating Those Found in Silver Chloride-Magnesium, Sea Water Activated Batteries

Duane W. Faletti and Michael A. Gackstetter

Applied Physics Laboratory, University of Washington, Seattle, Washington

ABSTRACT

Experimental determinations were made at temperatures of 5°-75°C of the electrolytic conductivity of simulated sea water activated AgCl-Mg battery electrolytes formulated from 4.5 to 19 °/oo (parts per thousand) chlorinity artificial sea water with 0-70g $MgCl_2$ added per liter of sea water.

The Applied Physics Laboratory, University of Washington, is conducting studies of the magnesium-silver chloride electrochemical couple in a sea water electrolyte. Because these studies require a knowledge of the voltage drop resulting from the electrical resistance of the electrolyte, an investigation was made of the electrical conductivity of sea water electrolytes.

If pure magnesium is used as the anode of a magnesium-silver chloride cell, two simultaneous reactions take place during the discharge: the electrochemical reaction

$$2AgCl + Mg \rightarrow MgCl_2 + 2Ag \qquad [1]$$

and the corrosion reaction

$$Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2 \qquad [2]$$

which gives magnesium its anode efficiency of approximately 70%. Therefore, the cell reaction modifies the electrolyte through the addition of soluble $MgCl_2$, particles of insoluble $Mg(OH)_2$, and hydrogen gas.

In order to simulate the electrolyte conditions that occur during normal operation of a sea water activated Mg-AgCl battery, the chlorinity, temperature, and added $MgCl_2$ concentration of the electrolyte were varied. Three basic electrolytes having chlorinities of 4.5, 9.0, and 19.0 °/oo were studied. The solution having a chlorinity of 19 °/oo follows the artificial sea water formula of Lyman and Fleming (1940) taken from ref (1) and presented in Table I.

Since the chlorinity is a measure of the concentration, per kilogram, of the ions found in sea water, the other two basic electrolytes represent dilutions of the 19 °/oo chlorinity by weight factors of 2.111 (19.0 °/oo/9.0 °/oo) and 4.222 (19.0 °/oo/4.5 °/oo) to give chlorinities of 9.0 °/oo and 4.5 °/oo, respectively. The temperature and added $MgCl_2$ concentration of each basic electrolyte were varied over the ranges of 5°-75°C and 0-70g $MgCl_2$ per liter of a base electrolyte at 25°.

Table I. Composition of artificial sea water of 19 °/oo chlorinity

Salt	g/Kg
NaCl	23.476
$MgCl_2$	4.981
Na_2SO_4	3.917

Apparatus and Procedure

The a-c impedance bridge employed in the conductivity program is an Electro-Scientific Industries Corporation Model 250 DA and operates at a frequency of 1000 cps. On the basis of measurements of reference (±0.05%) resistors, the manufacturer's guaranteed accuracy of ±0.3% is considered to be conservative. Compensation for cell reactance was achieved in the usual manner by placing a variable air capacitor in parallel with the variable resistance arm of the bridge.

A dip-type conductivity cell, Industrial Instruments, Inc., Model CEL-H50, was used. By measurement of the standard KCl conductivity solutions of Jones and Bradshaw (2-4), the cell constant was found to be 49.95 ± 0.20 cm^{-1} over a temperature range of 5°-80°C.

All of the electrolytes studied were made up from ACS reagent grade salts and distilled water having a measured conductivity of less than 4×10^{-6} mhos/cm. All weighings were made in air, and, with the exception of $MgCl_2$, all of the salts were weighed out in crystalline form. Since the degree of hydration of $MgCl_2$ is difficult to determine accurately, $MgCl_2 \cdot 6H_2O$ was dissolved in distilled water to form stock solutions which were analyzed for $MgCl_2$ content.

All conductivity measurements were made with the conductivity cell suspended in a Dewar flask containing the electrolyte. Appropriate precautions were observed to avoid contamination or dilution of the electrolyte and to insure temperature equilibrium between the cell and the electrolyte.

Each electrolyte sample was tested first at 25.0° and then consecutively at 5.0°, 50.0°, and approximately 75°C. An immersion heater was used for the 25° runs, and precooling or preheating of the electrolyte in closed containers for the low- and high-temperature runs. In order to minimize evaporation of the solvent water, no attempt was made to allow each preheated electrolyte to approach exactly 75° in the open Dewar flask. Instead, the temperature and cell resistance were recorded as soon as the bridge reading stabilized, indicating temperature equilibrium between the electrolyte and the cell. The temperatures so obtained varied from 71° to 80°C.

All temperature measurements were obtained with calibrated partial immersion mercury thermometers

and with estimated accuracies of ±0.1° at 5°, 25°, 50° and ±0.2° at 71°-80°C.

Tests were made to determine the reproducibility of the measurements and to check for errors in the high-temperature data caused by water evaporation. Reproducibility was determined by testing at 25° several carefully stored electrolytes both at the time of preparation and at intervals up to approximately 40 days after preparation. Errors due to water evaporation were determined by again taking measurements of some electrolytes at 25° after each of the 50° and 75° runs and comparing these with the initial 25° measurements. The results of these tests are discussed in the following paragraphs.

Discussion of Results

The specific conductivities measured for the 4.5, 9.0, and 19.0 °/oo chlorinity electrolyte series ($MgCl_2$ added in amounts of 0-70 g/liter of base electrolyte at 25°C) are given in Tables II, III, and IV, respectively.

It should be noted that the data for high temperatures given in Tables II-IV are reported at 75.0°, whereas the experimental data were taken at temperatures of 71°-80°C. Preliminary plots of measured conductivities vs. temperature were very nearly linear over 50° for each electrolyte. For convenience in reporting the data in tabular form, the 71°-80° data were extrapolated (or interpolated) to 75.0° by utilizing the slopes of the preliminary plots in the region between 75.0° and the experimental temperatures. The error introduced by this procedure is estimated to be less than ±0.1% and is considered to be negligible compared to the other sources of error discussed below.

By means of the tests described above, the 25° data were found to be reproducible to within ±0.3%, and the 50° and 75° data were found to be subject to evaporation errors of zero to +0.3% and zero to +0.7%, respectively.

Uncertainties in measured temperatures and $MgCl_2$ stock solution concentrations lead to estimated maximum errors of ±0.3% and ±0.2%, respectively.

Adding these errors to the ±0.4% for the cell constant and the ±0.3% for the bridge, the over-all maximum possible errors in the reported data are estimated to be ±1.2% at 5° and 25°, +1.5% to −1.2% at 50°, and +1.9% to −1.2% at 75°.

To the authors' knowledge, no other data exist in the literature for sea water with augmented $MgCl_2$ content. However, the agreement with literature values of this study's data for the basic electrolytes (artificial sea water with chlorinities of 4.5, 9.0, and 19.0 °/oo) is well within the estimated experimental error, *e.g.*, they differ from the data of Thomas *et al.* (5) by + 0.7 to −0.4% at 5° and 25°C.

Solubility and Diffusion of Hydrogen in Strong Electrolytes and the Generation and Consumption of Hydrogen in Sealed Primary Batteries

Paul Rüetschi

Leclanché S.A., Yverdon, Switzerland

ABSTRACT

Experimental means to measure the H_2 generation of negative electrodes are described. Results obtained with Zn electrodes in KOH solution show that H_2 generation is decreased by the addition of K_2ZnO_2 at KOH concentrations above 2N, but is increased at concentrations below 2*N*. These findings are interpreted in terms of ZnO or $Zn(OH)_2$ film formation and dissolution. Electrochemical consumption of hydrogen within the cells may be achieved on catalyzed auxiliary electrodes, held at a suitable voltage level by a regulating device, such as a diode.

A major reason for the deterioration of dry cells on storage is drying out (1). Loss of water by evaporation leads to shrinkage of the immobilized electrolyte and to the creation of cracks and channels, allowing access of air to the zinc electrode. The resulting electrochemical oxidation and dissolution of zinc is accompanied by an equivalent consumption of air-oxygen.

In order to avoid loss of water by evaporation, as well as leakage, during long-term storage or operation the cells must therefore be sealed. For applications in outer space a hermetic seal is imperative. However, those negative electrode materials which have the most desirable characteristics with respect to power output per unit volume and per unit weight, such as zinc or magnesium, are thermodynamically unstable in common aqueous electrolytes and thus evolve hydrogen according to

$$M + 2H_2O \rightarrow M(OH)_2 + H_2 \qquad [1]$$

which leads to pressure build-up within the cell. The rate of reaction [1] increases exponentially with temperature. While the self-discharge of the cell due to reaction [1] can be of insignificant proportions, the associated pressure build-up might become very annoying.

In the past, it has been recognized that the long-term storage of Leclanché-type dry cells (1-5) is closely related to the problem of gassing. A convenient way of measuring the corrosion of zinc due to reaction [1] is by placing an appropriate sample in a closed vessel containing the electrolyte and by following the hydrogen generation volumetrically (6-8).

If complete Leclanché-type dry cells are enclosed in glass or metal containers, analysis of the gas evolved indicates that it consists largely of H_2 and CO_2. Practically no oxygen is found since the latter is consumed by the zinc electrode in a manner corresponding to the "oxygen cycle" in sealed nickel-cadmium cells. The percentage of CO_2 depends strongly on the type of MnO_2 used, electrolytic and chemically activated ores producing a much greater quantity of CO_2. Aufenast and Müller (8) suggest that the CO_2 stems from the oxidation of sugars contained in the starches employed for the pastes. However, some of the CO_2 probably comes from carbonates contained in the ores or electrolytes employed. Some CO_2 evolution is also observed in sealed lead acid batteries as a result of the oxidation of separator material and suspended organic matter. In alkaline cells any CO_2 produced is absorbed by the electrolyte. On the other hand, H_2 evolution might pose a serious problem in sealed alkaline primary cells.

The rate of hydrogen generation is governed by the overvoltage. The extremely strong effects of impurities have long been recognized and investigated (8). In Leclanché-type cells the order of increasing catalytic action on hydrogen evolution is

$$Pb < Mn < Fe < Cu < Mo < As < Sb \qquad [2]$$

To reduce "local action" the technique of amalgamation has been practiced over 100 years. It is particularly effective in reducing hydrogen evolution on zinc electrodes in alkaline electrolytes (9). However, in dry cell electrolytes of *p*H 5-6, particularly at elevated temperatures, amalgamation tends to increase hydrogen evolution.

Organic and inorganic inhibitors have been utilized to decrease hydrogen evolution in dry cells (6). Chromate films on zinc electrodes have found com-

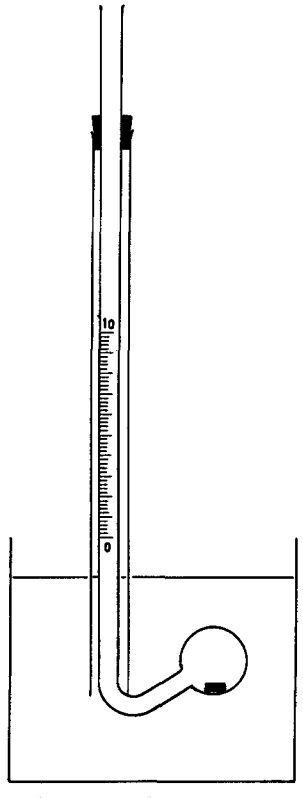

Fig. 1. Cell for the study of hydrogen evolution of negative electrodes.

mercial use as inhibitors (10). The type of starch used in the paste has a strong influence on charge retention. Vinal reports that colloidal proteins, as found in wheat flour, are good inhibitors.

Hydrogen Generation

In the present study the simple, but effective, volumetric device illustrated in Fig. 1 has been used to measure the rate of hydrogen evolution. A sample of the electrode material under study, *e.g.*, amalgamated zinc, was placed in the 20 ml round flask and the electrolyte level adjusted to the zero mark of the 10 ml calibrated capillary. The cell was immersed in a constant temperature bath. The glass tube surrounding the capillary served as thermal insulation. Hydrogen accumulated in the top of the spherical portion and displaced an equivalent volume of electrolyte into the capillary. Readings were corrected for water vapor pressure of the electrolyte, temperature, atmospheric pressure, and hydrostatic head. The gas volumes were expressed in terms of cubic centimeters at STP. Results obtained with this apparatus are shown in Fig. 2-5. These results refer to samples of 0.300g of amalgamated zinc powder in potassium hydroxide electrolyte. The samples were pretreated in the corresponding electrolyte for 2 to 20 hr, depending on the temperatures involved, to achieve steady-state conditions.

Figure 2 demonstrates the well-known effect of amalgamation, substantiating the findings of Snyder and Lander (9).

Of particular interest is the dependence of the hydrogen evolution rate on electrolyte concentration. Figures 3 and 4 illustrate corresponding results at 60°C with and without zinc oxide addition to the potassium hydroxide electrolyte, respectively, after an initial conditioning period of 20 hr. For zincate-free electrolytes the KOH concentration was determined by acidmetry using phenolphthalein as indicator. The carbonate concentration was smaller than 0.55 g/l in

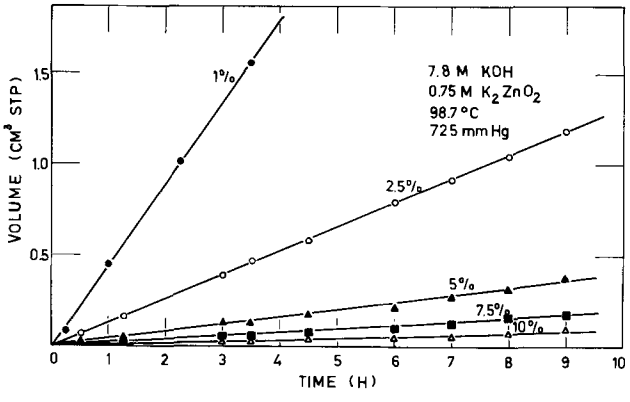

Fig. 2. Effect of amalgamation of zinc electrodes (1, 2.5, 5, 7.5, and 10% Hg) on hydrogen generation in potassium hydroxide at 98.7°C.

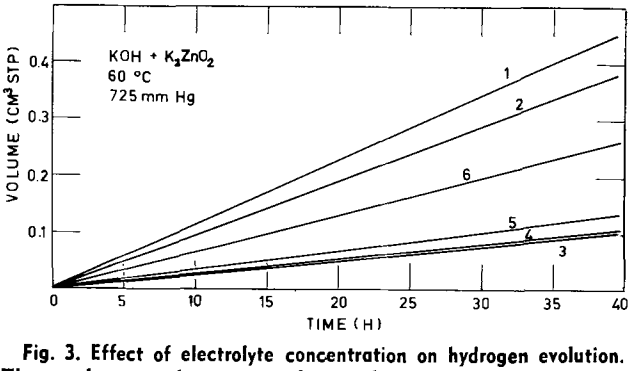

Fig. 3. Effect of electrolyte concentration on hydrogen evolution. The numbers on the curves refer to the electrolyte compositions given in Table I under KOH + K_2ZnO_2.

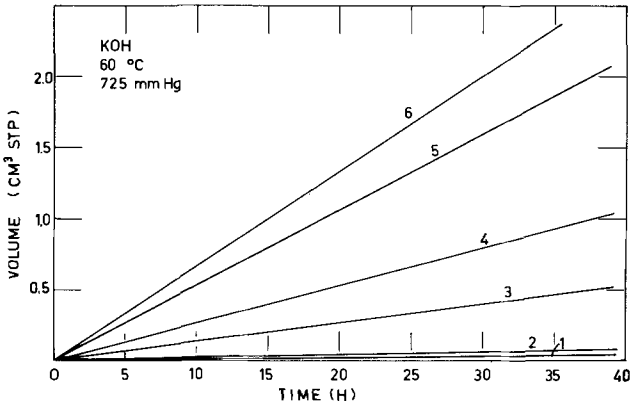

Fig. 4. Effect of electrolyte concentration on hydrogen evolution. The numbers on the curves refer to the electrolyte compositions given in Table I under KOH pure.

all cases. For electrolytes containing ZnO, the concentration of "free" KOH was determined by acidimetric titration, using methylorange, and by subtrating the normality of the zincate concentration, as determined by complexometric titration. Compositions of the electrolytes used are listed in Table I. The zinc samples contained 5% Hg. Gassing rates are summarized in Table II.

In Fig. 5 the gassing rate is plotted against the free potassium hydroxide concentration at three different temperatures. It is apparent that in relatively dilute electrolytes, that is below 2*N* KOH, the presence of K_2ZnO_2 increased the gassing rate, whereas above 2*N* KOH, the presence of K_2ZnO_2 strongly decreased the gassing rate. This result is in accord with the practice of alkaline mercury cell manufacture (11), but is at variance with the findings of Snyder and Lander (9).

Under the experimental conditions used by these authors, the electrolyte in the vicinity of the zinc electrodes became saturated with ZnO and its concen-

tration correspondingly decreased with time in accordance with the process

$$Zn + 2KOH \rightarrow K_2ZnO_2 + H_2 \qquad [3]$$

The results of Fig. 5 indicate that for zincate-free electrolytes the hydrogen evolution rate increases with KOH concentration. The reaction appears to depend on the rate of dissolution of the interfacial ZnO or $Zn(OH)_2$ film, formed by spontaneous reaction between the zinc and the water of the electrolyte. The zinc oxide solubility strongly increases with increasing KOH concentration.

The relatively high evolution rate in dilute KOH solutions containing zincate may then be explained by the presumption that the interfacial ZnO or $Zn(OH)_2$ layer formed on immersion of a fresh zinc electrode in such electrolytes is thinner, or less compact and less protecting (12) than in zincate-free electrolyte.

From a practical point of view it is of importance to consider the question how the hydrogen, once generated, is removed from the negative electrode surface. Bubble formation will occur only if the adjacent electrolyte layer is saturated with hydrogen. At very low evolution rates a substantial portion of the hydrogen will thus be removed by molecular diffusion. The shorter the diffusion path, that is, the thinner the electrolyte layer covering the negative electrode, the higher is the diffusion rate. In ordinary dry cells with immobilized or gelled electrolyte hydrogen removal by diffusion, without bubble formation, is desirable, since evolving hydrogen bubbles may create channels for the access of air to the zinc electrode, resulting in rapid corrosion.

Hydrogen Consumption

For operation of primary batteries in a hermetically sealed condition over prolonged periods of time hydrogen-consuming means within the cell may be employed. While it is known that hydrogen can be oxidized to water by homogeneous reaction with electrolyte solutions containing copper and silver salts (13), it is believed that electrochemical oxidation through heterogeneous reaction at an electrode surface could offer a practical solution. The use of catalytically active electrode surfaces for the removal of hydrogen in sealed cells was first suggested by Dassler (14).

It is known today that electrochemical reactions on diffusion electrodes take place on locations covered with a thin, wetting electrolyte film (15). For the process of hydrogen oxidation to take place, the hydrogen must dissolve in the electrolyte, diffuse across the liquid film, and react electrochemically at the electrode interface. Therefore, both hydrogen solubility as well as diffusion rate may play decisive roles in governing the speed of the over-all process.

The solubility of hydrogen is greatly decreased in strong, concentrated electrolytes, due to salting-out effects. Ions with large hydration shells are particularly effective in salting-out. Hydrogen solubility is therefore lower in KOH than in H_2SO_4 or NH_4Cl.

The solubility of hydrogen, as determined recently (16) is shown as a function of electrolyte concentration in Fig. 6.

The diffusion coefficient of hydrogen may be obtained from limiting diffusion currents to a rotating platinum disk electrode. According to the equation of Levich (17)

$$i_d = 0.62\, nFA\, c\, \nu^{-1/6}\, D^{2/3}\, \omega^{1/2} \qquad [4]$$

where n is the number of electrons, $\mathbf{F}$ the Faraday, A the electrode area, c the concentration (solubility of hydrogen), ν the kinematic viscosity, D the diffusion coefficient, and ω the rotational speed. New results derived in this manner are shown in Fig. 7.

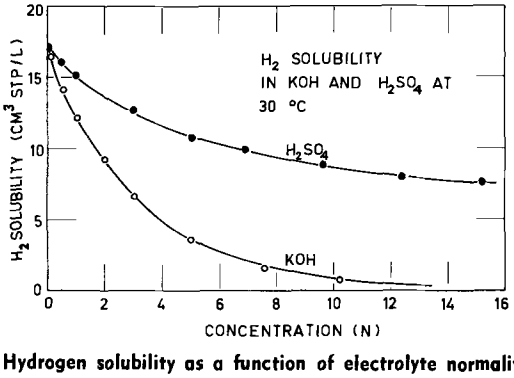

Fig. 6. Hydrogen solubility as a function of electrolyte normality.

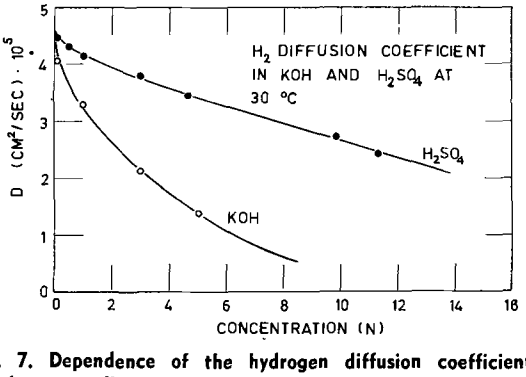

Fig. 7. Dependence of the hydrogen diffusion coefficient on electrolyte normality.

The electrochemical hydrogen ionization rate depends on electrolyte concentration, as demonstrated in Fig. 8, where the exchange current i_o of a platinized platinum electrode is plotted against electrolyte normality. These results were derived from current-voltage plots near the equilibrium potential of high-speed rotating disk electrodes. The decrease of the exchange current at high electrolyte concentration had been noted for alkaline solutions by Vielstich (18). The present result indicates a similar decrease at high acid concentrations.

At highly positive electrode potentials, that is above 500 to 900 mv *vs.* H_2 in the same solution, depending on the nature of the anions present, the electrochemical ionization of H_2 on platinum and similar materials is strongly inhibited by anion or oxygen adsorption (19). Although there has been reported consumption of H_2 on silver oxide electrodes in alkaline solutions at not insignificant rates (20, 21) and on nickel oxide electrodes (22) at very low rates, the results obtained so far with oxide electrodes are erratic (23) and seem to depend on factors which are not yet entirely understood. On the other hand, high rates of hydrogen consumption may be achieved consistently with auxiliary electrodes containing platinum metals, Raney nickel, or other H_2-catalysts, whose potentials are kept at a constant level between +100 and +400 mv with respect to a reversible H_2 electrode in the same solution, by applying voltage regulating means such as diodes (24, 25). An arrangement of this kind is shown for a primary Ag_2O-Zn cell in Fig. 9, where R signifies a high resistance in the order of $10^5/C$ ohm (C being the capacity of the cell in ampere hours) and where D is a forward or backward diode with a voltage drop in the order of 1v. The tiny current flowing through the resistor keeps the voltage of the auxiliary electrode at its working level even if temporarily no hydrogen should be present in the cell.

A practical three-terminal construction of a small sealed cell is indicated in Fig. 10.

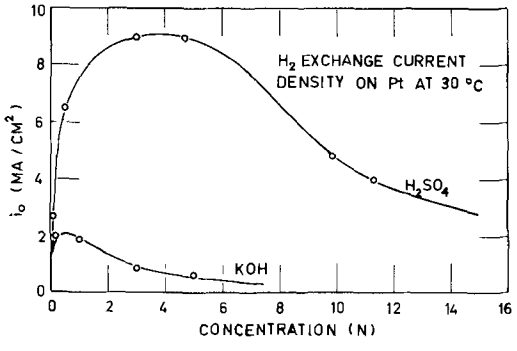

Fig. 8. Exchange current of a Pt-catalyzed hydrogen electrode as a function of electrolyte normality.

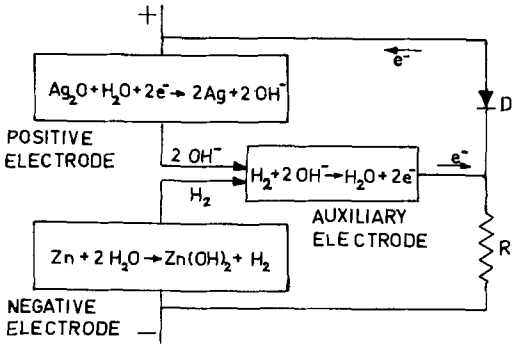

Fig. 9. Schematic representation of the generation and consumption of hydrogen in a sealed silver-zinc primary battery with auxiliary electrode.

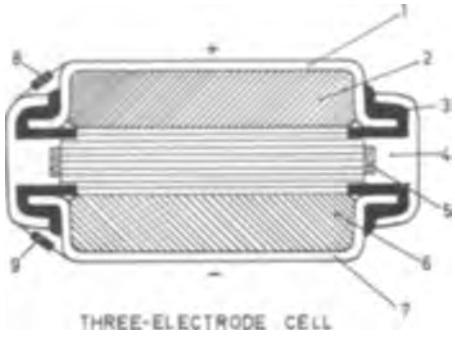

Fig. 10. Construction of a small sealed cell with auxiliary H_2-consuming electrode: 1, positive cell can; 2, positive electrode; 3, grommet seal; 4, side wall serving as auxiliary electrode terminal with crimp-seals; 5, auxiliary porous electrode; 6, negative electrode; 7, negative cell can; 8, diode; 9, resistor.

If the hydrogen-consuming electrode is barely wetted, ohmic drops, caused by ionic current flow in the thin electrolyte films, will cause certain parts of the electrode to exhibit a local potential near that of a reversible H_2 electrode. Anionic inhibition is then less of a problem even at relatively high external anodic potentials.

Under these conditions the following equation applies, up to relatively high anodic potentials, for the case of limiting H_2 diffusion across the thin, wetting film on a porous partly wetted electrode

$$I_a = (2DZ_m\mathbf{F}k_hs^2/\rho)^{1/2}\, p^{1/2}\, \eta_a^{1/2} \qquad [5]$$

where I_a is the current density/cm^2 of projected porous electrode surface; D the diffusion coefficient of H_2; $\mathbf{F}$ the Faraday number; k_h the Henry solubility constant of H_2; s the internal surface area (cm^2/cm^3); ρ electrolyte specific resistance; p partial H_2 pressure; η_a the applied electrode potential with respect to a reversible H_2 electrode in the same solution; and Z_m the electrons required per molecule (2 for H_2).

If the rate is controlled by the speed of electrochemical ionization at the interface, the current becomes

$$I_a = (2\tau_o s^2 k_o k_h/\rho\phi)^{1/2}\, p^{1/2} \exp(\phi\eta_a/2) \qquad [6]$$

where τ_o is the effective electrolyte film thickness, k_o the electrochemical rate constant, and, $\phi = \alpha n\mathbf{F}/kT$. In either case the current is proportional to the square root of internal partial H_2 pressure.

In conclusion, it can be stated that means are available to limit the generation and to accelerate the consumption of hydrogen in primary batteries, allowing the latter to be hermetically sealed.

Kinetics of the Attack of High-Temperature Molybdenum and Tungsten by Atomic Oxygen

Daniel E. Rosner and H. Donald Allendorf

AeroChem Research Laboratories, Inc., a subsidiary of Ritter Pfaudler Corporation, Princeton, New Jersey

ABSTRACT

Using microwave discharge, fast-flow system techniques coupled with resistance heating and monitoring of the reacting specimens, the true kinetics of metal atom removal for polycrystalline molybdenum and tungsten filaments attacked by atomic oxygen have been obtained in the nominal temperature range 1000°-2200°K at oxygen atom pressures in the range 10^{-3} to 5 x 10^{-2} Torr. Under these conditions the oxides of molybdenum and tungsten essentially volatilize as rapidly as they are formed, leaving the metal surface vulnerable to direct oxygen atom attack at constant (time independent) rates. Reaction probabilities are found to be up to 140 times those for O_2 attacking the same surface, are independent of O-atom partial pressure, and exhibit a much weaker temperature dependence than those for O_2. These observations are in accord with a Rideal-type mechanism in which O atoms from the gas phase strike chemisorbed oxygen, leading either to product formation and desorption, or surface-catalyzed oxygen atom recombination.

Owing to the rapidity of the chemical reactions involved and the desirability of measuring product distributions using existing mass spectrometer techniques, most fundamental studies of the oxidation kinetics of refractory metals that form oxides which are volatile at the reaction temperature have been carried out at very low O_2 pressures, typically much less than 10^{-3} Torr (1-3). Under these conditions one finds that the observed reaction probabilities and product distributions can be understood only in terms of the inferred population of adsorbed *atomic* oxygen (2, 3), *i.e.*, oxygen atoms arriving as part of oxygen molecules which are not dissociatively adsorbed on impact are denied any role in subsequent events leading to product formation-desorption. This being the case, the average reaction probability cannot exceed the "sticking" (dissociative adsorption) probability, which itself can be quite small ($<10^{-2}$) on crystallite surfaces already partially covered with chemisorbed oxygen (4, 5). Clearly the situation is quite different if the attacking gas is already dissociated, and it is of fundamental interest to inquire as to the consequences of prior dissociation on the observed rates of such heterogeneous reactions, particularly at high oxygen pressures.

This question is also timely in view of recent advances in aerospace technology since, as discussed in the Appendix, vehicle speeds are now high enough to cause significant dissociation of diatomic oxygen in the air wetting such vehicles. Yet relevant experimental data and detailed consideration of the role of atomic oxygen in the degradation of high-temperature materials is conspicuously absent from most recent oxidation (or "ablation") studies, a situation which, in part, motivated the present work. In addition, regions of the earth's atmosphere (>100 km) in which atomic oxygen is naturally present due to solar-induced photodissociation are being rocket-probed with increasing frequency, again raising questions about the response of materials in such environments.

Accordingly, the experiments reported herein were designed to provide the first high-temperature data on the attack of polycrystalline molybdenum[1] and tungsten by atomic oxygen under conditions such that the observed reaction rates: (*a*) would not be falsified by reactant or product diffusional limitations and thermal accommodation effects, and (*b*) could be directly compared with oxidation rates for diatomic oxygen attacking the same metal surfaces using the same experimental techniques, at reactant partial pressures of aerospace interest. Despite the rapidity of the O-atom attack, this has been accomplished at surface temperatures up to 2200°K by combining the conditions of low total pressure, high pumping speed, and small specimen size, as described below, using a microwave discharge to dissociate oxygen.

Experimental

The techniques and equipment used here are similar to those developed in connection with our previous

[1] The present work considerably extends (from 1500° to 2600°K) the preliminary results for molybdenum reported by the authors in (6) and presents for the first time the corresponding oxidation behavior for tungsten and some observations on one industrially important alloy of molybdenum (TZM). Extensive results for the reaction order in O_2 are also presented here.

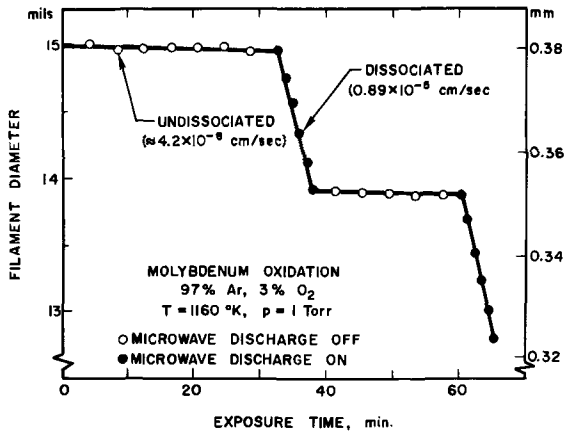

Fig. 2. Effect of dissociation on the oxidation rate of molybdenum

studies of the attack of high-temperature graphite and molybdenum by atomic oxidizers (6-9). Significant details are given here to facilitate an understanding of the results presented below.

Atom production.—As indicated schematically in Fig. 1, the apparatus consists of a Vycor discharge tube-Pyrex vacuum flow system coupled to a pair of mechanical pumps (not shown) providing a maximum capacity of about 25 l/sec. Metered diluent-O_2 gas mixtures (usually Ar/O_2, dilute in O_2) are passed through a 2450 MHz, 125w microwave-powered discharge cavity[2] 28 cm downstream of which the gas encounters the electrically heated filament being studied. Most of the experiments were carried out with the pressure level at the specimen location maintained at 1 Torr (1.316×10^{-3} atm) and the flow rate maintained at 21.7 cc (STP)/sec. This corresponded to a linear velocity of approximately 2×10^4 cm/sec in the discharge tube, or a residence time of 45 μsec/cm. As noted below, experiments at higher total pressures (up to 1 atm), using carrier gases other than argon (*e.g.*, He, N_2) and at various flow rates, were carried out to determine the true reaction order (reactant partial pressure dependence) and to verify the absence of diffusional falsification phenomena.

Reaction rate.—Reaction rates were inferred directly from continuous measurements of the resistance-time curve of electrically heated filaments of circular cross section. Together with current measurements, the voltage drop across the central 0.55 cm of each 3.1 cm long filament was continuously monitored using spring-loaded contacts (*cf.* Fig. 1) leading to a recording potentiometer. During a run the filament surface temperature was maintained constant (to within about ±5°K) by manually altering the direct current in accord with the output of an optical pyrometer, thereby allowing the decrease in filament diameter caused by the reaction (typically less than a total of 0.005 cm for an initial filament diameter of 0.0381 cm) to be calculated.[3] While the optical pyrometer was used to maintain constant filament temperature during an experiment, the absolute value of the surface temperature, which in the present experiments was in the range of 1040°-2600°K, was determined from the initial filament resistance, in accord with its resistivity-temperature relation (11, 12). A typical plot of inferred filament diameter versus time is shown in Fig. 2, in which data for both undissociated and dissociated oxygen are included for comparison. In each case the reaction rate (proportional to the absolute value of the slope) is seen to be constant in time, as expected for heterogeneous reactions forming volatile (nonprotective) oxides. Owing to the large increase in reaction rate on activation of the electrical discharge and the small concentrations of O_2 simultaneously present, except at the highest temperature investigated the observed reaction rate for the dissociated gas condition (discharge on) is dominated by the O-atom contribution, thereby necessitating only small corrections[4] (typically much less than 7%) for the O_2 contribution.

In the absence of the electrical discharge, our technique is similar to that described in an unpublished study (13) of the oxidation kinetics of molybdenum in air at subatmospheric pressures. Indeed, the results of ref. (13) could be reproduced[5] in the present equipment (see Fig. 3), thereby providing a check on a portion of the present methods and, incidentally, demonstrating that the results of ref. (13) were not influenced by oxygen transport (access) limitations.[6]

Atom detection.—Basic to the inference of reaction probabilities is the determination of absolute atom concentrations in the gas mixture emerging from the microwave discharge cavity. This has been accomplished by using the so-called $NO_2(g)$ light-titration technique described in ref. (14) and (15). The method

[2] The cavity used was type 2A (foreshortened ¾ wave coaxial) as described in (10).

[3] Results agreed well with periodic checks of the diameter reduction, as obtained from direct measurements on filaments observed under a microscope.

[4] For this purpose the O_2 reaction was assumed to be independent of the O-atom reaction, merely adding to the net rate. Experimental evidence for this independence is discussed later on.

[5] Slight but systematic departures from simple "power-law" (*i.e.*, constant reaction order) kinetics are now evident at pressures above 10 Torr (see Fig. 3).

[6] In ref. (13) flow rates were left unspecified. The present results, displayed in part in Fig. 3, were verified to be flow-rate independent.

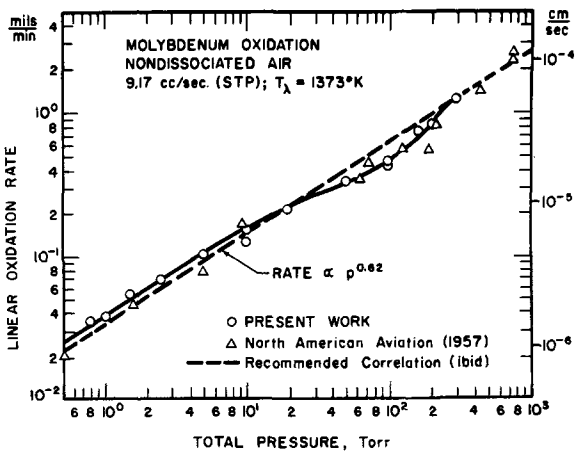

Fig. 3. Pressure dependence of the molybdenum oxidation rate in undissociated air at subatmospheric pressures; comparison with the work of ref. (13).

is a titration in the sense that one adds $NO_2(g)$ to the gas discharge products until the visible radiation (air afterglow) produced by the reaction sequence

$$O + NO_2 \rightarrow NO + O_2 \quad \text{(fast)} \quad [1]$$

$$O + NO \rightarrow NO_2 + h\nu \quad \text{(slow)} \quad [2]$$

vanishes (the titration "end point"). The $NO_2(g)$ flow rate at which this occurs is then an accurate measure of the initial O-atom flux (14, 15). $NO_2(g)$ was added through a retractable, perforated-tip Pyrex tube inserted at point C (see Fig. 1). Flow rates were determined using a critical flow orifice[7] calibrated against actual NO_2 absorption by Indicarb[8] CO_2 absorbent. At the pressure levels and flow rates investigated here, homogeneous O-atom losses by termolecular recombination or ozone production (see Discussion) between the discharge and the filament location can be ruled out on kinetic grounds, thereby eliminating the need for axial spatial resolution in the atom-detection technique. Radial gradients in the O-atom concentration are expected to be small due to the inefficiency of cool Vycor as an oxygen atom recombination catalyst (16). Moreover, the effects of any radial gradients in atom flux are minimized by the fact that only the central portion (0.55 cm) of the reacting specimen is monitored, whereas the upstream discharge tube (see Fig. 1) has an inner diameter of 1.06 cm.

Materials.—All of the data included here were obtained using commercially available polycrystalline materials. The pure molybdenum and tungsten (wolfram) filaments were cut from 0.0381 cm (15 mil) diam, high-recrystallization-temperature, drawn wire previously cleaned to remove surface oxides (Westinghouse Lamp Division, Bloomfield, New Jersey, Type A, Process C3H molybdenum and Type HRE Process C3I tungsten). The titanium-zirconium-molybdenum alloy (TZM) supplied by Sylvania Electric Products Inc., Towanda, Pennsylvania, (designation MT-104) contained 0.50% Ti, 0.099% Zr, and 0.040% C. Extra-dry-grade (Linde) oxygen, prepurified-grade argon (Linde), prepurified-grade nitrogen (Linde), high-purity-grade helium (Linde), and nitrogen dioxide (Matheson) cylinder gases were used without pretreatment.

Results—Molybdenum/Oxygen System

It is instructive to cast all experimental chemical kinetic results in terms of dimensionless reaction probabilities. In our previous work (6-9) and in the present case, this may be done without any assumptions as to the product gas species distribution[9] by introducing the oxidation probability ϵ, defined here as the ratio of the flux of molybdenum atoms (regardless of their chemical state of aggregation) away from the surface to the collision flux of O(g) or $O_2(g)$ with the surface. The molybdenum element flux, $Z''_{(Mo)}$, is obtained from the observed rate of filament radius change, the density of the filament (about 10 g/cc in the temperature range of interest), and the molecular weight of molybdenum (95.95 g/g-mole). The incident O(g) or $O_2(g)$ flux (Z''_O, Z''_{O_2}) is directly proportional to their known partial pressures and is obtained from the Hertz-Knudsen equation evaluated at the filament surface temperature[10] T

$$Z''_i = \frac{p_i}{kT} \cdot \left(\frac{kT}{2\pi m_i}\right)^{1/2} \quad [3]$$

where i = O or O_2, p_i and m_i are the partial pressure and molecular mass of species i, respectively, and k is the Boltzmann constant. It should be noted that if $Z''_{(Mo)}$ is experimentally found to be proportional to the n^{th} power of the oxygen partial pressure, where n is the reaction order, the probability ϵ reported herein will be proportional to the $n - 1$ power of oxygen partial pressure (and, hence, independent of the latter when the reaction is truly first order, *i.e.*, $n = 1$). It is also seen from Eq. [3] that the apparent activation energy locally inferred from an Arrhenius plot of ln ϵ *vs.* $1/T$ will exceed that obtained from a plot of ln $Z''_{(Mo)}$ *vs.* $1/T$ by the amount $\frac{1}{2}RT$, where R is the universal gas constant.[11]

Temperature dependence of the oxidation probability.—Figure 4, which considerably extends and supersedes the preliminary results reported in ref. (6), summarizes our data on the temperature dependence of ϵ for high-temperature molybdenum subjected to O or O_2 attack at comparable partial pressures. Except at the highest temperatures investigated (>2200°K), the O-atom reaction probability is seen to be considerably higher than that for O_2, the factor exceeding 100-fold at surface temperatures less than about 1200°K. The absolute value of the O-atom reaction probability is quite high (greater than 10^{-2} even at temperatures as low as 1040°K). Neither reaction displays simple Arrhenius behavior (constant activation energy), and neither reaction probability passes through a temperature maximum under the conditions investigated ($p_O = 10^{-2}$ Torr, $p_{O_2} = 3 \times 10^{-2}$ Torr, and $1060 < T < 2600$°K. However, as reported earlier (6), in the temperature range below about 1450°K both reaction probabilities exhibit simple Arrhenius behavior, with the O-atom activation energy (≈6 kcal/mole) being smaller than that for O_2 (26 kcal/mole) by a factor of 4.4. While the high-temperature (1680°-2620°K) branch for the O_2 reaction corresponds to an apparent

[7] Owing to the temperature-sensitive equilibrium $2NO_2(g) \rightleftarrows N_2O_4(g)$, the entire critical orifice metering system was kept immersed in a constant-temperature bath (305°K).

[8] Fisher Scientific Company, supplier.

[9] Thus, unless one is only interested in orders of magnitude, the probability ϵ introduced here should be distinguished from the fraction of the incident oxygen atoms or molecules which react. For example, if (as is often done) an author has assumed that molybdenum trioxide is the major reaction product, then ϵ (as defined here) would be larger than the reported fraction of O_2 molecules which react by the factor 3/2. More generally if α $MoO_2(g)$ molecules are produced for every $(1 - \alpha)$ $MoO_3(g)$ molecule, then the fraction of the incident O atoms which react is $[3(1 - \alpha) + 2\alpha]\epsilon$, and the fraction of the incident O_2 molecules which react is $\{[2(1 - \alpha)/3] + \alpha\}\epsilon$.

[10] At 1 Torr total pressure, under the conditions of most of the experiments reported here, the Knudsen number based on filament diameter (*i.e.*, the ratio of mean free path to filament diameter) was about 10^{-1}, the Mach number (ratio of local approach velocity to local acoustic velocity) was less than 0.6, and the Reynolds number based on filament diameter was about 10 (fluid property values are those relevant to the up-stream gas mixture). Under these conditions it is likely that approaching gas atoms or molecules make a sufficient number of collisions with other molecules (whose translational temperature has already been raised by the presence of the hot surface) to be raised to the filament temperature (see also Discussion: Absence of Transport Limitations). It should also be remarked that even if the system were isothermal and gas-phase encounters near the filament could be neglected, at the highest Mach numbers investigated here the average collision rate with the surface would not differ from the Hertz-Knudsen (Eq. [3]) by more than about 15% [see *e.g.*, ref. (7)].

[11] For example, at 2000°K the difference is 1.987 kcal/mole. This may be considerably greater than the scatter of available Arrhenius-type rate data, especially for low-activation-energy reactions.

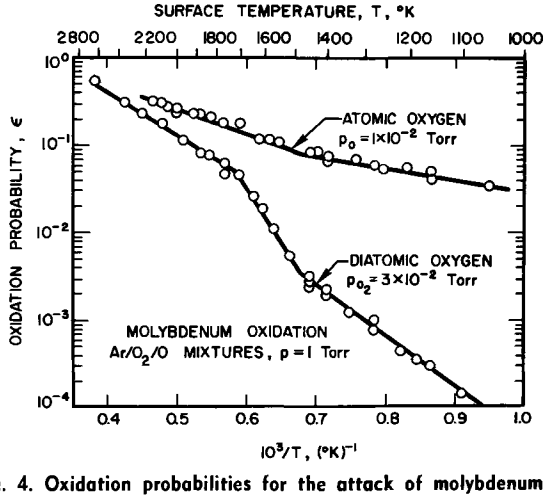

Fig. 4. Oxidation probabilities for the attack of molybdenum by atomic and diatomic oxygen; temperature dependence.

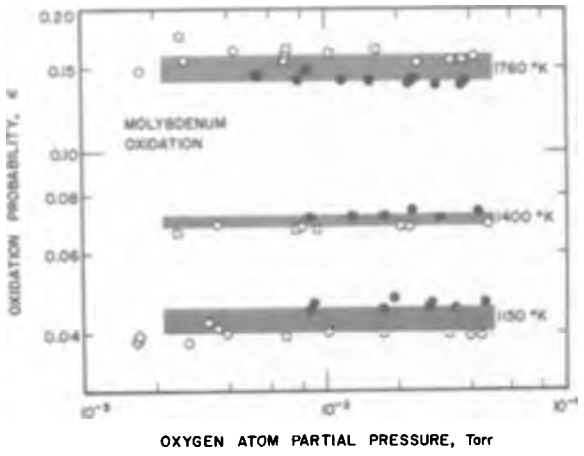

Fig. 5. Oxidation probabilities for the attack of molybdenum by atomic oxygen; oxygen pressure dependence (○ p = 1 Torr; •X_O = const., ◇ O-atoms produced from N + NO).

activation energy of 22 kcal/mole, at intermediate temperatures (≈1480°-1680°K) the apparent activation energy for this reaction is as large as ≈60 kcal/mole.

Kinetic order of the oxidation reactions.—To determine if the molybdenum reaction probabilities displayed in Fig. 4 are dependent on oxygen pressure,[12] an extensive series of constant-filament-temperature experiments was carried out. Interestingly enough, under all conditions investigated (see Fig. 5) the O-atom oxidation probability for molybdenum was found to be independent of O-atom partial pressure,[13] indicating a first-order heterogeneous reaction.

In contrast, the O-reaction probability showed a general tendency to decrease with increased O_2 pressure (see Fig. 6), indicating fractional order (typically between ½ and 1) kinetics. Moreover, the true kinetics display systematic and quite complex departures from simple power-law (straight line on log-log coordinates) behavior[14] (see Fig. 6, Table I, and the discussion below), frequently passing from an intermediate reaction order (0.57-0.66) at low O_2 pressures to a nearly first-order ($n \approx 1.04$) regime at high O_2 pressures, through an intermediate regime of very low (≈0.35) reaction order (see open points, Fig. 6 and Table I) which becomes more extensive at high filament temperatures.

[12] $O_2(g)$ data are also necessary in order to correct the O(g) + $O_2(g)$ data for the $O_2(g)$ contribution.

[13] In these experiments p_O was varied (over about a 30-fold range) in two distinct ways. In Fig. 5, results obtained at constant total pressure (1 Torr) by varying the O-atom mole fraction are shown as open circles; those obtained at constant O-atom mole fraction but variable total pressure are shown as darkened circles. Taking into account reproducibility factors in the absolute rates, the two sets of results are seen to be in substantial agreement, especially as regards reaction order. Our recent results at 1760°K using O-atoms produced from the reaction N + NO → N_2 + O (See Discussion) reveal no significant departures from first order behavior even one-decade lower in O-atom pressure than that shown in Fig. 5.

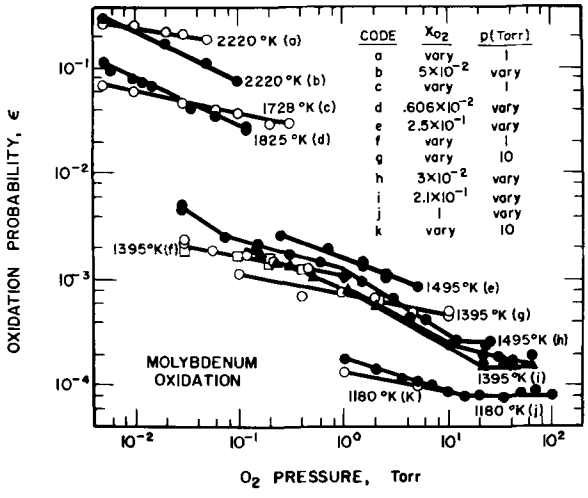

Fig. 6. Oxidation probabilities for the attack of molybdenum by diatomic oxygen; oxygen pressure dependence (open points pertain to constant total pressure; darkened points pertain to constant oxygen mole fraction; circles pertain to the carrier gas argon, triangles: nitrogen, and squares: helium).

Table I. Observed reaction orders; Mo(s)/O_2(g) reaction[a]

T, °K	p, Torr	X_{O_2}	n	Identification[a]
1180	10	0.1 to 1.0	0.80	k
1395	1	0.03 to 1.0	0.80	f
1395	10	0.01 to 1.0	0.81	g
1728	1	0.005 to 0.3	0.80	c

1495	450 to 760	0.03	1.04	h

[a] cf. Fig. 6.

An important feature of the O-atom results, not obvious from Fig. 5 alone, is that the reaction probability is independent of p_O despite the fact that the ratio p_O/p_{O_2} varied by a factor of about 10 for these experiments (6). Thus, under these conditions, O_2 plays no role in the O-atom oxidation reaction.[15] Interestingly enough, N atoms in amounts up to 1/10 of the O-atom concentration ($p_O = 10^{-2}$ Torr) did not noticeably affect the oxidation rate of 1150° and 1500°K molybdenum filaments.

O-atom attack of TZM alloy.—In view of the practical importance of the refractory metal alloys, exploratory experiments on the O-atom attack of TZM (0.5% Ti-0.1% Zr-molybdenum alloy) were carried out to determine if the oxidation rates are significantly different from those reported above for pure molybdenum. Interestingly enough, in all cases examined ($T \approx$ 1400°K and 2020°K, $p_O = 2.35 \times 10^{-2}$, or p_{O_2} = 1 Torr) the observed oxidation rates were within about 15% of the corresponding rates for pure molybdenum. This implies that unprotected TZM will likewise exhibit significantly reduced oxidation resistance in partially dissociated gaseous environments similar to those investigated here.

Results—Tungsten/Oxygen System

Similar experiments, but over a somewhat more restricted temperature range (≈1400°[16] to 2600°K) have been carried out on the oxidation kinetics of tungsten filaments, again with special emphasis on the effects of oxygen dissociation. In an analogous way, we define the oxidation probability ε as the ratio of the flux of tungsten atoms (regardless of their chemical state of aggregation) away from the surface to the collision flux of O(g) or O_2(g) with the surface. Here we use 19 g/cm³ as the mean density of the W(s)

[14] One interesting feature, discussed briefly in ref. (18) and evident in Fig. 6, is that experiments at constant pressure (variable O_2 mole fraction) lead to higher apparent reaction orders (≈0.80-0.82) than corresponding experiments at variable pressure (constant O_2 mole fraction, as in air; cf. Fig. 3), an effect which seems to be independent of whether the carrier gas is helium, nitrogen, or argon. As noted in ref. (18), this accounts for the apparently discrepant results reported for the Mo(s)/O_2(g) reaction in ref. (13) and by Berkowitz *et al.* (19), and Gulbransen *et al.* (20).

[15] A similar conclusion has been reached by Fryberg (21) for the O-atom attack of platinum.

[16] While filament temperatures lower than 1400°K are well within the pyrometer capability, for this reaction reliable measurements at such temperatures were precluded by the formation of thick tungsten oxide films on the reacting filaments.

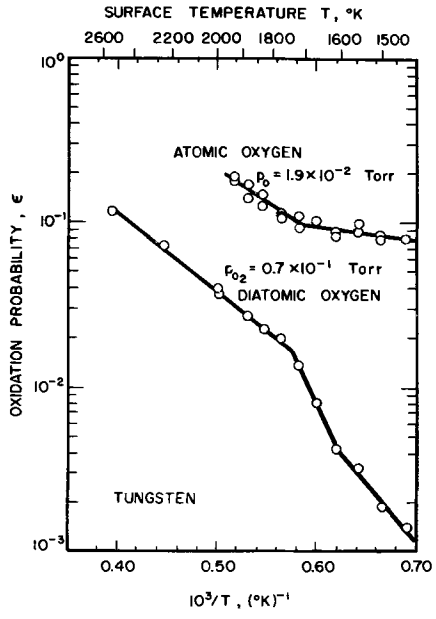

Fig. 7. Oxidation probabilities for the attack of tungsten by atomic and diatomic oxygen; temperature dependence.

filament material in the temperature range of interest and the tungsten molecular weight of 183.92 g/g-mole.

Temperature dependence of the oxidation probability.—An Arrhenius plot of our tungsten oxidation rate data is shown in Fig. 7,[17] which is qualitatively similar to the molybdenum plot shown in Fig. 4. Again, particularly at low surface temperatures (say <1700°K), metal atom removal per O-atom strike is much more likely than for an O_2 strike, the difference attaining a factor of about 56 (if the oxygen pressure were $p_O = 0.7 \times 10^{-1}$ Torr) at 1450°K. In this temperature range the O-atom oxidation probability is seen to be large in absolute value (of the order of 1/10) and weakly temperature dependent (apparent activation energy ≈ 4 kcal/mole). The corresponding apparent activation energy for O_2 below 1600°K is about 32 kcal/mole, in agreement with lower O_2-pressure data of Langmuir (24) and Eisinger (25).[18] Above about 1750°K (in the present case) the O_2 data exhibit a somewhat reduced temperature sensitivity (≈ 24 kcal/mole), in good agreement with data reported by Perkins, Price, and Crooks (28), and Walsh (29) at comparable O_2 pressures and temperatures. The absence of a maximum in the true reaction probability at temperatures below 2600°K when p_{O_2} is as large as 0.7×10^{-1} Torr (see Fig. 7) is also consistent with the observations of these authors and Singleton (see footnote below). As will be discussed (see Discussion Section on Mechanistic Considerations) the enhancement in oxidation rate due to dissociation (Fig. 7) is expected to be greatest at the "high" oxygen pressures[19] employed in the present work.

Kinetic order of the oxidation reactions.—The oxygen-pressure dependence of the tungsten reaction probabilities was investigated with results similar to those already reported for molybdenum. As displayed in Fig. 8, the O-atom attack was found to be first order (ϵ independent of p_O) over more than a decade change in O-atom partial pressure. We conclude that the reaction probabilities shown in Fig. 7 for the case $p_O = 1.9 \times 10^{-2}$ Torr would remain invariant with at least comparable changes in O-atom pressure.[20]

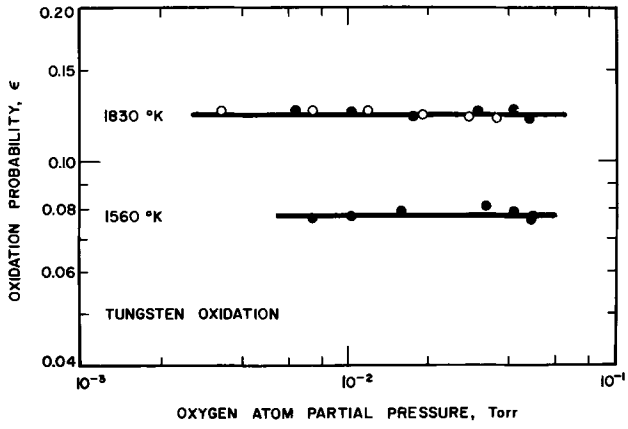

Fig. 8. Oxidation probabilities for the attack of tungsten by atomic oxygen; oxygen pressure dependence (○ p = 1 Torr; •X_O = const.).

Once again, the corresponding O_2 reaction displays fractional-order behavior (see Fig. 9, on which the apparent reaction order for each set of data is given) with complexities similar to those appearing in Fig. 6.[21]

Discussion

Identity of the active species.—Since electronically and vibrationally excited states can be produced in gas discharges, it is essential to prove that our O-atom attack data are not falsified by the enhanced reactivity that might be associated with such excitation. Based on the evidence presented below, we have concluded that the observed reactivity of the oxygen passed through the microwave discharge is due to the presence of ground-state O(^{3}P) atoms.[22]

First, using molybdenum filaments at 1150°K, we have shown that O atoms ($p_O \approx (1.5\text{-}3) \times 10^{-3}$ Torr, as determined by the NO_2 or NO light titration tech-

[19] Preliminary experiments have also been carried out to determine whether the simultaneous presence of N atoms affects the O-atom oxidation probability. No such effect was observed for an 1800°K tungsten filament when $p_O = 0.8 \times 10^{-2}$ Torr, $p_N = 4 \times 10^{-3}$ Torr.

[20] In particular, departures from simple power law (constant reaction order) behavior are observed, and constant-pressure experiments again tend to give higher apparent reaction orders than those carried out at a constant O_2 mole fraction.

[22] Conversely, the use of such filaments or thin films for inferring O-atom concentrations in novel environments is currently under investigation at this laboratory.

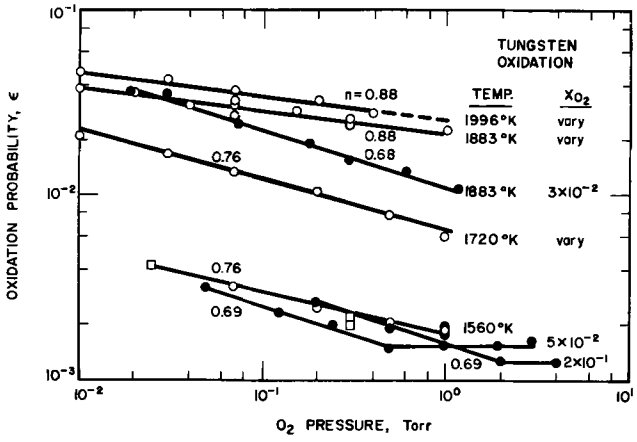

Fig. 9. Oxidation probabilities for the attack of tungsten by diatomic oxygen; oxygen pressure dependence (○ p = 1 Torr; •X_{O_2} = const.; □ carrier gas = helium; n = observed reaction order).

[17] Which corrects and supersedes the corresponding unpublished data reported in ref. (22) and (23).

[18] J. Singleton [J. Chem. Phys., 45, 2819 (1966)] has recently reported an activation energy of 33 kcal/mole at surface temperatures below 1500°K and at O_2-pressures between 10^{-3} and 10^{-5} Torr, in good agreement with ref. (24, 25) and the higher pressure data reported here. Gulbransen *et al.* (26) have reported 14.3 kcal/mole for this reaction; however, it is readily demonstrated that the data contained in ref (26) are subject to appreciable systematic errors due to the presence of diffusional limitations on the observed rates. Oxidation probabilities calculated from the correlation equation suggested in ref. (27) are appreciably lower than the data shown in Fig. 7 for the same reason.

[19] Compared with those which characterize most mass spectrometer studies of oxidation kinetics (<10^{-3} Torr).

nique) produced in two quite different ways yield the same results. One method, already discussed in some detail above, is to pass a microwave discharge through an Ar-O_2 mixture to produce O atoms directly. The second method (30, 31) is indirect in that N atoms are first produced in a pure nitrogen discharge, from which O atoms are produced upon downstream introduction of nitric oxide (via the rapid bimolecular reaction $N + NO \rightarrow N_2 + O$). Experimental results using this indirect technique for producing O atoms are shown as open diamonds (◇) in Fig. 5. Since the concentrations of excited atomic and diatomic oxygen are expected to be totally different in these two environments,[23] it is significant that the resulting oxidation rates agreed to within better than 10%.

Second, we have investigated the possibility of excited-molecule attack by introducing an oxidized silver foil upstream of the molybdenum filament when the microwave discharge was on. This foil recombines the O atoms produced in the discharge but admits electronically excited $O_2(^1\Delta_g$ and $^1\Sigma_g^+)$ molecules (33) (abbreviated hereafter as O_2^*). Similar experiments were carried out using HgO(s) mirrors which, from the work of ref. (33), not only preferentially remove O atoms but actually enhance the O_2^* concentration. Preliminary measurements showed that the reaction probability for O_2^* in the temperature range $1050° < T < 1500°K$ was somewhat greater than for ground-state O_2 but negligible compared to the O-atom probability, thereby validating our previous measurements and their interpretation.

Third, the very fact that the observed oxidation rates of molybdenum and tungsten increased linearily with O-atom partial pressure as inferred from the NO_2 light titration technique (see Fig. 5 and 8) constitutes further evidence (indirect) that excited oxygen molecules play a negligible role in the present work. These experiments cover about a 30-fold range of initial O_2 mole fractions (prior to discharging) and were carried out at microwave power levels from about 30 to 90% of full power. If excited oxygen molecules played a significant role in the observed kinetics, it is unlikely that simple first-order behavior would have been observed over the resulting range of $[O_2^*]/[O]$ ratios.

Finally, as suggested earlier (*cf.* Experimental-Atom Detection Section), the steady-state ozone concentrations resulting from the termolecular reaction $O + O_2 + Ar \rightarrow O_3 + Ar$ followed by $O + O_3 \rightarrow 2O_2$ [rate constants for which have been critically reviewed by Kaufman (14)] are of the order of only one-thousandth of the O-atom concentrations reported here. Hence, ozone production by 1-Torr microwave discharges through dilute O_2/Ar mixtures can be neglected safely.

Absence of transport limitations.—At pressures of technical interest, one of the many pitfalls in kinetic investigations of rapid heterogeneous reactions forming volatile products is that the observed reaction rates may be falsified (34-36) in part by oxygen supply and product molecule escape limitations in the immediate vicinity of (*i.e.*, diffusion "boundary layers" adjacent to) the reacting surface.[24] As demonstrated below, despite the efficiency of the high-temperature molybdenum and tungsten oxidation reactions, these difficulties have been avoided in the present work owing to the combined choice of high flow rates, small specimen size, and subatmospheric total pressure. Consequently, the observed departures of the molybdenum and tungsten oxidation probabilities from simple Arrhenius and power-law behavior are believed to be true kinetic phenomena, characteristic of the temperature and oxygen pressure levels investigated herein, and are not peculiar to this particular reactor configuration or choice of experimental techniques.

Two types of experiments have been used to rule out diffusional phenomena. One type consists of verifying that the observed reaction rates are independent of gas flow rate, as they should be if the kinetically controlled asymptote has been achieved.[25] Checks of this type were made[26] over the entire range of conditions for which data are reported herein, with particular attention to the high-temperature/high-pressure regime.[27] The onset of a flow rate dependence, in fact, dictated the high-temperature cut-off of the O-atom reaction probability data (see Fig. 4 and 7).

The other check for the absence of diffusional limitations, extensively used in the case of the O_2-oxidation reactions, was to verify that the observed oxidation rates were independent of the identity of the carrier gas (helium, nitrogen, or argon). Points appropriate to each of these carrier gases are superposed on Fig. 6 and 9 (see figure caption for coding). Despite the wide differences in molecular weight and effective "size" (cross section) of these molecules, the observed rates are seen to depend only on the O_2 pressure[28] and surface temperature, thereby ruling out transport limitations and demonstrating that these gases are true "inerts" with respect to the interfacial reactions studied herein.

Mechanistic considerations.—To anticipate oxidation rates under dissociated gas and temperature conditions other than those experimentally investigated here and for refractory metals other than molybdenum and tungsten, it is necessary to inquire into the mechanism underlying the striking increase in reactivity upon dissociation observed in the present work. Owing to the qualitative similarities in the results and properties of the two metals, it appears possible to discuss the molybdenum and tungsten oxidation kinetics jointly.

An intriguing feature of the observed kinetics is the comparative simplicity of the O-atom attack reactions, as revealed especially in the reaction order (*cf.* Fig. 5 and 6, 8 and 9). Indeed, the O-atom and O_2 attack data are so different in character one suspects that the two mechanisms have rather little in common. This would be fortunate since the task of rationalizing all kinetic subtleties of the Mo(s)/O_2(g) and W(s)/O_2(g) reactions is formidable and will not be attempted here. Suffice it to say that the O_2 data presented in Fig. 4, 6, 7, and 9 and previous work on the Mo(s)/O_2(g) and W(s)/O_2(g) reactions [1] to [3]; (which includes product distribution measurements) suggest a Langmuir-Hinshelwood-type mechanism (38). This means that product formation-desorption is the result of the mutual encounter of chemisorbed species,[29] the surface population of which is largely

[23] Indeed, O_2 is absent when N + NO technique is used.

[24] A distressing amount of "kinetic" data obtained in low-flow-rate furnace/microbalance devices or on electrically heated specimens located in quiescent (stagnant except for natural convection currents) oxidizing atmospheres are of limited value either because the role of diffusional limitations in determining the true local oxidizer concentration has not been appreciated, or "corrections" have been made based on theoretical models which account for only a fraction of the complicating phenomena (18).

[25] Strictly speaking, this is a necessary but insufficient condition since cases have been recorded in which (local) independence on flow rate (or "stirring") is a peculiarity of the flow system, *e.g.*, due to a drop in stirrer efficiency at high speeds (37).

[26] Double logarithmic (scale) plots must be used for this purpose. It is often argued that flow rate effects are absent based on a plateau-tendency exhibited on linear reaction rate *vs.* flow rate coordinates. However, a fractional power law, which is typical, even for diffusion-controlled reactions, is easily mistaken for a plot showing a true plateau, particularly in view of the scatter inevitable in limited, high flow rate kinetic data.

[27] Incidentally, the absence of flow rate and carrier gas identity effects also constitutes evidence that (owing to a sufficient number of collisions in the gas phase) the gas is brought up to the surface temperature at the time of reaction. The kinetic data reported here are thus relevant to the filament temperature, and not the ambient temperature of the upstream gas.

[28] For the O_2 reaction, however, a systematic dependence on total pressure has been observed (see Fig. 6 and 9, and the corresponding caption footnotes).

[29] Some chemisorbed O atoms are assumed to be strongly bound (*i.e.*, the "first" layer) and some comparatively weakly bound (the "second" layer). The true reaction probability passes through a maximum and decreases with further increases in surface temperature only when the surface has been denuded of the second layer and begins losing its first layer (1-3).

determined by a balance between dissociative adsorption and evaporation processes.

If one retained this view, the observed effect of prior dissociation on the reaction probability could be postulated to be due largely to an increased sticking probability and, hence, increased steady-state adatom coverage, *i.e.*, once an atom is adsorbed, its average residence time on the surface and the remaining elementary events leading to product formation would be similar to those in the O_2 case. While this mechanism cannot be ruled out completely as a contributor, it is difficult to reconcile it with the observed pressure-independent and temperature-insensitive O-atom reaction probability, and hence it is considered unlikely as the dominant mechanism.

Instead, we have postulated (6) that an entirely different route, of the so-called Rideal-type, [see *e.g.* ref. (38)] becomes available in the presence of ambient atomic oxygen, *i.e.*, a mechanism in which the reaction step on the surface involves an oxygen atom coming directly from the gas phase (not chemisorbed at the time of activated complex formation/reaction) striking adsorbed oxygen or metal suboxides. The metal oxide (MO_2, MO_3, . . .) complex thus formed[30] on the surface either evaporates as a stable product molecule (thereby contributing to the oxidation rate) or decomposes on the surface, liberating $O_2(g)$ (equivalent, therefore, to surface-catalyzed atom recombination). This mechanism can produce a high, p_O-independent reaction probability over a wide temperature range (see Fig. 4 and 7), since the dominant processes by which O atoms are removed from the "second" layer (*viz.* reaction or recombination immediately following an O-atom strike) are linear in O-atom pressure, as is the temperature-insensitive chemisorption rate. The adatom concentration is thus maintained at a high level in the presence of O(g), a situation which favors a high probability of sufficiently "direct" hits. In contrast, while the steady-state adatom concentration is also high at the lower temperatures investigated here for the O_2 reaction, the O_2 reaction probability drops sharply at these temperatures due to a combination of low sticking probability and surface mobility-activation energy requirements implicit in any Langmuir-Hinshelwood scheme. Hence, the mechanism described above is consistent with our finding that enhanced reactivity due to dissociation is most noticeable at the lower end of the temperature range (*cf.* Fig. 4 and 7). It is also interesting to note that, according to this mechanism, we would not expect a large oxidation rate enhancement due to dissociation at temperatures and pressures such that the metal surface is relatively bare, for under these conditions the O_2-sticking probability is itself high (3, 4) and, moreover, when O atoms are used as the oxidizer, the chance for "direct" hits by O-atoms on (near) adsorbed oxygen becomes small.[31]

Another interesting implication of the proposed mechanism (6), which warrants further investigation, is that it predicts the likelihood of an intimate relationship between the oxidation and recombination probabilities on the same surface. This is a consequence of the fact that both rate processes should depend on adatom coverage in the same way; hence, one would expect the ratio of ϵ to the recombination probability γ to be temperature dependent only.[32] By comparing the electrical power required to maintain the filament at prescribed temperatures both in the absence and presence of the electrical discharge we have made measurements of the sum of the recombination and oxidation heating of molybdenum filaments in the temperature range 1050°-1500°K, at O-atom pressures between 0.66×10^{-2} and 2.2×10^{-2} Torr. However, until a detailed knowledge of the product distribution[33] (and accurate thermochemical data) become available, calorimetric data alone cannot provide reliable absolute values for the recombination coefficient.

With regard to surface-catalyzed oxygen-atom recombination, which is itself a strongly exothermic process,[34] it should be remarked that the enhanced rate of metal removal in partially dissociated oxygen cannot be due to thermally induced "sputtering"[35] of molybdenum and tungsten due solely to localized heating. Thus, while these same metals also catalyze (to a comparable extent) the recombination of nitrogen atoms (40) [which give up 225 kcal/mole $N_2(g)$ formed] metal removal is negligible when electrically heated filaments are maintained in the presence of an electrical discharge through N_2 or Ar/N_2 mixtures. Metal removal is thus fundamentally associated with the formation of metal-oxygen chemical bonds, which undermine the strength with which the metal atoms involved are held in the lattice at the surface.

Finally, it seems likely that the kinks observed in the Arrhenius diagrams (Fig. 4 and 7) are related to shifts in the identity of the dominant product molecule (1, 2) and/or the state of oxide coverage on the surface[36] as opposed to structural changes in the polycrystalline filament material itself. Thus, while the low-temperature transitions observed for both molybdenum and tungsten happen to be in the recrystallization temperature range for these materials,[37] low-tem-

[30] Here M represents either a molybdenum or tungsten atom.

[31] Indeed, Schissel and Trulson (2) recently reported the results of a preliminary experiment revealing no significant difference in the reactivity of O(g) and $O_2(g)$ on tungsten at pressures below 10^{-4} Torr, presumably at surface temperatures higher than that at which the oxidation probability passes through is maximum. Regarding our postulated mechanism, it should be remarked that if (at sufficiently high temperatures) the monoxide, MO, becomes a significant reaction product, "direct hits" may not be necessary.

[32] While direct measurements of γ have not yet been made on oxidizing filaments, it should be remarked that the present measurements provide an upper bound to γ. This follows from the fact that an incident atom can either react, reflect, or recombine; hence, the sum of these probabilities (when suitably defined) must be unity and γ cannot be larger than the value calculated assuming zero reflection probability. For the case of only metal dioxide and trioxide formation, this leads to the bound:

$$\gamma \leq 1 - [3(1 - \alpha) + 2\alpha]\epsilon$$

which becomes $\gamma \leq 1 - 2\epsilon$ when only the metal dioxide is formed. Since ϵ has already approached ½ for O-atom attack of molybdenum at $\approx$ 2200°K (see Fig. 4), this suggests that oxidation becomes the dominant reaction path at high filament temperatures. Similar data for the C(s)/O(g) reaction (7, 8) and the Mo(s)/Cl(g), Ni(s)/Cl(g) reactions (9) indicate that the tendency for product formation to increase relative to atom recombination at high surface temperatures is common.

[33] The fact that the observed sum of the oxidation and recombination heating increases at low temperatures and then passes through a maximum near 1300°K suggests but does not prove that for the Mo(s)/O(g) reaction there is a transition from the dominant product $MoO_3(g)$ to the less exothermic formation of $MoO_2(g)$ in this temperature range.

[34] The O_2 bond dissociation energy ($\approx$118 kcal) is released on formation of one mole of O_2 from two moles of O atoms. For comparison, the molar heats of sublimation of molybdenum and tungsten are 155.5 kcal and 202.7 kcal, respectively, at 298.16°K (39), although it should be kept in mind that these latter values are not the strengths of individual (single) metal-metal bonds at the surface.

[35] Ordinary metal evaporation, or metal evaporation followed by gas-phase oxidation, is ruled out by the fact that the observed metal removal rates far exceed even the vacuum evaporation rates of these materials (by some 5 decades for molybdenum at 2000°K). These possibilities are also inconsistent with the observed dependence of the metal removal rates on surface temperature and the invariance under changes in gas flow rate (see Discussion, Absence of Transport Limitations).

[36] Initial encouragement for this view came from the fact that for the Mo(s)/O_2(g) reaction the low-temperature break occurs at about the temperature one would expect the product $MoO_3(g)$ to be in equilibrium with $MoO_2(s)$. For this calculation the $MoO_3(g)$ "kinetic" pressure adjacent to the filament was estimated directly from the observed reaction rate, whereas the $MoO_3(g)$ pressure in equilibrium with $MoO_2(g)$ was obtained from the Knudsen cell data of Blackburn *et al.* (41). We have also observed an emittance change at this temperature. However, similar calculations for the Mo(s)/O(g) reaction and the corresponding tungsten oxidations fail to produce similar agreement. In retrospect, even limited agreement is probably fortuitous, since the relevance of thermodynamic data on bulk oxides is open to question when one is dealing with surface oxides of molecular dimensions.

[37] Neither pure molybdenum nor pure tungsten (both body-centered cubic metals) undergo high-temperature phase transitions.

perature oxidation rate data on annealed filaments, *i.e.*, wires heated well above their recrystallization temperature for more than 5 min, failed to show significant filament annealing effects in either O_2 or O atoms. Moreover, it is inherently unlikely that (all else being equal) recrystallization and stress relief would give rise to higher probabilities as observed (see Fig. 4 and 7) on a temperature increase. For the W(s)/O_2(g) reaction it should be remarked that the high-temperature break, *i.e.*, reduction in apparent activation energy, shown in Fig. 7 is quite similar to that reported in ref. (28).

Homogeneous thermal dissociation.—At temperatures as high as 2600°K (see Fig. 4 and 7) and at p = 1 Torr the extent of O_2 dissociation predicted thermodynamically is appreciable. Indeed, based on the equilibrium constant at 2600°K (42): $[p_O p_{O_2}^{-1/2} = 10^{-1.636}$ $(atm)^{1/2}]$, the gas wetting the filament could attain an equilibrium O-atom partial pressure of 4.75×10^{-2} Torr,[38] even in the absence of a microwave discharge. At first sight, this casts doubt on the significance of the data in "undissociated oxygen" at these elevated filament temperatures (see Fig. 4 and 7). However, using reasoning similar to that given in ref. (9), we conclude that, while a sufficient number of collisions occur to ultimately raise the gas temperature to the filament temperature, not enough time is available for appreciable homogeneous O_2 dissociation in the immediate vicinity of the heated filament. Thus, if we compare the average residence time for a molecule within the thermal layer of the filament (at most, of the order of $d^2/D_{O_2\text{-}Ar}$, where d is the filament diameter and $D_{O_2\text{-}Ar}$, is the O_2-Ar Fick interdiffusion coefficient) with the characteristic time $(k_{d,Ar} n_{Ar})^{-1}$ for homogeneous O_2 dissociation (where $k_{d,Ar}$ is the appropriate dissociation rate constant,[39] and n_{Ar} is the argon number density), we find that the residence time is too small by more than six orders of magnitude. It seems reasonable to conclude that, even at the highest filament temperatures investigated here, O atoms were effectively absent as a potential reactant in all oxidation experiments carried out with the electrical discharge off.

Conclusions

Based on the experimental data and the foregoing discussion, the following conclusions may be drawn:

1. Using a microwave-discharge, subatmospheric-pressure, fast-flow system and resistance heating-monitoring of small (filament) specimens, it has been possible to study the true kinetics of rapid molybdenum and tungsten oxidation by both atomic and diatomic oxygen at partial pressures greater than 10^{-3} Torr and at temperatures in the approximate range 1000°-2600°K. Under these conditions the oxidation reactions are not falsified by oxygen transport limitations and proceed at constant (time-independent) rates, as expected for reactions forming volatile (nonprotective) products. Moreover, owing to the occurrence of an adequate number of gas-phase collisions in the immediate vicinity of the specimen, the data pertain to the most important case in which the translational temperatures of the incident (reactant) species and surface are essentially equal.

2. Oxygen dissociation causes a striking increase in the reaction probability, particularly at the lower end of the temperature range investigated here. For molybdenum and TZM alloy the enhancement is greater than two orders of magnitude at temperatures less than about 1200°K. For tungsten the corresponding enhancements are lower, the maximum observed being a factor of about 56 at 1450°K. Consistent with the reduction in apparent activation energy caused by oxygen dissociation, the O and O_2-reaction probabilities tend to become comparable at the highest temperature investigated (>2000°K), where the O_2-reaction probabilities themselves exceed 10^{-1} (see Fig. 4 and 7).

3. Whereas the O_2-attack reactions display a rather complex (fractional order) oxygen partial pressure dependence (see Fig. 6 and 9), the O-atom attack of both molybdenum and tungsten is found to be first order, corresponding to an oxidation probability which is independent of O-atom partial pressure (see Fig. 5 and 8) in the range 10^{-3} to 5×10^{-2} Torr.

4. Experiments in which atomic oxygen is produced in two distinct ways, and in which excited oxygen molecules are preferentially removed or enhanced upstream of the reacting filament, demonstrate that the observed reactivity of microwave-discharged O_2-Ar mixtures is due to the presence of ground state: O(^{3}P) atomic species. O_2 appears to play no essential role in the kinetics of these atom/metal reactions.

5. The large observed reaction probability, reduced activation energy, and first-order kinetics strongly suggest that the enhanced reaction probability exhibited by O-atoms is due to direct attack from the gas phase by a Rideal-type mechanism rather than merely the result of a Langmuir-Hinshelwood mechanism with an increased steady-state oxygen adatom coverage associated with increased sticking probability. Two interesting consequences of this mechanism (route) meriting further investigation are (*a*) an intimate relationship should exist between the oxidation and atom recombination probabilities on the same surface (6) and (*b*) significantly enhanced reactivity due to dissociation should disappear at temperatures and oxygen pressures such that an appreciable portion of the metal surface is bare (zero second layer coverage and partial first layer coverage).

Acknowledgments

It is a pleasure to acknowledge the extensive advice and assistance of Dr. A. Fontijn in the areas of excited species generation/detection/reactivity, the helpful criticism of Dr. S. C. Kurzius and other members of the laboratory staff, the assistance of A. Chiarello and A. D. Freda with a portion of the experiments, and W. W. Brenner with the microwave and other electrical instrumentation. The senior author also wishes to thank Dr. G. C. Fryberg (NASA) and Dr. J. Berkowitz-Mattuck (A. D. Little) for their helpful correspondence and interest in the present work. The authors are especially indebted to the Propulsion Division of the U.S. Air Force Office of Scientific Research for their sustained interest and financial support under Contracts AF 49(638)-1195 and AF 49(638)-1637; Lieutenant Colonel C. J. Donovan, Scientific Officer).

Manuscript received July 2, 1966; revised manuscript received Dec. 15, 1966. This paper was presented at the Philadelphia Meeting Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX

Oxygen Dissociation Produced by Hypervelocity Motion through the Earth's Atmosphere

While subsonic vehicles (*e.g.*, conventional aircraft) produce negligible chemical changes in the air through which they move, the kinetic energy represented by a hypersonic vehicle (*e.g.*, a reentering spacecraft or ballistic missile) is comparable to the dissociation energy of oxygen and (even) nitrogen molecules present in undisturbed air. As a result, even at low altitudes significant oxygen-atom concentrations are produced by the deceleration of air relative to such vehicles, a fact which must be considered in designing their heat protection systems.

Actual O-atom partial pressures experienced at a vehicle surface depend strongly on the altitude-ve-

[38] Compared to $p_O = 1 \times 10^{-2}$ Torr and 1.9×10^{-2} Torr, used in the molybdenum and tungsten oxidation experiments, respectively.

[39] An upper limit of $k_{d\text{-}Ar} \approx 10^{-17}$ cm^3 molecules^{-1} sec^{-1} can be estimated by extrapolating the 10% O_2-Ar shock tube data of Schexnayder and Evans (43) down to 2600°K.

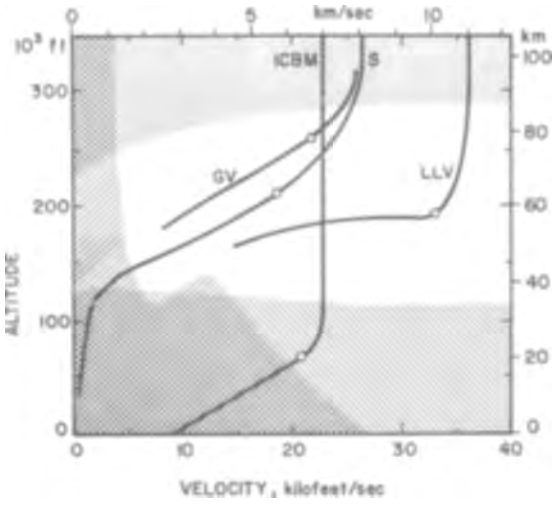

Fig. 10. Oxygen atom nonequilibrium regimes[44] encountered during the reentry of manned and unmanned vehicles into the Earth's atmosphere: ICBM = intercontinental ballistic missile, S = satellite, GV = glide vehicle, LLV = lunar lifting vehicle.

locity history ("trajectory") of the particular vehicle, as well as its over-all size. Typical trajectories for several classes of vehicles are shown in Fig. 10,[40] together with (*a*) (shaded) regions in which one can rule out appreciable O-atom concentrations for various reasons (outlined below) and (*b*) points (open circles) on each trajectory at which the conditions of aerodynamic heating are most severe. In the odd-shaped shaded region to the left (*i.e.*, low velocity), the vehicle kinetic energy is insufficient to thermodynamically produce appreciable oxygen-atom concentrations at the prevailing pressures. In the upper (high-altitude) shaded region the energies are sufficient, but the rates of dissociation are inadequate for bodies in the size range of aerospace interest. In the lower (low-altitude/high-density) shaded region, O atoms produced in the high-temperature regions of the flow undergo a sufficient number of termolecular encounters in the cooler gas regions near the surface to recombine (reforming O_2) in the gas phase. The remaining (unshaded) region is still seen to be quite

[40] This figure, a more detailed version of which is discussed from the point of view of aerodynamic heating in ref. (44), displays the trajectories of two ballistic (without aerodynamic lift) vehicles [earth satellite (S) and intercontinental ballistic missile (ICBM)] and two "lifting" vehicles [glide vehicle (GV) and lunar lifting vehicle (LLV)] differing widely in their initial (entry) speed. As a specific case of interest here, four recent Air Force (ASSET-ASV) glide test vehicles were boosted to altitudes of 196-212 kft at velocities of 16-19.5 kft/sec.

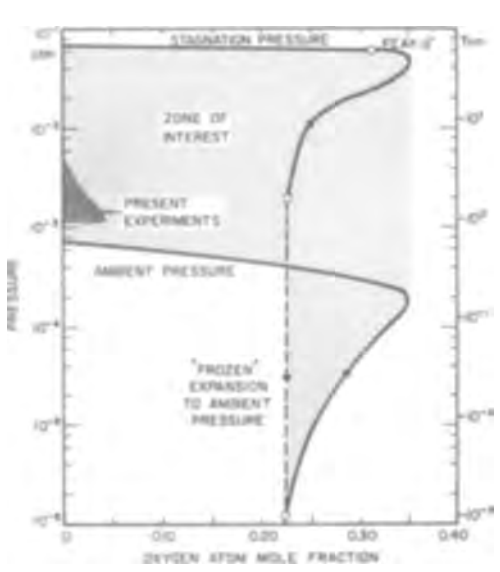

Fig. 11. Pressures and oxygen-atom concentrations simultaneously experienced during the reentry of vehicles with aerodynamic lift.

large, in fact we note that, of the vehicles shown, all but the ICBM experience peak heating rates under conditions such that high nonequilibrium oxygen-atom concentrations will be present.

For definiteness, let us now focus on the glide reentry vehicle (GV) since such vehicles are likely to make extensive use of the refractory metals of interest in the present investigation. Over its trajectory one can estimate the pressures and oxygen atom-mole fractions encountered at various points along the surface. Typical results are displayed in Fig. 11 for two extreme locations, *viz.*, the forward stagnation point or leading edge (at which the highest local pressures are experienced) and a point back along the surface at which the static pressure has dropped to that prevailing in the undisturbed atmosphere. All of the conditions shown shaded[41] are thus experienced at intermediate locations on the surface and hence are also of interest. While the resulting range of O-atom pressures far exceeds the capability of any one experimental technique, it is noteworthy that the techniques exploited in the present work provide true kinetic data within the region of interest (cf. Fig. 11). Moreover, owing to the comparative simplicity of the O-atom kinetics (*cf.*, Fig. 5 and 8) the present results can be extrapolated with respect to reactant partial pressure with greater confidence than those pertaining to O_2. Hence, the present work, and measurements currently in progress, enable rational estimates to be made of the consequences of bare metal exposure (*e.g.*, protective coating failure or deliberate transient use) in the reentry environment.

Contribution to the Mn-O Phase Diagram at High Temperature

A. Z. Hed[1] and D. S. Tannhauser

Department of Physics, Technion—Israel Institute of Technology, Haifa, Israel

ABSTRACT

Part of the phase diagram of the system Mn-O was determined in the temperature range 1100°-1800°C, and the range of oxygen partial pressure 1 atm $\leq P(O_2) \leq 10^{-19}$ atm. Data are presented of the ratio O/Mn within the MnO phase and of some of the boundaries of this phase. The data are based on a combination of thermogravimetric and electrical measurements and on direct observation of the melting oxide in the furnace.

Numerous investigations have been reported dealing with various aspects of the Mn-O system; however, none of them give a comprehensive account of the temperature-pressure-composition relations in the system Mn-O.

MnO, Mn_3O_4, Mn_2O_3, and MnO_2 are known to exist as stable crystalline phases and can be converted into each other by a suitable choice of temperature and oxygen partial pressure. Our work is concerned only with the oxides MnO and Mn_3O_4. MnO is generally assumed to deviate from stoichiometry, but there are large discrepancies between the quantitative data available for the various equilibria. This may be due partly to the fact that the equilibria states have been estimated by the combination of heat of formation and entropy data, each of which has a considerable limit of error, and partly to the fact that all data pertaining to the high-temperature region were measured after quenching the samples to room temperature.

Millar (1), Le Blanc and Wehner (2), Shomate (3), Moore, Ellis, and Selwood (4), and Hahn and Muan (5) investigated the composition of Mn_3O_4. Le Blanc and Wehner found Mn_3O_4 near 400°C to deviate considerably from stoichiometry, it being an excess oxygen compound. The other investigators who studied Mn_3O_4 at $T \geq 1000$°C found that it is practically stoichiometric.

The MnO phase was studied by Davies and Richardson (6) and in ref. (2, 4, 5). Davies and Richardson give quantitative data, while the other authors concluded only that the composition varied with the condition of preparation without quoting numbers.

The melting point of Mn_3O_4 has been reported by Hahn and Muan (5) as 1540°C in equilibrium with MnO and as 1567°C in air. Wartenberg *et al.* (7) reported the mp as 1590° ± 20°C, without specifying the atmosphere.

No measurements of the melting point of MnO as function of oxygen partial pressure were made. However, Singleton *et al.* (8) reported the value 1815° ± 7°C as the melting point of MnO in purified helium, and Glasser (9) deduced a melting point of 1850°C by extrapolation from the system MnO-SiO_2.

Experimental Technique

Two samples of manganese metal in the form of thin plates (Johnson-Matthey spectrographic stand-

[1] Present address: Battelle Memorial Institute, Columbus, Ohio.

ard), chemically thinned to 0.3 mm, were suspended in a vertical furnace. One sample was used to measure the electrical conductance, G, of MnO; the other, which weighed about 1g, served to determine the deviation from stoichiometry through thermogravimetric measurements. Mixtures of either O_2 and argon or CO_2 and CO flowed through the furnace at 0.7 cm/sec, the partial pressures of oxygen, $P(O_2)$, being calculated from the free energies of formation given by Coughlin (10). The manganese metal was oxidized for more than 12 hr at 1100°C in a flowing mixture of 100 parts CO_2 to 1 part CO, and the samples were then fired in various atmospheres

$$\left(20 \leq \frac{P(CO_2)}{P(CO)} \leq 100\right)$$

at 1550°C for 2 hr. The oxidation temperature was chosen to prevent melting of the metal [mp 1244°C (11)] before oxidation. At temperatures higher than 1350°C equilibrium of the samples with the atmosphere was established in less than 10 min after $P(O_2)$ was changed. The equilibrium times at temperatures lower than 1200°C were longer than 1 hr. Constancy of the resistance of the samples indicated the equilibrium state.

The conductance G was measured by a four-probe method with an a-c bridge described by Dauphinee and Mooser (12). The four Pt 10% Rh wires, which served as electrodes, were attached tightly to the sample through holes of 0.5 mm ϕ pierced by a concentrated jet of fine alumina powder (S. S. White Industrial "Airbrasive" unit).

For the gravimetric measurements we used a Cahn electrobalance, mounted on the furnace. The balance was used as a differential weighing device, since absolute weighing of the samples was not possible. The apparent weight of the sample is composed of its real weight, the weight of the hanging wires, and a fictitious weight caused by the hot flowing gases in the furnace. This fictitious weight depends on the geometry of the samples, temperature, molecular weight, and velocity of the gas mixture flowing in the furnace. Differential weighing along an isotherm keeping the gas velocity constant is affected only by changes of the molecular weight of the gas. This effect was measured on a dummy alumina sample and was estimated to be less than 100 μg over the range of our measurements.

The balance was used in the range of 100 mg with a sensitivity of 10 μg. This sensitivity was good enough, since turbulence caused random fluctuation of $\pm$ 50 μg in the apparent weight of the sample. The suspending wire was composed of two parts; the upper one in the less hot region of the furnace was a platinum wire. In the hottest part of the furnace we used a sapphire single crystal (Linde division of Union Carbide Corporation), which can be used up to 1520°C, the eutectic point of the system MnO-Al_2O_3 (13). For later experiments, which extended above 1520°C, we used iridium as a suspending wire.

The two samples were very close to each other, and a Pt/Pt 10% Rh thermocouple measured their temperature. Since the temperatures reached were very high, the thermocouple could not be relied on as being accurate for long periods, and it was often replaced and periodically checked against the melting point of palladium (1552°C).

For the visual determination of the melting point of the oxides we used thin (0.2-0.3 mm thick) oxide sheets suspended in the furnace by an iridium hook, so that their large face was horizontal. A palladium calibration wire was used near the sample in each run, in addition to the Pt/Pt 10% Rh thermocouple, for a better determination of the temperature. We heated the furnace at a rate that did not exceed 5°C/min, the sample being in a constant $P(O_2)$. The deformation of the sample indicated its melting point.

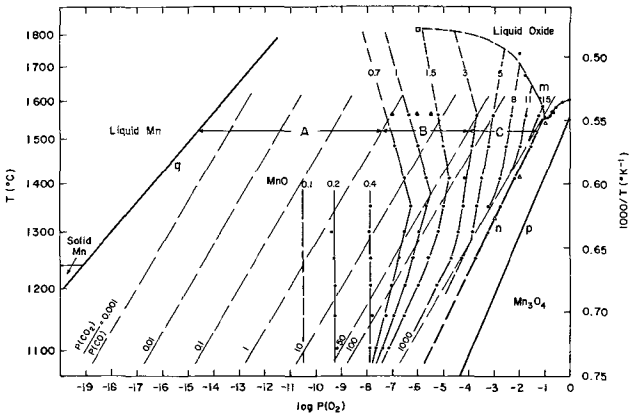

Fig. 1. Temperature pressure diagram of the system Mn-O in the temperature range 1100°-1800°C. In the MnO field experimental lines of constant composition are given with the value of their molar excess of oxygen, x, multiplied by 10^2. The boundary lines q and p are calculated according to Coughlin (10). The boundary n and part of m (•) are determined in this work, the point □ at 1815°C is taken from the work of Singleton *et al.* (8). The division into regions A, B and C is according to Fig. 3. For comparison representative points (▲) taken from Fig. 1 of ref. (6) are given for $x.10^2$ = 0.7, 1 and 1.5. Representative points (△) on the boundary n and n are taken from ref. (5). Lines of constant p $(CO_2)/P(CO)$ are superimposed (thin dashed lines).

It is obvious that this determination does not define a liquidus or a solidus line, but some value between these lines.

Results

Figure 1 shows the temperature-pressure diagram of the system Mn-O. The phase boundary Mn-MnO (q) is calculated from the free energies of formation given by Coughlin (10). We did not extend our measurements to these low oxygen partial pressures because Mn quickly evaporates from the oxide at these pressures. This made the determination of the deviation from stoichiometry very difficult. The manganese vapor also attacked the Pt 10% Rh electrodes, thus preventing electrical measurements in this range.

The MnO-Mn_3O_4 boundary (n) was determined by the sudden increase in weight of the sample as the oxygen partial pressure was slightly increased.

The melting point of Mn_3O_4 was found to decrease from 1600° $\pm$ 8°C at $P(O_2)$ = 1 atm to 1555° $\pm$ 5°C at about $P(O_2) = 10^{-1}$ atm. Maun and Hahn (5) reported an eutectic point in the system Mn-O at $P(O_2) = 10^{-1}$ atm, but mentioned 1540° $\pm$ 6°C as the mp at the eutectic composition. However, the calibration palladium wire used in each of our runs always melted before the deformation of the oxide, and we conclude therefore that the lowest mp in that system is not lower than 1552°C. The limit of error given above is slightly more liberal because of the possibility that the oxide sample with the higher heat content might be at a slightly lower temperature than that of the thermocouple.

The melting point of MnO as function of $P(O_2)$ was determined down to $P(O_2)$ = 0.01 atm, where the mp was found to be 1734° $\pm$ 10°C. We did not measure the mp at lower $P(O_2)$, since the thermocouple is not reliable at such a high temperature, and because the maximum operating temperature of our oven was 1800°C. However, we drew in Fig. 1 a curved line up to 1815°C, the melting point of MnO in purified helium determined by Singleton *et al.* (8). We estimated that the purified helium around their samples is equivalent to $P(O_2) = 10^{-6}$ atm. We did not take into account the value 1850°C mentioned by Glasser (9), since this value is an extrapolated one and not a measured value, as that of Singleton *et al.*

The calculation of x given near the lines of constant composition in Fig. 1 (see Fig. 2) requires knowledge

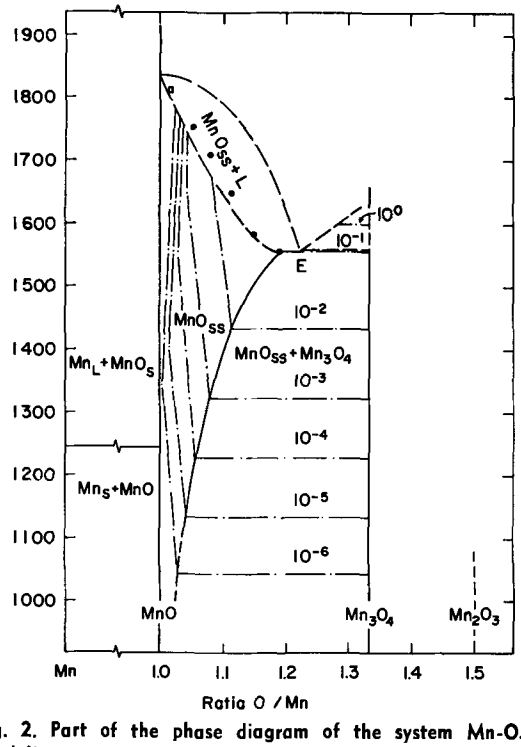

Fig. 2. Part of the phase diagram of the system Mn-O. Dot-dashed lines are oxygen isobars. Dashed lines are hypothetical solids and liquidus lines. The abscissas of the points in the MnO_{ss} + liquid field are based on extrapolation of the constant composition lines in Fig. 1. The abscissa of the eutectic point E is hypothetical. The point □ is taken from Fig. 1.

of the weight of MnO at stoichiometry (see Eq. [4] below). Since the gravimetric measurements were performed by a differential method, the stoichiometric weight of samples could not be determined directly, but was determined with the aid of the electrical measurements by the method of Fisher and Tannhauser (14).

Figure 3 shows isotherms of the conductivity G *vs.* log $[P(CO_2)/P(CO)]$. It is seen that the conductivity of MnO behaves differently in three regions, which are labelled A, B, C, respectively. In those parts of regions A and B which are not too close to the minimum in G, G can be expressed in the general form

$$G = K(T)\,[P(CO_2)/P(CO)]^{1/s} \qquad [1]$$

or, using the relation $P(O_2) = K'(T)\,[P(CO_2)/P(CO)]^2$, in the form $G = K''(T)P(O_2)^{1/2s}$ where s is negative in region A and positive in region B.

In this article only region B is discussed, since it is needed for the determination of the stoichiometric point. Region B is characterized by the value $s = 3.0 \pm 0.1$. This value fits the model proposed by Smyth (15), namely, that the dominant defects in region B are doubly ionized manganese vacancies. That this model gives the relation [1] with $s = 3$ can easily be proved (16) by applying the mass action law to the reactions

$$\tfrac{1}{2}O_2\ (\text{gas}) \rightleftharpoons O\ (\text{Lattice}) + V_M$$

$$V_M \rightleftharpoons V'_M + \oplus$$

$$V'_M \rightleftharpoons V''_M + \oplus$$

with the condition $[V''_M] >> [V'_M]$ and the assumption that the mobility, μ, of the positive free charge carriers, $\oplus$, does not depend on $P(O_2)$. $[V_M]$, $[V'_M]$, $[V''_M]$ are the molar fractions of manganese vacancies, nonionized, singly, and doubly ionized, respectively.

The molar excess of oxygen, x, defined by the formula MnO_{1+x}, which is equivalent to $Mn_{1-x}O$ at low x, is given by

$$x = [V_M] + [V'_M] + [V''_M] \qquad [2]$$

If now, in addition to $[V''_M] >> [V'_M]$, the relation $[V''_M] >> [V_M]$ holds as proposed by Smith (15), Eq. [2] will read $x = [V''_M]$ and the concentration of charge carriers p will be given by

$$p = [V'_M] + 2\,[V''_M] = 2\,[V''_M] = 2x \qquad [3]$$

A plot of $G = C\mu ep$ *vs.* x will be linear if the last relation holds. Such plots are shown in Fig. 4, and are seen to be linear in region B, a fact that supports the above assumptions.

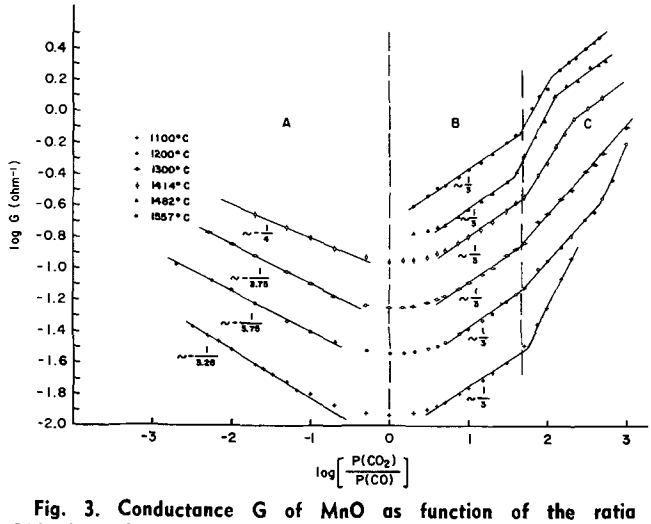

Fig. 3. Conductance G of MnO as function of the ratio $P(CO_2)/P(CO)$, at constant temperatures. The value of $P(CO_2)/P(CO)$ in the figure is the actual ratio of the gases in the furnace under equilibrium conditions, when mixtures of CO and CO_2 are used. When mixtures of Ar and O_2 are used, the ratio $P(CO_2)/P(CO)$ is calculated to give the correct oxygen partial pressure. A and B are regions where G behaves according to formula 1. The numbers give the values of 1/s. C is a region where the behavior of G is not well understood. The inaccuracy in the isotherm 1414°C may be ± 15°C, while the inaccuracy in the others does not exceed ± 5°C.

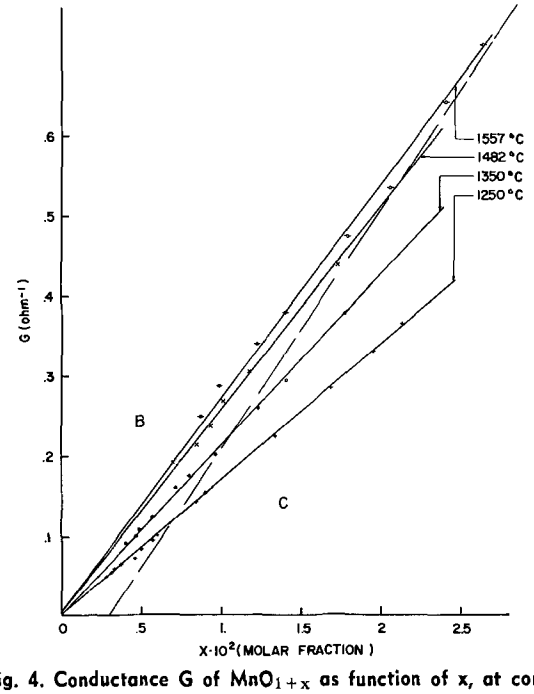

Fig. 4. Conductance G of MnO_{1+x} as function of x, at constant temperature, for low values of x. The line separating regions B and C is taken from Fig. 3 (see text).

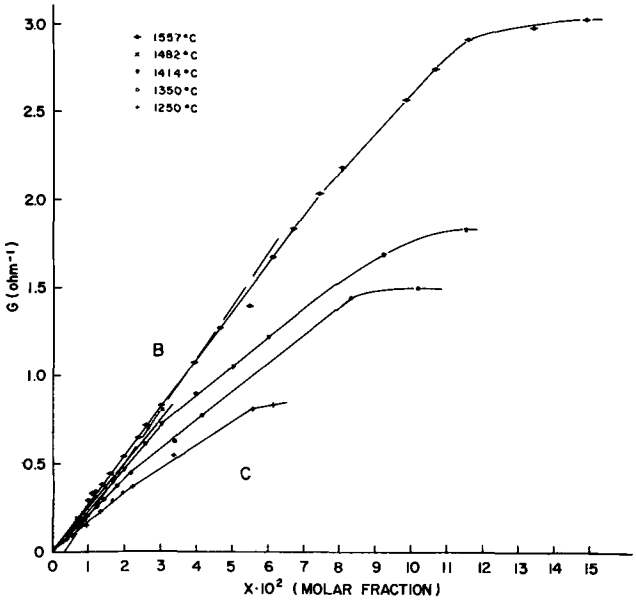

Fig. 5. Conductance G of MnO_{1+x} as function of x at constant temperature over the whole range of existence of the phase. The line separating regions B and C is taken from Fig. 3 (see text).

In Fig. 4 we drew the line that separates regions B and C in Fig. 3; no breaks in G *vs* x occur at that line. However, in Fig. 5, where the regions B and C are given in full, the expected breaks are seen. The fact that these breaks do not occur at the transition points indicated in Fig. 3, but at higher x (and therefore higher $(P(CO_2)/P(CO)$ ratios) is not well understood.

The zero point in Fig. 4 was determined by extrapolation of G *vs.* $M(x)$, the apparent weight at a composition MnO_{1+x}, to zero conductivity. Since from Eq. [3] we have $x = 0$ for $G = 0$, we will read on a graph of G *vs.* $M(x)$ for $G = 0$ $M = M(o)$, the apparent sample weight at the stoichiometric composition. x can then be calculated from the relation

$$x = \frac{[M(x) - M(o)] \times 54.94}{16\, M(Mn)} \qquad [4]$$

where 54.94 and 16 are the atomic weights of manganese and oxygen, and $M(Mn)$ is the weight of manganese contained in the oxide; this weight is determined separately before the oxidation of the specimens.

The errors in the determination of x arise principally from two causes: the systematic errors mentioned above, and the indeterminancy of the stoichiometric point caused by the scatter of the points in Fig. 4. The total error is estimated to be $\Delta x = \pm 10^{-3}$.

Another source of error is the extrapolation procedure; since at $x = 0$ G is not exactly zero, due to intrinsic conductivity. However, we could show by detailed analysis of the conductivity that this error is much smaller than the $\Delta x = \pm 10^{-3}$ mentioned above.

Breaks occur in the lines of constant x near the transition from region B to region C, and are probably due to the change of the ionization state of the manganese vacancies. The fact that the slopes of the lines of constant composition undergo a sharp change near 1375°C might be explained by a phase transition in the oxide. Some evidence for such a phase transition was found also in the electrical properties of MnO and will be reported later.

The composition of the MnO phase corresponding to the eutectic point was estimated by extrapolation to be near $MnO_{1.18}$, but it was not determined separately.

Measurements of the deviation from stoichiometry in region A are extremely difficult, since evaporation of manganese from the samples made the determination of weight change uncertain. At temperatures higher than 1400°C the evaporation is so severe that the platinum electrodes of the samples are attacked by the manganese vapor and destroyed, preventing continuous measurements of both x and G in region A.

For $T < 1400$°C we could however show experimentally, by taking the samples back and forth between regions A and B, that almost all the change in the apparent weight in region A was due to evaporation: only near 1400°C was a definite change of x in region A distinguishable. In Fig. 1 we draw a dashed line with $x = 0.001$, which shows approximately the lowest x definable by our method. For lower $P(O_2)$ MnO is practically stoichiometric (within the experimental error $x = \pm 0.001$). The fact that the conductivity in region A rises to fairly high values in spite of very small deviation from stoichiometry is probably due to very high mobility electrons and will be discussed in a later publication.

For the sake of completeness we drew from our results a phase diagram of the system Mn-O, given in Fig. 2. The Mn-MnO boundary is given by a straight line, since MnO practically reaches stoichiometric composition.

The Mn_3O_4 field is also a straight line, since no deviation from stoichiometry was found in that compound. The exact position of the eutectic point E is not determined in this work; its position in Fig. 2 is only hypothetical.

The temperatures at which deformations occur are not on the solidus line, but somewhat higher; we therefore drew a solidus line somewhat lower than our measured points.

The liquidus lines were not determined in this work, and in Fig. 2 they are hypothetical.

Discussion

Previous work on the system Mn-O was based mainly on measurements made after the sample was brought to room temperature, while the measurements in this work were made at the equilibria states themselves, giving us the advantage of direct observation of these equilibria.

In Fig. 1 we give the MnO-Mn_3O_4 phase boundary as measured in this work, and as calculated from the free energies of formation given by Coughlin (10).

Our measurements agree fairly well with the results of Hahn and Muan (5). The fact that the values calculated from the free energies of formation do not fit our experiments is probably due to the large deviation from stoichiometry of MnO near the boundary. In the calculation of that boundary we assumed the activity of MnO to be unity, an assumption not justified when dealing with nonstoichiometric compounds.

On the other hand, the Mn-MnO phase boundary, which is calculated from the free energies of formation of MnO given by Coughlin (10), is probably reliable, since, as we have shown above, MnO is practically stoichiometric in our region A (Fig. 1) to very low oxygen pressures, and it is therefore fairly safe to assume that it is stoichiometric at the boundary itself.

Mn_3O_4 was found to be practically stoichiometric, up to 1 atm oxygen, this again agreeing with the measurements of Hahn and Muan (5). The deviation from stoichiometry found by Le Blanc and Wehner (2) was probably due to the metastable condition of their experiments.

The highest measured deviation from stoichiometry was 15% excess oxygen, corresponding to $MnO_{1.15}$. Davies and Richardson (6) found the maximum deviation to be 4.4% and found a completely different dependence on $P(O_2)$ in the range $P(O_2) > 10^{-5}$ atm. This may be due to two different causes: (*a*) flushing of their oven with nitrogen before quenching the samples, (*b*) the quenching process itself.

Davies and Richardson equilibrated their samples in the temperature range 1500°-1650°C, where equilibria are quickly established. The partial pressure of oxygen in nitrogen, which is determined by impurities like O_2, H_2O, or CO_2, is usually very low, and may easily reduce the oxygen contents of the oxide at these elevated temperatures. As to the quench procedure, Davies and Richardson mention precipitation of Mn_3O_4, when they quenched samples equilibrated at $P(O_2) > 10^{-2}$ atm. This feature is known also in the system FeO (14), but it does not mean that at these oxygen pressures MnO does not exist at high temperature. At $P(O_2) < 10^{-6}$ atm, our results coincide with the results of Davies and Richardson (6), as shown in Fig. 1. In this case, the remark of Davies and Richardson, that only small amounts of gases pass over the sample, and therefore no further oxidation of the MnO sample is expected, applies.

The melting points of Mn_3O_4 found in this work are in good agreement with earlier workers. Our value of 1600°C at $P(O_2) = 1$ atm agrees with Wartenberg's (7) value of 1590° ± 20°C, and the values we found in air and at $P(O_2) = 0.1$ atm agree fairly well with those of Hahn and Muan (5) (see Fig. 1).

Acknowledgment

The authors wish to thank Mr. I. Dubner for his valuable technical help.

This work was partially sponsored by the Aerospace Research Laboratories under Contract No. AF 61(052)-825 with the European Office of Aerospace Research, United States Air Force.

Manuscript received April 13, 1966; revised manuscript received Dec. 19, 1966. This work constitutes part of the thesis submitted by one of the authors (A.Z.H.) to the Senate of the Technion in partial fulfilment of the requirements of the D.Sc. degree.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Note added in proof: Two new works dealing with the system Mn-O have recently been published. The electrical conductivity of MnO as a function of the oxygen partial pressure was measured by N. G. Eror (Dissertation Abstr., vol. 26, p. 3225 (1965-66)) between 900° and 1200°C. Eror found three different regions as in the present work, and he pointed out that the conductivity of MnO is anomalous at high oxygen partial pressure, in the sense that the conductivity decreases with increasing temperature at constant $P(O_2)$. This anomaly is well explained in the present work by the decrease of concentration of the cation vacancies (see Fig. 2, region C) when increasing the temperature at constant $P(O_2)$.

D. Q. Kim, Y. Wilbert, and F. Marion [*Compt. rend.*, 262C, 756 (1966)] found the different phase boundaries in the system Mn-O, and the position of the boundary MnO-Mn_3O_4 agrees qualitatively with the present work at high temperatures.

Mechanism of the Absorption Induced Electrode Potential Cells

I. Nature of the Potential

Henri L. Rosano, Charles J. Cante, and Evan Morgan

Department of Chemistry, The City College of The City University of New York, New York, New York

ABSTRACT

Previous experiments have shown that by using different electrode pairs and electrolytes, cells comprised of a wettable exposed electrode/electrolyte/immersed electrode may be sensitive to either ionizable or nonionizable vapors. When air containing a vapor was injected with syringes into the carrier gas stream entering a cell of the type described above, changes in cell potential or cell current were recorded. It was noted that the potential changes, as well as the current changes, obtained from the absorption induced electrode potential cells depended on the presence of a meniscus (solid/liquid and liquid/gas interfaces) on the exposed electrode. In the present paper the case of an ionizable vapor, hydrogen chloride, injected into the carrier gas stream entering a Ag/AgCl (exposed blade)/HCl aqueous/Ag/AgCl (immersed wire) cell has been investigated. It was concluded that (*i*) the absorption of vapor on the exposed electrode creates a momentary concentration cell with transference and (*ii*) the great sensitivity of these types of electrochemical cells can be attributed to an active zone located at the upper part of the meniscus.

In a previous paper (1), it was reported that a galvanic cell consisting of a platinum gauze electrode, which was partially immersed in a nitrochromic acid oxidizing mixture (70.3% HNO_3 saturated with 99.1% CrO_3), and a graphite electrode, which was completely immersed in the same electrolyte, responded to organic vapors. Introduction of short chain alcohol vapors into the system resulted in the production of a current which was recorded as a function of time. This was essentially a Berton cell (2-4).

Rosano and Scheps (1, 5) studied only the currents produced by organic vapors in an oxidizing electrolyte. In view of the complexities encountered with the nitrochromic electrolyte, it was decided to use different cells with simpler electrolytes in the investigation of the nature of the potential produced by absorption induced electrode potential (AIEP) cells.

Experimental Procedure

The electrolytes used in these investigations were aqueous solutions of potassium chloride and hydrochloric acid. The exposed electrodes were either (*i*) a Ag/AgCl blade (2.25 x 1.0 x 0.05 cm) or (*ii*) a semi-silvered, sand-blasted, glass blade and the immersed counter electrode was a Ag/AgCl wire (0.06 cm in diameter). Sand-blasted glass slides were covered with silver by sucrose reduction of a silver ammonia complex. The lower half of the blade was again sand-blasted to remove the silver on that section. Sand-blasting insures the wettability of the electrode. The vapor was hydrogen chloride. The carrier gas, nitrogen or air, continuously flowed through the cell. The effect of the air stream was negligible compared with the effect of HCl. The carrier gas was passed through a series of filters (anhydrous calcium chloride, potassium hydroxide, and charcoal) before entering the cell at a controlled flow of 60 cc/min. The basic cell design in all experiments is shown in Fig. 1. The glass container (internal diameter 3.6 cm) of the cell has a total volume of 60 cc. The volume of electrolyte used in all experiments was 15 cc.

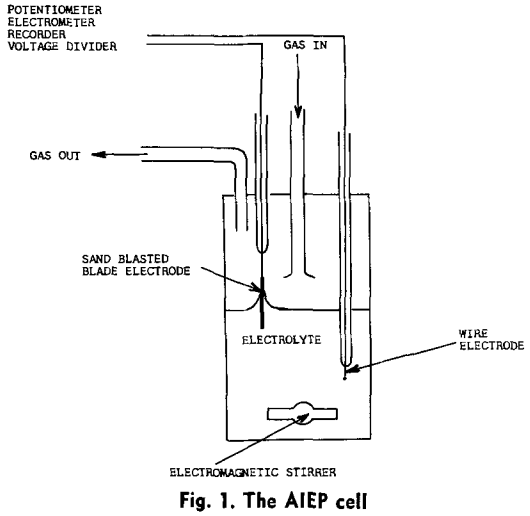

Fig. 1. The AIEP cell

A hydrochloric acid solution in a closed Erlenmeyer flask was allowed to reach equilibrium with its own vapor. A given volume of the HCl vapor was then withdrawn from the flask with syringes and subsequently injected into the carrier gas stream. All chemicals were reagent grade, and distilled water was used in the preparation of all solutions. The various electrolytes were uniformly stirred by a magnetic stirrer. These experiments were performed at room temperature (26° ± 1°C).

Measurement of cell potential.—Given volumes of HCl vapor were injected into a regulated stream of nitrogen entering a Ag/AgCl (exposed blade)/HCl or KCl (aqueous)/AgCl/Ag (immersed wire) cell. Two different experiments were performed: (*i*) for a fixed bulk concentration of KCl or HCl, the change in cell potential was recorded as a function of the volume of HCl vapor injected, and (*ii*) the change in cell potential was recorded when the bulk electrolyte concentration was varied while the volume of HCl vapor injected was kept constant. An electrometer (D.C. Multimeter, Model MV77B, Millivac Instruments) was used to measure the maximum potential changes which were recorded (Sargent Model SR Recorder) as a function of time. In order to justify the use of the recorder (balancing speed: 1 sec for full scale travel), it was necessary to determine the duration of the potential rise in a measurement of emf *vs.* time. An oscilloscope (Hewlett-Packard, Model 130C with Dumont Camera attachment) was used in place of the recorder. The time of the potential rise was found to

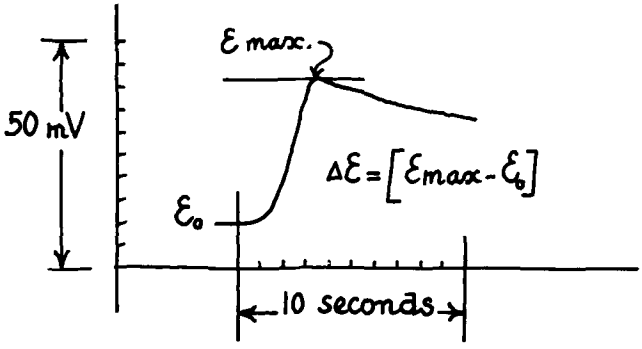

Fig. 2. Potential as time curve for the injection of HCl vapor into a Ag/Ag/Cl (exposed blade)/1M HCl/AgCl/Ag immersed wire cell illustrating the decay of the transient potential.

be of the order of 3-6 sec depending on the volume of vapor injected. Therefore, for convenience, the recorder was used in all our experiments. After injection of HCl vapor into the cell, the cell emf increases immediately to a maximum value (see Fig. 2). With time, the cell emf decays to its initial value. After repeated injections of HCl vapor, the cell emf does not return to its initial value but levels off at some higher emf due to the change in the bulk electrolyte concentration. The difference between the maximum instantaneous emf and the initial emf was selected as the parameter to be reported.

EMF of HCl *concentration cells with transference.*—The emf of HCl concentration cells with transference with measured (*e.g.*, Ag/AgCl/HCl, 1M // HCl, xM / AgCl/Ag where 1M — xM — 12M).

A priori it was postulated that the absorption of HCl vapor at the level of the meniscus formed on the exposed electrode would create a momentary concentration cell with transference between the exposed blade and the immersed wire electrodes of the absorption induced electrode potential cell. In order to estimate the maximum momentary concentration of HCl on the exposed electrode of the AIEP cell, the emf's obtained with the cell were compared to the emf's of a classical concentration cell with transference. According to our hypothesis, for the same emf's the difference in concentrations must be comparable for the two systems.

Influence of the dimensions of the exposed blade electrode on the cell emf.—2cc of HCl vapor were injected into the AIEP cell described above. The dimensions of the exposed blade electrode were changed in order to determine their effects on the emf obtained with a given injection. Experimentally, the emf is practically independent of the width of the blade. It is dependent on the relative position of the bottom of the blade with respect to the plane of the electrolyte (see Fig. 3).

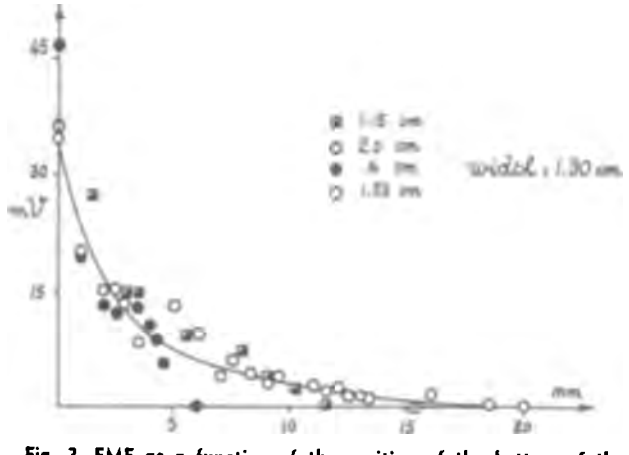

Fig. 3. EMF as a function of the position of the bottom of the blade electrode below the liquid-gas interface for a solid silver blade.

Influence of the position of the bottom of the exposed electrode at different levels in the meniscus.—Practically, the bottom of the Ag/AgCl blade cannot be above the plane of the solution otherwise the blade will not support a meniscus. Instead a sand-blasted, semisilvered, glass blade electrode was used. With this electrode it is possible to position the silvered part of the blade at any level in the meniscus; the bottom half of the electrode (sand-blasted glass) supports the meniscus (position measured with Gaertner cathetometer).

Results

Influence of the volume of HCl *vapor injected on the cell emf.*—In the first series of experiments the bulk electrolyte concentration was fixed at 1M so that data were obtained for the changes in emf as a function of the volume of HCl vapor injected. The experimental results are shown in Fig. 5. The upper abscissa of Fig. 5 represents the volume (cc's) of HCl vapor injected on a log scale. A curve was traced through the experimental points.

EMF's of concentration cells with transference.—The emf's of the concentration cells with transference were plotted on the ordinate of Fig. 5. A horizontal line, intersecting the experimental curve, was drawn for each measured emf. The intersections of these horizontal lines and the previously traced curve deter-

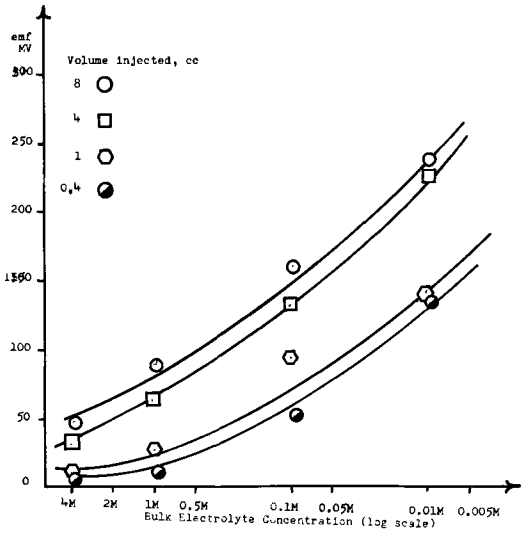

Fig. 6. EMF *vs.* the log of the bulk electrolyte concentration for a fixed injected volume of HCl vapor.

mined the position of the values of xM on the middle abscissa of Fig. 5.

Variation of Cell emf as a function of the bulk electrolyte concentration for a given injected volume of HCl *vapor.*—A fixed volume of HCl vapor was injected into the carrier gas stream entering a Ag/AgCl (exposed blade)/HCl (aqueous)/AgCl/Ag (immersed wire) cell. The maximum changes in emf for various concentrations of the electrolyte were measured. Results are shown in Fig. 6. In the potential measurement experiments no visible physical changes of the silver-silver chloride electrodes were observed.

Influence of the position of the bottom of the exposed blade electrode vs. the plane of the liquid-air interface.—Figure 4 is a representative experiment of the emf response *vs.* the relative position of the bottom of the silvered segment of the semisilvered electrode with respect to the maximum upper meniscus boundary. The surface tension of the electrolyte was measured before and after each experiment. The maximum height of the meniscus was calculated and taken as the origin on Fig. 4. An arrow indicates the vertical distance between the top of the meniscus and the horizontal plane of the electrolyte.

Discussion

Apparent HCl *concentration in the meniscus.*—When HCl vapor penetrates into a Ag/AgCl (blade)/HCl or KCl (aqueous)/AgCl/Ag (immersed wire) cell, it can be assumed that the concentration of chloride ion around the exposed electrode increases suddenly. The difference in chloride ion activity between the exposed and immersed electrodes suggests, as we have already mentioned, a concentration cell with transference. The maximum apparent concentration of HCl in the meniscus was estimated theoretically and experimentally.

The theoretical approach is the application of the Nernst equation (Eq. [3]) for concentration cells with transference (utilizing activity coefficients and transference numbers cited in the literature) and fitting the emf's corresponding to the various calculated concentrations to the experimental curve.

If the chloride ion concentration in the meniscus is the sum of the bulk chloride concentration and the contribution made by the injected HCl vapor which absorbed at the liquid-air interface, it can be written: $C_M = C_B + X$ (where C_M and C_B are the meniscus and bulk chloride ion concentrations, respectively, and X is the contribution of the absorbed HCl). Assuming that the expression for the emf of a concentration cell with transference (6) is applicable in our case it follows that

$$E \text{ (millivolts)} = \frac{2t_+RT}{n\mathbf{F}} \ln \frac{a_M}{a_B} \quad [1]$$

$$a_M = f_M C_M = f_M [C_B + X] \text{ and } a_B = f_B C_B \quad [2]$$

$$E \text{ (millivolts)} = \frac{2t_+RT}{n\mathbf{F}} \left[\ln \frac{C_M}{C_B} + \ln \frac{f_M}{f_B} \right] \quad [3]$$

Equation [3] can be rewritten as

$$E = \frac{2t_+RT}{n\mathbf{F}} \left[\ln \frac{f_M}{f_B} + \ln \frac{C_B + X}{C_B} \right] \quad [4]$$

where R is the gas constant, T was 299°K, $\mathbf{F}$ is the value of the Faraday-96,500 coulombs/equivalent, t_+ is the transference number of the hydrogen ion, a_M and a_B are the activities of the chloride ion in the meniscus and the bulk electrolytes respectively, C_M and C_B are the concentrations of the chloride ions in the meniscus and bulk, respectively, and f_M, f_B are the activity coefficients obtained from the literature (7). The results are presented on the bottom abscissa of Fig. 5.

The experimental approach, as was previously mentioned, has been to assume that identical emf's obtained with an AIEP cell and a classical concentration cell with transference must correspond to comparable concentration differences. Therefore, the variable concentration of the classical cell with transference is plotted on the middle abscissa of Fig. 5 to fit the experimental curve, emf *vs.* volume injected (cc's), obtained with the AIEP cell. The correspondence between the concentrations on the two lower abscissae is fairly good. The middle abscissa represents the apparent HCl concentration in the meniscus. Figure 5 therefore has three abscissae which represent from top to bottom: (*i*) the volume of HCl vapor injected into the cell, (*ii*) the HCl concentrations (xM) of the concentration cell with transference, and (*iii*) the calculated apparent meniscus concentration using the Nernst equation with transference. The two approaches are equivalent.

Respective contributions of the sheath of wetting and the meniscus of the exposed electrode to the cell emf.—Experimentally, the exposed electrode must be wettable by the electrolyte and form a meniscus in order to have a sensitive cell. The Laplace equation of capillarity (Eq. [5]) allows the determination of the height of a meniscus if the surface tension and density of the liquid are known (8).

$$h = (2\gamma/\rho g)^{1/2} \quad [5]$$

where h is the meniscus height (cm), g is the acceleration of gravity (cm/sec^2), ρ is the density of the liquid (g/cm^3) and γ is the surface tension (dynes/cm). For a liquid with γ = 72 dynes/cm (*e.g.*, water) h is 0.384 cm. Table I presents a few typical values of h calculated using Eq. [5] and experimental values of γ and ρ. When a wettable blade is vertically withdrawn from a liquid surface, it forms a meniscus. Beyond a certain height h, the maximum height of the meniscus, any further extension of the blade will only increase the sheath of wetting covering the blade above the top of the meniscus. If the blade is situated in an atmosphere saturated with water vapor, the sheath of wetting will cover the entire blade. Eventually, the sheath of wetting will slowly thin out due to drainage. On the other

Table I. Values of *h* from experimental data

Electrolyte	ρ density, g/cm^3	γ surface tension, dynes/cm	h, maximum meniscus height, cm
HCl, 1M	1.0156	72.4	0.381
Igepal, CO-630 in 1M HCl	—	30.8	0.267
Igepal, CO-730 in 1M HCl	—	35.4	0.249
KCl, 1M	1.0467	74.3	0.380

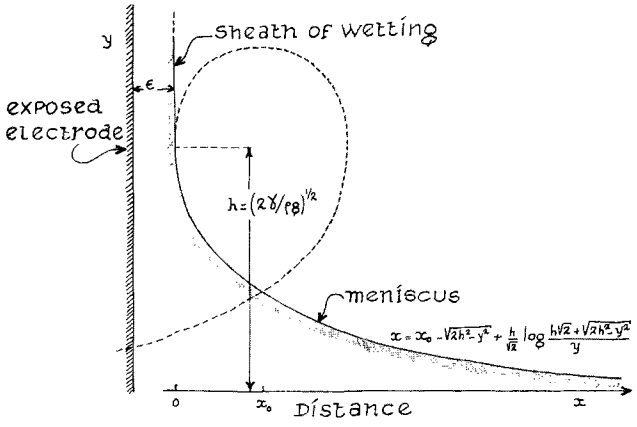

Fig. 7. Relationship between a wettable exposed electrode surface, sheath of wetting, and the meniscus formed on the exposed electrode.

hand, if the blade is situated in a continuously replenished atmosphere, as in our experiments, the sheath of wetting will evaporate down to a position relatively close to the upper boundary of the meniscus. The thickness of the sheath of wetting is determined by the electrolyte and the surface of the electrode. It represents the minimum possible liquid thickness of the electrode, (see Fig. 7).

Let us consider two cases in which: (*i*) the meniscus and the sheath of wetting are taken into account and (*ii*) the existence of the meniscus is disregarded and replaced by a film of thickness, ϵ, which forms a right angle boundary with the bulk electrolyte at the liquid-gas interface.

Let us assume, for the first case, that n moles of HCl vapor enter the cell and are absorbed into a volume $A \times \epsilon$ (where A is the total liquid-gas interface; 10.8 cm^2 in our case and ϵ is a thickness). The area of the meniscus and adjacent film can be estimated to be 10% of the total liquid-gas area or $0.1A$. As an example, when 1 cc of HCl vapor was injected into the carrier gas stream entering a Ag/AgCl (exposed blade)/1M HCl/AgCl/Ag (immersed wire) cell, the emf changed by 20.2 mv. From Fig. 5 (middle abscissa) the maximum apparent HCl concentration in the surface volume $A \times \epsilon$ should be 1.4×10^{-3} moles/cc. The increase in the number of moles of HCl after injection was 36.4×10^{-7} moles. This increase was determined by injecting the stated volume of vapor into an equivalent system in which the HCl electrolyte was replaced by distilled water. By measuring the *p*H of the distilled water before and after the injection of vapor, the increase in the number of moles of HCl was calculated. Of these moles, 3.64×10^{-7} were in a volume $0.1A \times$ cc's with an apparent concentration of 1.4×10^{-3} moles/cc. Therefore

$$\epsilon = \frac{3.64 \times 10^{-7}}{1.08 \times 1.4 \times 10^{-3}} \approx 2.4\mu$$

For the second case, let us assume that: (*i*) a film of uniform thickness, ϵ, exists in place of a meniscus, and (*ii*) that only 10% of the total moles of HCl entering the cell are absorbed into the volume: $2 \times L \times H \times \epsilon$, where L is the length of the blade along the liquid-gas interface, H is the height of the blade, and ϵ is the thickness of the sheath of liquid on the blade. For the experiment cited in case (*i*), the blade was 2.25 cm long by 0.6 cm high, therefore for case (*ii*)

$$\epsilon = \frac{3.64 \times 10^{-7}}{2 \times 0.6 \times 2.25 \times 1.4 \times 10^{-3}} \approx 1\mu$$

Mathematically the shape of the meniscus on a vertical planar surface is represented by

$$X = X^o - (2h^2 - y^2)^{1/2} + (h/\sqrt{2}) \ln \left[\frac{(h\sqrt{2} + \sqrt{2h^2 - y^2})}{y} \right] \quad [6]$$

where h is given by Eq. [5], y is the vertical height along the meniscus, X^o is a constant of integration, and X is the horizontal distance from the vertical surface. By substituting for X the calculated values of ϵ, 1, and 2.4μ, the corresponding values of y are $\sim h$, *i.e.*; right at the top of the meniscus (upper 0.2 mm). Therefore, the main contribution to the emf comes from the very top of the meniscus and from the sheath of wetting which extends vertically from the boundary of the meniscus. The fact that for a given injection of HCl vapor the emf obtained is the same regardless of the blade height above the meniscus line (Fig. 3 indicates that a blade 0.6 cm high and one 2 cm high give similar emf's when their bottoms are in the plane of the liquid-gas interface) demonstrates that the sheath of wetting on silver cannot extend vertically much more than 1 or 2 mm. In addition, by using a semisilvered, sand-blasted, glass electrode we were able to probe from the bottom to the top of the electrolyte meniscus and beyond. When the bottom edge of the silvered segment is placed at the top of the meniscus (the lower portion of the electrode is glass and is supporting the meniscus), the emf drops abruptly. If the silvered edge is raised beyond the top of the meniscus, the emf drops off to zero indicating that contact with the electrolyte has been broken—measurement of the electrical resistance further indicates that there is no longer any electrical contact (see Fig. 4). This fact further supports the above conclusion.

According to the previous argument, it was expected that a maximum emf would be obtained when the bottom of the blade was at the maximum height of the meniscus and even slightly above (in the sheath of wetting). At least thirty experiments similar to the one shown on Fig. 4 were performed. The maximum emf measured was generally obtained when the bottom of the exposed blade electrode had not yet reached the top of the meniscus.

This apparent contradiction between the experimental results and our prediction can be explained by assuming that the height of the meniscus can change instantaneously on the arrival of vapor (transient lowering of the surface tension and consequent decrease in the maximum height of the meniscus during the process of absorption). In addition, within 0.2 mm, 1 mm below the maximum meniscus height, the sheath of wetting is constant.

Essentially our conclusion is similar to the conclusion of Will (9), who studied the electrochemical oxidation of hydrogen on partially immersed platinum electrodes. He concluded that the electrode surface above the intrinsic meniscus is covered with a thin electrolyte film of a thickness comparable to or smaller than the surface roughness. The electrochemical process occurs almost exclusively at the upper edge of the meniscus and adjacent film close to it.

In a numerical example given by Will (9), the narrow band (active region) is 0.35 mm of the meniscus and 0.38 mm of the adjacent film with a film thickness of 1.0μ for the case of $8N$ H_2SO_4 electrolyte and an applied potential of 400 mv. The active region is responsible for 98% of the total response. Other recent works (10-15), have established similar behavior for several systems involving a partially immersed electrode.

EMF variation as a function of bulk electrolyte concentration for a fixed injected volume of HCl *vapor.*— In the case of HCl vapor, the exposed electrode is the anode. However, a mixed potential exists on the blade electrode when HCl vapors are injected into the cell. As a result, the blade electrode senses a whole range of HCl concentrations from the meniscus-sheath of wetting zone down to the bottom of the blade (which is positioned in the bulk of the meniscus). Reduction

must therefore occur at the bottom of the blade. In conclusion, the use of the Nernst equation allows only the calculation of the apparent instantaneous HCl concentration in the meniscus for a given volume of injected vapor. The solid lines on Fig. 6 have been calculated using equation 4 and the X values obtained from Fig. 5. It can be seen that the agreement with the experimental results is quite good. This agreement indicates that by using the Nernst equation we are in fact calculating an apparent HCl concentration which corresponds to a uniform concentration along the exposed electrode. However, in reality there is a gradient of concentration from the top to the bottom of the meniscus.

Conclusion

In the case of an ionizable vapor (HCl) and an absorption induced electrode potential cell with reversible electrodes, it is concluded that the emf response can be described as that of a concentration cell with transference. Moreover, the sensitivity of the cell (Δ mv) depends primarily on the presence of a meniscus on the exposed electrode. Although a mixed potential is set up on the exposed electrode when HCl vapor is injected into the cell, the emf between the exposed and immersed electrodes can be thought of as a concentration cell with transference.

This study also shows the unusual fact that the great sensitivity of this type of electrochemical cell is solely due to the active zone formed by the upper part of the meniscus and the lower part of the adjacent film.

Solid-State Electrochemical Cells Based on Charge Transfer Complexes

F. Gutmann,[1] A. M. Hermann, and A. Rembaum

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

ABSTRACT

Solid-state electrochemical cells have been devised using a variety of metals as anodes and electronically conducting charge-transfer complexes as cathodes. The product of the electrochemical reaction, the electrolyte, was formed *in situ*. Data are reported for halogen complexes as well as for complexes containing nitrogen compounds as acceptors. It is shown that the voltage-producing electrochemical reaction is the formation of the corresponding metal salt. Open-circuit voltages of 1.5-2.5v per cell were attained with magnesium or calcium anodes, and short-circuit current densities of up to 25 ma/cm^2 were found. Current-voltage characteristics have been studied as a function of temperature, and constant-load discharge curves are shown. Maximum power densities of one watt per pound and useful energy densities of 1 whr/lb are reported. An analysis based on irreversible thermodynamics is presented, and possible applications are suggested.

This paper reports the results of studies intended to explore the characteristics of a solid-state electrochemical cell. The aim is the direct conversion of chemical energy into electrical energy without the use of liquid or fused electrolytes at elevated temperatures, although permitting operation at such temperatures.

While devices have been described previously using silver anodes and silver halides as the electrolytes (1, 2), the voltages attained were of the order of 0.2-1.0v and the maximum current densities of 1-2 ma/cm^2, unless operated at relatively high temperatures.

[1] Department of Physical Chemistry, University of New South Wales, Sydney, Australia.

In this paper we report a greatly improved solid-state cell in which the electrolyte is formed *in situ* and the cathode is an electronically conducting charge-transfer complex.

The present results are to be construed as preliminary findings; the justification of this report rests primarily on the exciting commercial implications of the cell characteristics, *i.e.*, open-circuit voltages of up to 2.5v and short-circuit current densities of up to 25 ma/cm^2.

It will be useful to define a number of terms before presenting the data and the interpretation of results. A charge-transfer complex can be briefly defined in the Mulliken sense as a system involving the partial transfer of one or more electrons from a donor (typically, an aromatic hydrocarbon) to an acceptor (typically, a halogen or an organic compound of high electron affinity) (3).

One of the characteristics of charge-transfer complexes pertinent to the discussion of their use in power sources is their high electronic conductivity, greatly enhanced over that of either donor or acceptor. In the electrochemical cells discussed below, a metal halide or salt is produced but is not involved in the cell assembly; it will be designated nevertheless as the electrolyte in conformity with the traditional terminology, and the charge-transfer complex will be called the cathode. The term "inert electrode" will be used to designate an electrode on the cathode side of the complex whose free energy of formation with the acceptor of the complex is small (or zero) in comparison with that of the anode with the acceptor. The term "matched load" will be used to designate the resistance of a suitable external resistor in series with the cell in order to produce a terminal voltage equal to half of its open-circuit value. Other terms of an electrochemical nature (including polarity) maintain their normal usage. Definitions can be found in the references (4).

Experimental Technique

The energy producing reaction is the formation of either the metal halide from the elements or, as in the case of the tetracyanoquinodimethane (TCNQ) compounds as acceptors, of the metal salt. Thus, for example, the reaction of iodine with magnesium gives rise to magnesium iodide with the liberation of energy. In contrast to the cells cited in the references, the authors did not physically include the halide (or salt) in assembly of the cells, but merely allowed it to form at room temperature *in situ*. Thus a metal halide layer is formed on the surface of the anode and is permeable to ion motion, but seems to constitute an electronic insulator which prevents complete internal short-circuiting.

The chemicals used in complex preparation ranged from high-purity materials to that of reagent grade. Cell performance was found to be independent of fluctuations in purity level within this range. High molecular weight poly-N-vinylcarbazole of intrinsic viscosity in benzene = 0.84 dl/g, was obtained from the Borden Chemical Company; it was purified by precipitating it twice from a benzene solution with methanol and dried in a vacuum oven at 50°C. Resublimed iodine was used as received. Reagent grade perylene was kept in the presence of $CaCl_2$. Other chemicals were used as received with the exception of poly-2-vinylquinoline, which was prepared by anionic polymerization of 2-vinylquinoline in benzene using butyllithium as initiator. Carbon black was purchased from Cabot Corporation (Vulcan XC72R).

The following methods were used for complex preparations: (*i*) mixing of the components in an inert solvent (*e.g.* dichloromethane), the solvent being subsequently removed in high vacuum at 0°C; (*ii*) grinding in a mortar or melting the components together in cases where the melting point of the charge-transfer complex was relatively low. The method of preparation seemed to have little effect on the cell characteristics.

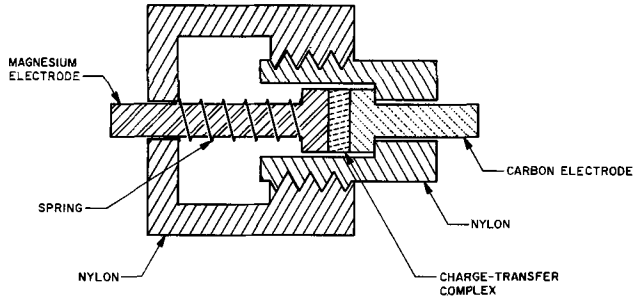

Fig 1. Sketch of test jig

The anode material was degreased and surface oxides were removed by abrasion or acid washing, followed by an acetone rinse and drying. Either technique seems suitable, the key feature being the necessity of assembly in a dry atmosphere to achieve reproducible results (see section on Experimental Results, below).

The complex was compacted in a hydraulic press under a pressure of about 100,000 lb/in.^{2}, yielding a pellet of ½ in. diameter and approximately 0.04 in. thickness. The metals were formed into disks of the same diameter, and the resulting sandwich was assembled in a Nylon or Teflon jig under small positive spring pressure (see Fig. 1). All currents quoted in this report refer to an area therefore of 1.26 cm^2.

Voltages and currents were measured with a Hewlett Packard 412A VTVM and a Keithley 610A electrometer.

Experimental Results

Cell composition.—Metal pure iodine systems.—In order to explore the suitability of anodes other than silver, a number of metals were tested, under standardized conditions, using a compacted pellet of pure iodine as the electrolyte and Pt, graphite, or Au as the counter electrode, thus forming a simple, well-defined system. Preliminary tests have shown that Pt as well as graphite and Au form good inert contacts to iodine. Results are summarized in Table I.

It is seen that the voltages previously reported for Ag (1) have been reproduced, but that considerably higher voltages are obtainable for Ba, Ca, and Mg in agreement with the high heat of formation of their iodides (5). This quantity is listed in Table I rather than the free energy of formation because of lack of data on the latter.

The system Mg/*iodine charge-transfer complex*/Pt *or* C.—A number of such systems were prepared and studied; results are summarized in Table II. Most of the complexes (*e.g.*, perylene-iodine, phenothiazine-iodine) were of sufficiently high conductivity to give a low internal impedance. A few of the complexes (*e.g.*, polyvinylpyridine-iodine) were characterized by relatively low conductivity; to those designated as such, a small percentage of carbon black (3-10% by weight)

Table I. Variation of the open-circuit voltage with the heat of formation of the metal iodide for cells of the type metal/I_2/Pt, C, or Au

Metal 1	Open-circuit voltage, v	Metal 2	Heat of formation of the metal-iodide[2], kcal-mole^{-1}
Ba	2.25	Au	−144
Ca	2.20	Pt	−127
Mg	1.85	Pt	−86
Al	0.82	Pt	−75
Ag	0.66	Pt or C	−15
Sn	0.23	Pt	
Fe	0.006	Pt	−30
Pt	0	Pt	0

Table II. Variation of the open-circuit voltage and short-circuit current with donor for cells of the type Mg/I_2-complex/Pt, C, or Au

Electrolyte, I_2 complexed with:*	Open-circuit voltage, v	Short-circuit current, μa
- - - 100% Iodine	1.85	1
Poly-N-vinylcarbazole	1.45	105
Poly-2-vinylquinoline	1.45	500
Poly-N-vinylcarbazole + carbon black	1.72	1000
Perylene	1.45-1.85	1100-16,000
Carbon black	1.4	1000
Polypropylene-carbon black	1.6	2300
Polyvinylpyridine-carbon black	1.75	1000-30,000
Phenothiazine-iodine	1.75	6500

* Approximately 50% I_2 by weight.

was added; the resulting cell performance is shown to be similar.

The heat of formation of MgI_2 predicts a reversible, open-circuit potential of 1.85v against an inert electrode (see discussion below). The deviations from this value are thought to be caused by imperfect formation of the magnesium iodide layer resulting in a small degree of internal short-circuiting.

From the Gibbs-Helmholtz equation we may write

$$E = \frac{\Delta H}{z\mathbf{F}} + T\frac{dE}{dT} \qquad [1]$$

where ΔH is the enthalpy change, *viz.*, −86 kcal/mole, z the number of electrons involved in the reaction, **F** the Faraday, E the open-circuit voltage, and T the absolute temperature.

For the MgI_2 reaction described in Eq. [1], $z = 2$. If one retains the first term only (Eq. [1]) and neglects the entropy contribution, one obtains the Helmholtz-Thomson equation which yields $E = 1.85$v. Direct measurement of dE/dT showed that it is negligible in the vicinity of room temperature. At temperatures above 45°C a value of about -5×10^{-4} v/deg was obtained. Since ΔH is negative, the voltage tends to drop with increasing temperature.

A value of 1.81v is obtained from the reverse (charging) current-voltage characteristics shown in Fig. 2. These curves refer to two different complexes both using Mg anodes and inert Pt counter electrodes.

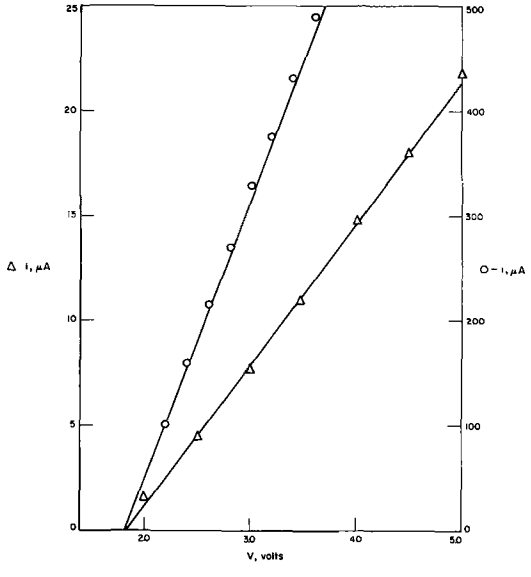

Fig. 2. Reverse (charging) characteristics. Points marked ⊙ refer to the system Mg/I_2-graphite complex/Pt, use right-hand scale for ordinates; points marked △ refer to Mg/I_2-poly-N-vinylcarbazole/Pt, use left-hand scale for ordinates.

In both cases it is seen that the relation is linear at higher values of applied voltage of reverse polarity and that extrapolation yields the potentiometric, zero-current voltage of 1.81v. Bromine complexes behave in a similar manner.

The short-circuit currents listed in Table II are limited by the resistance of the complex only in the first three cases; for pure iodine, for the poly-N-vinylcarbazole-iodine, and for the poly-2-vinylquinoline-iodine complex. The resistance of the complex for the other cells is of the order of 1-100 ohms, well below the value of the internal impedance. The large fluctuations from cell to cell in the short-circuit current have been found to be caused primarily by lack of controlled low humidity, leading to the formation of variable amounts of magnesium hydroxide [the formation of magnesium hydroxide on magnesium anodes has been studied in detail (6)]. When cells were assembled under 2% relative humidity, short-circuit currents of the order of 6-16 ma/cm² were obtained. This is thought to constitute a reasonable reproducibility in view of the crudeness of the contact method. However, it is felt that vacuum deposited anodes will further improve reproducibility.

It is appropriate to point out the effect of excess moisture in the complex or at the Mg/complex interface. With water in the complex in quantities of 5-20% by weight, or with a wet magnesium anode used in the cell assembly, initial performances of the cells were improved (current densities as high as several hundred ma/cm² were attained). However, the final values (reached after several minutes) of both the open-circuit voltages and the short-circuit currents were well below those presented in Table II. It appears that a controlled supply of water, by itself or in some suitable medium, may improve significantly the long-range cell characteristics. The effect of minute amounts of water on cell performance is unknown at this time and is subject of a present investigation.

Other iodine complex systems.—The results of a preliminary study of a number of other systems using iodine complexes and metals other than magnesium are listed in Table III.

The prior remarks about humidity seem pertinent to the barium and calcium cells. Calcium in particular was found to exhibit short-circuit current densities of the order of 3-4 ma/cm² in every case when the cells were assembled in a 2% relative humidity environment.

Noniodine systems.—The presence of iodine or, more generally, of halides is by no means a necessary condition for the electrochemical generation of useful electrical power, as seen from Table IV. Thus, the charge transfer complex between the donor graphite and the acceptor tetracyanoquinodimethane (TCNQ) yields a voltage of the same order and a current about 1 to 2 orders of magnitude below those obtained with the best of the iodine systems. Bromine complexes gave results comparable to those obtained with the iodine complexes, the voltages attainable being even higher,

Table III. Variation of the open-circuit voltage and short-circuit current with the anode metal for cells of the type metal/iodine-complex/inert electrode

Metal 1	Metal 2	Donor*	Open-circuit voltage	Short-circuit current, μa
In	Ni	Perylene	0.05	820
Cd	Pt	Perylene	0.008	2
Ba	Ni	Perylene	2.4	0.24-10
Ca	Ni	Perylene	2.5	1-4000
Ag	SnO	Poly-N-vinylcarbazole	0.66	0.2
Ca	Ni	Phenothiazine	1.8	2800-8000*

* Approximately 50% I_2 by weight, except for the phenothiazine cell whose composition was 2 to 1 by weight of iodine.

Table IV. Variation of the open-circuit voltage and short-circuit current with various iodine-free complexes for cells of the type Mg/iodine-free complex/Pt

Metal 1	Metal 2	Complex	Open-circuit voltage	Short-circuit current, μa
Mg	Pt	Poly-N-vinylcarbozole-Br_2-graphite	1.9	150
Mg	Pt	Poly-N-vinylcarbozole-$SbCl_5$	0.62	0.5
Mg	Pt	TCNE-graphite*	1.5	4
Mg	Pt	TCNQ-graphite**	1.50	150

* TCNE: tetracyanoethylene.
** TCNQ: tetracyanoquinodimethane.

in agreement with the higher heat of formation of $MgBr_2$.

It should be pointed out that the presence of a metal electrode is not a prerequisite for the electrochemical generation of useful power; however, an ionic concentration gradient across a potential barrier is essential. Thus, it was found possible to devise a wholly nonmetallic battery, based entirely on organic compounds. Work along these lines is proceeding.

Other variables: current-voltage relationships as a function of temperature and time.—A number of systems of the type Mg/I iodine complex have been discussed (see Table II). Typical current-voltage curves are shown in Fig. 3 and 4.

It has been shown that for cell assembly in uncontrolled humidity environments there was an improvement of cell characteristics with time. This "aging" effect has been observed with magnesium anodes in other types of cells (6). It is probably associated with the processes governing the formation and dissociation of the magnesium hydroxide layer mentioned previously. Figures 3 and 4 show quantitatively how aging improves cell characteristics. This effect is not observed for cell assembly in low humidity environment.

The overvoltage (Fig. 3 and 4) is taken as the difference between the (reversible) open-circuit potential, and the voltage actually obtained for a given current drain. Thus, the figures show two abscissae, actual terminal voltage and overvoltage; the latter is zero by definition when the current vanishes.

Figure 5 shows the temperature dependence of the current voltage characteristics of iodine complexed with poly-2-vinylpyridine and carbon black. Two features to be noted from this figure are that the cell es-

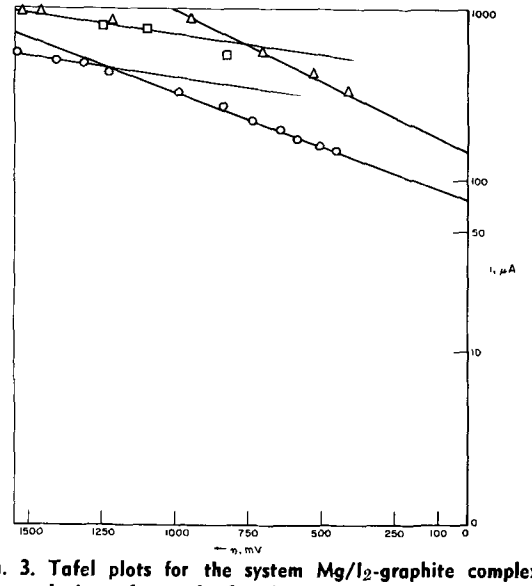

Fig. 3. Tafel plots for the system Mg/I_2-graphite complex/Pt. Points marked ⊙ refer to the freshly prepared cell, the other points refer to the same cell after three days' aging; △ were obtained on increasing the current and points □ on lowering the current. The abscissae here represent overvoltages.

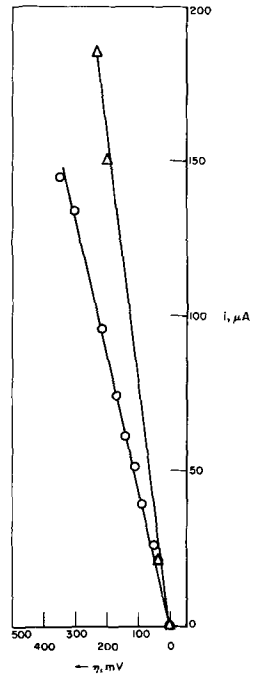

Fig. 4. Low overvoltage current-voltage characteristics. These data represent the low current region, continuing Fig. 3, but on a linear scale; they refer to the same system. Points marked ⊙ were obtained with the freshly prepared and points △ with the same cell aged for three days. The abscissae again reads overvoltages.

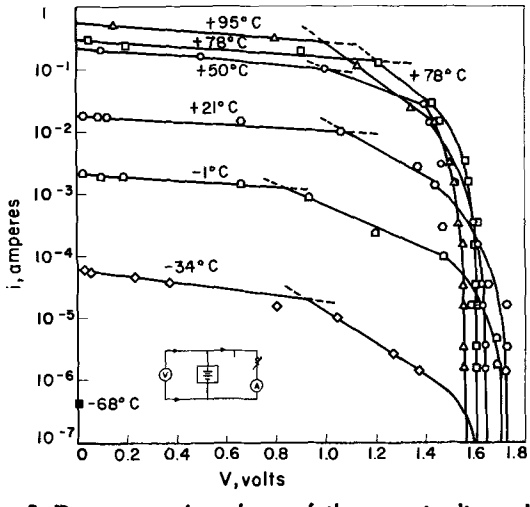

Fig. 5. Temperature dependence of the current-voltage characteristics for the system

Mg	Poly-2-vinylpyridine	40% by wt	C
	Iodine	50% by wt	
	Graphite	10% by wt	

sentially ceases operation below −68°C, and that the short-circuit current increases with increasing temperature, reaching 0.7 amp at 95°C. This dramatic increase of the current in the Tafel and diffusion regions can be analyzed by plotting the variation of the short-circuit current with reciprocal temperature. A plot of this type gives an excellent straight line below 50°C, whose slope corresponds to an activation energy of 15.6 kcal/mole and straight line above 50°C, whose slope corresponds to an activation energy of 5.99 kcal/mole. This particular cell was also cooled to 80°K for 10 min, recovering fully upon warming to room temperature.

Figure 6 shows discharge curves for the perylene-iodine complex (weight ratio 1:2) at various constant loads. The voltage drop rates have been determined in

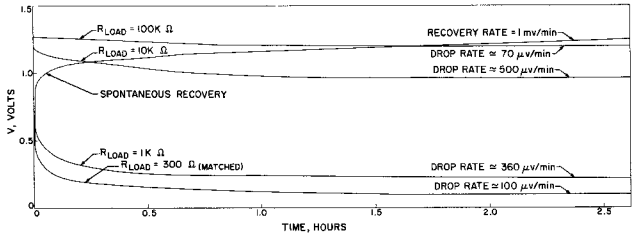

Fig. 6. Discharge curves at room temperature for the system Mg/perylene-iodine/Pt at various fixed loads. Also plotted is the spontaneous open-circuit voltage recovery measured after the discharge data were recorded.

the region designated in the figure; these rates decrease with increasing time. A spontaneous recovery curve is also recorded in Fig. 6; this plot was made by recording the time dependence of the open-circuit voltage immediately after the last of the discharge curves was completed. It can be inferred from the recovery curve that the decrease in current with time is due primarily to a nonequilibrium distribution of ions in the cell, and only in part due to the formation of the magnesium iodide layer (and consequent reduction in ion diffusion). The information that can be obtained from Fig. 6 (using cell weights of 0.5 g, including complex and electrode contributions) is summarized as follows: open-circuit voltage, 1.4v; initial, matched load, current density, 2.0 ma/cm^2; maximum power density (under matched load, initial time conditions): ~ 1 watt/lb; useful energy density (for 100 kohm, load assuming that a voltage below one half the open-circuit value is not useful): ~ 1 watt hr/lb. Further discharge data are being gathered to determine the energy efficiency of the cell.

Figure 7 shows a current-voltage characteristic of a cell using a poly-N-vinylcarbazole-iodine complex as the cathode. This is a system with a relatively high cathode resistance; the current is seen to remain limited by this IR drop and the Tafel region cannot be reached. The dynamic resistance of the system is 54,000

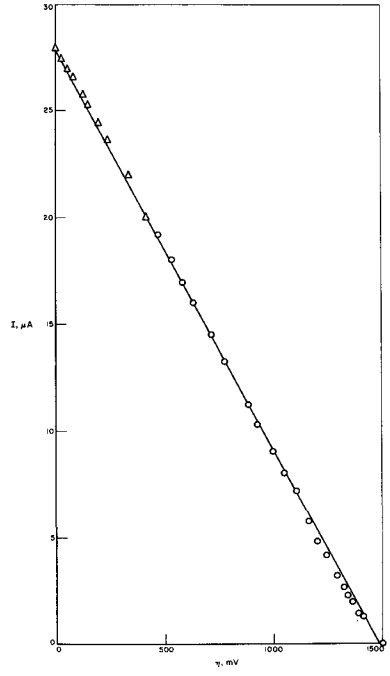

Fig. 7. Current voltage characteristic of the system Mg/I_2-poly-N-vinyl-carbazole complex/Pt. Points ⊙ and △ were taken at different times. The abscissae read overvoltages. The overvoltages are seen to be entirely determined by the ohmic series resistance of the cell.

ohm; while one can, formally, calculate an exchange current from this curve, little significance may be attached to it since the system does not operate under activation control. With this proviso, a value of i_o = 6 x 10^{-7} amp/cm^2 is reported.

Analysis: Thermodynamics of the Mg/I_2-C System

The room temperature current-voltage characteristics (Fig. 3 and 4) show that the Tafel equation is obeyed at current densities in excess of a few 100 μa/cm^2. At low current densities and correspondingly low values of overvoltage, the current is proportional to voltage. The current then obeys the relation approximately valid (7) for this region

$$i = \frac{i_o \eta \mathbf{F}}{RT} \qquad [2]$$

where i is the current corresponding to an overvoltage η, and i_o is the exchange current; R, T, and $\mathbf{F}$ have the usual meaning. From the slope, a dynamic resistance of 2300 ohms/cm^2 for freshly prepared Mg/I_2-C complex/Pt cell is obtained, valid up to about 156 μa/cm^2. This resistance corresponds to an exchange current density of 9.4 x 10^{-6} amp/cm^2. At higher current densities and thus higher overvoltages, a Tafel slope of —0.714 results; the exchange current density then follows by extrapolation as 58.3 μa/cm^2 which is not too different from the value obtained or the low current region.

The stoichiometric number γ of the rate-determining step represents the number of times this reaction has to occur for the over-all reaction to advance by one DeDonder unit. A value for γ may be obtained from the low current-density versus η plot, using the relation (8)

$$\gamma = \left| \frac{z\mathbf{F}i_o}{RT} \left(\frac{\partial \eta}{\partial i} \right)_{\eta \to 0} \right| \qquad [3]$$

This yields γ = 2.12, *i.e.*, practically 2, meaning that the rate-determining step must occur twice in order for the over-all reaction to be advanced by one unit. It is also assumed that there is no change in the rate-determining mechanism between the reversible region and the region of activation control.

From the slope of the current-voltage curve shown in Fig. 3, a value for the Tafel coefficient β_a = 0.018, valid for the region of activation control, is obtained for the freshly prepared Mg/I_2-C/Pt system. The electrochemical information thus available on this system is the following: number of electrons involved in the over-all reaction, z = 2; stoichiometric number, γ = 2; Tafel coefficient, β_a = 0.018; exchange current density, i_o = 9.4 μa/cm^2. We shall also assume that the affinity factor δ of the rate-determining step has a value very close to unity (9); the affinity factor is defined (9) as the number of electrons involved in one single rate-determining event.

In these solid-state electrochemical cells, we consider one reaction, in the present case, the formation of magnesium iodide. For the region of activation control, we may write

$$I = I_o \left(e^{\alpha_a \mathbf{F}\eta/RT} - e^{-\alpha_c \mathbf{F}\eta/RT}\right) \qquad [4]$$

where the first term refers to the forward and the second term to the reverse reaction. The transfer coefficients α_a for the forward and α_c for the reverse reaction must add up to unity

$$\alpha_a + \alpha_c = 1 \qquad [5]$$

We may also write (4)

$$\left.\begin{aligned} \beta_a + \beta_c &= (\alpha_a + \alpha_c)\frac{z\delta}{\gamma} \\ \alpha_a &= \beta_a/(\beta_a + \beta_c) \end{aligned}\right\} \qquad [6]$$

For the linear, low overvoltage region, we may also approximate

$$I \simeq I_o \frac{(\beta_a + \beta_c)\mathbf{F}\eta}{RT} \quad [7]$$

Since $\delta \simeq 1$, it follows that $\beta_a + \beta_c = 1$, so that

$$\begin{aligned} \beta_c &= 0.982 \\ \alpha_a &= \beta_a = 0.018 \\ \alpha_c &= \beta_c = 0.982 \end{aligned} \quad [8]$$

In irreversible thermodynamics

$$\gamma \tilde{A}^o = \delta \tilde{A} \quad [9]$$

Here, $\tilde{A}^o$ stands for the electrochemical affinity of the rate-determining step and $\tilde{A}$ for the total electrochemical affinity of the over-all reaction, given by

$$\tilde{A} = z\mathbf{F}\eta \quad [10]$$

The electrochemical affinity of the rate-determining step thus follows as

$$\begin{aligned} \tilde{A}^o = z\mathbf{F}\eta\delta/\gamma &= 6.9 \times 10^4 \text{ volt-coul/mole} \\ &= 16.5 \text{ kcal/mole} \end{aligned} \quad [11]$$

for the same cell operating under matched load conditions, $\eta = 750$ mv.

The increase in the degree of advancement (10) of the over-all, energy producing cell reaction, $d\xi/dt$, which may be equated to the conventional reaction rate v, is given by

$$i = z\mathbf{F}\frac{d\xi}{dE} = z\mathbf{F}v \quad [12]$$

Under matched load conditions a current density of about 500 μa/cm^2 is obtained using a Mg anode and an I_2-C complex as a cathode. Two electrons being involved, a reaction rate of 2.5 x 10^{-9} moles-cm^{-2} results. This may be inserted into the equation (11)

$$v = d\xi/dt = \left[\tau\frac{KT}{h}\exp\left(\frac{-\Delta\bar{G}^{\#}}{RT}\right)\right][C_s(1-\theta)] \quad [13]$$

where τ is a transmission coefficient, $\Delta\bar{G}_o^{\#}$ the electrochemical standard free energy of activation, C_s the concentration of the reactant at the Mg-electrolyte interface, and $(1-\theta)$ gives the specific fractional area available for the discharge of additional molecules at the surface. $\theta = f(v)$ and thus represents the fraction of the surface area covered with reaction product (MgI_2) at the given current. Generally, $\tau \simeq 1$. Direct measurement of the current at 20° and at 135°C showed an increase by a factor of 300; thus, $\Delta\bar{G}_o^{\#}$ = about 12.4 kcal/mole. At 300°K, the quantity in the square brackets, representing an effective surface concentration, results as 4 x 10^{-13} moles/cm^{-2} = 2.4 x 10^{11} molecules of I_2 per cm^2 area. Since a monolayer of I_2 contains about 5.2 x 10^{14} molecules cm^{-2}, this shows a coverage of about 4.6 x 10^{-4} of the total electrode area; $(1-\theta)$ = 4.6 x 10^{-4}. Thus only a minute fraction of the total electrode area is available for further internal discharge; most of the area is covered with the MgI_2 produced by the reaction.

Under reversible conditions, about 1/7th of a monolayer participates in the electrochemical reaction if the exchange current value of 1.4 x 10^{-5} amp/cm^2, valid for a freshly prepared cell, is used. The highest exchange current in well-aged cells, valid in the Tafel region before the onset of diffusion limitation, is 1.8 x 10^{-4} amp/cm^2. Then, about one-half of a monolayer is seen to participate in the electrochemical reaction. Thus, as soon as higher current densities are demanded from the system, the effective electrode area, available for the electrochemical process, tends to shrink rapidly until the previously calculated fraction of about 4.6 x 10^{-4} of the total electrode area is reached; "polarization" thus is due to the cumulative poisoning of the electrode surface by the accumulation of reaction product.

At high current densities and overvoltages, the slope of the Tafel plots in the I/V characteristics is seen to change, the current tending to saturate. It is seen from Fig. 3 that the slope of these lines is the same irrespective of aging and, indeed, the same for different samples. Thus, it is very likely that in this region the current is limited by diffusion and no longer is activation controlled. The limiting, diffusion current i_L is about 1 ma/cm^2. This may be written

$$i_L = Dz\mathbf{F}a/sn \quad [14]$$

where D is the diffusion coefficient of the reactant, a its effective surface activity, s the thickness of the diffusion layer, and n stands for the sum of the transport numbers of all the ion species engaged in the electrochemical reaction. Taking $n = 1$, and using concentration instead of the activity, we obtain, inserting the value for the effective surface concentration obtained before, *viz.*, 2.4 x 10^{11} molecules/cm^2, corresponding to 5.43 x 10^{17} molecules/cm^3, s = 0.046 cm. The thickness of the diffusion layer being about 0.5 mm, it follows that there is little or no virtue in using cathode layers much thicker than, say 1 mm or so (neglecting lifetime considerations). A value of D = 10^{-5} cm^2 sec^{-1} has been used, this being a reasonable value.

The instantaneous efficiency of energy conversion, H, may be calculated from irreversible thermodynamics using an equation derived by van Rysselberghe (12)

$$H = 1 - z\mathbf{F}(\Sigma\eta)/A \quad [15]$$

where $\Sigma\eta$ is the sum of all overvoltages and A the (instantaneous) chemical affinity of the cell reaction, $A = -(\partial G/\partial\xi)_{T,P}$. Using the value for the heat of formation of MgI_2 listed in Table I for A instead of the free energy change, which latter value is not available, yields H = 78%.

Reaction Mechanisms

Since the open-circuit voltages of a given metal are virtually the same with pure iodine and with iodine complexes as with the electrolyte, it appears that the energy producing reaction is the formation of the metal-iodide from the elements. This is further supported by the excellent agreement between the values of the open-circuit voltage and the energy of formation, see Table I. Two electrons are thus involved in the over-all reaction, and the value obtained for $\gamma = 2$ requires that the rate-determining reaction must be carried through twice for the over-all reaction to advance by one unit, *i.e.*, for the formation of 1 mole of MgI_2. Several reaction mechanisms may be devised to agree with these requirements. Thus, *e.g.*, the following mechanism is compatible with $z = 2$ and $\gamma = 2$

$$\left.\begin{array}{l} 2[Mg + I^- \rightarrow MgI + e^-] \\ 2MgI \rightleftarrows MgI_2 + Mg \\ \hline Mg + 2I^- \rightarrow MgI_2 + 2e^- \end{array}\right\} \quad [16]$$

The first step is the rate-determining one, while the second step involves a reaction at or near equilibrium. There must be, linked with the above reaction scheme, a further reaction as a source of I^- ions; this could well be

$$I_2 + 2e^- \rightleftarrows 2I^- \quad [17]$$

The reaction involved in the case of the halide-free electrolytes, viz., TCNQ-C and TCNE-C complexes, is less clear, Both TCNE and TCNQ are good electron acceptors, readily forming ions $TCNQ^-$ or $TCNE^-$. The electrode reaction then is likely to be

$$Mg \rightleftarrows Mg^{++} + 2e^-$$

$$2TCNQ + 2e^- \rightleftarrows 2TCNQ^-$$

$$Mg^{++} + 2TCNQ^{-} \rightleftarrows (TCNQ^{-}\_\_Mg\_\_TCNQ^{-})$$

$$Mg + 2TCNQ \rightleftarrows (TCNQ^{-}\_\_Mg^{++}\_\_TCNQ^{-}) + \text{energy} \quad [18]$$

This seems reasonable since the $Mg^{++}(2TCNQ)^{-}$ is known to exist.

Advantages and Practical Applications

These cells operate at room temperatures, but will stand elevated temperatures at least up to 130°C; thus, they are likely to be heat sterilizable. These are true solid-state devices; thus, they may be encapsulated and made as small as desired. They could be used for energizing microelectronic circuits where they may become an integral part of the circuit; the cell may be produced by sequential deposition processes occupying a minimum of space. They also should lend themselves very well for a variety of electromedical applications.

The energy density of the prototypes thus far studied is below the requirements for space vehicle power devices. It is certain however, that proper engineering and improvements due to further studies will improve present performance substantially. The iodine-complexes are known to be stable; the shelf-life may be limited, therefore, only by internal short-circuiting. The recovery even after prolonged short circuiting is very fast, usually within minutes. The cells lend themselves particularly well for the powering of firing mechanisms for pyrotechnic devices, like squibs, where a capacitor is charged from the primary power source.

The Effect of Pressure on the Dissociation of Carbonic Acid from Measurements with Buffered Glass Electrode Cells

The Effects of NaCl, KCl, Mg^{++}, Ca^{++}, $SO_4^{=}$, and of Boric Acid with Special Reference to Sea Water

A. Distèche and S. Distèche

Laboratory of General Biology, Zoology Institute, University of Liège, Liège, Belgium

ABSTRACT

The effect of pressure on the dissociation of carbonic acid has been investigated over a wide range of pH (*pa*H 5.1-9.6) and ionic strength (0-1.0) in NaCl and KCl, using junctionless glass electrode cell measurements. At 22°C, $\Delta V_1^\circ = -25.4$ cm^3 mole^{-1} and -25.6 cm^3 mole^{-1} for the first and second ionization steps, respectively. The directly measured *pm*H or *pc*H shifts induced by pressure in sea water between *pa*H$_1$ 5.1 and 9.1 are explained by the enhanced dissociation of H_2CO_3, HCO_3^-, $CaCO_3$, and $MgCO_3$, the effect of $SO_4^=$ and the interference of boric acid ($\Delta V_1^\circ = -32.1$ cm^3 mole^{-1}). Values of the ionization functions $k'_{(1)} = [H^+][HR^-]/[H_2R]$ and $k'_{(2)} = [H^+][R^=]/[HR^-]$ of carbonic acid, valid in natural seawater, have been determined at 22°C, at 1 atm and at 1000 bars together with the apparent dissociation constants ($pK''_{(1)}$ and $pK''_{(2)}$ used in oceanography to calculate $[CO_3^=]_{total}$, $[HCO_3^-]_{total}$ from *in situ pa*H values. Corrections are given for different types of reference half-cells, and an approach toward the absolute values of $pk_{(1)}$ and $pk_{(2)}$ in sea water is indicated.

The effect of pressure (p) on the dissociation constant (K) of a weak electrolyte (HR) is related to the corresponding volume change (ΔV) for the ionization reaction $HR \rightleftharpoons H^+ + R^-$ by the equation

$$\left(\frac{\partial \ln K}{\partial p}\right)_{m,T} = \frac{-\Delta V}{RT} \qquad [1]$$

Data are available for ΔV_1° at atmospheric pressure, zero salt concentration, and zero weak electrolyte concentration for carbonic acid calculated from density measurements, conductivity, and glass electrode determinations:

Reaction	Density, 25°C $-\Delta V_p^\circ$ (p = 1 atm) cm^3 mole^{-1}	Conductivity, 25°C $-\Delta V_p^\circ$ (p = 1 atm) cm^3 mole^{-1}	Glass electrode, 22°C $-\Delta V_p^\circ$ (p = 1 atm) cm^3 mole^{-1}
$H_2CO_3 \rightarrow HCO_3^- + H^+$	29.0 (1)	26.5 (2)	26.6 (3) (unbuffered cell) 25.5 (3) (buffered cell) 25.4 (this paper; buffered cell)
$HCO_3^- \rightarrow CO_3^= + H^+$	27.8 (1)	—	25.6 (this paper; buffered cell)

The ΔV_1° values from glass electrode measurements published in our earlier papers (3, 4) were obtained by extrapolation of ΔV_1 to zero KCl concentration over a limited ionic strength range (0-0.1).

In view of the interest in precise knowledge of the effect of pressure on the dissociation of carbonic acid for oceanographic work, the present paper deals with the determination between 1 and 1000 atm of the dissociation constants $K_{(1)}$ and $K_{(2)}$ and the ionization functions $k_{(1)}$, $k_{(2)}$ ($k_{(1)} = [H^+][HCO_3^-]/[CO_2]$, $k_{(2)} = [H^+][CO_3^=]/[HCO_3^-]$) in presence of NaCl or KCl, over a wide ionic strength range (0-0.8), at various buffer ratios (*pa*H 5.1-9.6). The effect of Ca^{++}, Mg^{++}, and $SO_4^=$ ions and boric acid is investigated to interpret the data obtained with natural sea water samples (4) and from direct in situ determinations (5, 6).

Theoretical

The theory underlying the determination of dissociation constants as a function of pressure has been discussed in previous papers (3, 4).

The buffered cell used for the present determinations is of the type:

Ag — AgCl	Ref. compartment HCl (0.01) MCl (m_3 — 0.01)	glass	x compartment HR(m_1) + MR(m_2) MCl (m_3)	AgCl — Ag

where M represents Na or K.

The emf (E) at pressure 1, or p, is expressed by:

$$E_{1,p}\,\mathbf{F}/2.3\,RT = \log (m_{H^+})^{ref}{}_{1,p} - \log (m_{H^+})^{x}{}_{1,p} + 2 \log \frac{(\gamma_{HCl})^{ref}{}_{1,p}}{(\gamma_{HCl})^{x}{}_{1,p}} \qquad [2]$$

For an acid HR of the strength of carbonic acid $\log K^m = \log (m_{H^+} m_1/m_2) + 2 \log \gamma_A$; $2 \log \gamma_A = \log (\gamma_{H^+} \gamma_{R^-}/\gamma_{HR})$; $m_{H^+} m_1/m_2 = k^m$ and:

$$(E_1 - E_p)\mathbf{F}/2.3\,RT = \log \frac{K^m{}_p}{K^m{}_1} + 2 \log \frac{\gamma_{A1}}{\gamma_{Ap}} + 2 \log \frac{(\gamma_{HCl})^{ref}{}_1}{(\gamma_{HCl})^{ref}{}_p} - 2 \log \frac{(\gamma_{HCl})^{x}{}_1}{(\gamma_{HCl})^{x}{}_p} \qquad [3]$$

The terms in γ_{HCl} cancel each other at infinite dilution of the weak electrolyte, but if m_1 and m_2 are small and if the salt effect of the weak acid is small, cancellation practically occurs for finite values of m_1 and m_2.

Equation [3] then simplifies to

$$(E_1 - E_p)\,\mathbf{F}/2.3\,RT = \log \frac{K^m{}_p}{K^m{}_1} + 2 \log \frac{\gamma_{A1}}{\gamma_{Ap}} = \log \frac{k'^m{}_p}{k'^m{}_1} \qquad [4]$$

the primes indicating that k' is only known approximately because of the former assumptions.

In the case of carbonic acid, extrapolation of $(E_1 - E_p)\,\mathbf{F}/2.3\,RT$ as a function of $\sqrt{\mu}$ leads easily to log $K^m{}_p/K^m{}_1$ and a double extrapolation first to zero weak acid concentrations at a given μ, and then to zero KCl or NaCl concentration, is not required.

It can be shown (7) that $\Delta V_1 = 1.016 \times (E_1 - E_{1000})$ if ΔV_1 is expressed in cm^3 mole^{-1}, E in millivolts, p in kg. cm^{-2}. E_{1000} is measured on the tangent of $E_1 - E_p = f(p)$ drawn through $p = 1$ atm. For carbonic acid, $E_1 - E_p = \Delta E_p$ is a linear function of p up to 1000 kg. cm^{-2}, so that E_{1000} corresponds to the emf effectively measured at 1000 kg. cm^{-2}.

Concentrations (m) and activity coefficients (γ) are given on the molal scale (mole per kg of pure solvent) in Eq. [1]-[4].

If the concentrations are expressed on the molar scale (mole per liter solution, c) the following classical equations ([5]-[10]) can be used to relate c, m, the corresponding activity coefficients, y and γ, the density (d) of the solution and of pure water (d_o), M_i the molecular weight of solute i. the dissociation constants and ionization functions K^c, k^c, K^m, k^m

$$m_i = c_i/(d - \Sigma c_i M_i/1000) \qquad [5]$$

$$c_i = m_i d/(1 + \Sigma m_i M_i/1000) \qquad [5']$$

$$\gamma = y[(d - \Sigma c_i M_i/1000)/d_o] \qquad [6]$$

$$m\gamma d_o = cy \qquad [7]$$

$$K^m = K^c/d_o;\; k^m = k^c(1 + \Sigma m_i M_i/1000)/d \qquad [8]$$

$$\log K^m{}_p/K^m{}_1 = \log K^c{}_p/K^c{}_1 - \log d_{op}/d_{o1} \qquad [9]$$

$$\log k^m{}_p/k^m{}_1 = \log k^c{}_p/k^c{}_1 - \log d_p/d_1 \qquad [9']$$

Combining [7] and [2] gives

$$\frac{(m\gamma)^{\mathrm{ref}}{}_{1,p}}{(m\gamma)^{x}{}_{1,p}} = \frac{(cy)^{\mathrm{ref}}{}_{1,p}}{(cy)^{x}{}_{1,p}} \qquad [10]$$

If the activity coefficients can be made to cancel in both ref and x compartments of the glass electrode, $(E_1 - E_p)\mathbf{F}/2.3\,RT$ will be equal to log $k'^m{}_p/k'^m{}_1$ and extrapolate to log $K^m{}_p/K^m{}_1$ as a function of μ (Eq. [4]) whatever the concentration scale used.

In aqueous solutions $d_p/d_1 = d_{op}/d_{o1} = 1.04$ at 1000 atm, log $d_{1000}/d_1 = 0.017$, and it is thus easy to use $(E_1 - E_{1000})$ to calculate the ratios of the dissociation constants and ionization functions either on the c or the m scale.

When the absolute values of $k'^m{}_1$, $k'^c{}_1$ are required, Eq. [5], [5'], and [6] can be used to calculate either ionization function from the results obtained on the c or the m scale, respectively.

In practice, if the highest precision is not required, $c \simeq m$ at 0.1M. At concentrations where the correction to calculate m from c is more important, the densities in the x and ref compartments of the glass electrode are nearly equal when the buffer concentration is small compared with the NaCl or KCl concentrations, and only m_{H+} needs be computed in the reference solution, since $m_{Cl^-}{}^{x} = m_{Cl^-}{}^{ref}$.

In the present paper, concentrations referring to the gross composition of the solutions are indicated on the molar scale, and to simplify the symbol M referring to molarity is omitted (0.5 NaCl means 0.5M NaCl). The hydrogen ion stoichiometric concentration [H$^+$] is represented by pcH = −log [H$^+$] on the c-scale and pmH on the m-scale, the hydrogen ion activity a_{H+} by paH = −log a_{H+} and if the distinction between pcH, pmH, paH is irrelevant, the symbol pH is used; subscripts p, 1, 1000 indicate pressure p, 1 atm, 1000 kg. cm^{-2} (ex. : pmH$_1$, pmH$_{1000}$); $\Delta E_{1000} = E_1 - E_{1000}$ in millivolts (mv).

Experimental

The equipment described in 1962 (7) is used. It is important in the experiments involving equilibration with either pure CO_2 or mixtures of CO_2 and nitrogen to saturate the silicone oil used in the glass electrode cell and to fill the cell with pipettes containing a controlled gas phase (3).

The glass electrode is made from Corning 015 glass, when no sodium error is to be expected. A commercial electrode, E.I.L.[1] n° 18331 unsensitive toward Na^+ at alkaline pH is used whenever necessary.

Corrections for asymmetry potential shift with pressure is made as described earlier (3, 4, 7). When both cell compartments contain the same solution ΔE_{1000} is generally between 0 and ±1.0 mv. Higher values indicate defective Ag-AgCl electrodes.

Highest grade reagents (Merck) and air-free bidistilled water (Pyrex) are used.

Results

First ionization function and first dissociation constant of carbonic acid in bicarbonate buffer in presence of NaCl *or* KCl, *at $p = 1$ atm and $p = 1000$ kg. cm^{-2}.*—Figure 1 shows ΔE_{1000} in mv as a function of $\sqrt{\mu}$ for various bicarbonate buffers at different buffer ratios, in presence of NaCl or KCl. Extrapolation to zero ionic strength gives 25.0 mv corresponding to $-\Delta V_1{}^o = 25.4$ cm^3 mole^{-1}, in agreement with our previous experiments (4).

Figure 2 gives the ionization function $pk'^c{}_{(1)} = -\log k'^c{}_{(1)}$ and $pK'^c{}_{(1)} = -\log K'^c{}_{(1)} = pk'^c{}_{(1)} + \dfrac{1.01\sqrt{\mu}}{1+\sqrt{\mu}}$ as a function of μ at $p = 1$ atm and $pK'^c{}_{(1)p} + \log d_p/d_1$ at $p = 1000$ kg. cm^{-2} (log $d_p/d_1 = 0.017$).

The absolute values of $pK^c{}_{(1)}$ (6.38) and $pk'^c{}_{(1)}$ are in good agreement with the data of Harned and Davis (8) and of Harned and Bonner (9) ($pK^m{}_{(1)} = 6.3809$ at 20° and 6.3519 at 25°C).

The concentration ratios $[HCO_3^-]/[CO_2]$ are computed from the equations of these authors and the same extrapolation function is found to fit our results and theirs. The 2 log $(y_{HCl})^{ref}/(y_{HCl})^x$ term in Eq. [1] (c scale) is calculated from the values of γ_{HCl} in NaCl and KCl taken from Harned and Owen (10). It is assumed that γ_{HCl} in the x compartment is only affected by the ionic strength, and the ratio of the activity coefficients is also supposed to be valid on the molar scale. At $\mu \geq 0.5$, γ_{HCl} practically cancels in both compartments.

At $\mu = 0.75$, $pk'^m{}_{(1)} = pk'^c{}_{(1)} - 0.007 = 5.995$. The correction is −0.005, −0.0057, −0.0065, −0.0073,

[1] Electronic Instruments Limited, Richmond, Surrey, England.

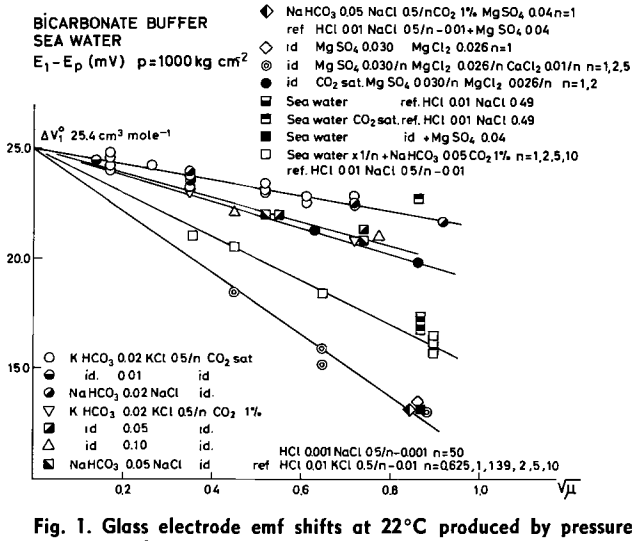

Fig. 1. Glass electrode emf shifts at 22°C produced by pressure (1000 kg.cm^{-2}), in bicarbonate buffers, at different buffer ratios, as a function of $\sqrt{\mu}$, in NaCl, KCl, in presence of Mg^{++}, Ca^{++}, $SO_4^=$ ions, and in sea water.

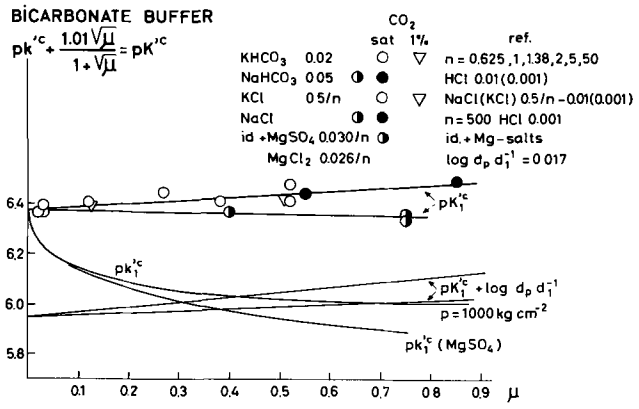

Fig. 2. First ionization function ($k'^c_{(1)}$) of carbonic acid and as a function of μ at atm pressure and 1000 kg.cm^{-2} in NaCl and KCl at 22°C. Effect of $MgSO_4$ + $MgCl_2$.

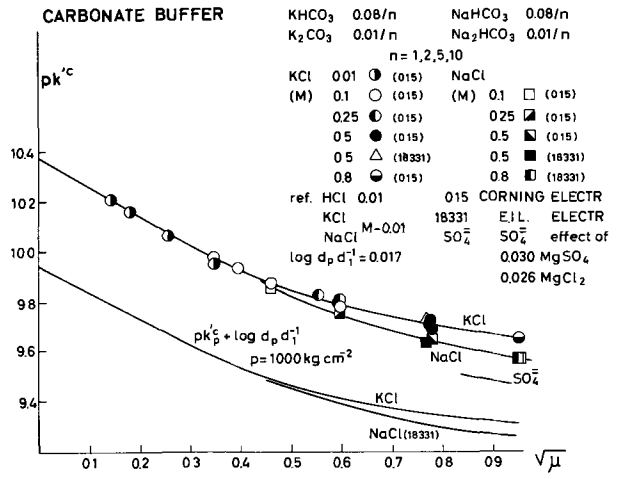

Fig. 4. Second ionization function ($k'^c_{(2)}$) of carbonic acid as a function of $\sqrt{\mu}$ at atm pressure and 1000 kg.cm^{-2} in NaCl and KCl at 22°C. Sulfate effect of 0.030 $MgSO_4$ (+0.026 $MgCl_2$).

−0.0081, −0.009 at μ0.5, 0.6, 0.7, 0.8, 0.9, 1.0, respectively (calculated from the density of NaCl solutions), and at $\mu = 0$, it is equal to −0.001.

Second ionization function and second ionization constant of carbonic acid in carbonate buffer in presence of NaCl *or* KCl, *at p = 1 atm and p = 1000 kg. cm^{-2}.*—Figure 3 gives ΔE_{1000} in mv, as a function of $\sqrt{\mu}$ for carbonate buffer in presence of NaCl or KCl.

Extrapolation to zero ionic strength gives 25.1 mv or $-\Delta V_1^o$ = 25.6 cm^3 mole^{-1}, which is practically the same result obtained in bicarbonate buffers. The value calculated by Owen and Brinkley (1) from density determinations is 27.8 cm^3 mole^{-1}.

Figure 4 shows the ionization function $pk'^c_{(2)}$ as a function of $\sqrt{\mu}$ at p = 1 atm, $pk'^c_{(2)p}$ + log d_p/d_1 at p = 1000 kg. cm^{-2}; the results in 0.5 and 0.8 NaCl do not depend on the buffer ratio and are identical either with $NaHCO_3$ 0.08 + Na_2CO_3 0.01 or with $NaHCO_3$ 0.025 + Na_2CO_3 0.025. $pK^c_{(2)}$ = 10.37 corresponds to the values published by Harned and Scholes (11) ($pK^m_{(2)}$ = 10.377 at 20°C, 10.329 at 25°C) who extrapolate their data between μ = 0.15 and 0.

At μ = 0.75, $pk'^m_{(2)1}$ = 9.60 − 0.007 in NaCl.

Effect of buffer ratio on the ionization of carbonic acid at 1000 kg. cm^{-2} in NaCl *and* KCl *solutions.*—Figures 1 and 3 show that, at a given buffer ratio, ΔE_{1000} extrapolates linearly to the same value at μ = 0, and that a change in the buffer concentration has the same effect as the corresponding μ change produced by an increase of the NaCl or KCl concentration. It is therefore easy to obtain a graphical estimate of ΔE_{1000} at a chosen ionic strength, even from isolated values measured at another ionic strength.

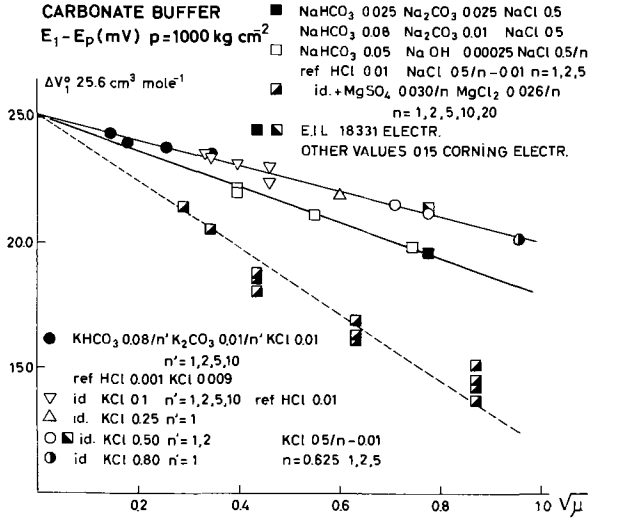

Fig. 3. Glass electrode emf shifts at 22°C, produced by pressure (1000 kg.cm^{-2}) in carbonate buffers, at different buffer ratios, as a function of $\sqrt{\mu}$, in NaCl or KCl, in presence of Mg^{++}, Ca^{++}, $SO_4^=$, and in sea water.

Curves 1 and 1′ from Fig. 5 give ΔE_{1000} at μ = 0.75 (ionic strength of sea water at Cl‰ = 20.0) as a function of pmH_1, in NaCl and KCl. The emf shifts depend only slightly on the total CO_2 concentration in the range investigated ($[HCO_3^-] + [CO_3^=]$ between 0.09 and 0.0025; arrows indicate the values at 0.0025 in Fig. 5).

The reason for the difference between the results in NaCl and KCl at $pmH_1 \geqq 8.5$ is, we believe to be correlated with the fact that, at 1 atm, the curves giving $pk'_{(2)}$ as a function of $\sqrt{\mu}$ (Fig. 3) demonstrate the greater tendency for carbonate ions to associate with Na than with K. Ion pairs like $Na^+ - CO_3^=$ or $Na^+ - NaCO_3^-$ will dissociate under pressure, and free $CO_3^=$ ions, hitherto masked for the carbonic acid equilibrium, will modify the buffer ratio, so that the pmH shift induced by pressure can be expected to be smaller than in a medium where association is less important or inexistent. We will see that magnesium and calcium ions which have a much larger tendency to form ion pairs with $CO_3^=$ than sodium ions also have a much larger lowering effect on the emf changes produced by pressure in carbonate buffers.

Since K^+ or Na^+ may also form ions pairs with HCO_3^-, a complete analysis of curves 1 and 1′ appears to be far from easy and would require the knowledge of $pk'_{(1)(2)}$ and $\Delta pk'_{(1)(2)}/\Delta p$ in absence of any ionic association; the dissociation constants of $NaCO_3^-$ and $NaHCO_3$ would have to be taken into account and also the equilibrium $2HCO_3^- \leftrightharpoons CO_3^= + H_2CO_3$, which is displaced when $CO_3^=$ or HCO_3^- is released in the solution. Besides the salt effect of NaCl or KCl would have to be known.

There is however no difficulty in considering that in the ionization functions $k'_{(1)}$ and $k'_{(2)}$, determined at atmospheric pressure or at 1000 kg. cm^{-2}, $[CO_3^=]$ and $[HCO_3^-]$ refer to the total concentration of $CO_3^=$ of HCO_3^-, ions present either as free ions or forming ion pairs with Na or K.

In the pmH_1 interval 8.5-9.5 the thus defined $pk'_{(2)1000}$ can be measured without ambiguity from curves 1 and 1′ of Fig. 5 since ΔE_{1000} is constant. The buffer ratio and the term 2 log γ_{A1}/γ_{Ap} in Eq. [3] are constant, the mean activity coefficient being referred to the total concentrations of free and masked ions. Log $k'^m_{(2)1000}/k'^m_{(2)1}$ is therefore equal to 0.315 (ΔE_{1000} = 19.0 mv) and 0.350 (ΔE_{1000} = 20.8 mv) in NaCl and KCl, respectively.

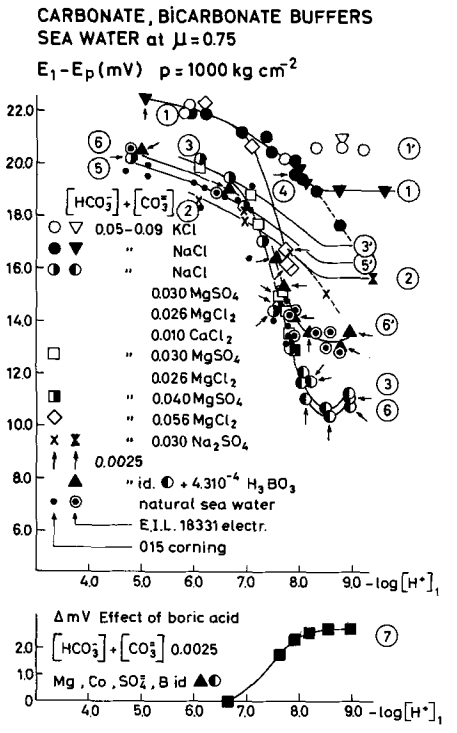

Fig. 5. Glass electrode emf shifts at 22°C produced by pressure (1000 kg.cm^{-2}) in bicarbonate, carbonate buffers, and sea water at $\mu = 0.75$, as a function of $pmH = -\log m_H$ measured at atm pressure. Curve 1, $NaHCO_3$, Na_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09 and 0.0025 (arrow) in 0.5 NaCl. Curve 1', $KHCO_3$, K_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09) in 0.5 KCl. Curve 2, $NaHCO_3$, Na_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09) in 0.5 NaCl; effect of Na_2SO_4 (0.030). Curve 3, $NaHCO_3$, Na_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09) in 0.5 NaCl; effect of $MgSO_4$ (0.030), $MgCl_2$ (0.026), $CaCl_2$ (0.01) (Precipitates are obtained at pH > 8.0). Arrows indicate results for $[HCO_3^-] + [CO_3^=] = 0.0025$ (see also curve segments 6). Curve 3', $NaHCO_3$, Na_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09) in 0.5 NaCl; $SO_4^=$ effect of $MgSO_4$ (0.030). Curve 4, $NaHCO_3$, Na_2CO_3, CO_2 ($[HCO_3^-] + [CO_3^=]$ 0.05 — 0.09 and 0.025 (arrows); effect of $MgCl_2$ (0.056). Curve 5, Natural sea water Cl $‰_0 \simeq 19.5$ (Atlantic), corrected at Cl$‰_0$ 20.0 ($\mu = 0.75$). Curve 5', Natural sea water; $SO_4^=$ effect. Curve 6, Artificial sea water: $[HCO_3] + [CO_3^=] = 0.0025$; 0.030 $MgSO_4$, 0.026 $MgCl_2$, 0.010 $CaCl_2$, 0.5 NaCl (with or without boric acid in the acid range). Curve 6', Artificial sea water with boric acid (4.3 10^{-4}) (alkaline range). Curve 7, Effect of boric acid; smoothed difference in mv between ($E_1 - E_{1000}$) in artificial sea water without boric acid (see curves 3 and 6) and ($E_1 - E_{1000}$) in the same with 4.3 10^{-4} boric acid (see curves 6 and 6').

Inspection of curve 1 further indicates that the results at $pmH_1 \leq 7.00$ are identical in KCl and NaCl. If one again assumes that the bicarbonate concentration corresponds to the sum of the free HCO_3^- ions and the undissociated sodium or potassium bicarbonate, log $k'^m_{(1)1000}/k'^m_{(1)1}$ is equal to 0.359 ($\Delta E_{1000} = 21.0$ mv) at pmH_1 7.0, 0.376 at pmH_1 6.0, and 0.385 at pmH_1 5.0. Here the term 2 log $\gamma_{A_1}/\gamma_{A_p}$ in Eq. [3] is not constant and depends on the buffer ratio.

The question that remains to be answered concerns the choice of suitable values for $pk'_{(1)1000}$ and $pk'_{(2)1000}$ in the pmH_1 range 7.0-8.5, where the emf changes induced by pressure depend on both ionization functions.

If we consider a solution containing NaCl and $NaHCO_3$ at atmospheric pressure, its $pmH_1 = \frac{1}{2}(pk'^m_{(1)1} + pk'^m_{(2)1})$; at $\mu = 0.75$, one finds $pmH_1 \simeq 7.8 = \frac{1}{2}$ (6.0 + 9.6) and $[CO_2] = [CO_3^=]$. At $pmH_1 = 7.8$, $\Delta E_{1000} = 20.0$ mv, and simple considerations show that $[CO_2]$ will remain equal to $[CO_3^=]$ if 2.3 $RT/\mathbf{F}$ log $k'^m_{(1)1000}/k'^m_{(1)1}$ and 2.3 $RT/\mathbf{F}$ log $k'^m_{(2)1000}/k'^m_{(2)1}$ are taken symmetric with respect to $\Delta E_{1000} = 20.0$ mv. For instance, 21.0 and 19.0 mv read at pmH_1 7.0 and 8.5 on curve 1 of Fig. 5. In that case the equilibrium $2HCO_3^- \rightleftharpoons CO_3^= + H_2CO_3$ is shifted. Thus, at $pmH_1 = 7.8$, if $[HCO_3^-] + [CO_3^=] = 0.05$, 6.10^{-5} HCO_3^- is formed at 1000 kg. cm^{-2} at the expense of 3.10^{-5} CO_2 and 3.10^{-5} $CO_3^=$, which corresponds to a 4% change of the initial CO_2 and $CO_3^=$ concentrations. At pmH_1 7.0 and 8.5, the change of either $[CO_2]$ and $[HCO_3^-]$ or $[CO_3^=]$ and $[HCO_3^-]$ is negligible when pressure is applied. If one could assume 2.3 $RT/\mathbf{F}$ log $k'^m_{(1)1000}/k'^m_{(1)1}$ and 2.3 $RT/\mathbf{F}$ log $k'^m_{(2)1000}/k'^m_{(2)1}$ to be equal to ΔE_{1000} read on curve 1 at any pmH_1 between 5.0 and 9.0, the CO_2, HCO_3^-, $CO_3^=$ concentrations would remain constant at any pressure. This is what happens at infinite dilution where $\Delta V^o_{(1)1} = \Delta V^o_{(2)1}$.

In KCl, if one neglects the slight minimum at pmH_1 7.8, 2.3 $RT/\mathbf{F}$ log $k'^m_{(1)1000}/k'^m_{(1)1}$ and 2.3 $RT/\mathbf{F}$ log $k'^m_{(2)1000}/k'^m_{(2)1}$ are equal within ± 0.25 mv over the range 7.0-9.0. However, this is an oversimplification since the minimum at 7.8 could be explained by the release of $CO_3^=$ and HCO_3^- from ion pairs. HCO_3^- behaves as a base at $pmH_1 < 7.8$ and as an acid at $pmH_1 > 7.8$, whereas the release of $CO_3^=$ always results in lowering the hydrogen ion concentration.

The choice of the values of $pk'^m_{(1)1000}$ at pmH_1 7.0 and $pk'^m_{(2)1000}$ at pmH_1 8.5 to be used in the pmH_1 interval 7.0-8.5 remains questionable, even in KCl, but there is no other alternative unless reliable values for $pk'^m_{(1)}$ and $pk'^m_{(2)}$ become available in absence of any ionic association. However, at the alkaline end of the pmH_1 interval 7.0-8.5, $pk'^m_{(1)}$ needs not to be known with great precision to calculate $[HCO_3^-]$ or $[CO_3^=]$. At pmH_1 8.0, an error of 0.02 ($\Delta E \simeq 1.2$ mv) in $pk'^m_{(1)1000}$ affects $[CO_2]$ by 2% and $[HCO_3^-]$ and $[CO_3^=]$ by only 0.1%.

The separate salt effect of NaCl on 2.3 $RT/\mathbf{F}$ log $k'^m_{(1)1000}/k'^m_{(1)1}$ can be estimated at $pmH_1 < 5.0$ since curve 1 in Fig. 5 seems to reach a plateau in the acid range and since ΔE_{1000} is known at 0 ionic strength (25.0 mv). Thus, for the salt effect, one finds 25.0 — 22.6 = 2.4 mv. This value fits with the fact that 2 ΔE_{1000} = 23.6 mv at $\mu = 0.75$ in a solution containing only NaCl and saturated with CO_2. At $\mu = 0$, 2 ΔE_{1000} = 26.2 mv (3) and the difference 26.2 — 23.6 = 2.6 mv.

It seems reasonable to assume that the difference between ΔV^o_1 found in pure CO_2 solutions and in bicarbonate buffer at 0 ionic strength might be related to the existence of $NaHCO_3$ ion pairs even when the concentration of $NaHCO_3$ becomes very small. The same effect occurs in other buffer systems investigated with the glass electrode technique: ΔV^o_1 is always found to be smaller in buffers than in the corresponding pure acid (3), and the explanation given above might be general.

Finally, one will notice (Fig. 5, dotted part of curves 1 and 2) that Corning 015 electrodes display an alkaline error in presence of NaCl at 1000 kg. cm^{-2} at $pmH_1 > 8.25$, although no such error can be detected even at 8.75 at atmospheric pressure.

Ionization of carbonic acid in presence of Mg^{++}, Ca^{++}, *and* $SO_4^=$ *in* NaCl *solutions, at concentrations found in sea water, at 1 atm and 1000 kg. cm^{-2} and at different buffer ratios ($\mu = 0.75$).*—When Ca or Mg salts are added to carbonate and bicarbonate buffers, it is well known [see Garrels, Thompson, and Siever (12)] that $MgCO_3$ and $CaCO_3$ ion pairs are formed and that the trapping of HCO_3^- ions is also to be considered. The dissociation of carbonic acid can still be described by the ionization functions $k'_{(1)}$ and $k'_{(2)}$ where $[CO_3^=]$ and $[HCO_3^-]$ refer to the free carbonate and bicarbonate ions (plus those bound to Na as seen in the preceding section), but it is also useful to define apparent ionization functions $k''_{(2)} = [H^+]\,[CO_3^=]_T/[HCO_3^-]_T$, $k''_{(1)} = [H^+]\,[HCO_3^-]_T/[CO_2]$ where $[CO_3^=]_T$ and $[HCO_3^-]_T$ correspond to the total amount of carbonate and bicarbonate. We will call $k'_{(2)}$ and $k'_{(1)}$ true ionization functions.

True and apparent ionization functions of carbonic acid in presence of Mg^{++}, Ca^{++} *and* $SO_4^=$, *in* NaCl *solutions at 1 atm* ($\mu = 0.75$).—Figure 6 gives the pmH_1 changes (in mv) produced when $MgCl_2$, curve 4; $MgCl_2 + MgSO_4$, curve 3; $MgCl_2 + MgSO_4 + CaCl_2$, curve 2; Na_2SO_4, curve 1 are added to bicarbonate and carbonate buffers at atmospheric pressure, as a function of pmH_1 measured in the solutions containing the added salts. The reference 0.01 HCl + 0.49 NaCl solution has the same salt composition as the buffer under test it is assumed that $m_{H+} = m_{HCl}$ and that the mean activity coefficient of HCl is the same in both compartments. The added salts are tested at concentrations normally found in sea water (Cl‰ = 20.0).

Effect of $SO_4^=$ *on the true ionization functions* $k'_{(1)1}$ *and* $k'_{(2)1}$.—Inspection of Fig. 6 shows that the effect of $SO_4^=$ ions can be distinguished from the effect of Ca and Mg.

$MgCl_2$ at $pmH_1 < 6.0$ obviously does not modify $k'^c_{(1)1}$ which is thus the same as in pure bicarbonate solutions at the same ionic strength. The ordinate difference between curves 3 and 4 in Fig. 6 shows but little variations over the pmH_1 interval considered and allows one to calculate $pk'^c_{(1)1}$ and $pk'^c_{(2)1}$. Thus for the investigated buffers ($MgSO_4$ 0.030, $[HCO_3^-] + [CO_3^=]$ between 0.0025 and 0.09) $pk'^c_{(1)1} = 5.89$ and $pk'^c_{(2)1} = 9.49$ at $\mu = 0.75$ (see Fig. 2 and curve segment in Fig. 4); $pk'^m_{(1)1} = 5.89 - 0.005$ and $pk'^m_{(2)1} = 9.49 - 0.005$. The correction for the change of concentration scale is somewhat smaller than in pure NaCl solutions and is based on a total salt content of 36.4g and the corresponding density of sea water 1.025 at 22°C (13).

Effect of Ca *and* Mg *and the apparent ionization functions* $k''_{(1)}$ *and* $k''_{(2)}$.—The shape of the curves of Fig. 6 which give the emf shifts resulting from the addition of Ca and Mg salts to bicarbonate and carbonate buffers can be understood if one bears in mind that removing a constant amount of $CO_3^=$ produces a pmH shift which is maximum at $pmH = \frac{1}{2}(pk'^m_{(1)} + pk'^m_{(2)})$. When the trapped $CO_3^=$ is a function of the initial $CO_3^=$ concentration, the maximum is broadened and shifted toward a more alkaline pmH. Removing HCO_3^- produces no shift at $pmH = \frac{1}{2}(pk'^m_{(1)} + pk'^m_{(2)})$, but results in an acidification or an alkalinization at more acid or more alkaline pmH values; HCO_3^- trapping is evident in Fig. 6 in the acid range especially when $CaCl_2$ is added to the more concentrated buffers already containing $MgSO_4$ and $MgCl_2$, but the same operation produces a precipitate at $pmH > 8.1$. No precipitates are observed in the diluted buffers. The data gathered in Fig. 6 can be used to calculate the dissociation constants of $MgCO_3$, $CaCO_3$, $MgHCO_3^+$, and $CaHCO_3^+$ as Garrels *et al.* (12) have done from paH determinations on bicarbonate and carbonate buffers before and after addition of $CaCl_2$ and $MgCl_2$. This problem, which involves lengthy calculations, is quite beyond the scope of the present paper and will not be dealt with.

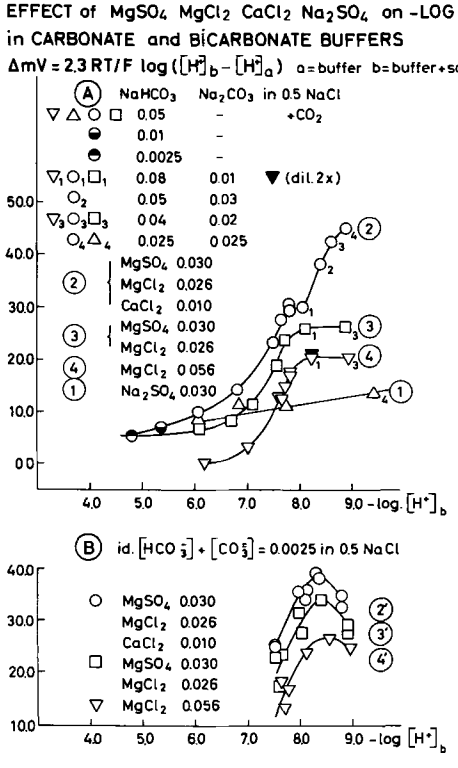

Fig. 6. Glass electrode emf shifts produced by the addition of $MgSO_4$, $MgCl_2$, $CaCl_2$, Na_2SO_4 to bicarbonate and carbonate buffers at atmospheric pressure. A. $[HCO_3] + [CO_3^=]$ 0.05 — 0.09 in 0.5 NaCl: Curve 1, effect of Na_2SO_4 (0.030); Curve 2, effect of $MgSO_4$ (0.030), $MgCl_2$ (0.026), and $CaCl_2$ (0.010). Precipitates are obtained at points 2, 3, and 4; result at pmH 4.8 corresponds to $[HCO_3^=] + [CO_3^=]$ 0.0025; Curve 3, effect of $MgSO_4$ (0.030) and $MgCl_2$ (0.026); Curve 4, effect of $MgCl_2$ (0.056). B. $[HCO_3^-] + [CO_3^=] = 0.0025$. (2'), (3'), (4') same as (2), (3), (4).

However, at $pmH_1 \geq 8.0$, Fig. 6 makes it possible to evaluate the apparent second ionization function of carbonic acid, $k''_{(2)}$, in presence of Ca^{++}, Mg^{++}, and $SO_4^=$ ions.

For buffers where $[HCO_3^-] + [CO_3^=] = 0.0025$, the emf shift due to the addition of 0.030 $MgSO_4$, 0.026 $MgCl_2$, and 0.010 $CaCl_2$ is equal to 38.0 mv at $pmH_1 \simeq 8.3$. With $pk'^c_{(2)1} = 9.67$ in the pure buffer, this leads to $pk''^c_{(2)1} = 9.67 - 0.65 = 9.02$ at $\mu = 0.73$; at $\mu = 0.75$, $pk''^c_{(2)1} = 9.015$.

More refined calculations taking into account the true ionization functions $k'^c_{(1)}$ (5.89) and $k'^c_{(2)}$ (9.49), the equilibrium $2HCO_3^- \leftrightharpoons CO_3^= + H_2CO_3$ which is displaced when $CO_3^=$ is removed, give a mean value of 9.015 ± 0.015 at $\mu = 0.75$ in the pmH_1 interval 7.9-8.5, with a minimum at 8.3 where $pk''^c_{(2)1} = 9.00$. On the molal scale $pk''^m_{(2)} = 9.015 - 0.005$, again at $\mu = 0.75$.

The agreement between the directly evaluated value of $pk''^c_{(2)1}$ and the calculated one, implies that, in first approximation, HCO_3^--trapping by Mg^{++} and Ca^{++} must be very small at $pmH_1 \geq 8.0$. Trapping of HCO_3^- to a greater extent than Na ions do, would lead to an apparent lowering of $pk'^c_{(1)}$ and also affect $pk''^c_{(2)1}$ but in a more complicated way, depending on pH. This problem will not be discussed here, and it will be assumed that between pmH_1 7.9 and 8.5 it is not necessary to introduce a first apparent ionization function, or that $pk''^c_{(1)} = pk'^c_{(1)}$ in buffers where $[CO_3^=] + [HCO_3^-] = 0.0025$.

Since $pk''^c_{(2)1} - pk'^c_{(2)1} = 0.48$, $[CO_3^=]_T \simeq 3\,[CO_3^=]$ and $[Mg - CaCO_3] \simeq 2\,[CO_3^=]$. At pmH_1 8.0 $[HCO_3^-] + [CO_3^=] = 0.0025$, $[CO_3^=] = 7.34\ 10^{-5}$, $[Mg - CaCO_3] = 1.45\ 10^{-4}$ or 0.22% of the total Ca and Mg concentrations, which is of the order of magnitude (0.28%) given by Garrels *et al.* (12, 15).

In buffers where $[CO_3^=] + [HCO_3^-] = 0.09$, $pk''^c_{(2)1}$ at pmH_1 8.1 is found equal to 9.12 when directly evaluated from curve 2, Fig. 6A, and equal to 9.10 when calculated at $\mu = 0.84$, taking reaction $2HCO_3^- \leftrightharpoons CO_3^= + H_2CO_3$ into consideration and neglecting the possibility of HCO_3^- trapping in the alkaline range. The apparent ionization function $pk''^c_{(2)1}$ is thus not only dependent on pH but also on the concentration of the buffering species. This remark is important and needs be taken into consideration when dealing with data to be valid in natural sea water.

True and apparent ionization functions of carbonic acid, in presence of Mg^{++}, Ca^{++}, *and* $SO_4^=$, *in* NaCl *solutions at 1000 kg. cm*$^{-2}$ ($\mu = 0.75$).—Comparison of curves 1 and 2 in Fig. 5 shows that ΔE_{1000} observed in pure buffer solutions is reduced by a constant amount in the presence of 0.030 Na_2SO_4, between pmH_1 6 and 9.5 (the reference 0.01 HCl + 0.49 NaCl solution has

again the same salt composition as the buffer under test and m_{H+} is assumed to be equal to m_{HCl}).

Curve 3 indicates that ΔE_{1000} drops progressively from 20.0 mv at $pmH_1 = 6.0$ to 13.1 mv at $pmH_1 = 7.90$ in 0.05 $NaHCO_3$ + 0.5 NaCl solutions containing 0.030 $MgSO_4$, 0.026 $MgCl_2$, and 0.010 $CaCl_2$ at various concentrations of CO_2.

At pH > 8.1 pressure has been applied to the solutions containing the precipitate (see p. 334). The reported emf shifts correspond to the measurements made during the second or third pressure run. The first run generally gives rather unstable values.

Nearly the same emf shifts are observed at pmH_1 7.8-7.9 with 0.04 $MgSO_4$ or 0.030 $MgSO_4$ + 0.026 $MgCl_2$ with or without 0.010 $CaCl_2$ (also see Fig. 1 and 3). Lowering of the total CO_2 concentration has not a great effect either. At $[CO_3^=] + [HCO_3^-] = 0.0025$, where no precipitates are observed, the results (indicated by arrows and curve segment 6 in Fig. 5) are about 0.3-0.4 mv lower than those obtained with buffers where $[CO_3^=] + [HCO_3^-]$ is between 0.09 and 0.05.

When both NaCl and Mg-Ca salt concentrations are reduced it can be seen from Fig. 1 and 3 that extrapolation to $\mu = 0$ again gives $-\Delta V^o_1 = 25.4$ cm^3 mole^{-1}. The scattering of the results can be explained by the large pH dependence of ΔE_{1000} in the alkaline range.

Adding 0.056 $MgCl_2$ alone to 0.5 NaCl + 0.05 $NaHCO_3$, saturated with CO_2, has no or little effect on ΔE_{1000} observed in pure bicarbonate buffer (Fig. 5, curve 4). Between pmH_1 6.2 and 7.85, ΔE_{1000} falls from 22.3 mv to 16.0 mv. The 6.3 mv difference is nearly the same as the 6.5 mv value obtained with 0.030 $MgSO_4$ + 0.026 $MgCl_2$ for the same pmH_1 interval. The difference between curve 3 and 4 is obviously due to the sulfate ions, since the total Mg concentration is kept constant.

We already have noticed a similar effect of $SO_4^=$ when 0.030 Na_2SO_4 is added to pure bicarbonate buffers (curves 1 and 2 in Fig. 5). The fact that $MgSO_4$ is less dissociated than Na_2SO_4 probably explains the difference in magnitude between the effects of 0.030 Na_2SO_4 and 0.030 $MgSO_4$. Since the ordinate difference between curve 4 and 3 is nearly constant, the $SO_4^=$ effect of $MgSO_4$ practically must be constant over the whole pmH_1 range. This observation allows one to extrapolate curve 3 parallel to curves 2 and 1 in the alkaline range (curve 3') and to dissociate the $SO_4^=$ effect from the more complicated Mg-Ca effect observed between 6.5 and 9.0.

To interpret the Mg-Ca effect, we will assume that the $MgCO_3$ and $CaCO_3$ ion pairs, formed at atmospheric pressure, further dissociate at higher pressures, liberating $CO_3^=$ ions which alter the $[CO_2]/[CO_3^=]$ ratio of the buffer, eventually shift reaction $2HCO_3^- \rightleftharpoons CO_3^= + H_2CO_3$, and thus oppose the acidification induced by pressure and caused by the dissociation constants shifts. This assumption leads to the admission that log k'^m_{1000}/k'^m_1, in presence of $MgCl_2$ has the same value, for each true ionization function, as found in pure bicarbonate buffer at the same pmH_1 and ionic strength, not only between pmH_1 5.5 and 7.0, but throughout the whole pmH_1 range. When $MgSO_4$ is substituted for part of the $MgCl_2$, log k'^m_{1000}/k'^m_1 is lowered by an amount corresponding to the $SO_4^=$ effect. One can then use the same arguments developed above and measure $pk'_{(1)}$ and $pk'_{(2)}$ at pmH_1 7.0 and 8.5, respectively, on curve 3 and 3'.

One thus finds that at $\mu = 0.75$, $[CO_3^=] + [HCO_3^-] = 0.0025$, log $k'^m_{1000}/k'^m_1 = 0.316$ (18.5 mv) for $k'_{(1)}$ and 0.283 (16.5 mv) for $k'_{(2)}$. In more concentrated buffers, these values become 0.325 (19.0 mv) and 0.290 (17.0 mv) at the same ionic strength and pmH_1.

At pmH_1 8.5, Fig. 5 further allows to obtain a direct estimate of the effect of pressure on the apparent ionization function $pk''_{(2)}$. At $[HCO_3^-] + [CO_3^=] = 0.0025$, log $k''^m_{(2)1000}/k''_{(2)1} = 0.178$ ($\Delta E_{1000} = 10.4$ mv). A more elaborate treatment using $pk'^m_{(1)1000}$ and $pk'^m_{(2)1000}$, taking into account the equilibrium $2HCO_3^- \rightleftharpoons CO_3^= + H_2CO_3$, the amount of $MgCO_3$ formed at atmospheric pressure, shows that log $k''^m_{(2)1000}/k''^m_{(2)1}$ increases from 0.178 at pmH_1 8.5, to 0.187 at 8.0, 0.190 at 7.9, and 0.214 at 7.6. A mean value of 0.183 ± 0.005 can be taken in the pmH_1 interval 8.0-8.5. The same value can be read from Fig. 5 at $pmH_1 = 8.5$ for the more concentrated buffers.

The effect of pressure on $pk''_{(1)}$ needs not be considered in the alkaline range since we have admitted that between pmH_1 7.9 and 8.5, $pk'_{(1)} = pk''_{(1)}$. At $pmH_1 \leq 7.0$, comparison of the curves of Fig. 5 and 6 for the more concentrated buffers, where HCO_3^- trapping by Ca^{++} seems obvious, shows that pressure must have only a very small effect on the dissociation of any trapped HCO_3^- ions.

Dissociation of carbonic acid in natural sea water (Cl = 20‰) at high pressures; effect of boric acid.— The reference compartment of the glass electrode contains 0.49 NaCl, 0.01 HCl, 0.030 $MgSO_4$, 0.026 $MgCl_2$ and 0.010 $CaCl_2$.

The sea water samples come from the Atlantic Ocean (north of Spain, Cl ‰ = 19.5) and have been equilibrated with $CO_2 + N_2$ mixtures, or small amounts of Na_2CO_3 have been added to cover the 5.0-9.0 pmH_1 interval. The emf shifts produced by increasing pressure from 1 atm to 1000 kg. cm^{-2} are corrected in Fig. 5 at $\mu = 0.75$ (Cl ‰ = 20.0). Scattering is higher than with artificial buffers; nevertheless, it is obvious that from pmH_1 5.0 to about 7.25 (curve 5), sea water follows the general pattern observed in bicarbonate buffers with added Mg, Ca, and sulfate ions. The quantitative agreement is good, although the data for natural sea water are about 0.3-0.4 mv below these for artificial sea water (arrows in Fig. 5). Extrapolation of the curve drawn in the acid range (curves 5 and 5'), parallel to curves 1, 2, 3', allows one to obtain log k'^m_{1000}/k'^m_1 for the first and second dissociation step: 0.314 (18.3 mv) and 0.278 (16.3 mv), respectively, at $pmH_1 = 7.0$ and 8.5. This corresponds to the shift of the true ionization functions which are assumed to have the same value at 1 atm as the corresponding functions determined in artificial sea water (see above).

At pH > 7.25, the data for natural sea water progressively depart from the results in artificial sea water containing Mg^{++}, Ca^{++}, and $SO_4^=$. At pH 8.5-9.0, ΔE_{1000} is about 3.0 mv higher in natural sea water and to nearly duplicate these results, 0.43 10^{-3} H_3BO_3 must be added, the pmH_1 being adjusted by the $[HCO_3^-]/[CO_3^=]$ ratio (curve 6', Fig. 5). The ordinate difference between curve 6' and the corresponding emf shifts observed in artificial sea water without boric acid is given by curve 7 which shows the effect of boric acid between pmH_1 6.5 and 9.0.

Preliminary experiments to investigate the effect of pressure on the dissociation of boric acid show that in NaCl 0.1, $\Delta V_1'$ extrapolates to −29.0 cm^3 mole^{-1} at zero borate buffer (H_3BO_3 + borax) concentration, to −30.7 cm^3 mole^{-1} in NaCl 0.01 and to −31.4 cm^3 mole^{-1} in NaCl 0.001; $\Delta V_1^o = -32.1$ cm^3 mole^{-1}. In 0.5 NaCl + 0.030 $MgSO_4$ + 0.026 $MgCl_2$ and 0.010 $CaCl_2$, at pH 7.9, $\Delta V_1'$ is equal to −23.1 cm^3 mole^{-1} (22.7 mv) at zero borate concentration, and the same value can be used at the boron concentration of sea water. Since in sea water $pk'^m_{(1)1} = 8.605$ for boric acid ($pk'^c_{(1)1} - \log y_{H+} = pK''^c_{(1)1} = 8.72$ [Lyman (13)], $pk'^m_{(1)1000} = 8.605\text{-}0.39 = 8.215$. These values correspond fairly well to the pmH_1 at which curve 7 of Fig. 5 reaches a maximum. It is also easy to verify that at $pmH_1 = 8.353$ and $[HCO_3^-] + [CO_3^=] = 0.0025$, the increase in HCO_3^- concentration at 1000 kg. cm^{-2} ($pmH_{1000} = 8.124$), calculated from the values of $pk''^m_{(2)}$ and $pk'^m_{(1)}$ for carbonic acid, obtained in artificial sea water without boric acid, corresponds to the decrease in H_3BO_3 concentration, estimated from $pk'^m_{(1)1}$ and

$pk'^{m}_{(1)1000}$ found for boric acid in sea water ($\Delta[HCO_3^-]_T = 0.39\ 10^{-4}$; $\Delta[H_3BO_3] = 0.38\ 10^{-4}$).

The interpretation of the pH changes induced by pressure in natural sea water is thus far from simple. The enhanced dissociation of carbonic acid observed in NaCl at the corresponding ionic strength is modified by the presence of sulfate ions, by the dissociation of $MgCO_3$ and $CaCO_3$, and by the dissociation of boric acid. The two last effects are pH dependent, and reaction $H_3BO_3 + CO_3^= \leftrightharpoons HCO_3^- + H_2BO_3^-$ must be considered.

Without going into the details of a quantitative analysis, it is immediately clear that the emf shifts observed at $pmH_1 > 8.0$ in artificial sea water containing boric acid or in natural sea water cannot be used for a direct estimation of $\Delta pk''_{(2)}/\Delta p$ for the second apparent ionization function; instead, $pk''_{(2)p}$ has to be taken equal to the corresponding function determined in artificial sea water without boric acid in order to calculate $[CO_3^=]_T$ and $[HCO_3^-]_T$ at pressure p. In artificial sea water, in absence of boric acid, log $k''^{m}_{(2)1000}/k''^{m}_{(2)1} = 0.183 \pm 0.005$ from pmH_1 8.0 to 8.5; in natural sea water, since ΔE_{1000} is somewhat lower, log $k''^{m}_{(2)1000}/k''^{m}_{(2)1}$ will be taken equal to 0.178 ± 0.005 in the same pmH_1 interval. If the greatest precision is required, the pH dependence of log $k''^{m}_{(2)1000}/k''^{m}_{(2)1}$ must be taken into account (see p. 335). The value of $pk''^{m}_{(2)}$ at 1 atm found in artificial sea water without boric acid (9.01, see p. 334) is taken to be the same in natural sea water. The complete set of ionization functions which we believe to be valid in natural sea water at 1 atm and at 1000 bars, within our basic assumptions, is given in Table II.

Some of the results of Fig. 5 have been indicated in Fig. 1 together with data obtained with 0.01 HCl + 0.49 NaCl as reference half-cell, and which are in agreement with our earlier results (4). $\Delta E_{1000} = 16.7$ mv instead of 13.4 mv at pmH_1 7.8; the difference of 3.3 mv is due to the effect of pressure on γ_{HCl} in the presence of $MgSO_4 + MgCl_2 + CaCl_2$ compared to γ_{HCl} in pure HCl or HCl + NaCl (see below). Dilution of sea water leads to erratic pressure-induced emf shifts, but sea water + 0.05 $NaHCO_3$, CO_2 1% can be diluted, and the extrapolation of the results to $\mu = 0$ gives $\Delta V_1^\circ = -25.4$ cm^3 mole^{-1} identical with the value found in pure bicarbonate (Fig. 1).

Apparent values of γ_{HCl}, y_{H^+} *in* HCl + NaCl *in presence of* Mg^{++}, Ca^{++}, $SO_4^=$; *effect of pressure.*— The apparent mean activity coefficient of 0.01 HCl on the molal scale in presence of $0.5/n$ — 0.01 NaCl, $MgSO_4$, $MgSO_4 + MgCl_2$, $MgSO_4 + MgCl_2 + CaCl_2$ is given in Fig. 7 for several values of n assuming $m_{H^+} = m_{HCl}$. The reference half-cell was filled with HCl 0.01, NaCl 0.09. The data for pure NaCl or KCl + HCl solutions are taken from Harned and Owen (10), and control experiments show that our results fit these curves with an error not greater than ± 0.002. From Eq. [6], log y can be calculated from log γ: in NaCl solutions at $\mu = 0.5$ log γ = log y — 0.004; the correction factor is —0.0047, —0.0055, —0.063, —0.0071, —0.008 at $\mu = 0.6$, 0.7, 0.8, 0.9, 1.0, and —0.006 at $\mu = 0.75$. At $\mu = 0.75$ in sea water, the correction becomes —0.004.

$MgCl_2$ alone has a much smaller effect on γ_{HCl}: addition of 0.056 $MgCl_2$ to 0.49 NaCl + 0.01 HCl makes log γ_{HCl} drop from $\bar{1}.864$ to $\bar{1}.849$.

The pressure dependency of γ_{HCl} in 0.01 HCl + 0.49 NaCl containing $MgSO_4$, $MgSO_4 + MgCl_2$ is represented in Fig. 8 either with 0.01 HCl + 0.49 NaCl as reference half-cell or 0.1 HCl. It is clear that $MgSO_4$ is the main cause involved.

In the preceding sections, it has been assumed continuously that γ_{HCl} measured in 0.01 HCl + 0.49 NaCl + 0.030 $MgSO_4$ + 0.026 $MgCl_2$ + 0.010 $CaCl_2$ has the same value in carbonate and bicarbonate buffers containing the same salts, in the range $[CO_3^=] + [HCO_3^-] = 0.09 - 0.0025$. That the specific salt effect

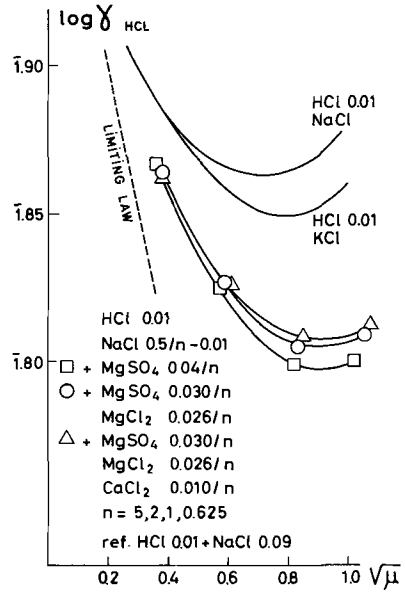

Fig. 7. Mean activity coefficient (γ_{HCl}) of HCl in NaCl, KCl; apparent values in presence of $MgSO_4$, $MgCl_2$, $CaCl_2$ as a function of $\sqrt{\mu}$.

of CO_2, $CO_3^=$, HCO_3^- is small, is demonstrated by Fig. 1, 2, 3, and 4, where it can be seen that changing the buffer concentration (at a given buffer ratio for Fig. 2 and 4) has about the same effect as changing the ionic strength. Comparison of the data of Fig. 5 further shows that lowering the $[CO_3^=] + [HCO_3^-]$ concentration from 0.09 to 0.0025 has only a very small effect on ΔE_{1000} at a given ionic strength (0.75).

Figure 7 also indicates that γ_{HCl} is fairly independent of μ in the region of the ionic strength of sea water. Corrections for salinity differences are thus very small; corrections however have to be made to take into account the eventual difference in Cl^- content between both glass electrode compartments, in order to calculate —log $[H^+]$, assuming γ_{HCl} to be equal in both solutions. Ordinary *pa*H electrodes with liquid junctions at first sight appear to be simpler to use, since the exact composition of the reference glass electrode half-cell does not have to be known with precision. However, conventional *pa*H electrodes display a much more sluggish response and great errors can be introduced

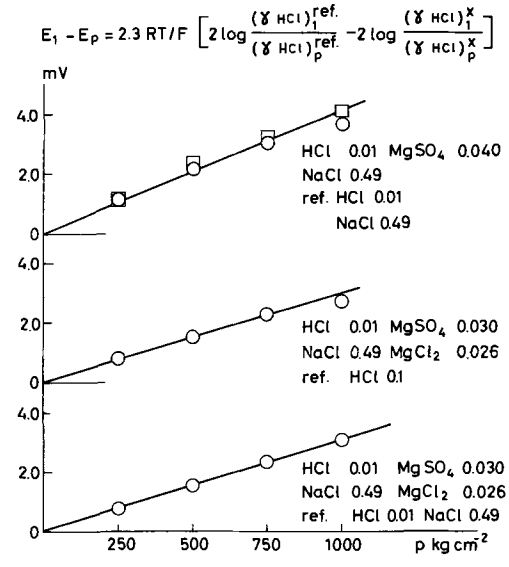

Fig. 8. Effect of pressure on 2 log $(\gamma_{HCl})^{ref}_1/(\gamma_{HCl})^{ref}_p$ — 2 log $(\gamma_{HCl})^{x}_1/(\gamma_{HCl})^{x}_p$ 2.3 $RT/F = E_1 - E_p$, where ref and x correspond to the inner and outer compartment of the glass electrode cell; effect of $MgSO_4$ and $MgCl_2$.

by the liquid junctions. Besides, the effect of pressure on these junctions would have to be taken into account, and the treatment of results based on single ion activity determination is open to criticism.

However, since most of the oceanographic data refer to *pa*H measurements, we have tried to measure *pa*H at atmospheric pressure in mixtures of HCl + NaCl or KCl + $MgSO_4$ + $MgCl_2$ + $CaCl_2$. Saturated KCl agar-agar junctions were used with calomel electrodes as inner and outer electrodes of the glass cell. Stable and reproducible results have been obtained in KCl with 0.01 HCl + 0.09 KCl in the reference compartment. The value indicated on Fig. 9 for log a_{H+} in 0.01 HCl + 0.09 KCl was checked with a hydrogen electrode—calomel electrode cell, and is close to the value reported in Harned and Owen (10), $\bar{3}.898$. The hydrogen ion activity in HCl + KCl was first measured, and the effect of the added salts was investigated either with 0.01 HCl + 0.09 KCl as inner solution or with 0.01 HCl + $0.5/n$ — 0.01 KCl, n being equal on both sides of the glass electrode. Trying to measure a_{H+} in HCl + NaCl with 0.1 HCl as inner solution resulted in erratic information. Reproducible data could only be obtained by systematically using KCl + HCl at the same ionic strength as inner solution.

The curves giving log a_{H+} in HCl + NaCl in presence of Mg and Ca salts have been determined by taking $0.5/n$ NaCl — 0.01 HCl for inner solutions and making n equal in both compartments. If one takes $c_{H+} = c_{HCl}$, log y_{H+} at $\mu = 0.75$ is $\bar{1}.887$ and one then can assume that it nearly has the same value in sea water. Anderson and Robinson (14) estimate log y_{H+} equal to $\bar{1}.880$ in sea water (Cl = 20.0‰) acidified to pH 3.3-3.9 with HCl, which is not too far from our value for log y_{H+}.

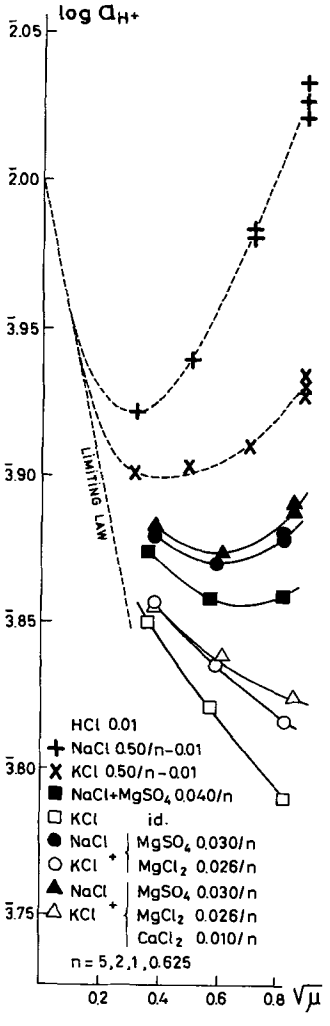

Fig. 9. Hydrogen ion activity (log a_{H+}), in 0.01 HCl + NaCl or KCl, in presence or not of $MgSO_4$, $MgCl_2$, $CaCl_2$ as a function of $\sqrt{\mu}$ (glass electrode with calomel electrodes and sat. KCl agar-agar salt bridges).

Evaluation of apparent dissociation constants $y_{H+}k'^{c}_{(1)} = K''^{c}_{(1)}$ and $y_{H+}k''^{c}_{(2)} = K''^{c}_{(2)}$ of carbonic acid in sea water at 1 atm and 1000 kg. cm^{-2}.—The apparent constants used in oceanography are defined as $K''^{c}_{(1)} = a_{H+} \times [HCO_3^-]_T/[CO_2] = y_{H+}\, k'^{c}_{(1)}$ and $K''^{c}_{(2)} = a_{H+} \times [CO_3^=]_T/[HCO_3^-]_T = y_{H+}k''^{c}_{(2)}$, where T refers to total concentrations. Since $\gamma m = yc/do$ (Eq. [7]) it follows that $pK''^{m}_{(1)(2)} = pK''^{c}_{(1)(2)} - 0.001$ at 1 atm.

According to Lyman (13), $pK''^{c}_{(1)} = 6.00$ and $pK''^{c}_{(2)} = 9.12$ at 22°C, Cl ‰ = 20.0. Taking our values $pk'^{c}_{(1)1} = 5.89$, $pk''^{c}_{(2)1} = 9.015$ valid for artificial sea water in the pmH_1 interval 7.9-8.5, and —log $y_{H+} = 0.11$, gives $pK''^{c}_{(1)} = 6.00$ and $pK''^{c}_{(2)} = 9.125$ which is in good agreement. Since $pk'^{c}_{(1)}$ has been determined at pmH_1 5.0 where obviously HCO_3^- trapping by Mg and Ca is very small or inexistent (see Fig. 6A), but where the effect of $SO_4^=$ can be measured, and since $pk'^{c}_{(1)}$ fits with the $pK''^{c}_{(1)}$ value given by Lyman, one comes to the conclusion that at alkaline pH, HCO_3^- trapping by Mg and Ca must be small in sea water, or that the HCO_3^- bound to Mg or Ca cannot be distinguished from that linked to Na. The problem is however not completely solved since in more concentrated buffers ($[CO_3^=] + [HCO_3^-] = 0.05 - 0.09$) HCO_3^- binding by Ca and Mg is obvious at pmH_1 7.0. Further analysis of these results and more experiments will be needed to decide whether or not HCO_3^- trapping persists in the alkaline range when $CO_3^=$ binding reaches its maximum, and to find out how it depends on the buffer concentration.

To estimate the effect of pressure on pK''_1 and pK''_2, the pressure dependence of γ_{H+} needs be known. It cannot be calculated in media as complex as sea water. Since however this uncertainty affects both pK'' and *pa*H identically, it has no bearing on the determination of the ratios $[CO_3^=]_T/[HCO_3^-]_T$, $[CO_3^=]_T/[CO_2]$ and $[HCO_3^-]_T/[CO_2]$ needed in oceanographic calculations to compute $[CO_2]$, $[HCO_3^-]_T$ $[CO_3^=]_T$ from *pa*H, $pK''_{(1)}$, $pK''_{(2)}$, and $\Sigma CO_2 = [CO_2] + [HCO_3^-]_T + [CO_3^=]_T$. The simplest assumption, which is to neglect the effect of pressure on γ_{H+}, leads to admit that $\Delta pK''^{m}_{(1)(2)}/\Delta p = \Delta pk''^{m}_{(1)(2)}/\Delta p$, so that in natural sea water at 1000 kg. cm^{-2}, $pK''^{m}_{(1)}$ and $pK''^{m}_{(2)}$ would, respectively, be equal to 6.00 — 0.314 and 9.125 — 0.178 (see p. 336) whereas $pK''^{c}_{(1)}$ and $pk''^{c}_{(2)}$ would become : 6.00 — (0.314 + 0.017) and 9.125 — (0.178 + 0.017), between pmH_1 8.0 and 8.5.

According to Buch and Gripenberg (16), the change of $pK''^{m}_{(1)}$ and $pK''^{m}_{(2)}$ with pressure are, respectively, 0.480 and 0.180 at 1000 bars, or 0.470 and 0.176 at 1000 kg. cm^{-2}. Their values were based on $\Delta V_1^\circ = -28.0$ cm^3 mole^{-1} for the first ionization step of carbonic acid and $\Delta V_1^\circ = -10.5$ cm^3 mole^{-1} for the second step assuming that the HCO_3^- ion would behave as acetic acid. Curiously enough our data fit almost exactly for $K''_{(2)}$, although the reasons of the small effect of pressure on $K''_{(2)}$ are completely different from what these authors thought them to be.

As we already indicated, $pk''_{(2)}$ and $pK''_{(2)}$ either on the molar or molal scale, determined in artificial sea water without boric acid at pressure p will give correct estimates for $[HCO_3^-]_T$ and $[CO_3^=]_T$ in the pmH_1 range 8.0-8.5, and it is theoretically possible, taking the boric acid effect into consideration, to calculate the *pm*H, *pc*H, or *pa*H of a given surface sea water sample brought to pressure p, or at the corresponding depth. It is however much more easy to read $\Delta pmH/\Delta p$ from Fig. 5, or to use Table I where we have given the *pa*H shifts on the molar scale in natural sea water

Table I. *pa*H at 1 atm and 1000 bar in natural sea water, molar scale*, Cl ‰ 20.0

* $\log y_{H^+}c_{H^+} = \log \gamma_{H^+}m_{H^+} + 0.016$ at 1000 bars (*c*, molar scale, *m*, molal scale); $\log \gamma_{H^+}$ is assumed not to vary with pressure; $-\log \gamma_{H_1^+} = 0.114$ and $-\log y_{H_1^+} = 0.11$.

predicted on the basis of Buch and Gripenberg's (16) estimates of $pK''_{(2)}$ and $pK''_{(1)}$ at 1000 bars and our experimental rounded off data.

The two series of values from *pa*H 7.5 to 8.0 reflect the scattering of the results of Fig. 5; to obtain set (*a*), 0.3 mv where substracted from curve 6' to take into account the difference between the results in artificial and natural sea water; set (*b*) corresponds to curve 3 between 7.5 and 7.9. To adapt these values to other types of water small corrections will have to be made to take into account differences in salinity, $SO_4^=$, Mg, Ca, and boric acid content.

The set of ionization functions and apparent dissociation constants based on the experiments described in this paper is given in Table II.

It is important to keep in mind that the ionization functions *k'*, *k"*, and also *K"* in Table II, can only be used to interpret emf measurements made with one particular type of reference half-cell. If other cells are used corrections have to be made affecting *pm*H and *pk'* identically.

Conclusions

A coherent set of ionization functions has been established on the molal and the molar concentration scales, from 1 atm to 1000 kg. cm^{-2} and at 22°C for carbonic acid in NaCl (KCl) over a wide range of ionic strengths, in the presence of Mg^{++}, Ca^{++}, and $SO_4^=$ ions, and in sea water. It allows the use of *pm*H or *pc*H measurements with a junctionless glass electrode cell and ΣCO_2 determinations to calculate the concentrations of CO_2, HCO_3^-, $CO_3^=$ (free and bound to Na, Mg, and Ca). Data are also available to take into account the increased dissociation of boric acid in natural sea water at high pressure. Corrections are given for different types of reference half-cells.

*In situ pa*H, pcH, or *pm*H values at any ocean depth have been determined for one type of surface water (Atlantic Cl = 20.0‰) and can simply be read from the experimental curve giving $\Delta pm\text{H}/\Delta p$ as a function of *pm*H, at 1 atm and 22°C, in the *pm*H interval 5.0-9.0. The data can be used at any other temperature if one assumes that the temperature coefficient of the ionization functions is independent of pressure or the pressure coefficient is independent of temperature. This assumption however plausible, remains to be proven experimentally. Small corrections for differences in salinity, sulfate, B, Mg, Ca concentrations will have to be established for other water types.

Detailed calculations will be given in a following paper and will be used for the quantitative interpretation of direct *in situ pc*H or *pm*H measurement at great ocean depths (5, 6).

The apparent mean activity coefficient of HCl has been measured in NaCl solutions in the presence of Mg^{++}, Ca^{++}, and $SO_4^=$ at atmospheric pressure and at 1000 kg. cm^{-2}, and also y_{H^+} at 1 atm. It is thus theoretically possible to calculate $y_{HCO_3^-}$ and $y_{CO_3^=}$ in the various bicarbonate and carbonate buffers investigated including sea water, since y_{CO_2} is known with rather good precision (9, 15).

The determination of y_{H^+} in NaCl in the presence of Mg^{++}, Ca^{++}, $SO_4^=$ allows correlation of the ionization functions obtained with junctionless glass electrode cells with the so-called apparent dissociation constants widely used in oceanography to calculate $[CO_3^=]_{total}$ and $[HCO_3^-]_{total}$. The results show that the apparent second dissociation constant is *p*H dependant with a rather broad minimum between $pm\text{H}_1$ 7.9 and 8.5, where the mean value of $pK''_{(2)}$ is 9.125 at 1 atm and 22°C. Since $pK''_{(1)} = 6.00$ at this temperature and pressure, both these values are in agreement with the data of Lyman (13).

	0.337	0.320			0.300	0.283	0.198	0.181

[a] $\log \gamma_{H^+}$ is assumed not to vary with pressure; the second row of data corresponds to rounded off values; c and *m* indicate the molar and molal concentration scale respectively.
[b] *T* indicates total concentrations.
[c] 0.017 = $\log d_{1000}/d_1$, where *d* is the density.

If one admits that the pressure dependence of γ_{H^+} can be neglected, then the effect of pressure, compared with data from Buch and Gripenberg (16), shows fortuitous agreement for the second apparent dissociation constant in the pmH_1 interval 8.0-8.5 (on the molal scale at 1000 bars, $pK''_{(2)} = 0.181$ against 0.180), but the effect of pressure on the first constant is much less than that predicted by these authors (at 1000 bars, $pK''_{(1)} = 0.320$ instead of 0.480).

The comparison must be considered with caution since we do not know the absolute values of the ionization functions and apparent dissociation constants, but it shows that one cannot simply assume, as Buch and Gripenberg did, that H_2CO_3 dissociates at high pressure in sea water in the same manner as at zero ionic strength and that HCO_3^- behaves as acetic acid.

The reduced effect of pressure on the apparent second dissociation constant of carbonic acid in sea water at $pmH_1 > 8.0$ corresponds to an apparent volume change of -10.6 cm^3 mole^{-1} instead of -25.6 cm^3 mole^{-1} observed at 0 ionic strength. This can be understood by taking into consideration : 1° the effect of NaCl on the pressure dependence of the mean activity coefficient of H_2CO_3 and HCO_3^-; 2° the effect of sulfate ions which does not depend on pH; and 3° the formation of $MgCO_3$ and $CaCO_3$ at atm pressure which dissociate under pressure, liberating $CO_3^=$ ions which alter the buffer ratio, the whole process being pH dependent.

The increased dissociation of boric acid, the result of which is again a function of the hydrogen ion concentration, explains why the pmH or pcH shift observed in sea water is progressively larger from pmH_1 7.0 to 9.0 than that predicted from the effect of pressure on the apparent ionization function of HCO_3^-, measured in artificial sea water without boric acid. Factors 1°, 2°, and 3°, on the contrary, really or apparently depress the effect of pressure on the ionization of carbonic acid. $MgCO_3$ and $CaCO_3$ thus appear to have a buffering action against hydrogen ion concentration changes induced by pressure in sea water although boric acid progressively and partially counteracts this effect at pmH_1 values greater than 7.0.

Starting from these considerations one might imagine that other buffer systems involving ion pairs or complex ions able to liberate anions capable of binding H^+ ions, could be prepared, where $\Delta pmH/\Delta p$ would be very small. Such media would be very useful in, for instance, the study of the specific effect of pressure on biological systems. Furthermore, if the effect of pressure on a given acid-base equilibrium is well known, changes produced by the pressure induced dissociation of added ion pairs offer a way to demonstrate their existence at atmospheric pressure.

The results which we have obtained at 1000 kg. cm^{-2} in pure carbonate and bicarbonate buffers in NaCl or KCl show, for example, that probably more ion pairs exist in NaCl than in KCl, in correlation with the difference observed for the corresponding ionization functions at atmospheric pressure. This observation might prove a clue to interpret the anomalies encountered when $\Delta V_1°$ is computed from glass electrode measurements by extrapolation at zero ionic strength (3). The values obtained in pure acid are always somewhat higher than in the corresponding buffers (-26.5 cm^3 mole^{-1} in H_2CO_3, -25.4 cm^3 mole^{-1} in bicarbonate buffer, for example). This effect could be explained if ion pairs still exist at the highest dilutions which are practical for precise emf determinations.

ADDENDUM[1]

Interpretation of the $SO_4^=$*-effect.*—It has been assumed in the preceding pages that $m_{H^+} = m_{HCl} = 0.01$ in the reference half-cells containing 0.03 $MgSO_4$ and the effect of $SO_4^=$ ions on the observed emf values have therefore been interpreted as a change which affects $k'_{(1)}$, $k'_{(2)}$, γ_{HCl} and γ_{H^+}. This "$SO_4^=$ — effect", observed in presence of NaCl + $MgCl_2$ and $CaCl_2$, is uncommonly large and of the same order of magnitude in each case as shown by the data obtained at $\mu = 0.75$:

	in NaCl	in sol. + $MgSO_4$	Δ
$pk'_{c(1)}$	6.00	5.89	0.11
$pk'_{c(2)}$	9.60	9.49	0.11
2 log γ_{HCl}	$\bar{1}$.734	$\bar{1}$.617	0.117
log γ_{H^+}	0.017	$\bar{1}$.887	0.13

Further, at 1000 kg cm^{-2}, $SO_4^=$ ions apparently increase $pk'_{(1)}$ and $pk'_{(2)}$ by a constant amount which corresponds to an emf shift between 2.0 and 2.7 mv, depending on the buffer concentration (Fig. 5), whereas the effect of the same pressure on the reference half-cell containing $SO_4^=$ is equal to 3.3 mv (Fig. 8). It actually appears that the greatest part of the $SO_4^=$ — effect must find its explanation in the formation of SO_4H^- ions in the reference half-cell, which invalidates the assumption $m_{H^+} = m_{HCl}$ [see Jones and Monk (17)]. Taking $K_{HSO_4^-} = 1.13\ 10^{-2}$, $\gamma_{SO_4^=} = 0.12$ $\gamma_{HSO_4^-} = 0.68$, assuming 54% of the sulfate to be free ions [see the data of Garrels and Thompson for sea water (15)] and $a_{H^+} = 7.7\ 10^{-3}$ ($paH = 2{,}113$, see Fig. 9), one finds $pmH_1 = 2.088$ instead of 2.00, which accounts for 80% of the apparent $SO_4^=$ — effect on $pk'_{(1)}$ and $pk'_{(2)}$ at 1 atm. One will notice that 2 log $\gamma_{HCl} = \bar{1}.698$ in 0.01 HCl + 0.49 NaCl + 0.056 $MgCl_2$ (see p. 336) and that at the same ionic strength, 2 log γ_{HCl} in 0.01 HCl + NaCl is equal to $\bar{1}.730$. Although the salt effects of individual ions are not necessarily additive, the difference 0.032 indicates that the $SO_4^=$ — effect is probably not larger than the calculated value 0.088, since the total effect of $SO_4^=$ and Mg^{++} is equal to 0.117. In other words, pmH_1 in the $SO_4^=$ containing reference solutions is found equal to 2.085 if one assumes that γ_{HCl} in 0.01 HCl + 0.49 NaCl + 0.030 $MgSO_4$ + 0.026 $MgCl_2$ has the same value as that derived from measurements in 0.01 HCl + 0.49 NaCl + 0.056 $MgCl_2$. At 1000 kg cm^{-2}, with $K_{HSO_4^-} = 2.26\ 10^{-2}$, $pmH_{1000} = 2.043$; the difference $pmH_1 - pmH_{1000} = 0.045$ represents equally 80% of the effect of pressure observed in Fig. 8. Further studies on the equilibrium of sulfuric acid will be necessary to verify these estimates, especially since $-\Delta V_1°$ for SO_4H^- is only known from density measurements, with values between 12.0 and 20.6 cm^3 mole^{-1} (Hamann, private communication).

If the above corrections were valid, then the values of pk', pk'', pmH given in this paper would have to be increased by 0.09 at 1 atm; the calculated values of paH_1 in Table I and the values of $pK''_{(1)1}$, $pK''_{(2)1}$ remain unchanged whatever the correction; $\Delta pk'$, $\Delta pk''$ at 1000 kg cm^{-2} and the corresponding ΔpH would have to be increased by 0.045.

These corrections would lead to another coherent set of dissociation functions to calculate the equilibrium of H_2CO_3 in sea water from the corresponding corrected pmH measurements giving exactly the same results as the set of functions of Table II.

Although a precise knowledge of the salt effect of $SO_4^=$ ions is needed for an approach toward the absolute values of $k_{(1)}$, $k_{(2)}$, and pmH in sea water, this search is only of academic interest for most of the oceanographic calculations. Finally, it appears that these could best be made from straight forward pwH $= -\log m_{H^+}\gamma_{H^+}\gamma_{Cl^-}$ determinations at any pressure (using half-cells without $SO_4^=$) and apparent constants defined as $K''\gamma_{Cl^-} = k'\gamma_{H^+}\gamma_{Cl^-}$, thus keeping the advantages of junctionless cells and eliminating the apparent arbitrariness of the different systems of ionization functions. Sufficient data are given in this paper to make this conversion, since the effect of pressure on γ_{HCl} can easily be calculated in pure HCl [see Harned and Owen (10), p. 507].

Acknowledgment

The authors wish to express their gratitude to Dr. R. G. Bates, Chief of Electrochemical Analysis Section, National Bureau of Standards, to Professor B. B. Owen, of the Scripps Institute of Oceanography, to Professor R. Pytkowicz and Dr. Culberson, Oceanography Department, Oregon University, for their help in preparing and discussing the manuscript.

Manuscript received July 5, 1966; revised manuscript received Dec. 14, 1966.

[1] Added on proof.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Standard Potentials of the Cl_2/Cl^- Electrode at Various Temperatures with Related Thermodynamic Functions

G. Faita, P. Longhi, and T. Mussini

Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy

ABSTRACT

The standard potentials of the Cl_2/Cl^- electrode have been redetermined over the temperature range 25°-80°C with an accuracy better than ±0.1 mv. The support for the Cl_2/Cl^- electrode was a tantalum foil coated with a Pt-Ir 45% alloy, which provided complete resistance to corrosion under the experimental conditions. Thermodynamic functions concerning the reactions:

$$Ag + \tfrac{1}{2}Cl_2 = AgCl \text{ and } \tfrac{1}{2}H_2 + \tfrac{1}{2}Cl_2 = H^+ + Cl^-$$

were calculated. Standard entropy values at 25°C for AgCl and Cl^- were obtained which are more accurate than those in the literature.

The present investigation has been carried out to redetermine the standard potential of the Cl_2/Cl^- electrode as accurately as possible over a wide range of temperatures. The data available in the literature refer to 25°C (1-8) excepting those deducible from Gerke's measurements (9) in the range 15°-35°C.

Reversible emf's of the cell

$$-Pt/Ag/AgCl/1.75M\ HCl/N_2 - Cl_2\ 10\%/Pt - Ir\ 45\%, Ta/Pt+ \quad [1]$$

have been measured at temperatures from 25° to 80°C. These emf's are functions of the Cl_2 pressure and are given by

$$E_1 = E^\circ_{Cl_2} - E^\circ_{AgCl} + (RT/2F) \ln p_{Cl_2} \quad [2]$$

where $E^\circ_{Cl_2}$ denotes the standard potential of the Cl_2/Cl^- electrode, and E°_{AgCl} denotes the standard potential of the silver/silver-chloride electrode. As the E°_{AgCl} values are known from the literature (10) and E_1 and p_{Cl_2} are measurable quantities, $E^\circ_{Cl_2}$ can be calculated at any temperature. Taking into account the atmospheric pressure, the solution levels in the electrode vessel and in the guard (see Fig. 1), and the equilibrium partial pressures of H_2O and HCl (11), the reversible emf's of the cell

$$-Pt/Ag/AgCl/1.75M\ HCl/Cl_2,\ 1\ atm/Pt - Ir\ 45\%, Ta/Pt+ \quad [3]$$

were obtained from the corresponding emf's of cell [1]. The emf of cell [3] is given by

$$E_3 = E^\circ_{Cl_2} - E^\circ_{AgCl} \quad [4]$$

so that, using the accurate values of E°_{AgCl} recently redetermined by Bates and Bower (10) over a wide range of temperatures, $E^\circ_{Cl_2}$ can be determined readily from E_3. Values of $E^\circ_{Cl_2}$ thus obtained are collected in Table I with corresponding values of E_3. Among the E°_{AgCl} values of various authors quoted in the literature, Bates and Bower's values (10) were preferred because they were obtained from a comparatively much greater number of measured cells.

The reason for using a low Cl_2 pressure in cell [1] arises from the need to minimize the difference in Cl^- activity in the two half-cells, owing to occurrence of the reaction $Cl_2 + Cl^- = Cl_3^-$ (12) in the chlorine electrode compartments.

Experimental

The structure of the chlorine electrode was as shown in Fig. 1. This structure permitted either bubbling the gas in, or passing it over, the solution. During our

Fig. 1. 70	1.10869 ± 0.00004	1.29651 ± 0.00008
80	1.10231 ± 0.00004	1.28104 ± 0.0001

measurements we checked that, once the solution was saturated and the equilibration of the system was attained, it did not matter whether the gas bubbled into, or simply passed over, the solution. Thus we generally kept the gas bubbling into the solution with the electrode foil almost completely immersed, gas passing over being used occasionally for a check.

The rate of flow of gas is not a critical parameter, within certain limits (*i.e.*, from near to zero up to 5 cm^3/min) if temperature equilibration has been previously attained. Another point that our preliminary experiments showed was that the only permissible materials for the chlorine electrode assembly were glass and polytetrafluoroethylene (PTFE). The system under study was readily poisoned by the use of either polyvinylchloride (PVC), or rubber connections, or silicon-greased stopcocks in the gas circuit. The gas stream, before entering the chlorine electrode compartment, was bubbled into a flask with a large gas chamber and into two Friedrich's saturators, all of them containing a 1.75M HCl solution identical to the one contained in the cell and kept in the same thermostatic apparatus. A large single stock of 1.75M HCl solution was prepared in order to get as many successive runs as required with an identical solution.

For truly accurate determinations of emf's for cell [1] the choice of electrode material for the chlorine half-cell is very important. The chemical nature of the substrate should be such that there is no corrosive attack by the Cl_2-containing solution of HCl. In addition the actual surface area of the electrode and the exchange current at it must be taken into account. The latter factor is of course very important in order to establish the degree of reversibility of any electrode (13).

The electrode metals which have been used mostly are either platinum (1, 7, 8) or Pt-Ir alloys (3, 4, 9) in a compact form. Platinum, however, is not fully appropriate as a substrate for chlorine electrodes because it is subject to corrosive attack by chloride solutions containing Cl_2. Preliminary experiments concerning both the resistance of the electrode materials to chemical attack by Cl_2-containing HCl solutions and the exchange current for the reaction $Cl_2 + 2e^- = 2Cl^-$ have been carried out in this laboratory. These experiments showed that the best material for our purpose was a Pt-Ir alloy with 45% of iridium. However, this alloy, if used as an electrode substrate in the form of a thin foil, would not be adequate because of its small surface. Thus, electrodes of the capillary-imbibition type, based on porous-graphite supports and prepared according to the technique described by Bianchi (16) were first tested. These electrodes, which proved to be very helpful in the study of other gases, were not suitable in the present case due to the slow attainment of the chlorine dissolution equilibrium in the pores of the graphite itself. Electrodes consisting of a foil of an inert substrate (Ti, Zr, Ta) coated with the Pt-Ir alloy according to the procedure described by Beer (15) were then tested. Those based on Ti and Zr gave rise to mixed potentials and were discarded. The tantalum-based electrodes behaved correctly and were selected for use in cell [1] for the systematic measurements of E_1. The method of preparation was as follows. A tantalum foil was scoured with quartz powder, washed, and dried; then it was brushed with a concentrated aqueous solution of H_2PtCl_6 + $IrCl_3$ with addition of isopropyl alcohol. Then it was introduced for 10 min into a furnace heated to 400°C in the presence of NH_3 vapors. This sequence, brushing and heating, was repeated 5-7 times until the quantity of deposited Pt-Ir alloy reached ≈ 1 mg/cm^2; then the electrode was kept for 1 hr in a furnace heated to 450°C in the presence of air, and subsequently chilled in air. Such electrodes did not give rise to any mixed potentials and showed complete resistance to chemical attack even under such drastic and extreme conditions as dipping into azeotropic hydrochloric acid saturated with Cl_2 at atmospheric pressure, at temperatures as high as 80°C. The exchange current, determined in the presence of Cl_2 at atmospheric pressure in 1.75*M* HCl, was 16 ma/cm^2 (apparent geometrical surface) at 25°C, and increased a little with temperature (*e.g.*, 20 ma/cm^2 at 45°C). Four freshly prepared electrodes and one aged electrode, all of them made up as above described, were compared over a period of 10 days at 60°C in 1.75*M* HCl, with Cl_2 bubbling in at atmospheric pressure. The bias potential was 0.01 mv.

The silver/silver-chloride electrode was prepared according to the electrolytic type (14). Its bias potential was 0.01 mv at 25°C, after aging. The stability of the silver/silver-chloride electrode (and that of the chlorine electrode as well) was frequently checked against a capillary-imbibition hydrogen electrode (16), over the experimental temperature range. To prevent any diffusion of dissolved Cl_2 from the chlorine electrode to the silver/silver-chloride electrode, appropriate stopcocks were kept closed between the two half-cells.

For the reversible emf measurements mentioned above, a type K-3 L&N potentiometer was used, having a type 610-B Keithley electrometer as null-point detector. The input resistance of the latter was greater than 10^{14} ohms so that it allowed the measurement of the cell emf's even with the said stopcocks kept closed between the two half-cells.

The temperatures of the system studied were regulated to ±0.02°C by means of a specially designed air-thermostat.

Results and Discussion

When determining the Cl_2/Cl^- electrode potential it is important to consider errors due to the change of activity of Cl^- ions because of the reaction $Cl_2 + Cl^- = Cl_3^-$. Also uncertainty in the Cl_2-N_2 mixture analysis has to be taken into account. The error due to the change in the activity of Cl^- ions at a given HCl molality, decreases by decreasing the Cl_2 fraction in the gas-mixture flow; its value with sign is calculable taking into account the equilibrium constant for the reaction Cl_2, aq. + Cl^-, aq. = Cl_3^-, aq., and making a reasonable assumption about the relevant molal activity coefficients, namely, $\gamma_{Cl_2} = 1$ and $\gamma_{Cl^-} = \gamma_{Cl_3^-}$. From Sherrill and Izard's data (12) this constant can be calculated to be 0.175 (mole/1000g $H_2O)^{-1}$ at 25°C. At temperatures other than 25°C, data for such a constant are unavailable. However, one must expect the value of this equilibrium constant to decrease slightly with increasing temperature from 25° to 80°C, by analogy with the behavior of the corresponding constants in the cases of the Br_3^- ion (17) and of the I_3^- ion (18). In any case, this variation of the equilibrium constant with temperature is a matter of minor importance, as far as the present calculation is concerned; and the value at 25°C was used over the whole range from 25° to 80°C. The chlorine solubility in HCl does decrease greatly with increasing temperature (19) from 25° to 80°C, so that the error in question is much lower at 80° than at 25°C (see below). In addition the effect of any error can be decreased by using chlorine as dilute in admixture with nitrogen as possible, but this must be compatible with good accuracy in analyzing the Cl_2-N_2 mixture. The uncertainty in the analysis of Cl_2-N_2 mixtures by gas

chromatography decreases as the amount of Cl_2 is increased. Thus a compromise must be reached between the low concentration of chlorine needed to minimize the error connected with possible changes in activity of the Cl^- ions and the higher concentrations of Cl_2 needed for accuracy in the analysis of the Cl_2-N_2 mixture. It must also be borne in mind that the concentration of the HCl solution may affect the stability of the potential of the silver/silver-chloride electrode. In fact, at HCl concentrations greater than 4*M*, the solubility of AgCl in HCl to form $(AgCl_{n+1})^{n-}$ complexes would begin to be significant (20) and would in turn affect the Cl^- ion activity. The operative conditions we chose (1.75*M* HCl; N_2 90%-Cl_2 10%) caused: (*i*) an error of +0.025 mv at 25°C, +0.019 mv at 30°C, +0.012 mv at 40°C, +0.006 mv at 50°C, and a negligibly small error (always of positive sign) at 60°, 70°, and 80°C. The values of this error, all of them being of definite and positive sign, were then subtracted from the corresponding emf readings at the appropriate temperatures, and were not included in the evaluation of the cumulative uncertainty; (*ii*) an uncertainty of ±0.013 mv at 25°C, and ±0.015 mv at 80°C, respectively, arising from the gas chromatographic analysis of the chlorine-nitrogen mixture. The chlorine percentage in the mixture was 10.03 ± 0.01.

The uncertainty due to the limits of temperature regulation for the system to be studied (to ±0.02°C) is ±0.012 mv at 25°C and ±0.013 mv at 80°C, since the temperature coefficient of the emf of the cell [3] is −0.60 mv deg^{-1} at 25°C and −0.63 mv deg^{-1} at 80°C, respectively, (see below). It is evident that these limits of uncertainty are nearly constant over the experimental temperature range. Further, if we take into account the previously mentioned bias potentials for the Cl_2/Cl^- electrode and for the silver/silver-chloride electrode, the cumulative uncertainty for the E_3 values is ±0.04 mv over the whole range of temperature of experiment.

The E_3 values quoted in Table I are mean values taken from about a dozen of cell measurements at each temperature, the deviations from the mean being within the limits of the cumulative uncertainty previously described.

Among earlier $E°_{Cl_2}$ values, those deducible from the data of Kameyama, Yamamoto, and Oka (7) are in substantial disagreement with the present work. Kameyama, Yamamoto, and Oka carried out two independent series of measurements at 25°C leading to two final $E°_{Cl_2}$ values (1.3589v and 1.3580v, respectively) which differ from each other by 0.9 mv. No explanation was given for this discrepancy. The cells measured by Kameyama, Yamamoto, and Oka consisted of calomel electrodes combined with chlorine electrodes on platinum substrates, with saturated KCl as supporting electrolyte. Thus, the above discrepancy may possibly be ascribed to two causes: (*i*) use of platinum (instead of an appropriate corrosion-resistant Pt-Ir alloy) as a substrate for the system Cl_2/Cl^-; (*ii*) poor reproducibility as well as erraticity of the calomel electrodes, depending on the method of preparation. Many factors causing unsatisfactory performance of the calomel electrode were recently pointed out by Hills and Ives (21-23) in a critical reexamination of works carried out prior to 1930. The $E°_{Cl_2}$ value deducible from Lewis and Ruppert's work (3) differs from the value in the present investigation by 0.7 mv. This discrepancy can be ascribed to the presence of air in the acid calomel electrode used by Lewis and Ruppert as a reference for the chlorine electrode, as was shown by Randall and Young (3, 22).

The data in Table I have been least-squared with the aid of a type 1620-20K IBM computer, giving the following polynomials for E_3 and $E°_{Cl_2}$ as functions of absolute temperature T

$$E°_{Cl_2} = 1.47252 + (4.82271 \times 10^{-4})T - (2.90055 \times 10^{-6})T^2, \text{ abs. v} \quad [5]$$

$$E_3 = 1.28958 - (4.31562 \times 10^{-4})T - (2.79220 \times 10^{-7})T^2, \text{ abs. v} \quad [6]$$

Both of these expressions fit the tabulated respective data with a maximum deviation of ±0.15 mv.

Introducing the E_3 values and the dE_3/dT temperature coefficients (resulting from the first derivative of Eq. [6]) into the following interrelated equations

$$\Delta G = -n\mathbf{F}E, \quad \Delta S = n\mathbf{F}dE/dT, \quad \Delta H = -n\mathbf{F}E + n\mathbf{F}TdE/dT \quad [7]$$

the values of $\Delta G°$, $\Delta S°$, and $\Delta H°$ for the cell reaction $Ag + \frac{1}{2}Cl_2 = AgCl$ can be readily calculated at every temperature of experiment. Using the same procedure with the $E°_{Cl_2}$ and the $dE°_{Cl_2}/dT$ values (the latter being taken from the first derivative of Eq. [5]), $\Delta G°$, $\Delta S°$, and $\Delta H°$ can also be determined for the chlorine-electrode reaction $\frac{1}{2}Cl_2 + e^- = Cl^-$ at any temperature of experiment. Taking the fundamental convention for which the standard potential $E°_{H_2}$ of the hydrogen electrode is zero at all temperatures (24), it follows that, for the reaction

$$H^+ + e^- = \tfrac{1}{2}H_2 \quad [8]$$

$\Delta G°$, $\Delta S°$, and $\Delta H°$ are zero at all temperatures. Then one obtains also

$$S°_{H^+} = \tfrac{1}{2}S°_{H_2} = 15.6055 \text{ cal deg}^{-1} \text{ mole}^{-1}, \text{ at } 25°C \quad [9]$$

Thus, conventionally, $\Delta G°$, $\Delta S°$, and $\Delta H°$ for the chlorine-electrode reaction are the same as for the reaction

$$\tfrac{1}{2}H_2 + \tfrac{1}{2}Cl_2 = H^+ + Cl^- \quad [10]$$

Table II collects the above mentioned data at 25°C and 1 atm and provides comparison with the corresponding data taken from the standard literature. From $\Delta S°$ for the reaction $Ag + \frac{1}{2}Cl_2 = AgCl$, and taking $S°_{Ag}$ and $S°_{Cl_2}$ from the literature (27, 28), one obtains $S°_{AgCl} = 23.056 \pm 0.004$ cal deg^{-1} mole^{-1}. This value is more accurate than the corresponding value available in literature (26) (*i.e.*, 22.97 cal deg^{-1} mole^{-1}). From $\Delta S°$ for reaction [10], using again the $S°_{Cl_2}$ datum in the literature (27) and taking into account the convention expressed by Eq. [9], one obtains $S°_{Cl^-} = -2.125 \pm 0.006$ cal deg^{-1} mole^{-1}. If one assumes, as customary, the convention $S°_{H^+} = 0.00000$ cal deg^{-1} mole^{-1} (25) instead of the convention [9], one gets the value $S°_{Cl^-} = 13.480 \pm 0.006$ cal deg^{-1} mole^{-1}, which is also more accurate than the corresponding value (*i.e.*, 13.17 cal deg^{-1} mole^{-1}) quoted in the literature. For the calculations involved throughout this paper, the following fundamental constants (17-19) were used: $\mathbf{F} = 23062.4 \pm 0.2$ cal absvolt^{-1} g-equiv^{-1}; $T_{0°C} = 273.16 \pm 0.01$°K, and $R = 1.98719 \pm 0.00008$ cal deg^{-1} mole^{-1}.

Potentiostatic Current-Potential Measurements on a Platinum Electrode in a High-Purity Closed System

Sigmund Schuldiner, Theodore B. Warner, and Bernard J. Piersma[1]

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

In a high-purity closed system, potential regions at which very slow reactions are rate-controlling were accurately separated and measured. Tafel regions and the possible reaction mechanisms on a Pt electrode in helium-saturated 1M H_2SO_4 from the H_2 to the O_2 formation reactions were determined. Effects of dermasorbed H and O atoms on transient and steady-state reaction rates were shown. Maximum oxidizable and reducible impurity levels were quantitatively determined both in solution and as adsorbed species on the working electrode surface. It was shown that the impurity levels were very low. Very small additions of hydrogen or oxygen in the critical transition region from net cathodic to anodic reactions did not appear to have catalytic effects. However, at oxygen partial pressures above 10^{-7} atm, a poisoning effect was apparent.

Recent work from this laboratory (1) has shown that gas-tight, closed electrochemical systems can be devised which will maintain a high degree of solution purity and electrode cleanliness over long periods of time. By maintaining such low levels of impurities it is possible to study reaction mechanisms in the so-called passive regions where reaction rates are so low that trace impurities could easily dominate the potential-current relationships. In order to demonstrate the feasibility of such studies and to explore the reaction mechanisms in the potential region from the gaseous hydrogen to the gaseous oxygen reaction, a potentiostatic investigation of the platinum electrode in 1M H_2SO_4 was undertaken.

Experimental

The closed electrochemical system, continuously purged with highly purified helium containing less than 1 part in 10^9 O_2, was essentially the same as previously reported (1). It consisted of a gas-tight, glass-pipe system mounted inside a N_2-filled controlled environment box. The main compartment of the cell contained a large Pt gauze electrode (~100 cm^2), a large tightly rolled cylinder of Pt gauze platinized in lead-free platinic acid (geometric area of about 30 cm^2), a Pt wire 5 cm long and 0.064 cm in diameter, and a Pt bead (at the end of a short length of exposed Pt wire) electrode with a true (2) area of 0.190 cm^2. All Pt was 99.99% pure; the beads were formed by melting the end of Pt wire with a hydrogen/oxygen flame. The side arm of the cell (1, 3) con-

tained both a miniature glass electrode and an αPd-H spiral wire electrode which was initially charged with enough hydrogen so that its potential was 75 mv positive to a NHE (normal hydrogen electrode). This αPd-H electrode contains less hydrogen and its potential is positive to the maximum αPd-H electrode (4). The glass electrode was $+0.585 \pm 0.005$v *vs.* NHE. The αPd-H electrode was the reference used to maintain potentiostatic control of the working electrode (Pt bead). The potential of this αPd-H reference was repeatedly checked against the glass electrode during the course of the investigation. The long-term changes in potential difference were ± 5 mv which is attributed to changes in the glass electrode. Short term changes were below the detectable limit of 0.001v.

Potentiostatic control, with a Wenking 61R Potentiostat, between the αPd-H reference and the Pt bead working electrode was maintained using the Pt gauze roll as the counter electrode. The potential between the Pt bead and glass electrode was monitored with a Keithley 610B Electrometer. Current flow between the Pt bead working electrode and the Pt gauze roll counter electrode was measured with a battery-operated Keithley 601 Electrometer and recorded on a Varian G-11A recorder. Necessary precautions were taken and checks made to avoid spurious microcurrents. Such spurious or background currents were in the 10^{-13} amp range.

In the experimental arrangement used, with counter and working electrodes in the same compartment, part of the product generated at the counter electrode might diffuse to the working electrode and yield an erroneously high current reading. A simple analysis shows that if the fraction, K, of the material generated at the counter electrode that reaches the working electrode is less than 1.0, then an unstable positive feedback condition cannot result. If K is ~ 0.1, then the current would be $\sim 11\%$ high. In our case with a tiny working electrode far removed from the counter electrode in a solution stirred with inert gas, K was estimated to be much less than 0.1 with a correspondingly lower error. The validity of this estimate was checked by taking additional data in a two-compartment cell in which the counter electrode was separated from the working by a glass frit, both compartments being continuously purged with He. These data agreed with the single-compartment data. Further, using the simple cell (3) several regions which showed the absence of stirring effects (Fig. 2b) demonstrated the absence of significant cross-diffusion of reactants on the measured currents.

After calibration of the glass electrode against the several Pt/H_2 electrodes, the run was started by stopping the H_2 flow into the cell. This hydrogen line was purged with helium, while being baked, for several hours. The line was then completely disconnected from the system. The environment box was then sealed and filled with N_2. The entire gas purification system and cell were continuously purged with pure helium at a flow rate of about 40 ml/min. For about one month, potential settings which ranged from 0.96 to 1.5v were applied to the Pt bead, wire and gauze electrodes. After this treatment, only the Pt bead was potentiostated at various potentials in the same range for about another month. At this time potential-current density measurements in the very low current density regions settled down and reproducible results were obtained. In the two month purification period the residual amounts of hydrogen and organic impurities were undoubtedly reduced to such a low value that erratic steady-state measurements were no longer obtained.

Normally, applied potentials on the working electrode were changed in such a way that current reversal was avoided. This was to approximate as closely as possible normal slow changes of species at, on, or in the working electrode. In all cases, a given potential was applied to the working electrode long enough so that a steady-state current density was achieved. The required time was strongly dependent on current density at very low current densities. This took a number of days. A current was considered steady-state if there was no monotonic trend in its mean value between successive time periods. Runs up and down the entire potential span were made. In addition, increasing and decreasing potentials were applied in individual Tafel

regions. Working electrode cleanliness tests (5), based on anodic charging curve linearity in the O_{ad} regions, showed the absence of detectable amounts of impurities. The temperature was 26° ± 2°C. The oxygen content of the environment box normally was about 0.05%.

Results and Discussion

The applied potential *vs.* steady-state current density relations are shown in Fig. 1 and 2. The data in Fig. 1 were taken under rapid stirring conditions (350 + ml/min flow of helium) so that mass transport to and away from the electrode is maximized and the data largely represents kinetic current densities at the set potentials. The data in Fig. 2a were obtained at a He flow of 40 ml/min; and Fig. 2b was obtained at each set potential by subtracting current densities obtained at slow helium flow rates, i_{40}, from the current densities at fast helium flow rates, i_{350}. Steady-state currents at the slower He flow rate were always smaller or equal to those found at faster He flow. Therefore, the data ($\Delta i = i_{350} - i_{40}$) in Fig. 2b represents the increased current densities due to increased diffusion rates at each set potential.

Because of the very low current densities obtained in the potential span studied, it is obvious that net surface processes are relatively slow so that the method used for separation of surface kinetic from solution diffusion controlled currents is accurate. In all cases (except where trace impurities are the primary reactants) the amounts of reactant (hydrogen ion or water) are present in large quantities; therefore, diffusion of these to the surface will not be rate-controlling. In the cases where diffusion of very small amounts of products away from the surface occurs, such mass transport phenomena could affect the currents measured. However, even in these cases surface processes must be slow and are to a large degree controlling.

Cathodic reactions.—The data in Fig. 1 and 2 show two distinct cathodic current regions (which were independent of successively increasing or decreasing potential settings) in the potential range from 0.06 to 0.46v. From 0.06 to 0.13v, Fig. 1 shows a Tafel slope of —0.04 whereas Fig. 2a shows a —0.035 and Fig. 2b a —0.03 slope. Since the datum in Fig. 2b is the current density difference between rapidly and slowly stirred solution, increased diffusion of small amounts of products away from the surface is indicated and the increase in current density is primarily owing to this diffusion. The —0.03 slope undoubtedly indicates that the diffusion of molecular hydrogen away from the electrode surface into solution is rate-controlling. Hence the Knorr (6, 7) mechanism is rate-controlling. On the other hand, the —0.04 slope shown in Fig. 1 confirms and extends the previous work of Schuldiner (8) who showed that when vigorously stirring with an inert gas that the rate-controlling step for the hydrogen formation reaction at very low active H coverages changes from combination of H_{ad} atoms to electrochemical desorption of H_{ad} atoms ($H^+ + H_{ad} + e = H_2$). In the referenced work (8) a —0.04 slope was obtained on Pt at potentials more noble than 0.02v. In Fig. 1, the minimum potential is 0.06v. The intermediate slope of —0.035v shown in Fig. 2a indicates mixed kinetic and diffusion control.

Following a transition region from 0.13 to 0.30v, Fig. 1 shows another Tafel slope of —0.10 which ranges from 0.30 to 0.46v. Figure 2b shows that in the entire potential range from 0.13 to 0.46v that there is no diffusion limiting component. Hence, a reasonable assumption is that in this potential range the Tafel slope of —0.10 indicates a slow discharge of H^+ to H as the rate-controlling step. Evidently under these potential conditions the surface coverage with H_{ad} atoms is so low that the electrochemical desorption mechanism is negligible and the energetics of the surface is such that slow discharge may be controlling. The amounts of H_{ad} formed in this region are so low that only a few monolayers would be involved over the several days in which the measurements were taken.

This is an interesting finding inasmuch as Horiuti and Polyani (9) concluded that as the heat of adsorption of H atoms increases, the rate of the discharge step would increase. Parsons (10) and Gerischer (11), however, showed that after a critical free energy of adsorption of H atoms is reached, the rate of the discharge step decreases. Our results at these very low coverages confirm the Parsons-Gerischer treatment. An examination of their rate equations for the case of very low surface coverage with H atoms and essentially zero H_2 partial pressure favors the possibility of H^+ discharge being rate-controlling under the given conditions. Slow surface diffusion or absorption or desorption steps which would be unaffected by solution stirring rates are possible also, but it is not obvious how these steps would give a —0.10 Tafel slope.

One of the most important aspects of the lack of solution stirring rate dependence in the 0.13-0.46v range is that this shows that the impurity level of reducible substances in our solution must be below a

level to give current densities in the order of 10^{-9} amp/cm^2. More will be said about reactable solution impurities in a later section.

In the vicinity of 0.46v there is a shift from a net cathodic to a net anodic reaction. In principle, in the total absence of reactive trace impurities and with sensitive enough potential control, one should find a potential at which zero current flows. This, of course, is a virtually impossible experimental condition to reach. However, the minimum current density reached in the transition from cathodic to anodic does give an indication of solution purity. Another important conclusion which can be reached is that at about 0.46v, the electrode is virtually completely free of sorbed hydrogen and oxygen. In the course of our experiments, after the Pt bead electrode was potentiostatically kept in the vicinity of 0.46v for many days, the open-circuit potential on this electrode was very close to 0.48v. This further indicates that a Pt electrode free of both hydrogen and oxygen will have a potential close to 0.46v. In other words, the open-circuit rest potential of pure Pt in a helium-saturated 1M H_2SO_4 solution $\approx$ 0.46v *vs.* NHE. The presence of dermasorbed H lowers that potential. Dermasorbed H can control the open-circuit potential down to as low as 0.18v (1).

Anodic reactions.—On the anodic side of the curves shown in Fig. 1, four distinct Tafel regions are obvious. One should further note that there are hysteresis effects except in the potential region above 1.7v. The reason for this hysteresis is most likely due to the dermasorption of atomic oxygen in the Pt skin which takes place at potentials above 1.4v. This always gave lower current densities at a set potential. Changing the potential in either a more positive or negative direction before this voltage is reached does not affect the current density-potential relation. However, once a 1.4v potential is exceeded, hysteresis occurs.

The potential region with the 0.03 Tafel slope is most likely owing to impurities in solution. The diffusion limiting overvoltage was undoubtedly a factor. This would indicate that oxidizable impurities, such as, hydrogen and organic species are present to an amount which can give a maximum current density of about 2 x 10^{-9} amp/cm^2. Thus, we have a very sensitive test for trace oxidizable impurities. Furthermore, the oxygen (or reducible) impurity level is at least an order of magnitude less. This will be discussed further in the next section.

In the Tafel region with a 0.12 slope (Fig. 1), an oxidation reaction is occurring which undoubtedly involves water. The formation of atomic oxygen is unlikely since no hysteresis effects are noted if the potential remains below 1v. The 0.12 slope indicates a one electron slow discharge. Some authors (12) have postulated the formation of hydroxyl radical

$$Pt + H_2O \rightarrow H^+ + Pt - OH + e \qquad [1]$$

At steady-state the level of OH adsorption is maintained constant by OH possibly decomposing to water and O_2. The data in Fig. 1 strongly support such a mechanism; however, it does not prove it. The data in Fig. 2a, b which show effects of diffusion control give essentially the same Tafel slopes. We have no ready explanation of this.

In the potential range from 1.0 to 1.1v (Fig. 1) a Tafel slope of 0.13 is found only when potentials above ~1.4v do not precede this range. Here, again, the slope indicates a one electron rate-controlling mechanism. At these potentials, previous experience at this and other laboratories indicates the formation of O atoms. The mechanism could be

$$Pt - OH \rightarrow Pt - O + H^+ + e \qquad [2]$$

Under steady-state the amount of O associated with the Pt would be constant, excess O being lost possibly by peroxide formation and decomposition. The atomic oxygen can be both dermasorbed in the skin of the Pt and be chemisorbed on the surface. In the 1.0-1.1v range represented by the 0.13 slope, dermasorption most likely occurs to only a small extent. This is indicated by going to a more anodic potential of 1.4v and then decreasing the potential (◈) points with no apparent deviation. The limiting current at about 3 x 10^{-6} A/cm^2 appears to be on Pt fully covered with O_{ad} with only small absorption of O atoms. The surface coverage with atomic oxygen probably varies in the first 0.13 slope range, but full coverage is obtained at values above 1.1v. Only when the potential rises to about 1.7v is there an indication that molecular oxygen is evolved in quantity and that saturation of the dermalayer is complete. This is shown both by the lower current densities on the decreasing potential curve and the fact that after reaching a potential of about 0.9v, a subsequent increase in potential to 1.36v will give a current density (◆, Fig. 1) somewhere between the two branches of the hysteresis loop. The degree of oxygen saturation of the dermalayer thereby appears to be both a function of potential and previous history.

The atomic oxygen formation region (1.0-1.7v) appears to give off a diffusable product as is evident from effects of diffusion currents obtained in Fig. 2a and b. Whether this product is O_2, H_2O_2, or something else is not obvious, although the rate of diffusion does generally follow the same potential independence seen for the kinetic reaction in Fig. 1. This is reasonable since the limiting current densities show that the rates of formation of products are independent of potential. This indicates that dermasorption of O atoms could be rate-controlling. At potentials above ~1.6v, the current density is independent of stirring rate. This shows that the rate-determining step in the oxygen gas formation reaction is so slow that it gives complete kinetic control and that diffusion away of molecular oxygen contributes nothing to the overvoltage.

The potential region above 1.6v is undoubtedly the molecular oxygen generation region, where the Tafel slope of 0.13 again indicates a rate-controlling step involving a one-electron reaction. This slope verifies Hoare's work (13). The total oxygen generating mechanisms may be

$$\left.\begin{aligned} &Pt + H_2O \rightarrow Pt - OH + H^+ + e \\ &Pt - OH \rightarrow Pt - O + H^+ + e \\ &Pt - O + H_2O \rightarrow Pt + H_2O_2 \\ &H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2 \end{aligned}\right\} \text{or, } 2Pt - O \rightarrow 2Pt + O_2 \qquad [3]$$

Under these conditions the Pt skin is saturated with dermasorbed O atoms and the current densities are independent of increasing or decreasing potentials.

After the electrode had been taken to potentials above 1.7v, on decreasing the potential to about 0.9v, the transient anodic current density decreased and eventually became cathodic. Under these conditions increasing the rate of He flow decreased the net cathodic current density. This can be explained by the fact that the anodic current increases with increased stirring rate (Fig. 2b). Thus the increased rate of the anodic reaction plus the cathodic reaction gave a lower net cathodic current. This cathodic current persisted for about two days and eventually returned to the anodic current indicated in Fig. 1 at this potential. These decreases in anodic current were undoubtedly due to the oxygen stored primarily in the dermalayer migrating to the surface and being reduced to water. The fact that increased He stirring appears to increase the rate of anodic reaction with little change in the rate of the cathodic reaction bears this out. This further indicates that dermasorbed oxygen is unstable at potentials below 1v, and even though the small hysteresis effects found at potentials below 1v are probably due to small traces of dermasorbed O, the bulk of these dermasorbed O atoms is removed. It is quite possible that at potentials below 1v that at least part of the source of dermasorbed O is from the in-

terior of the metal and this migration is so slow that its removal takes some time. Once the electrode is taken into the cathodic current region and held there for some hours, the potential *vs.* current behavior over the entire anodic current range is essentially the same as shown for the potential increasing values shown in Fig. 1.

Impurity levels in solution.—One of the goals of this investigation was to determine quantitatively the maximum levels of impurities in the solution. As mentioned above, the data in Fig. 1 indicated that the level of impurities which were reducible in the vicinity of 0.46v was below an amount which would give a cathodic current of -10^{-9} amp/cm² on the Pt bead electrode. This was determined by the lack of stirring effects in this region. It also was shown that the maximum amount of oxidizable impurity in the vicinity of 0.49v gave an equivalent of about 2×10^{-9} amp/cm². These current densities give upper limits of the amounts of both oxidizable and reducible impurities which actually react at the working electrode surface.

Since, as will be shown, the level of reducible impurity (most likely O_2) in solution is at least one order of magnitude less than oxidizable impurities (H_2 and organic species) reducible impurities will have an insignificant effect on the anodic current density due to oxidizable impurities. Similarly at cathodic current densities of -10^{-9} amp/cm², and at anodic current densities of 10^{-8} amp/cm², there are negligible impurity effects. To give some idea of how low these impurity levels are, the fraction of Pt surface which reducible impurities (mostly O atoms) contact in one second must be less than 2×10^{-6}; and the fraction of Pt surface which H atoms (or equivalent organic molecules) contact in 1 sec must be not more than 4×10^{-5}. Of course, this tells us nothing about the catalytic effects of these very small amounts of impurities. However, the data which will be given next on the effects of additions of trace amounts of hydrogen and oxygen indicate that at these low impurity levels, increased, but still very small, amounts of these impurities have no apparent catalytic effects.

Because of the very low net currents involved, the potential region from 0.46 to 0.50v is most sensitive to added impurities. By controlling the potential at 0.46 volt, the effects of trace amounts of hydrogen and oxygen[2] on the original net cathodic current is seen in Fig. 3. Controlling the potential at 0.50v gave the data shown in Fig. 4 and 5.

The data in Fig. 3 show that when successive small amounts of either hydrogen or oxygen are added to the helium gas stream to give the partial pressures shown, a detectable change in the cathodic current density is

[2] See ref. (14) for technique used for additions of small partial pressures of hydrogen and oxygen to helium carrier gas.

felt between 10^{-7} and 10^{-6} atm of H_2 or O_2. An estimate of the diffusion current that would result if all of the hydrogen or oxygen which reached the surface reacted can be obtained from the Nernst diffusion equation (15)

$$i_{diff} = \tfrac{1}{2}j = \frac{DF(C_o - C_s)}{2 \times 10^3\,\delta} \qquad [4]$$

where j is the calculated diffusion current density in amp/cm² (to put i_{diff} on a true area basis, the roughness factor of the electrode being ~2, j in Eq. [4] is divided by 2), D is the diffusion coefficient, **F** is the faraday, C_o is the concentration in the bulk of the solution in equiv/l, C_s is the concentration at the surface which is zero at steady state, and δ is the "effective thickness" of the boundary layer.

The current due to diffusion of dissolved gases to the electrode may be calculated using $D_{H_2} = 4.87 \times 10^{-5}$ cm²/sec (16), and $D_{O_2} = 1.98 \times 10^{-5}$ cm²/sec (16) and

$$[Co]_{H_2} = \frac{0.0149 \times 1000 \times 2}{22{,}400} P_{H_2}$$

$$= 1.33 \times 10^{-3} P_{H_2} \text{ equiv H/l}$$

$$[Co]_{O_2} = \frac{0.023 \times 1000 \times 4}{22{,}400} P_{O_2}$$

$$= 4.1 \times 10^{-3} P_{O_2} \text{ equiv O/l} \qquad [5]$$

where 0.0149 and 0.023 are the respective Bunsen coefficients [std. cc gas in 1 cc of 1M H_2SO_4 (17)] of H_2 and O_2, respectively, 2 and 4 are the respective number of electrons involved in H_2 oxidation and O_2 reduction, and P is the partial pressure of each gas in atm. Thus,

$$i_{diff,\,H_2} = 3.25 \times 10^{-6} \frac{P_{H_2}}{\delta} \text{ amp/cm}^2$$

$$i_{diff,\,O_2} = -4.06 \times 10^{-6} \frac{P_{O_2}}{\delta} \text{ amp/cm}^2 \qquad [6]$$

Since the changes in current densities found in Fig. 3, 4, and 5 on addition of either hydrogen or oxygen are due to their respective oxidation or reduction and assuming that the changes in current are primarily owing to the rate of diffusion of these gases to the surface

$$i_{res} = i_{meas} - i_{diff} \qquad [7]$$

In Eq. [7], i_{res} is the residual current density in the absence of added hydrogen or oxygen, i_{meas} is the measured current density found in the presence of added hydrogen or oxygen and is taken from Fig. 3, 4, and 5, i_{diff} are the diffusion currents calculated from Eq. [6]. The value of δ was adjusted to give the most constant i_{res} values. This gave a δ for H_2 of 0.035 cm and δ for O_2 of 0.02 cm. These were reasonable values when compared to the data of Ibl (18) for a δ in moderately stirred solution (40 ml He/min). Using these values of δ and Eq. [6] and [7], the results shown in Table I were obtained.

The data in Table Ia show that at 0.46v changes in the partial pressure of hydrogen give a constant i_{res} which is very close to the value found in the absence of added hydrogen. Hence current changes due to hydrogen at this potential are essentially diffusion-controlled. Table Ib at 0.50v also shows hydrogen diffusion control. At P_{H_2} above 1 x 10^{-4} atm a kinetic process is involved since the calculated diffusion current density does not account for all of the current density increase. For some reason at partial pressures above 10^{-4} atm, the rate of the oxidation reaction on the surface increases. This may be owing to changes in the catalytic properties of the surface.

The data in Table Ic and d concerning the effects of oxygen additions, however, cannot be simply attributed to diffusion control. At 0.46 and at 0.50v up to 1x10^{-6} atm added O_2 essentially shows $i_{res} \approx i_{meas}$. This means that i_{diff} is relatively insignificant. Even though the scatter at 0.50v is not too satisfactory diffusion control is apparently unimportant except at $P_{O_2} \geqq 10^{-6}$ atm. Since changes in the measured current density were rather small, the oxygen reduction reaction is relatively slow and even though real effects of added oxygen are apparent in Fig. 5, they are very small.

Table I. Effects of added H_2 and O_2 on i_{res}

(a) at 0.46v

P_{H_2}, atm	$i_{meas} \times 10^9$, amp/cm²	$i_{res} \times 10^9$ δ = 0.035 cm, amp/cm²

* ⊙ □ ■ curve Fig. 5.
** ⊕ ⊞ curve Fig. 5.

At 0.46v the i_{res} values are not constant at partial pressures above 1 x 10^{-7} atm added oxygen; also, the residual current densities are essentially equal to the measured current densities. Diffusion control is evidently a minor factor. It appears that the oxygen which gets to the surface effectively increases the rate of the hydrogen formation reaction. This appears to be a catalytic effect and may be attributed to the removal of catalytic poisons from the electrode surface by chemical oxidation. These poisons may be trace amounts of organic species or even hydrogen itself.

Even with the scatter found for different runs, it is obvious that the oxygen additions as low as 10^{-8} atm significantly decrease the net anodic current density. This specifically shows that the oxygen impurity must be at least an order of magnitude less than 10^{-8} atm and confirms previous estimates (1) of oxygen impurity in our closed system. Since at 10^{-8} atm, O_2 diffusion will give an $i_{diff,\,O_2}$ of about −2 x 10^{-12} amp/cm² and the actual current density found at O_2 additions of 10^{-8} atm (Fig. 5) is between 1 to 2 x 10^{-10} amp/cm², O_2 is only cancelling out a small part of the oxidizable impurity which must be an amount required to give an equivalent of about 10^{-10} amp/cm². Since the current density attributable to oxidizing impurities at 0.46v was about an order of magnitude more, we can conclude from this and the abnormally high effect of O_2 additions that oxygen is affecting the net anodic current density as a catalytic poison.

The sensitivity of this technique of determining maximum possible anodic and cathodic impurity levels and of the purity of the system used can be better demonstrated if the impurity effects are expressed in normal analytical terms of parts per million (g H_2 or O_2 per g solution). The conversion factors are

$$(2 \times 0.0149/22{,}400 \times 1.06)\, P_{H_2} = 1.25 \times 10^{-6} P_{H_2} \text{ [g } H_2 \text{ per g 1M } H_2SO_4\text{]}$$

and

$$(32 \times 0.023/22{,}400 \times 1.06)\, P_{O_2} = 3.1 \times 10^{-5} P_{O_2} \text{ [g } O_2 \text{ per g 1M } H_2SO_4\text{]}$$

where P_{H_2} and P_{O_2} are the gas partial pressures in atm, 2 and 32 are the respective molecular weights of H_2 and O_2, 0.014 and 0.023 are the Bunsen coefficients of H_2 and O_2 (17), respectively, 22,400 is the number of cubic centimeters of gas in one mole equivalent, and 1.06 is the specific gravity of 1M H_2SO_4. Thus the detection sensitivity is 10^{-7} ppm for O_2 and 10^{-6} ppm for H_2. Since oxidizable impurities could be partly organic species, the level of this impurity could be considerably less on a molecular basis, but would have to be more on a weight basis. The actual impurity levels in solution are easily an order of magnitude less than the maximum impurity levels determined.

The really critical impurity level, from an electrochemical viewpoint, would concern the fraction of available Pt sites covered with impurity. Here again from the data shown in Fig. 1 we have seen that reducible impurities which get to the surface give a current density which must be less than −1 x 10^{-9} amp/cm² and oxidizable impurities a current density of not more than 2 x 10^{-9} amp/cm². This means that less than 10^9 electrons are used in reducible impurities per cm²/sec and not more than 10^{10} electrons are donated by oxidizable impurities per cm²/sec. Since the total number of Pt atoms per cm² is about 1.3 x 10^{15}, then in 1 sec, less than one available Pt surface

site per million can be affected by a reducing impurity reaction and less than one available Pt surface site per 100,000 can be affected by an oxidizing impurity reaction.

Conclusions

1. In the potential range from 0.06 to 0.13v, under rapid stirring with He, the rate-controlling step is

$$Pt - H + H^+ + e = H_2$$

The net increased diffusion of H_2 away from the surface by rapid stirring can be determined by subtracting the current density under slow stirring from the current density under fast stirring. This indicated that the Tafel component due to increased diffusion gave a —0.03 slope. However, at slow stirring rates, diffusion and kinetic control were about equal.

2. A second Tafel region between 0.30 to 0.46v indicated a slow hydrogen ion discharge step.

3. The potential at which no net reduction or oxidation reaction occurs (transition point from net cathodic to net anodic reaction) and at which H and O adsorption is equal to zero is about 0.46v *vs.* NHE.

4. Four distinct Tafel regions were found in the anodic range from 0.46 to > 2v. These were: a region in which oxidizable impurities reacted; a region at which water was probably oxidized to give chemisorbed OH; a region in which chemisorbed and dermasorbed O was formed; a region in which O_2 was generated.

5. A hysteresis effect was found, once significant amounts of O were dermasorbed. This lowered the net reaction rates.

6. Impurity levels both in solution and on the electrode surface were determined. The maximum possible level of reducible impurity was found to be equivalent to an O_2 concentration of 10^{-7} ppm and a maximum oxidizable impurity level equivalent to an H_2 concentration of 10^{-6} ppm. The impurity levels of oxidizable and reducible species on the Pt surface were less than equivalent to 10^{10} and 10^9 electrons/cm^2/sec, respectively. This means that about one available Pt surface site per million per sec is affected by an impurity reaction. In a 10^{-12} Torr vacuum system, N_2 arrives at a surface at about 4 x 10^8 molecules/cm^2/sec (19). The rate of electrode contamination in our system is comparable.

7. Very small additions of hydrogen or oxygen in the critical transition region from net cathodic to net anodic reaction did not have catalytic effects, but when the partial pressure of these gases were above 10^{-7} atm catalytic effects were apparent.

8. Further experimental work is required using transient measurements in conjunction with potentiostatic control to determine the kinetic parameters in each of the Tafel regions to determine surface and dermasorbed layer coverages and other kinetic parameters.

9. This study has demonstrated that highly purified closed systems can give precise information concerning potential regions at which net reaction rates are very slow.

Manuscript received Oct. 21, 1966; revised manuscript received Dec. 15, 1966. This paper will be presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Technical Notes

The Transport of Hydrogen to Cylindrical Anodes in Stirred Electrolytes

Elton J. Cairns[1] and Adrian M. Breitenstein[2]

General Electric Research & Development Center, Schenectady, New York

Although the theory of mass transport has advanced a great deal in the last ten years, making it feasible to predict mass transport rates (limiting current densities) from the properties and geometry of simple systems (1, 2), there is still a strong tendency for electrochemists to use complicated geometries and flow conditions in their experiments. It is, therefore, of interest to determine how well the fundamentals of mass transport can be used in the correlation and prediction of mass transport rates (limiting current densities) in a typical stirred electrochemical cell.

[1] Present address: Argonne National Laboratory, Argonne, Illinois.
[2] Present address: Materials & Processes Laboratory, General Electric Company, 1 River Road, Schenectady, New York.

Experimental

The transport-limited electrode reaction chosen was the anodic oxidation of hydrogen dissolved in aqueous

electrolytes. The anode was a smooth platinum cylinder (0.0762 cm diameter, 2.07 cm long); the electrolytes and temperatures chosen were 1*N* $HClO_4$ at 25°C, 1*N* Cs_2CO_3 at 24°C, and 1*N* Cs_2CO_3 at 80°C. The Cs_2CO_3 was prepared and purified by methods already described (3, 4). The hydrogen was purified by diffusion through a silver-palladium tube. The test-electrode compartment of the cell was very large compared to the distance between the tips of the paddle stirrer blades and the test electrode; hence wall effects were expected to be small. The 2-bladed paddle stirrer measured 3.22 cm tip-to-tip, and the center-line distance between the stirrer shaft and the test electrode was 2.75 cm.

Limiting currents were measured for the anodic oxidation of dissolved hydrogen using two methods which yielded identical results: (*a*) steady-state measurement of the limiting current from the electrode held potentiostatically at 0.4v *vs.* the reversible hydrogen electrode in the same electrolyte at the same temperature (rhe); (*b*) pseudosteady-state limiting current determined from a current-voltage recording during a slow, potentiostatically controlled anodic sweep of 0.2 v/sec. The limiting current was taken at the current plateau in the range 0.4-0.6v *vs.* rhe. The electrode was given a pretreatment of alternate anodic and cathodic potentiostatic pulses before each measurement.

The stirring rate was measured by means of a stroboscope-tachometer, and was constant to within 2%. The range of stirrer speeds covered was 60-1000 rpm. The electrolyte was kept saturated with hydrogen by vigorous bubbling and stirring between limiting-current determinations. Bubbling was stopped during the measurements in order to eliminate any stirring due to the bubbles.

Results and Discussion

It would be very convenient if the limiting current density could be predicted from first principles for a system of the present geometry-transverse flow across a smooth cylinder. However, it has been shown from hydrodynamics, both theoretically and experimentally, that boundary layer separation occurs on the downstream side of the cylinder (5), yielding a problem which is mathematically intractible. The theory of mass transport is still very useful, even in this difficult situation, for predicting the types of functional relationships expected among the variables. Some of the useful relationships have been reviewed by Levich (6) and by Bird, Stewart, and Lightfoot (1). In general, such relationships as

$$\mathrm{Nu} = A\mathrm{Re}^{m}\,\mathrm{Sc}^{n} \qquad [1]$$

are expected, with m being less than unity (7). Extensive experimental studies of mass transport to and from flat plates, spheres, and cylinders, plus theoretical studies, indicate that n should be 1/3 (1, 2, 8).

If the dimensionless mass transport parameter j_D is introduced

$$j_D = \mathrm{Nu}\,\mathrm{Re}^{-1}\,\mathrm{Sc}^{-1/3} \qquad [2]$$

then Eq. [1] takes on the simpler form

$$j_D = A'\,\mathrm{Re}^{m-1} \qquad [3]$$

The simplest initial test of the above expressions for applicability to the present system was to test the behavior of i_L $\left(\text{or } \mathrm{Nu} = \dfrac{i_L D}{\Delta X_A\, CN\mathbf{F}\,\mathcal{D}_{AB}}\right)$ as a function of stirring speed $\left(\text{or } \mathrm{Re} = \dfrac{Dv\rho}{\mu}\right)$. If log i_L is plotted against log (stirrer speed), then the result should be a straight line of slope m. A typical test plot for H_2 in 1*N* Cs_2CO_3 at 24°C is shown in Fig. 1. The slope m is exactly 1/2, similar to results for dissolution of soluble cylinders in water and evaporation of water and other liquids from cylindrical surfaces into air (8). All other conditions tested (1*N* $HClO_4$, 25°C, and 1*N* Cs_2CO_3, 80°C) also yielded $m = 1/2$.

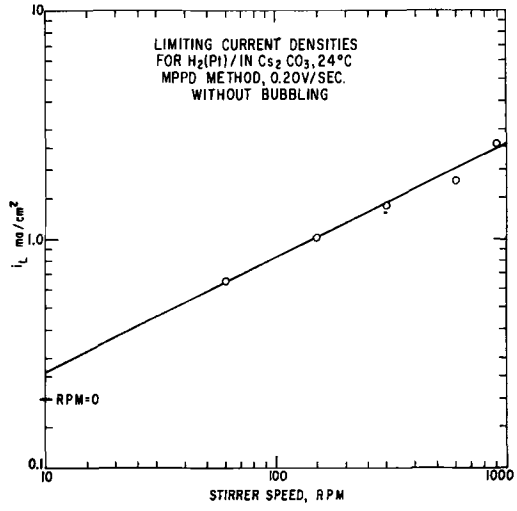

Fig. 1. Limiting current densities for the anodic oxidation of hydrogen in 1*N* Cs_2CO_3 at 24°C, as a function of stirrer speed. The slope is 0.5

In order to test further the applicability of Eq. [1] and [3], it is necessary to have values for all of the properties and variables in the dimensionless groups

$$\mathrm{Re} = \frac{Dv\rho}{\mu} \qquad [4]$$

$$\mathrm{Nu} = \frac{i_L D}{\Delta X_A\, CN\mathbf{F}\,\mathcal{D}_{AB}} \qquad [5]$$

$$\mathrm{Sc} = \frac{\mu}{\rho\mathcal{D}_{AB}} \qquad [6]$$

The characteristic dimension D is the diameter of the cylindrical electrode, 0.0762 cm; v is taken to be the linear velocity of the tip of the stirrer. The values of ρ were determined experimentally using a calibrated pycnometer. Viscosities (μ) were determined with an Ostwald viscometer. The value of $\Delta X_A = X_{A_\infty}$ is the solubility of hydrogen in the electrolyte under the experimental conditions (expressed as mole fraction). The solubility of H_2 in 1*N* $HClO_4$ at 24°C was determined using the value in water and an estimated salting-out constant based on values listed by Harned and Owen (9). For the solubility of H_2 in 1*N* Cs_2CO_3 at 25°C, the value for K_2CO_3 and Na_2CO_3 was used. To obtain the value for 80°C, a curve of log C_{H_2} *vs.* $1/T$ was prepared for H_2 in H_2O, and another for H_2 in 1*N* Cs_2CO_3 was constructed parallel to it, passing through the 25°C value. All solubility values were corrected to the appropriate hydrogen partial pressure.

The diffusion coefficient of H_2 in H_2O (10) was used to calculate values for $\left(\dfrac{\mathcal{D}_{AB}\mu}{T}\right)$ as a function of temperature. These values and the μ values for the electrolytes were then used to calculate $\mathcal{D}_{AB}$ values for hydrogen in the electrolytes. The properties of the systems studied are summarized in Table I. These properties were used to calculate the values of the terms for Eq. [3].

If Eq. [3] adequately represents the behavior of the system with respect to all properties and variables over the ranges investigated, then all data points should lie on a straight line of slope — 1/2 when log j_D is plotted against log Re. The plot in Fig. 2 shows clearly that all of the data for the three sets of experimental conditions are adequately represented by a single straight line having a slope of — 1/2 and a

Table I. Properties of systems used in hydrogen limiting current studies

Electrolyte	C_{H_2}, moles/cm³	$\mathcal{D}_{H_2-m}$, cm²/sec	μ, g/cm sec	ρ, g/cm³	p_{H_2}, atm
1N $HClO_4$, 25°C	8.268×10^{-7}	4.040×10^{-5}	8.926×10^{-3}	1.0550	0.975
1N Cs_2CO_3, 24°C	5.520×10^{-7}	3.482×10^{-5}	1.036×10^{-2}	1.1326	0.975
1N Cs_2CO_3, 80°C	2.816×10^{-7}	7.823×10^{-5}	4.152×10^{-3}	1.0945	0.5565

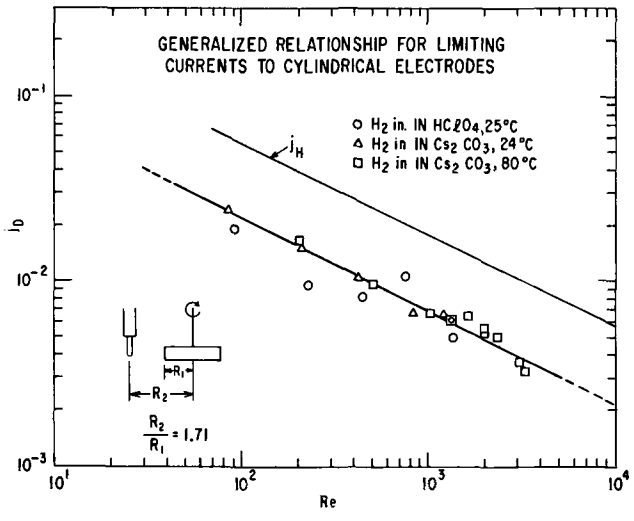

Fig. 2. Mass transport parameter j_D as a function of Reynolds number, for the limiting current of H_2 at a cylindrical anode in a simple paddle-stirred electrochemical cell.

value of A of 0.22 over the Reynolds number range from 80 to about 3500. The fact that a single line represents all of the data is good support for the validity of the relationships expressed by the chosen dimensionless groups, because i_L for a given stirring speed varied by more than 60% from one electrolyte to another. This large variation was caused largely by differences in the hydrogen concentration and diffusion coefficient and the viscosities of the electrolytes.

The line marked j_H represents the results for heat transfer to a cylinder as reported by McAdams (11), where the slope is — 1/2 and A is 0.6. Realizing that the stirrer-tip velocity is actually higher than the velocity of the fluid near the electrode, it is easily shown that a value 20% of the stirrer-tip velocity superimposes the present experimental results on the j_H line.

We can conclude that expressions of the form

$$j_D = A\,\mathrm{Re}^{-1/2}$$

and

$$\mathrm{Nu} = A\,\mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3}$$

accurately represent the mass transfer, *i.e.*, limiting current, behavior in simple stirred vessels commonly used by electrochemists. Furthermore, a single measurement of the limiting current for any system can be used to determine the value of A for each apparatus. Once the value of A is known, i_L can be calculated for any other set of conditions by substituting the appropriate values of the system properties into the above equations. The sensitivity of the results to the relative positions of the test electrode and the stirrer was not determined. However, it is expected that as long as the electrode-stirrer distance is significantly smaller than the distance of the stirrer and/or electrode from the vessel walls (say a factor of 3), the results will follow the functional dependence found here, but with a different numerical value for the parameter A.

Acknowledgment

It is a pleasure to thank Dr. A. D. Tevebaugh for his participation in the design and construction of the apparatus.

This work is a part of the program under contracts DA-44-009-AMC-479(T) and DA-44-009-ENG-4909, ARPA Order No. 247 with the U.S. Army Engineer Research and Development Laboratories, Ft. Belvoir, Va., to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plants for operation on ambient air and hydrocarbon fuels.

Manuscript received Nov. 7, 1966; revised manuscript received Dec. 30, 1966.

Oxide Dissolution and Its Effect on the Corrosion of 1100 Aluminum in Water at 70°C

Shiro Mori and J. E. Draley

Metallurgy Division, Argonne National Laboratory, Argonne, Illinois

The rate of corrosion of aluminum in water and in many aqueous solutions is generally believed to be limited by a film of oxide produced as corrosion product. If such a film is dissolving at a sufficiently great rate, it is clear that the corrosion rate will ultimately be determined by the dissolution rate. The rate at which dissolution occurs can be expected to depend on the concentration of aluminum oxide in the water. Such dependences have been reported by Dillon (1) and Dickinson (2) for pressurized water and by Hatcher and Rae (3) for in-reactor water well below the boiling point.

In our own research on the corrosion of 1100 aluminum, it has been observed that at 70°C and below, a heavy layer of porous, not significantly protective, bayerite covers a thinner layer (4, 5). This protective layer is believed to be boehmite on the basis of our own (4) and other observations of early formation (6-8). In laboratory exposure to refreshed distilled water, we have seen no evidence that the protective film dissolves or that the corrosion rate is influenced by corrosion product dissolution. In fact, contamination of the water with corrosion product (perhaps alkaline) has increased corrosion. In an effort to resolve these questions specimens have been exposed under circumstances where material balances allow the deduction of the variation of the corrosion product composition with time.

Specimens of 1100 aluminum and exposure conditions were the same (continuously refreshed, $> 10^6$ ohm-cm H_2O, saturated with oxygen) as in a previous investigation (5). Effluent water from the test chamber was accumulated by controlled-level evaporation in a flask to which sulfuric acid was originally added. Periodically, this solution was carefully removed, with acid rinsing, to a platinum dish and evaporated to dryness. The residue was dissolved in molten $KHSO_4$; this was then dissolved and analyzed colorimetrically for aluminum content. Extraneous aluminum was found to come from the source water (1-2 μg/l), from Pyrex glassware, and from the reagents (notably the $KHSO_4$). Correction was made by operating a blank specimen chamber, using the same water supply as for the chamber containing the specimen and making the identical analysis for aluminum. Sometimes the water flow rates were not identical for the two chambers, necessitating a calculated correction based on the concentration of aluminum in the "blank" water. All glass apparatus was leached for several weeks before use.

The amount of metal corroded from a specimen was measured at intervals, using the eddy current gauge developed for the purpose (9). At the same time the dried specimen was weighed, with its adherent corrosion product. The most reproducible drying was obtained overnight at room temperature in a desiccator containing anhydrous calcium sulfate (Drierite). An hour in the constant temperature, constant humidity balance room ensured reproducible readings on the microbalance.

Three quantities were thus available as a function of time: weight gain (G), metal loss by corrosion (L), and the aluminum content of the dissolved corrosion product (ξ). Using the assumption that the adherent corrosion product (as weighed) consisted entirely of boehmite (AlOOH) and bayerite [$Al(OH)_3$], the aluminum contents of these substances on the specimen were calculated from the following

$$b(\text{bayerite}) = \frac{27}{18}G + \frac{60}{18}\xi - \frac{33}{18}L$$

$$a(\text{boehmite}) = L - (b + \xi)$$

The five quantities are shown as a function of time in Fig. 1, for one specimen. The scale of the ordinate is sensitive; various amounts have been subtracted from the quantities in order to make it possible to plot them together. For example, G varied from about 57 to something under 61 mg/dm^2.

It is seen that for a period the amount of corrosion varied with the logarithm of time in accord with previous observations (5); unaccountably, this specimen then deviated from this behavior. The aluminum content of the dissolved corrosion product was much smaller and exhibited a quite different kinetic behavior, as shown on an expanded scale in Fig. 2. After the first 5 days, product dissolved at a constant rate, to provide 11.9 μg Al/dm^2-day in the water (about 0.4 μg Al/l).

The calculated adherent boehmite (Al content) is small and closely follows the metal-corroded curve in Fig. 1. From this it is judged that, predominantly, the

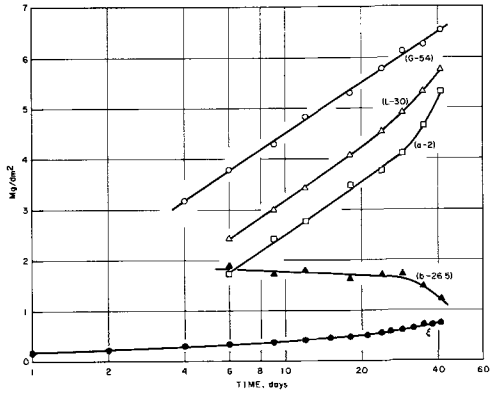

Fig. 1. Summary of corrosion for one specimen of 1100 aluminum in oxygenated water at 70°C.

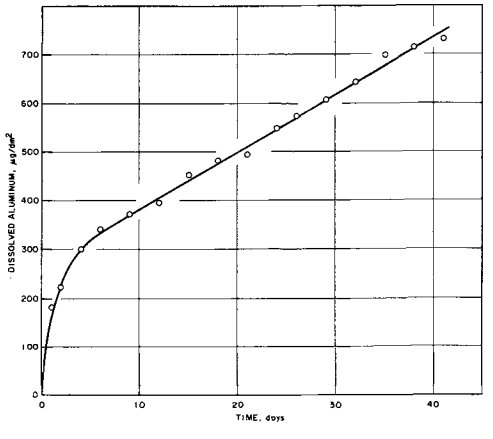

Fig. 2. Corrosion product dissolved from specimen of Fig. 1

corrosion process consists of the formation of boehmite, which is not subsequently lost. The bayerite, all formed within the first day or two of exposure (5), then slowly dissolves. The "b" points in Fig. 1 show too much scatter to judge curve shape. A least squares fit provides an average rate of dissolution of 14 μg Al/dm^2-day. (Compare with analyzed Al pickup of 11.9).

The results do not support these conclusions quite as well as has been suggested. The calculated value of "a" was negative for the first weighing. This is probably the consequence of a few per cent of excess moisture in the adherent corrosion product as weighed. This difficulty cannot be avoided readily; if bayerite is kept in a dry environment, moisture is continually lost past its nominal stoichiometric composition. If corrections are estimated for this factor, little change is made in the slopes of the "a" and "b" curves. It seems clear that within experimental error only boehmite is formed as a corrosion product (after the first few days), and that only the unprotective porous bayerite dissolves.

Similar data are available for two other specimens. Only small variations in behavior were exhibited; all data justify the concluding statement above.

These results obviously are not typical of some situations studied by other investigators. It is important to be aware that oxide dissolution can be important in determining aluminum corrosion rate, even though it is not so under conditions of this investigation.

Manuscript received April 11, 1966; revised manuscript received Dec. 21, 1966. This work was done under the auspices of the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

The Corrosion of 1100 Aluminum in Water from 50° to 95°C

J. E. Draley, Shiro Mori, and R. E. Loess

Metallurgy Division, Argonne National Laboratory, Argonne, Illinois

After an initial period of a few days duration, the amount of corrosion of 1100 aluminum in water below the boiling point varies with the logarithm of time (1-3). Reproducibility in measured rate constants has not been good. This is felt to be due largely to variation in test parameters such as the water refreshment rate and flow pattern, and the number and position of the specimens in the chamber. Sensitivity to these things has appeared to be maximum during the initial exposure period [cf. ref. (2)].

For purposes of considering reaction mechanisms it is desirable to know the dependence of corrosion behavior on temperature and dissolved oxygen concentration. Because of the variability of past results, it has not been possible to determine reliably the influence of these parameters. The present experiments were therefore run with identical flow rates and specimen disposition in order to provide comparable data.

Materials and general methods were the same as described previously (2). Water resistivity remained well above 1 megohm-cm; it was saturated with cylinder oxygen or helium to provide a choice of two levels of dissolved oxygen, and passed at a low rate (18 cc/min for first 4 days, then 8 cc/min) through the test chamber containing 4 specimens. For those instances where the saturating gas was helium, the oxygen content was monitored with a thallium column (small modification of Industrial Instruments Analyzer type OA-1). For the 50° and 70° tests, the water entering the cell averaged 0.41 mg O_2/l (range: 0.31-0.50); entering the 95° cell dissolved oxygen averaged 0.60 mg/l (range 0.43-1.00). Perhaps 3/4 of this amount would be expected to be lost to the gas phase when the solution was heated to 95°.

Specimens were from the same extruded rod as had been used previously. They were machined, annealed,
