and etched under the same conditions as before. They were removed periodically from the test, starting after 4 days' exposure, weighed to ± 10 μg (29 cm² area) after air drying (in the constant temperature and humidity balance room), and the change in the average metal radius determined to a ± 50Å with the eddy current gauge developed for the purpose (4). Gauge corrections for metallurgical change in the specimens at corrosion temperature were required only at 95°. Total test duration was typically 45 days.

Corrosion was approximately logarithmic in all six tests, for the 4-45 day interval. Data for two typical specimens in helium-saturated water are shown in Fig. 1 (70°) and Fig. 2 (95°). Slopes and logarithmic intercepts (extrapolated values at 1 day) of the metal corroded curves are given, for all specimens, in Table I.

There is a consistent increase in rate constant (slope) with increasing temperature, and with increased oxygen concentration. Intercepts are much lower at 95° than at 50° or 70°.

The specimen weight gains increased with time slightly more rapidly than did the metal losses at 50° and 70°, as illustrated in Fig. 1. At 95°, however, it can be calculated from Fig. 2 that (old) corrosion product was being lost to the water more rapidly than new product was being formed during the interval 4 to 47 days.

There is evidence in Table I that precautions were not sufficient to provide rate constants and intercepts which can be compared to obtain accurately the effects of temperature and oxygen content. It is possible, however, to make qualitative comparisons. At 95° there was an inverse relationship between intercept and rate constant. In fact, a continuous trend was observed in these values for specimens from the two tests (oxygenated and low-oxygen). Generally, higher oxygen content resulted in lower intercepts and higher slopes. This is logical in view of: (*a*) known ability of oxygen to diminish the local *p*H increase observed at the specimen surface during the initial stages of corrosion (1, 5), (*b*) the direct dependence of intercept on solution *p*H (1). From these factors, the absence of oxygen can allow the development of a higher *p*H and a thicker oxide (boehmite) film during initial stages; later, when the alkalinity has dispersed, the thicker film might lead to lower corrosion rate.

At 50° the presence of oxygen again generally led to lower intercepts and higher rate constants. Within each test there was correlation opposite to that at 95°: higher rate constants accompanied higher intercepts. At 50° (but not at 95°) a relatively heavy layer of porous bayerite [$Al(OH)_3$] forms during the initial exposure period. It is suggested that, when this layer is heavier, conditions are less favorable beneath the bayerite at what is believed to be the rate-controlling film of boehmite (AlOOH).

An Arrhenius plot of rate constants does not lead to a particularly good straight line. The approximate slope corresponds to the low activation energy of 4 kcal/g-atom. On the basis of the best kinetic model we have to date been able to develop, the corrosion rate is determined by the properties and thickness of a cracked layer of boehmite formed by degradation of the (always thin) primary product, perhaps also boehmite. Variation of the protectiveness (related to porosity) of such a layer with temperature is unknown; if the porosity decreased with increasing temperature, an unusually low temperature coefficient for the corrosion rate constant would be expected.

Manuscript received April 11, 1966; revised manuscript received Dec. 21, 1966. This work was done under the auspices of the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Oxide Film Growth over Five Years on Some Aluminum Sheet Alloys in Air of Varying Humidity at Room Temperature

Hugh P. Godard

Aluminium Laboratories Limited, Kingston, Ontario, Canada

The room temperature surface oxidation of aluminum in air has been extensively studied using various techniques (1-9). Vernon *et al.* (10) found that the oxide film growth followed a logarithmic law of the form

$$x = K_1 \log (at + c) \qquad [1]$$

where x is the film thickness at time t, and K_1, a, and c are constants. For dry oxygen, Hart (8) fitted his data to an inverse logarithmic relationship

$$1/x = -K_2 \log (t + t_0) + K_3 \qquad [2]$$

where K_2, K_3, and t_0 are constants. For moist oxygen, the growth law was said to be logarithmic during the first 10 hr and finally inverse logarithmic. Dignam (9) has shown that, if the decrease in specific ionic conduction of the film is taken into account, the anodic overvoltage across the film after exposure to dry oxygen obeys a logarithmic relationship with respect to time. In all instances it was concluded that a maximum

film thickness was reached and that this value and the rate of oxidation increased as the relative humidity increased.

In this note, we report the rate constants for the oxidation of aluminum and some of its alloys exposed to air at various relative humidities, at room temperature, for periods of five to six years. The oxidation rates were determined from weight gain data.

The 5 x 20 cm coupons were cut from sheet of ten commercial alloys produced by the Aluminum Company of Canada, Limited, Kingston Works. In addition, superpurity (S.P.) sheet (>99.99% Al) and twelve S.P. base experimental alloys containing single additions of Fe, Si, Cu, Mn, Zn, and Ga, prepared in these Laboratories, were included. The compositions are given in Table I.

The coupons were prepared by abrading them on both sides with a dry wire brush until a smooth satin-like texture was produced. Quite arbitrarily, it was assumed that the surface roughness factor was two, and this factor was used in all subsequent calculations of film thickness.

Eight coupons of each alloy were prepared and, after weighing on a microbalance, were stored on edge in desiccators. The relative humidity in the desiccators was 52, 72, 85, and 100%, respectively. The temperature was maintained in the 20°-25°C range over the five to six year period. The coupons were weighed at increasing intervals to two years, then again at five to six years.

Figure 1 is a semilogarithmic plot of the weight gain data for the CA-3S alloy at the four relative humidities. Initially, the weight gain (w) followed a logarithmic law, but as t increased the weight gains exceeded the values predicted by Eq. [1]. Similar curves were obtained for the other alloys. An attempt to fit the results to a log-log plot was no more successful.

Figure 2 shows a plot of $1/w$ vs. log t for the CA-3S alloys. It is obvious that the inverse logarithmic relationship observed by Hart (8) is obeyed in the present work. The data for all the alloys were analyzed by computer. A least squares fit was obtained between the experimental values t_i, w_i, and the line

$$1/w_i = -K \log (t_i + T_0) + K' \qquad [3]$$

Values of K and K' were calculated for a range of the parameter T_0 between 0 and 10 days in increments of 0.5 hr for the first 24 hr, in increments of 1.0 hr for 24 to 120 hr, and in increments of 2 hr for 120 to 240 hr. It was found that in all cases the variance (S^2) was smallest when $T_0 = 0$. Values of K, K', and S^2 for $T_0 = 0$ are given in Table II. These values indicate that the rate of oxidation increases with increasing humidity. It is possible, in view of the method of surface preparation, that the fit of the results to an inverse logarithmic relationship is fortuitous.

The thickness of the oxide films on the coupons after five years was calculated from the expression

$$\text{Thickness (Å)} = \frac{\text{wt gain } (\mu g/dm^2) \times 2.13}{\text{film density} \times \text{surface roughness factor}} \qquad [4]$$

where the atomic mass ratio $Al_2O_3/O_3 = 2.13$. The assumed film density was 3.0 g/cm^3, and the surface roughness factor taken as 2.0. The calculated film thickness (Table III) are included to give an idea of

the magnitude of oxide film growth at the end of five years.

The coupons exposed at 100% R. H. were observed to have dark spotty stains, which developed between two and five years. These spots were originally thought to be caused by droplets of condensation. However, this would be expected to lead to abnormally high weight gains since film growth is much more rapid under water and should give erratic results. On the contrary, the 100% R.H. results showed the smallest variation from the inverse logarithmic function so that the values are believed to be correct. No dark staining was observed at lower humidities, but some coupons exposed at 85% R.H. and 100% R. H. had a narrow band of white film along the edge of the coupon that rested on the desiccator plates.

Preliminary Study of the Chemical Polishing of α-Corundum Surfaces with Vanadium Pentoxide

M. M. Faktor, D. G. Fiddyment, and G. R. Newns

Post Office Research Station, Dollis Hill, London, England

Studies of the epitaxial deposition of thin films of silicon on inert substrates such as α-corundum require polished, clean surfaces free from work damage. Corundum substrates are usually obtained by accurately sawing wafers of the required crystallographic orientation from a large, single crystal. The faces of the wafers are mechanically polished by using diamond powder of diminishing particle size for each successive stage. These processes produce a high degree of polish and flatness, but they introduce work damage such as scratches and associated regions of strain and disorder in the surface. Work damage can be removed by flame-polishing (1, 2), immersion in hot orthophosphoric acid (3-5), and molten salts (1, 5-7), or by reaction

with silicon vapor (8, 9). Attempts to polish corundum wafers by immersion in various molten salts met with limited success, and etched surfaces were usually obtained. Some success was achieved with orthophosphoric acid, but this process was difficult to control and was sensitive to the crystallographic orientation of the corundum wafers. Specimens heated in a vacuum after orthophosphoric acid polishing evolved white fumes in which phosphorus was detected mass spectroscopically (10).

A preliminary examination of molten vanadium pentoxide as a polishing agent gave encouraging results which are reported here, although the investigation is still in progress because of the technological importance of the problem.

The polishing mechanism appears to be independent of crystallographic orientation, since wafers of poorly orientated material (as much as 20° from the basal plane) have been polished successfully.

Specimens were usually 1 cm square wafers of α-corundum cut from a large single crystal grown by the Verneuil process. The wafers were accurately cut, perpendicular to the "c" axis and were approximately 1 mm thick. Each face was lapped and mechanically polished with a final abrasive of 0.5μ diamond dust. Other specimens which were poorly orientated and with an inferior surface preparation (sometimes in the "as-sawn" condition) were also used.

Weighed specimens were suspended vertically in molten vanadium pentoxide by a fine platinum wire. The vanadium pentoxide was contained in a platinum crucible, and heating was carried out in a standard crucible furnace. Specimens normally remained static in the melt, but some specimens were rotated. Specimens were immersed slowly in the melt and allowed to cool slowly after removal from the crucible to avoid thermal shock. The residual solidified vanadium pentoxide was removed from the specimens by immersion in hot concentrated hydrochloric acid. Specimens were washed in distilled water followed by alcohol, and air dried before being reweighed and examined.

For obtaining of kinetic data a fresh charge of vanadium pentoxide was used for each experiment. In other experiments an original melt was sometimes reused, but concentration of alumina in the melt was noted.

Preliminary work was carried out with poorly orientated material having either a 1μ diamond powder final polish or the original sawn surface. Opaque specimens with as-sawn surfaces were rendered transparent by immersion in molten vanadium pentoxide (see Fig. 1).

In a few of these preliminary experiments a pale violet film or bloom appeared on surfaces after immersion in the melt. Immersion in concentrated hydrochloric, nitric or hydrofluoric acids, aqua regia, or a solution of catechol in hydrazine hydrate indicated that the bloom is moderately resistant to chemical attack. Prolonged heating (~24 hr) in air at 1200°C resulted in the complete disappearance of the bloom, but it is not clear whether removal was by evaporation or by diffusion into the specimen as weight changes on heating were insignificant ($< 1 \times 10^{-4}$g).

Blooming also occurred to a lesser degree in later work with well orientated and finished specimens. The majority of specimens did not develop bloomed surfaces after chemical polishing in vanadium pentoxide. As yet the conditions leading to bloomed surfaces and the composition of the bloom have not been elucidated.

Optical and Talysurf assessment was made on material which was well orientated and highly polished and were correlated with alumina weight loss. Figure 2 shows the effect on the surface as material is pro-

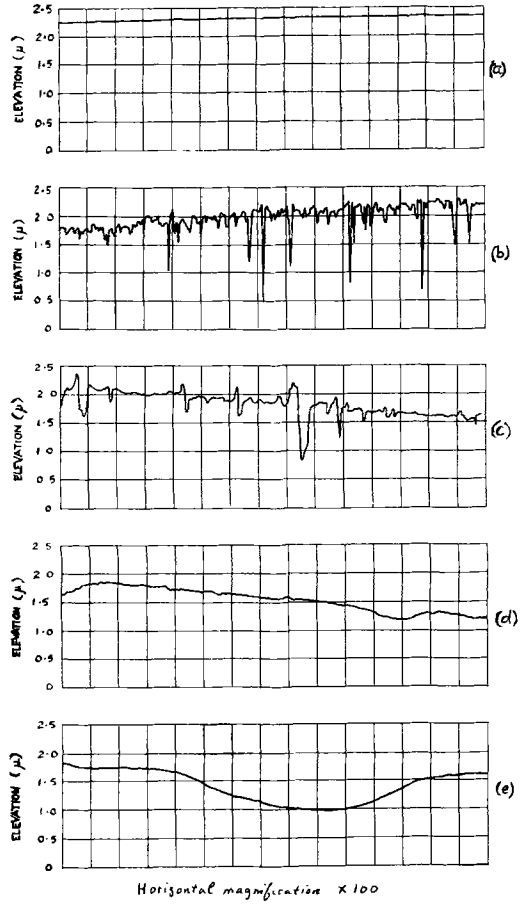

Fig. 3. Talysurf records of corundum surfaces: (a) original surface (0.5μ diamond dust polish); (b) after removal of 1.5μ; (c) after removal of 3.9μ; (d) after removal of 14.7μ; (e) after removal of 33.4μ.

gressively removed. The initial surface is highly polished but possesses numerous scratches. As dissolution occurs the scratches widen and become more marked. Scratches disappear and a substantially featureless surface is obtained when sufficient material has been removed. With further removal of material surfaces become somewhat striated in appearance. Polishing occurred over the whole surface and no significant edge effects were observed.

The Talysurf traces (Fig. 3) of surfaces obtained after different periods of immersion in vanadium pentoxide at 900°C demonstrate a marked smoothing of the surface as material is removed. It should be noted that since the Talysurf instrument had a diamond stylus 2.5μ in diameter, surface features of lesser dimension appear smaller than their actual size. Thus the depth of scratches from 0.5μ abrasive particles is not recorded accurately by Talysurf measurement, and the mechanically polished surface is better observed by the more revealing optical assessment.

Rates of dissolution plotted against time show an initially high rate of dissolution, decreasing as material is removed and eventually levelling out at a fairly constant vaue. Figure 4 shows a typical dissolution rate curve obtained at 800°C, from which the depth of the damaged layer can be estimated as approximately 30μ.

The rate of dissolution increases with temperature. In addition to enhancing the rate of attack, a higher melt temperature also affects the final surface appearance. Thus striations appear if a comparable amount of material is removed at a temperature 100° higher than that producing a featureless surface.

Rotation of a specimen in the melt (at 900°C) resulted in a higher rate of dissolution. The effect of rotation of the specimen on the final surface appearance is clearly seen in Fig. 5. In the absence of stirring a polished surface is obtained usually.

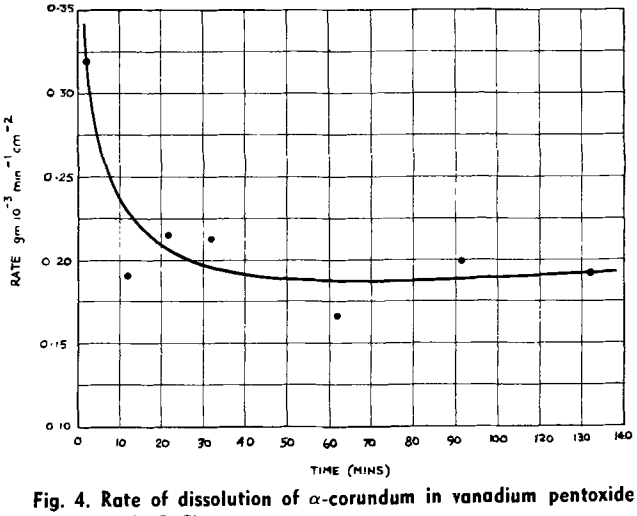

Fig. 4. Rate of dissolution of α-corundum in vanadium pentoxide against time (800°C).

An increase in alumina concentration in the melt lowers the rate of dissolution considerably and also affects the final appearance of a surface. With a melt containing no alumina initially, a high rate of attack occurs (30 μ h^{-1}) whereas in a melt containing originally 1.65% by weight of dissolved alumina only 1.5 μ h^{-1} was removed.

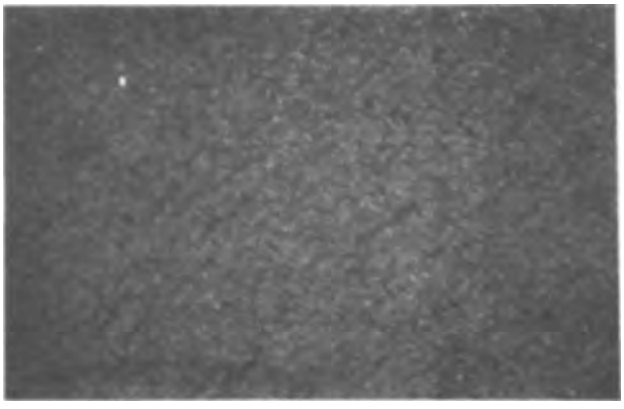

Fig. 5. Effect of stirring on surface appearance. (Magnification x 240). Rotated at 340 rpm 10 min at 900°C. (49μ removed).

Rapid Electronic Switching between Potentiostatic and Galvanostatic Control

Theodore B. Warner and Sigmund Schuldiner

United States Naval Research Laboratory, Washington, D. C.

For a number of applications it is desirable to obtain galvanostatic charging curves on an electrode that is kept under potentiostatic control at all other times. The transition time from one type of control to the other (the "switch time") should be as short as possible, for in this time the electrode potential may be ill-defined. Further, the time between the end of one galvanostatic pulse and the beginning of the next (the "potentiostat time") should be known accurately, and for adsorption rate studies it is desirable that a train of 2 pulses be provided. Existing solutions to this problem have generally involved mercury-wetted relays that have extremely rapid break times, but whose operate times of 3-5 msec make it difficult to reduce switch and potentiostat times much below 1 msec. The circuit described here operates automatically, eliminates the need for active switching circuitry, has an "on" switch time of 0.2 to 1.0 μsec at the beginning of the pulse, and an "off" switch time of from 6 to 20 μsec. The accuracy with which potentiostat time may be defined is limited only by the switch times.

Operation of the circuit, shown in Fig. 1, depends on the fact that the potentiostat, when an off-balance condition exists, will apply up to full output voltage (with about 1 μsec rise time) at the counter electrode until balance is again sensed. This step-change in output is used to back-bias D1 which thus isolates the potentiostat from the cell, prevents it from eliminating the off-balance condition, and keeps it driven to a

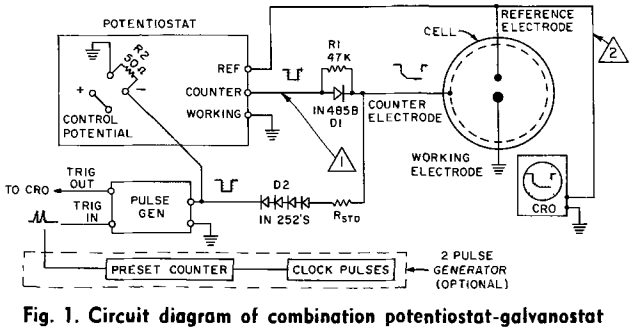

Fig. 1. Circuit diagram of combination potentiostat-galvanostat

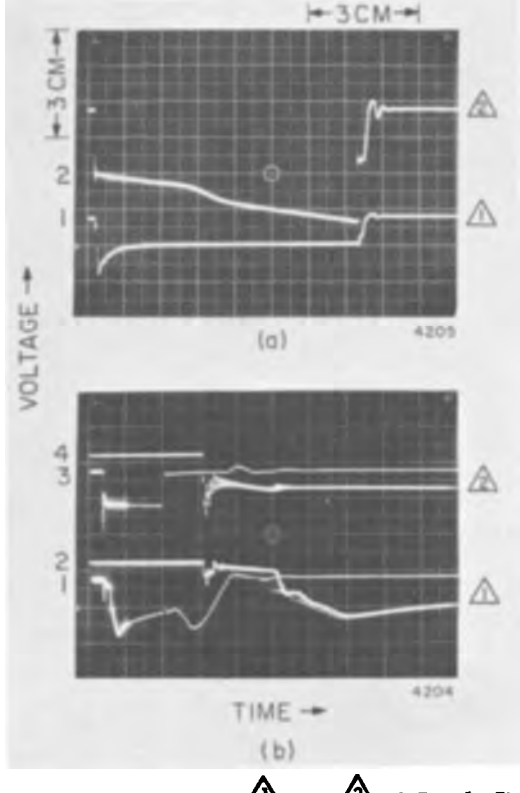

Fig. 2. Potentials at points 1 and 2 of Fig. 1. Fig. 2a: Pulse length 142 μsec, time 20 μsec/cm, voltage 10 v/cm trace 1, 1v/cm trace 2. Fig. 2b: Pulse length 8 μsec, time 5 μsec/cm for traces 1 and 3, 0.5 μsec/cm traces 2 and 4, voltage 10 v/cm traces 1 and 2, 2 v/cm traces 3 and 4. Traces 2 and 4 are expanded presentations of the first 5 μsec of traces 1 and 3, respectively.

limit. The desired off-balance condition is created by injecting the pulse generator output into the potentiostat reference circuit as well as directly into the cell. (The D2 diodes inhibit leakage currents between pulses and R_{std} gives constant current conditions.) The 47K resistor paralleling D1 permits enough current to flow to allow the potentiostat to regain control at the end of the pulse. Its size represents a compromise between degree of isolation desired when D1 is biased off, and the rate of resumption of potentiostatic control after the pulse is removed from the reference circuit.

In operation, the cell is under potentiostatic control except during the time of a galvanostatic pulse. The pulse generator may be used single shot or repetitively pulsed. If the optional apparatus within the dashed lines is included, the generator will provide two pulses whose time separation may be known as precisely as desired depending on the counter or clock generator used.[1]

[1] Any combination of compatible units may be used. In the circuit developed the components used were a Tektronix 547 oscilloscope with 1A1 plug-in, an Electropulse 3450 D pulse generator with 15 nsec rise time, a Wenking Fast Rise 61 RS potentiostat, a Hewlett Packard 5214L Electronic Counter (max. rate 100KC) counting the output from a Tektronix Type 105 Square Wave Generator. The preset counter gives one pulse at the start of counting and one when the preset count is reached. Thus pulses may be spaced a minimum of 10 μsec apart and a maximum of 99,999 times the basic clock rate chosen. Depending on the need for flexibility and time resolution, considerably simpler two-pulse generators may be substituted. Diodes D1 and D2 are noncritical; any of a large number of diodes having suitable power handling characteristics may be used.

Circuit operation is shown in Fig. 2. The working electrode has a real (1) area of 0.21 cm^2, current density was 3.1 amp/cm^2. A typical galvanostatic charging curve appears in trace 2 of Fig. 2a, while trace 1 shows the gating signal appearing at the potentiostat output. In this case the potentiostat was set at ~0.060v (NHE) and the 1*N* H_2SO_4 electrolyte was stirred with He at 10 ml/min. The "off" switch time in such a pulse may be variously considered to be between 6 and 20 μsec depending on how much potentiostat ringing can be tolerated. The "on" switching times are displayed in Fig. 2b, as well as the "off" times for the cases where the electrode is little polarized by the pulse. Traces 2 and 4 show that the working electrode is essentially polarized after 0.2 μsec, but that the potentiostat is not completely gated off until a total of 1 μsec has elapsed. The total "off" switching time is ~10 μsec.

The circuit as described applied negative pulses to the counter electrode which results in anodic working electrode polarization and an inverted display of this, as in Fig. 2a, trace 2. Cathodic polarization will result from using positive pulses and reversing D1 and D2.

Brief Communication

Carbon Dioxide Determination during the Galvanostatic Oxidation of Adsorbed Propane Intermediates

W. T. Grubb and M. E. Lazarus[1]

General Electric Research & Development Center, Schenectady, New York

After adsorption of an n-paraffin hydrocarbon at constant potential on a platinum anode in an acidic electrolyte, current peaks due to intermediates have been observed in subsequent oxidation by a linear anodic voltage sweep (1-3). Some of these peaks are not removed by cathodic hydrogenation, and it is supposed that these contain partially oxidized carbon because of their similarity to current peaks from carbon monoxide (3, 4) and reduced carbon dioxide (5). This communication presents confirmatory analytical evidence on this point which has been obtained by combining electrochemical experiments with simultaneous CO_2 analysis in the product gas using extremely high-area platinum-black electrodes.

A Teflon-bonded platinum-black electrode prepared by the method of Niedrach and Alford (6) was mounted in the arrangement shown schematically in Fig. 1 as the working electrode of a half-cell. The counter electrode and reference electrode were hydrogen on platinum black electrodes, the latter communicating with the working electrode through a Luggin capillary not shown. The working electrode was connected to an Anatrol Model 4100 Controller which maintained its potential against the hydrogen reference at a selected constant value. Alternatively, the controller was used as a constant current source by controlling potential across a fixed resistor in series with the cell. Temperature of the cell was maintained at 65° ± 0.5°C by means of a constant-temperature oil bath.

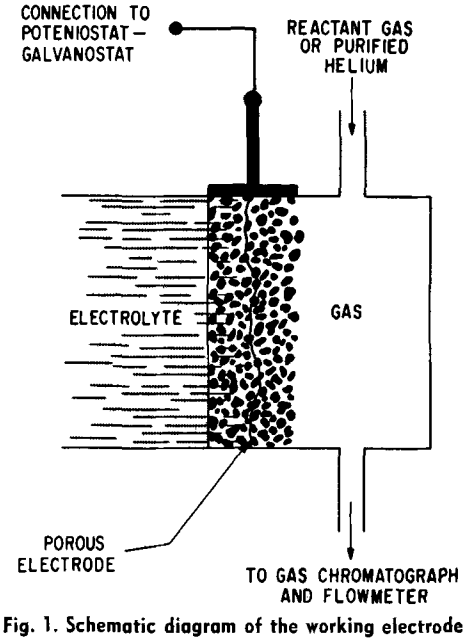

Fig. 1. Schematic diagram of the working electrode

[1] Present address: Knolls Atomic Power Laboratory, General Electric Company, Idaho Test Plant Site, Idaho Falls, Idaho.

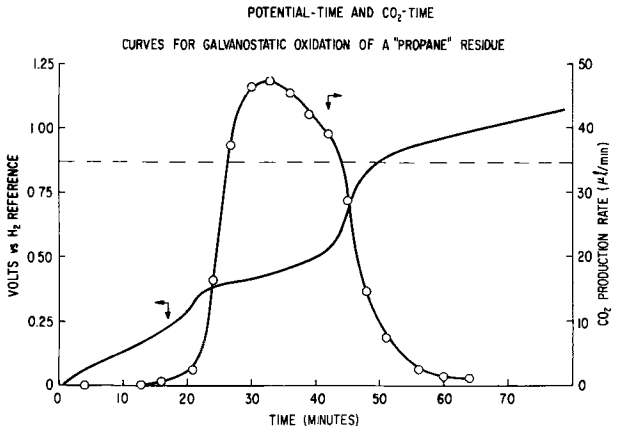

Fig. 2. Plot of CO_2 production rate and voltage *vs.* time for galvanostatic oxidation at 10 ma. The dashed line is the calculated CO_2 production rate for 4-electron oxidation.

Propane was adsorbed at 0.2v *vs.* the hydrogen reference with excess propane flowing through the gas space adjacent to the working electrode. When adsorption was complete, all gaseous propane was swept away with a purified helium purge while maintaining the same potential. The working electrode was then subjected to exhaustive cathodic hydrogenation with the helium purge continuing. The material remaining adsorbed was then oxidized at constant current, and voltage was recorded as a function of time. A voltage arrest or plateau typical of oxidation of carbonaceous species was observed. At the same time, product gas from the cell was swept into a gas chromatograph with a constant, known flow rate of purified helium gas and analyzed for carbon dioxide content. The rate of production of CO_2 from the anode was obtained from the product of the total gas flow rate and the volume fraction of CO_2 present.

Figure 2 shows the superimposed voltage *vs.* time and CO_2 *vs.* time curves. The CO_2 curve obviously coincides with the voltage arrest. Furthermore, the maximum rate of CO_2 production exceeds that which could be produced by a 4-electron oxidation reaction from the total 10 ma galvanostatic current employed (the dashed line in Fig. 2). This could only occur if the surface species contain carbon already partially oxidized, and thus the hypothesis about the nature of the nonhydrogenatable species produced on adsorption of propane is confirmed.

It appears that this type of experiment can provide useful information about hydrocarbon adlayers that is complementary to results obtained on microelectrodes by electrochemical methods.

SOLID STATE SCIENCE

Kinetics of Tantalum Corrosion in Aqueous Electrolytes, I

K. Lehovec and J. D'Amico[1]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The spontaneous growth of thin (6-20Å) oxide films on tantalum immersed into aqueous solutions of H_2SO_4, NaCl, and NaOH has been investigated by means of capacitance and voltage measurements. There is a rather rapid initial oxide growth rate in NaOH until a thickness of about 12Å is reached. Beyond that thickness and over the entire thickness range in the other electrolytes, the oxide thickness increases roughly in proportion to the logarithm of time. There is a small, but well established dependence of "oxide capacitance" on the pH of the electrolyte in which it is measured and a rather large, reversible temperature dependence of the oxide capacitance, which indicate that these thin oxide films do not behave as an ordinary dielectric.

In a previous paper (1) we studied the corrosion of tantalum in aqueous electrolytes while permitting an electric current to flow between the tantalum and the electrolyte through an external circuit.

The external current was monitored as a function of time, and the growth in oxide thickness was followed by means of capacitance measurements between the tantalum substrate and the electrolyte. The results seemed to indicate that for very thin oxide films, *i.e.*, oxide thickness in the range up to about 30Å, (*i*) a significant electron current flows through the oxide in addition to that through the external circuit, and (*ii*) the flow of ions through the oxide does not follow the law encountered in anodic oxidation of thicker oxide films, namely

$$i_I = A \exp BF \qquad [1]$$

where

$$F = (E - V)/d \qquad [2]$$

with V the potential between a standard calomel electrode to the electrolyte and the tantalum; d, the oxide thickness derived from the capacitance between the tantalum substrate and the electrolyte; and E, electromotive force of the reaction.

In the present paper the growth of an oxide film on tantalum immersed in an aqueous electrolyte was studied without permitting an external current to flow. In a subsequent paper an attempt will be described to separate experimentally the voltage and thickness dependencies of the ionic and electronic currents which flow through the oxide during spontaneous corrosion.

[1] Present address: Physics Department, Rensselaer Polytechnic Institute, Troy, New York.

Experimental

Origin and treatment of the tantalum samples used was described in ref. (1). High-purity vacuum annealed tantalum was etched in HF, rinsed for a few seconds in distilled water, and inserted in the aqueous electrolyte in which the spontaneous corrosion was studied. The test cell is shown in Fig. 1 and the test circuit in Fig. 2. The network on the upper right of Fig. 2 is not required for the present investigation, but has been included for reference in a subsequent paper. The counter electrode to the tantalum consisted of two sheets of black platinum spaced 0.5 cm apart from the tantalum. The electrolyte was circulated at a rate of 85-90 ml/min between the cell and a 12-liter constant temperature bath maintained at 20° ± 0.5°C.

Sulfuric acid, sodium hydroxide, and sodium chloride aqueous electrolytes were used. The sulfuric acid

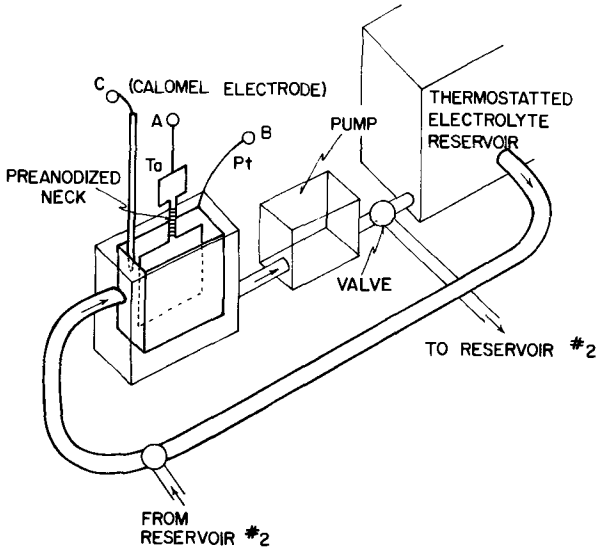

Fig. 1. Experimental arrangement

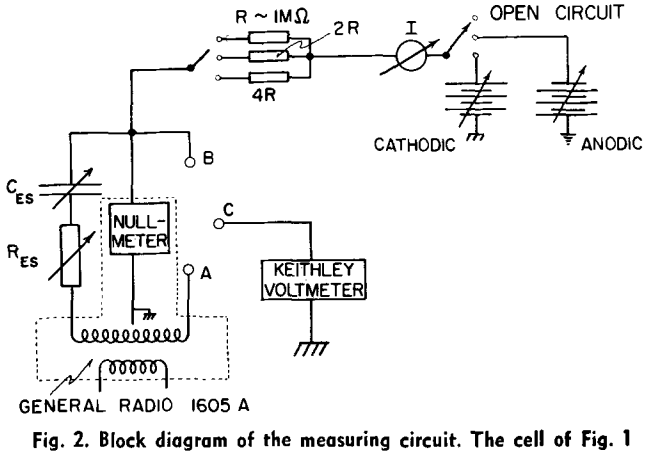

Fig. 2. Block diagram of the measuring circuit. The cell of Fig. 1 is connected to the points marked A, B, and C.

electrolyte had a pH of about unity which was measured with a Beckman Model H2 pH-meter. The pH of the strongly basic sodium hydroxide electrolyte was determined by titration with 1*N* HCl.

A saturated calomel electrode (SCE), Beckman Model 39970, was inserted in the electrolyte and the voltage, V, SCE *vs.* tantalum was measured with a Keithley Model 610BR Electrometer. This voltage is positive for spontaneous corrosion, but eventually becomes negative when anodic oxide is grown by passing an external current.

The a-c impedance, tantalum *vs.* platinum was measured with a General Radio Model 1650A impedance comparator, using a signal voltage of 8.6 mv rms, 100 Hz across the sample. The bridge was balanced by standard capacitors and resistors, indicated by C_{ES} and R_{ES}. The series resistance of the standard capacitor is included in R_{ES}. The time dependence of V and C_{ES} were recorded continuously by use of a Varian Model G22A Dual Channel Recorder.

Open-circuit d-c voltage *vs.* time data taken without the a-c voltage of 8.6 mv applied and the bridge still connected, or else, without the bridge connected at all were identical to those obtained with the small a-c voltage and the bridge connected.

Derivation of oxide thickness from capacitance.— From the equivalent series capacitance, C_{ES}, the quantity

$$d = S\epsilon\epsilon_0/C_{ES} \qquad [3]$$

was calculated using the macroscopic contact area $S = 18.8$ cm^2 between tantalum and electrolyte, the permittivity of free space ϵ_0, and the dielectric constant $\epsilon = 27.6$ (2) for Ta_2O_5. The quantity d will be identified with the "oxide thickness" in what follows.

The use of Eq. [3] to derive the oxide thickness requires justification since: (*a*) there may be contribution to C_{ES} from double layer capacitances at the tantalum oxide-electrolyte and platinum-electrolyte interfaces; (*b*) the "thick" film dielectric constant used might not apply to our "thin" films. (The value $\epsilon = 27.6$ has been determined at 1000 Hz (2), while our measurements were made at 100 Hz. However, the change of ϵ between 100 and 1000 Hz is quite small and not important for our conclusions); (c) the macroscopic sample area, $S = 18.8$ cm^2, might differ from the effective sample area due to a roughness factor $\neq 1$.

To investigate the contribution of solution double layers we proceeded as follows: Equivalent series capacitance and resistance, C_{ES} and R_{ES}, respectively, were measured for the same sample at 100 and 1000 Hz in H_2SO_4, NaCl, and NaOH electrolytes of various concentrations. These measurements were performed during a sufficiently short time and under conditions preventing significant changes of oxide thickness. For each electrolyte, values of the four equivalent circuit parameters of Fig. 3b were calculated from the real and imaginary parts of the measured impedances C_{ES} (f) and R_{ES} (f) of the circuit of Fig. 3a. C_p and R_p represent the capacitance and inverse conductance of the two double layers in the electrolyte at the tantalum oxide and platinum electrodes lumped into only one R_p-C_p combination to simplify the evaluation. C_o is the oxide capacitance. The equivalent parallel resistance R_T of the oxide has been omitted in Fig. 3b, since the time constant R_TC_o is of the order of seconds as concluded from the time constant of the d-c potential transient after passing a small external current through the sample. Thus, R_T should not affect the impedance at frequencies of 100 Hz and larger.

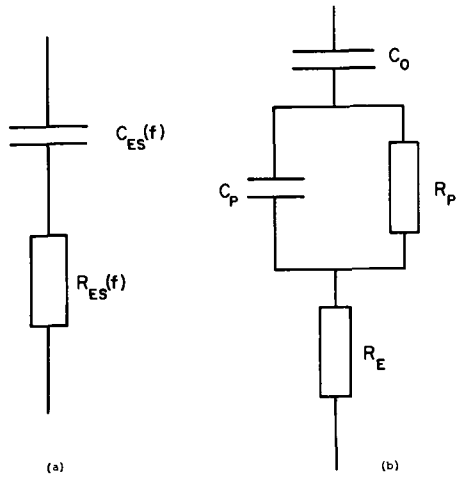

Fig. 3. Measured cell parameters (a) and cell equivalent circuit (b).

Table I gives results of several typical sets of measurements. Values of C_o in electrolytes of the same type, but different concentrations, differ only little. Moreover, at least a portion of these differences can be accounted for by a dependence of oxide capacitance on the pH of the electrolyte, to be discussed in more detail in conjunction with Table II. Thus we consider the near constancy of the values of C_o of Table I as supporting our simplified equivalent circuit Fig. 3b. It can be observed in Table I that for the most conductive electrolytes where $R_{ES} \sim 1$ ohm the oxide capacitance C_o differs from the equivalent series capacitance

† All thickness values computed by Eq. [3] using the C_o values for the electrolyte of lowest R_{ES}.
* 60 μa cathodic current applied during measurement to suppress the oxide growth which would occur otherwise by spontaneous corrosion.

C_{ES} measured at 100 Hz by less than 2%. In Table I we list data obtained with a sulfuric acid electrolyte using three different oxide thicknesses (on three different samples of tantalum). Values of $(C_o - C_{ES})/C_o$ with C_o measured at 100 Hz and for electrolytes of pH $\simeq$ 1 are 2.0, 1.7, and 1.5% for the thicknesses of 17.9, 15.4, 11.7Å, respectively. This suggests that Eq. [3] remains valid even for thicknesses below 11.7Å.

The use of "thick film" values for dielectric constant and density is justified by the following experiment: A known anodic charge was passed through an oxide film. The oxide capacitance, C_o, was calculated by means of the equivalent circuit of Fig. 3b, from impedance measurements at 100 and 1000 Hz. The increment in thickness derived from the C_o values before and after passing the anodic charge was 1.74Å. This value was corrected for the open-circuit oxide growth during the measurements (0.04Å) and for the oxide growth due to the internal electronic current during passage of the anodic charge (0.09Å) assumed to be equal[2] to the open-circuit growth which would have occurred during the same time interval if no anodic current would have been passed. With this correction the increment in oxide thickness resulting from the anodic charge and calculated from the change of C_o becomes 1.61Å compared to the 1.56Å calculated from Faraday's law using

$$\frac{\Delta d}{\int I dt} \simeq \lambda = \frac{M}{2F\rho Sz} = 3.1 \times 10^{-6}\ \text{cm/coul} \quad [4]$$

based on the molecular weight $M = 442$ of Ta_2O_5, the Faraday constant $F = 96{,}500$ coul/g-equivalent, the density (2) $\rho = 7.93$ g/cm^3, and the valence $z = 5$ for the tantalum ions. This good agreement supports the use of Eq. [3] to derive oxide thickness as well as the numerical values used in conjunction with Eq. [3] and [4]. Mutual compensation of several large errors in the constants is possible though unlikely.

In Table II capacitance measurements are listed for samples exchanged between different electrolytes. The data were analyzed in terms of the equivalent circuit of Fig. 3b, with the result that the oxide capacitance C_o depends somewhat on the nature of the electrolyte in a generally reversible manner.

Thicknesses measured in NaCl of 3.44 % wt [pH $\simeq$ 6] and in NaOH of pH $\simeq$ 13.5 are larger than those in H_2SO_4 of pH $\simeq$ 1 by about 2, and 4Å, respectively, in the range of oxide thicknesses 14-23Å. These differences in "oxide thickness" with the type of the electrolyte suggest a dependence of d on the pH. The change of about 4Å from H_2SO_4 of pH $\simeq$ 1 to NaOH of pH $\simeq$ 13.5 corresponds to about 0.3 Å/pH, *i.e.*, a relative change of about 2%/pH. Such a dependence would also account for most if not all of the changes of C_o in Table I in the same electrolyte with pH. Changes of oxide capacitance with pH have been reported by Vermilyea (3).

A further indication of an anomalous behavior of oxide capacitance is the large temperature dependence of C_o. Table III gives values of the apparent "oxide thickness" d derived from capacitance measurements by Eq. [3] when alternating the electrolyte temperature between 41° and 20°C. The oxide film chosen for these measurements was fairly thick (about 22Å) so that the oxide growth rates at these temperatures were only 5.5 x 10^{-4} and 1.6 x 10^{-4} Å/sec, respectively. The "thickness changes" with temperature were corrected for these growth rates and are listed under the heading Δd_{corr}. The resulting change of "oxide thickness" with temperature is −0.04 Å/°C, *i.e.*, −0.2%/°C.

[2] Actually the correction should be somewhat less since an external anodic current has the tendency to suppress the internal electron current.

Table III. Reversible change of oxide thickness, *d*, with temperature

Temperature change	Δd, A	Δd_{corr}, A
From 41 to 20°C	+0.93	+0.84
From 20 to 41°C	−0.72	−0.87
From 41 to 20°C	+0.91	+0.87

Our open-circuit measurements extended over the thickness range from about 5 to 20Å. At the lower thickness limit, the oxide growth rate became so large that balancing the bridge by hand was not possible. At the upper limit, the growth rate became quite slow so that extending the measurements any further was impractical. Film thicknesses in the range discussed here have been determined from capacitance measurements previously by Vermilyea (4) when studying air oxidation of tantalum.

Since there is an open-circuit potential $V_{Pt\text{-}Ta}$ of the order of several tenths of a volt, an anodic charge $C_{ES}V_{Pt\text{-}Ta}$ flows when connecting the bridge circuit to the cell. This corresponds to an increment of oxide thickness, $\Delta d = \lambda C_{ES}V_{Pt\text{-}Ta}$, of about 0.5Å. However, this growth occurs before balancing the bridge. Further growth of this type does not occur during the run since C_{ES} is decreased by switching off sections of the balancing capacitor.

As $V_{Pt\text{-}Ta}$ decreases during the open-circuit growth of the oxide, the standard capacitor is slowly discharged into the oxide capacitor, representing a cathodic bias current of the magnitude $-C_{ES} \cdot \partial V_{Pt\text{-}Ta}/\partial t$ (cathodic bias currents are counted here positive so that the minus has been added since $\partial V_{Pt\text{-}Ta}/\partial t < 0$). However, this cathodic bias current should have no significant effect on the growth rate if it is small compared to the ionic growth current, *i.e.*, if $-\partial V_{Pt\text{-}Ta}/\partial t << I_I/C_{ES}$ or using Faraday's law if $-\partial V_{Pt\text{-}Ta}/\partial d \simeq \partial V/\partial d << I_I[C_{ES}\ \partial d/\partial t]^{-1} = (\lambda\ C_{ES})^{-1}$. In the range investigated by us, the left-hand side of this inequality was two orders smaller than the right-hand side.

Results

Typical data of oxide thickness, d, *vs.* time, for spontaneous corrosion in aqueous H_2SO_4 (pH = 1), NaCl (3.4 % wt), and NaOH (pH = 13.5) solutions are shown in Fig. 4. Time is counted from insertion of the sample into the electrolyte, which is about 5 sec after the extraction from the HF-etch. The data are replotted in Fig. 5 as growth rate $\partial d/\partial t$ *vs.* oxide thickness, d.

After an initial growth period, the oxide thickness increases about linearly with the logarithm of time. This is similar to the observations by Vermilyea (4) on open air oxide growth on tantalum also using capacitance measurements to determine oxide thickness. Oxide growth in sulfuric acid resembles that in

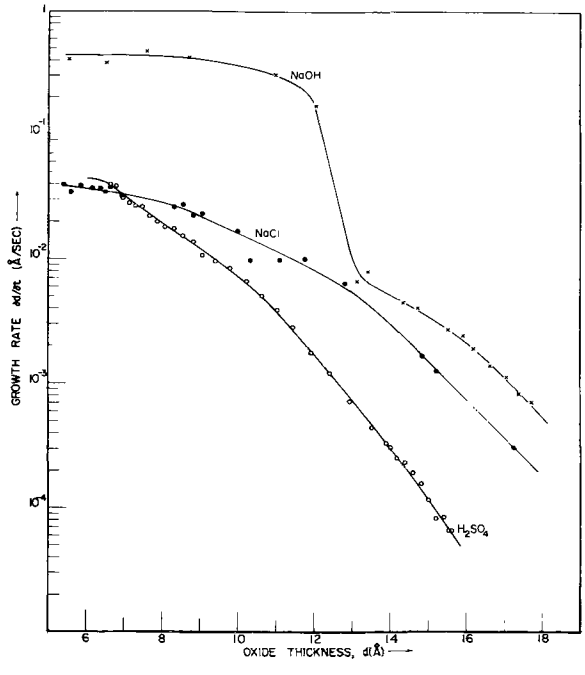

Fig. 5. Growth rate *vs.* oxide thickness during spontaneous corrosion.

sodium chloride electrolytes except that the growth rate is somewhat faster in the sodium chloride solution.

The growth behavior in the sodium hydroxide solution is quite different: After an initial growth at the rapid rate of 0.4 Å/sec (see Fig. 5) up to a thickness of about 12Å, there is a rather abrupt drop of growth rate by about an order of magnitude between 12 and 13Å, followed by a decreasing growth rate similar to that experienced in H_2SO_4 and NaCl solutions. The lateral displacement of the three curves of Fig. 5 may be in part due to the dependence of "oxide thickness" on the electrolyte in which the measurements were taken (see Table II).

Figure 6 shows the voltage (SCE *vs.* tantalum) in the three electrolytes as a function of thickness during open-circuit corrosion for the same runs used in the previous figures. In H_2SO_4 and NaCl electrolytes the voltage decreases in a monotonous fashion with time. In the NaOH-electrolyte the voltage passes through a maximum at the thickness at which the transition from the initial constant growth rate to a growth behavior similar to that in H_2SO_4 and NaCl occurs.

The occurrence of a voltage maximum during spontaneous corrosion in the NaOH electrolyte is an experimental fact which is unrelated to our thickness determination for capacitance measurements and the assumptions thereby made.

Discussion

An inspection of the curves $V(t)$ and $\partial d/\partial t$ *vs.* d for spontaneous corrosion (Fig. 5 and 6) shows that all electrolytes investigated by us behave similarly, except for the rapid initial oxide growth rate in NaOH, which ceases fairly abruptly when a thickness of 12Å (as measured in NaOH) is reached. The nearly constant growth rate of about 0.4 Å/sec corresponds to an ionic current of 65 μa/cm^2 by means of Faraday's law.

The initial growth behavior in the NaOH-electrolyte suggests the mechanism discussed by Mueller (5), *i.e.*, electrolyte transport through pores between the growing anodic film and that at about 12Å the transition occurs to a full coverage of the tantalum by oxide. The occurrence of this growth mechanism might be related to the small but finite solubility of Ta_2O_5 in NaOH.

With the exception of the initial growth in the NaOH electrolyte, the time dependence of oxide thickness is roughly in proportion to the logarithm of time with a proportionality constant $\partial d/\partial \ln t$ of the order of 1 to 3Å.

Observations which shed some doubt on the existence of a well-defined oxide film acting as a dielectric of width d are as follows: (*i*) the dependence of d on the electrolyte in which it is measured (Table II); and (*ii*) the reversible change of d by about 0.04 Å/degree or 0.2% per degree with temperature (Table III). These phenomena may arise by a portion of the oxide being so conducting that it contributes to the equivalent series resistance rather than to the equivalent series capacitance (6, 7). A conducting portion of the oxide may arise from a space charge of electrons in the oxide adjacent to the tantalum metal (8-10), or, more likely, by a space charge of protons in the oxide adjacent to the electrolyte (3). In the latter case, an

increase in the conducting portion of the oxide with H^+ concentration in the electrolyte (*i.e.*, decreasing pH) may be expected, in qualitative agreement with the decrease of "d" with pH of the electrolyte in which capacitance is measured (Table II). The space charges of electrons or protons in the oxide need not necessarily be of such magnitude as to modify significantly the d-c field strength in the oxide.

While the effects described are quite pronounced, the resulting thickness changes of at most 2Å are, nevertheless, very small compared to the total thickness d. It might be hoped, therefore, that identification of d with the total oxide thickness is a justified approximation, and in particular, that the ionic currents determined from $\partial d/dt$ by Faraday's law are not affected significantly.

The driving "force" of the corrosion process is the free energy change of the reaction between tantalum and water to form tantalum oxide. The reaction proceeds by migration of positive tantalum ions and/or oxygen ion vacancies from the tantalum toward the electrolyte, or possibly by migration of negative oxygen ions in the opposite direction. This charge migration tends to charge the tantalum negatively. In the absence of any additional charge flow for charge compensation, a potential equal to the emf of the reaction would rise across the oxide, the field in the oxide would vanish according to Eq. [2], and the ionic charge transport causing oxide growth would cease. Continuing oxide growth thus requires some mechanisms for charge neutralization, usually in the form of flow of electrons or holes. The potential across the oxide establishes itself at a level providing a balance of electronic and ionic flow at the thickness in question. Thus, a theoretical analysis of growth rate would seem to require assumptions on both electronic and ionic charge transports. In a subsequent paper we shall discuss methods by which we attempted to obtain experimental information on the voltage and thickness dependences of electronic and ionic charge transports. These values will then be compared to theoretical concepts of protective oxide film growth such as the Mott-Cabrera (11) mechanism and others.

Conclusions

1. Spontaneous corrosion of tantalum in aqueous electrolytes of H_2SO_4, NaCl, and NaOH is qualitatively similar, except for an initial rapid time-independent corrosion in NaOH which ceases abruptly at about 12Å thickness.

2. The oxide capacitance increases in the sequence H_2SO_4-NaCl-NaOH for a given sample when changing the electrolyte. This sheds some doubt on models treating thin oxide films as a perfect dielectric with a dielectric constant independent of the ambient electrolyte. Furthermore, there are abnormally large reversible changes of oxide capacitance with temperature, which indicate that the oxide does not behave as a perfect dielectric. However, since these changes in oxide capacitance are only a small fraction of the capacitance, the analysis of the measurements based on an "oxide thickness" as determined from capacitance appears to be a valid first order approximation.

Structure and Luminescence of the Phosphate-Vanadates of Yttrium, Gadolinium, Lutetium, and Lanthanum

Michael A. Aia

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Phosphate-vanadates of Y, Gd, Lu, and La, formed from powders at 1000°C, were solid solutions having the structure of either xenotime or monazite. Compositions containing 25-50 mole % $GdVO_4$, YVO_4, or $LuVO_4$ exhibited intense blue photoluminescence arising from absorption and fluorescence within the vanadate groups. The fluorescence of phosphate-vanadates activated by europium was also investigated and is compared to the fluorescence of the corresponding vanadates.

Reviews of the literature on the structures of the rare earth phosphates (1, 2) and vanadates (1, 3) have been published recently. In general, these compounds have either the xenotime (tetragonal) or the monazite (monoclinic) structure at ordinary pressures. A hexagonal form of $LaPO_4$ is also known (4). Scheelite structures are found in the rare earth vanadates and arsenates at high pressures (3). The cell constants for the phosphates, vanadates, and arsenates having the xenotime structure have been precisely determined (1).

Rare earth-activated luminescence in the phosphates (5, 6) and vanadates of Y, Gd, Lu, and La (7-14) has been actively studied, and YVO_4:Eu is used as the red-emitting component in cathode-ray tubes for color television (9, 14). Weak blue fluorescence is emitted by the unactivated vanadates of Y, Gd, and Lu at room temperature; at —196°C the fluorescence is much more intense (13). In the present work the crystallography and luminescence of solid solutions of unactivated rare earth phosphates and vanadates are examined. It is

shown that the blue emission arising from the vanadate groups is greatly enhanced when the vanadate concentration is diluted by adding a large amount (*e.g.* 75 mole %) of phosphate and firing to produce a solid solution of the vanadate in the phosphate.

Experimental Procedures

Preparation of samples.—Stoichiometric mixtures of $(NH_4)_2HPO_4$, NH_4VO_3, and the appropriate rare earth trioxide were heated in covered silica crucibles; for samples not containing phosphate a 40% excess of NH_4VO_3 was added to insure complete reaction of the trioxide.

Because the phosphates contained large amounts of unreacted rare earth oxide when prepared from solid $(NH_4)_2HPO_4$, they were precipitated at 90°C by slowly adding an excess of 0.4*M* $(NH_4)_2HPO_4$ solution to a 0.4*M* solution of the rare earth nitrate. After washing and oven drying, the phosphates were ground, sieved, and then fired like the other compositions. The powders were heated for 18 hr at 450°C, ground, and reheated for 4 hr at 1000°C, both times starting from a cold furnace. After grinding and sieving 150 mesh the powders were suspended in hot 10% NaOH (to remove unreacted V_2O_5), washed with water, and oven dried at 120°C. Although the purity of the rare earth oxides was alleged by the manufacturer to be 99.9% or better, the Gd_2O_3 contained sufficient Eu^{3+} to produce intense red luminescence in the samples high in $GdVO_4$; the Lu_2O_3 contained sufficient amounts of Tb, Eu, and Tm to produce the luminescence characteristic of those elements (13). Microscopic examination of the finished powders showed that the phosphates were micro-crystalline (particles $<1\mu$), while the vanadates were well crystallized (5-50μ); the phosphate-vanadates were intermediate (2-5μ). More crystalline phosphates have been prepared by using $Pb_2P_2O_7$ as a flux (2) or by hydrothermal treatment with aqueous phosphoric acid (15, 16a).

X-ray diffraction analysis.—A calibrated Philips-Norelco diffractometer was used with Ni filtered CuKα radiation. The scanning rate was one degree 2θ per minute. The d-spacings of the powder patterns were indexed with the help of a computer after starting from the indexing given for YPO_4 (xenotime) and $LaPO_4$ (monazite) in the ASTM Powder Data File (16). The cell parameters were then calculated by the method of least squares.

Luminescence measurements.—Excitation and fluorescence spectra were obtained on a dual-grating Aminco-Bowman spectrophotofluorometer with a xenon lamp as source and either a 1P28 or RCA 6217 photomultiplier as detector, depending on the wavelength region studied. The intensity of the blue luminescence of the compounds was measured relative to that of $CaWO_4$ (Sylvania type No. 2402) and $CaWO_4$:Pb (NBS 1026) using a 1P28 photomultiplier and Corning CS5-61 blue filter. A CS2-63 red filter was used with a 6217 photomultiplier to measure red brightness of samples activated by europium. Photoluminescence was excited by a G4T4 germicidal lamp with principal emission at 253.7 nm after filtering by a Corning 7-54 visible-light-absorbing filter. Cathodoluminescence was measured in a demountable cathode-ray tube after settling the powders uniformly at 5 mg/cm^2 onto Corning EC (electrically-conducting) glass and baking at 450°C; the phosphors were excited using a beam current density of 0.15 μa/cm^2 and an accelerating potential of 15 kv.

Results and Discussion

Unit-cell dimensions calculated from x-ray powder data are summarized in Table I. Values for YPO_4, YVO_4, $GdVO_4$, $LuPO_4$, and $LuVO_4$ are close to those of Schwarz (1). All the compounds of Y, Gd, and Lu had the tetragonal structure except $GdPO_4$ which was monoclinic, like the compounds of La. The addition of

25 mole % vanadate to $GdPO_4$ caused the occurrence of xenotime as the major structure. The formation of phosphate-vanadate solid solutions is indicated by the linear increase in the cell dimensions with increasing mole per cent vanadate, as shown on Fig. 1 and 2. Vegard's law is followed except in the case of the c_o parameter of the La compounds where there is a departure from linearity. In general, there was considerable line broadening, indicating lattice strain, in the diffraction patterns of the samples containing 25 mole % vanadate; $GdP_{0.75}V_{0.25}O_4$, $YP_{0.75}V_{0.25}O_4$, and $LuP_{0.75}V_{0.25}O_4$ contained about 10% $GdPO_4$, YPO_4, and $LuPO_4$, respectively.

Inspection under 253.7 nm light at room temperature showed that several of the phosphate-vanadates emitted bright blue fluorescence, similar in color and intensity to that of $CaWO_4$ phosphor. Under 365 nm light the samples were only feebly luminescent. Fluorescence and excitation spectra were obtained at room temperature. Typical uncorrected excitation and fluorescence curves are shown in Fig. 3 where $GdP_{0.75}V_{0.25}O_4$ is compared to both $CaWO_4$ and $CaWO_4$:Pb (NBS 1026). The apparent excitation peaks

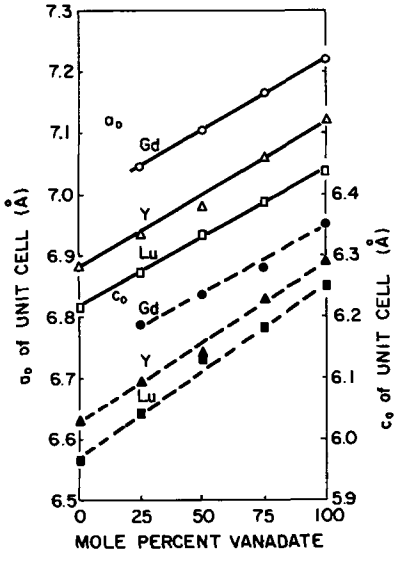

Fig. 1. Unit-cell parameters for the phosphate-vanadates with xenotime structure. Solid lines are a_o parameters; dashed lines are c_o parameters.

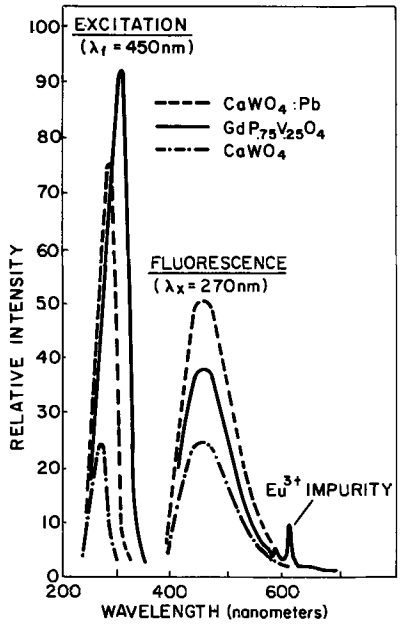

Fig. 3. Comparison of the photoluminescence of $GdP_{0.75}V_{0.25}O_4$ and standard blue phosphors.

of Fig. 3 are exaggerated in sharpness. In agreement with Kroeger (17), the excitation peak of $CaWO_4$:Pb lies at a longer wavelength (285 nm) than that of $CaWO_4$ (270 nm). The excitation peak of $GdP_{0.75}V_{0.25}O_4$ lies near 310 nm, as found for the vanadates of Y, Gd, Lu, and La (13). When excited at the optimum wavelength for $CaWO_4$, the fluorescence of $GdP_{0.75}V_{0.25}O_4$ is much more intense than that of $CaWO_4$, but less than that of NBS 1026. However, when excited at wavelengths from 290 to 320 nm, the $GdP_{0.75}V_{0.25}O_4$ is much brighter than NBS 1026, as can be seen from the excitation spectra.

A summary of the fluorescence and excitation peaks of the phosphate-vanadates is given in Table II. The relative intensities of blue fluorescence were measured under excitation by 253.7 nm light and by cathode rays and compared to $CaWO_4$. These results are also given in Table II. The excitation peak shifts to longer wavelengths as vanadate is combined with phosphate; the biggest changes occur with the first 25 mole % vanadate. Changes in the fluorescence peaks of Table II are due mostly to the effects of rare earth impurities whose luminescence is at longer wavelengths and becomes more pronounced as the vanadate concentration is increased.

In agreement with visual inspection, the brightest host luminescence was obtained at 25-50 mole % vanadate. Although the blue brightnesses in Table II

peak at 25% vanadate, the over-all brightnesses at 50% vanadate (not shown) were comparable, due to a greater component of emission at longer wavelengths as vanadate content increased. This was especially true for the samples containing Gd since the starting Gd_2O_3 contained an appreciable amount of Eu^{3+} which activates $GdVO_4$ and the phosphate-vanadates very efficiently (*e.g.*, see Fig. 3). Despite Eu^{3+} contamination the brightest blue phosphor was $GdP_{0.75}V_{0.25}O_4$ whose host emission was 31% greater than that of $CaWO_4$ under short uv light. Under cathode-ray excitation the relative intensities *vs.* $CaWO_4$ were lower, which may be partly due to the poor crystallinity of the samples containing phosphate.

Activation of $YP_{0.5}V_{0.5}O_4$ with rare earth ions was investigated. When 0.01 and 0.05 mole Eu, Tb, Ho, or Er were added the blue host emission (due to vanadate ions) was quenched; however, only Eu^{3+} produced an appreciable level of fluorescence at room temperature. Comparison of the fluorescence spectrum of Eu^{3+}-activated $YP_{0.5}V_{0.5}O_4$ with that of Eu^{3+}-activated YVO_4 revealed that the relative intensity of the line group peaking at 595 nm was appreciably greater in the phosphate-vanadate. Similar results were obtained with the Gd and La series containing Eu^{3+}. The red brightnesses of the samples compared to a commercial $Y_{0.95}Eu_{0.05}VO_4$ standard are given in Table III, together with the intensity of emission at 595 nm compared to that of the main emission at 619 nm. Despite smaller particle sizes and generally poorer crystallinity, the phosphate-vanadates activated by Eu^{3+} were comparable in brightness, but were more orange

in emission than their vanadate counterparts. The phosphors containing La were most orange in emission, but lowest in over-all brightness, as found previously (13); they also differ in that they have the monazite structure.

Summary

The unactivated rare earth phosphates-vanadates provide an interesting system in which the interaction of two types of ligand can be deduced, in the solid state, from x-ray and luminescence measurements. Phosphate is a good diluent for vanadate because it can substitute isomorphously in the xenotime structure and does not introduce undesirable absorption bands. Dilution with phosphate leads to considerable enhancement of the vanadate fluorescence which occurs in a broad band that peaks in the blue with the cations Y, Gd, and Lu. As with the undiluted vanadates, the addition of Eu^{3+} diminishes the host emission of the phosphate-vanadates and gives rise to intense emission in the orange and red regions of the spectrum. However, the transition probabilities of the Eu^{3+} fluorescence are altered appreciably by the phosphate ligands and the relative emission at higher energies (*e.g.*, 589 nm) is increased at the expense of the principal emission at 619 nm.

An Electronic Paramagnetic Resonance Study of the Chemistry of Mn^{++} during the Formation of Fluorapatite

J. A. Parodi

Lighting Research Laboratory, Lamp Division, General Electric Company, Cleveland, Ohio

ABSTRACT

Electronic paramagnetic resonance (EPR) is used to study the disposition of Mn^{++} among the various phases present during the course of the reaction producing fluorapatite, $Ca_{10-x}Mn_xF_2(PO_4)_6$ where $x = 1.5 \times 10^{-3}$. EPR spectra of Mn^{++} in the various phases are presented. Pertinent spectra of one firing mixture are presented and discussed. The distribution of Mn^{++} between some of the phases, principally calcium oxide and fluorapatite, is determined from relative intensities of EPR lines. The progress of solid solution of Mn^{++} in apatite is followed by the intensity of the apatite:Mn spectrum. In atmospheres of N_2 and $CO/CO_2 = 1/10$ solid solution of Mn^{++} is complete at 1100°. CaO is shown to have a strong affinity, relative to the other phases present, for low concentrations of manganous ion. It has been possible to follow the consumption of $Ca_2P_2O_7$ and CaO during the apatite forming reaction by means of EPR, but not CaF_2.

The chemical reactions involved in the formation of calcium halophosphate phosphor have been the subject of much research activity (1-9). For the most part the experimental methods employed (x-ray diffraction, differential thermal analysis, thermal gravimetric analysis, etc.) have lacked the requisite sensitivity to observe the behavior of manganese, because of its relatively low concentration, during the course of these reactions. Determination of the luminescent properties of halophosphates has been used to study the diffusion of Mn^{++} and also Sb^{+++} into the apatite lattice (10), but this approach gives no information about the presence of manganese in other phases. A method which allows for the direct observation of Mn^{++} in all of the phases which may be present during the course of the apatite forming reaction is that of electronic paramagnetic resonance (11, 12).

The work reported in this paper is an EPR (electronic paramagnetic resonance) investigation of the distribution of manganese among the various phases present during the formation of calcium fluorapatite. The study has been limited to calcium fluorophosphate because the EPR spectrum of Mn^{++} in this material is well defined and of relatively good intensity, whereas the corresponding spectra of chlorapatite and chlorfluorapatite are an order of magnitude weaker and show considerable variation from sample to sample of purportedly equivalent material. Also, in order to avoid a magnetically concentrated condition which would cause spin-spin broadening of the spectral lines

(13), it has been necessary to use about one hundredfold less manganese than is normal in halophosphate production.

Experimental

Preparation of materials.—All firing mixtures were formulated to yield, on completion of the reaction, a product of the composition $Ca_{10-x}Mn_xF_2(PO_4)_6$ where $x = 1.5 \times 10^{-3}$. Raw materials used were lamp phosphor grade $CaHPO_4$, $CaCO_3$, CaF_2, and various compounds containing Mn^{++} which were prepared as follows: (*a*) $CaHPO_4$: 2.5×10^{-4} Mn, by recrystallization of an aqueous slurry of $CaHPO_4 \cdot 2H_2O$ and manganous ion (12); (*b*) $CaCO_3$: 5×10^{-4} Mn, by precipitation from an aqueous solution of Ca^{++} and Mn^{++} with an ammonium carbonate solution; (*c*) CaF_2: 1.5×10^{-3} Mn by treatment of $CaCO_3$: 1.5×10^{-3} Mn with hydrofluoric acid; (*d*) $Ca_9MnF_2(PO_4)_6$ by firing a mixture of $CaHPO_4$, $CaCO_3$, CaF_2, and $MnCO_3$ at 1125°. Manganese was also added to the firing mixture as $Mn(NO_3)_2$ solution. The components of a given mixture were wet blended in acetone either by mortar and pestle or ball mill.

Portions of each of these mixtures were fired at 100° intervals over the range 600°-1200° for 10, 30, and 60 min in atmospheres of both N_2 and $CO/CO_2 = 1/10$. The purpose of the latter gaseous mixture was to provide a mildly reducing atmosphere (14) that would prevent Mn^{++} from oxidizing and at the same time not reduce phosphate.

Electronic paramagnetic resonance.—Electronic paramagnetic resonance of the polycrystalline samples was measured on a Varian Associates EPR spectrometer with a resonant frequency of 9160 MHz and a modulation frequency of 100 kHz. Approximately ¾ in. of powder at one end of a fused quartz sample tube (4 mm OD x 3 mm ID x 6 in. length) was used. The EPR spectra reproduced in this paper are potentiometric recorder tracings of the first derivative of absorption of microwave energy *vs.* the magnetic field, which increases from left to right in the figures.

Preparation of EPR standards.—Some of the raw materials used in the firing mixtures are too poorly crystallized and/or too magnetically concentrated in manganese to be good EPR standards. Differences in the following preparative procedures from those given above were made necessary by the requirements of good crystallinity and sufficient dilution of Mn^{++} to avoid spin-spin broadening.

Precipitated calcium carbonate is generally a mixture of vaterite and calcite. EPR spectra of $CaCO_3$:Mn preparations in which the proportions of vaterite and calcite varied were always the spectrum of Mn^{++} in the crystalline field of calcite only (15), the intensity increasing with calcite concentration. Irreversible transformation of vaterite to calcite occurs at 430°-440° (16), and at 500° the inversion goes rapidly. Precipitated $CaCO_3$: 10^{-4} Mn was heated for 1 hr at 500°, therefore, for use as an EPR standard. CaO: 10^{-4} Mn was made by igniting the carbonate for 1 hr at 1170° in an atmosphere of $CO/CO_2 = 1/10$. CaF_2: 10^{-4} Mn obtained by treatment of $CaCO_3$: 10^{-4} Mn with aqueous HF was heated at 1000° in a stream of nitrogen passed over NH_4HF_2 at 200°. This atmosphere was necessary to prevent the formation of CaO:Mn, which is produced very readily if only a trace of oxygen is available (17). The pyrophosphates were made by the thermal decomposition of $CaHPO_4$: 2.5×10^{-4} Mn.

The distribution of manganese between two or more phases was estimated from relative intensities of their EPR lines by comparison with standard mixtures of the above EPR standards.

Results and Discussion

Compounds that one might expect to be present during various stages of the reaction to form fluorapatite (at temperatures of 600° and greater) are γ-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$, $CaCO_3$, CaO, CaF_2, β-$Ca_3(PO_4)_2$, and $Ca_{10}F_2(PO_4)_6$ (1, 2). EPR spectra of Mn^{++} in solid solution in each of these compounds are given in Fig. 1 and 2. These are the basic spectra that have been used to determine the presence of manganese in these compounds in the fired mixtures. In this connection there are several points that should be discussed. First, it is noted that the first strong line of the apatite spectrum is free of interferences and that the lines of apatite are moderately strong and sharp. It is thus possible to detect low concentrations of apatite in the presence of other phases.[1] The spectral lines of CaO and $CaCO_3$ are much stronger than those of apatite and other phases which are likely to be present, and very low concentrations of these constituents can be detected in mixtures. For example, less than 1% of $CaCO_3$: 10^{-4} Mn in $Ca_{10}F_2(PO_4)_6$: 1.5×10^{-3} Mn and 0.1% of CaO: 10^{-4} Mn in γ-$Ca_2P_2O_7$: 5×10^{-4} Mn are detectable. On the other hand, the predominant spectral lines of γ-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$, and β-$Ca_3(PO_4)_2$ are relatively weak and are not at all well resolved from the strongest apatite lines, so that only relatively large amounts of these compounds are observable in the presence of apatite. The spectrum of CaF_2 has good intensity with one relatively strong, sharp line in the fourth hyperfine group ($m = \frac{1}{2}$), so that even

[1] See Appendix.

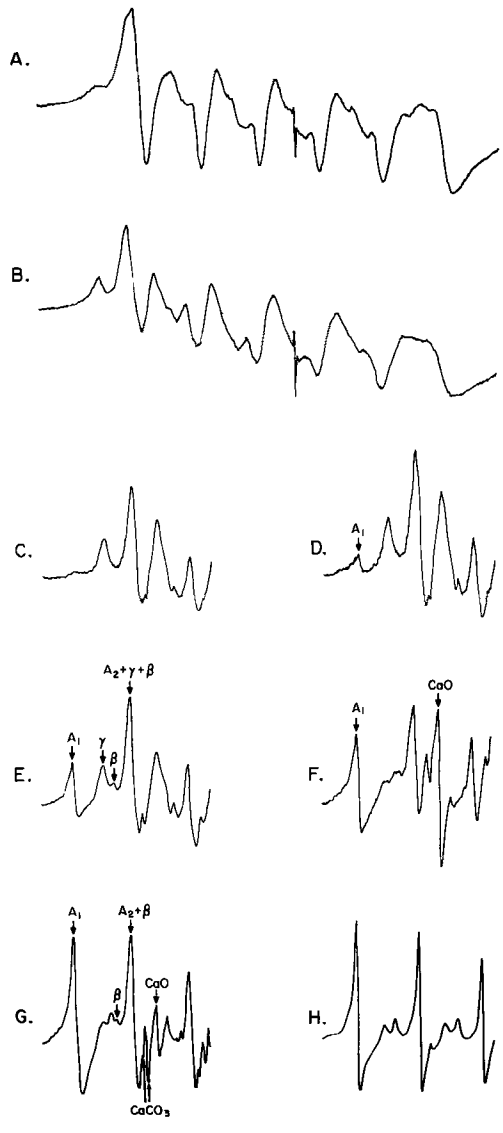

Fig. 3. EPR spectra of the mixture, $6CaHPO_4$:2.5x10^{-4}Mn + $3CaCO_3$ + CaF_2 fired in CO/CO_2 = 1/10:A, unfired mixture; B, 10 min, 500°; C, 60 min, 700°; D, 10 min, 800°; E, 60 min, 800°; F, 10 min, 900°; G, 10 min, 1000°; H, 60 min, 1200°.

though this line falls in a fairly complex region of the apatite spectrum the sensitivity for detection of calcium fluoride in fluorapatite is reasonably good; for example, 2% of CaF_2: 10^{-4} Mn in $Ca_{10}F_2(PO_4)_6$: 1.5×10^{-3} Mn is observable.

It is not practical to reproduce all of the original data, which are potentiometric recorder tracings of EPR spectra, but it will be instructive to present and discuss some of the salient spectra of one set of fired samples. A set which contains most of the spectra that are encountered is that obtained from firings in CO, CO_2 of the mixture, $6CaHPO_4$: 2.5×10^{-4} Mn + $3CaCO_3$ + CaF_2. For the unfired mixture the spectrum is, of course, that of $CaHPO_4$:Mn (Fig. 3a). At 500°, 10 min the dibasic calcium orthophosphate has largely decomposed to γ-$Ca_2P_2O_7$ (Fig. 3b). The spectrum is almost as well developed as that of the firing at 500° and 60 min, conditions which are known to effect complete decomposition. Except for some sharpening of the spectral lines, indicating better crystallinity, there is little change in the spectra over the 500°-700° range. There is probably a trace of apatite appearing at 700°, 60 min (Fig. 3c); this is definite at 800°, 10 min (Fig. 3d). At 800°, 60 min there is evidence for partial conversion of γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$[2] (Fig. 3e). In the presence of even only moderate concentrations of apatite:Mn the detection and estimation of $Ca_2P_2O_7$:Mn becomes difficult, because of factors mentioned earlier. It is possible nevertheless to make a plausible, if not unambiguous, estimate of the distribution of manganese between the pyrophosphates and apatite phases by determining the relative intensity of the first and second strong apatite lines (the first strong line of the pyrophosphates falls directly on the second apatite line) and comparing with standard mixtures. This was done over the range 800°, 10 min through 1000°, 10 min beyond which there is no indication of the presence of $Ca_2P_2O_7$. The spectrum of CaO:Mn first appears at 900°, 10 min, already at its maximum intensity for this set (Fig. 3f). The predominately CO_2 atmosphere has prevented significant decomposition of $CaCO_3$ to this point. Distribution of manganese between CaO and apatite is estimated as indicated in the following paragraph over the range, 900°, 10 min through 1100°, 30 min, above which only the apatite spectrum remains. These distribution coefficients together with those for $Ca_2P_2O_7$, apatite appear in Table I. At 1000°, 10 min (Fig. 3g) manganese is distributed through four phases: CaO, $CaCO_3$, β-$Ca_2P_2O_7$, and $Ca_{10}F_2(PO_4)_6$. A mixture containing 0.3% CaO: 10^{-4} Mn, 1.7% $CaCO_3$: 10^{-4} Mn, 49% β-$Ca_2P_2O_7$: 5×10^{-4} Mn, and 49% $Ca_{10}F_2(PO_4)_6$: 1.5×10^{-3} Mn has an EPR spectrum nearly identical to that of Fig. 3g. From the spectra presented it is clear that the intensity of the apatite spectrum is steadily increasing with firing temperature. Over the temperature range, 800°-1200°, the spectral intensity increase is 60 fold.

Insofar as it is possible to express the data more or less quantitatively, the results of the firings of the various mixtures are presented in Tables I through VI, for which a few words of explanation are desirable. Although the concentration of a paramagnetic species in a given phase is, strictly speaking, proportional to the total area under its EPR absorption curve and hence to the area under one of its absorption lines, it was considered sufficiently accurate for the purposes of this presentation to use the peak to peak distance of the first derivative of an absorption line as a roughly quantitative measure of the manganese concentration, provided it is below the level where line broadening would become a factor. Lines selected for intensity measurement are indicated by arrows in Fig. 1 and 2. The number of moles of manganese in one phase relative to the number of moles of manganese in another phase is called here the distribution coefficient of manganese between the two phases,

$$D \frac{\text{Phase 1}}{\text{Phase 2}}$$

For example,

$$D \frac{\text{CaO}}{\text{Apatite}} = \frac{\text{moles Mn in CaO}}{\text{mole Mn in } Ca_{10}F_2(PO_4)_6}$$

When attempting to get a picture of the relative amounts of manganese in two phases it is wise to determine the distribution coefficient of manganese between the two phases, because a consideration of the EPR line intensities alone can be misleading.

As the incorporation of manganese into fluorapatite is of prime importance let us confine our attention for the moment to the apatite spectral intensities (Table II). The appearance of very weak apatite lines at 700° is the first indication of manganese solid solution in apatite. At this temperature the predominant reaction to form apatite is that given by Montel (18), *viz.*, $18Ca_2P_2O_7 + 14CaF_2 \rightarrow 5Ca_{10}F_2(PO_4)_6 + 6POF_3$ (7). This reaction requires 2.8 moles of CaF_2 for each mole of apatite produced and at 700° goes to about one third of completion in reasonable firing times (19), so

[2] See ref. (12), Fig. 4 for spectra of mixtures of these two phases.

* Data of columns 13 and 14 were obtained from a mixture different from that of columns 7 and 8.

that one might expect about 1/10 the formulated amount of apatite to be produced in an hour at 700°. It is seen that the solid solution of manganese in apatite is far less than this, indicating that the driving force for the incorporation of manganese into the apatite lattice is very low at this temperature.

The effect of the ambient atmosphere on the solid solution of manganese in apatite is evident. In the temperature range of 700°-800° the mildly reducing atmosphere of CO, CO_2 promotes greater incorporation of manganese in apatite than the neutral nitrogen atmosphere. Except for the mixture containing CaF_2: Mn, the concentration of manganese dissolved in apatite is about the same for both atmospheres at 900°. At the highest temperatures used manganese incorporation seems to be somewhat better in nitrogen than in the reducing atmosphere. The detrimental effect of an oxidizing atmosphere is underscored by the results of firing one mixture in both N_2 and air. It is seen (last two columns of Table II) that only at 1170° is manganese incorporation as complete in air as in nitrogen. All of these results emphasize the fact that manganese must be in the manganous state before it can substitute for Ca^{++} in apatite. At low and intermediate temperatures it is expected that the Mn^{++} oxidation state would be favored by reducing (CO, CO_2) and neutral (N_2) atmospheres, in that order. For temperatures approaching 1200° the effect of a reducing atmosphere is not so significant, because, as is well known, the equilibria

$$6Mn_2O_3 \rightleftarrows 4Mn_3O_4 + O_2$$

and

$$2Mn_3O_4 \rightleftarrows 6MnO + O_2$$

shift to the right with increasing temperature (20, 21). The reason for better incorporation of manganese at 1100°-1200° in N_2 relative to CO, CO_2 is not clear. Possibly a manganese carbonyl (22, 23), which might be expected to be volatile at these temperatures, is formed in the latter atmosphere. $Mn_2(CO)_{10}$ can only be prepared in reasonable yield by treating a manganous salt suspended in a suitable organic solvent with carbon monoxide at several hundred atmospheres pressure in the presence of a powerful organometallic reducing agent (24, 25). But this does not preclude the possibility that minor amounts of this

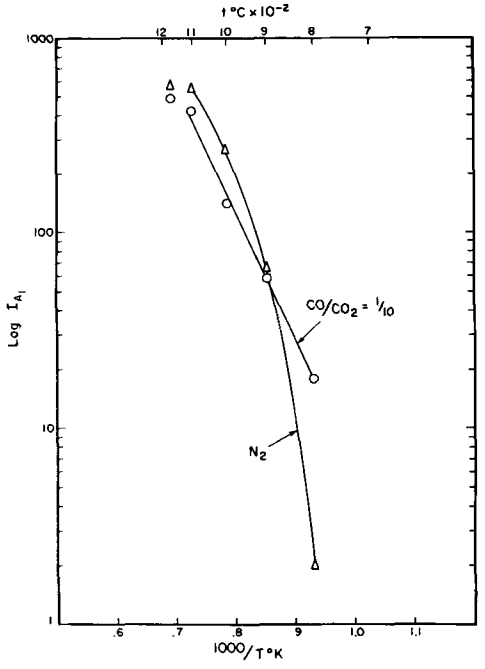

Fig. 4. Arrhenius plot of fluorapatite mixture fired 1 hr in N_2 and in CO/CO_2 = 1/10. Mn added as $CaCO_3$:5x10^{-4}Mn. I_{A_1} is intensity of EPR line of Mn^{++} in apatite (ref. Fig. 2).

compound, or some other combination of manganese and carbon monoxide, could be produced under the conditions described above.

Except for one firing mixture, that containing $CaHPO_4$:2.5 × 10^{-4} Mn [3], the amount of manganese in solid solution in apatite has leveled off at 1100° in both neutral and reducing atmospheres whereas in air a higher firing temperature (*e.g.*, 1170°) is required to bring about an equivalent amount of manganese incorporation. Insofar as solid solution of manganese is concerned, therefore, it should not be necessary to fire a halophosphate phosphor over 1100° in a nonoxidizing atmosphere.

If Arrhenius plots are made of the data of Table II, *i.e.*, log I_{A_1} *vs.* $1/T$, it will be observed that the curves approximate straight lines between 700° and 1100°. Because the EPR line intensity is proportional to the concentration of manganous ion in fluorapatite, it should be possible from this type of plot to determine the activation energy for solid solution of manganese in apatite. There has been no attempt to use the present data for such a purpose, because it is too inaccurate, but sufficient refinement of the measurements could be effected to make meaningful determination of the activation energy possible.

[3] A possible explanation for this is that the dibasic calcium orthophosphate used in this mixture is a laboratory preparation with different crystal shape and size distribution, and therefore different reactivity, from the factory produced $CaHPO_4$ used in all of the other mixtures.

Figure 4, which is presented as a more or less typical example of an Arrhenius plot of the data of Table II, also serves to illustrate two points discussed above. First it is noted that, in the CO, CO_2 atmosphere which has a CO_2 partial pressure of about 670 mm, apatite is produced at 800°. At this temperature the equilibrium partial pressure of CO_2 above $CaCO_3$ is 208 mm (26) and no CaO is produced as is evident from Table IV, so that the major contribution to apatite formation must be the reaction involving only CaF_2 and $Ca_2P_2O_7$. The second point illustrated is that in the reducing atmosphere incorporation of manganese in apatite is greater than in nitrogen at 800°. This brings up a question, however: if $CaCO_3$:5 × 10^{-4} Mn is not decomposing in an essentially CO_2 atmosphere how is the manganese being removed from it so that it may enter into the apatite? A reasonable answer might be that the mobility of manganese is enhanced by the presence of carbon monoxide at this relatively low temperature as well as at higher temperatures as indicated above. Support for this hypothesis is given by the observation of vapor phase transport of manganese at 600° in an atmosphere of water vapor and carbon monoxide (27). This, of course, implies that the necessity for manganese to be divalent is not the whole reason for better incorporation of manganese in apatite at 700°-800° in a CO, CO_2 atmosphere as compared with N_2.

Implicit in the discussion of the results to this point has been the idea of manganese possessing a degree of mobility, increasing with temperature, which enables it to become incorporated in the apatite structure. This is aptly demonstrated by the EPR spectra of the mixture containing $Ca_9MnF_2(PO_4)_6$ as the source of manganese (Table III). At low temperatures the spectrum is a single very broad structureless line of about 400 gauss half width, due to the presence of the magnetically concentrated manganese apatite. At 800° or 900°, depending on the atmosphere, very weak apatite lines superimposed upon the broad peak first appear. These relatively sharp lines gradually increase in intensity with increasing temperature until at about 1100° there is a plateau. Concurrently the broad apatite peak has decreased in strength and disappeared. Manganese has acquired enough mobility to diffuse out of the preformed apatite into the newly produced apatite.

In addition to the diffusion of manganese and its solid solution in the newly formed apatite another interesting phenomenon is occurring. In a nitrogen atmosphere lines of CaO:Mn appear weakly at 700°, increase in intensity to a maximum for 10 min firing at 1000°, and as the CaO is consumed in the apatite reaction disappear after 10 min at 1100°. Although at 800° there is no indication of manganese incorporation in freshly formed apatite, the CaO:Mn spectral

* $CaCO_3$:Mn is present, but line intensity is difficult to estimate because of poor resolution.

intensity has already attained one third of its maximum strength. Calcium oxide appears to be removing manganese from $Ca_9MnF_2(PO_4)_6$. Indeed this affinity of calcium oxide for manganese is so pronounced that if one attempts to produce $Ca_{10}F_2(PO_4)_6$:Mn from a mixture containing only a slight excess of CaO he will obtain the EPR spectrum of CaO:Mn only.

Another example of the affinity of calcium oxide for manganese is given by the firings of the mixture containing $CaCO_3{:}5 \times 10^{-4}$ Mn (Table IV). For nitrogen firings the spectrum of CaO:Mn first appears at 600°, reaches a maximum at 900°, and has disappeared at 1100°. As is expected, in an atmosphere which is principally carbon dioxide the decomposition of $CaCO_3$ is delayed until 900° when the spectrum of CaO:Mn is first noted. The intensity of the spectrum remains fairly constant over the 900°-1000° range, drops off at 1100°, and is zero at 1170°. It is observed that the maximum intensity is slightly less than one tenth the maximum intensity of the nitrogen firings. The lines are, however, one and one-half to twofold broader.

These differences are interpreted as follows. In nitrogen the rate of decomposition of $CaCO_3{:}5 \times 10^{-4}$ Mn is already very rapid before apatite formation becomes significant, so that a fairly large amount of unreacted CaO is produced with manganese in solid solution in the approximate molar concentration of 5×10^{-4}. On the other hand for the atmosphere, $CO/CO_2 = 1/10$, the rate of carbonate decomposition is still fairly slow when the formation of apatite becomes appreciable so that much of the calcium oxide is entering into the apatite forming reaction as soon as it is formed. The CaO that does not enter into the apatite reaction combines with a substantial proportion of the manganese produced by the decomposition of the carbonate. The concentration of manganese in calcium oxide is now high enough to cause significant spin-spin interaction evidenced by line broadening. From comparison with CaO:Mn preparations of known manganese content it is estimated that the manganese concentration varies from 7.5×10^{-4} to 8.5×10^{-4}M over the temperature range, 900°-1100°, corresponding to an enrichment of 50-70%.

The affinity of CaO for manganese is very striking in the case of CaF_2, CaO mixtures. When a mixture of CaF_2 with 1% CaO and manganous nitrate in the proportion, $Mn/Ca = 10^{-4}$, is fired for 2 min or longer at 1100° the resulting EPR spectrum is that of CaO:Mn only. Indeed, if CaF_2:Mn is fired for several hours in an atmosphere which contains only a trace of air, the EPR spectrum of CaF_2:Mn disappears and is replaced by that of CaO:Mn. One has to be very careful in preparing CaF_2:Mn for EPR purposes to exclude all traces of CaO and/or air (11, 28).

It must be emphasized that although the affinity of CaO for manganous ion is rather high for low concentrations of the latter such is not necessarily the case for higher concentrations.

There were three reasons for introducing manganese into the reaction mixture in one of a number of different phases. First it was believed that a more uniform dispersion of manganese in the mixture could be obtained by this expedient than by customary procedures. It was also of interest to know whether the ability of manganese to enter into the apatite structure is influenced by its source. As we have seen, except for the mixture containing $CaHPO_4{:}2.5 \times 10^{-4}$ Mn, manganese incorporation in fluorapatite in all cases levels off at 1100°. Finally, one might expect to be able to follow the consumption of a component which is a source of manganese by observing the change in strength of its EPR spectrum. As an example, for nitrogen firings of the mixture containing $CaHPO_4{:}2.5 \times 10^{-4}$ Mn (Table V), it is observed that the spectrum of $Ca_2P_2O_7$, the decomposition product of the acid phosphate, has essentially the same strength over the range 500°-800°, indicating little consumption. Over the 900°-1000° temperature interval the change in distribution of manganese between calcium pyrophosphate and apatite indicates that pyrophosphate is being used up in the apatite forming reaction. At 1100° there is no EPR evidence for the existence of $Ca_2P_2O_7$. This is substantiated by x-ray diffraction analysis.

For mixtures containing $CaF_2{:}1.5 \times 10^{-3}$ Mn as a source of manganese (Table VI), interpretation of the curves is not so readily accomplished. Because it is magnetically concentrated in manganese the spectrum of CaF_2:Mn in these mixtures consists of six broad, structureless lines. In a CO, CO_2 atmosphere these lines progressively diminish in strength between 700°, 10 min, and 800°, 10 min, at the same time picking up a little structure. The spectra for apatite and $CaCO_3$ appear at 800°, 10 min, but they are very weak and can account for only a very small proportion of the manganese which has disappeared from its CaF_2 environment. Thus one cannot infer from the EPR spectra whether CaF_2 is taking part in the apatite reaction or is simply losing its manganese. X-ray diffraction analysis, however, tells us that CaF_2 is being consumed over this firing range; the last CaF_2 is observed at 800°, 60 min. For samples prepared in a nitrogen atmosphere CaF_2:Mn is still observable after 10 min at 700°, but is not seen for longer firing times or higher temperatures. According to x-ray diffraction analysis, however, calcium fluoride is not entirely consumed until after 30 min firing at 1000°. Relatively intense CaO:Mn lines with very broad wings dom-

inate the spectra over the 700°-800° range. Calcium oxide has apparently accelerated the removal of manganese from calcium fluoride and combined with it.

In the case of mixtures containing $CaCO_3$: 5 × 10^{-4} Mn it is relatively easy to follow the decomposition of the carbonate to the oxide and the consumption of the latter during the formation of apatite. In a nitrogen atmosphere, decomposition of $CaCO_3$ seems to be complete for 10 min firing at 900° and calcium oxide is gone after 10 min at 1100°, whereas in the CO, CO_2 atmosphere traces of carbonate appear to persist, along with some calcium oxide, through 60 min of firing at 1100°, after which only the spectrum of apatite remains.

It turns out that the spectrum of calcium oxide, because of its high intensity and the great affinity of this compound for manganese, persists until the apatite reaction is virtually complete. Thus the course of the reaction can be followed by observing the CaO:Mn spectrum, or the distribution of manganese between calcium oxide and apatite.

Finally, it is worth mentioning that in none of the fired mixtures was there any evidence by EPR or x-ray diffraction for the formation of $Ca_3(PO_4)_2$ as an intermediate in the production of apatite. This is in accord with the findings of Rabatin and Gillooly (7).

Summary

Electronic paramagnetic resonance is used to study the disposition of Mn^{++} among the various phases present during the course of the reaction to form fluorapatite. For materials prepared in N_2 or CO/CO_2 = 1/10, solid solution of manganese in fluorapatite is first detected at 700° and is observed to increase exponentially through 1100°, at which temperature incorporation of manganese is virtually complete. Arrhenius plots of the EPR line intensity of Mn^{++} in apatite are approximate straight lines from 700° through 1100°. Over the range 700°-800°, incorporation of manganese in fluorapatite is better in the CO, CO_2 atmosphere than in N_2, whereas the reverse is the case over the range 1000°-1200°. Air inhibits the entry of manganese into the apatite structure, and only at temperatures approaching 1200° is solid solution complete. The differences in solid solution associated with the various atmospheres can be attributed largely to the necessity for manganese to be in the divalent oxidation state. However, in order to explain some of the observed behavior of manganese it is necessary to postulate volatile compound formation involving carbon monoxide. At 800° chemically bound manganese in apatite acquires enough mobility to diffuse into freshly formed apatite originally possessing no

manganese. At various stages of the reaction there is also evidence for the incorporation of manganese into $Ca_2P_2O_7$, $CaCO_3$, and CaO. The most conspicuous of these, from the point of view of frequency of occurrence, intensity, and persistence, is CaO:Mn, due in part to its inherently intense EPR spectrum, but also because of its strong affinity for manganese. It is possible to follow the consumption of $Ca_2P_2O_7$:Mn and CaO:Mn during the reaction by observation of their EPR spectra, but this is not feasible for CaF_2:Mn.

Acknowledgments

The author wishes to thank D. J. Ina and P. A. Hurst for preparation of samples, and L. S. Staikoff and J. R. Cooper for x-ray diffraction analyses. Preliminary work which led into the experiments reported here was conducted with the cooperation of R. L. Hickok and W. G. Segelken, to whom the author is also indebted for many helpful discussions.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX

It is appropriate to discuss the capabilities and limitations of EPR as a method for studying solid-state reactions. The EPR spectrum of a paramagnetic ion in solid solution in a given crystalline compound is characteristic of that compound. Thus, the presence of a paramagnetic ion in solid solution in a number of different identifiable crystalline phases can, in principle, be detected unambiguously. In practice this is not always possible; *e.g.*, if a paramagnetic ion is in a crystalline field of low symmetry, its EPR spectrum will in all likelihood be a broad characterless line, or for mixtures of compounds containing paramagnetic ions in solid solution the different EPR spectra may interfere with one another so severely that identification of the different constituents is not possible. Although one can detect with certainty the presence of a phase by EPR, one cannot in general use EPR as a criterion for the absence of a phase. Thus, a statement such as, "There is a trace of apatite appearing at 700°, 60 min," is intended to mean that the EPR spectrum of a mixture fired for 60 min at 700° showed the presence of a trace of Mn^{++} in solid solution in apatite, which phase may or may not have been produced at a lower temperature or shorter firing time. The area under the EPR absorption curve of a paramagnetic species is proportional to the number of absorbing ions and therefore the intensity of the EPR spectrum can be related to the amount of a paramagnetic ion in solid solution in a given phase. It should be realized, however, that there is some ambiguity in such a relationship, because, within limits where line broadening is not a factor, it does not distinguish between large and small amounts of the host phase. All that can be said, for example, is that there are Xg of Mn^{++} in solid solution in an unspecified amount of fluorapatite per gram of sample subjected to the resonance conditions. This is the meaning that should be read into the portions of this paper dealing with concentrations of manganese and its distribution among the various phases.

A Low-Temperature Synthesis of Manganese Activated Zinc Silicate of Superior Crystallinity

Gleb Gashurov and Albert K. Levine[1]

General Telephone & Electronics Laboratories, Bayside, New York

ABSTRACT

A new method for synthesis of manganese activated Zn_2SiO_4 is reported. The method, which is based on the reaction between ZnF_2 and SiO_2 in molten $ZnCl_2$, yields typically well-crystallized rods of 10 by 100μ; activation with manganese can be obtained during or after the synthesis. The fluorescence efficiency of material prepared in this manner is comparable to that of commercial Zn_2SiO_4:Mn phosphors.

Zinc silicate is usually synthesized by a solid-state reaction between ZnO (or $ZnCO_3$) and silicic acid. Typically, as when the manganese activated phosphor is prepared, the reaction between the thoroughly blended ingredients is carried out at 1200°C for about 2 hr. An electronmicrograph of a representative sample of zinc silicate obtained from such a synthesis is shown in Fig. 1. The material is seen to consist of irregularly shaped, often agglomerated and intergrown particles ranging from less than 1μ to several microns in size. The absence of well-developed faces is notable. The use of fluxes to promote crystallization and growth during synthesis is generally objectionable in the case of Zn_2SiO_4, since most common fluxes (*e.g.*, alkali and alkaline earth halides and sulfates) react with silica to form silicates (1). Wilke (2) fluxed $ZnSiO_4$ with small percentages of KCl and Li_2SO_4 at 920°C for 1 hr. His results show no increase in particle size with KCl, while there is an apparent increase with Li_2SO_4. No information is given on the morphology of the individual crystallites.

This paper reports a Zn_2SiO_4 synthesis which proceeds at temperatures considerably lower than those previously reported for solid-state preparation and which produces a material of superior crystallinity. Manganese activation can also be accomplished either during or after the synthesis to produce a green-emitting phosphor, comparable to the commercial product in fluorescence characteristics.

Materials and Measurements

The materials used were Mallinckrodt silicic acid (standard luminescent grade), Fisher $ZnCO_3$ (certified reagent), Fisher $ZnCl_2$ (certified reagent), and Fisher $MnCl_2 \cdot 4H_2O$ (certified reagent). Anhydrous zinc fluoride was obtained from the Chemical and Metallurgical Division of Sylvania Electric Products Inc. Silica was obtained by firing silicic acid in air at 1000°C for 2 hr.

X-ray measurements were made on a Norelco wide range goniometer. Manganese concentration in Zn_2SiO_4 samples was determined by the x-ray fluorescence method. Zinc and silicon were determined gravimetrically; colorimetric analysis was used in fluorine determination.

Present address: Richmond College of the City University of New York, Staten Island, New York.

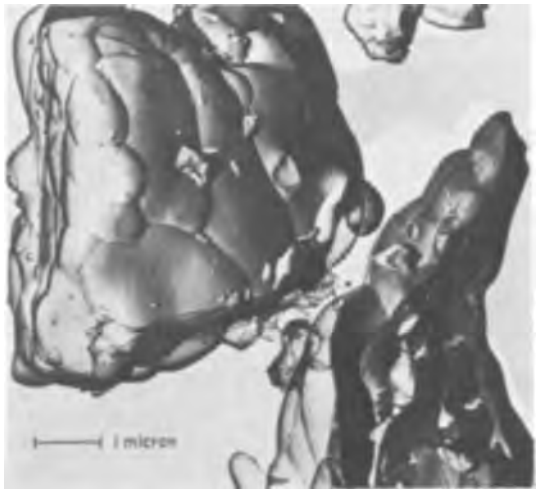

Fig. 1. Electronmicrograph of representative sample of commercially prepared Zn_2SiO_4:Mn phosphor.

Results and Discussion

The sluggishness of the solid-state reaction between zinc carbonate and silicic acid may be demonstrated by the fact that even after 2 hr at 1350°C the reaction is incomplete. The possibility of accelerating the formation of zinc silicate by heating the reactants under high pressure was investigated first. Samples containing an intimate mixture of ZnO and SiO_2 in their stoichiometric ratio were heated in a hot pressing assembly for 1 hr at 900°C under a pressure of 4 tons/in.^{2}. Although this treatment must have led to an improvement in the contact between reactants, the reaction was largely incomplete, and the major crystalline phase of the resulting product was ZnO. In fact, comparison of the various relevant peaks in the x-ray spectrum show that the ratio of ZnO to Zn_2SiO_4 obtained when the synthesis is carried out under pressure is approximately the same as that obtained when the sample is heated at the same temperature and atmospheric pressure. These results indicate that improvement in contact between ZnO and SiO_2 over the degree of contact obtained in normal blending is not a factor in the rate of Zn_2SiO_4 formation. Experiments by Jander and Riehl (3) indicate that the growth of Zn_2SiO_4 by solid-state reaction appears to proceed by the diffusion of ZnO through a zinc silicate layer which forms about a silica particle. In such a case, once a certain minimum degree of contact is established, the rate would be relatively insensitive to pressure.

The synthesis of zinc silicate by the reaction of ZnF_2 and SiO_2 has been described by Lenard, Schmidt, and Tomaschek (4). This method proceeds according to the following stoichiometry

$$2ZnF_2 + 2SiO_2 = Zn_2SiO_4 + SiF_4$$

Lenard *et al.* state that the synthesis is complete after 1 hr at 950°C. Since Lenard *et al.* give no description of the nature of the crystallites, we decided to investigate the synthesis in greater detail. Our results relative to the speed of the reaction agree with those of Lenard *et al.*; as a matter of fact we find that the reaction goes to completion within less than 1 hr at temperatures as low as 750°C. The completeness of the reaction was established by x-ray analysis which showed Zn_2SiO_4 as the only phase. The crystal size of the zinc silicate resulting from the fluoride synthesis is not, however, significantly different from that

obtained by reaction of the oxides; that is, in both cases the crystallites are small and of poor morphology. Nor is there any notable change in either crystal size or crystal habit when the ZnF_2-SiO_2 reaction is carried out at 900°C for longer periods, extending to 24 hr, or at 1200°C for 2 hr. This indicates that ZnF_2 reacts completely with SiO_2 particles in a short time to form small zinc silicate crystals; however, after the SiO_2 is consumed crystal growth proceeds very slowly. Furthermore, in the reaction with ZnF_2, the size of the SiO_2 particles appears to determine the size of the Zn_2SiO_4 crystals which are formed. A similar conclusion has been drawn (5) for the crystals synthesized by the reaction between SiO_2 and ZnO.

Diffusion processes and mass transport are much more rapid in liquid medium than in solid; hence it was decided to carry out the reaction between ZnF_2 and SiO_2 in molten zinc chloride. Zinc chloride was selected because (*i*) it exists in the liquid form over a suitably wide temperature range (318°-732°C); (*ii*) it is quite soluble in water and therefore can be easily separated from Zn_2SiO_4; and (*iii*) it has a common cation with Zn_2SiO_4 which eliminates the possibility of objectionable cation contamination. The initial experiments showed that zinc silicate of excellent crystallinity is obtained when ZnF_2 and SiO_2 are caused to react in molten zinc chloride. However, care must be exercised to insure that all SiO_2 reacts. Thus, for example, when 1.00g of ZnF_2, 0.58g of SiO_2, and 20g of $ZnCl_2$ are maintained at 600°C for 4 hr in a covered platinum crucible, the x-ray analysis of the resulting material after washing in boiling water shows Zn_2SiO_4 as the only crystalline phase. However, microscopic analysis reveals a relatively large number of large, irregularly shaped particles among the smaller well-formed Zn_2SiO_4 rods. The x-ray pattern of the irregular particles, which were separated from Zn_2SiO_4 rods by sieving, showed them to be amorphous, and the particles are presumed to be silica.

Significant reduction of the amount of unreacted silica and larger, more perfect zinc silicate crystallites are obtained when the reaction is carried out near 730°C, the boiling point of $ZnCl_2$. In this case provision must be made to condense $ZnCl_2$ vapor and return it to the system. The boiling also provides sufficient agitation to assist in the reaction. In this procedure an equimolar mixture of ZnF_2 and SiO_2 is placed together with a large excess of $ZnCl_2$ (35g of $ZnCl_2$ to 1g of ZnF_2) into a quartz flask provided with a long narrow neck. The flask is then lowered into a vertical tube furnace maintained at about 600°C. After 15 min the temperature of the furnace is raised, and the mixture refluxed at the boiling point of $ZnCl_2$ (730°C) for about 5 hr. To prevent bumping, the reaction flask is continuously agitated. After completion of the run, the mixture is poured into a quartz beaker, cooled and washed with boiling water to remove $ZnCl_2$. If the ingredients are sufficiently anhydrous, there is only little etching of the quartz flask.

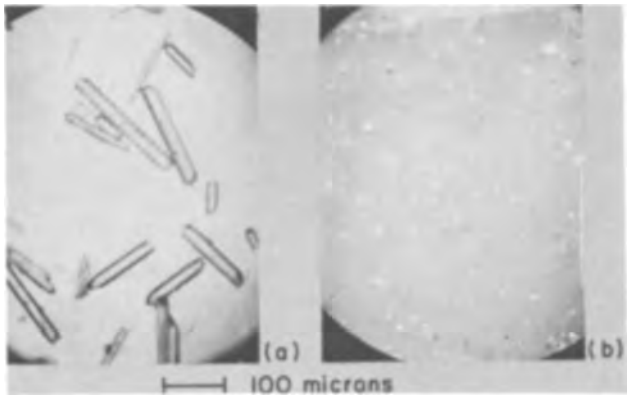

Fig. 2. Photomicrographs of (a) Zn_2SiO_4 prepared by the $ZnF_2/ZnCl_2$ method and (b) commercial Zn_2SiO_4:Mn (Sylvania #161).

Fig. 3. Electronmicrograph of Zn_2SiO_4 prepared by $ZnF_2/ZnCl_2$ method.

Figure 2a shows a photomicrograph of a typical Zn_2SiO_4 sample synthesized by the technique outlined above. For comparison (Fig. 2b), a photomicrograph of a sample of commercial Zn_2SiO_4:Mn phosphor, Sylvania No. 161, is included. One can see that the crystals prepared by the $ZnF_2/ZnCl_2$ method are on the average about 100μ in length and 10μ in cross section. An electronmicrograph (Fig. 3) of these crystals shows them to possess very well-developed faces. Examination under crossed polarizers reveals that most of the particles are strain-free crystals, and x-ray diffraction analysis shows α-Zn_2SiO_4 as the only crystalline phase. Chemical analysis of the synthesis product indicates that it contains some free silica. An assay of a typical product gives 30% by wt SiO_2 and 70% ZnO, whereas the respective stoichiometric values are 27 and 73%.

The following experiment indicates that the growth of Zn_2SiO_4 is controlled by its solubility and diffusion in molten $ZnCl_2$. A stoichiometric mixture of ZnF_2 and SiO_2 was placed at the bottom of a quartz tube, which was then filled to about 50% of its capacity with molten $ZnCl_2$ and heated to 600°C. During the first few minutes silica particles were observed to rise to the surface of the liquid and the solution acquired a gray color. After about 15 min all the particles sank to the bottom of the tube (probably indicating conversion of SiO_2 to Zn_2SiO_4) and the $ZnCl_2$ solution became colorless. Additional molten $ZnCl_2$ was then added to fill the tube to about 80% of its volume. The tube was sealed and placed in an inclined position in a horizontal tube furnace. A temperature gradient was established such that the lower end of the tube was at 690°C while the upper end was at 650°C. After 18 hr the tube was carefully removed, quenched to room temperature, and cut into sections. The quartz tube was only slightly etched, indicating little reaction with its contents. It was found that, while most of the Zn_2SiO_4 was in the hotter end, which had the initial charge, there was a significant amount of Zn_2SiO_4 in the cooler zone. There was, however, a notable difference in the size of the crystals. Figure 4 shows that the crystals grown in the hot zone are on the average a few microns in size, while those grown in the lower temperature region are up to 100μ in length. This result indicates material transport and deposition due to the temperature dependence of the solubility.

Large zinc silicate rods may also be obtained by heating silicon dioxide alone in boiling zinc chloride. The crystals obtained in this way are essentially of the same size and morphology as those prepared by the

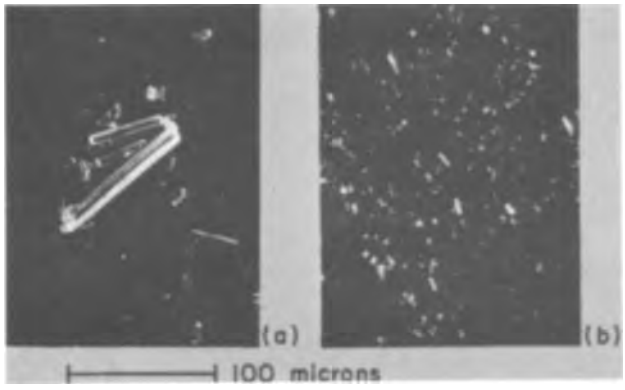

Fig. 4. Photomicrographs of Zn_2SiO_4 crystals grown in (a) the low-temperature zone and (b) the high-temperature zone of $ZnCl_2$ maintained at a temperature gradient.

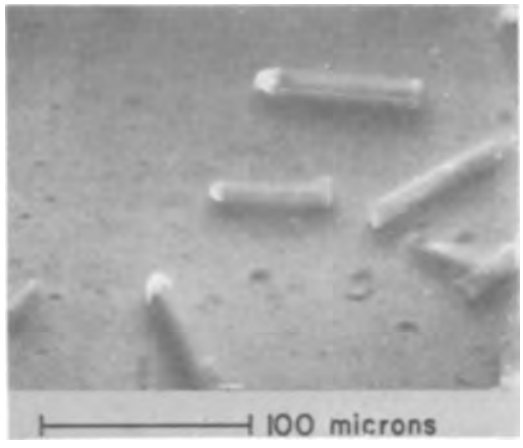

Fig. 5. Photomicrograph of Zn_2SiO_4:Mn crystals illuminated by their own emission when excited with uv radiation.

$ZnF_2/ZnCl_2$ method, although the reaction rate is substantially slower than that in the case of ZnF_2-SiO_2 reaction. For example, refluxing a mixture of SiO_2 and $ZnCl_2$ for 5 hr at 730°C produces Zn_2SiO_4 containing a very large excess of free silica. In a typical case, the composition of the solid phase was 47% SiO_2 by weight and 53% ZnO, whereas the stoichiometric composition of Zn_2SiO_4 is 27 and 73%, respectively. When a mixture of SiO_2 and $ZnCl_2$ was heated at 600°C for 5 hr, no zinc silicate was formed; the solid product after aqueous washing was shown to be amorphous by x-ray diffraction, and its weight was the same as that of the SiO_2 used in the experiment.

Crystallization experiments of the ZnF_2-$ZnCl_2$ type carried out at temperatures below the boiling point of zinc chloride, and in the absence of mechanical agitation, result in Zn_2SiO_4 rods which are mostly smaller than 25μ in length. In such syntheses the amount of unreacted silica is considerably larger than that found when the crystallization is carried out at the boiling point of $ZnCl_2$.

Luminescence of Zn_2SiO_4:Mn

Incorporation of manganese into zinc silicate may be accomplished by either of two techniques: (*i*) An aqueous solution of $MnCl_2$ is added to the Zn_2SiO_4 rods, the slurry is dried at 110°C for several hours and then fired under argon at 1200°C for 2 hr; the amount of manganese added is that which is desired in the final product. (*ii*) $MnCl_2$ is added to the inital reaction mixture, ZnF_2, SiO_2, and $ZnCl_2$, which is then refluxed for 5 hr. In the latter technique a large excess of manganese chloride is required to achieve the desired concentration level in the zinc silicate lattice, because of the miscibility of $MnCl_2$ in $ZnCl_2$ under the synthesis conditions. Table I presents results of photo- and cathodoluminescence measurements made on representative preparations. The output of a low-pressure mercury discharge, rich in 254 nm radiation, was used for uv excitation. Cathodoluminescence measurements were made by settling the materials on glass slides and exciting in a demountable assembly with 15 kv electrons. The light emitted from the phosphors was measured from the irradiated side. To obtain layers suitable for measurement, the rodlike crystals had to be fractured prior to settling. (Grinding was found to reduce the fluorescence efficiency.) This was accomplished by causing the Zn_2SiO_4 crystals to be carried by a high-speed stream of air directed at the wall of a bent quartz tube. The fractured crystals were, on the average, about one-third the length of the original crystals, and are still not well suited for the settling of cathodoluminescent screens. This comminution procedure was found to produce no significant change in the photoluminescence efficiency of the zinc silicate samples. The effect, if any, of the fracturing process on the cathodoluminescence efficiency of the material was not determined because with the large, unfractured rod-shaped crystals it was not readily feasible to form a suitable screen for reproducible measurements.

Table I. Luminescence of Zn_2SiO_4:Mn prepared by the $ZnF_2/ZnCl_2$ method

	Relative fluorescence efficiency	
	Excitation by 254 nm	Excitation by 15 kv electrons
Zn_2SiO_4:Mn (1 mole %), activated by procedure 1	88	93
Zn_2SiO_4:Mn (1.5 mole %), activated by procedure 1	90	90
Zn_2SiO_4:Mn (2.0 mole %), activated by procedure 1	100	92
Zn_2SiO_4:Mn (2.5 mole %), activated by procedure 1	98	89
Zn_2SiO_4:Mn (3.0 mole %), activated by procedure 1	98	86
Zn_2SiO_4:Mn (0.5 mole %), activated by procedure 2	80	75
Zn_2SiO_4:Mn (1.0 mole %), activated by procedure 2	98	84
Zn_2SiO_4:Mn (1.5 mole %), activated by procedure 2	113	85
Zn_2SiO_4:Mn (2.0 mole %), activated by procedure 2	104	78
Sylvania Zn_2SiO_4:Mn #161	100	100

The data show no significant difference in efficiency between samples activated by the two different synthesis procedures. There is, however, some reason to speculate that the intrinsic luminescence efficiency of Zn_2SiO_4:Mn rods may be higher than the values listed above. Because of the relatively smooth crystal surfaces, internal reflection of the fluorescence may be expected to reduce by a significant amount the luminous flux that might otherwise be intercepted by the detector. Comparison of Fig. 1 and Fig. 3, taken with the same magnification, shows the difference in surface smoothness between a particle of commercial Zn_2SiO_4:Mn phosphor and a crystal prepared by the method of this paper. Indeed, as Fig. 5 shows, under uv excitation the fluorescence from the well-crystallized rods is emitted predominantly from their ends which are inclined relative to their major faces.

Acknowledgment

Grateful acknowledgment is made to C. O. Creter for assistance in the experimental work, to R. Weberling and J. Cosgrove for chemical analyses, and to C. F. Tufts for the electron micrographs and for discussions relating to them.

Manuscript received Oct. 5, 1966; revised manuscript received Dec. 12, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

The Growth and Etching of Si through Windows in SiO_2

W. G. Oldham and R. Holmstrom[1]

Department of Electrical Engineering, University of California, Berkeley, California

ABSTRACT

A theory of the kinetics of vapor deposition and etching through small openings in an oxide layer on Si is developed and compared with experiments. A model that assumes equilibrium at the Si surface and purely diffusive transport through the gas phase is used to derive the concentrations and fluxes of the interesting gaseous species in the neighborhood of the window. The previously reported concave growth surfaces and convex etching surfaces are explained by the constriction of the flow near the edges of the windows. The measured etch rate is in quantitative agreement with theoretical estimates based on this model. Furthermore, the derived concentration profiles explain the appearance and relative size of the band of oxide free from Si overgrowth which surrounds each window in the growth experiments.

Because of the integrated circuit industry's interest in the epitaxial growth of Si on selected areas of Si wafers, some consideration has been given to the scheme of deposition through windows in an SiO_2 layer (1). The results reported thus far have been disappointing; growth on the oxide has been difficult to prevent, and growth in the desired region has usually been uneven (2). A typical result, which illustrates most of the features, is given in Fig. 1. Some important generalizations that may be made for small windows are: (*i*) the Si deposited in the windows is usually smooth and of satisfactory perfection; however, (*ii*) the thickness varies with position, *e.g.*, in the case of deposition without prior gas etching, the deposit is thicker near the edges than in the center; (*iii*) Si crystallites grow more or less uniformly over the surface of the oxide; except that (*iv*) a band of oxide free from crystallites generally surrounds each window.

To identify the important processes responsible for this behavior, some experimental and theoretical studies were made of a typical vapor deposition system. Because of the similarity of etching processes to growth processes and the technological importance of vapor etching, we include as well the investigation of etching through windows in an oxide layer.

In the following we first develop the theory of (*a*) the growth of Si through windows in the oxide, (*b*) the reaction of Si with H_2O, and (c) the growth of Si on the surface of the oxide. Second, we discuss our experiments on each of the above and finally make some conclusions regarding the control of such processes.

[1] Present address: Sprague Electric Company, North Adams, Massachusetts.

Theory of Growth and Etching of Si in and around Windows in the Oxide

General considerations.—In this laboratory, the system used for the deposition of Si is the thermal decomposition of $SiCl_4$. It is unnecessary to review the growth mechanisms in Si deposition since they are adequately treated in the literature. In particular, Shepherd (3) treats the kinetics of a typical system and refers to earlier works. Like Shepherd, we use a $SiCl_4$ system with cold reactor walls.[2] In order to discuss selective growth using this type of system quantitatively, it is necessary to determine whether the growth rate is limited by the surface kinetics of a particular reaction or by the mass transfer of some species into (or out of) the region of reaction. A series of experiments was conducted to determine the dependence of growth rate on the temperature of the substrate and on the mole ratio of silicon to hydrogen in the gas stream. A typical set of results is given in Fig. 2, which shows the logarithm of the growth rate plotted *vs.* the reciprocal of the temperature with the mole fraction of $SiCl_4$ in H_2 as a parameter.

The data show that at low temperatures there is little dependence on the amount of silicon; however, at high temperatures the growth rate is nearly proportional to the mole fraction of $SiCl_4$, *e.g.*, at 1270°C, the growth rate is $3.2 \cdot 10^{-4}$ μ/min/ppm $SiCl_4$ over the range 1000 to 8000 ppm $SiCl_4$. Furthermore, the growth rate becomes nearly temperature independent. Thus, both the temperature and concentration dependence of the growth rate indicate that it is possible to work in a regime where growth rate is mass-transport limited. Most of the experiments described here were conducted under such conditions.

Shepherd (3) provides very strong evidence that growth in such a regime as indicated by the left-hand

[2] Details of the apparatus are given in the experimental section.

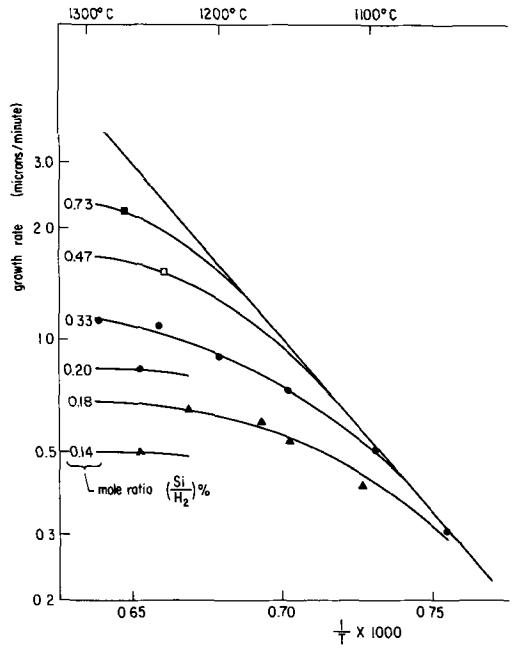

Fig. 2. Deposition rate of silicon for growth over large areas as a function of temperature and $SiCl_4$ concentration in the input stream.

part of Fig. 2 is indeed limited by transport through the gas phase. He calculates the absolute growth rate, assuming purely diffusive transport, and finds good agreement with data obtained in a horizontal reactor configuration. Such a calculation is more difficult for our reactor; however, the calculation becomes again feasible for the case of growth or etching in small windows and is treated in the next section.

Growth of Si through small openings in the oxide.— If we assume diffusion-limited kinetics, a calculation of the most important parameters in the growth process becomes feasible, provided that a sufficiently simple geometry is chosen. A small window in a much larger inactive surface is a tractable geometry if the additional assumption of a stagnant gas phase is made. We shall first calculate the concentrations of the various gaseous species in the neighborhood of the window in the oxide, then apply appropriate boundary conditions, and finally derive the fluxes of pertinent species. The details of the solution are given in the appendix; only an outline and summary of the calculation are given here.

The cylindrical coordinate system used in the calculation is shown in Fig. 3. The height above the surface of the Si wafer is z, and the distance from the z axis is ρ. The thickness of the oxide is assumed to be negligible, and a circular window of radius α is centered about the z axis. In the absence of growth on the oxide, the window acts as a sink in a surface of infinite extent. Furthermore, in the mass-transport limited regime, the window may be assumed to be a surface of equiconcentration. Because the flux through the oxide surface is zero, we may take advantage of the symmetry and solve the problem of a disk-shaped sink in an infinite region, that is, eliminate the oxide surface entirely.

For any gaseous species, we wish to find steady-state solutions to the diffusion equation

$$0 = \frac{\partial \Phi}{\partial t} = D\nabla^2\Phi \qquad [1]$$

subject to the boundary conditions

$$\Phi = \Phi_S \qquad z = 0,\ \rho \leq \alpha \qquad [2]$$

$$\Phi = \Phi_0 \qquad |z| + |\rho| \to \infty \qquad [3]$$

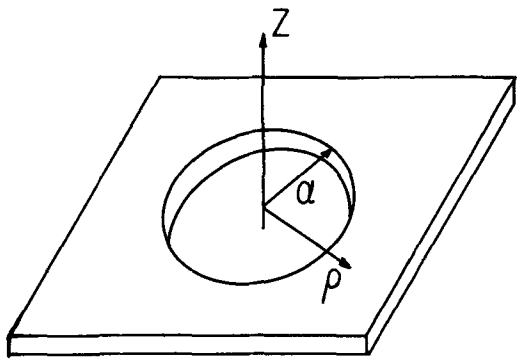

Fig. 3. Cylindrical coordinate system used to derive the concentration profiles. The radial coordinate is ρ and the radius of the window, centered on the z axis, is α.

where Φ denotes the concentration, and D is the diffusivity (assumed constant) of the particular species of interest. Φ_S is the surface concentration (in the Si window), and Φ_0 is the free stream concentration. The validity of applying the second boundary condition at ∞ rather than at a finite distance is established in the appendix. It is shown that as long as the window radius is small compared to effective boundary layer thickness for large area growth, the distance from the surface at which the concentration reaches the free stream concentration is not important and may be set at infinity.

The solution to Eq. [1] applies both to deposition and etching, only the relative magnitudes of Φ_0 and Φ_S are different for the two cases. As shown in the Appendix, the gaseous diffusion problem here is analogous to the electrostatic problem of a charged disk in an infinite three-dimensional space, and the latter has been solved (4). We obtain for the solution to Eq. [1]

$$\Phi(\rho, z) = \frac{\Phi_0 - \Phi_S}{\pi} \cdot 2\cos^{-1}\left[\frac{2\alpha}{\sqrt{(\alpha+\rho)^2+z^2} + \sqrt{(\alpha-\rho)^2+z^2}}\right] + \Phi_S \qquad [4]$$

Equation [4] gives the concentration at any point (z, ρ), and its derivatives give the various components of the flux densities at (z, ρ). We are particularly interested in the flux density incident on the surface of the bare Si magnitude of which is given by

$$\vec{F}(\rho) = -D\nabla\Phi|_{z=0} \qquad [5]$$

Evaluating Eq. [5] in the region $\rho < \alpha$ we have that

$$F(\rho) = D \cdot \frac{2}{\pi}[\Phi_0 - \Phi_S] \cdot \frac{1}{\sqrt{\alpha^2 - \rho^2}} \qquad [6]$$

It is seen that the magnitude of F is largest near the edges, in fact, it approaches ∞ as ρ approaches α. In spite of the singularity of Eq. [6] at $\rho = \alpha$, the total flux F, given by the integral of F over the surface $0 < \rho < \alpha$ is finite and is given by

$$F\ (\text{TOTAL}) = 4\alpha D[\Phi_0 - \Phi_S] \qquad [7]$$

Equation [7], when divided by the area, yields the average growth rate. Expressing the latter in more convenient units, we obtain for the velocity of the growing surface (or etching surface if $\Phi_0 < \Phi_S$)

$$V_{AVG} = 1.55 \times 10^{-20}\frac{D}{\alpha}(\Phi_0 - \Phi_S)\left(\frac{\mu m}{\text{min}}\right) \qquad [8]$$

We have used a molecular weight of 28 and density of 2.3 for Si and assumed that one Si atom is deposited (etched) for each molecule transported. C.G.S. units are used for all parameters. A rough idea of the uniformity of the growth rate over the surface may be

obtained by comparing the average growth rate with the growth rate at the center. If the latter is denoted by V_C, it may be readily verified from Eq. [6] and [7] that

$$V_C = \tfrac{1}{2}V_{AVG}$$

Equations [4]-[8] give the concentrations and fluxes of the various species in terms of the free-stream concentration Φ_o, and the surface concentration Φ_s. The former may be assumed to be equal to the input concentration; however, the latter depends on the thermodynamic properties of the Si surface, as well as on certain properties of the gases. We solve for Φ_s in the usual way, making use of the steady-state requirement of conservation of Cl atoms (or O atoms in the case of transport via SiO). In the case of chloride transport we must decide which species are important because the simultaneous solution for the surface concentrations in the presence of many interacting species is arduous. If the input gas is $SiCl_4$ in low concentrations in H_2, Lever's calculations (5) indicate that the important species present in the temperature range of interest are $SiCl_4$, $SiCl_2$, HCl, and H_2. Consider the growth of Si in such a system. Either $SiCl_4$ diffuses to the Si surface and reacts, or $SiCl_4$ first reacts in the gas phase with H_2 to form HCl and $SiCl_2$. The latter diffuses to the surface, or some combination of the two processes occurs. Fortunately, they give very similar answers for the growth rate, so only the former will be considered here.

We assume a net flux of $SiCl_4$ to the Si surface; the Cl balance is maintained by a flux from the surface of $SiCl_2$ and HCl. The reactions of interest are

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \quad [9]$$

and

$$SiCl_2 + H_2 \rightarrow Si + 2HCl \quad [10]$$

The equilibrium constants, denoted respectively by K_9 and K_{10}, may be obtained from the JANAF Tables (6). The order of mangitude of K_9 and K_{10} at 1500°K are 0.01 and 1, respectively; thus we need to consider only the flux of $SiCl_4$ toward the surface and HCl from the surface.[3]

Evaluating Eq. [7] for the two fluxes, we have for the conservation of Cl

$$-D_{HCl}[\Phi_o^{HCl} - \Phi_s^{HCl}] = \tfrac{1}{4}D_{SiCl_4}[\Phi_o^{SiCl_4} - \Phi_s^{SiCl_4}] \quad [11]$$

From Eq. [9] we have, in addition

$$\frac{(\Phi_s^{HCl})^4}{\Phi_s^{SiCl_4}} = K_9/(RT/N_0)^3 \quad [12]$$

in which R is the gas constant, T the temperature, and N_0 Avogadro's number. We assume ideal gas law behavior and constant H_2 pressure of 1 atm.

Equations [11] and [12] are the solutions for the surface concentrations in terms of the input concentrations. Either the pair Φ_o^{HCl} and Φ_s^{HCl} or the pair $\Phi_o^{SiCl_4}$ and $\Phi_s^{SiCl_4}$ may be used in Eq. [8] to obtain the growth rate. We note that the cases of etching and growth are completely symmetric, only the sign of $(\Phi_o - \Phi_s)$ changes. The expected profiles for growth and etching of Si through windows in the oxide, based on the initial rate, are given in Fig. 4. Of course these solutions are valid only when the boundary conditions as formulated are met in the physical system. Thus, as soon as growth or etching progresses to the point where the Si surface is no longer approximated by a flat disk, the solutions are invalid. This effect would modify the shape of the surface for etching in the manner of the dashed line in Fig. 4. An even more severe limitation is that no Si deposition occur on the oxide, at least within a few window radii. In almost all the growth experiments in this laboratory, deposition on the oxide did occur. Thus, in the experimental part

[3] We are interested in the concentration range of Cl in the gas stream of up to at most a few per cent. Thus for 1% HCl, we would have only 0.02% $SiCl_2$ at the surface.

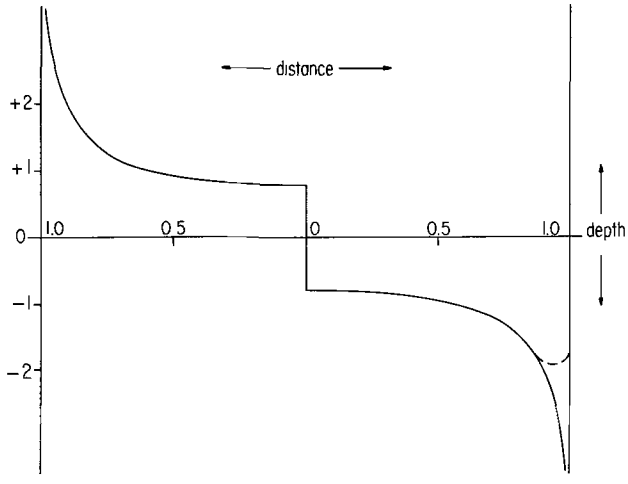

Fig. 4. Expected etching and deposition profiles across the bottom of the window in the oxide; the left half is for growth and the right half for etching. The solid curve is the theoretical prediction based on the initial growth (etch) rate. The actual shape would be modified by the constriction near the edge and for etching might look something like the dashed curve (arbitrarily sketched).

of this paper, we use the etching profile rather than the growth profile to compare with Fig. 4. In the presence of dense growth on the oxide, the growth rate in the window would be constant across the window and the same for all windows, as in normal epitaxy. That this is approximately true, even in the presence of a band of Si-free oxide surrounding the window, may be seen from the following argument. Suppose that the radius out to the edge of the Si-free band is ρ'. The Si from the ring $\alpha \lesssim \rho \lesssim (\alpha + \rho')/2$ is deposited in the window, in addition to the usual share from the region $\rho < \alpha$. The amount of this material is proportional to $\pi\alpha(\rho' - \alpha)$, *i.e.*, it is proportional to both α and the width of the Si-free band. We show in the next section that the width of the band is proportional to α, thus the amount of extra material is proportional to the window area.

Reaction of Si *with* O_2 *and* H_2O.—If oxygen is present in the epitaxial reactor, the etching of the silicon to form silicon monoxide competes with any deposition which may be taking place. In the temperature region of interest, the reaction

$$H_2O + Si \rightleftharpoons SiO + H_2 \quad [13]$$

is driven to the right as long as the concentration of silicon monoxide is less than the equilibrium concentration determined by the reaction

$$Si + SiO_2 \rightleftharpoons 2SiO \quad [14]$$

For silicon monoxide concentrations below the equilibrium value, stable silicon dioxide will not form on the silicon surface.

The oxygen concentration at which the oxide becomes stable may be calculated by considering the net oxygen flux in the system.[4] The dominant oxygen species are assumed to be silicon monoxide and water vapor, because of the hydrogen atmosphere and temperatures in excess of 1100°C. Our experiments to be described indicate that the oxidation of silicon to form silicon monoxide is sufficiently fast that the rate-limiting process is again mass transfer. As in the case of chloride transport, the condition that the net flux of oxygen in the system is zero can be expressed by

$$D_{SiO}\,\Phi_s^{SiO} = D_{H_2O}\,\Phi_o^{H_2O} \quad [15]$$

where D_{SiO} and D_{H_2O} are, respectively, the diffusion

[4] This calculation and its experimental verification have been carried out by Shepherd (7). Wagner made a similar calculation to determine the passivity of molten Si in an oxidizing atmosphere (8).

coefficients of SiO and H_2O in hydrogen, Φ_s^{SiO} is the surface concentration of SiO, $\Phi_o^{H_2O}$ is the concentration of H_2O in the gas stream, and we assume that Φ_o^{SiO} and $\Phi_s^{H_2O}$ are negligible in comparison with Φ_s^{SiO} and $\Phi_o^{H_2O}$, respectively. From Eq. [14] the vapor pressure of SiO over Si when SiO_2 begins to form is given by

$$\Phi_s^{SiO}(MAX) = (K_{14})^{1/2} \quad [16]$$

in which K_{14} is the equilibrium constant for reaction [14]. Combining Eq. [15] and [16], we obtain the maximum permissible water vapor concentration in the gas stream

$$\Phi_o^{H_2O}(MAX) = \frac{D_{SiO}}{D_{H_2O}} (K_{14})^{1/2} \quad [17]$$

Above this concentration, a stable oxide will form. Using 0.6 for the ratio (D_{SiO}/D_{H_2O}) (8) and the data for K_{14} from the JANAF Tables (6), we obtain for the maximum allowable H_2O pressure in the input stream in the neighborhood of 1500°K

$$P_{H_2O}(MAX) = 0.6 \exp\left(\frac{-11{,}300}{T}\right) \quad (\text{Atmos}),$$

about 100 ppm at 1150°C.

As in the case of growth, the reactor geometry prevents an exact calculation of the etch rate over large surfaces, however, the previous calculation, Eq. [1]-[8], apply directly to the etching through small windows. It is only necessary to solve for the surface concentration of SiO and H_2O. Denoting the equilibrium constant for reaction [13] by K_{13}, and making use of Eq. [15]

$$\Phi_s^{H_2O} = \Phi_o^{H_2O} D_{H_2O}/(K_{13} \cdot D_{SiO}) \approx 0 \quad [18]$$

We are justified in assuming that $\Phi_o^{SiO} << \Phi_s^{SiO}$ and $\Phi_s^{H_2O} << \Phi_o^{H_2O}$ because K_{13} is of the order of 100 in the temperature range of interest. Finally, from Eq. [8], the etch rate of Si in small windows of radius α is given by

$$V_{AVG} = 290 \cdot (T/T_0) \cdot \frac{P_{H_2O}}{\alpha} \quad (\mu\text{m/min}) \quad [19]$$

in which we have assumed ideal gas law behavior and used the approximate relationship

$$D_{H_2O} = D_O(T/T_0)^2$$

where $D_O = 0.7$, $T_0 = 273$ (11), and α is the window radius in centimeters.

Growth of Si *on* SiO_2.—As is apparent from Fig. 1, small crystallites of Si are deposited on the oxide, at least under some reactor conditions. In our system, such growth is in fact very difficult to prevent. Alexander and Runyan (2) have made an extensive study of the role of the growth conditions and the cleanliness of the oxide surface in determining the density and size of these crystallites, including purposely contaminated surfaces. We repeated a few of these experiments and made similar conclusions, namely, that any handling or contamination greatly increases the nucleation of Si on the oxide. Exposure to photoresist materials is particularly beneficial in enhancing dense, nonuniform nucleation.

Bicknell *et al.* suggest that oxygen-deficient sites provide locations for the formation of nuclei (9). Oxygen-deficient sites could be produced by the hydrogen reduction of the oxide surface by the reactions

$$SiO_2 + H_2 \rightleftharpoons SiO + H_2O \quad [20]$$

$$SiO_2 + 2H_2 \rightleftharpoons Si + 2H_2O \quad [21]$$

Both of these reactions are thermodynamically favorable at deposition temperatures, but experimental evidence indicates that they are quite slow. We baked wafers for 30 min in hydrogen at 1150°C and found only pinhole formation, but no measurable reduction in over-all oxide thickness. A rough calculation predicts that equilibrium for the reaction would produce a reasonably fast (*i.e.*, 50 Å/min) oxide etch rate under the conditions of the experiment. Our failure to observe such a reduction indicates that either the above reactions are kinetically limited and far from equilibrium under our conditions, or the rapid pinhole formation produces sufficient SiO via reaction [14] that reactions [20] and [21] are suppressed. We consider the former as the more likely explanation as virtually no thickness decrease was observed except in the pinholes.[5]

The apparently very small rate constant for reaction [20], plus the well-established contamination effects indicate that, at least under most reactor conditions, the role of oxygen-deficient sites in nucleation is minimal. In any case we may still draw some quantitative conclusions provided that the nature and density of the nucleation sites may be controlled. Suppose that the free energy change $-\Delta G$ for reaction [9] in the presence of crystalline Si is $\equiv -\Delta G_S$ per atom deposited. Growth on the oxide is inhibited compared to growth on Si if the average free energy change per molecule, $\equiv -\Delta G_0$ is less than $-\Delta G_S$. Clearly, $-\Delta G_0$ is a function of the number of atoms participating, and the nucleation rate is a strong function of the concentration. One might speak of supersaturation then in the sense of some combination of gaseous species sufficiently far from the equilibrium values (determined by $-\Delta G_S$) to drive the reaction to the right and achieve a given nucleation rate. The effect of contamination is to provide sites with $-\Delta G(\equiv -\Delta G_C)$ larger than $-\Delta G_0$ for a given number of atoms participating. Thus the supersaturation to achieve a given nucleation rate is lowered.

If $-\Delta G_C$ or the density of sites cannot be controlled from wafer to wafer, some conclusions may still be drawn by comparing different areas on one wafer, for which such control is considerably easier.

The variables controlling the rate of nucleation during the early stages of growth are of major importance in the explanation of the width of the silicon-free oxide band surrounding the windows. In order for the growth to take place on the oxide, the $SiCl_4$ must be reduced to silicon. We assume for simplicity that $SiCl_4$ does not react in the gas stream but diffuses to the surface before reacting. With this simplification, nucleation may be described in the form of a typical heterogeneous reaction, *i.e.*, (*i*) diffusion of $SiCl_4$ to the surface; (*ii*) adsorption of $SiCl_4$ on the surface; (*iii*) formation of nuclei by reaction of H_2 and $SiCl_4$ to form Si and HCl (this reaction may proceed by intermediate reactions involving other silicon species); (*iv*) desorption of HCl; and (*v*) diffusion of HCl away from the surface. If $SiCl_4$ reacts in the gas stream to form $SiCl_2$ or $SiHCl_3$, the above process will remain unchanged except for a change in the diffusing and reacting species. A similar argument holds if $SiCl_2$ is a reaction product; however, under our conditions HCl is favored as a reaction product.

If one of the steps in the series listed above is slower than the others, it will control the nucleation rate. Steps (*i*) and (*v*) are not rate limiting since before the nuclei are formed, the rate of formation of nuclei is not controlled by diffusion; *i.e.*, no concentration gradients are set up until growth starts. Because of the band of silicon-free oxide, we conclude that the driving force for the rate-limiting step appears to vary as a function of distance from the edge of the window. Because the rates of these processes are concentration dependent, we are interested in evaluating

[5] It is interesting that the rate constant measured by Grove and Deal (10) for the water oxidation of silicon, i.e., the reverse of [21] when combined with the equilibrium constant for [21], predicts an etching rate of less than one monolayer an hour. Of course, such a calculation is open to some criticism as the species involved in the H_2O oxidation of silicon has not been positively identified, and the SiO_2-Si interface is somewhat different than the H_2-SiO_2 interface in our experiments.

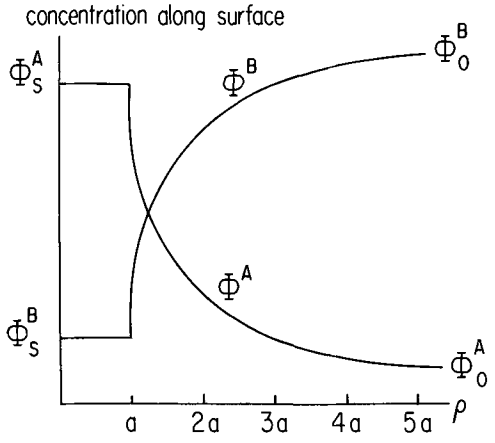

Fig. 5. Concentrations Φ^A and Φ^B of two gaseous species, A and B, along the surface of the oxide. For species A, $\Phi_S{}^A > \Phi_0{}^A$, whereas for species B, $\Phi_S{}^B < \Phi_0{}^B$. The subscript s denotes values on the Si surface, *i.e.*, $\rho \leq \alpha$, and the subscript o denotes the limiting value as $\rho \to \infty$.

the concentrations of the various species in the gas phase along the surface of the oxide. Evaluating Eq. [4] for $z = 0, \rho > \alpha$, we obtain

$$\Phi(\rho) = (\Phi_0 - \Phi_S)\frac{2}{\pi}\cos^{-1}(\alpha/\rho) + \Phi_S \qquad [22]$$

This function is plotted for the two cases $\Phi_0 > \Phi_S$, $\Phi_0 < \Phi_S$ in Fig. 5. In our model, the concentrations of all species follow such curves, only the values Φ_0 and Φ_S vary. The significance of these plots is that some combination of such curves gives the supersaturation. Noteworthy about the function is that the distance at which the value of Φ has decreased (increased) some fraction of its total change is proportional to the window size, and further, Φ drops (increases) from Φ_S most of the way to Φ_0 in a few window radii. Even though the boundary layer thickness for the reactor is on the order of centimeters, effective boundary layer thicknesses vary with window size and are of the order of α.

Experimental

Apparatus and procedures.—The epitaxial growth system used in these experiments is similar to the vertical system used by Theuerer (12). The $SiCl_4$ is held in a Pyrex container suspended in an ice-water bath. This arrangement does not lead to a constant mole ratio of $SiCl_4$ to H_2, hence it is necessary to measure the mole ratio for each run. This is accomplished by bubbling the output gas stream from the reaction chamber through a standard solution of NaOH with a suitable indicator. Airco ultra-high-purity hydrogen (less than 2 ppm impurities) is used without further purification. A rather standard procedure is used, a 5-min reactor purge in H_2 and a 5-min prebake in H_2 at 1200°C, followed by the etching or growth experiment. When oxygen is used, it is added in the form of a 2% oxygen-in-argon mixture prepared in this laboratory. The substrate temperature is measured with an optical pyrometer calibrated at the melting points of silicon and germanium. The thickness of the resulting epitaxial layers is determined by measuring stacking fault size.

Deposition of Si *in windows in the oxide.*—As previously noted (2), the deposition rate in small windows is a function of the window size, although in previous work the ratio of Si area to SiO_2 area rather than window size, has been used as a parameter. Quantitative data are difficult to obtain, however, as growth on the oxide initiates after some short period under deposition conditions. As soon as Si is nucleated on the oxide, our model is invalidated, and no comparison can be made between growth rates, for example in windows of different size. However, the qualitative observations that deposition rate decreases with increasing window size and that the growth rate is higher near the edges of the window, agree with the model. Furthermore, the simple modification of the theory in the presence of growth on the oxide predicts that the growth rate is independent of window size for long growth times. This is in agreement with our observations.

Etching of Si *with* O_2.—For convenience, we introduced O_2, rather than H_2O, into our system for the etching studies. Hence all the water concentrations quoted are effective H_2O input concentrations, equal by definition to twice the actual O_2 input concentrations. If the O_2 is converted into H_2O reasonably far from the wafer surface, then this procedure is correct. If, on the other hand, O_2 diffuses most of the way to the surface before being converted to H_2O, some corrections might seem necessary. Each O_2 molecule transports two Si atoms; however this factor is taken into account in doubling O_2 concentrations to obtain effective H_2O concentrations. Only the difference in diffusion constants produces a difference then and, because the latter would only be expected to be 10-20%, it will be ignored.

The wafers used in this study were all nominally of (111)-plane orientation and had five windows with radii of 1, 2, 4, 6, and 8 mils etched through the oxide by standard photolithographic techniques. The windows were at least 0.25 in. apart in order to minimize interactions. The wafers were subjected to a variety of temperatures and oxygen concentrations. The experimental results for the etch rate in the center of the window are plotted in Fig. 6. The important results to note are that for the larger windows the etch rate is: (*a*) proportional to oxygen concentration, (*b*) inversely proportional to window radius, and (*c*) relatively insensitive but inversely related to temperature.

The theoretical etch rate in the center of the window was calculated with Eq. [19] and is plotted for each concentration in Fig. 6.[6] The theory predicts an etch rate of approximately twice the experimental rate for the larger window sizes.

A possible explanation of the difference between the theoretical and experimental etch rates is the presence of a nonzero background of SiO. Silicon monoxide, in excess of the amount formed by H_2O etching in the windows, is supplied by the oxidation of the silicon covering the susceptor and by the undercutting mechanism (2) at the edges of the windows. The latter source of SiO would explain the larger deviations from the theory at the small windows. If SiO is pro-

[6] The temperature of the substrate is used because of the small effective boundary layer thickness on the order of α.

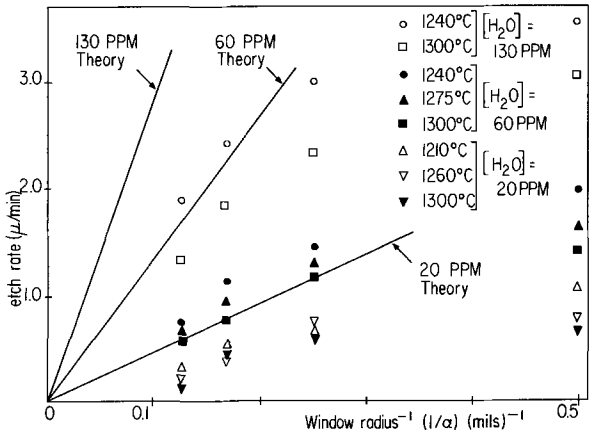

Fig. 6. Etch rate of Si through small windows in the oxide by oxygen. The solid curves give the theoretical etch rates for the three concentrations stated.

duced at a constant rate around the perimeter of each window, then the effect on the etch rate will be larger in the small windows since the ratio of area to perimeter is smaller. Other contributions to the difference between experiment and theory could come from backstreaming of the reaction products from the Si-coated susceptor, from kinetic limitations of the etch rate, and from the significant depth of the holes. The latter mechanism is particularly attractive because it predicts larger deviations for smaller holes as observed.

The experimental temperature dependence is small, but is in the opposite direction of that predicted by either a kinetic or diffusion argument with respect to the primary etching reaction. An excess in the SiO background concentration, either from the perimeter of the window or from the Si susceptor, could cause such a temperature dependence; however we cannot evaluate these or other possibilities.

The profile across the bottom of the window was measured both by a Talysurf and using the limited depth of field of a metallurgical microscope. A typical Talysurf plot is shown in Fig. 7 for 16, 12, and 8 mil windows. The theoretical profiles, from Fig. 4, are shown as dots on the 16 and 12 mil plots for comparison. Similar results were obtained on all samples examined using both methods of measurement. While the general shape of the predicted profile is substantiated, the agreement is not quantitative. The etch rate is too slow near the edges, leading us to conjecture that the production of SiO by the reaction of SiO_2 with Si around the perimeter of the windows is responsible. Jackson has reported the etching of essentially flat-bottomed holes through windows in SiO_2 (13). However, he indicates that the proper combination of temperature, HCl concentration, growth rate, geometry, and orientation are required, indicating that the mass transport regime examined in this paper is not operative.

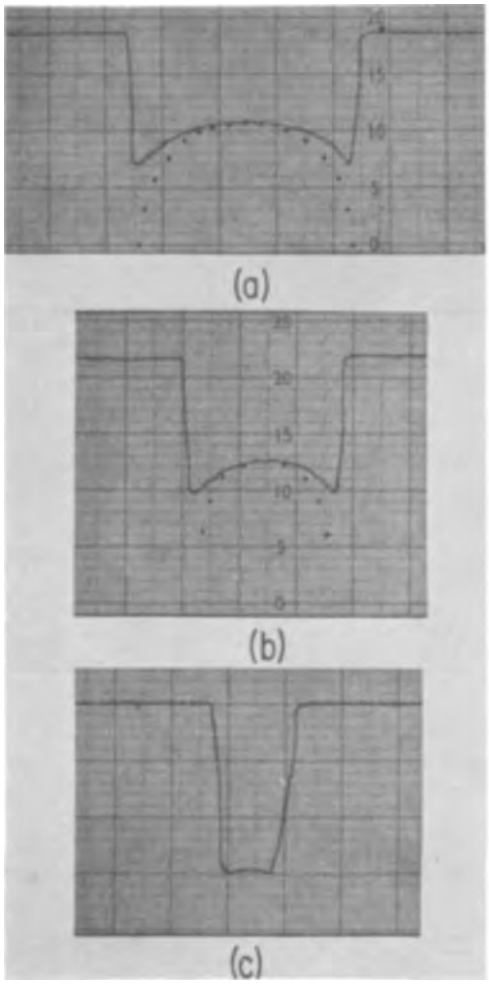

Fig. 7. Profile of the bottom of the window after an O_2 etch. The theoretical prediction, adjusted to match at the center is shown as a series of dots. (a) 16 mil diameter window; (b) 12 mil diameter window; (c) 8 mil diameter window. Vertical scale: 1 μm per division, horizontal scale: 50 μm per division.

Growth of Si *on the oxide.*—As pointed out earlier, the nucleation rate of Si on SiO_2 depends both on reactor environment and previous history of the specimen. Some attempts were made to vary the surface preparation to control the surface properties and determine the most important contaminants, but no information beyond that reported by Alexander and Runyan (2) was obtained. In fact, the rather poor control over the nucleation density was the general rule in our experiments. Nevertheless some experiments were made to try to understand the Si-free band with the hope that the necessary supersaturation for nucleation is nearly constant over a given wafer, however much it might be lowered by contaminants. We made special attempts to prepare several wafers identically in order that some process parameters could be varied and comparisons made between wafers.

We first established that the width of the Si-free band surrounding each window is a characteristic of the reactor and surface condition only and not a strong function of the growth time. In Fig. 8(a) and (b) we demonstrate this for a wafer that has been removed and photographed after 1 min, then placed back in the reactor for 4 min. One notes that the only effect of increasing the growth time by a factor of five is to increase the crystallite size; the density of crystallites in the region close to the window does not increase. This is an important observation, because it implies that the reactor conditions in the very beginning of the growth cycle control nucleation in the neighborhood of the window.

We propose the following model: When deposition is initiated by admitting $SiCl_4$, the bare Si surface remains essentially in equilibrium with the gas stream, but the concentrations of the various chlorides build up over the surface of the oxide. Some time after they exceed the supersaturation required for nucleation, depending on the kinetics, Si begins to nucleate on the oxide. After the Si crystallite density has built up to something less than that indicated by Fig. 8(a), nucleation ceases even on the bare region remaining near

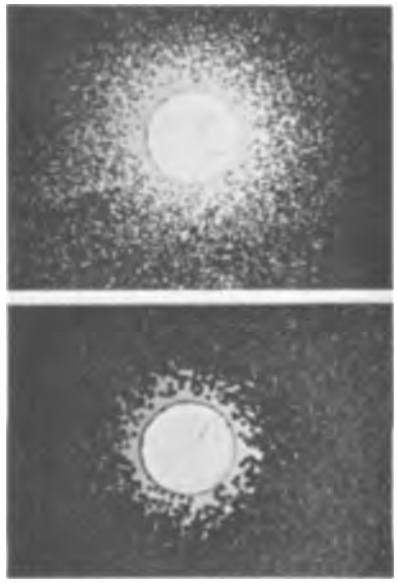

Fig. 8. Comparison of the nucleation rates on the oxide during the initial and later stages of growth. (a) (top) after 1 min of growth. (b) (bottom) the same wafer after 5 min of growth. The diameter of the window is 8 mils.

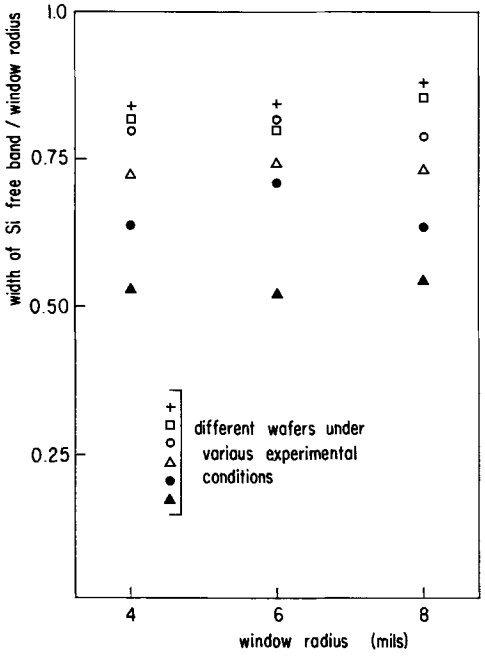

Fig. 9. Ratio of window radius to width of Si-free band for several wafers.

the edge of the window because the large amount of Si present maintains the Si concentration in the gas phase below the supersaturation required for nucleation on the oxide. Hence, the concentration profiles, Eq. [22], control the width of the Si-free band. As noted earlier, Eq. [22] indicates that the ratio of the width of the band to the radius of the window will be constant on a given wafer. Such has been found to be the case over a very wide range of reactor conditions. Typical results are shown in Fig. 9 which, in addition, illustrates the rather large scatter in the data, presumably due to contamination effects. Because these experiments bear out the role of the concentration profiles in determining the bandwidth, we attempted to determine further which species are crucial in determining nucleation rate, and to what power their concentrations appear in the nucleation rate equations. We were successful only in establishing that HCl is not the most important species in controlling the nucleation rate. The addition to the gas stream of concentrations up to one half the input $SiCl_4$ concentration had no effect on the nucleation density. We note that Jackson had success in controlling the nucleation on the oxide with the addition of HCl (13), however the concentrations were not given; therefore the results are not necessarily in contradiction to ours. Varying the $SiCl_4$ pressure, we found that large changes were produced in the nucleation density; however, no quantitative information was possible because of the variations in crystallite size, which made bandwidth comparisons difficult, and because of contamination, which produced large differences between one wafer and another.

These experiments suggest that the rate-limiting process in nucleation is probably adsorption of some silicon chloride species, or its subsequent decomposition reaction. Both processes would be strongly sensitive to foreign substances on the surface and could be independent of the HCl pressure. Much more precise experiments are needed in this area before even these tentative conclusions can be accepted.

In an attempt to test the hypothesis of oxygen-deficient sites (1), various amounts of oxygen were added to the gas stream during deposition. It was found that O_2 decreased the crystallite density for a given growth time, *i.e.*, lowered the nucleation rate. However, the addition of O_2 during the H_2 prebake prior to the deposition, with none present during the deposition, had similar effects. It was found that the most effective procedure was to add O_2 during the 5-min prebake and during the deposition.[7] The effectiveness of a prebake in O_2 suggests that O_2 might simply be an etchant for some of the contaminants on the oxide, *e.g.*, adsorbed hydrocarbons. However, experiments on oxides transported directly from the oxidation furnace to the deposition chamber also showed a reduced nucleation rate with O_2 prebake. Our oxides were not satisfactorily clean even in the latter experiments, however, in comparison with the oxides grown *in situ* by Alexander and Runyan (2). The hypothesis of oxygen-deficient sites cannot be dismissed, but in our laboratory, contaminants are playing a larger role than such sites.

Conclusions

A model has been developed for the concentration profiles in the gas phase around a small opening in an oxide-covered Si surface. The average etch rate of Si using water vapor, as well as the local etch rate across the surface of the window, agree with the predictions of the model. The observations that the growth and etch rates are higher near the edge of the window are explained by the crowding of the flux lines in this region.

The presence of a Si-free band around the window, even when dense nucleation on the oxide occurs, is the consequence of the steady-state profiles derived. The role of oxygen in hindering nucleation on the oxide is still not clear.

If a uniform growth rate across the window surface is intended, deposition under conditions which prevent nucleation on the oxide is not desirable. In fact, one method of assuring uniform growth in the window is to have dense growth on the oxide, eliminating the strong concentration gradients near the edge of the window responsible for the uneven growth. On the other hand, if gas etching is employed prior to deposition, then a clean oxide is mandatory in order that the etched-out volume, deeper at the edges, be exactly refilled by a growth, thicker at the edges, resulting in a flat surface. Any reactor conditions that prevent growth on the oxide, do not result in rough growth, and introduce no kinetic limitations other than diffusion in the gas phase can presumably be used successfully in such an "etch and backfill" process.

APPENDIX

Derivation of the Concentration Profiles

To solve Eq. [1], subject to the boundary conditions given by Eq. [2] and [3], we first solve the easier problem in which the second boundary condition is replaced by

$$\Phi = 0 \quad |z| + |\rho| \to \infty \qquad [23]$$

The problem is the analog of the problem in electrostatics of a charged metallic disk in an infinite medium. By analogy of Eq. [1] with LaPlace's equation, Φ and D are the duals of potential Φ' and dielectric

[7] Of course, the surface of the epitaxial Si suffered because the O_2 does not etch the Si smoothly at these concentrations and temperatures.

constant ϵ, respectively. Further, the gaseous flux density is the dual of the dielectric displacement, and by Gauss's law, the integrated normal component of the flux density over a surface is the dual of the charge enclosed by the surface. We make use of this duality because the electrostatic problem has been solved (4) and has the solution

$$\Phi'(\rho, z) = \frac{Q}{4\pi\epsilon\alpha} \sin^{-1} \frac{2\alpha}{\sqrt{(\alpha+\rho)^2+z^2}+\sqrt{(\alpha-\rho)^2+z^2}} \quad [24]$$

where Φ' is the potential, and Q is the charge residing on the disk. We may express Q in terms of Φ'_s, the potential at $z = 0$, $\rho < \alpha$. Before we write the dual to this equation we may alter the second boundary condition by adding a constant to Φ' everywhere, which allows both a finite potential at ∞ and an arbitrary potential at some finite boundary, independent of Φ_s. This boundary condition permits the potential (concentration) to be specified at a distance equal to the thickness of some boundary layer. In order that the present solution remain valid, we must apply the boundary condition over an equipotential surface of the present solution. These surfaces are ellipsoids that may be specified by the radius ρ_b of the circle formed by their intersection with the plane $z = 0$. Eliminating Q in terms of the surface potential Φ'_s (surface concentration Φ_s) and specifying that the concentration equals Φ_o, the free-stream concentration, over the equiconcentration surface that intersects the plane $z = 0$ in a circle of radius ρ_b, we have for the dual of Eq. [24]

$$\Phi(\rho, z) = \frac{\Phi_o - \Phi_s}{\cos^{-1}(\alpha/\rho_b)} \cos^{-1} \left[\frac{2\alpha}{\sqrt{(\alpha+\rho)^2+z^2}+\sqrt{(\alpha-\rho)^2+z^2}} \right] + \Phi_s \quad [25]$$

In this work we are concerned with very small windows; α is typically 2-16 mils. Typical growth rates such as exhibited in Fig. 2 correspond to effective boundary layer thicknesses of centimeters, the exact value depending on the model that is used. Hence, α is much less than any conceivable boundary layer in our system, and $\cos^{-1}(\alpha/\rho_b)$ will be approximated by $\pi/2$.

A Method of Growing CuCl Single Crystals with Flux

Minoru Soga, Rikizo Imaizumi, Yoshihiro Kondo, and Takahiro Okabe

Department of Electronics Engineering, Shizuoka University, Hamamatsu, Japan

ABSTRACT

This report describes a method of growing CuCl single crystals of the zinc blende phase directly from a melt which contains a flux such as $SrCl_2$ or $BaCl_2$. The presence of the flux at 2 mole % depresses the temperature of the melt below 407°C. The melting point of pure CuCl is 422°C, thus making it possible to grow the crystal without going through the phase transition from the wurtzite phase at 407°C. Because of the elimination of the phase transition in the solid, strain-free single crystals of large size, particularly in the direction of growth, can be grown by this method. As a consequence, a very large Pockels effect (maximum phase difference of 240°) can be obtained from a cell made by this method.

Cubic CuCl has a large Pockels effect (1) and can be used for electrooptic light modulators. Optical modulators using cubic crystals such as CuCl have some advantages over dihydrogen phosphate modulators (3).

However, it is difficult to grow strain-free CuCl single crystals of a practical size by the usual Bridgman method, principally because CuCl has a phase transition at 407°C (2).

CuCl crystals have the zinc blende phase in the temperature range below 407°C and the wurtzite phase from 407° to the melting point at 422°C. Therefore, crystals grown from the melt are in the wurtzite phase at first and then convert to the zinc blende phase when cooled below 407°C. This phase transition occurs in the solid state so that there remains in the crystal a heavy strain which can not be eliminated by annealing.

If the melting point of CuCl is depressed below the transition point, however, the solid-state phase transition is eliminated and CuCl should crystallize in the zinc blende phase directly from the melt (3). The crystal thus obtained should be almost free from strain.

Purification.—CuCl is purified first by recrystallizing and then by zone refining as follows: Commercial grade CuCl powder (slightly blue-colored), the purity of which is guaranteed 85% or better, is recrystallized in hydrochloric acid. The recrystallized snow-white leafy CuCl is then washed repeatedly with acetic acid until the hydrochloric acid is completely eliminated before being dried in an air bath at 120°C.

The dried CuCl is put in a clean quartz tube. The air within the quartz tube is flushed out by pure nitrogen gas in order to avoid oxidation of the melted CuCl during the zone refining process. Before the zone refining process, the nitrogen gas is pumped out of the quartz tube while the CuCl is baked at 350°C and the tube is sealed off. The quartz tube loaded with CuCl is passed through a zone refining furnace with a speed of about 100 mm/hr. A colorless transparent CuCl crystal is obtained after some twenty passes of zone refining. The pure CuCl thus obtained is ready for the next process, *i.e.*, single crystal growing.

Crystal growing.—The crystal growing procedure is the same as the usual Bridgman method, except for adding flux. The structure of the furnace and the

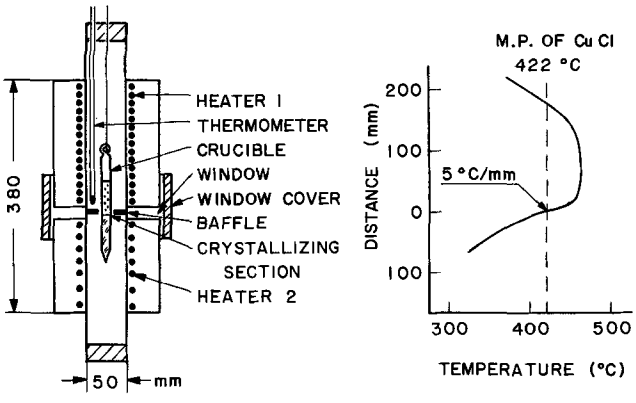

Fig. 1. (a). (left) Structure of the furnace for growing CuCl single crystals; (b). (right) temperature distribution of the furnace.

temperature profile, as measured with the quartz tube not present, are shown in Fig. 1. The voltage applied to the heaters is stabilized within 0.1%, and the temperature fluctuation of the furnace is less than ±1°C throughout the procedure. The temperature gradient of the furnace at the crystallizing section is approximately 5°C/mm.

The purified CuCl and a flux are placed in a quartz tube (8 mm inner diameter) which is used as a crucible. The crucible is sealed off as described in the previous section and then is placed in the furnace. CuCl and the flux are melted and mix themselves during the initial stage of the procedure; then a CuCl single crystal of zinc blende phase begins to grow from the capillary section of the bottom end of the crucible as the crucible moves through the furnace. Our experience shows that a growth rate of 1 mm/hr or less is adequate.

Selection of flux.—Various anhydrous chlorides, each of which was a special grade having 99% or better purity, were further purified by recrystallizing or zone refining for use as fluxes.

The amount of flux required to depress the melting point of CuCl to 407°C was about 1.8 mole % in each case, independent of the valence of the cation. Therefore 2 mole % of flux was added to the CuCl, assuming a small weighing error.

As a result of crystal growing experiments, the fluxes were divided into two groups as shown in Fig. 2, where each chloride used as a flux is represented by a small circle or a group of three circles. Three circles a, b, c, of a group correspond to the lattice constants of the a, b, and c axes of the chloride crystal, respectively. Abscissa and ordinate indicate the radii of the cation (4) and the crystal lattice constants of the corresponding chloride, respectively. A white circle represents a chloride which leaves the CuCl crystal transparent while a black circle represents a chloride which makes the crystal opaque at room temperature, though both depress the melting point of CuCl.

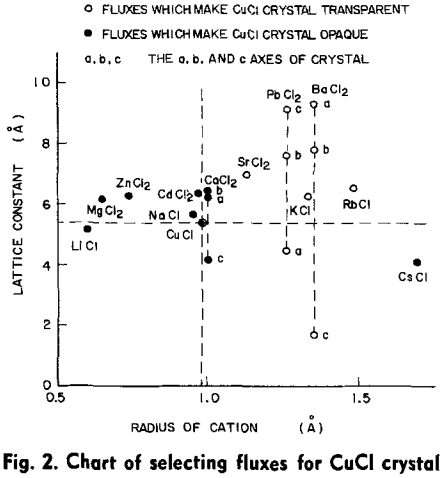

Fig. 2. Chart of selecting fluxes for CuCl crystal

It is seen from Fig. 2 that chlorides whose cation radius and a lattice constant are somewhat larger than those of CuCl, such as $SrCl_2$, $BaCl_2$, and RbCl, are suitable for flux.[1] These chlorides are segregated easily when CuCl crystallizes because of their large cation radius and lattice constant.

As the volume of the melt decreases, the concentration of flux in the melt increases above its initial value of 2 mole % by segregation. When the concentration of flux in the melt reaches about 5 mole %, the crystal becomes opaque, even when such suitable fluxes are used.

It was found that $SrCl_2$ and $BaCl_2$ had a slight tendency to react with the quartz tube, and the crystal grown in the crucible was adherent to the wall.

Preparation of the electrooptic cell.—After being removed from the crucible, the single crystal rod is annealed at 350°C for 24 hr to reduce the strain caused by adherence to the crucible wall. The crystal must undergo another 24-hr annealing at 250°C after the cutting and shaping processes. The surface of the cell becomes less transparent after the second annealing. This, however, can be eliminated by washing it in nitric acid, distilled water, acetic acid, and trichloroethylene, in this order, each for a few seconds. As the final process of the electrooptic cell preparation, electrical contacts are made by conductive paint on the top and bottom surfaces of the cell.

Characteristics.—Characteristics of CuCl single crystals grown by the flux method are shown in Table I, where the corresponding parameters of single crystals grown without flux are also shown for comparison purposes. The methods of measuring these parameters are described in the next section.

The single crystals grown by the flux method have a comparatively small optical strain as shown in Table I. This is due to the elimination of the solid-state phase transition, and the remaining small strain is easily reduced by annealing.

The elimination of the phase transition makes it possible to grow crystals of large size, in particular, in the direction of growth. A strain-free single crystal cube of 5 mm on each edge is easily obtainable by the flux method.

Specific resistance and breakdown field of the crystals grown with $SrCl_2$ or $BaCl_2$ flux are increased. The optical density is somewhat increased by flux which remains in the crystal. However, this slight drawback is not important compared to the marked improvements of the breakdown field and specific resistance. Since this increase of optical density is small, the amount of flux remaining in the crystal seems to be very small.

Because of the high breakdown field, it is possible to apply high electric field to the cell. Consequently, a large electrooptic effect is obtained as shown in

[1] Japanese Patent Pending. This work was sponsored by the Ministry of Education of Japan.

Table I. Characteristics of CuCl single crystals grown by the flux method

Flux, adding 2 mole % to CuCl	Optical strain, per mm	Optical density	Specific resistance, ohm-cm	Breakdown field, kv/mm
$SrCl_2$	0.005	0.20	5×10^8	1.45
$BaCl_2$	0.007	0.19	6×10^8	0.83
$PbCl_2$	—	0.58	1.5×10^8	—
KCl	—	1.1	1×10^6	—
RbCl	—	0.47	9×10^6	—
Growing without flux	0.02	0.12	3.5×10^8	0.58

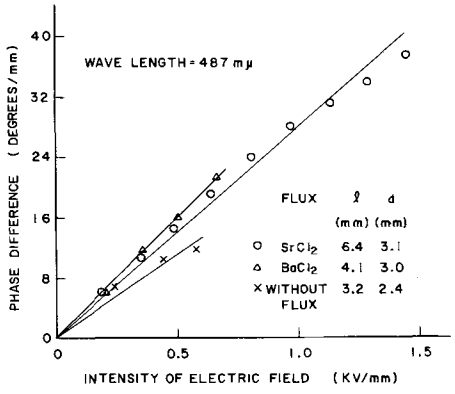

Fig. 3. Electrooptic effect of CuCl single crystals grown by adding fluxes and without flux.

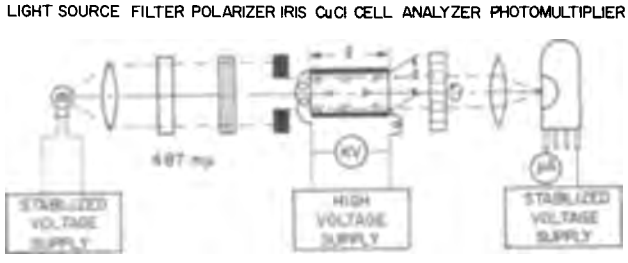

Fig. 4. Optical arrangement for measurement of electrooptic effect and optical strain of the CuCl cells.

Fig. 3. For example, a maximum phase difference of 240° was observed by the cell grown with $SrCl_2$ flux. The size of the cell used in this experiment was 6.4 mm in its axial length and 3.1 mm in its height, which is the distance between the electrodes. The maximum intensity of the applied electric field was 1.45 kv/mm as shown in Fig. 3.

The crystals grown with KCl or RbCl flux have larger optical density and lower specific resistance, which indicate a considerable amount of flux remaining in the crystal. For this reason, KCl and RbCl are inferior to $SrCl_2$ and $BaCl_2$ as flux.

Measurement.—Electrooptic effect.—Figure 4 shows the experimental arrangement for measuring the electrooptic effect. The directions of polarization of the polarizer and the analyzer are crossed. Phase difference can be measured as follows: First, read the transmitted light intensity when a voltage is applied to the cell; Second, with no voltage applied to the cell, rotate the analyzer to obtain the same light intensity as obtained before. Then the phase difference through the cell is given by twice the rotation angle of the analyzer.

Optical strain.—If the cell has no strain, no light is transmitted through the analyzer unless a voltage is applied to the cell. For the case of the actual cell, however, a certain amount of leakage light is transmitted even when no voltage is applied. This is due to the strain remaining in the cell. Therefore, an "optical strain" can be expressed in terms of ratio of the transmitted light intensity with crossed polarizers to the transmitted light intensity through the analyzer when it is parallel to the polarizer.

Conclusions

A method of growing CuCl single crystals of zinc blende phase directly from the melt with a flux has been developed.

Chloride fluxes whose cation radius and a lattice constant are somewhat larger than those of CuCl depress the melting point of CuCl below its transition point and leave the CuCl crystal transparent at room temperature.

It is found that $SrCl_2$ and $BaCl_2$ of 2 mole % are suitable for the flux and a growing rate of 1 mm/hr or less is adequate.

CuCl crystals grown by this method have several advantages; for example, reduction of strain, enlargement of crystal size, and increase of breakdown field and specific resistance.

A large electrooptic effect has been observed on cells made by this method.

Control of Photoconductive Properties in Cadmium Selenide

Brian Sunners

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Some aspects of the chemistry of sintered cadmium selenide photoconductors are presented. A tentative scheme is outlined whereby electrical requirements for such photoconductive devices can be used to define the chemistry of the sintered layer. Experimental methods are outlined, and the effects of some process variables on the electrical properties are described. The application of the method is described.

Various aspects of the chemistry of sintered polycrystalline photoconductive layers of group II-VI compounds have been reported in the literature (1-3), but as yet these systems are not completely understood. The available information gives only an indication of the present state of the chemical art and, as such, is not sufficient to define the parameters required to prepare a photoconductor that meets any given set of electrical specifications. Previous approaches have apparently been designed to formulate a chemical description of the system, and no attempt has been made to relate electrical properties quantitatively

with the chemical constitution. In this paper, we will describe this new approach and present a tentative scheme whereby electrical specifications may be used to outline the type and concentration of dopants required to yield cadmium selenide photoconductors with the required range of properties.

As the geometry of the photoconductor system is governed by various mechanical considerations, light sources, interconnections, etc., the electrical requirements for the photoconductor must be related to the properties of known materials on a "per square" basis. The electrical requirements are, usually, the resistance under given conditions of illumination, the dark resistance, and the fall time from the "on" condition to a given resistance level. Also operating temperature limits may be set. As the rise times are usually very fast and therefore acceptable compared to the fall times, they will be neglected in this treatment. In addition, as we have found that a fully compensated binary compound photoconductor of the type considered here has a dark resistance greater than 10^{10} ohms per square, this value also will be considered adequate in all cases. The remaining properties, light resistance and fall time, can be considered in more detail. The photoconductivity (light resistance^{-1}) and the recombination time are related by the equation[1]

$$R_L = (\alpha H \tau e \mu a)^{-1} \qquad [1]$$

where R_L is light resistance, H photons/sec/cm^2, e electronic charge, τ recombination time, μ mobility of majority carrier, a number of squares in parallel, α quantum efficiency. This relationship is derived from the fundamental equation for conductivity

$$\sigma = ne\mu$$

The recombination time τ will be equal to the fall time τ_0 only in the absence of all trapping effects. However, if the time of photocurrent decay is measured only over the initial portion of the decay, then the effects of trapping can be largely discounted. For practical purposes, however, light intensities must be high in order to observe this condition, and, in general, fall times are greater than recombination times by factors dependent on trap distributions and free carrier concentrations (4).

This effect has been used to determine the mobility of current carriers by measurements of photocurrent and fall time to $1/e$ of the maximum value as a function of increasing incident light energy. This measurement gives values for μ as τ_0 approaches τ, and the saturated value of τ_0 gives the mobility value. Of more practical value is the "device" mobility $\mu\tau$, measured under specified conditions of illumination. This is generally lower than the true mobility because light intensities fall below the saturation value and

[1] The author is grateful to Dr. A. S. Miller, now of National Research Corporation, for a discussion of this relationship.

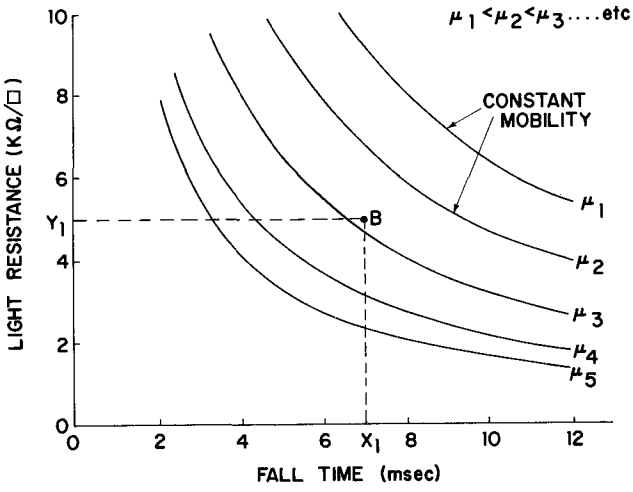

Fig. 2. Relationship between fall time, light resistance, and mobility. Light resistance is measured under 1000 μw/cm² from neon lamp.

appreciable numbers of electrons are trapped. Some values of device mobilities are shown in Fig. 1.

The relationship

$$R_L = (\alpha H \tau e \mu a)^{-1}$$

is illustrated in Fig. 2. In this figure, it has been assumed that the required properties are indicated by X_1 and Y_1. All points within the square Y_1BX_1O therefore lie in specification. Theoretically, material with a carrier mobility of exactly μ_3 can meet the specifications, but, in practice, as the photoresistance and the fall times are temperature sensitive, any increase in the device operating temperature causes an increase in the light resistance and a decrease in the fall time because of thermal desensitization. As the mobility remains relatively constant over small ranges of temperature change, any given set of photoconductor properties will shift along the lines of constant mobility as indicated in the figure. A material with the minimum mobility (μ_3 as shown in Fig. 2) will meet specification only over a very narrow temperature range and, therefore, is not a practical working material. The higher the mobility that can be achieved, the larger the operating temperature range will be. In addition, properties must be selected such that the photoresistance is at a maximum at the highest specified working temperature (along Y_1B) and such that the fall times are at a maximum at the lowest specified working temperature (along X_1B). This effect is shown in Fig. 3, which is taken from data for a large number of photoconductors measured under operating conditions. The contour lines (distribution of properties) represent

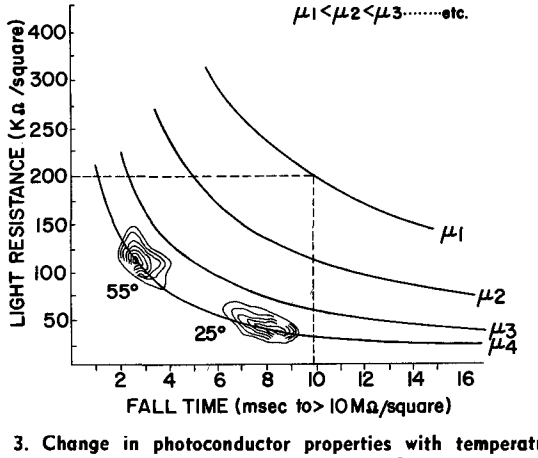

Fig. 3. Change in photoconductor properties with temperature. Light resistance is measured under 1000 μw/cm² from neon lamp.

the spread in the properties at specific temperatures. We can now define the problem as control of carrier mobility; this has been effected by adjusting acceptor and donor impurity concentration and the relative ratio. However, polycrystalline materials (powder or sintered) are usually prepared in such a way as to leave considerable doubt as to the exact concentration and nature of the donors present, particularly in the case of systems involving the use of halide fluxes, and so to determine this number, we have developed a solid-state titration, described below. This enables us to achieve the necessary control of acceptor-to-donor ratio. For maximum sensitivity, the optimum ratio has been quoted as 1.05 (5).

Experimental Methods

Cadmium selenide was mixed with cadmium chloride and dilute solution of copper chloride in the required proportions. Water, glycol, and glycerol were added to form a paste of a consistency suitable for screen printing. This paste was deposited on an aluminum oxide substrate having prefired platinum electrodes and was then carefully air dried. The photoconductors were fired in an atmosphere of flowing nitrogen in a furnace lined with a quartz tube. Typical temperature cycles are shown in Fig. 4. The electrical properties were measured at 10v d.c. and the response to neon light was determined. The effect of varying the light intensity has been explored previously (1, 2) and, in this work (for practical purposes), was maintained at an incident energy level of 300 $\mu w/cm^2$.

Impurity doping.—It should be noted that no "donors" are deliberately added to the above mixture; the chloride (usually described as a donor) is required in this process because of its fluxing action. In fact, chloride probably does enter the lattice as a donor, and selenium vacancies may also occur as donors. Thus to fix the acceptor and donor concentrations as required above, we must determine the total donor concentration and, if possible, distinguish between electrically active impurities and crystal defects as a function of processing variables.

Based on an observation by Avinor (6) that the maximum rate of change of dark current with acceptor concentration in single crystals of CdS occurs when the acceptor and donor concentrations are equal, we have developed a solid-state titration method to determine the concentration of both vacancy and impurity donor centers. A typical titration is carried out by preparing and processing a number of photoconductors, each under identical conditions, with the one exception that the added acceptor (copper) concentration is varied in steps throughout the series. It must be assumed that change in the copper concentration causes no other changes (vacancy concentration, etc.) in the material and that a constant fraction of the added copper enters the lattice as an electrically active species. Reisman and Birkenblit (7) have shown that the first assumption is probably valid but that a $Cu^{+} \rightleftarrows Cu^{++}$ equilibrium probably exists.

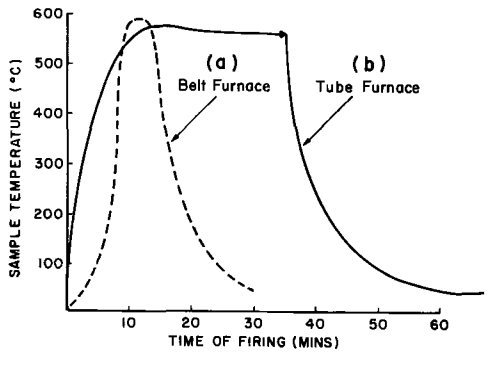

Fig. 4. Photoconductor firing cycle

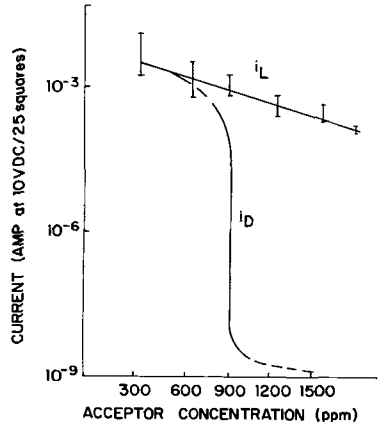

Fig. 5. Change in photoconductor properties with acceptor concentration; light resistance is measured under 300 $\mu w/cm^2$ from a neon lamp.

We must therefore assume that this equilibrium is constant for identical processing conditions. The properties of the resulting photoconductors are strongly dependent on the total copper concentration (Fig. 5); and, by analogy to Avinor's work, the maximum rate of change in dark current is interpreted as the "equivalence point" of the titration. A typical titration curve is shown in Fig. 5. We now have a tool for examining the effect of process variables on the chemistry of the photoconductor and so should be able to proceed to relate such processes to the required electrical properties. Copper "acceptor" concentrations and donor concentrations obtained by titrations are relative and relate, we assume, to the added acceptor concentrations by the position of the equilibrium referred to above; that is, by a constant factor. This simple picture of copper and chloride impurities neglects the possibility of other electronically active centers such as lattice defects and vacancies, or impurities in the starting material. (A typical analysis is shown in Table I.) The existence of selenium vacancies up to 10^4 ppm may be expected (8) and is, in part, confirmed by the effects of the post treatment described below so that we can add selenium vacancies to the list of electronically active centers that can be examined by the titration method.

Post treatment.—If a titration series of nitrogen-fired photoconductors is reheated to 200° or 300°C in nitrogen containing about 2 mm selenium vapor (sulfur vapor may be used), then the titration point decreases typically from 1200 to 300 ppm copper (atom parts per million). We assume that the decrease is due to the loss (filling) of 900 ppm selenium vacancy donors. Support for this assumption is obtained by examining the donor concentration as a function of cadmium chloride flux concentration. Figure 6 shows that the total donor concentration after firing is proportional to the initial flux concentration and extrapolates to about 1000 ppm at zero flux concentration, again presumably due to selenium vacancies. The low value obtained at 2½% (W/W) $CdCl_2$ is probably due to incomplete sintering action at this low flux level. It should be further noted that nonpost-treated photoconductors are not as stable as after post treatment and that some have properties that change even at room temperature

in a direction that parallels the effect of post treatment. The effect of change in firing time at peak temperature, shown in Fig. 7, is not inconsistent with this postulate: the "selenium vacancy" concentration increases with time, whereas the copper concentration appears constant. The effect of temperature on the equivalence point is less marked, but there is a maximum in the photosensitivity of all fully compensated materials between 550° and 575°C, believed to be a result of variation in the chloride concentration. Obviously gas flow velocities are critical in order to achieve reproducible chloride vapor concentrations, and effects are frequently observed due to variations in position when two or more photoconductor stripes are fired together.

It might be argued that the two-step process could be eliminated by firing in an atmosphere containing nitrogen and a critical pressure of selenium; we have explored only the possibility of firing in nitrogen/oxygen mixtures. The photocurrents of such materials are slightly higher than post-treated photoconductors, and the equivalence point is lower, 200 ppm. It is not clear why this should be lower than the usual value (change in the $Cu^+ \rightleftarrows Cu^{++}$ equilibrium may be responsible), but this point has not been pursued because it has been found difficult in air to keep dark currents reproducibly low. This may be due to the formation of cadmium oxide on grain boundaries; in the extreme case of high oxygen concentration (>20%) and long firing time, cadmium oxide can be detected by x-ray diffraction as might be expected.

Carrier mobility.—Measurements of the carrier mobility have been made in materials with a number of different donor concentrations and have shown that the mobility increases with donor concentration (Fig. 8), although it might be initially expected that the mobility would decrease with increasing impurity concentration. However, it is known that carrier mobility also increases with increasing light level, *i.e.*, with increasing number of carriers (9-11) and dependence of a similar nature has been noted by Kroger on cadmium sulfide single crystals (12). Thus, by fixing the donor concentration of a sintered layer by controlled processing, it is possible to select (within limits) the mobility required to meet device design specifications. Values of the speed and sensitivity still have to be fixed so that at room temperature they fall at the slow and sensitive end of the constant mobility lines in Fig. 2. As shown in Fig. 5, the addition of acceptors beyond the equivalence point results in a loss in photosensitivity and a decrease in the fall time; yet the mobility remains constant over a wide range of acceptor concentrations (10). The decrease in fall time may be due to the fact that an uncompensated acceptor forms a recombination center (13). Thus, the acceptor concentration may be adjusted to move the properties to the left or to the right along the constant mobility lines of Fig. 2. This then permits a material to work within its maximum temperature limits without going out of specification.

If in an attempt to decrease R_L, the acceptor concentration must be decreased to such an extent that erratic low dark resistances result, then the mobility is too low for maximum temperature latitude although all other electrical specifications may be met. From this, it might be deduced that in all cases it is desirable to have as high a mobility as possible and to increase the working temperature range of the material by adding acceptors. This, however, is not the case, as other phenomena are observed as the acceptor-to-donor ratio increases. We have already stated that the stability of high donor concentration materials may be less than with lower levels of doping, and Fig. 9 shows another effect, the "fatigue" or short-term photodegradation, arbitrarily defined as i_{30}/i_0, where i_0 is the initial photocurrent and i_{30} is the current after 30 min continuous illumination. The effect of increased acceptor concentration would obviously be undesirable when the device duty cycle involves long "on" times or short recovery times. Thus, the duty cycle must be considered in selecting the appropriate material.

Application.—By taking an arbitrary set of specifications, we can illustrate an application of the above scheme. The conditions of illumination were given as

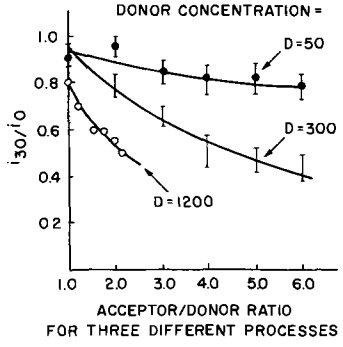

Fig. 9. Effect of acceptor/donor ratio on light fatigue. The acceptor/donor ratio is defined as the added acceptor divided by the titration equivalence point; light resistance is measured under 300 μw/cm^2 from a neon lamp.

1000 μw/cm^2 from a neon bulb, covering approximately a 25 square device. Required are $R_1 \leq 10$ kohm/sq and fall time to 70% $R_L < 5$ msec. Equation [1] gives an approximate value of 50 cm^2 v^{-1} sec^{-1} for the mobility (assuming unit quantum efficiency and ignoring trapping effects); anticipating some device temperature rise and consequent desensitization, we will attempt to utilize a higher mobility material (higher donor concentration) and add excess acceptors to permit sufficient temperature flexibility without conceding device stability (both short and long term). This mobility should require a donor concentration of 1200 ppm (Fig. 8), a number referred to in many of the examples above. However, in these examples, the donor concentration consists of 300 ppm chloride donor ions and 900 ppm selenium vacancies, and thus the material is not as stable as one that has been post-treated to remove (according to our hypothesis) vacancies. Thus the chloride or other donor impurity must be brought up to the 1200 ppm level to obtain a material with sufficient stability. This has been done on a pilot-line scale where the furnace atmosphere is saturated with cadmium chloride vapor. This method has the added advantage of improving uniformity; we lose the end effect by which the first and last units of each substrate are of lower sensitivity or by which the first and last substrates differ from the rest of the run. It is interesting to note that the donor concentration before post treatment is between 1800 and 2100 ppm, showing that the selenium vacancy concentration (600 to 900) is slightly reduced in line with the reduced time at peak temperature in the continuous belt furnace (see Fig. 4 and 7.) Addition of 1500 ppm copper to the material gives the properties outlined in Fig. 3.

Acknowledgments

The author wishes to acknowledge the assistance of his co-workers in this project including Dr. A. S. Miller, Dr. A. H. Mones, D. L. Bowman, and the late Dr. R. S. Schwartz; many of the suggestions and results in this paper have been drawn from their work.

Manuscript received June 9, 1964; first revised manuscript received July 14, 1966; second revised manuscript received Jan. 12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Phase Equilibria in the Cd-Se System

R. A. Burmeister, Jr.,[1] and D. A. Stevenson

Department of Materials Science, Stanford University, Stanford, California

ABSTRACT

A consistent set of temperature-composition and pressure-temperature data has been obtained for the Cd-Se system by combining the results of several previous investigations. It is shown that CdSe vaporizes congruently and that the range of congruent sublimation extends to temperatures in excess of 1200°C. Values of the standard free energy, enthalpy, and entropy of formation of CdSe are derived from the experimental vapor-solid equilibrium data. The activity coefficients of Cd and Se in the liquid phase in equilibrium with solid CdSe are calculated from the experimental data. The liquid is found to exhibit nearly ideal behavior in the region $N_{Se} = 0.0$ to 0.4 for Cd, and $N_{Se} = 0.6$ to 0.77 for Se. The relationship of these data to the attainable concentration ranges of crystalline imperfections is discussed.

Pure binary semiconducting compounds exist over a narrow range of composition by the incorporation of native point defects. The concentrations of these defects may play a dominant role in controlling the electrical and optical properties of these compounds. Because the range of composition is extremely small, it is not operationally feasible to adjust the defect concentration by direct compositional control of the solid. The composition of the equilibrium vapor, however, changes appreciably over the stability range of the solid compound. The control of the component vapor pressure in equilibrium with the solid thus provides a convenient experimental method for adjusting the defect concentration. A description of the high-temperature equilibria between liquid, solid, and vapor phases is essential for this purpose. This information

[1] Present address: Hewlett-Packard Laboratories, Palo Alto, California.

is also important for determining the range of temperature and pressure suitable for crystal growth of the compound. Vapor-solid equilibrium data may be used to evaluate basic thermodynamic properties such as the standard free energy, enthalpy, and entropy of formation of the compound. These thermodynamic properties provide information concerning the nature of the binary system and a quantitative measure of the stability of the compound.

Studies have previously been made of various aspects of phase equilibria in the CdSe system. The minimum vapor pressure has been studied as a function of temperature by several investigators (1-6). The temperature-composition diagram was determined in an independent investigation (7), and recently three-phase (solid-liquid-vapor) equilibrium data have been reported (6). In this paper the data obtained in earlier investigations are combined and revised where necessary to construct a set of temperature-composition (T-X) and pressure-temperature (P-T) diagrams. This information is used to derive thermodynamic data for CdSe and to describe the general behavior of the Cd-Se system.

Solid-Vapor-Equilibria

It is well established that most IIb-VIa compounds sublime according to the equation

$$MX_{(s)} \rightleftarrows M_{(v)} + \tfrac{1}{2}X_{2(v)} \qquad [1]$$

at temperatures well below the maximum melting point (4).

For CdSe, the equilibrium constant corresponding to Eq. [1] is

$$K_p(T) = P_{Cd}P_{Se_2}^{1/2} \qquad [2]$$

At any temperature the total vapor pressure over the solid is the sum of the partial pressures

$$P_T = P_{Cd} + P_{Se_2} \qquad [3]$$

The condition for minimum total vapor pressure is obtained by setting $\partial P_T/\partial P_{Cd} = \partial P_T/\partial P_{Se_2} = 0$, yielding

$$P_{Cd} = 2P_{Se_2} \qquad [4]$$

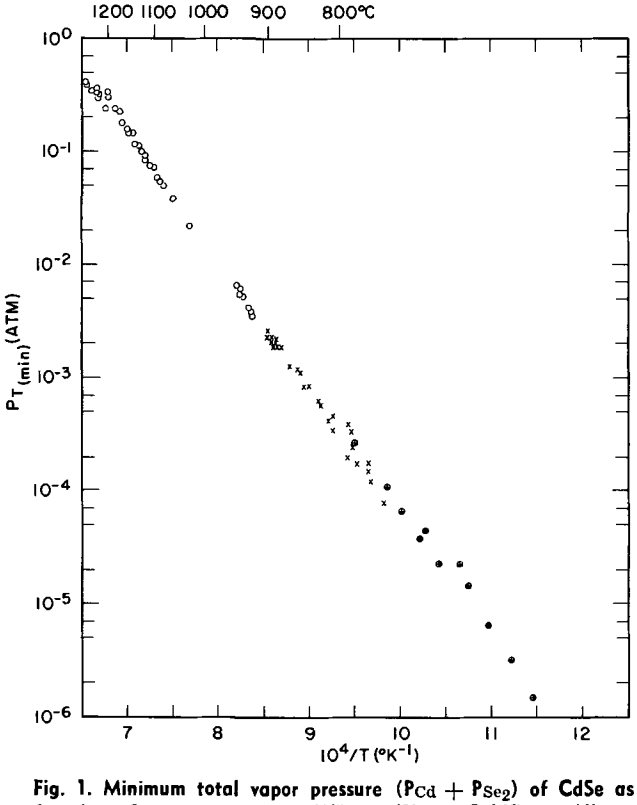

Fig. 1. Minimum total vapor pressure ($P_{Cd} + P_{Se_2}$) of CdSe as a function of temperature: x, Wösten (3); o, Goldfinger (4); o, Shiozawa (6).

Combining Eq. [2], [3], and [4] gives

$$K_p = \frac{2}{3\sqrt{3}} P_{T(min)}^{3/2} \qquad [5]$$

Several different methods have been used to determine $P_{T(min)}$ as a function of temperature, including Knudsen cell (1,4), Bourdon gauge (2), and transpiration techniques (3). Shiozawa (6) employed a novel variation of the "boiling point" method (8) commonly used for liquids. The results of the experimental measurements, shown in Fig. 1, are in good agreement. The measurements of Somorjai (2) have not been included, since they were made using a closed system and therefore do not represent the minimum total pressure (9). Knudsen cell measurements, although corresponding to an effusive steady state which is slightly different from a state of congruent sublimation, give essentially the same value for the minimum total pressure (10).

The standard heats of sublimation corresponding to reaction [1] were calculated from the data of Fig. 1 by use of the Van't Hoff equation, and the values obtained are given in Table I. The corresponding values for the standard entropy of sublimation are shown in Table II. It is not possible to make a Third Law calculation to substantiate the Second Law values given here, since the necessary low-temperature heat capacity data for $CdSe_{(s)}$ are not available.

In order to calculate the standard heat of formation of CdSe at 298°K from the vapor pressure data it is necessary to estimate the heat capacity change for the sublimation reaction. Shiozawa (6) applied Kopp's rule to $CdSe_{(s)}$ using tabulated C_p values for $Cd_{(v)}$ and $Se_{2(v)}$ (11), obtaining an approximate value of $\Delta C_p = 2.8$ cal/deg-mole. Wösten estimated a value of 3 cal/deg-mole for the same reaction. The standard heat of formation of $CdSe_{(s)}$ at 298° from $Cd_{(s)}$ and $Se_{(s)}$ calculated by use of these estimated values of ΔC_p are shown in Table III, together with the results of the emf measurements of Terpilowski *et al.* (12).

The experimental values of the standard entropy of CdSe at 298°K are summarized in Table IV.

Solid-Liquid-Vapor Equilibria

Shiozawa (6) has made experimental studies of the solid-liquid-vapor equilibria in the CdSe system. In these experiments, the partial pressure of Cd or Se over a CdSe crystal was fixed by means of a reservoir of the elements held at a lower temperature. The three-phase equilibrium points were determined by noting the points of incipient melting. The vapor pressure of liquid Cd was obtained from the data of Kelley (13), which are in good agreement with the recent measurements of Brebrick *et al.* (10) and Van Gool (14). The data for the three-phase line corresponding to Cd-saturation are shown in Fig. 2. Note that the maximum melting point will in general not correspond precisely to the minimum vapor pressure as shown. The difference in the maximum sublimation point and the maximum melting point cannot be determined precisely due to the lack of experimental data in this region. It is expected that the difference is rather small.

In evaluating the data for the Se-saturated three-phase line, it is necessary to consider the equilibria among the various vapor species of Se. Illarionov and Lapina (15) have shown that the dominant species in selenium vapor are Se_2, Se_4, Se_6, and Se_8 and have determined the relevant equilibrium constants. More recently Brebrick (16) investigated the vapor species over liquid selenium using optical density techniques. These data can be combined with the total pressure measurements of Brooks (17) to give partial pressure of any species as a function of temperature.[2]

In the temperature range investigated by Shiozawa, the dominant species are Se_2 and Se_4.[3] We have corrected that data of Shiozawa for the $Se_{2(v)} \rightleftarrows Se_{4(v)}$ equilibrium and obtained the results shown in Fig. 3. Also shown in the figure is the partial pressure of Se_2 over pure liquid selenium.

The maximum melting point of CdSe was determined by Shiozawa to be 1268° ± 2°C, as compared to the value of 1239°C reported by Reisman *et al.* (7). Part of this discrepancy may be due to the difference in experimental methods employed. Shiozawa employed visual examination of melting of vapor grown single crystals in a sealed quartz ampoule with a relatively large free volume. Reisman used weighed elements in a DTA capsule with a relatively small free volume. In the latter method, an excess pressure of one of the components is more likely with a consequent reduction in melting point in accordance with Fig. 2 and 3.

By combining the data of Fig. 1 through 3 with the T-X diagram it is possible to calculate the activity coefficients of Cd and Se in the liquid phase in equilibrium with solid CdSe, using the following relationships

$$\gamma_{Cd} = \frac{1}{N_{Cd}} \left(\frac{P_{Cd}}{P^{\circ}_{Cd}} \right) \quad [6]$$

$$\gamma_{Se} = \frac{1}{N_{Se}} \left(\frac{P_{Se_2}}{P^{\circ}_{Se_2}} \right)^{1/2} \quad [7]$$

where γ_i denotes the activity coefficient, N_i the mole fraction, P_i the partial pressure, and the superscript $^{\circ}$ denotes the pure component.

The activity coefficients obtained in this manner are plotted in Fig. 4. No values are shown for the region $0.675 \leq N_{Se} \leq 0.995$, since in this region the liquid consists of two phases (7). The activity of Cd in the liquid phase in equilibrium with solids CdSe shows only a slight deviation from Raoult's law in the region $0.0 \leq N_{Se} < 0.4$. Near the region of compound formation there is a very sharp negative deviation from ideality, as expected.

The solid-vapor equilibrium data can be combined with the liquid-solid vapor equilibrium data to construct a pressure-temperature diagram which indicates the limits of solid stability. This diagram is shown in Fig. 5. The ordinate has been expressed in terms of cadmium pressure rather than total pressure, since only one partial pressure can be independently

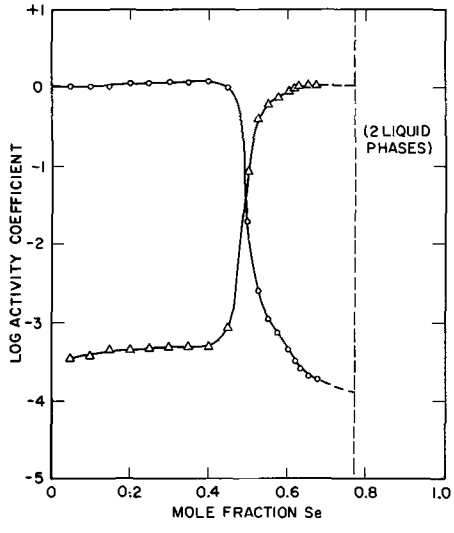

Fig. 4. Activity coefficient of Cd (o) and Se (x) in the liquid in equilibrium with $CdSe_{(s)}$.

[2] Recent measurements of the total pressure of Se vapor over liquid Se by Bonilla and Shulman (18) deviate significantly from those of Brooks, particularly at high temperatures. The reason for the discrepancy is not clear. Since the agreement among the other independent measurements (15, 17) is quite good, we have chosen their data for our calculations.

[3] Shiozawa (6) used the data of Kelley (13), which includes only the Se_2 and Se_6 species.

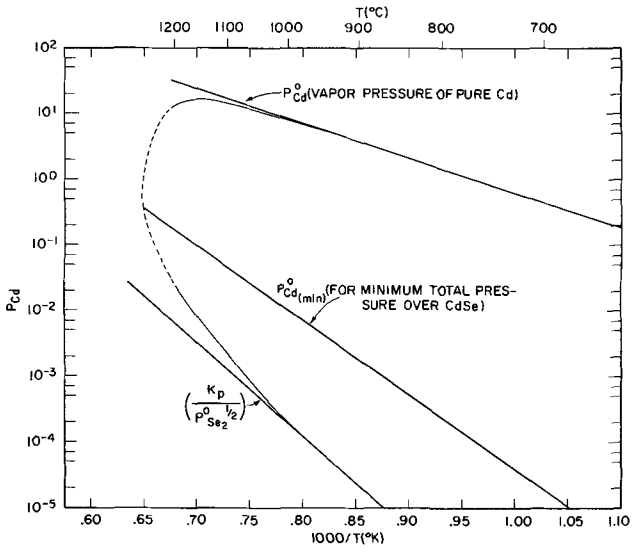

Fig. 5. P-T diagram of the Cd-Se system in the region of CdSe

controlled at a given temperature. The projection of the experimentally determined portion of the three-phase blade onto the *P-T* plane is represented by a solid curved line; the dashed portion is an extrapolation. Also shown on this diagram are the lines representing the vapor pressure of pure cadmium (P°_{Cd}) and that of pure selenium ($P^{\circ}_{Se_2}$). The latter has been expressed as an equivalent cadmium pressure by use of the equilibrium constant data derived from the minimum vapor pressure measurements.

Discussion

It has been suggested previously that CdSe does not exhibit congruent sublimation (7). While this may be true for short transient period at the beginning of the vaporization process, the experimental data summarized in this paper clearly indicate that the steady-state vaporization of CdSe is a two-phase sublimation process in which the solid and the vapor have the same composition. If the vaporization of CdSe proceeded only by a three-phase process, as postulated by Reisman (7), the total pressure over the vaporizing solid would be equal to that of the liquid phase present. At temperatures below ~950°C the vapor pressure of the liquid phase is nearly equal to that of the pure component [see Fig. 1 of ref. (7) and Fig. 2-4 of this paper]. The pressures measured experimentally over the solid during steady-state vaporization, however, are several orders of magnitude smaller than those over the liquid phase. Furthermore, the linear behavior of log $P_{T(min)}$ *vs.* $1/T$ up to 1200°C (Fig. 1) would not be expected if a three-phase vaporization process obtained. Under three-phase vaporization, the liquidus would change composition with temperature in accord with the T-X diagram. This change is reflected in the log *P vs.* $1/T$ diagram [see, for example, the data for HgSe (19)].

Since the concept of congruent sublimation is germane to this discussion, we wish to examine it in more detail. The basic requirement for congruent sublimation in a binary compound MX is that the saturated vapor pressure temperature curves of both components (corresponding to the full width of the solid phase field) overlap. The temperature range of congruent sublimation corresponds to the region of overlap. As a consequence of Gibbs-Konovalow theorem (20), the congruently subliming solid will produce the minimum total pressure at a given temperature. It should be recognized, however, that the congruently subliming solid need not be stoichiometric. The congruent sublimation of a nonstoichiometric compound MX_{1-y} where y denotes the nonstoichiometry and the vapor of X is diatomic, can be represented as

$$MX_{1-y(s)} \rightleftarrows M_{(v)} + \left(\frac{1-y}{2}\right) X_{2(v)} \qquad [8]$$

By following the differentiation procedure outlined in the section on Solid-Vapor-Equilibria, the relationship

$$P_M = \left(\frac{2}{1-y}\right) P_{X_2} \qquad [9]$$

is found for congruent sublimation. Expressions for K_p and P_T can be obtained in a similar manner.

In the case of CdSe, the saturated vapor pressure curves do overlap up to the highest temperatures (1200°C) for which experimental data are available. This can be seen from the data for Fig. 2, 3, and 5. The compound can therefore sublime congruently during steady-state vaporization in this temperature range. This is in distinct contrast to the behavior of III-V compounds such as GaAs and GaP, where congruent sublimation is limited to much lower temperatures (21). The difference in behavior is largely attributable to the magnitude of the difference in vapor pressures of the elemental components, which is small in the case of Cd and Se but large in the case of GaAs and GaP (21). Other II-VI compounds which have comparable elemental vapor pressures and therefore a large degree of overlap of the *P-T* curves should also sublime congruently up to temperatures near the melting point.

A question of central importance is the degree of nonstoichiometry of the congruently subliming solid, since the condition of congruent sublimation pertains in most phase crystal growth processes. The data of Reisman (7) suggest that the congruently subliming solid is nonstoichiometric with an excess of Cd. A quantitative knowledge of the exact composition of the congruently subliming solid as a function of temperature would allow corrections of Eq. [1] through [5] to be made as outlined above. Since the nonstoichiometry is undoubtedly less than 1 a/o, these corrections will be slight.

The pressure-temperature diagram (Fig. 5) is of considerable value in studies of properties of CdSe related to point defect concentrations. At any specific temperature, the attainable values of $P_{Cd_{max}}$ and $P_{Cd_{min}}$ can be ascertained. At a temperature of 900°C, for example, the extremes in pressures for the solid CdSe phase are $P_{Cd_{max}} = 3.8$ atm and $P_{Cd_{min}} = 2.3 \times 10^{-5}$ atm. These data can be used to predict the relative maximum and minimum concentrations for point defects consistent with a given defect equilibrium. A determination of the concentration and charge state of crystalline defects at high temperature obtained, for example, from high-temperature Hall effect measurements as a function of Cd pressure, would accurately define the width and position of the solid phase field on the T-X diagram. This information is required to draw firm conclusions concerning the attainability of p-type conductivity in CdSe by stoichiometry control.

The variation of the activity coefficients with composition along the liquidus (Fig. 4) shows a very small deviation from ideality for Cd on the Cd side of the diagram and for Se on the Se side of the diagram, except in the vicinity of the compound, *viz.*, 40-60 a/o Se, where pronounced negative deviation is observed. This behavior is somewhat different from that found in III-V systems (21). The existence of a wide range of nearly ideal behavior has important implications in predicting the phase equilibria of other II-VI compounds. It is possible, for example, to construct large portions of the P-T diagram by assuming the validity of Raoult's law in the appropriate regions (22).

The fact that the minimum total pressure of CdSe at the melting point is less than 1 atm is of practical importance in crystal growth processes since it indicates that CdSe can be grown from the melt without need for elaborate high pressure apparatus. In experiments of this type it is imperative to achieve an

initial composition close to or equal to the congruently subliming composition, since in a closed system an extremely small amount of excess Cd or Se may produce pressures considerably in excess of one atmosphere at the melting point.

Acknowledgments

The authors are indebted to Mr. L. Shiozawa of the Clevite Corporation for providing much of his experimental data at an early date. They are also grateful to Dr. R. F. Brebrick of Lincoln Laboratories for valuable comments concerning the selenium pressure data. Portions of this work were sponsored by the United States Atomic Energy Commission under Contract AT(04-3)-283.

Manuscript received July 26, 1966; revised manuscript received Dec. 5, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Vacuum Thermal Etching of Germanium and Silicon Surfaces

G. J. Russell and D. Haneman

School of Physics, The University of New South Wales, Sydney, Australia

ABSTRACT

The surface structures formed on {111}, {110}, and {112} surfaces of silicon and germanium heated in the temperature ranges 900°-1380°C for silicon and 650°-937°C (mp) for germanium have been detailed. The changes in topography were found to be markedly dependent on the degree of undersaturation maintained during heating, as well as on the temperature range. The {111} surface of germanium was particularly sensitive to surroundings of the crystal. The proximity and shape of the surroundings influenced the free evaporation rate from the heated surface. Either "worms" or oriented pits formed according to whether the degree of undersaturation was low or high. The various topographical changes are discussed in terms of bond breaking, surface atom mobilities, and free energy minimization.

Surface changes on heat treated germanium and silicon surfaces, under nonoxidizing conditions, have been reported by a number of authors (1-11). The surface changes appear to be diverse in nature. A systematic study has not been made. For surfaces heated to within a few degrees of their melting points geometrical pits were observed (1), each one with a hillock protruding from the center. On partially melted {111} silicon (2) and germanium (3) surfaces, triangular pits were not reported but only hillocks. Differing results have also been reported for silicon and germanium surfaces heated to temperatures well below the mp in high vacuum. The surface changes on the low index surfaces of silicon vary from geometrical thermal pits on all surfaces (4, 5) to an apparently smooth surface containing hillocks on the {111} surface (6) and a "sandblasted" surface structure on the {110} and {100} surfaces (4, 6). These changes are markedly dependent on temperature. However Batdorf and Smits (7) observed that vacuum thermally etched {111} silicon surfaces contain a number of flat-bottomed etch pits for the same temperature range that Hagstrum (6) reported a smooth surface containing hillocks.

For germanium surfaces heated in high vacuum, only observations on the {111} surface have been reported. The initial surface changes reported appear to be inconsistent in that "pocking" of the surface at a temperature of 850°C was first observed by Gatos and Lavine (8) while Gabor (9) found geometrical pits and hillocks as well as straight line pits in the temperature range 570°-850°C. In this latter case, it was found that a number of structures were dependent on the experimental conditions. For temperatures close to 850°C however, a number of authors (8-11) report the presence of "wormlike" structures. According to Haidinger and Courvoisier (10) these "worms" are hillocks which modify their structure with temperature.

The mechanism for the formation of the worm structure on the {111} germanium surface is not fully understood and has been discussed by Haidinger and Courvoisier in terms of surface GeO_2 particles (left after chemical etching) which initiate the worms and by Gatos and Lavine who postulate that surface oxide controls the thermal etching of the surface, the limiting factor being the rate of removal of the oxide present on the surface.

It is desirable to obtain further information on the behavior of the various low index single crystal surfaces of silicon and germanium, both to account for some of the above discrepancies and to provide more complete data to assist in providing explanations for the observed changes.

Experimental

Single crystals of silicon and germanium were cut so that the front surface exposed a {111} plane and the side surfaces exposed {110} and {112} planes, each surface being oriented to within ½ degree by x-ray methods. Several thin silicon and germanium wafers exposing {111} and {$\bar{1}\bar{1}\bar{1}$} planes were also prepared. The surfaces were lapped, polished (0.1μ, Cr_2O_3) and chemically etched before being placed in a high vacuum system for heating. The background pressure was $\sim 10^{-9}$ Torr and pressures in the range 10^{-7}-10^{-8} Torr were maintained during heating.

The silicon surfaces were chemically etched in a solution of 100 : 16 : 44 HNO_3 : HF : CH_3COOH (4) while the germanium surfaces were generally chemically etched in either CP4 or CP4B. In all cases the reaction was stopped with distilled water. The surfaces appeared flat and free of damage under high power optical microscopy, with etch pit (1-6μ) density of the order of 10-200 per cm^2. The crystals were then rinsed in concentrated HF followed by distilled water, and then placed in molybdenum holders, to minimize contamination effects. These were enclosed in an all glass high vacuum system, the front {111} crystal surface being heated by electron bombardment, Fig. 1. Because surroundings were sufficiently far from the crystal surface to remain cool and not return vapor, the conditions correspond to high undersaturation, the percentage ratio R of the crystal evaporation rate to the free evaporation rate being ~100%. (The side {110} and {112} surfaces were heated partly by electron bombardment and partly by conduction from the front surface.)

The surface temperatures of the silicon surfaces were obtained from calibrated optical pyrometer measurements using emissivity data (12) to ±20°C. The temperatures of the Ge surfaces were measured by a combined pyrometer and thermocouple technique, but the temperature could not be given to better than approximately ±25°C in most cases.

The three low index surfaces of germanium were also thermally etched in a second high vacuum system under conditions of low undersaturation. The crystals were placed in a quartz tube under continuous evacuation and heated by an axial oven. The nearness and high temperature of the surrounding walls resulted in appreciable return of germanium vapor (R = <1 − 25%). The surface temperature was measured by a calibrated chromel-alumel thermocouple, the head of which was spaced from the germanium surface by a small, thin molybdenum sheet as germanium attacks the thermocouple material. Measurements were accurate to ± 7°C and the temperature difference across the crystal face was <1°C and along the crystal length ~2°C.

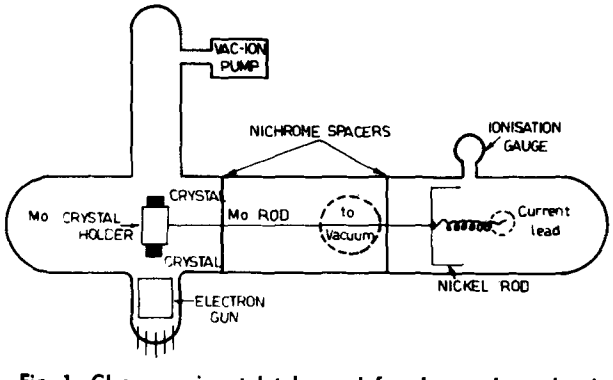

Fig. 1. Glass experimental tube used for electron beam heating of silicon and germanium crystals.

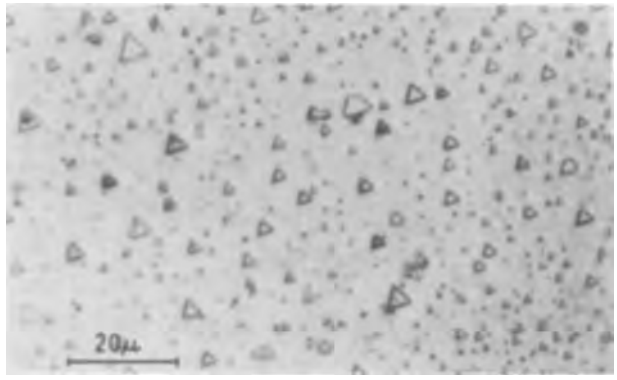

Fig. 2. Triangular thermal pits on the {111} silicon surface, temperature 1080°C; heating time 30 hr.

The surface structures before and after heating were examined at room temperature by high power optical and electron microscopy (shadowed replicas).

Results

The surface topographies observed on the three low index surfaces of silicon and germanium which had been heated in high vacuum under a high undersaturation are summarized in Table I and Table II.

The silicon surfaces were studied in the temperature range 900°-1380°C and for heating times of 2.3-115 hr, while the germanium surfaces were studied in the temperature range 650°C to the melting point (937°C) and for heating times of 0.03-52 hr. In both cases the resultant surface changes were found to be significantly temperature dependent (for observable surface changes), and the observed surface topographies can be approximately correlated to temperature ranges.

The nucleation sites for thermal pit formation on silicon and germanium surfaces appeared to be ran-

Table I. Silicon surfaces, high undersaturation

Surface	Temperature range, °C	Surface structure
{111}	900-1110	Triangular thermal pits exposing {311} planes (mainly 80° with respect to the surface, some 29.5°) and {111} plane, Fig. 2.
	1110-~1250	Transitional surface structure. The triangular pits "deteriorated" at the lower limit and a "scalloped" background with small hillocks formed at the upper limit, Fig. 3.
	~1250-1380 (mp 1412)	Surface covered with hillocks* and a wavy stepped background structure, Fig. 4.
{112}	900-1130	Triangular thermal pits with exposed {111} planes.
	1130-1180	Thermal pits began to "deteriorate" in a way similar to that observed for the {111} surface.
	1180-~1250	A "sandblasted" (4) surface structure is formed which changes to a much smoother background surface structure and hillocks at the upper limit, Fig. 5a.
	~1250-1380	Surface covered with hillocks* and a wavy stepped background structure.
{110}	900-1050	Striation thermal pits and about an equal number of hexagonal thermal pits, both types of pits exposing {111} and {311} planes, Fig. 5b.
	1050-1130	Striation thermal pits and a small number of large hexagonal thermal pits at the lower limit.
	1130-1180	Thermal pits began to "deteriorate" in a way similar to that observed for the {111} surface.
	1180-~1250	A "sandblasted" surface structure is formed which changes to a much smoother background surface structure and hillocks at the upper limit.
	~1250-1380	Surface covered with hillocks* and a wavy stepped background structure.

* The hillocks appeared to be flat-topped, but by careful replication it was found that a small "globule" had formed on each hillock top during heating.

Surface	Temperature range, °C	Surface structure
{111}	650-~800	Hexagonal-like thermal pits with exposed {111} and {311} planes. A number of triangular thermal pits exposing {111} planes were also observed, Fig. 6.
	~800-<937 (mp 937)	Triangular thermal pits with exposed {111} planes. A small number of hexagonal-like thermal pits exposing {111} and {311} planes were also observed.
	~937	Surface broken up forming hillocks with an associated pit structure.
{112}	650-<800	Hexagonal-like thermal pit structure with exposed {111} and {311} planes and several triangular pits exposing {111} planes, Fig. 7.
	~800-<937	Triangular thermal pits with exposed {111} planes.
	~937	Surface broken up forming hillocks with an associated pit structure.
{110}	650-~800	Hexagonal thermal pits and several striation thermal pits, both types of pits exposing {111} and {311} planes.
	~800-<937	Striation thermal pits and a large number of very small hexagonal thermal pits, both types of pits exposing {111} and {311} planes.
	~937	Surface broken up forming hillocks with an associated pit structure.

dom. Dislocations intersecting the surface were found to be present at the base of a number of the thermal pits but there existed no one-to-one correspondence.

For {$\bar{1}\bar{1}\bar{1}$} germanium surfaces of thin wafers heated in high vacuum under a high undersaturation by conduction of heat from the electron bombarded front surfaces, the dominant surface features were hexagonal-like and triangular thermal pits as in Table II. However, a wormlike formation was detected after heating to ~725°C and worms were present after temperatures of 900°C. After 725°C heating, a number of

Fig. 6. Hexagonal thermal pit on a {111} germanium surface, temperature 775°C, heating time 43 hr, angle of shadowing ~32°.

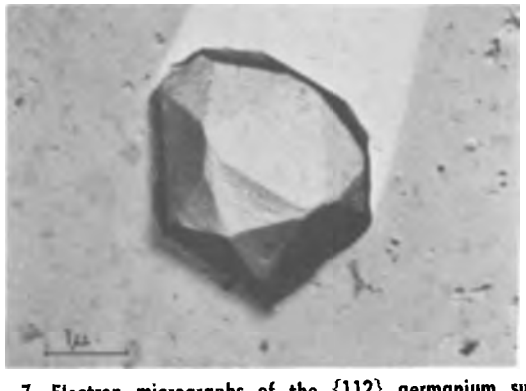

Fig. 7. Electron micrographs of the {112} germanium surface showed that a number of the hexagonal-like thermal pits had eight sides meeting the {112} surface, as above, temperature 650°C, heating time 30 hr, angle of shadowing ~20°.

Fig. 8. Worms on a {111} germanium surface, temperature 861°C, heating time 10 hr.

Fig. 9. Worm on a {111} germanium surface. The hillock in the triangular pit worm-head is prominent; temperature 736°C, heating time 30 hr, angle of shadowing ~30°.

the hexagonal-like (and triangular) thermal pits pointed in the $<2\bar{1}\bar{1}>$ directions due to the increased exposure of {311} planes.

Radiation heating of the low index surfaces of germanium in a high vacuum system giving conditions of low undersaturation caused the formation of a number of somewhat different structures which are summarized in Table III.

The worms were found to be pits, and not hillocks as reported by Haidinger and Courvoisier (10), and to

Table III. Germanium surfaces, low undersaturation

Temperature range, °C	Heating time, hr	R, %	Surface	Surface structure
669-861	10-34	5-10	{111}	Worm formation, Fig. 8.
738-867	10-30	25	{111}	Worm formation and a number of small triangular and hexagonal-like thermal pits.
669-861	10-34	25	{112}*	For temperatures <790°C triangular thermal pits exposing {111} planes and hexagonal-like thermal pits exposing {111} and {311} planes. For higher temperatures triangular thermal pits exposing {111} planes.
792-867	10-30	10	{112}	Triangular thermal pits with one side "deteriorated" and {111} planes exposed.
669-861	10-34	25	{110}*	Striation thermal pits exposing mainly {111} planes, {311} planes also being observed in a number of cases. Several very small hexagonal pits observed for temperatures $\gtrsim$ 750°C.
749	30	10	{110}	Mainly striation pits and a number of very small worm like features.
802-886	5-30	<1	{110}	Worm formation, the worms being relatively small compared with those observed on the {111} surfaces.

* At a temperature of 861°C, heating time 10 hr, several small worms were also observed on these surfaces.

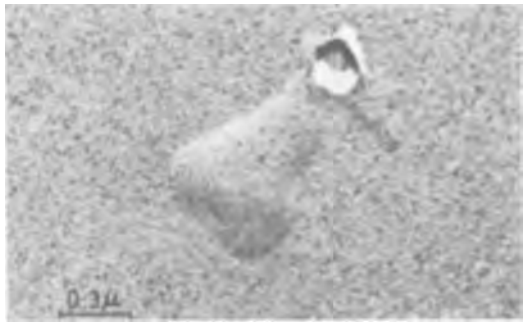

Fig. 10. Pear-shaped worm on a {111} germanium surface; temperature 742°C, heating time 30 hr, electron bombarding voltage 500v, angle of shadowing ~25°.

have the following characteristics: worm formation occurs predominantly on the {111} surfaces; the worms are connected to triangular pits on the {111} surface, as in Fig. 9 (at low temperature $\leq$750°C the triangular pits had either $<\bar{2}11>$ or $<2\bar{1}\bar{1}>$ directions on the same surface while for higher temperatures the pits had only the $<\bar{2}11>$ direction and exposed {111} planes); a small hillock is associated with each worm, generally associated with the triangular worm-head; the shape of the worm is very sensitive to temperature gradients on the surface; the worms increase in length and surface area with increasing temperature and heating time, and a large number of planes are exposed by the worms.

Consideration of the above results indicated that the degree of undersaturation maintained during heating of the germanium surfaces had a profound effect on the surface changes, causing either triangular (and hexagonal) or worm like etch figures at high and low undersaturations respectively. To obtain more detailed information the {111} surface was studied intensively.

Simultaneous electron bombardment (very low power) and radiation heating of {111} germanium surfaces in high vacuum under a low undersaturation ($R \sim$ 5-10%) resulted in a number of surface changes which were voltage dependent. Under various experimental conditions the following surface changes took place; at 200-500v, temperatures 742°-792°C, heating time 30 hr, "pear-worms" (Fig. 10) and several triangular and hexagonal pits formed; at 850v, temperature 807°C, heating time 30 hr, pear-worms, worms, and several triangular and hexagonal pits formed; at 1000v, temperature 780°C, heating time 30 hr the pear-worms were absent, the normal worm formation occurred, and a large number of triangular pits were observed.

In each case where pear-worms were observed, their size was notably smaller than that of normal worms. Their structure consisted of a type of hemispherical head, the planes exposed not being well defined. A hillock associated with each pear-worm was again observed, while very small hillocks were observed on the surface between the pear-worms in several cases.

In a number of cases a "reference" crystal exposing a {111} germanium surface was placed beside the electron bombarded crystal and held at a negative voltage with respect to the rest of the system. The {111} surface of the reference crystal developed worms, but the surface also appeared to have been ion bombarded, the amount of surface damage increasing with electron bombarding voltage (13).

Thus, the different surface structures observed on the {111} germanium surfaces of the experimental crystals can be interpreted in terms of a change in the undersaturation maintained in the experimental tube during heating. The bombarding electrons ionize the germanium vapor atoms, these are then removed at a negative electrode, and the undersaturation is increased. The mechanism for the formation of the pear-worms is not fully understood.

The effect of depositing germanium atoms from a beam onto a hot {111} germanium surface was also studied. The {111} surface was heated resistively, temperature 716°C for 7.5 hr, under free evaporation conditions in high vacuum and hexagonal and triangular thermal pits resulted. A beam of germanium atoms impinging on a hot {111} surface (the beam density being slightly larger than the calculated number of atoms evaporated), temperature 722°C for 7.5 hr, caused almost complete suppression of the thermal pits and worm formation was observed. These conditions correspond to low undersaturation, and confirm the previous conclusion that triangular etch figures are suppressed by returning Ge vapor.

The final experiment consisted of placing a clean molybdenum sheet in front of a {111} germanium surface heated in high vacuum under a low undersaturation. This resulted in the formation of triangular and hexagonal thermal pits and almost complete suppression of worms. The molybdenum sheet reached approximately the same temperature as the {111} surface and the surface of the molybdenum sheet facing the {111} germanium surface was found to have a thin coating of germanium which would increase the undersaturation maintained during heating.

These tests confirmed that the undersaturation maintained during vacuum heating of germanium surfaces is a very important factor in determining surface topography changes.

Discussion

Even though germanium and silicon have the same lattice structure a number of different topographical features formed on corresponding surfaces of the two crystals.

Heating low index surfaces of silicon and germanium under high undersaturation in high vacuum to relatively low temperatures resulted in basically the same surface change. Geometrical pits formed in all cases, the planes exposed by the pits being mainly {111} planes, but in many cases {311} planes were exposed as well. Simple mechanisms based on bond breaking can be postulated for the initial pit formation. The pits of atomic dimensions then grow by various processes. These include preferential evaporation which involves the propagation of steps on the surfaces and the inhibition of lateral motion of steps at the surface-pit kink positions perhaps in part by adsorbed species (14), such as GeO_2, SiO_2 (8). Thus the pits form a geometrical shape. The planes exposed by the pits indicate that there must be sufficient time for the material to be removed by exposing low surface energy crystallographic planes. The variation in facet size of the {311} planes with temperature may be considered as a variation of specific surface free energy with temperature as discussed by Herring (15).

On increasing the temperature, the topographical features on the germanium surfaces appeared not to change even at temperatures close to the melting point; however, for silicon surfaces a number of changes were observed. The most significant change is the formation of hillocks and a stepped surface structure on the {111}, {112}, and {110} silicon surfaces at a temperature of approximately 1250°C. This temperature is similar to that found by a number of workers (1257°-1280°C) to be necessary to "clean" silicon surfaces on the atomic scale by heat-treatment alone. This similarity of temperatures may have some significance. Germanium surfaces do not undergo these surface topographical changes as a function of temperature. It may be noted that germanium surfaces cannot usually be "cleaned" by high vacuum heat-treatment alone, although Jona (16) has reported a chemical treatment for {111} germanium surfaces that leads to clean surfaces after a very long period of heat treatment (~20 hr).

The cause of the hillock formation on the silicon surfaces appears to be the aggregation of refractory surface impurities into "globules" which mask the underlying surface during evaporation. From the work of Newman and Wakefield (17) it appears that silicon carbide precipitates may be the refractory impurities in the globules.

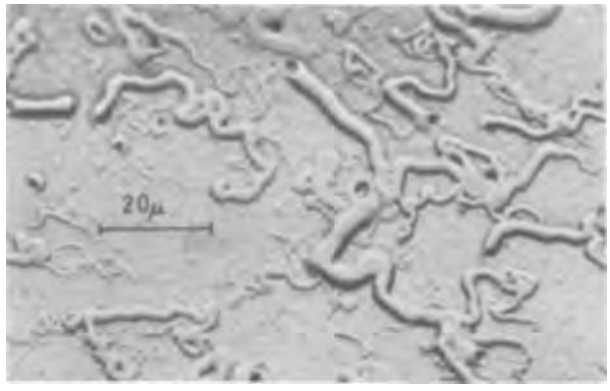

Fig. 11. Worms and hillocks on a {111} germanium surface. Oblique lighting used. The worm-heads have a triangular pit structure; temperature 792°C, heating time 30 hr.

The stepped surface structure can be explained by the nucleation of steps at the crystal edges and the movement of these steps across the surfaces with a mechanism such as time dependent impurity adsorption (18) or pinning by the hillocks to cause the formation of the observed submacroscopic steps. The crystal edges must be protected by "impurities" at the lower temperatures.

The mechanism proposed as an explanation of the worm formation is analogous to that proposed for the formation of surface structures on a partially melted {111} germanium surface. Near the melted region, the surface broke up at random sites, forming hillocks and an associated pit structure. The hillocks are assumed to obtain material for growth from the surrounding pit (1). Close to the melted region the hillocks moved toward the hottest region leaving behind a type of worm pit structure while closer to the melted region the hillocks grew rapidly in size and appeared to move according to the mechanism proposed by Pfann (19) for a two-phase eutectic system.

The above mechanism may be applied to the worm formation which occurs at lower temperatures. The hillocks which are observed could be germanium-impurity aggregates (GeO_2 is probably the impurity) the excess germanium now being supplied by the returning germanium vapor. The favored sites for the initial hillock formation appear to be the thermal pits, Fig. 11. These hillocks migrate from the pits along surface temperature gradients and form the worm structure by preferential evaporation of the surface atoms in the immediate vicinity.

The above mechanisms for worm formation must of course apply to all surfaces of germanium. The reason for the ease with which the {111} germanium surface forms worms can be considered in terms of surface energy criteria. A small increase in the surface energy of the {111} surface during heat-treatment is found (pit formation) and so hillock formation is possible. For the {110} and {112} surfaces, heat-treatment appears to lead to a decrease in the surface energy, whereas hillock formation would increase this energy. Thus, hillock formation on these latter surfaces should be suppressed by preferential reevaporation of the excess germanium from the hillocks.

The topographical changes reported in this work for the {111}, {110}, and {112} silicon and germanium surfaces after heat-treatment in high vacuum show that changes on each surface are dependent on the experimental conditions and the temperature, the heating time being of secondary importance for the ranges studied.

Technical Notes

Growth of CdS from Liquid Cd Solution

Naim Hemmat and Martin Weinstein

Tyco Laboratories, Inc., Waltham, Massachusetts

Single crystals of the wide-band gap II-VI compounds (CdS, ZnS, CdTe, etc.) have been prepared from the melt and from the vapor phase. Growth from solution, although not applied previously, has many advantages in the specific case of such refractory crystals, since the temperature of growth could be significantly lower than that of the other methods. Such problems at high temperatures as contamination from the crucible and excessive constituent vapor pressures would therefore be minimized. If a proper solvent is chosen, purification may also be accomplished during growth. From a basic standpoint also, solution growth from metallic solution is less susceptible to local uncontrollable temperature fluctuations; therefore, crystals of exceptional perfection and homogeneity can be grown more easily by this technique.

For these reasons an attempt was made to show the feasibility of growing bulk CdS from Cd solution. Cadmium essentially chose itself as the solvent since (*i*) the solubility of CdS in liquid Cd is known (1), (*ii*) Cd solvent extraction has been previously shown to be effective in the purification of CdS (2), and (*iii*) the use of Cd eliminates the need for a third constituent.

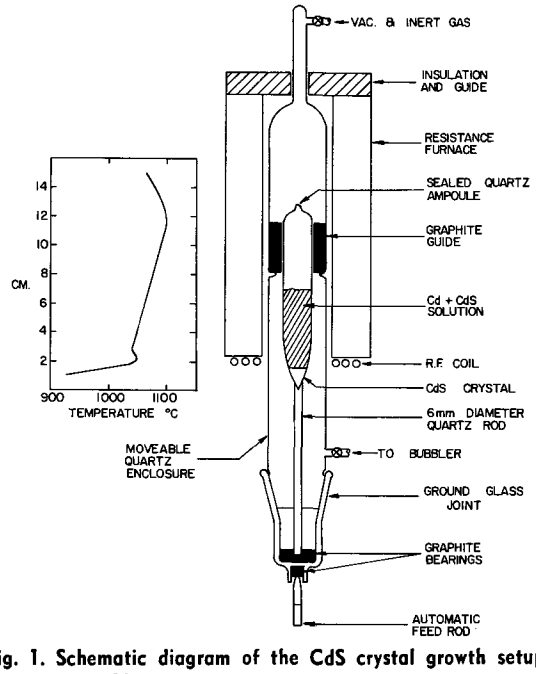

Fig. 1. Schematic diagram of the CdS crystal growth setup and temperature profile.

Procedure

Figure 1 is a schematic diagram of the crystal growth setup and its accompanying temperature profile. Approximately 21g of high-purity Cd (99.9999%) and 2.9g of high-purity sulfur (99.999%) were placed in the quartz ampoule and sealed under vacuum ($\sim 5 \times 10^{-6}$ mm Hg). The S charge was then slowly heated in contact with Cd to form CdS. Care was taken to minimize severe reaction. In this case since such a large excess of Cd was present, little trouble was encountered. The quartz ampoule was 16 mm OD, 2 mm thick, and 5 in. long. The quartz rod served to increase the radiation heat transfer at the initial point of nucleation. As can be seen from the temperature profile, the resistance furnace was controlled so that the maximum temperature (1080°C) was at the top of the ampoule. A pancake rf coil was provided to produce a peak temperature of 1050°C and a sharp thermal gradient at the liquid-solid interface. After the reaction was complete, the quartz ampoule was placed in the furnace with its pointed end at approximately 1020°C. The ampoule was then lowered through the temperature gradient at a rate of 2.5 mm

Fig. 2. Photograph of typical (2.5 cm long) polycrystalline CdS boule grown from Cd solution.

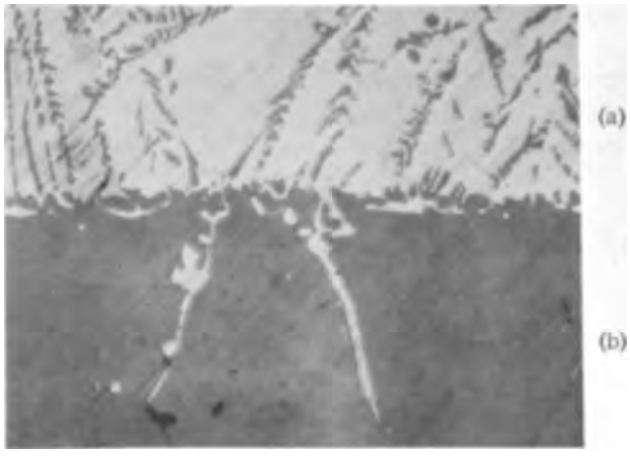

Fig. 3. Longitudinal cross section through a CdS-Cd solvent composite ingot 50 X: (a) Cd; (b) CdS boule.

per day. The growth interface was maintained at approximately 940°C.

Results

Figure 2 is a photograph of a typical 2.5 cm long polycrystalline CdS boule grown from Cd by the above technique. The 5 mm Cd zone is clearly seen on the left. In the best cases the ingots contained single grains of CdS, 4 mm^2 in cross section and 3-4 mm in length. After polishing the surface, the polycrystalline boules appeared yellowish in color and were quite transparent. No preferred growth direction was observed.

Observation of quenched ingots indicated a fairly diffuse boundary between the Cd solvent zone and the polycrystalline boule. Figure 3 is a longitudinal cross section through the CdS boule-Cd solvent composite ingot. As can be seen, a slight amount of Cd is found entrapped in the grain boundaries near the interface. Little, if any, free Cd was found in the first portion of the boule to grow. This may be due to migration of the entrapped Cd after growth took place. CdS dendrites frozen out in the Cd solution can also be seen easily. In some cases hexagonal CdS platelets (Fig. 4) were also found at the upper portion of the Cd solvent zone.

The resistivity of the polycrystalline material was approximately 10^{-1} ohm-cm. The impurity concentration was found to be similar to that of crystals grown from the constituent elements from the vapor phase (3 ppm atomic total) (3).

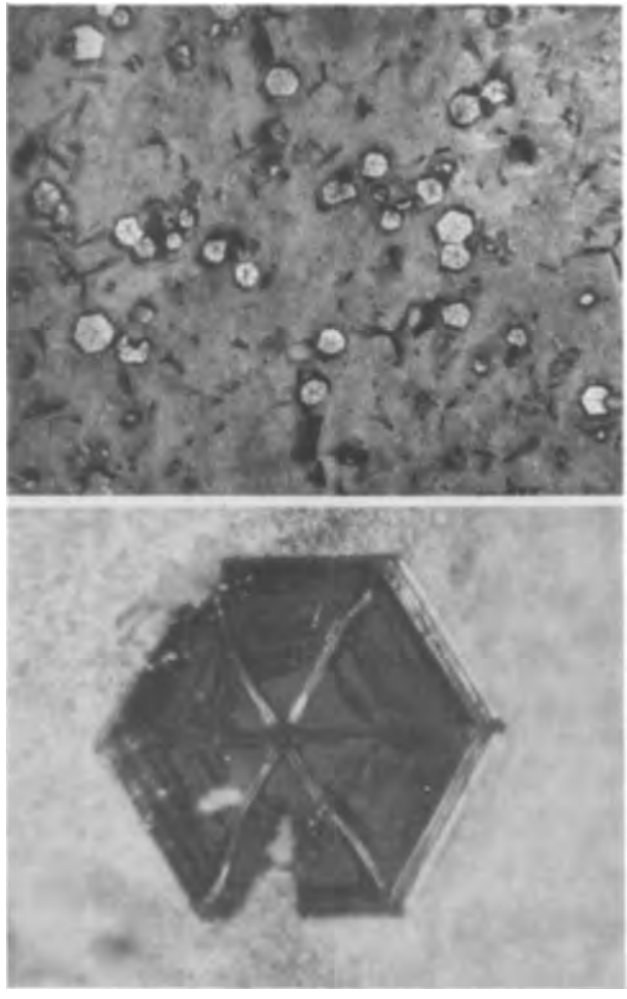

Fig. 4. Hexagonal CdS platelets, on the top surface of the Cd: (a) (top) magnification ca. 30X; (b) (bottom) ca. 260X.

It is clear from this initial attempt that it is feasible to grow crystals of CdS from Cd solution. With proper control of the thermal conditions and with proper seeding, it should be possible to grow well-defined large single crystals of CdS and the other high gap II-VI semiconductors at temperatures significantly below those used for vapor phase and melt growth.

Anodic Oxide Growth Behavior on Silicon

J. Kraitchman[1] and J. Oroshnik[2]

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

Phosphorous doped anodic oxides grown on silicon have previously been shown to be suitable n-type dopant sources (1). During diffusion drive-in, large out-diffusion losses can occur from these oxides. These out-diffusion losses can be prevented by using a nondoped anodic oxide as a shield (2). The nondoped anodic oxide is grown on top of the original phosphorous doped oxide by reanodizing in a KNO_2-tetrahydrofurfuryl alcohol (THF) solution to about twice the original forming voltage.

We have observed similar large out-diffusion losses during drive-in from boron doped anodic oxides grown on silicon (anodization in polyhedral borane acid-tetrahydrofurfuryl alcohol solutions). These out-diffusion losses from the boron doped oxides were not prevented by the technique used with the phosphorous doped oxides. Moreover, drastically reduced doping levels in the silicon after drive-in were obtained on samples which were reanodized in the KNO_2-THF solution. Experiments, to be described below, indicated that the neutral anodic oxide was growing underneath the boron doped oxide rather than on top of it. This growth behavior appears to be responsible for its failure to prevent out-diffusion losses from the boron doped oxides.

Borane anodic oxides and neutral anodic oxides can be distinguished by their etch rates in a structure-sensitive etch such as p-etch (3).

Experimental

Two types of samples were prepared. Both types of samples were first anodized in the borane acid-THF solution. In type I only part of the borane oxide was reanodized in the nitrite-THF solution. In type II the entire borane oxide plus an unanodized portion of the silicon was reanodized in the nitrite-THF solution.

The oxide regions were etched in a diluted form of p-etch (3 parts HF, 2 parts HNO_3, and 645 parts H_2O). Oxide thickness was determined by visual comparison with known standards. The standards were calibrated by multiple-beam interference techniques. A plot of oxide thickness as a function of total etch time yielded the etch rates, permitting identification and location of the faster and slower etching oxides within the reanodized region.

[2] Present address: Corning Glass Works, Raleigh, North Carolina.

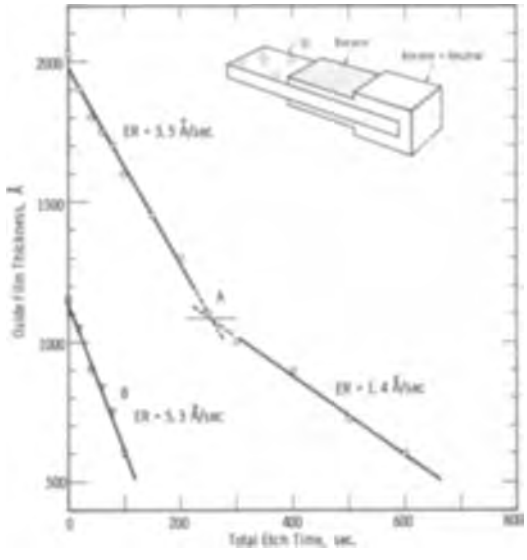

Fig. 1. Etch rate plot of a type I sample

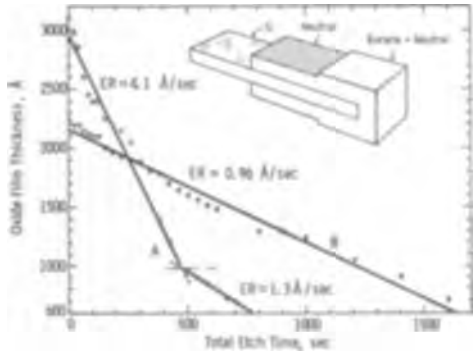

Fig. 2. Etch rate plot of a type II sample

An etch rate plot for a type I sample is shown in Fig. 1. In the reanodized region two different etch rates are readily distinguishable (see curve A). The upper layer has a rapid etch rate of 3.5 Å/sec. The lower layer has a slow etch rate of 1.4 Å/sec. Curve B is an etch rate plot of the region anodized only in the borane-THF solution, which has a rapid etch rate of 5.3 Å/sec.

Figure 2 shows the etch rate plot for a type II sample. This plot shows the same characteristics as the previous one. The upper layer of the reanodized region has a rapid etch rate of 4.1 Å/sec, while the lower layer has a slow etch rate of 1.3 Å/sec (see curve A). Curve B is a plot of the region anodized only in the nondoping solution, which has a slow etch rate of 1.0 Å/sec.

Results and Discussion

Table I is a summary of etch rates determined from rate plots for a number of samples of both types. This tabulation reveals that the etch rates of the oxide layers in the reanodized region lie between the limiting values characteristic of the rapid-etching borane anodic oxide, and the slow-etching neutral anodic oxide. The upper layer always etches somewhat slower than the free borane anodic oxides. Concurrently, the lower layer always etches somewhat faster than the free neutral anodic oxide.

Instead of the anticipated result of a slow-etching upper layer, and a rapid-etching lower layer in the reanodized region, exactly the opposite is obtained. This suggests that during the reanodization, growth

Table I. Summary of etch data on samples of both types

Sample type	Etch rate, Å/sec			
	Free* borane	Upper layer	Lower layer	Free* neutral
I	5.3 ± 0.3	3.5 ± 0.1	1.41 ± 0.06	
I	5.8 ± 0.3	5.1 ± 0.9	1.66 ± 0.07	
I	6.0 ± 0.3	5.2 ± 0.8	1.48 ± 0.07	
II		4.8 ± 0.2	1.85 ± 0.22	0.80 ± 0.02
II		4.1 ± 0.2	1.29 ± 0.04	0.96 ± 0.03

* Free, indicates an independent measurement of a single layer oxide taken simultaneously with the compound region measurements.

is not proceeding at the oxide-electrolyte interface by migration of silicon ions through the oxide. Instead, growth is proceeding at, or close to the oxide-silicon interface by migration of oxygen ions through the boron oxide.

In the boron doped oxides, the mobility of the oxygen diffusing species may be enhanced by the presence of boron. Oxygen migration in these oxides presumably occurs by diffusion of oxygen vacancies. Boron doping would be expected to increase the oxygen vacancy concentration in these oxides and thus increase the diffusion rate of oxygen vacancies.

The etch rate data also suggests that the upper layer is not "pure" borane anodic, and the lower layer is not "pure" neutral anodic oxide. While somewhat oversimplified, the following picture appears to explain the observed results. During reanodization, while oxide growth proceeds primarily by migration of oxygen (or an oxygen-bearing species) through the boron doped layer, some silicon migration also occurs. Thus, some nondoped oxide is grown within the boron doped oxide. Simultaneously, some boron doped oxide is trapped within the growing neutral layer. The result is an upper layer consisting essentially of boron doped oxide admixed with some neutral oxide, and a lower layer consisting essentially of neutral oxide containing a small amount of boron doped oxide.

In summary, etch rate measurements reveal the existence of two distinct layers. In reanodizing to a higher voltage in a nondoping solution "over" a preexistent borane anodic oxide, the nondoped oxide grows between the borane anodic oxide and the silicon. This is possibly the first known instance where anodic oxidation of silicon proceeds at, or close to the oxide-silicon interface. The upper, rapid-etching anodic oxide has been modified during reanodization so that it etches slower than a free borane oxide. The underlying, slow-etching anodic oxide etches somewhat faster than a free nondoped oxide.

Recrystallization of Germanium Thin Films on Insulating Substrates by Electron Beam Zone Melting

C. T. Naber

Research Division, McDonnell Company, St. Louis, Missouri

There is a need in thin film microelectronics for single crystal semiconductor thin films of device quality. Most previous attempts at attaining single crystal thin films on insulating substrates centered on an epitaxial process in which the crystalline properties of the deposited film are strongly dependent on the crystalline properties of the substrate. Recently, techniques of recrystallization of germanium films by electron beam zone melting have demonstrated interesting possibilities for the formation of large area single crystal thin films on both metallic and insulating substrates (1-5). The most successful results in obtaining large area single crystal germanium films on insulating substrates are reported by Maserjian (3) who formed single crystal thin film regions of approximately 0.6 mm^2 on single crystal sapphire substrates. In the research described here, attempts were made to form large area single crystal thin films of germanium on both single crystal and polycrystalline substrates by electron beam zone melting.

Germanium, which was specified intrinsic by the supplier and exhibited n-type conductivity by the hot-point probe technique, was evaporated from a tungsten boat in a vacuum of about 5×10^{-6} Torr onto substrates which were heated to about 500°C. The thicknesses of the films were between 50,000 and 200,000Å. After deposition, the films were placed in an electron beam processor where an electron beam of small cross section and appropriate intensity was scanned across an area of the film in a particular manner so as to create a process of melting and recrystallization. In order to reduce the thermal strains induced during processing, the film and substrate were preheated to about 600°C. A number of substrates were investigated; only polished sapphire and polished alumina were found to be compatible with electron beam zone melting of germanium films.

In one scan pattern investigated the electron beam was oscillated laterally over the film in a triangular wave fashion with a frequency of 0.5 cps and amplitude of about 5 mm and simultaneously swept along the film at slow speeds (0.1 to 1.0 mm/min) perpendicular to the direction of oscillation. The voltage and current of the electron beam were adjusted so that the beam power was sufficient to form a small circular molten zone in the film. Beam currents of about 0.5 ma and beam voltages between 25 and 35 kv were used for most of the films. Figure 1 shows regions of germanium films on sapphire and alumina processed in this manner after etching in WAg (6) along with x-ray back reflection Laue patterns. As can be seen, long slender crystal grains appear in the processed region. The spotty character of the germanium rings in the back reflection Laue pattern indicates the presence of relatively large crystal grains of various orientations. It was found that the size of the crystal grains formed in the processed region increased with increasing temperature of the heated zone during processing. The largest crystal grains were formed when the electron beam parameters were adjusted to heat the film to a temperature just below the value at which the molten zone would break into globules. The largest crystal grains observed were about 0.2 mm wide and 5 mm long.

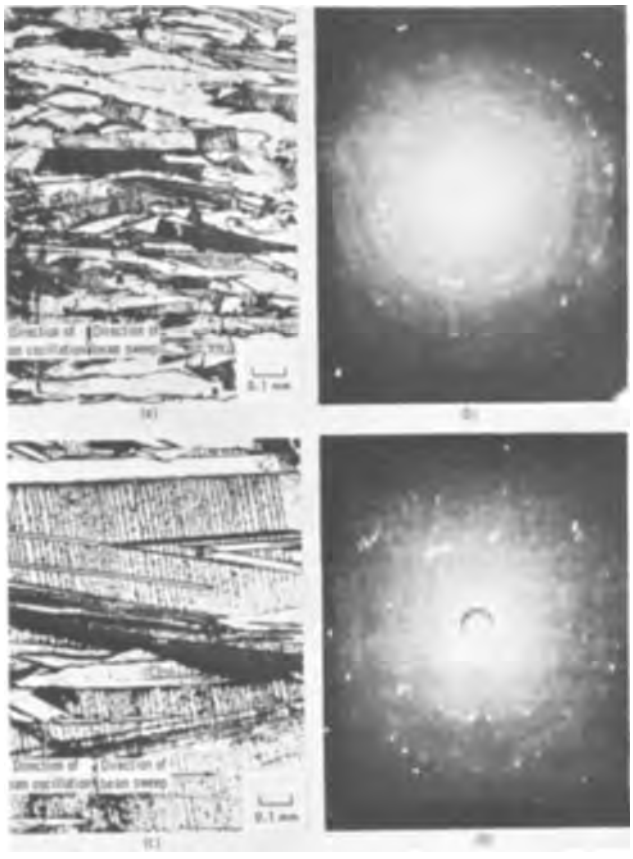

Fig. 1 (a). Photomicrograph of processed region of Ge film on polished alumina; (b) Laue back-reflection photograph of film in (a); (c) photomicrograph of processed region of Ge film on sapphire; (d) Laue back-reflection photograph of film in (c).

After deposition and prior to electron beam processing, all films exhibited p-type conductivity as determined by the hot-point probe technique. After processing, the regions that had relatively large crystal grains exhibited n-type conductivity while the regions that had relatively small grains exhibited p-type conductivity. Photomicrographs of sections of a germanium film on polished alumina after etching in WA_g with grain sizes characteristic of p-type and n-type conductivity are shown in Fig. 2(a) and 2(b). The region of the film shown in Fig. 2(a) which has smaller crystal grains than the region shown in Fig. 2(b) exhibited p-type conductivity while the region shown in Fig. 2(b) exhibited n-type conductivity. There is some question in the literature as to whether the p-type character of vacuum deposited germanium films is due to: (*i*) structural defects (7-10), (*ii*) impurities (11), or (*iii*) surface states (12, 13). Since the conductivity type of the film changed from p-type to n-type when the size of the crystal grains increased and since the regions of the film containing the larger crystal grains certainly have fewer structural defects than the regions containing smaller crystal grains, it appears that structural defects which act as acceptor centers are responsible for the p-type character of the films investigated.

Hall measurements at room temperature were made on a few processed and unprocessed films on sapphire. The Hall mobilities of the processed films ranged from as low as 50 $cm^2/(v\text{-}sec)$ with a charge carrier concentration of about 1.3×10^{17} cm^{-3} to as high as 1200 $cm^2/(v\text{-}sec)$ with a charge carrier concentration of about 6.7×10^{16} cm^{-3}. After the Hall measurements were made, the films were etched and were found to consist of a wide variety of crystal grain sizes. The largest crystal grains were observed in the film which exhibited a mobility of 1200 $cm^2/(v\text{-}sec)$.

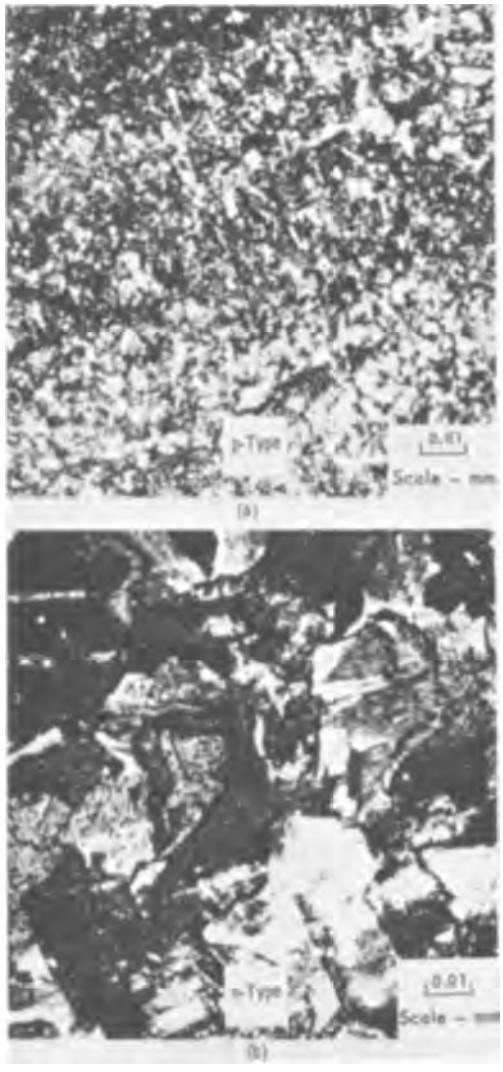

Fig. 2 (a). Photomicrograph of processed region of Ge film on alumina exhibiting p-type conductivity; (b). Photomicrograph of processed region of Ge film on alumina exhibiting n-type conductivity.

In another scan pattern, the electron beam was programmed to sweep across the film in a spiral with a frequency of rotation of about 0.5 cps. Figure 3 is a photomicrograph of a film processed in this manner

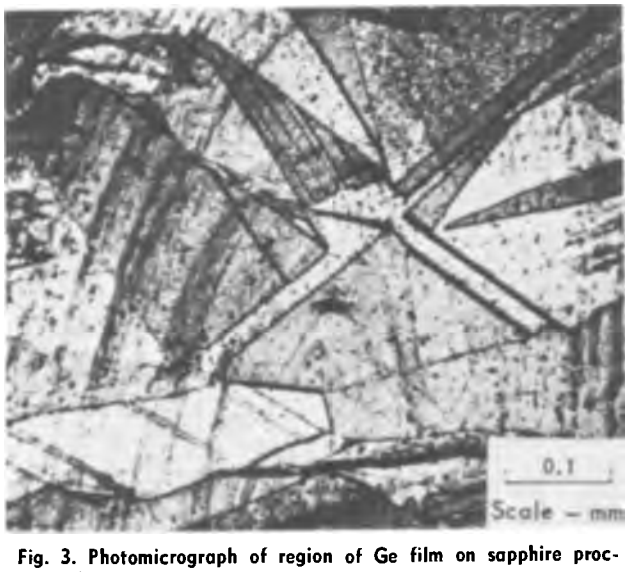

Fig. 3. Photomicrograph of region of Ge film on sapphire processed with spiral pattern.

after etching. As can be seen, relatively large crystal grains appear in the processed region.

The results of this research indicate that recrystallization can be induced in germanium films on insulating substrates by electron beam zone melting. Similar recrystallization effects were observed in germanium films deposited on both single crystal sapphire and polycrystalline alumina. This indicates the recrystallization process is independent of the crystalline properties of the substrate. The principal technological difficulty involved in the process is the maintenance of a stable molten zone through the entire thickness of the film.

Ohmic Contacts to GaAs by a Simple Low Temperature Alloying Process

D. K. Jadus, H. E. Reedy, and D. L. Feucht

Department of Electrical Engineering, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

Standard alloying techniques allow one to make good ohmic contacts to the elemental semiconductors, but they do not work well on gallium arsenide (1-3). In this report a simple low-temperature process is described for making shallow ohmic contacts to n-, ν, or p-type gallium arsenide. The contacts are made by alloying appropriate metallic spheres into bulk GaAs at temperatures between 300° and 450°C in an ambient of argon, hydrogen, and hydrogen chloride gas. The contacts obtained in this manner have very shallow penetration depths and thus offer significant advantages for contacting thin epitaxial layers of GaAs. Similar results using metal-halide fluxes have rerently been reported (4). The results described below show that good ohmic contacts using Sn spheres can be made to n-type GaAs having a bulk resistivity in the range of 0.012 to 10^8 ohm-cm at alloying temperatures as low as 300°C with a resulting penetration depth of less than 0.1μ. Shallow ohmic contacts were also made to p-type GaAs having a bulk resistivity of 0.0065 to 0.33 ohm-cm using Zn, In + 1% Zn and Cd spheres at alloying temperatures near the melting point of the spheres.

The alloying apparatus consists of a carbon strip hot stage with a Pyrex cover and gold or nickel plating on all metal parts in contact with the gas ambient. This gas ambient consists of Ar-15% H_2 gas plus approximately 5% high-purity anhydrous HCl gas,[1] delivered by noncorrodable tubing. The small HCl component serves to clean the spheres and promote wetting. Without HCl the spheres do not wet, adhere well, or make ohmic contact to the GaAs at these low temperatures. It is observed that at a temperature below the sphere's melting point a white haze, almost certainly the metal dichloride, appears on the sphere. This haze disappears abruptly as the sphere melts, and an extremely bright surface on the sphere is observed. It is possible that this process is microscopically identical to that of Schwartz and Sarace (4) in that the metal dichloride is formed and serves as the flux; however, no observable deposit of metal halide remains after the alloying cycle is completed.

To make a contact, the clean GaAs wafer is placed on the carbon strip and one or more clean spheres are placed on the surface to be alloyed. The Pyrex cover is placed over the carbon strip assembly and sealed, and the assembly is purged by flowing about 100 alloy stage volumes of Ar-15% H_2 through the stage. The Ar-H_2 flow is reduced to 1 vol/min and 2-5% by volume of HCl is added to the gas flow. After 5 volumes of flow, the carbon strip temperature is raised quickly to the alloying temperature for 1-5 sec, and then allowed to cool. The HCl is purged, and the sample is removed.

For the alloy contacts reported here, the GaAs was lapped, moderately etched in methanol-0.5% bromine, rinsed in methanol and trichlorethylene, and stored in trichlorethylene until used. The alloy spheres were cleaned in dilute HCl, rinsed in distilled water and methanol and stored in trichlorethylene. Alloy contacts to unetched, but organic solvent cleaned epitaxial GaAs layers yield identical results.

The following characteristics of the alloy contacts were investigated: penetration depth, area wetted by the sphere for a given temperature and substrate orientation, and maximum current density or electric field strength obtainable in the GaAs without departing from an ohmic relation at the contact.

Metallurgical evidence on the penetration depth into commercial GaAs was obtained by preparing alloyed samples under conditions known to result in ohmic contacts, and either sectioning and lapping perpendicular to the direction of alloy penetration or removing the alloy dot from the surface by etching in HCl. A typical Sn contact alloyed at 400°C for 5 sec in the (111)As face of n-type GaAs, is shown sectioned and lapped to a 1μ finish in Fig. 1a. A similar Sn contact alloyed at 300°C in the same (111)As face is shown sectioned and lapped to a 1μ finish in Fig. 1b at a greater magnification. The alloy penetration depth into the sample at 400°C is 7.5μ, but no penetration is apparent for the 300°C case. Figure 2a is a view of the

[1] Precision Gas Products Inc., Linden, New Jersey.

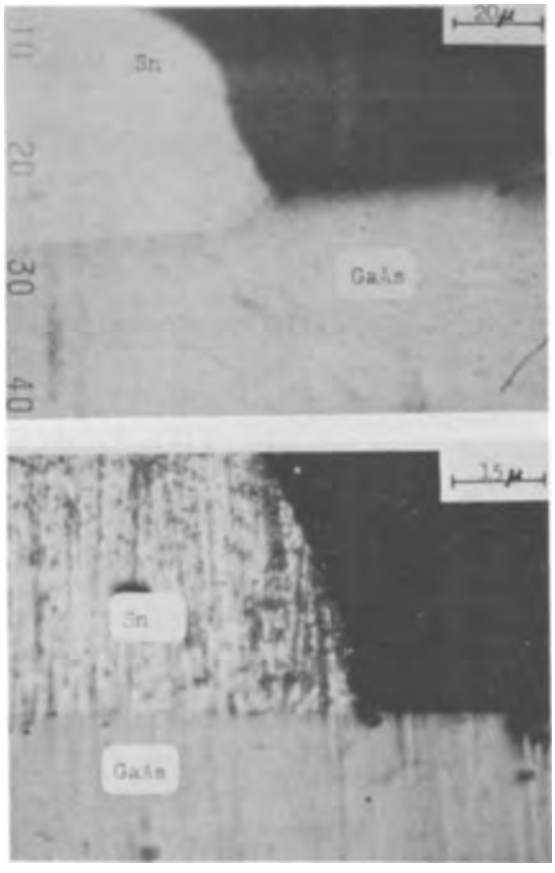

Fig. 1. Cross-section of Sn alloy on (111)As face of GaAs at: a *(top)* 400°C, b *(bottom)* 300°C.

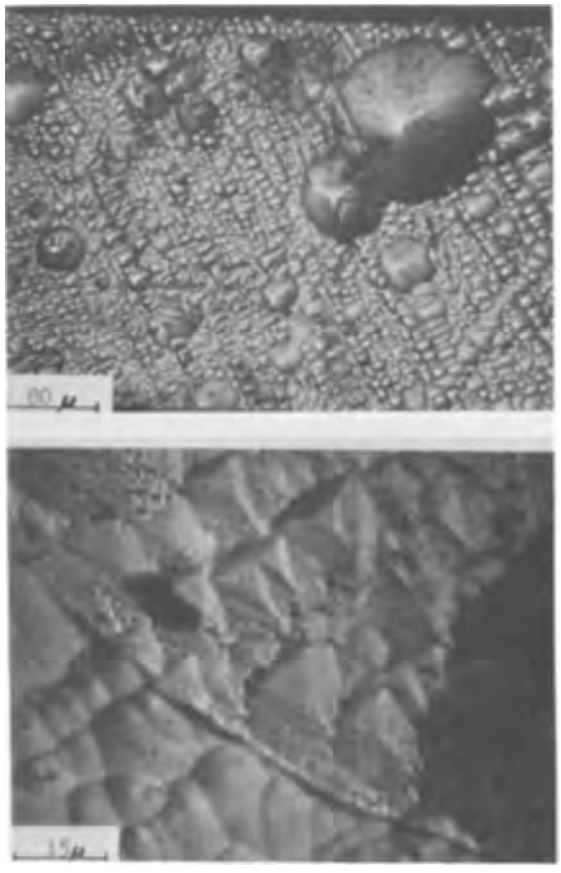

Fig. 2. Surface of (111)Ga face after alloying at 300°C and removal of the Sn dot to show wetted area: a *(top)* 200x, b *(bottom)* 1100x.

(111)Ga face of GaAs after a 300°C alloy and dot removal in acid. The outer ring is the boundary of the area wet by the 10 mil Sn sphere and is approximately 9.7 x 10^{-3} in. in diameter. A section of the region of the alloyed area is shown in greater magnification in Fig. 2b. The portion of this wafer inside the curved line was wetted by the Sn, the exterior was not. The significant observation is that this ohmic contact has not visibly altered the surface structure of the sample. Photographs of the alloyed face prepared as in Fig. 2 for the crystal orientations (111)As, (110), (100), and (111)Ga show that under identical conditions at 300°C a 10 mil Sn sphere wets an area of diameter 15.6, 10.7, 10.7, and 9.7 mils, respectively, with a deviation of less than ±0.5 mils. Holding the contact at these alloying temperatures for several minutes does not visibly increase the wetted areas.

A typical Zn contact alloyed at 430°C for 2 sec to p-type GaAs is shown sectioned and lapped to a 1μ finish in Fig. 3. No alloy penetration is evident, and furthermore there is no perceptible difference in wetted area on the (111)Ga or (111)As faces.

The electrical contact to heavily doped n GaAs was evaluated by determining the maximum current density that was achievable without departing from ohmicity. For 10 mil Sn spheres alloyed at 300°C on the (111) faces of 0.012 ohm-cm GaAs the i-v characteristics of the structure remained linear at a current density of 1.5 x 10^4 amp/cm^2. The measurements were made using 2 μsec pulses on a structure in which the current density was approximately uniform. For Sn spheres alloyed at 250°C the contacts had high resistance and were unreliable.

The electrical contact to n type GaAs in the resistivity range appropriate for Gunn effect devices is described by experiments on 100 ohm-cm GaAs. The nonlinear i-v characteristics and large temperature coefficient of resistance reported (5) and confirmed by our observations for bulk GaAs in this resistivity range necessitated a more careful study of the nature of the contacts. For this investigation the voltage measured at a contact carrying current was compared to the voltage measured at an adjacent noncurrent carrying contact as a function of voltage level. For 5 mil Sn spheres alloyed at 300°C these two voltages were directly proportional up to a field strength in excess of 2000 v/cm in the bulk material. From these measurements it is clear that the voltage drop of the current carrying contact must be quite small compared to the bulk drop. Gunn effect devices have not been made to determine if this contact shows any improvement over present contacts. Similar alloy contacts to 4 ohm-cm GaAs also appeared to be ohmic, although because of heating it was impossible to obtain a large field or high current density in the bulk material.

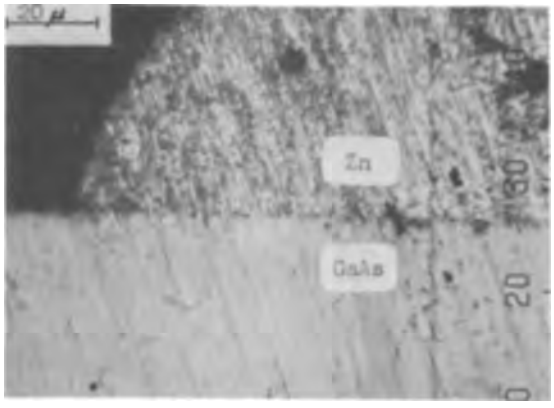

Fig. 3. Cross section of Zn alloy on (111)As face of GaAs at 430°C.

The extent to which an ohmic contact may be made to semi-insulating GaAs was tested using commercial 10^8 ohm-cm material with Sn spheres alloyed on the opposite faces at either 300° or 400°C. The i-v characteristic of such a device is linear up to 10^4 v/cm at room temperature in the dark. When illuminated strongly by a microscope lamp at room temperature the current for a particular voltage is much increased and is related to the voltage by $I = KV^2$ up to 5×10^3 v/cm indicating space charge limited flow. The contact photovoltage due to the same intensity of illumination is less than 5 mv, indicating that the contacts do not add any appreciable voltage drop.

Ohmic contacts to p-type GaAs were obtained by the same alloying technique using Zn, In + 1% Zn or Cd spheres at an appropriate temperature. In order to obtain good ohmic contacts with Zn, it was necessary to alloy the Zn spheres at approximately 430°C (10°C above the melting point) for 1 to 2 sec, in order to limit the formation of Zn_3As_2 (4). Good ohmic contacts, capable of carrying greater than 800 amp/cm^2, on 0.33 and 0.0065 ohm-cm p-type GaAs, were obtained using this technique. Ohmic contacts were also obtained on p-type GaAs by alloying In + 1% Zn spheres at approximately 160°C. Although ohmic contacts may be made to p-type GaAs using Cd spheres they must be alloyed at 400°C (considerably above their melting point) in order to obtain wetting.

GaAs alloy diodes were made using the above techniques on n- and p-type GaAs. When Sn spheres were alloyed to p-type GaAs at 500°C good diodes were obtained on 0.33 ohm-cm material similar to the results of Schwartz *et al.* (4). On 0.0065 ohm-cm p-type GaAs, however, nonlinear resistors resulted. In and In + 1% Zn spheres alloyed into 0.012 ohm-cm n-type GaAs just above their melting points yielded good GaAs diodes also. When using the Zn spheres, however, it was determined that in order to obtain an ohmic contact with Sn following the Zn alloy it was necessary to etch the sample lightly.

Epitaxial Deposition of GaAs in an Argon Atmosphere

R. C. Taylor

IBM Watson Research Center, Yorktown Heights, New York

Of the several methods currently available for epitaxial deposition of GaAs, the open tube method using Ga and $AsCl_3$ in a hydrogen atmosphere has given material with the best electrical properties to date for applications such as Gunn effect devices (1). In the present investigation, argon was substituted for hydrogen as the carrier gas. There are several potential advantages suggesting the use of argon for the purpose of obtaining better and more reproducible films. Among these are: substitution of an inert species for a reactive one to eliminate at least one reaction from the system, substitution of a heavier carrier gas to minimize the density differential between the carrier and the reacting species and decrease any compositional gradient existing in the gas phase, and elimination of the hydrogen reduction of quartz as a source of silicon contamination to give a purer GaAs deposit.

Experimental

The apparatus and procedures used were similar to those employed by other investigators of the Ga-$AsCl_3$ system (2, 3) the principal difference being the use of argon throughout in place of hydrogen. The main part of the apparatus was a 30 mm ID quartz reactor tube into which was inserted a 25 mm ID quartz liner to facilitate loading and cleaning. The reactor tube extended through a high-temperature (source) zone in which the temperature was uniform to within 1°C for 3 to 4 in., and a downstream low-temperature substrate (deposition) zone in which the temperature gradient was 10°C/in. Pure argon was metered into the reactor through two stainless steel and quartz lines, one line going directly into the reactor and the other through a quartz bubbler containing $AsCl_3$ where saturation of the gas stream took place. Exhaust gases passed out of the reactor at the downstream end through a quartz end cap into an oil bubbler. Source and substrate holders were of quartz, the substrate holders being platforms attached to thermocouple tubes which could be positioned through a Teflon seal in the exhaust cap.

The Ga source temperature was maintained at either 800° or 850°C for the argon runs and at 850°C for comparative hydrogen runs. GaAs substrate temperatures varied with the $AsCl_3$ flow rate but were normally 650°-700°C during argon runs and 700°-750°C during hydrogen runs. The $AsCl_3$ bubbler was at 25°C. Temperatures were controlled to within 1°C during a run. The flow of argon through the $AsCl_3$ was varied over a range which resulted in a flow of 3×10^{-4} to 3×10^{-3} moles/hr of $AsCl_3$. All materials employed in the runs were of a minimum purity of 99.999% and were used without further purification.

After polishing the GaAs substrates (Czochralski crystals, Cr doped), the Ga source and the substrates were weighed and loaded into the reactor which was then flushed with argon at a high flow rate. After flushing, both source and substrates were raised to the source temperature and the substrates were vapor-etched in a high Ar/$AsCl_3$ flow. The flow rate was then lowered to a normal deposition rate and the substrates lowered to deposition temperature. Deposition usually proceeded overnight after which the $AsCl_3$ flow was terminated, the temperatures were measured, and the furnaces shut off. The films were removed at a low temperature. Under the proper conditions, mirror smooth films with thicknesses ranging from 1 to 15 mils were grown with crystallographic quality equal to those grown in hydrogen.

Table I. Effect of substrate temperature on growth rate.

Carrier gas	$AsCl_3$ flow, moles/hr	Substrate orientation	Max. growth rate temp, °C	Max. growth rate, μ/hr	Temp range for epitaxy, °C
Ar	3×10^{-4}	10° off 111A	650	20	540-680
Ar	1.5×10^{-3}	5° off 111B	700	35	580-730
H_2	1.5×10^{-3}	5° off 111B	750	25	640-780

Chemical analysis of the byproduct condensate was performed by dissolving the material in an aqueous 5% sodium hydroxide solution and titrating for Ga with EDTA and for Cl with AgSCN.

Results and Discussion

Effect of substrate orientation and temperature on growth rate.—Substrates with nine different orientations were studied in argon. The growth rate decreased in the order: 10° off 111A, 7 °off 110, 110, 100, 10° off 111B, 5° off 111A, 5° off 111B, 111A, and 111B. Under flow conditions of 3×10^{-4} moles/hr of $AsCl_3$ in 25 cc/min of argon the growth rate at a substrate temperature of 650°C varied from 20 μ/hr on 10° off 111A to 4 μ/hr on 111B. Since the ratio of arsenic in the vapor to the amount of Ga being formed by GaCl disproportionation is 1 : 1, one can expect the growth rate to be fastest on stoichiometric surfaces. This is found to be true with the basic planes of *110*, *100*, and 111. When the orientation is a few degrees off of a basic plane, the high-index plane that results has a surface composed of a large number of small steps. The stepped structure consists of "treads" and "risers" which are made up of the basic planes (4). Deposition on such a surface should be energetically favored with the result that a plane a few degrees off of a basic plane would have a higher growth rate than the basic plane. This is also seen to be true.

Several runs were made to establish the dependence of growth rate on substrate temperature. The results of two argon runs and a comparative hydrogen run are shown in Table I. The source temperature was 850°C. Above the high-temperature limit for epitaxial deposition etching took place, while below the low-temperature limit the film was polycrystalline. In all cases epitaxial growth occurred over about a 150°C temperature range with the temperature of maximum growth rate about 30°C below the high-temperature limit for epitaxy. Increasing the $AsCl_3$ flow rate increased both the growth rate and the temperature for maximum growth rate, and under identical conditions growth in the hydrogen system took place 50°C higher than in argon. Growth rate fell off very rapidly at temperatures above the maximum growth rate temperature due to less supersaturation of the gas phase and possibly some substrate etching or vaporization. It fell off at lower temperatures, but much more slowly, due to a reduced reaction rate of Ga (or GaCl) and As at the substrate surface. The temperature of maximum growth rate was independent of source temperature over the range studied and independent of substrate orientation.

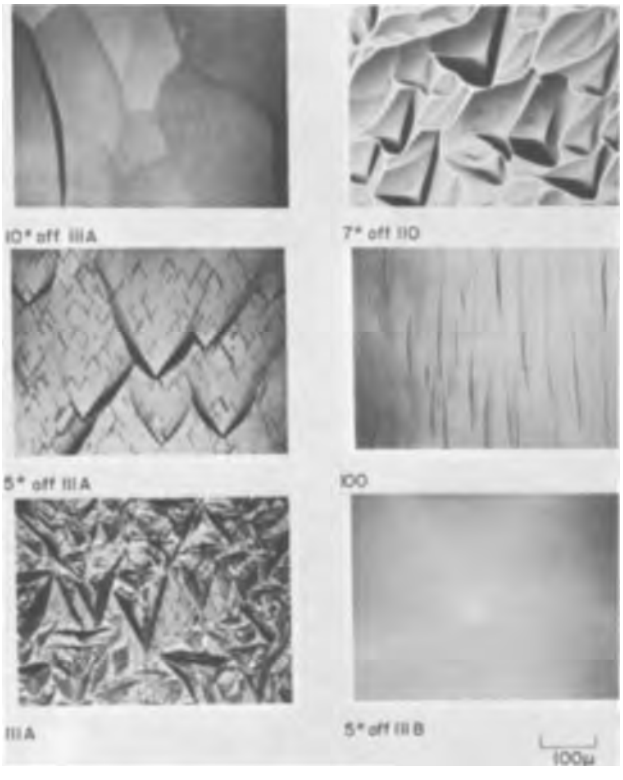

Fig. 1. Effect of substrate orientation on film surface morphology

Effect of substrate orientation and temperature on film surface.—The effect of substrate orientation on the appearance of the deposit was studied for all nine of the aforementioned orientations in the argon system. Films were grown at the maximum growth rate temperature of 650°C at a flow rate of 3×10^{-4} moles/hr of $AsCl_3$. Several of the argon system, as-grown, surfaces are shown in Fig. 1. It can be seen that the pits and stacking faults which are abundant in films deposited on substrates oriented on 111A or 5° off 111A, are not observed in a film deposited on a 10° off 111A substrate. Similar observations were made by Gabor (5) on GaAs films grown on germanium and his explanation of the observations with regard to independent nucleation on two sides of a stacking fault followed by film propagation may apply equally well here. Growth on substrates oriented 5° off 111B resulted in mirror-smooth films which were far superior to those on all other orientations. It is believed that the etching effect of the $AsCl_3$ vapor is the main factor in determining film surface morphology. One would therefore expect some differences in the films grown in hydrogen since in that case the etchant is HCl produced by hydrogen reduction of the $AsCl_3$ (3).

A study was made in the argon system of the effect of substrate temperature on film surface morphology with films of equal thickness on substrates oriented 10° off 111A, grown with an $AsCl_3$ flow of 3×10^{-4} moles/hr. Growth occurred on the substrates over the temperature range of 540°-680°C. At 540°C a grainy, polycrystalline film resulted which converted at a slightly higher temperature to an epitaxial film with severe pitting. As temperature increased, the pits (conical in shape as in Fig. 1, 5° off 111A) diminished in number and increased in size, finally becoming shallow depressions in a fairly smooth film at about 640°C (see Fig. 1, 10° off 111A). At 680°C continuous growth no longer occurred, only occasional epitaxial islands being present. In a similar study made on substrates that were oriented 5° off 111B no pitting occurred, all films being relatively smooth, with mirror like surfaces at the higher temperatures. Apparently the reason for this is that the $AsCl_3$ vapor used in the vapor etch preferentially pits the 111A surface but polishes the 111B. Thus the surface morphology of the film is determined primarily by substrate vapor etching, and the degree of conformity to the substrate surface is determined by the surface mobility of the depositing atoms as a function of substrate temperature.

Transport reactions of the system.—In both the argon and the hydrogen systems, the ratio of the amount of gallium transported from the source to the amount

Table II. Proposed intermediate reactions.

Reaction	Hydrogen	Argon
$AsCl_3$ reduction	$2AsCl_3 + 3H_2 \rightarrow 6HCl + \frac{1}{2}As_4$	
Ga transport	$6HCl + 5Ga \rightarrow GaCl_2 + 4GaCl + 3H_2$	$5Ga + 2AsCl_3 \rightarrow GaCl_2 + 4GaCl + \frac{1}{2}As_4$
Dichloride red.	$GaCl_2 + \frac{1}{2}H_2 \rightarrow GaCl + HCl$	
Disproportionation	$5GaCl \rightarrow 2\frac{1}{2}GaCl_2 + 2\frac{1}{2}Ga$	$4GaCl \rightarrow 2GaCl_2 + 2Ga$
Deposition	$2\frac{1}{2}Ga + \frac{1}{2}As_4 \rightarrow 2GaAs + \frac{1}{2}Ga$	$2Ga + \frac{1}{2}As_4 \rightarrow 2GaAs$

Table III. Electrical properties of GaAs films.

Carrier gas	Resistivity, ohm-cm		Mobility, cm^2/v-sec		Carrier conc, $1/cm^3$	
	298°K	77°K	298°K	77°K	298°K	77°K
H_2	1.6	0.5	6700	32000	6×10^{14}	4×10^{14}
Ar	1.3	0.8	5200	12000	1×10^{15}	6×10^{14}

of $AsCl_3$ introduced into the system was found to be approximately 5/2. To arrive at equations for the over-all reactions, analysis of the byproducts was carried out.

Hydrogen system.—In runs where flow conditions were such that no deposition of GaAs took place, the entire amount of Ga transported from the source was recovered at the exhaust end of the reactor as metallic Ga and as a gallium chloride; 50% was recovered as metallic Ga and 50% as a white chloride. The chloride was identified as the dichloride, $GaCl_2$, rather than the trichloride claimed by other investigators of this system (2, 3). Identification was made from the analytically determined Ga/Cl ratio of 1/2, and by the approximate melting point. The chloride was found to condense as a solid in the temperature range of 150°-200°C. The melting point of the trichloride is 77°C and of the dichloride, 170°C (6). When flow conditions were such that epitaxial deposition of GaAs took place, 50% of the Ga from the source was still recovered as the dichloride, but the amount of metallic Ga byproduct was reduced proportionately to the amount of GaAs deposited. The over-all reaction in the hydrogen system may therefore be expressed as

$$5Ga + 2AsCl_3 + \tfrac{1}{2}H_2 \rightarrow 2\tfrac{1}{2}GaCl_2 + 2\tfrac{1}{2}Ga + HCl + \tfrac{1}{2}As_4 \quad [1]$$

with the gallium and arsenic products that appear in elemental form decreasing as GaAs is formed. It can be seen that there will always be some excess Ga as a byproduct.

Argon system.—In the argon runs there was never any metallic Ga as a byproduct. It always appeared as GaAs. Under all flow conditions, 60% of the Ga removed from the source was recovered as a $GaCl_2$ byproduct. The over-all reaction may be expressed as

$$5Ga + 2AsCl_3 \rightarrow 3GaCl_2 + 2GaAs \quad [2]$$

The amount of GaAs appearing as an epitaxial deposit and the amount appearing as a polycrystalline byproduct was determined by temperature and flow conditions.

Although there is not enough data to establish conclusively the intermediate reactions occurring in the system, nor to preclude the formation of $GaCl_3$ (which could recombine with Ga at a low temperature to form $GaCl_2$), the intermediate reactions leading to the above over-all reactions may be proposed tentatively on the basis of the observations made. They are shown in Table II based on $GaCl_2$ and GaCl as the dominant gallium chloride species. The As_4 vapor initially produced is dissolved by the Ga until saturation occurs. In both systems, the rate of formation and transport of gallium chlorides is constant throughout the runs, both during and after saturation of the Ga with As_4. There might also be additional hydrogen reduction of GaCl at a higher temperature than where disproportionation occurs, accounting for the fact that under equal conditions deposition in the hydrogen system occurs 50°C higher than in the argon system.

Electrical properties.—Electrical properties were measured on the films grown in both the argon and the hydrogen systems. The results are shown in Table III for a 3 mil thick film grown in argon at 700°C and a 5 mil thick film grown in hydrogen at 750°C. Both were grown on semi-insulating GaAs substrates oriented 5° off 111B. The hydrogen system film was grown at a higher $AsCl_3$ flow rate than the argon system film. Considering the differences in growth conditions and the lack of additional purification procedures, the results are comparable. It seems probable that with the higher purity potentially obtainable in the argon system due to lower growth temperature and reduced silicon contamination, the electrical quality of films grown in argon can eventually surpass that of films grown in hydrogen.

Brief Communications

Determination of Microscopic Rates of Growth in Single Crystals

August F. Witt and Harry C. Gatos

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

In our studies (1) as in those of others (2) it has become apparent that the various impurity heterogeneities in the form of periodic or random striations or in the form of an impurity "core" in single crystals pulled from the melt are intimately associated with the microscopic rate of growth. No method has been available for the direct determination of the microscopic rates of growth as a function of time and location in the solid-melt interface. The present communication reports on the development of such a method.

We have introduced in the melt high frequency (of the order of 50 Hz) and low amplitude vibrations without altering the growth characteristics of the crystal. Such vibrations are reflected in the crystal in the form of very sharp impurity striations superimposed on the regularly appearing impurity or other heterogeneities. From the known frequency of the vibrations and the separation of the resulting striations one can readily determine the microscopic rates of growth. Appropriately prepared cross sections of the single crystals (or polycrystals) allow the analysis of the growth process in the various parts of the interface as a function of time. By employing suitable etching techniques and interference contrast or dark field microscopy, striations 0.2μ apart can be distinguished. This distance represents the limit of light microscopy resolution. The distance between two striations under the growth conditions of the crystal depicted in Fig. 1 corresponds to growth which has taken place in 1/20 sec. Higher frequencies (of the order of 100 Hz) have been successfully employed. There appears to be no reason for setting an upper limit to the useful frequency range. It is believed that the increased resolution of electron microscopy will lead to a significant decrease in the observable growth time intervals.

We have developed this method employing InSb and pulling from the melt by a Czochralski-type technique. Small amounts of tellurium (of the order of parts per million) were introduced in the melt as the detecting impurity. The high-frequency vibrations were introduced by coupling (contacting) a vibrating rod to the crucible containing the melt. A signal generator and an audio amplifier were used as the source of the known frequencies. Vibrations can also be introduced electrically, eddy currents. Crystals were pulled with and without rotation. By introducing and then discontinuing repeatedly the high frequency vibrations during the growth of a large number of crystals it was shown that the vibrations do not interfere with the growth characteristics under study.

Two typical instances of the use of the high frequency vibrations are shown in Fig. 1 and 2. It is seen in Fig. 1 that the separation of the striations due to the constant frequency of vibrations reaches a maximum between two successive rotational striations in the "off core" region. The separation then decreases, and near the rotational striation no vibrational striations are visible. Obviously, the rotational striations are associated with a very slow microscopic rate of growth and in fact with remelting. It is also apparent from Fig. 1 (immediately before and after each rotational striation) that the microscopic rate of growth is smaller in the "core" region than in the "off core" region. The curved lines on the figure reflect interference of the introduced vibrations with random vibrations present in the experimental arrangement.

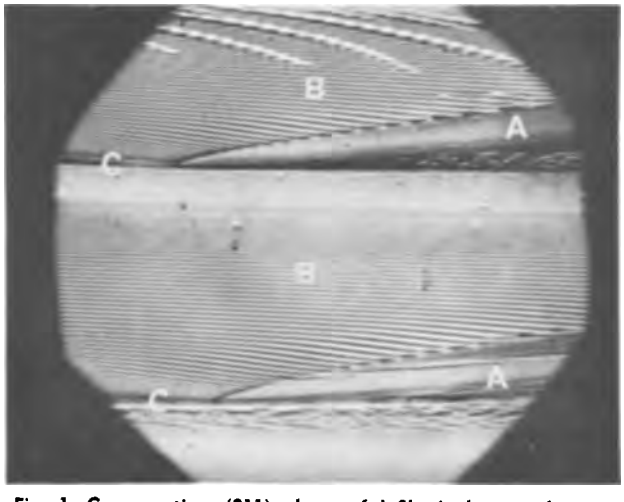

Fig. 1. Cross section, (211) plane, of InSb single crystal grown in the <111> direction. A, "core" region of crystal (see for details Witt and Gatos, *This Journal, 113*, 808 (1966); B, "off core" region of crystal; C, rototional striations (remelt lines). Growth direction is perpendicular to the "core" A. Striations due to the high frequency vibration (20 Hz) are clearly shown. Magnification ca. 600X.

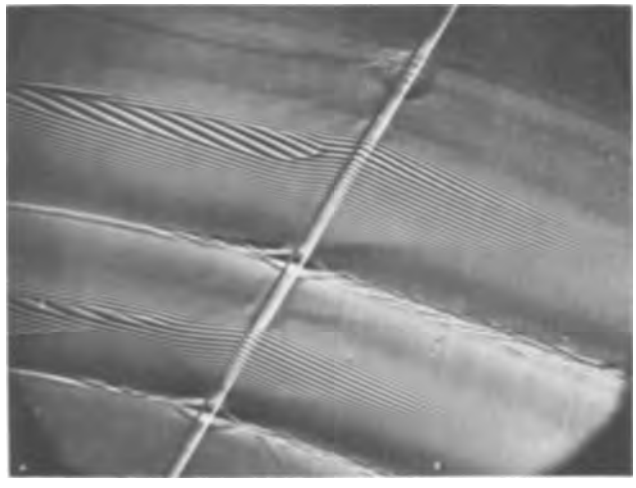

Fig. 2. Cross section, (211) plane, of InSb crystal grown in the <111> direction (orientation as in Fig. 1). Twin boundaries are clearly visible. Magnification ca. 600X.

Figure 2 depicts the presence of a twin in the grown crystal. It should be noted that striking differences in the rate of growth can be seen on either side of the twin boundary and for quite some distance away. No quantitative analysis will be presented here. Although not shown in the figure it is of interest to point out that before the twin appears there is a disturbance in the microscopic rate of growth.

We believe that the present method can serve as a unique tool in observing variations in growth conditions at the solid-melt interface. It can further provide quantitative information regarding the incorporation, distribution of impurities during crystal growth and the formation of crystal defects, orientation effects, and other aspects of the solidification process in general.

Observation of Etching of n-Type Silicon in Aqueous HF Solutions

S. M. Hu and D. R. Kerr

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

This note reports the observation of the etching in silicon in aqueous solutions of hydrofluoric acid. Measurements were made on n-type, 2 ohm-cm wafers of <111> orientation with HCl vapor-etched surfaces. After masking a portion of the surface with wax, wafers were placed in HF solutions at 25°C for periods on the order of 15 hr. In this time sharp steps were obtained which were measurable by Tolansky interferometry to an accuracy of ±50Å after evaporation of aluminum to increase reflectivity. For concentrated (48%) HF a rate of 0.3 Å/min was observed. To be assured that this etching action was not caused by the presence of dissolved molecular oxygen in aqueous HF solution, anti-oxidant hydroquinone was added to the solution. Again, the etching was observed. The independence of the etching process on dissolved oxygen was also shown by the fact that continuous bubbling of oxygen through dilute HF did not change the etch rate. It was further found that concentrated (48%) HF solution etched silicon at a lower rate than dilute HF solution. We then concluded that the etching action is most probably caused by the oxidation of silicon by the hydroxyl ions in the aqueous solution.

It is obvious, from the extreme disparity between the etch rates of SiO_2 and silicon, that the oxidation of the silicon must be the rate-controlling step in the silicon etching with SiO_2 being removed as fast as it is formed. One then expects that the silicon etching rate should be a function of the OH^- ion concentration, provided there are no other oxidants present in the solution. A number of solutions were prepared without any other oxidants except the variation of OH^- concentration by means of dilution by pure water as well as by adding hydrochloric acid, sodium fluoride, and sodium acetate. The solution compositions, the calculated OH^- ion concentrations, and the observed etch rates are given below:

Composition of solution	[OH-], moles/l	Etch rate, Å/min
H_2O 96 cc + HF (48%) 4.5 cc + HCl (40%) 8 cc	10^{-14}	0.29
HF (48%)	10^{-13}	0.30
H_2O 40 cc + HF (48%) 10 cc	2×10^{-13}	0.47
H_2O 40 cc + HF (48%) 10 cc + $NaC_2H_3O_2$ 3g	3×10^{-12}	0.59
H_2O 96 cc + HF (48%) 2.0 cc + NaF 4.3g	3.5×10^{-11}	0.78

Results are plotted in Fig. 1. As seen from the results, the dissolution rate of the silicon is far from directly proportional to the OH^- ion concentration in the aqueous solutions. It appears that the reaction between OH^- ions in the solutions and the silicon proceeds via an intermediate step of adsorption, which occurs very fast. The rate-controlling step is then the reaction between the adsorbed OH^- and the silicon surface. Let us assume that this reaction rate is proportional to the surface concentration of adsorbed [OH^-]. If the adsorption followed a Langmuir isotherm, one would expect $r = dc/(1 + gC)$ where r is the etch rate, C is the [OH^-] concentration in the solution, and d and g are constants. As seen in Fig. 1 such a function does not fit the data. Over a certain range of [OH^-] concentration, however, adsorption could follow a Temkin isotherm (1). This would give $r = a + b \log C$, which follows the data more closely.

ELECTROCHEMICAL SCIENCE

The Alkaline Manganese Dioxide Electrode

I. The Discharge Process

David Boden, C. J. Venuto, D. Wisler, and R. B. Wylie

The Electric Storage Battery Company, Carl F. Norberg Research Center, Yardley, Pennsylvania

ABSTRACT

The cathodic reduction of γ-MnO_2 in alkaline electrolyte has been studied by examination of constant current discharge curves, by x-ray diffraction and by chemical analysis. The reaction has been shown to take place by a three-step process whereby an amorphous intermediate is formed by assimilation of protons in the γ-MnO_2 lattice. As reduction proceeds the intermediate crystallizes to give Mn_3O_4 and finally $Mn(OH)_2$ depending on the electrode potential. The rapid increase in electrode resistance at approximately half of the capacity has been related to the formation of interfacial films of Mn_3O_4.

The cathodic reduction of γ-MnO_2 in alkaline electrolyte has been the subject of considerable investigation (1-6).

Cahoon and Korver (2) on the basis of x-ray crystallographic and chemical analyses concluded that the reaction proceeded by three steps. First, the manganese dioxide is reduced simultaneously to Mn_4O_7 and $Mn(OH)_2$. The second step is the reduction of Mn_4O_7 to Mn_3O_4 and $Mn(OH)_2$, and the final step is the reduction of Mn_3O_4 to $Mn(OH)_2$.

The existence of Mn_4O_7 and $Mn(OH)_2$ at the start of discharge was questioned by Bell and Huber (4) who, based on x-ray diffraction analysis, found no evidence of these compounds. It was postulated that this was perhaps attributable to the different current densities employed in the two studies. They concluded that the reaction proceeded by the homogeneous reduction of γ-MnO_2 to $MnO_{1.7}$ followed by the heterogeneous phase reduction of $MnO_{1.7}$ to $MnO_{1.47}$ and finally the heterogeneous reduction of $MnO_{1.47}$ to $Mn(OH)_2$. In this study $MnO_{1.7}$ was identified as MnO(OH) and $MnO_{1.47}$ as γ-Mn_2O_3.

It was pointed out by Kozawa and Yeager (5) that both of these studies were conducted with standard alkaline MnO_2 cells containing zinc electrodes which could possibly lead to complications in interpreting the results. In addition to this, the electrodes were subjected to a rigorous washing and drying procedure before analysis which may have caused changes in their chemical composition. Kozawa and Yeager concluded that the reaction proceeded by two steps, the first being the reduction of MnO_2 to MnO(OH) and the second the reduction of MnO(OH) to $Mn(OH)_2$.

The clear differences in the above results suggest that further work should be done to clarify the course of the discharge reaction. In the present work the cathodic reduction of γ-MnO_2 in alkaline electrolyte is interpreted on the basis of discharge curves, chemical and x-ray diffraction analysis.

Experimental

The electrodes were prepared by compacting 1g of a mixture containing 87.5% electrolytic MnO_2 and 12.5% micronized graphite around a platinum wire at 5279 kg · cm^{-2}. The electrodes were cylindrical in shape having the dimensions 0.635 cm in diameter by 0.635 cm in height. Available oxygen analyses conducted by the arsenous acid method (7) indicated that the sample of MnO_2 used had an empirical formula of $MnO_{1.92}$ giving the electrodes a nominal capacity of 0.45 amp hr based on the following discharge reaction

$$MnO_{1.92} + 1.92H_2O + 1.84e = Mn(OH)_2 + 1.84\,OH^- \quad [1]$$

The electrodes were discharged at 5 ma · cm^{-2} in 7M KOH solution at 25°C. The cell used is shown in Fig. 1. The potential of the electrodes was measured against an Hg/HgO reference electrode and converted to the hydrogen scale for plotting. Resistive polarization between the Luggin capillary tip and the electrode was measured throughout the discharge by an interruptor technique employing a Tektronix Model 535 oscilloscope. The current was interrupted for a period of 10 ms and then initiated by use of a switch. The potential transients (break and make) were recorded on the screen of the oscilloscope and photographed with a Polaroid camera. The IR drop was determined from the break in the initial part of the transient. The

amount of oxygen diffusing to the cathode from the nickel counter electrode during discharge was neglected (5). Discharge curves recorded in this way were very reproducible, a typical curve with its corresponding IR transient being shown in Fig. 2. Two well-defined steps of approximately equal capacity are observed in the discharge curve, the first corresponding to the change $MnO_{1.92}$-$MnO_{1.52}$ and the second to the change $MnO_{1.52}$-$MnO_{1.21}$. The IR transient shows a gradual increase up to the end of the first step in the discharge curve at which point a rapid increase to a maximum is observed after which the resistance decreases to a final steady reading about six times greater than the initial value.

X-Ray Diffraction and Chemical Analyses

Electrodes prepared as described above were placed on discharge at a current of 12.5 ma (5 ma · cm^{-2}). At 0.1 increments of the nominal capacity, representative electrodes were removed from the circuit, crushed, covered with a thin film of Durco cement to prevent atmospheric oxidation, and submitted to x-ray diffraction and available oxygen analysis. No washing or drying procedures were carried out to prevent possible changes in the chemical composition due to atmospheric oxidation. The available oxygen value was compared to the theoretical value calculated from the assumption that 2**F** of electricity are required to reduce 1 mole of γ-MnO_2. Thus the coulombic efficiency of the reaction was determined together with the true empirical formula of the reduced oxide. The results of the available oxygen analyses are shown in Table I.

X-ray patterns obtained from electrodes discharged to various depths are shown in Fig. 3, and corresponding d-values calculated from the patterns are shown in Table II.

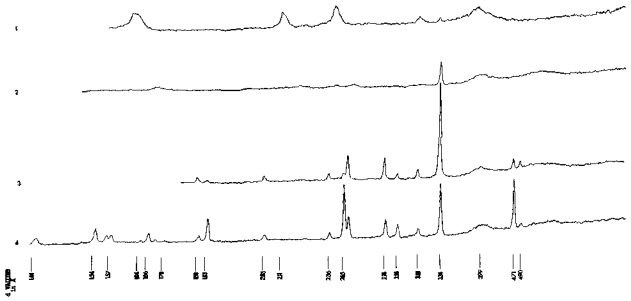

Fig. 3. X-ray diffraction patterns of γ-MnO_2: 1, starting material; 2, discharged to $MnO_{1.72}$; 3, discharged to $MnO_{1.52}$; 4, discharged to $MnO_{1.22}$.

Examination of the x-ray analyses reveals that the initial starting material is composed of γ-MnO_2 together with a small amount of β-MnO_2 and quartz as an impurity. In the initial stages of the discharge the lattice dilation observed by Bell and Huber and Brenet (8) is clearly seen. However, no d-values characteristic of the formation of new compounds are apparent. As discharge proceeds peaks having d-values characteristic of Mn_3O_4 begin to become apparent in the x-ray pattern and at levels below $MnO_{1.34}$ manganous hydroxide is detected. The chemical analyses indicate that the coulombic efficiency is 100% in the early stages of the discharge. Below $MnO_{1.5}$ the coulombic efficiency drops, presumably due to reduction of water at the cathode.

Discussion

The cathodic reduction of γ-MnO_2 in alkaline electrolyte is seen to proceed by two well-defined steps. The first step occurs between $MnO_{1.92}$ and $MnO_{1.52}$. In this region, x-ray analysis fails to detect any new crystalline phases as has been observed by other workers in $(NH_4)_2SO_4$ electrolyte (9). This is in contrast to the results of Bell and Huber who concluded that MnO(OH) is formed at the start of discharge. These authors based their conclusion on the existence of a line of d-value 1.07Å which was observed in one of their cells. The relative intensity of this line to the most intense line of MnO(OH) at d = 4.17Å is 30%. The 4.17Å line was not observed in their electrodes, therefore it seems unlikely that the 1.07Å line should be seen. It is probable that this line is in fact that observed in the starting material at 1.06Å, the slight difference being attributable to lattice dilation. If the line corresponding to 1.07Å is interpreted as above, the results of Bell and Huber and the present work are in fairly good agreement. No evidence of $Mn(OH)_2$ or Mn_4O_7 is seen in the initial stages of discharge, contrary to the findings of Cahoon and Korver.

The available oxygen analysis shows that the γ-MnO_2 is being reduced with 100% coulombic efficiency in this region; therefore changes must be occurring in the composition of the electrode. A possible explanation is that protons are being assimilated into the lattice thus causing dilation accompanied by some strain (8) according to

$$MnO_2 + nH^+ + ne = MnO_{(2-n)}(OH)_n \quad [2]$$

or

$$MnO_2 + nH_2O + ne = MnO_{(2-n)}OH_n + nOH^- \quad [3]$$

This process continues until the lattice is strained to the point at which it becomes unstable and crystallizes to a more stable phase. The intermediate formed is amorphous to x-rays and would not be detected by conventional techniques. Examination of the x-ray patterns of Fig. 3 clearly shows the increasingly amorphous nature of the reaction product in the early part of the discharge. At a composition approaching $MnO_{1.44}$ rapid recrystallization to a new phase is observed with

B = βMnO_2; γ = γMnO_2; G = graphite; Q = quartz; M = Mn_3O_4; H = $Mn(OH)_2$.

many new peaks appearing in the x-ray pattern. These peaks give d-values characteristic of Mn_3O_4 which is probably formed by a reaction of the type

$$3MnO_{(2-n)}(OH)_n + (4-3n)H^+ + (4-3n)e = Mn_3O_4 + 2H_2O \quad [4]$$

This result is essentially in agreement with that found by Cahoon and Korver. At this point in the discharge curve a rapid drop in potential is observed together with a sharp increase in the electrode resistance. This is similar to observations made on the Leclanché cell (10) and is consistent with the rapid recrystallization of a highly resistive oxide at the electrode/electrolyte interface or at the electrode/contact interface. The distinction between Mn_3O_4 and γ-Mn_2O_3 is difficult on the basis of x-ray values because the compounds have very similar x-ray patterns. A number of peaks are present however in the Mn_3O_4 pattern (d = 1.57, 1.534, 1.43) which are absent in γ-Mn_2O_3, and these were observed in our results. The weight of evidence thus lies with Mn_3O_4 although the existence of γ-Mn_2O_3 cannot be completely ruled out.

At a composition approaching $MnO_{1.34}$ manganous hydroxide is starting to crystallize, and this process continues until the end of discharge. To determine whether $Mn(OH)_2$ is formed from Mn_3O_4 or the amorphous phase an experiment was conducted whereby an electrode composed of Mn_3O_4 and graphite was subjected to electrochemical reduction under the same conditions as the γ-MnO_2 electrodes. A number of coulombs were passed equivalent to the complete reduction of Mn_3O_4 to $Mn(OH)_2$ based on the reaction

$$Mn_3O_4 + 4H_2O + 2e = 3Mn(OH)_2 + 2OH^- \quad [5]$$

The electrodes were then analyzed by x-ray diffraction and chemical analysis. No evidence of reduction could be detected by either method. It thus appears clear that $Mn(OH)_2$ is a reduction product of the amorphous phase according to

$$MnO_{(2-n)}OH_{(n)} + (2-n)H^+ + (2-n)e = Mn(OH)_2 \quad [6]$$

Conclusion

The cathodic reduction of γ-MnO_2 in strongly alkaline solutions proceeds by the following steps.

1. Protons are assimilated into the γ-MnO_2 lattice causing dilation and the formation of an amorphous phase according to

$$MnO_2 + nH^+ + ne = MnO_{(2-n)}OH_{(n)}$$

2. Protons are taken up by the intermediate until saturation is reached whereupon it recrystallizes to form Mn_3O_4.

$$3MnO_{(2-n)}OH_{(n)} + (4-3n)H^+ + (4-3n)e = Mn_3O_4 + 2H_2O$$

3. At potentials below 0.40v *vs.* hydrogen the amorphous phase crystallizes directly to $Mn(OH)_2$

$$MnO_{(2-n)}OH_{(n)} + (2-n)H^+ + (2-n)e = Mn(OH)_2$$

The final product of discharge is $Mn(OH)_2$ although any Mn_3O_4 formed is not subsequently reduced and remains in the electrode.

Structure and Stoichiometry of Nickel Hydroxides in Sintered Nickel Positive Electrodes

Michael A. Aia

General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Differential thermal analysis (DTA) is shown to be a powerful tool in the study of the structure of electrochemically active materials. DTA was combined with chemical and x-ray diffraction analysis to follow both the electrolytic development in KOH solutions and the thermal decomposition of the charged state of sintered nickel electrodes impregnated with nickel hydroxide. The charged state contains active oxygen, insoluble potassium, water of constitution, and water of hydration. The electrochemical capacity is close to the electrochemical equivalent of the active oxygen formed on charging. The layer lattice is distorted and decomposes exothermically to NiO when heated above 100°C.

The formation and state-of-charge of Ni positive electrodes have been studied extensively by chemical analysis (1-3), magnetochemical analysis (3), x-ray diffraction (1-4), and recently by infrared absorption analysis (5). To date, no definitive information has been obtained by differential thermal analysis (DTA) although considerable effort has been expended (6).

The present work shows that valuable insight into structural changes occurring in Ni positive electrodes can be obtained by DTA, provided that the instrumental parameters are recognized and controlled. Compositional analyses are made at various states-of-charge to show how the electrolyte interacts with the electrochemically active material.

Experimental Methods

The DTA apparatus was a standard unit manufactured by the Robert L. Stone Company of Austin, Texas. The sample holders contained a Platinel II, ring-type differential thermocouple, which is especially suited for precise work with small samples because of the high sensitivity of Platinel II (comparable to chromel-alumel) and the readily reproducible sample geometry. Samples were prepared by grinding the sintered electrode with a mortar and pestle, after thorough washing and drying at 60°C. Analysis for active oxygen in the ground electrodes gave results in good agreement with those found by Labat (3) for electrodes analyzed immediately after charging (see Fig. 6). The sample (1-10 mg) was weighed into a small, disposable Al pan which then was placed on one side of the thermocouple ring. A pan containing an inert reference material was placed on the other side. A 10 mg pellet of Al, made from Al foil, was a good reference material for the conditions used. The results were more reproducible and trends were much better defined when the samples were pelletized. The samples were not diluted with inert material, although this is common practice in DTA work. All the thermograms shown were traced directly from the experimental curves.

A flow of about 60 cm^3/min of helium was passed through the sample chamber to inhibit oxidation reactions. Oxidation of the sintered nickel in the electrodes was shown to have a negligible effect below 350°C by making blank runs with carbonyl nickel powder and also by analyzing for hydrogen in the gases liberated from the samples using a mass spectrometer; a maximum of 0.5 cc H_2 (STP) per gram of sample was evolved. The furnace was programmed to give a linear temperature rise of 10°C/min. The effect of heating rate was investigated and is reported below. Heating was terminated at 500°C because the reactions of interest occurred at lower temperatures.

Samples of $Ni(OH)_2$ were precipitated at 100°C from nickel salts with various anions using methods given by Cairns and Ott (7). Samples of electrode materials were prepared after thorough washing and drying of 80% porous sintered Ni plaques (0.5 x 2.25 x 0.045 in.) impregnated with 96% nickel hydroxide-4% cobalt hydroxide (1.1g) by a procedure similar to that described by Fleischer (8). All eletrochemical cycling was done in 7*N* KOH solution with a typical carbonate content of 0.5 g/l. Electrodes were washed overnight with running cold water and, in some cases, with boiling water in a continuous extractor. For electrodes dried in vacuum, a pressure of 5×10^{-2} Torr was maintained by a mechanical pump.

A simple magnetic susceptibility technique was developed to determine the weight per cent of active material in the impregnated plates both before and after cycling. This determination eliminated the need for mechanical separation of metallic nickel before analysis. The amount of metallic Ni (ferromagnetic) was determined directly, while the active material (paramagnetic) was obtained by difference. The magnetic method makes use of the fact that the magnetic susceptibility of the active material is very low compared with that of metallic nickel. Details of the procedures are as follows. A 5-15 mg sample (weighed to 0.1 mg) of the powdered electrode material was added to a previously weighed glass sample tube, and the total weight was recorded. The apparent weight increase per milligram of the sample in a magnetic field of about 500 oe was determined by suspending the tube from one arm of a balance at a fixed distance between the poles of a large permanent magnet. The balance was capable of weighing reproducibly to 0.01g. An apparent weight gain of 50 mg/mg sample was typical, indicating that the force of magnetization was high compared with the sample weight. These results would be expected for a sample containing a high percentage of a ferromagnetic material such as metallic nickel. The weight increase for a 10 mg sample of carbonyl nickel powder was then determined in the same manner and was, typically, 100 mg/mg. To calculate the percentage of metallic nickel in the electrode material the weight increase per milligram of sample was divided by that of the nickel powder and then multiplied by 100%. Synthetic standards containing 50:50 of carbonyl nickel powder and chemically precipitated (7) $Ni(OH)_2$ or $Ni_2O_3 \cdot H_2O$ were analyzed by this method; the resulting values of metallic nickel were accurate to within 1.5%. Unformed plates were found to contain 50 ±2% green nickel-cobalt hydroxide; after 1 to 100 cycles in 30% KOH, 47-52% of active material was found. These and other results gave direct evidence that the sintered Ni matrix of

electrodes of this type was not appreciably oxidized during electrochemical cycling, even with extensive overcharging, and further established that the samples used for DTA could be considered to consist of 50% Ni-50% active material.

Nickel was analyzed by precipitation with dimethylglyoxime and also by atomic absorption. Potassium and cobalt were determined by atomic absorption. Active oxygen was determined by dissolving 0.1g of the powdered electrode material in sodium acetate-buffered acetic acid solution containing potassium iodide and starch indicator solution; the iodine liberated was titrated with 0.1*N* sodium thiosulfate solution. The active oxygen [O] was then calculated using the following equation

$$(\text{Volume of } Na_2S_2O_3, \text{ml})\ (\text{Normality})\ \frac{16}{2000} = \text{g [O]}$$

Water was determined by heating at 400°-600°C in a stream of argon and collecting the effluent in a preweighed drying tube containing magnesium perchlorate. Correction for the metallic nickel in the samples was made before calculating the results given in Table II.

Results and Discussion

To detect reproducible differences in thermal behavior, the important experimental parameters must be carefully controlled. These parameters include sample weight, sample particle size, crystallinity, and shape, sample geometry, and heating rate. For example, the effect of heating rate on the decomposition of $Ni(OH)_2$ is demonstrated in Fig. 1. There is a gradual loss of loosely bound H_2O up to about 200°C where the lattice begins to decompose by dehydroxylation. It can be seen that the dehydroxylation reaction appears to occur more discretely as the heating rate is increased. The temperature at the reaction peak (T_{max}) increases considerably over the range 5-16°C/min but changes only slightly from 16-20°C/min. The fact that the same amount of dehydroxylation occurs within each DTA peak was determined by graphical integration of the area under each peak. The results are summarized in Table I. A heating rate of 10°C/min was selected for all subsequent work because it was convenient and gave reproducible thermograms.

Effect of anions during precipitation of $Ni(OH)_2$.—In the impregnation of sintered Ni plaques for use in batteries Ni nitrate, perhaps because of higher solubility, is usually preferred over Ni sulfate. However the sulfate is used to make the active material for tubular Ni electrodes. It is of interest to know what effects the Ni salt has on the precipitated $Ni(OH)_2$. Figure 2 gives a comparison of the DTA thermograms

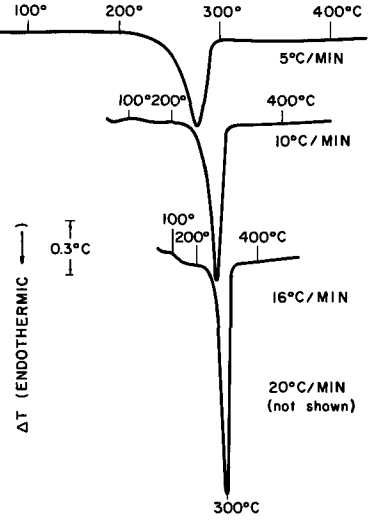

Fig. 1. Effect of heating rate on decomposition of $Ni(OH)_2$

Table I. Effect of heating rate on the dehydroxylation of $Ni(OH)_2$ precipitated from nitrate solution

Rate of heating, °C/min	Threshold decomposition temp, °C	T_{max}, °C	Relative area under peak

10	220	294	97
16	222	304	98
20	222	306	97

of $Ni(OH)_2$ precipitated from four different Ni salt solutions. The $Ni(OH)_2$ from the nitrate exhibits the sharpest decomposition peak. Dehydroxylation of $Ni(OH)_2$ prepared from the formate and acetate starts and peaks over the same region of temperatures (225°-296°C) as the nitrate. The behavior is different for the sulfate-derived $Ni(OH)_2$ which does not start to decompose until 262° and does not peak until 324°C (confirmed by duplicate runs). The difference in thermal behavior has been attributed by Duval (9) to the absorption of $SO_4^=$ ions which are eliminated only beyond 700°C. Similar sorption problems are known to occur when nickel chloride is the starting material. DTA thus readily shows the effects of changing the anion in the precipitation process.

Changes in structure with electrochemical cycling.—Tuomi (10) has discussed the process known as forming in nickel electrode technology. Forming occurs during initial electrochemical cycling in alkaline solution and induces complex chemical and crystallographic changes, and, especially, a stable electrochemical capacity. Cycling is manifested by the development of so-called higher oxides of Ni during the oxidation part of the cycle (charging) and by subsequent reduction to a material having the over-all structure of $Ni(OH)_2$ during discharge. The changes in $Ni(OH)_2$ due to cycling are still not well char-

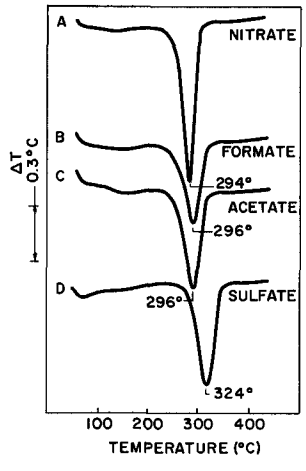

Fig. 2. Effect of nickel salt used to prepare $Ni(OH)_2$

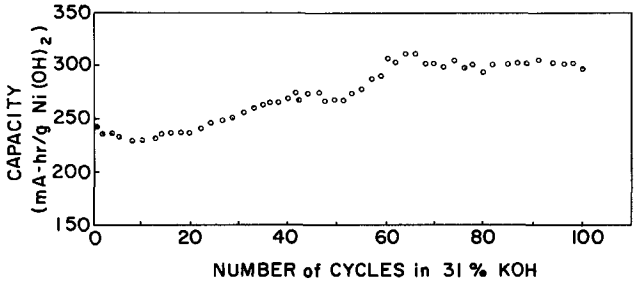

Fig. 3. Changes in positive capacity with cycling for the electrodes used in this work. Each electrode contained 1.1g $Ni(OH)_2$. For a transfer of one electron the theoretical capacity is 289 ma·h/g $Ni(OH)_2$. Electrodes were charged 3 hr at the 2-hr rate, and discharged at the 2-hr rate to 0.0v vs. Hg/HgO reference.

acterized. For example, the infrared spectra of pure $Ni(OH)_2$, unformed $Ni(OH)_2$, and formed $Ni(OH)_2$ are practically indistinguishable from each other (5), and yet considerable changes in the DTA thermograms, as well as in the storage capacity and composition, occur as a function of cycling. It is shown in Fig. 3 that for the sintered Ni electrodes used in this work, the capacity initially drops slightly, then builds up to a plateau after 60 cycles, for the conditions indicated. The results are typical of several electrodes studied. At a later point (Table II) we will see that appreciable amounts of tightly bound potassium and active oxygen are always found in electrodes after formation.

Additional effects of forming $Ni(OH)_2$ are shown in the DTA curves of Fig. 4. Considerable structural reordering occurs during the forming process. For example, the $Ni(OH)_2$ in an unformed plate (curve A) is well crystallized and decomposes much like pure $Ni(OH)_2$ precipitated from Ni nitrate at 100°C (Fig. 2, curve A), except that its dehydroxylation starts at lower temperatures and peaks at 268° instead of 294°. This difference could not be traced to the presence of Ni metal from the matrix of the electrode and seemed to be due to the smaller particle sizes of the electroformed $Ni(OH)_2$. The same amount of active material (5 mg) is represented in both Fig. 2 and 4 (curves A). A drastic lowering of the over-all crystallinity of the $Ni(OH)_2$ occurs when the plate is charged and discharged for the first time in 31% KOH (Fig. 4, curve B). Subsequent cycling at the 2.5-hr rates of charge and discharge only partially restores the crystallinity lost during the first cycle, even after 100 cycles (curves C and D). These findings offer indirect evidence that the $Ni(OH)_2$ in sintered Ni electrodes undergoes a pronounced decrease in particle size or ordering during the electrochemical formation processes. Because the capacity (and presumably the available surface area) decreases during formation cycling (Fig. 3), it seems more probable that the DTA curves reflect more a decrease in ordering than in particle size. Garn (11) has shown how the mode of thermal decomposition of minerals, observed by DTA, is closely related to the crystal size and the structural ordering (*i.e.*, the crystallinity) of the samples.

Evolution of the charged state.—Thermal dehydroxylation of $Ni(OH)_2$ forms NiO and H_2O. The reaction is endothermic and causes a well-defined DTA peak above 200°C, as shown in Fig. 1, 2, and 4. A broader endotherm that appears at lower temperatures is caused by the evolution of loosely bound H_2O from the lattice. These DTA peaks are also observed in discharged electrodes (Fig. 4), in which the active material is known to have the over-all structure of $Ni(OH)_2$. A good picture of some of the changes that occur in $Ni(OH)_2$ during the charging process is given by DTA. For example, Fig. 5 shows the thermograms for electrodes in progressively increasing states-of-charge ranging from the green, unformed state (curve A) to the extensively overcharged state (curve J).

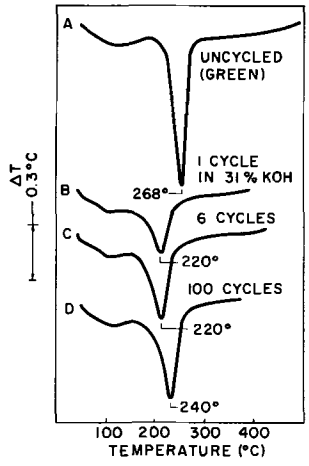

Fig. 4. Effect of formation and cycling on thermal behavior of $Ni(OH)_2$ in impregnated positive electrodes. Cycled plates were discharged to 0.0v vs. Hg/HgO reference.

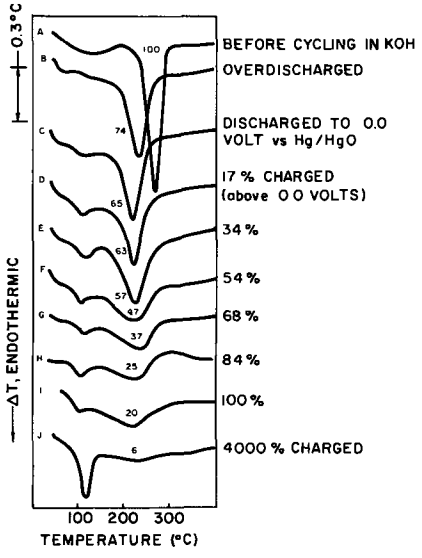

Fig. 5. Development of the charged state of $Ni(OH)_2$ impregnated positive electrodes.

The gradual decrease of dehydroxylation of $Ni(OH)_2$ as a well-defined reaction is seen by the decrease in the relative areas under the characteristic $Ni(OH)_2$ peak; the relative areas are indicated by the numbers given in Fig. 5. Dehydroxylation occurs, however, even in material that has been greatly overcharged, indicating that this structural feature of $Ni(OH)_2$ is retained in the highest states-of-charge. We shall see later (Fig. 8) that part of the endotherm caused by decomposition of the charged state is obscured by a concurrent exo-

* Electrodes were discharged to 0v then charged with the indicated per cent of 1 F/g-atom (Ni + Co).
** The active material also contained 2.1-2.5% cobalt, *i.e.* the electrodes were impregnated with a coprecipitated mixture of 96% $Ni(OH)_2$-4% $Co(OH)_2$.
*** Potassium and water were determined on samples which were washed extensively with boiling water in a continuous extractor.

thermic reaction, believed to be caused by extensive lattice reordering and loss of surface area during the conversion of the charged state of NiO.

When $Ni(OH)_2$ is charged, the broad peak near 120°C (Fig. 5, curve A) becomes sharply defined indicating the presence of a discretely bound species. This sharp peak is characteristic of the charged state and is found in materials containing as little as 15-20% of charge, which was the amount remaining in electrodes discharged to 0.0v *vs.* Hg/HgO (*e.g.*, Fig. 5, curve C). Simultaneous DTA-effluent gas detection (12) confirmed that the peak at 120°C was accompanied by the evolution of gas, which proved to be water of hydration. Drying experiments showed that 8.9% H_2O was lost from overcharged active material which partially decomposed to NiO when dried to constant weight at 140°C, after it had been previously dried under vacuum at 25°C for 18 hr. Under the same drying conditions, over-discharged material lost only 4.0% H_2O and showed only the x-ray diffraction pattern of $Ni(OH)_2$. It is obvious that dehydroxylation occurs at a lower temperature in the charged state than in the discharged state.

Using DTA, it was established that the sharp DTA peak characteristic of water of hydration in the charged state reflects the zeolitic properties of the lattice, *i.e.*, H_2O was quickly taken up from the ambient atmosphere after the electrode was heated (in helium) to temperatures as high as 520°C. From this it appears that the H_2O lost at 120°C can function as a means of mass transport during electrochemical cycling and may be associated with K^+ ions. Because vibrations characteristic of free hydroxyl groups are not found in the infrared spectrum of the charged state (5), the potassium cannot be present as KOH.

Analysis of composition.—To establish a chemical basis for understanding the charging process the Ni, Co, K, H_2O, and active oxygen content of electrodes was determined as a function of the state-of-charge. Analytical results are summarized in Table II. Total oxygen (not shown) was determined by neutron activation analysis and found to be essentially the same in both the overdischarged and overcharged states, 33.6 and 33.8%, respectively. This agrees with the result that the sum of active oxygen and water is 1.3 g · mole/g · atom Ni + Co.

From Table II it can be seen that potassium and active oxygen,[1] [O], are not detected in uncharged, green plates but are always found in plates that have been cycled. As the electrodes are brought to 100% charge (1**F**/g atom Ni) and then overcharged in 31% KOH solution, both K and [O] increase to large values. The potassium was insoluble and could not be removed by extended washing with boiling water; however, 80% of the active oxygen or the bonding that gives rise to active oxygen was lost after just 1 hr in a continuous extractor. Migration of potassium ion proceeds in a direction which is contrary to the flow of current, as suggested earlier by Tuomi (10). The distribution of insoluble potassium in nickel-oxide electrodes has recently been studied qualitatively by electron probe analysis with similar results (13).

Table II shows that after overcharging, K comprises about 14 mole % of the cations in the active material. The nature and bonding of the K^+ ions and their effect on the structure requires further study; it is possible that the K^+ ions occupy cation defect sites (*i.e.*, Ni^{2+} sites) or are bound between layers of oxygen octahedra (as in micas) or are substituted for protons on hydroxyl sites. If the alkali metal cations go into Ni^{2+} sites, then it would be expected that Li^+ ions would more favorably replace Ni^{2+} ions than would K^+ ions, on the basis of ionic radii. Electrodes

[1] The active oxygen is expressed as [O] to indicate that after dissolving in acid it has the strong oxidizing properties of atomic or nascent oxygen and is capable of oxidizing iodide to iodine in acid solution; this reaction is commonly used to determine [O] in H_2O_2. There is, however, no physical evidence that O-O linkages exist in the active material.

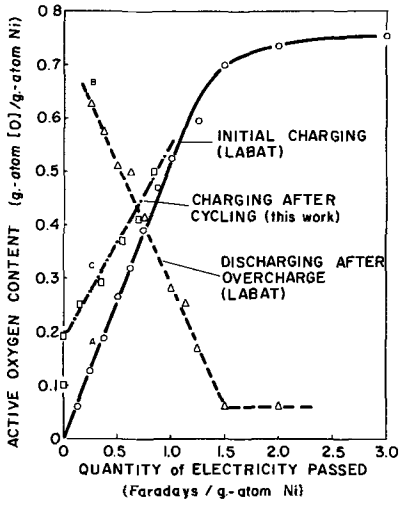

Fig. 6. Active oxygen content as a function of charge passed during polarization in concentrated KOH solutions. The polarization times were 4 hr/F for curves A and B, and 2.7 hr/F for curve C.

charged in saturated LiOH solution showed a maximum Li content of only 0.004% after washing. This result is in apparent disagreement with the evidence for the formation of $LiNiO_2$ species during charging in LiOH found by Tuomi. However, the washing may have caused hydrolysis of the lithium nickelate to yield LiOH and NiOOH.

The electrochemical activity of $Ni(OH)_2$ arises from complex electronic and crystallographic interactions between the nickel ions and hydroxyl groups in the structure. However, it appears realistic to discuss the general mechanism of the electrochemical activity as if the oxidation were originating at the OH sites in the lattice. One is interested in knowing how the electrochemical equivalent of active oxygen in the compositions suggested by Table II is related to the Faradaic capacity of the electrodes. The electrochemical equivalents of active oxygen were calculated from the present results (Table II) and also from data given by Labat (3). These results are summarized in Fig. 6. Curve A shows that on the initial charging, the active oxygen, determined without washing or drying the electrode, increases linearly with the amount of current passed and attains the theoretical value of 0.5 [O] after 1**F** has passed (*i.e.*, 100% efficiency); overcharging is less efficient. When the electrode is discharged after overcharging (curve B), the loss of active oxygen is 0.45 [O]/**F**, which represents an efficiency of 90%. It is obvious that there is hysteresis; both curve B and Table II show that an appreciable amount of [O] is retained after overdischarging. Curve C indicates that although [O] is not produced as efficiently during recharging (lower slope than curve A), after 1**F** of recharging current the mole ratio is about 0.55 [O]/Ni because the line does not start at zero [O]. It seems reasonable to conclude that the active oxygen content gives an adequate indication of the extent of change in Ni-O bonding which gives rise to energy storage by nickel hydroxide.

Labat has shown that the magnetic susceptibility (which reflects the number of unpaired electron spins) decreases almost linearly with the increase of active oxygen content over the range 0-1 g · atom [O] per g · atom Ni during charging of $Ni(OH)_2$ (3). He interpreted this behavior as proof of the formation of Ni(III) and Ni(IV) valence states during charging of $Ni(OH)_2$. The rigorous establishment of the valence of the nickel atoms requires spectroscopic information concerning the electronic states of the system and has not been investigated in the present work. One problem encountered in the present study should, however, be mentioned. Although not shown in Table II, electrodes were prepared with an active oxygen content

of 1.4 g · atom [O]/g · atom Ni after extensive overcharging in saturated LiOH (Li content of the electrode was <0.005%). This ratio indicates that nearly 3 F/g atom Ni were chemically stored. To explain this ratio in terms of valence changes, one would have to postulate a Ni(V) state, which is not reasonable. The point made is that, while Labat was able to correlate magnetic susceptibility and active oxygen content of nickel hydroxides, one is not always able to correlate active oxygen content with the valence state of nickel.

An over-all, oversimplified electrochemical reaction for the generation of active oxygen could be

$$2\,OH^- \rightarrow [O] + H_2O + 2e^- \qquad [1]$$

The source of OH^- groups could be either the electrolyte or the $Ni(OH)_2$ itself. In the first case, mass transport of [O] from the electrolyte to the active material is implied. In the second case, only intramolecular rearrangement of adjacent OH groups of $Ni(OH)_2$ is implied. Mass transport of [O] from the electrolyte should not decrease the amount of water of constitution (*i.e.*, the number of OH groups) in the $Ni(OH)_2$, whereas intramolecular rearrangement should cause the conversion of more than half of the OH groups to [O]. The last column of Table II shows that the total H_2O content of the dried, charged state is much less than that of the discharged state. The lower hydroxyl content is confirmed by thermal analysis. The DTA curves of Fig. 5 clearly show the decrease of water of constitution (hydroxyl groups) as a function of increasing state-of-charge. Other thermal methods of analysis also show that decomposition of the lattice of the charged state is accompanied by the evolution of O_2 as well as H_2O and that the amount of H_2O of constitution is much lower than that for $Ni(OH)_2$; the results of thermogravimetric and mass spectrometric analysis will be presented in detail in a later report. The present results suggest that the increase in active oxygen in the charged state is accompanied by the loss of total H_2O and of OH groups of the $Ni(OH)_2$. Infrared analysis (5) has shown that the OH and H_2O groups of the charged state are hydrogen bonded.

Drying of charged electrodes.—Static thermal analysis of the charged state was performed to determine the effects of drying temperature on the structure, weight loss, and charge retention of overcharged plates dried in vacuum (5 x 10^{-2} Torr) at temperatures of 25°-300°C, after thorough washing. Figure 7 summarizes the results of drying experiments. X-ray diffraction analysis showed only diffuse bands for the dried, active material and a gradual transition from the layer structure of γ-NiOOH (1) to that of NiO as indicated on Fig. 7. The lines that have been attributed to β-NiOOH were not detected in any of the samples. In this paper γ-NiOOH is used to refer to a set of diffuse x-ray diffraction lines (and particularly a line around d = 6.8-7.0Å) which have been reported in the literature. It should be made clear that the actual composition of the charged state is considerably more complex than NiOOH and that the crystal structure is still unknown.

The capacity curves in Fig. 7 show that the charged electrode must be dried above 100°C before an appreciable loss in capacity is observed on the initial discharge. Capacity is lost rapidly at 150°-250°C where lattice decomposition occurs, as would be predicted from DTA (Fig. 5). The amount of lost capacity that can be regained on subsequent recycling decreases as the drying temperature increases, as seen by the convergence of the capacity curves. There is still a measurable amount of capacity in the electrode after drying at 300°C. The correlation between structure and retention of capacity can be further deduced directly from Fig. 7.

The weight loss from the charged electrodes was determined up to 400°C by thermogravimetric analysis at reduced pressure (15 Torr, air) of a powder sample previously dried at 25°C *in vacuo* (Fig. 7, curve C). The values of weight loss obtained from the static experiments were slightly different and were uncertain because the electrodes almost certainly regained some weight by sorption processes during cooling. For example, nickel oxide produced by thermal treatment of $Ni(OH)_2$ below 400°C is known to be a very active "getter" of gases (14). The capacity lost by the charged state during drying is an increasing function of the amount of weight lost by the active material only above 100°C. Weight loss above 100°C reflects the extent of loss of active oxygen and of decomposition of the layer lattice to form NiO with the rocksalt structure.

The dried samples were also examined by DTA, and some of the results are shown in Fig. 8. The curves reveal three main features, a sharp endothermic peak near 100°C, a broad endothermic peak near 230°C, and a very broad exothermic peak near 300°C. The origin of the first two peaks has been discussed previously; it is only necessary to add that the reappearance of the

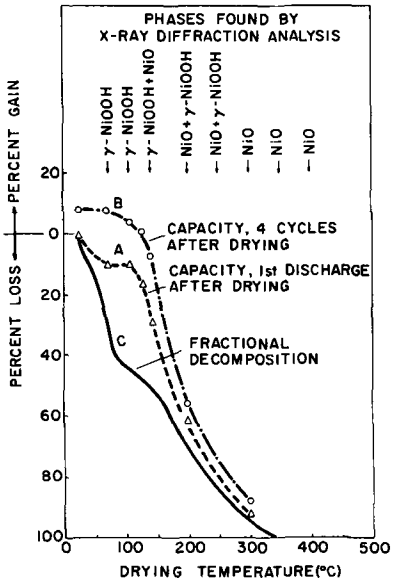

Fig. 7. Capacity loss, weight loss, and structure, as a function of drying temperature. Curves A and B show positive electrode capacity after drying and cycling in 31% KOH as per cent of capacity before drying. Curve C shows weight loss as per cent of the total weight loss (17.7% of the active material) by thermogravimetric analysis in air at a heating rate of 125°C/hr.

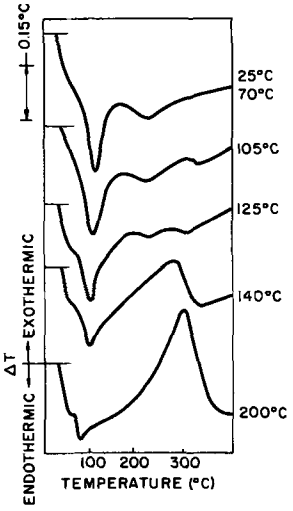

Fig. 8. DTA of charged nickel positive electrodes after thermal treatment at indicated temperatures.

first peak in samples that had been dried above 105°C indicates rehydration and confirms the zeolitic nature of the lattice. The broad exothermic reaction observed in the charged electrodes dried at 140° and 200° is of a type frequently encountered in solids undergoing extensive reordering or recrystallization, as discussed by Garn (11). The peak can be explained by postulating that extensive reordering and loss of surface area accompany the transformation of the distorted layer lattice of the charged material to the rocksalt lattice of NiO. It is also possible that exothermic recombination of oxygen atoms to form O_2 occurs; pyrolysis in a mass spectrometer showed that the evolution of O_2 peaked near 300°C. However, the loss of O_2 from MnO_2 and Mn_2O_3, two other compounds containing active oxygen, has been shown to be an endothermic process (15). The exothermic peak seems to provide additional evidence that the layer lattice is highly disordered and thermodynamically unstable in the charged state. A sample dried at 300°C (not shown) did not exhibit the exotherm; this confirmed x-ray diffraction results which indicated that the charged material had almost entirely converted to NiO during drying above 250°.

Summary

Differential thermal analysis (DTA) has been demonstrated to be a powerful tool in the study of the electrochemically active materials and to provide structural information not easily obtained by other methods of analysis. The main results are as follows:

1. The initial cycling of a green (unformed) $Ni(OH)_2$-impregnated electrode causes a drastic change in the atomic ordering and chemical composition of the active material, which is only partly restored after 100 cycles in KOH solution.

2. The development of a distorted layer lattice during the charging of well-crystallized $Ni(OH)_2$ is readily followed by DTA.

3. Thermal analysis of the charged state of the nickel hydroxide electrode is characterized by (*a*) a well-defined endothermic reaction near 120°C due to evolution of zeolitic H_2O which may be associated with K^+ ions, (*b*) a broad endothermic reaction peaking near 225°C, caused by decomposition of the layer lattice to form O_2, H_2O, and poorly crystallized NiO, and (*c*) a broad exothermic reaction peaking near 300°C, which suggests reordering of the distorted lattice during formation of well-crystallized NiO and additional O_2 and H_2O.

4. Chemical analyses of the active material demonstrate that at least some of the active oxygen is produced at the expense of hydroxyl groups of $Ni(OH)_2$ during charging and that active oxygen accounts for the electrochemical capacity of the electrode. Potassium ions are taken up from the electrolyte and bound to the lattice during charging in concentrated KOH solution; on the contrary, lithium ions are not taken up during charging in saturated LiOH solution at 25°C.

5. After thorough washing to remove electrolyte, charged electrodes may be vacuum dried at temperatures up to 100°C with little loss in initial or permanent capacity.

Acknowledgment

The electrodes and powder samples were prepared by M. S. Pak. The chemical analyses were performed under the supervision of R. Weberling, J. Cosgrove, and D. Oblas of the Materials Analysis Section. The x-ray diffraction patterns were supplied by A. Calvano. The author benefited from frequent discussions with F. P. Kober and from the encouragement given to the work by P. Goldberg. He is grateful also to J. P. Harivel, of the research laboratories of Societe d'Accumulateurs Fixes et de Tractions, (SAFT), Paris, for providing details on the analytical procedure for active oxygen.

Manuscript received Sept. 21, 1966; revised manuscript received Jan. 17, 1967. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

The Anodic Dissolution of Cadmium

J. W. Johnson, E. Deng, S. C. Lai, and W. J. James

Departments of Chemical Engineering and Chemistry, The University of Missouri at Rolla, Rolla, Missouri

ABSTRACT

The anodic dissolution of cadmium has been studied in aqueous solutions containing Cl^-, Br^-, I^-, Ac^-, $SO_4^=$, and NO_3^- ions. The normal valence (+2) was found in all solutions with the exception of NO_3^-. The apparent valence (calculated) of cadmium ions in nitrate solutions varied from 1.2 to 2.0 and was found to be a function of NO_3^- concentration, current density, and temperature. An anodic dissolution mechanism has been proposed involving local corrosion and disintegration of the anode which is consistent with the experimental results.

Since early in this century, various investigators have noted and reported discrepancies in the actual and theoretical quantities of Cd dissolving anodically in certain oxidizing electrolytes (primarily nitrates) (1-3). This phenomenon has also been reported for Mg (4,5), Be (6,7), Zn (8,9), Al (10,11), and Sn (12,13), to name a few.

Several theories have been proposed to explain the behavior. They are: (*a*) complex ion ($Cd \cdot Cd^{+2}$) formation, (*b*) uncommon valence ion (Cd^+) formation, (*c*) film control, (*d*) local corrosion, and (*e*) disintegration. The uncommon valence ion theory has been widely accepted, but recent papers have somewhat discounted its validity, especially as pertains to Be (7), Mg (4,14,15), and Zn (9,16). Experiments carried out in this laboratory with amalgamated anodes also make it doubtful that the theory applies to Cd (17).

This investigation concerns the anodic dissolution of Cd in electrolytes (*ca.* neutral) containing various anions both with and without Cd ions present. The anions selected show some variation in the solubilities of their Cd salts and a considerable variation in their ability to complex with Cd ions. Also, they have been associated with studies of the anodic disintegration of other metals (18-23). It was hoped that some insight might be gained on the processes responsible for the low faradaic efficiency.

Experimental

The Cd anodes were prepared from ASARCO special high-purity (99.999+%) rod. All solutions employed analytical grade chemicals and distilled water. The anodes were fabricated by press-fitting small machined Cd specimens into Teflon holders. A platinized-platinum cathode was used. The electrolyses were carried out in the usual H-cell (300 ml electrolyte capacity) under an inert atmosphere (prepurified nitrogen). When no Cd ions were initially present in the electrolyte, the Cd dissolved was determined by EDTA titration. When Cd ions were present, a direct weight loss method was used. A calomel (1*N*) reference electrode in conjunction with a salt bridge was used for the potential measurements. The apparatus and procedure have been described (7,9).

Apparent valence of Cd *in nitrate electrolytes in the absence of* Cd^{+2}.—The anodic dissolution of Cd was studied in KNO_3-K_2SO_4 solutions at temperatures of 25°, 45°, and 65°C. The NO_3^- concentration was varied from 0 to 1*N*, while the total electrolyte concentration was held constant at 1*N* to insure good conductance. Apparent valences were calculated using the equation

$$V_i = \frac{VW}{W_i} \qquad [1]$$

where V_i is the apparent valence of the dissolving Cd, V normal valence = 2, W is the calculated weight of Cd lost from the anode (determined from coulombic data), and W_i is the actual weight of Cd lost from the anode (determined by titration or weight loss).[1] The apparent valence of the Cd ions as a function of current density is shown in Fig. 1a, b, and c for the various temperatures. It may be noted that the apparent valence is affected by current density, NO_3^- concentration, and temperature. In these solutions (with the exception of 1*N* K_2SO_4), a gray film, later shown to be a mixture of $Cd(OH)_2$ and minute Cd particles, was formed very rapidly on the anode surface on be-

[1] Note also that the apparent valence is the product of the current efficiency of the anode and the normal valence.

ginning the electrolysis. The film appeared to thicken with some darkening as the current density was increased. At higher current densities, > 0.010 amp · cm^{-2}, small portions of the film spalled off the surface. These portions turned completely white [Cd → $Cd(OH)_2$] within a few minutes if allowed to remain in contact with the electrolyte or moist air. The extreme reactiveness is believed to be due to the small size of the metallic particles. Numerous attempts to determine quantitatively the amount of particles formed as a function of current density were unsuccessful. However, a small amount of the spalled gray film was collected by rapidly removing the anolyte from the cell during electrolysis, filtering with a vacuum filter, and rinsing the film thoroughly with dry acetone. Although much of the gray color faded during this operation, the remainder was stabilized by the acetone rinse. An x-ray analysis showed the film to be a mixture of Cd and $Cd(OH)_2$. Microscopic studies showed a $Cd(OH)_2$ matrix with metallic particles dispersed throughout.

Apparent valence of Cd *in various electrolytes in the presence of* Cd^{+2}.—Apparent valence measurements were made in $CdCl_2$-KCl, $CdBr_2$-KBr, CdI_2-KI, $CdSO_4$-K_2SO_4, $Cd(Ac)_2$-KAc, and $Cd(NO_3)_2$-KNO_3 solutions at 25°C. The ionic strength was held constant at 1.5. The Cd^{+2} concentration was varied from 10^{-3} to 1*N* and the current density from 10^{-3} to 10^{-1} amp·cm^{-2}.

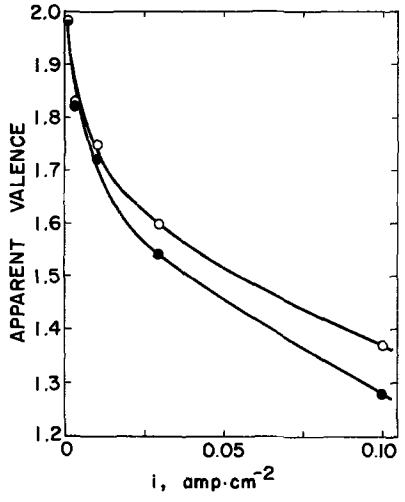

Fig. 2. Apparent valence of cadmium dissolving anodically in $Cd(NO_3)_2$-KNO_3 solutions (ionic strength = 1.5) at 25°C. ○, 1N Cd $(NO_3)_2$; •, 0.001, 0.01, and 0.1N $Cd(NO_3)_2$.

The normal valence of two was obtained for Cd in all solutions except those containing NO_3^-. Figure 2 shows a plot of the apparent valence *vs.* current density for these latter solutions. In all the electrolytes, except those containing NO_3^-, a very thin, tightly adherent, brownish-black film was noted. This was believed to be CdO as reported by Huber (24). In NO_3^- solutions, a gray film similar to that mentioned previously was present.

Polarization studies.—Potentials of the Cd electrode were measured at 25°C in solutions of $CdCl_2$-KCl, $CdBr_2$-KBr, CdI_2-KI, $Cd(NO_3)_2$-KNO_3, $CdSO_4$-K_2SO_4, and $Cd(Ac)_2$-KAc. The current density was varied from 10^{-3} to 10^{-1} amp · cm^{-2}. The overpotentials were calculated as the difference between the electrode potential at a given current density and the rest potential (potential at zero current density) in the same solution. Very stable potentials were obtained within a few minutes in all solutions except those containing NO_3^-. In NO_3^- solutions, the potentials fluctuated widely at current densities greater than 10^{-2} amp · cm^{-2}. The fluctuations seemed to be associated with a rapid passivation and activation of the electrode, possibly caused by spalling of the gray film from the electrode. Rest potentials and Tafel slopes for the Cd electrode in the various electrolytes are shown in Table I. The linear portions of the curves existed over a current range of approximately one order of magnitude (10^{-3} to 10^{-2} amp · cm^{-2}). Above current densities of 10^{-2} amp · cm^{-2}, the potential rose rapidly, probably due to IR drop in the reference and/or passivation of the metal. The potentials were not noticeably affected by stirring.

Discussion

The deviation from Faraday's law of the anodic dissolution of Cd is evidently associated with the nitrate ion. Its oxidizing capability must be important as the production of nitrite ion in an amount nearly equivalent to the deviation has been reported (8, 17). In this study, it alone of the anions present possessed this capability.

Nitrate ions are most likely reduced at local cathodic sites on the Cd surface. That such sites are active during anodic dissolution is shown by the evolution of hydrogen that occurs simultaneously with such processes on certain metals. The conspicuous absence of evolved hydrogen during the anodic dissolution is probably due to the high hydrogen overpotential of Cd. The apparent valence in the various electrolytes

can be readily explained if NO_3^- acts as a depolarizer. In solutions containing no NO_3^-, local corrosion cannot occur and the normal valence is observed. When NO_3^- is present, it removes hydrogen from the local cathodes, corrosion proceeds along with anodic dissolution, and a valence lower than normal is observed. The metallic particles appearing in the gray surface film probably result from a disintegration of the electrode caused by a combination of local corrosion and anodic dissolution. These two processes would undermine and dislodge particles whose formation is initiated by the protection of an area by the local cathodic (depolarization) reaction. Also, uneven current densities on the electrode surface caused by nonuniform or disrupted surface films would lead to a similar situation.

With this concept of the anodic dissolution, a model can be described mathematically to give the apparent valence of Cd as follows.

Consider the total rate that Cd is being removed from the electrode surface as the summation of separate rates in a manner similar to that proposed by Hoey and Cohen (15). For this case, anodic dissolution, local corrosion, and disintegration will be considered. Thus

$$r_t = r_e + r_c + r_d \qquad [2]$$

but,

$$W/W_i = r_e/r_t = r_e/(r_e + r_c + r_d) \qquad [3]$$

and from Eq. [1]

$$V_i = 2r_e/(r_e + r_c + r_d) \qquad [4]$$

The rate of anodic dissolution is proportional to the current density in the external circuit as related by Faraday's law

$$r_e = k_e i \qquad [5]$$

The local corrosion rate would be a function of several variables, among which are the electronegativity of the metal, the number of local cathodes (purity and metallic structure), hydrogen ion concentration, depolarizer (NO_3^-) concentration, corrosion potential, and the rate at which local cathodes are uncovered. Undoubtedly, the expulsion of Cd ions from the electrode during the anodic dissolution (passage of current) ruptures the protective film and exposes the metal underneath. A greater rate of rupturing the film (increasing current) will expose more metal with its associated local cathodes and allow local corrosion to occur faster, *i.e.*, the rate at which local cathodes are uncovered is a function of current density. This is essentially the concept proposed by Robinson and King (25) in which the corrosion rate of a metal increases with increasing current. Thus, for a given metal specimen

$$r_c = k_c' i^a C^b_{NO3-} C^f_{H+} C^g_{Cd+2} \qquad [6]$$

If the local corrosion rate is controlled by the depolarization reaction rather than by the deposition of H^o on the local cathodes, then C_{H+} and C_{Cd+2} should have little influence, and

$$r_c = k_c\, i^a\, C^b_{NO3-} \qquad [7]$$

Disintegration was proposed as occurring as a consequence of local corrosion, so as a first approximation

$$r_d = k_d' r_C = k_d\, i^a\, C^b_{NO3-} \qquad [8]$$

therefore

$$\begin{aligned} V_i &= 2k_e i/(k_e i + k_c i^a C^b_{NO3-} + k_d i^a C^b_{NO3-}) \\ &= 2/(1 + k' i^m C^n_{NO3-}) \\ &= 2 - 2k' i^m C^n_{NO3-} + 2(k' i^m C^n_{NO3-})^2 - \ldots \end{aligned} \qquad [9]$$

Neglecting terms with orders of two or higher gives

$$V_i = 2 - k\, i^m\, C^n_{NO3-} \qquad [10]$$

which can be conveniently tested with data from Fig. 1 and 2. Log-log plots of $2 - V_i$ *vs.* i and C_{NO3-} are shown in Fig. 3 and 4. Average values for m and n evaluated from the slopes of these plots are 0.49 and 0.41, respectively. The lines through the data points in the figures have been drawn using these slopes. This is seen to correlate the data very well.

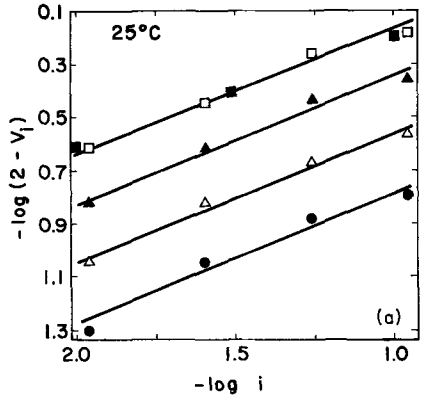

Fig. 3a. Effect of current density on the apparent valence of cadmium at 25°C. ●, 0.03N KNO_3-0.97N K_2SO_4; △, 0.1N KNO_3-0.9N K_2SO_4; ▲, 0.3N KNO_3-0.7N K_2SO_4; □, 1N KNO_3; ■, 1N $Cd(NO_3)_2$.

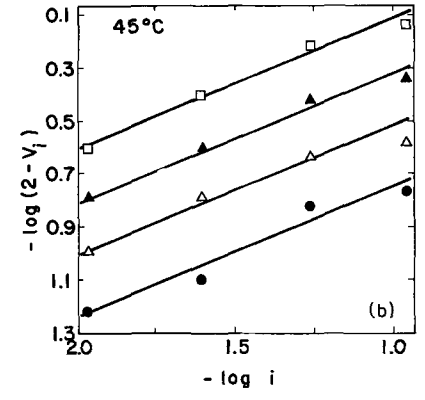

Fig. 3b. At 45°C. Symbols are the same as in Fig. 3a

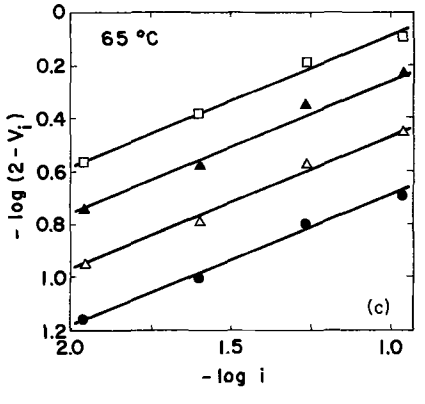

Fig. 3c. At 65°C. Symbols are the same as in Fig. 3a

The effect of C_{Cd+2} can be seen by leaving this term in Eq. [6] and reducing it in the previously described manner to

$$V_i = 2 - k\, i^m\, C^n_{NO3-}\, C^p_{Cd+2} \qquad [11]$$

Figure 5 shows a log-log plot of $(2 - V_i)\ C^{-0.41}_{NO3-}$ *vs.* C_{Cd+2} for various constant current densities. These plots are approximately linear, with a slope p equal to 0.005, thus showing that the effect of Cd^{+2} is slight.

The constancy of the exponents in Eq. [10] and [11] with temperature compels the proportionality constant k to account for the temperature variation of V_i. An

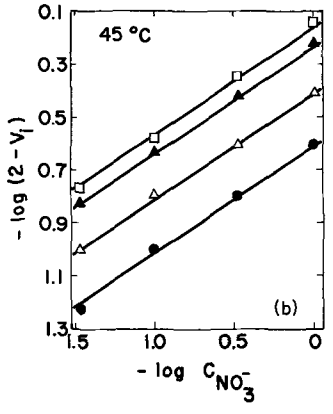

Fig. 4b. At 45°C. Symbols are the same as in Fig. 4a

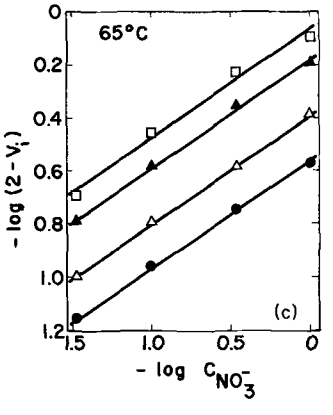

Fig. 4c. At 65°C. Symbols are the same as in Fig. 4a

Arrhenius plot was prepared as shown in Fig. 6 which gave an activation energy of 810 cal and k equal to 8.72 exp (—810/RT). Inasmuch as the k-value is a ratio of rate constants (see Eq. [9]), this activation energy should be regarded more as a method of expressing a temperature variation rather than as having any mechanistic significance. Substituting numerical values in Eq. [10] gives

$$V_i = 2.00 - 8.72\ i^{0.49} C^{0.41}{}_{NO_3^-} \exp(-406/T) \quad [12]$$

which can be used to calculate the apparent valence of Cd ions (or the current efficiency of the Cd anode).

Linear regions were observed in the overpotential *vs.* log i plots at current densities less than 0.01 amp · cm^{-2}. Since the current efficiencies were approximately 100% in all the solutions except NO_3^-, the slopes can probably be associated with the electrochemical dissolution mechanism. Lake and Casey (26)

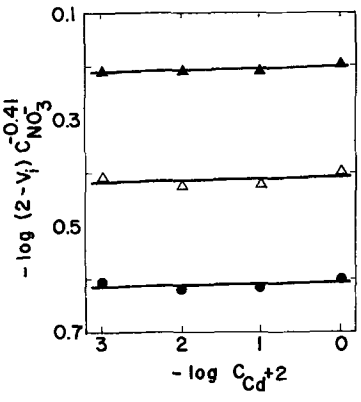

Fig. 5. Effect of Cd^{+2} concentration on the apparent valence of cadmium at 25°C. •, 0.01 amp·cm^{-2}; △, 0.03 amp·cm^{-2}; ▲, 0.10 amp·cm^{-2}.

have suggested that Cd dissolves either as the oxide or as a complex and that $Cd(OH)_2$ precipitates when solubility limits are reached. This, together with observations from these studies, suggests a mechanism as follows

$$Cd(s) + H_2O\ (aq) \rightarrow Cd(OH)(s) + H^+\ (aq) + e \quad [13]$$

$$Cd(OH)\ (s) \rightarrow CdO\ (s) + H^+\ (aq) + e \quad [14]$$

$$CdO\ (s) + 4\,X^-\ (aq) + H_2O \rightarrow CdX_4^=\ (aq) + 2\,OH^-\ (aq) \quad [15a]$$

or

$$CdO\ (s) + H_2O\ (aq) \rightarrow Cd^{+2}\ (aq) + 2\,OH^-\ (aq) \quad [15b]$$

where X^- represents halide ions which are known to complex readily with Cd^{+2}. For either [15a] or [15b] controlling, the theoretical Tafel slope would be 30 mv, approximately equal to that observed. In nitrate solutions, the anodic dissolution is accompanied by local corrosion and disintegration whose rates are varying with current density. Therefore, the measured potentials are probably mixed potentials and do not have mechanistic significance.

Conclusions

The anodic dissolution of Cd has been studied in aqueous solutions containing various cations (K^+, Cd^{+2}) and anions (Cl^-, Br^-, I^-, Ac^-, $SO^=$, NO_3^-). The calculated valence of the Cd ions was the normal value (+2) in all solutions except those containing NO_3^-. In the latter solutions, the calculated (apparent) valence was less than two (anodic efficiency less than 100%) and was a function of NO_3^- concentration, current density, and temperature.

The low efficiency of the Cd anode in nitrate solutions is explained in terms of a mechanism in which the anodic dissolution is accompanied by local corrosion and disintegration. The role of NO_3^- is that of

a depolarizer which removes H° from local cathodic sites on the anode surface. (Cd has a relatively high hydrogen overvoltage and hence hydrogen is not evolved.) Momentary protection of portions of the anode surface (local cathodic sites, uneven film formation, or film disruption) allows anodic dissolution to undermine and ultimately detach metal particles from the surface. These particles are noted in surface films on the anode and the phenomenon by which they are formed has been termed "anodic disintegration." This mechanism leads to a mathematical model which is consistent with the experimental results.

Rate-Controlling Processes in the High-Temperature Oxidation of Tantalum

John Stringer[1]

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

The oxidation of tantalum in the temperature range 500°-950°C is approximately linear. At atmospheric pressure, the rate constant increases with temperature in the temperature range 500°-650° and 800°-950°C, but decreases slightly as the temperature increases from 650° to 800°C. The reaction rate depends on the square root of the oxygen pressure at low pressures and high temperatures, but at lower temperatures the pressure dependence decreases as the pressure increases. On the basis of experimental evidence in the literature, it is concluded that in the temperature range 500°-800°C the rate-controlling process is a reaction at the interface between the atmosphere and a layer of tantalum pentoxide growing adherently on the metal surface. This interface reaction is preceded by an equilibrium adsorption of oxygen on the interface, the adsorption taking place with dissociation. In the temperature range 800°-950°C, the over-all linear rate is a consequence of the diffusion-controlled growth of adherent pentoxide to a critical thickness, at which the scale fails from the metal. The corollary to this conclusion is that the rate of the diffusion process must be strongly dependent on the oxygen pressure.

The oxidation of tantalum, and the not-dissimilar oxidation of niobium, has been studied extensively for both practical and theoretical reasons. The reaction kinetics are of considerable interest, since the dependence of the reaction rate on both temperature and oxygen pressure is unusual.

After an initial period (a few minutes at 950°C and a few hours at 500°C) the reaction rate becomes approximately constant (linear rate law). The linear rate constant increases with temperature from 500° to 650°C and from 800° to 950°C, but decreases slightly in the temperature range 650°-800°C. The rate constant increases with pressure, the effect decreasing as the pressure increases. Increasing the temperature increases the pressure at which the pressure-dependence starts to diminish.

The principal reaction product is tantalum pentoxide, Ta_2O_5. The oxide grows adhering to the metal surface and is formed under compressive growth stresses. Eventually these cause the scale to fail from the metal surface. Growth of adherent oxide recommences immediately on the freshly exposed metal surface, and repetition of this process produces a laminated detached scale. In addition to the pentoxide, platelets of a suboxide are formed penetrating into the metal from the scale/metal interface. Finally, oxygen also dissolves in the metal.

While the oxidation of niobium has a number of points of similarity to that of tantalum, notably in the temperature- and pressure-dependence of the rate

[1] Present address: Department of Metallurgy, University of Liverpool, Liverpool, England

constant, there are also a number of important differences. In addition to the pentoxide, stable lower oxides are formed. The platelets of a metastable suboxide are much less evident, particularly at higher temperatures. Finally, the pentoxide exhibits a phase change at approximately 800°C, and there is a clear change in the reaction kinetics associated with the change.

In this paper, the effect of a number of variables on the kinetics and reaction-product morphology are reviewed in an attempt to identify the rate-controlling processes in the oxidation of tantalum in the linear oxidation region for temperatures of 500°-950°C and oxygen pressures of 1-60,000 Torr.

Effect of Experimental Variables on Experimental Results

Impurities in the metal.—No systematic study has been made of the effect of impurities on the rate of oxidation of tantalum, but the rate constants reported by a number of investigators (1-5) over a period of 10 years using tantalum from a number of sources agree closely, suggesting that the effect of impurities is small.

Insufficient observations of the other features such as scale structure and morphology were reported in most of the earlier investigations to permit evaluation of the effect of impurities on these.

Grain size.—Only one systematic study of grain-size effects has been made and that was relatively limited in scope (6). No effect of grain size on reaction rate was observed. There do appear to be differences in the scale morphology and in the suboxide platelet distribution as a function of grain size. In coarse-grained samples, long, straight suboxide plates are formed, and these produce pores in the outer detached pentoxide (7). In fine-grained samples, in contrast, the size of the platelets is limited by the grain size, and thus the voids in the pentoxide are difficult to discern. While the grosser features of the scale on coupon specimens are not obviously affected by the tantalum grain size, it has been demonstrated that, over convex surfaces, the pore lines can act as paths for tensile fractures in the detached scale (6, 7). Therefore, it is possible that the scale morphology over convex surfaces may show a grain-size dependence.

Cold work.—Cold work apparently has no effect on the linear oxidation rate in this temperature range (6). The suboxide plates appear curved in cold-worked specimens, but apart from this there is no apparent effect on oxide morphology.

Surface preparation.—Since the linear oxidation is a thick-film, steady-state process, no effect of initial surface preparation would be expected, and, in fact, none is observed (6).

Specimen shape.—It has been demonstrated that, at 820° and 925°C, ¼-in. diameter spheres oxidize more rapidly than ½-in.-diameter spheres which in turn oxidize more rapidly than coupon specimens (6). This is consistent with the tendency of coupon specimens to oxidize more rapidly at the edges and corners than at the centers of the flat faces. The scale formed over convex surfaces contains fissures normal to the metal surface penetrating inward from the outside, and it appears that these fissures are produced by tensile stresses in the outer layers of the oxide, generated by the pressure of the newly forming oxide layers beneath. There is no obvious difference at steady state in the structure of the oxide plates as a function of specimen shape.

Specimen texture.—There is a clear orientation dependence of the oxidation rate at the higher temperatures. At 925° and 820°C {110} faces oxidize more rapidly than any others; {100} faces oxidize more slowly (8). At 600° and 500°C there is no obvious effect of orientation. As a consequence, one might expect the oxidation rate to be a function of texture at high temperatures. No study of this has been made yet.

The oxide structure is clearly a function of orientation. Under steady-state reaction conditions, the suboxide platelets are always formed parallel to $\{100\}_{Ta}$ throughout this temperature range. At higher temperatures the lines of pores above the platelets act as crack paths, and, if the plates lie at 45° to the surface, scale fracture under the compressive growth stresses is facilitated. As a result, the laminations in the detached scale are much thinner above {110} faces than above {100} faces (8).

Gaseous impurities.—Small amounts of gaseous impurities in the oxidizing atmosphere have not been studied in any detail, but they appear to have a negligible effect on the oxidation rate and the scale structure.

Temperature and Pressure Dependence of the Oxidation Rate

The first experiments on the pressure dependence of the oxidation rate were performed by Peterson *et al.* (1), who described their results by the empirical equation

$$\text{rate} = K_1 \frac{K_2 P_{O_2}}{1 + K_2 P_{O_2}} \qquad [1]$$

Later, Cowgill and Stringer (9) pointed out that at low pressures this reduces to

$$\text{rate} \propto K_1 K_2 P_{O_2} \qquad [2]$$

whereas experiment showed that

$$\text{rate} \propto k\, P_{O_2}^{1/2} \qquad [3]$$

Accordingly, these investigators (9, 3) suggested replacing Eq. [1] by

$$\text{rate} = K_1 \frac{K_2 P_{O_2}^{1/2}}{1 + K_2 P_{O_2}^{1/2}} \qquad [4]$$

This point was confirmed by Kofstad (4), who suggested a modified form of Eq. [4].

On a direct plot of rate *vs.* pressure, there is not a great deal of difference between the fit obtainable with Eq. [1] and [4]; but a plot of log rate *vs.* log pressure, by expanding the low pressure region, emphasizes the difference between the two forms.

Figure 1 shows a set of results for the oxidation of a tantalum coupon at 600°C. The full line is the best fit using Eq. [4]; with the rate in g/cm²/sec and the pressure in Torr, $K_1 = 6.53 \times 10^{-6}$, and $K_2 = 0.031$. In Fig. 2 the same equation is plotted over five orders of pressure and compared with constant pressure data from the literature. Plainly, the agreement between the various investigators is excellent: it is not possible to fit these data using Eq. [1].

The empirical Eq. [1] and [4] can be interpreted in terms of a reaction mechanism in which the rate-controlling process is linearly dependent on the ad-

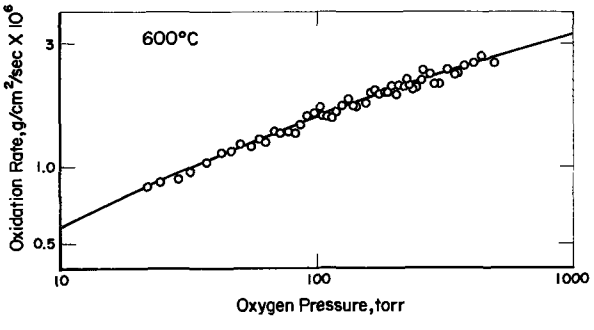

Fig. 1. Pressure dependence of the oxidation of tantalum at 600°C; data from a varying pressure experiment.

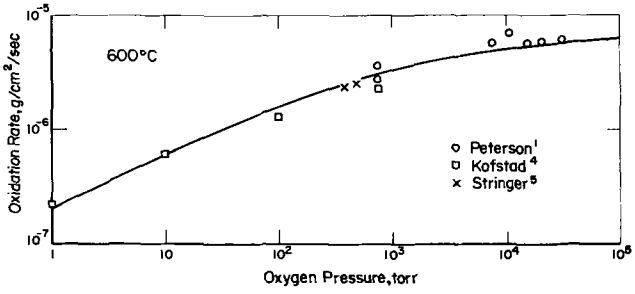

Fig. 2. Pressure dependence of the oxidation of tantalum at 600°C; constant pressure data from the literature. The curve is the same as for Fig. 1.

sorbed oxygen concentration at some interface. In the case of Eq. [1] the oxygen is adsorbed as molecules; in the case of Eq. [4] the adsorption takes place with dissociation, and the oxygen is adsorbed as atoms.

If this is the situation, one may expect that the temperature dependence of K_1, which is related to the rate of the rate-controlling process, will be given by a conventional Arrhenius equation

$$K_1 = K^{\circ}_1 \exp\left(\frac{-Q_1}{RT}\right) \qquad [5]$$

and the temperature dependence of K_2, which is related to the adsorption process, will be given by a Langmuir expression

$$K_2 P_{O_2}^{1/2} = K^{\circ}_2 T^{-5/2} \exp\left(\frac{Q_2}{RT}\right) \qquad [6]$$

In this expression, the $T^{-5/2}$ term arises from the temperature dependence of the concentration of the gas phase at constant pressure T^{-1} and the temperature dependence of the reciprocal of the partition function of the gas for unit volume, $T^{-3/2}$. In these expressions R is the gas constant, T is the absolute temperature, and Q_1 and Q_2 are positive energies. Conventionally, K°_2 is regarded as being independent of temperature, but the temperature dependence of K°_1 is more uncertain: it is assumed to be small in comparison with that of the exponential term. Substituting [5] and [6] into [4]

$$\text{rate} = \frac{K^{\circ}_1 K^{\circ}_2 T^{-5/2} \exp\left(\frac{Q_2 - Q_1}{RT}\right)}{1 + K^{\circ}_2 T^{-5/2} \exp\left(\frac{Q_2}{RT}\right)} \qquad [7]$$

In this work, both K°_1 and K°_2 are regarded as being independent of temperature.

Figure 3 shows the rate constants reported in the literature by a number of investigators, corrected to a pressure of 760 Torr where necessary using the experimentally determined pressure dependence. The full line is drawn according to Eq. [7] with Q_1 = 67,700 cal/mole and Q_2 = 70,000 cal/mole. The fit is quite good over the range 500°-820°C. The $T^{-5/2}$ terms cannot be neglected, since the variation of the exponential terms is small at elevated temperatures, but the shape of the curve does not depend significantly on their inclusion: the value of Q_2 is merely altered slightly.

One would expect this mechanism to cease to operate at high temperatures and low pressures because the adsorbed surface concentration would fall so low that the adsorption step would become the rate-determining process. At 760 Torr and 800°C the volume per molecule in the gas phase is approximately 10^{-19} cm^3. Assuming the sites on the adsorption interface are roughly 4 x 10^{-8} cm apart, the surface concentration will equal the mean concentration in the atmosphere adjacent to the surface when the fractional surface coverage θ falls to approximately 10^{-2}. One would not

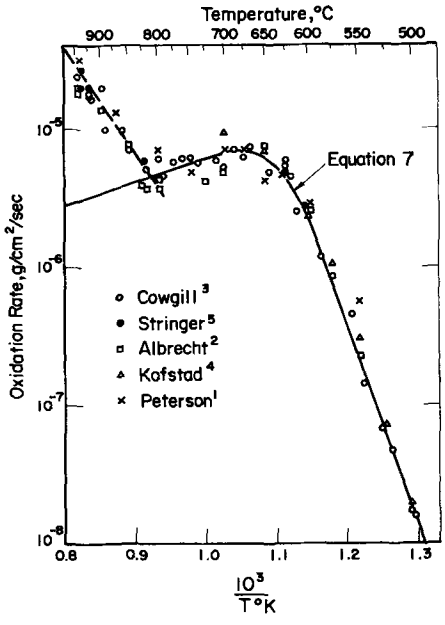

Fig. 3. Oxidation rate of tantalum as a function of temperature at an oxygen pressure of 760 Torr showing the fit of the adsorption model.

expect therefore that the mechanism would continue to describe the reaction when θ is appreciably less than this.

The fractional coverage of the adsorption interface θ is given by

$$\theta = \frac{K_2 P_{O_2}^{1/2}}{1 + K_2 P_{O_2}^{1/2}} \qquad [8]$$

and Fig. 4 shows θ calculated for the curve shown in Fig. 3. At the temperature at which Eq. [7] ceases to describe the experimental results, θ is approximately 10^{-3}, close to the estimate above. However, it must be stressed that this merely indicates that the mechanism does not continue to give a fit to the data in regions where this is physically unlikely: it does not predict or help in understanding the high-temperature process.

For the empirical fit of the data shown in Fig. 2 one calculates $\theta_{760} = 0.46$, which is the value at 628°C according to Fig. 4. The experimental data at 650°C are shown in Fig. 5, and good fit is obtained with K_1 = 8.0 x 10^{-5} and K_2 = 0.004. These two values correspond to $\theta_{760} = 0.099$, equivalent to a temperature of 679°C according to Fig. 4. While these agreements

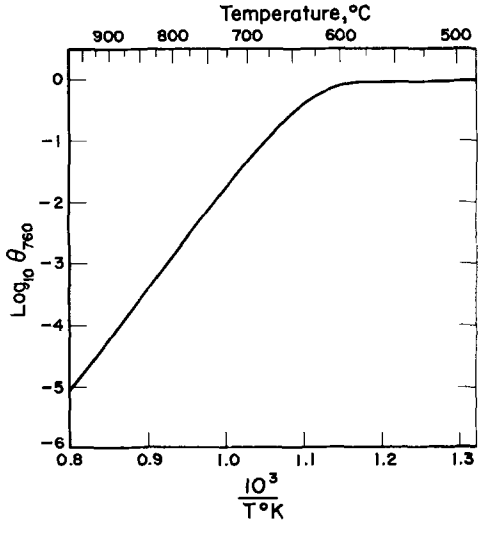

Fig. 4. Fractional surface coverage at an oxygen pressure of 760 Torr, θ_{760}, as a function of temperature.

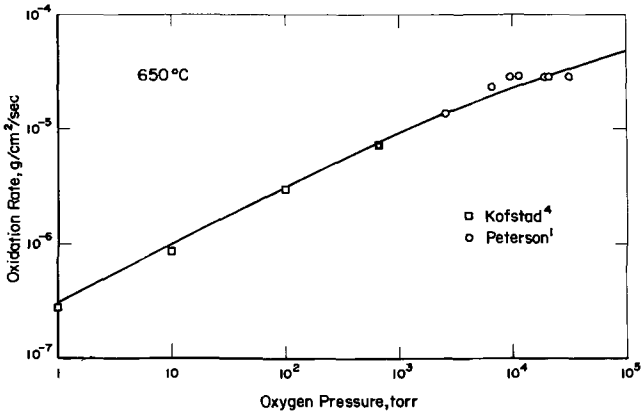

Fig. 5. Pressure dependence of the oxidation of tantalum at 650°C.

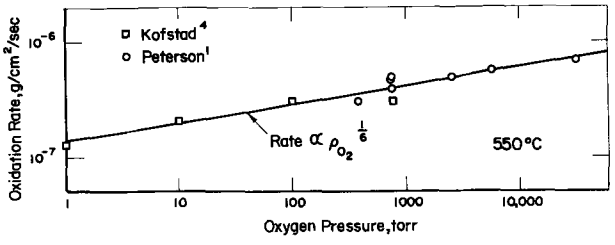

Fig. 6. Pressure dependence of the oxidation of tantalum at 550°C.

are not exact, they are sufficiently close to be satisfactory.

There are some important defects in the theory, however. Equations [4] and [7] imply that, as the pressure changes, the general form of the temperature dependence remains the same, and, in particular, that the negative slope of the higher temperature range remains the same. Kofstad's data (10) suggest that this is not so; at 10 Torr and below the rate increases slightly with temperature in the range 650°-800°C. No other investigation in this temperature and pressure range has been reported.

At 550°C one would expect θ_{760} to be in the range 0.92-0.98, but the published data of Kofstad (4) and Peterson (1) shown in Fig. 6 are better fitted by an equation of the form

$$\text{rate} \propto P_{O_2}^{1/6} \qquad [9]$$

However, this may be fortuitous. Kofstad's data alone are not inconsistent with Eq. [4] and correspond to a high value of θ.

Scale Morphology

It is clear that the properties of the tantalum pentoxide scale vary as a function of temperature. At the low temperatures the scale is soft and weak, and the layers in the laminar detached scale are thin. At high temperatures the scale is hard and strong, and the layers are much thicker. Actually, the scale is most fragmentary at about 600°C; the scale formed at 500°C appears to be far more coherent with a greater layer thickness, and the scale at 820°C is clearly much more continuous. Typical scales are shown in Fig. 7. Because of this, it is tempting to suggest that the origin of the maximum in the rate of 650°C and the anomalous temperature dependence between 650° and 800°C is related to the changing properties of the scale. In fact, this suggestion has been made by Aylmore, Gregg, and Jepson (11) in the case of niobium.

If the oxidation is assumed to take place by the repeated (parabolic) diffusion-controlled growth of adherent scale layers to a critical thickness at which they fail, an average linear rate constant K_l will result

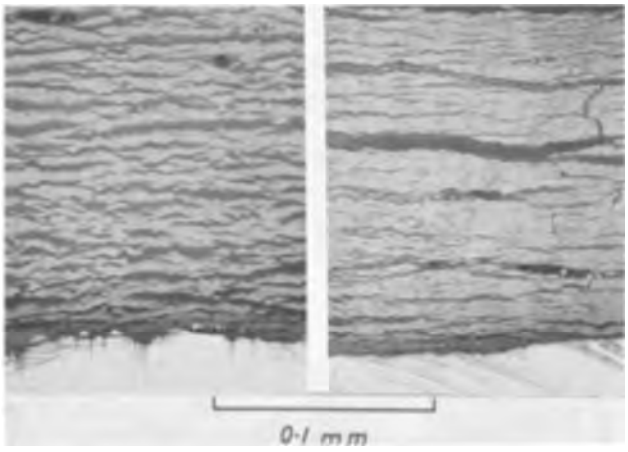

Fig. 7a. Cross sections of oxidized samples showing the lamina thickness in the detached pentoxide. Sample oxidized at 500°C, 450 Torr.

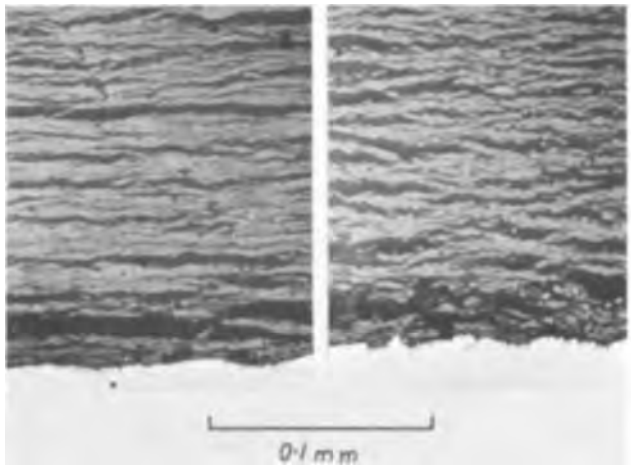

Fig. 7b. Oxidized at 600°C, 450 Torr

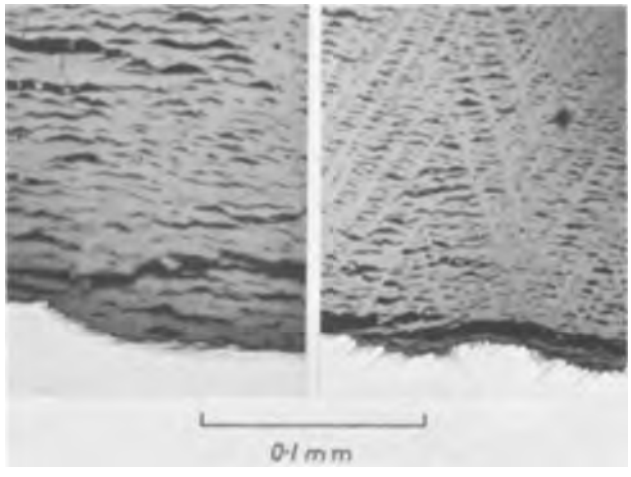

Fig. 7c. Oxidized at 820°C, 450 Torr

which is related to the parabolic rate constant K_p and the critical scale thickness w_c

$$K_l = \frac{K_p}{w_c} \qquad [10]$$

If the anomalous temperature dependence is solely a result of the change in the scale properties, one can easily calculate, using Eq. [9] and Fig. 3, the sort of change one would need to see in the critical scale thickness. Between 600° and 800°C the scale should

increase in thickness by approximately 100 times. It is extremely difficult to obtain a quantitative measure of the layer thickness because of the wide variation from point to point, the loss of resolution due to multiple reflection in the oxide, and the indeterminate effects of cooling; but it is difficult to obtain a value of greater than 10 times for the change in the layer thickness in this temperature range.

However, the qualitative parallel between the temperature dependence of the rate and that of the scale layer thickness is interesting and may well be significant.

Suboxide Structure and Morphology

Since the suboxide or suboxides are metastable at all temperatures, one cannot prepare them in bulk to examine their properties. The metal + suboxide/pentoxide interface is irregular, and one must polish some way back from the interface to obtain good x-ray results, but the volume fraction of the suboxide is too small even at very short distances from the interface and the structures appear to be too close to that of tantalum itself to obtain reasonable results. Further, all one's observations of necessity must be made on specimens cooled from reaction temperature. Studies have been made on the structure of the suboxides formed in the very early stages of the oxidation, prior to the complete coverage of the surface by the pentoxide, using high-temperature x-ray diffraction and hot-stage metallography (12). It is dangerous to assume, however, that these suboxides are the same as those present in the steady-stage process (8) since, for example, the growth stresses associated with the adherent Ta_2O_5 are absent.

Recently, Stringer (7) pointed out that, above suboxide platelets lying more or less normal to the metal/oxide interface, lines of pores are formed in the pentoxide and argued that the existence of these pore lines in the scale is evidence for the presence of the platelets at reaction temperature. Using this as an indication, it appears very likely that all the platelets observed in cross sections of specimens cooled from steady-state reaction in this temperature range were present at temperature and have not precipitated on cooling. Pore lines are evident in scales formed at 600°-950°C, although as the temperature decreases they become more difficult to see.

All the platelets formed during the steady-state (linear) reaction in the temperature range 500°-925°C are parallel to $\{100\}_{Ta}$ (8).

Finally, Fig. 8a shows, in polarized light, a section through the broad part of a platelet in a specimen oxidized at 925°C, 450 Torr. There is evidence of an internal structure, which might suggest a transformation in the platelet on cooling. However, the same type of internal structure is observed in platelets formed throughout the whole temperature range, (Fig. 8b shows the internal structure in plates formed at 500°C) so that any transformation must take place below 500°C. It is also possible that this is a domain structure formed at temperature, but so far it has not been possible to determine this.

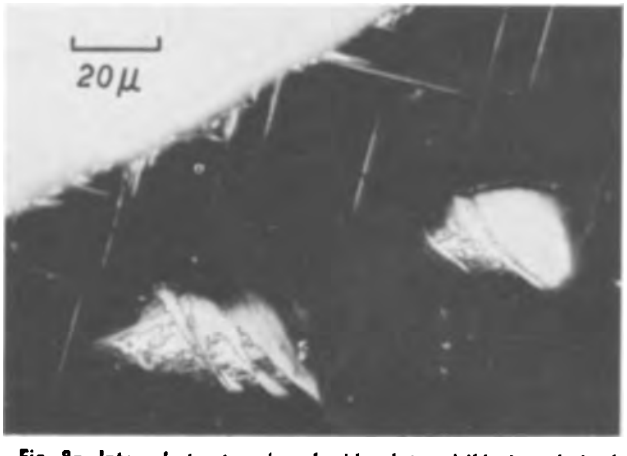

Fig. 8a. Internal structure in suboxide plates visible in polarized light; oxidized at 925°C, 450 Torr.

Fig. 8b. Oxidized at 500°C, 450 Torr.

It appears, therefore, that one cannot interpret the observed temperature dependence of the rate constant in terms of a change in structure or habit of the suboxide. Every indication is that they are the same throughout the whole temperature range. While the number of platelets seems a little less at 950°C than at lower temperatures, there appear to be at least as many at 800° as at 600°C, so that again one cannot explain the anomalous temperature dependence in terms of varying volume fraction of suboxide at the interface.

Scale Failure Modes

The scale grows adhering to the metal surface, and in cross section it appears that both Ta_2O_5/Ta and Ta_2O_5/suboxide interfaces may exist. However, it may be that a very thin layer of suboxide is present between the pentoxide and the metal, and in fact in polarized light a bright line is often visible between the metal and the adherent oxide, both of which appear dark. The dark coloration of the adherent pentoxide in polarized light is of interest. It also appears dark in oblique (dark-field) illumination but white in normal illumination, whereas the detached oxide appears white in all illumination. The color is darkest at the oxide/metal interface and becomes lighter away from the interface (5). The effect may be due to a stoichiometry gradient across the scale, but the striking similarity between polarized light and dark-field illumination suggests that the effect may be due to the absence of internal reflection from flaws in the oxide.

An adherent scale growing under compression on a metal surface may fail either by shear or by blistering from the metal surface. Clearly, shear is a much easier process and is probably much more common; blister-type fractures are sometimes observed, however. For tantalum oxidized at 925°C, 450 Torr, it has been observed that above $\{110\}_{Ta}$ faces the oxide lamellae are much thinner than those above the $\{100\}_{Ta}$ faces, and that this occurs because the pore lines which result from the oxidation of the suboxide plates act as crack paths (8). At 820°C this feature is still evident, but at lower temperatures there is no obvious dependence of laminar thickness on orientation. This may be because a new mode of scale failure operates at low temperatures, or may suggest that a single crack, once nucleated, propagates over a large distance. The oxidation rate is also a function of surface orientation, and in general the faces with the thinnest layer thickness oxidize most rapidly.

The oxidation rate is also a function of surface curvature at higher temperatures, and there is some evidence to suggest that the layer thickness also varies with surface curvature. Stringer (6) reported that at 820° and 925°C ¼-in.-diameter spheres oxidized more rapidly than ½-in.-diameter spheres which in turn

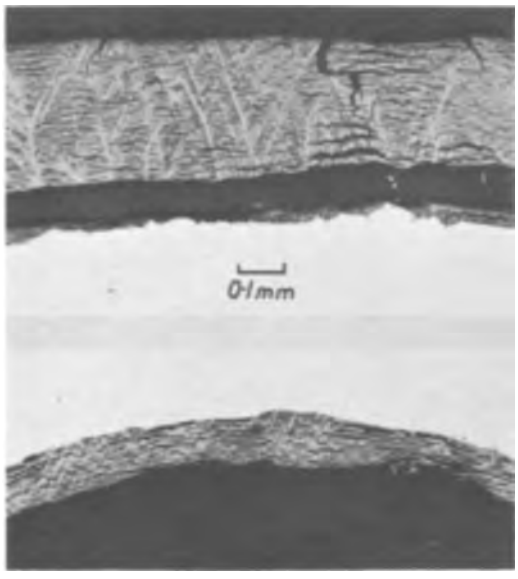

Fig. 9. Scale formed on the outer (upper photograph) and inner (lower photograph) surfaces of a tantalum tube oxidized 100 min at 820°C, 420 Torr; outer radius 6.35 mm, inner radius 1.45 mm, length 9.5 mm.

oxidized more rapidly than coupons. There was no detectable effect of surface curvature on the rate at 600°C. The scales on the spheres contained large radial fissures, apparently due to the tensile stresses produced in the outer layers of the scale by the outward pressure of the newly forming oxide.

Figure 9 shows the scale formed on the outer and inner surfaces of a cylinder oxidized at 820°C. The outer radius of the tube was 6.35 mm, the inner radius was 1.45 mm, total length was 9.5 mm. The cylinder was machined from bar stock and recrystallized, using the same preparation techniques that were used for the spheres (6) to eliminate any possibility of texture effects. The total oxide thickness was approximately three times greater on the convex outer surface than on the concave inner surface. The difference in rate diminishes as the inner radius increases; Figure 10 shows the scale formed on the outer and inner surfaces of a cylinder of internal radius 5.87 mm and external radius 6.35 mm, oxidized at 820°C. The difference in rate is negligible, although the scale formed on the outer surface contains the radial fissures and that on the inside does not. Clearly, the radial fissures do not affect the oxidation rate, and thus the difference in rate for the smaller radius must lie in the scale-fracture process at the interface. The scale layers on the concave surface are thicker in the case of the smaller diameter cylinder, but apparently not as much as three times greater. However, this cannot be determined quantitatively with any great precision. The general effect is much the same at 925°C

Although it is difficult to make categoric statements on the basis of cooled and sectioned samples, it seems likely that the interfaces present in the system are

atmosphere/Ta_2O_5

Ta_2O_5/suboxide

suboxide/Ta

and, possibly,

Ta_2O_5/Ta

One cannot dismiss the possibility of very thin layers of other suboxides, but no evidence for these has been produced. Interfaces between the atmosphere and the metal and between the atmosphere and the suboxides either do not exist or are transitory.

Rate-Controlling Processes

Plainly, the "repeated-parabolic" scaling model described before accords well with the anisotropy of

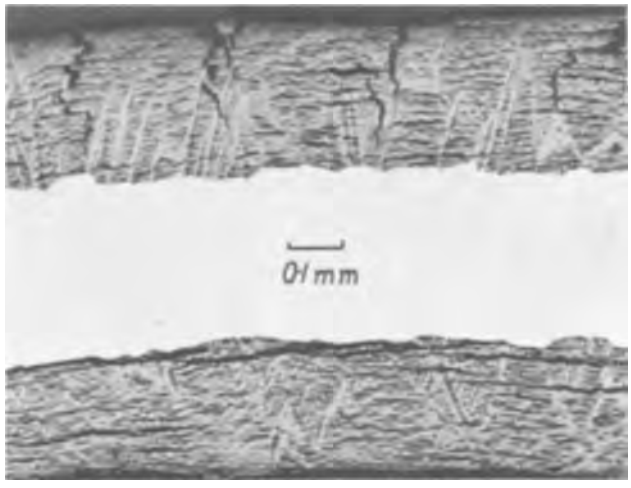

Fig. 10. Scale formed on the outer (upper part) and inner (lower part) surfaces of a tantalum tube oxidized 90 min at 820°C, 420 Torr; outer radius 6.37 mm, inner radius 5.86 mm, length 6.34 mm.

oxidation at elevated temperatures, and numerically the agreement is fair: at 925°C the {110} faces oxidize 5 to 10 times as fast as the {100} faces, and the scale laminations over the {100} faces are 5 to 10 times thicker than those over the {110} faces. If one accepts that failure of the scale is easier on a convex than on a concave surface, it also accords with the curvature-dependence of the oxidation rate at high temperatures, although here the quantitative fit is less easy to evaluate.

However, while qualitatively the variation in laminar thickness parallels the temperature dependence of the rate constant, the quantitative agreement is poor. In addition, it is difficult to reconcile the high pressure dependence of the linear rate constant with this model.

The defect structure of Ta_2O_5 is apparently complicated. Hartmann (13) reported that it was an n-type semiconductor, and, since marker experiments indicate a mobile anion, it was generally assumed that oxygen vacancies were mobile. However, Kofstad (14) has shown that the oxide is p-type at higher oxygen pressures and n-type at lower oxygen pressures, the transition pressure increasing as the temperature increases. An n-type oxide would not be expected to show a significant dependence of diffusion-controlled growth on the oxygen pressure, but a p-type scale should exhibit pressure-dependent growth. The magnitude of the pressure dependence depends on the detailed defect structure, but Kofstad (10) has shown that at pressures in the range 1-760 Torr at 900°C there is an initial parabolic growth of Ta_2O_5 for which

$$K_p \propto P_{O_2}^{1/5.5} \qquad [11]$$

While the critical scale thickness would not be expected to show any direct dependence on the oxygen pressure, it might depend on the rate of the diffusion-controlled growth, thus enhancing the apparent pressure dependence of K_l. However, it would be very surprising if w_c varied as $(K_p)^{-2}$, which would be required to give the observed pressure dependence of K_l.

A linear reaction rate may also result from an interface controlled process. In this event, the reaction rate is linear on a microscopic scale; the adherent growth of the scale to the critical thickness is also linear. There is, of course, nothing in the scale morphology incompatible with this concept.

If the adherent Ta_2O_5 layer is very thin, so that transport through it is very rapid in comparison with the reactions at the pentoxide/metal + suboxide interface, the oxygen activity at this interface would equal that at the atmosphere/pentoxide interface, and so a rate-controlling process at the inner interface would not be incompatible with the observed pressure de-

pendence of the reaction. However, in general, some oxygen-activity gradient must exist across the adherent layer to provide the driving force for the oxygen flux required by the reactions at the inner interface, and so one would expect the oxygen activity at the inner interface to be rather less than that at the outer scale/atmosphere interface. This would have the effect of reducing the apparent pressure dependence of the reaction.

It would appear more likely, therefore, that the rate-controlling process is a reaction at an interface in direct contact with the atmosphere, although one cannot at this stage reject the alternative possibility. The observed temperature dependence may then be explained in one of two ways:

(*A*) The reaction interface or the interface process changes abruptly at 800°C. Below this temperature, oxygen is adsorbed on an interface, dissociating as it is adsorbed. The agreements with the adsorption model in the range 500°-800°C are regarded as real; the apparent disagreements, in the low temperature-pressure dependence, for example, are due to experimental variations between the different investigators. Above 800°C the rate-controlling process is situated at a different interface, again between the atmosphere and one of the solid phases; or, alternatively, there is a change in the rate-controlling process at the original interface. There is insufficient evidence to indicate whether or not an adsorption process precedes this high-temperature reaction.

(*B*) Again there are two reaction interfaces involved, but in general both are present simultaneously. As the temperature is raised the relative area of one increases. The low-temperature temperature dependence is then typical of one of these processes, and the high-temperature temperature dependence of the other. The anomalous temperature range is where both contribute to a significant extent, and is thus a transition region. The low-temperature process is independent of the oxygen pressure, and the high-temperature process depends on the square root of the oxygen pressure. Increasing the pressure at any temperature increases the relative contribution of the low-temperature process, so the adsorption-type pressure-dependence curves again represent transition processes. All the numerical fits with the adsorption model are regarded as fortuitous. This model is much more qualitative than the first.

It is possible to combine the features of these models: one can regard the temperature dependence as being due to a gradual transition in rate-controlling mechanism, but accept that one or both of these processes involve an adsorption step.

However, as discussed earlier, there is every indication that the oxide and suboxide structure and morphology is essentially the same throughout the whole temperature range, and that, in particular, the only interface between the atmosphere and a solid phase is between the gas and the adherent pentoxide layer. For the high-temperature process, furthermore, it is extremely difficult to see how an interface process can show such a clear dependence on the surface curvature or on the scale failure process.

Conclusions

On the basis of the arguments presented above, it appears that the only tenable model for the oxidation involves two distinct processes.

In the range 500°-800°C the fit with the adsorption model seems far too good to be accidental. Not only can the temperature dependence in this range be explained, but the values of θ calculated from the temperature dependence at constant pressure agree quite well with those calculated from the pressure-dependence data at constant temperature. In addition, the process ceases to operate at about the temperature one would expect from a rough calculation.

Since the only interface with the atmosphere is at the outer surface of the adherent Ta_2O_5 layer, the adsorption must take place there. If one accepts that no internal interface process can show a linear dependence on the oxygen concentration at that interface, it follows that the rate-controlling process must also be at the Ta_2O_5/atmosphere interface. The reactions at this interface may be written

$$O_2/gas \rightarrow 2\,O_{ads} \quad [12]$$

$$O_{ads} + O\square/x \rightarrow O/Ta_2O_5 \quad [13]$$

or,

$$O_{ads} \rightarrow O\,\triangle/x \quad [13a]$$

Here the subscript x indicates the outer surface of the adherent scale layer. The ionicity of the species has not been considered, The oxygen vacancies are produced (or oxygen interstitials are consumed) in the scale-forming process at the metal/scale interface

$$2Ta/_{metal} \rightarrow Ta_2O_5 + 5\,O\square/o \quad [14]$$

or

$$2Ta/_{metal} + 5\,O\,\triangle/o \rightarrow Ta_2O_5 \quad [14a]$$

$$O\square/o \xrightarrow{\text{diffusion}} O\square/x \quad [15]$$

$$O\,\triangle/x \xleftarrow{\text{diffusion}} O\,\triangle/o \quad [15a]$$

Similar equations involving possible suboxides may be written, but they do not affect the over-all mechanism. Equation [13] is regarded as the slow step in this sequence.

However, while it is less likely, the reactions at the outer interface may be rapid and the diffusion through the adherent oxide very rapid, and, provided the adherent layer is thin enough, the oxygen activity may be effectively the same at the inner interface as at the outer.

The reaction mechanism clearly alters above 800°C, and, because of the dependence of the rate on surface curvature and because of the apparent correlation between laminar thickness and the linear rate, one must conclude that above 800°C the linear rate is a result of a repeated parabolic process, with the diffusion step (Eq. [15]) being the slow process.

In fact, Kofstad (10) has shown that the initial nonlinear reaction at 900°C is parabolic and that at higher temperatures and lower pressures the rate curves do have the appearance of repeated parabolas. This is probably due to the fact that w_c increases as the temperature is increased so that the "smoothing out" of the repeated parabolae to an over-all linear rate is not possible. The activation energy of the high-temperature process contains the temperature dependence of the parabolic growth rate and the temperature dependence of the scale layer thickness. Since the latter clearly increases with temperature, the real temperature dependence of the parabolic rate constant must be greater than that of the linear rate. The activation energy for the linear rate is approximately 35,000 cal/mole, while Kofstad (10) gives an activation energy of 45,000 cal/mole for the initial parabolic rate in the range 900°-1050°C.

However, in this range the linear rate constant depends on the square root of the oxygen pressure (approximately). According to Kofstad (10) the parabolic rate constant varies as $P_{O_2}^{1/5.5}$ at pressures above the n → p transition and is independent of pressure at pressures well below the transition. Therefore, for the linear rate to exhibit the observed pressure dependence, the critical scale thickness w_c (which cannot depend directly on oxygen pressure) must depend on the rate, and in fact

$$w_c \propto (K_p)^{-2} \propto P^{-1/3} \quad [16]$$

It is extremely difficult to measure w_c with any accuracy, but at 1000°C Kofstad's data (10) show no obvious pressure dependence of the scale thickness at the break-away from the initial parabola. At 1200°C w_c is approximately 1.5 times as great at 1 Torr as at

10 Torr; Equation [16] gives a value of 2.15. While the data are clearly insufficient to confirm or deny the model, they are equally clearly not inconsistent with it.

Acknowledgment

The experimental work was performed by R. O. Dodds and the metallography by C. H. Brady. The research was supported by the Columbus Laboratories of Battelle Memorial Institute. Thanks are due to Per Kofstad, 1966 Institute Fellow at the Columbus Laboratories, who made a number of helpful criticisms and suggestions.

Manuscript received Nov. 10, 1966. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Carburization of Fe-Cr Alloys During Oxidation in Dry Carbon Dioxide

C. T. Fujii and R. A. Meussner

Naval Research Laboratory, Washington, D. C.

ABSTRACT

Iron-chromium alloys (1-15 w/o [weight per cent] Cr) oxidized in dry carbon dioxide at 700°, 900°, and 1100°C form duplex scales which are similar in structure to those generated in H_2O-Ar atmospheres, *i.e.*, a detached but continuous outer layer of iron oxides (predominantly FeO) and a porous inner layer of FeO and Fe-Cr spinel particles. Carburization accompanies this oxidation at all temperatures, and the resulting microstructural changes, the carbides formed, the hardness increases and the carbon content of homogeneous specimens are related to the equilibria of the Fe-Cr-C system. The carburization and the continued high oxidation rates, in spite of the detached duplex structure of the scale, require that a gaseous transfer of oxygen and carbon occur within the voids separating the outer and inner oxide layers. This requirement suggests a carbon permeation of the dense outer scale and the generation of a CO_2-CO atmosphere in these voids which is carburizing as well as oxidizing to the alloy.

The high-temperature oxidation of iron-chromium alloys in carbon dioxide produces two-layered scales which are very similar in structure to those generated on these alloys in atmospheres of H_2O-Ar (1). An example of this scale structure is illustrated by the micrograph of Fig. 1. The outer layer of iron oxides is dense and crack-free while the inner layer of wustite and an Fe-Cr spinel is relatively porous. The oxidation process generates large voids between the outer and inner scale layers, but the extension of these voids does not appear to alter the high oxidation rates of these alloys. In fact, these rates are comparable to that of pure iron where the scale remains rather adherent and the diffusion of iron is unhindered by voids.

Within the proper experimental limits of time and temperature linear rates are observed for the oxidation of iron in CO_2-CO mixtures, and there is general agreement that the reaction at the gas:oxide interface is the rate determining process (2-4). Thus, the diffusion of iron through the oxide is sufficiently rapid to preclude the observation of parabolic oxidation rates. Similarly, the oxidation rates of Fe-Cr alloys indicate that an adequate flux of iron to the gas:oxide interface is maintained in spite of the extensive voids separating the outer from the inner scale layer. Although this detachment is never complete, the remaining columns of oxide connecting the two layers appear to be adequate as diffusion paths for the iron required by the oxidation reaction at the outer-oxide:gas interface. Since the integrity of the outer detached scale layer is preserved, an alternative source of iron must be provided to augment the "normal" diffusion process through the connecting oxide columns if the high oxidation rates are to be sustained.

The experimental evidence in the previous study of the oxidation of Fe-Cr alloys in water vapor indicated a substantial contribution to the iron flux in the

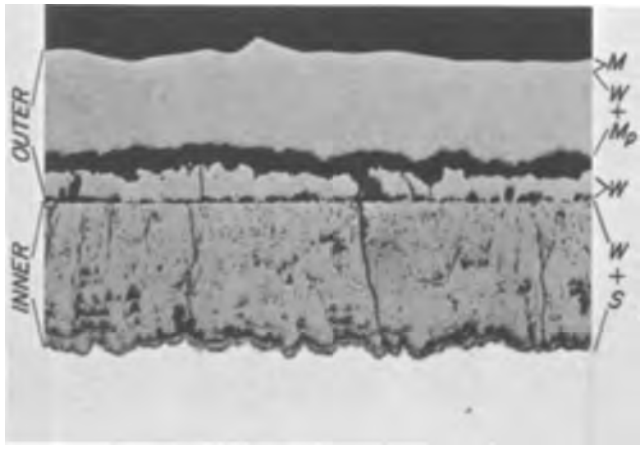

Fig. 1. Unetched microstructure of a typical two-layered scale, from Fe-15Cr alloy oxidized for 24 hr at 900°C in 1 atm of dry CO_2. Magnification approximately 60X.

outer scale layer by the decomposition of wustite at the inner surface of this oxide layer (1, 5). The iron released by this process diffuses through the scale and reforms FeO at the gas: oxide interface, and the oxygen released provides the atmosphere for the growth of the inner scale. The transport of oxygen across the voids is necessarily gaseous, and in this case a H_2O-H_2 mixture was suggested as the vehicle for the transport of oxygen within the voids. A similar mechanism for the oxidation of iron and Fe-Si alloys in oxygen-water vapor mixtures has been subsequently and independently suggested by Rahmel and Tobolski (6, 7).

The present detailed metallographic study of the scales formed on the Fe-Cr alloys oxidized in carbon dioxide suggests that a gaseous transport of oxygen from the outer to inner scale layer also occurs in this system and that carbon is an active participant as a carrier. Thus, a CO_2-CO atmosphere is generated in the voids, and the mechanism by which the two-layer scale structures are formed in carbon dioxide is analogous to that in H_2O-Ar atmospheres. This analogy requires that the scale is permeable to carbon. However, in contrast to oxidation in water vapor where the solution of hydrogen in the alloy produces no structural changes, the accumulation of carbon in the alloy is easily discerned through microstructural evidence (carbide precipitation in many instances) and hardness increases. Evidence for the carburization of the alloy is provided in the detailed description of the specimen structures in the present paper. A subsequent paper will describe the effects of temperature, carbon dioxide partial pressure, and alloy content on the oxidation rates.

Because these results show carburization in a highly oxidizing atmosphere (CO_2 at atmospheric pressure) they suggest that similar effects may occur during the oxidation of many complex high-temperature alloys in carbon bearing atmospheres. Thus accelerated oxidation rates as well as significant changes in the chemistry and properties of these alloys may stem from this vapor transport process. These effects have been largely ignored in evaluations of alloy oxidation, and only a few recent publications give any attention to contamination of the alloy by carbon during oxidation (8-11). Even in basic studies of the oxidation mechanisms of iron and binary iron alloys in which CO_2-CO atmospheres are often employed, carburization accompanying oxidation appears to have escaped the notice of most previous investigators.

Experimental

The apparatus used in continuously recording the weight-gain of the specimen during each experiment and the essentials of the gas purification and metering systems, have been previously described (5). Commercial "bone-dry" grade carbon dioxide, passed through two traps cooled by dry ice-acetone, provided the oxidizing atmosphere at a flow rate of 200 ml/min (approximately 16 cm/min linear flow rate in the oxidation chamber) and 1 atm pressure. The specimens were of the same alloys used in the previous study, and the same annealing and chemical cleaning procedures were used in preparing these specimens (5).

Table I. Composition of Fe-Cr alloys

Element	Weight per cent of element in the alloy				
	Fe-1Cr	Fe-5Cr	Fe-10Cr	Fe-15Cr	Fe-20Cr
Cr	0.99	5.0	9.9	14.8	19.5
C	0.001	0.007	0.005	0.005	0.007

N*	—	0.0010	0.0019	0.0028	0.0037

* The oxygen and nitrogen contents were determined by vacuum fusion, not determined in Fe-1Cr alloy.

The compositions of the alloys are shown in Table I. All of the experiments were terminated by lowering the furnace from around the oxidation chamber, thus causing the specimen to cool rapidly in the flowing carbon dioxide atmosphere. The results reported here are from oxidation experiments at 700°, 900°, and 1100°C. At each temperature, the oxidation times were approximately constant for all alloys and the total weight gain per unit area of all specimens were approximately equivalent, *i.e.*, 50 hr at 700°C yielding a weight gain of 25 mg/cm^2; 24 hr at 900°C, 70 mg/cm^2; and 3 hr at 1100°C, 70 mg/cm^2.

Examinations of the oxidized specimens included studies of the surface character of the outer scale layer, powder x-ray diffraction analysis of the outer and inner scales, identification of carbides, carbon analyses, detailed metallographic studies, and microhardness measurements. The oxide samples for the x-ray diffraction analyses were carefully removed from one side of each specimen leaving the oxide layers on the reverse side intact. The specimen was then vacuum impregnated and mounted in an epoxy resin for metallography and hardness measurements.

Oxidation Results

While the oxidation experiment is kinetic in nature and thermodynamic equilibrium is not attained in all parts of the system, the oxide structures and the carbides precipitated in the alloys at temperature are, nevertheless, in agreement with the Fe-Cr-O equilibrium diagram from Seybolt's work (12) and the equilibrium data of the Fe-Cr-C system reported by Bungardt, Kunze, and Horn (13). There must be a finite oxygen solubility in the alloy and a carbon solubility in the oxides, but these are assumed to be very limited, and thus the constructions of the respective ternary diagrams are not significantly altered. The fact that the oxides and carbides observed experimentally conform to the equilibrium diagrams indicates that these assumptions are reasonable.

For the description of the oxidation products and the carburization data, the scale structures may be conveniently divided into (*i*) outer scale, (*ii*) inner scale, and (*iii*) subscale and alloy. Since the oxide structures are similar to those produced in H_2O-Ar atmospheres, and these have been described in detail previously (1), the present emphasis will be on the differences in the structures of these specimens oxidized in carbon dioxide and those oxidized in water vapor, and on evidence of carburization of the alloys.

The constitution and microstructural characteristics of the scales formed on Fe-Cr alloys in carbon dioxide are summarized in Table II. These are general observations and apply to all alloy compositions investigated, *i.e.*, the 1, 5, 10, and 15 w/o Cr alloys. The differences in the structures and composition of the oxides which may be ascribed to chromium content will be described in the text in the appropriate sections.

Outer scale.—The composition of the outer scale is dependent on the temperature and the oxidation time. Lower temperatures and longer times favor increasing amounts of the higher oxides of iron because of the decreased rate of iron delivery to the gas: oxide interface. This tendency toward the progressive generation of layers of the higher iron oxides is indicated by the summary of the outer scale structure in Table II where it can be seen that a magnetite surface layer and a hematite surface layer formed on the 900° and 700°C, respectively.

Figure 2a shows the scale structure produced on an Fe-5Cr specimen oxidized for 50 hr at 700°C. This outer scale structure, typical for all of the alloys oxidized at this temperature and for this length of time, is composed of three oxide layers, wustite, magnetite, and hematite. Covering the surface of the thin hematite layer is a dense growth of fine hematite needles. The moderate thickness of the middle layer of magne-

Table II. Summary of constitution and microstructural characteristics of scales and alloys

Feature	Temperature (oxidation time)		
	700°C (50 hr)	900°C (24 hr)	1100°C (3 hr)

Legend of abbreviations: H, hematite, αFe_2O_3; M, magnetite, Fe_3O_4; M_p, *magnetite ppt'd on cooling*; W, wustite, FeO; S_p, FeCr spinel, $(Fe,Cr)_3O_4$; R, rhombohedral Cr_2O_3 or $(Cr,Fe)_2O_3$.

tite indicates that the initial formation of this layer occurs relatively early since this is a comparatively slow growing layer. The source of the voids which are visible within this layer has not been established.

The scales formed at 900° and 1100°C are structurally similar except that as a consequence of the shorter oxidation time and the higher temperature, the surface magnetite is not generated on the specimens in the 1100°C group. With this exception the microstructure of an Fe-15Cr specimen oxidized at 900°C (Fig. 1) is typical of specimens from the 900° and 1100°C experiments. The outermost wustite layer at both temperatures is oxygen-rich, and evidence for this is the proeutectoid precipitation of magnetite in this outer layer in all of these specimens. With extended oxidation times a second wustite layer is usually generated on the inner scale surface as shown in Fig. 1. This layer is free of precipitated magnetite, an indication of the difference in the oxygen content of these two wustite layers which comprise the outer scale.

The external topography of these specimens were characteristic of the oxide phase at that surface, *i.e.*, short red needles of hematite at 700°C, dull, rough, magnetite crystals at 900°C, and large, lustrous, highly faceted wustite crystals at 1100°C. The wustite surfaces formed in carbon dioxide produced no needles or whiskers, which had been characteristic of these surfaces formed in $0.1H_2O$-0.9Ar atmosphere. This

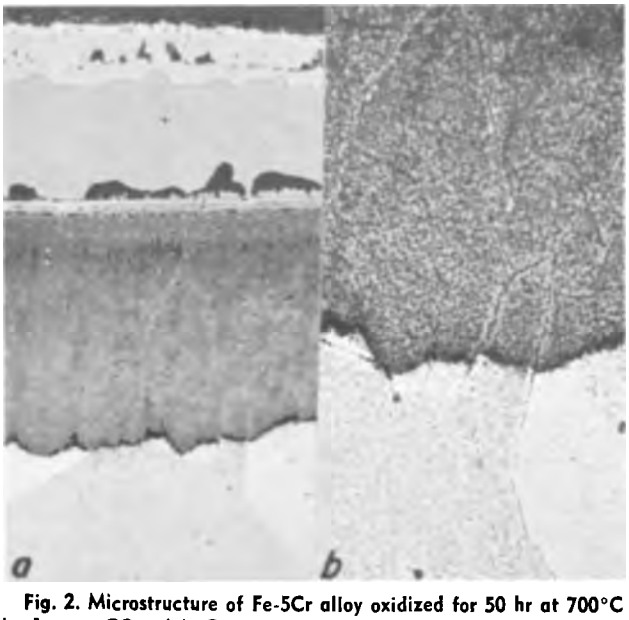

Fig. 2. Microstructure of Fe-5Cr alloy oxidized for 50 hr at 700°C in 1 atm CO_2. (a) General structure of scale and alloy etch: picral + HCl; magnification approximately 225X; (b) inner scale and alloy showing fine carbide distribution; etch: picral + HCl; magnification approximately 375X.

change in the wustite topography, as well as the greater proportion of the higher oxides of iron at 700° and 900°C, is probably related to the higher oxidation rates obtained in pure carbon dioxide at 1 atm pressure.

Chemical analysis of bulk outer scales from specimens oxidized at 900° and 1100°C showed 0.1-0.3 w/o Cr present in these detached outer oxides. (None of the more adherent outer scales from the 700°C specimens could be removed without gross inner scale contamination.) However, further analysis by fluorescence methods of the outer and inner surfaces of these outer scales revealed that the chromium was not uniformly distributed in this oxide layer. The chromium was concentrated on the inner side of the wustite layer (as high as 2-3 w/o Cr) and none was detected at the external surface. This suggests that the presence of chromium in these scales is due to the adherence of Fe-Cr spinel particles to this wustite layer during its detachment from the inner scale, and that there is no appreciable chromium mobility in wustite. The solubility of chromium in this phase has been generally regarded as being low, but recently Levin and Wagner showed by electrical conductivity measurements that above 860°C as much as 0.67 w/o Cr is soluble in wustite (14). In the present experiments, Fe-Cr spinel particles were not obvious in the metallographic sections of these scales. A substantial chromium solubility in wustite would explain the absence of a chromium-rich second phase; however, it is possible that much of the chromium detected in these wustite layers is present as small spinel particles adhering to the inner surface.

The extent of the voids which separate the outer and inner scale layers is related to the oxidation temperature. As shown in Fig. 2a, at 700°C the voids are small, and thus substantial areas of adherence between the scales remain. At 900°C the detachment is much more extensive and frequently, as in Fig. 1, the outer scale appears to be completely detached. However, other sections of the structure show wustite bridges connecting the layers, but the total cross-sectional area of these connecting oxide bridges is small. A similar detached outer scale develops at 1100°C, except that the increased oxidation rate at this higher temperature generates an even larger void volume. These voids between the outer and inner scales are a result of the growth processes responsible for the formation of the two-layer structure and are not due to cooling at the termination of an experiment. Any mechanism proposed for the oxidation of these alloys must necessarily provide a means for maintaining an iron flux to the outer-scale: gas interface in spite of these voids.

Inner scale.—The inner scale at all three temperatures is porous and composed of two phases, wustite and an Fe-Cr spinel. The ratio of spinel to wustite in this layer increases with increasing chromium concentration in the alloy, but remains relatively independent of the oxidation time. Accompanying the in-

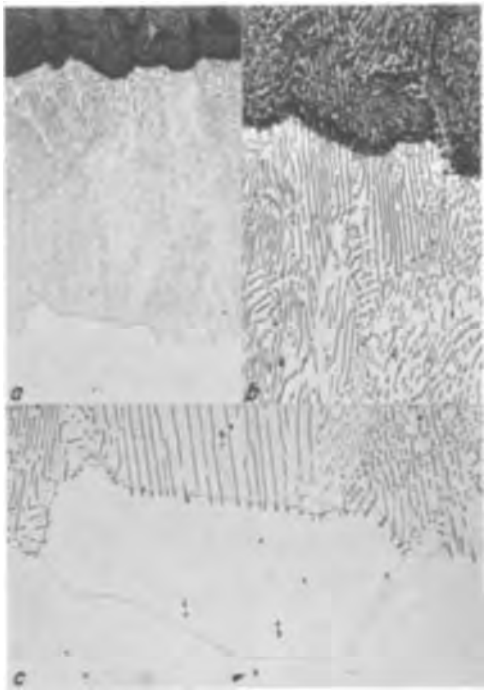

Fig. 3. Carbide formation in Fe-15Cr alloy oxidized for 24 hr at 900°C in CO_2 (Fig. 1 shows general scale structure). (a) Inner scale and alloy showing lamellar carbides, magnification 110X; (b) inner-scale:alloy interface, magnification 250X; (c) lamellar carbide zone:ferrite interface, magnification 250X. All etched with picral + HCl.

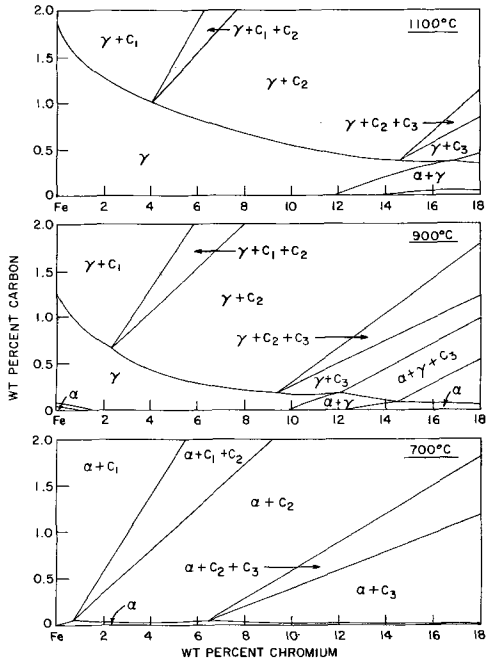

Fig. 4. Isothermal sections of the Fe-Cr-C system at 700°, 900°, and 1100°C [after Bungardt, Kunze, and Horn (13)] in which C_1 = $(Fe,Cr)_3C$, C_2 = $(Fe,Cr)_7C_3$, and C_3 = $(Fe,Cr)_4C$.

crease in spinel formation is an increase in the porosity of the inner scale. In the ferritic alloys, in which carbides are formed during the oxidation experiment, spinel replicas of the carbides are produced in the inner scale as these carbide particles become accessible to the oxidant at the inner-scale:alloy boundary. The spinel replicas are clearly shown in the microstructures of Fig. 2b and 3b for two ferritic alloys oxidized at 700° and 900°C, respectively. It can be seen that the carbide distribution pattern in the alloy is maintained in the spinel replicas of the inner scale. All specimens in which carbides were precipitated at temperature show this in the inner oxide structure. These include the Fe-5Cr, Fe-10Cr, and Fe-15Cr specimens oxidized at 700°C and the Fe-15Cr specimen oxidized at 900°C.

Subscale and alloy.—Internal oxidation and carburization occurring in the alloy in the region of the inner-scale:alloy interface produce metallographically observable changes as well as a hardening of the alloy. These reactions occur concurrently, and both must significantly alter the chromium activity in this zone. In contrast to the relatively high population of Fe-Cr spinel or rhombohedral oxide particles formed by internal oxidation in H_2O-Ar atmospheres, the competitive carburization reaction markedly reduces the depth of this zone and the size and population of the oxide particles precipitated. The metallographic and optical characteristics of the internal oxide particles formed in carbon dioxide are similar to those formed in water vapor, and it is assumed that these oxides formed in carbon dioxide are of similar compositions, *i.e.*, an Fe-Cr spinel or rhombohedral oxide [$(Fe,Cr)_3O_4$ or $(Fe,Cr)_2O_3$].

Electron microprobe scans of several of these specimens revealed a relatively uniform chromium distribution throughout the alloy and no indication of the pronounced chromium depletion in the region of the alloy adjacent to the subscale noted in the water vapor-oxidized specimens (1). The lack of a chromium gradient and the relatively limited number and size of subscale particles in the zone of internal oxidation are undoubtedly related to and affected by the presence of carbon in these alloys. The uniformity of the hardness profiles suggests that the mobility of carbon in these alloys is high and much greater than that of oxygen or chromium. Under these conditions, the lack of a zone of chromium depletion and the diminution in internal oxidation may not be entirely unexpected if the presence of carbon reduces the mobility of chromium or significantly reduces the solubility or diffusivity of oxygen in the alloy.

Carburization Results

The carburization accompanying the oxidation of these Fe-Cr alloys is clearly indicated by the changes in the microstructure and hardness of the remaining alloy. The resulting microstructures appear to conform to those predicted by the Fe-Cr-C ternary diagrams of Fig. 4 which were constructed from the equilibrium data of Bungardt, Kunze, and Horn (13). For the ferritic specimens (those that remain ferritic at the oxidation temperature) the interpretation is rather straightforward. However, for the austenitic specimens the interpretation is complicated by the nature and kinetics of the decomposition of the chromium-carbon austenite during the rapid cooling of the specimen at the termination of the oxidation experiment. Within the broad range of alloy compositions and oxidation temperatures employed in these studies, a multitude of variations in microstructures were observed. All of these provide evidence of an active carburization accompanying the oxidation reactions in pure carbon dioxide. A number of the more significant aspects of these specimens will be discussed in the following sections.

The histogram of Fig. 5 is a convenient means of ordering the hardness data from this series of experiments. These hardness values are average microhardness measurements (5-10 measurements averaged) taken at midthickness of the specimen (stippled) and taken near the inner-scale:alloy interface (horizontal hatched). The difference in these two average hardness values reflects the compositional variation from edge to center. Since electron microprobe studies of other specimens oxidized under similar conditions have revealed no significant variation of the chromium content of the alloy across the thickness of the specimens, this hardness variation is ascribed to a carbon gradient. The constitution of the alloy at the oxidation temperature is indicated above each of the bars of the histogram. In this designation "C" indicates

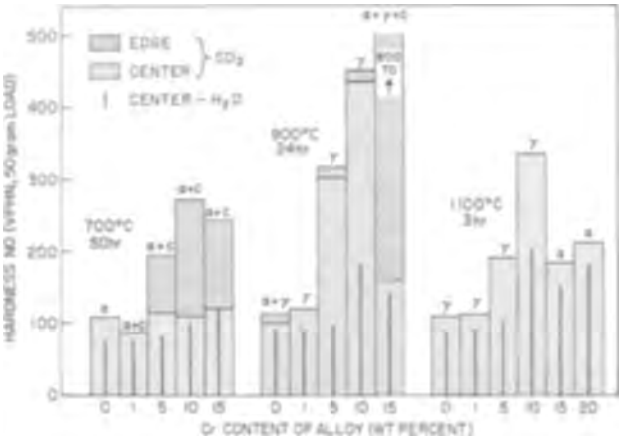

Fig. 5. Histogram of the changes in hardness of the alloy resulting from oxidation in 1atm CO_2. Solid bars indicate hardness of these alloys oxidized in a carbon free atmosphere, *i.e.*, H_2O + Ar.

a carbide present at temperature. The solid bars superimposed on this plot represent the hardnesses of identical specimens oxidized in water vapor and, thus, the hardness of the carbon-free alloys when cooled under very similar conditions. The increases in the hardness of the alloys oxidized in carbon dioxide immediately suggest that the specimens have been carburized during the oxidation.

700°C specimens.—Iron and all of the Fe-Cr alloys are ferritic at 700°C and, as shown in Fig. 4, none can take up much carbon without exceeding the solubility limit of the α-field. With the exception of the iron specimen, all were carburized to such an extent that carbides formed in the alloys at temperature. The iron specimen revealed no evidence that carbides formed, but sufficient carbon had dissolved to delineate the sub-grain structure on etching. Contrastingly, the Fe-1Cr specimen contained fragmentary grain boundary films of carbides and little, if any, carbide within the grains. With increased chromium content the activity of carbon is reduced. The resultant increased activity gradient accelerates carbon solution and leads to a rapid saturation of the ferrite and carbide precipitation. Hence the higher carbide concentration and edge hardness in the higher chromium alloys. The spinel replicas of the carbides in the inner scale, shown for a Fe-5Cr alloy in Fig. 2b, are ample evidence that the carbides were generated during the oxidation. This figure shows a continuous grain boundary film of carbide and a dense distribution of carbide particles within the grains. The grain boundary carbide frequently permeated the entire thickness of the specimen, while the grain body carbides were concentrated near the inner-scale: alloy interface and generally absent at the mid-thickness of the specimen.

For the identification of the carbides formed in these alloys during the oxidation-carburization, the carbides were chemically extracted and examined by x-ray diffraction. The specimens employed, and the results obtained, are listed in Table III. Two specimens from the 900°C oxidation series are included: the Fe-15Cr specimen of Fig. 3 which formed a lamellar carbide layer during oxidation, and the Fe-5Cr specimen which metallograpically showed no evidence of carbide. The latter specimen thus served as a check on the metallography and a "blank" on the extraction method. Polished specimens of each of these samples were coated with a thin evaporated carbon film and then deeply etched in a 2 v/o (volume per cent) bromine-methanol solution. By virtue of the surface carbon film and the network of grain boundary carbides, the extracted carbides retained their relative positions within the specimen and permitted sampling from selected areas for x-ray diffraction studies. The central portion of the 700°C specimens contained predominantly grain

Table III. Phases extracted from Fe-Cr specimens oxidized in carbon dioxide

Specimen		Extracted phases		
Alloy, w/o	Oxidation temp, °C	Grain body	Grain boundary	Alloy: innerscale
1	700	(no specimen)	$\underline{C_1}+C_2$	$C_1+C_2+S_p$
5	700	C_2	C_2	C_2+S_p
15	700	$\underline{C_2}+C_2$	$C_2+\underline{C_2}$	$C_2+C_2+S_p$
15	900	C_3		$W+S_p$
5	900	"C"		$W+S_p$

Note: the underscored carbide phase is the *major* constituent in the extracted mixture.
Phase designations: C_1, $(Fe,Cr)_3C$ [orthorhombic]; C_2, $(Fe,Cr)_7C_3$ [rhombohedral]; C_3, $(Fe,Cr)_4C$ [cubic]; "C", very fine carbides or carbon; S_p, $(Fe,Cr)_3O_4$ [spinel]; W, FeO [cubic].

boundary carbides; the region near the inner-scale: alloy interface contained both grain boundary and grain body carbides. Samples from these areas were unavoidably contaminated with the complementary carbide, but significantly enriched in one type so that the grain boundary and grain body carbides could be identified by their relative intensities in the two diffraction patterns. The predominant phase in the x-ray sample is underlined in the table.

The carbides identified in the 700°C specimens are in substantial agreement with the equilibrium carbides to be expected from the Fe-Cr-C system of Fig. 4. The only exception is the rhombohedral $(Fe,Cr)_7C_3$ carbide (C_2) found present in the grain boundaries of the Fe-15Cr specimen. The lamellar carbide formed in the Fe-15Cr specimen at 900°C was identified as the cubic $(Fe,Cr)_4C$ carbide (C_3). A more complete analysis of the microstructure of this specimen will be offered in a succeeding section. The Fe-5Cr "blank" specimen supported the metallographic observation, *i.e.*, no carbide particles were recovered. The extracted material was extremely fine and yielded only weak, broad, diffraction bands. Thus the carbon was retained in solution in the acicular (martensitic) matrix, or precipitated during cooling as extremely fine carbides —either too fine to diffract, or too fine to survive the chemical extraction.

The last column of Table III identifies the phases in samples scraped from the alloy interface of the inner scale. In addition, x-ray diffraction patterns were obtained from samples from various positions within the inner scale. These results indicate that at 700°C, oxidation of the carbides to spinel replicas is completed within the inner scale, while at 900°C this oxidation is rapid and virtually complete at the inner-scale: alloy interface.

900°C specimens.—As indicated by the hardness data of Fig. 5, the series of specimens oxidized for 24 hr at 900°C shows the greatest variation in hardness changes produced by the carburization. The expansion of the γ-loop by carbon, shown in Fig. 4, permits the austenite phase to form in the normally ferritic end members of the alloy series, *i.e.*, Fe-1Cr and Fe-15Cr. Sufficient carbon was also introduced into the iron specimen to cause the surface adjacent to the inner scale to transform to austenite, *i.e.*, a carbon concentration in excess of 0.015 w/o. On cooling, carbon was rejected as discontinuous carbides at the new ferrite boundaries. The Fe-5Cr and Fe-10Cr alloys are, of course, fully austenitic at this temperature when carbon-free.

The carbon concentration in the Fe-1Cr specimen was sufficient to convert the entire specimen to austenite. During cooling the growth of primary ferrite (low C and low Cr) concentrated the carbon in the remaining austenite. The enriched austenite subsequently transformed at a relatively high temperature to colonies of fine pearlite. Since the matrix is low C, low Cr ferrite, the hardness of the specimen remains virtually unaltered. The microstructures of Fig. 6

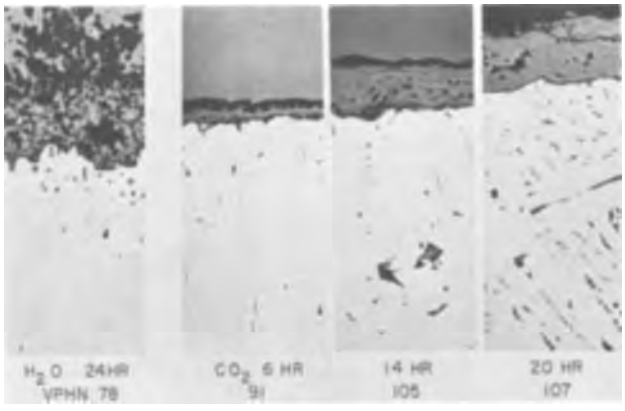

Fig. 6. Progressive pearlite formation in Fe-1Cr alloy oxidized at 900°C in CO_2. Comparative microstructure of alloy oxidized in H_2O + Ar at left; etch: Nital + picral. Magnification approximately 200X.

illustrate the progressive increase of pearlite in the structure (progressive increase of carbon in the alloy) with increasing oxidation time in carbon dioxide. The left microstructure is of a specimen oxidized in water vapor at 900°C. Under these conditions the alloy remained completely ferritic and the internal oxidation zone penetrated deeply into the alloy. These differences in the microstructure of the specimens oxidized in water vapor and carbon dioxide give clear evidence of carburization in the carbon dioxide atmosphere and, equally significant, show that the carbon concentration increases as the oxidation period is lengthened.

The Fe-5Cr and Fe-10Cr alloys, both fully austenitic at 900°C, can dissolve rather large amounts of carbon. In the Fe-5Cr specimen the carbon containing austenite rejects some ferrite on cooling and the remainder of the enriched austenite transforms to a martensite of moderate hardness. The Fe-10Cr specimen should reject a low C, high Cr ferrite as a primary phase; however, even this reaction is suppressed by the rapid cooling and a martensitic structure of relatively high hardness results.

The microstructure of the Fe-15Cr alloy oxidized at 900°C has been illustrated in Fig. 3 and the identity of the lamellar carbides established as $(Fe,Cr)_4C$ through x-ray diffraction (Table III). X-ray fluorescence analysis of the same sample used for the diffraction study indicated an Fe:Cr ratio near one, *i.e.*, 52-54% Fe, 48-56% Cr. These results are in accord with the 900°C isotherm of the Fe-Cr-C system (Fig. 4). The core of the sample remains ferritic, but may dissolve up to 0.05 w/o C, thus the slight increase in hardness of this phase shown in Fig. 5. The boundary between the ferrite core and the lamellar carbide zone corresponds to the $\alpha + \gamma + C_3$ three-phase field. Faintly visible at this interface is a second narrow zone. This might well correspond to the $\alpha + C_3$ field required by the phase diagram, for it contains only these two phases. However, it may represent the regrowth of ferrite around the carbides during cooling. To accommodate either interpretation requires only a minor adjustment in the ferrite composition or the phase boundaries, but neither is known with sufficient accuracy to permit this distinction. The matrix of the zone containing the lamellar carbides was austenite during the carburization at 900°C and from Fig. 4 would contain approximately 0.12 w/o C. This high-carbon austenite, transformed to martensite on cooling, together with the high concentration of lamellar carbides produce the very high hardness of this layer.

1100°C specimens.—The microstructure and hardness changes of the 1100°C series of specimens require little comment because those containing up to 10 w/o Cr are rather similar to the 900°C austenitic specimens. However, it should be noted that although these specimens were exposed to the oxidation-carburization reactions for only 3 hr (the oxidation rates were very high at this temperature), the hardness increases, and hence the total carbon solution, are considerable and not much lower than those produced at 900°C in 24 hr. Thus, both reactions, oxidation and carburization, occur at greatly increased rates at 1100°C.

The Fe-15Cr and Fe-20Cr specimens remain ferritic at this temperature and, unlike any of the other specimens, these alloys produce an initial rhombohedral (Cr_2O_3) scale that is protective. The protectiveness of this scale is short-lived for the 15 w/o Cr alloy but moderately durable for the 20 w/o Cr alloy. As a consequence, the scale formed on the Fe-20Cr specimen varied in thickness and the attack on the underlying metal was correspondingly varied. The Fe-15Cr specimen which ultimately achieved an oxidation rate only slightly lower than that of the lower chromium alloys, showed only a minor increase in hardness at this temperature and did not generate the lamellar carbide layer observed in this alloy at 900°C. The phase equilibria of Fig. 4 suggest the reason for this great change in the observed carburization. At 1100°C it is unlikely that the carbon potential is adequate to stabilize a carbide, for this would require the production of austenite containing more than 0.45 w/o C. The lack of a stable carbide means that there is no way to deplete the alloy of chromium to permit austenite to form at lower carbon potentials. Thus the alloy remains ferritic, becomes saturated with carbon at a low concentration, and shows only a minor increase in hardness. Near the inner-scale:alloy interface small regions were observed which may have been austenite at 1100°C as a result of chromium depletion through oxide formation. However, these were always small isolated areas and this interpretation is rather speculative. The observed microstructure and hardness changes, however, are compatible with a carburizing process occurring during oxidation. In this case, just as with iron at 700°C, the saturation level for carbon in the ferrite is very low.

Correlation of hardness and carbon content.—In the preceding sections the microstructures and hardness changes were shown to be compatible with the phase equilibria of the Fe-Cr-C system, the new phases generated within the specimens were identified as carbides, the progressive formation of pearlite in the Fe-1Cr specimens oxidized at 900°C was illustrated, and a few estimates of the carbon concentrations achieved have been deduced from the observed phase transformations. In order to develop a correlation between the carbon content and hardness for one alloy composition, specimens were systematically carburized, the hardness measured, and the specimens then analyzed for total carbon content. The Fe-10Cr alloy was selected for this study because at 900°C it is austenitic, capable of dissolving significant amounts of carbon without the complication of carbide formation, and had shown a dramatic hardness increase when oxidized in carbon dioxide at this temperature. Accordingly, specimens of this alloy were carburized in an atmosphere in which the CO_2-CO ratio was controlled at 0.3. At this low oxygen potential wustite is not stable, and little oxidation accompanied the carburization. Four specimens were carburized in this atmosphere for periods of 1-20 hr at 900°C. Following the carburization of each specimen, the CO_2-CO atmosphere was replaced with purified argon and a 15-hr diffusion period at 900°C provided to remove the edge-to-center carbon gradient. After sectioning and measuring the hardness of each specimen, the surface oxide was removed by grinding and the specimens analyzed for carbon by combustion.

The data from these carburized specimens are shown in Fig. 7 (open circles), together with the zero carbon datum point (H_2O-Ar oxidation at 900°C) and three points (triangles) from subsequent experiments in which large specimens of the Fe-10Cr alloy were oxidized in CO_2-CO atmospheres (1 to 4 CO_2-CO ratios) at 1000°C and analyzed for carbon. An extrapolation of these data to the hardness measured for the Fe-10Cr specimen oxidized in pure carbon dioxide

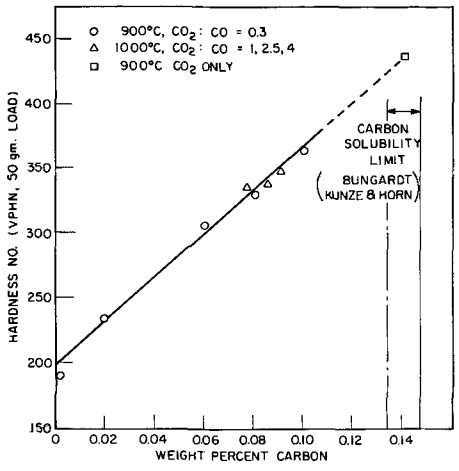

Fig. 7. Correlation between hardness and carbon content of Fe-10Cr alloy oxidized in CO_2 and CO_2-CO atmospheres.

(square) indicates a carbon content of 0.14 w/o. This carbon concentration nearly coincides with the solubility limit of carbon in austenite containing 10 w/o Cr as determined by Bungardt *et al.* (13), Fig. 4. The higher hardness at the edge of this oxidized specimen may indicate a very limited amount of carbide present in this area, thus suggesting that the carburizing potential of the gas phase within the scale structure is high even though the oxidizing atmosphere employed is pure carbon dioxide. Similarly the 330 VPHN hardness of the Fe-10Cr alloy oxidized at 1100°C (Fig. 5) suggests that a carbon content of approximately 0.08 w/o was achieved during the 3 hr of exposure to carbon dioxide.

Discussion

The recent literature provides other evidence for the accumulation of carbon in Fe-Cr alloys, in stainless steels, and in certain special steels used in fabrication of atomic reactor components. These carbon accumulations occurred during oxidation experiments in carbon dioxide or CO_2-CO mixtures which are normally considered non-carburizing (8-11). The rationale for the carburization of the alloys and steels under these conditions appears to be that the accumulation of carbon monoxide, a reaction product, eventually renders the oxidizing atmosphere, carburizing as well. To account for the carburization of a variety of Cr-bearing steels in a flowing carbon dioxide atmosphere, McCoy suggested that the presence of pores in the outer oxide layer provided gaseous pathways and pockets for accumulation of carbon monoxide. On the other hand, Jepson, Antill, and Warburton, in an extensive study of the reaction of a 20Cr-25Ni Nb-stabilized steel in carbon dioxide and carbon monoxide, suggest that carbon has considerable mobility in the oxide. Thus it was proposed that the carburization of the steel in these studies was caused by carbon which was deposited on the oxide surface and then transferred through the oxide by a diffusion mechanism. These, then, represent two divergent views on the mechanism for the observed carburization of the steels. There is probably merit in both views because the scales differ in composition and structure in these two studies and this could lead to different means by which carbon accumulates in the steels. Clearly, it is necessary that the scales be carefully examined and characterized before any coherent and logical scheme for the oxidation and carburization of these alloys and steels can be offered.

The present experiments show that the outer layer of the duplex scale structure is continuous and free of any cracks, fissures, or pores which are observable by optical microscopic methods. The kinetic results suggest that this sound scale condition is maintained throughout the experiment and, thus in order to carburize the alloy, carbon must permeate the growing outer wustite layer. The carbon solubility and mobility in wustite have not been established, but the experimental indications are that the presence of a dense scale *per se* does not deter the carburization of the alloy. On the contrary, outer scale integrity is necessary to prevent direct access of carbon dioxide, which is decarburizing, to the porous inner scale and the alloy. Carbon accumulation in the alloy implies that there is a solubility and a mobility of carbon in wustite which are sufficient to sustain the diffusional transport of carbon through the outer scale.

While the experimental evidence suggests a carbon permeation of the outer scale (no evidence of direct admission of gaseous carbon dioxide), there is doubt as to the reaction which is responsible for the initial carbon deposition on the external oxide surface. Carbon dioxide is generally considered noncarburizing under these experimental conditions, and, therefore, the generation and local accumulation of carbon monoxide is clearly a necessary prerequisite for carburization to occur. The experiments show that the rate of carbon accumulation in the alloy closely parallels the oxidation rate, but this is not unexpected since the generation of carbon monoxide is directly related to the oxidation rate. What remains obscure is the nature of the surface reaction of the adsorbed carbon monoxide which yields carbon. Reactions such as [1] a disproportionation of carbon monoxide or [2] the reduction of carbon monoxide are often suggested as carburizing processes. These reactions are represented by the partial equations

$$2CO_{(ads)} \rightarrow CO_{2(g)} + C \qquad [1]$$

$$CO_{(ads)} \rightarrow [O] + C \qquad [2]$$

where subscripts (ads) and (g) are abbreviations for "adsorbed" and "gas", [O] is an oxygen incorporated into an oxide lattice site at the surface, and C is free carbon on the oxide surface. However, neither is entirely satisfactory in the present instance, since reaction [1] is hindered by the high proportion of carbon dioxide in the atmosphere and the high temperature, and reaction [2] is precluded by the fact that carbon monoxide is reducing to all three iron oxides. It is conceivable that the feasibility of reaction [1] is enhanced by a sufficient local accumulation of carbon monoxide so that, kinetically, the reaction can occur. However, there is no direct evidence for this, and further speculation about the surface carbon monoxide reaction appears unwarranted at this time.

While the processes responsible for the production and transport of carbon through the outer scale remain unresolved, the continued high oxidation rates in spite of extensive voids and the carburization of the alloy in a normally decarburizing atmosphere suggest the generation of a CO_2-CO atmosphere within the voids. Thus the mechanism for the oxidation of the Fe-Cr alloys in carbon dioxide is similar to that proposed for H_2O-Ar atmospheres (5) with the CO_2-CO replacing the H_2O-H_2 as the oxygen carrier between the outer and inner scale layers. In this situation, however, the carburizing reaction has significant consequences in that considerable structural changes occur within the alloy, a point obviously worthy of consideration in the structural use of similar materials at high temperature in normally noncarburizing CO_2-CO mixtures. The generation of an oxidizing-carburizing atmosphere within the voids and the prevention of direct access of carbon dioxide by a dense, continuous outer oxide layer, are both necessary to explain the observations in the present experiments.

DTA and X-ray Studies of Electroless Nickel

J.-P. Randin, P. A. Maire,[1] E. Saurer,[2] and H. E. Hintermann

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

Electroless nickel and mixtures of nickel and phosphorus powders were studied by differential thermal analysis. The evolution of heat during the rise of temperature of the electroless nickel specimens is either 17 or 11% of the heat of formation of Ni_3P, which is the final reaction product. The value of 17% corresponds to electroless nickel with phosphorus contents $\leq$ 8 w/o, that of 11% to contents $>$ 10 w/o. X-ray analysis has shown that the reaction product is Ni_3P and that no other phosphide is present. Thus one may assume, that electroless nickel in the as-plated state is a supersaturated solid solution of phosphorus in nickel as a metastable intermediate state between that of a mixture of nickel plus phosphorus and the equilibrium system of nickel plus Ni_3P.

Electroless nickel is a binary alloy of nickel and phosphorus. According to Gutzeit (1), the phosphorus content varies between 3 and 15 w/o depending on the bath composition and the deposition parameters.

Several authors (2, 3) expect the phosphorus to be present as nickel phosphide Ni_3P in the as-plated electroless nickel. Fléchon (4) indicates that the chemical reactivity of the alloy presents some analogy with elementary phosphorus. Further, Graham, Lindsay, and Read (5) show that electroless nickel is not amorphous as several authors believed (2, 4, 6), but is rather a supersaturated solid solution of phosphorus in crystalline nickel. Goldenstein, Rostoker, Schossberger, and Gutzeit (2) present some qualitative thermodynamic data on this matter.

In an attempt to establish the nature of the chemical state of phosphorus in as-plated electroless nickel, x-ray and differential thermal analysis (DTA) were carried out on this system.

Experimental Procedure

Preparation of deposits.—An acid bath of the following composition was used: $NiCl_2 \cdot 6H_2O$: 30 g/l; $CH_2(OH)COOH$: 30 g/l; $COOH(CH_2)_2COOH$: 10 g/l; NaF : 3 g/l; NaOH to adjust the desired *p*H. The reducing agent was sodium hypophosphite, added to the bath in a concentrated solution of 500 g/l at constant rate. If the *p*H and the nickel concentration are kept constant during the entire deposition time, coatings of uniform phosphorus distribution can be obtained (7). By adjusting the *p*H of the bath between 5.0 and 4.0; deposits with phosphorus contents between 3.5 and 11.4 w/o are produced for an introduction rate of hypophosphite of 0.05 mole/h. Powdery samples were prepared by seeding the bath with palladium chloride. Electroless nickel was also deposited on pure nickel[3] wire and the coatings stripped off thereafter mechanically. The differential thermal analysis carried out on both types of samples did not show any noticeable difference. The deposits on nickel wire, however, showed a strong preferred orientation.

Differential thermal analysis.—The measurements were made with a Netzsch[4] microcalorimeter under argon atmosphere either in a nickel sample holder or in Pyrex phials sealed under vacuum. The heating rate was 2°/min, the weight of the samples 500-600 mg. The accuracy of the measurements depends largely on the reaction rate and is assumed to be ±5% for samples containing 12 w/o phosphorus and ±20% for alloys with phosphorus contents of about 4 w/o. The high phosphorus alloys have sharper reaction peaks.

X-ray.—The x-ray investigation was carried out on cylindrically agglomerated powder samples of 1 cm^2 cross section, pressed at 25 t/cm^2. Particles smaller than 400 mesh (37 mμ) were used. Under these conditions of pressure and particle size distribution, the intensity of the diffraction lines was insensitive to further changes of these two parameters towards higher pressures and smaller particle sizes. The samples did not exert any preferred orientation.

The diffraction peak intensities and the angular position of its maxima were determined on a Philips x-ray diffraction unit equipped with a scintillation counter and a pulse height analyzer. Filtered CoK_α radiation (voltage 30 kv, current 10 ma, Fe filter) was used. The scanning speed was 1/8° 2θ per minute. The width of the divergence slit was 1°, that of the receiving slit 0.2 mm.

Results and Discussion

Differential thermal analysis.—All the reactions are

exothermic. The shape of the DTA curves, *i.e.*, ΔT *vs.* temperature, depends on the phosphorus content of the electroless nickel (Fig. 1).

At phosphorus contents larger than 10 w/o one single sharp peak appears at a temperature of 310°C. At lower percentages of phosphorus two reactions are observed. Between 6 and 8 w/o phosphorus a diffuse line of low intensity shows up covering the entire temperature interval from 200° to 300°C. The second peak appears at the same temperature of 310°C as before, yet less intensive and markedly broadened toward the high-temperature side of the scale. At low phosphorus concentrations of some 4 w/o, broadening of this latter peak is even more pronounced, and the reaction fades away only toward 420°C.

Thus, two reaction areas can be distinguished : one below 300°C, the other above 300°C. The reaction heat of the former will be called Q_1 that of the latter Q_2. The measured Q_1 and Q_2 are plotted on Fig. 2 as a function of the phosphorus content. The heat Q_2 is proportional to the phosphorus content of the electroless nickel while Q_1 passes through a maximum at about 8 w/o phosphorus and vanishes thereafter at a concentration higher than 10 w/o. It appears that the total heat released is proportional to phosphorus content only up to 8 w/o.

Two reactions occur at concentrations below 10 w/o while only one is observed above this concentration.

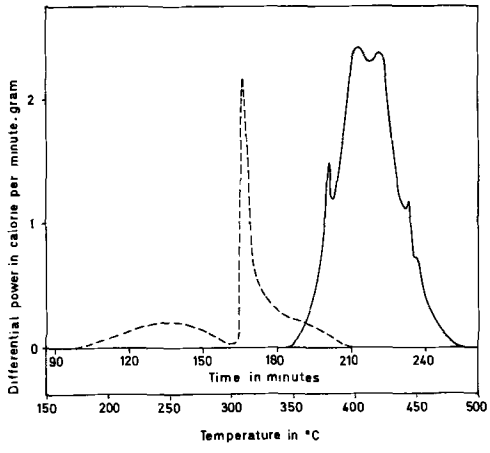

Fig. 3. DTA curves of electroless nickel and Ni + red phosphorus at intermediate phosphorus contents: — — — electroless nickel 7.8 w/o phosphorus; ——— Ni + 7.8 w/o red phosphorus.

An x-ray study on two samples containing 8 w/o phosphorus, one heated to completion of the reaction, the other to partial completion only, namely to 550° and 285°C, respectively, revealed two distinct phases. For heat-treated samples at 285°C the x-ray diagrams compare well to those obtained by Graham *et al.* (5) for as-plated electroless nickel, while those heat-treated to completion of the reaction show sharp diffraction peaks of a phosphide and a nickel phase.

Comparison between heats of reaction of a nickel-phosphorus mixture and of electroless nickel.—Mixtures of nickel[5] with red[6] or white[7] phosphorus produce heats of reaction of the same order of magnitude (Fig. 3). They compare well with the results found by Weibke and Schrag (8) who indicate a value of 48.4 kcal/mole for the formation of Ni_3P at 630°C. As mentioned before, the heat of reaction of the electroless nickel is a function of its phosphorus content. The heat Q_2 of the single reaction which occurs at phosphorus contents above 10 w/o is 5.9 kcal/mole Ni_3P. The total heat of reaction $Q_1 + Q_2$ for alloys with less than 8 w/o phosphorus is 8.9 kcal/mole Ni_3P.

These results are in accordance with those of Goldenstein *et al.* (2) who state that the thermal evolution of specimens with phosphorus contents of 7-10 w/o is considerably higher than 1 kcal/mole.

Ni_3P is the last product of a series of reactions in the solid state for both electroless nickel and a mixture nickel + red phosphorus, as will be shown in the next section. However, the heat evolved on heating of electroless nickel is only some 11-17% of the heat of formation of Ni_3P.

X-ray.—Nickel and nickel phosphide, Ni_3Po, samples were studied by x-ray diffraction methods. Fléchon (4) indicates for Ni_3P a tetragonal structure (a = 8.91Å, c = 4.39Å) and states the extinction condition to be h + k + l = 2n. Unfortunately almost all the Ni_5P_2 and Ni_2P lines coincide with those of nickel or Ni_3P, so that it is impossible to assert the existence of a Ni and a Ni_3P phase only.

To prove that all phosphorus of the samples is transformed during heating to Ni_3P with the exclusion of any other phosphide, it had to be shown that by allowing the stoichiometric amounts of Ni and P to form Ni_3P to react, *i.e.*, 14.96 w/o phosphorus, no pure phase of Ni was allowed to remain at completion of the reaction. The procedure to prepare and investigate the samples is given in some details hereafter: samples of between 0 and 15 w/o phosphorus content were pre-

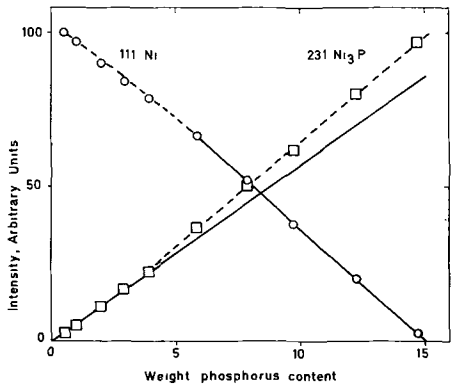

Fig. 4. Intensity of the 111 and 231 reflections of Ni and Ni_3P, respectively, as a function of the phosphorus content on agglomerated powder samples of a mixture of Ni + Ni_3P at different concentrations in phosphorus. ○ 111 Ni; ---- □ 231 Ni_3P; ——— calibration curve.

pared by mixing and pressing powders of Ni and Ni_3P. The reflections 111 of nickel and the 231 of Ni_3P were recorded and measured as they show strong intensities and are well separated from other lines. Figure 4 shows that from a value of 5 w/o phosphorus onward the intensity of the 111 reflection of nickel decreases linearly with increasing phosphorus content and intercepts the abscissa at 15 w/o. The intensity of the 231 reflection of Ni_3P does not rise linearly with increasing phosphorus content. Rather, due to weaker absorption of the diffracted beam and stronger secondary radiation, a deviation of the intensity toward higher values becomes progressively important as the phosphorus concentration of the samples continues to increase. As a consequence, the measured diffraction intensities from electroless nickel have been corrected by the amount of this effect. This is for each phosphorus concentration the ordinate difference between the experimentally determined curve and its tangent through 0 w/o phosphorus.

Three series of electroless nickel samples were analyzed after a heat treatment at 400°, 500°, and 800°C, respectively. X-ray intensity measurements were also performed on a mixture of carbonyl-nickel + red phosphorus heated at 800°C. For all samples a linear decrease of intensity of the 111 reflection of nickel and its disappearance at the stoichiometric composition was observed. The relation of the corrected intensities of the 231 line of Ni_3P *vs.* phosphorus content is linear too, and shows an intercept at the abscissa at 0 w/o phosphorus (Fig. 5). These results demonstrate that heat-treated electroless nickel consists solely of the two phases: Ni and Ni_3P, with the exclusion of any other phosphide.

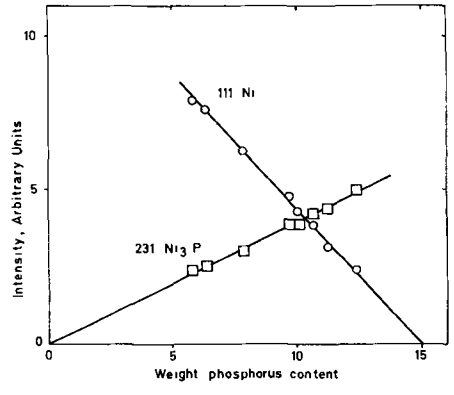

Fig. 5. Intensity of the 111 reflection of Ni and corrected intensity of the 231 reflection of Ni_3P from electroless nickel heat treated at 800°C for 2 hr as a function of its phosphorus content: ○ 111 Ni; □ 231 Ni_3P.

The lattice parameter of electroless nickel samples annealed at 800°C after agglomeration was determined using Nelson-Riley extrapolation techniques. Values between 3.5237 and 3.5242 ± 0.0003Å were obtained. The average of these values compare well with the ASTM value of 3.5238Å. The atomic radii of phosphorus and nickel are 1.28 and 1.24Å, respectively (9), *i.e.*, they differ by somewhat more than 3%. From the copper-phosphorus system for which the atomic radii of both elements are the same, *i.e.*, 1.28Å (9), it has been shown (10) that the addition of 0.58 w/o phosphorus to copper changes its lattice parameter from 3.6078 kX at 0 w/o phosphorus to 3.6092 kX at 0.58 w/o phosphorus. By analogy it can be concluded that the same amount of phosphorus in nickel would change its lattice parameter even more drastically. Hence, from the very excellent concordance of the measured lattice parameter for electroless nickel with the ASTM value, it must be concluded that the phosphorus content in the heat-treated nickel phase is very low and that therefore only a little if any phosphorus occupies substitutional or interstitial positions in the lattice of the heat-treated electroless nickel.

Conclusions

Differential thermal analysis shows that the heat evolution during heating of electroless nickel corresponds to about 17% of that of the heat of formation of Ni_3P for phosphorus contents smaller than 8 w/o, and about 11% of this heat of formation for samples containing more than 10 w/o phosphorus. Further it could be shown by x-ray analysis that the reaction product is Ni_3P at the exclusion of the presence of any other phosphides. The nickel phase in heat-treated alloys contains very little or no phosphorus in interstitial or substitutional positions.

Therefore the as-plated electroless nickel may be, as proposed by Graham *et al.* (5), a supersaturated solid solution of phosphorus in nickel as a metastable intermediate state between that of a mixture of nickel plus phosphorus and the equilibrium system of nickel plus Ni_3P. It can be considered that this intermediate state includes phosphorus atoms chemically bonded to nickel atoms as a phosphide since 83-89% of the heat of formation of the stable state of nickel plus Ni_3P is released. This latter supposition is not confirmed by previous work of other authors (2, 5) as they do not find any diffraction lines from a phosphide phase in their electron diffraction studies. However, as the diffraction lines of nickel and phosphides often coincide wholly or in part and as the grain size of the as-plated electroless nickel is extremely small and therefore causes a strong line broadening, the diffraction lines from a phosphide phase would be hardly discernible. Moreover, the phosphide phase is expected to precipitate in extremely small grain size, too.

Acknowledgment

The authors wish to thank Professor P. Dinichert, Director of the L.S.R.H. for his advice and interest in this work and for permission to publish this paper. They also wish to acknowledge the valuable assistance of Dr. E. Hofer in the x-ray studies, particularly the lattice parameter determination.

Manuscript received Oct. 24, 1966; revised manuscript received Feb. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Penetration of Electrophoretic Deposits into Cylindrical Tubes

Douglas A. Olsen and Peter J. Boardman

and Stephen Prager

Department of Chemistry, University of Minnesota, Minneapolis, Minnesota

ABSTRACT

The process of electrophoretic deposition of organic coatings has the inherent advantage of superior penetration of the electrodeposited film into the interior of hollow metal objects. In the work reported here a mathematical treatment of the extent of penetration of electrodeposited film into a tube is developed, based on a model that assumes electrophoretic deposition ceases when either (*i*) the film is sufficiently thick to block the passage of current or (*ii*) the supply of polymer particles to the substrate is inadequate. Experimental data relating the length of film penetration to polymer concentration, applied voltage, tube radius, and time are also reported. Good agreement between theory and experiment is obtained.

The electrophoretic deposition of organic materials was first reported by Sheppard and Eberlin (1) in 1925. In the intervening years there has been a wealth of information published on the use of classical electrophoresis for separations and for studying double layer phenomena. Investigations of electrophoretic deposition and of the electrode reactions involved in the process have been few and fragmentary, however. One of the more complete studies was that of Fink and Feinleib (2) in 1948, which also includes a rather complete bibliography of earlier work.

Recently the phenomenon of electrophoretic deposition has been successfully applied to an industrial painting process (3), and additional reports, mostly of a practical nature, have begun to appear (4). From several studies (2, 5, 6) of the electrophoretic deposition of synthetic resins the following facts have been obtained. Of the two steps in the process, that of movement of the particles toward the electrode and that of reaction at the electrode, the latter is the controlling step. Deposition of the resin at the anode occurs as a result of coagulation by metal ions and/or hydrogen ions, with the metal ions being formed by anodic dissolution of the metal and the hydrogen ions resulting from the anodic discharge of hydroxyl ions. The deposition obeyed Faraday's law at least approximately. Unlike the deposition of metals, the electrical equivalent weight of a resin is variable depending on the degree of neutralization.

From a practical point of view the electrophoretic deposition process has several inherent advantages. One of them is its so-called "throwing power" which is the subject of this investigation and is defined as the ability of an electrophoretically deposited resin film to penetrate into the interior of a hollow metal object (6). In practical terms this ability permits the formation of resin films in difficult to reach corners, nooks, and pockets of an irregular work piece (7). The deposition of films on interior surfaces, however, is a considerably slower process than on exterior surfaces. Previous work in this laboratory (6) has shown that the actual deposition mechanism on the metal surface remains the same, but that the potential gradient controlling the migration of emulsion particles to the interior anode surface changes as deposition occurs. In the present study a mathematical formulation of throwing power has been developed and the validity of the resulting equations has been tested.

Mathematical Formulation

Before proceeding to the mathematical formulation of this section it is instructive to consider a qualitative view of throwing power (6). Figure 1 shows two views of an idealized throwing power apparatus, *viz.*, a hollow cylindrical anode immersed in a resin dispersion and perpendicular to a flat cathode. The electric field is represented by the equipotential surfaces shown as solid lines. At the onset of electrodeposition the field would be as shown at the left of Fig. 1. The emulsion particles being drawn to the anode follow the lines of force which are everywhere perpendicular to the equipotential surfaces. As shown, at $t = 0$ an emulsion particle in the bulk of the dispersion would migrate to the outside of the metal tube. The emulsion particles inside the tube are not subjected to an electric field and are not attracted to the inner wall of the tube. At the entrance to the tube one component of the field is perpendicular to the inner wall thus providing lines of force for the emulsion particles to follow. Thus, the outside of the tube is completely coated within a few seconds from the onset of the electrodeposition. On the inside of the tube, the mouth is coated immediately while the interior regions of the tube are not coated at all. Turning now to the right of Fig. 1, the process of electrodeposition is shown

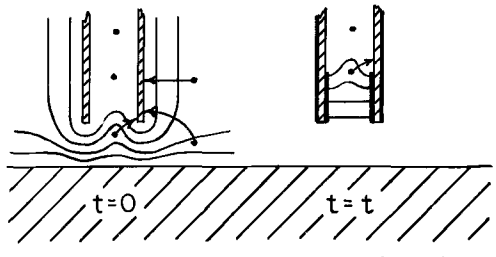

Fig. 1. Lines of force and emulsion particle pathways during electrophoretic deposition.

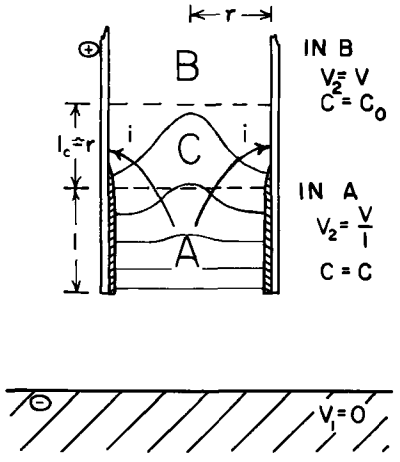

Fig. 2. Expanded view of the tube interior near the transition region.

after a period of time. The equipotential surfaces are shown only for the inside of the tube since the outside of the tube has long since been coated. Toward the mouth of the tube there is an electrodeposited layer which is essentially a nonconductor. The equipotential surfaces are now perpendicular to the nonconducting deposit except in the transition region. As at $t = 0$ deposition occurs only in the transition region. As the coated region is enlarged the transition region penetrates into the tube.

In order to develop a mathematical formulation from the qualitative point of view of Fig. 1 it is necessary to consider the transition region in greater detail. At any instant the tube can be divided into three regions as shown in Fig. 2. In region A the walls have been covered by an insulating film of resin; in this region the potential is essentially constant over a given cross section of the tube, the potential does vary linearly with distance along the axis, *i.e.*, there is an axial potential gradient V/l. In region B the potential is constant at V. Region C is the transition region, and, as discussed above, it is here that deposition of resin occurs on the walls of the tubes. It is to be expected that the length of C will be proportional to r with a proportionality constant of order unity. No current flows from C into B, since there is no potential gradient in B. Since one component of the field in C is perpendicular to the wall there is also a component of the current density perpendicular to the wall. Hence all the current flowing from region A into region C by virtue of the potential gradient in region A must pass out through the wall of the tube in region C. Thus the current density, i, on this portion of the tube wall is given by

$$2\pi r^2 i = \pi r^2 \kappa \frac{V}{l} \qquad [1]$$

where κ is the conductivity of the suspension. Equation [1] may be simplified to give

$$i = \frac{\kappa}{2}\frac{V}{l} \qquad [2]$$

From this point on, two possible models may be considered. It is assumed that the deposition in region C ceases (or is at least considerably slowed down) due to: (*a*) the insulating properties of the deposited film, *i.e.*, the deposition ceases after the passage of a given quantity of coulombs, or (*b*) the depletion of resin particles from the dispersion in the immediate vicinity of the tube wall. It is expected that the former would be dominant at long times, when the current density i has become low because of the large value of l, whereas the latter would tend to be more important during the initial stages of the experiment, when i is still relatively high.

Proceeding to the mathematical formulation of model (*a*) it has been shown elsewhere (6) that the deposition of resin obeys Faraday's laws. Thus the mass m deposited per unit area per unit time is given by

$$\frac{1}{A}\frac{dm}{dt} = \frac{R}{\mathbf{F}} i \qquad [3]$$

where i is the current density, R is the equivalent weight, and $\mathbf{F}$ is Faraday's constant. From Eq. [3] it is obvious that the rate of deposition of resin per unit area in region C is proportional to the current density. It is also apparent that after a time t_c the rate of deposition in region C is markedly reduced, due to the insulating properties of the deposited film of some limiting surface density ρ

$$t_c = \frac{\rho}{\frac{1}{A}\frac{dm}{dt}} \qquad [4]$$

Since t_c is the time taken for resin of surface density ρ to deposit over the width r of region C, the film is advancing at a velocity dl/dt given by

$$\frac{dl}{dt} = \frac{r}{t_c} \qquad [5]$$

Substitution from Eq. [2], [3], and [4] into Eq. [5] gives

$$\frac{dl}{dt} = k\frac{rC_0V}{l} \qquad [6]$$

where $k = \alpha R/2\rho\mathbf{F}$, and where it has also been assumed that the conductivity κ is proportional to the resin concentration C_0 with a proportionality constant α. This, of course, does not imply that the resin dispersion carries the current, but rather that current transporting ions are introduced into the dispersion in proportion to the resin concentration.

The regime described by model (a) is dominant at long times, *i.e.*, when the time t and the length of penetration l exceed certain critical values t^* and l^*. Thus Eq. [6] may be integrated with these values as lower limits to give

$$l^2 - l^{*2} = 2krC_0V(t - t^*) \qquad [7]$$

In order to evaluate t^* and l^* it is first necessary to deal with the regime described by model (b) which is dominant at times less than the critical value t^*.

To treat model (b) we must calculate the time t_c required for the resin concentration of the dispersion at the tube wall to drop from $C = C_0$ to $C = 0$ under the application of a constant current density i. This decay is controlled by the diffusion equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad [8]$$

where D is the diffusion constant of the resin and x is the distance from the tube wall. Equation [8] is subject to the initial condition

$$C(x,0) = C_0 \qquad [9]$$

and the boundary condition

$$i = \epsilon D\frac{\partial C}{\partial x} \qquad \text{at } x = 0 \qquad [10]$$

ϵ being a constant of proportionality. The solution of Eq. [8] subject to Eq. [9] and [10] is given by Carslaw and Jaeger (8)

$$C(0,t) = C_0 - \frac{2i}{\epsilon}\left(\frac{t}{\pi D}\right)^{1/2} \qquad [11]$$

The time t_c when the resin concentration drops to zero is therefore

$$t_c = \frac{\pi\epsilon^2 D C_o^2}{4i^2} \quad [12]$$

Just as for model (a), after time t_c the rate of deposition in region C is reduced. In this instance, however, the rate is reduced because of the exhaustion of resin from the vicinity of the interface and not because of the insulating properties of the built-up film. Once again we can argue that it takes a time t_c to cover a strip of width r, and that the velocity of the advancing film is given by

$$\frac{dl}{dt} = \frac{r}{t_c} \quad [13]$$

Substitution of Eq. [2] and [12] into Eq. [13] then gives

$$\frac{dl}{dt} = k' \frac{rV^2}{Dl^2} \quad [14]$$

where $k' = \alpha^2/\pi\epsilon^2$. Since Eq. [14] is expected to apply at short times it may be integrated, ignoring effects near the entrance of the tube, subject to the conditions that $l = 0$ at $t = 0$ and that $t < t^*$, *viz.*

$$l = \left(\frac{3k'}{D}\right)^{1/3} r^{1/3} V^{2/3} t^{1/3} \quad [15]$$

The transition from regime (b) to regime (a) will occur when the values of dl/dt calculated from Eq. [6] and [14] are of a comparable magnitude; to obtain l^* we therefore equate the right-hand sides of Eq. [6] and [14]

$$l^* = \frac{k'}{k} \frac{V}{C_o D} \quad [16]$$

and substitution of Eq. [16] into Eq. [15] then gives

$$t^* = \frac{k'^2}{3k^3} \frac{V}{C_o^3 D^2 r} \quad [17]$$

so that Eq. [7] becomes

$$l = \sqrt{2krC_oVt + K\frac{V^2}{C_o^2 D^2}} \qquad K \equiv \frac{k'^2}{3k^2} \quad [18]$$

At $t = t^*$ the first term of Eq. [18] is twice the second term, and it also becomes more dominant with increasing time.

As will be seen below the experimental results show that $t > t^*$ applies most of the time. Thus the discussion is concerned chiefly with the verification of Eq. [18]. For $t < t^*$ Eq. [15] would apply.

Experimental Procedure

The determination of throwing power of an electrophoretically deposited film is an extension of a procedure reported previously for films deposited on exterior surfaces (6). Essentially the procedure consists of submerging a clean bare steel tube (0.9 cm ID by 25 cm in length) in an emulsion contained in a circular one gallon tank (6.5 in. ID by 7.5 in. high). The tank acts as the cathode and the steel tube as the anode. The rectifier (Dresser Electric Company, Detroit, Michigan) used in this work operates within 0-1000v d.c. and 0-5 amp with a capacity of 10,000w.

The throwing power was measured as the length of penetration of the electrodeposited film into the interior of the steel tube. Initially the tubes were sawed open and the length of penetration measured. In later tests a thin metal strip was inserted into the tube. After the test was completed the strip was removed and the length of penetration was easily measured. The steel tube could not be reused without thorough cleaning. The length of penetration into the hollow tubes was measured as a function of voltage, resin concentration, tube radius, and time.

The resins used in this work were proprietary polycarboxylic acid resins of an experimental nature. Of necessity resins from several batches were used; however, they were all similar in nature to AROLON® EP7992-15-104 resin (Archer Daniels Midland Company) which has an acid value of 50 to 60. The resins were first neutralized to about 40% of the acid value with diethyl amine with sufficient water added to make a paste. The emulsions were prepared by inverting the water-amine-resin paste in about equal parts of water and then adding slowly with rapid agitation sufficient water to make an emulsion of the desired per cent solids; 6% in most instances.

Results and Discussion

As will be discussed in this section model (a) is the dominant model, and consequently Eq. [18] provides the best understanding of the relationship between the length of penetration and the other variables. The various dependencies necessary to test the validity of Eq. [18] are obtained by rearrangement and are of the form $y = mx + b$.

The first such equation is

$$\frac{l^2}{V} = 2krC_o t + K\frac{V}{C_o^2 D^2} \quad [19]$$

which predicts a linear graph of l^2/V plotted *vs.* V for the region $t > t^*$. As can be seen from Fig. 3 a graph of l^2/V *vs.* V is almost independent of V thus establishing that the slope K is small and is effectively zero between 200 and 600v. From a consideration of Eq. [17] it is also apparent that a small value of K dictates a small critical value t^*. Therefore it is to be expected that most of the effects observed in this study will be due to regime (a) where $t > t^*$.

Since K is effectively zero Eq. [18] predicts a linear graph of l plotted *vs.* $\sqrt{V}$ passing through the origin. This is shown to be true experimentally in Fig. 4.

The other variables to be considered are resin concentration C_o, tube radius r, and time t. Rearrangement of Eq. [18] gives

$$l^2 C_o^2 = 2krC_o^3 Vt + K\frac{V^2}{D^2} \quad [20]$$

which predicts a linear $l^2C_o^2$ *vs.* C_o^3 dependence pass-

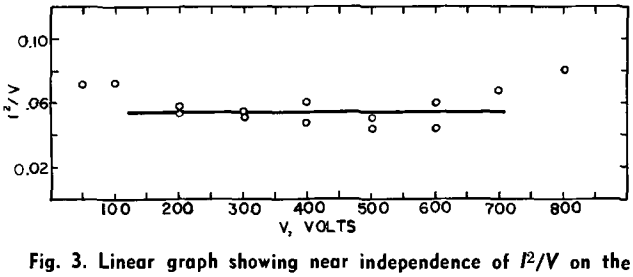

Fig. 3. Linear graph showing near independence of l^2/V on the applied voltage V.

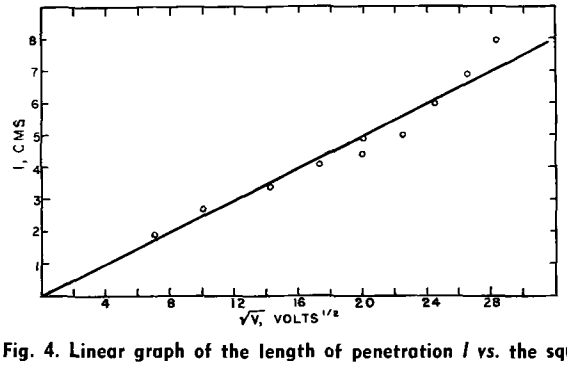

Fig. 4. Linear graph of the length of penetration l *vs.* the square root of the applied voltage $\sqrt{V}$.

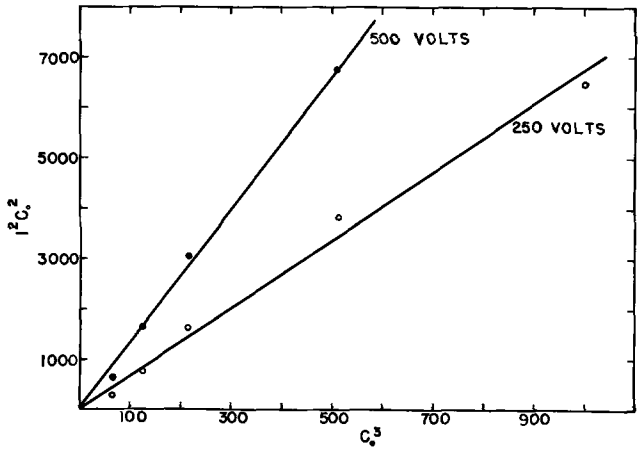

Fig. 5. Linear graph of $l^2C_o^2$ vs. C_o^3 predicted by Eq. [18] for negligible K.

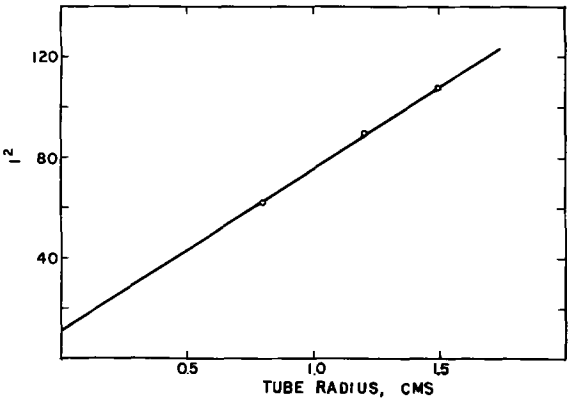

Fig. 6. Linear graph of l^2 vs. tube radius r

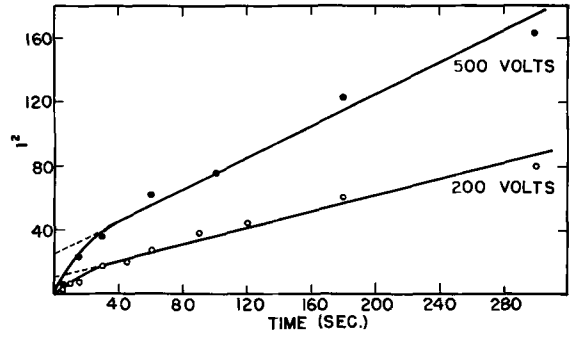

Fig. 7. Linear graph of l^2 vs. time t

ing through the origin provided K is negligible. In a similar manner

$$l^2 = 2krC_oVt + K\frac{V^2}{C_o^2D^2} \qquad [21]$$

where a linear graph of l^2 vs. r is predicted and which will pass through the origin if K is negligible. The experimental verification of a negligible K for each dependence is shown in Fig. 5 and 6, respectively. Close inspection of Fig. 6 shows that a straight line intercepting the ordinate near the origin is also a possibility thus indicating K may be small rather than zero. For the time dependence Eq. [22]

$$l^2 = 2krC_oVt + K\frac{V^2}{C_o^2D^2} \qquad [22]$$

predicts a linear l^2 vs. t passing through the origin if K is negligible. If the graph of the experimental results shown in Fig. 7 is extended it intercepts the ordinate near the origin. Thus K is, at best, small in this instance. Some variation in K between dependencies is expected since slightly differing experimental resins were used for each. From Eq. [17] for a finite K there is a finite critical value of the time t^*. Prior to time t^* Eq. [15] shows that l^2 vs. $t^{2/3}$ dependence would be expected. Such a dependence when replotted on l^2 vs. t coordinates is not inconsistent with the short time period data of Fig. 7.

[a] In this series the electrophoretically deposited resin was baked between runs thus providing a cured film insert.
[b] In this series the inserts were thin lengths of tygon tubing.

A consideration of Eq. [7] presents the interesting possibility of placing insulating inserts in the tubes prior to deposition. If the length of the insert exceeds l^* then t^* coincides with the onset of deposition (*i.e.*, $t^* = 0$). Thus Eq. [7] becomes

$$l^2 - l^{*2} = 2krC_oVt \qquad [23]$$

where l is considered to be the length of penetration of film plus the length of the insert. Thus if uniform deposition times are used the quantity $l^2 - l^{*2}$ should be constant for all values of l and l^*. This is shown to be true experimentally in Table I where values of $l^2 - l^{*2}$ are displayed and are seen to essentially constant.

In view of the good agreement between the theory developed above and experimental results shown here it is very probable that the model on which the theory is based is indeed realistic.

In regard to possible applications of this study Eq. [18] shows that, of the factors considered, the most practical means of increasing the length of penetration into a tube is to increase the applied voltage or the resin concentration. If the constant K is sizeable an increase in the applied voltage would be especially effective.

Finally, the equations developed here should also describe penetration of aerosols into electrically charged tubes such as encountered in electrostatic spraying. It is also possible that the present work, with suitable modifications, might describe the anodizing of interior surfaces of cylindrical tubes.

Annealing Behavior of Fine-Grained Nickel Electrodeposits

R. Weil, H. J. Sumka,[1] and G. W. Greene[2]

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey

ABSTRACT

The effect of thickness on the annealing behavior of fine-grained nickel electrodeposits was studied. The first structural change on heating occurred at 310°C in the thinnest sample (0.13μ) and at 255°C when the thickness exceeded 1.2μ. Heating slightly above these respective temperatures resulted in the same structure regardless of the original thickness. The mechanism by which the first structural change occurred and which therefore was independent of thickness appeared to consist of crystallite rotation rather than uniform boundary movement. The structural changes in the samples were recorded by cinematography during annealing in the electron microscope.

In an earlier study (1), of the annealing of several types of nickel electrodeposits, it was found that microstructural changes in the bulk portion occurred at lower temperatures than those near the surface. This observation corresponded to the findings of Bailey (2) and Hu (3) that the recrystallization temperatures of cold-worked, thin films were higher than those of bulk. However, a quantitative study of the effect of the sample thickness on the annealing temperature at which structural changes occur has not yet been conducted. Electrodeposits are especially suited for such an investigation because by the proper choices of substrate and plating conditions it is possible to produce specimens with the same structure over a wide range of thicknesses. A study of the effect of thickness on the annealing behavior of electrodeposits was therefore undertaken. In addition, thin electrodeposits were heated in the electron microscope and the structural changes directly observed and recorded by cinematography in order to investigate the mechanisms of recrystallization.

Experimental Procedure

Nickel deposits ranging in thickness from 0.13 to 40μ were plated in a Watt's bath also containing 1 g/l 1-5 naphthalene disulfonic acid (Na salt). The substrate, an electroformed, fine-grained and randomly oriented copper sheet, and the plating conditions were the same as in the earlier (1) experiments. A special holder was constructed which exposed an area of 6.00 x 6.00 cm of the substrate to the plating solution. The average thicknesses of the specimen were then calculated from the weight of metal deposited. It was assumed that the density of the electrodeposits was the same as that of wrought nickel.

Small specimens were cut out of the center region of each deposit. The copper substrate was stripped from the deposit in an aqueous solution containing 500 g/l CrO_3 and 50 g/l H_2SO_4. The pieces were annealed in vacuum at various temperatures for 1 hr and then examined by transmission-electron microscopy. The thicker deposits were thinned by the Bollmann (4) method from both sides after annealing. Thinning from both sides insured that the foil which was examined came from the center part of the deposit. The first annealing temperature was selected on the basis of the earlier study (1). If no structural change was observed, the temperature was raised. If a change was observed, the temperature was lowered. This procedure was followed until a temperature range not exceeding 10°C was determined, at the lower end of which no structural change had occurred and at the upper end of which an alteration had taken place.

A 700Å-thick deposit was produced in the same manner as the thicker ones. Specimens from this deposit supported on nickel grids were placed in the heating stage of a Hitachi HU-11 electron microscope. The temperature was raised to 320°C and the structural changes were recorded on motion picture film using a Bolex camera with a f 1.4 Switar lens focussed on the fluorescent screen of the electron microscope.

Results

A typical structure of the deposits in the as-plated condition is shown in Fig. 1. It consists of fine crystallites with poorly defined boundaries and some contrast variation within each. The change in the structure upon annealing is shown in Fig. 2. Larger grains have formed. However, these grains still exhibit substructure as well as twin markings. The boundaries between the small crystallites of the remaining matrix have become more clearly defined.

As already indicated, it was possible to determine the range of less than 10°C between the highest temperature at which a structure like Fig. 1 was still observed and the lowest at which a morphology like that shown in Fig. 2 was seen. These temperature ranges, called

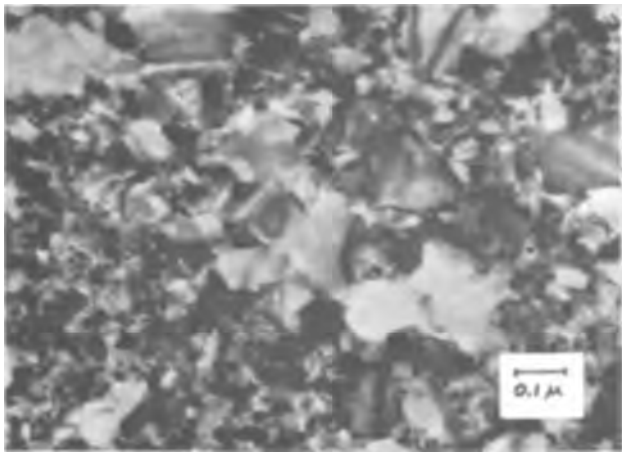

Fig. 2. First structural changes on annealing

T_{sc}, for the samples of various thicknesses are listed in Table I and graphically represented in Fig. 3.

An attempt was made to find the cause of the somewhat anomalous behavior of specimen 104. The discrepancy was reproducible and thought to be due to variation in the purity of the deposit. In view of the bath additive used, the sulfur content was indicative of the amount of codeposited foreign material. The sulfur contents are therefore listed in Table I. It is seen that samples 103 and 104 have lower sulfur contents than the rest. However, the T_{sc} of sample 103 falls on the curve with the other sample. Therefore no definite reason for the anomalous behavior of sample 104 can be given at this time.

Samples annealed at the upper temperature of the T_{sc} range exhibited essentially the same structure regardless of thickness. It therefore appears that the mechanisms in the early stage of recrystallization were not thickness dependent.

When the thicker samples were annealed at temperatures considerably above T_{sc}, relatively large, fully recrystallized grains were formed. In the thin foils, however, heating to corresponding temperatures resulted in certain areas becoming thicker at the expense of others as shown in Fig. 4. The areas devoid of metal, which have the light contrast, consisted of nickel oxide, as identified by electron diffraction. Figure 4 shows that the metal regions had recrystallized. The grains are smaller however than those obtained in thicker samples after annealing at corresponding temperatures. In many instances, the oxide regions were observed to be continuous, surrounding the metallic ones.

By examining the motion picture film of the annealing of thin foils in the heating stage of the electron microscope it was possible to make some deductions about the mechanism responsible for the first structural changes. A series of enlargements of every sixth frame of the motion picture is shown in Fig. 5. The time interval between the frames in Fig. 5 was ½ sec. It can be seen that the larger grains of the kind shown in Fig. 2 form by the coalescence of small crystallites. This phenomenon can be observed in several areas in Fig. 5. In the region designated in the eighth picture by the letter A there is initially a small crystallite showing light contrast. Immediately to the left of this crystallite is another which is gray in the first frame and becomes progressively lighter. When the two crystallites have the same contrast, there is still a small darker stripe separating them. In the last frame this

stripe has almost disappeared. A similar process in which crystallites of varying dark shades assume the same black contrast can be seen in region B. In the area under C an initially small, light-contrast crystallite grows not by uniform boundary motion, but rather by a process which results in neighboring regions slowly changing contrast. Two other crystallites which become light with increasing time can also be seen to join the light one, marked C at its upper left corner. The contrast was not usually uniform throughout such a growing region and its substructure could be observed readily by tilting the specimen. Unfortunately the crystallites were too small to permit the determination of their individual orientation.

Discussion

There are several possible reasons for the effect of thickness on T_{sc}. All the samples were found by electron diffraction to be covered with an oxide film. Such a film is probably an impediment to the motion of defects. In addition to the oxide, adsorbed material as well as surface tension can impede the processes which are believed to be responsible for producing the first structural changes on annealing. Internal microstresses of the type which broaden diffraction lines are believed (1) to be associated with the excess stored energy of electrodeposits of the fine-grained, randomly oriented type used in this study. These stresses thus provide the driving force for the processes which occurred on annealing. Such stresses can be relieved partially near the surface which would result in a weaker driving force and a correspondingly higher temperature at which the processes can start in the thin samples. A study of the relationship between microstress and the annealing process is currently in progress, and an additional one on the effects of surface contamination is planned.

As the type of structure shown in Fig. 2 was observed in all samples regardless of thickness, it is probable that the mechanism observed in the motion picture is common to all the deposits which were studied. The regions of uniform contrast become the recrystallized grains.

The size of these grains appears to depend on the thickness of the deposits. The effect of thickness on the grain size after recrystallization in cold-worked material was studied by Furubayashi, Fujita, and Taoka (5). These investigators found an increase in grain size with increasing sample thickness with a very sharp rise when the sample thickness exceeded 1μ. The same relationship appears to apply to electrodeposits. As Fig. 4 illustrates, the thin films can actually increase their thickness locally so as to be able to form larger grains.

The formation of the larger grains from the small crystallites shown in Fig. 5 can only be explained by a crystallite-rotation mechanism. As the contrast is determined primarily by the deviation of crystal planes from a diffracting position, the observed matching of the shading implies a lattice rotation. Thus it appears that neighboring crystallites rotate to match the lattice orientation of the growing grains. The matching of the lattice planes at the stage shown in Fig. 2 is, however, not complete in all directions as tilting into different diffraction conditions revealed a misorientation. Twins were also frequently observed. Votava (6) observed similar contrast variation within growing recrystallized grains in copper, which had been cold-worked. Hu (7) suggested that recrystallized grains form by coalescence of subgrains in cold-worked metals. It would be desirable to have further proof of the rotation mechanism. Therefore some experiments with initially larger-grained deposits which would permit an accurate determination of the crystal orientations by electron diffraction are planned.

Adsorption, Absorption, and Degassing in the Oxygen-Niobium System at Very Low Pressure

R. A. Pasternak[1] and B. Evans[2]

Stanford Research Institute, Menlo Park, California

ABSTRACT

The interaction of low-pressure oxygen with niobium has been investigated at temperatures between 300° to 2100°K. Four main kinetic patterns can be distinguished. At temperatures close to 300°K adsorption proceeds to the formation of a saturated surface layer. At intermediate temperatures (about 500°-800°K) a thin oxide layer is formed; simultaneously oxygen dissolves and diffuses into the metal. At higher temperatures (800°-1700°K) oxygen dissolves rapidly and irreversibly; the observed kinetics can be explained by a surface mechanism involving two adsorption states. Finally, at very high temperatures (1700°K and higher) niobium oxides evaporate from an oxygen-niobium solution. The kinetics of evaporation indicates that a mixture of NbO_2 and NbO evolves, the composition of which shifts from the former to the latter with decreasing oxygen concentration.

The mechanism of sorption of active gases by refractory metals is of considerable interest in the context of corrosion and embrittlement. Nitrogen sorption by niobium at high temperature and low pressure has been described recently (1-3). This paper presents the results of a similar investigation of the oxygen-niobium system.

Experimental

The sorption kinetics of the oxygen-niobium system was investigated by the constant pressure technique [described in detail elsewhere (1-3)]. In this approach the sorption rates are measured directly, and the amounts sorbed are found by integration.

The sample, a ribbon, is heated by means of a simple d-c bridge circuit which supplies virtually constant power. The temperature of the sample remains constant during sorption since its emissivity is not significantly affected by dissolved gas (4, 5). The observed change in resistance is thus a measure for the concentration of solute. It has been shown previously that for the oxygen-niobium system (6) [and also for the nitrogen-niobium system (7)] the resistance at constant temperature is proportional to concentration and that this proportionality is independent of temperature, *i.e.*, Mathieson's rule is obeyed. Gebhardt and Rothenbacher (6) report a resistivity $\rho_0 = 13.96$ μohm cm at 273°K for clean niobium and a resistivity coefficient of solution $\gamma = \Delta\rho/\rho_0 \cdot 1/c = 0.30$ $(a/o)^{-1}$ for the temperature range 273°-1273°K. The resistivity ρ_0 of the one sample to which all the data given here refer, was 14.5 μohm cm, and in the sorption runs at high temperatures a linear relationship was observed also between resistance and amount of gas dissolved.

[2] Present address: Field Emission Corporation, McMinnville, Oregon.

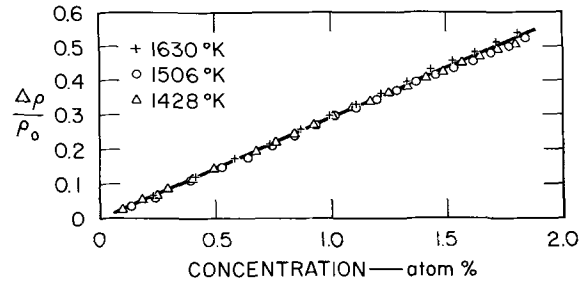

Fig. 1. Increase in the resistivity due to dissolved oxygen, expressed as fraction of the resistivity of pure Nb at 273°K.

This is shown in Fig. 1 for three runs at 1428°, 1506°, and 1630°K. The curves coincide; the average resistivity coefficient of solution is 0.3 ± 0.02 $(a/o)^{-1}$ and was assumed to apply over the entire temperature range studied. The agreement with the previous value (6) is undoubtedly fortuitous in view of the uncertainties in the measurement. The amount of oxygen dissolved in the sample could now be obtained independently by integrating the sorption rate curves based on pressure measurements, and by resistance measurements. Any discrepancy would indicate formation of an oxide phase (which would have a different resistivity from the metal) either in the bulk or on the surface.

Moreover, resistance measurements permitted a quantitative evaluation of the kinetics of the degassing reaction, which is not associated with pressure changes (see section on results); they were also the basis for defining the sample purity. A sample was assumed to be free of oxygen, if after repeated heating to about 2100°K its room temperature resistance did not decrease further.

The sample temperature was measured above 1300°K with an optical pyrometer, or was derived from resistance measurements after correcting for the effect of dissolved gas. Lower sample temperatures were defined in terms of a linear interpolation of resistance between 300° and 1300°K.

A magnetic deflection-type mass spectrometer served to monitor CO contamination (generally encountered in ultrahigh vacuum systems) as well as the pressure dependence of the ion gauge sensitivity. CO partial pressures consistently below 1% were found, even at high sample temperatures. The gas source was analytical grade oxygen from a glass bottle, connected to the system by a bakeable ultrahigh vacuum valve. Between 10^{-7} and 10^{-5} Torr, the ion gauge and mass spectrometer readings were proportional; at lower pressures the ion gauge readings were consistently higher. This discrepancy has been explained by oxygen ion emission from the grid of the ion gauge (8); the pressures given here are therefore based on the mass spectrometer readings.

The samples for this and the nitrogen study were thin ribbons rolled from high-purity, zone-refined stock. They all were originally microcrystalline with a (110) texture. At the end of the experiments they exhibited large crystals of 1 mm magnitude, and high preferred orientation; however, (110), (111), (100), and (311) textures were observed for different samples. The reason for this variation is obscure. The effects of surface orientation on the sorption kinetics were not explored quantitatively, but the over-all

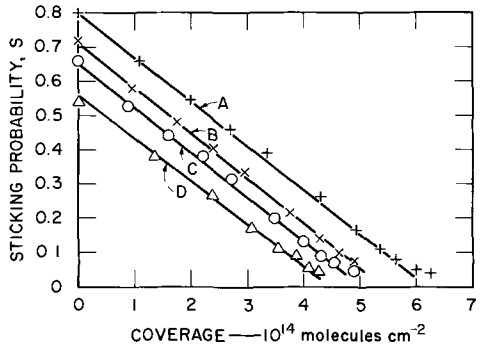

Fig. 2. Sticking probability of oxygen at 3 x 10^{-8} Torr on niobium at 300°K, as function of coverage. Curves A to D are for oxygen concentrations in the sample of 0, 0.01, 0.02, and 1 a/o.

kinetic pattern did not differ significantly for the four samples studied. Data are reported for only one of them; its dimensions were 24 x 0.112 x 0.0025 cm.

Results and Discussion

This low-pressure study is concerned primarily with the mechanisms of adsorption, solution in the homogeneous metal phase, and degassing. Four patterns of interaction can be distinguished; they are determined by temperature, and to a lesser extent by pressure.

Adsorption at room temperature.—In Fig. 2 linear plots of sticking probabilities *vs.* amount adsorbed are shown. The sample was flash heated for a few seconds to about 1800°K in ultrahigh vacuum, and after it had cooled to ambient temperature (which required about 2 min) it was exposed to oxygen at a pressure of 3 x 10^{-8} Torr. Curves A, B, and C represent adsorption runs for oxygen concentrations in the sample of about 0, 0.01, and 0.02 a/o. The concentrations were established by flash heating the sample after repeatedly adsorbing oxygen on it; the adsorbed oxygen is not released but dissolves. Curves identical to D are found at larger oxygen concentrations in the sample (here 1 a/o). The four sticking probability curves are approximately parallel, straight lines. The deviations at very low sticking probabilities are likely to be an ion gauge artifact.

The linearity of the curves suggests that adsorption of molecular oxygen on unoccupied sites is the rate-determining step at room temperature. Their parallel displacement indicates that the oxygen coverage on a flash-heated sample increases significantly with the oxygen concentration in the bulk. This appears to be a true bulk effect since long-time annealing at temperatures between 1300° and 1800°K does not reproduce the sticking probability curve of a clean sample. The sample can be reactivated only by removal of oxygen from the bulk of the sample (see below). The relationship between bulk concentration and surface properties will be discussed in more detail later.

Sorption at intermediate temperatures.—At temperatures above approximately 500°K sorption proceeds beyond an amount equivalent to a monolayer. In Fig. 3 the sticking probability and the resistance observed in a typical run are plotted *vs.* time. Constant power input equivalent to an initial temperature of 745°K was established; then, at t_1, oxygen was admitted at a pressure of 3 x 10^{-6} Torr. The initially high sticking probability drops gradually to a low constant value; the resistance decreases also and goes through a minimum at t_2. When at t_3 the gas flow is stopped, the resistance increases more rapidly and approaches a constant value. We explain these observations as follows. Since the sample is heated at constant power, the decrease in resistance (*i.e.*, in temperature) between t_1 and t_2 indicates an increase in its emissivity; this is ascribed to the build-up of a surface oxide[3] which is also expected to have a smaller sticking probability for oxygen, than the metal. Either a uniform oxide skin is formed which grows in thickness or initially separate oxide patches gradually coalesce over the entire surface. At t_2 a quasi-steady state is reached; the rate of adsorption becomes equal to both the rate of diffusion of oxygen through the oxide layer and into the metal; the emissivity (and the temperature) is now constant, and the sample resistance increases because of gas solution (which undoubtedly takes place also in the time interval between t_1 and t_2). After t_3, the resistance increases more rapidly because the oxide layer dissolves gradually, and consequently the emissivity decreases, until the original temperature is finally re-established. The oxygen concentrations derived by integration of the rate curve, and from the increase in resistance, 0.23 and 0.24 a/o, agree closely.

At 3 x 10^{-6} Torr, the described kinetic pattern was observed to about 800°K. The upper temperature limit increases with pressure.

The study of the sorption mechanism in the intermediate temperature range was not pursued systematically despite its potential value for diffusion measurements and its significance in respect to corrosion, since the present investigation is focused on the mechanism of homogeneous solution and degassing.

Sorption at high temperatures.—In sorption experiments at high temperatures the resistance increases proportionally with the amount sorbed (Fig. 1); no oxide phase is formed and the gas dissolves uniformly in the metal. In Fig. 4 three sorption curves at a pressure of 3 x 10^{-6} Torr are shown; they are expressed as sticking probability *vs.* bulk concentration. The initial sticking probabilities are approximately the same, 0.7, and the same constant value of 0.2 is ap-

[3] The electron diffraction pattern of a surface film which was stripped from a similar sample indicates that NbO is formed.

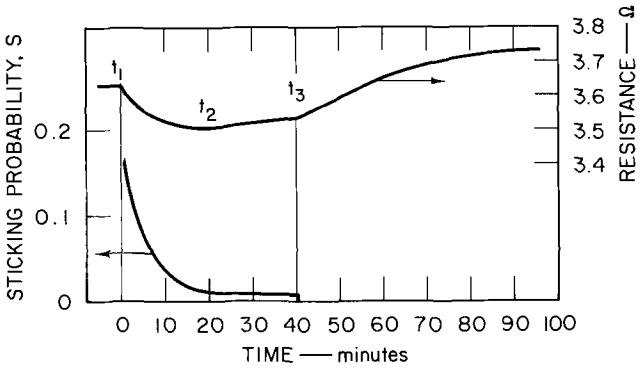

Fig. 3. Resistance and sticking probability as function of time during oxygen sorption at 3 x 10^{-6} Torr. Constant power input is maintained into the sample, equivalent to an initial temperature of 745°K.

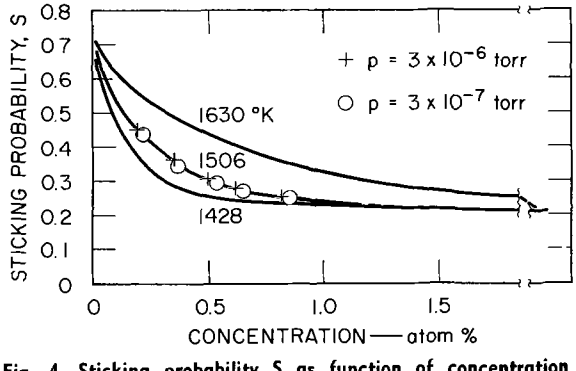

Fig. 4. Sticking probability S as function of concentration at constant, high temperatures. Control pressure 3 x 10^{-6} Torr, except when marked differently.

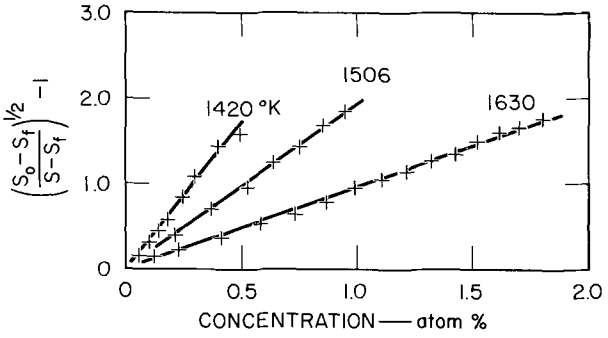

Fig. 5. Data of Fig. 4 plotted in the form of $[(S_o - S_f/S - S_f)^{1/2} - 1]$ vs. concentration (see text).

proached at high concentration.[4] However, the initial part of the curve is steeper at lower temperatures. (The theoretical interpretation, Fig. 5, will be discussed later.)

The sticking probabilities are functions of concentration and temperature only and are established virtually instantaneously after any change in conditions. The pressure independence is illustrated by the curve for 1506°K in Fig. 4. In this run the pressure was alternated between 3 x 10^{-7} and 3 x 10^{-6} Torr. The sticking probabilities at the two pressures lie on the same smooth curve. No pressure effects on the sticking probability were observed in other high-temperature experiments, *i.e.*, the sorption rates are proportional to pressure.

The temperature dependence of the sticking probability was studied also at approximately constant concentrations. Oxygen at a pressure of 3 x 10^{-7} Torr was sorbed in well-defined increments, and the sticking probabilities were rapidly measured for a series of temperatures. In order to minimize the exposure to oxygen and the concentration change during such a temperature series, the temperatures were derived from the resistances (which were corrected for the effect of dissolved oxygen). Constant sticking probabilities were established virtually instantaneously from whichever direction the new temperature was approached. The data, in a presentation which will be discussed below, are given in Fig. 6. The closely

[4] The sticking probability remains constant even when eventually a new phase precipitates (indicated by a change in the slope of the resistance curve). Since formation of a surface oxide, which has a low activity for oxygen adsorption, would be accompanied by a drop in sticking probability, the oxide phase apparently precipitates internally.

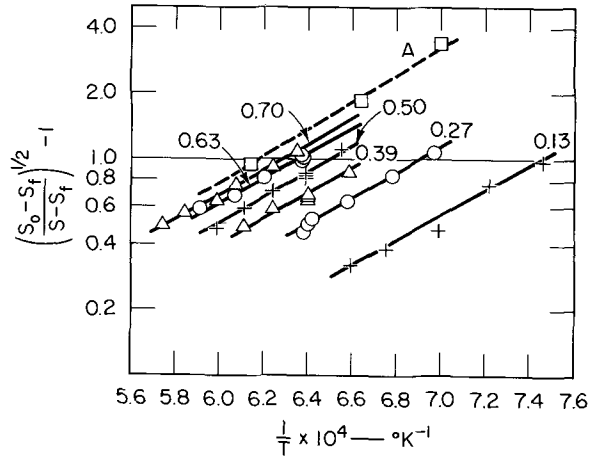

Fig. 6. Plots of log $[(S_o - S_f/S - S_f)^{1/2} - 1]$ vs. reciprocal temperatures at constant concentrations (marked in atom per cent). Curve A is derived from the slopes of the straight lines in Fig. 5, and is equivalent to the plot for unit concentration.

bunched points represent measurements at both increasing and decreasing temperature. (Sticking probabilities larger than one half the maximum value tended to drift downward probably because of an increase in concentration, and are not included.)

A model for explaining the high-temperature kinetics must take into account the following observations and postulates in addition to the detailed kinetics: (*A*) Diffusion is so fast relative to the rate of sorption that dissolved oxygen is at all times virtually uniformly distributed in the metal. This deduction from experiments is supported by an estimate, analogous to that for nitrogen in niobium (2), based on the known diffusion coefficient of oxygen in niobium (9). (*B*) No oxide is formed on the surface or in the bulk. This is indicated by the linearity between resistance and total concentration. Also, the concentrations in this study are far below the saturation limit of oxygen, and no high concentration can be built up at the surface because of the high diffusion rate. (*C*) Removal of oxygen from the sample in any form is insignificant at the temperatures of the experiments (see next section). (*D*) The sample surface exhibits quite uniform crystallographic orientation. Since samples of different orientation show the same kinetic pattern, crystallographic surface heterogeneity cannot be an essential factor in the sorption kinetics. (*E*) The dependence of the observed sticking probability on only bulk concentration and temperature indicates that an equilibrium between oxygen in the bulk and on the surface exists.

We postulate that oxygen adsorbs irreversibly in two independent atomic states differing in binding energy, and that the adsorption process in either state is described by $O_2 + 2$ sites $\rightarrow 2\,O$. Then, the rate law (referred to unit area) assumes the form

$$\frac{dM}{dt} = \nu p S = \nu p[k_1(n_1 - \sigma_1)^2 + k_2(n_2 - \sigma_2)^2] \quad [1a]$$

and

$$S = k_1(n_1 - \sigma_1)^2 + k_2(n_2 - \sigma_2)^2 \quad [1b]$$

where S is the observed sticking probability, k_i are the rate constants of adsorption, n_i the total numbers of sites, and σ_i the coverages in the two states. We further assume that the two adsorption states are at all times in quasi equilibrium with the solution, *i.e.*, transfer between bulk and surface is rapid. These equilibria are given by

$$\frac{\sigma_i}{n_i - \sigma_i} = K_i^o \frac{C}{1 - C} \approx K_i^o C = K_i c \quad [2]$$

where the solute density C is expressed as a fraction of all the interstitial positions in the metal structure and K_i^o is the distribution coefficient. Since in our experiments the bulk concentration, c, is always small, of the magnitude of 1 a/o, $(1 - C)$ is approximately unity and Eq. [2] can be simplified as shown. By rearrangement of Eq. [2] one obtains

$$(n_i - \sigma_i) = \frac{n_i}{1 + K_i c} \quad [3]$$

We finally assume that K_1 is small (thus, $(n_1 - \sigma_1) \approx n_1$) and that K_2 is large. These two assumptions are equivalent to the statement that the free energy change for transfer of oxygen atoms from the surface to the bulk is small for state 1 and large for state 2. By substitution in Eq. [1b] the rate law, in terms of bulk concentration, is

$$S = k_1 n_1^2 + k_2 n_2^2 (1 + k_2 c)^{-2} \quad [4]$$

The experimental sticking probability is for an oxygen-free sample, *i.e.*, at the beginning of the run,

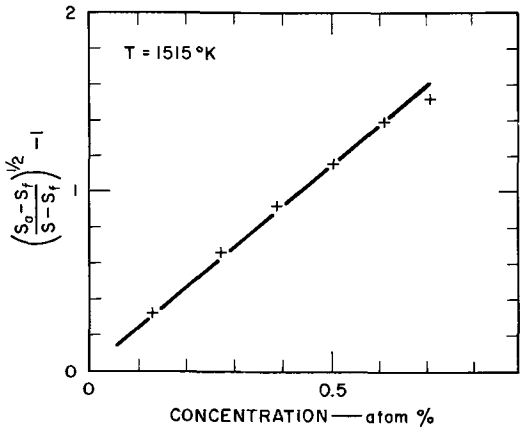

Fig. 7. Plot of $[(S_0 - S_f/S - S_f)^{1/2} - 1]$ at 1515°K vs. concentration, derived from Fig. 6.

$S_0 = k_1 n_1^2 + k_2 n_2^2$; and at higher concentrations it approaches the value $S_f = k_1 n_1^2$. Both limiting values are found to be temperature independent; thus, adsorption in either state is not activated. By introducing the limiting conditions in Eq. [4] and rearranging we obtain

$$f(S) \equiv \left(\frac{S_0 - S_f}{S - S_f}\right)^{1/2} - 1 = K_2 c \qquad [5]$$

This general function of S is dependent on both the oxygen concentration in the bulk and on temperature, since the distribution constant K_2 is temperature dependent also ($K_2 = K_0 \exp[\Delta H/RT]$).

As a test of the postulated model, $f(S)$ was derived from the three experimental sticking probability curves given in Fig. 4 and plotted *vs.* c (Fig. 5); a good fit to straight lines is obtained. The logarithms of the three slopes plotted *vs.* $1/T$ (Fig. 6, curve A) lie approximately on a straight line also. Moreover, the function $f(S)$ was evaluated from the sticking probabilities at constant concentrations, measured as function of temperature in the sorption run at 3 x 10^{-7} Torr (see above), and its logarithm was plotted *vs.* $1/T$ (Fig. 6). The points for each concentration define parallel straight lines; they are also parallel to line A which formally represents the data points for unit concentration. As a final test, the function $f(S)$ at 1515°K was read from Fig. 6, plotted *vs.* concentration (Fig. 7). The points lie on a straight line which passes through the origin, as required by [5].

A heat of 27 kcal/g atom is derived from Fig. 6 for the transfer of adsorbed oxygen in state 2 into the bulk; i.e., the oxygen atoms have an appreciably higher binding energy on the surface than when dissolved. An energy barrier for solution of gases exists also for other metals, such as molybdenum or tungsten; they adsorb active gases, but do not dissolve them to any significant extent.

Our model also explains at least qualitatively the effect of oxygen concentration on the room temperature adsorption kinetics. On flash heating an oxygen-covered sample, the adsorbates in both states dissolve. However, during cooling, the surface state of high binding energy is partly repopulated, and at higher bulk concentration, it approaches saturation. However, the state of low binding energy remains unoccupied. Thus, the observed sticking probabilities will decrease with bulk concentration to approach a constant value. (Low energy electron diffraction or field emission microscopy studies of surface coverage and its dependence on bulk concentration would be valuable for confirming our model for sorption and solution.)

The mechanism of oxidation of niobium has been studied previously, however mostly at moderate or higher pressures (10-14). Even in three recent investigations (15-17) which are closest in experimental conditions to the present study, the pressures employed were still higher by a factor of about one hundred or more. Large cross sections of the samples, compared to that used here, in combination with the higher pressure may have caused concentration gradients which would affect the sorption kinetics (16). Moreover, integral amounts, sorbed during rather large time intervals, were measured by gravimetric methods or derived from resistances; the concentration increments in each step were usually of the magnitude of 1 a/o. Thus, no data on the detailed kinetics of sorption at very low concentrations could be obtained. However, these studies agree in gross features with the present one. Proportionality between sorption rate and pressure, and a linear rate (here found at concentrations above approximately 1 a/o) were observed. Gebhardt and Rothenbacher (16) also report high initial sticking probabilities of about 0.5. The slight decrease of the initial sticking probability with temperature, which contrasts with the constancy found here, may be an artifact arising from the linear extrapolation of the integrated rate curves from higher to zero concentration.

High-temperature degassing.—When a sample containing oxygen is heated in ultrahigh vacuum, the pressure in the system does not increase significantly even at 2100°K, *i.e.*, no molecular oxygen is evolved. This is in agreement with the thermodynamics of the Nb-O system. The vapor pressure of oxygen over its solution in niobium, as derived from the dissociation pressure of NbO and its solubility in niobium (18), is very low ($p_{O_2} \approx 10^6 c^2 \exp[-18000/RT]$ Torr); at 1 a/o and 2100°K, it is about 10^{-13} Torr. However, on prolonged heating, the sample resistance decreases to approach a constant value. Simultaneously, and dark deposit forms on the wall, which very actively sorbs oxygen when it is subsequently admitted. Since the vapor pressure of the metal is insignificant except at the highest temperatures employed, an unsaturated oxide must evaporate.

The kinetics of the evaporation process was measured quantitatively, by maintaining the sample, which previously had been loaded with a known amount of oxygen, at constant temperature and recording continuously its resistance. At the end of each run which, especially at lower temperatures, extended only over a limited resistance interval, the sample was thoroughly degassed at 2100°K. The final resistance at room temperature was higher than prior to the particular sorption-degassing cycle, by about 1-2% for every atom per cent of oxygen dissolved. This suggested evaporation of a mixture of NbO and NbO_2. The resistances measured during the runs were corrected for the removal of metal (assuming a constant O/Nb ratio of the vapor) and were converted to oxygen concentrations by the relationship given in the experimental section.

First or second order kinetics can be expected depending on which species evaporates predominantly

$$\ln c_0/c = k_1 t$$

or

$$\frac{1}{c} = \frac{1}{c_0} + k_2 t$$

The experimental data fit well the second order kinetics at higher concentrations (Fig. 8). Thus, it appears that primarily NbO_2 evaporates, according to $Nb_{(s)} + 2\,O_{(s)} \rightarrow (NbO_2)_{gas}$. The Arrhenius plot (Fig. 9) of the rate constants k_2 derived from the linear part of the rate curves results in an activation energy of 120 kcal/g mole of oxygen (or NbO_2), and in a preexponential factor of 10^{11} (a/o min)$^{-1}$. Since for our sample the volume-to-surface ratio was about 10^{-3} cm, the preexponential factor for a ratio of unity would be about 10^8 cm (a/o min)$^{-1}$.

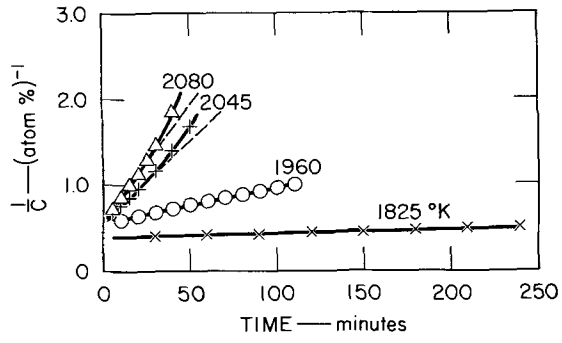

Fig. 8. Second order rate curves for oxygen removal from the sample.

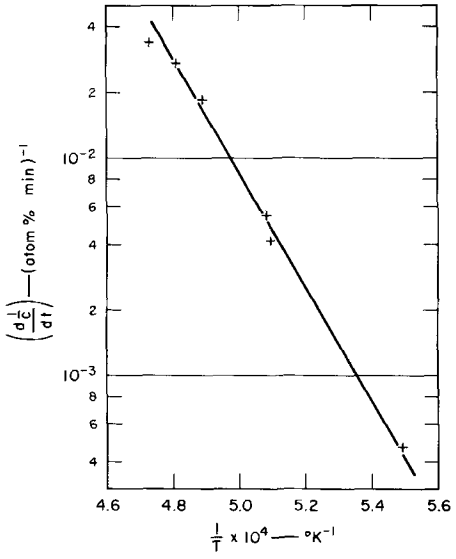

Fig. 9. Arrhenius plot of the second order rate constants for oxygen removal from the sample.

Deviations from the second order plot are found at lower concentrations, in a direction which may represent the approach to a first order rate law (Fig. 8). However, the low concentrations are rather unreliable because of the uncertainty in the definition of the final resistance, and their quantitative interpretation in terms of a first order rate law did not lead to consistent results.

The oxygen removal from niobium, (and from tantalum) has been thoroughly investigated by Gebhardt *et al.* (19). At 1900°-2300°K, oxygen and niobium evaporated from a 1.6 a/o solution in the atomic ratio of about 1.4-1.2. The kinetics of degassing obeyed a first order law at low concentrations, *i.e.*, NbO was apparently the principal evaporating species. The activation energy of evaporation was 130 kcal/g atom of oxygen (or NbO). Deviations in the direction of a second order law were noticeable at concentrations approaching 1 a/o. Thus, the kinetic patterns observed by Gebhardt *et al.* and by us are at least qualitatively similar. Moreover, for identical temperatures the absolute oxygen evaporation rates per unit area, at an oxygen concentration of 1 a/o, differ by less than a factor of 10. This agreement is rather close in view of the experimental uncertainties, particularly in temperature.

Finally, the observed similar activation energies of evaporation of the two species from solution is in agreement with the small temperature dependence of the Nb/O ratio, observed by Gebhardt *et al.* They are also close to the heats of sublimation estimated from the literature; they are 134 and 131 ± 15 kcal for NbO and NbO_2, respectively.

Comparison between Sorption Mechanisms of Oxygen and of Nitrogen

The low-pressure interaction of nitrogen with niobium has been described previously (1, 2) and has also been compared with preliminary data for oxygen (21).

The kinetics of high-temperature sorption both of nitrogen and of oxygen by niobium can be explained to a large extent by the thermodynamics of the two systems. The heat of solution of nitrogen is rather low, about 50 kcal/g atom; therefore the solution, which is atomic, decomposes at higher temperatures into nitrogen and the metal, and no volatile nitride exists. Consequently, high-temperature sorption of nitrogen is reversible and obeys an approximately parabolic rate law in respect to concentration. Moreover, the heat of adsorption is of the same magnitude as the heat of solution; thus, the surface coverage is found to be always low at the low nitrogen concentrations studied. For oxygen, the heat of solution is high, 90 kcal/g atom; thus, molecular oxygen is not released; however, at very high temperatures oxygen is removed in the form of volatile niobium oxides. Moreover, two adsorption states apparently exist. The heat of adsorption in one of them is appreciably higher than the heat of solution, and therefore significant surface coverages are encountered even at low bulk concentration. The resulting irreversible kinetics of oxygen has been discussed in detail in the preceding sections.

The high-temperature sticking probabilities on the clean metal are about 0.8 for oxygen and 0.05 for nitrogen; this large difference may be indicative of the higher affinity of niobium for oxygen. These sticking probabilities are temperature independent for either gas; thus adsorption is nonactivated.

Finally, the room temperature kinetics for the two gases is significantly different also. The sticking probability curve for nitrogen, which is approximately horizontal to quite high coverages [found also for nitrogen and molybdenum (21) and on tungsten (22) filaments], is not affected by the nitrogen concentration in the bulk. The linear curve for oxygen, however, shifts with bulk concentration, thus indicating an increase in initial surface coverage. The saturation coverage for nitrogen is about half that of oxygen on the clean sample; moreover, it was found in exploratory experiments that nitrogen was not adsorbed when the oxygen concentration in the sample was significant. Thus, it appears that at room (or high) temperature nitrogen adsorbs on niobium only in the surface state of high binding energy, but we suspect that at lower temperatures it would occupy the low energy state also. A similar two-step adsorption is found in the nitrogen-molybdenum (23, 24) and nitrogen-tungsten systems (22).

Electrochemical Studies in Molten Li_2CO_3-Na_2CO_3

H. E. Bartlett[1] and K. E. Johnson[2]

Chemistry Department, Sir John Cass College, London, England

ABSTRACT

It has been confirmed that C and O^{2-} are the cathode products and CO_2 and O_2 the anode products of electrolyzing Li_2CO_3-Na_2CO_3 at 550°C. In the presence of oxide, CO_3^{2-} is oxidized at platinum to $CO_2 + \frac{1}{2}O_2$ by a 6-electron process involving the substrate metal. Ag^+/Ag is a satisfactory reference electrode for the concentration range 4×10^{-3} to $4 \times 10^{-2}M$ Ag^+. Formal potentials of other systems on a molal scale are: Co^{2+}/Co — 0.946v, Ni^{2+}/Ni — 0.862v, CO_2, O_2/CO_3^{2-} — 0.270v, Ag^+ in SO_4^{2-}/Ag + 0.253v. Several other metals corrode or are noble. Ag is corroded by $CO_2 + O_2$ mixtures to a saturation concentration of $1.3 \times 10^{-1}M$ Ag^+ to 550°C. On cooling solutions of Ag^+ in Li_2CO_3-Na_2CO_3, a black precipitate of metal is obtained. The bearing of these observations on the corrosion of carbonate fuel cell cathodes is discussed.

Molten carbonates are well known as fuel cell media, but the basic electrochemistry of these solvents has received attention only recently.

The electrolytic reduction product of molten carbonates at temperatures below 600°C has been identified qualitatively as carbon (1-4), and the reduction product at 700°C is thought to be carbon monoxide (2).

The products of oxidation of the melts were shown to be carbon dioxide and oxygen in ratios strongly dependent on conditions (5): at high current densities the CO_2:O_2 ratio approaches 2:1 while at low current densities it is about 1:6 and in the presence of Na_2O_2 about 1:3. Plots of the discharge potential at low current densities *vs.* pO^{2-} and $\log_{10} p_{CO_2}$ were both shown to have slopes of 80 mv at 560° (1) from which it was concluded that O^{2-} was the species discharged under these conditions. Other experiments indicated that oxide was discharged at a more negative potential than carbonate ion itself.

EMF measurements have established the reversibility of the CO_2, O_2/CO_3^{2-} electrode in Li_2CO_3-Na_2CO_3 at 700°C (6) and of the O_2/O^{2-} electrode (at fixed CO_2 pressure) in carbonate (7) and carbonate-sulfate (8) melts.

A theoretical emf series for molten carbonates has been obtained (9) and an experimental order of reactivity of certain metals deduced from potentiostatic polarization curves (10). The reactions of silver in molten carbonates have been observed variously: the transfer of silver from a working fuel cell cathode to the anode (11), the loss in weight of silver upon anodizing (12, 13), the dependence of O^{2-} discharge potential at Ag on pO^{2-} in only basic melts (14), and a reduction wave for a 5×10^{-2}M Ag_2O solution in $(LiNaK)_2CO_3$ (14) have been reported. The limited corrosion of Pt to Li_2PtO_3 was also noted (12).

The present study was designed to establish a practical emf series for Li_2CO_3-Na_2CO_3 at 550°, to investigate the limiting electrode reactions at this temperature and to attempt to throw light on the working of a silver cathode in a carbonate fuel cell.

The success of the work was governed by the ability to use alumina for containing the solvent, a fact which is determined by reaction kinetics and not thermodynamics. The only other material which could be used in current-carrying as opposed to equilibrium studies, magnesia, suffers from two disadvantages: its acid solubility and its iron impurity content.

Experimental

AnalaR Na_2CO_3 and reagent grade Li_2CO_3 were oven dried at 120°C and mixed in equimolar proportions. [The eutectic mixture contains 53.3% Li_2CO_3 and melts at 500° (15)]. A large Purox alumina crucible (250 ml capacity), containing smaller aluminous porcelain or alumina crucibles, was then filled with the mixture and placed in a glass envelope which was stoppered by an aluminum foil-lined silicone bung.

The system was heated under vacuum in an air or potassium nitrate thermostat for 12 hr at 350°C, the temperature was raised to 450°C and dry CO_2 (dried by silica gel and molecular sieve, grade 4A) was admitted to the envelope. The temperature was then raised to 550°C and maintained at 550°C for 12 hr after which the silicone bung was replaced by one bearing the electrodes. The process of melting reduced the bulky powder to a liquid with surfaces 0.5 cm below the tops of the smaller crucibles which thus became wetted. The compartmenting crucibles could also be wetted by upsetting and righting them. The films of molten carbonate served later as salt bridges between compartments.

The electrodes consisted of (*a*) rods or coiled wire supported by thin alumina tubes (Co, Ni, Rh, Fe, Ag,

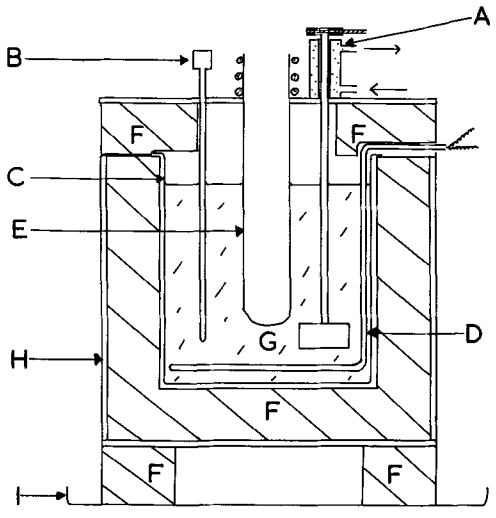

Fig. 1. Molten salt thermostat: A, water-cooled bearing for stirrer; B, thermometer probe; C, stainless steel container; D, stainless steel sheathed electrical heating element; E, glass envelope; F, alumina firebrick insulation; G, molten KNO_3; H, asbestolite box; I, aluminum safety tray.

Cu) and (b) thin Pt wire sheathed in glass well above the melt level, with and without Pt foil at the end. For the CO_2, O_2/CO_3^{2-} electrode, mixtures of the gases were bubbled over Pt foil electrodes, after having been mixed in two, 1*m* drying tubes; their proportions were measured by means of capillary flow meters, in turn calibrated with a bubble flow meter. Silver sulfate reference electrode solutions (16) were prepared from dry Ag_2SO_4 and oven-dried $(Li,Na,K)_2SO_4$ (mole ratio 78:8.5:13.5) and placed in closed aluminous porcelain tubes (Thermal Syndicate type 525 or Andermann's Pythagoras porcelain).

A 50 ml capacity outer alumina crucible and one compartment were used in the gas analysis experiments. In these, any oxygen was displaced by nitrogen before the electrolysis and the evolved gases were collected in a gas buret. The actual analyses were performed with a Haldanes' apparatus (17) using 25% KOH and alkaline pyrogallol as absorbents. Successive samples of gas were analyzed until the CO_2 content reached a constant small value.

Either an air thermostat or a molten salt bath was employed for the measurements. The air thermostat had two disadvantages: the heating elements burnt out fairly frequently and the mild steel fans had a working life of only six months. The molten nitrate bath (Fig. 1) could not be used safely above 570°C because of slow distillation of KNO_3. Both thermostats were controlled by a Fielden type TCB7 temperature controller which switched 10% of the heating current through a bank of resistors when the temperature, as determined by the thermometer probe, became too great. The temperature at any point remained constant to ±1°, and the temperature gradient in the region of the cell compartments was 0.5° cm^{-1}. The temperature within the cell was measured by a chromel-alumel thermocouple.

Current-voltage curves were obtained with a Cambridge photographic polarograph (rate of polarization 300 mv min^{-1}, full scale deflection 350 μa). A Wadsworth potentiostat was used for controlled potential work. Large currents were derived from a bank of accumulators or an Eliminac d-c power supply and the charge measured with a hydrazine sulfate coulometer (18). A Metrohm coulometer type ME211 was the source of small constant currents (up to 20 ma with an accuracy of ±0.2%) for coulometric generation of metal ions in solution; it contains a built-in stop-clock. Potentials were measured with a Pye portable or a Cropico type P3 potentiometer.

At the completion of a set of measurements the compartments were removed with gold-tipped tongs and, after cooling, washed on the outside, dried, and weighed. The carbonate on the inside was then dissolved out in dilute HCl and the crucibles dried and reweighed. If oxide was present, it was determined by difference, the CO_2 evolved with HCl being weighed. Silver was dissolved in nitric acid and determined gravimetrically as chloride. Cobalt was determined colorimetrically as the Nitroso-R complex (19). Nickel in solution was determined by cathode ray polarography using a K1000 model polarograph (Southern Instruments Ltd.): the peak height at —0.97v *vs.* a mercury pool was compared for the unknown and several standards at *p*H ~ 8.

Results

Electrolytic reduction.—A bulky black mass of carbon was obtained at a platinum cathode at 550°C upon electrolysis of a compartmented melt. The weight of material insoluble in HCl produced by passing 230 coulombs was 7.1 mg compared with 7.0 mg to be expected for a 4-electron process. Greater charge yielded less carbon than expected, and it was found in these cases to have spread along the salt bridge and reached the anode compartment. Microchemical analysis of an acid-insoluble sample gave 90% C, 1% S, and 9% residual alkali metal salts. X-ray analysis showed this material to be amorphous. Tests for CO, carbide, and free alkali metal as reduction products proved negative.

Electrolysis with a potential difference exceeding 3v yielded some sulfide in addition to carbon (presumably from sulfate impurity).

The quantity of oxide produced at the cathode was not reproducible but was always in excess of that predicted for CO_3^{2-} reduction to C because of some thermal decomposition.

Electrolytic oxidation.—The results of oxidation at 1 cm^2 Pt electrodes are presented in Table I. With uncompartmented cells, a brown film formed on the anode and the CO_2 : O_2 ratio departed from 2 : 1 when a small volume of melt was used.

Current-voltage curve.—The current-voltage curve obtained with a dipping Pt micro-electrode is depicted in Fig. 2; it was not reproducible in detail from —0.5 to —1.45v *vs.* the Ag^+/Ag reference electrode.

Metal ion/metal systems.—Silver.—Silver was anodized under CO_2 at 1 atm pressure, and the current efficiency found to be close to 100% (coulombs passed 9.76, Ag^+ expected 10.9 mg, Ag^+ found 10.7 mg). With melts prepared merely by melting oven-dried salts under CO_2 (3) the current efficiency was poor. Solutions of Ag^+ in the melt were colorless, but decomposed to form black silver metal on cooling. Con-

1.90	8.9	4.2	2.1:1	70.7	1.8
2.90	16.1	8.4	1.9:1	141.5	2.0
3.90	3.11	1.54	2.0:1	80.3	6.0
4.70	3.56	3.14	1.1:1	94.6	6.2

1 and 2 refer to compartmented, 3 and 4 to uncompartmented cells.

centration cells were generated coulometrically, and the measured emf's are presented in the Nernst plot in Fig. 3 where the gradient in the concentration range 4 x 10^{-3} to 4 x $10^{-2}M$ is 0.163v. The reversibility of the Ag^+/Ag electrode was further confirmed by the micropolarization response of one electrode with respect to one unpolarized and its stability as a function of time, *e.g.*, the emf between a Ag/Ag^+ in carbonate electrode and a Ag/Ag^+ in sulfate electrode (see below) was constant to ±3 mv for 8 hr.

A significant impurity in the carbonates is chloride so the effect of added chloride (KCl) on the Ag^+/Ag potential was studied: at low concentrations of Cl^- there was no effect (cf. Fig. 3) but at higher concentrations (~2*M*) the potential became unstable and a white not a black precipitate separated on cooling.

Simple weight loss experiments showed that silver immersed in the carbonate was not corroded by CO_2 alone, but was corroded by O_2 (together with the minimal amount of CO_2 formed thermally) and even more by a 2:1 mixture of CO_2 and O_2.

Cobalt and nickel.—Only with melts prepared as outlined under Experimental could cobalt and nickel be coulometrically oxidized under 1 atm CO_2 to solutions of the bivalent ions, which were blue and red-brown, respectively. On cooling the nickel solutions a green color formed and CO_2 was evolved. The current efficiencies determined were 100 and 98% (Co^{2+} expected for 22.5 coulombs = 6.88 mg; Co^{2+} found = 6.85 mg; Ni^{2+} expected for 12.5 coulombs = 5.33 mg; Ni^{2+} found = 5.2 mg). The results of concentration cell studies appear in Fig. 4 where the line of theoretical slope is drawn through each set of points.

With wet melts (where the samples were not vacuum treated before melting) a black precipitate was obtained on anodizing cobalt and either a green or a black film formed on a nickel anode. When bearing the green film, a nickel electrode had a rest potential of —0.6v and when bearing the black film a rest potential of —0.1v (*vs.* 0.01m Ag^+/Ag reference electrode). The black film only formed at high current densities.

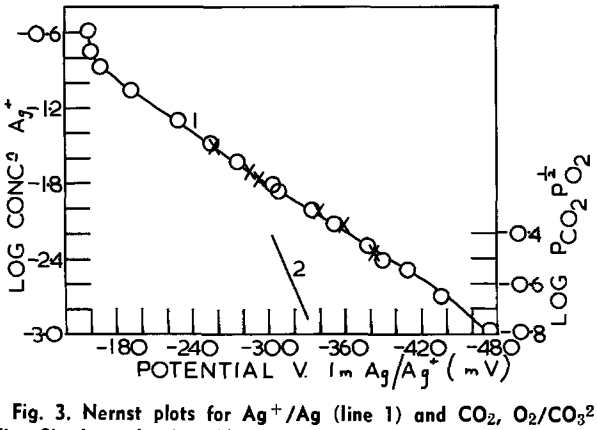

Fig. 3. Nernst plots for Ag^+/Ag (line 1) and CO_2, O_2/CO_3^{2-} (line 2) electrodes in $LiNaCO_3$ at 550°. O measurements without added chloride; X measurements with 0.354M chloride.

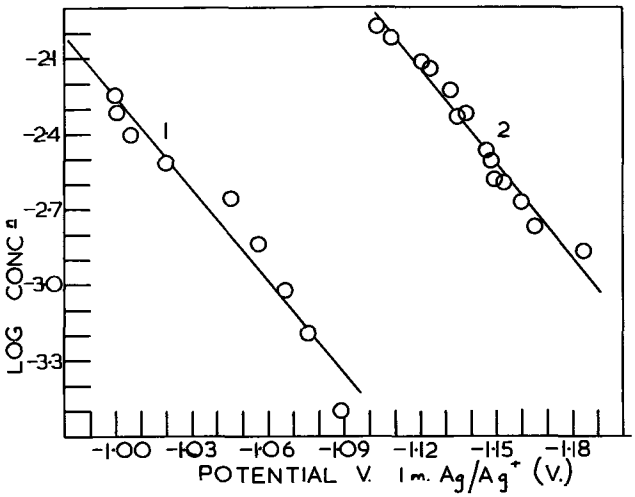

Fig. 4. Nernst plots for Ni^{2+}/Ni electrode at 570° (line 1) and Co^{2+}/Co electrode at 540° (line 2) in $LiNaCO_3$.

Other metals.—Iron reduced the solvent and rhodium and platinum proved to be noble. Copper became covered with oxide and colored the melt green on anodization; it had a rest potential of ~ —0.45v (*vs.* 0.01*M* Ag^+/Ag) after this treatment.

Silver sulfate electrode.—Concentration cell measurements on the system Ag/Ag^+ in Li_2CO_3-Na_2CO_3// Ag^+ in $(Li,Na,K)_2SO_4/Ag$ are plotted in Fig. 5 where the line has the theoretical Nernst slope. All the points are within 15 mv of the line, but the stability of each individual sulfate electrode was ±1 mv. The silver sulfate electrode, unlike the silver carbonate electrode, behaved ideally under nitrogen or air.

CO_2, O_2/CO_3^{2-} *electrode.*—A silver sulfate electrode was calibrated *vs.* an Ag^+ in Li_2CO_3-Na_2CO_3 electrode and then used to study the potential of the CO_2, O_2/CO_3^{2-} electrode as a function of gas composition. The Nernst equation for the system at 550° is

$$E = E^{0\prime} + 0.0815 \log_{10} p_{CO_2} p_{O_2}^{1/2}$$

and Fig. 6 shows a plot of E *vs.* $\log_{10} p_{CO_2} p_{O_2}^{1/2}$ where the line has the theoretical slope. The range of oxygen partial pressure, p_{O_2}, studied was 0.056 to 0.775, above which the electrode response was sluggish and a

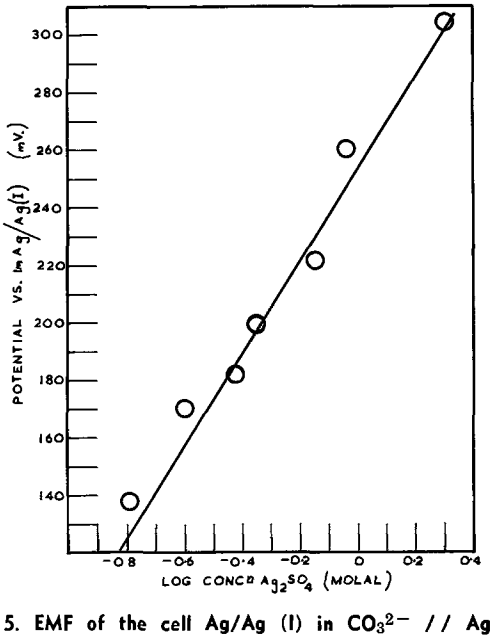

Fig. 5. EMF of the cell Ag/Ag (I) in CO_3^{2-} // Ag (I) in SO_4^{2-}/Ag as a function of Ag_2SO_4 concentration; temperature, 540°C.

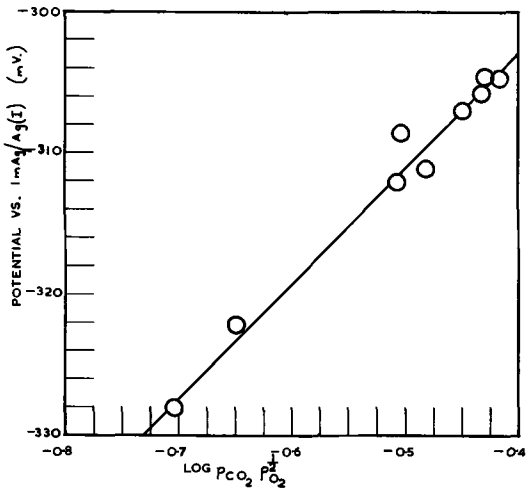

Fig. 6. Nernst plot for CO_2, O_2/CO_3^{2-} electrode in $LiNaCO_3$ at 550°.

brown film formed on the Pt indicator electrode. The emf passed through a maximum at $p_{O_2} \simeq 1/3$, as the Nernst equation predicts.

Discussion

Solvent electrode processes.—Electrolytic reduction of the melt at 550°C undoubtedly yields carbon and oxide but the experimental observations do not distinguish between the processes

$$(a)\quad CO_3^{2-} + 4e^- \rightarrow C + 3\,O^{2-}$$

$$(b)\quad CO_3^{2-} \rightleftharpoons CO_2 + O^{2-}$$
$$CO_2 + 4e^- \rightarrow C + 2\,O^{2-}$$

$$(c)\quad CO_3^{2-} + 2e^- \rightarrow CO + 2\,O^{2-}$$
$$2CO \rightarrow C + CO_2$$
$$CO_2 + 4e^- \rightarrow C + 2\,O^{2-}$$

or

$$(d)\quad CO_3^{2-} \rightleftharpoons CO_2 + O^{2-}$$
$$CO_2 + 2e^- \rightarrow CO + O^{2-}$$
$$2CO \rightarrow C + CO_2$$
$$CO_2 + 4e^- \rightarrow C + 2\,O^{2-}$$

although the yield of carbon rules out processes (*c*) and (*d*) without the final 4-electron step. Thermodynamic calculations (20) for pure Li_2CO_3, the more readily reduced component of the mixture, indicate that at 550°C the reduction of CO_2 to C should occur at —1.01v (*vs.* $CO_2,O_2/CO_3^{2-}$) and the reduction of CO_3^{2-} to C should occur at —1.65v. The formation of CO is not favored, by either route, below 700°. The current-voltage curve could be ascribed to the reduction of dissolved CO_2 followed by direct reduction of carbonate, but it is not possible to exclude residual moisture and heavy metals as the source(s) of the residual current up to —1.45v. Sulfate impurity is clearly not reduced at these potentials.

Electrolytic oxidation of the pure melt yielded CO_2 and O_2 according to the process

$$CO_3^{2-} - 2e^- \rightarrow CO_2 + \tfrac{1}{2}\,O_2$$

The oxide concentration at the anode of a small uncompartmented cell would be expected to be high so that significant contributions from the process

$$O^{2-} - 2e^- \rightarrow \tfrac{1}{2}\,O_2$$

are not then unexpected. The brown film formation and the yield of 1 mole of CO_2 per 6**F** in the uncompartmented cell electrolyses may be reconciled with the oxidation of Pt to Li_2PtO_3 (12), *e.g.*

$$Pt + CO_3^{2-} - 6e^- \rightarrow Pt^{4+} + CO_2 + \tfrac{1}{2}\,O_2$$

$$Pt^{4+} + 2Li^+ + 3\,O^{2-} \rightarrow Li_2PtO_3$$

These findings are supported by the work of Arkhipov, Trunov, and Stepanov (5).

Table II. Formal potentials in Li_2CO_3-Na_2CO_3

Couple	Temperature, °C	$E^{0\prime}$ *M*, v	E^0 M, v	$E^{0\prime}$ mole fraction, v	E (9)
Co^{2+}/Co	540	−0.946(±0.008)	−0.921	−1.036	−0.94
Ni^{2+}/Ni	570	−0.862(±0.009)	−0.835	−0.955	−0.89
$CO_2,O_2/CO_3^{2-}$	550	−0.270(±0.002)	−0.220	−0.451	−0.55
Ag^+/Ag	540-570	0	0	0	0
Ag^+ in SO_4^{2-}/Ag	540	+0.253	+0.250	+0.274	

EMF series.—This is very limited. Table II shows the formal potentials of the various electrodes on three concentration scales. The densities of carbonate and sulfate solvents were taken as 2.029 (21) and 2.13 ml^{-1} (22) respectively. The column E (9) refers to the calculated potentials of the pure salts at 600°C (9) and shows reasonable agreement with $E^{0\prime}$ mole fraction in Li_2CO_3-Na_2CO_3. The corrosion of Ag, Ni, and Co reported by Janz and co-workers (9, 23) using a ternary alkali carbonate mixture above 600°C, was not apparent in this solvent at 550°C. This corrosion may be the result of insufficient drying of melts since films, and a precipitate were formed by Co and Ni in wet Li_2CO_3-Na_2CO_3 or it may merely reflect the instability of Ag_2CO_3 solutions at 600° (see later). Ag_2CO_3 itself and Ag_2O both decompose to the metal below 500°C. The details of film and precipitate formation constitute a separate study: it suffices to suggest that CoO,NiO, and "Ni_2O_3" are probably the entities concerned.

The Nernst plot for Ag^+ in carbonate shows curvature at both high and low concentrations. At high concentrations we would expect CO_3^{2-} discharge and at low concentrations, corrosion to Ag^+ by impurities.

Indeed, the formal potential of the $CO_2,O_2/CO_3^{2-}$ electrode is negative with respect to that of Ag^+ in carbonate, and this implies that the reaction

$$2Ag^+ + CO_3^{2-} \rightarrow 2Ag + CO_2 + \tfrac{1}{2}\,O_2$$

would be spontaneous when all the components were at unit activity and the reverse process would proceed at 550°C until an activity of Ag^+ equal to $1.4 \times 10^{-2} M$ was reached. This corresponds to the point at which lines 1 and 2 of Fig. 3 cross. In fact a maximum concentration of Ag^+ of $1.3 \times 10^{-1} M$ can be generated, from which we deduce an activity coefficient of 0.11 for this particular solution. Further passage of current through a silver anode in a melt $1.3 \times 10^{-1} M$ in Ag^+ only led to evolution of CO_2 and O_2. Concentrations corresponding to the upper curved portion of Fig. 3 would include Ag metal corroded from the electrode.

The experiments with added chloride were not definitive beyond indicating a reaction at high Cl^- concentrations.

Corrosion of Ag in fuel cells.—When silver metal is made the working cathode of a fuel cell, CO_2 and O_2 are passed over it and will naturally corrode it until the saturation concentration of Ag^+ is obtained. If the Ag^+ is removed from the cathode by diffusion or cooling, in which case Ag is precipitated, further metal will be corroded from the cathode. The greater corrosive nature of mixtures of CO_2 and O_2 over O_2 alone is consistent with the order of electrode potentials (5) and is particularly important in this context.

The mixture of spent fuel gases containing H_2O with the cathode oxidant is also liable to accelerate the corrosion.

Galvanostalametry: A Technique for Chemical Analysis

John L. Sligh and Abner Brenner

National Bureau of Standards, Washington, D. C.

ABSTRACT

A method utilizing a novel technique to designate the end-point of a diffusion controlled electro-reducible or -oxidizable reaction has shown promising analytical capability. The apparatus consists of a J-shaped, evacuated glass tube in which a column of electrolyte is suspended under tensile stress in the longer limb. One electrode is sealed into the top of the J and the other into the short limb. The formation of a minute amount of gas at the upper electrode by electrolytic discharge of hydrogen or oxygen causes the column of electrolyte to suddenly drop. It has been found that, in the constant-current electrolysis of a suitable supporting electrolyte containing an electroreactive ion, the transition time required for the column to drop is a function of the concentration of the ion. The use of this method as an analytical tool and its relationship to chronopotentiometry are discussed.

A survey of the principles and applications of galvanostalametry was the subject of a previously published paper by the present authors (1). Briefly, the method involves the dropping of a vertical column of electrolyte which is metastably suspended in an evacuated glass tube under the tensile stress of its own weight. Electrolytic production of a gas (usually hydrogen or oxygen) at an indicator electrode which is sealed into the top of the column causes the column of electrolyte to suddenly collapse. The fall of the column indicates the final stage in an electrolytic reaction, similar to the point of inflection in a plot of electrode potential *vs.* time in chronopotentiometry.

The suspension of the electrolyte in the evacuated tube results from the adhesion of the liquid to the top of the glass tube and the cohesion of the liquid. It is well known that liquids possess considerable tensile strength. Briggs (2) showed that only a monomolecular layer of hydrogen or oxygen on the indicator electrode sufficed to disturb the metastable equilibrium and cause the column to drop. This characteristic makes the method a very sensitive means for the detection of the initial generation of gas at an electrode. The fall of the column immediately breaks the electrical circuit, and this feature can be used to record the period of current passage automatically.

The analytical application of galvanostalametry depends on the relation that the transition time or the period before the column drops (with passage of a constant current) varies with the concentration of an electrochemically active substance (except for the constituents of water). The fall of the column indicates that the concentration of the oxidizable or reducible ion at the electrode solution-interface has been depleted and a new reaction, the discharge of hydrogen or oxygen, has begun. The measured time must be corrected by a blank, which is the period before the column drops in the presence of a supporting electrolyte, that is one which involves only the decomposition of water on electrolysis. For most of the experiments, the blank amounted to about 0.3 sec. This subject is discussed in more detail in the text.

Apparatus

The apparatus described in the previous publication (1) has been simplified and made smaller for the analytical applications. An attractive feature of the galvanostalametric procedure is the relative economy of the experimental equipment compared to that of other automatic electroanalytical methods.

The analytical cell, shown in Fig. 1, was constructed in two pieces. The main part consisted of a vertical glass tube, the lower end of which terminated in an elbow which enlarged into a spherical reservoir of about 30 ml capacity. The latter was equipped with a tubular opening which was used for introducing the electrolyte and the secondary electrode, as well as for evacuating the vessel. The upper end of the vertical tube carried an "O" ring, connector for connecting to the top part of the cell. This part was a small vertical

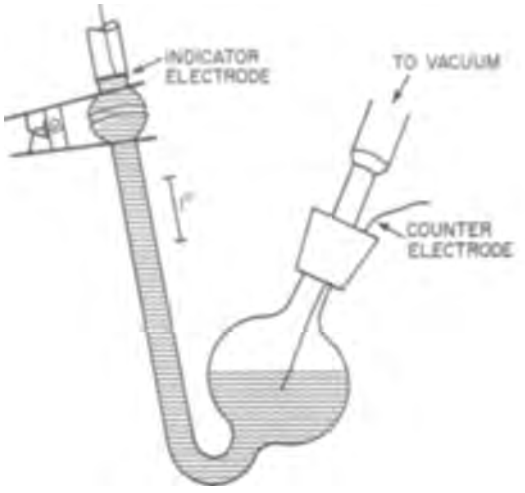

Fig. 1. Diagram of vessel used for analytical applications of galvanostalametry. Length of column of liquid, 25 cm; diameter of column, 7mm; volume of bulb, 30 ml.

extension in which was sealed a platinum disk, 0.5 cm in diameter, serving as indicator electrode. The extension was readily attached to the main section with a clamp to make a vacuum-tight vessel. The demountable feature of the extension, holding the indicator electrode, was a considerable improvement over the earlier apparatus, as it permitted easy removal for cleaning and inspection. The vessel was evacuated by an ordinary vacuum pump after introducing the electrolyte. The degree of evacuation was not critical as it was limited by the vapor pressure of the liquid. A good aspirator can be used.

The period of electrolysis, which was terminated by the dropping of the columns, could be timed with an ordinary stop watch. Since most of the determinations were of the order of only several seconds, timing was done more accurately with an electric stop clock with the smallest division 0.01 sec, thus permitting estimation to a few milliseconds. The dropping of the column caused almost a complete cessation of current flow and at the same time a large voltage build-up across the electrolytic cell. The timer could be stopped automatically by a relay which was triggered either by the increase of voltage across the cell or by the decrease of voltage across a resistor.

An investigation with an oscillograph showed that the time interval between the incipient drop of the column and the cessation of current flow was about 0.3 sec. The stoppage of current was not instantaneous because a diminishing current continued to flow between the falling liquid and the electrodes via the film of liquid draining down the walls of the tube. This period of time could constitute a serious loss of precision in experiments which involved a transition time of only a few seconds. The precision of determining the end-point was considerably improved by using an electronic relay that operated on a change of about 100 mv, which is about 1% of the voltage change that occurred across the cell at the end-point. This increased the precision in detecting the initiation of the dropping of the column to a few hundredths of a second.

Details of Experimental Manipulation

About 20 ml of the electrolyte to be examined was introduced into the cell through the tubular opening in the reservoir by a means of a 20 ml graduated syringe. A length of vacuum rubber tubing fitted with a screw clamp was attached to the tubulation, and the cell was evacuated. The screw clamp was adjusted continuously to avoid violent boiling of the solution. On completion of the evacuation, the screw clamp was tightened. At this point the levels of electrolyte in the column and the reservoir were equal. The cell was next inverted slowly, permitting the solution to flow from the reservoir into the evacuated tube. This must be done carefully as a sudden impact of the liquid would produce minute bubbles which would rise very slowly. After residual gas bubbles had floated upward and were trapped in the reservoir, the vessel was righted; the column of liquid then remained suspended in the vertical tube. Electrical connections were made to the electrodes, a constant current was passed, and the period of its duration measured before the fall of the column. A delay of 2 min was interposed between successive measurements, to allow the electrode to return to a reproducible condition. Consecutive measurements generally checked within 1 or 2%.

In most of the experiments a constant current of 2.5 ma was used with the platinum electrode (area 0.2 cm^2). The current from a 135v battery passed through a resistance in series with the cell. The resistance served to keep the current approximately constant despite the development of polarization in the cell.

Transition Time Involved in the Decomposition of Water

The analytical application of galvanostalametry depends on the time (transition time) required to deplete the concentration of an electrochemically active ion (with a constant current) at the electrode solution-interface. The dropping of the column indicates this time. As already noted, the collapse of the column results from the discharge of hydrogen or oxygen, which form a monomolecular film of gas on the electrode. Thus the analytical determination also involves a transition time for the electrolysis of water and the relation of this transition time to that required for the discharge of the other ions must be made clear.

The first experiments with the dropping of the column were done by Briggs (2) who discharged a condenser through electrodes. His results indicated that the dropping of the column, in the absence of reactive ions other than hydrogen and oxygen, was dependent on the passage of a certain minimum number of coulombs through the system, which we shall refer to as the critical charge. He did not determine the time of current flow, but since the discharge of a condenser was used the time was short.

The present experiments were made to determine if the blank transition time in water (0.5M H_2SO_4) for the formation of a monolayer of hydrogen, followed a relationship similar to that of other electroactive ions. Since the current from a condenser is not constant, the current was obtained from a square wave generator in pulses ranging from a millisecond to about 1 sec. Because the charges obtainable were small, an indicator electrode of small area was chosen so that the current density on it would be of sufficient intensity to cause the column to drop. The indicator electrode was made by sealing a platinum wire 0.4 mm in diameter in glass tubing and then exposing the cross section of the wire.

In these experiments, the procedure for determining the transition time consisted in making a series of determinations using square wave pulses. In each successive experiment the amplitude of the pulse, having a fixed pulse width, was increased until one was found that caused the column to fall.

The results of the measurements, which are given in Table I, confirm Briggs' view that, to a first approxi-

Table I. Cathodic pulse current data showing the approximate constancy of the critical charge in 0.5M sulfuric acid.

0.1	46	4.6
0.5	12.5	6.25
1.0	7.25	7.25
5.0	2.1	10.5
10.0	1.1	11

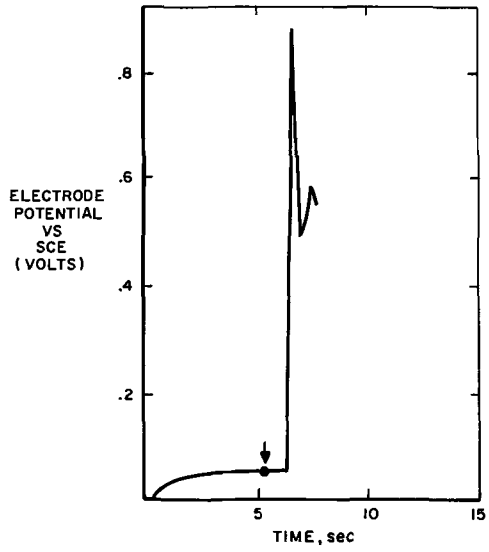

Fig. 2. Relation between voltage and time in the dropping of a column by anodic oxidation of 0.05M iodide ion in 0.5M sulfuric acid solution. The trace was made with an oscillograph. The arrow indicates the position of the point of inflection of the curve that would be used for chronopotentiometry.

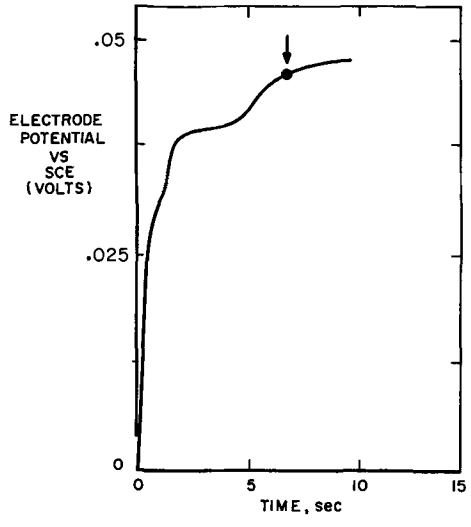

Fig. 3. Amplified portion of the curve of Fig. 2 in the region of the point of inflection. Trace obtained with an oscillograph.

mation, a constant amount of charge is required to drop the column. The variation in the critical charge was only about threefold for a more than a 300-fold variation in the duration of the pulse. Thus, to a first approximation, $Q_c = It_a$ = constant, where Q_c is the critical charge, I is the current, and t_a is the transition time for water. The transition time t_a is, thus, inversely proportional to the current

$$t_a = \frac{Q_c}{I}$$

This point of inflection was found to precede the dropping of the column in galvanostalametry. It was observed with a recording oscillograph that has a full-scale response of less than 1 msec. A reproduction of an oscillograph trace is shown in Fig. 2. The point of inflection indicated by the arrow was too small to be clearly seen on the same trace as that including the galvanostalametry end-point. To make the inflection point clear, an amplification of the lower part of Fig. 2 is shown in Fig. 3.

This observation shows that the galvanostalametry transition time includes a small additional time (for the critical charging of electrodes) beyond the point of inflection. However, this does not cause a difficulty in analytical determinations, since a calibration can be made with solutions of known concentration.

Galvanostalametry Determinations of Concentration

For determination of the concentration of an ion by galvanostalametry, a calibration curve was made using a few solutions of known concentration. The plot of the square root of transition time *vs.* concentration was linear. The reproducibility of determinations was usually of the order of 1.5% under the best conditions. With some ions, difficulties were occasionally encountered owing to the failure of the electrode to function. This will be discussed in the relevant places in the following treatment of analytical applications. Both homogeneous and heterogeneous electrode reactions were investigated.

The transition time for the discharge of hydrogen or oxygen, therefore, differs from the transition time t_b for the discharge of ions which are under diffusion control as given by the Sand (3) equation

$$t_b = K\left(\frac{C}{I}\right)^2$$

where K is a constant, C is concentration (mole/cm^3), and I is the constant electrolysis current (amp).

This latter relation limits the applicability of galvanostalametry for short transition periods, such as milliseconds. This is because as the current I increases, the transition time t_b for the discharge of an ion decreases rapidly (inversely as the square of the current), whereas the transition time, t_a, for the decomposition of water decreases more slowly. Thus, in the range of milliseconds, the value of t_b becomes of the same order as t_a and there is a loss of accuracy in determining t_b.

The effect of a short transition time on a determination is shown by the data in Table II. In these experiments the current used in each experiment was increased as the iodide concentration was increased, so as to keep the transition time in each experiment about 1 msec. The critical charge (blank correction in the absence of iodide ion) was relatively large, 7.5 x 10^{-6} coulombs. The quantity of charge used for discharging iodide ion is considered to be the difference between the blank and the value given in column 2. It ranged from about 1 x 10^{-6} coulombs for the 0.01M iodide solution to about 5 x 10^{-6} coulombs for the 0.10M solution, which values are smaller than the blank correction. These data show that galvanostalametry would not be very accurate for small transition times because of the large blank correction.

Relation of the End-Points of Galvanostalametry and Chronopotentiometry

The end-point in chronopotentiometry is the point of inflection of a curve of electrode potential *vs.* time. The change in voltage at the end-point varies with the system, but it is not large, ordinarily of the order of several tenths of a volt. The end-point of the reaction is best obtained from a graph.

Table II. Effect of sodium iodide concentration on the critical charge for a fixed transition time of 1 msec in 0.5M sulfuric acid

Molar concentration	Critical charge, coulombs × 10^{-6}	Coulombs* for oxidation of iodide ion
0.00	7.5	—
0.01	8.6	1.1
0.04	10.4	2.9
0.1	12.0	4.5

* Critical charge with iodide present minus critical charge at zero concentration.

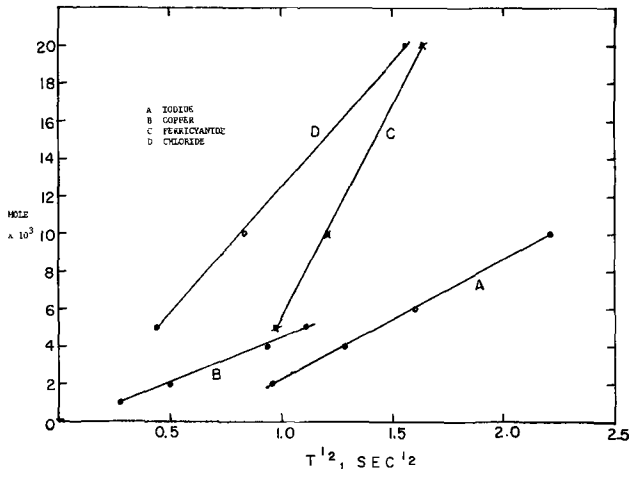

Fig. 4. Relation between concentration and time in the dropping of a column in galvanostalametry experiments.

Copper ion in copper sulfate solution.—A copper plated platinum indicator electrode was used for determining the copper ion concentration in copper sulfate solutions acidified with sulfuric acid. A platinum indicator electrode was not satisfactory, because the copper had to be dissolved anodically before each determination, and this procedure altered the surface of the platinum sufficiently to influence the transition times for subsequent copper determinations. The data obtained with several different concentrations of cupric ion are plotted in Fig. 4. The reproducibility was about 1.5%.

Cadmium.—Transition times for the reduction of cadmium ion were well defined at a platinum indicator electrode employing cadmium chloride in a supporting electrolyte of 1.0M sodium sulfate at pH 5. Measurements made at a constant current of 2.5 ma (current density of 12 ma/cm^2) are shown in Table III. The cadmium deposit was anodically removed from the platinum electrode between each determination, as subsequent determinations on the cadmium coated electrode yielded larger transition times than those obtained on platinum. Presumably, this difference was caused by an oxide film on the cadmium deposit. A transition time was not obtained in a solution 0.5M in sulfuric acid because of the greater ease of hydrogen discharge.

Oxidation of iodide ion.—The oxidation of iodide ion in a supporting electrolyte of 0.5M sulfuric acid yielded the most reproducible results of any of the determinations. A reproducibility greater than 1.5% was obtained with a platinum electrode and the results were not influenced by the care of the electrode. Typical results are given in Fig. 4.

Chloride.—The chloride determination was studied in a solution of cadmium chloride which was 0.5M in sulfuric acid. A platinum indicator electrode was used as anode. The dependency of the transition time on the chloride ion concentration is shown by data in Fig. 4.

Table III. Transition times for various ions as a function of concentration at a constant current of 2.5 ma

* High values observed for dichromate and permanganate ions indicate the dependence of galvanostalametry on equivalent concentration.

The ability to determine chloride ion by galvanostalametry was unexpected, because on the one hand the discharge of oxygen should occur before that of chloride, and on the other, discharge of chlorine in the gaseous state should drop the column.

Bromide.—The galvanostalametry determination of bromide ion was made with sodium bromide in a supporting electrolyte of 0.5M sulfuric acid. The transition time for the oxidation of the bromide ion was well defined, but successive measurements yielded shorter transition times than the initial value. Reproducible values of the transition time having the same value as the initial one were obtained by allowing the platinum electrode to stand idle for at least 2 hr between successive determinations. A more convenient method of normalizing the electrode was to apply an alternating current of 200 Hz at a current density of 5 amp/dm^2 for about 30 sec to the electrode after a determination. This permitted successive determination to be made without delay. Data obtained for a few bromide solutions of various concentrations are shown in Table III. A plot of these results show a marked deviation from linearity, probably due to the expedient employed to normalize the electrode.

Permanganate.—The experiments with permanganate ion were conducted with a solution of potassium permanganate in a supporting electrolyte of 0.5M sulfuric acid with a platinum electrode used as cathode. The transition times were about the same as those for solutions of other ions of the same normality.

The data in Table III show that the transition time varied with concentration in a regular manner. The use of this technique may be of interest in filling a gap in electrochemical methods, inasmuch as polarography is not suitable for determining permanganate ion (4).

Dichromate.—Dichromate was determined by cathodic reduction in a supporting electrolyte of 0.5 sulfuric acid. The determination of the transition time was attended with some difficulty because the result was dependent on the condition of the platinum electrode. For example, no indication of a transition time was observed if the electrode was cleaned in concentrated nitric acid. However, if it was treated anodically in the test solution prior to the determination, cathodic transition times were obtained similar to those observed with permanganate ion. Furthermore, the electrode continued to be serviceable for an entire series of determinations without additional anodic treatment. Similar to the results for the permanganate ion, the transition time was of the same order of magnitude as that obtained with simpler ions of the same normality.

Ferricyanide ion.—The determination of this ion also depended on the condition of the platinum indicator cathode, and the phenomena were similar to that observed with the dichromate ion. No transition time was observable with ferricyanide in a supporting electrolyte of 0.5M sulfuric acid until the electrode had once been made anodic.

Oxalate.—The determination of oxalate ion was also complicated by the necessity for specially treating the platinum anode. In contrast to the two preceding cases, no transition time was observed if the electrode was first made anodic. Satisfactory results were obtained after treating the anode with nitric acid. The data showing the variation of transition time with concentration are given in Table III. The absence of a transition time with an oxidized platinum electrode was previously reported by Lingane (5).

Discussion

The range of concentrations covered in our investigation was 10^{-3} to 10^{-2} equivalents per liter for the most part, since the prime objective was the applicability of the technique to the determination of a

variety of ions in moderately dilute solution. However, concentrations up to 1*N* were easily measured with reproducible transition times. For the best precision, the transition times should be held to less than 10 sec. Concentrations smaller than $10^{-4}N$ were difficult to measure with any precision.

The graphs in Fig. 4 show that generally the square root of the transition time is a linear function of concentration. However, the straight lines appear to be directed toward the origin in only two cases, namely, copper and cadmium. Therefore, the relation between the transition time, t, and the concentration, C, does not, in general, follow Sand's equation for linear diffusion

$$t_b = K\left(\frac{C}{I}\right)^2$$

Chronopotentiometry has been shown to follow this law closely (6, 7).

The following explanation is offered for the failure of all of the plots of C *vs.* $t^{1/2}$ to pass through the origin in the galvanostalametry experiments (see Table III and Fig. 4). In all these experiments it is necessary to subtract from the experimentally determined time for dropping of the column a blank or correction term. The latter represents the time required for the column to fall with a solution which contains the supporting electrolyte (for example, sulfuric acid) in the absence of the electrochemically active ion (which is to be determined). This correction or blank is valid in the experiments in which a metal is deposited at the cathode, because the solution at the electrode interface is almost completely depleted of the depositing ions and contains only the supporting electrolyte. This is the probable reason that the plots of C *vs.* $t^{1/2}$ pass through the origin for the determination of cadmium and copper ions. However, in the determination of anions, the solution at the interface at the moment the column is dropped contains a high concentration of the soluble oxidation product, for example, bromine or ferrocyanide ion. The correction or blank for an electrode in these media may be considerably larger than that for a solution in their absence containing only the supporting electrolyte. This discrepancy appears in the plots for the anions (except chloride ion) as an apparent transition time for zero concentration (where the extension of the straight line plot crosses the x-axis).

The slopes of the plots of C *vs.* $t^{1/2}$ approximately agree with Sand's equation

$$\text{Slope} = \frac{C}{t^{1/2}} = \frac{2i}{\pi^{1/2}n\mathbf{F}AD^{1/2}}$$

In the experiment for cadmium in Table III, the experimental value of the slope is 0.0125. The value calculated from the above equation with $n = 2$; $\mathbf{F} = 10^5$ coulombs; $A = 0.2$ cm^2, and $D = 10^{-5}$ is 0.024 which is of the right order of magnitude. The slopes of the plots for permanganate and dichromate ion (Fig. 4) are both approximately 0.0045. These are also of the right order of magnitude, since the slopes should be about 1/3 that of the line for cadmium, since $n = 5$ and 6 for these ions.

The difficulty encountered with reproducibly conditioning the indicator electrode requires more study. This difficulty applies also to chronopotentiometry. The sensitivity of the transition time to the surface condition of the electrode indicates that the galvanostalametry technique might be used to study and evaluate the catalytic nature of metal surfaces.

The galvanostalametric technique has several practicable advantages for the determination of a single ion. First of all, simple equipment is required, and no reference electrode or expensive recording instrument for measurement of electrode potential are needed. The end-point of the determination is both visual and dramatic and the determination itself can be made very rapidly. As a demonstration, an electric timer, actuated by the electronic cutoff mentioned earlier, was used to determine the concentration of copper ion in a copper sulfate solution. By using a large current, the transition time was reduced to less than a second. The dial of the timer was directly marked in units of concentration. On pushing an electrical switch, the dial of the timer spun and stopped almost in the twinkling of an eye, giving the concentration. We have dubbed this technique "Push-button analysis" and believe that it should find application in routine work.

The main drawback to galvanostalametry is the restriction on the composition of the solution to be analyzed. For example, if several electroreducible ions were present, such as cadmium, copper, and silver cations, a composite result for all three would be obtained at the cathode. In such a situation, chronopotentiometry would permit the determination of the most readily discharged metal (silver) by virtue of the point of inflection of the voltage-time curve. However, the following points of inflection would represent simultaneous discharge of two or more cations and the computation of each is sufficiently complicated to be difficult if not infeasible.

The Role of Hydrogen Peroxide in Oxygen Reduction at Platinum in H_2SO_4 Solution

A. Damjanovic, M. A. Genshaw, and J. O'M. Bockris

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The rotating disk electrode with a concentric ring is used to analyze the role of H_2O_2 in the reduction of O_2 to H_2O in acid solutions. No H_2O_2 is formed as an intermediate in the reaction path of oxygen reduction to water. Only when the residual impurities from the not sufficiently purified solutions are adsorbed at the electrode does a parallel reaction path appear in which H_2O_2 is formed as an intermediate that does not reduce further to H_2O with any significant rate. The mechanism of O_2 reduction to H_2O involves a first charge transfer step as rate-controlling under Temkin conditions of adsorption.

In the study of the mechanism of oxygen reduction to water, it is desirable to establish what part hydrogen peroxide is playing in the over-all reaction. In electroreduction of O_2 at Pt electrodes the rotating disk electrode with a concentric ring (1-4) was successfully used to examine whether H_2O_2 is formed or not (5-11). However, it was not possible to distinguish if H_2O_2 is formed as an intermediate in an over-all reaction path or if it is produced in a parallel reaction.

The method of the rotating disk electrode with a ring has recently been extended to enable a diagnostic plot to be made which permits a clear distinction between reaction intermediates and the products in a parallel reaction path (12). This diagnostic plot is obtained from the equation

$$\frac{I_d}{I_r} = \frac{x+1}{N} + \frac{x+2}{N} \cdot \frac{1.61\, k_3 \nu^{1/6}}{D^{2/3}\omega^{1/2}} \qquad [1]$$

In this equation, I_d is the current at the disk electrode, I_r is the current at the ring electrode, and x is the ratio of the current at the disk electrode due to the reaction which does not result in the formation of intermediates to the current at the same electrode due to the formation of intermediates, N is the geometric factor for the electrode assembly which can readily be obtained (2-4), k_3 is the rate constant for the further reaction of intermediate at the disk electrode, ν is the kinematic viscosity, D is the diffusion coefficient of intermediates, and ω is the angular velocity. The plot of I_d/I_r *vs.* $\omega^{-1/2}$ enables the quantities, x and k_3, to be obtained, and hence, to distinguish between reaction intermediates and products of a parallel reaction.

This method, using the rotating disk electrode with a ring, together with the usual kinetic measurements, is used here to analyze the mechanism of oxygen reduction at platinum electrodes in acid solutions with a particular emphasis on establishing what part H_2O_2 is playing in the over-all electrode reaction.

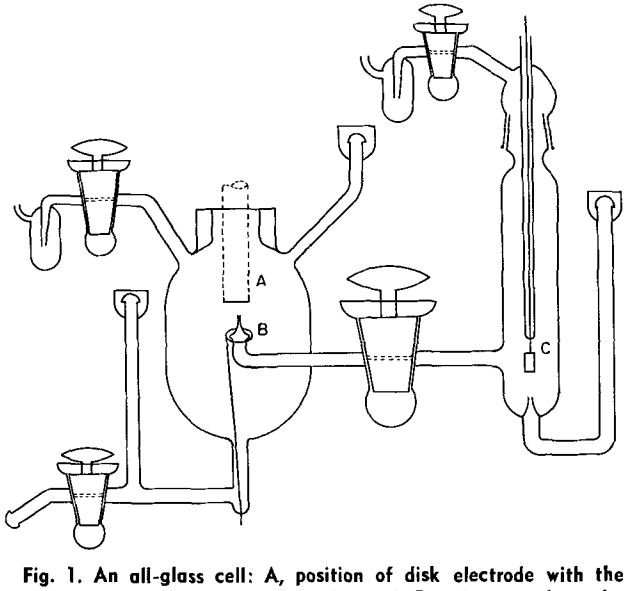

Fig. 1. An all-glass cell: A, position of disk electrode with the concentric ring; B, counter electrode; and C, reference electrode.

Experimental

The rotating disk apparatus is a modified version of the design used by Yeager at Western Reserve University. The electrode consists of a platinum cylinder which is press fit into Teflon. In the present experiments, the area of the disk electrode is 0.178 cm^2. The factor N is 0.38, as calculated from the dimensions of disk and ring electrodes (13) and confirmed by an experiment with a redox reaction ($Fe^{+++} \rightarrow Fe^{++}$).

The rate of rotation of the electrode assembly was determined by comparing a signal produced by a coil placed near a magnet attached to the shaft of the disk electrode with that of a standard frequency produced by an audio oscillator.

The all-glass cell is shown in Fig. 1. It consists of a spherical main compartment which has a water seal at the top to match the mating part on the shaft bearings assembly. Gas inlets are provided above and below the solution level. The inlet above the solution level permits the maintaining of a slight overpressure of oxygen without stirring the solution using a gas bubbler as an outlet. The reference electrode is a hydrogen electrode located in a compartment isolated by a closed stopcock from the main compartment.

A thin capillary from the reference electrode extends upward toward the center of the disk electrode. The counter electrode is a platinum disk which surrounds the Luggin capillary and is placed parallel to the rotating disk electrode. This shape and the position of the counter electrode were chosen to give as uniform a current density as possible.

For the electrochemical purification of the solution a separate vessel, illustrated in Fig. 2, was attached to the cell. It consisted of a tube packed with a platinized platinum gauze as one electrode and a small platinum wire as a counter electrode. An additional small compartment was attached to this tube to hold a calomel reference electrode. A nitrogen gas pump was used to circulate the solution through the purification vessel and the main cell.

The cell, purification vessel, and gas trains were cleaned thoroughly before use. Between experiments the cell was soaked in a mixture of HNO_3 and H_2SO_4. The purification trains for oxygen and nitrogen were often regenerated.

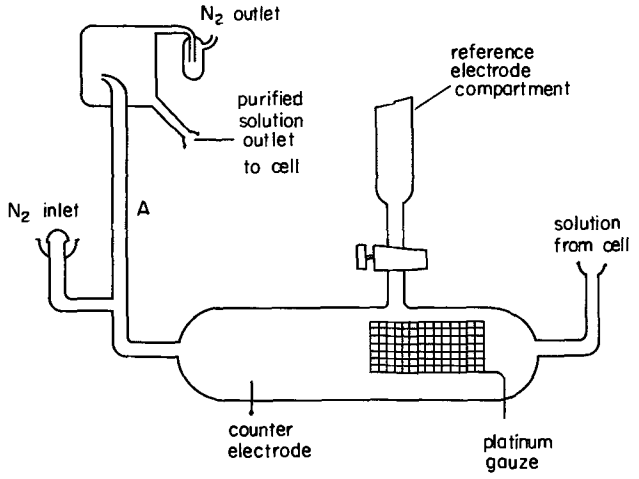

Fig. 2. Cell for the electrochemical purification of solution. This is an attachment to the main cell.

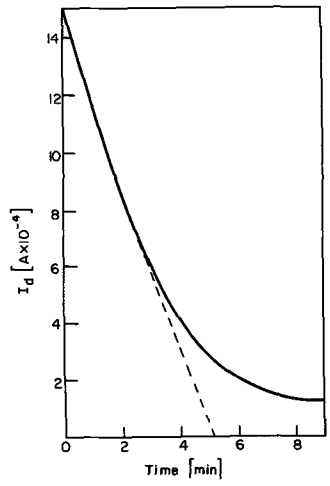

Fig. 3. Time dependence of current at the disk electrode in "insufficiently" purified solutions. Potential of the disk is 0.40v. $\omega = 120\ \pi\ \text{sec}^{-1}$.

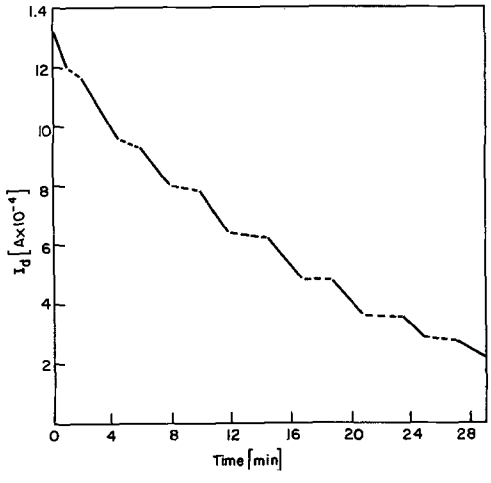

Fig. 4. Time dependence of current at the disk electrode with interrupted rotation. Solid line, $\omega = 120\ \pi\ \text{sec}^{-1}$; dotted line, $\omega = 0\ \text{sec}^{-1}$. Potential of the disk electrode is 0.60v.

The disk electrode with the ring was mechanically polished using 0.3 μ Gamel as a final polishing medium. The ring electrode was then lightly platinized. Both electrodes were thoroughly washed before experiments with sulfuric acid and conductivity water. The electrode pretreatment consists of potentiostating the disk electrode first at 1.4v for about 1 min and then at 0.0v for another minute.

Sulfuric acid solutions (0.1*N*) were prepared from Baker Analyzed reagent H_2SO_4 and conductivity water. Two procedures were used to purify the solution. In one, sulfuric acid was treated (14) by H_2O_2. For the present experiments, this purification procedure was found insufficient, and in the following it is referred to the solution purified by this procedure as "insufficiently purified." In the second procedure, the electrochemical purification was carried out by potentiostating the platinized gauze in the purification vessel at about 300 mv anodic to a hydrogen electrode in the same solution[1] while the solution was circulated through the purification vessel. This circulation was achieved when bubbles of N_2 forced the solution to rise in a tube (A, Fig. 2). Prepurified nitrogen, which was used for this purpose, was further purified by passing through two charcoal traps at the temperature of solid CO_2. After the purification by potentiostating (for 5 to 10 hr), the vessel was separated from the main cell by stopcocks. The solutions purified in this way are referred to here as "pure."

During the electrochemical purification, the solution was saturated by N_2. After the purification, the N_2 is replaced by O_2 at 1 atm.

A Wenking 61R potentiostat was used to control the potential of the disk electrode. The potential of the disk electrode was usually changed in steps of 50 mv in the potential range of 1.0-0.0v. If H_2O_2 is formed at the disk electrode it diffuses to the ring electrode. The ring electrode is kept at 1.4v so that all H_2O_2 diffusing to it is oxidized. At this potential the contribution to the ring current from the O_2 evolution is small. The ring electrode potential was controlled with a low impedance potential divider using the disk electrode as a reference. Keithley 600 A electrometers were used for current measurements.

Results

Electrode behavior in "insufficiently purified" solutions.—At all potentials below about 0.8v, the current at the disk electrode was time dependent and usually reaches a steady value in time of the order of minutes. The fastest change in the current occurs between 0.4 and 0.2v at electrodes which were brought to these potentials after they had been potentiostated anodic to 1v (for a few seconds) and then reduced at 0.0v for about 10 sec. This is illustrated in Fig. 3 for an electrode at 0.4v. The rate of change of current, and the time for an electrode at a given potential to come to a steady state is strongly dependent on the rate of electrode rotation. If the rotation is interrupted, a far smaller decrease in disk current is observed during the time the electrode is stationary, as shown by the dashed line in Fig. 4. The ring current also changes with the potential of the disk electrode and time.

The dependence of the disk current upon potential and time for a given rate of disk rotation is shown in Fig. 5. A maximum in the disk current is observed at about 0.6v, and a minimum at about 0.3v. This maximum may be obtained either by increasing or decreasing disk potential as indicated by arrows in the figure. The maximum, however, tends to decrease with time. The initial "activity" of an electrode can, however, be restored if the electrode were brought to a potential anodic to 1.0v for a short (order of seconds) time, followed by the reduction at 0.0v.

The plots I_d/I_r, where I_d and I_r are the steady-state currents at the disk and ring electrodes, respectively, *vs.* $\omega^{-1/2}$ are given in Fig. 6. A series of lines, one for each electrode potential, are parallel to the $\omega^{-1/2}$ axis.

At low current densities, Tafel behavior is observed with $\partial V/\partial \log i = -0.07$v, and the exchange current density $\log i_o = \overline{10.7} \pm 0.3$.

[1] In the following, all potentials refer to hydrogen electrode potential in the same solution.

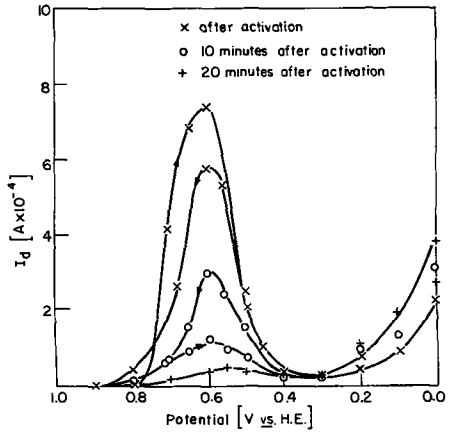

Fig. 5. Current at the disk electrode *vs.* potential in "insufficiently purified" solution. Effect of time on the current is shown. Arrows indicate the direction of measurements.

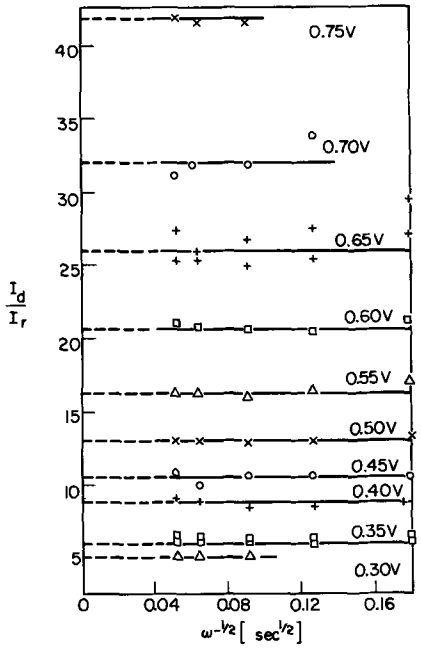

Fig. 6. Dependence of I_d/I_r on $\omega^{-1/2}$. Potentials of the disk electrode are given in the figure.

Electrode behavior in "pure" solutions.—The electrochemical purification by potentiostating at 0.3v proved to have a profound effect on the electrode behavior. The rate of decrease of the disk current with time is one to two orders of magnitude less than that in the "insufficiently purified" solutions. No significant current over the residual one was observed at the ring electrode for any potential of the disk electrode except those cathodic to about 0.15v. In Fig. 7, currents at the disk and ring electrodes are plotted *vs.* disk potential for a given rate of rotation. After the limiting current at the disk electrode was reached, the current changes little with potential until below about 0.15v when it starts decreasing. Just at that point, current at the ring electrode increases.

At low currents, Tafel behavior is observed with $\partial V/\partial \ln i$ and log i_o having about the same values as in "insufficiently purified" solution. A plot of log $(1-I)/I_{lim}$ *vs.* log I has a slope of 1. This shows that the reaction is first order in respect to oxygen (15). Here, I is the disk current for a given potential in the range close to the limiting current, I_{lim}.

When toluene was added to a "pure" solution, the rate of decrease of the disk current became similar to that in "insufficiently purified" solutions (Fig. 8).

Discussion

The following experimental observations made in this work and elsewhere need discussion:

1. Hydrogen peroxide is formed in oxygen reduction on Pt in acid solutions (5, 6, 7, 16-30).
2. The yield of hydrogen peroxide is a function of potential and time (17, 18).
3. The oxygen reduction currents (to H_2O) at a constant potential are higher and the yield of hydrogen peroxide lower following an activation process of oxidation and reduction (16, 18, 21, 23).
4. In "insufficiently purified" solutions, the rate of the decrease of oxygen reduction current increases with the increasing rate of disk rotation. and
5. Much less hydrogen peroxide is produced in "pure" solutions.

These observations may be discussed in terms of the following models:

1. An electrode surface changes with time of contact with the solution. For instance, each individual grain of the polycrystalline electrode exposes initially one crystal plane to the solution. With time, via surface diffusion of adions, new crystal planes form at which catalytic activity changes (decreases).
2. A small amount of oxides on the electrode surface acts catalytically for oxygen reduction (23). It

is possible that, during oxygen reduction, these oxides are gradually being reduced and the over-all catalytic activity decreases.

3. It was suggested (5, 6) that the adsorption of anions or cations changes with potential and time and induces changes in the rate of oxygen reduction to H_2O and H_2O_2. and

4. Adsorption of impurities blocks the surface of the electrode and causes a change in the activity and also in the reaction path.

Change of the disk current with time.—Since the time dependence of disk current is strongly dependent on the rate of electrode rotation,[2] diffusion from the solution must be playing a major role in the changes which are occurring at the electrode surface. If the observed time dependence is due entirely to diffusion of some species to the electrode surface, a concentration of these species may be estimated in the following way.

For the diffusion to a rotating disk, Levich (31) gives the formula

$$j = 0.62\, D^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, c \qquad [2]$$

where c is the concentration of residual species in the solution, and other symbols are the same as in Eq. [1]. The steady-state disk current corresponds to the reaction rate at the surface at equilibrium coverage by adsorbed species. If the change in the current is attributed to a complete cessation of the reaction at those sites which are covered by adsorbed species, then the reaction rate for a given potential is related to the coverage by these species.

By extrapolating the initial line in Fig. 3 to zero current, it is calculated that about 300 sec would be required to reach a monolayer coverage. If it is now assumed that each molecule diffusing to the surface covers only one site at the surface (a low assumption if the species are organic), the monolayer coverage is about 2.5×10^{-9} mole/cm^2. The diffusional flux is then about 10^{-11} mole/sec cm^2. Using 10^{-5} cm^2/sec for D, 10^{-2} cm^2/sec for ν, and 378 sec^{-1} for ω, c is calculated to be 1×10^{-7} mole/l. This low concentration of species in the solution can already account for the observed change in disk current if initially all species reaching the electrode surface become adsorbed at it. After the electrochemical purification of the solutions the concentration of the species must be much lower than this as the change with time in disk current is much less.

If the electrode surface was undergoing some structural change (surface recrystallization or oxide reduction), there is no obvious reason for the dependence of the change in the disk current on the rate of rotation. There is also no reason why purification of the solution would affect the rate of this change. Hence, the observed change with time of disk current cannot be caused by changes in the properties of the electrode surface, which do not involve interaction of the surface with species diffusing from the solution.

It is unlikely that the adsorption of ions from the sulfuric acid can be causing the time dependent effects. The concentration of the sulfuric acid ($0.1N$) is so high that the adsorption cannot be diffusion controlled. If a slow activated adsorption process was occurring, no dependence on the rate of rotation should be observed. Ion adsorption has been observed on mercury to be a rapid process which is probably complete within 1 sec (32). Furthermore, the electrochemical purification should not affect the observed rate by which disk current changes with time.

Adsorption of residual impurities.—The adsorption of residual impurities from the solution may account for the observed time effect. The calculated concentration of 1×10^{-7} mole/l of species which are causing the effect is consistent with usually estimated (33, 34) concentration of residual impurities in insufficiently purified H_2SO_4 solutions. Slower changes with time of the disk current which are brought about by the electrochemical purification supports the model involving the presence of trace impurities in the solution. These impurities can be removed by the electrochemical purification used in this work.

Nature of the residual impurities.—Residual impurities appear to be oxidizable at the platinum electrode at higher potentials ($\geqq \sim 1$v). Thus, the depolarization of an electrode observed in the oxygen evolution at low current densities when sulfuric acid is not sufficiently purified is apparently due to the oxidation of the impurities. If such solution is anodically pre-electrolyzed, depolarization occurs at lower current densities (35, 36).

A fact which supports the identification of the impurities as organic compounds is the apparent partial reversibility of the adsorption. The maximum in the disk current as a function of potential is obtained starting from either the cathodic or the anodic direction. The increase in the cathodic current when the potential is made more anodic must be due to a decrease in the extent of "inhibition" of the reaction. The decrease in "inhibition" is likely due to the desorption of the "inhibiting" species, which are not easily oxidized at these low potentials.

The experiment in which toluene was added to "pure" solution shows that toluene causes the same type of effect as the residual impurity in "insufficiently purified" or impure solutions (Fig. 8). This also supports the view that the residual species in the solution are of organic nature.

With the passage of time, however, the apparent desorption with the change in potential occurs less and less readily until it is no longer noticed (see Fig. 5). This behavior requires a change in the nature of the adsorbed species. With organic molecules such changes may occur if they are partially oxidized at the surface. After a slow partial oxidation has occurred, the desorption of the "carbon skeleton" (37) would be much more difficult than the desorption of the original molecules. Alternately, if a spectrum of organic compounds is present as residual impurities, the most strongly adsorbed will displace the ones which are less strongly adsorbed, resulting in a decrease in the ease of desorption.

It appears, therefore, that organic, rather than inorganic, species are likely residual impurities that adsorb on the electrode surface.

Mechanism of O_2 reduction in the presence of residual impurities.—Adsorbed impurities greatly effect the mechanism and the kinetics of O_2 reduction, particularly in the potential range cathodic to about 0.7v.

If O_2 reduction proceeds along two paths so that

$$O_2 + 4H^+ + 4e^- \xrightarrow{k_1} 2H_2O \qquad [3]$$

$$O_2 + 2H^+ + 2e^- \xrightarrow{k_2} H_2O_2 \qquad [4]$$

$$H_2O_2 + 2H^+ + 2e^- \xrightarrow{k_3} 2H_2O \qquad [5]$$

reaction [3] represents one over-all path, and [4] and [5] the other in which H_2O_2 is formed as an intermediate which may reduce further to H_2O with the rate proportional to k_3, then the diagnostic plot given by Eq. [1] can be applied here.

The lines parallel to the $\omega^{-1/2}$ axis in the I_d/I_r *vs.* $\omega^{-1/2}$ plot (Fig. 6), show that k_3 is zero for the potentials at which the measurements were made. The intercepts at ordinate are greater than $1/N$ and change with potential. This means, according to Eq. [1], that x is not zero and that it changes with disk potential. With the definition of x as the ratio of the current due to reaction [3] to that due to reaction [4], it follows that O_2 reduction proceeds in two parallel reaction paths. Since $k_3 \approx 0$, the H_2O_2 formed in a parallel reaction

[2] In "insufficiently purified" or not purified solutions.

path (Eq. [4]) does not reduce further to H_2O with any appreciable rate.

The question still remains, whether in the path of oxygen reduction which leads to water (Eq. [3]), H_2O_2 is also formed as an intermediate but has a high rate constant for the further reduction of the hydrogen peroxide to water. If this were the case, then H_2O_2 which is produced in the other path (Eq. [4]) presumably on sites of different activity would be expected to diffuse to the sites which are active for H_2O_2 reduction in the hypothetical path

$$O_2 \rightarrow H_2O_2 \xrightarrow{\text{fast}} H_2O \qquad [6]$$

Since H_2O_2 would be produced at all sites on the surface and only be reduced at some sites, the rate constant for reduction of H_2O_2 would be averaged over the surface so that the diagnostic plot would resemble that for a single path ($x = 0$) with H_2O_2 as an intermediate which has a dependence on the rate of rotation. This is clearly not the case, as I_d/I_r is not dependent on the rate of rotation. Hence, the path of oxygen reduction which leads to water does not have a hydrogen peroxide intermediate.

In "pure" solutions, I_r approaches zero. Hence, at low coverage with residual impurities, all the oxygen is reduced to water (and no diagnostic plot is possible).

Now, the adsorption of impurities causes a decrease in the over-all rate of oxygen reduction (decrease in I_d with time) and this is concurrent with an increase in the amount of hydrogen peroxide formed (increase in I_r). Thus, the adsorption results in the appearance of the additional path in which H_2O_2 is produced.

Since, in the absence of the effect of impurities, no H_2O_2 is produced, and in the presence of impurities, H_2O_2 is produced in a path parallel to the path which does not involve the formation of intermediate, it is rationalized that hydrogen peroxide is produced at sites which are affected by impurities, and the water producing path occurs at sites not affected by impurities. Furthermore, since Tafel slopes and i_o's are approximately the same both in pure and in insufficiently purified solutions and the Tafel region corresponds to a region of minimum hydrogen peroxide formation (I_d/I_r in Fig. 6 is sharply increasing at potentials more anodic than 0.65v and Tafel region is anodic to 0.70v) the mechanism of oxygen reduction to H_2O in both solutions are expected to be the same. This supports the deduction that the sites at which H_2O is formed in insufficiently purified solution are not affected by adsorbed impurities (adsorption free sites).

Mechanism of O_2 reduction to water.—It has recently been discussed (38, 39) that on Pt electrodes O_2 reduction may occur either on oxide covered or on oxide free surfaces. The mechanism of the reaction on these two types of surfaces are not the same. The electrode pretreatment in the present work ensures that the disk electrode is oxide free.

The experimental facts relevant to determine the mechanism are the following: (*i*) H_2O_2 is not an intermediate in the reaction path; (*ii*) the reaction is the first order in respect to oxygen; and (*iii*) $\partial V/\partial \ln i \approx -RT/\mathbf{F}$. Parameters under (*ii*) and (*iii*) are the same as previously reported (38). The pH dependence as reported by other workers (38) is given by $\partial V/\partial \text{ pH} \approx -100$ mv.

The stoichiometric number can be obtained from (40)

$$p' - p'' = p/\nu \qquad [7]$$

where p' is the reaction order of the rate-controlling step for the forward reaction, and p'' for the backward reaction. p is the over-all forward reaction order for the reaction given by Eq. [3], and ν is the stoichiometric number.

Experimentally, it is found that $p' = 1$. Since, in general (40) $p'' \leq 0$, and $\nu \geq 1$, p'' must be equal to zero, and the stoichiometric number is one.

The formation of intermediates such as $O_2^=$, HO_2^-, and H_2O_2 are excluded, as hydrogen peroxide is not detected. If positively charged intermediates are excluded, the possible intermediates which can form before the rate-controlling step are hence O_2^- and HO_2.

Reaction path under Langmuirian condition of adsorption.—The equation (41)

$$b_c = -\frac{\nu RT}{(n_c + \beta n^*)\mathbf{F}} \qquad [8]$$

restricts the number of permissible paths. In this equation b_c is the cathodic Tafel slope, n_c the number of electrons transferred before the rate-determining step, n^* the number of electrons transferred in the rate-controlling step, and β the symmetry factor ($=\frac{1}{2}$). Since $\nu = 1$, and $b_c = -RT/\mathbf{F}$, and since n_c and n^* must be integral numbers, two possibilities arise

$$n_c = 1,\ n^* = 0 \qquad [9]$$

and

$$n_c = 0,\ n^* = 2 \qquad [10]$$

The second possibility requires a simultaneous two electron transfer which is highly improbable. Thus, only the first possibility is tenable. The path must then have a single electron transfer followed by a rate-controlling step which does not have an electron transfer. The following paths satisfy this requirement

Path (A) $O_2 + e^- \rightleftharpoons O_2^-$ [11]

$O_2^- \rightarrow$ products [12]

Path (B) $O_2 + H^+ + e^- \rightleftharpoons HO_2$ [13]

$HO_2 \rightarrow$ products [14]

The path A is not pH dependent, and path B has a pH dependence of $-RT/\mathbf{F}$, and neither is in agreement with the reported dependence (38) for $(\partial V/\partial \text{pH})$ of -100 mv. Hence, under Langmuir conditions, neither of the permissable paths are tenable.

Reaction path under Temkin conditions of adsorption.—Since the coverage with adsorbed oxygen species is approximately linear with potential in the Tafel region of oxygen dissolution and the intermediate values of coverages are reported (38, 42), the kinetics under Temkin adsorption conditions should be considered. If the rate-controlling step is according to

$$M + O_2 + H^+ + e^- \rightarrow MHO_2 \qquad [15]$$

where M stands for a site at the metal surface, then all reaction steps after this step must be considered as being in quasi-equilibrium. Such a step is

$$MOH + H^+ + e^- \rightleftharpoons M + H_2O \qquad [16]$$

The rate expression for [15] under Temkin conditions is (38, 43, 44)

$$i = k[H^+][O_2] \exp(-\beta\mathbf{F}V/RT) \exp[-\beta f(\theta)] \qquad [17]$$

Now, $f(\theta)$ can be obtained from [16] if the rate expressions for forward and backward reaction are equated and $\ln \theta$ term is neglected in respect to θ. It is

$$f(\theta) \approx V\mathbf{F}/RT - \ln[H^+] \qquad [18]$$

Substituting [18] into [17]

$$i = k[H^+]^{3/2}[O_2] \exp(-V\mathbf{F}/RT) \qquad [19]$$

This rate expression gives a pH dependence of $-3RT/2\mathbf{F}$, which is close to that reported (38). Thus, under Temkin conditions the first charge transfer is rate-controlling. This analysis confirms the previous one (38) concerning the mechanism of O_2 reduction on oxide free Pt electrodes in acid solution.

Formation of H_2O_2 below 0.15v.—In pure solutions, H_2O_2 is formed only in the region cathodic to about

0.15v (Fig. 7). In this potential region (0.2-0.0v) hydrogen is adsorbed at the electrode (45-50). At 0.1v hydrogen adsorption already amounts (46) to ~180 μcoul/cm^2. The sites which become occupied by hydrogen may not any longer be suited for oxygen adsorption which is required for the reduction to water. Then, a chemical reaction between the oxygen and adsorbed hydrogen may occur

$$O_2 + 2H \rightarrow H_2O_2 \quad [20]$$

If it is assumed that this reaction occurs on the sites covered by adsorbed hydrogen, its rate expression[3] is

$$i_{H_2O_2} = k_2[O_2]\theta_H^2 \quad [21]$$

The rate expression for the reaction of direct reduction of O_2 to H_2O then becomes

$$i = k[O_2](1 - \theta_H) \exp(-VF/RT) \quad [22]$$

when allowance is made for the decrease in area for the reaction due to the coverage with adsorbed hydrogen.

As θ_H approaches unity, the reaction product changes from H_2O to H_2O_2. Thus the change in the products observed can be accounted for qualitatively by this model.

However, the model has one drawback. A rhodium electrode also becomes covered with a monolayer of adsorbed hydrogen (51) at 0.00v. Hence, a similar behavior would be expected. However, no increase in the yield of hydrogen peroxide was observed (52), even at 0.00v. This is an evidence that geometric factors alone are not causing the changes of product observed at platinum. An alternative explanation is suggested below.

It is now established (53) that O_2 reduction to H_2O on bare Pd electrodes follow the same path and has the same rate-controlling step as on bare Pt electrodes. On gold electrodes, the mechanism is different and the product of the reduction is H_2O_2. In a series of palladium-gold alloys, the mechanism changes at the alloy composition where the d-band is expected to become filled. If unpaired d-electrons are a requirement for reduction of O_2 to water, then the hydrogen peroxide may be produced when all of the d-electrons are paired. The unpaired d-electrons of the surface atoms may be paired by interaction with the adsorbed H, and as a consequence of this, O_2 may no longer dissociate on adsorption, and O_2 reduces to H_2O_2 rather than H_2O. This model would predict a smooth change-over from no H_2O_2 to a quantitative yield of H_2O_2 when all of the d-electrons are paired, and the change in product from H_2O to H_2O_2 should occur in the initial region of hydrogen adsorption, *e.g.*, from 0.30 to 0.15v. However, this need not be the case since even a very small number of unpaired d-electrons which may remain at 0.15v can maintain the reduction to water. This is seen from the behavior of gold-palladium alloys which show a slow change in kinetics for oxygen reduction as the number of unpaired d-electrons decreases. The fact that on Rh electrode H_2O_2 is not a product even at 0.0v does not exclude above the model. Rhodium is expected to have about 1.7 unpaired d-electrons per atom. Thus, the adsorption of one hydrogen atom per one rhodium atom cannot result in a complete pairing of d-electrons and cause a change in the reaction product.

Summary of the Conclusions

In the case of oxygen reduction on Pt electrodes, the method of the rotating disk electrode with a concentric ring is shown to be useful in distinguishing between the reaction intermediates and the products in a parallel reaction path.

Oxygen reduction at oxide free Pt electrodes in pure acid solutions is a four electron process leading to H_2O. The rate-controlling step is consistent with the first charge transfer under Temkin conditions of adsorption. Hydrogen peroxide is not an intermediate in the path leading to water. In these pure solutions, H_2O_2 is formed only at potentials cathodic to 0.15v. This is interpreted as being due to the presence of adsorbed hydrogen at the electrode.

At potentials anodic to about 0.15v hydrogen peroxide forms only if the solution contains residual impurities, mostly organic ones, which adsorb at the surface. In this case, H_2O_2 forms in a reaction path parallel to that in which O_2 is reduced to H_2O. The rate of further reduction of H_2O_2 to H_2O is small in comparison to the rate at which H_2O_2 is formed.

[3] If reaction [20] occurs in two stages then θ_H should replace θ_H^2 in Eq. [21].

Gallium Arsenide Electrode Behavior

W. W. Harvey

Ledgemont Laboratory, Kennecott Copper Corporation, Lexington, Massachusetts

ABSTRACT

The anodic dissolution reaction of GaAs was found to proceed quantitatively in well-stirred solutions of KOH and $HClO_4$ with the formation of soluble, tripositive Ga and As compounds. Disintegration of the anode was noted under natural convection. Passivity ensued at high anodic currents in $HClO_4$ electrolyte, with an abrupt active-passive transition and a gradual passive-transpassive transition. In H_2SO_4 electrolyte, the passive region extended to the highest attainable anodic potentials. No substantial differences in electrochemical behavior were found between Ga(111) and As($\bar{1}\bar{1}\bar{1}$) surface orientations. The influence of the semiconductor properties of p-type GaAs on the cathodic polarization was confined to low current densities. Galvanostatic anodic-cathodic cycling revealed significant details of the photopotentials and eliminated the hysteresis in the cathodic polarization curves.

It was anticipated that, following the diversion of much research emphasis in semiconductor physics from germanium and silicon to compound semiconductors, workers in the field of semiconductor electrochemistry would also turn to the latter materials. It happens, however, that germanium and, to a lesser extent, silicon possess physical and chemical properties which are peculiarly favorable for revealing effects of bulk semiconductor properties on electrode behavior. For this and other reasons, the literature, at the beginning of the present investigation, contained a bare handful of papers on gallium arsenide electrochemistry—so fundamental a characteristic as the stoichiometry of the anodic dissolution reaction had not been established.

Williams (1) had concluded from his study of photovoltaic effects at binary-semiconductor/electrolyte interfaces that GaAs behaves as an inert electrode capable of exchanging electrons with a redox couple in the solution. This conclusion was based on observations that the electrode potential of n-type GaAs *vs.* saturated calomel varied in the same direction as the oxidation potential of the redox couple, and became strongly more negative on illumination. Subsequently, Haisty (2) experimented with photoetching and gold chemiplating of GaAs. Plating was observed at the nonilluminated and etching at the illuminated region on n-type material. The reverse occurred for p-type material when the photovoltage had the opposite sign. The results obtained by the two investigators are consistent except for the matter of inertness. Haisty noted that in fairly concentrated acid or base the anodic oxidation products were soluble, but in other electrolytes a film was formed.

A study of electrolytic polarization and photopotentials for both n- and p-type GaAs was carried out by Pleskov (3), who reported that the limiting anodic current for n-type is proportional to the incident light intensity at low values of the latter. Breakdown was observed to occur at a critical potential which varied in an inverse manner with the bulk electron concentration. The occurrence of avalanche breakdown and the low magnitude of calculated hole diffusion currents as compared to observed anodic currents, together with imperfect saturation of the latter led the author to conclude that holes are supplied mainly by space charge generation. Influences of semiconductor properties on cathodic polarization behavior were not as pronounced as the chemical effects responsible for hysteresis in the recorded curves.

In a meeting presentation, Greenberg and Sanders (4) reported measurements of current multiplication at n-type GaAs electrodes. They obtained sharp saturation of the anodic current and, for the ratio of limiting anodic current to absorbed light intensity, the values 2.1 and 1.5 in 1.0*N* HCl and 1.0*N* KOH, respectively. Anodic current resulted in dissolution of the crystals, whose surfaces acquired "unstable brown films."

Such was the state of knowledge of the GaAs/electrolyte interface. The observed similarities and differences with respect to germanium and silicon electrodes

were generally in accord with what was known or anticipated concerning the electronic and chemical properties of GaAs. Recently, three rather more extensive studies of GaAs electrochemistry have been published. Included are the measurements of differential capacitance and cathodic reduction of surface oxides by Birintseva and Pleskov (5), the determination of the hole participation factor and the current efficiency of anodic dissolution by Efimov and Erusalimchik (6), and the investigation of the anodic dissolution mechanism for (111)- and $(\bar{1}\bar{1}\bar{1})$-oriented surfaces by Gerischer (7). Certain findings of the present research are in disagreement with earlier reported results; these and some previously unexplored electrochemical features will be elaborated on.

Stoichiometry of the Electrode Reactions

One bit of information presently unavailable, yet essential for the calculation of standard potentials of possible electrode reactions, is the standard free enthalpy of formation $\Delta G°_{298}$ of gallium arsenide. Thermochemical data (8) for several related compounds are presented in Table I, which also lists electronegativities from Pauling (9) and from a more recent compilation (10) [two and three significant figures, respectively]. No correlation is evident between the standard enthalpies of formation of the compounds GaSb, InAs, and InSb and differences in electronegativities of the constituent elements. As a rough approximation, the unknown $\Delta H°_{298}$ for GaAs was taken to be the same as that of InSb (—3.5 kcal/mole).

When this assumed value is combined with the standard entropy of formation from Table I, the quantity —3.1 kcal/mole is obtained for $\Delta G°_{298}$ of GaAs. The absolute error cannot be so great as to alter the conclusions to be drawn from Table II; namely, that the 6-electron anodic reactions are favored over the corresponding 8-electron reactions in both acid and alkaline solution and that cathodic hydrogen evolution is much more probable than arsine formation.

Experimental

Gallium arsenide electrodes were fashioned in the form of (111)-oriented disks, 4-mm or 8-mm diameter, and of the order of 1-mm thick. The (111), "A" or gallium faces were distinguished from the $(\bar{1}\bar{1}\bar{1})$, "B" or arsenic faces by etching the initially abraded surfaces in $1HF:1H_2O_2:1H_2O$. The identification of polarity according to the chemical etch patterns was confirmed for one pair of surfaces by means of anomalous x-ray dispersion. The crystals from which electrodes were cut had the following characteristics

n-type (undoped)	0.85 ohm-cm, 2.0 x 10^{15} carriers/cm^3, mobility 3700 cm^2/v-sec
p-type (Zn-doped)	0.012 ohm-cm, 4.2 x 10^{18} carriers/cm^3, mobility 125 cm^2/v-sec

Table I. Electronegativities and thermochemical data

	IIIA	VA	III-V	$-\Delta H°_{298}$
	Ga	As	GaSb	5.0 ± 0.2 kcal
Pauling	1.6	2.0	InAs	7.4 ± 0.6 kcal
Gray	1.81	2.18	InSb	3.5 ± 0.1 kcal
	In	Sb		
Pauling	1.7	1.9		
Gray	1.78	2.05	GaAs: $\Delta S°_{298}$ = −1.4 cal/deg	

Table II. Standard potentials for some GaAs electrode reactions

	$\Delta G°$, kcal	$E°$, v
$GaAs + 2H_2O = Ga^{+3} + HAsO_2(aq) + 3H^+ + 6e^-$	−16.5	+0.11
$GaAs + 4H_2O = Ga^{+3} + H_3AsO_4(aq) + 5H^+ + 8e^-$	+9.3	−0.05
$GaAs + 8OH^- = H_2GaO_3^- + AsO_3^- + 3H_2O + 6e^-$	−128.0	+0.92
$GaAs + 12OH^- = H_2GaO_3^- + AsO_4^{-3} + 5H_2O + 8e^-$	−159.3	+0.86
$GaAs + 3H^+ + 3e^- = Ga + AsH_3(g)$	+47.0	−0.69
$GaAs + 3H_2O + 3e^- = Ga + AsH_3(g) + 3OH^-$	+102.3	−1.47

The provision of suitably low resistance electrical contacts proved an important consideration, particularly for n-type electrodes. A satisfactory procedure consisted of sputtering gold onto a clean, freshly abraded surface and then effecting some penetration of the gold into the GaAs surface layer by heating in a reducing atmosphere (H_2/N_2 mixture) for ½ hr at 300°C. For the majority of experiments a bead of indium was alloyed to the gold layer, thus permitting a reliable pressure contact to be made. Where accurate electrode weight changes were required, "precipitated silver metal" was compacted between the sputtered gold layer and a metal rod.

Current-voltage characteristics of pairs of contacts affixed to opposite faces of the same specimen were measured. Electrical contacts were considered satisfactory when the combined resistance of contacts plus electrode was constant and not significantly greater than the resistance of electrode alone (as calculated from the bulk resistivity) over the current range of interest. Thereupon the superfluous contact was removed. Of the previously cited publications dealing with aspects of GaAs electrode behavior, only that of Pleskov (3) makes specific note of concern with and the means employed for circumventing rectification and high resistance at the metal-GaAs contacts.

Electrodes were cemented with Apiezon W black wax into a circular recess at the end of a glass capillary tube. The wax and projecting edge of the GaAs disk were then coated with commercial purified paraffin, excluding all but the desired face from contact with the electrolyte. It was thus possible to make advantageous use both of the adhesiveness of the black wax and the chemical inertness of the paraffin. The surface was most often wet-abraded (3000-mesh garnet) before mounting as indicated and subsequently was generally chemically polished (10 v/o Br_2 in methanol) before insertion in the electrochemical cell.

A Pyrex cell was employed which could accommodate up to three working electrodes, symmetrically situated with respect to a pivotal Luggin capillary. The counter electrode compartment was separated from the main body of the cell by a glass frit. A stream of purified, deoxygenated nitrogen served to purge both the cell volume and the electrolyte in a connected solution reservoir. Reagent grade salts and perchloric acid were used without purification; sulfuric acid and alkaline solutions were made up from Acculute volumetric standards. The distilled water used had room temperature resistivity in excess of 10^{-6} ohm-cm and was obtained from an all-Pyrex still fed with demineralized and Millipore-filtered water. The cell temperature was 25°C throughout and, unless otherwise noted, experiments were carried out in room light and with magnetic stirring of the electrolyte.

Results and Discussion

Over-all electrode reactions.—In agreement with the observations of other investigators, n-type GaAs electrodes were found to exhibit a large, negative photovoltage on open circuit; p-type electrodes showed a smaller, positive photovoltage in the solutions studied. Furthermore, the limiting anodic current for n-type was both very small in the dark and extremely sensitive to light. Gas was evolved at appreciable current densities during cathodic but not anodic polarization; the steady-state anodic reaction was always GaAs dissolution. In a number of cases a loosely adherent brown coating formed on the anode; this substance was isolated and found by x-ray diffraction to be gallium arsenide rather than some oxidation product. [Greenberg and Sanders (4) and Gerischer (7) reported a dark coating, whose identity was correctly established by the latter.]

The indicated disintegration or undermining of the anode could be eliminated by effecting vigorous mass-transport conditions at the interface. Table III summarizes coulometric measurements carried out on ini-

Table III. Coulometry of the anodic dissolution reaction for p-GaAs, 20 ma/cm²

Expt. No.	Surface	Disk diameter, mm	Electrolyte	Electron number
1	A(111)	4	0.5*N* KOH	5.88_0
2	A(111)	8	0.5*N* KOH	5.92_6
3	B($\bar{1}\bar{1}\bar{1}$)	8	0.5*N* KOH	5.99_2
4	B($\bar{1}\bar{1}\bar{1}$)	8	1.0*N* $HClO_4$	5.99_8
5	A(111)	8	1.0*N* $HClO_4$	6.10_0

tially abraded p-type anodes at 20 ma/cm² and 25°C, with magnetic stirring of the electrolyte. Anode weight losses were determined directly. In general, as techniques were refined the electron number more closely approached the value 6; the single instance of an apparent electron number in excess of 6 appeared to be due to severe attack of the rim of the GaAs disk, leading to possible exposure of the edge of the gold film to the electrolyte.

Following anodic dissolution, a positive test was obtained for arsenite in the electrolyte. It appears certain that gallium arsenide normally undergoes anodic dissolution with the formation of trivalent gallium and trivalent arsenic, a conclusion in agreement with that expressed in ref. (6) and (7). Moreover, the stoichiometry is the same for both surface polarities. In experiments 2-5 of Table III, the cathode was a GaAs disk of surface polarity opposite to that of the anode. There were no weight changes of the cathodes, within weighing errors, attending prolonged cathodic hydrogen evolution at current densities of 20 and 80 ma/cm². Evidently, arsine formation is not a significant part of the cathodic process at the current densities indicated.

Electrode polarization characteristics.—Preliminary anodic etching experiments with an n-type GaAs hemisphere in 0.5*N* KOH, carried out perforce under strong illumination, gave some indication of a reduced rate of attack along the [110] zone, including the (111) plane, as compared to the ($\bar{1}\bar{1}\bar{1}$) plane. However, the anodic etch patterns were not nearly so well defined as those obtainable with germanium hemispheres—one infers a lower degree of crystalline perfection for the GaAs—and the polarization experiments to be described allow little distinction to be made between the electrode kinetics of nominally A and B surfaces. On the other hand, anodic dissolution of both surfaces is definitely retarded relative to other orientations. Only one example is given by the photographs of Fig. 1, which depict the surface of an n-type electrode of B($\bar{1}\bar{1}\bar{1}$) surface polarity following anodic etching in 2*N* NaOH under illumination. There is clear evidence of higher-than-average current density at the rim of the disk; there also appears to be little remaining of the original surface orientation. The major reflecting planes in this particular etch pattern were identified as ($\bar{2}\bar{2}3$) by means of a two-circle goniometer.

Figures 2 and 3 illustrate the similarity in polarization behavior of the nominally A and B surfaces. The data points were obtained potentiostatically and represent quasistationary current densities measured at roughly 30-sec intervals. It is apparent that little quantitative significance can be attached to rest potentials in this system. On the other hand, the anodic polarization behavior was nicely reproducible, obeying a Tafel relation over at least four decades of current density. Within experimental error, Tafel slopes were the same (82 mv) for both electrodes.

The upward swing of the anodic curves at the highest current densities is an indication of a resistive component of the electrode potential measured *vs.* the saturated calomel half-cell. Thus, the data at high

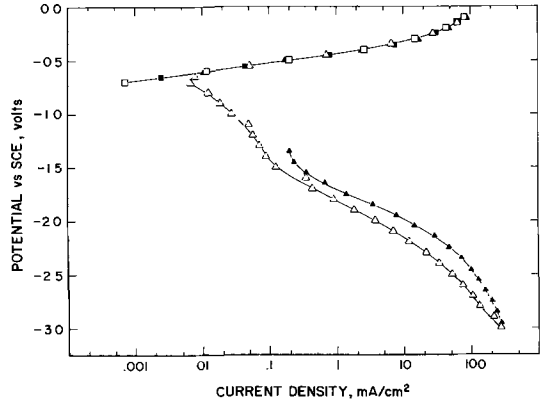

Fig. 2. Anodic and cathodic polarization curves for a p-GaAs, A(111) electrode in 0.5N KOH, 25°C: △, incr. $|\eta|$; ▲, decr. $|\eta|$; □, incr. $|\eta|$ (repeat); ■, decr. $|\eta|$ (repeat). The symbol η in this and subsequent figure captions stands for "overpotential."

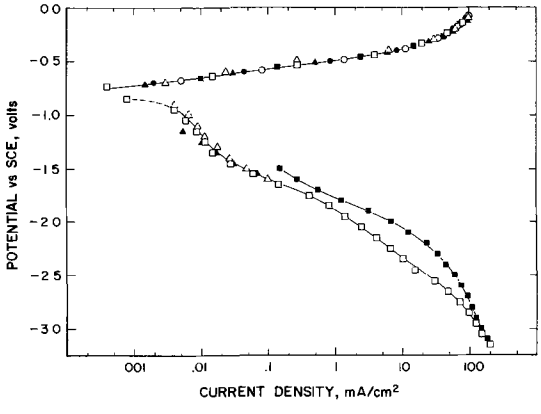

Fig. 3. Anodic and cathodic polarization curves for a p-GaAs, B($\bar{1}\bar{1}\bar{1}$) electrode in 0.5N KOH, 25°C. Sequence of measurements: △, ▲, □, ■, ○, ● (see Fig. 2 caption).

anodic overpotentials, when replotted as potential, U, *vs.* (linear) current density, j, yield straight lines with slopes, $R = dU/dj$, equal to 2.8_3 and 3.0_5 ohm-cm^2 for the A and B electrodes, respectively. The indicated magnitude of R is too large to be accounted for by the corresponding quantity for semiconductor bulk plus electrical contact to the back surface and is probably determined by the effective resistance (11) between electrode and Luggin capillary tip. Actually, for these and other cases it was found that the subtraction of jR from the measured electrode potentials apparently overcompensates for ohmic resistance; the corrected Tafel plots invariably leveled off at high current densities.

The cathodic behavior was more strongly influenced by chemical factors than by bulk semiconductor properties. Note in this regard the absence of an electron-limited current, together with an insensitivity to illumination at all but the lowest cathodic currents. These findings are in general agreement with those of Pleskov (3). The curves reported here were obtained subsequent to anodic polarization, and it is clear from examination of Fig. 2 and 3 that beyond a certain region of cathodic overpotential the nature of the GaAs surface becomes altered so that the polarization curve is not retraced on decreasing the overpotential. By way of comparison, Birintseva and Pleskov (5) obtained evidence for the anodic formation of a surface oxide phase in acid solution, but only of the order of one monolayer of cathodically reducible oxidation product in alkaline solution.

In addition to a shift of approximately 0.8v to more positive potentials, as compared to the 0.5*N* KOH electrolyte, the anodic polarization curves for p-type GaAs in 1.0*N* $HClO_4$ exhibit a passive region. Results for one surface orientation only are shown (Fig. 4), since the data for the second are virtually superposable, even to the extent of reproducing all details of the complicated cathodic behavior. The effect of prior anodic polarization on the cathodic behavior was more pronounced in the acid electrolyte, consistent with more extensive oxidation of the electrode surface. As in the alkaline electrolyte, the cathodic behavior of the p-type electrodes employed was much more a function of their chemical than of their semiconducting nature.

In 1.0*N* $HClO_4$ the anodic Tafel slope was 68 mv. The resistive contributions to measured overpotentials in the prepassive region were 1.5_4 and 1.8_8 ohm-cm^2 for an A and a B electrode, respectively, multiplied by

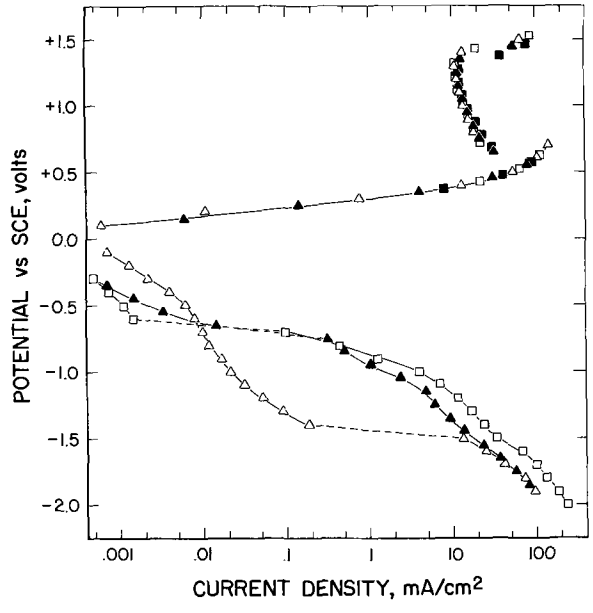

Fig. 4. Anodic and cathodic polarization curves for a p-GaAs, B($\bar{1}\bar{1}\bar{1}$) electrode in 1.0N $HClO_4$, 25°C. Sequence of measurements: same as Fig. 2.

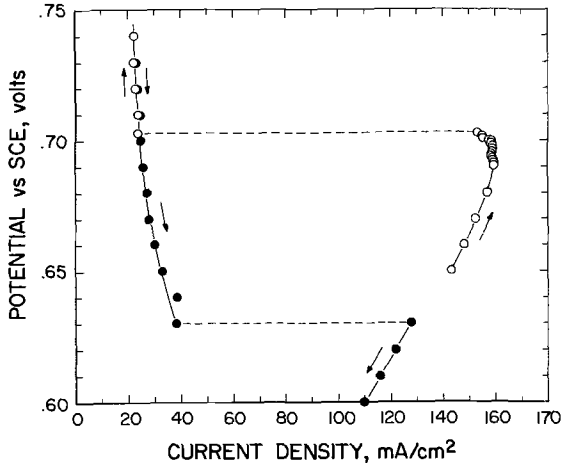

Fig. 5. Details of the active-passive transition for a p-GaAs, B($\bar{1}\bar{1}\bar{1}$) electrode in 1.0N $HClO_4$, 25°C.

current density. The transition from active to passive condition was abrupt; the critical potential could be located potentiostatically to within 1 mv (Fig. 5). Reestablishment of the active condition was attended by pronounced hysteresis, although the passive-to-active transition was equally abrupt. In the absence of stirring, current densities were lower in the prepassive and throughout the passive regions, but intense light had no perceptible effect on the kinetics.

By contrast to the active-passive transitions, that between passive and transpassive regions was gradual with, moreover, a drifting of the current at a fixed electrode potential. It is possible that the former is, in reality, continuous in keeping with the suggestion of Osterwald (11) relative to the effect of an included jR component.

Anodic polarization in $HClO_4$ to the extent indicated by Fig. 4 (about 30 sec/point) resulted in deep pitting of the GaAs surface and heavy attack of the rim. Although, as shown in Fig. 6, the pits formed on an A and a B surface are readily distinguishable (as in chemical etching), the microtextures of the rest of the surface and, indeed, of the pits themselves proved to be rather similar. The passive film is not thought to be the dark coating which appeared at high anodic current densities, since the latter could be dislodged mechanically, but was not reduced electrochemically.

The most pronounced effect of changing the anion from perchlorate to sulfate was the extension of the passive region to the most positive attainable potentials. The anodic polarization data given in Fig. 7 are for an A(111) surface orientation; results were virtually identical for a B($\bar{1}\bar{1}\bar{1}$) electrode as well as for

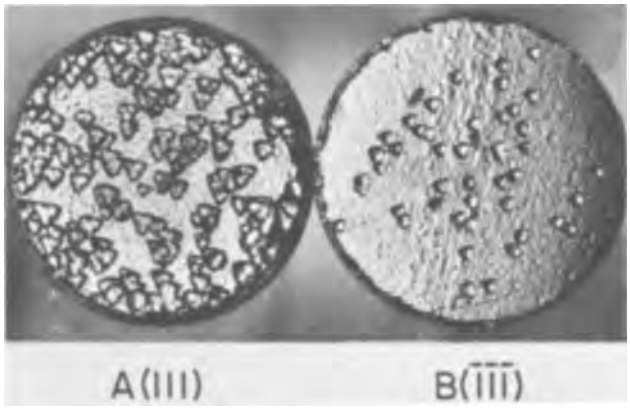

Fig. 6. Gross appearance of differently oriented p-GaAs electrodes, 8-mm diameter, following anodic passivation experiments in $HClO_4$.

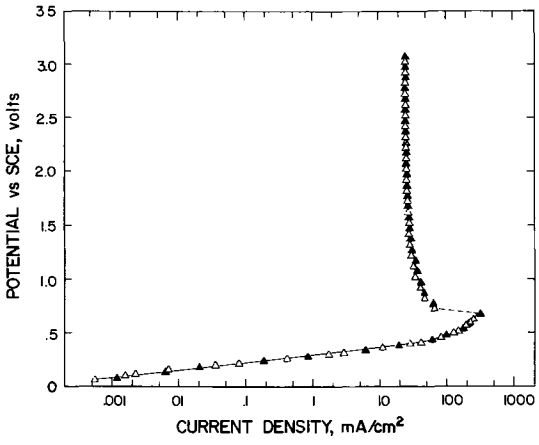

Fig. 7. Anodic polarization behavior of a p-GaAs, A(111) electrode in 1.0N H_2SO_4, 25°C: △, incr. η; ▲, decr. η.

a second A(111) electrode. The value of b derived from Fig. 7 is 62 mv. The active-passive transition was abrupt in both directions, but without appreciable hysteresis.

Additional comparisons of passivation characteristics in the two solutions are interesting. Thus, the Flade potential in 1.0*N* H_2SO_4 and that for the direction of increasing overpotential in 1.0*N* $HClO_4$ have sensibly the same value, namely about +0.70v *vs.* SCE; however, the maximum current density is greater in the former (~325 as compared to ~150 ma/cm²), as is the passive current density (~25 as compared to ~15 ma/cm²). The difference in *p*H between normal solutions of sulfuric and perchloric acid is thought to be insufficient to account for differences in passivation behavior, especially since hydrogen ion is a product of the anode reaction. One is led to a consideration of the probable composition of the passive film.

Both the sulfate and perchlorate of trivalent gallium have appreciable solubilities, as confirmed in separate experiments. It was also found that a gallium arsenite could not be isolated, although gallium arsenate was precipitated in the *p*H range 2-8. Arsenic trioxide is known to be only moderately soluble in acid solution, as noted by Straumanis and Kim in their report (12) on the growth of As_2O_3 crystals on GaAs etched with dilute and concentrated HNO_3 and also with aqua regia. (It would be difficult to reconcile their identification of the product as As_2O_3 with the known reducing properties of this substance were it not readily demonstrable in the laboratory that the oxidation of solid As_2O_3 by the reagents employed proceeds very slowly at room temperature.) Haisty (2) identified a dark blue film formed on p-type GaAs in dilute KCl by photogalvanic etching as β-Ga_2O_3, which is also the product of thermal oxidation (13). However, as noted previously, oxide films were formed only at intermediate *p*H's.

The published observations most pertinent to the passivation behavior of GaAs are possibly those of Revesz and Zaininger (14), who obtained a Ga_2O_3-As_2O_5 film by anodic oxidation of p-type GaAs in acetic anhydride saturated with KNO_3. They concluded that the film was essentially amorphous with a Ga/As atom ratio of 1.3, possibly a glass modification of the silica-like composite oxide $GaAsO_4$. It is conceivable that an anodic film of this nature is formed at sufficiently high current densities in aqueous acid electrolytes, leading to retardation of the anodic dissolution reaction. The rate of the implied further oxidation of arsenic to the +5 state would likely be enhanced by perchlorate and so result in diminished passive and maximum prepassive currents relative to H_2SO_4 electrolyte.

The narrowness of the range of passive potentials observed in $HClO_4$ is probably a consequence of the

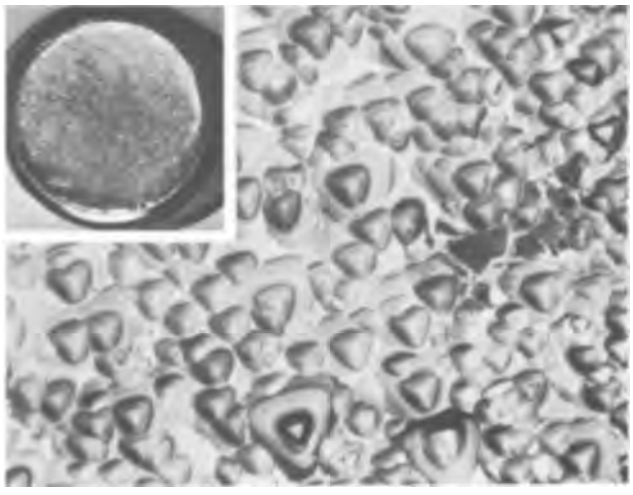

Fig. 8. Gross appearance (inset) and surface features of a p-GaAs, A(111) electrode, 4-mm diameter, following anodic passivation experiments in H_2SO_4. Magnification before reproduction: 200X.

severe pitting which occurs (Fig. 6). The absence of pits on GaAs electrodes having undergone similar anodic treatment in H_2SO_4 provides a marked contrast (Fig. 8). Visible in the latter figure are vestiges of a loosely adherent, dark film of GaAs. The strongly nonuniform distribution of electrode current density associated with pitting and transpassivity is probably also responsible for the hysteresis in the active-passive transition observed in $HClO_4$ electrolyte. There follows a consideration of some experiments performed with the aim of understanding better the cathodic behavior.

Cathodic photopotentials.—It was of interest to explore further the photoresponse of p-type GaAs cathodes. The absence of an electron-limited current has been noted here as well as by others, although Pleskov (3) found the overpotential for hydrogen evolution to be greater for p-type GaAs ($p = 2 \times 10^{18}$ cm^{-3}) than for n-type ($n = 10^{18}$ cm^{-3}). It seems clear that at the higher current densities the electrons required for the cathodic process are either generated at a sufficient rate within the electrode or at its surface or are derived from the valence band. The abrasion of the back surface prior to applying the gold contact is not thought to be a factor because of the very short lifetime and consequent short diffusion length of minority carriers in GaAs (15).

Initially, the positive photopotential was enhanced by application of a small cathodic current. The clear indication is that the negative space charge was increased in the way expected for consumption of minority carriers by the cathodic reaction. Continuous illumination at very low cathodic current densities

caused the magnitude of the photopotential to decrease more rapidly than in the dark (Fig. 9). The contribution of continued cathodic current to the observed relaxation of the photopotential may result from the change in the chemical state of the surface, with an attendant adjustment of the potential difference across the interface. Superposed on this effect is that of continued illumination (Fig. 9), which appears to be associated with a trapping phenomenon; possibly the light is absorbed by trapping centers and effects the release of minority carriers.

At somewhat higher cathodic current densities (Fig. 10), the cathodic photopotential becomes both larger and less time dependent. At still higher current densities, the cathodic charging curve is characterized by overshoot and, eventually, by greatly diminished photoresponse.

It was found that the quasistationary potentials obtained from cyclical charging yield polarization curves in which much of the previously encountered complicated cathode behavior is absent (Fig. 11). Evidently, the chemical state of the GaAs surface is altered in a more reproducible way as a consequence of anodic-cathodic cycling. From Fig. 11 it is seen that not only do the curves for increasing and decreasing overpotential coincide, but the cathodic branch has now a well-defined Tafel region. The values of the coefficient b in the given electrolyte are 62 mv for the anodic branch and 300 mv for the cathodic. The anodic photopotentials (not shown) were small throughout.

The following interpretation of the cathodic photopotentials is offered. Up to about 10 μa/cm^2 the cathode potential under illumination is sensibly constant, indicating that the light was sufficiently intense to bring the surface region to the flat-band condition (not that for the unpolarized electrode, which occurs at a potential slightly more anodic than the rest potential, but that corresponding to the new surface configuration brought about by cathodic current). Thereafter the light potential begins to fall off and for a decade or so of current density does so in parallel with the dark potential. In this range, increments of overpotential fall largely across the space-charge region. At still higher current densities an increasing fraction of the applied overpotential falls across the interface, with the consequence that the chemical state of the surface becomes more drastically altered—conceivably, surface As atoms are removed as arsine, leaving a Ga surface—and the light potential approaches the dark. Eventually, the semiconductor nature of the p-type GaAs is no longer manifest in its cathodic behavior.

Remarks

Certain difficulties experienced in studies of gallium arsenide electrochemistry stem from the compound nature of the electrode material; in most instances it probably does not make sense to think in terms of the composition GaAs in the immediate vicinity of the interface with the electrolyte. That is, one must consider that the existence of a surface layer with Ga/As atom ratio different from unity is the probable state of affairs. Thus, the usual picture of the Helmholtz layer may not be adequate for the electrode side of the interface.

The indistinguishability in polarization behavior of the (111) and $(\bar{1}\bar{1}\bar{1})$ surface orientations may be related to the factor just mentioned. There is also the likelihood, as mentioned earlier, that as a consequence of preferential etching, little of the real surface retains the (111) or $(\bar{1}\bar{1}\bar{1})$ orientation. Finally, as suggested by Gerischer (7) to explain similarities in anodic behavior, dismantling of the crystal by anodic reaction probably proceeds by removal of Ga and As atoms in pairs rather than singly.

There are serious discrepancies in the literature regarding the participation of holes in GaAs electrode processes. A photoinjection method indicated that 2.8-4.0 holes (4) are required per GaAs unit entering the electrolyte at the limiting anodic current. On the other hand, studies based on the redox method developed by Gerischer and Beck (16) for germanium give variously 1-6 (6) and 6 (7) for the same quantity.

A great deal more knowledge has to be gained before the contributions of different possible sources to the supply of minority carriers can be sorted out. Probably generation-recombination in the field of the space charge region is more important than in the volume, but the relative importance of thermal generation-recombination at the surface is not known. Some results presented here point to trapping as a factor in the charge distribution, whereas other authors have invoked field-induced ionization of deep lying impurities. In short, it may not be profitable to attempt to fit the electrochemical behavior of compound semiconductors wholly within the simple model which works well for germanium.

Acknowledgments

The author is indebted to M. J. Redman for solubility measurements of gallium compounds, to A. N. Mariano for x-ray work and optical goniometry, to E. J. Moreau for metallography, and to M. R. Randlett for gold sputtering. The assistance of A. E. Clark with the experimentation is gratefully acknowledged.

Note added in proof: Since this paper was written, two items of especial pertinence have appeared in the literature. It has been reported that $-\Delta G^\circ_{298}$ for GaAs is of the order of 9 kcal/mole [A. S. Abbasov *et al.*, *Doklady Akad. Nauk S.S.S.R.*, **170**, 1110 (1966)]. Hence, the standard oxidation potentials of Table II are too positive by $0.26/n$ v, where n is 3, 6, or 8. Recently, Gerischer and Mattes [*Z. physik. Chem. Neue Folge*, **49**, 112 (1966)] have demonstrated convincingly the attainability of electron-limited currents with p-GaAs cathodes. Observations of others to the contrary are probably not ascribable to cathodically produced electron-hole generation centers, as may form on Ge cathodes. Very likely, it will be found that certain techniques of producing contacts to the back surface result in obliteration of the inherent limiting current.

Manuscript received Nov. 23, 1966. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Transient Response of Chemically Interacting Solid-Gas Systems

I. Theoretical Considerations

Seong T. Hwang and G. Parravano

Department of Chemical and Metallurgical Engineering, University of Michigan, Ann Arbor, Michigan

ABSTRACT

The transient response of the rate of a surface reaction between gas and solid phases is discussed mathematically. The over-all reaction is assumed to be the results of two elementary steps: adsorption of reactants and desorption of products. Expressions for the nonsteady rates of the two steps are derived and applied to the case of simultaneous occurrence of both steps. This results in a surface catalyzed reaction. It is shown how the analysis of the transient response permits the determination of some of the fundamental parameters of the elementary steps including the values of the step rate constant, the nature and concentration of the adsorbed intermediates. The contribution of nonsteady state kinetics to the elucidation of basic problems on the reactivity of solid surfaces is outlined.

The elementary steps of solid-gas reactions involve physical and chemical phenomena taking place at different rates. This is particularly valid for chemical changes occurring at a phase boundary, since the peculiar environment and structure of a phase boundary provides a wider spectrum of possibilities and conditions. Thus, a range of reaction relaxation times is to be expected in heterogeneous kinetics: from rapid electronic transitions, to slow transfer of atoms or ions among surface positions, and between surface and bulk phases. A detailed study of these various processes is a formidable, but necessary task for reaching a comprehensive understanding of heterogeneous and surface processes.

In the past, studies have been performed on the nonsteady rate of reaction of FeO in CO_2-CO and H_2O-H_2 mixtures (1) and of decomposition of HCOOH on Pd (2). In general, relatively high temperatures are preferred for these investigations, since the identification of the physical process corresponding to the measured relaxation times may be carried out with more confidence.

In view, however, of the fact that many surface reactions, mostly catalytic, take place at lower temperatures with fast rates, it is pertinent to inquire how far the pattern of physicochemical behavior emerging from high-temperature studies can be extrapolated to the lower temperatures of interest. To investigate this problem and to find out the extent to which low-temperature results may be utilized to extract meaningful information about surface-gas interactions, we have analyzed theoretically the transient response of chemically interacting solid-gas systems and performed experimental investigations to test the theoretical analysis.

Two considerations guided the present effort: first, the scattered but extensive literature reports of initial drifts of surface activity of many solids used as catalysts; in some cases, the direction of the activity change with time was qualitatively related to and found consistent with the reaction scheme derived from steady state velocity information (3); second, a close scrutiny of the nonsteady state behavior should be of great interest for mechanistic studies in hetero-

geneous and surface reactions since the reactivity of the phase boundary is greatly influenced by chemical interactions with the surrounding phase occurring during the establishment of the reaction steady state.

The nonsteady state discussed in this work is characterized by the time dependence of the reaction conversion, resulting from a forced perturbation of one of the reaction parameters under conditions of negligible kinetic influence of mass and heat transfer effects. The present communication summarizes the theoretical derivations and their use to obtain information on the value of the rate constants of some of the elementary reaction steps and upon the nature of the reaction intermediates. In the following communication (4) the application of the analysis to experimental results is outlined.

Description of the Model

Consider an ionic solid, MX, whose nonmetallic component is assumed to be in the form of X^{-2} ions, interacting with gas phase molecules AX and B, according to the equations

$$AX(g) + MX\ \text{surface} \underset{\overleftarrow{k_1}}{\overset{\vec{k_1}}{\rightleftharpoons}} A(g) + X_a \qquad [1]$$

$$B(g) + X_a \underset{\overleftarrow{k_2}}{\overset{\vec{k_2}}{\rightleftharpoons}} BX(g) + MX\ \text{surface} \qquad [2]$$

where X_a represents species adsorbed on the MX surface. Simultaneous occurrence of reactions steps [1] and [2] yields the over-all catalytic reaction

$$AX(g) + B(g) \rightleftarrows A(g) + BX(g) \qquad [1a]$$

Two points are noteworthy in connection with this model: (*a*) the individual reaction steps [1] and [2] modify the stoichiometry and, thus, the metal/nonmetal ratio of MX; and (*b*) this ratio is influenced by X_a only and not by the adsorption of any other species (reactants and/or products).

As was shown previously (5), the rates of reactions [1] and [2] may be plotted as a function of the nonmetal/metal ratio of the catalyst (Fig. 1). This ratio, expressing the influence of the surface on the reactivity of the system, constitutes a reaction variable, together with the partial pressure of the gas phase components. If it is assumed that the total surface concentration of X, $[X_{aT}]$, remains unchanged during the reaction steady state, $\dot{X}_{aT} = 0$, it is possible to state that the numerical difference between the rates of reactions [1], $\dot{X}_a(1)$, and [2], $\dot{X}_a(2)$, gives the net rate of change of the surface concentration of X, $\dot{X}_{aT} = \dot{X}_a[1] - \dot{X}_a[2]$. If reaction [1a] is carried out with constant partial pressures $(p^o_{AX})_1$ and $(p^o_B)_1$ in a flow system, the steady state condition is represented by point A (Fig. 1). Modification of the reactant partial pressures to $(p^o_{AX})_2$ and $(p^o_B)_2$ produces a new steady state (point E, Fig. 1), corresponding to a different value of the nonmetal/metal ratio of the solid.

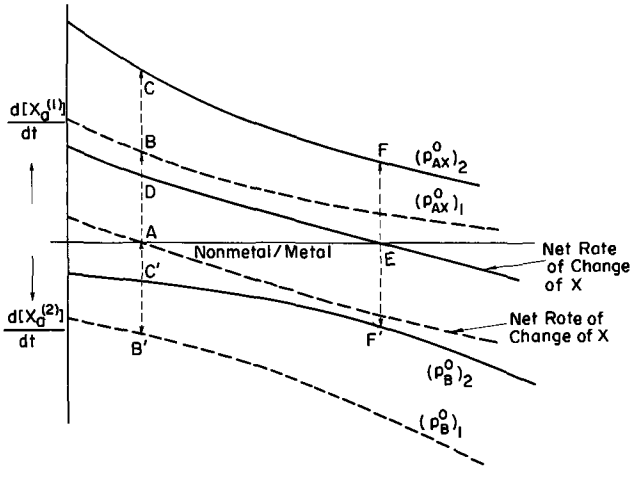

Fig. 1. Adsorption and desorption rates of X_2 *vs.* nonmetal-to-metal ratio in MX, $p^o_{AX_2} > p^o_{AX_1}$, $p^o_{AX_1} + p^o_{B_1} = p^o_{AX_2} + p^o_{B_2}$

Nonsteady-State Reaction Kinetics

The total amount of reaction intermediate which at any time is adsorbed on the MX surface is given by the algebraic sum of the amounts initially present, $X_a(i)$, and those resulting from reaction [1], $X_a[1]$ and reaction [2], $X_a[2]$

$$X_{aT} = X_a(i) + X_a[1] + X_a[2] \qquad [3]$$

The reaction conversions for step [1] α_1, and step [2], α_2, are defined as

$$\alpha_1 = \frac{p_A}{p^o_{AX}} = \frac{X_a[1]}{hp^o_{AX}} = \frac{p^o_{AX} - p_{AX}}{p^o_{AX}} \qquad [4]$$

$$\alpha_2 = \frac{p_{BX}}{p^o_B} = -\frac{X_a[2]}{hp^o_B} = \frac{p^o_B - p_B}{p^o_B} \qquad [5]$$

where the superscript ^{o} refers to values at time $t = 0$ and h is a suitable constant. Expressing the influence of the surface on the reaction rate by means of the surface coverage, θ, the latter becomes for the reaction step [1] θ_1 and [2] θ_2

$$\theta_1 = \frac{X_a(i) + X_a[1]}{S} = \frac{X_a(i) + hp^o_{AX}\alpha_1}{S} \qquad [6]$$

$$\theta_2 = \frac{X_a(i) + X_a[2]}{S} = \frac{X_a(i) - hp^o_B\alpha_2}{S} \qquad [7]$$

where S is the surface area of MX. The rates of steps [1] and [2] may, then, be simply formulated

$$-\frac{dp_{AX}}{dt} = \vec{k}_1\, p_{AX}(1-\theta_1) - \overleftarrow{k}_1\, p_A\, \theta_1 \qquad [8]$$

$$-\frac{dp_B}{dt} = \vec{k}_2\, p_B\, \theta_2 - \overleftarrow{k}_2\, p_{BX}(1-\theta_2) \qquad [9]$$

where $\vec{k}_1$, $\vec{k}_2$, $\overleftarrow{k}_1$, and $\overleftarrow{k}_2$ are the forward and backward rate constants for step [1] and [2], respectively.

Substituting expressions [4], [5], [6], and [7] in Eq. [8] and [9], integrating from $t = 0$ to $t = t$ to obtain the relationships $\alpha_1 = f(t)$ and $\alpha_2 = f(t)$ and substituting the latter in Eq. [8] and [9], the rates of conversion change as a function of time are found to be

$$\frac{d\alpha_1}{dt} = \left[\vec{k}_1\left(1 - \frac{X_a(i)}{S}\right) - \alpha_1{}^o\left(\vec{k}_1\frac{h}{s}p^o_{AX} + \vec{k}_1 - \vec{k}_1\frac{X_a(i)}{S} + \overleftarrow{k}_1\frac{X_a(i)}{S}\right)\right] \exp\left[-\left(\vec{k}_1\frac{h}{S}p^o_{AX} + \vec{k}_1 - \vec{k}_1\frac{X_a(i)}{S} + \overleftarrow{k}_1\frac{X_a(i)}{S}\right)t\right] \qquad [10]$$

$$\frac{d\alpha_2}{dt} = \left[\vec{k}_2\frac{X_a(i)}{S} - \alpha^o{}_2\left(\vec{k}_2\frac{h}{S}p^o_B + \vec{k}_2\frac{X_a(i)}{S} + \overleftarrow{k}_2 - \overleftarrow{k}_2\frac{X_a(i)}{S}\right)\right] \exp\left[-\left(\vec{k}_2\frac{h}{S}p^o_B + \vec{k}_2\frac{X_a(i)}{S} + \overleftarrow{k}_2 - \overleftarrow{k}_2\frac{X_a(i)}{S}\right)t\right] \qquad [11]$$

In the derivation of Eq. [10] and [11], the terms containing α^2 have been neglected, since reaction [1a] proceeds from left to right and the absolute magnitude of the coefficients of the α^2 terms is always smaller than that of the linear terms in α. Furthermore for small values of the reaction conversion $\alpha^2 << \alpha$. Equations [10] and [11] represent the time variation of the rate of reaction conversion during the nonsteady rate period and may, therefore, be used to characterize the nonsteady state rate of reaction steps [1] and [2].

The linear plot of the logarithms of the rate of change of reaction conversion *vs.* time gives (for step [1])

$$\text{slope} = \vec{k}_1 \frac{h}{S} p^{o}_{AX} + \vec{k}_1 - \vec{k}_1 \frac{X_a(i)}{S} + \overleftarrow{k}_1 \frac{X_a(i)}{S} \quad [12]$$

$$\text{intercept} = \alpha^{o}_1 \left(\vec{k}_1 \frac{h}{S} p^{o}_{AX} + \vec{k}_1 - \vec{k}_1 \frac{X_a(i)}{S} + \overleftarrow{k}_1 \frac{X_a(i)}{S} \right) - \vec{k}_1 \left(1 - \frac{X_a(i)}{S} \right) \quad [13]$$

A similar, two equation system is obtained for reaction step [2]. Under the experimental conditions generally employed in surface studies (see following paper) (4) $\overleftarrow{k}_1 \frac{X_a(i)}{S} << \vec{k}_1 \frac{h}{S} p^{o}_{AX}$, and the terms in $\overleftarrow{k}_1$ and $\overleftarrow{k}_2$ in the slopes and intercepts of the linear plots of Eq. [10] and [11] may be neglected. Consequently, from systems of equations of the type of [12] and [13] it is possible to evaluate $\vec{k}_1$, $\vec{k}_2$, $X_a(i)$, S and h.

Reaction Intermediates

The problem of deriving information on the chemical nature of the surface intermediate X_a is dependent on the model of the reactive surface used. If the catalytic solid is an ionic (or partly ionic) compound, a logical choice for the surface centers responsible for surface reactivity are point defects, ionic and/or electronic. This assumption permits the formal discussion of surface defect reactions in a manner similar to that employed for the crystal interior. It is, however, necessary to distinguish between two sets of conditions under which the surface chemical equilibrium between adsorbed species and the solid is: (*a*) rapidly established in relation to the time constant of the rate experiments; (*b*) not rapidly established. In the first instance, it is possible to apply the mass action expression to surface defect reactions, while this will not be possible in the second instance. The latter case corresponds to the formation of a surface space charge layer of thickness considerably larger than ionic radii.

The chemical nature of the reaction intermediate is directly related to the type of surface bonding between adsorbent and adsorbate during reaction [1a]. We shall discuss the instance in which adsorbed X species are considered to occupy surface positions equivalent to normal lattice sites, even though some of the neighboring atoms may be missing. To express this in a simple fashion one may consider three limiting cases: neutral X_a, singly charged ion X_a^{-1}, and doubly charged ion X_a^{-2}. Whenever equilibria between adatoms and surface sites are established, the following reactions should be considered

$$X_{aT} + 2e^- = X^{-2} \quad \text{(n-type)} \quad [14]$$

$$X_{aT} = X^{-2} + 2e^+ \quad \text{(p-type)} \quad [15]$$

$$X^{-}{}_{aT} + e^- = X^{-2} \quad \text{(n-type)} \quad [16]$$

$$X^{-}{}_{aT} = X^{-2} + e^+ \quad \text{(p-type)} \quad [17]$$

Since X^{-2} ions are the constituents of the MX lattice, in large excess and randomly distributed, it is justifiable to set $[X^{-2}] \cong$ constant. From reaction equilibria [14] to [17], one obtains

$$[X_{aT}] = K_{14} \frac{1}{n^2_{e-}} \quad \text{(n-type)} \quad [18]$$

$$[X_{aT}] = K_{15}\, n^2_{e+} \quad \text{(p-type)} \quad [19]$$

$$[X_{aT}^{-1}] = K_{16} \frac{1}{n_{e-}} \quad \text{(n-type)} \quad [20]$$

$$[X_{aT}^{-1}] = K_{17}\, n_{e+} \quad \text{(p-type)} \quad [21]$$

where K_{14} to K_{17} are the equilibrium constants of reactions [14] to [17] and n_{e-}, n_{e+} are the concentrations of excess electrons and electron holes, respectively. Equations [18] to [21] relate the concentration of the adsorbed intermediate, as X_a or X_a^{-1}, to the electron or hole concentration. If the adsorbed intermediate is present as X_a^{-2} ions, it is clear that the concentration of the latter will not be dependent on the electron or hole concentrations.

If reaction equilibria [14] to [17] do not occur rapidly, it is possible to obtain the relations between the concentrations of the intermediate and excess electrons or electron holes by means of the condition of electrical neutrality for any volume element of the solid, including the surface

$$[X_{aT}^{-1}] = C\,(n_e^{o} - n_{e-}) \quad \text{(n-type)} \quad [22]$$

$$[X_{aT}^{-1}] = C'\,(n_{e+} - n^{o}_{e+}) \quad \text{(p-type)} \quad [23]$$

$$[X_{aT}^{-1}] = \frac{C}{2}\,(n^{o}_{e-} - n_{e-}) \quad \text{(n-type)} \quad [24]$$

$$[X_{aT}^{-2}] = \frac{C'}{2}\,(n_{e+} - n^{o}_{e+} \quad \text{(p-type)} \quad [25]$$

where C, C' are appropriate constants. In this instance if X_a is present as a neutral species, $[X_a]$ becomes independent of n_{e-} and n_{e+}.

By means of Eq. [3], [10], and [11], it is possible to derive an expression between the total amount adsorbed, X_{aT}, and the sum of the rates of conversion change: $(d\alpha_1/dt) + (d\alpha_2/dt)$. Substitution in this latter expression of the appropriate Eq. [18] to [25] permit the development of a series of relationships between reaction conversion and electron or hole concentration. These expressions are unique for each of the various cases discussed and may be used as a criterium for evaluating the role of the three intermediates considered. The detailed derivations are presented elsewhere (6), while the results are schematically plotted in Fig. 2 and 3. The graphs show that the various possibilities arising from: (*a*) electronic nature of surface (p- or n-type), (*b*) presence or absence of surface space charge, and (*c*) chemical nature of the adsorbed intermediate, may be uniquely distinguished. In addition to the cases reported in Fig. 2 and 3, it should be recalled that whenever the intermediate is the neutral species X_a and surface-bulk equilibria are not readily set up, $[X_a]$ is independent on the activity of electrons or holes, while a similar situation arises for the reaction intermediate X_a^{-2} whenever surface-bulk equilibria are readily established. Cases intermediate among those considered are characterized between the appropriate limiting possibilities. Thus, nonsteady-state kinetic results may be used to arrive at definite information on the nature of the reaction intermediates, its concentration, and its bonding characteristics.

Physical Quantities Required for the Application of the Derived Expressions

The graphical representation of the rate equations for the various conditions considered (Fig. 2 and 3) permits the interpretation of nonsteady rates in terms

$$B = \frac{p^{\circ}_{AX}\frac{h}{S}\left[\vec{k}_1\left(1-\frac{X_i}{S}\right)-\frac{d\alpha_1}{dt}\right]}{\frac{\vec{k}_1 h}{S}p^{\circ}_{AX}+\vec{k}_1-\vec{k}_1\frac{X_i}{S}+\overleftarrow{k}_1-\frac{X_i}{S}} + \frac{p^{\circ}_{B}\frac{h}{S}\left(\frac{d\alpha_2}{dt}-\vec{k}_2\frac{X_i}{S}\right)}{\frac{\vec{k}_2 h}{S}p^{\circ}_{B}+\vec{k}_2\frac{X_i}{S}+\overleftarrow{k}_2-\overleftarrow{k}_2\frac{X_i}{S}}$$

of the reaction models discussed. It is, therefore, of interest to point out the experimental measurements needed for the application of the theoretical analysis.

At the outset it is necessary to set up a reaction steady state to define the initial surface coverage of the solid phase [$X_a(i)$]. This is done in a flow reactor by establishing well-defined experimental conditions of partial pressures, flow rate, and temperature. The set of conditions defines an arbitrary, but reproducible steady state, reaction conversion, and surface concentration of intermediate species. Subsequently, a condition of nonsteady-state rate of reaction is obtained by perturbing through a step change one of the reaction variables, the most suitable being the partial pressures of one or both of the reagents without modifying the total pressures. During the nonsteady period, the conversion of AX and B is followed by chemical or equivalent analytical method. Simultaneously, the variation of the concentration of electrons (or electron holes) in the solid is determined by means of a convenient technique (electrical conductivity, thermoelectric power). Thus, the experimental values of α_1, α_2, n_{e^-}, n_{e^+} as a function of time can be introduced into Eq. [10] and [11], and plots similar to Fig. 2 and 3 may be drawn. Comparison between the theoretical and experimental slopes of the linearized plots permits the determination of the correct model of the reaction and reaction intermediates. The time range used in performing the perturbation and in following the response of the system determines the kind of phenomena which are recorded. Thus, if one confines the perturbation time in the milli or microsecond range and records the system response within a similar space of time, elementary steps of electron transfer, rearrangement, and excitation are likely to be observed and studied. On the other end, longer transient and response times are related to slow activated transfer of matter across, along and beyond the phase boundary.

Conclusions

The study of the conversion of a surface reaction during nonsteady-state conditions together with the simultaneous determination of the electron or hole concentration of the catalyst may be used to obtain information on the nature of the reaction intermediates, of the surface bonding and reactivity. This knowledge is the basis for a rational approach to the understanding of surface reaction, and of phenomena related to surface reactivity, namely, surface heterogeneity, promotion, poisoning, and doping effects.

Transient Response of Chemically Interacting Solid-Gas Systems

II. Reduction Oxidation Reactions on Cobalt Ferrite

Seong T. Hwang and G. Parravano

Department of Chemical and Metallurgical Engineering, University of Michigan, Ann Arbor, Michigan

ABSTRACT

The transient behavior of the reacting system: $N_2O + CO \rightarrow N_2 + CO_2$ on cobalt ferrite, $CoFe_2O_4$, was studied experimentally by perturbing the reaction steady state with a rapid variation in the N_2O and CO partial pressures, at 190° and 300°C. To follow the nonsteady behavior, measurements were carried out on the time dependence of the reaction conversion and of the thermoelectric power of the sample. The latter quantity was used to calculate the variation of excess or defect electron concentration of the sample during the transient state. Two ferrite samples were used: $Co_{0.994}Fe_{2.006}O_4$ (n-type) and $Co_{1.097}Fe_{1.903}O_4$ (p-type). The experimental results have been analyzed according to the treatment of nonsteady reaction rates presented in the previous communication. The analysis showed that at 300°C the oxygen, adsorbed on the cobalt ferrite surface during reaction, is in the form of neutral oxygen atoms, O, for n-type cobalt ferrite, and intermediate between neutral oxygen and singly ionized oxygen ions, O^-, for p-type samples. At 190°C, adsorbed oxygen is wholly in the form of O^- ions. The results are discussed in the light of previous studies on the structure and surface reactivity of $CoFe_2O_4$.

In the previous communication (1) expressions for the nonsteady state of solid-gas reactions have been derived and the treatment has been aimed at obtaining information on the nature of the intermediate species formed at the surface as a result of the heterogeneous reaction. In order to apply the theoretical considerations to a practical situation, we have studied the nonsteady rate of oxidation of $CoFe_2O_4$ with N_2O and reduction with CO. It is assumed that the reduction and oxidation steps may be represented by

$$N_2O_{(g)} + \text{Surface} \rightarrow N_{2(g)} + O_{(ads)} \quad [1]$$

$$CO_{(g)} + O_{(ads)} \rightarrow CO_{2(g)} + \text{Surface} \quad [2]$$

The measurements were carried out with reaction steps [1] and [2] occurring simultaneously by using a gas mixture of N_2O + CO. The nonsteady rates of reaction steps [1] and [2] were followed by measuring the conversions to N_2 and CO_2. The kinetic analysis (1) of the transient behavior permitted the independent determination of the forward rate constants of steps [1] and [2].

Under steady-state conditions, the rates of steps [1] and [2] are equal, and the surface acts as a true catalytic agent.

The choice of $CoFe_2O_4$ was dictated by the possibility of producing ferrite phases with excess or defect electrons without the need to introduce doping agents or drastic variations in the chemical composition of the catalyst. The preparation of cobalt ferrite phases with excess or defect of electrons is simply obtained by modifications of the Co/Fe ratio (2). The electronic structure of $CoFe_2O_4$ has been investigated in detail, and as a result measurements of thermoelectric power may be used to follow the concentration of excess or defect electrons during reaction conditions. It is then possible to throw light on the interesting question of the relation between the nature of the reaction intermediate, surface reactivity and electronic structure of the solid.

Experimental

Materials.—$CoFe_2O_4$ was prepared by means of standard ceramic techniques, involving three successive firings and ball millings. Two samples with final compositions of $Co_{0.994}Fe_{2.006}O_4$ (n-type) and $Co_{1.097}Fe_{1.903}O_4$ (p-type) were prepared. Compositions were determined by chemical and x-ray fluorescence analysis.

The finished spinel powder was pressed at 24,000 psig into cylindrical samples and sintered at 1130°C for 12 hr in air. The sintered samples (particle size $\approx 10\mu$) were air cooled and ground with disk emery paper to obtain slabs having dimensions of 7/16 x 1/32 x 13/16 in. Electrical contacts to the samples were made by coating both ends with "liquid bright gold," and subsequent heating to about 600°C to decompose the solvent. N_2O, CO, and O_2, from commercial cylinders, (prepurified grade) were dried before use. CO was passed through Ascarite and He through CuO (350°C) and a charcoal trap cooled with dry ice.

Apparatus.—The ferrite slab was supported in the reaction vessel by two pieces of 2 mm bore capillary tubings, grooved at each end to hold the sample tightly in place. Au foils were mounted at each end between the capillary tubing and the slab, and the ends were pressed firmly by Au plated springs, hung between the support and the capillary tubing. The temperature gradient across the sample, generally between 2°-3°C, was controlled by a secondary Au heating coil wound on the outside of the capillary tubing. The thermoelectric emf was measured by Au wire leads, spot welded on each Au electrode. Temperatures at both ends of the sample were measured by chromel-alumel thermocouples, spot welded to each Au foil. The thermoelectric emf for temperature indication was measured with a potentiometer and a d-c null detector, while the thermoelectric power of the sample was obtained with a d-c microvoltammeter.

Procedure.—A sketch of the apparatus is shown in Fig. 1. Gases from the purification train passed through flowmeters and into the reactor-thermoelectric power cell. CO_2 was collected in two wash bottles in series, containing a known amount of a 0.1*N* $Ba(OH)_2$ solution. N_2 was analyzed by gas chromotography. A solenoid valve was used to obtain a stepwise change in the partial pressures of the reactants during the nonsteady-state experiments. The total pressure of the system was always maintained at 1 atm.

In the adsorption and desorption experiments, He was passed through the reaction vessel until the sam-

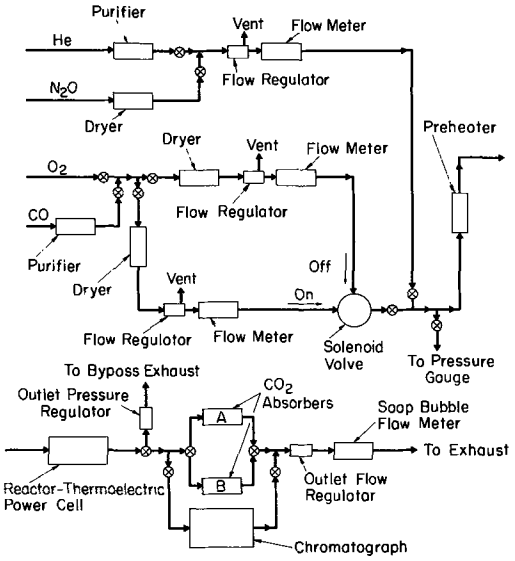

Fig. 1. Apparatus used for nonsteady-state rate experiments

ple thermoelectric power reached a constant value. O_2 was then introduced into the stream and the variation in the thermoelectric power as a function of time was noted. For reaction rate experiments the conversions of N_2O and CO, the thermoelectric emf and temperatures at both ends of the catalyst were measured as a function of time. The total pressure and flow rate were kept constant before and after the stepwise change in the partial pressures of the reactants. Thermoelectric power and conversion changes could be returned to the initial values whenever the original ratio of reactant gas partial pressures was restored around the sample.

Additional details on the materials and procedures used are recorded elsewhere (3).

Experimental Results

Preliminary investigations showed that the thermal emf was a linear function of the temperature gradient, ΔT, with ΔT values up to 24°C, and that for $\Delta T = 0$, a small emf was present (Fig. 2). This error does not directly influence the thermoelectric power measurements, and no effort was made to eliminate it. The values of the thermoelectric power during O_2 adsorption and desorption is shown in Fig. 3 and 4. The results indicated a decrease in thermoelectric power of both samples on O_2 adsorption, suggesting that the concentration of excess electrons decreased in the n-type sample (Fig. 3), while that of electron holes increased in the p-type sample (Fig. 4). From previous work (2a), it was claimed that $CoFe_2O_4$ be-

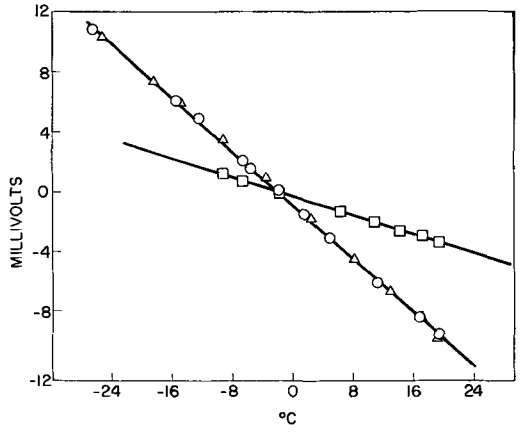

Fig. 2. Thermoelectric emf vs. temperature differences in various gases for $Co_{0.994}Fe_{2.006}O_4$; T (average), 300°C; total pressure, 1 atm; □, He; △, O_2; ⊙, air.

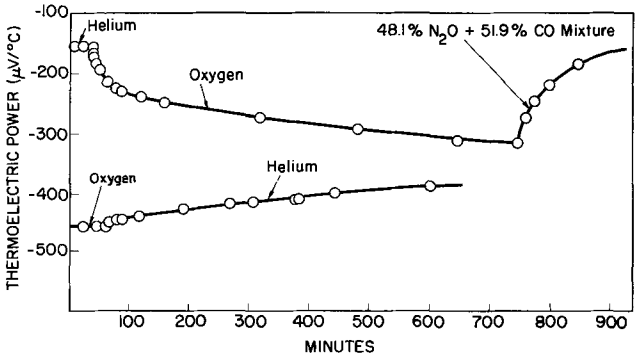

Fig. 3. Thermoelectric power of $Co_{0.994}Fe_{2.006}O_4$ vs. time in He, O_2, and N_2O + CO mixture; T, 300°C; total pressure, 1 atm.

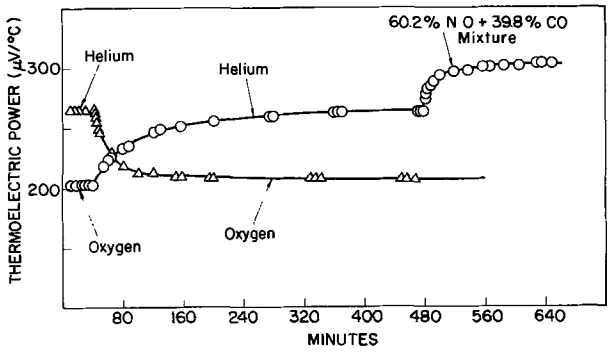

Fig. 4. Thermoelectric power of $Co_{1.097}Fe_{1.903}O_4$ vs. time in He, O_2, and N_2O + CO mixture; T, 300°C; total pressure, 1 atm.

comes a two carrier semiconductor in air at > 160°C. This fact was confirmed in subsequent observations on the variation of thermoelectric power of $CoFe_2O_4$. On n-type samples it was found that O_2 adsorption at 250°C decreased at first the negative thermoelectric power. Upon further adsorption, the samples became p-type and the positive thermoelectric power increased with O_2 adsorption. The results reported on Fig. 3 show that at 300°C, O_2 adsorption increased the negative thermoelectric power of an n-type sample in apparent contrast with the previous observations. Similar considerations apply to the results reported in Fig. 4. Apparently, the temperature of the transition between single to double carrier behavior depends critically on sample composition, particularly near the minimum and maximum values of the thermoelectric power. Introduction of a mixture of 48.1% N_2O + CO into the reactor during the chemisorption experiments produced changes in the thermoelectric power of the sample in the direction of increasing the concentration of electrons for n-type (Fig. 3), or in the direction of decreasing the concentration of electron holes for p-type (Fig. 4).

The rates of reactions [1] and [2] were not influenced by the gas flow rate within the range used in the nonsteady-state experiments, 18 to 40 cc/min (Fig. 5).

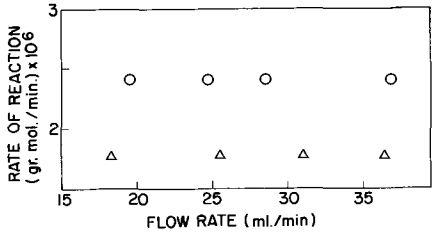

Fig. 5. Rate of reaction vs. flow rate, T, 300°C; p_{N_2O}, 0.398 atm; p_{CO}, 0.602 atm; ⊙, $Co_{0.994}Fe_{2.006}O_4$; △, $Co_{1.097}Fe_{1.903}O_4$.

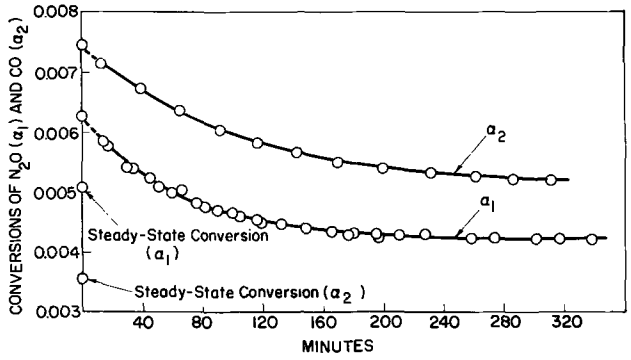

Fig. 6. Conversions of N_2O and CO vs. time after a stepwise change in partial pressures, for $Co_{0.994}Fe_{2.006}O_4$; initial steady state $p°_{N_2O}$ = 0.410 atm; $p°_{CO}$ = 0.590 atm; final values p_{N_2O} = 0.605 atm; p_{CO} = 0.395 atm; T, 300°C.

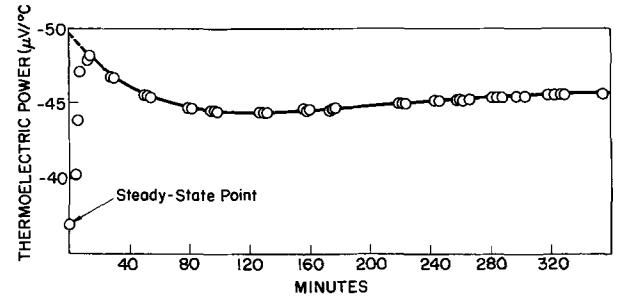

Fig. 7. Change of thermoelectric power as a function of time after a stepwise change in partial pressures for $Co_{0.994}Fe_{2.006}O_4$; initial steady state: $p°_{N_2O}$ = 0.590 atm; $p°_{CO}$ = 0.590 atm; final values: p_{N_2O} = 0.605 atm; p_{CO} = 0.395 atm; T, 300°C.

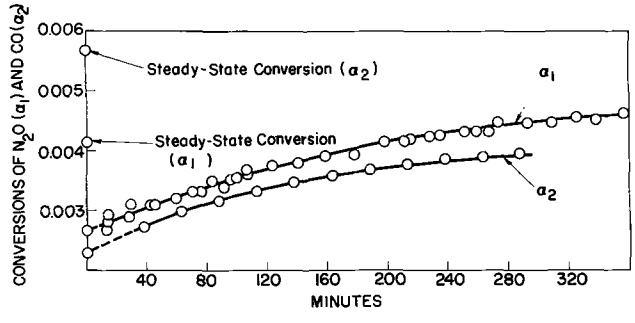

Fig. 8. Conversions of N_2O and CO vs. time after a stepwise change in partial pressures for $Co_{0.994}Fe_{2.006}O_4$; initial steady state: $p°_{N_2O}$ = 0.578 atm, $p°_{CO}$ = 0.422 atm; final values: p_{N_2O} = 0.402 atm; p_{CO} = 0.598 atm; T, 300°C.

After the establishment of a reaction steady state, nonsteady-state conditions were obtained by a stepwise perturbation of partial pressures of both reactants at the same total pressure, temperature, and flow rate which prevailed at the steady-state conditions. Figure 6 shows the conversions of N_2O and CO, defined as

$$\alpha_{N_2O} = (p°_{N_2O} - p_{N_2O})/p°_{N_2O} = p_{CO_2}/p°_{N_2O},$$

$$\alpha_{CO} = p_{CO_2}/p°_{CO}$$

where the superscript o refers to initial steady-state conditions, and Fig. 7 gives the values of the thermoelectric power as a function of time for the n-type ferrite at a temperature of 300°C, when p_{N_2O} and p_{CO} were changed from 0.410 and 0.590 atm (steady-state conditions) to 0.605 and 0.395 atm.

Figures 8 and 9 show the results for the same ferrite samples subjected to changes in p_{N_2O} from 0.578 to 0.402 atm, and in p_{CO} from 0.422 to 0.598 atm.

Figures 10 and 11 present reaction conversions and thermoelectric power as functions of time for the

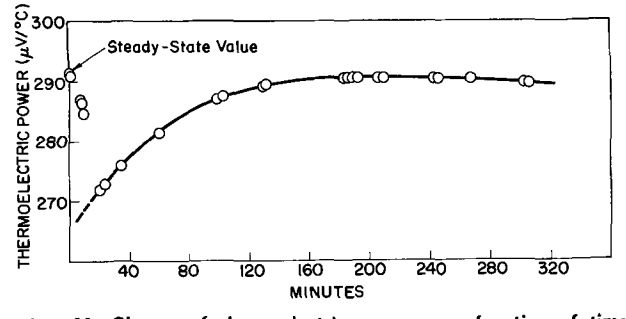

Fig. 11. Change of thermoelectric power as a function of time after a stepwise change in partial pressures for $Co_{1.097}Fe_{1.903}O_4$; initial steady state: $p°_{N_2O}$ = 0.397 atm, $p°_{CO}$ = 0.603 atm; final values: p_{N_2O} = 0.599 atm, p_{CO} = 0.40 atm; T, 300°C.

p-type ferrite sample at a temperature of 300°C, when p_{N_2O} and p_{CO} were changed from 0.397 and 0.603 atm (steady-state values) to 0.599 and 0.401 atm, respectively.

Figures 12 and 13 present similar results for the p-type sample at a temperature of 190°C.

Discussion

By graphical differentiation of the experimental results, the values of $\ln(d\alpha_1/dt)$ and $\ln(d\alpha_2/dt)$ were calculated as a function of time, and are plotted in Fig. 14, 15, 16, and 17. The plots show that the straight-line relation, required by Eq. [10] and [11] in the preceding paper, is well obeyed. The analytical treatment of these equations requires that the condition $\overleftarrow{k}_1 \frac{X_a(i)}{S} << \vec{k}_1 \frac{h}{S} p°_{N_2O}$ be obeyed. In this expression $\overleftarrow{k}_1 X_a(i)$, S, and h are the step rate constant, the amount of adsorbed intermediate initially present, the surface area, and a constant, respectively. Typical re-

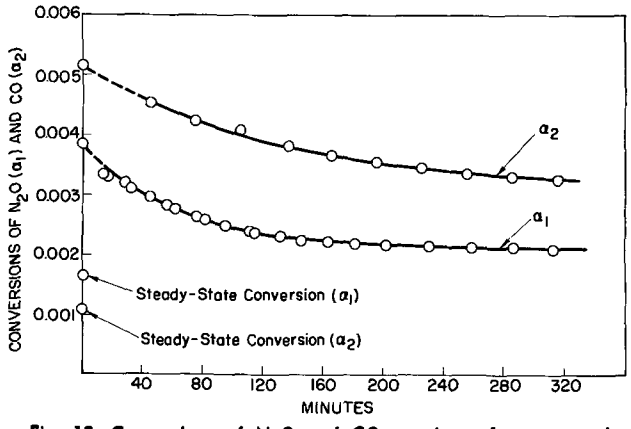

Fig. 12. Conversions of N_2O and CO vs. time after a stepwise change in partial pressures for $Co_{1.097}Fe_{1.903}O_4$; initial steady state: $p°_{N_2O}$ = 0.396 atm; $p°_{CO}$ = 0.604 atm; final values: p_{N_2O} = 0.603 atm, p_{CO} = 0.397 atm; T, 190°C.

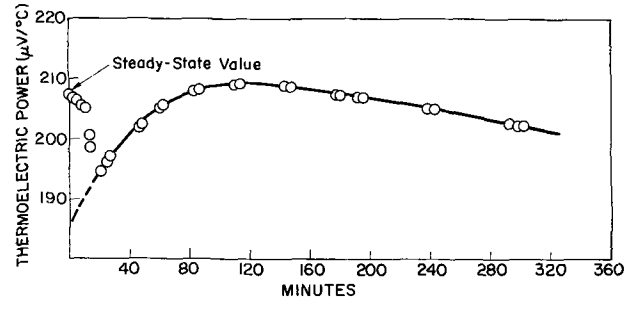

Fig. 13. Change of thermoelectric power as a function of time after a stepwise change in partial pressures for $Co_{1.097}Fe_{1.903}O_4$; initial steady state: $p°_{N_2O}$ = 0.396 atm, $p°_{CO}$ = 0.604 atm; final values: p_{N_2O} = 0.603 atm, p_{CO} = 0.397 atm; T, 190°C.

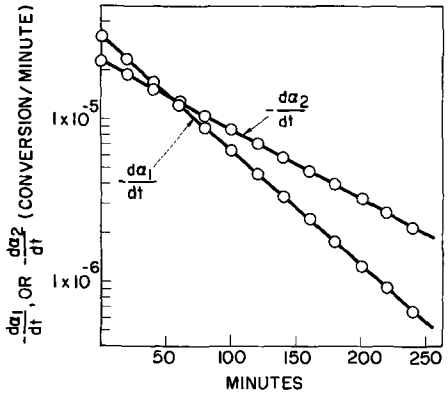

Fig. 14. Rate of change of conversion of N_2O or CO as a function of time for $Co_{0.994}Fe_{2.006}O_4$; initial steady state: $p°_{N_2O}$ = 0.410 atm, $p°_{CO}$ = 0.590 atm; final values: p_{N_2O} = 0.605 atm, p_{CO} = 0.395 atm; T, 300°C.

sults (3) at 300°C show that $\vec{k}_1 \frac{h}{S} p°_{N_2O} + \overleftarrow{k}_1 \frac{X_a(i)}{S}$ = 0.01618 and $\vec{k}_1 \left(1 - \frac{Xa(i)}{S}\right) = 6.85 \times 10^{-5} > \frac{X_a(i)}{S} \overleftarrow{k}_1$. Thus, the above condition is satisfied. Although no generalization about the validity of this condition is possible and each case must be verified, it is clear that the condition will always be satisfied provided that h is made large enough (large reactor volume). By means of the values of the calculated slopes and intercepts of the plots in Fig. 14 to 17, it is possible to obtain the numerical values of $\vec{k}_1$ and $\vec{k}_2$, the forward rate constants for steps [1] and [2], and of

the initial surface coverage with adsorbed oxygen, θ, for the various experimental conditions. The results of the calculations are collected in Table I.

The calculation of the initial surface coverage $\theta = \frac{X_a(i)}{S}$, reported in Table I, is based on information on S, the total catalytic surface available, as determined directly from the rate measurements. It is instructive to compare the value of S obtained from the rate experiments with that directly determined by BET measurements. From the present results, the following values of h/S (atm^{-1}) were calculated: 218.7 (n-type, 300°C), 384.9 (p-type, 300°C), 401.0 (p-type, 190°C). Since $h = \frac{V}{RT} = \frac{201.5}{82.06 \times 573} = 4.28 \times 10^{-3}$ (g atoms/atm), where 201.5 is the reactor volume in cc, then, $S = h/218.7 = 1.958 \times 10^{-5}$ g atom. Taking the cross-sectional area of an adsorbed oxygen atom equal to 13.5Å (2), we obtain $S = 6.02 \times 10^{23} \times 1.98 \times 10^{-5} \times 13.5 \times 10^{-20} = 1.62$ m^2 which corresponds to a specific surface area of (1.62/1.94) = 0.833 m^2/g, to be compared to a value of 0.850 m^2/g from BET measurements. Similar calculations for the other catalysts are collected in Table II.

The comparison between the two sets of values is satisfactory, and it may be taken as supporting evidence for the reaction scheme and kinetic derivation presented. It should be noted that the value A_K is temperature dependent. This is a result of the method of derivation used.

By means of the plots presented in Fig. 2 and 3 of the preceding paper (1), it is possible to obtain information on the chemical nature of the oxygen intermediate. To this end, the following expressions relating electron concentration to thermoelectric power were used (2a)

$$eQT = -\alpha - \bar{k}T \ln \frac{N}{n_{e-}}, \quad (n_{e-} >> n_{e+}) \qquad [3]$$

$$eQT = \beta + \bar{k}T \ln \frac{N}{n_{e+}}, \quad (n_{e-} << n_{e+}) \qquad [4]$$

where e, Q, N, n_{e-}, n_{e+}, $\bar{k}$, α, and β are the electron charge, the thermoelectric power, the number of ions per cc in $CoFe_2O_4$, the excess electron, and the defect electron (hole) concentrations, the Boltzmann constant, and two constants (2a), respectively. To employ Eq. [3] and [4], the following assumptions must be made: (a) the numerical values of n_{e-} and n_{e+} are small enough to permit the use of Boltzmann statistics; (b) the value of N is constant in the composition range employed; (c) the significant energy levels in $CoFe_2O_4$ include only localized levels for Co^{II} and Fe^{II}, and no normal bands (from oxygen or metal ions) are introduced. Equations [3] and [4] show that the thermoelectric power in $CoFe_2O_4$ is dependent on the concentration of electrons or electron holes, the temperature, and bulk composition. At constant temperature and composition, electron (de)localization accompanying adsorption or desorption of O_2 induces a change in the thermoelectric power of the solid. Since reaction step [1] corresponds to O_2 adsorption, while reaction step [2] corresponds to O_2 desorption, it is conceivable to attribute to these steps the observed variations in thermoelectric power in the course of our experiments with N_2O and CO.

Quantitatively, it was found (7) that the changes in thermoelectric power on adsorption can be described by

$$\frac{(n_e-)_c}{(n_e-)_o} = \exp\left\{\frac{\omega}{\delta}\frac{Q^c - Q^o}{\kappa}\right\} \text{ for } \delta < \omega$$

and

$$\frac{(n_e-)_c}{(n_e-)_o} = \exp\left\{\frac{Q^c - Q^o}{\kappa}\right\} \text{for } \delta \geqq \omega$$

where $(n_e-)_c$, $(n_e-)_o$, Q^c, and Q^o are the electron concentration and thermoelectric power after and before adsorption, respectively, and δ and ω are the thickness of the surface space charge layer and of the thermal gradient, respectively. The value of δ is small (appendix B), but the value of ω is not known. Thus, the application of Eq. [3] and [4] is valid only if $\delta \leq \omega$. If $\delta > \omega$, the application of Eq. [3] and [4] will give an upper limiting value for n_{e-}. It should be recalled that in previous work on the adsorption of O_2 and H_2 on $CoFe_2O_4$ (4) in the same temperature range employed in the present investigation, the condition $\delta \leq \omega$ was found to be valid.

Solving Eq. [3] and [4] for n_{e-}, n_{e+} and substituting the values into Eq. [18] to [25] and [10] and [11] of the preceding paper (1), it is possible to obtain expressions relating the sum of the conversion changes $(d\alpha_1/dt) + (d\alpha_2/dt)$ to the corresponding Q values.

As explained in the previous communication (1), linear plots of the reaction conversion *vs.* Q yield different slopes according to the equation used to characterize surface equilibrium (Eq. [14] to [17] of the preceding communication). Thus, the expected slopes differ for each of the assumed types of surface oxygen.

If surface equilibria are not established during reaction conditions, the analysis will not yield linear plots of the function $\ln (d\alpha/dt) = f(Q)$. In this instance, Eq. [22] to [25] of the preceding communication (1) should be used.

The details of the analysis are reported elsewhere (3), and only a summary of the results is given here. It was found that the experimental results could be easily fitted when the assumption of the establishment of surface equilibria is made. The corresponding mathematical equations relating chemical conversion to thermoelectric power for the two possibilities of neutral surface intermediate O, and singly ionized O^- are:

(a) Neutral surface intermediate, O:

$$\ln \left\{ \frac{p^o_{N_2O}\frac{h}{S}\left[\vec{k}_1\left(1 - \frac{[O]_1}{S}\right) - \frac{d\alpha_1}{dt}\right]}{\vec{k}_1\frac{h}{S}p^o_{N_2O} + \vec{k}_1 - \vec{k}_1\frac{X}{S} + \overleftarrow{k}_1\frac{[O]_1}{S}} + \frac{p^o_{CO}\frac{h}{S}\left(\frac{d\alpha_2}{dt} - \vec{k}_2\frac{[O]_i}{S}\right)}{\vec{k}_2\frac{h}{S}p^o_{CO} + \vec{k}_2\frac{[O]_i}{S} + \overleftarrow{k}_2 - \overleftarrow{k}_2\frac{[O]_i}{S}} + \frac{[O]_i}{S} \right\} = -\frac{2}{3}10^{-8}\frac{e}{Q} + C'_1 \qquad [5]$$

where C'_1 is a constant, and the equation is valid for n- or p-type samples.

(b) Singly charged surface intermediate, O^-:

$$\ln \left[\frac{p^\circ_{N_2O} \frac{h}{S} \left[\vec{k}_1 \left(1 - \frac{[O]_i}{S} \right) - \frac{d\alpha_1}{dt} \right]}{\vec{k}_1 \frac{h}{S} p^\circ_{N_2O} + \vec{k}_1 - \vec{k}_1 \frac{[O]_i}{S} + \overleftarrow{k}_1 \frac{[O]_i}{S}} + \frac{p^\circ_{CO} \frac{h}{S} \frac{d\alpha_2}{dt} - \vec{k}_2 \frac{[O]_i}{S}}{\vec{k}_2 \frac{h}{S} p^\circ_{CO} + \vec{k}_2 \frac{[O]_i}{S} + \overleftarrow{k}_2 - \overleftarrow{k}_2 \frac{[O]_i}{S}} + \frac{[O]_i}{S} \right] = \frac{1}{3} 10^{-8} \frac{e}{k} Q + C'_2 \quad [6]$$

where C'_2 is a constant and the equation is valid for n- or p-type samples. A typical plot of Eq. [5], constructed by means of the experimental results, is presented in Fig. 18. All experimental results could be fitted with either Eq. [5] or [6].

A calculation of the order of magnitude of the thickness of the surface space charge layer (Debye length), expected on the surface of $CoFe_2O_4$ during adsorption, corroborates the conclusion on the ready establishment of surface-bulk equilibria. In fact, the electron concentration for the n-type sample, computed with Eq. [3] from the minimum observed value of the thermoelectric power, $-50(\mu v/°C)$, and $T = 300(°C)$, $\alpha = 1kT$ (erg), $N = 1 \times 35 \times 10^{22}$ (cc^{-1}), is found to be $n_{e^-} = 2.005 \times 10^{22}$ (cc^{-1}) at 300°C. Similarly, from Eq. [4] and the maximum observed value of the thermoelectric power, 290 ($\mu v/°C$) for the p-type sample and $\beta = 6kT$ (erg), it is found that $n_{e^+} = 1.89 \times 10^{23}$ (cc^{-1}).[1] With these limiting values and $\epsilon = 12$, the Debye length is of the order of a few angstroms for both samples (3). The possibility of doubly ionized oxygen as a surface intermediate, O^{-2}, requires, as previously explained, that no influence of the reacting mixture upon the thermoelectric power be found (1). Since this was not observed, O^{-2} ions are eliminated as kinetically significant. The comparison between the expected and observed reaction between conversion and thermoelectric power for the two cases, O^- and O,

[1] This value is about one order of magnitude larger than the number of metal ions per cubic centimeter of the spinel (1.35×10^{22}). It should be noted that, for the energy level scheme of $CoFe_2O_4$ here employed (2a), equating N in Eq. [3] and [4] to the number of metal ions per cc in the solid is permissible with very narrow energy levels only. This condition determines the numerical value of the transport coefficient β. Taking $\beta \approx 4kT$, then $n_{e^+} \approx N$.

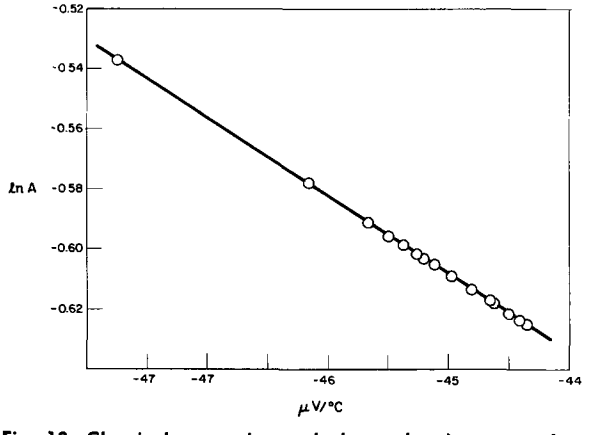

Fig. 18. Chemical conversion and thermoelectric power plotted according to Eq. [5]. A, left hand side of Eq. [5] steady state: $p^\circ_{N_2O} = 0.410$ atm, $p^\circ_{CO} = 0.590$ atm; nonsteady state: $p^\circ_{N_2O} = 0.605$ atm, $p^\circ_{CO} = 0.395$ atm; $Co_{0.994}Fe_{2.006}O_4$, 300°C, total pressure = 1 atm.

Table III. Nature of surface oxygen intermediate during the oxidation and reduction of surface cobalt ferrite

* From Eq. [3] and [4] of this paper and [18] to [25] of preceding paper.

is presented in Table III. The results show that for the n-type ferrite, good agreement is obtained by assuming that neutral oxygen species cover the surface during reaction steps [1] and [2], while for the p-type sample the assumption of monocharged ions is in better agreement at low temperature. With increasing temperature there is more contribution from neutral species.

From these conclusions, it is possible to single out three important observations. The first refers to the time constant of the adsorption and desorption effects. As shown, the former is in the range of minutes or more, and the question arises as to the physical nature of this phenomenon. It is clearly a case of "slow" adsorption. Many adsorption systems previously investigated exhibit an initial rapid adsorption (seconds or less) followed by a slow adsorption (hours). While it is not too difficult to relate the rapid process with electronic transitions and transfers, it has been generally more difficult to establish the nature of the slow process. It has been variously attributed to adsorption, surface diffusion, or reaction with the solid (5). In the present case it is not easy to see how the latter can take place with a formal surface coverage of less than a monolayer. Diffusional exchanges with the interior of the solid can be ruled out as kinetically significant. In fact, a simple calculation shows that at 300°C the time required for diffusion of a few per cent of adsorbed species in the crystal interior is of the order of seconds for a layer of thickness comparable to the size of the ferrite particles used (Appendix A). Thus, the most likely possibility is that the observed relaxation effects are resulting from slow, activated surface diffusional transport. Although we have not determined whether a slow decrease of surface area of the samples took place during the experiments, we suggest that the nature of the surface transport is similar to that controlling sintering of small solid particles at low temperatures. A large amount of ill-defined surfaces are generally present in powdered solids at grain boundaries and other macroscopic crystal imperfections. The rearrangement of matter along and into the imperfections is kinetically significant during sintering. At low temperatures this process is controlled by surface diffusion, and the rate of the latter is influenced by adsorption from the surrounding gas atmosphere (8). Therefore, it is suggested that the long relaxation times for adsorption and desorption found in this study are related to surface mass transport effects of the solid. Pore contribution to these effects was probably quite small since it can be shown that most of the active surface was external. In fact, assuming cubic particles with a density of 5.2 (4) (g/cc) and 10μ size, the theoretical surface area is 0.115 (m^2/g). This value is within an order of magnitude of the value obtained from the rate experiments (Table II).

The second important observation refers to the different electronic localization which is experienced by the adsorbed oxygen on the two spinel samples. The results show that (a) there is more electron localization in the p-type sample; the presence of electron holes in the semiconducting solid produces a more

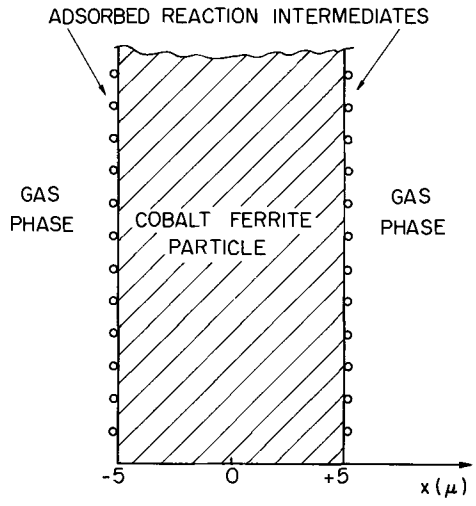

Fig. 19. Model used for bulk-surface diffusion calculations

polarized surface bond; (*b*) electron localization increases with decreasing temperature. Since Co^{+3} and Fe^{+2} ions are responsible for the difference in physicochemical properties of the two samples, it is conceivable that the variations in electron localization of the surface bond may also be ascribed to these ions, a more ionic bond being established between Co^{+3} and O_2 in respect to Fe^{+2} and O_2. At present there is no independent support for such a conclusion.

The final observation refers to the actual rate of the catalytic reaction. In fact, it has been found that the rate of the reaction was faster on the n-type ferrite as compared to the p-type. Since gas phase oxidation conditions prevailed, this result is at variance with correlations on the catalytic activity indicating that for oxidation reactions (N_2O decomposition), p-type oxides induce a faster catalytic rate (6).

It should be emphasized that this result has been obtained without the use of solid state doping, and it is, therefore, free of the criticism often expressed on the influence of doping and its concentration on the solid surface.

Conclusions

The applications of the theoretical analysis of the transient behavior of solid-gas systems to the reduction and oxidation of the surface of various samples of $CoFe_2O_4$ have shown that: (*a*) electron localization of the bond linking the adsorbed oxygen intermediate to the ferrite surface is larger for p-type than for n-type samples and, as a result, the intermediates for reactions [1] and [2] are O (n-type), O and O^- (p-type) at 300°C and O^- (p-type) at 190°C; and (*b*) the kinetic reactivity of the adsorbed oxygen is larger for O than O^-; thus, n-type ferrite is more reactive than p-type ferrite.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX A

The possible contribution to the observed effects of ionic diffusion between the interior and the surface of the crystal may be easily evaluated. Consider the idealized model of a slab of ferrite of uniform thickness of 10μ, and let us calculate the unidimensional diffusion of oxygen ions through the slab. To simplify matters, let us assume the following boundary conditions, $C = C_0$ and $-5 \times 10^{-4} \leq x \leq 5 \times 10^{-4}$ (cm) for $t = 0$, and $C = C_s$ and $x = \pm 5 \times 10^{-4}$ (cm) for $t \geq 0$, where x is the distance between the two surfaces of the slab, starting from the slab median (Fig. 19). These conditions mean that the concentration of oxygen ions is C_0 throughout the solid during steady-state conditions. At the time of the stepwise pressure change ($t = 0$), the concentration of oxygen at the surface becomes C_s. The solution of the one dimensional Fick's second equation gives

$$C_s - \overline{C} = \frac{8(C_s - C_0)}{\pi^2} \sum_1^\infty \frac{1}{(2n-1)^2} \exp[-(2n-1)^2 \pi^2 Dt/a^2] \quad [A\text{-}1]$$

where D, $\overline{C}$, and a are the diffusion coefficient, the average concentration of oxygen in the solid, and ½ the slab thickness, respectively. Using the values $D = 3 \times 10^{-12}$ cm²/sec (2b), $a = 5\mu$, the times required for 0.5 and 1% of the adsorbed oxygen to diffuse into the bulk of the solid are found to be 6 and 22 sec, respectively. This time is much smaller than that corresponding to the response studied in this investigation (5-6 hr).

APPENDIX B

The use of the Debye expression, $\delta = \left(\frac{\epsilon kT}{8\pi ne^2}\right)^{1/2}$, for the calculation of the thickness of the surface space charge layer, δ, is based on the validity of the application of the Boltzmann distribution under our experimental conditions. This is a permissible procedure whenever the following conditions are satisfied: $E - E_F > kT$ for n-type and $E_F - E > kT$ for p-type samples, where E_F is the Fermi level. Using the values $E - E_F = 0.275 - \nu$ and $E_F - E = 0.275 + \nu$ (2a) where $\nu = -kT/2 \ln \mu_2/\mu_1 = -(0.0295/2) \ln 10^4 = -0.136$ ev (190°C) and $\nu = -0.0025$ (300°C), it is found: $E - E_F = 0.500$ ev > 0.0489 ev ($= kT$ at 300°C); $E_F - E = 0.051$ ev (300°C); $E_F - E = 0.139$ ev > 0.0295 ev ($= kT$ at 190°C). In these equations μ_1 and μ_2 represent the electron and the electron hole mobilities. Therefore, the Boltzmann expressions are applicable and the use of the Debye expression for the calculation of the space charge layer is valid.

Technical Note

Instrumentation for Potentiostatic Corrosion Studies in Distilled Water

C. A. Youngdahl and R. E. Loess

Metallurgy Division, Argonne National Laboratory, Argonne, Illinois

Aspects of polarization measurements in high-resistance media, such as distilled water, have been discussed in previous articles (1, 2). The advantages of measuring the sample metal potential when no current is flowing (the interrupter technique) have been noted, and apparatus has been described. An important part of the instrumentation employed is a specialized pulse voltmeter in the measurement circuit, as indicated in Fig. 1(a). Potentiostatic corrosion studies, as distinct from polarization curve measurements, may be made in distilled water corrosion environment by a similar technique, as shown in Fig. 1(b). A simple potentiostat circuit is connected to the pulse voltmeter through an adjustable bias voltage supply. Incorporated in the potentiostat are automatic means of adjusting the polarization current, as shown, to maintain the selected polarization potential between the sample and reference electrode. Unidirectional polarizing current is employed to simplify the system: if current reversal is needed during a given test, manual adjustments are required.

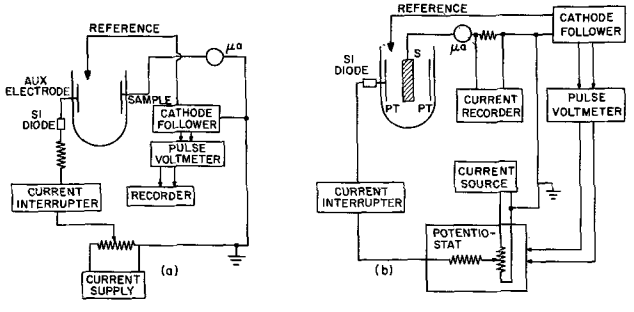

Fig. 1(a). Apparatus for measurement of polarization curves. Fig. 1(b). Apparatus for potentiostatic corrosion studies.

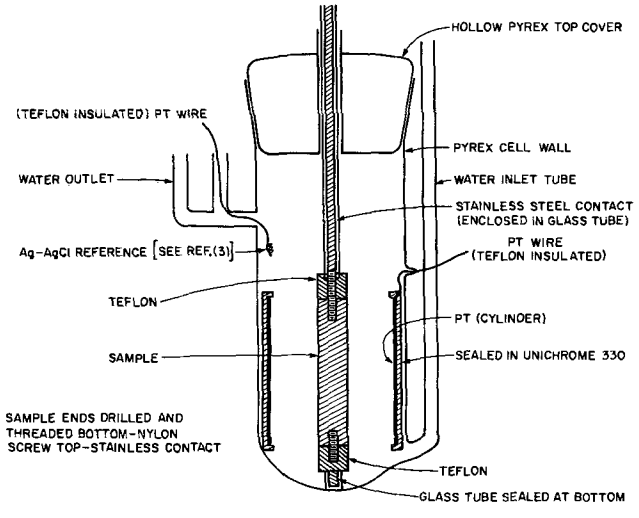

Fig. 2. Sectional view of polarization cell

What follows will deal primarily with pulse voltmeter circuitry similar to that in ref. (1), appropriately modified for connection into a potentiostat loop and for the benefits deriving from semiconductor components. A circuit for an electromechanical potentiostat built prior to the general advent of transistors (and now in use) is included. Behavior of the control loop system in corrosion studies of aluminum samples in 70°C distilled water is described.

Polarization Cell: Physical and Electrical Characteristics

The geometry and materials of construction of the sample-cell system, shown in Fig. 2, determine its electrical behavior and thus will be described briefly. The Pyrex cell is held in a 70°C water bath to maintain constant temperature. The corrosion medium is degassed, distilled water of R_s = 1.0-1.6 megohm cm (25°C) prior to entry into the cell. The water is heated to 70°C and added to the cell at the rate of 6 ml/min to refresh the cell solution, the excess overflowing to the drain. A constant solution resistivity is not attained because of the influence of sample corrosion, the rate of which changes with time. A hollow platinum cylinder of 5.75 cm ID fits closely inside the closed, cylindrical cell and serves as a current-carrying electrode. The outer surface and edges of the platinum are insulated with an inert wax (Unichrome 330) to prevent error due to uneven current density, an effect discussed in (2).

The sample is a solid cylinder of 1100 aluminum, 0.89 cm in diameter and 9.72 cm long (27.18 cm^2 surface area). Sample ends are blanked off with Teflon insulators to maintain equal current density at all exposed areas. The platinum and aluminum pieces are positioned coaxially, and the heights of the exposed surfaces are equal, again to produce uniform (though unequal) current density over both electrodes. The reference contact is a silver/silver chloride electrode (3) in the solution at the point where water leaves the cell. This arrangement minimizes addition of unwanted chloride ion to the test solution in the cell. The solution resistance between sample and platinum resulting from this construction changes typically from a relatively low and variable value at the beginning of test to about 18 kohms after several hours due to changes in resistivity noted above.

The open-circuit solution potential difference between sample and reference electrode (after an initial equilibration period and without externally applied current) is near 800 mv. The controlled potential selected for a given run may be within a few hundred millivolts above or below this value, and a maximum deviation of 10 mv from the voltage selected has been deemed acceptable. Sufficient circuit resistance is employed to nullify the effect of the sam-

ple-platinum voltage as an unwanted source of polarizing current.

It is of importance to note that during polarizing current interruptions the potential of a polarized specimen tends to decay slowly toward the open-circuit value. This property of the cell-sample system makes it unnecessary generally to provide external means of driving the sample potential in the direction of natural decay, *i.e.*, the externally applied polarizing current may be unidirectional. The advantage of this will become evident in a subsequent discussion of pulse voltmeter circuit operation. Another pleasant consequence of the relatively slow rate of decay of sample potential is to reduce the potentiostat rise time requirement to a range easily accommodated by electromechanical techniques. Further discussion of sample potential decay is included in subsequent sections.

Current Supply and Current Interrupter

The current supply indicated in Fig. 1(b) is not a critical component of the system. Voltage supplied to the 20 kohms potentiometer shown has typically been 75-90v. A 20 kohms slider resistor (shown) limits the cell current to a maximum of 4.5 ma (@ 90v), a value somewhat higher than the maximum needed for control of the sample.

The interrupter of Fig. 1(b) is the vacuum tube circuit described in ref. (1). The circuit interrupts the polarizing current for 6 msec once every 100 msec. Precise timing is not necessary nor is synchronization with external circuitry. Leakage resistance across the (vacuum tube) switch must be greater than 10 megohms during current interruptions to prevent a potential error greater than 1 mv (due to solution IR drop) in the cell herein described, given the solution resistances and polarization current levels encountered in the present work. Noise presented by the interrupter to the cell during current interruptions must likewise be sufficiently small or reproducible to satisfy the accuracy requirements. The aforementioned circuit fulfills these needs. A transistorized interrupter is currently being evaluated and appears satisfactory although relatively limited with respect to maximum polarizing source voltage at an acceptable leakage current value.

Character of the Voltage Measurement Problem

Pulsating polarization current flowing through the cell produces a pulsating voltage pattern at the measurement terminals, *i.e.*, the sample and reference electrode contacts, as shown in Fig. 3. Note that the figure represents the reference electrode voltage as varying

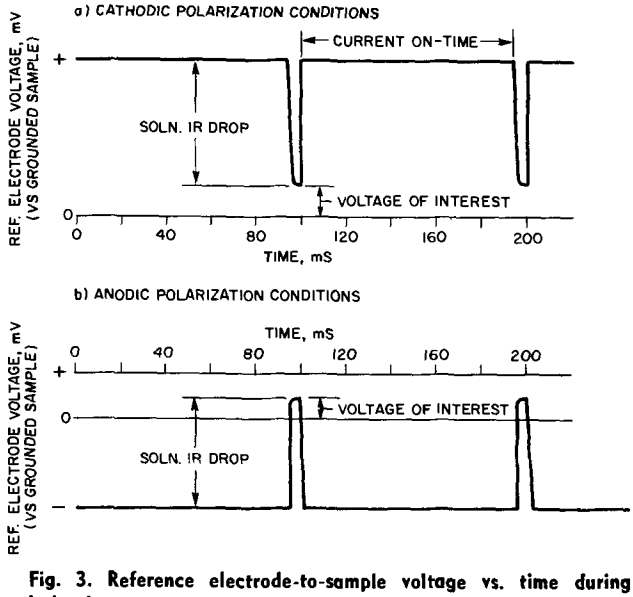

Fig. 3. Reference electrode-to-sample voltage vs. time during polarization.

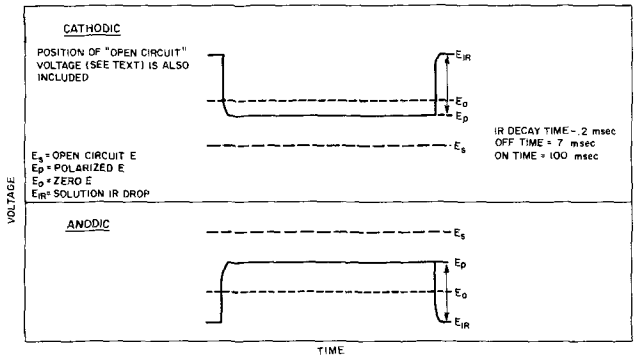

Fig. 4. Input signal during current interruption; biased suitably for presentation to PVTM.

with respect to a fixed metal sample potential; since the sample, having a relatively large surface area, is in practice grounded, and the instrumentation is constructed accordingly. As the figure indicates, the voltage of interest, *i.e.*, the sample-to-reference electrode voltage, is present by itself only about 6 msec of every 100 msec period. During the remainder of each period the polarization current flows through the solution, producing a variable voltage (IR drop) across the solution, which acts in series with the voltage of interest to produce the results shown in Fig. 3. The measurement scheme requires that the decay of the solution IR drop be complete (to within the acceptable error limit) before the voltage of interest has decayed significantly, as suggested in Fig. 4. Under these conditions, the voltage of interest may be monitored accurately during the 6 msec interruption period. No difficulty with respect to voltage decay has been encountered with the cell arrangement described. The relatively rapid IR voltage decay is achieved by maintaining sufficiently low cell-to-ground capacitance (except at sample surface), which includes the capacitance in wiring connected directly to the cell (except that of the grounded sample). The apparatus can accommodate somewhat greater IR decay times, which have been encountered in higher resistance cells.

Pulse Voltmeter: Design Considerations and Functional Description

The pulse voltmeter receives a fluctuating voltage such as those of Fig. 3. Its function is to determine the value of the voltage of interest regardless of the value of the solution IR drop voltage and to provide a nonpulsating output voltage which varies in accord with the former. The fluctuating voltage is biased as shown in Fig. 4 and presented to the voltmeter circuit, given in Fig. 5(b) and (c).

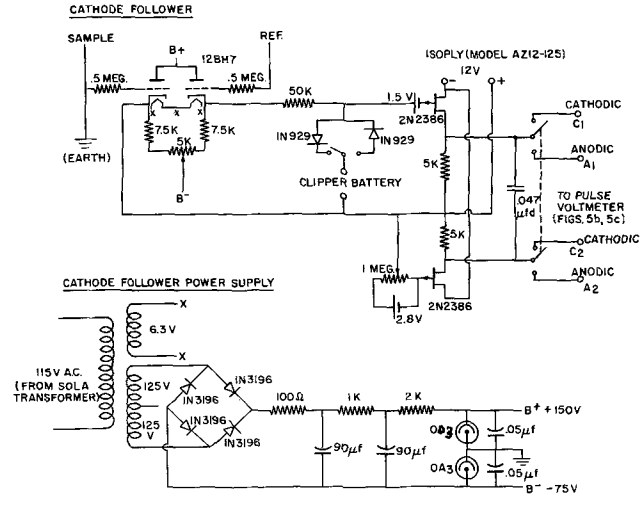

Fig. 5(a). Voltmeter circuit

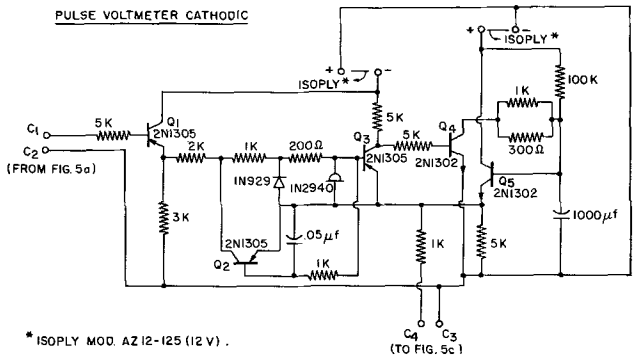

Fig. 5(b). Voltmeter circuit

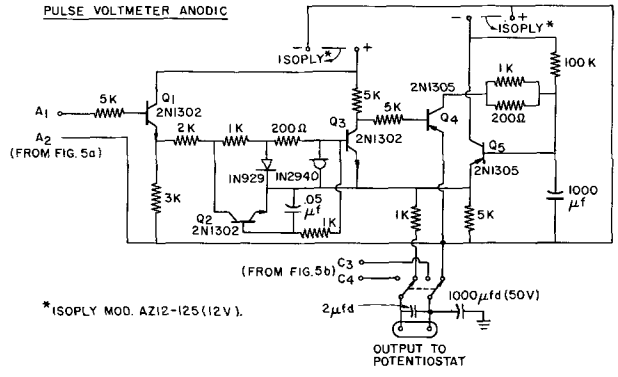

Fig. 5(c). Voltmeter circuit

Isolation and signal conditioning stages.—A vacuum tube cathode follower input stage [Fig. 5(a)] is employed to provide a high input resistance and minimum input capacitance, thus minimizing the amount of cell loading through the reference electrode. A balanced circuit design is used to avoid error due to changes in ambient temperature. Voltage excursions greater than 2v occur only when the irrelevant solution IR pulses are present and would impose design difficulties in succeeding circuitry. These excursions are therefore limited in the clipping circuit following the cathode follower. The amplitude-limited pulses are then transferred by a source follower impedance transformer to the pulse voltmeter proper.

Pulse voltmeter proper.—It has been found feasible to evaluate voltages such as those of Fig. 3 directly, without need of d-c amplification. Such a technique has been described in (1), in which a thyratron detector was employed. The present application differs from that of (1) in that voltmeter output leads which do not pulsate with respect to ground are desired for connection to succeeding potentiostat circuitry. The use of a readily inverted tunnel diode detector and choice of either npn or pnp transistors as needed permit design freedom not available in (1) and facilitate realization of the behavior desired.

Functionally, the voltmeter proper consists of (*i*) a voltage-triggered oscillator having a sharp threshold (stable within a 10 mv band), and (*ii*) a storage capacitor connected to a slow charging path and to a keyable, rapid discharge path controlled by the oscillator. These elements are shown functionally in Fig. 6. Individual cycles of the oscillator cause small decrements of charge in the capacitor. A stable loop is formed by connecting the capacitor back to an input terminal of the oscillator. With no voltage applied to input A, the capacitor will charge to the voltage threshold value of the oscillator, which will then produce pulses as needed to hold the capacitor voltage at that value. Since the circuit is so arranged that voltage inputs at A and B are additive, a small voltage applied to A reduces that needed at B to maintain the threshold voltage level. Thus the small voltage applied at A results in an equivalent decrease in voltage at the output terminal. Appropriate selection of charging rate (relatively slow) in relation to discharge rate (determined by oscillator frequency and discharge resistance) permits short pulses at A to function similarly to a steady voltage applied at that point. While the rates employed have been selected appropriately for the polarization system described, these rates are not critical values within the appropriate range. In Fig. 5 the voltage triggered oscillator circuit includes the components connected between the emitter of Q1 and the base of Q3. The discharge circuit consists of Q3 and Q4. Q1 and Q5 serve as impedance transformer emitter followers, and the storage capacitor and charging source components are evident. Two pulse voltmeter circuits are provided, one for cathodic and the other for anodic polarization conditions.

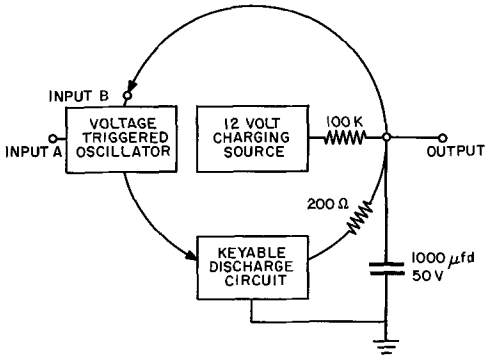

Fig. 6. Functional sketch of pulse voltmeter

Sensitivity and stability such as that of the tunnel diode discriminator make possible the foregoing method of polarization voltage measurement. The voltage sensitivity of this circuit is in the range of 1 mv, permitting realization of low over-all error in the range of 10 mv as specified above. Temperature stability of the IN2940A diode specified should be superior to that of the IN2940 actually used by the authors. Drift of voltmeter output voltage with the input shorted was observed to be less than 10 mv for periods of 10 days with laboratory air temperature variations of ±0.5°C.

Potentiostat

The potentiostat, indicated in Fig. 1(b), employs thyratron voltage discriminators which monitor the output voltage of the voltmeter. These tubes switch motor control circuits to adjust a potentiometer in the

Fig. 9. Mock cell for apparatus tests

current supply as shown. The amount of current is thus changed to restore the desired electrode potential difference. A circuit diagram of the potentiostat presently used is given in Fig. 7. The apparatus may be made from components commonly found in the laboratory.

If an additional potentiostat unit of this type were to be constructed by the authors, tunnel diode sensing circuit and transistors might be substituted for the thyratrons and relays of the rather out-dated circuit given. Alternatively a feedback amplifier controlled potentiostat scheme appears applicable. An arrangement being evaluated is sketched in Fig. 8. As another alternative, commercially produced potentiostats are available and may be employed, since requirements to be met in this section are not unusual. (However, the known commercial units are comprised largely of circuits and components superfluous in this application.) Interested readers may contact the authors for current results of a continuing evaluation of alternative potentiostat schemes.

Operational Procedure

Initial adjustments.—Initial adjustments are made with the cathode follower disconnected from the cell and the measuring input shorted. Cathode follower balance and source follower bias controls are adjusted for zero voltage difference between the signal leads at the output of each of these stages. The input short is then removed and replaced by a d-c voltage source equal to the desired polarization potential. The source follower bias control is again adjusted to restore the stage output voltage to near zero: a value of 0.3v is preferred, negative for cathodic and positive for anodic polarizing conditions. The output voltage of the pulse voltmeter then assumes a steady value which is taken as the setpoint for potentiostatic control: the potentiostat bias is adjusted to stop the correcting motor under these conditions. (See below for minor correction to accommodate offset error during operation.) The cathode follower input is then disconnected from the known voltage source and connected to the cell. The control loop is closed by connection of the polarizing current lead to the cell, and the system is allowed to control the potential of interest. Manipulation of the motor speed and override controls of the potentiostat in initial minutes of the test facilitates prompt assumption of control at the desired potential by the automatic system. The manual adjustment period is minimized by presetting the current source, given some foreknowledge of the current value required.

Apparatus tests and maintenance.—An advantage of the control mode employed over the feedback amplifier mode arises from the infrequent need for automatic corrective action after a relatively steady polarization condition is reached. The control loop described may be opened for the purpose of brief apparatus checks merely by switching off the motor power: polarizing current remains at a steady value, and apparatus tests and adjustments may be accomplished without disturbing the cell conditions, with the measuring apparatus disconnected from the cell.

The bias values described above are checked periodically, since bias changes affect the control setpoint directly. Tests are made at intervals of several days and adjustments made if needed. Interrupter power supply batteries have been changed weekly: replacement schedules for bias cells have not been determined.

When a potentiostatic corrosion test is not in progress, operational tests are made conveniently with the mock cell shown in Fig. 9. Derivation of component values is explained in the figure. With the mock cell connected in place of the polarization cell and capacitor C in the circuit, the voltage across C should be maintained automatically at a setpoint established in the manner described above, regardless of gradual changes in R_2 and R_4 (Fig. 9). An offset error of the order of 10 mv is normally observed, which is rather independent of polarization current in the range of 10 μa to 1 ma, and thus may be allowed for in setpoint adjustment. Capacitor C may be switched out (and the system readjusted) to observe the offset error directly or to test operationally for interrupter leakage.

Acknowledgment

The equipment described is in use in a study of the aqueous corrosion of aluminum under potentiostatic conditions, being conducted by J. E. Draley and R. E. Loess of the Metallurgy Division.

This work was done under the auspices of the U. S. Atomic Energy Commission.

Manuscript received Dec. 12, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Brief Communication

A Rapid Solid-Electrochemical Method for Studying High-Temperature Diffusion in Metals

Douglas O. Raleigh

North American Aviation Science Center, Thousand Oaks, California

A method involving the measurement of diffusion-limited currents in the solid-electrolyte cell Ag| AgBr| Au was used to determine the diffusion coefficient of silver in silver-gold alloys at 400°C. D values of order 10^{-14} cm^2/sec were measured at five points in the alloy composition range 10-60 a/o Ag in a single day's experiment with one metal sample. D values from duplicate runs on a gold single crystal agreed to an average of 3% and matched results on a polycrystalline gold foil to an average of 12%. By contrast, standard metallurgical techniques involving radiotracers and sectioning generally cannot be extended below $D \sim 10^{-11}$ cm^2/sec and require several weeks of annealing as well as precise sectioning techniques.

In a previous publication (1), results were reported on measurements of the double layer capacitance of the solid electrolyte AgBr against Pt and Au electrodes. The method involved the use of so-called solid state polarization cells, which have the general configuration

reversible electrode| solid electrolyte| inert electrode

and of which the cell Ag| AgBr| Au is an example. These cells have the property that if a potential of suitable polarity (negative at the Ag electrode in the present case) and small compared to the electrolyte decomposition potential is applied, there can be no steady-state ionic cell current. Under these conditions, the inert electrode interface functions to first order as a capacitative interface and, for the present cell, a steady-state silver activity $a_{Ag} = \exp(-\epsilon\mathbf{F}/RT)$ is electrochemically defined at this interface. Here, ϵ is the applied cell voltage, and $\mathbf{F}$ is Faraday's constant. In the previous work, potential steps were applied to similar cells and the transient cell current used to determine the double layer capacitance. In the case of Pt inert electrodes, the transient cell current could be unambiguously assigned to double-layer recharging (1, 2), but effects were reported for Au electrodes that involved the diffusion of metallic silver into the electrode at surface activity a_{Ag}. The purpose of the present study was to ascertain whether such effects could be used to determine the diffusion coefficient of Ag in Au and whether a general method for studying diffusion in metal systems might be involved.

Solid-electrolyte cells have been used previously for the study of rate processes at elevated temperatures (3), most recently by Rickert (4) in measuring the diffusion of oxygen in silver at 760°-900°. General application of these methods to metal diffusion, however, (in particular to small D values) requires knowledge of the relative roles of double layer charging and low-level electronic currents in the electrolyte. In the present cell, applying a voltage E establishes activity a_{Ag} on the time scale of the AgBr| Au double layer charging. For the Au electrode, it is believed that this activity is manifested as a partial monolayer of electrodeposited silver (1, 2). If Ag diffuses from the electrode surface to the interior, activity a_{Ag} is maintained by the electrodeposition of more Ag on the surface, a process involving the migration of Ag^+ ions in the electrolyte and the electrons in the external circuit. Since each Ag atom diffusing into the electrode is thus replaced, the diffusion flux is measured exactly by the cell current. This "diffusion current" persists until the kinetics of the diffusion process become negligible. At this point, the Au electrode has the characteristics of an Au-Ag alloy of activity a_{Ag}.

If the applied voltage is now changed to E', a new silver activity a'_{Ag} is established at the Au surface, and diffusion occurs until the Au electrode is re-equilibrated at a'_{Ag}. The situation is analogous to placing an infinite reservoir of silver at activity a'_{Ag} on the surface of an Ag alloy of silver activity a_{Ag}. If C_0 and C_1 are the atomic silver concentrations corresponding to a_{Ag} and a'_{Ag}, the diffusion current will be given by the well-known Cottrell equation

$$i = \mathbf{F}A(C_1 - C_0)(D/\pi t)^{1/2}$$

where A is the electrode area. Use of the current-time data and known activity-composition data (5, 6) for the Ag-Au system to determine D values depends on whether the diffusion current (which decays as $t^{-1/2}$) is still large enough to be seen against the low-level electronic cell current (7) when the double-layer charging process is completed.

In the experimental arrangement, a single-crystal pellet of AgBr, prepared as previously described (8), was springloaded between a square of Ag foil and a planar gold electrode. The latter was a polycrystalline foil in run 1 and a gold single crystal pellet in runs 2 and 3. In runs 1 and 2, a silver wire was embedded in the periphery of the AgBr pellet, about midway between the main electrodes, to serve as a reference electrode. Because of the short diffusion lengths involved ($\sqrt{Dt}$), it was important to have a smooth gold surface for A in the Cottrell equation to correspond to the geometric electrode area. Electropolishing in fused 1:1 NaCl-KCl at 750° gave a specular surface on which electron micrographs showed no significant roughness down to 500Å. The assembled cell was outgassed and heated under vacuum to the neighborhood of the AgBr melting point (425°) with an applied potential (231 mv) corresponding to 10 a/o Ag at the Au interface at 400°. Interface contact was achieved either by flash-melting the electrolyte in the neighborhood of the electrodes (runs 1, 3) or prolonged annealing under pressure just below the melting point (run 2). The cell was then cooled to 400°, placed under an argon flow, and about an hour allowed for equilibration.

Five successive voltage steps were applied at about 75-min intervals, each corresponding to a 10 a/o increase in the Ag concentration at the Au electrode surface. In runs 1 and 2, the cell voltage and voltage steps were applied with an electronic potentiostat (1,2), using a voltage follower in the feedback from the reference electrode. This arrangement, however,

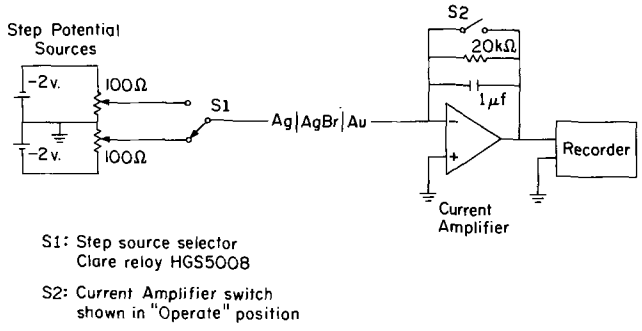

Fig. 1. Circuitry diagram for run 3

was found unnecessary because of negligible polarization at the Ag electrode and negligible iR drop in the electrolyte during the diffusion measurements. In consequence, the voltages in run 3 were applied directly via two battery-voltage divider setups and the use of a mercury relay to switch the cell between them. A low-impedance current-recording device was afforded by the use of a Philbrick SP656 operational amplifier in conjunction with a Moseley X-Y recorder. Figure 1 shows the arrangement for run 3.

Current-time data were recorded continuously for about 300 sec after voltage step application and intermittently till the application of the following step. Initial peak currents $\sim$ 100 μa were obtained which fell gradually to the approximate level of the steady-state electronic current (several μa). Following data acquisition from the last voltage step in run 1, the cell was cooled to room temperature at the existing voltage (55 mv, corresponding to 60 a/o Ag at 400°) and dismantled. The Au electrode had a uniform silvery appearance where it had contacted the electrolyte. In run 2, the cell voltage was returned to 231 mv after the last voltage step, the cell allowed to equilibrate, and then cooled under bias and dismantled. In this case, the electrode interface had a gold appearance. In all runs, the electrolyte was found to be bonded tenaciously to both electrodes. For run 3, the Au single crystal from run 2 was cleaned of any adherent AgBr in hot concentrated HBr, rinsed, dried, and reassembled into a new cell.

In all cases, plots of cell current *vs.* $t^{-1/2}$ were extremely linear in the range 10-100 sec after step application and showed only minor variations from linearity (0.1-0.3 μa) at times out to 4500 sec (75 min). The Y-intercept ($t = \infty$) gave values of the constant electronic current whose magnitude and cell voltage dependence were in excellent agreement with theory (9) and previous experiment (7). At times below 10 sec, the current showed an upturn from linearity attributable to residual double layer recharging, in accord with previous studies (1, 2). The slopes of the plots in the 10-100 sec range were used, together with the activity-composition data of Wachter (5) and Kubaschewski (6) for the Ag-Au system at 400°, to calculate D values. Results are shown in Fig. 2. Since the voltage steps represent jumps from one composition to another, the D values are arbitrarily plotted at the median compositions.

A further experimental point should be mentioned. The use of successive voltage steps to determine D values across the composition range assumes that, in the time between successive steps, diffusion has proceeded sufficiently to result in an essentially uniform composition over the diffusion distance represented by the 10-100 sec data range (~30-100Å). This assumption was tested in one instance by repeating a voltage step after an overnight wait at the initial potential. The resultant current slope agreed to several per cent.

Slifkin *et al.* (10) have measured the self-diffusion coefficient of Ag in a number of Ag-Au alloy compositions at 635°-1010° by standard metallurgical techniques and derived empirical expressions for its temperature dependence. For comparison with our results, self-diffusion coefficients at 400° were calculated from these expressions, plotted as a function of composition, and interpolated values at our compositions taken from a best smooth curve through the points. The Darken equation (11) was then used with available thermodynamic data (5, 6) to calculate the corresponding chemical diffusion coefficients for comparison with our D values. The results are plotted on Fig. 2. Agreement ranges from good to remarkable, considering the inherent uncertainties in such a comparison and in D values in general.

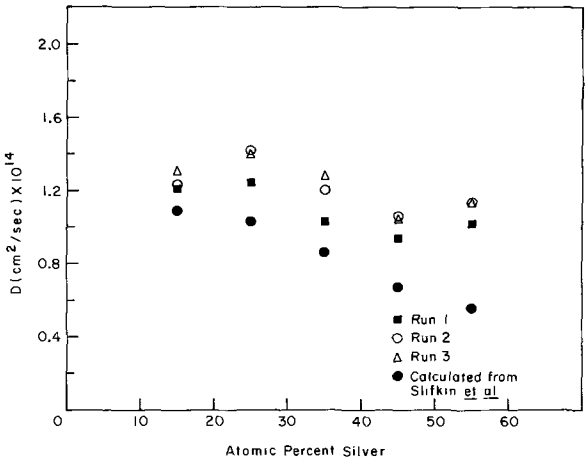

Fig. 2. Diffusion coefficient of Ag in Au-Ag alloys of various compositions at 400°.

It is felt that the present method may have wide applicability. A solid electrolyte cell Me| MeX| M′ may be used as a source of fixed and controllable activity of metal Me at the M′ surface to study diffusion over a wide range of alloy composition. It is required that metal M′ be more noble than Me to avoid side reaction with the electrolyte. Application to other solid-electrolyte systems (*e.g.*, Cu| CuI, Pb| $PbCl_2$) will require investigation of their electrochemical properties, which it is hoped this work will stimulate. Further results on the present system will be reported shortly (12) and in a future publication.

Acknowledgment

The author is greatly indebted to Mr. Harry Crowe for considerable assistance in all phases of the experimental work.

SOLID STATE SCIENCE

Kinetics of Tantalum Corrosion in Aqueous Electrolytes, II

K. Lehovec and John D'Amico[1]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Transients of the voltage between a tantalum foil and an aqueous electrolyte have been induced by application of d-c current or else a-c voltage steps during the growth of a thin protective oxide film. These transients were analyzed in terms of the dependences on voltage and oxide thickness of (*a*) the ionic current causing the oxide growth and (b) the current required for charge neutralization. Certain discrepancies between the theoretical model used to analyze the transients and the experimental data indicate a more complex behavior of the oxide than that of an ideal capacitor shunted by a voltage dependent resistor responding instantaneously to changes in the voltage.

In a previous paper (1) the spontaneous corrosion of tantalum in aqueous electrolytes was investigated by measuring capacitance and voltage changes *in situ*. This paper attempts to clarify the mechanism of oxide growth.

The growth of a protective oxide film involves two processes; (*i*) a transport through the oxide film of the ions which participate in film growth, and (*ii*) a current flow which neutralizes the charge transported by these ions. Usually this neutralizing current is carried by electrons and/or holes, although it is conceivable that other carriers such as protons can be involved in special cases. However, for the sake of brevity, we shall refer to the two currents mentioned under (*i*) and (*ii*) as the ionic and the electronic currents, I_I and I_E. A more precise description would be "the ionic current leading to film growth" for I_I and "the current through the oxide causing charge neutralization, but not oxide growth" for I_E.

The rate of oxide film growth can be derived assuming a simple mechanism for one of the two currents, I_I or I_E, as the rate-determining factor for corrosion resulting in a continuous film of the reaction product. For instance, diffusion of ions involved in film growth leads to parabolic corrosion kinetics (2). In the case of the protective oxide films formed on Al and Ta in air, tunneling of electrons through the film providing charge neutralization (3), or else injection of ions from the metal interface by a high field mechanism (4), have been postulated as the rate-determining processes. The latter mechanism (4) (Mott-Cabrera theory) has found wide acceptance in the literature. However, in the case of air oxidation of tantalum at or near room temperature, discrepancies with the Mott-Cabrera theory (4) have been observed (5).

In the case of anodic oxidation of tantalum and aluminum both anions and cations contribute simultaneously to the ionic current I_I (6-8). Moreover, the ionic transport may conceivably proceed in several charged states, such as OH^- and O^{--}. There are possible contributions to I_E by electron transport, hole transport, and even by transport of H^+ ions (9-11). For a given species such as electrons, there may be several competing transport mechanisms, *e.g.*, diffusion and field driven current flow in the bulk of the oxide, tunneling through the entire oxide, and thermionic emission across barriers at the boundaries of the oxide, or even across the entire oxide. Interaction of various charge carrying species may occur. Space charges may lead to a significantly nonlinear voltage distribution. The structure and dielectric properties of the oxide in close proximity to the metal substrate may conceivably differ from those of the bulk of macroscopically thick anodic oxide films. Image force potentials extend through most, if not all, of the oxide films encountered in spontaneous corrosion of Al and Ta in air, and the discrete nature of charges at the outer oxide surface leads to large field variations in the oxide along the metal-oxide interface. Last, but not least, the oxide growth may be governed by charge transport at certain structural faults (12-16), particularly, when means for lateral charge transport along the outer oxide surface exist, as in the case of corrosion in an electrolyte.

In view of all these actual or potential complications, it would be rather remarkable if a single mechanism based on a simple concept should be able to account for the formation of protective oxide films on tantalum and aluminum.

The corrosion of tantalum in aqueous electrolytes appears to be particularly well suited to investigate the mechanism of the formation of a protective film, since (*i*) no tantalum is dissolved in the electrolyte and (*ii*) the presence of a conducting outer phase (the electrolyte) enables continuous measurements of the potential across the oxide and of the oxide thickness by means of the oxide capacitance. The transformation of the measured capacitance into the oxide thickness utilizes the plate capacitance formula and thus involves surface area and dielectric constant of the oxide. Significant contributions to the capacitance from electrolyte space charge layers can be avoided by using highly conducting electrolytes and measuring at sufficiently low frequencies. Potential errors in determining oxide thickness, *d*, from capacitance measurements have been discussed in ref. (1).

[1] Present address: Rensselaer Polytechnic Institute, Troy, New York.

The growth rate of the oxide film is determined by the requirement of quasi-charge neutrality[2] (Kirchhoff's law)

$$I_E = I_I + I \quad [1]$$

in conjunction with Faraday's law

$$\partial d/\partial t = \lambda I_I \quad [2]$$

In Eq. [1] we have included the more general case that an external d-c current, I, is permitted to flow. The numerical value for the coefficient λ in Eq. [2] is the same as used in ref. (1).

From the measured capacitance as a function of time, t, the oxide thickness, d, has been derived by the plate-capacitor equation and the ionic current was obtained from Faraday's law [2]. Using Kirchhoff's law [1] the electronic current was then derived. However, since both oxide thickness and voltage change with time simultaneously, experimental methods must be devised to determine the relation between I_I and I_E and V and d. Over a small range of oxide thickness, d, and oxide voltage, V, the dependencies of the ionic and electronic current on d and V can be characterized by the four coefficients

$$\alpha_E = \partial \ln I_E/\partial V]_d \quad [3]$$

$$\alpha_I = \partial \ln I_I/\partial V]_d \quad [4]$$

$$\beta_E = \partial \ln I_E/\partial d]_V \quad [5]$$

and

$$\beta_I = \partial \ln I_I/\partial d]_V \quad [6]$$

of a Taylor series of ln I_E and ln I_I. These coefficients have been defined in terms of the logarithms of currents rather than currents proper in view of the nearly exponential dependencies of these currents on voltage [constant Tafel slope]. Thus α_E and α_I are the Tafel slopes of the ionic and electronic currents.

This paper deals with experimental methods to derive these coefficients and a comparison of the results with theoretical values expected for various simple charge transfer mechanisms through the oxide.

Experimental Methods

Sample preparation, test cell and measurement circuit were the same as described in (1) and shown in its Fig. 1 and 2. In order to determine the voltage and thickness relations for the currents I_I and I_E, an external electrical signal was applied to the oxide and its effect on the d-c voltage, and on the growth rate was measured. Two techniques have been used, the "d-c method" and "transient method."

D-C method.—After spontaneous corrosion had proceeded for a certain time, a series of cathodic d-c current pulses was passed through the sample as shown in the lower curve of Fig. 1. The d-c voltage and equivalent series capacitance of the cell responded as shown in the upper and middle portions of the figure. The following effects can be noted: Following the stepwise change of the cathodic current, there is a transition to a new quasi-stationary level of voltage and capacitance. This transition will be analyzed in more detail in Fig. 2. At present we are interested in the shift of d-c potential marked ΔV in Fig. 1 and in the quasi-stationary rates of capacitance change before and after the change of cathodic current. The ionic current can be derived from the quasi-stationary rate of capacitance change with time by combining the plate capacitance equation with Faraday's law leading to the relation given in Fig. 1. In this manner the relation $I_I(V)$ is obtained. The relation $I_E(V)$ is then obtained by Kirchhoff's law (1). During the sequence of small cathodic currents the oxide thickness continues to increase. In order to obtain the relations $I_I(V)$ and $I_E(V)$ at a constant oxide thickness, a correction for the change in oxide thickness is required. This correction will be discussed in Appendix D, using the relations developed in the Appendices A and B.

A drawback of the d-c method is the fact that the corrections to constant thickness (Appendix D) require certain parameters, which have to be taken from the open-circuit corrosion data of the preceding period. In some cases these parameters vary fairly rapidly with oxide thickness so that the values used for the correction may become ill-defined.

For large cathodic currents one has $I >> I_I$, and, therefore, $I \simeq I_E$, so that the cathodic current voltage relation $I(V)$ provides directly the electronic current relation $I_E(V)$. Thus, in order to derive $I_E(V)$, no significant time interval of the quasi-stationary state is required since I_I is not needed. Thickness corrections become unimportant. However, at these large cathodic current densities, hysteresis phenomena may be encountered. It is impractical to wait until the "hysteresis" has fully decayed after a current switch since this would necessitate a significant correction to constant thickness.

The difficulties arising from "hysteresis" and from the correction for constant oxide thickness led us to favor the a-c method to be described in the next section, which rapidly alternates small cathodic and anodic bias voltage so that no d-c current results.

Transient method.—This method utilizes the voltage transient following a stepwise change in an external signal, such as d-c current I (Fig. 1) or else a small applied a-c voltage in the audio-frequency range (Fig. 2). A transient is characterized by its time constant, τ, and the voltage increment ΔV, which were determined as follows (Fig. 2): The linear voltage-time relationship following the transient was extrapolated through the transition period and formed the

[2] It will be shown in Appendix E that charge neutrality, while not exactly satisfied, is a very good approximation.

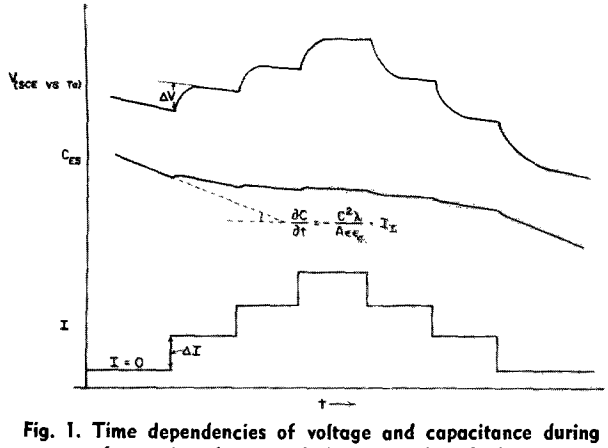

Fig. 1. Time dependencies of voltage and capacitance during a sequence of stepwise changes of the external cathodic current, I.

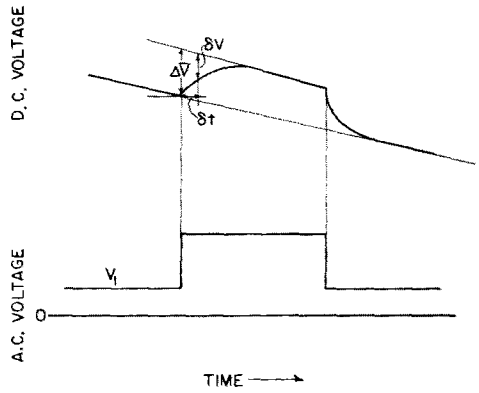

Fig. 2. Transients of d-c voltage ΔV following a stepwise change in the a-c voltage amplitude V_1.

base line for determination of voltage increments δV. A semilogarithmic representation of voltage increment *vs.* time increment δt since the switch of the external signal gave a straight line, provided that the changes of a-c voltage amplitude (in the case of Fig. 2) or else of external current ΔI (Fig. 1) were sufficiently small. From the slope of these plots τ was obtained and extrapolation to $\delta t = 0$ gave ΔV.

From the time constant τ and the oxide capacitance[3] an equivalent parallel resistance can be calculated by means of

$$R_\tau = \frac{\tau}{2\,C_{ES}} \qquad [7]$$

The factor 2 is added because the cell capacitance lies parallel to the capacitance C_{ES} of the symmetric branch of the bridge circuit.

In the case of the voltage transient induced by the change in the electrical current, ΔI, a "d-c incremental resistance" can be defined by

$$\overline{R} = \Delta V/\Delta I \qquad [8]$$

The experimental data used for the theoretical analysis of the growth mechanism in terms of ionic and electronic currents, I_I and I_E, were: (*i*) the change of quasi-stationary d-c potential, ΔV, before and after the transient, respectively; (*ii*) the time constant, τ, of the transient; (*iii*) the incremental field during quasi-stationary growth periods

$$F_i = -\partial V/\partial d \qquad [9]$$

and (*iv*) the "attenuation length" l, of the growth rate, defined by

$$l = -\frac{\partial d}{\partial \ln[\partial d/\partial t]} \qquad [10]$$

The "oxide thickness" d is determined by the plate capacitance equation from the equivalent series capacitance of the cell which was monitored continuously by means of an a-c signal of about $V_1 = 9$ mv amplitude and 100 Hz frequency. During the transient studies the amplitude was raised temporarily to about 30 mv as shown on bottom of Fig. 2.

In order to obtain a unique correlation between α_E, α_I, β_E, and β_I and the four experimental parameters ΔV, τ, F_i and l, we assumed that I_E and I_I are instantaneous functions of voltage V and oxide thickness, d. As will be shown in the Appendices A and B, this assumption leads to the relations given in Table I for the case of sufficiently small amplitudes of the a-c voltage V_1. Actually the value V_1^2 listed in Table I should be replaced by ΔV_1^2 *i.e.*, the value of V_1^2 during the increased a-c amplitude minus the value of V_1^2 which was continuously applied at the oxide film. In order to simplify notation, the analysis of Appendix A and B assumes that no a-c signal is applied except when inducing a transient.

[3] It is shown in ref. (1) that the oxide capacitance can be approximated by the equivalent series capacitance of the cell, C_{ES}, at 100 Hz in high-conductivity electrolytes.

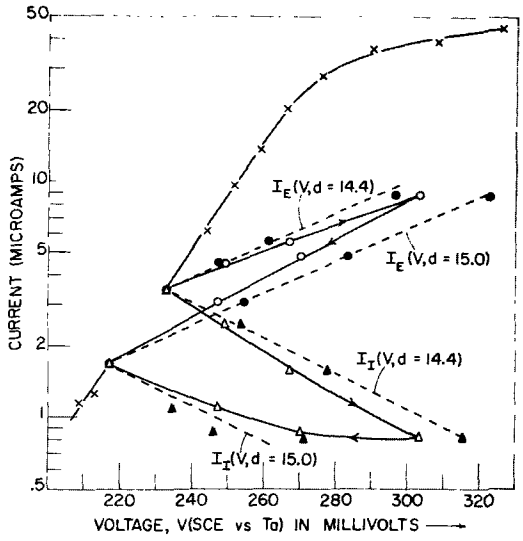

Fig. 3. Ionic and electronic currents as functions of the voltage, SCE vs. Ta, (a) during spontaneous corrosion, $I°_I = I°_E$, points marked by x; and (b) during a sequence of cathodic currents I = 2, 4, 8, 4 and 2 microamps; ionic currents uncorrected (△) and corrected (▲) to constant thickness; electronic currents uncorrected (O) and corrected (●) to constant thickness.

Appendix C contains the analysis of the d-c voltage transient induced by a large change in a-c amplitude V_1.

Experimental Results

D-C analysis.—Figure 3 shows an example of the voltage dependences of the ionic and electronic currents as obtained by the d-c analysis. The points marked by x are the open-circuit growth rates, converted into ionic currents by Eq. [2] and plotted *vs.* the open-circuit voltage. When the oxide thickness reached the value $d = 14.4$Å, a series of cathodic currents, $I = 2$, 4, 8, 4 and 2, μa, was passed through the sample. The voltages at the end of each constant current period, and the corresponding growth rates transferred into I_I, are marked by open triangles. The electronic currents marked by circles were obtained by Kirchhoff's law [1] from these I_I-values and the external currents. The curve connecting the ionic currents and that connecting the electronic currents do not retrace for ascending and descending external currents due to the change of oxide thickness during the sequences of cathodic currents. Corrections to "constant oxide thickness" have been made by shifting the voltage for each current point in accordance with Eq. [2] of Appendix D. The points for ascending cathodic currents have been corrected to the initial thickness, $d = 14.4$Å, and those for descending cathodic currents to the final thickness, $d = 15.0$Å. The points at the largest applied current, $I = 8.0$ μa; for which $V = 305$ mv, $I_I \simeq 0.8$ μa, and $I_E = 8.8$ μa, thus appear twice

Table I. Expressions for α_I, α_E, β_I, and β_E in the special cases: $I = 0$ (spontaneous corrosion); $I \simeq -I_I°$ (large anodic currents) and $I_I° \simeq 0$ (large cathodic currents)

Coefficient	$I = 0$	$I \simeq -I°_I$	$I°_I \sim 0$
α_I	$-\frac{C_{ES}}{I_I°\tau} - 2\frac{\Delta V}{V_1^2}$	$\frac{2\,C_{ES}}{I\tau} = -\frac{4\,\Delta V}{V_1^2}$	—
α_E	$\frac{C_{ES}}{I_I°\tau} - 2\frac{\Delta V}{V_1^2}$	—	$\frac{2\,C_{ES}}{I\tau} = -\frac{4\,\Delta V}{V_1^2}$
β_I	$-\left(\frac{C_{ES}}{I_I°\tau} + 2\frac{\Delta V}{V_1^2}\right) F_i - l^{-1}$	$\frac{2\,C_{ES}}{I\tau} F_i = -\frac{4\,\Delta V}{V_1^2} F_i$	—
β_E	$\left(\frac{C_{ES}}{I_I°\tau} - 2\frac{\Delta V}{V_1^2}\right) F_i - l^{-1}$	—	—

each after the correction, once on the curve for $d = 14.4$Å and once on the curve for $d = 15.0$Å.

The correction to constant thickness requires the slopes α_I and α_E of the corrected curves, as well as F_i, l, and d for each measured point. It is easy to find self-consistent values of α_I and α_E since the slopes of the corrected curves do not differ greatly from those of the uncorrected curves. Values for F_i and l were obtained by extrapolation of graphs using the open-circuit corrosion data prior to $d = 14.4$Å.

The corrected points $I_E(V, d = 14.4\text{Å})$, $I_E(V, d = 15.0\text{Å})$ and $I_I(V, d = 14.4\text{Å})$ fall on straight lines. However, the corrected points $I_I(V, d = 15.0\text{Å})$ deviate considerably from the straight line drawn with a slope equal to that of $I_I(V, d = 14.4\text{Å})$. This deviation which will be termed here "hysteresis" is an after effect of the passage of large d-c currents and relaxes substantially slower than the time constants τ usually observed for a voltage change following a stepwise change of current.

The slopes of the dotted lines in Fig. 2 provide $\alpha_I = -17.4$ v^{-1} and $\alpha_E = 16.4$ v^{-1}; and the vertical displacements of the dotted lines in combination with the thickness increment $\Delta d = 0.6$Å provide $\beta_I = 2.6$Å^{-1} and $\beta_E = -0.73$Å^{-1}. By drawing the two dotted lines for I_I parallel to each other, and also those for I_E, we have ignored a possible dependence of α_I and α_E on d. The accuracy of the d-c analysis is affected adversely by hysteresis phenomena and assumptions on F_i and l which enter the correction to constant thickness and this prevents us from obtaining the dependences of α_I and α_E on d for small increments of d.

Coinciding curves I_E (V) for different d-values were found for some samples. Furthermore, in these cases these curves coincided also with spontaneous corrosion data, $I^o_E \simeq I^o_I$ *vs.* V. This indicates that in these samples the electronic current depends only on voltage, but not on thickness; *i.e.*, that $\beta_E \simeq 0$. Such behavior is expected if charge neutralization occurs at a fault which is not blocked by the oxide growth.

Figure 3 shows that I_I and I_E depend exponentially on the voltage, V. This suggests to define α_I and α_E as derivatives of the logarithm of currents. The coefficients α_I and α_E are thus related to the anodic and cathodic transfer coefficients.

The exponential dependences of I_I and I_E on voltage are used in the analysis of the voltage transient in Appendix A.

Transient analysis—spontaneous corrosion.—Table II lists values of $\overline{R}$ and R_τ for the cathodic current steps mentioned in the caption of Fig. 3. Note that R_τ is slightly, but consistently larger than $\overline{R}$. Values of $\overline{R}$ calculated by Eq. [5] of Appendix A with α_I, α_E, I_I, and I_E from Fig. 3 are given in the last column of the table. The increase of $\overline{R}$ for descending current steps relative to that for ascending current steps arises not only from the increase in oxide thickness which has taken place, but is affected also by the hysteresis phenomenon mentioned previously.

Figure 4 shows a typical dependence of the d-c voltage change $\overline{V} - V_O = \Delta\overline{V}$ on the a-c voltage amplitude V_1. The relation between $\overline{V} - V$ and V_1 is

Table II. D-C and a-c resistances, $\overline{R}$ and $R\tau$, as function of the cathodic currents for the data of Fig. 2. Also listed is $\overline{R} = (\alpha_E I_E - \alpha_I I_I)^{-1}$ according to Eq. [A-5] with I_E, I_I, and α_I, and α_E from Fig. 2

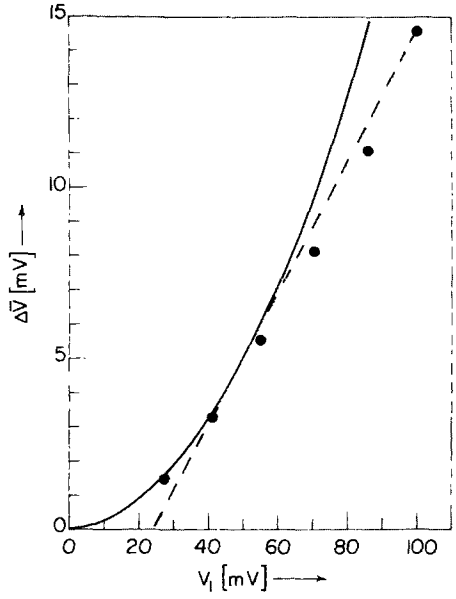

Fig. 4. D-C voltage change as function of a-c voltage amplitude. Full line Eq. (15) of Appendix A and dotted line Eq. (5) of Appendix C, using $\alpha_I = -25$ V^{-1} and $\alpha_E = 17$V^{-1}.

quadratic for sufficiently small a-c voltages and becomes linear for large a-c voltages. The quadratic range and the linear range have been fitted by the theoretical expressions Eq. [15] of Appendix A and Eq. [5] of Appendix C with $\alpha_I = -25$ v^{-1} and $\alpha_E = +17$ v^{-1}, and I = 0. Since α_I and α_E depend on oxide thickness, these values cannot be compared immediately with those of Fig. 3.

It may seem that a better fitting linear approximation could be achieved by a different selection of α_I and α_E. However, Eq. [5] of Appendix C defines not only the slope of the linear relation, but also the point of intersection. In addition, the coefficient of the quadratic approximation of Eq. [15] Appendix A must match the experimental data. Thus, we have three experimental data to be fitted by the choice of two constants α_E and α_I.

Figure 5 shows the ratio $(\overline{V} - V_o)/V_1^2$ of the quadratic range (small V_1) as function of the oxide thickness during open-circuit corrosion for three aqueous electrolytes of widely varying pH-values, namely, sulfuric acid of pH $\simeq$ 1, a highly concentrated (3.44 w/o) NaCl-solution of pH $\simeq$ 7 and a NaOH-electrolyte of pH $\simeq$ 13.5. Figure 5 shows a minimum at 13.5Å in sulfuric acid electrolyte and at 16Å in sodium chloride electrolyte. Figure 6 shows time constants, τ, as function of the oxide thickness, d, for the same runs as used in the previous figures: τ increases with oxide thickness except at thicknesses $d \lesssim 9$Å in sulfuric acid.

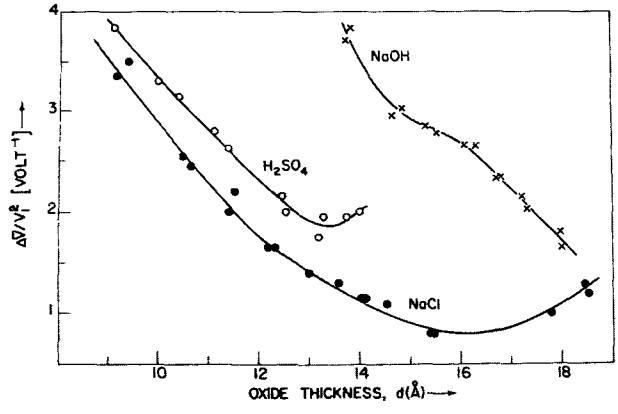

Fig. 5. $\Delta\overline{V}/V^2_1$ vs. d during spontaneous corrosion

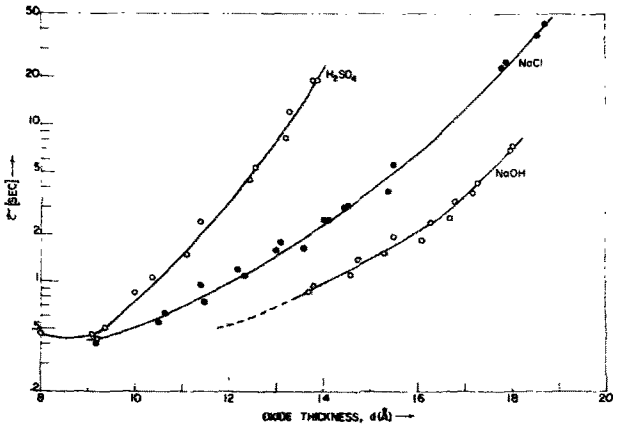

Fig. 6. τ vs. d during spontaneous corrosion

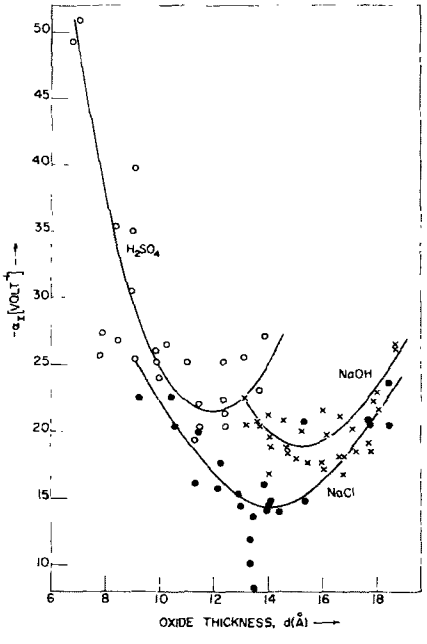

Fig. 7. α_I vs. d during spontaneous corrosion

The lateral displacement of the curves for the three electrolytes in Fig. 5 and 6 is in agreement with the changes in apparent thickness as measured in different electrolytes for the same oxide film (1). Values of F_i and l can be derived from the figures given in ref. (1) and, therefore, will not be presented here.

The values of $(\overline{V}-V_o)/V_1^2$ and $C_{ES}/(I_1^o\tau)$ can be combined with data of F_i and l to obtain the α's and β's by the equations listed in Table I. I_1^o was derived by Faraday's law, Eq. [2], from the growth rate. The steep dependence of τ on d shown in Fig. 6 is partly compensated by that of I_1^o on d in the product $I_1^o\tau$.

The coefficients α_I (Fig. 7) and β_I (Fig. 8) are obtained by addition of terms of equal sign (Table I); on the other hand, α_E (Fig. 9) and β_E (Fig. 10) are obtained by subtraction so that the resulting value can be quite inaccurate if each term is much larger than their difference. This applies particularly to β_E. Points in the Fig. 7-10 for the same electrolyte include results from several different samples and runs, which in part, accounts for the wide scatter of the points. Reproducibility of the α's and β's of a sample in the same electrolyte (NaOH) was good in four identical runs performed.

The dominant term for α_I, α_E and β_I is $C_{ES}/\tau I_1^o$ which accounts for the similar trend of these coefficients with d. The coefficient β_E (Fig. 10) is generally negative except at very small thicknesses in sulfuric acid where positive values appear. However, these positive values

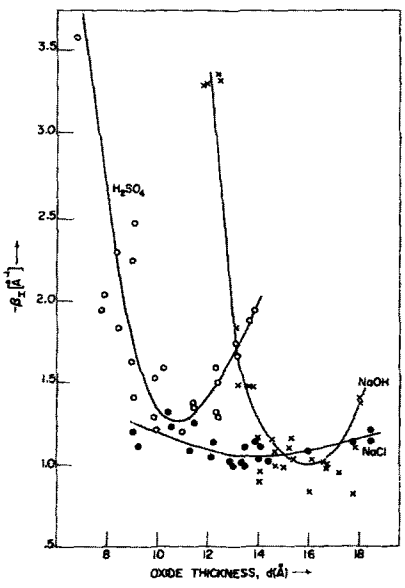

Fig. 8. α_E vs. d during spontaneous corrosion

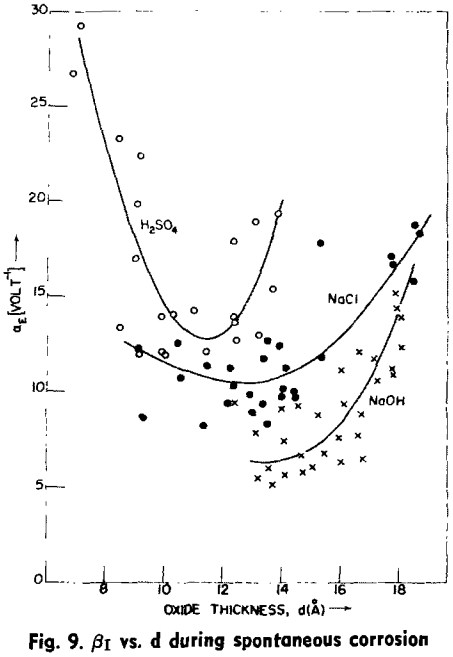

Fig. 9. β_I vs. d during spontaneous corrosion

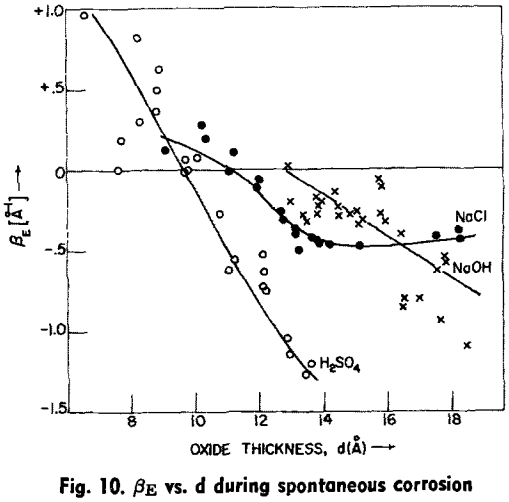

Fig. 10. β_E vs. d during spontaneous corrosion

could be the results of some small experimental error since β_E is obtained as the difference of two large values.

Transient analysis—anodic oxidation.—Values of α_I and β_I for thicknesses larger than 20Å can be obtained conveniently by using anodic oxidation. During constant current anodic oxidation the oxide thickness, d, and the voltage, V, vary linearly with time until a certain voltage, which we shall call "leakage potential" is approached. At this potential, the leakage current through the oxide (presumably electrons flowing from the electrolyte to the tantalum) becomes equal to the external current. When the leakage potential is approached, the oxide growth slows down and eventually stops. With increasing current densities, the leakage potential shifts to larger negative voltages, SCE *vs.* Ta, and the corresponding oxide thickness increases.

Figure 11 shows the incremental field F_i obtained by Eq. [9] from the electrode potential *vs.* oxide thickness for constant current anodization in H_2SO_4 and NaCl electrolytes. Above 20Å, the incremental fields are nearly constant over a wide range of thicknesses until the respective leakage potentials are approached and the incremental fields decrease. The curve for an electrolyte of NaOH is quite similar.

Comparison of thickness increment with anodization current indicated that the assumption of 100% current efficiency was satisfied through the thickness range where F_i remained constant.

Figure 12 shows the dependence of the time constants, τ, on thickness. When the leakage potential is approached, the time constants fall off rapidly. In the range where Faraday's law is satisfied, τ is found to be constant with thickness in the case of NaCl, but decreases slightly in the case of the NaOH electrolyte and by as much as a factor 1.5 in the range from 15 to 50Å in the case of the H_2SO_4-electrolyte.

At constant current anodization of 100% efficiency α_I can be calculated from τ, and, independently from $(\overline{V} - V_0)/V_1^2$ (Table I). However, it was found that the α_I-values calculated from $\Delta V/V_1^2$ are larger than those calculated from τ. An example is shown in Fig. 13 where the expression

$$B = -\alpha_I \cdot d \qquad [11]$$

has been plotted for anodic oxidation. Also plotted

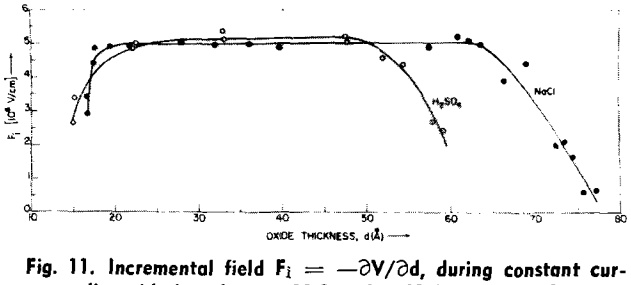

Fig. 11. Incremental field $F_i = -\partial V/\partial d$, during constant current anodic oxidation; I = —11.9 and —31.6 μA for H_2SO_4 and NaCl electrolytes, respectively.

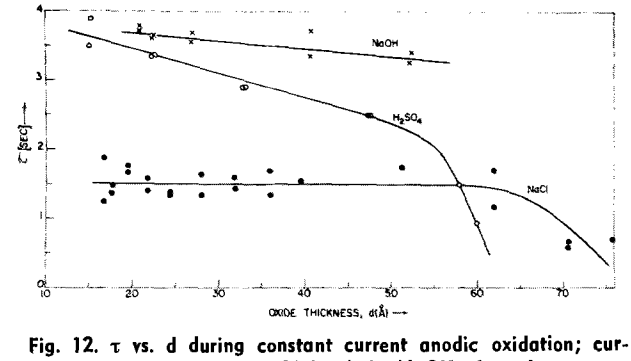

Fig. 12. τ vs. d during constant current anodic oxidation; currents as in Fig. 11; I = —11.9 μA in NaOH electrolyte.

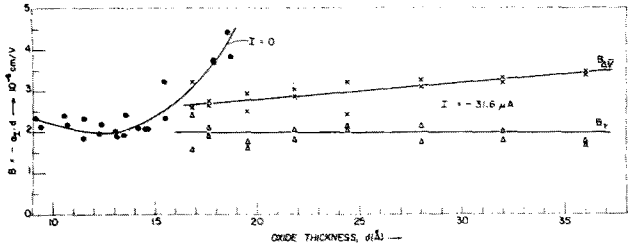

Fig. 13. B = $-\alpha_I d$ during spontaneous corrosion (•) and during constant current anodic oxidation (x, △) in NaCl electrolyte. The growth rate during spontaneous corrosion corresponded to an internal current of 24 μa at 12.3Å and 0.31 μa at 18.6Å.

are values of B for spontaneous corrosion, where measurements of τ and $\Delta\overline{V}$ must be combined in order to obtain α_I by the expressions of Table I.

In general, α_I is a function of V and of d. Comparing the values of α_I, (*a*) from anodic oxidation and (*b*) from open-circuit corrosion, at the same thickness d, we may expect differences in α_I, since the voltages in both cases are different. Only if thicknesses and voltages and thus the ionic currents were equal, we would expect equal α_I's. This was approximately the case at the minimum of the α_I– curve during open-circuit corrosion, where the ionic current by Eq. [2] is about 10 μa, which is of the same order as the current of 31 μa used during anodic oxidation. For thicknesses larger than those corresponding to the minimum of α_I, the current density at spontaneous corrosion drops off rapidly to values of the order of 1 to 0.1 μa when the spontaneous corrosion becomes so slow that experiments were stopped.

From the values of α_I and F_i, we may obtain $\beta_I = \alpha_I \cdot F_i$ in the range of anodic oxidation of 100% efficiency, *i.e.*, if $I = -I_I$. Since F_i is very nearly constant in this range, the plots of β_I reflect essentially the behavior of α_I and will not be given.

The range where the leakage potential is approached is characterized by (*i*) $I_I < -I$; (*ii*) a decrease in F_i; and (*iii*) a decrease in τ. The fact that $I_I < -I$, suggests that the electronic current I_E so far neglected, becomes noticeable and eventually dominant. An analysis of F_i, l, τ and $(\overline{V} - V_0)/V_1^2$ in this range could be used in principle to obtain α_E and β_E for the electronic current near the leakage potential. However, it was found that the behavior near the leakage potential differed so widely for different samples and even for different runs of a given sample that no such analysis was attempted.

Temperature dependence.—Preliminary measurements indicated that $\Delta V/V_1^2$ decreases with increasing temperature during spontaneous corrosion and may even change its sign. Since $\Delta V/V_1^2 = (-\alpha_I - \alpha_E)/4$ (Table I), this indicates that either α_E increases with temperature much more than $-\alpha_I$, or else $-\alpha_I$ decreases much more than α_E.

Capacitance transients.—During the transient studies, reversible changes of capacitance with external cathodic current, I (Fig. 1) and with a-c voltage, V_1, at zero external current were observed. The magnitude of these capacitance changes is shown in Table III. Note that the change of cathodic current by 0.4 μa and the change of a-c potential from 11 to 169 mv cause

Table III. Effect of a cathodic current *I*, and of an a-c potential V_1 on the d-c potential and on capacitance ($C = 270$ μf; $d \approx 17$Å); pH ~ 1, H_2SO_4 electrolyte.

I, μa	V_1, mv	ΔV, mv	τ, sec	ΔC_{DS}, μf	Δd, A
0 → 0.4	11	37	180	+0.5	−0.032
0.4 → 0	11	−40	210	−0.5	+0.032
0	11 → 160	34	46	+5.5	−0.35
0	160 → 11	−36	205	−6.4	+0.41

changes of d-c potential of similar magnitude; however, the changes in capacitance are an order of magnitude larger in the case of the a-c voltage. This shows that the capacitance changes are not merely due to the d-c voltage changes.

Discussion

We shall first discuss the values of the coefficients α_I, α_E, β_I, and β_E as expected for various charge transport mechanisms which either have been observed on "thick" anodic oxides (thick in comparison to the range covered by our investigation) or else have been proposed to occur during the air oxide formation on tantalum and aluminum.

These values will then be compared with the α_I, α_E, β_I and β_E coefficients derived from our experiments. Finally, we shall discuss observations which cast some doubt on the validity of the simple model used by us to extract the α's and β's from our experimental data.

The reaction

$$2Ta + 5H_2O \rightarrow Ta_2O_5 + 5H_2 \qquad [12]$$

generates an electric field in the oxide of a polarity which tends to move positive charges from the metal toward the electrolyte or negative charges in the opposite direction. These are the flow directions for the cations and anions participating in oxide growth. The emf of the reaction [12] is (in volts)

$$E = 1.05 + 0.059 \cdot (pH) \qquad [13]$$

since 0.81v is the free energy of the reaction under standard conditions and 0.24v is the correction for the SCE *vs.* the hydrogen electrode. Equation [13] provides 1.1, 1.4, and 1.9v for our electrolytes H_2SO_4, NaCl, and NaOH, respectively. When a voltage V is applied across the oxide, the average field in the oxide becomes

$$F = (E - V)/d \qquad [14]$$

If E is a constant, independent of oxide thickness, then

$$d\frac{\partial F}{\partial d} = -F + F_i \qquad [15]$$

During constant current anodization in the thickness range where F_i is a constant (Fig. 11), Eq. [15] is satisfied by $F = F_i = \text{const}$, so that Eq. [14] can be transformed into

$$E = V + d\,F_i \qquad [16]$$

E-values derived in this manner were $E \approx 0.9$v for the H_2SO_4 and NaCl-electrolytes, and 1.6v for the NaOH-electrolyte. The differences between E_1 by Eq. [16] and E_2 by Eq. [13] are similar to those reported by Vermilyea (17) for the HNO_3 and NaOH-electrolytes of pH = 0.6 and 13.5, respectively. The discrepancy between E_1 and E_2 may arise from contact potentials Ta *vs.* electrolyte-oxide interface.

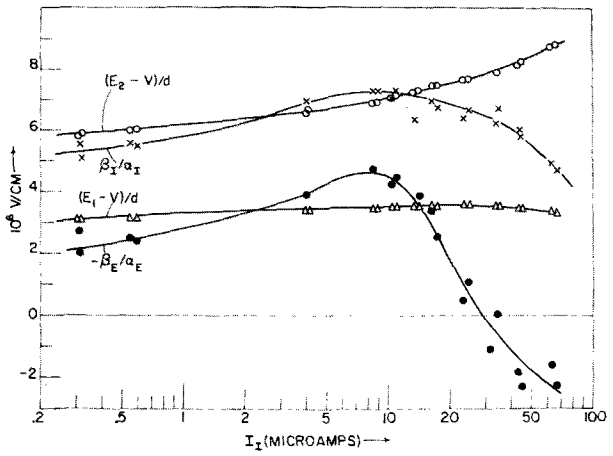

Fig. 14. β_I/α_I, $-\beta_E/\alpha_E$ and $F = (E-V)/d$ as functions of the ionic current derived from the growth rate during spontaneous corrosion in NaCl-electrolyte; $E_1 = 0.9$v and $E_2 = 1.4$v.

If the ionic current, I_I, would depend on thickness and voltage only through the average field F of Eq. [14] with E being constant the relation

$$\beta_I/\alpha_I = F \qquad [17]$$

should be valid, as seen readily from the definitions of β_I and α_I. This relation is indeed satisfied for constant current anodization, $I_I \approx -I$, where $\beta_I/\alpha_I = F_i$ (Table I), and since $F = F_i$, if $\partial I/\partial d = 0$.

In order to investigate whether the relation [17] applies in the range accessible by spontaneous corrosion, β_I/α_I and F were plotted *vs.* I_I (Fig. 14). Two curves for F are shown, one based on $E_1 = 0.9$v and the other on $E_2 = 1.4$v. The experimental values β_I/α_I show a pronounced downtrend toward the right. The curve $(E_2 - V)/d$, while fitting β_I/α_I at lower ionic currents exhibits a pronounced uptrend at higher currents. The curve $(E_1 - V)/d$ exhibits a slight downtrend at higher ionic currents, but lies much lower than β_I/α_I at the lower ionic currents. Thus we conclude that either the ionic current cannot depend on voltage and oxide thickness through the field F, or else the parameter E in Eq. [14] for F is not a constant (18), but changes from low values $E \simeq E_1$ to higher value $E \simeq E_2$, as the oxide thickness increases and the ionic current decreases. The Mott-Cabrera theory (4) is based on an exponential dependence of the ionic current on the field (14). Such a relation is not in agreement with the coefficients β_I and α_I as determined by us. Studies of air oxidation (5) of tantalum at or near room temperature also do not support the Mott-Cabrera theory.

Since the dependence of the ionic current through the oxide on voltage and thickness changes significantly at the small oxide thicknesses encountered in spontaneous corrosion, it appears doubtful that the corrosion currents can be derived by comparing the voltage-time dependence during spontaneous corrosion to values extrapolated from the voltage-current dependence for thicker anodic films (19, 20).

Studies of anodic oxidation of tantalum and other valve metals lead to the relation (21)

$$I_I = A \exp BF \qquad [18]$$

for oxide films which were generally much thicker than those encountered in spontaneous corrosion for oxide films. If this relation applies, our coefficient α_I is related to B by Eq. [11]. The B-values thus obtained for constant current anodization (Fig. 13) are indeed of the order of the transient B-values given in the literature (22, 23, 24).

In the range $d \gtrsim 13$Å, *i.e.*, for the thicknesses larger than that at the minimum of α_I at spontaneous corrosion, the values of $B = -\alpha_I \cdot d$ from spontaneous corrosion differ from those derived during constant current anodization (Fig. 13). This suggests that B for these thin oxides depends on the ionic current density, I_I, or on the voltage, V, and is not a constant as observed for thick anodic oxides where Eq. [18] and [14] appear to apply fairly well.

Recently the relation

$$I_I \simeq A' \exp B'\sqrt{F} \qquad [19]$$

has been proposed (25) instead of Eq. [18]. This relation leads to a dependence of α_I on V, which is much too small, however, to account for the differences of $B = -\alpha_I d$ for spontaneous corrosion and anodic oxidation shown in Fig. 13.

The expression [14] for the average field in the oxide implies that the changes in the measured voltage, ΔV, extend entirely across the oxide, and not partially across a solution double layer. If part of ΔV

would extend across such a double layer, $\overline{R}$ should be larger than R_T, while, in fact, R_T appears to be slightly larger than $\overline{R}$ (Table II).

The carriers causing charge neutralization move opposite to the flow which is induced by the average electric field [14]. Carrier flow against the electric field can occur by: (*a*) thermionic emission; (*b*) tunneling, and (c) diffusion. Furthermore, the possibility of localized flow at faults in the oxide, even pinholes, must be considered.

With respect to the last mentioned possibility, there is a large amount of evidence for leakage paths localized at faults or defects in the oxide (12-16). Vermilyea described techniques to make these spots visible by plating out metals (16). The spreading resistance into the electrolyte at these leakage points provides an upper limit for the current flow. If the entire potential V extends across this spreading resistance, the coefficient α_E should be the reciprocal of the voltage, V, which is of a reasonable order of magnitude.

If the number of flaws remains unchanged as the oxide grows, we would expect that $\beta_E = 0$. On the other hand, if the number of flaws or their effective area decreased due to blocking by lateral oxide growth from adjacent regions, negative values of β_E should arise.

Regarding the charge transfer mechanisms through the bulk oxide, evidence suggests electron rather than hole flow (16). Mott (3) has discussed thermionic emission and tunneling of electrons through a thin oxide barrier of height W. Theoretical expressions for α_E, β_E and $-\beta_E/\alpha_E$ for these cases are listed in Table IV.

The electron current due to thermionic emission is governed by the Boltzmann factor $e^{-W/kT}$, which lead to $\beta_E = 0$ and $\alpha_E = 40$ v^{-1} at room temperature, in disagreement with the experimental data. The observed values, $\alpha_E \simeq 10$ v^{-1}, could arise by a dual barrier model of symmetric potential barriers, as discussed for oxygen reduction on passivated Zr (26). Such dual barriers might exist at the faults where oxide growth is prevented and most of the current I_E is concentrated.

The tunnel current is governed by the factor[4] $\exp\left[-2d\left(\frac{2m^*W}{h/2\pi^2}\right)^{1/2}\right]$ provided that the tunneling is not limited by the lack of acceptors at the oxide electrolyte interface. Numerically $2\left(\frac{2m^*W}{h/2\pi^2}\right)^{1/2} \simeq 1$Å, for m^* equal to the free electron mass and $W \simeq 1$ ev. Table IV indicates that the ratio $-\beta_E/\alpha_E$ is independent of m^* and should be larger than $2F$. The data of Fig. 14 shows that $-\beta_E/\alpha_E$ is smaller than $2F$. Therefore, the tunnel model does not seem to account for the observed values of β_E and α_E.

Since none of the existing theories on the growth of protective films agrees with the experimental data for α_I, β_I, α_E and β_E, we have speculated on novel mechanisms which may explain these data. The existence of a minimum for α_I, α_E and β_I suggests that there is a transition from one dominant mechanism to another, or else that there is a fairly drastic change in the behavior of the dominant mechanism. As a possible cause for such a drastic change, we like to mention the following: From the average charge density at the oxide-electrolyte interface, $\epsilon\epsilon_0 F$, one may derive the average spacing of these charges. For sufficiently thin oxide films, the field at the tantalum opposite to these charges will be much larger than the average field of Eq. [14]. Moreover, the actual field at the metal oxide interface at positions opposite to a positive tantalum ion just arrived at the oxide electrolyte interface may even have a polarity opposite to that of the average field. This would, of course, facilitate the flow of electrons to preserve charge neutrality.

As a possible explanation for positive values of β_E, it is suggested that the net electron current arises as the difference of a forward current Ta to electrolyte and a back flow, electrolyte toward metal. The decrease of the back flow with increasing oxide thickness may cause positive values of β_E for the net current.

However, before theorizing in detail on the mechanisms of current transport, it would be well to have available measurements on the temperature dependences of α_I, α_E, β_I and β_E; and to clarify the following inadequacies of the model on which the derivation of α_I, α_E, β_I and β_E was based: (*i*) the dependence of "oxide thickness" on the electrolyte in which it is measured (1, 27); (*ii*) the unusually large temperature dependence of the oxide capacitance (1); (*iii*) the dependence of oxide capacitance on current, I, and on the amplitude of a-c voltage signal (Table III) [see also (27)]; (*iv*) the discrepancy between $\overline{R}$ and R_T (Table II); (*v*) the discrepancy between α_I as determined (*a*) from the time constant τ and (*b*) from the voltage change ΔV of a transient during anodic oxidation.

The evaluation of α_I from ΔV requires an assumption on the coefficient γ_I of the quadratic term in the dependence of current on voltage (Appendix A). The assumption made was based on the exponential voltage dependence shown in Fig. 3, in which case $\gamma_I/\alpha_I = \alpha_I/2$. In the case that Eq. [19] with [14] applies, one has $\gamma_I/\alpha_I = (\alpha_I/2)\left(1 - \frac{1}{B'\sqrt{F}}\right)$ which approaches the relation (A-13) for $B'\sqrt{F} >> 1$. It thus appears that the assumption made on γ_I does not account for the discrepancy between α_I (ΔV) and $\alpha_I(\tau)$.

In a formal manner one might use the identity $\alpha_I(\Delta V) = \alpha_I(\tau)$ of Table I to derive a value of $C_o \neq C_{ES}$ by means of the Eq. [4] of Appendix A. This value of C_o should be characteristic for the time constants of the transient, $\tau \simeq 1$ sec, rather than for 100 Hz at which C_{ES} is measured. However, such a formal treatment would not be sufficient to describe the results of slow changes in the space charge distribution in the oxide which may occur following the switch to a new, constant potential across the oxide.

The observations listed under (*i*) — (*v*) above indicate that the oxide does not behave as an ideal capacitor shunted by a resistor which is an instantaneous function of voltage. Further evidence for this statement are: The observations of Van Winkel *et al.* (22) regarding the frequency dependence of the equivalent parallel resistance of the oxide (changes as large as a factor of 3 between 100 and 1 Hz measured with anodic d-c current flowing) and the well-known discrepancy between the B-values of the relation [18] as derived by d-c (21) and transient methods (22-24).

Conclusions

1. The coefficients, $\alpha_I = \partial \ln I_I/\partial V)_d$, $\alpha_E = \partial \ln I_E/\partial V)_d$, $\beta_I = \partial \ln I_I/\partial d)_V$, and $\beta_E = \partial \ln I_E/\partial d)_V$, have been derived as functions of oxide thickness by combining measurements of the time dependences of V and d with those of time constant τ and voltage change $\Delta\overline{V} = \overline{V} - V_o$ of certain transients. The model used pre-

[4] The shape of the barrier may change the numerical coefficient of the exponent slightly, but that should not affect the following discussion.

Table IV. The coefficients α_E and β_E for thermionic emission and tunnel emission as suggested by Mott (3)

	α_E	β_E	$-\beta_E/\alpha_E$
Thermionic emission	q/kT	0	0
Tunnel emission[+]	$\left(\frac{2m^*}{h/2\pi^2}\right)^{1/2} qd$	$-2\left(\frac{2m^*W}{h/2\pi^2}\right)^{1/2}$	$2(F + \phi/d)$

[+] Using $W = \phi + q(E - V)$.

dicts a relation between $\Delta\overline{V}$ and τ at constant current anodization of 100% efficiency. However, this relation is only approximately satisfied, which sheds some doubt on the validity of the values obtained for α_I, α_E, β_I and β_E beyond a first order estimate.

2. The coefficients α_I and β_I during anodic oxidation at constant thickness in the thickness range 20-50Å are generally consistent with an anodic current depending on voltage and oxide thickness only through the average field $F = (E - V)/d$. The Tafel slope, $B = \partial \ln I_I/\partial F = -\alpha_I d$ agrees with published values derived by transient methods.

3. A plot of the growth rate during spontaneous corrosion *vs.* β_I/α_I shows that the ionic current is not merely a function of the electric field, F, particularly during the initial part of spontaneous corrosion.

4. The experimental evidence indicates that the growth of a protective oxide film on tantalum is more complex than assumed earlier (3, 4). Likely complicating factors include structural defects, and strong space charge polarization in the film, several species participating in the charge transfer mechanism and the fields due to discrete charges in thin oxides being quite different from those of quasicontinuous charge densities.

5. Clarification of the growth mechanism requires experimental methods to determine α_I, α_E, β_I and β_E as functions of oxide thickness and temperature. An improved model for evaluation of transients is required which removes the discrepancy between $\alpha_I(\tau)$ and $\alpha_I(\Delta V)$ at constant current anodization.

Manuscript received Nov. 7, 1966; revised manuscript received Feb. 3, 1967. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX A

Transients of Small Magnitude

The following mathematical analysis is based on the assumption that the currents I_I and I_E at a constant temperature are well-defined functions of oxide thickness and of voltage V. By development for small increments from the point d_o, V_o I_I^o, one obtains

$$I_I/I_I^o - 1 = \alpha_I(V - V_o) + \beta_I(d - d_o) + \ldots \quad [A\text{-}1]$$

and

$$I_E/(I_I^o + I) - 1 = \alpha_E(V - V_o) + \beta_E(d - d_o) + \ldots \quad [A\text{-}2]$$

where the relation [1] has been used for the quasistationary currents I_I^o and I_E^o before the transient. During the transient the conservation of charge requires that

$$(C_{ES} + C_o)\ \partial V/\partial t = I_I + I - I_E \quad [A\text{-}3]$$

which reduces to Kirchhoff's law [1] in the quasistationary state $\partial/\partial t = 0$. In Eq. [A-3] C_o denotes the oxide capacitance, and C_{ES} is the capacitance in the symmetric branch of the bridge circuit. Inserting [A-1] and [A-2] into [A-3] and letting $I \to I + \Delta I$ and $d - d_o \simeq 0$, one obtains an exponential voltage relaxation of time constant

$$\tau = \frac{C_{ES} + C_o}{\alpha_E(I_I^o + 1) - \alpha_I I_I^o} \quad [A\text{-}4]$$

and of amplitude

$$\Delta V = \Delta I[\alpha_E(I_I^o + I) - \alpha_I I_I^o]^{-1} \quad [A\text{-}5]$$

According to these relations the resistances defined by Eq. [3] and [4] ought to be equal provided that $C_o \simeq C_{ES}$. Because of $\overline{R} = R_\tau$, measurement of ΔV and of τ for the same current pulse do not provide two independent relations for calculating α_E and α_I. In the special case that $I = 0$, Eq. [A-5] provides a well-known expression (28) for the "corrosion resistance" in terms of the anodic and cathodic transfer coefficients which are related to α_I and α_E, respectively.

Next we shall analyze the transient generated by an a-c voltage applied at the oxide. Let

$$V = \overline{V} + V_1 \sin \omega t \quad [A\text{-}6]$$

where $\overline{V}$ is the time average over an a-c cycle. Let us consider first the case of quasistationary corrosion at $I = 0$. In this case, Kirchhoff's law $\overline{I_E} = \overline{I_I}$ applies to the time averages of the electronic and ionic currents. However, Kirchhoff's law does not apply to the instantaneous currents. During the cathodic half of the cycle the electronic current prevails, and during the anodic half of the cycle the ionic current prevails. If the dependence of I_E and I_I on $\overline{V}$ is nonlinear, the d-c potential $\overline{V}$, has to adjust in order that $\overline{I_I} = \overline{I_E}$. The time dependence of this adjustment is described by Eq. [A-3] with I_I, I_E, and V replaced by $\overline{I_I}$, $\overline{I_E}$, and $\overline{V}$. In order to analyze the change $\Delta\overline{V}$ which arises from the step increase of V_1, developments of I_E and I_I to higher than first order terms are required.

Let

$$I_I = I_I^o[1 + \alpha_I(V - V^o) + \gamma_I(V - V^o)^2 + \ldots] \quad [A\text{-}7]$$

Insert Eq. [A-6] and average over a cycle to obtain

$$\overline{I_I} = I_I^o[1 + \alpha_I(\overline{V} - V^o) + \gamma_I(\overline{V} - V^o)^2 + \gamma_I V_1^2/2 + \ldots] \quad [A\text{-}8]$$

The corresponding expression for $\overline{I_E}$ is obtained by replacing I_I^o by $I + I_I^o$ and α_I, γ_I by α_E, γ_E. Inserting these expressions into the relation $\overline{I_E} = \overline{I_I} + I$ provides

$$\Delta\overline{V} = \overline{V} - V^o = \left[\frac{V_1^2}{2}\right] \cdot \frac{I_I^o\gamma_I - (I_I^o + I)\gamma_E}{-I_I^o\alpha_I + (I_I^o + I)\alpha_E} \quad [A\text{-}9]$$

if we neglect $\gamma_I(\overline{V} - V^o)$ *vs.* α_I, and $\gamma_E(\overline{V} - V^o)$ *vs.* α_E as small order terms. Inserting Eq. [A-9] into [A-8] and neglecting the term $\gamma_I(\overline{V} - V^o)^2$ we obtain

$$\frac{\overline{I_I} - I_I^o}{I_I^o} = \frac{V_1^2}{2} \cdot \frac{(I_I^o + I)(\alpha_E\gamma_I - \alpha_I\gamma_E)}{-I_I^o\alpha_I + (I_I^o + I)\alpha_E} \quad [A\text{-}10]$$

Experimental data (Fig. 2) suggest voltage-dependences for I_E and I_I of the forms

$$I_I = I_I^o\, e^{\alpha_I(V - V_o)} \quad [A\text{-}11]$$

and

$$I_E = (I_I^o + I)\, e^{\alpha_E(V - V_o)} \quad [A\text{-}12]$$

so that

$$\gamma_I = \alpha_I^2/2 \quad [A\text{-}13]$$

and

$$\gamma_E = \alpha_E^2/2 \quad [A\text{-}14]$$

Inserting these values into Eq. [A-9] and [A-10], one obtains

$$\Delta V = \overline{V} - V^o = -(V_1^2/4) \cdot \frac{I_I^o\alpha_I^2 - (I_I^o + I)\alpha_E^2}{I_I^o\alpha_I - (I_I^o + I)\alpha_E} \quad [A\text{-}15]$$

and

$$\frac{\overline{I_I} - I_I^o}{I_I^o} = \alpha_E\alpha_I\frac{V_1^2}{4} \cdot \frac{(I_I^o + I)(\alpha_I - \alpha_E)}{-I_I^o\alpha_I + (I_I^o + I)\alpha_E} \quad [A\text{-}16]$$

The expression [A-4] for the time constant τ applies regardless of whether the transient is caused by a change in the external current or in the a-c voltage. Elimination of α_E from the Eq. [A-15] and [A-4] leads to a quadratic equation for α_I with the roots

$$\alpha_I = \frac{2C_{ES}}{\tau I}\left\{1 \pm \left[\left(\frac{I + I_I^o}{I_I^o}\right)\left(1 + \frac{\tau I}{2C_{ES}}\frac{4\Delta V}{V_1^2}\right)\right]^{1/2}\right\} \quad [A\text{-}17]$$

Expressions for the special cases: $I = 0$ (spontaneous corrosion), $I \simeq -I_I^o$ (large anodic current) and $I_I^o \simeq 0$ (large cathodic current) are listed in Table I.

APPENDIX B

Determination of the Coefficients β_E and β_I

Having determined α_I and α_E, we may obtain β_I and β_E from the changes of d-c voltage $\overline{V}$ with thickness d, and of thickness with time as follows: Insert Eq. [A-1] and [A-2] into Eq. [1] and differentiate with respect to d, to obtain

$$-\frac{\delta V}{\delta d} = F_i = \frac{\beta_I I_I^o - \beta_E (I + I_I^o)}{\alpha_I I_I^o - \alpha_E (I + I_I^o)} \quad [B\text{-}1]$$

The second relation required to calculate the β's is provided by the time dependence of the oxide thickness. Since $\partial d/\partial t$ is related to I_I by Faraday's law [2], one obtains for the expression [10] by means of [A-1] and [9]

$$l = -I_I^o \cdot \{[\partial I_I/\partial d]_V + [\partial I_I/\partial V]_d \cdot \partial V/\partial d\}^{-1}$$
$$= (\alpha_I F_i - \beta_I)^{-1} \quad [B\text{-}2]$$

By solving the Eq. [C-1] and [C-2] for β_I and β_E, one obtains

$$\beta_I = \alpha_I F_i - l^{-1} \quad [B\text{-}3]$$

and

$$\beta_E = \alpha_E F_i - l^{-1} \cdot I_I^o/(I + I_I^o) \quad [B\text{-}4]$$

Thus measurements of $V(d)$ and $d(t)$ permit the determination of F_i and l, which, combined with α_I and α_E, yield β_I and β_E. Expressions for special cases are listed in Table I.

APPENDIX C

Transients of Large Magnitude

According to Eq. [A-9], the voltage change ΔV depends quadratically on the a-c amplitude in the limit of the small signal approximation, where terms of higher than the second order in Eq. [A-7] can be neglected. In the case of larger a-c signals, and if Eq. [A-11] is valid, we have

$$\bar{I}_I = I_I^o \cdot e^{\alpha_I(\bar{V} - V_o)} \cdot f(\alpha_I V_1) \quad [C\text{-}1]$$

where

$$f(y) = 1/(2\pi) \int_0^{2\pi} e^{y \sin x}\, dx \quad [C\text{-}2]$$

is the modified Bessel-function of order zero, which can be approximated for $y >> 1$ by

$$f(y) \approx e^y/\sqrt{2\pi y} \quad [C\text{-}3]$$

Inserting Eq. [B-1] with [B-3] and the corresponding equation for $\bar{I}_E$ into Kirchhoff's law, one obtains the dependence of ΔV on V_1 for $|\alpha_I| V_1 >> 1$, and $\alpha_E V_1 >> 1$, which becomes for the special case that $I = 0$:

$$\bar{V} - V_o = \frac{|\alpha_E| - |\alpha_I|}{\alpha_I - \alpha_E} V_1 + \frac{\ln|\alpha_I/\alpha_E|}{2(\alpha_I - \alpha_E)} \quad [C\text{-}5]$$

APPENDIX D

Corrections to Constant Thickness for the D-C Analysis

One has from Eq. [A-1]

$$\delta I_I = I_o[\alpha_I \delta V + \beta_I \delta d] = I_o \alpha_I \delta V^* \quad [D\text{-}1]$$

where

$$\delta V^* - \delta V = \frac{\beta_I}{\alpha_I} \delta d = \left(F_i - \frac{1}{\alpha_I l}\right) \delta d \quad [D\text{-}2]$$

In transforming the last equation, we used Eq. [B-3] to eliminate β_I. Since $\alpha_I < 0$ and $F_i > 0$, both terms in parenthesis are positive. A similar correction applies to I_E *vs.* V. However, since $\alpha_E > 0$, F_i and $-1/\alpha_E l$ have opposite signs. It turns out that $F_i - 1/\alpha_E l$ is negative, so that the correction of the voltage scale for the $I_E - V$ plot has the opposite sign to that of the $I_I - V$ plot.

APPENDIX E

Validity of Kirchhoff's Law for Quasi-Stationary Condition

The average field in the oxide layer is given by [14] assuming that changes of the measured potential electrolyte *vs.* tantalum during oxide growth arise entirely from potential changes across the oxide, *i.e.*, that potential changes across the double layer in the electrolyte adjacent to the oxide can be neglected.

Since the oxide growth rate during spontaneous corrosion decreases with time, the ionic current through the oxide decreases accordingly, and this requires some change of the field F with time. This in turn requires that

$$S\epsilon\epsilon_0\, \partial F/\partial t = I_I - I_E \neq 0 \quad [E\text{-}1]$$

which appears to contradict our assumption $I_I = I_E$ in the quasi-stationary case. However, the left hand side can be transformed by means of [12], [2], and [9] into $C_{ES}\lambda I_I(F_i - F)$ where we used $C_o = S\epsilon\epsilon_0/d \simeq C_{ES}$. Thus Eq. [E-1] becomes

$$\frac{I_I - I_E}{I_I} = C_{ES}\lambda(F_i - F) \quad [E\text{-}2]$$

Insertion of numerical values on the right-hand side gives values smaller than, or of the order of 10^{-3}, so that $I_I \simeq I_E$ appears to be a valid approximation.

The same argument can be applied to the case of a finite external current.

Deposition of Tantalum and Tantalum Oxide by Superimposed RF and D-C Sputtering

F. Vratny

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The advantages and flexibility of glow discharge diode sputtering for the deposition of thin films can be greatly extended by the simultaneous application of a d-c and rf field at the cathode. The combined field increases the plasma density and prevents the formation of a dielectric film on the cathode during reactive sputtering. This technique allows: (*i*) operation at sputtering pressures of 0.5-2.0 millitorr with a tantalum deposition rate of ~80 Å/min, or a two-fold increase in tantalum deposition rate for pressures in the 10 to 20 millitorr range; (*ii*) high deposition rates (50 to 100 Å/min) for the deposition of Ta_2O_5 and MnO_x by reactive sputtering in pure oxygen.

Cathodic sputtering has proven to be an important process in the field of microelectronics for the deposition of many thin film materials (1). This technique is particularly important for tantalum based films which have a wide use for fabrication of reliable resistors and capacitors (2). However, the technique of cathodic sputtering is limited in its capacity for thin film formation since the deposition rate is largely determined and limited by the sputtering pressure and cathode voltage. Typically at a cathode voltage of 4 kv and a current density of 0.25 ma/cm^2, a sputtering pressure of 20 millitorr, and a 13 to 16 cm diameter cathode, the deposition rate of tantalum is about 80Å/min. This rate can be increased by a factor of about three by variation of the sputtering pressure, voltage, and interelectrode spacing. For this range of deposition rates, the depositing tantalum film incorporates substantial quantities of inert sputtering gas as well as many reactive residuals that are present in the vacuum system during deposition. At a pressure of 20 millitorr of inert gas and an initial pressure of 2×10^{-6} Torr, there is as much as 10 a/o (atomic per cent) impurity, of which about 2% is argon (3). This amount of rare gas may affect the electrical properties and stability of these films. Enhancement of the deposition rate should reduce the impurity content of these films. Alternatively, reduction of the sputtering gas pressure, without loss of deposition rate, should reduce the amount of inert gas in the film.

Tantalum oxide is particularly difficult to deposit as the deposition rate in pure oxygen is in the range of 0.5 to 5.0 Å/min (4). Several techniques are available to enhance the deposition rate as the microwave oxygen plasma techniques of Ligenza (5), the Hot Cathode Discharge (6) techniques, which is not generally applicable to reactive sputtering, the magnetic confinement Penning Discharge (7) technique which may be inconvenient for magnetic film deposition and physically difficult to realize in many vacuum systems.

Alternately, Moore (8) and Gawehn (9) employed rf techniques to generate ion beams for sputtering, while Wehner (10) employed an rf technique to sputter dielectrics directly. The technique of rf dielectric sputtering has been explored in depth by Jorgenson and Wehner (11) and Davidse and Maissel (12) for the preparation of thin films.

The method described in this paper represents a more flexible technique as it combines a number of separate functions by applying both d-c and rf power directly to the sputtering cathode. It is possible to employ metallic cathodes for both the deposition of metallic and dielectric films.

When an rf field is applied to a discharge, the charged particles decribe oscillatory paths in response to the alternating field. Electrons traveling under the influence of a superimposed rf and d-c field have a larger total path than with a d-c field alone. The larger path increases the probability of electron-gas atom collisions leading to an increase in positive ion current density at the cathode for a given pressure. This results in an increase in the rate of sputtering and film deposition. The manner in which electrons interact in a gas is dependent on the gas pressure or electron mean free path, the frequency of the rf field and the interelectrode spacing. At low pressures where the mean free path is greater than the interelectrode separation, the electrons are excited and traverse the electrode space with almost no gas collisions. As an example in argon, electrons (13) with an energy of 0.4 ev at a pressure of 10 millitorr have a mean free path of 10 cm or roughly the dimension of conventional interelectrode spacing. At pressures where the mean free path of the electron is less than the interelectrode spacing yet the frequency of the field is less than the collision frequency of the gas the electrons make many collisions for each oscillation of the field and the electrons tend to drift in phase with the field. An example of this method of ion generation is found in low frequency (60 ~) a-c and a-c + d-c sputtering (14) where the electrons alternately bombard the cathode and substrate.

At higher frequency, the electrons can make many oscillations of smaller amplitude between gas collisions. In this case, the electron cloud would appear to be stationary and would result in an intense plasma which can be extracted by a superimposed d-c field. This is the range of frequency of interest to this particular paper for it is by the "standing" cloud that we hope to produce an intense ion cloud that can be extracted by a d-c field. At still higher frequencies (microwave), the electrons are under the influence of a standing wave with oscillatory electric and magnetic components and as a result the electrons are distributed in space in response to cavity parameters, *i.e.*, cell or electrode dimensions and the frequency that is producing the standing wave.

The presence of the rf field serves further to prevent the formation of a dielectric layer at the cathode during reactive sputtering with electronegative gases. As the ion density can be maintained by the rf field, the resultant bombardment at the cathode decreases the chance of significant insulator formation. Should an insulator surface be produced, the rf induced charge at the surface (10) would maintain the sputtering process and further decrease the insulator formation process. Due to the higher ionization probability and the reduction in the breakdown strength of the gas (19), the rf field permits operation at lower sputtering pressures than are normally encountered in d-c diode sputtering. Finally, these processes can be

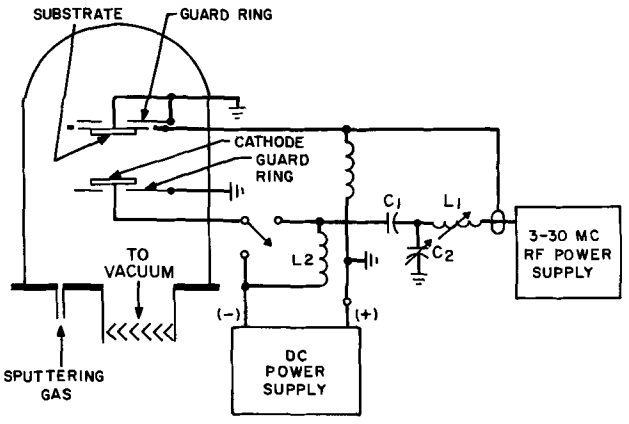

Fig. 1. Schematic of thin film deposition system

utilized with the usual large diameter (10-40 cm) cathodes encountered in d-c diode sputtering configurations, therefore not sacrificing the uniformity and film producing capability found in such systems.

Experimental

The vacuum chamber used in this work was a stainless steel bell 46 cm in diameter by 92 cm high and had a view port in line with the cathode. It was pumped by a 10.2 cm oil system that was liquid nitrogen trapped, see Fig. 1. This system had an ultimate pressure of 1 x 10^{-6} Torr and a leak rate of 0.05 millitorr liter/sec. Sputtering gas was admitted at a constant flow rate and the desired pressure was maintained by throttling the pump with a high vacuum valve. The cathode was 13 cm in diameter and 7.6 cm from the substrate. Normally, the bell jar, the fixtures, and the substrate were held at ground potential and either d-c or d-c and rf power was transmitted to the cathode through a coaxial line. The simultaneous application of power required a filtering network to protect personnel and equipment. A capacitor (C_1) was used on the rf line and an inductor (L_2) was used on the d-c line. Coupling or impedance matching to the sputtering machine was accomplished by link or transformer couple as well as T,L- and pi-networks (15). An L-network (C_2 and L_1) is indicated in Fig. 1. Alumino borosilicate glass slides to be coated were cleaned in Alconox and Igepal followed by a sequential rinse in water, hydrogen peroxide, and distilled deionized water.

Results

In a rare gas (argon) used for direct metal deposition, the application of rf power to a normal d-c diode sputtering arrangement produces an increase in the plasma density, as indicated by the larger plasma conductance (see Fig. 2). Using only d-c plasma excitation at 50 millitorr of argon, the current at a given voltage is smaller [curve (I)] than with combined plasma excitation by d-c and 100w of rf power [curve (II)]. In this example, the plasma conductance is improved by a factor of three at 500v, a factor of two at 1000v, and a factor of ½ at 2500v. At lower pressures (5 millitorr), the d-c excited plasma has a very small conductance at 3000v and a zero conductance at 2000v [curve (III)]. Yet, with superimposed d-c and rf plasma excitation there is a significant conductance for voltages as low as of 500v. The significance of the large plasma conductance is that it makes feasible a much lower pressure range for sputtering.

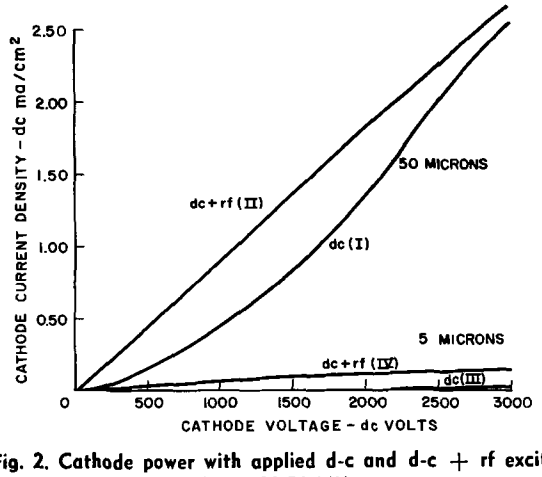

Fig. 2. Cathode power with applied d-c and d-c + rf excitation in argon; rf power ≈ 100w at 13.56 MHz.

Table I. Comparison of the deposition rate of tantalum with and without rf enhancement

Method	Argon pressure, millitorr	Deposition rate, Å/min	d-c Current density, ma/cm²
d-c	20	80	0.35
d-c + rf	20	176	0.50
d-c	1.5	0*	0
d-c + rf	1.5	76	0.23

* Discharge could not be maintained: cathode diameter 13 cm, cathode spacing 7.6 cm, cathode voltage 4 kv.
rf Power ≈ 200w, V = 280 Vpp, 13.56 mc.

These improvements in the plasma density, the plasma conductance, are reflected in the deposition rate of the cathode material. As an example (Table I) in the sputtering of tantalum, at a pressure of 20 millitorr of argon and a d-c cathode potential of a 4 kv, we have a deposition rate of ~80 Å/min of tantalum. With the application of d-c and rf plasma excitation, the rf at 200w, there is a deposition rate of 176 Å/min.

Further, by reducing the sputtering pressure to ~1.5 millitorr, a glow discharge could not be obtained with a d-c potential alone on the cathode. With the d-c + rf plasma excitation, not only could a discharge be obtained but the sputtering rate was ~76 Å/min, nearly that obtained at 20 millitorr, and the process was more efficient in terms of current density. A significant feature in this phase of the work is the ability to use lower sputtering voltages for a given pressure, *i.e.*, the 80 Å/min sputtering rate might easily have been obtained with rf + d-c plasma excitation at 20 millitorr and a 3 kv cathode potential.

In a reactive gas, the d-c discharge deposition rate is inversely proportional to the reactive gas partial pressure. As an example (Fig. 3) for the reactive

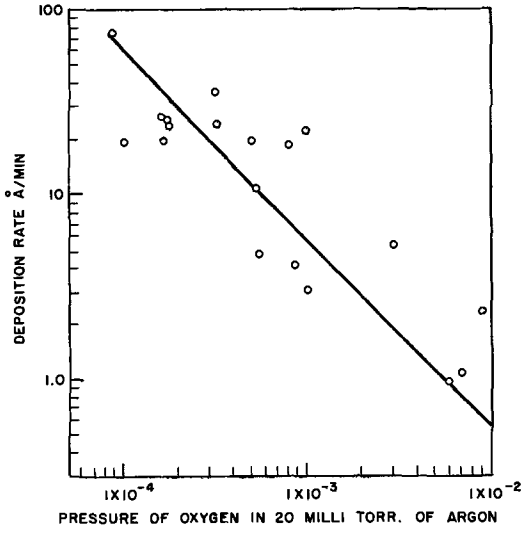

Fig. 3. Deposition rate of tantalum oxide as a function of oxygen partial pressure in argon (Å/min = 6 x $10^{-3}/P_{O_2}$); cathode voltage 4 kv, total pressure 20 millitorr.

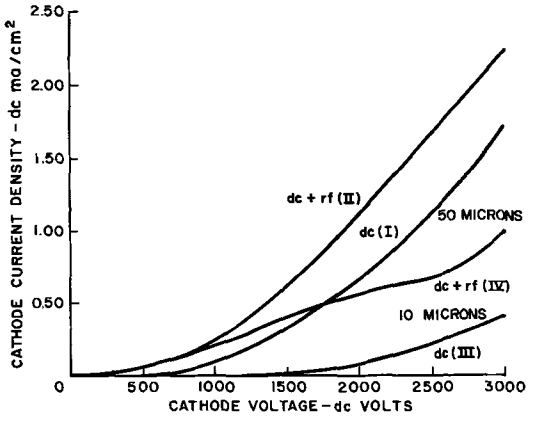

Fig. 4. Cathode power with applied d-c and d-c + rf excitation in oxygen; rf power ≈ 100 w at 13.56 MHz.

sputtering of tantalum oxide by the d-c diode sputtering technique, the deposition rate has been found to be relatively constant over the range corresponding to oxygen solution in tantalum. The deposition rate begins to drop however, in the range in which tantalum oxide begins to precipitate (at about 1 x 10^{-4} Torr). Higher pressures are normally used to assure stoichiometry, but at a loss in the deposition rate. At a pressure of 1 x 10^{-3} Torr the deposition rate is 5 Å/min.

The rf + d-c plasma excitation method appears to offer a solution to this problem for the plasma conductance in pure oxygen is improved by dual excitation (Fig. 4). At a high pressure (50 millitorr) a 100% improvement occurs in the plasma conductance at voltages above 1000v (curve I for d-c plasma excitation, curve II for d-c + rf excitation) while at low pressure (10 millitorr), the improvement is more pronounced with as much as a factor of two improvement in the plasma conductance at 1500-2000v (curve III for d-c plasma excitation, curve IV for d-c + rf excitation).

The improvement in the plasma density, the plasma conductivity, is directly correlated with an improvement in the deposition rate of the tantalum oxide insulating film. As an example (Table II), the deposition of tantalum oxide from a tantalum cathode is 0.1 Å/min by d-c diode reactive sputtering at a cathode potential of 4 kv and an oxygen pressure of 20 millitorr. With 200w of rf power added, the deposition rate is 58 Å/min. Manganese oxide is sputtered from a manganese cathode at a deposition rate of 1 Å/min by the d-c diode sputtering technique while the addition of 200w of rf power increases the deposition rate of ~100 Å/min. Aluminum oxide is sputtered from an aluminum cathode at 8 Å/min by the d-c diode sputtering technique. Addition of 200w of rf power increases the deposition rate to ~80 Å/min.

Component Results

The data for single samples, at one thickness and set of conditions, is found in Table III. For tantalum

Table II. Oxide film comparison of the deposition rate of oxide film materials with and without rf enhancement of the rate in oxygen

Method	Cathode material	Deposited material	Deposition rate, Å/min
d-c	Tantalum	Ta_2O_5	0.1
d-c + rf	Tantalum	Ta_2O_5	58
d-c	Manganese	MnO_x	1.0
d-c + rf	Manganese	MnO_x	100
d-c	Aluminum	Al_2O_3	8
d-c + rf	Aluminum	Al_2O_3	80

Cathode diameter 13 cm, cathode spacing 7.6 cm, cathode voltage 3-4 kv.
rf Power ≈ 200w, V = 280 Vpp, 13.56 mc, oxygen pressure ≈ 20 millitorr.

Table III. Comparison of oxide film materials prepared by d-c + rf sputtering technique

	Ta-Ta_2O_5 gold	Ta-Ta_2O_5* MnO_x-gold	Ta-Al_2O_3 gold
Thickness (Å) of oxide	1000	2000 Ta_2O_5 300 MnO_x	400
Capacitance per unit area ($\mu f/cm^2$)	0.26	0.096	0.25
Tan δ(1kc)	0.02	0.007	0.01
ϵ	26	22	10
Area = 0.1 cm^2			

* Anodic tantalum oxide of ~ 2000Å.

oxide deposited on tantalum, at a thickness of 1000Å, the capacitance per unit area (0.1 cm^2) is 0.26 $\mu f/cm^2$, with a calculated dielectric constant of ~26 and a dissipation factor of 0.02. The dissipation factor is at least ten times better than film prepared by other vacuum techniques and is nearly as low as tantalum oxide films prepared by aqueous anodization (16) which typically exhibit a dissipation factor of less than 0.01.

For manganese oxide deposited on anodic tantalum oxide we find that at a thickness of 300Å of manganese oxide a capacitance per unit area of 0.096 $\mu f/cm^2$ results and a dissipation factor of 0.007. This is comparable in quality to anodically prepared tantalum oxide (17) with metal counter electrodes, which has a capacitance density of 0.1 $\mu f/cm^2$ and dissipation factor less than 0.01, while the dissipation factor is considerably improved compared to thermally formed manganese oxide. For aluminum oxide deposited on tantalum at a thickness of 400Å a capacitance per unit area of 0.025 $\mu f/cm^2$ and a dielectric constant of ~10 with a dissipation factor of 0.01 results. This result is better than previously reported information on alumina films as these films exhibit a nominal dielectric strength measured at a voltage ramp of ~30 v/min of roughly 1 x 10^6 v/cm for 0.1 cm^2 samples compared with previously reported results of 6 x 10^5 v/cm for 0.0625 cm diameter spot samples (18).

The general method of rf + d-c plasma excitation demonstrates advantages for the deposition of metal films. First it can be used without alteration of presently existing d-c diode sputtering equipment. The technique is particularly useful at lower pressure and lower cathode voltages for studies of sputtering gas impurity effects and growth and orientation effects that are determined by the deposition rate. It also allows for the direct deposition of dielectrics from metal cathodes which are generally more readily available in higher purity than many dielectric materials. Therefore many dielectric materials can be directly deposited by this technique.

Manuscript received Oct. 27, 1966; revised manuscript received Dec. 22, 1966. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Incorporation of Ions in Anodic Oxide Films on Zirconium and Their Effect on Film Behavior

J. C. Banter

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Transmission spectra of anodically formed ZrO_2 films show that certain anions such as phosphate, sulfate, and several carboxylates are incorporated in these films when they are formed in solutions containing these ions. Furthermore, hydrous ZrO_2 films result from anodizing in strongly oxidizing electrolytes. Films formed in many other solutions contain no incorporated ions. Film conductivity and thickness measurements indicate that incorporated ions increase the electrical resistance of the films, as well as limit their growth. It is suggested that these effects arise from lowered rates of diffusion of electrons and oxygen ions through the films and that the lowered diffusion rates result from the space charge created by the incorporated ions.

In prior work on anodic oxide films on zirconium (1, 2) we formed our films in a complex organic solution containing water, glycerin, ethyl alcohol, and lactic, citric, and phosphoric acids. This solution was developed for the specific purpose of minimizing the variations in film thickness across the surface of anodized polycrystalline specimens. The solution met this purpose admirably. However, we had noticed for some time that anodic films formed in this solution were always thinner than those formed at comparable voltages in the more commonly used 1% KOH solution. We also noted that films formed in this solution dissolved into the zirconium-base metal at a much slower rate during vacuum annealing than did those formed in 1% KOH (3).

These observations suggested that the films formed in these two solutions differed in some manner. Therefore, we initiated an experimental program to see if we could determine the nature of this difference and what effects it might have on the film behavior. This paper reports the results of this investigation and those of additional work which was suggested by preliminary results.

Experimental

Rectangular specimens of 0.020-in. thick zirconium foil were prepared by a previously described procedure (2). Oxide films were formed on specimens by anodizing for 30 sec at constant voltages in the organic solution as well as in each of the following solutions: 0.5M H_3PO_4, 0.5M H_2SO_4, 0.5M citric acid, 0.5M oxalic acid, 0.5M lactic acid, 1% KOH, 0.5M $(NH_4)_3BO_3$, saturated H_3BO_3, 0.25M Na_2MoO_4, 0.5M $K_2Cr_2O_7$, 0.5M K_2CrO_4, and 0.5M KNO_3. Clear windows of the oxide film were made on each specimen by dissolving the base metal away from a rectangular area with a 20% solution of bromine in ethyl acetate. The infrared transmission spectrum of each of these films was then recorded on a Perkin-Elmer Model 21 spectrophotometer.

Other duplicate specimens were anodized for 30 sec at a constant voltage of 100v in all of the above solutions except lactic acid, H_3BO_3, $K_2Cr_2O_7$, K_2CrO_4, and KNO_3. The reflectance of each of these specimens was recorded throughout the ultraviolet-visible region of the spectrum with a Perkin-Elmer Model 4000 A spectrophotometer equipped with a spectral reflectance attachment. The film thicknesses were calculated from the observed interference patterns using refractive index and phase shift data reported elsewhere (1, 4).

The d-c conductivity of each film was then measured. The specimens were masked with electrical tape so that only a known flat area of about 0.75 cm^2 was exposed. The specimen was connected in series with a Model 610 B Keithley electrometer and an external power supply. One electrical contact was made directly to the substrate and the other contact was made to the exposed oxide by immersing it beneath the surface of a pool of mercury. A known voltage (1-2v) was applied across the film, and the current flow was read from the electrometer. The applied voltage was always greater than 100 times the full-scale input drop of the electrometer so the film resistance was given simply by dividing the applied voltage by the measured current. Conductivities were calculated from the exposed film areas, film thicknesses, and the measured resistances.

To check for suspected differences in their chemical reactivities, films were formed on two specimens to approximately the same thickness (1700Å) in two different electrolytes. One film was formed at 100v in the organic solution, and the other was formed at 63v in 1% KOH. Each specimen was dipped into a 5% solution of HF for successive 10-sec periods with the specimen being washed free of HF between each dip. The film thickness was estimated after each dip by comparing its interference color with those on a set of standard specimens whose thicknesses had previously been determined spectrophotometrically, and varied from 0 to 3500Å. The infrared transmission spectrum of a film formed in the organic solution and chemically thinned in this fashion was also recorded.

Results

The spectrum of the anodic film formed in the 1% KOH solution is shown in Fig. 1. The ZrO_2 absorption band at 14.3μ seen in this spectrum recurs in the

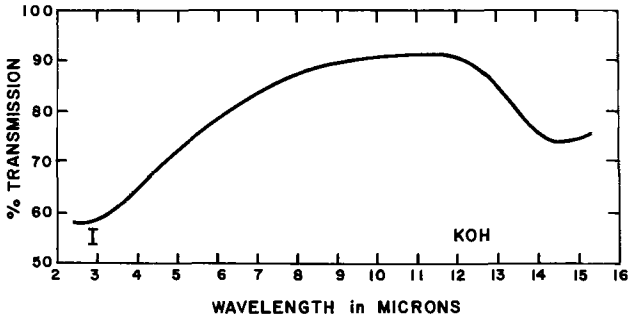

Fig. 1. Infrared transmission spectrum of an anodic ZrO_2 film formed at 125v in 1% KOH solution.

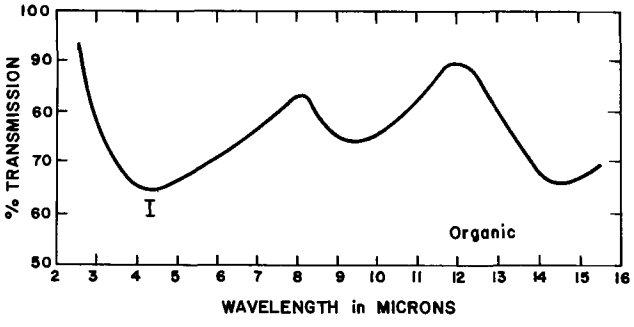

Fig. 2. Infrared transmission spectrum of an anodic ZrO_2 film formed at 400v in the organic solution.

spectra of all the films measured. The band just below 3μ is not a true absorption band but a minimum in the transmitted intensity resulting from first-order interference effects in the film. Similar interference minima occur in most of the spectra to follow, and their position is noted by the letter I on each spectrum.

The spectrum of the film formed in the complex organic solution shown in Fig. 2 exhibits an absorption band at about 9.3μ which was not seen with the KOH film. Miller and Wilkins (5) have shown that the absorption band for the phosphate ion in inorganic compounds falls between 9 and 10μ. Therefore, the 9.3μ band observed here is attributed to phosphate ions incorporated in the film during anodization. A similar band occurs in the spectra of films formed in H_3PO_4 solutions.

An absorption band appears at 9.0μ in the spectrum of the film formed in H_2SO_4 as shown in Fig. 3. This band is characteristic of the sulfate ion suggesting that it is also incorporated into anodically formed films.

Figure 4 presents the spectrum typical of films formed in solutions of the organic acids. The double absorption bands with peaks at about 6.5 and 7.2μ in this spectrum are typical of absorption arising from the resonance between the two possible C-O bonds in the carboxylate ion structure. This indicates the presence of oxalate, lactate, and citrate ions in these films, again presumably incorporated during anodization.

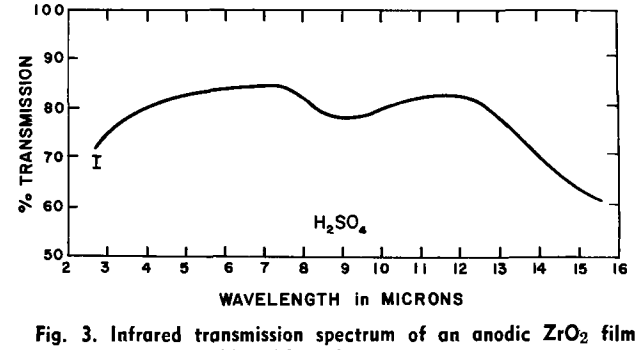

Fig. 3. Infrared transmission spectrum of an anodic ZrO_2 film formed at 100v in 0.5M H_2SO_4 solution.

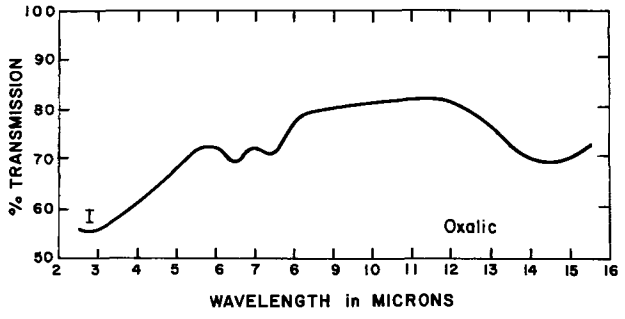

Fig. 4. Infrared transmission spectrum of an anodic ZrO_2 film formed at 150v in 0.5M oxalic acid.

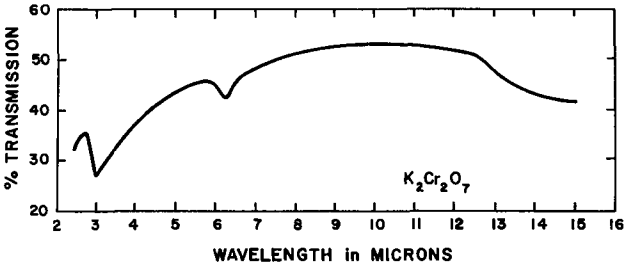

Fig. 5. Infrared transmission spectra of anodic ZrO_2 films formed at 100v in 0.5M $K_2Cr_2O_7$.

Neither the spectra of the films formed in the borate solutions nor the spectrum of the film formed in Na_2MoO_4 exhibit absorption bands other than those attributable to the film itself or interference effects. Thus, these films are similar to the one formed in KOH in that they apparently contain no impurity ions.

The spectrum of the film formed in $K_2Cr_2O_7$ is shown in Fig. 5. The two absorption bands at 3.1 and 6.2μ in this spectrum are at positions corresponding to the stretching and bending modes of the O-H bond in bound water. These two bands, as well as the broadening of the 14.3μ ZrO_2 band, are characteristic of the hydrated oxide indicating that such an oxide is formed on anodization in these solutions. There is no indication of other ions in these films. The spectra of the films formed in both K_2CrO_4 and KNO_3 also indicate a hydrated film.

The results of the thickness and conductivity measurements are summarized in Table I. The films formed in solutions which produced incorporated ions were much thinner, on the average, than those formed in solutions producing ion-free films. The conductivities of the two types of film also differ, with the average value for ion-free films being about 35% higher than the average value for the films containing ions.

The dissolution by HF of the two films formed to approximately the same thickness in KOH and the complex organic solution is represented in Fig. 6. The KOH film did not appear to dissolve at all after 2 min exposure to the HF. The organic film dissolved rapidly at first; but on reaching a thickness of about 950Å after 90-sec exposure, the dissolution ceased. The 9.3μ ab-

Table I. Thickness and conductivities of anodic oxide films formed on zirconium at 100v in various anodizing solutions

Anodizing solution	Film thickness, A		Film conductivity (ohm^{-1} cm^{-1}) × 10^{14}	
	Specimen 1	Specimen 2	Specimen 1	Specimen 2
Organic	1780	1736	1.50	1.68
0.5M H_3PO_4	1801	1775	1.89	1.69

sorption band attributed to phosphate ion was not evident in the spectrum of the chemically thinned film.

Discussion

The detection of incorporated ions in anodic films was not completely unexpected. Plumb (6) and Bernard (7) both found phosphorus in anodic films formed on aluminum in phosphate solutions, and Bogoyavlenskii and Dobrotvorskii (8) found both carbon and cobalt occluded in such films formed in carbonate solutions containing cobalt in a complex anion. Bernard and Randall (9) found boron in anodic Al_2O_3 films formed in borate-glycol solutions. Others (10-12) have variously reported the occlusion of phosphorus and sulfur in anodic tantalum and niobium oxide films formed in phosphate or sulfate solutions.

Many of these workers have suggested that the incorporated materials are present in the films as anions. However, the spectrographic and radiochemical methods they used to detect their presence could not truly define the chemical species. The present work shows quite clearly that the impurities found in the anodic films on zirconium are present as phosphate, sulfate, and carboxylate ions, and lends credence to the speculations of these prior workers.

It was surprising that the KOH film was not attacked by the HF solution. However, this fact gives an indication of the distribution of the phosphate in the film. Smyth, Tripp, and Shirn (10) and Randall, Bernard, and Wilkinson (11) have shown that in anodic films formed on tantalum in phosphate solution, there is a phosphorus-free layer of oxide adjacent to the metal surface. Above this they found a second layer, of thickness equal to 50-65% of the total film thickness, through which the incorporated phosphorus was evenly distributed. The portion of the film formed in the complex organic solution remaining after the initial dissolution of about 750Å of its thickness was not attacked further on exposure to the HF solution. This remaining layer was shown to be ion-free, as was the KOH film which was not attacked by the HF. This indicates that the phosphate ion contained in the film was held in the outer 750Å layer that was dissolved. This layer represented about 44% of the total film thickness. Thus, it appears that the phosphate-ion impurities are incorporated in thinner layers in anodic films on zirconium than in anodic films on tantalum. Whether the phosphate impurities are evenly distributed in this layer, as they are in films on tantalum, cannot be definitely determined from these results. However, the dissolution rate of this outer layer appears to be reasonably constant as the thickness decreases suggesting such a distribution. Although no attempt was made to determine the distributions of the sulfate or carboxylate ions occluded in the films, they would presumably be similar to that of the phosphate ion. Draper (12) feels that sulfur found in films formed on tantalum and niobium in sulfate solutions is distributed throughout the thickness of the films, but presents no real evidence in support of his position.

Because of their ease of preparation, anodic oxide films on zirconium are often used in experimental studies with the assumption that results may be equated with the behavior of corrosion films under the same conditions. The detection of impurity ions in anodic films formed in phosphate, sulfate, and carboxylate solutions, and the detection of a hydrated oxide product when anodizing in electrolytes containing strongly oxidizing ions suggests that films formed in these particular solutions should not be used for this purpose. These films are not strictly equivalent to corrosion films, which are presumably pure oxide. In fact, solutions other than those investigated here may also produce films with ion impurities; and great care should be exercised in choosing electrolytes in which to form films for such use. Present results indicate that films formed in solutions of $(NH_4)_3BO_3$, H_3BO_3, Na_2MoO_4, and especially those formed in dilute KOH should be suitable to use in this capacity since they appear to be free of occluded ions.

Indeed, the ions occluded in films lead to other types of film behavior quite different from that observed with ion-free films. For example, the ions seem to impart greater electrical insulating character to the films as indicated by the higher conductivity of the ion-free films. Results of the thickness measurements further suggest that these ions very effectively limit the film growth during anodization. This growth is generally pictured as proceeding via the diffusion of oxygen in the form of oxide ions through the film toward the metal with a counter diffusion of oxide-ion vacancies and electrons. It was shown (11) that the phosphorus in anodic films on tantalum was immobile in the layer of oxide in which it was contained. If the ions detected here are similarly immobile, they could create a stationary negative space charge which would oppose the diffusion of both oxide ions and electrons through the films. This would lower both the ionic and electronic conductivity of the film during its growth, thereby producing thinner films for a given voltage than would be obtained were the space charge not present. A similar limiting of the mobility of oxygen was suggested for phosphorus-containing films on tantalum (10). This model for the growth-limiting effect suggests that pre-anodizing zirconium to cover it with one of these ion-containing films may prove beneficial in increasing its corrosion resistance. It has been reported (10) that tantalum covered with an anodic film containing occluded phosphorus gained 25% less weight when heated at 400°C in oxygen than did tantalum with a film containing no phosphorus.

The drastic reduction of the rate of dissolution of anodic films on zirconium into the underlying metal is apparently a further consequence of the presence of ion impurities in these films. For example (3), the thicknesses of films formed on zirconium in the complex organic solution and 1% KOH decreased by 50 and 710Å, respectively, when the specimens were heated in vacuum at 450°C for 16 hr. This dissolution process is also considered operative in the over-all corrosion mechanism of the metal, and any decrease in the rate of dissolution should improve its corrosion behavior. Since the ions are confined to an outer layer of the film, it is not immediately clear just how they affect a process occurring some distance away at the metal-oxide interface. One possible explanation is that the kinetics of the dissolution are such that the rate-controlling step is the filling of anion vacancies which result from the dissolution with oxygen ions from the outer portion of the films. The rate of filling these vacancies would then be equivalent to the rate of diffusion of oxygen ions through the outer oxide layer containing the ions. This model agrees well with the experimental observations.

Conclusions

Polyatomic ions such as phosphate, sulfate, and various carboxylates are incorporated in anodic oxide films formed on zirconium in solutions containing these ions. These ions are occluded in an outer layer of the film with ion-free oxide between this layer and the substrate metal. The presence of these ions greatly affects the chemical reactivity of the films. The ions also appear to enhance the electrical resistivity of the films and limit their growth rate as well as their rate of dissolution into the underlying metal. These effects are attributed to the ions creating an immobile space charge in the outer layer which opposes the diffusion of both oxygen ions and electrons through this portion of the film.

The Effect of Various Optical Radiations and Water Vapor on the Trapping Spectrum of CdS

Paul A. Faeth

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

ABSTRACT

Trapping levels in a cadmium sulfide single crystal were studied by the thermally stimulated current method. In all, six trapping levels were detected in the crystal. A study of the shallow traps, which occurred at 0.04, 0.12, and 0.13 ev below the conduction band edge, indicated that electrons could be excited directly to the 0.13 ev level. A peak in the photoconductivity was observed at —60°C when the crystal was cooled in the presence of IR and 533 mμ light. The center with level at 0.13 ev appears to behave as a recombination center for temperatures greater than —60°C and as a trapping center which can be emptied optically at temperatures less than —60°C. Other experiments involving cooling during illumination indicated the presence of another trapping level which apparently could not be filled from the conduction band. Water vapor which was adsorbed on the crystal surface produced thermally stimulated current (TSC) peaks at 80°-100°C in the absence of any treatment of the crystal by light. The appearance and magnitude of these TSC peaks were affected by light as well as the partial pressure of water vapor. Pumping over the crystal with adsorbed water present also stimulated currents. Both of the latter observations are believed due to the dissociation of an adsorbed species such as $(H_2O)^-$ on the crystal surface.

Cadmium sulfide is a material of considerable interest because of its photoconductive properties. It has found wide use as a photoconductor and more recently has shown promise as a solar cell material (1). The photoconductive properties of cadmium sulfide are modified by the presence of electron and hole traps in the crystal (2, 3) and by adsorbed gases, which may produce electrical effects similar to traps (4-6). It is reasonable to suppose, therefore, that the operation of devices such as the cadmium sulfide solar cell will be affected by the presence of traps and adsorbed gases. Indeed, adsorbed water vapor seriously damages cadmium sulfide solar cells and photoconductors.

In an effort to obtain further insight into the effect of gases and light on the photoconductive properties of cadmium sulfide, an experimental study was made of some of the effects of water vapor and light on the trapping spectrum of cadmium sulfide. Water vapor is notorious for causing experimental difficulties in high vacuum equipment. Unless special precautions and equipment are employed which remove and eliminate water from the system one cannot be sure that the presence of water vapor is not somehow responsible for some of the experimental effects observed. In less elegant vacuum systems this is especially true. In addition, the use of light in the presence of water vapor may cause additional effects such as photosorption to occur. Several experiments were performed which seemed to indicate this may be the case.

The effect of various illuminations and water vapor on trapped carriers was studied in a single crystal of high resistivity cadmium sulfide by using the TSC technique. Various wavelengths of light were used singly and in combination with other wavelengths to populate the trapping levels. The purpose of this procedure was to make qualitative observations of the manner in which radiation filled and emptied the traps in a relatively dry system. In another series of experiments, water vapor was allowed to adsorb on the crystal surface. The effect on the thermally stimulated current was observed in order to determine qualitatively if adsorbed water vapor affected this electrical property of the crystal. The trapping levels observed in this research on cadmium sulfide occur at energies

which are in good agreement with those previously reported for electron traps, and it is assumed that only electron traps were observed.

Experimental Apparatus and Procedure

The determination of trap depths in cadmium sulfide by measuring the TSC is a most informative technique. The TSC is that additional current produced in the crystal when mobile carriers are released from trapping centers by thermal energy. The mobile carriers are usually excited into the trapping centers by illumination with optical radiation at low temperatures. Recent reviews of this subject for cadmium sulfide have been given by Nicholas and Woods (7) and Dittfeld and Voigt (8).

The measuring system that was used is similar to the one described by Bube (9). A beam splitter was provided so that the sample could be exposed to two different water-filtered radiations, either simultaneously or separately. Only estimations of intensity were made. Specific radiations or bands were obtained by using narrow band interference filters and/or Wratten (W-) filters and a quartz-iodine light source (10). The sample was exposed to light through a photographic shutter.

The sample was contained in a vacuum-jacketed Dewar and could be exposed to various gaseous atmospheres. Helium was used as the heat-transfer medium. Oxygen, nitrogen, and helium gases were introduced through a liquid-nitrogen cold trap. Oxygen and nitrogen used in the pumping experiments were distilled from the cold trap to a pressure of 1 atm into the measuring system which was at room temperature. The sample was then cooled to liquid nitrogen temperature. The crystal did not come in contact with a pool of liquid O_2 or N_2. Water vapor was carried into the system by passing helium through a bubbler at room temperature.

The specimen of cadmium sulfide was obtained from the Clevite Corporation. The crystal was sulfur compensated and had an initial dark resistivity of about 10^{10} ohm-cm. The crystal had been grown by evaporating pure cadmium sulfide in an inert atmosphere and had less than 1 ppm of electrically active centers. Ohmic indium contacts were used in conjunction with platinum leads. In most cases a potential of 180v was applied across the sample. A low order external resistor (2.9×10^4 ohms) in series with the sample was used as a current detector. The voltage change across this resistor was monitored with a nanovoltmeter and was recorded.

Only minor difficulty was encountered in obtaining reproducible dark current measurements from day to day. In general, the dark current which was measured without optical stimulation from liquid-nitrogen temperature to the highest temperature of the run was reproducible, but it was observed that the previous history (11) of the sample was important to the reproducibility of the dark current obtained. Repeated measurements of the dark current showed only slight displacements if the sample was consistently stored in the dark. It was further observed that infrared radiations at liquid-nitrogen temperatures caused the dark current to be suppressed. Subsequent experiments of white-light-excited TSC curves always resulted in peak suppression (12, 13) after an IR radiation and indicated a residual effect of the infrared radiation that was not easily dissipated between cycles.

The data for trap depth calculations were obtained by heating the crystal at various linear heating rates (β) and observing the temperature of maximum conductivity (T_m). Trap depths were determined from plots of the equation $\ln T_m^2/\beta = E/kT + \text{const.}$ (3, 7). Once having established the trap energies associated with the various peaks a constant heating rate was not used for other TSC experiments (unless specified) since a relatively fast rate appeared to improve peak resolution. The rapid heating rate was linear up to

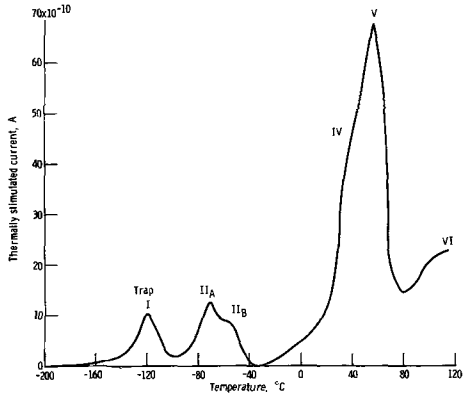

Fig. 1. Thermally stimulated current curve of as-received cadmium sulfide sample.

—70°C at which temperature deviations could be observed. The deviations were constant between runs.

Experimental Results and Discussion

The observation of a specific trap emptying and the relative concentration of trapped carriers depends on a number of variables (2) among which are: (*i*) the previous history of the sample; (*ii*) the radiation used as stimulation (including radiation combinations); (*iii*) the temperature at which the radiation took place; and (*iv*) the ambient atmosphere and its effect on (*i*), (*ii*), and (*iii*).

A typical thermally stimulated current curve is shown in Fig. 1. This curve was generated by cooling the crystal in the dark, illuminating it with white light and then warming it. Figure 1 shows the current peaks produced from the trapping levels which are designated as I, II_A, II_B, IV, V, and VI. Trap III (Fig. 3) could not be filled by the technique used to fill the other traps and will be discussed below. The two peaks, II_A and II_B, appeared as one if 533 mμ illumination time was applied for times greater than 1 min. The low-temperature traps I, II_A, and II_B, had energy depths below the conduction band edge of 0.042, 0.12_5, and 0.13_1 ev, respectively. These values are the least squares average of 12 determinations using heating rates in the range 0.04-0.3°C/sec.

Traps IV, V, and VI found at higher temperatures were not as reliably reproduced as those occurring at low temperatures. They could occasionally be induced to appear by subjecting the crystal to special treatments. However, reliable data could not be obtained which would permit significant trap depth calculations.

An attempt was made to fill electronic traps near the conduction band of cadmium sulfide by exciting electrons with optical radiation directly from the valence band (12). Kulp (14) reports that direct filling can be accomplished from a level 1.79 ev below the conduction band with wavelengths greater than 690 mμ for special cadmium sulfide "storage" crystals. The TSC of the two traps located at 0.04 and 0.13 ev mentioned above was observed after 30-sec excitation at liquid nitrogen temperatures with 501, 533, 578, and 697 mμ radiation. A transient, as well as a small sustained photoconductivity, was observed during excitation with the 500 series. Wavelengths greater than 697 mμ indicated no photoconductivity of either kind. The participation of the conduction band during excitation in these cases limits an interpretation of direct filling from the valence band. Even though the relative filling of the two traps was as expected for direct filling, one cannot be certain of the origin of all electrons that have entered the trap.

Cooling during illumination.—Another set of experiments was performed to demonstrate in a more definitive way that electrons were being excited from the valence band to shallow trapping levels near the

conduction band and involved cooling during illumination. Cooling in the presence of white light produced a curve similar to those obtained by Bube (15) and Kulp (14). As the temperature was reduced, the photocurrent increased showing a broad peak cresting at about —80°C. Bube explained this effect as a change in a defect center from a recombination center to a trapping center as the temperature was lowered. If a shallow trapping center participates in the photoconductive process and is being populated directly from the valence band, a change in the photoconductivity might be observed as the number of electrons excited to this level is changed. An attempt was made to observe such an effect with the known level at 0.13 ev. A band of light (533 mμ peak) was applied to the crystal whose energy was slightly more than enough to excite electrons from the vicinity of the valence band to this level above room temperature. At liquid nitrogen temperature the filter energies were not sufficient to promote electrons to the trap level from the valence band due to the displacement of the band edge. Cooling in the presence of 533 mμ light produced only a steady decrease in the photoconductivity; the expected change in the photoconductivity was not observed. Subsequent TSC curves showed, however, that electrons were trapped in the 0.13 ev level. The absence of the expected change may be due to this center behaving as a recombination center at higher temperatures and as a trapping center at lower temperatures in which case the conduction band may not be involved appreciably. Bube (15) has observed a maximum in the decay time at about —50°C for CdS:Cl:Cu crystals, but little corresponding change in the photoconductivity.

At low temperatures the application of IR to a filled trap system produced transient current flow indicating that electrons were being excited to the conduction band. Some of this conductivity resulted from the emptying of the shallow trap levels. A TSC determined after such treatment indicated that the shallow traps were empty. Cooling in the presence of IR · ($\lambda > 800$ mμ) to keep the shallow traps empty and 533 mμ light to fill them from the valence band produced the curve shown in Fig. 2. This curve can be explained by assuming a mechanism similar to that proposed by Bube. Although the peak temperature at —60°C may have no special significance, it is very

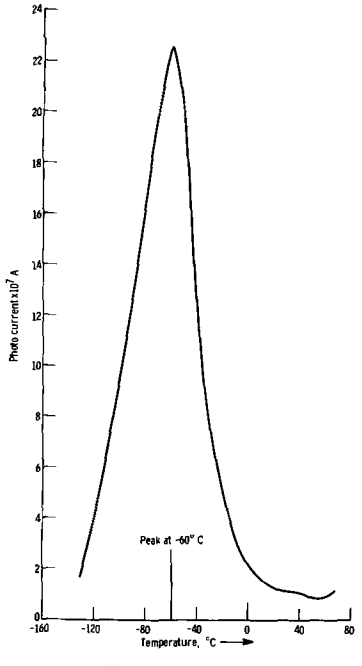

Fig. 2. Photocurrent of CdS crystal as a function of temperature using 533 mμ light and IR.

nearly the same as that found for the TSC emptying of the 0.13 ev level and suggests that the Fermi level may be in the vicinity. At temperatures above —60°C the center appears to behave as a recombination center. Below —60°C the center behaves as a trap which can be optically emptied.

The decrease in photoconductivity shown in Fig. 2 for temperatures less than —60°C can be explained if the effect of the variation of band gap with temperature is considered. The use of white light in such an experiment readily provides combinations of all the energies needed to promote a sustained high photoconductivity at all temperatures below —60°C. Consequently, the effect of the movement of the band edge is masked. If electrons are excited directly from the valence band to the level at 0.13 ev, the number excited can be reduced as the band gap increases and will be limited by the pass of the filter and the density of states in the valence band. At —60°C the energy between the valence band edge and the trap level is calculated (3) to be about 2.33 ev and corresponds with the energy peak of the 533 mμ filter from the valence band edge. If a high density of states is concentrated at the valence band edge, the energy profile of the filter may be reflected in the photoconductivity as the temperature decreases. If the density of states decreases as the edge is approached from below (16), something other than the filter profile might be expected. Some discrepancy may also arise if the thermal and optical excitation energies from the valence band to the trap level are not equivalent. The energy difference from the peak to half peak of the filter was about, ±0.03 ev. The energy difference calculated from Fig. 2 for temperatures less than —60°C due to the displacement of the band edge from peak to half peak is about 0.02 ev. The decrease in photoconductivity below —60°C appears to be due to the decreased participation of the 0.13-ev level in the photoconductive process and is probably due to the inability of any of the wavelengths applied to promote electrons to this level.

Another series of experiments was performed during which time the irradiation was applied to the sample continuously during the cooling process. Woods and Nicholas (13) using cadmium sulfide and Bube (17) using cadmium sulfide and mixed cadmium sulfide-cadmium selenide crystals have performed similar experiments and report a new trap at 0.73-0.83 ev. As mentioned above, when the white light was used, the photocurrent decreased as the temperature was reduced from 100°C, leveled near room temperature, reached a maximum near —80°C, and then decreased steadily until liquid-nitrogen temperature was reached. After cooling in the presence of white light (heat filter passing wavelengths less than 800 mμ), the resultant TSC curve (solid curve of Fig. 3) showed the presence of peak III occurring at about 0-10°C. Traps I and II were well filled and trap II showed no resolution.

A similar experiment was conducted by using only 533 mμ illumination and resulted in the long dashed curve, which shows the exclusion of the new peak. (Traps I and II were filled as shown by the solid curve, but are excluded from the drawing for clarity.) A detail of the area around 0°-10°C is shown in the inset of Fig. 3. Although photoconduction was evident during the cooling process (electrons in the conduction band), it did not appear that trap III could be filled from the conduction band. The behavior of the system indicated by the solid and long-dash curves suggested the necessary participation of at least a second wavelength present in white light to achieve the filling of trap III.

To test this hypothesis the specimen was exposed to two illuminations simultaneously as the sample was cooled. The primary illumination was 533 mμ light; the secondary illumination was a band of light formed by the heat filter and various Wratten filters.

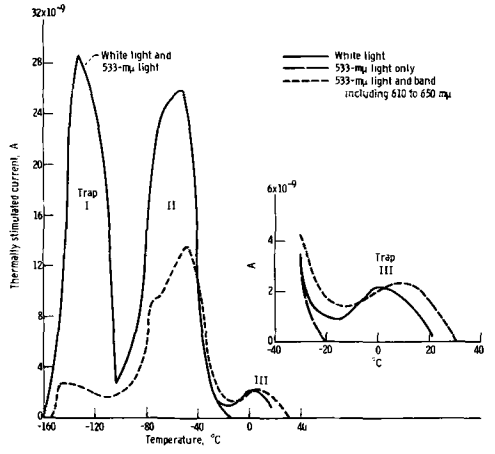

Fig. 3. Thermally stimulated current curve obtained after cooling during illumination.

The Wratten filters were changed between experiments and were such that additional increments of shorter wavelengths could be passed with each succeeding filter in the series. This procedure revealed that the secondary wavelength needed to allow trap III to fill lay in the region 610-650 mμ. The short-dash curve (Fig. 3) illustrates the results. Secondary wavelengths greater than 650 mμ did not produce a filling of trap III and indicates a threshold energy for filling of about 2.0 ev. Further support for direct filling of traps is found in these results, since the energy complement required to fill the reported trap at 0.41 ev (7) directly from the valence band would correspond to a wavelength of about 621 mμ. It is also apparent from Fig. 3 (short-dash curve) that the secondary wavelength tends to keep the shallow traps empty.

Bube (17) has shown that a similar trap appears to fill most efficiently when the Fermi level is about 0.45 ev below the conduction band. Assuming that trap III is the same as that observed by Bube (17) and Nicholas and Woods (7), the results illustrated in Fig. 3 indicate that this trap can be filled readily by direct excitation from a lower state which, on the basis of the threshold required, appears to be near the valence band.

Effect of water on thermally stimulated current.—An interesting effect on the TSC was produced by water vapor. Since Bube (18) has shown that water vapor produces a reduced photoeffect for cadmium sulfide, it was pertinent to determine whether water vapor would affect the TSC. Consequently, a series of experiments was performed in which water vapor was purposely introduced into the system. The sample was then cooled to liquid nitrogen temperature, and the TSC was measured without illumination of the sample at any time. Without exception a complex peak appeared in the vicinity of 80°-100°C. The partial pressure of water vapor in the system was subsequently decreased by reducing the total pressure to 1/6 atm. The pressure was then restored to 1 atm with dry helium. The results of a series of such manipulations are shown in Fig. 4. The results indicate that the presence of water vapor produces simulated TSC peaks, the areas of which are a function of the partial pressure of water in the system. The appearance of two peaks in curves 2 and 3 immediately suggests a heterogeneous surface, with at least two different sorption sites.

After pumping for several hours at room temperature the normal dark current curve could be obtained. However, infrared (30 sec) illumination (W-87) at room temperature followed by cooling to liquid nitrogen temperature (no illumination) and subsequent heating indicated the reappearance of the 80°-100°C peak (but to a much reduced degree). When white light was used as excitation at room

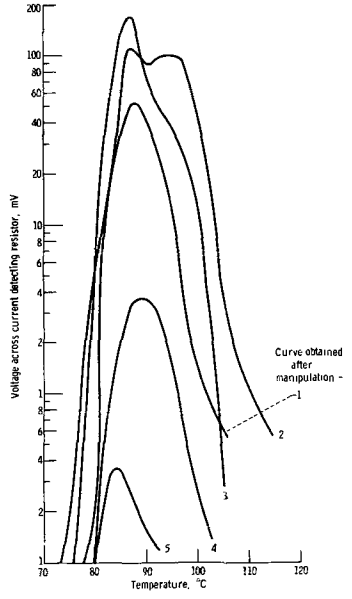

Fig. 4. Thermally stimulated current curves produced by manipulating water vapor pressures; heating rate 0.28°C/sec.

temperature, a broad TSC peak was produced which crested in the 80°-100°C region. Similar experiments in a relatively dry system did not produce this peak. The appearance of a TSC peak under these conditions might be attributed to photosorption of water vapor since small amounts of water vapor undoubtedly were still present. The work of Sebenne and Balkanski (19) has shown that water is adsorbed by cadmium sulfide surfaces, at which place these authors suggest it attaches an electron to form $(H_2O)^-$ ions. Desorption of sorbed water by heating the crystal could release electrons to the bulk of the crystal from the breakup of such a species and thereby produce a peak in the TSC.

After water vapor had been introduced and substantially removed by pumping to give the normal dark current curve. TSC curves, obtained by illumination with white light at liquid nitrogen temperatures, showed that the peaks at 60° and 100°C were separate and building (Fig. 5). After three temperature cycles without changing the charge of helium, a broad peak tending to crest near 80°C was produced. This result suggests possibly that the amount of water vapor on the surface of the crystal was increasing between cycles and was probably coming from the walls of the sys-

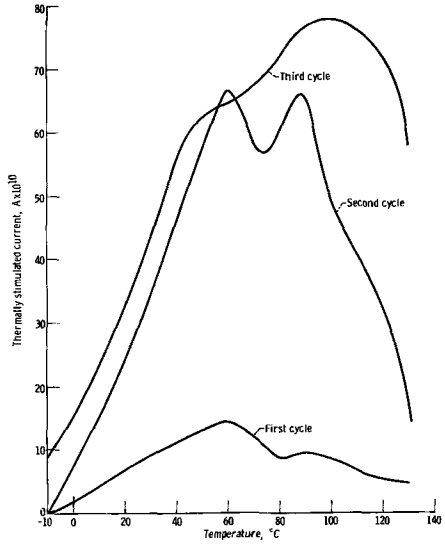

Fig. 5. TSC obtained by thermal cycling without changing He

tem at higher temperatures. Further pumping on the system again reduced the peaks in the region 60°-100°C.

The low-temperature traps (I and II) remained relatively empty during these water treatments, although their presence could be detected. This result indicates that sorbed water vapor has hindered the filling of these levels and can be explained in part by assuming some of the sorbed water acts in the capacity of recombination centers (3) and/or traps as indicated by the TSC peaks shown in Fig. 4. If the capture cross section and the escape cross section for the shallow traps are small (7, 17), then the presence of relatively large capture cross-section centers such as sorbed water vapor could hinder the filling of the shallow traps. This could be accomplished if electrons in the conduction band reacted at a faster rate with recombination centers than with empty shallow trapping centers. The IR wavelengths of white light probably were effective also in maintaining these levels empty.

After water treatment and subsequent removal by pumping only, a TSC, obtained using 533-mμ-illumination for 2 min at liquid nitrogen, showed the strong reappearance of electrons in traps I and II and the absence of the 80°-100°C peak. This result would seem to indicate that these shallow levels are preferentially filled by this excitation (in the absence of IR but in the presence of small amounts of sorbed water vapor) and that the filling process probably involves a substantial amount of direct filling from lower levels. If electrons in the shallow traps are to recombine via the conduction band, they must enter the conduction band via a relatively small escape cross section ($< 10^{-22}$ cm^2) (7) before recombination can occur, in which case electrons so trapped (directly) would be expected to be observed via a TSC. This result also suggests that the shallow traps were not destroyed, but could not be filled using the white light conditions mentioned above. The same experiment performed in the presence of larger partial pressures of water showed a water peak as in Fig. 4 and also the peaks of traps I and II.

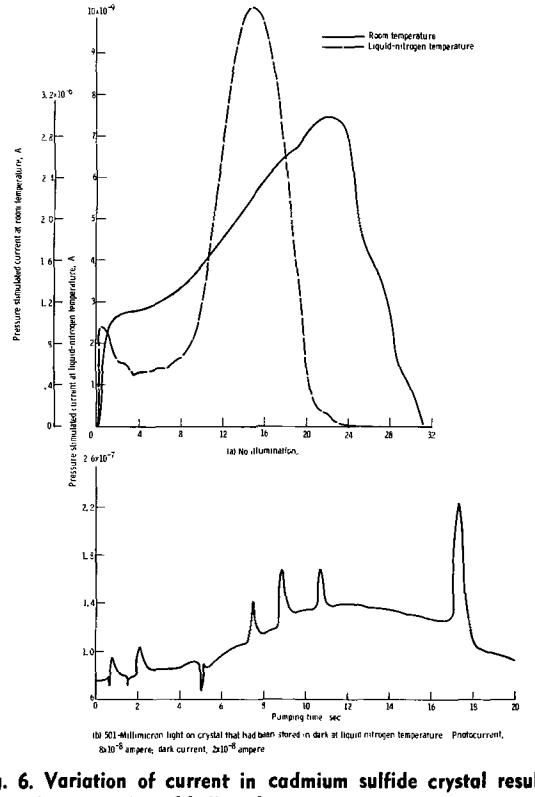
Bryant and Cox (20) find a trap at 0.86 ev which empties at ~100°C. This trap seems to have some similarity to the 100°C trap noted above and might be attributed to adsorbed water vapor. These authors believe this trap to be the one located at 0.83 ev by Nicholas and Woods (7), in which case it could also be the trap located by Bube (17) at 0.73 ev. Nicholas and Woods describe this trap as one which empties via first-order decomposition of an unusual trap complex. This description fits that of an adsorbed species such as $(H_2O)^-$ or O_2^- in the case of oxygen and has been suggested by Bube (17), in the case of oxygen, as a possible explanation for the photochemical processes observed by these authors. The apparent cross section of this center in cadmium sulfide is reported as ~ 10^{-15} to 10^{-14} cm^2 (7, 17) and compares reasonably well with the cross-sectional area of an adsorbed gas molecule (~ 10.6Å^2 for water at 24°C) (21). If an electron becomes associated with a sorbed water molecule as $(H_2O)^-$ on the surface of cadmium sulfide, then the escape cross section of the electron on dissociation of this species and the effective area of the sorbed molecule may be similar. The fact that adsorbed water appears to produce recombination as well as trapping centers suggests that fast and slow states, respectively, are likely to be found on the surface of CdS.

Effect of pumping on the TSC.—Evacuation of the helium in the system between experiments frequently produced a current spike as the pressure decreased below approximately 1 mm. This peculiar effect was reproducible and was observed at room and liquid nitrogen temperatures (Fig. 6). After a dark current determination, if the sample was returned to liquid nitrogen temperature in the dark, was pumped and a current spike obtained, a subsequent TSC measurement would show a peak at 60°C. This result supports the idea that surface trapped electrons are associated with sorbed gases and that on desorption via pumping some electrons remain trapped. If the Fermi level extends to the surface (22), dissociation of a surface trapped species such as O_2^- (at liquid N_2) located below the Fermi level might result in the creation of a surface trapped electron associated only with the solid surface. A subsequent TSC could indicate the presence of the new surface-only trapped electron. The pumping effect was not observed in an oxygen or nitrogen atmosphere. At room temperature the pumping spikes could be obtained only after illumination (white light or 533 mμ). Infrared (W87) illumination occasionally produced the spikes but not always. The fact that pumping at room temperature would not produce a current pulse unless the crystal was first illuminated suggests that at room temperature the number of sorbed species (most likely to be residual H_2O) increases when the free electron concentration is increased by illumination.

The areas under the curves of Fig. 6(a) for room temperature and liquid nitrogen temperature pumping correspond to the participation of 6.5 x 10^{13} and 1.2 x 10^{11} electrons/cm^2, respectively. These values represent a participation of less than 10% of the surface at room temperature and less than 1% at liquid nitrogen temperature.

The curve illustrated in Fig. 6(b) is typical of the pumping curves obtained after the crystal had been stored in the dark for several weeks (a "rested" crystal). The curve was obtained by pumping over the crystal during continued illumination with 501 mμ light at 78°K. After continued application of the pumping sequences the curve illustrated in Fig. 6(a) was typical of the results obtained.

The results presented above seem to indicate that water vapor in addition to O_2 may be an active component of residual air when studies are made of the trapping properties of cadmium sulfide. Sorbed water appears not only to act as a recombination center but also as an electron trap. The adsorption of water vapor



(b) 501-millimicron light on crystal that had been stored in dark at liquid nitrogen temperature. Photocurrent, 8×10^{-8} ampere; dark current, 2×10^{-8} ampere

Fig. 6. Variation of current in cadmium sulfide crystal resulting from cyclic evacuation of helium from system.

alone is sufficient to produce TSC peaks and seems to be related to some of the unusual thermal and vacuum effects noted for traps in cadmium sulfide. Illumination in the presence of adsorbed water vapor causes deep traps to appear while shallow traps remain relatively empty. Direct filling of shallow traps using appropriate monochromatic radiation less than the band edge can occur even in the presence of recombination centers. Direct filling is also evident when trap III is filled using a threshold energy of approximately 2.0 ev.

Manuscript received March 25, 1966; second revised manuscript received Jan. 23, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Ternary Condensed Phase Systems of Gallium and Arsenic with Group IB Elements

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Data obtained from a series of differential thermal analysis studies have been used, along with x-ray and electron beam microprobe analyses, and a regular solution interpolation procedure to construct a major part of the equilibrium ternary liquidus-solidus phase diagrams of the Ga-As-Cu, Ga-As-Ag, and Ga-As-Au systems. In these systems the GaAs primary phase field occupies a major part of the phase diagram.

Studies of the Ga-As-Cu, Ga-As-Ag, and Ga-As-Au ternary systems have been undertaken because of the current interest in gallium arsenide p-n junctions made by diffusion or solution growth, in photo- and electroluminescence of variously doped gallium arsenide and in the fabrication of ohmic contacts on GaAs. The ternary phase diagrams define the conditions for the existence of GaAs in the presence of a third component, and contain part of the data necessary for the interpretation of diffusion and solubility studies which are needed to further our understanding of the incorporation of a dopant material into a binary semiconductor.

These systems are of particular interest because Cu, Ag, and Au are particularly rapid diffusers in GaAs, have rather deep lying acceptor states which are as yet not well understood, and in the case of copper, represent a major source of contamination of GaAs.

The Binary Phase Systems

Ga-As.—Gallium and arsenic form a single congruently melting compound, GaAs, with a melting point of 1238°C (1, 2). Thurmond (3) has utilized the solubility measurements of Koster and Thoma (2) and Hall (4), along with an adaptation of the regular solution treatment of Vieland (5) to construct the binary GaAs liquidus curves.

Ga-Cu.—This system has been summarized by Hansen (6). It is characterized by the existence of four major peritectically formed intermediate phases with rather extensive composition ranges. There is only one eutectic point on the liquidus curve. This point occurs on the gallium rich side of the diagram at 29.6°C.

Ga-Ag.—The Ga-Ag system has been summarized by Hansen (6). It is characterized by the existence of four major phases formed peritectically or by solid state transitions. Two of the important peritectic transformations occur at 611° and 326°C. There is only one eutectic point on the liquidus. This occurs at 29.7°C and approximately 97 a/o (atom per cent) Ga.

Ga-Au.—This system has recently been re-evaluated by Cooke and Hume-Rothery (7). The system consists essentially of a solid solution region and several peritectically formed solid solution phases in the gold rich region. The liquidus temperature drops very sharply in the gold rich region to a first eutectic at 346.7°C and about 70 a/o Au. Other eutectics occur at 339.4°C and about 65 a/o Au, 448.6°C and 45 a/o Au and 30°C near 100% Ga. The compounds AuGa and $AuGa_2$ melt congruently at 461.3° and 491.3°C, respectively.

As-Cu.—A limited amount of information is available for the As-Cu system and has been summarized by Elliot (8). The system is characterized by the existence of an extensive solid solution region of arsenic in Cu, a congruently melting compound Cu_3As (mp 827°C) and a peritectically formed transitional compound Cu_5As_2. A compound of approximate composition Cu_8As is formed via a solid state reaction at 380°C. There are eutectic points at 685° and 81.5 a/o Cu, and at 600°C and 54 a/o Cu. No information is available for compositions containing more than about 45 a/o As.

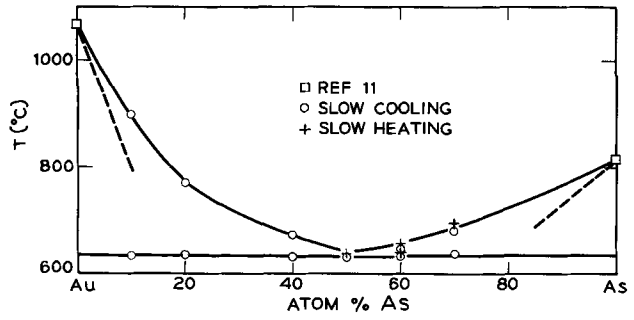

Fig. 1. Thermal effects observed on cooling and heating mixtures in the As-Au binary system.

As-Ag.—The As-Ag system is essentially simple eutectic in nature with an extensive region of solid solubility and several transitional solid solutions in the silver rich region. The eutectic point occurs at 540°C and 25.3 a/o As. The system has been summarized by Hansen (6) and Elliot. (8).

As-Au.—The liquidus curve for this system is presented here. It appears that the system is of the simple eutectic type with the eutectic composition at 51 a/o As and at 632° ± 3°C. The liquidus data and eutectic temperature reported here (Table I, Fig. 1) differ considerably from the data reported earlier by Schleicher (9). Since the latter work was done in open crucibles, there is some doubt about the composition of the samples studied and a disagreement in reported liquidus temperature is not surprising. The difference in eutectic temperature, 635°C (this work) and 665°C (ref. 2), cannot be accounted for.

The data reported here are in reasonable agreement with the limiting slopes (which represent lower limits for solid phases with no mutual solid solubility) calculated from

$$\frac{d \ln x}{d\, 1/T} = -\frac{\Delta H_m}{R}$$

on the arsenic and gold rich sides of the diagram as shown in Fig. 1.

Electron beam microprobe studies of samples with compositions on each side of the eutectic showed only phases consisting of Au or As present with only a very slight amount of mutual solid solubility.

Experimental

Semiconductor grade arsenic with purity better than 99.99% was used in this work. Reclaimed gallium with purity better than 99.99% was used, and for many of the runs GaAs was used instead of the elements. The use of GaAs was necessary when the relative amounts of Ga and As were high in order to prevent explosions resulting from the exothermic reaction of the elements. The GaAs was generally prepared from the elements by passing arsenic vapor over liquid gallium. The copper used was high conductivity grade, the silver was a reagent grade with purity better than 99.99% and the gold was obtained from Engelhard with purity better than 99.9%.

Fused-silica capsules with volumes of about 3 cm^3 which were about two-thirds filled with melt were used for the differential thermal-analysis experiments. The experimental details are similar to those which have already been described for the study of the Ga-As-Zn system (10), except that most cells, other than those used for studies in the As-Au binary system, were held at about 1250°C for a short time before cooling.

In an attempt to determine the extent to which errors resulting from supercooling occur, DTA analyses for a number of points were obtained by both heating and cooling. The rates of heating and cooling were varied from about 1°C/min to about 5°C/min.

X-ray and electron beam microprobe analyses of the DTA samples were done by standard techniques where possible. In regions of the systems where large amounts of Cu, Ag, or Au were present it was not possible to obtain powder samples, and no attempt was made to obtain x-ray data in these regions.

Results

The temperatures at which thermal effects were observed when melts of various compositions were cooled are given in Table I for the As-Au system, in Table II for the Ga-As-Cu system, in Table III for the Ga-As-Ag system, and Table IV for the Ga-As-Au system. In each case T_1 represents the temperature at which the surface of primary crystallization is reached, T_2 is the temperature at which a second solid phase precipitates, T_3 is the temperature at which a ternary eutectic or peritectic transition occurs, and T_4 is attributable either to solid state transitions or further eutectic transitions.

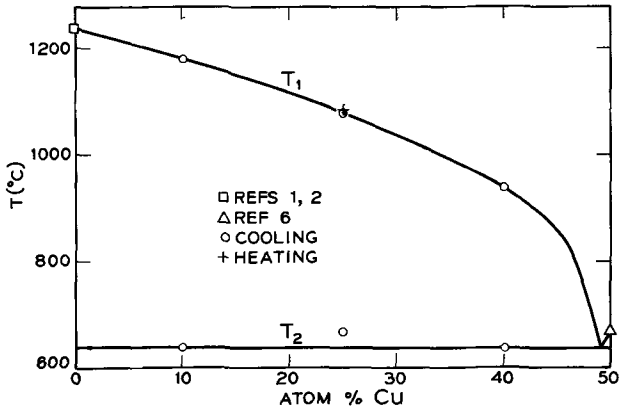

Fig. 2. Thermal effects observed on cooling and heating mixtures with compositions on cut A (Fig. 11) in the Ga-As-Cu system.

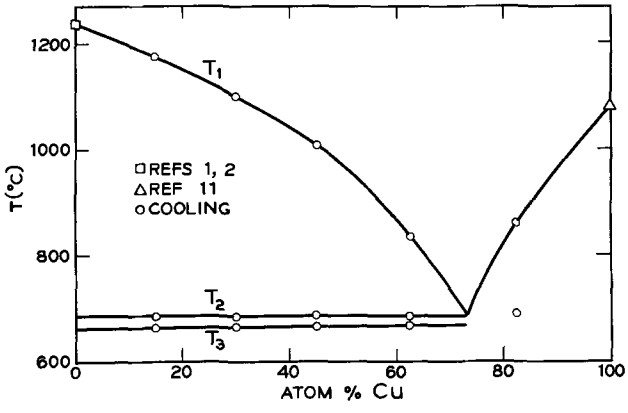

Fig. 3. Thermal effects observed on cooling mixtures with compositions on cut B (Fig. 11), the GaAs-Cu cut, in the Ga-As-Cu system.

The data given in Tables I, II, III, and IV are plotted in Fig. 1-10. The melting points of pure Cu, Ag, Au, and As were taken as 1083°, 961°, 1063°, 817°C, respectively (11). For each ternary system data were obtained along the following three cuts in the ternary system; Cut A, GaAs to 50 a/o Ga-50 a/o metal; cut B, GaAs to 100% metal; cut C, GaAs to 50 a/o As-50 a/o metal. When necessary data were obtained for other compositions in the ternary system. Since the major objective of this work is to delineate the GaAs primary phase field of each of the systems, most of the experimental data was obtained in that part of each phase system and no attempt has been made to delineate in detail the portions of the phase diagrams involving other primary phase fields.

Construction of the Ternary Phase Diagrams

The ternary diagrams were constructed primarily by the use of the binaries described above as boundaries and cuts A, B, and C as guides for the location of isotherms, eutectic boundaries, and eutectic and peritectic points. As will be discussed separately for each ternary diagram below, x-ray and electron beam microprobe data were used in the interpretation of the DTA data.

The ternary isotherms in the GaAs primary phase field were interpolated by a regular solution procedure. This procedure was recently suggested by Furukawa and Thurmond (12), and has been applied by them to the 900°C isotherm of the Ga-As-Cu system and by this author to the Ga-As-Ge and Ga-As-Sn systems (13) among others. The application of the procedure in this work is identical to that already reported for the group IV elements with Ga and As (13).

The Ga-As-Cu *system.*—For this system DTA data were obtained along cuts A, B, and C and for several other compositions in the ternary, (Fig. 2-4). The ternary diagram with isotherms in the GaAs primary phase field computed as described above is shown in Fig. 11. The regular solution estimations calculated from the data on the Ga and As sides of the diagram [as described in ref. (13)] were in good agreement for the 1100°C isotherm but were in increasingly poor agreement at lower temperatures. As described previously (13), the isotherms drawn are interpolations of the computed curves weighed to favor each computed isotherm in the region where it was most applicable. The experimental data of Furukawa and Thurmond (12) for compositions on the 900°C isotherm are shown in Fig. 11. Luzhnaya *et al.* (14) have reported liquidus data for the Cu_3As-GaAs cut which are in agreement with this work.

The DTA thermal effects noted for compositions along cut A (Fig. 2) are attributable to the primary phase precipitation of GaAs at T_1, the precipitation of an alloy based upon Cu_9Ga_4 at about 640°C (T_2), and the peritectic formation of $CuGa_2$ at 238°C (T_3). All three phases were identified by their x-ray powder patterns.

The thermal effects observed for cut B (Fig. 3) are attributable to the primary precipitation of GaAs at T_1 from 0 to 73 a/o copper, to the precipitation of the alloy based upon Cu_9Ga_4 at about 686°C (T_2) and to a ternary eutectic at 667°C where GaAs, Cu_9Ga_4, and Cu_3As precipitate simultaneously. The three phases mentioned were identified by their x-ray powder patterns. In addition a phase indexed as Cu_6As but referred to as Cu_8As by Elliot (8) was observed in the x-ray photographs. This phase forms by a solid state reaction at about 380°C according to Hansen (6). A corresponding thermal effect was not observed in this work.

The thermal effects noted for compositions along cut C (Fig. 4) are attributable to the primary precipitation of GaAs at T_1, the precipitation of As at 606°C (T_2), and to a ternary eutectic at 594°C (T_3) at which GaAs, As, and Cu_3As precipitate simultane-

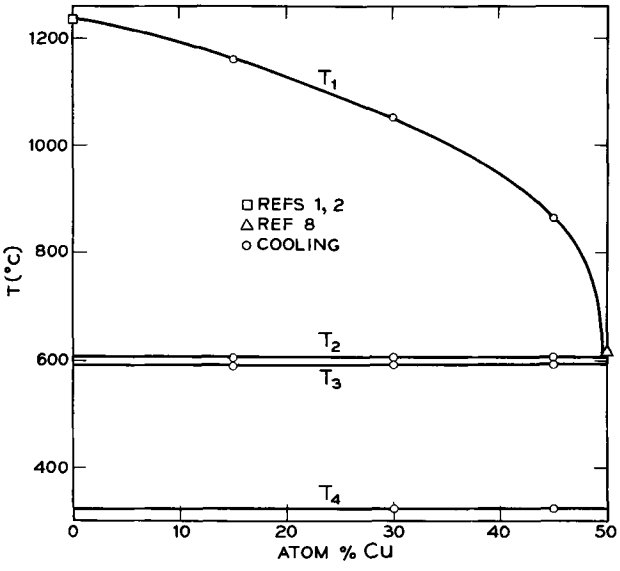

Fig. 4. Thermal effects observed on cooling mixtures with compositions on cut C (Fig. 11) in the Ga-As-Cu system.

ously. The x-ray patterns contained too many lines for unequivocal identification, but are consistent with above interpretation, as are the results of the electron beam microprobe examination of the DTA samples.

The isotherms for the copper rich regions, the positions of the boundaries between primary phase fields near the Cu-As binary and the ternary eutectic points at 667° and 594°C have not been determined precisely, but have been drawn in Fig. 11 in such a manner as to be consistent with the experimental data. The subliquidus thermal effects of Luzhnaya *et al.* are not consistent with the phase diagram of Fig. 11 in the region of Cu_3As. Further study is required to clarify this region of the system. The 1200° isotherm was obtained simply by interpolating the data on cuts A, B, C, and the Ga-As binary, and drawing the isotherm through the points thus obtained.

The Ga-As-Ag *system.*—For this system data was obtained only along cuts A, B, and C, (Fig. 5-7). The ternary diagram with isotherms computed as described above is shown in Fig. 12. The regular solution curves calculated separately for the isotherms in the GaAs primary phase field from experimental data on each

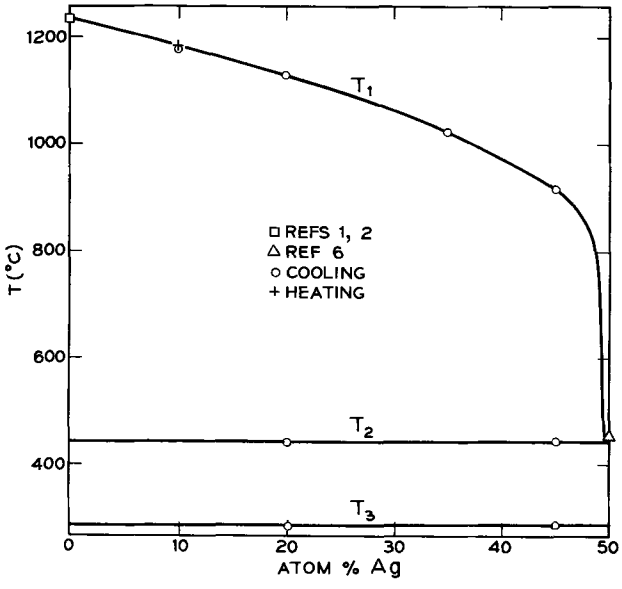

Fig. 5. Thermal effects observed on cooling and heating mixtures with compositions on Cut A (Fig. 12) in the Ga-As-Ag system.

side of the phase diagram [as described in ref. (13)] gave sets of curves which were in excellent agreement with each other. Gubskaya *et al.* (15) have reported DTA data for one point in this system at the ternary composition Ag_3GaAs_2. Their data are consistent with the data reported in this work.

The thermal effect (T_3) noted for several points in cut A at 285°C (Fig. 5) apparently results from the peritectic formation of a phase based on the phase which precipitates at 326°C in the Ga-Ag binary (6). Electron beam microprobe measurements show that in a DTA sample on cut A the phases present were GaAs, Ag (principally), and a phase containing roughly similar amounts of Ag and Ga.

Cut B (Fig. 6) resembles, but is not, a true pseudobinary. For starting compositions in the 0-82 a/o Ag region, T_1 represents the primary precipitation of GaAs. T_2 is the intersection of the GaAs crystallization path with the eutectic valley for the simultaneous precipitation of GaAs and silver alloys. The crystallization path for compositions in the Ag primary phase is not strictly on cut B and T_2 in this region is slightly different from T_2 in the GaAs primary phase field. Electron beam microprobe measurements indicate that for starting compositions on cut B in the GaAs primary phase field the only phases present in the cooled DTA samples are GaAs and Ag. The amounts of Ga and As dissolved in the Ag appear to be small.

The DTA, x-ray and microprobe data for samples on cut C (Fig. 7) are consistent with the interpretation that T_1 represents the precipitation of the GaAs primary phase, T_2 the precipitation of As along

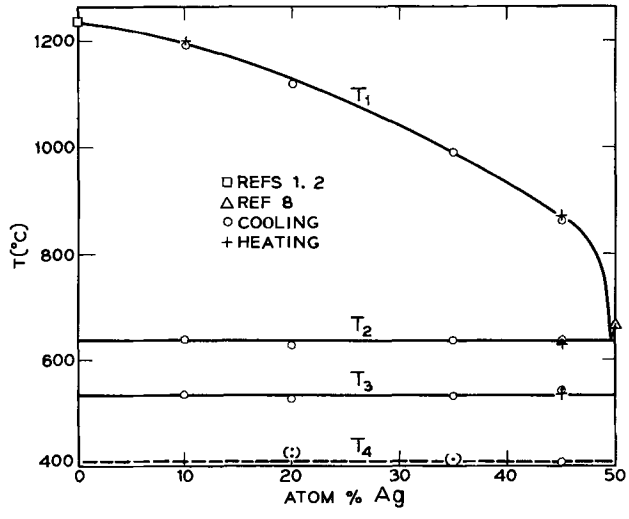

Fig. 7. Thermal effects observed on cooling and heating mixtures with compositions on cut C (Fig. 12) in the Ga-As-Ag system.

with GaAs, and that T_3 is the ternary eutectic representing the simultaneous precipitation of GaAs, As, and an intermediate phase based upon the binary phase designated Σ by Hansen (6). T_4 apparently represents the decomposition of the Σ phase to As and Ag alloys, corresponding to the transition in the As-Ag binary at 374°C (6).

In the ternary diagram (Fig. 12) the positions of the isotherms in the Ag primary phase field, the location of the eutectic boundaries between the primary phases, and the position of the ternary eutectic observed in samples with starting compositions on cut C are drawn to be consistent with the data of Fig. 5-7 but have not been determined precisely.

The Ga-As-Au *system.*—For this system DTA data was obtained along cuts A, B, and C (Fig. 8-10), at two other points along a fourth selected cut (cut D, Fig. 13) in the GaAs primary phase field and at one point on the $AuGa_2$-GaAs cut. The regular solution isotherms calculated as described in ref. (13) from the DTA data on the Ga and As rich sides of the system were in poor agreement. The data along cut D and the $AuGa_2$-GaAs cut were obtained in order to aid in the drawing of the ternary isotherms in the GaAs primary phase field. The additional data showed that even though the calculated isotherms were in poor agreement with each other when extrapolated across the phase diagram, a close approximation to the correct isotherm was obtained when the curves were drawn so as to strongly favor each computed isotherm in the region where it was most applicable.

The GaAs-GaAu system (cut A, Fig. 8) appears to be pseudobinary in nature, consisting almost entirely of the primary phase field of GaAs. The observed eutectic point at ~440°C is somewhat in doubt because of extensive supercooling in runs in which it was observed. The phases GaAs and GaAu were observed in x-ray powder photographs and confirmed with electron beam microprobe examination of the cooled DTA samples.

The liquidus curve of cut B (Fig. 9) resembles that of a simple eutectic system, T_1 representing the first formation of GaAs or Au on cooling the liquid. Au is precipitated in a solid solution which may contain as much as 25 a/o Ga. The T_2 curve in the gold rich region must vary with composition in this region as a consequence of the varying composition of the Au-Ga solid solution which is the primary phase. T_3 is probably the temperature at which a ternary eutectic comprising GaAs, As, and Au containing 1-3 a/o Ga precipitates. The T_3 thermal effect is ambiguous. The DTA curves for several samples gave evidence that two thermal effects may occur near T_3.

The cooled DTA samples from cut B were examined primarily with an electron beam microprobe. In all cases GaAs was observed. Arsenic crystals were observed in samples which contained more than 50 a/o Au in cut B. The arsenic crystals were probably not resolved by the microprobe in samples very rich in GaAs. The Au phase was observed in all samples and contained amounts of Ga varying from about 3 a/o to about 25 a/o. Varying Au-Ga concentrations are to be expected since the composition of this alloy varies while it precipitates.

The temperatures at which thermal effects were

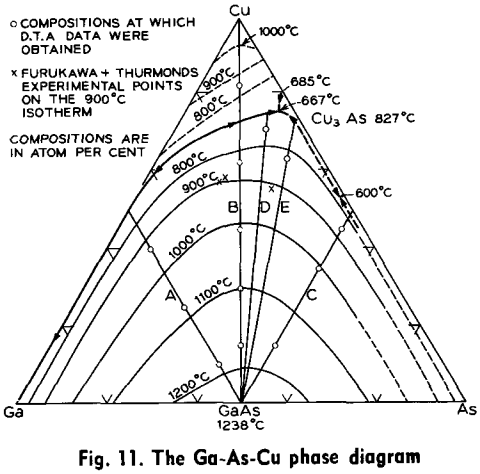

Fig. 11. The Ga-As-Cu phase diagram

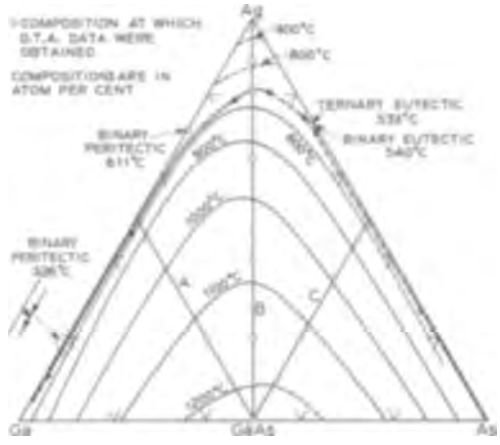

Fig. 12. The Ga-As-Ag phase diagram

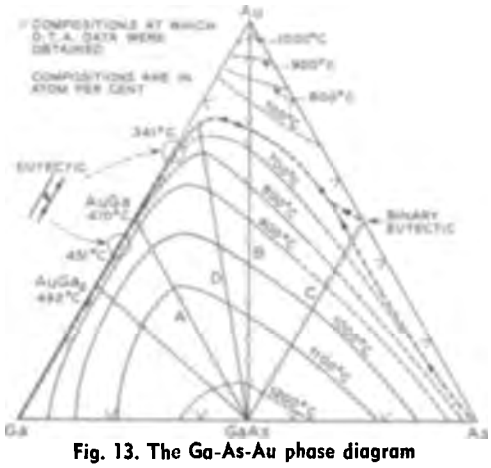

Fig. 13. The Ga-As-Au phase diagram

noted in cut C are shown in Fig. 10. Over most of the composition range T_1 clearly is the result of the primary precipitation of GaAs, and T_2 results from the first precipitation of As. T_3 seems to be the result of two thermal effects very close in temperature.

At gold concentrations at and above 35 a/o the situation is less well defined. The two thermal effects at T_3 separate and are shown in Fig. 10 as T_3 and T_3'. In all cases the only solid phases observed with the microprobe are GaAs, As, and Au containing small amounts of Ga in solid solution. In samples containing more than 35 a/o Au it is no longer possible to identify GaAs as the primary phase in electron beam microprobe photographs of polished samples. It is obvious that further study will be needed to clarify the ternary diagram in the region of the As-Au binary.

Only one experimental point was obtained on the GaAs-$AuGa_2$ cut. X-ray powder photographs and microprobe studies reveal GaAs and $GaAu_2$ as the only phases present in the sample. Only T_1 and T_2 thermal effects were noted with T_2 being identical (within experimental error) with the melting point of $GaAu_2$. It may be concluded therefore that the GaAs-$AuGa_2$ system is essentially a true pseudobinary system consisting almost entirely of the primary phase field of GaAs.

The positions of the isotherms in the Au primary phase field, the position of the ternary eutectic near the Au-As binary, and the location of the eutectic boundaries between the primary phases have not been determined precisely, but have been drawn in Fig. 13 in such a manner as to be consistent with the data of Fig. 1, 8-10 and the available data for the Ga-Au binary.

Conclusion

Extensive portions of the ternary liquid-solid phase diagrams of the Ga-As-Cu, Ga-As-Ag, and Ga-As-Au systems have been obtained. Emphasis has been placed on delineation of the position of isotherms in the GaAs primary phase field, and the determination of the extent of this phase field. Other primary phase fields and the boundaries between them have been identified and delineated in somewhat less detail.

Acknowledgments

The author is indebted to C. D. Thurmond for his helpful suggestions during the course of this work. The aid of Mr. S. Sumski with some of the experimental work, and of Mr. H. Schreiber for the electron beam microprobe studies is gratefully acknowledged.

Manuscript received Nov. 30, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Large Area Silicon Junctions by Epitaxial Growth Technique

T. L. Chu and G. A. Gruber

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Epitaxial growth is a promising junction formation technique for large area silicon devices because of its ability to provide: (*i*) silicon layers with chemical and structural perfection superior to conventional silicon crystals, (*ii*) flexible dopant concentration and distribution, and (*iii*) p-n junctions of better perfection than diffused junctions. Using the pyrolysis of silane in a flow system, epitaxial silicon layers of good structural perfection, as indicated by chemical etching and optical microscope examinations, have been deposited on {111} oriented substrates at 1080° at rates up to 1.5 μ/min. The resistivity of the grown layer was controlled by using diborane and phosphine as p- and n-dopants, respectively. The radial resistivity of epitaxial layers has been found to be of considerably better uniformity than that of conventional silicon crystals. Large area epitaxial p-n junctions prepared by depositing *n*- and p-layers successively on low resistivity n-type substrates have been found to be superior to diffused shallow junctions in electrical characteristics and are advantageous for the fabrication of power devices.

The epitaxial growth of silicon using the thermal reduction or decomposition of silicon compounds on surfaces of silicon substrates has been utilized extensively in the fabrication of integrated circuits and other types of small area devices during the past few years. In these epitaxial devices, the dopant concentration and distribution have been programmed and controlled to an extent not obtainable by other fabrication techniques. In addition to the flexibility of dopant control, the epitaxial growth technique is potentially capable of providing silicon layers with chemical and structural perfection superior to conventional silicon crystals. Both Czochralski and float-zone crystals used for device fabrication have been shown to possess various types of microdefects and inhomogeneous dopant distribution (1-3). The quality of silicon crystals, therefore, becomes a limitation of the performance of many types of large area devices, and the epitaxial approach appears attractive. Furthermore, the use of the epitaxial growth technique could also eliminate the defects, such as dislocation clusters, slip lines, stress, etc., introduced into the vicinity of p-n junctions by the alloying or diffusion processes.

The epitaxial growth technique is promising for the formation of large area junctions. However, the requirements of the properties of epitaxial layers, such as the crystal perfection, radial resistivity uniformity, etc., are more stringent and more difficult to achieve for large area devices than those for small area devices. For large area devices, these properties must be highly uniform over the entire area of the device to minimize localized breakdown. The crystal perfection of the epitaxial layer is particularly important since one major defect in the layer renders a large area device useless. Nevertheless, these requirements can be fulfilled by optimizing the growth conditions, and epitaxial growth will ultimately become an important technique for the fabrication of large area devices.

In this work, the advantages of the epitaxial growth technique have been utilized for the preparation of silicon p-n junctions of a few square centimeters area. Using the pyrolysis of silane and appropriate dopants, shallow junctions were prepared by depositing n- and p-layers successively on low resistivity n-type substrates. Similar junctions were also prepared by the diffusion technique. Epitaxial structures were found to have considerably better electrical characteristics than diffused junctions. They have yielded, after emitter diffusion, power transistors with good characteristics. The experimental methods and results are described in this paper.

Epitaxial Growth of Silicon by Silane Pyrolysis

The epitaxial growth of silicon can be achieved in a gas flow system by the thermal reduction of silicon halides and the pyrolysis of silane. The silane process has been reported by several workers (4); the relative merits of this process and the commonly used tetrachloride process are fairly well established. The pyrolysis of silane is thermochemically and kinetically more favorable than the thermal reduction of silicon tetrachloride. Silane is thermochemically unstable at room temperature and above and decomposes rapidly at temperatures above 600°C, thus enabling the growth of silicon at lower temperatures. The use of lower substrate temperature not only reduces the diffusion of impurities between adjacent layers of silicon, but also minimizes the liberation of impurities from the susceptor used for the support and heating of substrates. Furthermore, the pyrolysis of silane is essentially chemically irreversible; the undesirable consequences of chemical transport associated with the tetrachloride process can be eliminated, and the resistivity of the epitaxial layer can be better controlled. On the other hand, the silane process has the disadvantage that the thermal instability of silane tends to promote nucleation by pyrolysis in the gas phase. The solid silicon formed in the gas phase is in the form of large atomic clusters of random orientation, and the deposition of these clusters on the growing interface would interfere with oriented growth. The gas phase nucleation, however, can be suppressed by optimizing the experimental conditions.

The pyrolysis of silane was carried out at atmospheric pressure using hydrogen as a diluent. Semiconductor grade silane, purchased from the Gray Chemicals Company, was used without further purification. This material was found to yield n-type silicon with an electrical resistivity higher than 100 ohm-cm. Hydrogen was purified by diffusion through a palladium-silver alloy. Hydrogen-diborane, hydrogen-arsine, and hydrogen-phosphine mixtures, purchased from the Matheson Company, were used as dopants. All reactant gases were passed through a filter before entering the deposition tube to remove any solid particles. The substrates were n-type, 0.008-0.012 ohm-cm Czochralski silicon slices of 1-in. diameter, with main faces of {111} orientation.

The deposition process was carried out in a horizontal, water-cooled fused silica tube of 55 mm ID. The support, heating, and surface preparation of substrates have been described previously (5). During the growth process, hydrogen at a flow rate of 21 l/min was used as the diluent for silane, the concentration

of silane in the reactant was 0.01-0.5% and the substrate temperature was in the range of 1050°-1200°C. The structural perfection of the epitaxial layer was evaluated by chemical etching and optical microscope techniques (6), and the resistivity profile of the epitaxial layer was evaluated by the spreading resistance technique (7).

Deposition Rate and Structural Perfection

In the epitaxial growth process under study, the first important consideration is to minimize homogeneous nucleation through the pyrolysis of silane in the gas phase. This condition can be achieved by using water-cooled reaction tube, low partial pressure of silane in the reactant, and high gas-flow velocity over the substrate surface. Using deposition apparatus of a given geometry and a given flow rate of the diluent, the gas phase nucleation was found to be insignificant in a limited range of reactant composition and substrate temperature. In general, the extent of the gas phase nucleation decreased with decreasing temperature, and at a given temperature, the contribution of gas phase reactions increased with increasing concentration of silane. At 1080°C, for example, epitaxial silicon of good crystal perfection was obtained using a hydrogen-silane mixture containing 0.5% silane or less at a flow rate of 21 l/min. When the concentration of silane was increased to 0.7%, however, polycrystalline inclusions were incorporated into epitaxial silicon due to the gas phase nucleation. Also, as the substrate temperature was increased to 1200°C, the gas phase reaction became pronounced when the silane concentration was only 0.3%.

The deposition rate of silicon can be adjusted over a wide range by varying the concentration of silane in the reactant. Figure 1 shows the average deposition rate of silicon at a substrate temperature of 1080°C, using a hydrogen flow rate of 21 l/min, as a function of the concentration of silane. This rate was 1.5 and 0.19 μ/min when the reactant contained 0.5 and 0.013% silane, respectively. The lower growth rate is useful for accurate thickness control of thin layers. In the temperature range 1050°-1150°C, the average deposition rate was essentially the same within the experimental error, indicating that the deposition process in this temperature range is diffusion-controlled. At higher temperature, say 1200°C, the deposition rate decreased due presumably to the increased contribution of gas phase reactions.

Under conditions where the gas phase nucleation is negligible, epitaxial silicon deposited by the pyrolysis

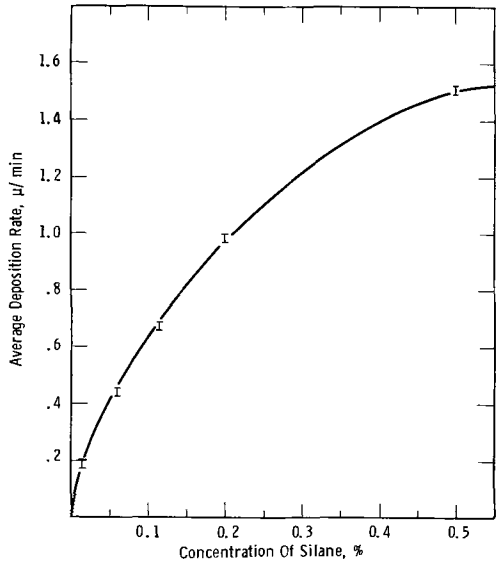

Fig. 1. Average deposition rate of silicon as a function of concentration of silane in hydrogen. Hydrogen flow rate = 21 l/min, substrate temperature = 1080°C.

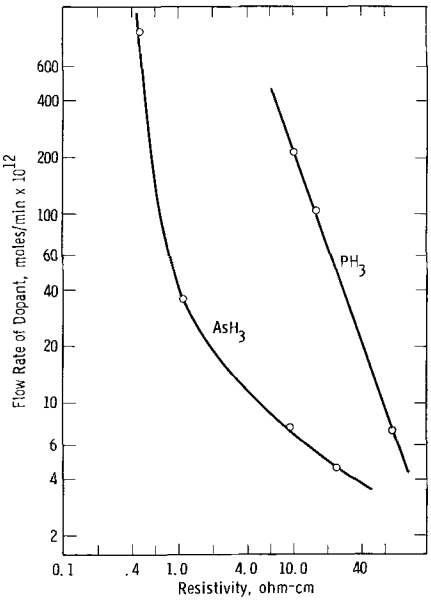

Fig. 2. Resistivity of n-type epitaxial silicon as a function of flow rate of arsine and phosphine. Silicon was deposited by the pyrolysis of silane at 1080°C using hydrogen containing 0.2% silane at a flow rate of 21 l/min.

of silane was found to be essentially free of process-induced defects, such as stacking faults, growth pyramids, polycrystalline inclusions, etc. Furthermore, the structural perfection of epitaxial silicon was independent of the deposition rate up to 1.5 μ/min.

Resistivity Control of Epitaxial Silicon

Epitaxial silicon deposited from silane at 1080°C, without intentional doping, was n-type with a resistivity higher than 100 ohm-cm. The control of resistivity of n-type epitaxial silicon by using arsine and phosphine as dopants was studied in a series of experiments using hydrogen containing 0.2% silane at a flow rate of 21 l/min. The substrates used in these experiments were p-type, and the resistivity of the epitaxial layer was determined by the four-point probe technique. The results are shown in Fig. 2, where the resistivity of epitaxial silicon, in the range of 0.4-60 ohm-cm, is plotted as a function of the flow rate or arsine and phosphine. At a given flow rate of the dopant, the doping efficiency of arsine is considerably higher than that of phosphine. For example, when the epitaxial layer was of 10 ohm-cm resistivity, the P/Si ratio in the gas phase was approximately twelve times that in the solid silicon, and the As/Si ratio in the gas phase was about one-half of that in the solid. This can be attributed to the higher thermal stability of phosphine. The thermal instability of arsine would result in more rapid depletion of arsine than silane when the reactant mixture is passed through the reaction tube, and large resistivity variations among specimens in a run have been observed. Thus, in spite of the considerably higher diffusion coefficient of phosphorus in silicon than that of arsenic in silicon, the use of phosphine as a dopant is more advantageous for minimizing resistivity variations.

The resistivity of p-type epitaxial silicon was controlled by using diborane as a dopant. At a given substrate temperature, the maximum obtainable concentration of boron in epitaxial silicon was found to be considerably lower than the solubility of boron in silicon at the same temperature. At 1080°C, for example, the highest boron concentration obtained was approximately 2×10^{17} cm^{-3}, irrespective of the B_2H_6/SiH_4 molar ratio in the reactant mixture. This is less than one-thousandth of the solubility of boron in silicon at the same temperature (8). To obtain epitaxial silicon of higher dopant concentration, it was necessary to

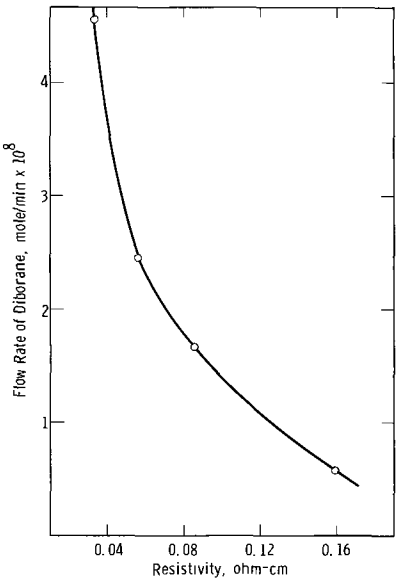

Fig. 3. Resistivity of p-type epitaxial silicon as a function of flow rate of diborane. Silicon was deposited by the pyrolysis of silane at 1140°C using hydrogen containing 0.1% silane at a flow rate of 21 l/min.

carry out the deposition at higher substrate temperatures. Figure 3 shows the resistivity of p-type epitaxial silicon, deposited at a substrate temperature of 1140°C using hydrogen containing 0.1% silane at a flow rate of 21 l/min, as a function of the flow rate of diborane. Under these conditions, epitaxial silicon with boron concentrations higher than 10^{19} cm^{-3} was obtained. The doping efficiency of diborane was approximately 25%.

To determine the radial resistivity profile of epitaxial silicon, a spreading resistance probe was applied to the as-grown surface of epitaxial silicon specimens along several diameters at various intervals. In many cases, epitaxial silicon was found to possess less radial resistivity fluctuations than float-zone or Czochralski crystals. An example is shown in Fig. 4 where the local resistivity of an n-type, phosphorus-doped epitaxial silicon layer with an average resistivity of 5 ohm-cm was measured along a diameter at 1 and 0.1 mm intervals. In all cases, the deviation of the local resistivity from the average resistivity was less than 10%.

Large Area Shallow p-n Junctions

Large area shallow p-n junctions were prepared by both diffusion and epitaxial techniques. In the former, n-type epitaxial layers of 10 ohm-cm resistivity and 25μ thickness deposited on 1-in. diameter 0.01 ohm-cm n-type substrates were subjected to boron diffusion at 1150°C, using boron tribromide as a diffusant in a flow system. The junction depth was 5μ, and the surface concentration of boron in silicon was approximately 10^{18} cm^{-3}. These junctions, approximately 4 cm^2 in area, were found to support voltages up to 200v; however, the reverse currents were often rather high, 100 ma or higher, at these voltages. To determine the cause of the softness of these functions, many specimens were made into mesas and the reverse characteristics of each mesa determined. It was found that mesas with high reverse currents invariably had many localized areas with etch figures of various shapes associated with high concentrations of dislocations, as shown in Fig. 5 and 6. Etch figures shown in Fig. 5 were due to contaminants on the specimen surface; the reaction between silicon and contaminants at the diffusion temperature yielded sufficient stress to generate dislocations. Etch figures shown in Fig. 6 were due to tweezer or probe marks introduced into the specimen by various handling processes before diffusion; the stress caused by these damages were relieved during the diffusion process by the formation of dislocations. The process-induced defects are, therefore, responsible for the high reverse currents of the mesas under consideration. Since the reverse currents of these mesas were found to be reduced considerably after a gettering process at 900°C, using phosphorus pentoxide as the gettering agent (9), one may conclude that the precipitation of heavy metals at dislocations is more harmful than the dislocations themselves. On the other hand, mesas with no or very few etch figures exhibited reasonably

good reverse characteristics even before the gettering process. Thus, while diffusion-induced defects only reduce the yield of small area devices, they are very serious in large area devices. Also, the fabrication of large area defect-free shallow junctions by the diffusion technique is a difficult and exacting task.

Large area epitaxial p-n junctions were prepared by depositing 15-30μ of 5-10 ohm-cm n-type layers and 5-6μ of 0.1-0.5 ohm-cm p-type layers successively on 0.01 ohm-cm n-type substrates. An example of the resistivity profile of an epitaxial structure is shown in Fig. 7 where an 18-μ, 4 ohm-cm n-layer and a 6-μ, 0.3 ohm-cm p-layer were deposited. Junctions of approximately 4 cm^2 were isolated from the epitaxial structures by a grooving technique. The reverse voltage of these junctions depends on the resistivity and thickness of the n-layer. For example, the epitaxial junctions were found to support 350 and 200v when the n-layer resistivity and thickness were 10 ohm-cm, 30μ, and 5 ohm-cm, 20μ, respectively. The reverse currents at these voltages were usually 1 ma or less. However, polycrystalline inclusions in the epitaxial layer were found to cause high reverse currents at low voltages. Epitaxial junctions with even one inclusion supported less than 50v.

The epitaxial growth technique is, therefore, superior to the diffusion technique for the fabrication of large area shallow junctions. Furthermore, the preparation of epitaxial junctions is considerably simpler in practice than epitaxial-diffused junctions used in certain types of devices such as transistors. The epitaxial junctions described above, after phosphorus emitter diffusion at 1100°C, have produced transistors with a current carrying capacity of 100 amp, V_{CE} = 170v at 1 ma, V_{CB} = 175v at 1 ma, and h_{FE} = 15 at 10 amp (10).

Summary and Conclusions

The epitaxial growth of silicon by the pyrolysis of silane in a flow system has been studied in detail with the objective of using this technique for the preparation of large-area junction structures. Large area epitaxial silicon layers of good structural perfection, uniform radial resistivity profile, and with resistivity controlled over a wide range have been deposited on silicon substrates of {111} orientation under a variety of conditions.

Shallow p-n junctions of a few square centimeters area have been prepared by both diffusion and epitaxial techniques. The diffused junctions frequently showed high reverse currents due to process-induced defects. The electrical characteristics of epitaxial junctions were considerably better, and power transistors have been prepared from these junctions after the emitter diffusion. Epitaxial growth is, thus, a promising junction formation technique for large area silicon devices.

Acknowledgments

The authors wish to thank Dr. P. J. Kannam and Mr. R. G. Mazur for their valuable contributions to this work. This work was supported in part by the George C. Marshall Space Flight Center of the National Aeronautics and Space Administration under Contract NAS8-11432, and the Air Force Cambridge Research Laboratories under Contract AF16(628)-4220.

Phase Relations and Thermoelectric Properties of the Alloy Systems $SnTe\text{-}Bi_2Te_3$ and $PbTe\text{-}Sb_2Te_3$

Richard A. Reynolds

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

The phase relations in the quasi-binary systems $SnTe\text{-}Bi_2Te_3$ and $PbTe\text{-}Sb_2Te_3$ have been determined using differential thermal analysis, x-ray diffraction, electron microprobe, and optical metallographic techniques. The system $SnTe\text{-}Bi_2Te_3$ forms a continuous series of solid solutions from 45 to 100% Bi_2Te_3, and the maximum solubility of Bi_2Te_3 in SnTe was found to be about 5%. The system $PbTe\text{-}Sb_2Te_3$ contains a eutectic and exhibits little solubility of either component in the other. Measurements of the thermal and electrical properties of the $SnTe\text{-}Bi_2Te_3$ alloys showed that they are either n-type or p-type depending on composition, and that the carrier concentrations are degenerate ($\geqq \pm 6 \times 10^{19}/cm^3$). At 300°K Seebeck coefficients are typically 90 $\mu v/°K$. The thermal conductivity is about 1.3×10^{-2} watts/°K-cm and nearly independent of temperature and composition. The maximum thermoelectric figure of merit obtained at 300°K for these alloys was $0.66°K^{-1}$.

The quasi-binary alloy systems $PbTe\text{-}Sb_2Te_3$ and $SnTe\text{-}Bi_2Te_3$ were investigated in order to determine their phase relations and thermoelectric properties. The possibility of the formation of ternary compounds in these systems was suggested by previous investigation (1) of the quasi-binary system $PbTe\text{-}Bi_2Te_3$, in which the compound $PbTe \cdot 2Bi_2Te_3$ was found, and the quasi-binary system $SnTe\text{-}Sb_2Te_3$, in which the compound $SnTe \cdot Sb_2Te_3$ was found. The object of the investigation was to determine whether or not there existed compositions which possess properties useful for thermoelectric power generation applications. The binary compounds and their ternary isomorphous alloys (*e.g.*, PbTe-SnTe alloys) possess useful thermoelectric properties; hence, the cross-substitutional alloys $SnTe\text{-}Bi_2Te_3$ and $PbTe\text{-}Sb_2Te_3$ may possess unique and useful properties and investigation of these alloy systems is required.

Materials and Experimental Procedure

Materials used to make specimens were of the following purities (weight per cent): Sb, 99.99%; Pb, Sn, Bi, and Te, all 99.999%.

Specimens for metallographic, x-ray, and physical property measurements were weighed as 10 or 20g samples, placed in quartz capsules with an inside diameter of 8 or 10 mm, and sealed at a pressure of 10^{-3} Torr. The samples were melted, after which the capsules were rocked vigorously for mixing and then quenched in water. Samples for annealing were cut from the as-cast ingots and encapsulated in quartz tubes at a pressure of 10^{-3} Torr.

Samples for x-ray diffraction studies were ground to powder with a mortar and pestle, sifted through a 300 mesh screen, and mounted on glass slides. Diffraction patterns were determined on a Norelco Diffractometer using Cu K_α radiation. Identical results were obtained on ground samples and ground and annealed samples.

Metallographic specimens were mounted in bakelite and mechanically polished with 0.1μ alumina. Etching was done either with a solution of 1 part HNO_3, 1 part HCl, and 2 parts saturated solution of $K_2S_2O_8$ in H_2O, or with a cathodic etching apparatus.

Resistivity measurements were made with a Keithly Milliohmmeter, which contained its own chopped d-c current supply. The use of chopped current prevented the occurrence of temperature gradients in the specimen due to the Peltier effect at the current lead-specimen contacts. Current contacts and potential measuring contacts were soldered for measurements from 77° to 300°K. Above 300°K pressure contacts were used.

Seebeck coefficients were determined using a ΔT across the specimen of 10°-20°C. Thermocouple and Seebeck voltages were measured with an L&N K-3 potentiometer. Soldered contacts were used.

Thermal conductivity was measured by the steady-state method of Stamper and Bryant (2). Samples used were 8 mm in diameter and 6 mm long.

Hall effect measurements were made using the method of Dauphinee and Mooser (3). The system used was capable of measuring Hall coefficients as small as 0.05 cm^3/coulomb, but in all cases (except pure Bi_2Te_3) the Hall coefficient was found to be smaller than this.

Differential thermal analysis (DTA) was performed using 50g samples, and employed indium as the comparison standard. The DTA capsules were cylindrical (22 mm diameter by 25 mm long) and had a thermocouple well in the bottom. The capsules were sealed at a pressure of 10^{-3} Torr. Heating and cooling rates were varied between 1.6 and 4.0°C/min. Reactions in the specimen capsule leading to temperature differences between the sample and the standard of 2°C or more could be detected. An automatic control circuit cycled each sample through the temperature range of interest, and each point of the DTA data represents the average of two or more cycles. All points were reproducible to ± 1°C, except the cooling points on the liquidus lines, which scattered a little more due to varying degrees of supercooling in each cycle.

Since the heat effects associated with reactions occurring in the solid state are usually very small, and the solid-state transformation kinetics are very slow in these alloy systems, the DTA data for these systems furnish no conclusive evidence about the phase relations at temperatures below the solidus temperature.

Results

The System $PbTe\text{-}Sb_2Te_3$.—DTA measurements revealed the existence of a quasi-binary eutectic between the two binary compounds (Fig. 1). X-ray diffraction data showed only the diffraction patterns of PbTe and Sb_2Te_3 in all the alloys. Optical metallographic examination showed that all compositions were two-phase, containing only PbTe and Sb_2Te_3. The maximum solubilities of Sb_2Te_3 in PbTe, and of PbTe in Sb_2Te_3 were both less than 5%.

The lack of appreciable terminal solid solubility and the failure to form new phases discouraged performing further work on alloys in this system.

The System $SnTe\text{-}Bi_2Te_3$.—Results of the DTA measurements are plotted in Fig. 2 (a phase diagram will be proposed after consideration of all experimental

data). In samples of less than 60% Bi_2Te_3 the heat effect on cooling associated with the isothermal arrest at 581°C was very small (less than 1% of the total heat evolved). On heating, this arrest was observed only in the 85% Bi_2Te_3 alloy. In alloys containing less than 60% Bi_2Te_3 the only isothermal arrest during heating occurred at 601°C. The appearance of the arrest at 581°C on cooling alloys containing less than 85% Bi_2Te_3 is due to peritectic incasement (4) occurring during the liquid-solid transformation. Absence of this arrest in the heating cycle is due to annealing occurring while the DTA sample was in the solid state during the cycling process. Metallographic and x-ray data described below show that alloys containing more than 45% Bi_2Te_3 are all single-phase, thus ruling out the possibility that the isothermal reaction at 581°C is due to a eutectic reaction.

Optical metallographic examination of samples annealed at 550°-580°C revealed that compositions containing 5-40% Bi_2Te_3 were two-phase, but compositions containing 45% or more Bi_2Te_3 were single-phase (Fig. 3a and 3b). Samples annealed at temperatures lower than 550°C did not yield any conclusive data because the annealing kinetics were extremely slow. Examination of as-cast alloys revealed that SnTe is the primary phase of solidification in compositions of less than 60% Bi_2Te_3.

X-ray diffraction patterns of annealed alloys containing 40% or less Bi_2Te_3 exhibited the diffraction patterns of SnTe and a second phase of hexagonal structure (see Fig. 3a). Annealed specimens containing 45% or more Bi_2Te_3 exhibited only the lines of one phase having the crystal structure of Bi_2Te_3 (hexagonal). The c/a ratio for this phase showed a monotonic increase from 6.68 at 45% Bi_2Te_3 to 6.88 at 85% Bi_2Te_3 and 6.97 at 95% Bi_2Te_3. The indexed pattern of several Bi_2Te_3 alloys are given in Table I. The change in c/a is due entirely to an increase in c as the Bi_2Te_3 content is increased from 45 to 100%. It should be noted that the DTA measurements showed the 85% Bi_2Te_3 alloy to melt isothermally, and that Fig. 3b suggests that it is single-phase.

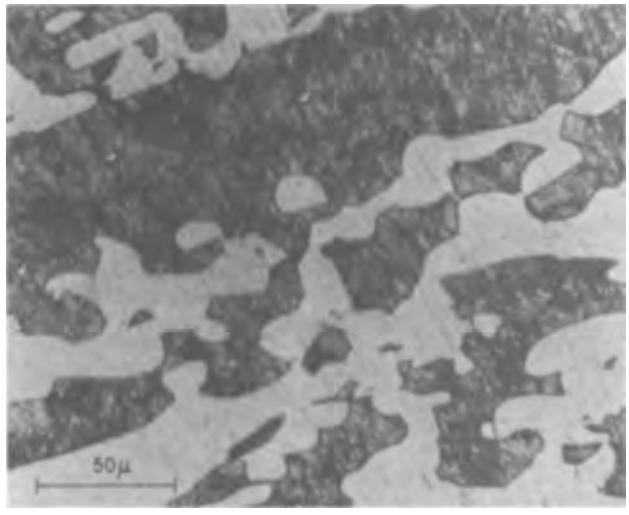

Fig. 3a. Micrograph of etched 75 mole % SnTe-25 mole % Bi_2Te_3 alloy. Dark phase is SnTe.

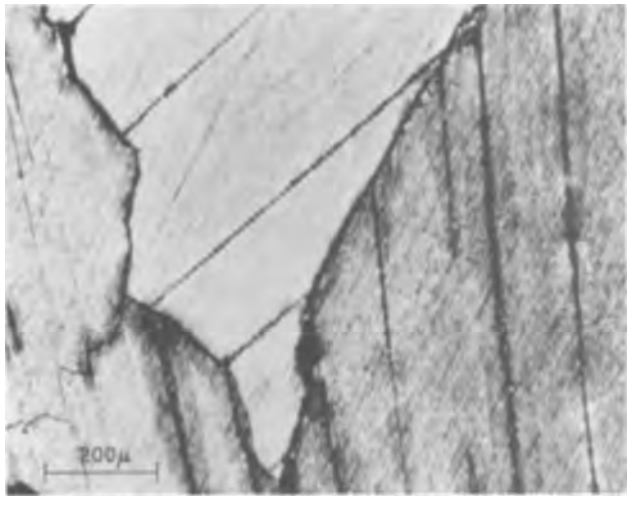

Fig. 3b. Micrograph of etched 15 mole % SnTe-85 mole % Bi_2Te_3 alloy.

In order to confirm that the 85% Bi_2Te_3 alloy is single-phase, the sample in Fig. 3b was subjected to electron microprobe analysis. Nine x-ray intensity measurements to determine local compositions were done at random positions on a polished and etched surface of 1 cm diameter using a 1.0μ diameter spot size. Within 95% confidence the Bi, Te, and Sn contents were identical at all nine sampling spots, thus confirming that the 85% Bi_2Te_3 alloy is single-phase and homogeneous.

Seebeck coefficient measurements showed that alloys up to 47.5% Bi_2Te_3 were p-type; 50% Bi_2Te_3 alloys were n-type as cast but became p-type on annealing; alloys between 52.5% and 85% Bi_2Te_3 were n-type; alloys containing 95% or more Bi_2Te_3 were p-type. Resistivity vs. temperature for several annealed samples is given in Fig. 4. The small positive temperature coefficient of resistance suggests the alloys are degenerate. The broad maximum in the curves at about 300°C may be a result of the long heating times in-

Table I. X-ray diffraction data for $SnTe$-Bi_2Te_3 alloys. Patterns have been indexed for a hexagonal crystal structure, but can also be indexed for a rhombohedral crystal structure. All observed diffraction lines are listed, but all possible reflections are not. The pattern of the 95% Bi_2Te_3 alloy is indistinguishable from that of pure Bi_2Te_3

volved (1-2 hr) causing decomposition of the specimens. The Hall coefficient was too small to be detected in alloys containing 95% or less Bi_2Te_3, apparently due to a low mobility and high carrier concentration.

Table II gives the Seebeck coefficients near room and liquid nitrogen temperatures for compositions near 50% Bi_2Te_3.

Table III presents thermal conductivity data for compositions near 50% Bi_2Te_3, together with published values for SnTe and Bi_2Te_3. The measured value of K has been divided into lattice (K_l) and electronic (K_{el}) contributions by assuming the alloys to be degenerate electronic conductors and computing K_{el} from the formula

$$K_{el} = \frac{\pi^2}{3}\left(\frac{k}{e}\right)^2 \frac{T}{\rho}$$

where k is Boltzmann's constant, e is the electronic charge, T the absolute temperature, and ρ the resistivity.

Discussion of the System $SnTe$-Bi_2Te_3

The DTA data alone (Fig. 2) would suggest the existence of an intermediate phase which melts by peritectic reaction at 601°C and has a composition of about 50% Bi_2Te_3, and that a eutectic reaction occurs at 581°C and 85% Bi_2Te_3. However, x-ray, electron microprobe, and metallographic results all show a continuous series of solid solutions from 45 to 100% Bi_2Te_3. These two groups of data may be reconciled if it is assumed that there exists a single phase between 45 and 100% Bi_2Te_3, the phase being formed by peritectic reaction at about 45% Bi_2Te_3 and 601°C, and exhibiting a minimum in the liquidus at 85% Bi_2Te_3 and 581°C. The presence of the 581°C reaction in alloys containing less than 85% Bi_2Te_3 is the result of nonequilibrium freezing during the peritectic reaction as explained previously. This conclusion is supported by the observation that the heat effect at 581°C is observed on heating only in the 85% Bi_2Te_3 alloy. A phase diagram showing the course of the liquidus and solidus lines is presented in Fig. 5.

The high solubility of SnTe in Bi_2Te_3 is favored by two factors if it is presumed that the Sn atoms occupy Bi sites in the Bi_2Te_3 lattice. First, the Sn sites in SnTe are octahedrally coordinated by Te and the Bi sites in Bi_2Te_3 are nearly octahedrally coordinated by their six nearest neighbor Te atoms (10). This suggests that the nature of the chemical bonds between

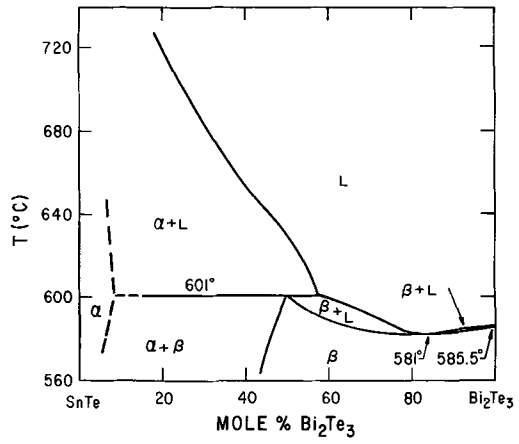

Fig. 5. Proposed phase diagram for the quasi-binary system $SnTe$-Bi_2Te_3.

Sn and Te are similar to those between Bi and Te, so that Sn can easily be incorporated into the Bi_2Te_3 crystal. Second, the Sn atom is smaller than the Bi atom, so that relative size should not prevent the substitution of Sn for Bi in Bi_2Te_2. If Sn is incorporated on Bi sites, then there would be a stoichiometric deficit of one Te atom for every two SnTe molecules dissolved in the Bi_2Te_3 crystal. This deficit may be accommodated by either the formation of Te vacancies, or by the creation of antistructure defects [the antistructure defect is a Bi atom on a Te site, or *vice versa*, and is believed to be the predominant native disorder in Bi_2Te_3 (6)].

It is not possible to determine with certainty whether the degenerate carrier concentrations and changes in carrier type are direct consequences of the incorporation of Sn into the Bi_2Te_3 lattice, or of a high concentration of lattice defects as occurs in SnTe (5) and Bi_2Te_3 (6). Since the incorporation of SnTe molecules into Bi_2Te_3 produces a Te deficit (see above) and Bi_2Te_3 which has a Te deficit is p-type (6), conduction by holes should be favored in these alloys. Furthermore, Sn has been observed to act as an acceptor in Bi_2Te_3 when added in small amounts (7, 8). Thus the expected electrical activity of Sn would also favor p-type conductivity. The fact that the SnTe-Bi_2Te alloys are n-type over most of the single-phase region suggests that the addition of large amounts of Sn to Bi_2Te_3 alters either the method of incorporation of Sn into the lattice or the bandstructure of the crystal. The former possibility might arise due to the large stoichiometric deficit of Te resulting from the incorporation of SnTe into the Bi_2Te_3 lattice. The latter possibility might arise due to the changes in the lattice parameters on alloying Bi_2Te_3 with SnTe. Soonpaa (9) has correlated carrier type with the c/a ratio of Bi_2Te_3 alloys and concluded that alloys are either n-type or p-type depending on whether c/a is greater or less than 6.98. The n-type SnTe-Bi_2Te_3 alloys, which have $c/a < 6.98$, are in conflict with Soonpaa's conclusions.

The best thermoelectric figure of merit for the SnTe-Bi_2Te_3 alloys which can be computed from the experimental data is 0.40-0.66 x 10^{-3}/°K at 300°K for compositions near 50% Bi_2Te_3. Although this best value could be improved somewhat by using higher purity materials and more precise control of the Sn:Bi:Te ratios, it still is sufficiently less than the figure of merit of other materials currently available to make these alloys of little commercial importance.

ELECTROCHEMICAL SCIENCE

Fuel Cell Oxidation of Hydrogen on Movable, Partially Submerged Platinum Anodes

H. J. Davitt and L. F. Albright

School of Chemical Engineering, Purdue University, Lafayette, Indiana

ABSTRACT

The electrochemical oxidation of hydrogen was investigated potentiostatically at 30°C and atmospheric pressure using two movable flat-plate platinum anodes which were partially immersed in 1.0*N* H_2SO_4. The importance of meniscus formation, electrolyte film formed on the exposed portion of the anode, surface roughness, and hydrogen adsorption on the exposed portion of the anode is demonstrated by transient currents resulting from vertical movements of the anodes. The two anodes of different surface roughnesses, one surface altered by sandblasting and the other by platinizing, were tested at the following conditions: (*a*) stationary positions, (*b*) lowering and raising at constant rates (0.7 to 23.8 cm/min), and (*c*) sudden lowering and raising (greater than 480 cm/min). Surface roughness was a determining factor in the evaluation of the data. The roughness of both anodes was temporarily changed by an electrochemical oxidation-reduction technique. The results of the investigation lend support to the thin film model for porous gas diffusion electrodes.

The mechanism occurring on fuel cell electrodes is very complex because of surface geometry including surface roughness, equilibrium conditions, and thermodynamic and kinetic considerations (1). Several investigators (2-9) who considered some of the more theoretical aspects of the fuel cell reactions believe that mass transport of the reactant to the electrode is often if not always rate-limiting; however, they do not agree on the controlling step. Diffusion of dissociated hydrogen on the electrode has been suggested as the controlling step (5). Will (9) and Maget and Roethlein (6), however, believe that the predominant transport step is through the upper portion of the intrinsic meniscus and the adjacent film, in which case the entire surface of the electrode above the meniscus has a high ohmic resistance permitting poor ionic mobility and hence presumably allowing little current flow. Pshenishnikov *et al.* (7) reported results on smooth electrodes in which the film above the meniscus actually contributed more current than did the meniscus itself. Weber *et al.* (8) came to essentially the same conclusions as did Will; however, they believe that a 3-phase zone exists. Cobb (2), using molten carbonates as electrolyte, indicated that the meniscus as well as its shape plays a very important role in the electrochemical reaction. The meniscus is considered by most to be involved in the hydrogen transfer. Certainly the meniscus characteristics would be significantly affected by surface roughness.

Since the rate-determining step of molecular hydrogen transport is often through the meniscus, reduction of this resistance would result in much higher currents. Ennis (3) found for example that, if the anode were raised or lowered in the electrolyte at a constant rate, larger currents were obtained than those of a stationary electrode at equilibrium. In addition, transient currents resulted from fast vertical movements of the partially immersed anode. In all cases these currents were larger than steady-state values and decayed quickly to equilibrium. Will (9) reported high transient currents on lowering the anode, but he found that the currents were depressed on raising it. The apparent contradiction found by Will and Ennis concerning the nature of the transient currents has not yet been explained, but may be caused by differences in the surface roughness of the electrodes.

In the present investigation, two anodes were roughened by sandblasting and by electrochemical techniques. Surface roughness has been found important in explaining factors which affect transient currents when the anodes are raised or lowered.

Equipment and Operating Procedures

The fuel cell consisted of two compartments connected by a fritted glass disk. The anode compartment was constructed of a partially submerged glass cylinder into which the anode could be raised. The top of the cylinder was fitted with a rubber stopper containing hydrogen inlet and outlet ports. The other compartment contained the counter electrode.

The anodes used were 0.0075-cm (0.005-in.) thick platinum foil approximately 2.5 cm wide by 8.0 cm long. A No. 20 gauge platinum wire was spot welded to the top of each electrode and connected through a rubber cap on each Pyrex glass tube to a No. 18 gauge copper wire. Surface roughness of the platinum foil anodes was modified in the following manner: anode S was sandblasted and cleaned in concentrated hydrofluoric acid; anode R was platinized for 120 sec in a 10% chloroplatinic acid solution at a current density of 18.5 ma/cm^2. The anodes were cleaned before most runs in hot concentrated nitric acid (dilution 1:3) and washed with distilled water before use; this procedure will be termed the "normal" electrode conditions. In some cases, the anodes were "activated" by an oxidation-reduction technique in 2.0*N* H_2SO_4: oxygen was evolved at the anode for 12 hr at a current density of approximately 0.17 amp/cm^2, it was washed with distilled water and reduced in a similar sulfuric acid solution for 4 min at a current density of approxi-

mately 0.05 amp/cm². The platinum oxide layer was believed to be completely reduced in this latter step since a hydrogen equilibrium potential was obtained in less time than it took to set up the cell and make a measurement (less than 3 min).

The electrolyte was 1.0*N* H_2SO_4 prepared from 96.5% reagent grade sulfuric acid. The electrolyte was saturated with hydrogen gas and maintained at 30° ±0.2°C. A saturated calomel electrode (SCE) was used as a potential reference, and unless otherwise stated all potentials are referred to this standard. A Duffers Model 600 potentiostat with auxiliary equipment was used to control the potential of the anode to within ±0.005v. A Sargent Model SR automatic self-balancing potentiometer was used to record the current output of the cell.

A specially designed elevator, which could be driven by motor or turned by hand, was used to raise or lower the anodes to within ±0.02 cm. A ring stand, fitted with stops and a sliding clamp attached to the anode Pyrex glass tube, was used to raise and lower (snap-raise or snap-lower) the test electrodes by hand rapidly.

Results

Anodes at stationary positions.—The currents obtained with the platinized anode and the sandblasted anode at various stationary positions were measured as a function of the emergent height (the distance between the top edge of the anode and the surface of the electrolyte) for the following conditions: 0.15 and 0.55v applied voltage and for both a "normal" anode and for one that had been preoxidized-reduced just before the run. The relationships of current to height for the "normal" platinized anode, Fig. 1, curves 1 and 2, are similar to those explained earlier by Will (9). At emergent heights of 6-8 cm, the meniscus was ragged; the currents were also less regular and consistent.

Immediately after the preoxidation of the platinized anode, the currents obtained at 0.55v (curve 4) were generally lower by about 1 ma than curve 2; however, these currents tended to increase toward curve 2 within several hours. This gradual increase in current with time was not observed at 0.15v. The results for the sandblasted anode are shown in Fig. 2, and each curve shown is the average of several runs which also gave reasonably good reproducibility as indicated by a statistical evaluation. The current obtained with the sandblasted anode were often as low as 40% of those obtained with the platinized anode. Preoxidation of the sandblasted anode caused the current to increase by about 100% (although currents were generally less than for the other anode) for applied voltages of both 0.15 and 0.55v. Both anodes when preoxidized gave similar currents at 0.55v.

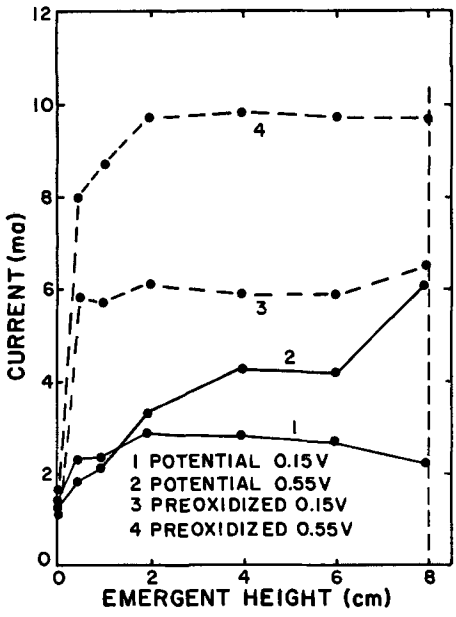

Fig. 2. Average current as a function of the sandblasted anode's emergent height under normal and preoxidized-reduced conditions at potentials of 0.15 and 0.55v.

Although the surface areas of the two anodes used in this investigation were not measured directly, the results and methods of preparing the anodes are quite similar to those of Will (9) for two of his anodes. It seems safe to conclude that relative surface roughness of the anodes are also similar, namely 10 and 88, respectively.

Anodes moved at steady rates.—Numerous runs were made in which the two anodes were raised or lowered at various constant rates. Figure 3 indicates such results for the platinized anode as a function of

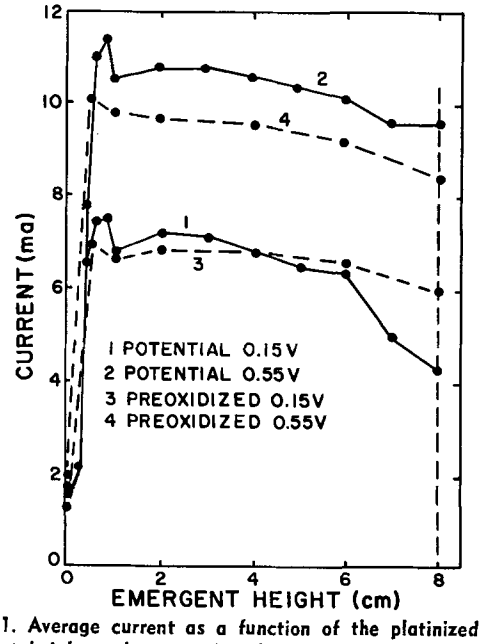

Fig. 1. Average current as a function of the platinized anode's emergent height under normal and preoxidized-reduced conditions at potentials of 0.15 and 0.55v.

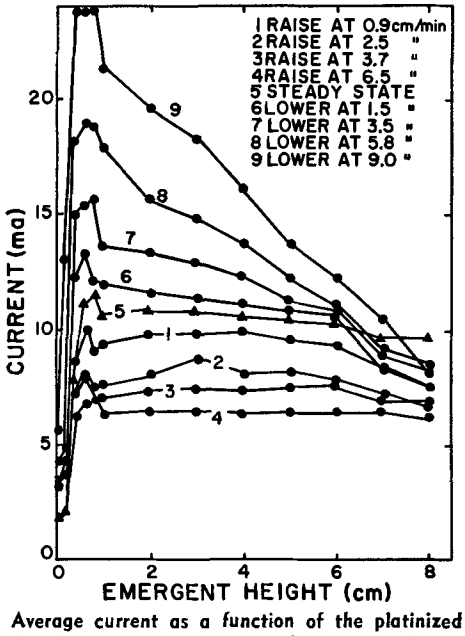

Fig. 3. Average current as a function of the platinized anode's emergent height with average rate of raising and lowering as parameters; potential 0.55v.

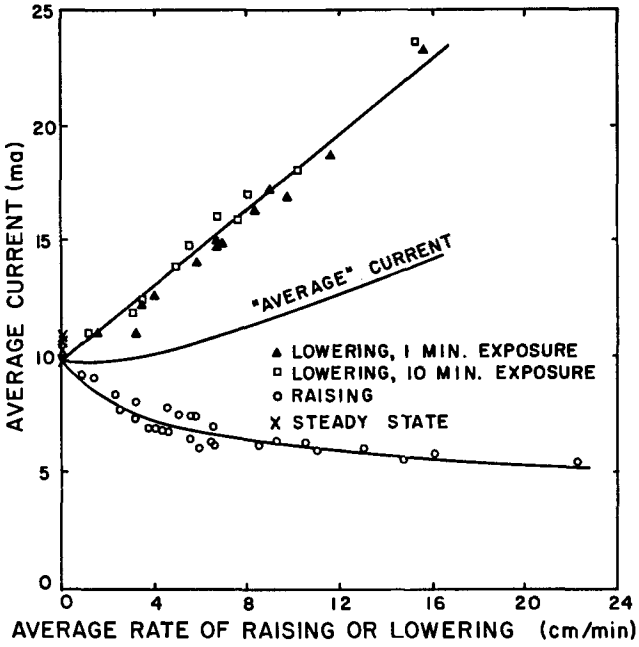

Fig. 4. Average current as a function of average rate of raising and lowering the platinized anode at a potential of 0.55v.

emergent height as the anode was moved at 0.55v. The current clearly increased as the rate of lowering increased. Curve 5 is for the stationary anode (also curve 2 of Fig. 1). Raising the anode caused the current to decrease as is indicated by curves 1-4.

The average current for each run shown in Fig. 3 was determined by graphically integrating and averaging. Figure 4 shows a plot of these average currents as a function of the average rate of raising and lowering the anode. Runs in which the anode was exposed to hydrogen for 10.0 min before lowering perhaps gave slightly higher currents by about 5% than those with 1.0-min exposure; however, more data would be required to evaluate this difference statistically. The middle curve of Fig. 4 designated as "average" current is the arithmetical average of the curves for lowering and raising. Such an average current might be expected if a cylindrical rotating anode were to be used in a fuel cell. In such a fuel cell, one portion of the anode would correspond to the raising experiments and the opposite portion to the lowering experiments.

Similar runs were made for the sandblasted anode at 0.55v, and the results are shown in Fig. 5. The currents obtained were significantly less than those obtained with the platinized anode. However raising the sandblasted anode at rates greater than about 4 cm/min increased the current. Experiments were also made at

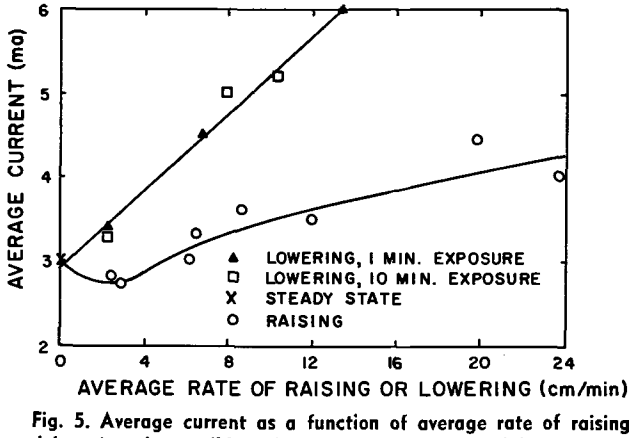

Fig. 5. Average current as a function of average rate of raising and lowering the sandblasted anode at a potential of 0.55v.

Table I. Constants for Eq. [1] and [2]

Anode	Applied voltage, v	a	b	c	d
Platinized	0.15	6.6	0.99	5.1	0.50
Platinized	0.55	9.8	0.82	9.0	1.24
Sandblasted	0.15	2.1	0.22	—	—
Sandblasted	0.55	2.9	0.23	—	—

0.15v in which both anodes were moved at steady rates. The types of curves obtained were similar to those obtained at 0.55v.

Average currents for runs in which the anode was lowered could in all cases be fitted by the following type of empirical equation

$$\text{Current} = a + b \text{ (rate of lowering in cm/min)} \quad [1]$$

Currents for the platinized anode as the anode was raised were correlated at rates from 0.9 to 22 cm/min by the following empirical equation

$$\text{Current} = c - d \ln_e \text{ (rate of raising in cm/min)} \quad [2]$$

Values of a and b and of c and d were determined by regression analyses, and Table I indicates the values obtained. The value a represents the average current for the stationary anode. The significance of these values will be discussed later.

Currents after sudden raising or lowering of anode. —Numerous experiments were made in which both anodes were suddenly raised or lowered in less than 0.5 sec from one position to another. These changes in position are designated as snap-raises and snap-lowerings. In all cases the emergent height of the anodes was never less than 2.0 cm. Figure 6 indicates the results of runs for the platinized anode as it was moved from emergent heights of 2-6 cm and back for both 0.15 and 0.55v. When this anode was raised, the current decreased in the first second, then immediately increased somewhat (to a value less than steady state), and then decreased slightly for about 0.5 min. From 0.5-10.0 min the current increased slightly and leveled off after about 10 min. When the anode was snap-lowered, the current increased to a value off the scale of the recorder (*i.e.*, greater than 12.5 ma). The current decreased to less than 12.5 ma within 6 sec, a minimum current was experienced after about 1 min, and then the current increased slightly and leveled off by the end of 10 min.

Preoxidation of the platinized anode did not have any significant effect on the transient currents obtained during snap-raises and lowerings. In all runs with

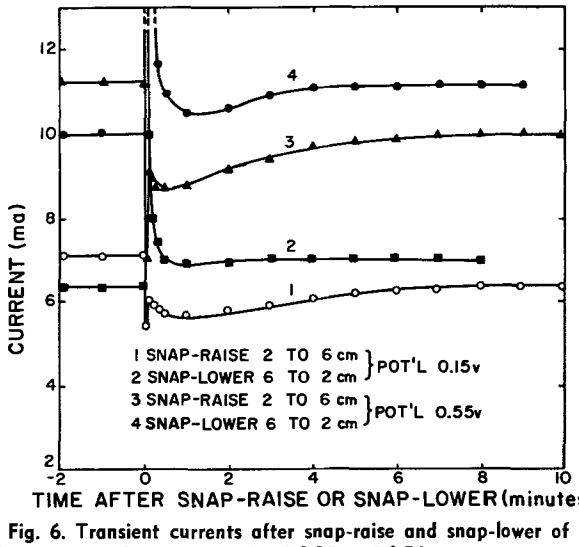

Fig. 6. Transient currents after snap-raise and snap-lower of the platinized anode at potentials of 0.15 and 0.55v.

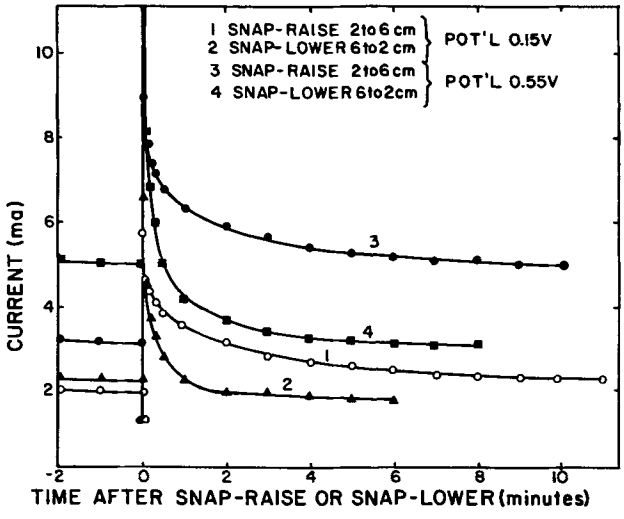

Fig. 7. Transient currents after snap-raise and snap-lower of the sandblasted anode at potentials of 0.15 and 0.55v.

this anode, the meniscuses obtained during snap-raises and lowerings looked smooth and well-formed.

The currents obtained with snap-raises and lowerings of a "normal" sandblasted anode are shown in Fig. 7. The general characteristics of the curves obtained are similar to those of the platinized anode except that the transient currents on raising were about 3 times greater than the currents at stationary conditions. When the sandblasted anode was then preoxidized and snap-raised at 0.55v, the results obtained 160 and 1730 min after preoxidation are shown as curves 2 and 3 of Fig. 8. Curve 1 is shown for purposes of comparison (also curve 3 of Fig. 7). Preoxidation drastically changed the type of curves obtained with snap raises; there was an instantaneous current reduction, quick rise of current above the steady-state value; the current then decreased to a minimum after about 0.5 min and then increased to a plateau by the end of 10 min. After 1730 min (about 29 hr), the character of the curve was similar to that of curve 1, although the currents were higher in all cases. Snap-lowering runs for the preoxidized sandblasted anode showed the same phenomena as previously described and shown in Fig. 7.

Discussion and Results

Results of this investigation support the postulate that the rate-controlling step of the over-all process is

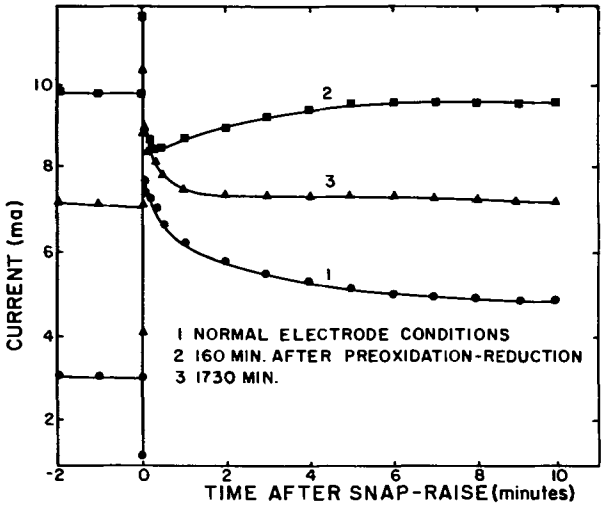

Fig. 8. Transient currents after snap-raise of the sandblasted anode under normal and preoxidized-reduced conditions at a potential of 0.55v.

mass transfer of the hydrogen to the anode through the upper edge of the meniscus and of the film just above it. As indicated in Fig. 1 and 2, the maximum current is obtained just as the meniscus first develops when the anode is raised from the electrolyte.

Surface roughness was found to be an important factor in the transient currents developed as the anode was raised or lowered. With the sandblasted anode which was macroscopically rough but microscopically smooth, good agreement was obtained with the results of Ennis (3), *i.e.*, increased currents were obtained as the anode was both lowered and raised. With the platinized anode, however, which is microscopically rough, good agreement was obtained with the results of Will (9), *i.e.*, increased currents when the anode was lowered but decreased currents as it was raised. The preoxidation-reduction of the sandblasted anode probably microscopically roughened the anode (11, 12), resulting in transient currents for raising that were intermediate between those of the two anodes under normal conditions (see Fig. 6 and 8).

Shibata (11, 12) concludes that preoxidation-reduction of platinum produces an active unstable platinum surface with an activity comparable to the platinized-platinum electrode. Comparisons of Fig. 1 and 2 and of Fig. 6 and 8 can be interpreted in terms of this model. After the preoxidation-reduction technique the current *vs.* emergent height curves (Fig. 1 and 2) of both anodes were more regular, indicating a more uniform surface. At 0.55v (curve 4, Fig. 1) the current of the peroxidized platinized anode was initially lower than under normal conditions (curve 2). Some active sites may have been "sealed off" by the production of this temporary active surface. Such a phenomenon was not apparent at 0.15v or on the sandblasted anode at either potentials.

Will and Knorr (10) found that essentially no hydrogen adsorbs on platinum electrodes at potentials greater than 0.4v relative to the normal hydrogen electrode (NHE). Will (9) states that a voltage gradient probably exists in the meniscus-film region parallel and adjacent to the anode, starting from the applied potential in the bulk solution and decreasing toward the reversible hydrogen electrode potential. This voltage gradient resulting from the slow transport of hydrogen ions from the reaction zone into the bulk electrolyte causes concentration gradients of molecular and atomic hydrogen to exist along the anode surface. Therefore, a larger portion of the exposed anode surface should be at potentials low enough for hydrogen adsorption at 0.15 than at 0.55v, relative to the saturated calomel electrode. Consequently, on lowering the anode, the slope of the curve of average current *vs.* average rate of lowering should be larger at 0.15 than at 0.55v. The platinized anode supports this postulate since the corresponding slopes were found to be 0.99 and 0.82 ma/cm/min (Table I). However, for the sandblasted anode, the two different potentials had little or no affect on the slope. Since the meniscus on the sandblasted anode was ragged on lowering, the film, if one existed, was presumably extremely thin; consequently a large voltage gradient existed and most of the exposed anode surface at both potentials was at a potential lower than 0.4v (NHE).

As mentioned previously the sandblasted anode was macroscopically rougher than the other anode, due to the sandblasting. Therefore, when the platinized anode was suddenly raised, the liquid film which was pulled up was undoubtedly smaller and drained more quickly than the corresponding film on the other anode which tended to "hang up" on the coarse structure. The preoxidation-reduction technique discussed earlier should produce a temporary surface structure on the sandblasted anode somewhat intermediate between these two extremes. This intermediate condition was shown to exist (see Fig. 8) and did slowly revert back to the normal condition.

When both anodes were quickly raised, the current

instantaneously decreased. This could be due to either or both of the following: (*i*) an increased film thickness resulting in a larger barrier to hydrogen diffusion, or (*ii*) by removal of that portion of the anode which was originally in equilibrium near the top of the meniscus and replaced by a lower portion of the electrode in equilibrium with a much smaller concentration of hydrogen. The film apparently drains very rapidly from the platinized anode as evidenced by the short peaks following the first instantaneous decrease (curves 1 and 3, Fig. 6). These same peaks for the sandblasted anode are quite large (curves 1 and 3, Fig. 7) indicating that the film drained slowly enough to permit establishment of high currents. These transient currents are not believed to be affected by the potentiostat, since it has a stated rise time of 25 μsec for a 0.01v square wave input.

Upon constant raising of the anode (Fig. 4 and 5), the effect of surface roughness is apparent at speeds much slower than those of a rapid or snap-raise. The sandblasted anode shows a modest current increase following a small depression at very slow rates of raising, whereas, the platinized anode exhibits a continuously decreasing current of an asymptotic nature.

Results of these experiments support the theory that a liquid film exists above the intrinsic meniscus and that no 3-phase zone exists. During experiments with the platinized anode when it was raised from an emergent height of 6.0-7.0 cm, the portion of the electrode directly above the apparent meniscus edge appeared to become "dry" with a very distinct upper boundary. This dry region encompassed that portion of the electrode greater than 6.0 cm which was previously discussed and regarded as nonuniform. As this portion of the electrode became dry, the current which was initially at steady state decreased approximately 0.5 ma to a new steady state. The actual shape of the meniscus itself probably changed during this film separation and accounted for the current decrease. It is important to note that a distinct visible film boundary did exist. This phenomenon was not observed on the sandblasted anode. The existence of the film may depend on surface roughness, and if the film does exist it contributes very little to the total current.

Conclusions

Surface roughness of a partially submerged platinum anode has an important effect on currents at a stationary electrode and the transient currents obtained when the anode is raised or lowered. Surface roughness affects both the meniscus and film formation, which in turn affects the currents. Preoxidation followed by reduction temporarily alters the surface roughness of platinum.

At stationary electrode conditions, a thin film covers the exposed portion of partially submerged, heavily platinized-platinum electrodes. This film may or may not cover the exposed portion of a partially submerged "smooth" anode; however, this film was not found to contribute significantly to the total current.

Substructures in Oxide Scales on Nickel, Cobalt, and Nickel-Cobalt Alloys

G. C. Wood, J. M. Ferguson, B. Vaszko, and D. P. Whittle

Corrosion Science Division, Department of Chemical Engineering, The University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

Scales produced on nickel, cobalt, and nickel-cobalt alloys in pure oxygen at 1000° and 1200°C have been studied, after different cooling procedures, in plan and section by optical and electron microscopy. Very large columnar grains are separated from the metal core by a thin layer of fine equiaxed grains. Subgrain boundaries are revealed on the surface of nickel-rich scales by a form of growth or by thermal etching and of cobalt-rich scales by Co_3O_4 precipitation. In section, the visibility of Co_3O_4 decorating subboundaries can be accentuated by preferential chemical etching. Growth facets and steps and thermal etch pits produced by surface processes are clearly evident on scale surfaces, certain of the etch pits probably being associated with emergent dislocations. Control of the alloy composition and cooling conditions leads to precipitation of Co_3O_4 either randomly, or along subgrain boundaries, or as very fine particles along preferred directions in the (Ni,Co)O grains.

Following the very early studies of oxidation phenomena, in which the elementary ideas of kinetic, mechanical, structural, and topographical aspects were proposed, came a long period in which the field was dominated by kinetic studies which reached, in some cases, a considerable degree of sophistication. In recent years, however, the limitations of this approach have been appreciated by many workers, and kinetic

measurements have been supplemented by carefully documented topographical, structural, and microanalytical information.

Thus, to characterize an alloy oxidation process reasonably fully it is necessary to know the kinetic rate constants for the surface oxide and any internal oxide formation, together with the interdiffusion coefficient of the alloying elements and the solubility and diffusion rate of oxygen in the alloy. Additionally, a full knowledge of morphological, epitaxial, structural, and microanalytical data is required at various stages of oxidation and often a rate-determining layer must be isolated. The lattice defect structure and semiconducting properties of this layer must be ascertained by techniques such as electrical conductivity measurements and radioactive tracer techniques.

The state of development of the oxidation field has now reached the stage where, in addition to the above information, much more must be established about phenomena affecting the mechanical properties of films and scales, factors which are highly significant in determining the oxidation behavior. By analogy with the study of metals and ceramics, there are two approaches whereby this more fully integrated picture of the oxidation process may be attempted. One involves the direct measurement of mechanical properties of oxides and oxide/metal combinations such as the stress developed, tensile properties, creep rates, fracture properties, and hardness. Preliminary measurements along these lines have already been made by other workers (1-9), although much remains to be done. The second approach, an essential one in the long run to understand processes such as slip, fracture, and creep fully, is to establish a sound understanding of the grain structure and substructural detail of films and scales. This involves a knowledge of grain nucleation, recrystallization, and grain growth phenomena during scaling and subsequently of subgrain boundary and dislocation distribution. In certain instances precipitation phenomena within the scale are also important. The present paper reports a preliminary study of such phenomena in scales.

Information on the substructure and mechanical properties is most urgently needed for oxides such as Cr_2O_3, Al_2O_3, Nb_2O_5, and ZrO_2 which commonly fail by spalling. However, although the problem is by no means as severe with nickel and cobalt, the oxides of these metals are much easier to study in this way and are therefore more suitable for preliminary studies. Thus nickel-cobalt alloys, which are homogeneous and single-phase, produce single layers of a single oxide solid solution (Ni,Co)O when oxidized above 900°-950°C, cobalt being only slightly preferentially oxidized. Such layers grow according to a parabolic relationship mainly by the outward movement of cations, and metal concentration gradients have recently been obtained through such scales at various stages of oxidation (10). The system has the additional advantage that on cooling scales below 900°-950°C, Co_3O_4 is precipitated within the scale to an extent determined by the alloy composition and the cooling rate, thus permitting study of preferential sites for precipitation. This is because (Ni,Co)O, saturated with oxygen at the oxidation temperature, becomes supersaturated on cooling, thus promoting the precipitation. Additionally, for slow cooling in oxygen or air the surface layers would tend to be converted to Co_3O_4 by continued oxidation.

Experimental Procedure

In preparing the scaled specimens which were to be studied in plan and section by optical and electron microscopy, it was recognized that as well as identification of normal growth features, recourse would probably be necessary to the established methods of observing substructure in metals, namely thermal etching, chemical etching, and defect decoration. A form of thermal etching was obtained by carrying out the oxidation at high temperatures. Decoration could be controlled to some degree by careful choice of the alloy and cooling conditions.

Annealed specimens of nickel, cobalt, and of Ni-10.9% Co and Ni-80.0% Co, of purity in excess of 99.95%, were used for most experiments, but comparable results were also obtained for the pure metals with spectrographically pure material. The surfaces were generally electropolished at 0.39 amp/cm^2 in 60% sulfuric acid (s.g. 1.6) at 30°C for 3 min or lightly mechanically polished on 1μ diamond suspension. After washing in alcohol and drying, the specimens were oxidized by immediate exposure to pure flowing oxygen for various times at 1000° or 1200°C. They were subsequently cooled by quenching in water, by furnace cooling (2°C/min) or generally at an intermediate rate of approximately 150°C/min. Unless otherwise stated in the captions the last cooling rate is applicable.

Certain scales were examined directly in plan, but others were fractured by bending the completely oxidized specimen or were prepared conventionally in section, finishing on diamond suspension. The grain structure of scales in section on pure nickel was sometimes revealed by a relatively long polishing time. With cobalt and Ni-80.0% Co it could be accentuated by etching in 30% V/V HCl in ethyl alcohol at 50°C for 15-30 sec, which functions by attacking Co_3O_4 precipitates in grain boundaries. Microhardness traverses across scale sections were made at room temperature, using a Reichardt microhardness tester with loads in the range 5-100g, but usually 50g.

The electron microscopical examination of the surfaces of the scales was made using standard replica techniques, in conjunction with an A.E.I., E.M.6 microscope. The two-stage formvar/carbon replica technique was found to be the most suitable. This produced a carbon replica, negatively shadowed with a platinum/carbon alloy, nominally normal to the surface. The alternative method, involving chemically stripping a direct carbon film as a replica, was also used with relatively flat surfaces where it could easily be removed.

Results and Interpretation

At the present stage of development of this work, the causes of all the surface features cannot be precisely stated because of general ignorance of the relative contributions of directional preferential growth through the oxide lattice, surface diffusion, and evaporation and surface-tension phenomena. For the sake of presentation, it will be assumed that the very large crystal facets, involving entire grain or subgrain surfaces, are due to preferential growth along certain directions whereas smaller steps, striations, or etch pits within the grains are due to surface diffusion and possibly evaporation. The term "thermal etching" will be employed although it is recognized that this process, as employed as a technique in revealing the surface structure of metals and ceramics, is often carried out *in vacuo*, conditions clearly favoring evaporation processes. However, thermal etching is also known to occur in gaseous atmospheres, including those which are mildly oxidizing. The oxide surface will be attempting to assume a minimum surface free energy configuration revealing close-packed planes, grain boundaries, and dislocation networks. This simple picture will require substantial modification in due course. The possibility of obtaining surface features due to mechanical deformation of the oxide or to vacancy coalescence on cooling should not be neglected.

Unfortunately it is not possible to make a quantitative appraisal of the phenomena at this stage. This would require a very detailed study of each factor discussed and would in any case be rendered difficult by existing doubts about surface tension, surface diffusion, and evaporation contributions to surface features on all materials and about 1:1 correlation between etch pits and emergent dislocations.

Table I. Scale Thicknesses

Alloy	Oxidation time and temperature	Scale thickness, μ
Nickel	12 hr, 1200°C	40
Ni-10.9% Co	4 hr, 1000°C	13
	5 min, 1000°C	10
Ni-80.0% Co	50 hr, 1000°C	270
	12 hr, 1200°C	500
Cobalt	12 hr, 1200°C	900

Scale thicknesses.—In those cases where scales have been examined in plan, it is of value to know the scale thicknesses; consequently these are given in Table I.

Oxide grain size and distribution.—Figure 1a shows a section through a thick scale produced on nickel by oxidation for 288 hr at 1200°C. The action of the diamond polishing suspension is sufficient to delineate the grain boundaries mildly and gives clearer results than etching in boiling orthophosphoric acid solution which tends to stain the specimen. The scale consists of a single major layer with large columnar grains extending from the outer interface to a thin region of fine equiaxed grains adjacent to the metal. The pores in this inner region appear to be associated with the more friable oxide there. Scales on zone-refined nickel have large grains extending nearer to the metal.

Figure 1b shows in section a remarkably uniform and pore-free single-layer scale on cobalt oxidized for 4 hr at 1000°C. During cooling at 150°C/min, Co_3O_4 precipitation has clearly occurred along the columnar grain boundaries and to some extent at preferred sites within the grains in the outer half of the scale and probably nearer the metal, although it is not visible there through being small. A similar section of a cobalt specimen, completely oxidized in 65 hr at 1200°C, cooled at 150°C/min and etched in alcoholic hydrochloric acid solution, is depicted in Fig. 1c. Again,

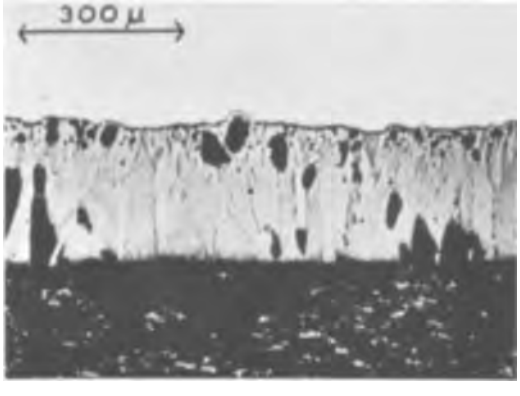

Fig. 1a. Grain size and distribution in section. Nickel oxidized for 288 hr at 1200°C.

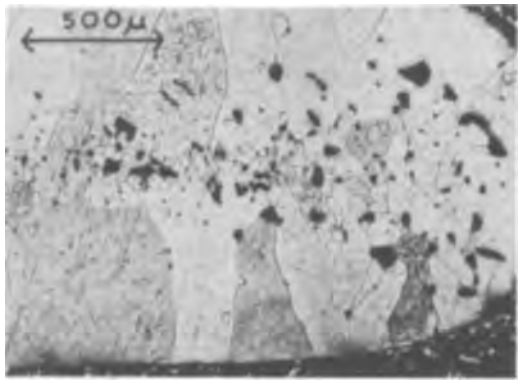

Fig. 1c. Grain size and distribution in section. Cobalt fully oxidized after 65 hr at 1200°C, etched.

massive outer columnar grains are separated by an inner layer of fine grains. The latter may be partly associated with impurities collecting there and inhibiting grain growth, or affecting mechanical constraints near the metal/oxide interface by reducing scale plasticity, as indicated by Vallée (17). It is noteworthy that the region of small equiaxed grains is thicker near the end of the specimen which could indicate that mechanical factors operative there influence the structure, although clearly the scale has been sufficiently plastic to accommodate volume changes in this vicinity. Indeed the scale has shown sufficient plasticity to accommodate virtually all volume changes because, apart from a few pores which may have been produced or enlarged during the polishing process, there is no gap in the center of the specimen as often occurs when scales grow by cation diffusion. Special experiments on spheres, cylinders, and various angular specimens with very sharp corners all showed adherent uniform scale on cooling from 1000° or 1200°C, confirming that scale plasticity at these temperatures is sufficient to eliminate effects of mechanical factors on the oxidation rates.

Etching reveals the relatively fine precipitation of Co_3O_4 within the grains because it acts by attacking the Co_3O_4. It is likely that the Co_3O_4 is decorating subgrain boundaries but it is difficult to be precise at this magnification. Additionally there is a tendency for Co_3O_4 precipitation from scales on pure cobalt to be so extensive that its location is sometimes throughout the grains in a random fashion. The general grain structures just described are somewhat similar to those previously reported for nickel (13), cobalt (15, 17), and iron (25).

Microhardness traverses across sections of the thick scales at room temperature showed that the hardness values decreased from 650-750 kg/mm^2 for NiO to 450-500 kg/mm^2 for (Ni,Co)O on Ni-80% Co and 300-350 kg/mm^2 for CoO. These ranges cover the scatter from numerous specimens examined, repeated values from individual specimens giving much closer results. The small equiaxed grains near the metal/oxide interface and at the ends of the specimens gave values 10-20% lower than in the outer columnar grains. Co_3O_4 precipitates, of the size observed here, also seemed to reduce the measured hardness of CoO-rich grains by a similar amount. There was, however, no obvious hardness gradient across any scale section. In the case of the Ni-80% Co alloy, where such a gradient would be expected on the grounds of composition changes, this is because the grain size and precipitation effects would tend to obscure the gradient. The hardness values were generally independent of the oxidation temperature within the experimental error. Hardness values of these oxides which are relatively brittle at room temperature can only be considered as relative and do not directly imply similar trends at temperature. The measurements were generally made with a 50g load, although the values were apparently un-

affected in the range 5-100g. Douglass (6), working on ZrO_2, used much higher loads and found a dependence of hardness with load under these conditions. Although hardness values obtained at temperature are obviously more valuable, it is still useful to have measurements of scale properties at or near room temperature, because spalling on cooling or thermal cycling is clearly partly determined by the latter.

Figure 2a displays the massive grains on the surface of cobalt oxidized for 12 hr at 1200°C, followed by quenching in water, the characteristic grain shape and grain boundary network showing remarkably clearly. The apparent size of these grains lies in the range 100-400μ, which agrees well with values measured in section. No Co_3O_4 is evident in this specimen because its deposition was prevented by the rapid water quench. By analogy with similar grains on cobalt (18) and nickel (13), examined by x-ray diffraction techniques, the large flat surfaces parallel to the surface may be identified as {100} planes and the sides of the few large pits in the grain boundaries in Fig. 2a and 2b (appearing black) as {111} planes. These large faceted pits seem more common on nickel surfaces, particularly at high temperatures (19). Similar surface grain patterns have been reported by other workers (14, 16). In one study of cobalt oxidation the grain surfaces are reported to be flatter at higher temperatures and on annealed surfaces (17).

Figure 2b displays the effect of cooling a similarly oxidized specimen at about 150°C/min. Co_3O_4 is precipitated in a relatively finely divided form at preferred sites in the surface, such as subgrain boundaries and other regions of dislocation emergence. The distribution is similar to that of the specimen shown in section in Fig. 1c.

The surface of the scale on Fig. 3a, which was produced on Ni-80.0% Co by oxidation for 70 hr at 1200°C and cooled at 150°C/min, shows some irregular cracks. These may well have followed subgrain boundaries decorated by Co_3O_4 during the cooling process. This emphasizes the importance of reactions occurring during the cooling process as well as at temperature and the effects of the differential cooling characteristics of the alloy and scale. For comparison, Fig. 3b shows a fracture surface of a scale on cobalt, completely oxidized for 65 hr at 1200°C and subsequently cracked in half. Fracture steps are clearly visible, and the dots indicate Co_3O_4 precipitates, comparable in size to those seen in plan, which could well act as stress raisers. Cracks were transgranular in the oxide which is not very ductile at room temperature.

Oxide subgrain size and distribution.—Electron microscopy enables the subgrain structures to be studied in much greater detail. Thus, Fig. 4a shows the surface of a scale in Ni-10.9% Co oxidized for 4 hr at 1000°C, this scale being about 13μ thick (Table I) and having a surface composition of (Ni,Co)O containing about 20% cobalt without any Co_3O_4 precipitate (10). The outer surfaces of the columnar grains viewed in plan are about 1.5-5μ wide, and the subgrains within them are typically 1.5 x 0.4μ. The fine veinlike structure revealing the subgrains is produced by the surface phenomena mentioned previously. It is worth

noting that the melting points of NiO and CoO are 1960° and 1805°C, respectively.

Another method of showing up the subgrain structure, displayed for Ni-80.0% Co oxidized for 5 min at 1000°C (Fig. 4b), is to select the alloy and cooling conditions so that Co_3O_4 is precipitated preferentially along the boundaries. The subgrains are somewhat larger than for Ni-10.9% Co which is to be expected because of the faster oxidation rate. This micrograph also demonstrates that such precipitation is not always necessarily associated with surface topographical features. Thus, the Co_3O_4 is not related to the stepped surface, the origin of which is discussed in latter sections. Some of the small dots indicated may be Co_3O_4 nuclei.

Growth facets, steps and striations, and etch pits.— Figure 5a shows the surface of a nickel specimen oxidized for 12 hr at 1200°C. Apart from the large flat grains, previously identified by analogy as {100} surfaces and the large facets in grain boundaries which have {111} surfaces, numerous pits are present within the grains, aligned in two directions. It is likely that these are thermal etch pits and are not produced by vacancy coalescence on cooling or indeed by directional growth. The large faceted pits in the grain boundaries possibly originally grew from such pits although, as indicated earlier, they may have appeared by directional lattice growth. The typical pit size is 2-5μ and there are approximately 10^6 pits/cm^2 which lies within the very wide range of 10^6-10^9/cm^2 for the dislocation density in annealed materials. It cannot be stated categorically that the pits were initially associated with emergent dislocations, but this is likely. The method seems to have possibilities for revealing dislocations in thermally formed oxides, for example by the observation of etch pit location after progressive macroscopic film thinning. Chemical etching in hot nitric acid, which is said (19) to produce dislocation etch pits in NiO produced by flame fusion and subsequent annealing at 1620°C in argon, failed to increase the pit density.

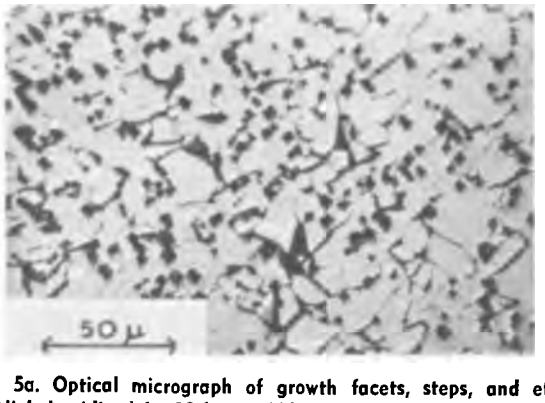

Fig. 5a. Optical micrograph of growth facets, steps, and etch pits. Nickel oxidized for 12 hr at 1200°C.

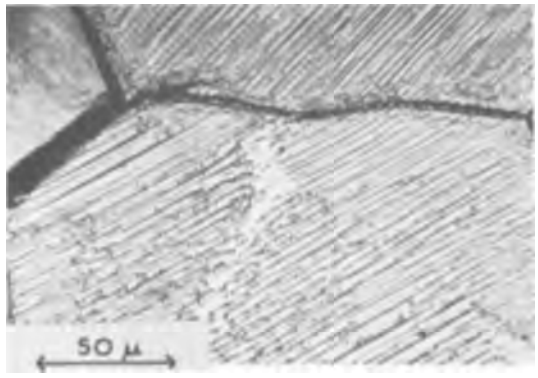

Fig. 5b. Optical micrograph of growth facets, steps, and etch pits. Ni-80.0% Co oxidized for 12 hr at 1200°C and furnace cooled.

Numerous steps, extending entirely across a grain in a direction depending on its orientation, are depicted in Fig. 5b. This specimen of Ni-80.0% Co was furnace cooled after oxidation for 12 hr at 1200°C so the surface is very rich in Co_3O_4. Although the steps are related to growth phenomena and surface diffusion they bear similarity to striations which have been observed during nucleation processes on metal surfaces.

Figure 5c shows a remarkable wealth of detail on the surface of a specimen of Ni-80.0% Co oxidized for 50 hr at 1000°C. Within each clearly visible grain are terraces of growth steps revealing cubic planes. There are also possibly a few terraced etch pits and a display of fine pimplelike particles which are the Co_3O_4 precipitate particles.

The differences from specimen to specimen and from region to region in those features of surface topography related to surface diffusion processes are determined in part by impurities as well as the oxide substructure, temperature, and cooling rate. These impurities, derived from the gas or conceivably from the metal, poison surface sites and thus control the step size and the rate of step movement across the surface.

Certain of the features visible in the optical microscope are examined at greater magnification in electron micrographs in Fig. 6. For example Fig. 6a gives considerable detail of very fine steps or striations, of different orientation from grain to grain. These are only a fraction of a micron in size, compared with the micron-size steps observed on the specimen in Fig. 5b. Figure 6b gives the detail of grains about 10μ in size. Certain regions of certain grains are covered with fine pock marks, typically 1000Å in diameter with about 10^8/cm^2. An important feature is that the grains appear truncated, supporting the idea of removal of material. In certain regions the pock marks look like fine etch pits without any special shape.

The pits on the surface of scale on nickel (Fig. 5a) are shown at much higher magnification in Fig. 6c. Some of the pits are square, confirming the surface

faces of the large grains to be {100}, but some are rectangular, possibly due to the joining together of two smaller pits. There are also small features at the pit bases which have not yet been identified.

Pits of a similar type, but much smaller and less sharply defined, were found on Ni-80.0% Co oxidized for 12 hr at 1200°C and water quenched (Fig. 6d), which would therefore possess a (Ni,Co)O surface containing about 80% cobalt, without any Co_3O_4 pre-

Fig. 6d. Ni-80.0% Co oxidized for 12 hr at 1200°C and water quenched.

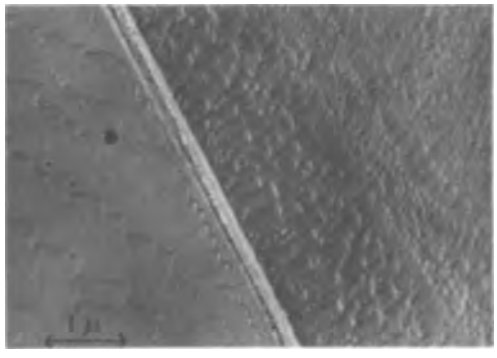

Fig. 6e. Ni-80.0% Co oxidized for 12 hr at 1200°C and furnace cooled.

cipitation. The pit density over the surface is $10^7/cm^2$ and their size is in the range 0.2-1.5μ.

The ranges of size, shape and number of pits on the surfaces of the specimens illustrated in Fig. 6c and 6d are in general agreement with comparable features observed with metals and ceramics (21-23).

Figure 6e is of interest because it shows a scale grain boundary at high magnification on furnace-cooled Ni-80.0% Co oxidized for 12 hr at 1200°C. The surface will be nearly all Co_3O_4, and the different step shapes are visible on either side of the boundary.

Figure 7 shows aligned growth features in some grains on a specimen surface, which will be almost

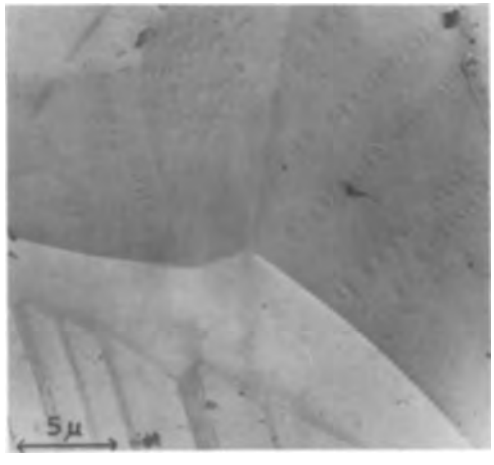

Fig. 7. Electron micrograph of terraces and lined up shallow etch pits on cobalt oxidized for 12 hr at 1200°C and furnace cooled.

entirely Co_3O_4. These are rows of what are apparently shallow etch pits, all in the same direction within a given grain, but in different directions from grain to grain. It may be proposed that these etch pits are associated with rows of emergent dislocations. The etch pits are generally 0.1-1μ apart, being closer near boundaries where they stop. These features are remarkably similar to dislocation pile-ups observed by transmission in thin foils of stainless steel (22) and also in lithium fluoride (23). The separations in stainless steel were typically 0.04μ and in lithium fluoride 2-10μ. Variations in stacking fault energy make direct comparisons impossible. The origin of the pile-ups, if such they are, is not known, but it should be pointed out that the outer Co_3O_4 layer was produced on cooling slowly and some plastic deformation must have occurred during this process. This explanation is favored by the shallowness of the pits, which would have been produced in a relatively short time at a lower temperature than others described earlier. Large widely separated steps are apparent on other parts of the micrograph.

Nature of Co_3O_4 precipitation in scales.—When the surface of Ni-80.0% Co oxidized for 5 min at 1000°C and cooled at 300°C/min was examined by electron microscopy the grains and subgrains were clearly revealed (Fig. 8a). Certain grains show a fine veined structure revealing subgrains, but the most important feature is the directional precipitation of small Co_3O_4 particles during cooling, there being two main directions of alignment. The Co_3O_4 particles are typically 1000-5000Å wide and up to a micron in length, but this depends on the grain orientation. They are rodlike in shape and there are about 10^7-10^8/cm^2, suggesting they are at dislocation sites. It is, however, conceivable that the precipitation is of a Widmanstatten-type, but this is difficult to judge purely from surface considerations. One reason for this fine separated precipitation is that the cooling rate was almost twice as fast as with previous specimens showing agglomerated precipitate.

Unfortunately this very fine precipitation, which could well be used for dislocation decoration studies, is difficult to reproduce because it is a critical function of composition, temperature, cooling rate and oxygen pressure. For example Fig. 8b, which was prepared at a slightly slower cooling rate, shows (at higher magnification) acicular Co_3O_4 particles, but these are somewhat larger and appear randomly distributed within the scale.

Conclusions and Discussion

1. For nickel, cobalt, and Ni-Co alloys, oxidized at 1000° or 1200°C, large columnar grains are separated from the metal core by a thin layer of fine equiaxed grains. Differential polishing characteristics of the regions of different grain size probably at least partly explain reports of double-layer scales in earlier work.

2. Subgrain boundaries may be revealed on the surface of nickel-rich scales by the growth form or thermal etching and of cobalt-rich oxides by Co_3O_4 precipitation. In section it is often advisable to accentuate this by chemical etching.

3. Growth facets and steps and thermal etch pits produced by surface processes are evident on scale surfaces. Certain of the etch pits are probably associated with emergent dislocations. Sometimes shallow etch pits, lined up in a direction related to the orientation of the oxide grain, may reveal rows of piled up emergent dislocations.

4. Co_3O_4 can be precipitated randomly, or along subgrain boundaries or as very fine particles along preferred directions in (Ni,Co)O grains. This technique is promising as a method of obtaining dislocation decoration in thermally formed oxides.

The immediate problem is clearly to obtain a more fully documented picture of the influence of alloy composition, temperature, oxygen pressure, cooling rate, and degree of cold work of the metal on the features observed. It should be possible to study substructure in the oxides of similar metals such as iron (9, 26) and copper (9) and subsequently in oxides of chromium, niobium, and aluminum. The feasibility of following dislocation distribution through scales, possibly by thinning, should be attempted using thermal and chemical etching and decoration techniques. Methods of examining thin films, thinned regions of thick scales, and partly oxidized foils by transmission are also clearly desirable, particularly in view of the greater wealth of comparable micrographs of this type in the allied fields of metals and ceramics. It must be recognized that the structure of oxides, and consequently their properties (4, 5), may be quite different when forming by passage of a large ionic flux in one direction from when formed by compaction of powders or other means. It is also generally held that behavior in a barrier layer of oxide next to the metal determines the stress developed, adhesion properties, etc., to a large degree. Nevertheless, the properties of bulk scales will undoubtedly have some influence on behavior because they have to attempt to maintain continuity with the metallic core during growth and subsequent cooling. Various aspects of this work are now in hand. The long-term hope is that the substructure of scales may eventually be used to explain their mechanical properties, about which much more information is likely to emerge in the next decade. When these two aspects have been fully explored, an "integrated theory" of many metal and alloy scaling processes will be much nearer completion.

On the Passivity of Iron-Chromium Alloys

I. Reversible Primary Passivation and Secondary Film Formation

Robert P. Frankenthal

Edgard C. Bain Laboratory For Fundamental Research,
United States Steel Corporation Research Center, Monroeville, Pennsylvania

ABSTRACT

Electrochemical studies, as well as microscope observations, on an Fe-24% Cr alloy in H_2SO_4 have shown that at least two distinct, potential-dependent films are formed. The primary film, which is responsible for the initial passivation, is stable only within a few millivolts of the primary activation potential. A secondary film, which forms at more positive potentials, grows to a thickness greater than 10Å and, with increasing potential and time, becomes very stable and resistant to reduction. The primary passivation process is reversible. The "thickness" of the primary film at the primary activation potential corresponds to less than the equivalent of one oxygen atom per surface metal atom. From this "thickness" and from the *p*H-dependence of the primary activation potential (81 mv/pH), it is suggested that the primary passivation process forms a film containing chromium and oxygen ions and possibly also some constituent of the electrolyte solution.

The passivation of iron-chromium alloys has been studied widely, yet our understanding of the mechanism of this process is still very limited. Two basic problems have not been resolved: (*i*) the composition and thickness of the passivating film and (*ii*) the effect of the *p*H of the electrolyte solution on the activation potential, *i.e.*, the potential corresponding to the initial rise in the anodic current upon going from the passive region into that of anodic dissolution.

Olivier (1) reported that 0.008 coulombs/cm^2 were required to passivate an 18% Cr alloy; combining this with results from B. E. T. measurements, he concluded that the thickness of the passivating film was about 20Å. The data of Heumann and Schürmann (2) indicate that 0.2 coulombs/cm^2 are required to passivate this alloy. King and Uhlig (3) interpret their anodic polarization data to indicate that the passivating film is an adsorbed film of oxygen, as does Kolotyrkin (4) from his capacitance data. However, Aronowitz and Hackerman (5) believe that the passivating film consists of an adsorbed monolayer of oxygen through which cations migrate to form an amorphous oxide on top of the adsorbed layer.

Rocha and Lennartz (6), using a potentiodynamic method (120 mv/hr), obtained a dependence of the activation potential on pH of 120 mv/*p*H for alloys with Cr content > 14%, as well as for Cr;[1] King and Uhlig (3) indicated that this dependence is a function of the rate of potential sweep and adjusted their sweep rate so that they obtained an activation potential shift of 59 mv/*p*H. Aronowitz and Hackerman (5) claim that it is not possible to remove the passivating film on alloys with Cr content > 12% without severe cathodic treatment or repolishing the surface. While the data in the above references are significant and instructive, much of the interpretation is speculative and based on incomplete knowledge and understanding of the systems.

In this paper we have combined light and electron microscope observations with electrochemical mea-

[1] Vetter (7) tries to show that the data of Rocha and Lennartz for chromium can be forced to give a slope of 58 mv/*p*H.

surements in the hope of obtaining a better understanding of this complex system. We will show that the film that is stable in the neighborhood of the activation potential, and which shall be called the primary passivating film, is different from the film that exists at more positive potentials and is called the secondary film. The primary film may be formed and reduced reversibly, that is, no hysteresis is observed in the potential-current relationship; while the secondary film is difficult to reduce. A primary activation potential is associated with the primary passivation process and its dependence on *p*H is quite different from that of the apparent activation potential (associated with the secondary film), which has been measured by other investigators.

Experimental

The alloy investigated was a high-purity, vacuum melted Fe-24% Cr alloy which had the following analysis: Cr-23.8%; C-0.0075%; N-0.0068%; O-0.050%; P-<0.005%; S-0.004%; Si-<0.01%; Al-<0.005%; Cu-<0.01%; Mg-<0.001%; no other elements were detected. The electrodes were machined as previously described (8) except that flats were ground on the cylinder so that microscope examinations could be made easily. After machining the electrodes were annealed for 150 hr at 760°C and quenched in water. The surface layer was removed by mechanical polishing on "microcloth" using 1μ alumina particles. The cell, electrolyte preparation, potentiostat, potential-drive apparatus and auxiliary equipment have been described previously (8). Potentials are reported relative to the standard hydrogen electrode (SHE). The electrolyte was 1*N* H_2SO_4, except in the experiments in which the effect of *p*H was studied. In these experiments the ionic strength was kept constant by the addition of K_2SO_4. All experiments were conducted at 24°C.

Just before insertion into the cell, the samples were electropolished by the method of Sewell *et al.* (9). On insertion into the cell, the specimen surface was cathodically reduced at —0.5v for several minutes, and then the potential was rapidly switched to the initial potential for that experiment.

Coulometric reduction of the passivating film was done by using a standard amperostatic circuit consisting of a battery and a variable resistance. The potential of the electrodes was followed with a Beckman Research *p*H-meter and recorded on a Honeywell Electronik 19 recorder. To observe the nature and the extent of the anodic attack on the surface, light microscopy and electron microscopy using germanium-shadowed carbon replicas were employed.

Results

Potential-current relationships.—The potential-current relationships are a function of the direction in which the potential is changed, the rate of potential change, the potential at which the surface is passivated in the case of the potential being varied from the passive into the active region, and the mode of surface preparation. These effects are shown partly in Fig. 1 and in Table I, and they are summarized in this section.

Figure 1 depicts the potential-current relationships for the alloy in 1*N* H_2SO_4 as measured under three different sets of experimental conditions to be described below. The cathodic loop (indicated by the breaks in the curves) is due to the evolution of hydrogen. The activation potential, E_a, corresponding to the initial rise in the anodic current upon going from the passive region into the anodic loop, is the minimum in the cathodic loop of either curve. In the system under discussion, the activation potential can easily be determined to within ±1 mv and reproducibility is better than ±2 mv for any given set of experimental conditions.

In Fig. 1 curve "a", the data indicated by the squares give the potential-current relationship for a potential sweep from negative to positive potentials. This curve may be measured either by the potentiostatic steady-state technique or by the potentiodynamic method at 100 mv/hr. If one reverses the direction of potential sweep, *i.e.*, goes from the passive region to more negative potentials, the potential-current relationship shows a hysteresis (Fig. 1, curve b) the extent of which is dependent on the rate of potential sweep and the passivating potential. Curve b was obtained by passivating at +0.5v and sweeping the potential at 100 mv/hr.

Reversibility can, however, be achieved, that is the hysteresis can be completely eliminated (Fig. 1, curve a, circles) if the surface has been carefully reduced and etched so as to remove all traces of films prior to passivation and if the passivation potential is not permitted to exceed the activation potential by more than a few millivolts (<5 mv). The following treatment is necessary to achieve this reversibility. The surface is cathodically reduced at —0.5v; the potential is then shifted to the value corresponding to the peak anodic current density and held for a sufficient time to permit between 100 and 200 atomic layers to be anodically dissolved. With the potential still maintained at this value, the electrolyte is flushed from the cell and clean electrolyte is introduced. The potential is then rapidly shifted into the passive range, within 5 mv of the activation potential. By this procedure it was possible to achieve complete reversibility of the potential-current curve,[2] independent of the length of time of passivation. The activation potential determined in this manner was reproducible to better than ±2 mv. It will be referred to as the primary activation potential to dif-

Table I. Variations in the apparent activation potential, E_a, with rate of potential sweep and passivating potential, E_p

* Steady-state determination. The potential was maintained at any value until the current was constant for at least 10 min. As the activation potential was approached, the potential was varied in steps of 2 mv.
** Primary activation potential.
*** Not measurable due to the fact that at these high potential sweep rates E_a is so negative that it is masked by the high cathodic hydrogen evolution current.

[2] This cannot be associated with enrichment of one of the alloy components in the surface layer during anodic dissolution since curve b can be measured in the manner indicated in the text after anodic dissolution.

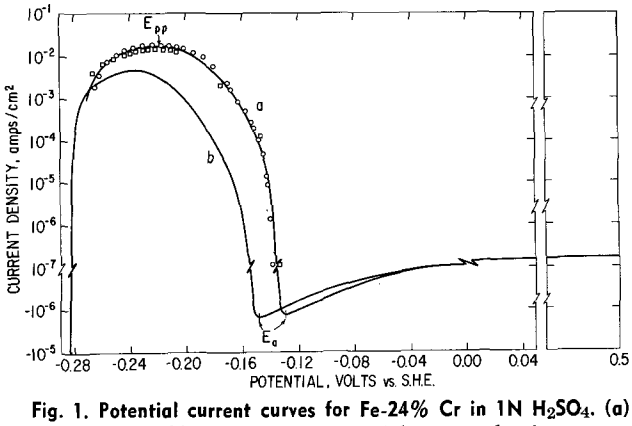

Fig. 1. Potential current curves for Fe-24% Cr in 1N H_2SO_4. (a) Illustrates reversible behavior in potential range of primary passivating film. □-(—) to (+) potential sweep; o-(+) to (—) potential sweep; (b) illustrates hysteresis due to presence of secondary film.

ferentiate it from the apparent activation potential, such as observed in curve b, Fig. 1.

The apparent activation potential for sweeps from positive to negative potentials is a function of the passivation potential and the rate of the potential sweep. Some typical results in 1*N* H_2SO_4 are summarized in Table I.

Mode of breakdown of passivating film.—Pickering and Frankenthal (8) showed that during a potential sweep at 100 or 200 mv/hr from +0.5v into the anodic loop, local breakdown of the passivating film occurs followed by crystallographic pitting of the substrate; physical or chemical inhomogeneities in the passivating film not associated with dislocation termini or grain boundaries in the alloy appear to be the most probable sites for film breakdown.

It has now been observed that local breakdown of the passivating film followed by pitting of the substrate occurs (Fig. 2) if the surface is passivated at potentials as near as 10 mv to the primary activation potential prior to a slow potential sweep, *e.g.*, 100 mv/hr, into the anodic loop. If the specimen is passivated within 5 mv of the primary activation potential and then the potential is swept into the anodic loop, pitting is never observed, but only a general attack over the surface (Fig. 3), indicating that the passivating film has been reduced uniformly. If the surface is passivated at 5 to 10 mv positive with respect to the activation potential prior to the potential sweep, a uniform attack is observed over most of the surface. However, a few grains (perhaps 10%) show pitting instead of general attack. In this case the observed pits were always triangular indicating an effect of crystallographic orientation on the structure of the passivating film. When the potential of a specimen after passivation at +0.5v is swept to within less than 5 mv of the primary activation potential, maintained there until a steady state is achieved (several hours) and then swept into the anodic loop, only a general attack over the surface, and not pitting, is observed.

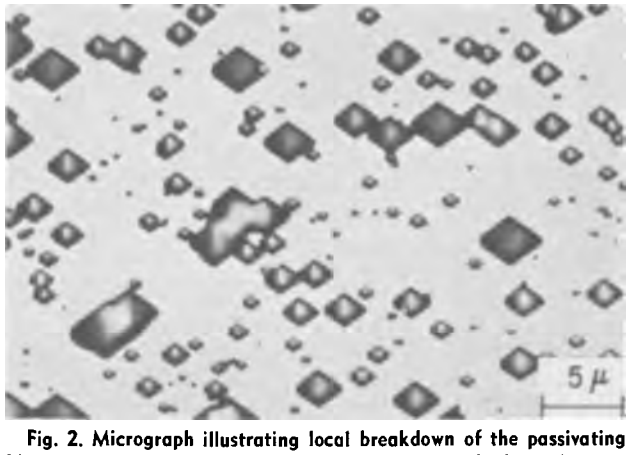

Fig. 2. Micrograph illustrating local breakdown of the passivating film as evidenced by crystallographic pitting of the substrate. Surface passivated at +0.5v prior to potential sweep.

Fig. 3. Carbon replica of surface illustrating general reduction of passivating film as evidenced by general corrosion of the surface. Surface passivated at —0.12v prior to potential sweep.

Cathodic chronopotentiometry.—To learn more about the properties of the passivating film, cathodic potential-time curves were measured at constant current. Such curves for a surface passivated at potentials near the primary activation potential are shown in Fig. 4. The potential associated with each curve is the potential of passivation. The primary activation potential is —0.130v, and the curve for the reduction of the passivating film formed at this potential is shown. At —0.140v the potential corresponds to the lower part of anodic loop, the observed current density being 5 μa/cm^2. At —0.100 the potential is well into the passive region. The observed "thickness" (expressed in millicoulombs/cm^2) of the passivating film at the primary activation potential lies between 0.40 and 0.68 mc/cm^2 and is independent of the length of time of passivation. A value of 0.7 mc/cm^2 corresponds to an oxygen to surface-metal-atom ratio of 1:1, assuming a two-electron transfer per oxygen atom and an average density of surface metal atoms of 2 x 10^{15}/cm^2, as calculated from the density of the alloy. The observed variations in "thickness" are most likely due to variations in the surface roughness factor for the different specimens used. Since the geometric area was used to calculate the coulombic density, all the values are high. Two other errors may affect the coulometric measurements: (*i*) only a partial correction[3] was made for the current due to hydrogen evolution at the film-reduction potential, again resulting in measured thicknesses that are too high; (*ii*) low thicknesses would be measured if self-activation, due to side reactions, occurred concurrently with the cathodic reduction. If self-activation were operative, the measured thickness would increase with increasing current density (decreasing time for reduction). From Fig. 5 it is concluded that appreciable self-activation that would significantly change the measured thickness does not occur at the primary activation potential. However, at more negative passivation potentials, self-activation does occur during cathodic reduction as evidenced by the apparent increase in thickness with increasing cathodic current density for a specimen passivated at —0.140v (Table II). On opening the circuit after passivation at this potential, self-activation occurred within 72 sec; at the primary activation potential and at more positive potentials self-activation does not occur on opening the circuit.

The potential-time curves for a specimen passivated

[3] The correction made was equal to the net cathodic current density measured at the reversible activation potential. Since the reduction potential is more negative, the cathodic current density would be somewhat higher, but not easily ascertainable.

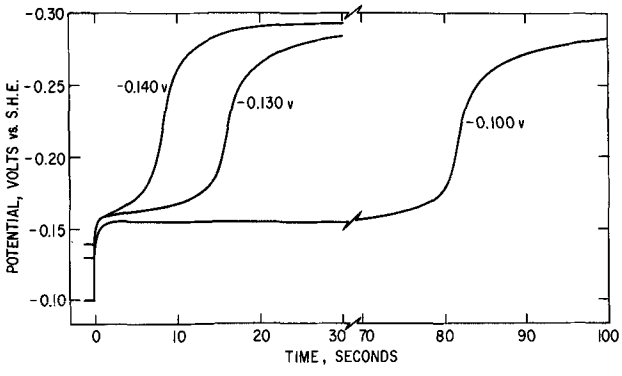

Fig. 4. Cathodic reduction after passivation at different potentials near the reversible activation potential. Current density is 25 μa/cm^2. Passivation potential indicated next to each curve.

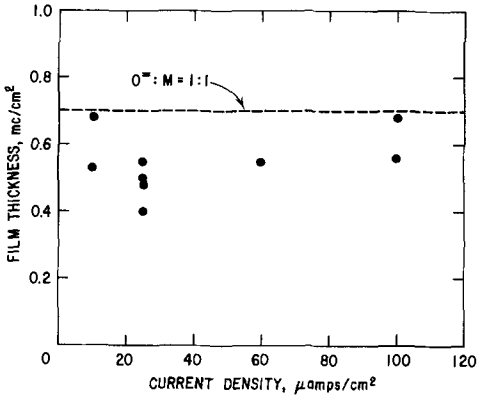

Fig. 5. Effect of cathodic current density on the coulombic thickness of the primary passivating film at the reversible activation potential.

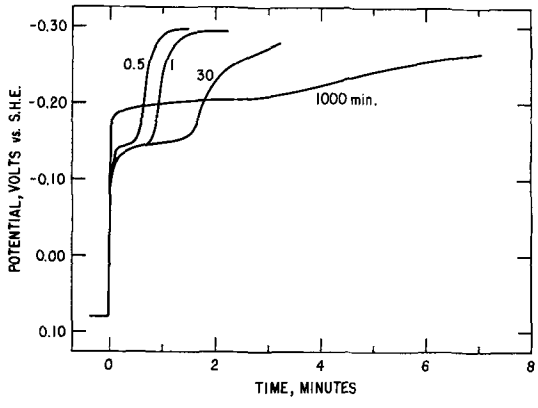

Fig. 6. Cathodic reduction after passivation at +0.08v for different length of time. Current density is 25 μa/cm². The time of passivation, in minutes, is given next to each curve.

for different times at +0.08v prior to reduction of the passivating film are shown in Fig. 6. After passivating the surface for 0.5 min the current density was still greater than it is after complete passivation; after 1 min the surface was completely passive. The reduction potential for a surface passivated up to 30 min is —0.14v. At 30 min the potential break is not as sharp as at the shorter times, while at 1000 min the potential break is almost completely washed out and the reduction potential has been shifted to about —0.20v. In Fig. 7 the potential-time relationship is given for a surface passivated at +0.48v for 2 min. The potentials of both the peak and the plateau following it are considerably more negative than those observed after passivation at +0.08v (Fig. 6). The peak has previously been observed by Caplan, Harvey, and Cohen (10); the potential of it as observed by Caplan *et al.* is the same as that shown here if a correction is made for the difference in pH of the solutions used.

Effect of solution pH.—The effect of the electrolyte solution pH in the range of 0-2 on the primary activation potential, E_a, is shown in Fig. 8, along with the effect of the pH on the primary passivation potential, E_{pp}, *i.e.*, the potential corresponding to the peak anodic current density (see Fig. 1). The relationships may be described by

$$E_a = -0.107 - 0.081\ pH$$

Table II. Apparent variations in film thickness with cathodic current density; surface passivated at —0.140v

and

$$E_{pp} = -0.204 - 0.060\ pH$$

If the experiments are performed so as to measure the apparent activation potential instead of the primary one, a variety of E_a — pH relationships can be obtained depending on the passivation potential and the rate of potential sweep. For example, if the surface is passivated at +0.5v and a sweep rate of 100 mv/hr is employed, the observed relationship is

$$E_a = -0.113 - 0.100\ pH$$

over the same pH range and with the same degree of scatter as shown in Fig. 8. This is in reasonable agreement with the work of Rocha and Lennartz (6), who used a sweep rate of 120 mv/hr.

Discussion

The results show that the passivating film in the immediate potential neighborhood (within 5 mv) of the primary activation potential has quite different properties from the film that is stable at more positive potentials. The former will be referred to as the primary passivating film and the latter as the secondary film.

Primary passivating film.—It has been demonstrated that starting with a cathodically reduced and anodically etched surface, the primary passivation process is reversible, *i.e.*, no hysteresis is observed. This has not heretofore been established for either ferritic or austenitic chromium steels (Cr content >12%). On the contrary, the general belief has been that the

passivation of these alloys is an irreversible process (5, 6, 11, 12) in the sense that the anodic polarization curves show a hysteresis, such as illustrated in Fig. 1. The present work, however, clearly shows that the primary passivating process is reversible and that irreversibility results from secondary effects at potentials exceeding the primary activation potential by more than 5 to 10 mv. The proper surface pretreatment is essential to achieve reversibility. For example, cathodic reduction for several minutes at —0.5v, at which potential the current density is approximately 30 ma/cm^2, was found not to be sufficient. The anodic dissolution that is necessary apparently undercuts any remaining film on the surface.

The potential-current behavior also correlates with the microscope observations (Fig. 2 and 3). The primary passivating film is reduced uniformly over the surface, as would be expected for a film that is formed and reduced reversibly. However, as the passivation potential is made more positive and the degree of irreversibility increases, the reduction of the film becomes both localized and more difficult (Fig. 2 and Table I).

The thickness of the primary passivating film, as measured coulometrically, shows that the passivating process introduces less than the equivalent of one $O^=$ per surface metal atom into the passivating film (Fig. 5). Self-activation, the only error that could make the observed values low, was shown not to be significant. On the other hand, a correction for the two approximations made, roughness factor equal to 1, and the approximate correction for hydrogen evolution, would make the true thickness less than the measured thickness. After anodic dissolution during surface preparation, the surface is etched; a reasonable value for the roughness factor would be between 1.2 and 2. A further semiquantitative correction can be made for the hydrogen-evolution current. Assuming Tafel behavior and a slope of 60 mv/current decade, the current can be extrapolated from the primary activation potential to the film reduction potential; applying this correction reduces the calculated thickness by roughly 20%. Taking both the above corrections into consideration, a more correct ratio of $O^=$/metal atom appears to be between 0.2 and 0.5.

The slope of the plot of *p*H *vs.* the primary activation potential does not agree with any of the previously published results (3, 6, 7). This is not surprising since these workers measured the apparent activation potential instead of the primary activation potential. Under those conditions the slope is a function of the kinetics of the reduction of the secondary film and is not related to the primary passivation process.

For understanding the mechanism of passivity, it is the reaction that produces the primary passivating film at the primary activation potential that is important, because with the formation of the secondary film no further decrease in the anodic reaction rate is observed (Fig. 1). Since the primary passivating film has not previously been detected, it is not possible to apply published[4] theories of passivity directly to its formation. These [*e.g.*, see ref. (5), (13), and (14)] might better apply to the formation of the combined primary and secondary passivating films as they exist at potentials more positive than the primary activation potential. We propose two hypotheses not mutually exclusive that can explain the observed data for the primary passivating film.

The first hypothesis envisions a film of chromium and oxygen ions covering the surface. Using the upper limit of 0.5 for the ratio of oxygen ions to surface metal atoms at the primary activation potential, the concentration of oxygen in the film is 1 x 10^{15} atoms/cm^2. With an ionic radius of 1.40Å and a simple square lattice, this quantity of oxygen would cover 78% of the surface. Assuming the other 22% to be covered by chromium ions with an ionic radius of 0.7Å, the ratio of chromium to oxygen in the film would be approximately one, which is a very reasonable value.

On the other hand, if the ratio of oxygen ions to surface metal atoms is close to the lower limit of 0.2, one may suggest either a lower valence state for the chromium ion or the introduction of some constituent(s) of the electrolyte solution into the film to account for complete coverage. The latter is, perhaps, more reasonable since the variation of passive behavior of metals and alloys from electrolyte to electrolyte is well known.

The variation of the primary passivation potential, E_{pp}, with *p*H (60 mv/*p*H) is consistent with the variation of an equilibrium potential for a simple metal-oxygen interaction. The variation of the primary activation potential, E_a, with *p*H (81 mv/*p*H) is not as easily understood. It may be determined by kinetic factors, in which case its meaning is obscure. However, it may also be determined by the quasi-equilibrium reaction that established the passivating film at this potential, in which case it is diagnostic for the mechanism of passivation. That the primary activation potential may be an equilibrium potential stems from the following experimental facts: (*i*) this potential can be approached from either direction; (*ii*) the primary passivating film at this potential is stable with respect to time; (*iii*) the rate of dissolution and reformation of the film at steady state is exceedingly small, less than 10^{-7} amp/cm^2 (the current density in the passive potential region); hence it is quite possible that the exchange current density for the equilibrium reaction is larger than this kinetic rate. Thus, the potential may be an equilibrium potential for the reaction that forms a film of fixed composition from the metal and solution constituents. The dependence of 81 mv/*p*H may then be explained by assuming that the activity of the solution constituent in the film is *p*H-dependent. For example, if $SO_4^=$ were the constituent its activity would be governed by the equilibrium $HSO_4^- \rightleftarrows H^+ + SO_4^=$. At other potentials between E_{pp} and E_a, one may then expect the film to have a different composition, *i.e.*, activity of oxygen, a specific composition being associated with each potential.

The irreversible formation of the secondary film is evidenced by its localized reduction (Fig. 2). From the hysteresis (Fig. 1, curve b) and from the data in Table I it is evident that the reduction of the secondary film is also very slow with respect to the rates of potential change employed. This is shown by the shift of the apparent activation potential in the negative direction with increasing rate of potential change and by the lower anodic current densities in curve b, indicative of some residual film on the surface at these potentials. The shift of the apparent activation potential in the negative direction with increasing positive passivating potential may be due to either a thickening of the passivating film with increasing potential or to an aging effect which changes some of the properties of the film. It will be argued later that both occur.

In the case of the localized breakdown of the secondary film, the apparent activation potential corresponds to the initial breakdown of the local sites. Much, but not all, of the secondary film can be reduced given sufficient time, as demonstrated by the experiment in which the surface was allowed to reach a steady state at a potential close to the primary activation potential after having been passivated at +0.5v; the potential sweep that followed then resulted in a general attack on the surface. It was also possible to passivate a surface at +0.5v and then do a slow potential sweep into the anodic loop; upon allowing the current to remain at any potential in the anodic loop, it would eventually drift close to the appropriate value on the reversible potential-current curve (a, Fig. 1). However, complete reversibility of the curve could not be achieved under these conditions, indicating that traces of the secondary film still remained on the sur-

[4] Uhlig (15) has recently proposed that the passivating film is initially similar to the reconstructed nickel-oxygen layer proposed by investigators in the low-energy electron diffraction field.

face. This was most evident at potentials near the activation potential, at which the currents were sufficiently low so that small deviations could easily be observed.

That the growth and formation of the secondary film is a slow process can best be seen from the cathodic reduction curves in Fig. 6. Although the surface was completely passivated after 1 min, the coulombic thickness after 30 min is approximately twice that after 1 min. The film reduction potentials for 0.5, 1, and 30 min correspond closely to those for the reduction of the primary passivating film. However, after 30 min one sees the first signs of irreversibility as the potential break is no longer so sharp; after 1000 min the potential break is completely washed out and the reduction potential has been shifted 60 mv negative. Both observations show that the film has become very difficult to reduce. From this it appears that the secondary film forms by a thickening of the primary film followed by growth of a film of a different nature. It is suggested that the thickening may be due to the completion of coverage of the surface with a monolayer of oxygen. Further adsorption of oxygen is then accompanied by the diffusion of metal ions into the adsorbed array, thereby forming an amorphous oxide or hydroxide layer, which constitutes the secondary film. This process would be both time and potential dependent as has been found for the formation of this film.

The secondary film forms much faster at +0.48v than at +0.08v and is even more difficult to reduce (Fig. 7). It is thus impossible to determine the thickness of the film formed at +0.48v.

Summary and Conclusions

1. The primary passivation process is reversible and a primary activation potential is associated with it.
2. The primary passivating film, containing less than one $O^=$ per surface metal atom, exists only in the immediate potential neighborhood of the primary activation potential.
3. At more positive potentials a secondary film, which does not further decrease the anodic current density, is formed by a process that involves both a thickening of the primary passivating film and then an aging process.
4. It is suggested that the primary passivation process forms a film containing chromium and oxygen ions and possibly also some constituent of the electrolyte solution.

Acknowledgment

The author wishes to thank Dr. S. Barnartt, S. S. Brenner, R. A. Oriani, and H. W. Pickering for many helpful discussions. Thanks are also due to Mrs. G. L. Cleaveland for help with much of the experimental work and to R. C. Glenn for the electron microscopy.

Manuscript received Jan. 10, 1967; revised manuscript received March 13, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Platinum Oxidation Kinetics with Convective Diffusion and Surface Reaction

R. W. Bartlett

Stanford Research Institute, Menlo Park, California

ABSTRACT

The rate of oxidation of platinum is affected by the reversible surface reaction, $O_2 + Pt \leftrightarrows PtO_2(g)$, and by transport of the oxide vapor through a gaseous boundary layer. Both are considered in an analysis of the oxidation kinetics. Mass transfer coefficients for diffusion of the oxide vapor are calculated from the Nusselt numbers applicable to specific sample geometries and flow conditions. The equilibrium constant for oxidation of platinum is used to calculate the forward and backward specific rate constants for steady-state oxidation at the surface. A combined rate equation, including both convective diffusion and surface oxidation, is derived and used to calculate oxidation rate curves at a variety of pressures and temperatures. Good agreement with experimental data is obtained. Rate predictions in high velocity flow where experimental data have not been taken are presented.

At temperatures above approximately 800°C, platinum oxidizes slowly to produce a volatile species, $PtO_2(g)$, that is comparatively unstable (1). The PtO_2 molecule may diffuse away from the oxidizing platinum surface and subsequently dissociate or, because of collisions with surrounding gas molecules, return to the platinum surface for dissociation on impact. During oxidation at fixed temperature, pressure, and other parameters affecting the oxidation process, a steady-state condition will result at the platinum surface in-

volving the forward and backward rates of the reversible oxidation reaction

$$O_2(g) + Pt \underset{k_b}{\overset{k_f}{\rightleftarrows}} PtO_2(g) \qquad [1]$$

to yield a net oxidation of platinum and migration of $PtO_2(g)$ away from the surface.

Several experimental factors can influence the gaseous diffusion and alter the apparent oxidation rate. This situation was first recognized by Fryburg and Murphy (2), who pointed out that the use of furnaces for measuring the rates of oxidation of platinum has lead to widely varying results that are highly dependent on the gas flow rate. With the exception of the work by Fryburg and co-workers (3, 4) previous experimental rate studies of the oxidation of platinum (5-8) have failed to consider the role of diffusion of $PtO_2(g)$ from the platinum surface. This omission is understandable in view of the commonly held misconception that gaseous diffusion is kinetically important only when oxidation rates are very fast. As late as 1963, arguments for Langmuir-type adsorption of molecular oxygen followed by dissociation were presented (8) to explain the failure of the platinum oxidation rate to increase in direct proportion with the oxygen pressure except at very low pressures.

The purpose of this paper is to present a kinetic treatment of the oxidation of platinum, considering simultaneously (*i*) convective diffusion of $PtO_2(g)$ through the gaseous boundary layer adjacent to the sample and (*ii*) the surface oxidation reaction.

Oxidation rates are calculated independently of experimental data, using boundary layer theory and the equilibrium constant (1) for oxidation of platinum to $PtO_2(g)$ (Eq. [1]). Rates are calculated for free convection, *e.g.*, convective mixing caused by gravity forces only, and for a few cases of Newtonian forced flow convection. The approach is similar to a previous study of the oxidation of tungsten (9), which occurs by an irreversible reaction and is rate limited by the convective diffusion of oxygen to the surface.

The calculated rates are compared with Fryburg's experimental data (3, 4). Fryburg employed small (0.0287 cm wide) electrically heated platinum ribbons mounted in a cold wall chamber. At pressures above 100 mm Hg, the ribbon was extended horizontally rather than used as a vertical hairpin element. Chamber size is an important consideration since a quantitative analysis of free convective diffusion of $PtO_2(g)$ in the gaseous boundary layer adjacent to the sample depends on an absence of convective hindrance by the container. Fryburg's chamber diameter was 3.2 cm. Since the boundary layer thickness is related to the characteristic dimension of the sample, in this case the ribbon width, no difficulties from the container wall are encountered for a free convection analysis.

Theory.—The oxidation rate could be calculated from either a surface reaction rate equation or a convective diffusion equation separately if the steady-state value of the platinum oxide vapor pressure at the surface, $p_{PtO_{2(s)}}$, were known. The value of $p_{PtO_{2(s)}}$ cannot be measured conveniently since any measuring probe would disturb the boundary layer. However, $p_{PtO_{2(s)}}$ is the parameter connecting the gaseous diffusion step and the surface reaction step of the oxidation process. Because the gaseous diffusion rate, $\dot{X}_D$, and the surface reaction rate, $\dot{X}_S$, must be equal (there are no other material sources and sinks)

$$\dot{X}_D = \dot{X}_S \qquad [2]$$

p_{PtO_2} is uniquely determined for any set of conditions, temperature, pressure, sample configuration, and flow.

The boundary-layer diffusion rate is described in terms of the escape of $PtO_2(g)$ from the surface through an oxygen or air envelope by the following equation

$$\dot{X}_D = \left(\frac{M_o}{\rho}\right)_{Pt} k_m \frac{(p_{PtO_{2_s}} - p_{PtO_{2_\infty}})}{p_t} \qquad [3]$$

where $\dot{X}_D$ is a metal recession rate (cm/sec), (M_o/ρ) is the ratio of equivalent weight to density for platinum required to convert a molar oxidation rate to a surface recession rate, k_m is the mass transfer coefficient which is calculated using boundary layer theory, $p_{PtO_{2_\infty}}$ is the platinum oxide vapor pressure beyond the boundary layer ($p_{PtO_{2_\infty}} \doteq 0$), and p_t is the total pressure or the stagnation pressure in a flowing system. For oxidation in oxygen $p_t = p_{O_2}$ and for oxidation in air or mixtures of inert gas and oxygen, $p_t > p_{O_2}$.

The platinum surface oxidation rate, $\dot{X}_S$, based on the steady-state condition for the reaction given by Eq. [1], is

$$\dot{X}_S = \left(\frac{M_o}{\rho}\right)_{Pt} (k_f p_{O_2} - k_b p_{PtO_{2_S}}) \qquad [4]$$

Since the oxidation rate is slow and $p_{O_2} >> p_{PtO_{2S}}$, there is no perturbation in the oxygen pressure as the surface is approached. Fryburg and Petrus have shown that the activation energy for oxidation is equal to the free energy of reaction determined by Alcock and Hooper (1), *i.e.*, the low-pressure oxidation of platinum can be calculated from equilibrium data in a manner analogous with Langmuir's method for calculating vapor pressures from rates of evaporation. It is assumed that the unstable PtO_2 molecules are dissociated on striking the platinum surface, which is equivalent with an assumed condensation coefficient of unity. Consequently, the backward rate constant k_b in Eq. [4] is the surface collision frequency of PtO_2 molecules based on gas kinetics

$$k_b = (2\pi MRT)^{-1/2} \qquad [5]$$

where M is the molecular weight of PtO_2. The specific rate constants are related through the equilibrium constant, K_{eq}, for the oxidation reaction of Eq. [1]

$$K_{eq} = k_f/k_b \qquad [6]$$

Inserting Eq. [5] and [6] in Eq. [4] yields

$$\dot{X}_S = \left(\frac{M_o}{\rho}\right)_{Pt} (2\pi MRT)^{-1/2} (K_{eq} p_{O_2} - p_{PtO_{2S}}) \qquad [7]$$

By combining the diffusion and surface rate Eq. [2], [3], and [7], the unknown PtO_2 vapor pressure at the surface can be eliminated

$$\dot{X} = \frac{\left(\frac{M_o}{\rho}\right)_{Pt} (2\pi MRT)^{-1/2} K_{eq} p_{O_2}}{1 + \frac{(2\pi MRT)^{-1/2} p_t}{k_m}} \qquad [8]$$

Equation [8] is valid at all pressures and temperatures where a volatile platinum oxide species is produced. It covers both the convective diffusion controlled rate region (high pressures) and the surface reaction controlled rate region (low pressures). It is valid for static and flowing gases and for mixtures of oxygen and nitrogen or other inert gases, and through the dependence of the mass transfer coefficient, k_m, it includes the effect of sample size.

All of the terms in Eq. [8] are system constants. The most complex of these is the mass transfer coefficient, k_m, which is related to the dimensionless Nusselt number (10) for mass transfer Nu_m

$$k_m = \frac{Nu_m p_t D}{L R T_g} \qquad [9]$$

where D is the gaseous diffusion coefficient, L is the

characteristic sample dimension (ribbon width), R is the gas constant, and T_g is the average gas temperature. The diffusion coefficient varies with gas temperature and pressure and was calculated with the Chapman-Enskog equation

$$D_{(cm2/sec)} = \frac{1.86 \times 10^{-3} \sqrt{\frac{1}{M_{O_2}} + \frac{1}{M_{PtO_2}}} \left(\frac{T_g^{3/2}}{p_t}\right)}{\sigma^2_{O_2} \Omega_D} \quad [10]$$

using the collision cross section $\sigma = 3.433$ and parameter $\Omega = 0.74$ for oxygen (11). The Nusselt number is obtained from published semiempirical correlation curves relating the Nusselt number with the Grashoff number and Schmidt number for free convection and the Reynolds number and Schmidt numbers for forced convection (Newtonian flow). These correlations are used extensively in engineering analyses of fluid processes. In calculating free convection rate data, the correlation curve for vertical surfaces (12), in which μ_g is the gas viscosity and g is the acceleration of gravity, was used, see Fig. 1. The Chapman-Enskog theory was used to calculate the gas viscosity. Oxidation rate calculations in the laminar flow range were made for long cylinders (wires), using the Chilton-Colburn type of correlation by Sherwood and Pigford (13) shown in Fig. 2. Further details on calculating mass transfer coefficients for simple sample geometries are given by Bird, Stewart, and Lightfoot (10).

Results and Discussion

Isothermal rate curves calculated with rate Eq. [8] for oxidation of platinum in pure oxygen and air are shown in Fig. 3, for a ribbon width of 0.0287 cm and

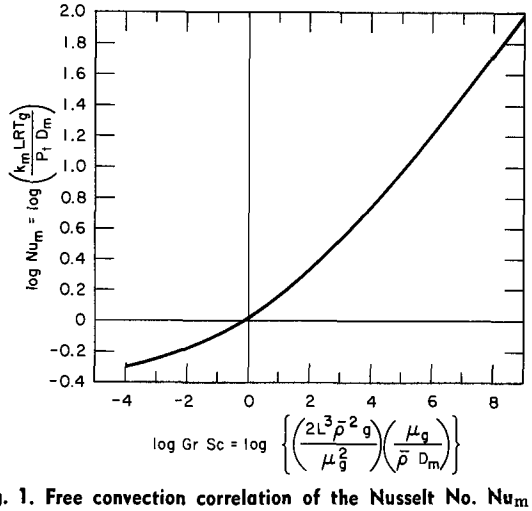

Fig. 1. Free convection correlation of the Nusselt No. Nu_m with Grashoff No. Gr and Schmidt No. Sc for vertical surfaces (12).

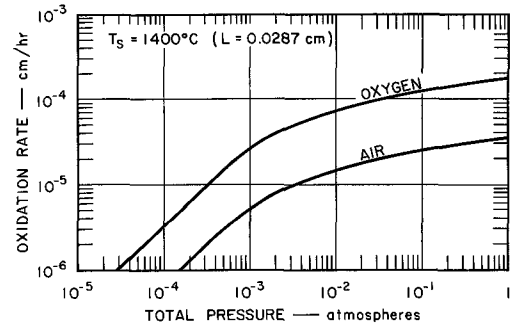

Fig. 3. Calculated static platinum oxidation curves for 0.0287 cm ribbon at 1400°C based on Eq. [8].

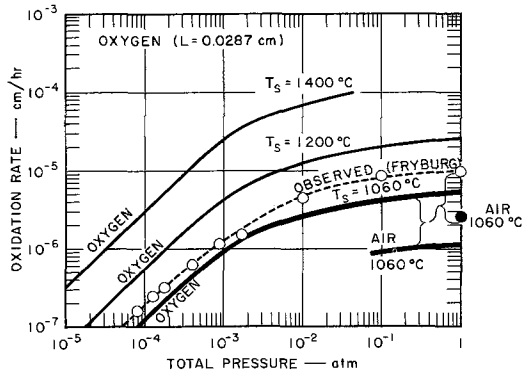

Fig. 4. Comparison of calculated rate curves with experimental oxidation data points for 0.0287 cm platinum ribbons.

temperature of 1400°C. The rate in air is lower because $p_t > p_{O_2}$. Although nitrogen is chemically inert, it impedes the transport of PtO_2 molecules through the boundary layer.

From Fig. 3 and rate equation [8], it can be seen that at low pressures the oxidation rate is directly proportional to the oxygen pressure, the rate is controlled by the surface reaction, and $1 >> (2\pi MRT)^{-1/2} p_t/k_m$. At high pressures, the oxidation rate increases very slowly with pressure, the rate is controlled by PtO_2 diffusion, and $1 < (2\pi MRT)^{-1/2} p_t/k_m$.

Calculated platinum oxidation rate isotherms are also shown as solid curves in Fig. 4. Curves of oxidation in oxygen at 1060°, 1200°, and 1400°C are presented, and a partial curve for oxidation in air at 1060°C is included. The equilibrium constants (1) used in making the rate calculations are listed in Table I. The effect of air ($p_t > p_{O_2}$) is to lower the oxidation rate to about one-fourth of the rate in the same partial pressure of oxygen. These curves are based on a free convection correlation (Fig. 1) with the characteristic dimension, $L = 0.0287$ cm, the ribbon width used by Fryburg (3, 4).

The experimental results obtained in static oxygen by Fryburg and Petrus at 1060°C are shown as open data points in Fig. 4. The solid datum point is their experimental value for oxidation in static air at 1 atm. For both air and oxygen, the theoretical rates calculated independently of the experimental data agree with the experimental data within a factor of two, or less, over the entire oxygen pressure range, and the lowered oxidation rate in air is correctly estimated. Calculated theoretical rates agreed equally well with

Table I. Equilibrium constants for oxidation of platinum[1]

$Pt + O_2 \rightleftarrows PtO_2(g)$

Temp, °C	K_{eq}
1060	5.9×10^{-7}
1200	2.5×10^{-6}
1400	1.3×10^{-5}

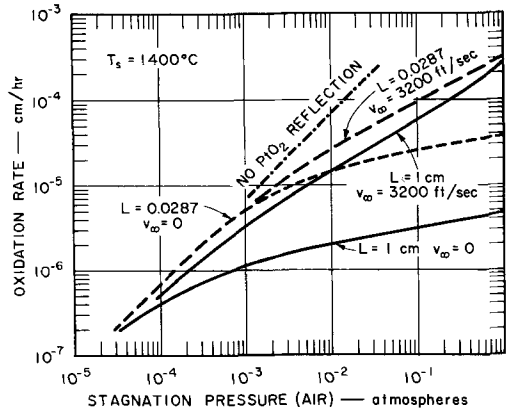

Fig. 6. Effect of forced flow on the oxidation rates of 0.0287 cm diameter platinum wire and 1 cm diameter platinum cylinders.

experimental rates at other temperatures and pressures, but since the experimental data were most extensive at 1060°C the comparison at this temperature is presented.

The effect of sample size on calculated theoretical platinum oxidation rates (free convection) are shown in Fig. 5. Calculated oxidation rates decrease with increasing ribbon width in agreement with experimental results.

Calculation of platinum oxidation rates in a high velocity air stream were made using the correlation of Fig. 2 for long cylinders. Isothermal oxidation rate curves were calculated for a free stream velocity of 3200 ft/sec (equivalent velocity behind the bow wake) for two cylinders, a 0.0287 cm diameter wire and a 1 cm diameter rod. The high flow rate curves are compared with curves for static oxidation of the same samples in Fig. 6. The curves show oxidation rate *vs.* stagnation pressure. In making a direct comparison between static air oxidation rates and forced flow oxidation rates, consideration should be given to the increase in stagnation pressure over ambient pressure in high velocity streams.

At low-pressures, high-gas flow velocities have little effect on the oxidation rate since there are too few gas molecules present to form a diffusion boundary layer. Subsequently, as pressure decreases the oxidation rate asymptotically approaches the steady-state surface oxidation rate that would occur with no reflection and dissociation of PtO_2 molecules in the surface. At high pressures, high flow velocities increase the oxidation rate because of the decreased boundary layer thickness and corresponding increase in the mass transfer coefficient, k_m.

Conclusions

In summary, oxidation rates of platinum can be calculated from the Nusselt number, using accepted dimensionless fluid correlations. The equilibrium constant, K_{eq}, for platinum oxidation is needed to establish the oxide vapor pressure at the metal surface required for a solution of the boundary layer diffusion problem. With this limited amount of information, oxidation rates can be calculated over a large temperature range and pressure range in good agreement with experimentally observed rates. The method also permits a valid calculation of oxidation rates in high gas velocities where experimental determinations of rate data are difficult, and the rate equation accounts for differences in oxidation rates caused by sample size and inert gas dilution (air *vs.* oxygen).

Stress Corrosion Cracking of Titanium Alloys

I. Ti:8-1-1 Alloy in Aqueous Solutions

T. R. Beck

Boeing Scientific Research Laboratories, Seattle, Washington

ABSTRACT

Stress corrosion cracking of titanium: 8% Al-1% Mo-1% V alloy notched tensile specimens was investigated in various salt solutions under potentiostatic conditions. Stress corrosion cracking of duplex annealed Ti:8-1-1 alloy occurred in chloride, bromide, and iodide solutions, but did not occur in other solutions such as fluoride, hydroxide, sulfide, sulfate, nitrate, or perchlorate. The ultimate strength was strongly dependent on potential. The velocity of crack propagation and current flowing into the crack in chloride, bromide, and iodide solutions were linearly related to the applied potential above a potential of —900 mv to the saturated calomel electrode. An electrochemical mechanism controlling the velocity is implied.

The first known report on stress corrosion cracking (SCC) of titanium dates back to Kiefer and Harple, 1953 (1), who described cracking phenomena with commercially pure titanium in red fuming nitric acid. "Hot salt cracking" of titanium alloys was discovered in the mid 1950's in connection with creep in turbine blades. The subject became very active in the early 1960's because of the impact of SCC on the supersonic transport program. This phenomenon becomes significant above 250°C. A considerable amount of sponsored research has been conducted on this topic, some of which has been reported (2).

The first known report of stress corrosion cracking of titanium alloys in room temperature aqueous environments was that of Brown, 1965 (3). He found that precracked specimens of titanium: 8% aluminum-1% molybdenum-1% vanadium alloy (Ti:8-1-1) were susceptible to SCC in sea water. This touched off a new flurry of investigation for suitable less-susceptible alloys. Although much applied work was done and suitable, less-susceptible alloys were found, the mechanism of SCC in titanium alloys was unknown.

A basic research program to study the mechanism of titanium SCC was begun at the Boeing Research Laboratories in 1965. This paper describes results of the initial electrochemical studies with Ti:8-1-1 alloy. A discussion of electrochemical theory will follow in another paper (4).

All potentials recorded in the experiments are given in millivolts in this paper. Unless otherwise stated, the saturated calomel electrode (SCE) is the zero standard of reference.

Experimental

Titanium: 8-1-1 was chosen as the alloy for initiating the program because it had been shown by prior investigators to be one of the commercially available titanium alloys most susceptible to SCC. It was available in two heat-treatments; mill annealed and duplex annealed. The mill annealed treatment consisted of holding the sheet at 788°C for 8 hr, followed by furnace cooling. The duplex annealed treatment consisted of reheating mill annealed sheet to 788°C for 15 min followed by air cooling. The composition and tensile properties of the material used in this investigation are given in Table I.

Tensile tests were performed with notched specimens in a 10,000 kg Instron Model TT universal testing instrument. The specimens were gripped in Instron G-61-10F Type 10F wedge action jaws.

The tensile specimen geometry is shown in Fig. 1. The criteria for selection of the specimen geometry were:

1. The specimens should be such a size and shape that stress corrosion cracking could be produced.
2. The specimens should fit the jaws and capacity of the tensile machine.

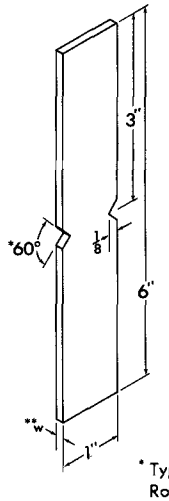
3. The specimens should be inexpensive and easy to produce and use so that hundreds could be used to screen environmental effects.

It was also considered desirable that the specimens should be designed according to fracture mechanics



* Typical Notch Root Radius = 0.001"
**w = 0.05 to 0.06"

Fig. 1. Tensile specimen geometry

concepts, but this was not compatible with the above criteria. It is intended to follow up later with larger size specimens designed according to fracture mechanics concepts.

Specimens were prepared by shearing from sheet stock slightly oversize blanks; the two long edges were machined to finished dimensions. The first specimens were double notched, but later specimens were single notched. Tolerance on the net section width was held to ±0.002 in. The cutter was resharpened between the final passes during cutting of the notches in order to minimize cold working and to obtain a more precise notch root radius. Most specimens had a notch root radius of 0.001 in. Cutting oil was subsequently removed from the specimens by a kerosene followed by an acetone rinse. The later samples were anodized to 70-80v in a 1N sulfuric acid bath to minimize electrolytic reactions on the surface during the tensile tests. Specimens were not precracked. In the tensile tests, a crosshead velocity of 0.005 cm/min was selected as standard for most of the tests. This selection was made after a preliminary screening to determine effect of crosshead speed on specimen strength as described under results. The specimens were usually preloaded in the elastic region to about 1000 kg (2200 lb) at a crosshead velocity of 0.05-0.10 cm/min. This procedure permitted tests to be completed in a period of 10-30 min. Rapid testing was considered necessary in order to evaluate a wide range of environments. Force *vs.* time plots were recorded in each test.

Tests were made in air and in various electrolyte solutions with the specimen potentiostatically held at a preset potential. The Teflon cell configuration used in the potentiostatic tests is illustrated in Fig. 2. A Wenking Model 6379 TR potentiostat was used. Electrical connection to the specimens was made through the wedge action jaws. Current flowing to the specimen was recorded *vs.* time during the test using an x-axis speed of 1/50 in./sec on a Moseley Model 2D x-y plotter.

The first tests were made with 3½% sodium chloride (0.6M solution) corresponding to the total salt content of sea water. Other salt solutions for comparison were also made 0.6M. Concentration effects were studied later.

Results

Load-time curves.—Typical load-time curves for single-notched duplex annealed Ti:8-1-1 specimens are shown in Fig. 3. Failure in 0.6M sodium chloride is compared to that in air. The ultimate force, U_S, at failure in sodium chloride solution at a titanium potential of —500 mv is considerably less than the ultimate force, U_A, in air. The typical appearance of fracture in salt solutions under SCC susceptible conditions is shown in Fig. 4. The fracture is initially square under SCC conditions, later changing to slant shear failure. In air, the duplex annealed Ti:8-1-1 specimens failed almost entirely in slant fracture. The period of propagation of square fracture in NaCl is designated by B and the period of slant fracture by C in Fig. 3. Most specimens were preloaded to 1000 kg (2200 lb) as shown, in order to save time. The first visible evidence of a plastic zone by appearance of a dimple on the surface around the root of the notch occurred at 1300 to 1500 kg.

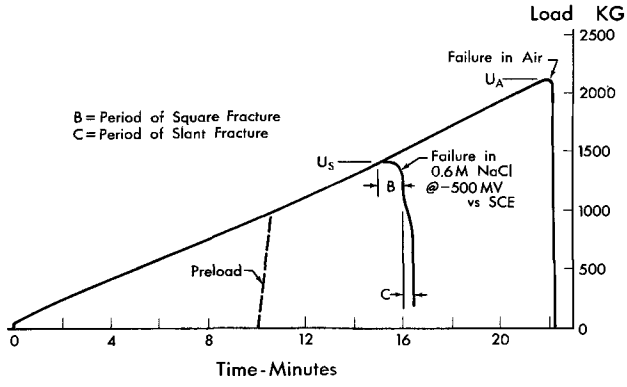


Fig. 3. Load-time curves for single-notched duplex annealed Ti:8-1-1 specimens.

Current-time curves.—A typical plot of current flowing under SCC conditions is given in Fig. 5. In the period, A, before SCC commences, the current mea-

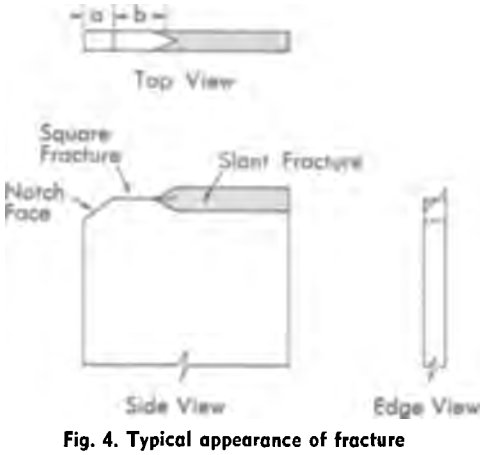

Fig. 4. Typical appearance of fracture

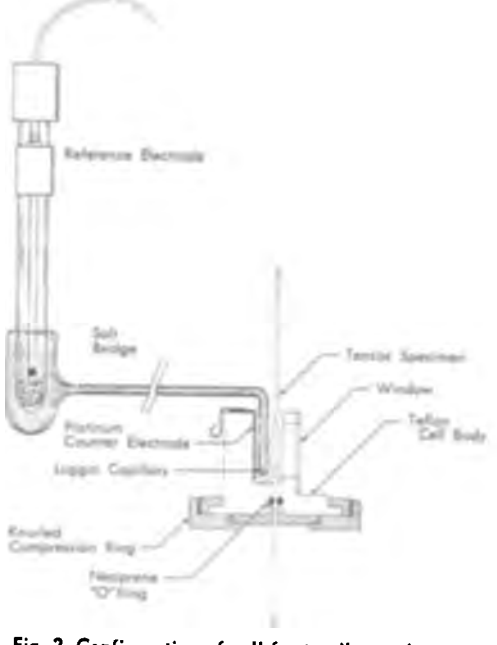

Fig. 2. Configuration of cell for tensile specimens

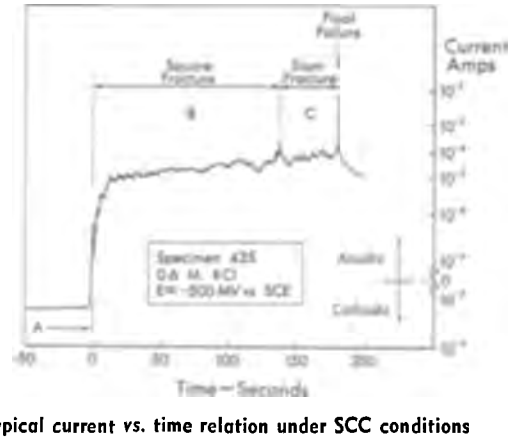

Fig. 5. Typical current *vs.* time relation under SCC conditions

sured is that flowing to the old exterior surface of the specimen. This current may be anodic or cathodic depending on the salt solution and applied potential. Later specimens were anodized to minimize this background current. Anodizing did not appear to influence the SCC behavior. When stress corrosion cracking started, the current jumped in the anodic direction designated by the region B in Fig. 5. Transition to the shear mode or slant failure, region C, was accompanied by a peak in current. The peak correlated with the observed change on the specimen surface from square to slant fracture. A high anodic current peak accompanied the final failure. Time for propagation of square fracture could be directly measured from the current time plots, which were obtained for every run. In cases where the background current in period A was large, either anodic or cathodic due to high positive or negative polarization, the crack propagation current and time were sometimes obscured.

A typical pattern of current *vs.* time for a potential giving immunity to stress corrosion cracking is shown in Fig. 6. The first evidence of anodic current pips is difficult to define, but there was generally a peak at point X followed by a long period of an irregular current of a few microamperes until slant failure occurred. Point X generally occurred at a load of about 1400 kg for the single-notched duplex-annealed Ti: 8-1-1 specimens. The irregular anodic current is presumably due to anodizing of metal in cracks in the oxide film in the plastic zone around the root of the notch. Because of its low value, this current was easily obscured by current flowing to the old surface.

Effect of crosshead velocity.—Early in the program, the effect of crosshead velocity was investigated in order to determine a suitable value to use in the tests. Results are shown in Fig. 7 for the double-notched, duplex-annealed Ti: 8-1-1 specimens in air and in 0.6M sodium chloride at a potential of —500 mv. The strengths plotted are the ultimate values, U_A and U_S, illustrated in Fig. 3. Stress corrosion cracking appeared to occur at crosshead velocities of less than 10^{-1} cm/min. A velocity of 5 x 10^{-3} cm/min was chosen as standard for all subsequent tests as this gave measurable differences in a short period of time.

The stress shown at the right of Fig. 7 was based on the notch section area. The unnotched specimens with slightly higher strength had the same net cross section

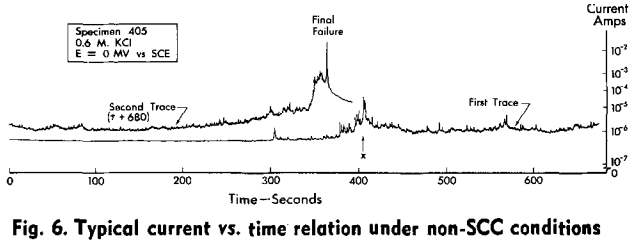

Fig. 6. Typical current *vs.* time relation under non-SCC conditions

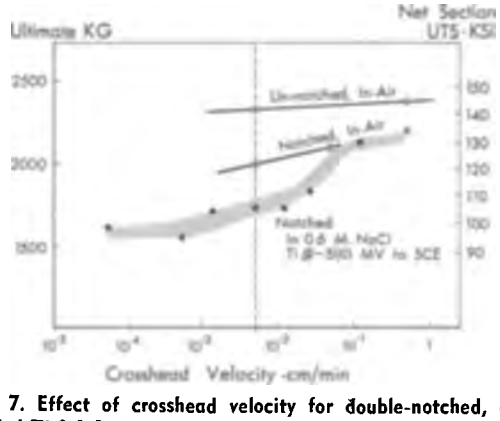

Fig. 7. Effect of crosshead velocity for double-notched, duplex-annealed Ti:8-1-1.

as the notched specimens at the notched section indicating that duplex annealed Ti: 8-1-1 is notch sensitive. There appears to be reasonable agreement of tensile strength of the unnotched specimens to the data in Table I for duplex-annealed Ti: 8-1-1.

Effect of notch radius.—The effect of notch radius was investigated in order to specify the tolerance on the machining of the notches and to determine variability in results due to this factor. Double-notched specimens of duplex-annealed Ti: 8-1-1 alloy were machined with notch root radii of 1, 2, 5, and 20 mils (0.0025, 0.005, 0.012, and 0.05 cm) for these tests. Two specimens had a notch root radius of about 0.5 mils (0.0012 cm), produced by pressing a knife blade into a 1 mil radius notch.

Results in air and 0.6M lithium chloride, potassium bromide, and potassium iodide solutions are shown in Fig. 8. The results in air and in LiCl at a potential +1000 mv were within the same scatterband and indicated some notch sensitivity. Specimens in LiCl at —500 mv showed SCC susceptibility for notch radii of 5 mils and less, but SCC immunity for 20 mil radius. All specimens with notch radii in the range of 1 to 20 mils were susceptible in KBr and KI at a potential of +1000 mv. Two specimens with 20 mil notch radius were electropolished in the notches and tested at +1000 mv in KI solution; little or no sensitivity was indicated.

It was decided, based on these tests, to use 1 mil radius machined notches as standard.

Effect of halide ions.—Stress corrosion cracking of Ti: 8-1-1 alloy in aqueous environments at room temperature has been found to be very specific to three ions; chloride, bromide, and iodide, and to date no others. Other anions investigated were fluoride, hydroxide, sulfide, sulfate, nitrite, and perchlorate. There also appeared to be no cation effect within the limits of accuracy of the experiments for the alkali and alkaline earth cations used. The ultimate load *vs.* potential for neutral fluoride, chloride, bromide, and iodide is given in Fig. 9. The experimental points are not shown for the purpose of clarity, but the scatterband width is indicated in the lower left of Fig. 9.

At potentials more negative than about —1000 mv, the specimens appeared to be cathodically protected in all solutions. At all potentials, the NaF solution gave results in the same scatterband as the air values. At potentials more positive than —1000 mv, SCC susceptibility in varying degrees occurs in chloride, bromide, and iodide solutions. A region of anodic protection

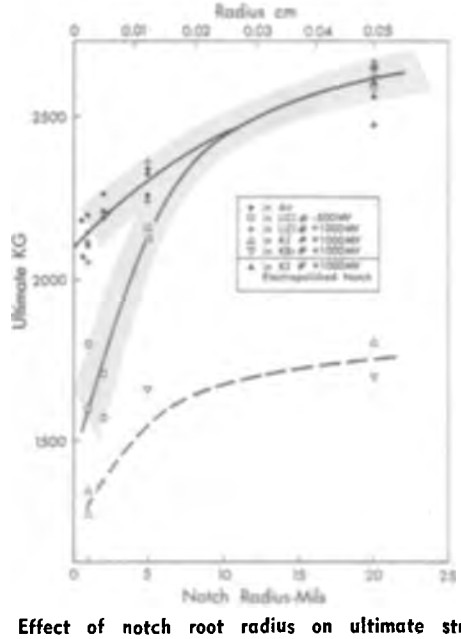

Fig. 8. Effect of notch root radius on ultimate strength

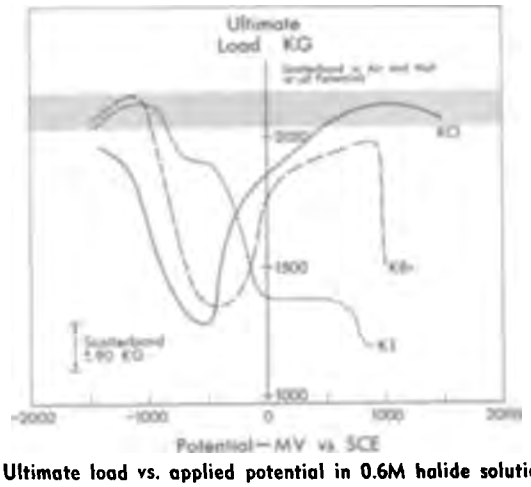

Fig. 9. Ultimate load vs. applied potential in 0.6M halide solutions

occurs in chloride and bromide solutions. Pitting corrosion and flocculent white precipitate were observed at +1000 mv in KBr solution and +2000 mv in LiCl solution. A photograph of a specimen failed in 0.6M KBr solution, Fig. 10, shows the pits and short radial lines on the surface that appeared to be normal to the stress direction around the notches. Although there was a decrease in strength in KI solution at about +700 mv, no pitting or white precipitate were observed.

The ultimate strength shown in Fig. 9 is actually a measure of the stress for initiation of stress corrosion cracking, but there is a close correlation to propagation. It was found, for example, that SCC could be initiated at —500 mv in chloride solution and stopped by switching the potential to either the anodic or cathodic protection zone. It was also found that SCC could be initiated at higher loads than normal at —500 mv by first loading in the anodic or cathodic protection zone to a point approaching failure at that potential and then switching to —500 mv.

The power of the potentiostatic technique is demonstrated in Fig. 9. Specimens on open circuit have a rest potential that is variable depending on metal composition, history of the surface, trace impurities in solution, etc. A range of at least +500 to —500 mv was observed on titanium. In this range many changes occur, accounting in part for the large variability in strength observed by others under open-circuit conditions.

Crack propagation velocity and associated current.— Crack propagation velocity was measured by two means: (*i*) by visually observing the progress of the crack past scribed pencil lines on a specimen surface, and (*ii*) by dividing the square-fracture length (b in Fig. 4) by the square-fracture time (B in Fig. 5). A comparison of the two methods is shown in Fig. 11. There appeared to be reasonable good agreement for this specimen at —500 mv in 0.6M LiCl.

It would have been desirable to make all velocity correlations using initial crack velocity from visual observation of crack length. This was a tedious measurement and only a few were made. Data were available, however, from the experiments already made to calculate average crack velocity. If the ratio of average velocity to initial velocity is relatively constant, correlation using average velocity appears justified at this time.

Average crack propagation velocity was found to be linear with applied potential in 0.6M chloride, bromide, and iodide solutions for those specimens that failed below about 1500 kg load. These data, based on square fracture length and time, are plotted in Fig. 12. This is probably one of the more significant findings in this work thus far, as it demonstrates that, once initiated, the crack propagation velocity is determined by electrochemistry.

The current during square-fracture crack propagation as measured from current *vs.* time plots such as shown in Fig. 5 is plotted in Fig. 13. The average initial current and the average final current just before initiation of shear fracture appear to be linear with applied potential. The average current was estimated by drawing by eye a horizontal line through about 30

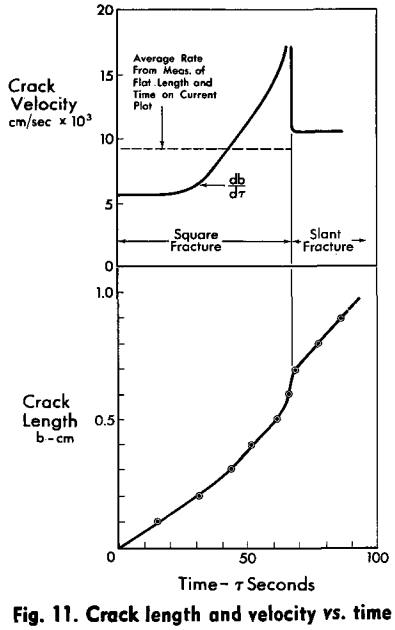

Fig. 11. Crack length and velocity vs. time

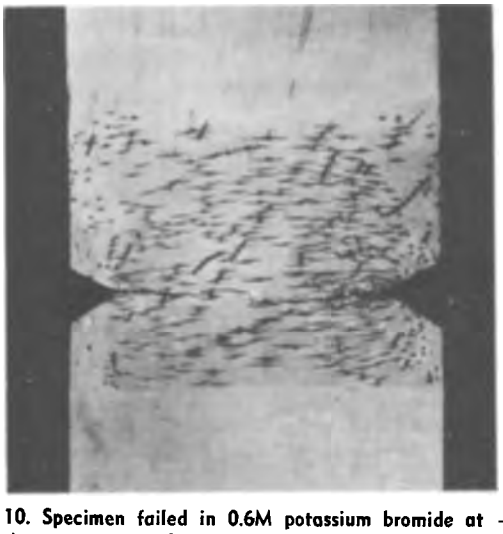

Fig. 10. Specimen failed in 0.6M potassium bromide at +1000 mv (pitting corrosion condition).

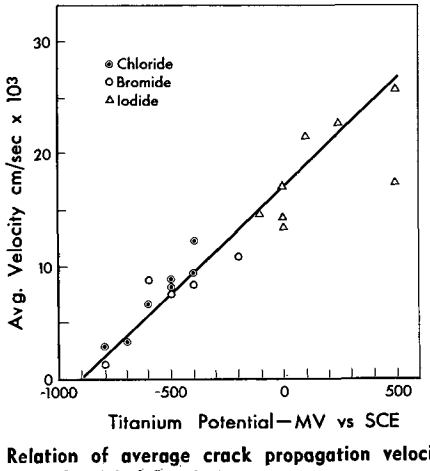

Fig. 12. Relation of average crack propagation velocity to applied potential in 0.6M halide solutions.

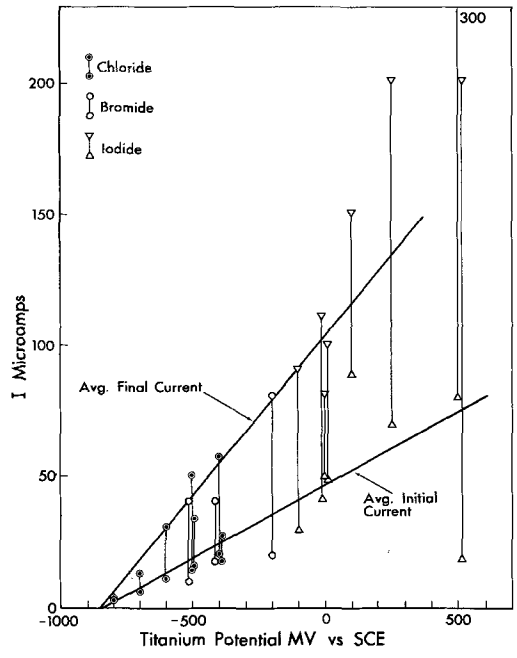

Fig. 13. Relation of crack propagation current to applied potential in 0.6M halide solutions.

sec of the irregular current plot. That the ratio of final current to initial current appears to be constant up to at least zero mv to SCE lends some assurance that the correlation using average velocity was justified.

The values of the intercepts on the potential axes in Fig. 12 and 13 play an important role in the analysis presented in the following paper (4). The intercepts in Fig. 12 and 13 are —900 and —850 mv, respectively.

Effect of concentration.—The effect of concentration was studied using hydrochloric acid solutions. The pattern of strength *vs.* potential was similar to that shown in Fig. 9 at concentrations from 6M to 0.006M. At 0.0006M anodic protection did not occur until about +1000 mv. The resistivity of the solution was apparently too high for the potentiostat to maintain effective control.

It was found that stress corrosion cracking in chloride solution could be suppressed by addition of hydroxide or fluoride. SCC was suppressed in iodide solution by addition of hydroxide or perchlorate. The molar ratio of inhibitor to SCC agent to suppress SCC completely was on the order of 10-100 to 1.

Effect of temperature.—Temperature of the specimen and electrolyte from 0° to 74°C had little effect on ultimate load within the limits of experimental error in chloride electrolytes with specimen at —500 mv as shown in Table II. Further, the relatively small change in velocity with temperature suggests control by mass transport rather than kinetics.[1] The temperature of 0°C was obtained by pouring liquid nitrogen into the cell until the surface of the electrolyte froze to ice around the specimen. The 74°C temperature was obtained by shining heat lamps on the specimen and cell and controlling temperature with an epoxy insulated thermocouple in the electrolyte.

Effect of heat-treatment.—Experiments were conducted to investigate the effect of heat treatment of Ti:8-1-1 and the preliminary results are summarized in Fig. 14. The results on duplex-annealed material have already been described. In contrast it can be seen that notched specimens of the alloy in the mill-annealed condition are relatively brittle under all conditions of test and are relatively insensitive to the environment.

Fractographic analysis.—Numerous electron photomicrographs of square-fracture surfaces have shown that specimens fractured in aqueous salt solutions exhibited transcrystalline cleavage of the α-phase in Ti:8-1-1 alloy. Ductile rupture occurs in the β-phase.

[1] Note added in proof: Subsequent experiments indicate an activation energy on the order of 2 kcal.

Table II. Effect of temperature on ultimate load and crack propagation velocity at potential of —500 mv in chloride solutions

Specimen No.	Electrolyte	Temp, °C	Ultimate load = kg	Crack velocity, cm/sec × 10^3
473	0.6M KCl	0	1500	4.6
Avg. of several specimens	0.6M KCl	21	1300 ± 90	8
145	0.6M LiCl	74	1340	5.0[a]

[a] Velocity could be larger than this value because time of transition to shear could not be determined.

Conclusions

The following conclusions are based on experiments with duplex annealed Ti:8-1-1 alloy specimens in aqueous solutions:

1. Notched specimens are susceptible to stress corrosion cracking in chloride, bromide, and iodide solutions.
2. Notched specimens are not susceptible in fluoride, hydroxide, sulfide, sulfate, nitrite, or perchlorate solutions. Fluoride, hydroxide and perchlorate were found to inhibit SCC in chloride, bromide, and iodide solutions for molar concentration ratios in excess of 10-100 to 1.
3. No significant cation effect was observed for hydrogen ion and alkali and alkaline earth metal ions.
4. SCC is accompanied by an anodic current.
5. There is a maximum rate of elongation of notched tensile specimen above which shear failure occurs rather than SCC.
6. Precracking is not necessary, but there is a minimum notch root radius above which SCC does not occur in chloride solutions. SCC was found to occur in bromide and iodide solutions with a larger root radius, at potentials above the pitting potential. Electropolishing the notch inhibited SCC in iodide solution.
7. The load for initiation of SCC appeared to be related to the first visible indication of plastic deformation around the root of the notch.
8. Cathodic protection occurred at potentials more negative than —1000 mv to SCE in chloride, bromide, and iodide solutions. An anodic protection zone of potential occurred in chloride and bromide but not in iodide solution.
9. Susceptibility occurs in hydrochloric acid solutions to concentration at least as small as 0.0006M (20 ppm).
10. Average velocity of crack propagation during SCC is linearly related to potential in chloride, bromide, and iodide solutions. Data for the three ions were correlated by the same line which had an extrapolated intercept of —900 mv to SCE at zero velocity. There is

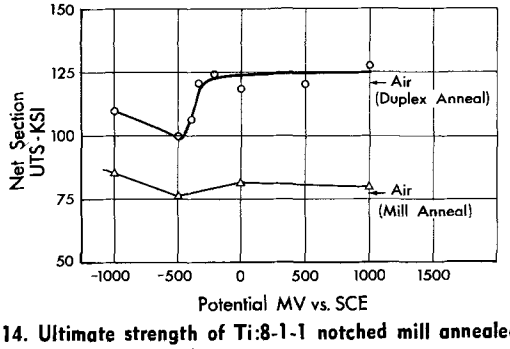

Fig. 14. Ultimate strength of Ti:8-1-1 notched mill annealed and duplex annealed in 0.6M LiCl.

a relatively small temperature effect on velocity from 0° to 74°C.

11. The anodic current during SCC was also related linearly to potential in chloride, bromide, and iodide solutions. An electrochemical mechanism controlling velocity is implied.

12. Electron photomicrography indicates transcrystalline cleavage of alpha phase on SCC fracture faces.

Electrodeposition of Coherent Deposits of Refractory Metals

V. Mechanism for the Deposition of Molybdenum from a Chloride Melt

S. Senderoff and G. W. Mellors

Research Laboratory, Consumer Products Division, Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

After observing an irreversible step in the electrode process in all cases of coherent deposition of metals from molten fluorides, a chronopotentiometric study of the KCl-LiCl-K_3MoCl_6 system which produces coherent molybdenum deposits was undertaken. It was found that in this case also, the electrode process was irreversible at 600°C, a temperature at which coherent deposits are produced, and became more reversible as the temperature increased. The irreversible behavior of the electrode and the decrease of bath stability with decrease in concentration of molybdenum could be explained on the basis of the following mechanism

$$[Mo_2Cl_9]^{-3}(l) + 3Cl^-(l) \underset{\text{slow}}{\rightleftharpoons} 2[MoCl_6]^{-3}(l) \qquad (A)$$

$$[MoCl_6]^{-3}(l) + 3(e) \rightarrow Mo^0(s) + 6Cl^-(l) \qquad (B)$$

$$\left|\begin{array}{l}\\ \Delta \rightarrow\end{array}\right. \frac{2}{5}Mo(s) + \frac{3}{5}MoCl_5(g) + 3Cl^-(l) \qquad (C)$$

The failure of the electrode to behave in a Nernstian manner at 600°C is ascribed to the slowness of the dissociation in step (*A*). Its more nearly Nernstian behavior at 700° and 800°C probably results from the increased rate of this dissociation and is associated with decreased coherency of deposits at these temperatures.

In a recent series of papers (1-4) it was shown that in each case in which a coherent deposit of a refractory metal was obtained from fused salt systems, the metal production step in the electrode process was irreversible. In niobium and tantalum deposition, the irreversibility was apparently the result of a slightly soluble intermediate, while in the case of zirconium, it may have resulted from corrosion of the the deposit by the solvent. In all of these studies the system under investigation was a fluoride electrolyte which had been demonstrated to be a general medium for the coherent deposition of refractory metals (5). It had been shown earlier that a chloride electrolyte may be used to deposit molybdenum (6) coherently under certain conditions, and a study of static potentials in this system indicated that the Mo/Mo^{3+} electrode behaved reversibly in accordance with Nernst's Law (7). The study of the kinetics of the electrode process by chronopotentiometry was undertaken to determine whether reversibility of the electrode was maintained under the dynamic conditions during deposition or whether it was a property of the static electrode system only.

Experimental

The general procedures and equipment used in previous investigations (2-4) were used with the following modifications:

1. The reference half-cell consisted of a silver rod immersed in solution of 1 mol % AgCl in the KCl-LiCl eutectic mixture (41.2 mol % KCl-58.8 mol % LiCl) contained in a recrystallized alumina crucible (Morganite ΔRR). This crucible was held in the cup designated C in Fig. 2 of ref. (4).

2. The test solutions were prepared by making an electroplating solution with K_3MoCl_6 in KCl-LiCl as described earlier (6) and electrolyzing until satisfactory plates were produced. This solution was quickly frozen, analyzed, and portions were then added to purified KCl-LiCl to make the diluted solutions required for chronopotentiometry. The K_3MoCl_6 was prepared as previously described (8).

3. The crucible containing the test solutions [designated I in Fig. 2, ref. (4)] was molybdenum.

Chronopotentiometric runs were made with a platinum disk 1 cm^2 in area as indicator electrode and a molybdenum strip as counter electrode. As will be dis-

cussed below, the solutions were unstable at low concentrations and high temperatures so each concentration was run as rapidly as possible at various current densities at the lowest temperature (600°C), then at higher temperatures, and finally cooled and a few current densities repeated at the initial temperature of 600°C. Only those runs in which the transition time constant of the initial chronopotentiograms was reproduced at the end of the run were used in interpreting the results. Samples for analysis were taken at the conclusion of each set of runs at a fixed temperature.

Results

The electroplating bath which formed the stock solution for the chronopotentiometric runs contained 4.8 w/o (weight per cent) Mo (8.8×10^{-4} moles/cc at 600°C)[1] at a mean valence of 2.9 as determined by chemical analysis.[2] This solution could not be used for chronopotentiometric studies since at this high concentration a microelectrode 0.01 cm^2 in area was required in order that reasonable current densities and transition times could be employed. Such electrodes were made by sealing platinum or tungsten wires in a quartz tube, but did not yield satisfactory chronopotentiograms. Satisfactory runs were made on diluted solutions containing initially 1.7×10^{-4}, 1.0×10^{-4}, and 5.8×10^{-5} moles/cc Mo, but the last of these lost 36% of its molybdenum content within the short time required to complete nine chronopotentiograms at 600°C. A solution starting with 3.5×10^{-5} moles/cc lost 97% of its molybdenum content after only five runs at 600°C and could not be used to obtain significant data. The two more concentrated solutions showed negligible molybdenum losses at 600°C but lost concentration slowly at 700° and 800°C. Because of the progressive instability of the solutions with decreasing concentration and increasing temperature, only a limited range of concentrations could be studied.

Figures 1A and 1B are typical cathodic chronopotentiograms at 600° and 700°C. They show a single plateau at —0.18 and 0.0v, respectively. The small irregularity near —0.7v is caused by a trace impurity and may be ignored. The static potential observed on a molybdenum electrode in this solution is +0.05v at 600° and 700°C *vs.* the Ag/AgCl (0.3M), KCl, LiCl electrode, and is nearly independent of temperature except when the electrolyte decomposes, thereby decreasing the concentration and raising the mean valence. At 800°C, values varying between +0.17 and +0.23v are observed for the static potential, the variability being related to the instability of these dilute solutions at this temperature.

[1] Density data taken from ref. (9).

[2] The sample is dissolved in excess ferric sulfate and back titrated with dichromate. The mean valence is calculated from the titer and the total Mo content. The latter is determined colorimetrically on the thiocyanate complex of molybdenum after dissolving the sample and fuming it in H_2SO_4 containing a few drops of HNO_3.

Figures 2A, B, C are cathodic-anodic chronopotentiograms at 600°, 700°, and 800°C, respectively. While at 600°C the ratio of backward-to-forward transition times is 1.0, this ratio is anomalously large at 700°C (1.7) and 800°C (3.3). Table I shows the chronopotentiometric data for the results at 600°, 700°, and 800°C.

Discussion

Stability of the solution.—Although the plating solution at a concentration of 4.8 w/o Mo is stable up to at least 800°C, the approximate fivefold and tenfold dilutions represented by solutions I and II in Table I showed slight concentration losses at 700°C and additional losses at 800°C. The dilution of approximately 15-fold represented by solution III fell from a concentration of 5.8×10^{-5} to 3.7×10^{-5} moles/cc even at 600°C and was too dilute at 800°C for satisfactory study. On diluting the plating solution to 1/25 of its original concentration, it decomposed at 600°C before even a few runs could be made. Upon decomposition, a volatile material is evolved from the solution and a dark powder is precipitated. When this approximately 25-fold dilution was quenched after a 2-hr hold at 600°C, two layers developed. The white upper layer contained less than 10^{-6} moles/cc Mo, and the lower black one contained 3.4×10^{-4} moles/cc Mo. The initial nominal concentration based on the dilution of the plating bath was 3.5×10^{-5} moles/cc, and the x-ray spectrum of the black material showed lines characteristic of Mo metal and MoO_2 (the latter undoubtedly a product of the aqueous separation procedure). One may conclude that the decomposition is a disproportionation yielding a volatile higher chloride of molybdenum and molybdenum metal. However, while a disproportionation may be furthered by higher temperature, it is extremely unusual for it to be enhanced by dilution. In fact, if the process is of the nature of

$$5MoCl_3(l) \leftrightarrows 2Mo(s) + 3MoCl_5(g) \qquad [1]$$

then decrease in concentration of $MoCl_3$ in solution (as K_3MoCl_6) should drive the reaction to the left rather than toward additional disproportionation. To account for the observed effect of temperature and concentration, another process must be postulated in addition to the observed disproportionation. While in aqueous systems dilution frequently results in decomposition of complexes and disproportionation, this would not be expected in this case since the concentration of the ligand, chloride ion, is essentially unaffected by varying the concentration of $MoCl_3$ in a large excess of KCl-LiCl. One process which would be

favored by decreasing concentration is dissociation of a polymer to form a monomer in solution. The equilibrium

$$M_n \leftrightarrows nM \qquad [2]$$

is driven to the right on decreasing the concentration in accordance with the equilibrium expression

$$\frac{[M]^n}{[M_n]} = K \qquad [3]$$

Polynuclear ions such as $[W_2Cl_9]^{-3}$, $[Mo_2F_9]^{-3}$, $[Mo_3Cl_7]^{-1}$, and others are known and, if one may postulate that an ion such as $[Mo_2Cl_9]^{-3}$ exists, the concentration dependence of the decomposition can be explained by a process such as

$$[Mo_2Cl_9]^{-3}(l) + 3Cl^-(l) \leftrightarrows 2[MoCl_6]^{-3}(l)$$
$$\rightarrow \frac{6}{5}MoCl_5(g) + \frac{4}{5}Mo(s) + 6Cl^-(l) \qquad [4]$$

That is, if the molybdenum is present in a stable binuclear ion in equilibrium with a less stable mononuclear one, decreasing the concentration favors dissociation of the binuclear to the mononuclear ion, which then disproportionates. Increasing the temperature can be expected to increase the tendency toward disproportionation of the mononuclear ion. A spectroscopic study could probably settle definitely the question of whether such a binuclear (or polynuclear) ion of molybdenum exists, and the behavior with dilution described above can only be considered as very indirect evidence for it. However, as will be seen below, the concept will prove useful again in correlating the kinetics of the electrode reaction.

The electrode process.—Examination of Table I reveals that the transition time constant, $i\tau^{1/2}/C$, is reasonably invariant at 600°C at all concentrations and also at 700°C at the higher concentrations. In Fig. 3 are plotted the values of $i\tau^{1/2}$ *vs.* C from Table I. Because of the restricted range of concentrations accessible for study and the unreliability of the data at low concentration and high temperature, too much significance cannot be ascribed to the straight lines drawn. Therefore, it cannot be unambiguously demonstrated from these data that the reaction is subject to diffusion control, although it may be.

However, it can be shown conclusively in a number of ways that the reaction is not reversible at 600°C, and that it becomes more nearly reversible and approaches Nernst behavior at higher temperatures. First, examination of Fig. 2A reveals a 0.4v difference of potential between the anodic and cathodic processes at 600°C. In a reversible process this should be twice the IR drop. If it is assumed that the 17 x 10^{-5} moles/cc K_3MoCl_6 does not materially change the conductivity of the KCl-LiCl mixture [2.34 Ω^{-1} cm^{-1} at 600°C (9)], it is calculated that the IR drop at 100 ma/cm^2 on 1 cm^2 electrodes 1.5 cm apart is a maximum of 0.064v. The observed difference is therefore more than six times the IR drop, and can only represent irreversibility of the electrode process. This difference in potential between the anodic and cathodic processes decreases to 0.3v at 700°C and to 0.18v at 800°C. At 800°C the conductivity of the KCl-LiCl mixture is 3.14 Ω^{-1} cm^{-1} so that the IR drop at 175 ma/cm^2 with the same electrode configuration is 0.084v. Here the total difference is almost exactly twice the IR drop, indicating that at 800°C the anodic and cathodic processes are nearly reversible. Table II indicates the approach to reversibility of the electrode process with increasing temperature.

Table II. Comparison of IR drop in electrolyte with observed polarization of anodic and cathodic processes

Temp, °C	KCl-LiCl Eutectic, κ, ohm^{-1} cm^{-1}	C.D., amp/cm^2	2 x IR, v (1.5 cm electrode separation)	Observed potential difference, v (from Fig. 2)
600	2.34	0.100	0.128	0.4
700	2.81	0.150	0.162	0.3
800	3.14	0.175	0.168	0.18

An identical conclusion can be reached by comparing the $E_{1/4}$ values of the cathodic reduction with the observed static potential values. In Table I it is seen that the average $E_{1/4}$ values at 600°, 700°, and 800°C are, respectively, —0.18v, —0.03v, and +0.11v. The static potential, which is almost temperature independent, is +0.05v. Because measurements become difficult at 800°C, the $E_{1/4}$ value observed is probably not significantly different from the static potential; at 700°C it is polarized cathodically by only 80 mv, and

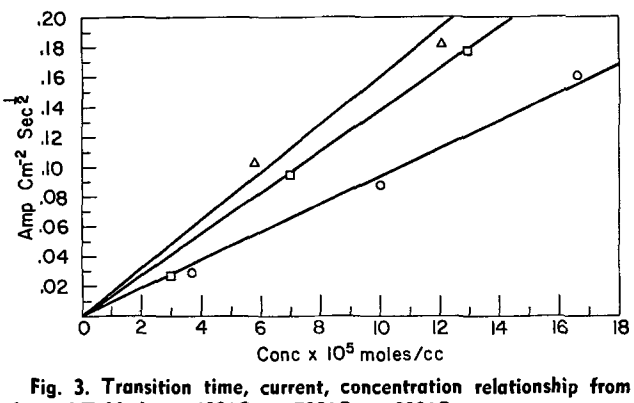

Fig. 3. Transition time, current, concentration relationship from data of Table I. ⊙ 600°C; ⊡ 700°C; △ 800°C.

at 600°C by 230 mv, again showing a considerable departure from reversibility at 600°C with nearly reversible behavior at 800°C. The variation of $E_{1/4}$ with the concentration expected when a metal is the product of the reaction is not detectable in these experiments, because at 600°C the variation of one decade in concentration for a three-electron reaction will produce a change in $E_{1/4}$ of only 58 mv. Since the variation of concentration was less than fivefold, the expected change in potential over the whole concentration range is about 35 mv, which is at the borderline of the precision of these measurements.

Selis (7) gives the static standard potential of Mo/Mo^{3+} with respect to Pt/Pt^{++} on the molar scale of Laitinen (10) as —0.603v at 450°C. In the present work a static potential value of +0.05v at 600°C was observed between Mo/Mo^{3+} (0.1M) and Ag/Ag^{+} (0.3M). Since the temperature coefficients of these cells are very small, the difference of 150°C in temperatures of measurement may be ignored and on converting the observed static potential to the standard value on the same scale, a standard potential of —0.72v is obtained. This may be considered reasonable agreement in view of the different methods, conditions, and solutions used.

A final and probably conclusive demonstration of the lack of reversibility at 600°C with approach to reversibility at the higher temperatures is the plot of E *vs.* $\log f(t)$ as a test for Nernstian behavior. Visual comparison of the shapes of the plateaus in Fig. 1A and 1B is sufficient to demonstrate that they are very different from each other. A plot of E *vs.* $\log (\tau^{1/2} - t^{1/2})/t^{1/2}$ and *vs.* $\log (\tau^{1/2} - t^{1/2})$ for the cases of the soluble and insoluble products, respectively, did not produce straight lines for any chronopotentiograms taken at 600°C. Where the best straight line was drawn through as many points as possible, ridiculous n values, some as low as 1.0, others as high as 8.5, were obtained, depending on how the line was drawn through the curve of points. However, an example of these plots for one of the chronopotentiograms taken at 700°C is shown in Fig 4. The excellent straight line obtained with the plot for the insoluble product case [*i.e.*, $f(t) = \log (\tau^{1/2} - t^{1/2})$] gives from its slope an n number of 2.8. An average of 11 such plots gives an n number for the reaction of 2.66 ± 0.28 in good agreement with the three-electron reduction expected from these trivalent molybdenum solutions. It is significant that this is the first case observed in this study of refractory metal deposition in which linear behavior was found with the plot for an insoluble product. Previous cases where insoluble intermediate compounds were observed still showed linear behavior with the plot of soluble products. This may be explained by pointing out that a slightly soluble compound must first saturate the liquid at the interface and by that time most of τ has been completed. However, it is clear that when an extremely insoluble material such as a refractory metal is deposited at the electrode, the case for an insoluble product holds strictly. It is also interesting that at 600°C the ratio $t_{anode}/t_{cathode}$ is equal to 1.0, as shown in Fig. 2A. This confirms that an insoluble product is produced, and since the electron number (at 700°C) has been shown to be three, this insoluble product must be molybdenum metal. The higher $t_{anode}/t_{cathode}$ ratios obtained at higher temperatures are anomalies and are believed to be due to molybdenum which entered the platinum before the chronopotentiometric run began. It was observed that mere immersion of the platinum in the electrolyte at 700° and 800°C produced a thin diffusion coating of molybdenum in the platinum which must be removed by vigorous treatment with 1:1 HNO_3 or by anodizing in the molten electrolyte.

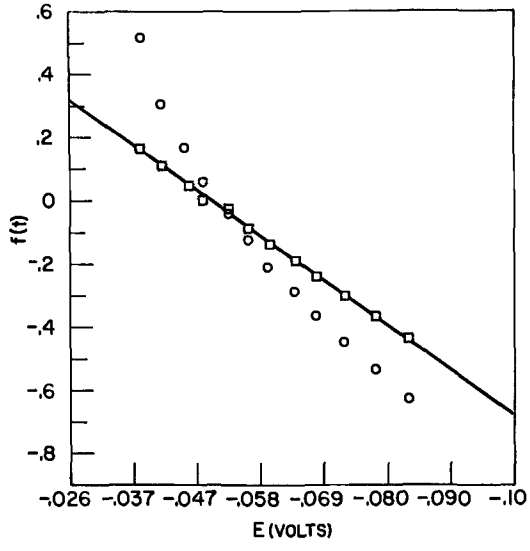

Fig. 4. Nernst plot of chronopotentiogram for reduction of K_3MoCl_6 in KCl-LiCl. ⊙ f(t) = log $(\tau^{1/2} - t^{1/2})/t^{1/2}$; ⊡ f(t) = log $(\tau^{1/2} - t^{1/2})$. Temp, 700°C; current density, 100 ma/cm²; concentration, moles/cm³ = 7 x 10^{-5}.

From the foregoing it is evident that the molybdenum is reduced from the trivalent state to metal at 600°C in a single irreversible step which progressively becomes more reversible as the temperature is raised, so that at 800°C all criteria for reversibility are satisfied. The criteria for reversibility, which in this investigation proved most significant, were cathodic-anodic potential difference, polarization of $E_{1/4}$, and the Nernst plot of E *vs.* $\log (\tau^{1/2} - t^{1/2})$. This observation of the irreversibility at 600°C must be correlated with the observation over ten years ago that the molten chloride-molybdenum plating solution gave good coherent deposits only at 600°C and that at 900°C powders were obtained (6). Steady-state polarization tests performed at that time also indicated notably higher polarization at 600°C than at higher temperature (11). This observation of coherent plates associated with irreversibility at low temperature, and decreasing coherency at higher temperatures coupled with increasing reversibility of the system is another example of the close connection between coherent plating and irreversible electrode behavior.

Reactions of the reducible species.—One apparent anomaly still requires explanation as does the source of the irreversibility of the system. Selis (7) found by static potential measurements exact Nernst dependence on concentration of the observed equilibrium potential at temperatures between 460° and 540°C. Under the dynamic conditions of chronopotentiometry, however, Nernstian behavior is not observed at 600°C. This may be explained if a slowly established equilibrium is displaced by the electrode process so that in static measurement an equilibrium always exists such that the concentration of the potential determining species is proportional to the total molybdenum concentration, while in the cathodic process at a finite rate the equilibrium state is not maintained. A polynuclear ⇆ mononuclear ion equilibrium of the type of reaction [4] can be such a process. If the mononuclear ion is reduced electrolytically to metal as fast as it is produced, it would not be able to disproportionate; and if its concentration is kept low by a slow rate of dissociation of polynuclear ion, the electrode would not behave in a Nernstian manner. Finally, the value of $n = 3$ calculated from the static potential data by Selis and from the chronopotentiometry of the present work indicates that the six-electron reduction of the binuclear complex is totally irreversible under these conditions and thus does not affect the potential measurements. It is interesting, therefore, that the same postulate which is consistent with the concentration dependence of the stability of the solution can also explain the observations regarding the static and dynamic electrode potentials in the system.

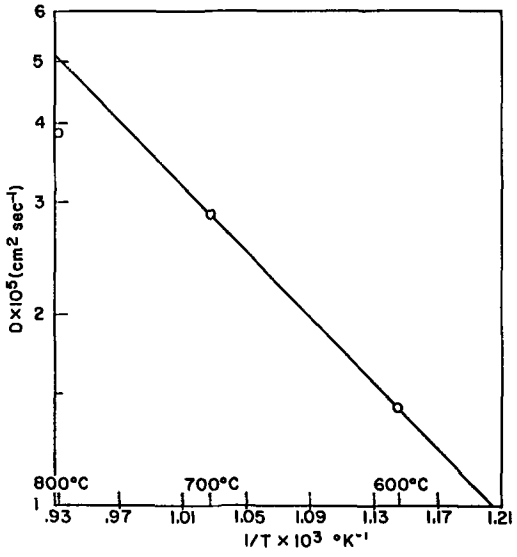

Fig. 5. Activation energy for diffusion of chloromolybdate (III) ion in KCl-LiCl.

Transport properties.—By taking $n = 3$ one can calculate the diffusion coefficient, D, of the reducible species, $[MoCl_6]^{-3}$, from the lines of Fig. 3, the slopes of which equal $\frac{1}{2}\pi^{1/2}n\mathbf{F}D^{1/2}$. At 600°, 700°, and 800°C, respectively, these equal 1.43×10^{-5}, 2.89×10^{-5}, and 3.87×10^{-5} cm^2 sec^{-1}. A plot of log D *vs.* $1/T$ is shown in Fig. 5 in which only the two lower temperatures are used to draw the line because of the poor reproducibility of the measurements at 800°C. The slope of the line corresponds to an activation energy of 11.9 kcal mol^{-1}, and may be compared with the value of 9.8 kcal mol^{-1} for the trivalent bismuth ion obtained by Thalmayer *et al.* (12) in the KCl-LiCl solvent. The value of the diffusion coefficient at 750°C taken from the line of Fig. 5 is 3.8×10^{-5} cm^2 sec^{-1}, which is one-half that found for Ag^+ in the same solvent at that temperature (13) and is a reasonable difference which one would expect for a trivalent as compared to a monovalent ion (12).

Summary

The electrodeposition of molybdenum from the chloride electrolyte occurs as a single three-electron irreversible step at 600°C. It becomes more reversible with increasing temperature, while at the same time the plate becomes less coherent. The source of the irreversibility has not been unambiguously established, but the peculiar decomposition of the electrolyte with decreasing concentration suggests that a slow[3] dissociation of a binuclear (or polynuclear) ion to a mononuclear one may be involved both in the irreversible electrode reaction and in the chemical decomposition. The postulated process may be written:

$$[Mo_2Cl_9]^{-3}(l) + 3Cl^-(l) \xrightarrow{\text{slow}^3} 2[MoCl_6]^{-3} \quad (1)$$

$$[MoCl_6]^{-3}(l) + 3e \rightarrow Mo^0(s) + 6Cl^-(l)$$

$$\xrightarrow{\Delta} \frac{2}{5}Mo(s) + \frac{3}{5}MoCl_5(g) + 3Cl^-(l)$$

[3] The actual rate of the dissociation has not been determined but it is undoubtedly of an order corresponding to the operating current density range of the plating process (~50 ma/cm^2).

Vapor Deposition of Tungsten by Hydrogen Reduction of Tungsten Hexafluoride

Process Variables and Properties of the Deposit

Jean F. Berkeley, Abner Brenner, and Walter E. Reid, Jr.

National Bureau of Standards, Washington, D. C.

ABSTRACT

An investigation of the variables involved in the deposition of tungsten from a mixture of tungsten hexafluoride and hydrogen has shown that the fastest rate of deposition (about 5 mils thickness in 2 min) was obtained at atmospheric pressure with a hydrogen/tungsten hexafluoride ratio of 1.5 (by volume) at a temperature of 800°-850°C. The presence of hydrogen fluoride or chloride in the reacting gases diminished the rate of deposition. The deposits had about the same hardness, electrical conductivity, and density as commercial wrought tungsten. The tensile strength of the deposits was about 30,000 lb/in.^{2}. The internal stress within the deposits was also about 30,000 lb/in.^{2}. Codeposition of carbon, from carbon monoxide, greatly increased the hardness of the deposits.

About 1958, the Metal Deposition Section of the National Bureau of Standards undertook an investigation of the deposition of tungsten, which project was supported by the Special Projects Section of the Department of the Navy. This organization was interested in producing either tungsten nozzles or graphite nozzles coated with tungsten for use on rocket engines. Since tungsten has not been electrodeposited from aqueous solutions in the uncombined state (although it has been codeposited with other metals as alloys), the only processes considered were electrodeposition from fused salt baths and deposition from the vapor phase.

We were not successful in obtaining smooth tungsten deposits 1 or 2 mm thick from fused salt baths. We tried the borate-tungstate bath of Davis and Gentry (1) and various baths prepared (in the absence of air) by dissolving tungsten dichloride or tetrachloride in melts of alkali chloride or fluorides. Subsequently, McCawley, Kenahan, and Schlain (2) and Mellors and Senderoff (3) obtained improved results from fused salt baths.

We found deposition of tungsten from the vapor phase by published methods also unsatisfactory. Deposition of tungsten from the vapor of the carbonyl (4) was too slow, and sufficiently thick, smooth deposits could not be obtained from either this system or the tungsten hexachloride-hydrogen system (5).

We modified the latter process by substituting tungsten hexafluoride for tungsten hexachloride and obtained very superior results (6). At about the same time that we were engaged on this phase of the investigation we learned that the Bureau of Mines (7) was also working on this process for the purpose of producing highly pure tungsten. The hexachloride is a solid (mp 270°C) which requires a temperature above 200°C to produce an adequate vapor, whereas the hexafluoride is a gas at room temperature (bp 19°C) and was easily passed into the reaction chamber from a commercial cylinder. No lower valent halides were formed and deposition of tungsten occurred over a wider range of temperature and vapor composition.

The hexafluoride process found some special applications (8-13) for preparing objects of tungsten, but has yet no large use. In particular, it is now in operation for the production of tungsten spherules (12) which are used in powder metallurgy. The conditions of deposition which have been used for these various items were essentially those which were disclosed in the initial brief publications on the subject (6) and may not have been the optimum.

Since the process appears to have potential engineering and commercial applications, more information on the operation of the process and on the properties of the deposit was warranted. The objective of this investigation was to determine the effects of the operating variables on the rate of deposition and on some of the properties of the deposits and to investigate other phenomena associated with the reaction.

Experimental Apparatus and Procedure

Although the vapor plating process allows a wide latitude of choice of equipment, for this research we required an experimental setup that enabled specimens of uniform thickness to be prepared at a controlled temperature from a reaction mixture of known composition. The commonly used flowing system was not satisfactory because the gases could not be proportioned with sufficient accuracy, and a deposit of uniform thickness was not obtained because of the more rapid deposition on the windward side of the substrate. Temperature control of the specimen was also more difficult in a flowing system.

In this investigation we deposited tungsten from a static volume of gas. The substrate was a nickel tube about 4 in. (10 cm) long, 0.125 in. (3.0 mm) in diameter with a wall thickness of 0.01 in. (0.25 mm). The end of the tube was plugged so that deposition did not take place on the inside. We believe that the results obtained with the static system are qualitatively applicable to the flowing system, that is, a change in the value of a process variable produces changes of the same type and direction in both static and flow systems.

The tube was inductively heated by being suspended in a work coil about 1.5 in. (4 cm) in diameter and 6 in. (15 cm) long. Five to 15 sec were required to reach a temperature of 1000°C. The temperature of the tube during deposition was measured with a thermocouple, which was placed in the interior of the tube. Temperature was controlled within about 10° by manually operating the cores of three auxiliary coils (all water cooled) which were in series with the main work coil. The temperature was constant within this limit over the central 2-in. length of the tube.

The reaction chamber (see Fig. 1) was a cylinder of stainless steel about 10 in. (25 cm) in diameter and 24 in. (60 cm) long. It had a volume of approximately 1 ft^3 (30 liters). This large volume was necessary to prevent the concentrations of the reacting gases from changing from their initial values by more than 5 or 10%.

In preparing the chamber for an experiment it was first evacuated to about 0.05 Torr. Hydrogen was introduced to the desired pressure, as read on a mercury

Fig. 1. manometer, and next the tungsten hexafluoride. The two gases were then mixed by a motor driven propeller in the bottom of the reaction vessel. This was necessary because of the large difference in the density of hydrogen and tungsten hexafluoride (the latter being about 150 times more dense than hydrogen).

The induction unit was next turned on and maintained at the required temperature long enough to provide a thickness of deposit which usually ranged between 3 and 10 mils (75 and 250μ). The rate of deposition varied from about 1 to 3 mils/min, hence, a plating period of 2-3 min was adequate.

To permit the plating of more than one specimen from a single filling of the reaction chamber, the latter was provided with an air lock, as shown in Fig. 1. The main part of the air lock was a vacuum-tight sliding gate valve, which had an opening about 2 in. (5 cm) in diameter. Several specimens could be obtained from a single filling of the chamber before the composition of the gases changed more than 10%. The reactive gas mixture could be allowed to remain in the chamber for a few weeks without detriment to the plating process.

At the conclusion of a set of runs the gases in the reaction chamber were removed by drawing dried air through the equipment with a water aspirator, which also served to absorb WF_6 and HF.

The plated specimens were treated with nitric acid to dissolve the nickel substrate. Thus, the tungsten specimen was obtained in the form of a thin-walled tube. The tubular shape of the specimen made possible the handling of the fragile deposits without mechanical damage.

The special items of equipment and the procedures involved in the measurement of the properties of the deposits are described under each property.

Effect of Plating Variables on the Rate of Deposition and Appearance of Deposit

Ratio of reactants.—The reaction involved in the deposition of tungsten from the hexafluoride is

$$WF_6 + 3H_2 \rightarrow W + 6HF$$

Although the stoichiometric ratio of the reactants is three volumes of hydrogen to one of tungsten hexafluoride, this ratio did not give the optimum results at all temperatures. To a first approximation, at a given temperature, the rate of deposition appeared to depend upon the concentration of tungsten hexafluoride in the gas. For example, at 800°C a faster rate of deposition was obtained with a ratio of hydrogen to tungsten hexafluoride of 1.5 than with 3.0, as shown in Fig. 2. Over the lower part of the temperature range, there was little difference in rate between the ratios, as the curves for the latter seem to branch from a common trunk. Figure 3 gives the data of Fig. 2 in a different form. It shows that at 500°C the rate is not affected by the ratio of reactants. The rates of deposi-

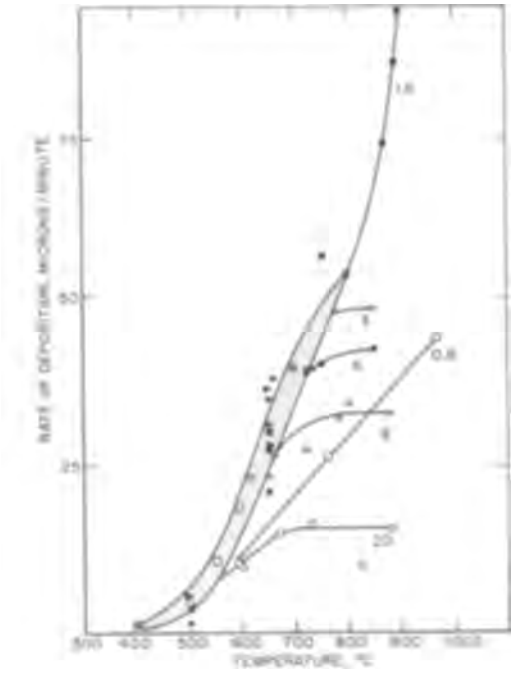

Fig. 2. Rate of deposition of tungsten from various gas compositions at 1 atm. The number on a curve represents: (Partial pressure of H_2)/(Partial pressure of WF_6). The shaded area indicates (a) that the curves run together at lower temperatures and (b) that the relation between thickness and temperature is not reproducible enough to be represented by a line.

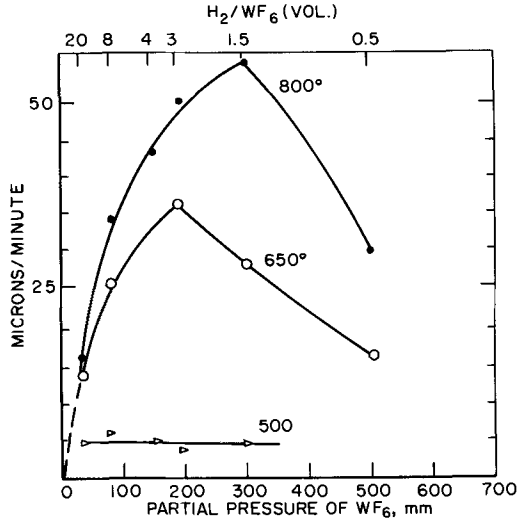

Fig. 3. Rate of deposition of tungsten as a function of the concentration of WF_6.

tion shown in Fig. 2 are to be considered as illustrative only, inasmuch as the rate varies with the size and shape of a specimen and on the period of time that the deposition is allowed to proceed.

Pressure of gas.—Figure 4 shows that the rate of deposition increases with the total pressure of the mixed reactants. There appeared to be no advantage in operating the process at a pressure lower than atmospheric. In this respect the process differs from most other vapor deposition processes, which usually operate at less than atmospheric pressure, often with the addition of a diluent gas.

Miller and Barnett (14-16) deposited tungsten at a pressure of only about 10^{-3} Torr for the purpose of obtaining thin deposits in the range of 1000Å in thickness. Deposition was very slow, about 300Å/hr. This result is in accord with the trend in Fig. 4.

We made a few experiments in a bomb at pressures up to 170 atm to determine if this made possible the deposition of tungsten at a lower temperature. The lowest temperature at which deposition occurred was 300°C. At 400°C the reduction of tungsten hexafluoride to metal was about 90% complete. In some of these experiments a higher than stoichiometric ratio of hydrogen to tungsten hexafluoride was used in the expectation of obtaining tungsten fluorides in which the metal had a lower valence than 6, but no such compounds were observed. However, Golovanov and coworkers (17) obtained brightly colored di-, tetra-, and pentafluorides of tungsten at a temperature of 275°C.

Temperature.—As already mentioned, deposition of tungsten can take place at a temperature of 300°C, but the rate is too low for the process to be practicable. This confirms the observations of Golovanov *et al.*, who reported metal deposition at 300°C but not at 275°C.

Figure 2 shows that the rate of deposition increases rapidly with temperature. The lowest temperature at which deposition proceeded at a practicable rate was 500°C.

Heestand *et al.* (17A) also reported a considerable increase in rate of deposition with temperature. They operated the process at a lower concentration of WF_6 ($H_2/WF_6 = 70$ or 140 at 10 or 20 Torr) than we did and, consequently, their rates of deposition ranged from 1/10 to 1/100 of those which we give in Fig. 2. Another reason for the difference is that they deposited the tungsten in a heated tube, under which conditions the composition of the gaseous mixture varied along the tube.

The appearance of the deposits varied considerably with plating conditions, especially with temperature. Also, the deposits grew rougher with increasing thickness. Figure 5 shows representative surfaces obtained on the substrate of nickel tubing mentioned earlier. For ratios of Vol. H_2/Vol. WF_6 greater than 3 the deposits became increasingly dendritic as the temperature rose above 650°C. At a temperature above 1000°C the deposits were masses of crystals or dendrites, not a coherent coating. However, at a ratio of 0.5 the deposits were as smooth at 950°C as the deposits obtained at a ratio of 3 at 650°C. We cannot indorse Hoertel's view (17B) that the rate of deposition must be less than 2 mils (50μ) per hour (at an $H_2/WF_6 = 4$ and a temperature of 550°C to 600°C) to obtain a smooth deposit.

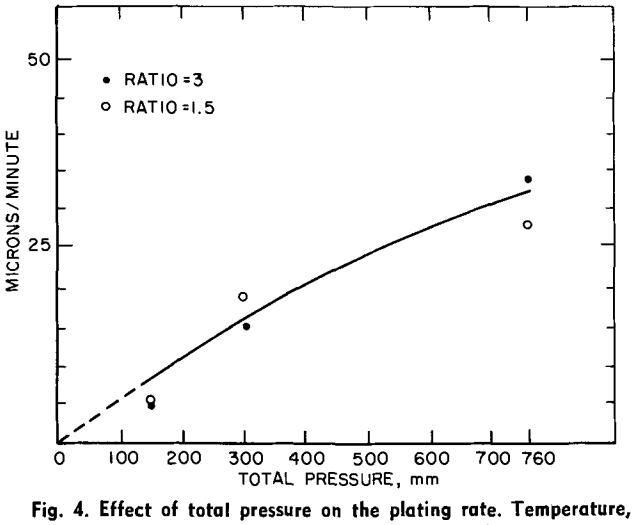

Fig. 4. Effect of total pressure on the plating rate. Temperature, constant at 650°C. Ratio = Partial pressure of H_2/Partial pressure of WF_6.

The possibility of finding gaseous compounds which added to the reacting gases will prevent the formation of dendrites and yet permit rapid deposition of thick coatings at the elevated temperatures is touched on below.

Agitation.—Qualitatively, we noted that a rapid flow of the reacting gases over a specimen increased the rate of deposition. A few experiments were made in our static system with the nickel tube rotating a few hundred revolutions per minute. The results were not very reproducible, but indicated an increase in the rate of deposition of 20-50%. Also, it resulted in smoother coatings at elevated temperatures.

Effect of oxygen, hydrogen fluoride, and hydrogen chloride on the rate of deposition.—In depositing tungsten from the static reacting gases, we noted that the rate of deposition decreased gradually, until about half or more of the available tungsten had been deposited. At this point sometimes the deposition ceased to occur on a fresh nickel tube. A low rate could be obtained at a higher temperature, or by depositing on a tungsten instead of a nickel substrate.

This decrease in the rate of deposition indicated that hydrogen fluoride was probably responsible, since there was still a substantial concentration of tungsten hexafluoride in the gas. This idea was confirmed by adding hydrogen fluoride directly to a chamber of unreacted hydrogen and tungsten hexafluoride. A concentration of hydrogen fluoride equal to about 25% of the volume of the reacting gases was sufficient to inhibit deposition of tungsten. The concentration at which the cut-off of deposition occurred was not ascertained. The effect of hydrogen fluoride on the deposition is important, because its inhibiting effect must be taken into consideration in any explanation of the mechanism of deposition. It is likely that the increased rate of deposition resulting from an increase in the rate of flow of gas or from agitation of the substrate may result as much from the removal of hydrogen fluoride as to the replenishment of the reacting gases at the surface of the substrate.

Concentrations of oxygen up to about 0.5% of the volume of reacting gases did not seem to have an appreciable effect on the rate of deposition or on the appearance, including microstructure, of the deposit. This was fortunate as it indicated that the reaction chamber did not have to be subjected to a high vacuum before admitting the reacting gases.

The effect of hydrogen chloride on the plating process was qualitatively determined. A concentration of one percent by volume reduced the rate of deposition by more than 50% and caused a finer microstructure (see Fig. 5 and 8).

Mechanical Properties of Deposits

Hardness.—The hardness measurements were made with a Knoop indenter on polished cross section of the deposits. The hardnesses of smooth deposits ranged between 600 and 1100 Knoop (see Table I). The latter hardness was that of a deposit produced at 500°C. The hardness of a dendrite of tungsten deposited at 900°C was 410 VHN.

Mills and co-workers (18) measured the Diamond Pyramid Hardness of tungsten tubes with a 100g load and obtained values ranging between 350 and 450 VHN.

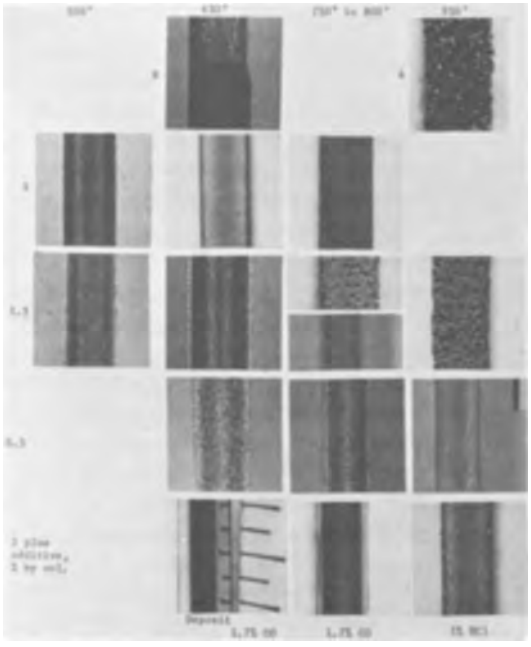

Fig. 5. Surface view of vapor deposited tungsten. Number refers to ratio vol. H_2/vol. WF_6. Magnification ca. 1½X.

They found no difference in the hardness of tubes obtained by vapor deposition and those prepared by extrusion at temperatures of 1200° and 1800°C. Basche (13) gave data on the hardness of various kinds of tungsten after annealing to temperatures between 800° and 2800°C. The range of hardnesses was about the same as reported by Mills and co-workers, but their vapor deposited tungsten was a little softer than sintered and wrought tungsten. Hoertel (17B) obtained Knoop hardness numbers between 400 and 500 (with a 100g load) on tungsten deposited between 500° and 600°C.

Tensile strength.—The specimens used for the measurement of tensile strength were similar to those employed in a study of the properties of chromium deposits (19). Tungsten tubes, formed as described above, about 1 in. long, of uniform wall thickness, were cemented by epoxy resin into two cylindrical metal fittings, one at each end. A 4 or 5 mm band of tungsten was left exposed. In some tests a 2 mm wide band of this exposed tungsten was anodically etched to form a necked-down section (about 20%) to induce breaking in this area. However, not all of the samples broke precisely within the etched zone. A few broke on a diagonal crossing both etched and unetched portions. Two samples broke in the unetched zone. The measurements in Table I are based on the cross-sectional area measured at the break. The strength of samples that were unetched, even though the break occurred near the fitting, agreed very well with that of the etched samples, indicating that the etching was not necessary.

The tensile strengths averaged about 30,000 lb/in.^{2} with no clear trend with conditions of deposition. The tungsten specimens heat treated at various temperatures showed a small increase in tensile strength.

Stress.—The magnitude of the stress in tungsten deposits is important since, if too high, it could prevent the fabrication of tungsten articles by plating on a master. We had determined that heat-treatment of vapor-deposited tungsten at temperatures above 900°C relieved stress, and, therefore, it would not be expected to occur in deposits produced at or above that temperature.

The measurement of the stress was done by the well-known method of depositing a metal on one side of a thin metallic substrate and measuring the resulting change of curvature. The tungsten was deposited at an elevated temperature, but the measurement of the change in curvature was done at room temperature. Hence, the use of a substrate of any other metal than tungsten would have introduced a curvature resulting from differential thermal expansion. The substrates for the test specimens were, therefore, prepared from tungsten itself.

The first step in preparing the specimen was the production of a tube of tungsten by vapor deposition. Tungsten up to a thickness of 5-10 mils (125-250μ) was deposited upon a nickel tube about 0.75 in. (2.0 cm) in

diameter and a few inches long. The tube was cut into rings about 0.5 in. (1.0 cm) wide and the wall was slit at one place in a direction parallel to the axis of the tube. The nickel substrate was then dissolved. The bands were annealed at 800°C or above in an inert atmosphere to relieve stress. In making a determination of stress, the tungsten band was placed on a graphite fixture [for figure, see (20)], so as to allow tungsten to deposit only on the outside surface of the band. A tensile stress in the tungsten deposit caused the slit to become wider. The change in the curvature of the band that resulted from the plating operation was determined by measuring the change in the width of the slit wtih a microscope before and after tungsten deposition. Since the changes were small the change in the width of the slit could be considered as equal to the change in the circumference, ΔC, of the band.

The temperature at which the deposits for stress measurement were produced was not definite, because the band and the graphite fixture required from 10 to 30 sec to come up to temperature or to cool down. Since the period of deposition at the desired temperature was only a minute or two, a fair proportion of the deposit was produced at intermediate temperatures. Thus, the stress must be considered as relating to a range of temperature rather than to a single temperature.

Physical Properties

Density.—The density of tungsten tubes, prepared as noted above was determined by the method of loss of weight on immersion in water. The densities (see Table I) varied from 19.02 to 19.23 g/cm^3 at 25°C. The value for tungsten is given in the literature as 19.3 g/cm^3 (21) (from x-ray data).

Electrical resistivity.—The electrical resistivity of tungsten was determined using tubes of uniform cross section, prepared as described above. The uniformity was checked by examining the contour of the tubes in a shadow-graph. The specimens were suspended in an oil bath maintained at room temperature.

The measurements were made by passing a current of known strength through the tube and measuring the voltage across a 1-cm length. The resistance, R, was then calculated. The resistivity, ρ, in ohm-cm is given by the equation

$$\rho = \frac{Rg}{19.2\,LD}$$

where R is the resistance of sample, ohms, g the weight of sample, g, L the length of sample, cm, and D the distance between voltage contacts, cm.

The average value of the electrical resistivity (see Table I) was 5.3 microhm-cm. This value is approximately the same as that given in the literature for commercial tungsten, which is 5.6 microhm-cm (21).

Structure of Deposits

All of the deposits obtained by vapor deposition from the simple gas mixture were columnar, and the cross section looked very much like that of electrodeposits from an acid copper bath or a Watt's nickel bath (20). Some of the deposits were fine-grained like the deposit from a nickel chloride bath (see Fig. 6).

The presence of carbon monoxide in the reacting gases produced a hard deposit containing tungsten carbide which was laminated (to be discussed later). Some exploratory experiments with several other additives to the reacting gases, for example, $TiCl_4$, MoF_6, BF_3, $GeCl_4$, $ReCl_5$ yielded deposits with slightly smaller grain structure. The addition of MoF_6 caused a laminated structure. The addition of $SiCl_4$ reduced the efficiency of the process and caused larger crystals. No analyses on the deposit were performed. NH_3 and H_2S, possible reducing agents, reacted with the WF_6.

There is a good possibility that suitable additives can be found which will reduce the tendency of the deposit to become nodular or dendritic at high temperature (see Fig. 8.) If this can be achieved, then deposits of tungsten 2 mm thick could be built up in an hour. There is some indication of this in experiments conducted with jets of reacting gases, for example, WF_6, impinging on a substrate in an atmosphere of hydrogen. In this circumstance a button of tungsten can be quickly built up in the region where the jet of WF_6 strikes.

Fig. 6. Microstructure of vapor deposited tungsten. The ratio = vol. H_2/vol. WF_6.

X-ray examinations of a few deposits indicated growth essentially only in the [100] direction, radially from the center of the rods. The temperature of deposition was from 500° to 800°C (see Table I). The geometry of the tungsten tubing limited our results to qualitative interpretation. McMurray and co-workers (22) had already reported that a preferred orientation of the deposits occurred with the (100) or the (111) planes parallel to the substrate. They found indications that the vapor-deposited tungsten would yield a surface of more uniform electron emission than a randomly oriented tungsten surface.

Supplemental Observations

Yield of tungsten from WF_6.—Since tungsten in the form of hexafluoride is expensive, a high yield of metal from the compound is important. In experiments in which the mixed gases with an adequate ratio of hydrogen were passed through a long, hot tube, almost all of the compound was reduced to metal. In the experiments (at 650°C) in which the reacting gases passed through a short heated section, for example, in deposition on a rocket nozzle, or over objects suspended in the gas stream, the deposition was only about 50% efficient. In the experiments with the static reactants, the rate of deposition on the tubular nickel substrates became very low when about one-half of the tungsten had been deposited out of the gas.

Reversibility of the reaction.—We made an experiment to determine if the tungsten deposit was attacked by HF. The effect of HF on tungsten in the absence of WF_6 was noted by heating vapor-deposited tungsten in commercial anhydrous HF (purity 99.9% min.) at 1 atm pressure. A slight weight-loss occurred amounting to 1 mg/cm^2 (0.5μ thickness) at 750°C and 4 mg/cm^2 (2μ thickness) at 1000°C in 10 min. Since the concentration of HF in the reacting gases during

tungsten deposition is much less than 1 atm it is not likely that the reaction reverses during the plating operation.

Uniformity of thickness of tungsten deposits.—In deposition from the vapor phase, the problem of metal distribution is smilar to that which occurs in electrodeposition. A thicker deposit occurs on edges and corners of a substrate and also on the windward side of a specimen placed in a flowing stream of reacting gases (20). More uniform distribution of the coating over an irregularly shaped object can be obtained by suspending the latter in an atmosphere of hydrogen and leading the WF_6 to the vicinity of concave or internal surfaces by means of small tubes.

The distribution of tungsten that occurs when the mixed gases flow through a heated tube has some special features that have not been explained. This matter is important because it will have a bearing on the elucidation of the mechanism of the reaction. In our experiment a copper-plated steel tube about 2.5 cm in diameter and 40 cm long was heated in a tube furnace. The hydrogen and tungsten hexafluoride were passed through individual injectors (about 0.5 cm diameter) which were placed inside the steel tube and extended to its center. The gases were thus heated up to temperature before they mingled at the center of the steel tube. The latter also contained a partition at the center to prevent the gases from flowing to the front end of the tube. In this experiment the maximum thickness of deposit (see Fig. 7) was obtained about 6 cm from the point where the gases mixed. Spacil and Wulff (23) first noticed this peculiar type of distribution in the deposition of molybdenum by the passage of molybdenum pentachloride vapor and hydrogen through a heated tube.

Heestand *et al.* (17A) also observed the maximum thickness of tungsten in a tube for deposition between 500° and 700°C. They explained this as owing to the time required for the mixture of gases to come up to temperature after entering the heated tube. However, this explanation is not valid in the light of our experiment in which the gases were preheated before mixing in the center of the hot zone.

Another peculiarity of the metal distribution was that the deposit was of nonuniform thickness circumferentially at the center of the steel tube where the gases mingled. The deposit in the 6 o'clock position was considerably thicker than in the 12 o'clock position. This result suggests that in our experiment the odd distribution might have been caused by a lack of mixing of the gases at the point where they issued from their individual tubes. To settle this point, it would be necessary to perform another experiment in which a rotating propeller is placed at the point where the gases emerged.

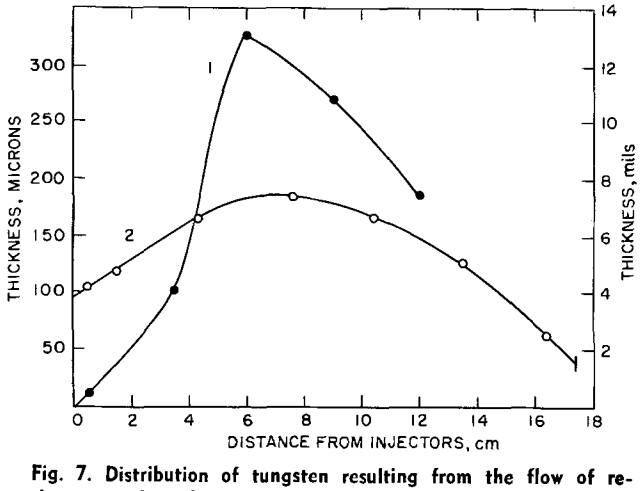

Fig. 7. Distribution of tungsten resulting from the flow of reacting gases through a heated tube. Curve 1, 640° to 670°C; curve 2, 670° ± 5°C.

The addition of HF to the reacting gases (in the proportions by volume, $HF/H_2/WF_6$ = 1.7/1.5/0.5) caused the maximum to be less pronounced, as shown in Fig. 7, curve 2, and also made the circumferential metal distribution more uniform. However, the yield of tungsten (based on amount of WF_6) was only about 40% in the presence of HF as compared with almost 100% in its absence.

Adhesion.—The adhesion of the coating was satisfactory to nickel, copper, molybdenum, graphite, and to some ceramics. Adhesion to steel was not adequate, probably because the surface of the latter was attacked before deposition began. This explanation is similar to that given by Wlodek and Wulff (24) to explain the problem with adhesion encountered in the vapor phase deposition of molybdenum from the pentachloride.

Codeposition of carbon.—Addition of carbon monoxide to the reacting gases resulted in the codeposition of carbon with tungsten. In these experiments the ratio of hydrogen to tungsten hexafluoride was 3.0. From a reaction mixture containing 1.7% CO by volume, at 650° and 750°C, smooth bright deposits were obtained (see Fig. 5). The deposit obtained at 850°C was rough. The rate of deposition in the presence of carbon monoxide was less than half that in the simple gas mixture, as shown in Fig. 9. Tungsten deposited from a gas mixture containing 5.2% CO by volume was smooth but not bright.

Table I shows the hardness and carbon content of the deposits. The high hardness of the deposit is of technologic interest. It scratches glass with ease. The carbon contents of about 2.4% indicate that this deposit must consist of more than 75% tungsten carbide, W_2C. The microstructure of representative deposits, as shown in Fig. 8, had distinct laminations.

Some of the thin carbide deposits seemed very weak, because they broke into fragments when the nickel substrate was dissolved, although deposits about 1 mm thick remained intact. The friability of the thin deposits may be enhanced by the differential thermal expansion between the nickel substrate and the deposit on cooling.

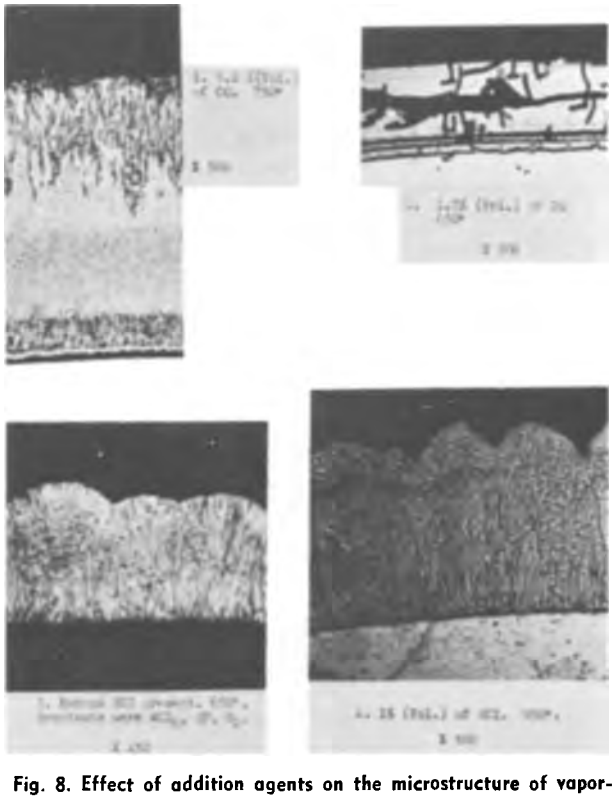

Fig. 8. Effect of addition agents on the microstructure of vapor-deposited tungsten.

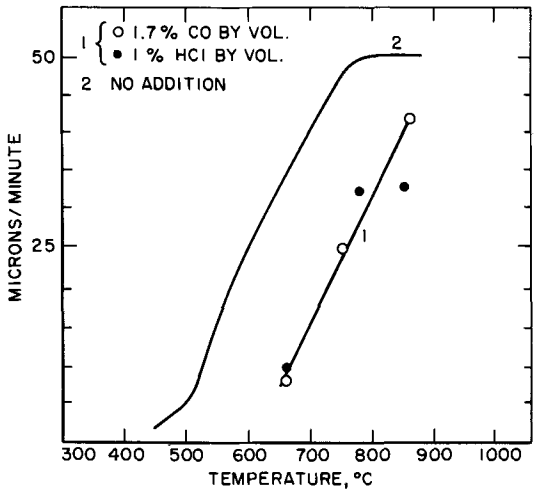

Fig. 9. Effect of separate additions of carbon monoxide and hydrogen chloride on the rate of deposition of tungsten from a mixture of 3 volumes of hydrogen and one of WF_6. Curve 2 was taken from Fig. 2.

Hoertel (17B) found that the grain size of tungsten was reduced by introducing butane, propane, or carbon dioxide into the reacting gases. The deposit obtained with butane (2% by volume) contained about 0.05% carbon; that obtained with propane (4% by volume) contained 0.04% carbon; and that obtained with carbon dioxide (24% by volume) contained 0.02% carbon. The Knoop hardness numbers of these deposits were, respectively; 1315, 1050, and 1220.

Summary of New Phenomena Observed

Any explanation of the mechanism of the reaction must take into consideration the following new phenomena which we observed in this investigation:

1. Inhibiting effect of the product HF and of HCl on the reaction.
2. Nonreversibility of the reaction (tungsten with HF).
3. Maximum in the distribution of tungsten in a heated tube.
4. Occurrence of the maximum rate of reaction of 800°C at a nonstoichiometric composition of the gas ($H_2/WF_6 = 1.5$), and at 500°C the lack of dependence of rate on composition.

Acknowledgment

The authors wish to acknowledge the support of the Special Project Office of the Department of the Navy, under whose sponsorship the initial work was done between 1958 and 1962 that led to our development of the tungsten hexafluoride process for depositing tungsten. They wish to thank the Materials Laboratory of the Wright-Patterson Air Force Base for continuing to support the project from 1963 to 1965, during which time they further investigated the process and measured some of the properties of the deposits, as reported in this publication.

Manuscript received July 29, 1966; revised manuscript received Feb. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX I

Purity

A study of the purity of vapor-deposited tungsten was not included in our program, as this phase of the subject had been extensively investigated by Nieberlein and Kenworthy (7) and Hoertel (25), all of the Bureau of Mines. Data have also been published by Mills and co-workers (18) and Taylor and Boon (26). The data from these various sources showed that vapor-deposited tungsten was purer than commercial tungsten used for powder metallurgy, having less than 0.01% total impurities, although some of the specimens had only about 60 ppm of impurities. Table II gives some typical analyses of vapor-deposited tungsten in comparison with other kinds. The large amounts of nickel or iron found in some samples probably came from the substrate upon which the tungsten was deposited. The analysis of a sample of tungsten which we had deposited was included in the report of Mills *et al.* (18). The purity fell within the limits shown for vapor-deposited tungsten in the table.

APPENDIX II

Process of Deposition Utilizing Tungsten Hexachloride as Intermediate

The deposition of tungsten from the hexafluoride is expensive because of the cost of the compound.

Since tungsten hexachloride is less expensive than the hexafluoride, a process utilizing the former would be economically advantageous. The direct use of the hexachloride in the deposition process, however, has some drawbacks, as noted earlier.

The reaction of tungsten hexachloride with hydrogen fluoride

$$WCl_6 + 6HF \rightarrow WF_6 + 6HCl$$

to produce the hexafluoride was first investigated by Ruff *et al.* (27). They mixed about a three-fold excess of liquid HF with WCl_6 and after the reaction, had some difficulty in separating the last traces of HF, which boils at about the same temperatures as WF_6. We found that passage of the gaseous HF through a tube or vessel filled with a large excess of WCl_6 resulted in the reaction of most of the HF, and the gases emanating from the reaction vessel could be directly lead into the reaction chamber and used for the deposition of tungsten. However, because of the presence of much HCl, the reaction was much slower than with the uncontaminated reactants.

The method of operating the reaction was as follows: The hexachloride was placed in a polyethylene bottle or tube which was warmed to about 50° to 70°C and the HF passed through. An endothermic reaction took place, and the vessel became perceptibly cooler. Although tungsten deposition was accomplished directly from the effluent gases, which contain WF_6 and HCl, the deposition would have proceeded faster if the HCl had been removed. Plans for this were made but not carried out. The separation of WF_6 and HCl could easily be made by passing the gases through a cool chamber in which the WF_6 would liquify and be drawn off while the gaseous HCl was allowed to escape.

In one experiment we utilized the above reaction for removing HF from the gases of our static reaction chamber. During a plating run the gases were continually circulated through a bottle of WCl_6 and back into the reaction vessel. No particular benefit accrued since the HCl was not removed from the system.

Absorption of Electrolytic Hydrogen by Nickel and Iron-Nickel Alloys

Thomas C. Franklin and P. E. Hudson[1]

Chemistry Department, Baylor University, Waco, Texas

ABSTRACT

A study was made of the absorption of electrolytically generated hydrogen by nickel and iron-nickel alloys. It was shown that the experimental rate law for the absorption of hydrogen is

$$\text{Rate of Absorption} = k[H_{ads}] + I$$

By controlling the current density it was possible to obtain experimental conditions such that the rate law agreed with the following mechanism

$$H_{ads} \rightarrow H_{abs}$$

It was shown that the primary cause for changes in the rate of absorption of hydrogen on alloying iron with nickel is changes in the amount of adsorbed hydrogen.

In conjunction with a series of correlation studies on the effect of hydrogen on different processes at solid metal electrodes and the effect of additives on these processes (1-4), a study was made of the effect of additives in solution on the rate of absorption of hydrogen into nickel wire, electrodeposited nickel, and electrodeposited iron-nickel alloy electrodes.

In earlier studies, Schuldiner and Hoare (5) found no penetration of hydrogen through palladized nickel plates or foils. In a later study, Szklarska-Smialowska and Smialowski (6) reported the formation of nickel hydride phase ($NiH_{0.7}$) when nickel was cathodically charged under appropriate conditions. In a study involving the oxidation processes at nickel electrodes, Weininger and Breiter (7) postulated that there were two forms of hydrogen sorbed at the nickel electrode. Devanathan and Selvaratnam (8) quantitatively determined the fractional coverage of the nickel electrode by hydrogen atoms. They assumed that only one hydrogen species was present and that this was the electrochemically active one.

In the present investigation emphasis was placed on the effect of solution additives, changes of hydrogen generating current density, and alloying on the rate of absorption of hydrogen.

[1] Present address: TRACOR, Inc., Austin, Texas.

Experimental

The electrodes were prepared by sealing varying lengths (2-30 cm) of the sample in Teflon spaghetti. The nickel wire electrodes were mechanically polished with emery cloth, degreased in acetone, washed with distilled water, then redistilled water, and placed in the cell for study.

The nickel plated electrodes were prepared by plating nickel wires prepared as above for a definite length of time at a known current density. The plating station was a constant current coulometer (9, 10) with a milliammeter and timer placed in the circuit. After plating, the samples were rinsed with redistilled water and placed in the cell for study.

The plating bath was of the Watts type and contained 240g of hydrated nickel sulfate ($NiSO_4 \cdot 6H_2O$), 45g of hydrated nickel chloride ($NiCl_2 \cdot 6H_2O$), and 30g of boric acid in one liter of solution. After dissolving the components, nickel carbonate was added to raise the pH. The solution was filtered and the pH lowered to 4.0 by adding dilute sulfuric acid (11).

The electrodes to be plated with iron-nickel alloys were nickel wires pretreated as previously described. The iron-nickel alloys were plated using a mixture containing different amounts of the Watts-type bath previously described and an iron sulfate bath (12). The relative composition of the alloys was determined by use of a General Electric Model XRD-5 X-ray Spectrometer.

The coulometric techniques previously used (1-4) in studies of hydrogen at solid electrodes were used in this study. Hydrogen was generated on the electrodes for varying lengths of time at at constant current density and for varying current densities at constant times by connecting the cell to a power supply. The cell was then connected to the polarograph, and the hydrogen was electrolytically oxidized. The nonpolarizable electrode was a large platinum gauze electrode. The solution was 2N sodium hydroxide.

In the experiments on the effect of additives, measured amounts of a solution of the additive in 2*N* sodium hydroxide were added to the bath. Hydrogen was then generated on the electrode electrolytically, and the hydrogen on the surface was analyzed coulometrically.

In all cases the reagents were the purest available commercially. The temperature of the cell was maintained at 25° ± 0.1°C.

A diagram of the apparatus is shown in Fig. 1.

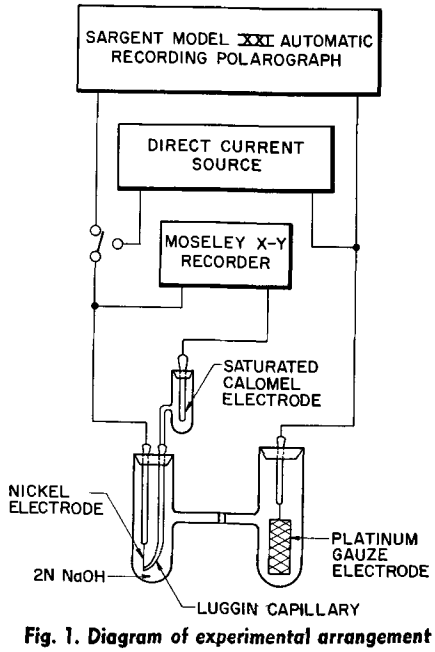

Fig. 1. Diagram of experimental arrangement

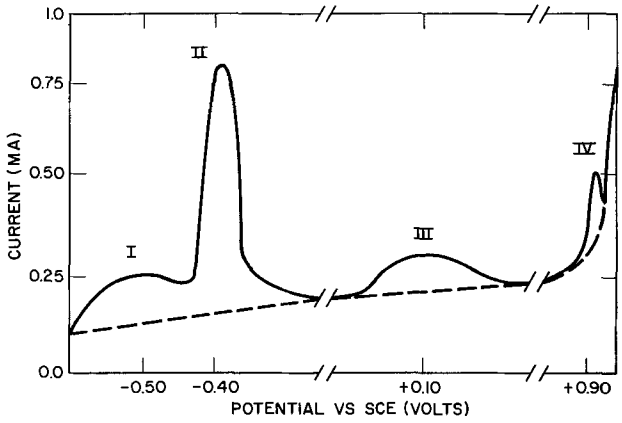

Fig. 2. Current-voltage curve for the oxidation processes at the nickel wire or electrodeposited nickel electrode.

Data and Discussion of Results

Effect of additives on the rate of penetration of hydrogen.—The general appearance of the current voltage curves for the oxidation processes at the nickel or plated nickel electrodes in 2*N* sodium hydroxide solution is shown in Fig. 2. As can be seen, four maxima appear in the curve, indicating that there are four oxidation processes, differing in potential, occurring at the electrode.

In 2*N* NaOH average values for the potentials at maxima I, II, III, and IV were —0.50, —0.40, +0.10, and about +0.91v, respectively, measured against a saturated calomel electrode (SCE).

Weininger and Breiter (7) proposed that the oxides of nickel are formed by the following mechanisms:

$$(a)\ Ni + OH^- = NiOH + e^-$$

$$(b)\ NiOH + OH^- = Ni(OH)_2 + e^-$$

$$(c)\ Ni(OH)_2 + OH^- = NiO(OH) + H_2O + e^-$$

Electrodes of varying length were prepared and the number of coulombs required for the formation of maxima III and IV determined. The results in Table I show that maxima III and IV required essentially the same number of coulombs for formation. From the comparison of the potentials and the number of coulombs involved with the data of Weininger and Breiter, it can be concluded that maxima III and IV can be identified as being caused by the formation of $Ni(OH)_2$ (III) and NiO(OH) (IV). Since, in the scheme of Weininger and Breiter, there should be a third peak due to the formation of NiOH, this maximum must coincide with maximum II of Fig. 2. It is evident that maximum II is much larger than either maximum III or IV, and thus it is apparent that the formation of NiOH is accompanied by another anodic process. This accompanying process is probably the oxidation of one form of hydrogen, since this is the accepted region of hydrogen oxidation. Maximum I in Fig. 2, which is at the most negative potential, is caused by the oxidation of another form of hydrogen.

In summary, the maxima in Fig. 2 may be described as being caused by: (*a*) the oxidation of one form of hydrogen; (*b*) the oxidation of a second form of hydrogen and the formation of NiOH; (c) the formation of $Ni(OH)_2$; and (*d*) the formation of NiO(OH).

Since the main concern of this work was the in-

Table I. Comparative area of maxima III and IV

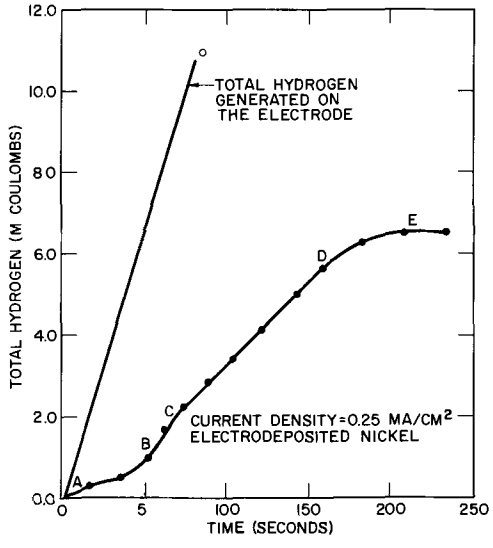

Fig. 4. Effect of time of generation on total hydrogen at the electrode.

vestigation of the hydrogen maxima, a correction due to the overlap of hydrogen oxidation and formation of NiOH was applied to all calculations and determinations involving the second form of hydrogen.

Figure 3 is a typical current-voltage curve in the hydrogen region for the oxidation of a nickel wire or electrodeposited nickel electrode on which hydrogen has been electrolytically generated. The existence of various forms of hydrogen on platinum has been shown by a number of workers (2, 13-17) and on iron by Matsuda and Franklin (4). The potentials of the two maxima were compared with the potentials observed by Matsuda in experiments run under identical conditions. The potentials of both the first and second peaks on nickel agreed within experimental error with potentials obtained by Matsuda for the oxidation of hydrogen sorbed on iron. In agreement with Matsuda, peak I has been attributed to the oxidation of adsorbed hydrogen and peak II to the oxidation of absorbed hydrogen.

The area under I can then be taken as the number of coulombs needed to oxidize adsorbed hydrogen while the area under II minus the area under peak IV can be taken as the number of coulombs needed to oxidize hydrogen in the interior of the metal. This is possible since the area under peak IV corresponds to the coulombs needed to convert $Ni(OH)_2$ to NiOOH. This corresponds to one electron for each surface nickel atom. This is the same number of coulombs that was needed to convert the nickel to NiOH. Since peak II is caused by both the oxidation of absorbed hydrogen and the formation of NiOH, this many coulombs must be subtracted.

Figure 4 shows the variations of the total area under the maxima with charging time. A similar curve was obtained with variations in current density holding the generating time constant. Examination was made of these curves along with an examination of the original current-voltage curves and a visual examination of the electrode during the charging process. These indicated that up to the region of point B, no hydrogen was visibly desorbed and in the preponderance of cases studied, only the first maximum was found on the current-voltage curves. Therefore, it was concluded that in this region the charging current was being used to reduce oxides and form adsorbed hydrogen. In the next region, BC, hydrogen begins to absorb in the nickel as shown by the formation of the second peak and in the straight line portion, CD, a steady state is reached in which hydrogen is desorbing and absorbing as fast as it is generated. This steady state was shown in that the first peak stopped growing and only the second peak increased in this region. Therefore, the major process occurring in the straight line portion, CD, other than desorption of hydrogen from the surface of the electrode, was the absorption of hydrogen by the nickel.

From these observations it was concluded that the slope of CD was a measure of the rate of absorption of hydrogen by nickel from a surface with a constant steady-state amount of adsorbed hydrogen on the surface.

The curves described above were observed for both electrodeposited nickel and nickel wire electrodes.

Figures 5 and 6 show typical families of curves obtained when 2,7-naphthalenedisulfonate ion was used as an additive and when the length was varied. Similar curves were obtained with different current densities and different additives. At low charging current densities, there was a decrease in the rate of absorption (the slope of CD) at low concentrations of the disulfonate ion, but at higher concentrations the slope increased.

At high charging current densities, there was a regular decrease in the slope with increasing concentration of the disulfonate ion. Figure 7 shows plots of the rate of absorption (the slope of CD) compared to the amount of adsorbed hydrogen. Curve A in Fig. 7 shows results obtained with different nickel electrodes. The area was varied by varying the length of wire and plating time. Some of these points are from unplated nickel and others from plated nickel.

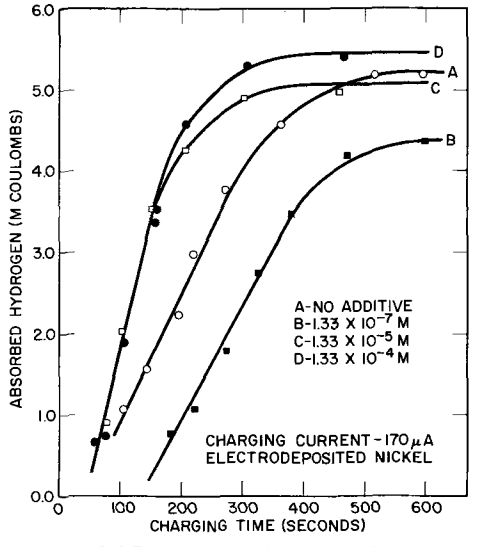

Fig. 5. Effect of 2,7-naphthalenedisulfonate ion on amount absorbed hydrogen.

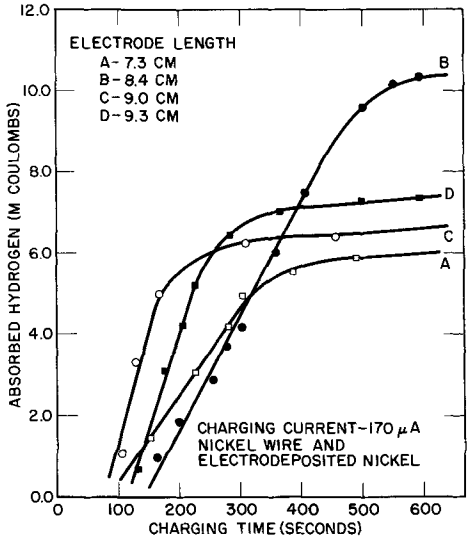

Fig. 6. Effect of surface area on amount of absorbed hydrogen.

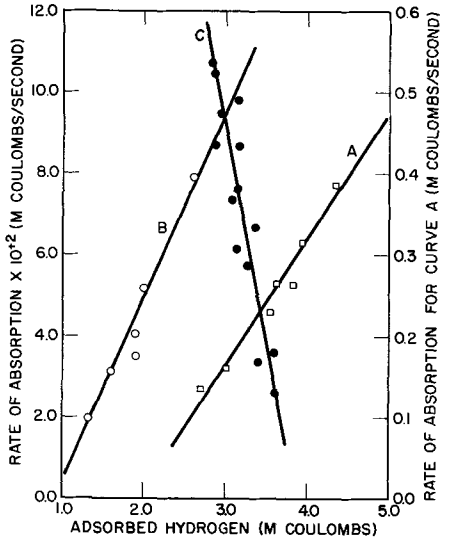

Fig. 7. Variation of rate of absorption with area under first maximum: curve A, no additive and charging current of 170μa; curve B, disodium 2,7-naphthalenedisulfonate and charging current of 1.6 ma; curve C, disodium 2,7-naphthalenedisulfonate and charging current of 170 μa.

It is apparent from these curves that the rate of absorption of hydrogen is directly proportional to the amount of adsorbed hydrogen. In the experiments performed at different charging current densities, both with and without additives, the following equation is followed

$$\text{Rate of Absorption} = k[H_{ads}] + I$$

Both the intercept I and k are influenced by changes in current density and by the presence of an additive. With any one current density and additive, k and I were constants.

This kinetic equation is indicative of a complex mechanism. The first term, however, is the expected rate law for the usually expected mechanism of absorption:

Mechanism: $H_{ads} \rightarrow H_{abs}$ (A)

Rate law: $\text{Rate of Absorption} = k[H_{ads}]$ (I)

Effect of Alloying on the Rate of Penetration of Hydrogen

In order to study the alloy systems, a generation current (1.6 ma) was selected that gave an intercept close to zero. It was assumed that since the rate law under these conditions was identical to the rate law in Eq. (I), the secondary effects were negligible and the primary mechanism of absorption was given in Eq. (A).

Table II. Composition of the iron-nickel alloys

Alloy #B	% Iron	% Nickel
1	78.0	22.0
2	73.0	27.0
3	66.0	34.0
4	51.0	49.0
5	30.0	70.0

The composition of the iron-nickel alloys prepared is shown in Table II. By using data similar to that in Fig. 5 and 6, one obtains Fig. 8 and 9, which show the rate of penetration for the various alloys. As before a straight-line relationship exists. Correcting the slopes of these lines by compensating for their varying lengths and radii, one can obtain the plot shown in Fig. 10, which shows the rate constant as a function of al-

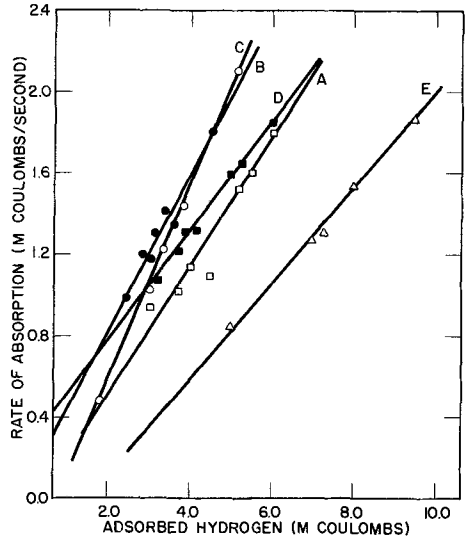

Fig. 8. Variation of rate of absorption with area under first maximum: disodium 2,7-naphthalenedisulfonate and charging current of 1.6 ma. Curve A, alloy No. 1; curve B, alloy No. 2; curve C, alloy No. 3; curve D, alloy No. 4; curve E, electrodeposited iron.

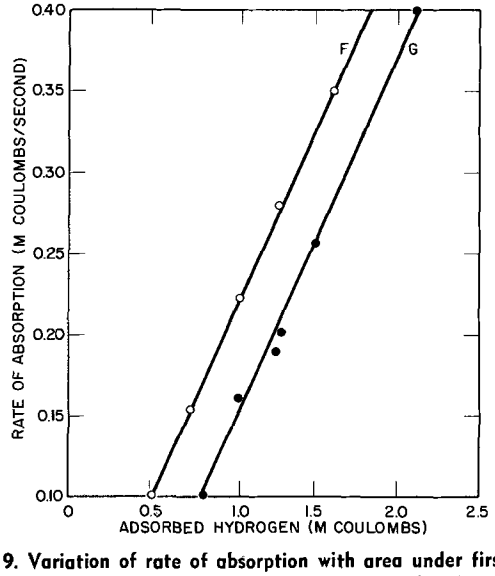

Fig. 9. Variation of rate of absorption with area under first maximum: disodium 2,7-naphthalenedisulfonate and charging current of 1.6 ma. Curve F, alloy No. 5; curve G, electrodeposited nickel.

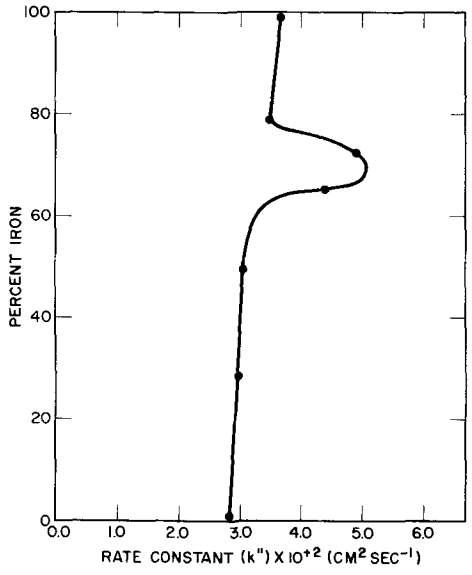

Fig. 10. Variation of rate constant with alloy composition

loy composition. There is a general decrease in the rate constant as the amount of iron in the alloy decreases except in the region between 65 to 75% iron. In this region, McKeehan (20) observed a change in crystal structure and noted a possible coexistence of the two structures and that either arrangement was on the verge on instability. It is of interest to note that on a plot of electrical resistance (of iron-nickel alloys) *vs.* percentage alloying element, there is a maximum in the curve at 30% nickel. This and several other anomalies in this region are ascribed to the fact that the iron-nickel alloys may be either ferrite, austenite, or both (21). An explanation for this increase in rate of penetration is that there are more grain boundaries in this region, and this presents an ease of penetration along these boundaries.

Summary

It has been shown that the experimental rate law for the absorption of hydrogen is

$$\text{Rate of absorption} = k[H_{ads}] + I$$

By controlling the current density it has been possible to obtain experimental conditions such that the rate law agreed with the following mechanism

$$H_{ads} \rightarrow H_{abs}$$

Studies of the effect of alloying iron with nickel show that the primary cause for changes in the rate of absorption of hydrogen is changes in the amount of adsorbed hydrogen.

The Mechanism of the Electrooxidation of Acetylene on Gold

J. W. Johnson, J. L. Reed, and W. J. James

Departments of Chemical Engineering and Chemistry, The University of Missouri at Rolla, Missouri

ABSTRACT

Acetylene has been oxidized anodically in aqueous solutions at 80°C on gold electrodes. It was found that the partial oxidation to CO_2 was accompanied by a polymer formation. Effects of potential, acetylene partial pressure, *p*H, and temperature on the rate (current) were measured. A discontinuity in the Tafel curves was noted that indicated a change in the reaction mechanism with potential. The discontinuity was also *p*H dependent. A mechanism involving the discharge of H_2O and/or OH^- has been proposed that is consistent with the experimental results.

The electrooxidation of acetylene has been studied previously on platinized platinum electrodes (1). A reaction mechanism of the following sequence was proposed

$$C_2H_2\ (sol) \rightleftarrows C_2H_2\ (ads)$$
$$H_2O \rightleftarrows OH\ (ads) + H^+ + e$$
$$C_2H_2\ (ads) + OH\ (ads) \xrightarrow{\text{r.d.s.}} \ldots$$

The nature of the electrode is important in this mechanism as it is the source of oxygen-containing species (originating from water) for the oxidation reaction. The coverage of this species on platinum in the potential region where acetylene is oxidized is given by Dahms and Bockris as *ca.* 0.1. They also show the coverage on gold which is much smaller. This offers an indirect test of the mechanism in that it is an opportunity to observe the effect of decreasing the surface concentration of the oxygen containing species. In addition, the absence of electrons in gold for forming covalent bonds with adsorbed reactants and intermediates gives it important characteristics that deserve further study.

Experimental

Cell and apparatus.—The electrolytic cell was similar to that described previously (2, 3) unless otherwise stated. The working electrode (anode) was a rectangular piece of fine gold foil (0.005 in. thick) with a geometric area of 30.2 cm^2. The auxiliary electrode (cathode) was constructed of platinized platinum gauze. The procedure for activating the electrodes has been reported (2, 3). The reference electrodes were mercury-mercurous sulfate (1*N* H_2SO_4) for acid solutions and calomel (1*N* KCl) for basic solutions and were at 25°C during the experiments. All potentials of the gold anode are referred to the SHE as zero at the temperature of the experiment by means of the procedure described quantitatively below. All studies were made potentiostatically (except as noted) and at 80°C except for the activation energy determinations which ranged from 50° to 80°C.

Potential calculations.—The potentials listed in Table I were used in calculating the potentials of the gold anode. All, with the exception of those indicated with asterisks, were experimentally measured values. The measured potential differences between the gold anode and the reference electrodes were

$$\Delta V_{meas} = V - E_{ref,25}$$

In order that V might be referred to the SHE at the temperature of the experiment, the following relations were used

1. For the calomel (1*N* KCl) reference electrode

$$\begin{aligned} V &\equiv V - E_{H,t} \\ &= V - E_{C,25} - (E_{C,t} - E_{C,25}) + (E_{C,t} - E_{H,t}) \\ &= \Delta V_{meas} - (E_{C,t} - E_{C,25}) + (E_{C,t} - E_{H,t}) \end{aligned}$$

2. For the mercurous sulfate (1*N* H_2SO_4) reference electrode

$$\begin{aligned} V &\equiv V - E_{H,t} \\ &= V - E_{S,25} - (E_{S,t} - E_{S,25}) + (E_{S,t} - E_{C,t}) + (E_{C,t} - E_{H,t}) \\ &= \Delta V_{meas} - (E_{S,t} - E_{S,25}) + (E_{S,t} - E_{C,t}) + (E_{C,t} - E_{H,t}) \end{aligned}$$

Numerical values for terms shown in the parentheses were taken from Table I.

Reagents.—Sulfuric acid, sodium sulfate, sodium carbonate, and sodium hydroxide, "Fisher Certified" reagents; acetylene, Matheson purified (>99.6% purity); nitrogen, Matheson prepurified (>99.997% purity); and distilled water. Acetylene-nitrogen mixtures were made with the use of a dual-flow proportioner.

Coulombic efficiency.—The apparatus and procedure used to determine the coulombic efficiency in acidic solutions have been described previously (1). The cell was operated galvanostatically. In basic solutions, a gravimetric procedure was used in which the CO_2 absorbed in the 1*N* NaOH anolyte was precipitated as $BaCO_3$ by addition of barium acetate solution. The precipitate was collected, dried, weighed, and the CO_2 equivalent calculated. The exit gases from the cell were passed through a barium hydroxide absorber to insure that no CO_2 was escaping.

Table I. Data used for potential calculations

Electrodes	ΔE, v	Electrodes	ΔE, v

Results

Rest potentials.—Nitrogen was passed through the anodic and cathodic compartments for about 1 hr to remove oxygen from the cell. The flow through the anolyte was then replaced with acetylene or acetylene-nitrogen mixtures at a rate of 90 cm^3 (STP)/min. The values shown in Table II were obtained immediately on the admittance of acetylene and behaved similarly to those on platinum (1). The rest potentials varied very slightly in acidic solution, but the variation approached $\simeq$ —140 mv/pH unit in basic solutions. The rest potentials were independent of acetylene partial pressure.

Coulombic efficiency.—The results of the coulombic efficiency studies are shown in Table III.

After each test in acidic and neutral solutions, the anolyte was orange-brown in color, and the electrode had a thin, dark brown resinous film on it. The presence of the film had no noticeable effect on the current-potential relationships. At a constant potential, the current remained relatively constant (less than 10% change) for periods in excess of 24 hr, even though the film was forming. In 1*N* NaOH, the coloring of the electrolyte was present, but no film was formed on the electrode. Later experiments showed the film formed in the acidic electrolyte to be soluble in hot NaOH solutions, thus explaining its absence in the basic electrolyte.

By-product analysis.—Various tests and analyses were performed on the anolyte (both acidic and basic) and the resinous film from the acidic solutions in order to characterize the by-products.

1. The anolyte was extracted with ethyl ether, benzene, carbon tetrachloride, and n-hexane. Upon concentration of the extract, only the ether showed visible signs of any extracted material. An infrared spectrum of the extract indicated the presence of C=C and O—H bonds. A trace of the IR spectrum is shown in Fig. 1.

2. Negative results were obtained when the electrolyte was subjected to aldehyde and ketone tests,

indicating an absence of CHO and C=O groups in the by-products.

3. The resinous material was subjected to solvation tests in the solvents mentioned above plus acetone, methanol, 2*N* H_2SO_4, and 2*N* NaOH. Only in hot NaOH did the resin dissolve readily. Concentration of the acetone and methanol solvents showed visible signs of dissolved material. An infrared spectrum of the acetone solution confirmed the O—H bond and indicated a C—O bond, possibly a C—OH bond (see Fig. 1). An emulsion of the resin was also prepared with fluorlube, but IR analysis was unsuccessful.

4. A carbon-hydrogen-oxygen analysis[1] of the resinous film gave a C:H:O atomic ratio of approximately 2:2:1.

The most likely structures of the by-product that are consistent with the analyses are an unsaturated polyhydroxyl compound and a mixed hydroxyl structure with ether linkages. Any structure of the latter type with the proper C:H:O ratio contains an unconjugated enol form which has doubtful stability with respect to a keto shift. Thus, it seems that the most probable structure is of the type, —C(H)=C(OH)—C(H)=C(OH)—. A poly-hydroxyl structure of this type would be stable due to the conjugated bonding. It would also behave chemically similar to a phenol which accounts for its solubility in strong base.

Analysis of the exit gases from the electrolysis cell showed that no volatile, partially oxidized hydrocarbons were present. Hence, it was assumed that the only by-product was the polyhydroxyl compound at various degrees of polymerization.

Current-potential relation.—Tafel curves are shown in Fig. 2. The current values at a constant potential could be reproduced within 5%. There seems to be a transition region (discontinuity) in the plots for *p*H values of six and greater. This region is shifted upward along the Tafel curve as the *p*H is increased. The slope of the Tafel curve, both above and below the transition region, is approximately 140 mv. The increasing slope at the upper end of the curves is assumed to be due to either passivation phenomena or ohmic drop in the reference circuit. The time effects were essentially the same as those for the oxidation of acetylene on platinum (1). However, unlike platinum, no potential region of complete passivation was found for the gold electrode below oxygen evolution.

*p*H *effect.*—The effect of *p*H at constant ionic strength is also shown in Fig. 2. Qualitatively, in strong acids, $\partial \log i/\partial pH \simeq 0$. This value increased with *p*H, reaching unity in basic solutions.

[1] Analysis performed by Galbraith Laboratories, Knoxville, Tennessee.

Temperature effect.—The effect of temperature on current in 1*N* H_2SO_4 and 1*N* NaOH (above and below the transition region) is shown in Fig. 3. Activation energies were calculated and are shown in Table IV.

Values of $\partial(E_a)/\partial V$ are approximately equal to αF = —11.5 kcal/v for α = 0.5. In 1*N* NaOH, it should be noted that the potential change does not account for the entire difference between activation energies above and below the transition region. This suggests that some change or alteration may have been made in

(Potentials vs. SHE = 0 at 80°C).

the reaction mechanism. Due to mixed reactions, the reversible potential could not be evaluated in order to calculate the true (chemical) activation energy.

Pressure effect.—Partial pressure studies were made in 1*N* H_2SO_4 and 1*N* NaOH. The results are shown in Fig. 4. In 1*N* H_2SO_4, the pressure effect ($\partial i/\partial p$) was negative. In 1*N* NaOH below the transition region, the pressure effect started out negative, then became positive at pressures <0.1 atm. In 1*N* NaOH above the transition region, the effect was positive at pressures >0.1 atm and approached a constant value at pressures <0.1 atm. Under the latter conditions (1*N* NaOH, above transition region), appreciable residual currents were noted when the acetylene flow was stopped after several minutes of electrolysis. Other measurements made in fresh electrolyte showed the pressure effect to be positive over the entire range, 0.01 to 1 atm. However, due both to the residual currents and the smallness of the values, it was felt that only measurements above 0.1 atm were of sufficient accuracy to be considered valid for pressure-current correlations.

Discussion

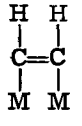
Adsorption of Acetylene

The adsorption of acetylene on Pt has been discussed in the previously mentioned paper (1). The isotherm (Langmuir) was formulated as

$$\frac{\theta_A}{(1-\theta_A)^4} = K_p P_A$$

where θ_A is the fractional coverage by acetylene, p_A is the acetylene partial pressure, and K_p is the adsorption constant for the isotherm relating coverage to partial pressure. The order of magnitude of K_p, estimated both by an indirect method and correlation of experimental data, was 10^4-10^6 atm^{-1}. No data are available which would allow an independent evaluation of K_p for acetylene adsorption on Au from solution.

The most probable attachment of acetylene to a metal surface is (4)



There is evidence that acetylene forms covalent bonds with the metal surface in the case of Pt and Au by rearrangement to dsp hybrids (4, 5). Platinum has 0.5 vacant d-orbitals per atom available for covalent bonding, thus acetylene was assumed to have a 4 site attachment (1). Gold has no statistically calculated d-orbitals available for covalent bonding (6), therefore the number of sites occupied (covered) will be ascertained from a scaled diagram of an acetylene molecule adsorbed on a gold surface (Fig. 5). The acetylene covers only two sites, but possibly blocks two others due to its size. Therefore, the isotherm for the adsorption of acetylene on Au is taken as

$$\frac{\theta_A}{(1-\theta_A)^n} = K_p P_A \qquad [1]$$

where n can be equal to 2 or more.

Reaction Mechanism

The rate-determining step below the transition region must exhibit the following characteristics: (*i*) Be the first electron transfer since the Tafel slope is $2(2.3\ RT/F)$, (*ii*) involve a species other than adsorbed acetylene, (or derived therefrom) since $\partial i/\partial p < 0$, and (*iii*) exhibit essentially no *p*H dependence in strong acid solutions but show a dependency, ∂ log $i/\partial p$H $\simeq 1$ in strong base solutions.

Above the transition region, the rate-determining step must: (*i*) again be the first electron transfer since the Tafel slope remains $2(2.3\ RT/F)$, (*ii*) involve adsorbed acetylene (or a species derived therefrom) since $\partial i/\partial p > 0$, and (iii) exhibit a *p*H dependence ∂ log i/∂ *p*H $\simeq 1$ in going from weak acid to strong base solutions.

There is apparently competition (branching reactions) between intermediates species in regard to the formation of the resin material and total oxidation products, CO_2 and H^+ (or H_2O). As the faradaic efficiency was not greatly affected by potential or *p*H, this competition probably occurs after the r.d.s. in the different regions. The effect of acetylene partial pressure on the efficiency will be discussed later.

Below the transition region (b.t.r.), the substances involved in the r.d.s. must be OH^- or H_2O. This is as proposed previously as a source of OH radicals involved in the oxidation of acetylene and ethylene on Pt (1-3). Currents depending on the discharge of OH^- would be diffusion limited up to *p*H's of 6 to 8 at the current densities used in this study. Thus, the reaction sequence can be represented as

$$C_2H_2 \rightleftarrows C_2H_2\ (ads) \qquad [2]$$

$$\left.\begin{aligned} H_2O &\rightarrow OH\ (ads) + H^+ + e \\ OH^- &\rightarrow OH\ (ads) + e \end{aligned}\right\}\ \text{r.d.s.} \qquad [3a],\ [3b]$$

$$C_2H_2\ (ads) + OH\ (ads) \rightarrow \ldots$$

$$\rightarrow CO_2 + H^+ + \text{electrons} + \text{resin} \qquad [4]$$

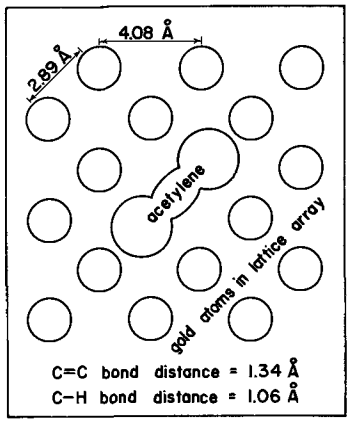


Fig. 5. Schematic diagram of an acetylene molecule adsorbed on a gold surface.

The anodic oxidation of acetylene can be expressed as

$$i_{b.t.r.} = n\mathbf{F}(k_{3a}a_{H_2O} + k_{3b}a_{OH^-})(i - \theta_T)\exp(\alpha\mathbf{F}V/RT) \quad [5]$$

where k_{3a} is the rate constant for water discharge and k_{3b} is the rate constant for OH^- discharge. The coverage of OH radicals is very low (6), and the coverage of all other intermediates can be neglected in comparison with θ_A since they occur in the reaction sequence after the r.d.s. Thus, $\theta_T \simeq \theta_A$, and

$$i_{b.t.r.} = n\mathbf{F}(k_{3a}a_{H_2O} + k_{3b}a_{OH^-})(1 - \theta_A)\exp(\alpha\mathbf{F}V/RT) \quad [6]$$

Above the transition region (a.t.r.), the r.d.s. involves either adsorbed acetylene or a radical derived therefrom. The dissociative adsorption of acetylene can be disregarded due to previous considerations of the energy involved (1) and to the pH effect observed in this study. The studies on Pt (1) also indicated there was no hydrolysis of acetylene in solution. A reaction sequence that meets all the requirements is

$$C_2H_2 \rightleftarrows C_2H_2\ (ads) \quad [7]$$

$$C_2H_2(ads) + H_2O \rightarrow C_2H_2OH(ads) + H^+ + e \quad [8a]$$

$$C_2H_2(ads) + OH^- \rightarrow C_2H_2OH(ads) + e \quad [8b]$$

(r.d.s.)

This gives the anodic oxidation rate as

$$i_{a.t.r.} = n\mathbf{F}(k_{8a}a_{H_2O} + k_{3b}a_{OH^-})\theta_A\exp(\alpha\mathbf{F}V/RT) \quad [9]$$

pH dependence.—Current-pH values were calculated from Eq. [6], representing rates below the transition region, considering the term $[n\mathbf{F}(1 - \theta_A)\exp(\alpha\mathbf{F}V/RT)]$ constant at a given potential over the entire pH range. The contribution of $k_{3a}a_{H_2O}$ was calculated from an experimental value of the current in 1*N* H_2SO_4. Here the contribution from OH^- discharge would be negligible due to its low concentration. The contribution of $k_{3b}a_{OH^-}$ was calculated in 1*N* NaOH assuming $k_{3a}a_{H_2O}$ to be insignificant. Experimentally this is justified as the $\partial \log i/\partial$ pH $\simeq 1$ in strong base. It was necessary to make a correction for the electrolyte pH at the electrode-solution interface due to the diffusion, away from the electrode, of H^+ produced by the reaction. This correction was significant only for bulk electrolyte pH's in the range 5 to 9. Using these constants, the pH dependence from Eq. [6] over the entire pH range is shown in Fig. 6. The experimental data are also included for comparison. Above the transition region, where Eq. [9] applies, it was not possible to consider the contribution of $k_{8a}a_{H_2O}$ as experimental data were available only for pH's > 6. Evaluating $k_{8a}a_{OH^-}$ in a similar manner as described above gives the pH-current relationship also shown in Fig. 6. It can be seen that Eq. [6] and [9] correlate these experimental data in their respective regions.

Partial pressure dependence.—Qualitatively, the rate dependence on acetylene partial pressure can be summarized as follows. (*A*) acid solution (below transition region), $\partial i/\partial p < 0$, Eq. [6] applies. (*B*) Base solutions (above transition region), $\partial i/\partial p > 0$, Eq. [9] applies. (*C*) Base solution (below transition region), for $p > 0.5$ atm, $\partial i/\partial p < 0$, and for $p < 0.5$ atm, $\partial i/\partial p > 0$, *i.e.*, Eq. [6] applies at higher pressures while Eq. [9] applies at the lower ones.

The data from acid solutions (b.t.r.) were correlated using Eq. [6] for which the acetylene coverage was calculated from Eq. [1] with assumed values of n and K_p as 4 and 10^4, respectively. The procedure for these calculations has been described (1). The predicted values as well as experimental data are shown in Fig. 7.

A similar treatment of data from base solution (a.t.r.) using Eq. [1] and [9] is also shown in Fig. 7. Here, values of n and K_p were 8 and 2.5, respectively. It should also be pointed out that $n = 4$ and $K_p = 3.5$ correlated the data within experimental errors, although not as well as the first-mentioned values. These pressure effects can be related to a reaction mechanism if it is assumed that the amount of acetylene adsorbed onto gold decreases as the pH of the solution increases, and H_2O (or OH^-) will undergo discharge only when adsorbed adjacent to an adsorbed acetylene molecule. The first assumption is consistent with trends noted for the adsorption of some other organic compounds from solution (7). Since the oxide (hydroxide) coverage on gold is very low at these potentials in the absence of adsorbed acetylene (6), then H_2O (or OH^-) discharge does not occur readily. Thus, the second assumption could be considered feasible. With these assumptions, the coverages of acetylene on gold can be pictured as shown in Fig. 8a and 8b. In the first case (Fig. 8a) for high coverage, it can be seen that most any adsorption site available for H_2O (or OH^-) will be adjacent to an adsorbed acetylene molecule; thus H_2O (or OH^-) will be discharged and the rate will be proportional to $(1 - \theta_A)$. If due to geometric considerations, four adjacent vacant sites were necessary

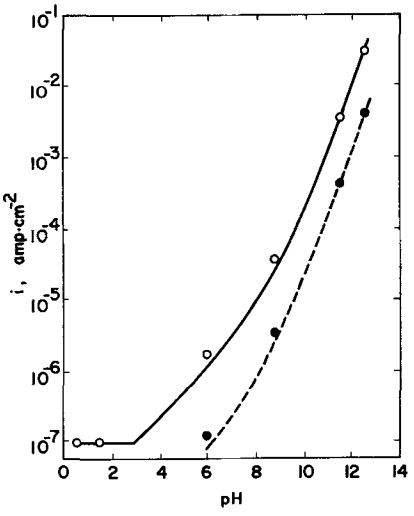

Fig. 6. Theoretical current pH relation at constant potential = 0.40v. (—, Eq. [6]; ○, experimental data below transition region; - -, Eq. [9]; ●, experimental data above transition region).

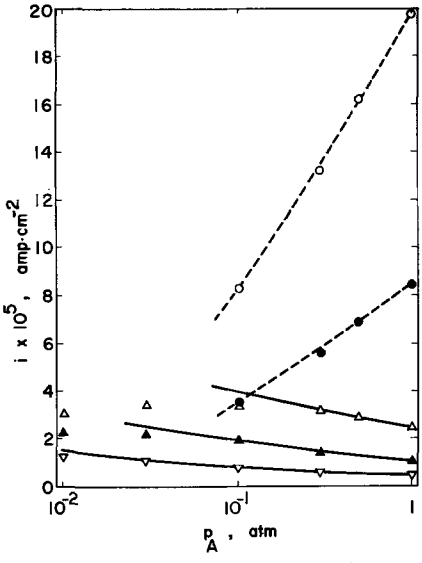

Fig. 7. Theoretical current-acetylene partial pressure relation as a function of potential at 80°C. (○, 0.268v, 1N NaOH; ●, 0.218v, 1N NaOH; - -, Eq. [9], data above transition region; △, 0.732v, 1N H_2SO_4; ▲, 0.682v, 1N H_2SO_4; ▽, 0.632v, 1N H_2SO_4; —, Eq. [6], data below transition region) (Potentials vs. SHE = 0 at 80°C).

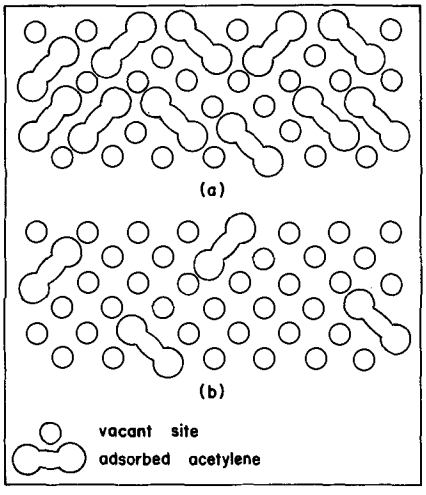

Fig. 8. Schematic diagram of acetylene molecules adsorbed on a gold surface at (a) high and (b) low coverage.

for the acetylene to adsorb, then this model would be consistent with the values of $n = 4$ and $K_p = 10^4$. In the second case (Fig. 8b) for low coverage, there are considerable available sites for water (or OH^-) to adsorb that are not adjacent to adsorbed acetylene molecules. Discharge does not occur on these sites, therefore, the rate is proportional to θ_A rather than $(1 - \theta_A)$. This case is consistent with the lower value of K_p (equal to 2.5). The higher value of n can also be rationalized to some extent if one considers that, for reaction to take place, acetylene must adsorb on a spot that has more than four adjacent vacant sites so that the discharge of water can be accommodated.

Acetylene coverages have been calculated for Eq. [6] and [9] and are shown in Table V. These coverages are also such that Langmuir-type adsorption is approximated.

In base solutions (b.t.r.) where the pressure dependence changes from negative to positive, *i.e.*, the expression for the current changes from Eq. [6] to Eq. [9], there would necessarily have to be a higher acetylene coverage than in base solutions above the transition region. This would suggest the acetylene coverage may have some potential as well as pH dependence.

Reaction products.—The most probable explanation for the incomplete oxidation of acetylene on a gold electrode is similar to that suggested by Dahms and Bockris pertaining to the anodic oxidation of ethylene on various rare metals (6). Using Pauling's equation (8) for the strength of a covalent bond between a metal and a carbon atom, it can be shown that the Au-C bond is about 45 kcal less than the Pt-C bond. Thus, a partially oxidized intermediate could break away from an Au surface before being completely oxidized much easier than from a Pt surface. Due to the reactiveness of the partially oxidized compounds (possibly radicals) and acetylene, polymerization products would be expected.

Summary

The anodic oxidation of acetylene has been studied at 80°C in solutions of H_2SO_4, Na_2SO_4, and NaOH of constant ionic strength. The reaction rate was determined as a function of potential, pH, acetylene partial pressure, and temperature. Coulombic efficiencies were determined for CO_2 production in both acidic and basic solutions. Two regions of linear Tafel behavior separated by a transition region were found.

The following kinetic parameters were noted:

Below the transition region

$$\frac{\partial V}{\partial \log i} = 140 \text{ mv}, \frac{\partial i}{\partial p} < 0$$

$$\frac{\partial \log i}{\partial \text{ pH}} = 1 \text{ (weakly acidic and basic solutions)}$$

Above the transition region

$$\frac{\partial V}{\partial \log i} = 140 \text{ mv}, \frac{\partial i}{\partial p} > 0$$

$$\frac{\partial \log i}{\partial \text{ pH}} = 0 \text{ (moderate to strong acid solutions)}$$

$$\frac{\partial \log i}{\partial \text{ pH}} = 1 \text{ (weakly acidic and basic solutions)}$$

The acetylene was partially oxidized to CO_2 with some polymer formation. The coulombic efficiency for CO_2 production was 60 ± 5% in acidic and 80 ± 10% in basic solutions and decreased with decreasing acetylene partial pressure. The most probable structure of the polymer was $-\overset{H}{\underset{|}{C}}=\overset{OH}{\underset{|}{C}}-\overset{H}{\underset{|}{C}}=\overset{OH}{\underset{|}{C}}-$. Activation energies in the linear Tafel regions varied from 12-20 kcal. The potential dependence of the activation energy, $\partial E_a/\partial V$, was −12 kcal/v.

The reaction mechanisms in the linear Tafel regions were interpreted in terms of the following sequences.

Below the transition region

$$C_2H_2 \rightleftarrows C_2H_2 \text{ (ads)}$$

$$\left.\begin{aligned} &H_2O \rightarrow OH \text{ (ads)} + H^+ + e \\ &OH^- \rightarrow OH \text{ (ads)} + e \end{aligned}\right\} \text{r.d.s.}$$

$$C_2H_2 \text{ (ads)} + OH \text{ (ads)} \rightarrow \ldots$$

Above the transition region

$$C_2H_2 \rightleftarrows C_2H_2 \text{ (ads)}$$

$$\left.\begin{aligned} &C_2H_2 \text{ (ads)} + H_2O \rightarrow C_2H_2OH \text{ (ads)} + H^+ + e \\ &C_2H_2 \text{ (ads)} + OH^- \rightarrow C_2H_2OH \text{ (ads)} + e \end{aligned}\right\} \text{r.d.s.}$$

The discharge of H_2O and/or OH^- was necessary to explain the observed pH effect.

The Thermal Temperature Coefficient of the Calomel Electrode Potential between 0° and 70°C

I. Experimental Results in Aqueous Potassium, Sodium, Lithium, Calcium Chlorides and in Hydrochloric Acid

Andre J. de Bethune, Henry O. Daley, Jr., Nancy A. Swendeman Loud, and G. Robert Salvi

Laboratory of Physical and Nuclear Chemistry, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

The initial thermal temperature coefficient of the calomel electrode potential has been measured between 0° and 70°C for aqueous 1.0, 0.1, and 0.01*m* potassium chloride, sodium chloride, lithium chloride, hydrochloric acid and 0.5, 0.05, and 0.01*m* calcium chloride. Thermal diffusion of the electrolyte was impeded by the use of Vycor intermediate (thirsty glass) glass plugs in the salt bridges between the two banks of electrodes, one of which was kept at 35° while the other was varied from 0° to 70°. The thermal emfs of the fifteen cells investigated exhibited a slight curvature concave to the temperature axis. The hot electrode had the (+) polarity (cathodic in a battery sense) in all cases. Experimental data can be fairly represented by quadratic equations, and least squares values of the quadratic constants are given. The initial thermal temperature coefficients are compared with prior thermal emf data on the calomel electrode. The relative thermal emfs of the same electrode in different salts at constant chloride ion concentration are compared with values deduced from prior thermal emf observations on calomel and silver chloride electrodes or calculated from the transport entropies of chlorides obtained in thermal diffusion studies.

The thermal temperature coefficient $(dV/dT)_{th}$ of the potential of an electrode is the temperature derivative of dE/dT_2 of the initial emf (*i.e.*, before thermal diffusion sets in) $E = V'' - V'$ of the thermal cell

$$\mathrm{Cu}(T_1,V')/\mathrm{Electrode}(T_1)/\mathrm{Electrolyte}(T_1)/\mathrm{Electrolyte}(T_2)/\mathrm{Electrode}(T_2)/\mathrm{Cu}(T_2)/\mathrm{Cu}(T_1,V'') \quad [1]$$

in which the temperature T_1 is fixed and T_2 varies. The thermal temperature coefficient is given a positive value when the hot electrode is the (+) or cathodic terminal of the thermal cell, as is the case experimentally with all calomel electrodes studied.

The thermal temperature coefficient of the calomel electrode potential was originally studied by Gockel (1) and later in more detail by Richards (2). Subsequent investigations were conducted by Fales and Mudge (3), Ewing (4), Sorensen and Linderstrom-Lang (5), Kolthoff and Tekelenburg (6), Bjerrum and Unmack (7), Burian (8), Young (9), Wingfield and Acree (10), Cary and Baxter (11), and Ikeda and Kimura (12) (who investigated only differences between temperature coefficients in various aqueous chlorides). In most thermal emf studies, the temperature differential has been kept between 5° and 10°C, and the thermal temperature coefficient assumed to be valid at the median temperature, which was usually between 15° and 25°C.

Thermal emf data (13, 14) can be used to determine relative values of the entropies of diffusion transport S^D (Soret transport entropies), and of the conjugate heats of transfer Q^*, of electrolytes. They can also throw light on the several ionic transport entropies, *viz.*, the ionic entropy of electrochemical transport S^{E}_i (the so-called "absolute" partial molal entropy of an ion), and the ionic entropy of migration transport S^{M}_i [the entropy of transfer, Eastman's entropy, in Agar's (15) terminology], with its conjugate ionic heat of transfer Q^*_i, as well as the sum of the two ionic transport entropies $\bar{\bar{S}}$ $(= S^{E}_i + S^{M}_i)$ introduced by Temkin and Khoroshin (16) as the entropy of the moving ion, and referred to by Agar (15) as the transported entropy of the ion. Because of the intrinsic interest of thermal emfs as an experimental source of information for these transport entropies of electrolytes and ions, the thermal temperature coefficient of the calomel electrode was reexamined in the present investigation by measuring the thermal emf between banks of half-cells at 35°C, and at a variable temperature t ranging from 0° to 70°C, for three levels of concentration of five different aqueous chloride electrolytes.

Experimental

The thermal emf of the calomel electrode was determined for the following electrolytes: potassium chloride, sodium chloride, lithium chloride, and hydrochloric acid at 25°C concentrations of 1.0, 0.10, and 0.01 moles per liter, and calcium chloride at 25°C concentrations of 0.50, 0.05, and 0.01 moles per liter. The salts and acid used were of reagent grade. The sodium, potassium, and lithium salts were dried at 110°C and the solutions prepared by dilution of the weighed dried salt in a volumetric flask. Hydrochloric acid solutions were prepared directly by dilution of stock concen-

trated acid, and checked by titration with standard base. Calcium chloride dihydrate was weighed directly from the stock bottle, the resulting solution checked by titration with standard silver nitrate. The concentrations of the solutions used in the preparation of the calomel electrodes are listed in Table I. For each solution, the molality was computed from the 25°C molarity via International Critical Tables densities (17) since it is temperature invariant.

The apparatus consisted of 8-in. 25-mm diameter test tubes which were made into calomel half-cells with platinum in soft-glass connectors. The salt bridges were made of ¼ in. Tygon tubing with Vycor intermediate (thirsty glass) plugs (18) in each end to prevent thermal diffusion of the electrolyte. In most determinations five half-cells were connected together through a common graduated cylinder and thermostated at a given temperature until they agreed within ±0.2 mv. An identical arrangement was made in the other temperature bath. A single salt bridge provided the electrolytic connection between the graduated cylinder in the fixed temperature bath and that in the variable temperature bath.

Emf values were obtained by thermostating one bath at 35.0° ± 0.1°C and by heating the variable bath to 75° and letting it cool slowly to 35°, or alternatively by cooling the variable bath to 0° and allowing the bath to warm up slowly to 35°C. The emf of the cell was measured at intervals of one to two degrees as the variable temperature bath slowly drifted in temperature. A check for hysteresis was made by also taking emf values as the variable temperature bath was slowly heated to 75° from 35° or slowly cooled to 0° from 35°, and also by taking steady-state readings with the variable bath held at a constant temperature. No hysteresis was found in excess of the experimental scatter which generally amounted to about ±0.1 to 0.5 mv in emfs that ranged up to 33 mv between the hot and cold electrodes at the extrema of temperatures. The polarity of the calomel thermal cells was observed to be (+), *i.e.*, cathodic in a battery sense, at the hot electrode in every single instance studied.

The bias between the two banks of half-cells was measured at the beginning and at the end of each "hot" and "cold" run, by the following technique: in a "hot" run, the thermal emfs observed in the heating and cooling portions of the run between 35° and 42°-45°C were plotted on an expanded scale and extrapolated linearly to 35°, since the data are linear in this range. In a "cold" run, the same was done between 35° and 28°-25°C. The observed emfs at higher or lower temperatures were then corrected for the 35° bias obtained in this manner, so that the thermal potential of a bank of calomel electrodes was, in each instance, referred to the potential of the same bank of electrodes at 35°C.

Results

For each of the fifteen calomel half-cell systems studied experimentally (Table I), several hundred thermal emf values were recorded between 0° and 70°-75°C. Plots of these thermal emf values *vs.* temperature were not quite linear. In each instance, there was a slight curvature concave to the temperature axis. This corresponds to a negative value of the second thermal temperature coefficient $(d^2V/dT^2)_{th.}$ The experimental data have been fitted by computer to the parabolic equation

$$V_t - V_{35} = A_{35}(t-35) + B(t-35)^2 \qquad [2]$$

The least-squares values of the constants A_{35} and B, in millivolts, are given in Table I and are valid over the temperature range investigated 0°-70°C. The deviations of the several parallel runs generally amounted to a few tenths of a millivolt from the least-squares quadratic curve. The standard deviations of the mean observed values are given, at the selected temperatures of 5°, 20°, 50°, and 65°C, in Table II. Cubic equations were also computed by the method of least-squares. Since the cubical constants amounted to only a few thousandths of a microvolt, positive or negative, in each case, it was decided to retain the simpler quadratic form as a more convenient and adequately precise vehicle for the summarizing of the several thousand thermal emf points observed in this study.

The original least-squares quadratic equation [2] was converted to the equivalent 25°C quadratic equation

$$V_t - V_{25} = A_{25}(t-25) + B(t-25)^2 \qquad [3]$$

by noting that the 25°-value of the A constant is equal to the first-derivative of [2] at 25°, *i.e.*

$$A_{25} = [d(V_t - V_{35})/dt]_{25} = A_{35} - 20\,B \qquad [4]$$

Values of A_{25} are also given in Table II and give directly, in millivolts per degree, the thermal temperature coefficient of the corresponding calomel electrode at 25°C.

Discussion

In Fig. 1 to 5, the initial thermal temperature coefficients of the fifteen calomel electrode systems investigated in this study have been plotted, *vs.* temperature in the range 0°-70°C, as the straight lines computed from the first derivatives of the quadratic thermal emf equations [2] or [3]. The experimental scatter corresponding to the standard deviations of Table II is indicated by the vertical lines. The points plotted give the thermal temperature coefficients as determined in the work of previous observers beginning with Richards (2). Generally the agreement between the straight lines deduced from our experimental thermal emfs and the independent experimental data is good. Particularly noteworthy is Richards' fragmentary data on the 0.5*m* KCl-calomel

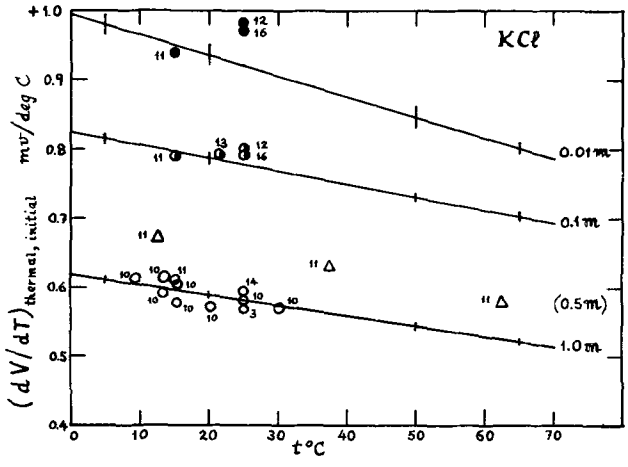

Fig. 1. Potassium chloride

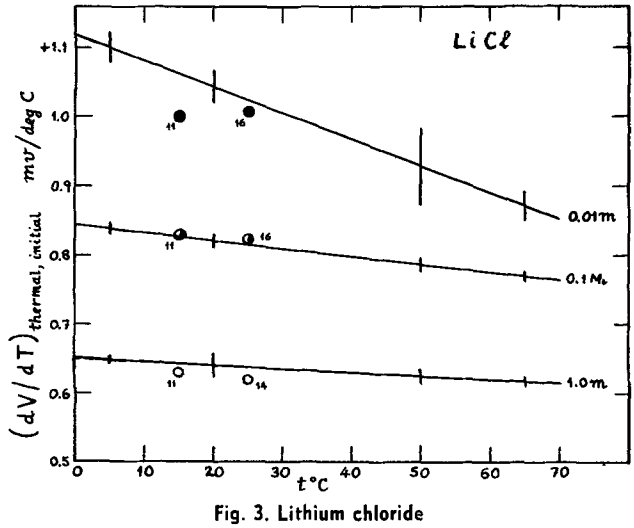

Fig. 3. Lithium chloride

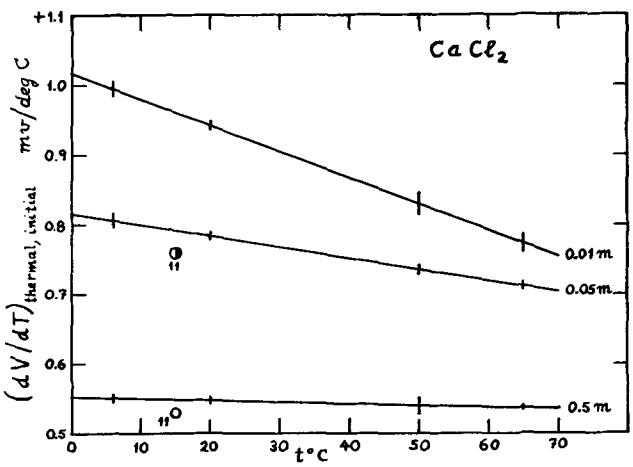

Fig. 4. Calcium chloride

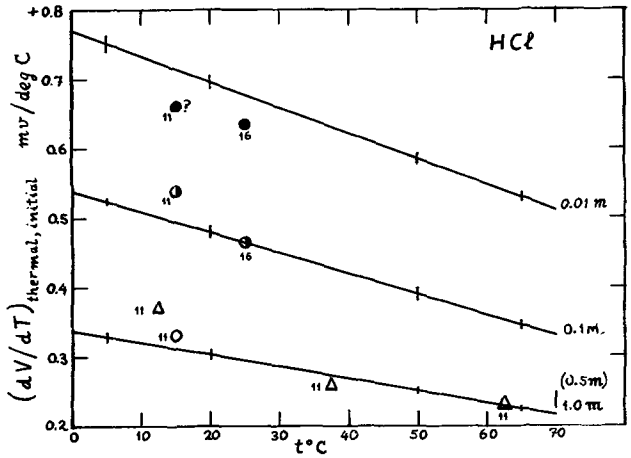

Fig. 5. Hydrochloric acid

electrode (triangles in Fig. 1) which are found to lie at the correct logarithmic spacing between our 0.1m and 1.0m KCl lines.

The comparison of the rather sparse prior data on calomel thermal temperature coefficients with our own observations shows excellent agreement for potassium, sodium, and calcium chlorides, for the 0.1m and 1.0m lithium chloride, and for the 0.1m hydrochloric acid. For the 0.01m lithium chloride (Fig. 3) and 0.01m hydrochloric acid (Fig. 5), our own temperature coefficient is a bit higher than the prior data.

Another comparison of the present data with prior experimental work is provided from the relative thermal emf of the same electrode in different chloride salts, *i.e.*, from the differences between the initial thermal temperature coefficients observed in two different electrolytes of the same chloride ion concentration. If the assumption is made, to a first approximation at least, that the electrode temperature effect is the same in both electrolytes at the same chloride ion concentration, the difference between the two initial thermal temperature coefficients measures the difference between the thermal liquid junction potentials, the Δtljp, of the two salts. At the same chloride ion concentration, these Δtljp's should be the same between the same two salts, regardless of the particular chloride-ion electrode system used. Thus the calculation of Δtljp's permits a direct comparison of the present data, and of other calomel thermal cell data, with the silver-silver chloride thermal emf studies initiated by Eastman and Goyan (19) and pursued by Goodrich (20), Bernhardt and Crockford (21), Crockford and Hall (22), and Haase and Schönert (23).

In the irreversible thermodynamic theory of thermal cells (13), it is shown that the difference between ini-

tial thermal temperature coefficients for different salts, when the electrode temperature effect can be considered eliminated, takes the following form for chloride-ion electrodes

$$(dV/dT)_{th,\,init}(\mathrm{MCl}) - (dV/dT)_{th,\,init}(\mathrm{KCl}) = \Delta \mathrm{tljp}\ (\mathrm{MCl}-\mathrm{KCl}) = (1/\mathbf{F})\,[t_K S^D(\mathrm{KCl}) - t_M S^D(\mathrm{eq.\ MCl})] \quad [5]$$

where S^D is the entropy of diffusion transport (per gram equivalent) of the salt and the t's are transference numbers. The entropy of diffusion transport (per mol) is related to the Soret coefficient, $d \ln a_\pm/dT$, *i.e.*, to the fractional change in mean ion salt activity resulting from thermal diffusion across a temperature gradient, by the expression

$$S^D(\mathrm{MCl}) = -\nu RT(d \ln a_\pm/dT) \quad [6]$$

where ν is the number of ions per molecule of the salt. Thus the measurement of Δtljp's provides a relative method for the determination of entropies of diffusion transport of salts if the value for one salt is known from an independent thermal diffusion experiment. The method, however, is sensitive to small errors in the measured thermal emfs. Conversely, Eq. [5] permits a calculation of Δtljp's from the entropies (or heats) of diffusion transport of salts as determined in thermal diffusion experiments such as those of Agar (15), Chanu (24), Tanner (25), and Butler and Turner (26).

The Δtljp's of sodium, lithium, and calcium chlorides and of hydrochloric acid, referred to potassium chloride of the same chloride ion concentration, are plotted for 1.0, 0.1, and 0.01*m* chloride ion, in Fig. 6, 7, and 8, *vs.* temperature between 0° and 70°C. The lines are based on the present series of experiments and represent the differences between the lines of Fig. 2, 3, 4, and 5 and the corresponding line in Fig. 1 (KCl). The numbers refer to the legends of the figures and identify the observers of the prior experimental data. Points labelled 9, 11, and 16 are based on relative thermal emfs of calomel electrodes; points labelled 2, 6, 7, and 8, on relative thermal emfs of silver-silver chloride electrodes; points labelled 1, 4, 5, and 15, on the results of thermal diffusion studies. In Fig. 6 (0.1*M* chloride ion), the points labelled 2 and 6 have been computed by interpolation between 0.05 and 0.25*M* chloride ion solutions.

The comparisons provided by Fig. 6-8 show generally good agreement, *i.e.*, within about ±20-50 μv/degree, between the present work and prior investigations for most of the salt pairs studied. The present results are about 40 to 60 μv/degree higher in 0.01*M* lithium chloride, and about 60 to 100 μv/degree higher in 0.01*m* hydrochloric acid. These comparisons and those of Fig. 1, 3, and 5 suggest that the thermal emfs here reported in 0.01*m* lithium chloride and hydrochloric acid may perhaps be systematically high, while those of 0.01*m* potassium chloride are perhaps systematically low. Thermal emf work has proved more troublesome in the dilute solutions, as already observed by Richards (2), especially at higher temperatures.

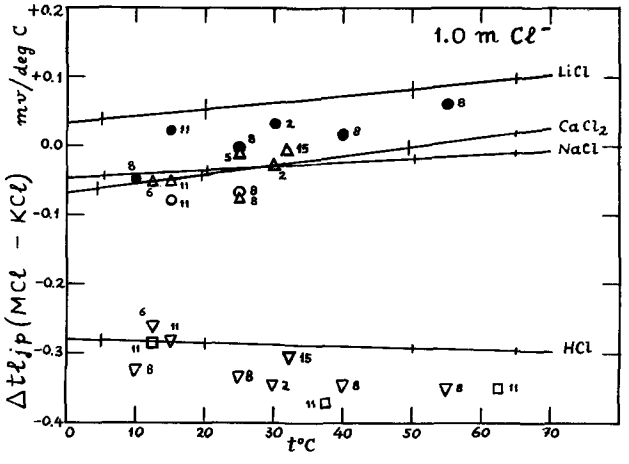

Fig. 6-8. Differences of thermal liquid junction potentials, Δtljp, referred to KCl as zero, in 1.0, 0.1, and 0.01M chloride ion. • LiCl; △ NaCl; ○ $CaCl_2$; ▽ HCl; □ HCl (0.5M, in Fig. 6). References for the points are the same as for Fig. 1 to 5.

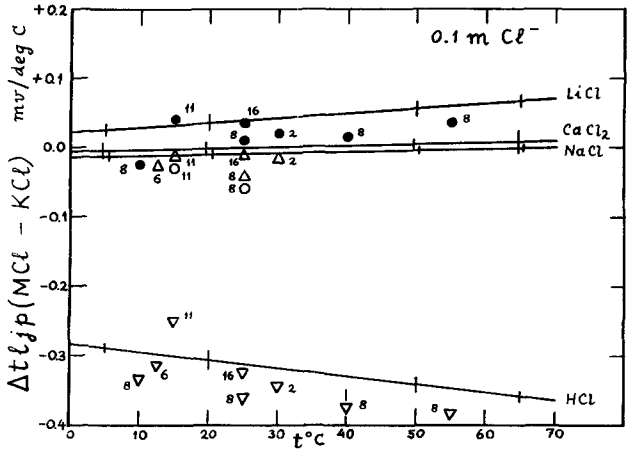

Fig. 7. 0.1*m* chloride

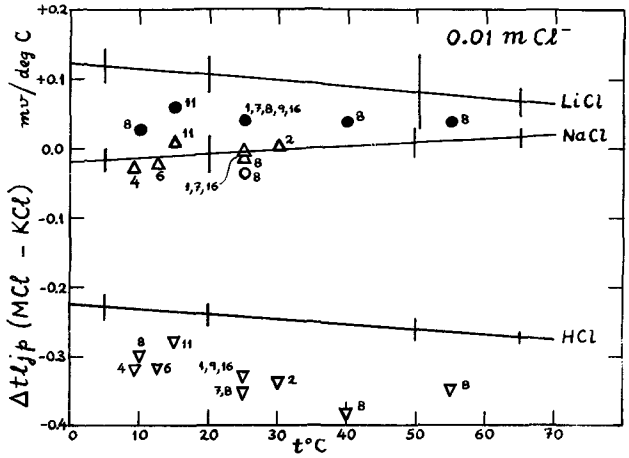

Fig. 8. 0.01*m* chloride

The thermodynamic consequences of this present experimental investigation, particularly the determination of the entropies of diffusion transport S^D of the electrolytes involved (relative to potassium chloride), and of the moving entropy $\bar{\bar{S}}$ of the chloride ion, and the estimation of the entropies of electrochemical transport S^E and of migration transport S^M of chloride and hydrogen ion, will be developed in Part II of this study.

Acknowledgment

The authors wish to express their thanks to The Electrochemical Society and the National Science Foundation for Research Fellowships (HOD), to the International Nickel Company of New York, and the Office of Saline Water of the U. S. Department of the Interior, for financial support extended to various phases of this project. They also wish to thank James A. Ahearn, Jr., George Allendorf, Salvatore A. Carrano, and Thomas P. O'Connor, for their assistance with some of the measurements, and Mary Ellen Farrey for assistance with the computer work.

Manuscript received Sept. 29, 1966; revised manuscript received Feb. 15, 1967. This paper is based on the Ph.D. dissertation of H. O. Daley, Jr., and the M.S.

Thesis of N. A. Swendeman (Mrs. Loud), and G. R. Salvi. Portions of this work were presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Technical Notes

Porous Carbon Fuel Cell Electrodes from Polymer Precursors

M. W. Reed and W. C. Schwemer

LTV Research Center, Dallas, Texas

The problem in obtaining an active fuel cell electrode can be considered twofold: (*i*) preparation of a corrosion resistant, conductive substrate of narrow pore spectrum to serve as a support for a catalyst specific for the desired electrode reaction, and (*ii*) deposition of an adherent, active catalyst at some step of the electrode processing. An ideal diffusion-type electrode, besides being an electronic type conductor, should be inert to the electrolyte, reactants, and products of the fuel cell. The electrode should have mechanical strength, a narrow pore size spectrum, and a disordered surface in order to furnish a large number of sites for catalyst deposition. The electrode should have specificity for the electrode reaction and a long operating life without change in electrochemical performance, physical properties, and corrosion resistance. In addition the fabrication process should produce homogeneous electrodes with reproducible properties. The fuel cell electrodes considered here are of the diffusion type with free electrolyte and gaseous reactant on opposite sides. The electrolyte is held in the pores by capillary pressure and tends to form a meniscus concave to the electrolyte; in wetted electrodes diffusion through the electrolyte film above the meniscus has been shown to be limiting in certain fuel cell electrode reactions (1).

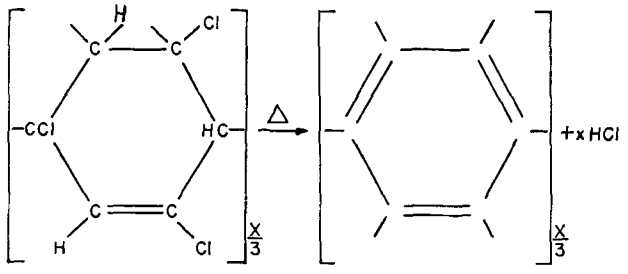
The preparation of porous fuel cell electrodes using polyvinylidene chloride, Saran A*, as a carbon precursor by the pyrolysis reaction, $(CH_2C\,Cl_2)_x \rightarrow 2xC + 2xHCl$, shows promise. The controlled thermal decomposition of Saran A gives a stoichiometric yield of carbon free from the impurities usually found in carbons from natural sources. Saran carbon is characterized by toughness and strength not present in other carbons of equivalent density. The corrosion resistance of Saran carbons appears superior to those carbons from natural sources. Two reasons possibly contribute to this: (*a*) the lower impurity level and (*b*) the homogeneous, isotropic structure of Saran carbon which consists of only one phase. Conventional carbons have a heterogeneous, two-phase structure of conventional carbons arising from the use of a carbon source such as petroleum coke and an easily carbonized binder such as sugar.

It is known from x-ray data that poly (vinylidene chloride) consists of vinylidene chloride monomer units joined in a head-to-toe arrangement. The first step in the pyrolysis results in the liberation of hydrogen chloride and the formation of a linear polyene

[1] Saran A, courtesy Dow Chemical Company.

with alternating hydrogen and chlorine. The second step is a cyclization to a six-membered ring presumably through a Diels-Alder mechanism (2):

$$(C_2H_2Cl_2)x \xrightarrow{\Delta} (CH = CCl)x + xHCl \xrightarrow{\Delta}$$



Further evolution of hydrogen chloride then occurs leading to a completely aromatic structure. Data from Jackson indicate that graphite crystallites of approximately unit cell dimensions are present in fully pyrolyzed Saran carbons (3). Saran carbon is not graphitized on a macro scale during heating to 3000°C.

Porous Saran carbon is prepared by using polyvinylidene chloride, Saran A, $(CH_2CCl_2)_x$ as the precursor; a simplified flow sheet for the Saran carbon is shown in Fig. 1. Step 1 involves compacting the powder at between 780-3500 psi by either conventional die or hydrostatic compaction of the powder in a bag. The compacts have enough green strength without a binder at this stage to be weighed and placed in a vacuum oven.

The compacts are heated to 125°C (step 2) in 30 in. Hg vacuum. The pump should be protected from the evolved HCl, boiling point —84°C, by liquid nitrogen traps. The temperature is increased to 175°C (step 3) at 10°C/hr and held for 16 hr under the 30 in Hg vacuum (step 4). The Saran pyrolysis reaction, $(CH_2C\,Cl_2)_x \rightarrow 2xC + 2xHCl$, becomes extremely rapid in the 165°-170°C range. The compacts change from white to black in color during the 175°C pyrolysis. The compacts are placed in a furnace and heated under inert gas atmosphere or vacuum to 1000°C (step 5) which completes the Saran pyrolysis to carbon.

The pore spectra and density of the carbon may be varied in a controlled manner by changing the particle size and compacting pressure of the precursor Saran powder. In this respect, the process is similar to conventional ceramic or powder metallurgical techniques.

Typical physical properties of porous uncatalyzed Saran carbon are given in Table I.

The relationship between final pyrolysis temperature and surface area of Saran carbon is shown in Fig. 2. These data indicate that pyrolysis temperatures above 1100°C should be avoided for maximum area.

Pore spectra curves are plotted in Fig. 3. The carbon pressed at 1300 psi has most of the pores between 3 and 8μ average diameter while the 930 psi specimen

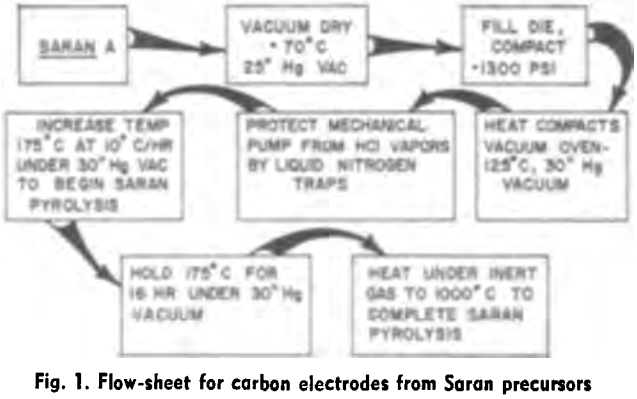


Fig. 1. Flow-sheet for carbon electrodes from Saran precursors

Table I. Physical properties of Saran carbon

Compacting pressure, psi	930	1300	2000
Apparent density, g/cm³	0.686	0.731	0.745
Available porosity, %	61.9	59.4	58.6
Available porosity, cm³/g	0.902	0.814	0.786
Surface area (4), meters²/g	1300	1300	1300
Permeability, N_2, millidarcies	53.6	46.9	30.3

has a wider pore spectra between 3 and 15μ. The carbon pressed at 2000 psi has a narrow spectrum between 1 and 4μ. A narrow pore spectrum allows a gas-liquid interface to be established in a thin electrode, the thin electrode being necessary from mass transport considerations. Gas pressures greater than about 1 psig are required to prevent electrode flooding. The electrodes, being of the gas diffusion type, must be operated near the gas break-through pressures for maximum performance.

Photomicrographs, of porous Saran carbon show the 930, 1300, and 2000 psi material in Fig. 4. Notice the

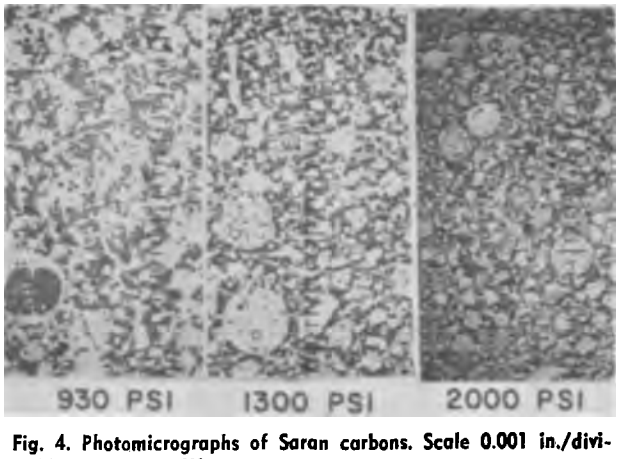

Fig. 4. Photomicrographs of Saran carbons. Scale 0.001 in./division. Magnification 50X.

small porosity apparent within the large, *ca.*, 0.004 in., carbon particles, as well as the more dense appearance of the 2000 psi material.

Electrochemical evaluation of the electrode was by the single electrode technique as given by Reed and Brodd (6). Constant direct current was impressed between the test electrode and a counter electrode. Potential was measured between the test electrode and a reference electrode through the electrolyte path in the Luggin capillary. Mercury-mercuric oxide was the reference used with potassium hydroxide electrolyte; mercury-mercurous sulfate was the reference used with sulfuric acid electrolyte. Testing was limited to fuel cell cathode materials with either air or oxygen as the oxidant. An interrupter technique was used to determine the resistance of the operating electrode (7); the data are plotted from reversible oxygen potential after correction for ohmic drop. The ohmic drop correction is 0.174v at 100 ma/cm^2 for the data on Fig. 6, for example. The open-circuit potential of these electrodes has been found to be about 0.2v below the reversible oxygen potential, indicating a peroxide mechanism at open circuit and low current densities (8). The cell exposes 5 cm^2 of electrode area to the electrolyte. The oxygen used was 99.5% minimum purity O_2. The air used was passed through an anhydrous calcium sulfate drying tower. The potassium hydroxide electrolyte was prepared by dissolving Baker reagent grade pellets (86.2 w/o KOH) in distilled water. The sulfuric acid electrolyte was prepared by diluting Baker reagent grade (97.3% H_2SO_4) with distilled water.

Polarization data in sulfuric acid electrolyte for oxygen and air electrodes with Saran carbon substrates are plotted in Fig. 5. The effect at 25°C of using air rather than oxygen is seen as a decrease in current density from 95 to 40 ma/cm^2 at a polarization of 0.465v. Moderate heating of the cell produces significant decreases in the polarization of air electrode; at 100 ma/cm^2 polarization decreases by 0.09v to 0.495v. Further, performance at 59°C on air is almost as good as that using oxygen at 25°C, 0.495v *vs.* 0.475v at 100 ma/cm^2. The polarization of the oxygen electrode at 59°C is 0.47v at a current density of 200 ma/cm^2. The increase in cell temperature from 25° to 59°C reduced the polarization by 0.1v. Note that the curves become markedly nonlinear at current densities above 70 ma/cm^2. The relatively thick, *ca.* 0.070 in., electrodes become diffusion limited at this point. The platinum catalyst used in these tests was deposited by impregnating the porous Saran carbon substrate with chloroplatinic acid at a vacuum of about 25 in. Hg. After infrared drying the platinum was reduced *in situ* by hydrogen at 400°C. Other catalyst techniques were evaluated; none were as reliable for making active cathodes.

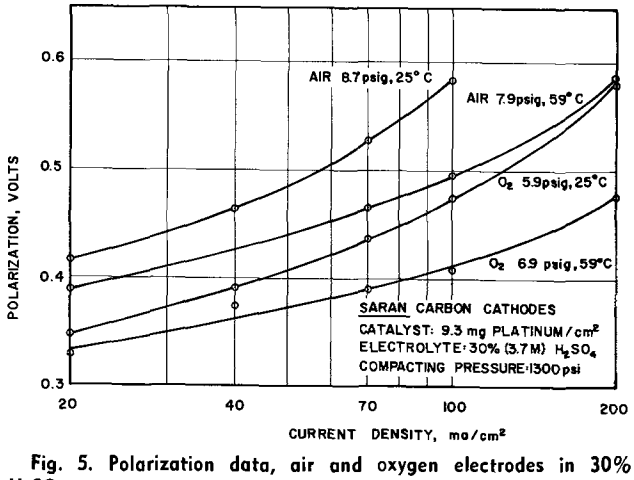

Fig. 5. Polarization data, air and oxygen electrodes in 30% H_2SO_4.

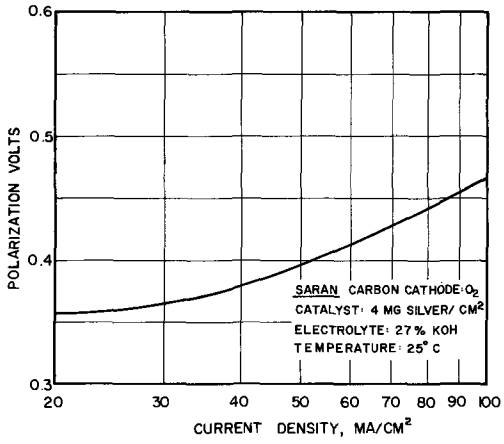

Fig. 6. Polarization data, oxygen electrode in 27% KOH

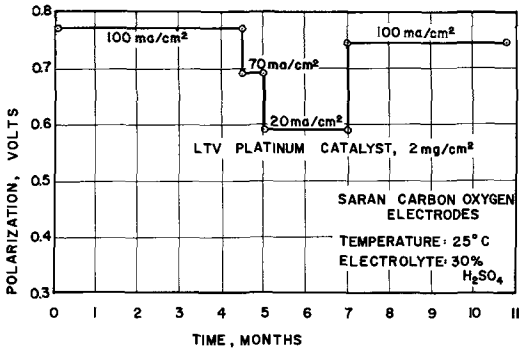

Fig. 7. Life test data, oxygen electrode in 30% H_2SO_4

Figure 6 is a polarization *vs.* current density plot of Saran carbon as an oxygen electrode material in potassium hydroxide at an oxygen pressure of 7.6 psig. The silver catalyst, 4 mg/cm^2, was deposited from a silver amine solution by reduction with formaldehyde. The polarization is 0.47v at a current density of 100 ma/cm^2. The Saran was pressed initially at 1300 psi.

The life tests in sulfuric acid of the Saran carbon cathodes compacted initially at 1300 psi have reached over ten months as shown in Fig. 7. The initial 4.5 months were at a constant current density of 100 ma/cm^2. This was changed to 70, then 20 ma/cm^2 for the next 2.5 months. The current density was changed again back to 100 ma/cm^2 for an additional four months and are still in progress. The polarization is the same or lower than when the tests were started.

Conclusions

Electrodes made of carbon from Saran polymer precursors can be made having controlled pore size spectra in the range useful for diffusion-type fuel cells.

Life tests have established that the chemical stability of the Saran carbon in acid electrolyte will allow its use in fuel cells designed for long life.

Catalysts of high activity and specificity may be deposited on the porous carbon to make fuel cell cathodes with low polarization characteristics.

Measurement of the Anodic Oxide Film Growth on Iron for Hours

Norio Sato and Takenori Notoya

Physical Chemistry Laboratory, Faculty of Engineering, Hokkaido University, Sapporo, Japan

In a previous study (1) of the kinetics of anodic oxide film growth on iron in a neutral solution, it was found that in the steady growth region the rate of thickening of the oxide varies with both film thickness and electrode potential in accordance with the equation

$$i = k' \exp(\beta E - Q_T/B) \quad [1]$$

where E is the potential, Q_T the film thickness, and k', β, and B are constants. Accordingly, under galvanostatic condition the potential is a linear function of the film thickness

$$E = E' + KQ_T \quad [2]$$

and at constant potential

$$i = A \exp(-Q_T/B) \quad [3]$$

which can be integrated to the equation of logarithmic law

$$Q_T = a + b \ln(t - t_0) \quad [4]$$

Increase of the film thickness, Q_T, during potentiostatic oxidation can be measured electrochemically by integrating the current-time curve obtained. However, since after a certain period of time the anodic current falls to less than the limit of experimental error, it becomes difficult for extended periods of time to obtain an accurate measure of the amount of charge passed during potentiostatic oxidation. The present note reports another convenient method for estimating the thickness of the oxide film formed by prolonged oxidation.

The experimental procedure was almost the same as that described in previous papers (1-3); the specimen was an electropolished carbonyl iron sheet of 5 x 1 cm, and the solution was a deaerated aqueous mixture of 0.15N boric acid and 0.15N sodium borate (pH = 8.42). Before the measurement, the air-formed or passive oxide film on the specimen was completely removed by cathodic reduction, and the solution was renewed at least three times.

The specimen was anodically oxidized at a constant potential of 0.0v (SCE scale) at 25° ± 0.1°C for eight different periods of time ranging from 0.5 to 50 hr, which was immediately followed by the galvanostatic oxidation at a current density of 10 μa/cm^2. Results of the galvanostatic oxidation subsequent to the potentiostatic oxidation for the various periods of time are shown in Fig. 1. It can be seen in agreement with Eq. [2] that the potential rises linearly with increase of ΔQ_T in the steady growth region, and that the $E - \Delta Q_T$ curve in the straight line range shifts in a parallel fashion toward the more noble potential region with increased time of the preceding potentiostatic oxidation and hence with increasing the initial thickness of the oxide film ${}_sQ_T$

$$E = E' + K(\Delta Q_T + {}_sQ_T) \quad [5]$$

Accordingly, ${}_sQ_T$, the thickness of the oxide film grown during the preceding potentiostatic oxidation, can be estimated from Eq. [5], where K and E' are constants at constant current density.

From Eq. [5]

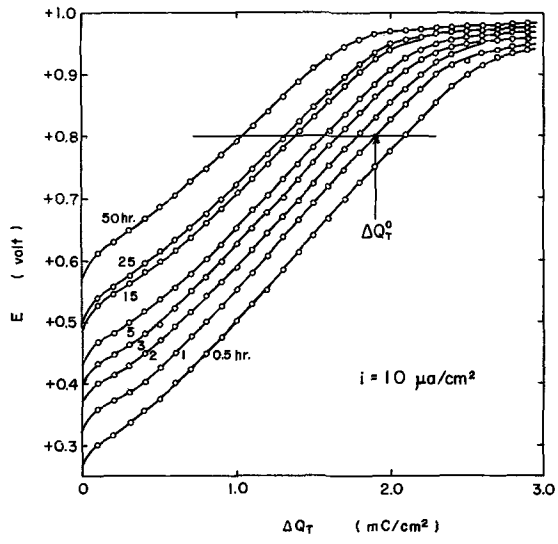

Fig. 1. Change of potential with coulomb passed during galvanostatic oxidation at 10 μa/cm^2 subsequent to potentiostatic oxidation at 0.0v for eight different hours.

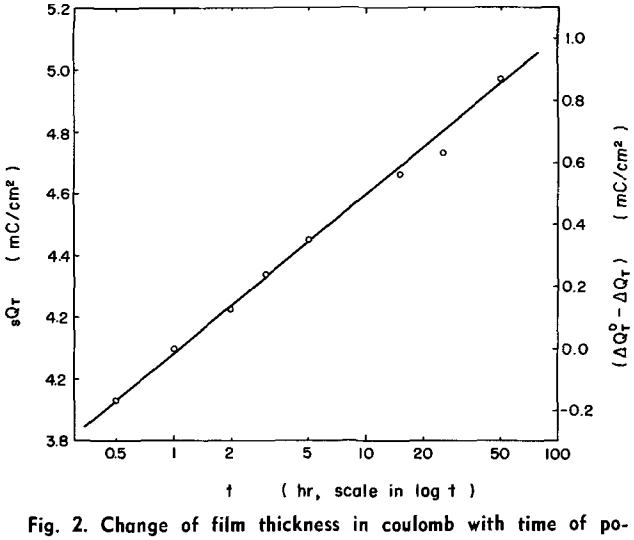

Fig. 2. Change of film thickness in coulomb with time of potentiostatic oxidation at 0.0v.

$$ {}_sQ_T = \frac{E - E'}{K} - \Delta Q_T $$

and at a given potential

$$ {}_sQ_T = {}_sQ_T^{\circ} + (\Delta Q_T^{\circ} - \Delta Q_T) \quad [6] $$

where ${}_sQ_T^{\circ}$ is a known value of ${}_sQ_T$ which can easily be measured with sufficient degree of accuracy by integration of the current-time curve obtained, for example, a value of ${}_sQ_T^{\circ}$ (1 hr, 0.0v) = 4.10 mC/cm^2 being obtained for 1 hr potentiostatic oxidation at 0.0v. The difference $(\Delta Q_T^{\circ} - \Delta Q_T)$ in coulombs at a given

potential, for example, of +0.8v can be calculated from the galvanostatic oxidation curves shown in Fig. 1.

The oxide film thickness, ${}_sQ_T$, thus calculated is plotted against the logarithm of time of the potentiostatic oxidation at 0.0v in Fig. 2. A straight line can be drawn to fit the data, indicating that at constant potential the anodic oxide film thickens according to the same kinetics represented by Eq. [3] and [4] for extended periods of time to 50 hr.

Electrodeposition of Coherent Deposits of Refractory Metals

VI. Mechanism of Deposition of Molybdenum and Tungsten from Fluoride Melts

S. Senderoff and G. W. Mellors

Research Laboratory, Consumer Products Division, Union Carbide Corporation, Cleveland, Ohio

In a recent report (1) it was shown that the deposition of molybdenum from a chloride melt occurs by an irreversible single step reduction, but that the usual treatment of the chronopotentiometric data was not definitive because of instability of the electrolyte in the dilute range of composition required for chronopotentiometry. In a similar study of molybdenum and tungsten deposition from a fluoride melt (2) the instability on approximately tenfold dilution of the plating solution was even greater and the concentration and temperature range amenable for study was even smaller than in the case of the chloride-molybdenum system. Nevertheless it was possible to demonstrate by techniques equivalent to those used in the chloride system that the deposition of coherent metal also involved an irreversible reduction as in all previous cases (3), and that the irreversibility was greater in the fluoride system, and extended to higher temperatures, than the molybdenum-chloride system (1).

Molybdenum deposition.—A plating solution was prepared by reacting MoF_6 with molybdenum metal in a molten eutectic mixture of KF (0.42), LiF (0.47), NaF (0.11) as described previously (2). After sufficient electrolysis to produce satisfactory plates, the solution contained 6.6 w/o (weight per cent) Mo at a mean valence of 3.3. This was diluted to yield three samples containing 0.55, 0.51, and 0.40 w/o Mo and chronopotentiograms were run on these samples as described previously (1), using a Ni/NiF_2, alkali fluoride// reference electrode (3).

During the 1-2 hr that it took to run the chronopotentiograms at 600°, 700°, and 800°C, the solutions lost 15 to 19% of their molybdenum content and the mean valences of molybdenum had risen to 4.0 or higher. The scatter of points in the $it^{1/2}$ *vs.* C plots was too great for any conclusions to be drawn from them. Plots of E *vs.* log $(\tau^{1/2} - t^{1/2})/t^{1/2}$ were nonlinear as were those of E *vs.* log $(\tau^{1/2} - t^{1/2})$. The linearity of the plots of the latter function improved with increasing temperature so that for the chronopotentiograms run at 800°C the plots were nearly linear, but the average electron number, n, calculated from the slopes was 2.0 ± 0.2. Since the total reaction was known to be reduction of trivalent molybdenum to metal, and since only a single plateau[1] was observed (see Fig. 1) this can be interpreted only as either a two-electron slow step in the reaction, or an inapplicability of the Nernst plot. In either case it implies irreversibility of the reaction.

The irreversibility is confirmed by examining the cathodic-anodic chronopotentiograms of Fig. 2 and the data in Table I, in which ΔE is the difference in E value between the initial portions of the cathodic and anodic plateaus and κ is the calculated specific conductance of the ternary alkali fluoride solvent. This was obtained from the conductivity data of Yim and Feinleib (4) for the individual components by assuming ideal additivity, *i.e*, $\kappa_{mix} = \sum_i N_i\kappa_i$ where N_i is the mole fraction of component i. In the 800°C case the

[1] When the mean valence exceeded 4.0, a second plateau at approximately 1v appeared. Under these conditions unsatisfactory deposits are obtained.

[a] Calculated assuming ideal solution.

conductivity data from (4) is extrapolated only about 100°C and, even if the nonideality might cause the resistivity to be as much as 30% greater than calculated as it is in the KCl-LiCl eutectic mixture (5), the observed value of ΔE would still be considerably in excess of twice the IR drop, the value expected for reversible systems. At the lower temperatures the difference between ΔE and 2(IR) is even larger. Comparison of ΔE in the fluoride system with that in the chloride melt (1), reveals that in spite of the higher conductivity of the fluoride melt, ΔE remains greater in the fluoride than in the chloride solution. Finally the average $E_{1/4}$ values for the chronopotentiograms such as those of Fig. 1 are —0.48 ± 0.06v at 600°C, —0.34 ± 0.04v at 700°C, and —0.24 ± 0.02v at 800°C. The static potential is —0.1v with little change with temperature. $E_{1/4}$ thus shows considerable polarization even at the highest temperature.

It can be concluded, therefore, that on the basis of the same criteria used in the case of the chloride melt, reduction of trivalent molybdenum to metal in fluorides is irreversible. That considerable irreversibility extends to 800°C in the fluorides, but not in the chlorides, is significant in view of the excellent plates obtained at this elevated temperature from the fluoride melt, while in the chloride, lower temperatures (*ca.* 600°C) are best for plating.

Tungsten deposition.—A plating solution containing 3.53 w/o W in the ternary alkali fluoride eutectic mixture was prepared by reacting WF_6 with tungsten metal in the molten fluoride mixture (2). The mean valence of the tungsten was 4.48. This was diluted to 0.32 w/o W by addition of alkali fluoride, and chronopotentiograms were run in tungsten crucibles at 600°C. A typical result is illustrated in Fig. 3. An average of six such runs gave an $E_{1/4}$ value of —0.34 ± 0.04v compared to a static potential of —0.05v. At higher temperatures results obtained were irreproducible due to rapid change in solution composition. Reduction in concentration of tungsten was small but its mean valence rapidly increased to 5 or above. When the valence reached 5, another plateau at —0.8v appeared and probably corresponded to the reduction of a higher valence state from which poor deposits are produced.

Another set of chronopotentiograms at 600°C on a solution containing 1.69 w/o W gave an average $E_{1/4}$ value of —0.28v and a static potential of +0.08v. The poor reproducibility even at 600°C is probably the result of composition variations during the course of the run, especially in the more dilute solution. Measurements at the higher concentration, however, required very high currents and were difficult to make.

In Fig. 4 is shown a cathodic-anodic chronopotentiogram for the deposition and dissolution of tungsten metal at 600°C. The difference in potential between the

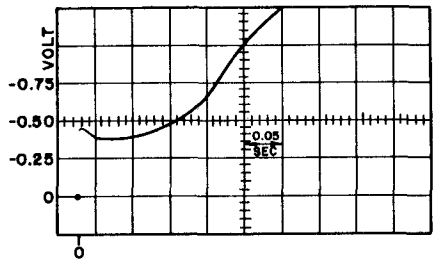

Fig. 3. Chronopotentiogram for deposition of tungsten metal from fluoride electrolyte. Temperature, 600°C; concentration, 3.6 x 10^{-5} moles/cc (0.32 w/o W); current density, 100 ma/cm^2.

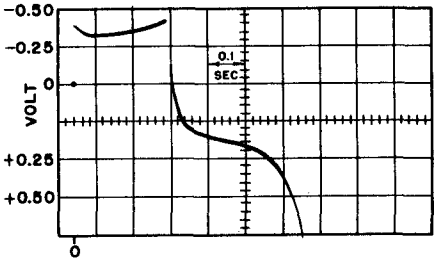

Fig. 4. Cathodic-anodic chronopotentiogram for deposition and dissolution of tungsten metal; cathodic portion on left. Temperature, 600°C; concentration, 3.6 x 10^{-5} moles/cc; current density, 75 ma/cm^2; $t_{anode}/t_{cathode}$, 1.08.

cathodic and anodic processes of 0.65v compared with 0.05v corresponding to twice the IR drop is even greater than in the molybdenum case and this indicates even greater irreversibility.

Another probable indication of irreversibility is the initial maximum in the chronopotentiogram of Fig. 3 which may result from crystallization or nucleation overvoltage.

From these results it is clear that the reduction of molybdenum and tungsten to produce coherent metal deposits from the fluoride melt involves an irreversible process as is true in all other cases of coherent deposition thus far investigated. The instability of the dilute baths makes it difficult to determine the cause of the irreversibility, but since the behavior is qualitatively similar to that of the Mo-chloride system (1), it is likely that the irreversibility arises from the same cause, *i.e.*, slow dissociation of a polynuclear complex anion of molybdenum and tungsten with fluoride to a mononuclear ion.

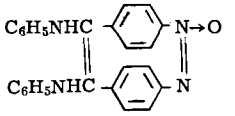
The Electrochemical Reduction of N-*p*-Nitrobenzylaniline

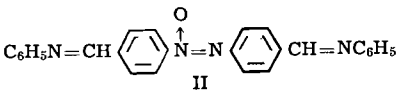
S. Wawzonek, T. Plaisance,[1] and T. McIntyre

Department of Chemistry, University of Iowa, Iowa City, Iowa

The report of Elbs and Gaumer (1) that the electrolytic reduction of N-*p*-nitrobenzylaniline in weakly alkaline ethanolic solution gave *p*-dianilinoazoxystilbene (I) could not be duplicated. The reduction under all



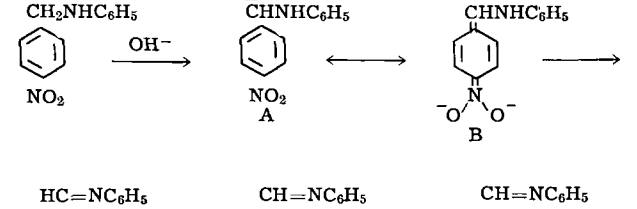
I

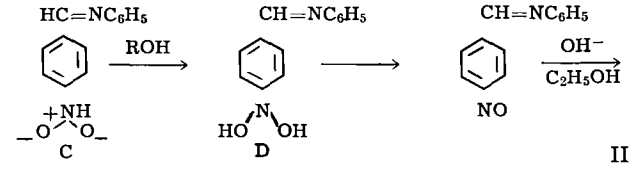


II

conditions tried gave *p*-azoxybenzylideneaniline (II). This structure was indicated by its infrared and nmr spectra, conversion to *p*-azoxybenzaldehyde melting at 193° with hydrogen chloride in ethanol, and comparison with an authentic sample (2). Elbs, Nacken, and Hofmann (3) reported that their compound was converted by hydrogen chloride in ethanol to a dihydrochloride melting at 191°C. No elemental analysis was given, however, to confirm the structure.

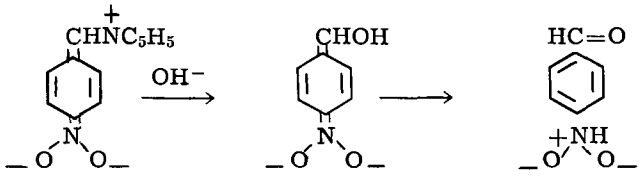
p-Azoxybenzylidenaniline can be formed from N-*p*-nitrobenzylaniline by simple treatment of the latter in ethanol with sodium hydroxide or sodium carbonate; no electrolytic reduction is necessary. In the electrolysis, hydroxide ion, formed since sodium acetate was used as an electrolyte, could cause the reaction. A similar type of reaction is reported when *p*-nitrobenzylpyridinium chloride or bromide is treated with aqueous alkali; *p*-azoxybenzaldehyde is formed (4). The following mechanism is suggested for this reaction;





II

The formation of the anion A parallels the formation of the anion from *p*-nitrotoluene in t-butyl alcohol containing potassium *t*-butoxide (5). Eneamines containing a hydrogen on the nitrogen (B) are not stable but rearrange to the Schiff's base. The product in this case would be an intermediate (D) which is often postulated for the reduction of a nitro compound to a nitroso compound. The latter compounds in basic ethanol produce azoxycompounds (6). The conversion of *p*-nitrobenzylpyridinium chloride to 4, 4'-azoxybenzaldehyde would differ in the second step; hydroxide ion would displace the pyridine and form E which would lead to the formation of the product by similar steps.

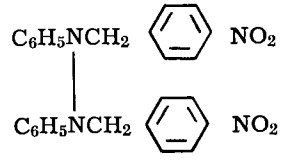


E

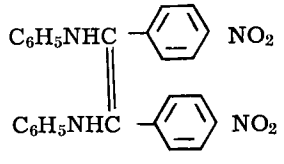
Attempts to prepare the cyclic compound (I) by other methods were not successful and led to high melting products. 4, 4'-Dinitrobenzil (7) on electrolysis gave a solid which melted above 360°C. The azoxy and carbonyl absorptions in the infrared were normal and not shifted to a higher frequency as would be expected if a strained ring were formed. The compound was insoluble in dimethylformamide and dimethylsulfoxide and could not be examined further.

The benzoin condensation of *p*-azoxybenzaldehyde was also attempted even though this compound probably has the transconfiguration. As expected a polymeric material was obtained melting above 345°C. A high melting compound was also obtained from the electrolytic reduction of this compound.

Electrolytic oxidation of *p*-nitrobenzylaniline at a platinum anode in acetonitrile containing sodium perchlorate gave the hydrazine (III) rather than the desired stilbene (IV). The structure (III) was indicated by the ir and nmr spectra.



III



IV

The latter compound (IV) would be a critical intermediate in the formation of the cyclic compound (I). It could exist in the cis configuration necessary for further cyclization because of the size of groups involved. If the dimerization proceeded first through the azoxy group, the trans isomer would result and lead, on further reaction, to linear structures. The products actually isolated from Elbs (1) procedure melted from 180° to 270°C. The formation of the hydrazine (III) instead of the stilbene (IV) definitely eliminates the possibility of forming a cyclic product (I) in the electrochemical reduction of N-*p*-nitrobenzylaniline.

Experimental

p-Azoxybenzylidenianiline (II).—The procedure of Elbs (3) was employed. *p*-Nitrobenzylaniline (10.4g) in ethanol (120 ml) was treated with a solution of sodium acetate (2.4g) in water (6 ml) and placed in a 250-ml beaker which served as the cathode compartment. The anode compartment consists of a Coors porous cup (10.8 by 2.0 cm) and was filled with a similar solution of sodium acetate in water and alcohol. The cathode was nickel sheet metal, 3.8 cm wide and 10.8 cm long formed into a cylinder. The anode was a carbon rod 0.6 cm in diameter and 10 cm long. A power supply capable of producing 4.0 amp/dm^2 was used to carry out the electrolysis.

The electrolysis was carried out at the boiling point of the solvent and gave after 2 min a quantitative precipitation of the product. Prolonged electrolysis reduced the yield to 6.2g. If the electrolysis was carried out until 4700 coulombs (10% excess) were used the yield dropped to 3.1g. The resulting yellow solid sintered in the range from 180° to 270°C, and on repeated crystallizations from dioxane and from benzene gave a product which sintered at 185° and melted at 223°-228°C. The use of a saturated solution of sodium carbonate and a lead anode (10 cm long, 5 cm wide, and 0.3 cm thick) in the anode compartment did not change the nature of the product and only caused a faster precipitation in the cathode compartment.

The same product was obtained by using zinc and

[1] NASA Trainee, 1963-1966.

alkali in methanol, sodium hydroxide and ethanol and sodium carbonate and ethanol as reducing agents and by treating p-azoxybenzaldehyde with aniline in the presence of acetic acid. Alway (2) reported a melting point of 185°-192°C for this compound. The infrared spectrum did not show any absorption above 3200 cm^{-1} and therefore eliminated structure I for the product. Frequencies were obtained at 1637 and 1590 cm^{-1} for C = N and phenyl and 1310 cm^{-1} for the azoxy group.

The NMR spectrum in hexamethylphosphoramide at 110°C gave singlets at δ = 8.20 and δ = 8.30 ppm for the =CH hydrogen, a singlet at δ = 6.72 for the 10 phenyl hydrogens, and a complex peak centering at δ = 7.56 ppm for the other 8 aromatic protons.

p-Azoxybenzaldehyde.—This compound was formed when the reduction product (II) was treated with either gaseous hydrogen chloride in ethanol, concentrated hydrochloric acid, and ethanol and aqueous boiling acetic acid. The compound melted at 193°C [(2) 194°-195.5°C.]

Electrolytic reduction of 4,4'-dinitrobenzil.—4,4'-Dinitrobenzil (7) (1.0g) dissolved in a mixture of dioxane (50 ml) and water (18 ml) containing sodium acetate (1g) was reduced electrolytically in the cell described earlier. The anode compartment contained a lead anode and a saturated solution of sodium carbonate. At a potential of 6v a current of 1.2 amp was obtained, and the electrolysis was allowed to proceed for 3 hr. The product was a yellow solid which deposited on the cathode and melted above 360°C. It was insoluble in alcohol, dioxane, nitrobenzene, dimethylsulfoxide, dimethylformamide, and hexamethylphosphoramide. The infrared spectra gave a peak at 1310 cm^{-1} for the azoxy group and a broad peak in the 2510 to 3000 cm^{-1} region for an hydroxyl group.

Benzoin condensation of p-azoxybenzaldehyde.—p-Azoxybenzaldehyde (0.5g) was refluxed with sodium cyanide (0.1g) in ethanol (100 ml) and dioxane (5 ml) for 1 hr. The resulting yellow precipitate (0.38g) melted above 345°C and was difficult to purify. The infrared spectra gave bands at 3700 cm^{-1} for the hydroxyl and 1715 cm^{-1} for the carbonyl groups.

Electrolytic reduction of p-azoxybenzaldehyde.—The reduction of this compound was carried out using a modification of the procedure of Elbs (3). The electrolytic solution consisted of ethanol (100 ml), water (6 ml), dioxane (25 ml), and sodium acetate (4g). A yellow solid (60% yield) formed during the first 10 min of the electrolysis and melted above 320°C.

1,2-Diphenyl-1,2-bis,(p-nitrobenzyl)hydrazine (III).—A mixture of a solution (60 ml) of 0.5*M* sodium perchlorate in acetonitrile, pyridine (5 ml), and p-nitrobenzylaniline (1.0g) was electrolyzed at a platinum gauze anode. The cathode compartment consisted of a Coors porous cup and contained 0.5*M* sodium perchlorate in acetonitrile and a coil of 16 gauze copper wire as a cathode. The electrolysis was carried out using 8v, which gave a current of 0.5 amp; after 2 hr the current dropped to 0.05 amp. The resulting anolyte was concentrated to 20 ml and treated with ether (200 ml). The sodium perchlorate which precipitated was removed by filtration, and the ether was washed with water and dried over sodium sulfate. Chromatography on alumina gave 1,2-diphenyl-1,2-bis (p-nitrophenyl) + hydrazine (III) (0.3g). Recrystallization from carbon tetrachloride gave a solid melting at 161°-162°C which showed no NH bands in the infrared. Peaks were obtained at 690 and 755 cm for the five adjacent free hydrogen atoms in the phenyl groups, at 850 cm^{-1} for the two adjacent hydrogens in the p-nitrobenzyl group, and at 1475 and 1365 cm^{-1} for the nitro group. The nmr spectrum gave a singlet at δ = 4.83 ppm for the methylene protons and several peaks in the region δ = 6.7-8.1 ppm for the aromatic protons.

Anal. Calcd for $C_{26}H_{22}O_4N_4$; C, 68.70; H, 4.88; N, 12.32. Found: C, 68.42; H, 4.85; N, 12.40.

Air Depolarized Electrolytic Oxygen Generator

R. A. Wynveen and K. M. Montgomery

TRW Equipment Laboratories, TRW Inc., Cleveland, Ohio

An electrochemical technique has been tested for obtaining pure oxygen from ambient air. The oxygen is separated from the nitrogen and other inerts by reacting the oxygen at a cell cathode and simultaneously electrolytically evolving oxygen at the cell anode.

A schematic drawing illustrating the basic assembly of a single cell and the electrode reactions are shown in Fig. 1. The process continues as long as air and power are supplied to the cell. In the event of loss in the air supply, the cathode reaction would revert to evolution of hydrogen and the over-all process becomes a conventional water electrolysis cell.

Experimental Technique

The cell used to evaluate the operating parameters is shown in Fig. 2. The electrodes consisted of a porous layer of platinum black and Teflon spread uniformly on and supported by a fine mesh nickel screen.[1] Each electrode had an area of 6¼in.^{2}. The electrolyte was a 32% solution of KOH. The end plates were nickel and then gold-plated stainless steel.

Air entered the top of the cathode compartment, passed through a baffling system, and exited through the bottom of the cell. The gas passage was designed to prevent nitrogen stagnation pockets from forming.

In the anode compartment the baffling was not necessary. Oxygen is evolved regardless of gas compartment geometry. The baffles were put into the oxygen side so that the gas compartments could be interchanged.

A schematic diagram of the test rig used in the single-cell tests is shown in Fig. 3. A compressed air

[1] American Cyanamid type AB-1.

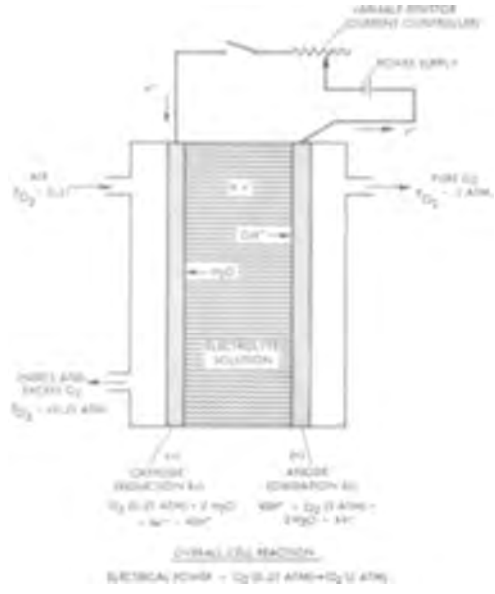

Fig. 1. Cell reactions and schematic of the TRW oxygen generator.

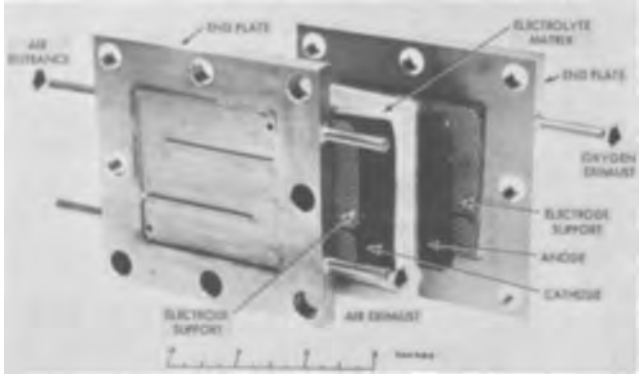

Fig. 2. Single-cell oxygen concentrator

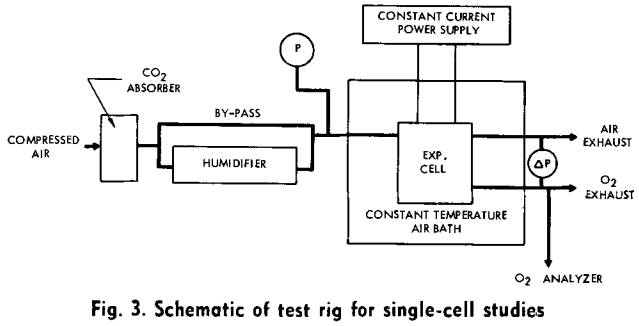

Fig. 3. Schematic of test rig for single-cell studies

source was used when cell tests were conducted at ambient pressure. A vacuum pump, simultaneously connected to the air and oxygen exhausts, was used when inlet pressures less than ambient were being tested.

The air was passed through a CO_2 absorber to remove the traces of carbon dioxide found in air to prevent it from neutralizing the KOH electrolyte. To prevent the cell from desiccating it was necessary for the net transfer of water into and out of the concentrator to be zero. This was accomplished by bubbling the air through a humidifier located in a constant temperature water bath. The vapor pressure of the water in the air entering the concentrator was thus made equal to the vapor pressure of the electrolyte, at the cell operating temperature, by controlling the water bath temperature. The moisture content of the incoming air was varied depending on the temperature and concentration of the electrolyte.

A pressure gauge was used to monitor the air inlet pressure, and a differential pressure gauge was used to measure the difference in pressure between the exit air stream and exit oxygen stream.

Results and Discussion of Results

A coulomb balance was made to demonstrate that the reactions occurring were the four electron reactions given in Fig. 1. The current put through the concentrator correlated with the oxygen consumed and the oxygen evolved as experimentally measured. The calculated and experimentally measured values of the oxygen output agreed with each other within 0.1% when four was used as the number of electrons transferred in the process.

The theoretical reversible voltage for this reaction is 0.01v. Because of activation polarization and to a small extent concentration polarization and ohmic losses, the voltages required during the electrochemical concentrating process ranged from 60 to 100 times greater than the theoretical value. The exact value was found to depend on air flow rate, air inlet pressure, cell operating temperature, number of accumulated operating hours on the cell, and cell moisture balance.

The data presented in Fig. 4 show a typical performance curve obtained with the cell. The top curve shows the voltage required to separate the oxygen and includes the IR drop. The bottom curve represents the IR free voltage. All IR free data were taken with a transistorized version of the Kordsch-Marko bridge (1).

A typical resistance value for the cell, evaluated at 100 ASF, was 0.0008 ohm-ft^2 or 0.74 ohm-cm^2.

The air flow rate into the cell was four times the stoichiometric (theoretical) air flow rate, T, for the oxygen being generated.

The air flow rate may also be expressed in terms of the percentage of the oxygen removed from the incoming air stream and transported to the anode compartment. Thus a flow rate of $4T$ means 25% of the oxygen found in the incoming air is consumed at the cathode and generated at the anode. Two T would mean 50% of the O_2 is removed, while 3 and $5T$ mean 33 and 20% are removed, respectively.

The data presented in Fig. 5 are the IR free performance contributed by the individual half-cells. The reference electrode was a platinum black-Teflon composite (the same as used for the cell electrodes), electrically isolated from the anode, but located against the porous matrix material in the same plane as the anode. The reference electrode was fed with pure oxygen from an external source through an isolated manifold system but at the same pressure as the anode compartment.

The limiting current density for the cell in the range of 120 to 130 ASF results from a gas phase polarization at the cathode. Proper geometrical design of the cathode compartment can extend the current density

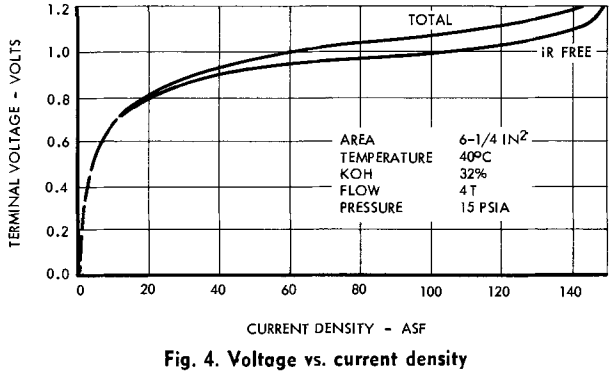

Fig. 4. Voltage vs. current density

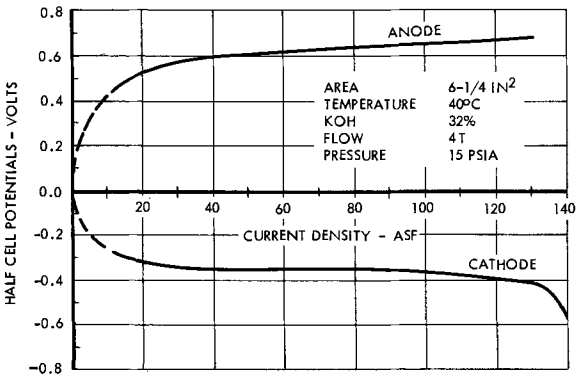

Fig. 5. Half-cell performances

over which one can operate before reaching the limiting value.

The performance of the cell is dependent on the flow rate of the incoming air. This dependency is illustrated in Fig. 6 for flow rates corresponding to 2*T*, 3*T*, 4*T*, and 5*T*. The power required to generate a given quantity of oxygen decreases as the flow rate increases although increasing the flow rate to above 5*T* had little effect on lowering the power required.

As may be observed from the curves, there is a decided difference in onset of the limiting current density between flow rates of 2*T* and 3*T*. At 4*T* and 5*T* the performance still improves (power required decreases), but at a slower rate. For this cell geometry it was found that flow rates greater than 5 had little effect on improving the concentrator's performance.

Cell performance is dependent on inlet air pressure as well as inlet air flow rates. This is illustrated in Fig. 7. Here experiments were performed at inlet pressures of 4, 6, 8, 11, and 15 psia. A constant air mass flow rate was used for all the tests. As the inlet air pressure increased the performance increased.

Both air flow rates and inlet air pressures are important in regard to cell performance. However, the cell's moisture balance is also critical. In Fig. 8 are

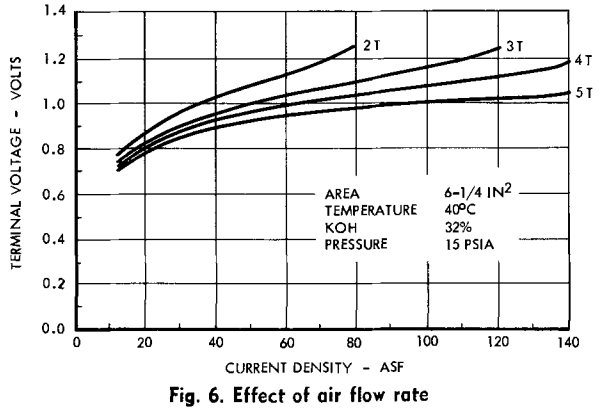

Fig. 6. Effect of air flow rate

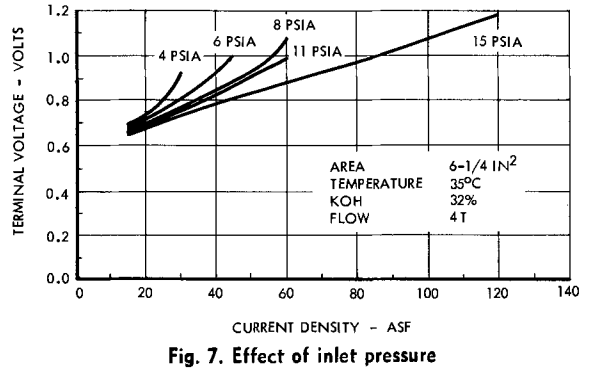

Fig. 7. Effect of inlet pressure

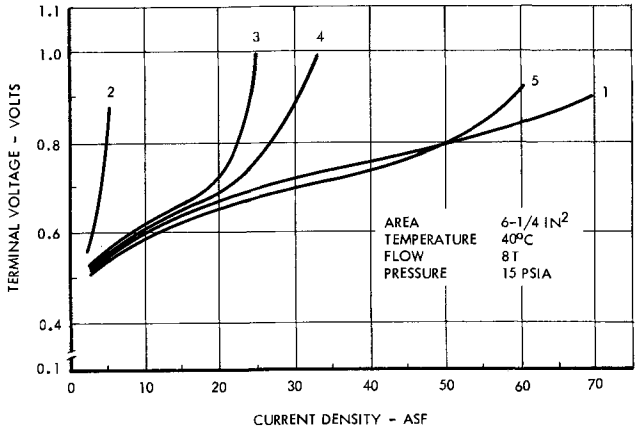

Fig 8. Effect of cell moisture balance

presented data taken during the time the cell's moisture content was varied.

Curves 1 through 5 were all obtained with the same cell. Curve 1 was the initial performance obtained while the cell had a proper moisture balance between that required by the cell and the air feed stream. Curve 2 was obtained after the cell had been desiccated, *i.e.*, that the water content of the incoming air was less than that required to match the vapor pressure of the electrolyte. Curves 3, 4, and 5 illustrate the improvement in cell performance, as the cell was brought back to its initial moisture conditions. The results presented in this figure emphasized the importance of moisture balance on cell operation and the importance of knowing that such a balance exists when performance (parametric) data are taken.

At any one moisture balance a typical family of parametric (flow rate, pressure, etc.) curves can be obtained. All experimental data presented previously were obtained under balanced moisture conditions. When the previously presented data are collected under the conditions represented in curves 2, 3, or 4 of Fig. 8, an entirely different group of relationships is found. The trends are the same, but the magnitude of values, such as the limiting current density, is markedly different. In addition, if the effect of variables, such as flow rate, is determined while the cell is either going into or out of moisture balance, the true effect of this variable is not observed. In fact, the general trends can be reversed merely by noting the change in cell performance. Therefore, moisture balance is truly important in evaluating a cell's performance characteristics.

Electrode activity is also influential. Initial performance curves taken on a cell assembled with new electrodes were always better. However, in all of these experiments the electrodes had been tested for a sufficient number of hours (typically 100-200 hr) so that changing of electrode activity was not likely to obscure the results of these tests.

These data indicate that it is essential to know the condition of the cell's moisture balance in determining the effect of parameters on cell performance when the electrolyte is held in a porous matrix.

For a cell to be reliable in producing oxygen its performance over a long period of time must be demonstrated. Data illustrating concentrator performance for over 600 hr are shown as Fig. 9. Here the current density was held constant at 40 ASF and the voltage was followed as a function of time. The variation in voltage from 0.7 to 0.9v may be observed. The tests were concluded at the end of 600 hr for sake of convenience in the laboratory.

Conclusions

The four-electron transfer process for concentrating oxygen from ambient air was experimentally demonstrated by observing that a coulomb balance predicting

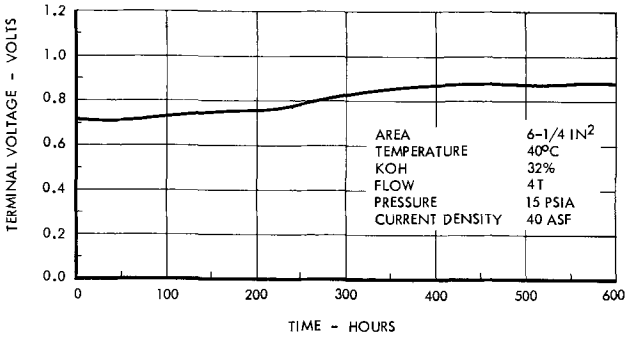

Fig. 9. Oxygen concentration performance over extended time period.

the quantity of gas generated in a given time period was within 0.1% of the experimental quantity of gas collected over this same time period.

The performance of the concentrator cell was found to vary with inlet air flow rates, inlet air pressures, and moisture balance between the water content in the inlet air stream and the vapor pressure of the electrolyte.

The limiting current density of the cell greatly increased between inlet flow rates of $2T$ and $3T$. The performance was still better at $4T$ and $5T$ but the rate of gain was slower. The higher the inlet pressure of the air stream, the better was the performance of the cell. At a 4 psia inlet this limiting value was 30 ASF. At 15 psia this limiting value was beyond 120 ASF.

In a single test the limiting current density of the cell could be varied anywhere from 5 ASF to beyond 120 ASF, depending on what the moisture balance relationship was between cell electrolyte and the vapor pressure of the water in the incoming air stream.

On the Mechanism of Oxygen Evolution at Iridium Electrodes

A. Damjanovic and M. K. Y. Wong

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

Recently, the mechanisms of oxygen reaction at iridium electrodes were analyzed both for acid (1*N* $HClO_4$) and for alkaline (1*N* KOH) solutions (1). Then available kinetic parameters were found consistent with the reaction paths listed in Table I. On the basis of indirect evidence it was suggested that the likely reaction path is the "electrochemical oxide" path (2) with the second reaction step in the anodic direction as the rate-controlling at low cathodic and anodic, and the first reaction step as the rate-controlling at high anodic overpotentials. Here, additional evidence is presented supporting the electrochemical oxide path for oxygen evolution at iridium electrodes.

The pH dependence of overpotential in oxygen evolution in acid solution can discriminate between electrochemical oxide path and the other two paths of Table I. In acid solution both at low and high η's, $d\eta/dp$H is positive for the second, rate-controlling, step of the electrochemical oxide path, and negative for the third steps of the latter two paths, where the $d\eta/dp$H dependence is the same. In alkaline solution, the $d\eta/dp$H is negative both at low and high anodic overpotentials but with different values. Observed dependences are also given in Table I.

Table I. Calculated and observed pH dependence of overpotential in oxygen evolution

	Acid		Alkaline	
	Low η	High η	Low η	High η
Electrochemical oxide path (2)				
$S + H_2O \rightarrow SOH + H^+ + e^-$	RT/F	RT/F	$-RT/F$	$-RT/F$
$SOH \rightarrow SO + H^+ + e^-$	$RT/3F$	RT/F	$-RT/3F$	$-RT/F$
$2SO \rightarrow 2S + O_2$				
$S + H_2O \rightarrow SOH + H^+ + e^-$	RT/F	RT/F	$-RT/F$	$-RT/F$
$SOH + H_2O \rightarrow SOHOH + H^+$	0		$-RT/F$	$-RT/F$
$SOHOH^- \rightarrow SOHOH + e^-$	$-RT/3F$	$-RT/F$	$-RT/3F$	$-RT/F$
$SOHOH \rightarrow SO + H_2O$				
$2SO \rightarrow 2S + O_2$				
"Krasilshchikov" path (3)				
$S + H_2O \rightarrow SOH + H^+ + e^-$	RT/F	RT/F	$-RT/F$	$-RT/F$
$SOH \rightarrow SO^- + H^+$	0		$-RT/F$	$-RT/F$
$SO^- \rightarrow SO + e^-$	$-RT/3F$	$-RT/F$	$-RT/3F$	$-RT/F$
$2SO \rightarrow 2S + O_2$				
Observed dependence at Ir	+18	+48	−15	−55

Potential-anodic current density relationships are determined both in $HClO_4$ and KOH solutions of different concentrations. The experimental procedure, including the purification of the solutions, was the same as in a previous work (1). In Fig. 1 and 2, results are given for acid and alkaline solutions, respectively. These results confirmed the reported characteristics of two distinct linear V-log i regions in evolution both in

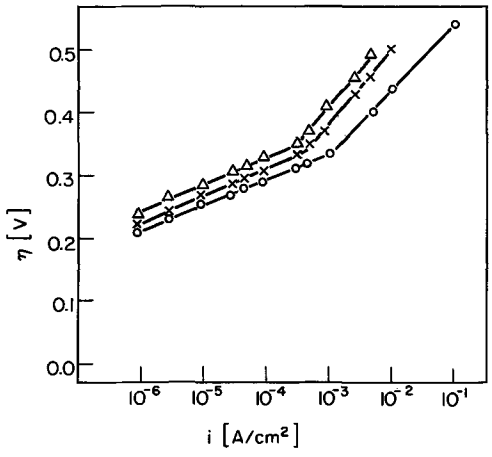

Fig. 1. V-log i at Ir in acid solutions. Open circles, pH 0.9; crosses, pH 1.9; triangles, pH 2.9.

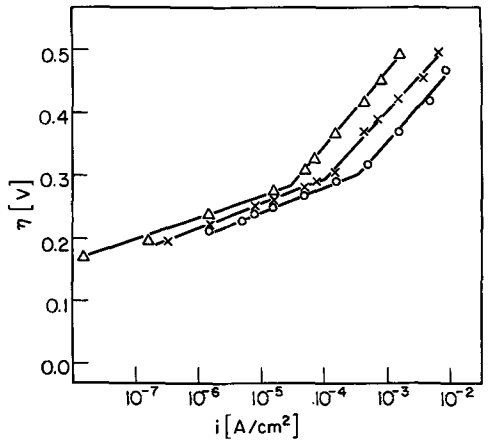

Fig 2. V-log i at Ir in alkaline solutions. Open circles, pH 14; crosses, pH 13; triangles, pH 12.

acid and in alkaline solutions with the Tafel slopes at low η's corresponding to $2RT/3F$ and at high η's to $2RT/F$. The pH dependence of overpotential in acid solutions are close to +18 and +48 mv/pH at low and high overpotentials, respectively. In alkaline solution these are −15 and −55 mv/pH. These dependences are in agreement only with the calculated dependences for the electrochemical oxide path. Present experimental evidence, hence, supports the electrochemical oxide path for oxygen evolution at Ir electrodes.

Improvement of a Square-Wave Technique for Capacitance Measurements

R. G. Barradas and E. M. L. Valeriote

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

The development of a square-wave charging technique for the measurement of differential capacities of the electrical double layer has been described by Hackerman and co-workers (1, 2). This method is based on analysis of the repetitive charging and discharging of the electrical double layer through a series resistance R_s. An evaluation of the technique was carried out by the authors (3) who observed a substantial dependence of the measured capacitance-potential curves, and their reproducibility, on the value of R_s. Agreement with electrocapillary data and with capacity-potential curves obtained by the impedance bridge method appeared to be better for larger values of R_s. Because of the interdependence of the experimentally variable quantities (3), values of R_s large enough to give good agreement could not be used without a change in other parameters. The simplest resolution of this problem proved to be a reduction of the area of the mercury electrode.

Experimental Results

Experiments were carried out as previously reported (3). However, in place of the 5 cm² mercury pool, a hanging mercury drop electrode of about 7 mm² area was used (Fig. 1) for which the size of the mercury drop could be controlled by an Agla micrometer syringe (Burroughs Wellcome and Company, London) similar to that reported by Narayan (4). The area of the drop could not be absolutely calculated, possibly because creepage of the solution up the glass capillary may have caused some effective increase of the amount of mercury surface exposed to the solution, and drop areas had to be calculated by relative methods. For the data displayed in Fig. 2, showing the variation of capacity with potential for a 1*N* KCl solution, the area was calculated by comparison of the differential capacity (per unit area) reported by Grahame and Parsons (5) at one potential with the total capacity determined by the charging technique at that poten-

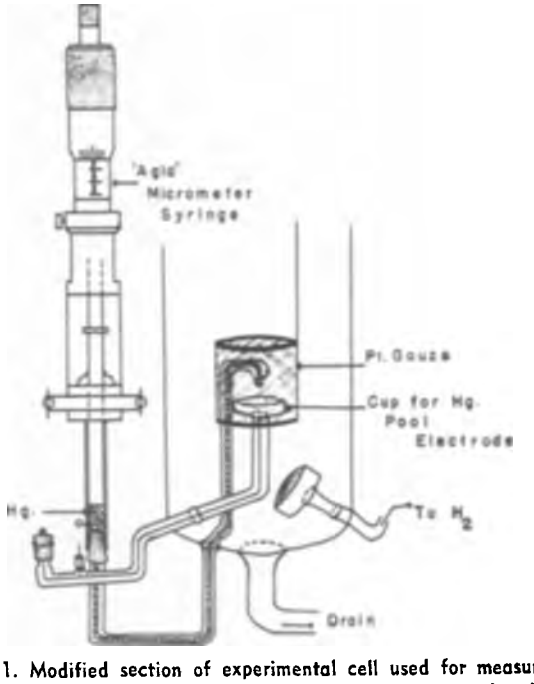

Fig. 1. Modified section of experimental cell used for measurement of double layer capacities by the square-wave charging technique.

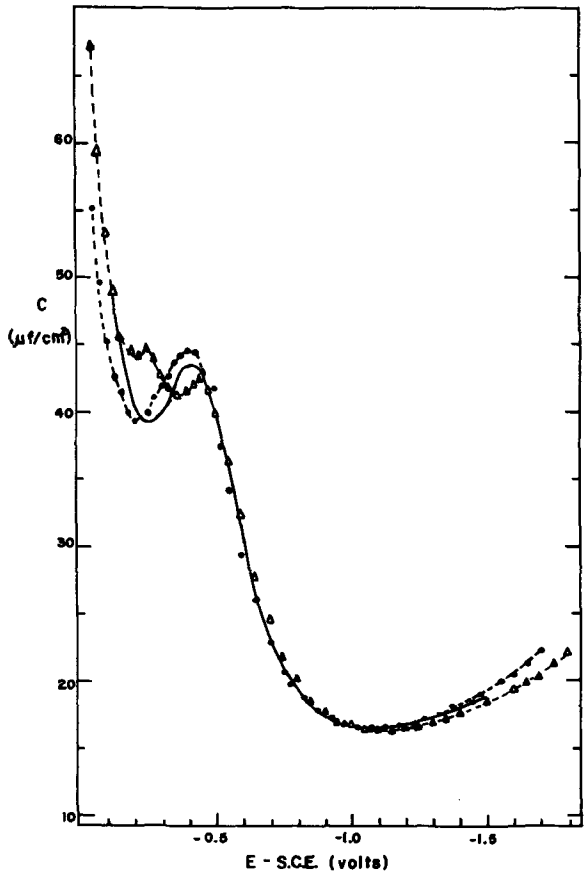

Fig. 2. Dependence of capacity on potential: Grahame and Parsons (5)-solid curve; 1N KCl measured with cathodic polarization, - - - △; 1N KCl measured without cathodic polarization, - - - •.

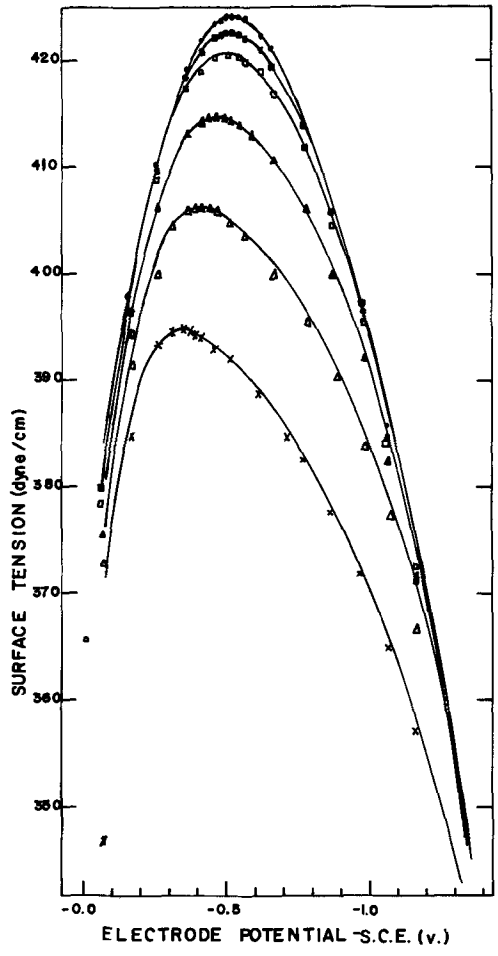

Fig. 3. Comparison of electrocapillary data (points) and doubly integrated capacity data (solid curves) for 1N KCl and 1N KCl with various concentrations of added furfurylamine. 1N KCl •; concentration of furfurylamine in 1N KCl; 0.003M ■, 0.01M □, 0.03M ▲, 0.10M △, 0.30M X.

tial. The solid curve in Fig. 2 is the data of Grahame and Parsons (5); the points were obtained for R_s = 77 K "with" and "without cathodic polarization." In the case of the curves obtained with cathodic polarization the potential was rapidly switched from —2.0v (SCE) to the potential at which the capacity was to be measured immediately before the determination.

Figure 3 displays a comparison of directly determined electrocapillary data (7) with doubly integrated capacity curves for various concentrations of furfurylamine in 1*N* KCl. The calculated surface tension data were obtained by numerical integration (6) on an IBM-7094 Computer using integration constants determined in this laboratory (7). No cathodic polarization was used when organic additives were present since it would have interfered with the attainment of adsorption equilibrium.

Discussion

For 1*N* KCl, the region of the hump at anodic rational potentials was distorted somewhat when cathodic polarization was employed, but good agreement was obtained over all of the remainder of the curve [cf. ref. (1) and (3) in which poor agreement with the literature was reported over substantial potential ranges for various inorganic electrolytes]. Without cathodic polarization there is excellent agreement at all cathodic rational potentials and only small differences at anodic rational potentials; the shape of the hump was reproduced more satisfactorily. This appears to indicate that the solution was sufficiently pure and that no advantage is gained by cathodic prepolarization. Upon additions of furfurylamine a good comparison with directly determined electrocapillary data (7) was observed (Fig. 3), and correspondingly good results were also obtained for other related organic systems.

The improved agreement would appear to support in part the suggestions of Brodd and Hackerman (2) concerning the use of the technique in determining electrode areas. Areas might be measured by comparison of capacities between small enough samples of the same metal provided that the area of at least one sample is determined by an independent method such as a gas adsorption technique.

In summary, we conclude that as expected the square-wave method is less accurate and dependable than the impedance bridge technique for fundamental double layer studies. A preferable choice would be the automatic method (8, 9[1]) of recording capacity-potential curves by the use of a phase-sensitive device supplementary to a polarograph, which gives better agreement with the results of Grahame and Parsons (5). Further evidence using the automatic recording method for mercury Teflon capillary and platinum electrodes will be later presented elsewhere (10).

Metal Membrane Electrodes

E. B. Buchanan, Jr., and J. L. Seago

Department of Chemistry, University of Iowa, Iowa City, Iowa

The specificity and simplicity of the measurement of pH with the glass electrode has induced many chemists to search for other ion-specific electrodes. A number of such electrodes have been suggested. In general, they involve the measurement of the potential developed by a concentration cell. The difference in concentration within the cell is maintained by an appropriate membrane. Thus, the ion-specific electrode is not a simple electrode but rather one-half of a concentration cell. The important element in a successful electrode of this type is the membrane. The membrane should respond to a single ionic species. For this purpose electrodes have been developed which utilize membranes fabricated from ion exchange resins (1-7), clays (8, 9), and either collodion, or paraffin, or silicon rubber which is imbedded with the crystals of a salt of the desired ion (10-15).

There are many theories and much diversity of opinion on the mechanism by which these electrodes operate. Some explanations propound a transport of ionic material through the membrane while others involve a Donnan potential developed at the surface (11, 13-15).

This study encompasses a series of membranes which involve an oxidation-reduction reaction at the surface and electron transfer through a bipolar membrane. For this purpose cells of the form

$$\text{SCE/Sample Soln.//Membrane//Ref. Soln./SCE}_{\text{(Metal)}}$$

were constructed. The metals and their respective ions selected for study were copper, cadmium, silver, and thallium. By maintaining the concentration of the solution on one side of the membrane constant and varying the concentration of the opposing side, the concentration dependence of each cell was studied.

Experimental

Apparatus.—The electrode was constructed by sealing the metal foil or billet to the end of an 18 mm glass tube. The seal was made with Hot Melt Glue obtained from Montgomery Ward. Figure 1 shows the experimental apparatus.

Potential measurements were made with a Cary Model 31 vibrating reed electrometer equipped with a Cary/Honeywell Multi-range Recorder. A recorder response of 1 mv/in. was used where possible. Otherwise, a response of 3 mv/in. was employed.

Procedure.—The concentration dependence of the membrane electrode was evaluated by measuring the potential that was developed between a pair of matched reference electrodes when the metal membrane separated the two halves of a concentration cell.

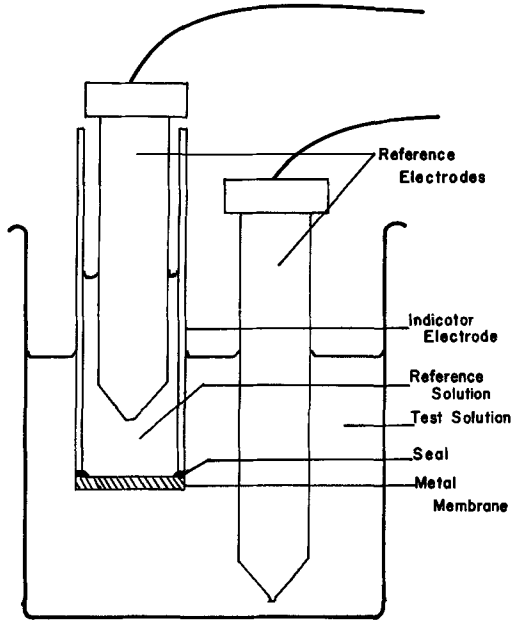

Fig. 1. Metal membrane electrode cell assembly

The solution on one side of the membrane, reference side, was maintained at a constant metal ion concentration of 0.01M. The solution on the other side, sample side, was varied between the limits specified below.

The effects of atmospheric oxygen, acidity of the solutions, and amalgamation of the membrane surfaces were examined in an attempt to achieve a theoretical response from the cells. Atmospheric oxygen was excluded from the solutions by deaerating the solutions with a rapid stream of nitrogen and storing the deaerated solutions in a nitrogen-filled glove bag. The bag is available from I²R, 108 Franklin Street, Cheltenham, Pennsylvania. The effects of acidity on the measured potential were examined by preparing two sets of solutions, one set containing only the salt of the desired ion, the other set containing, in addition to the salt, 1M sulfuric acid. The surface condition of the membrane was considered as a factor which could also influence the potential of the cell. Both the polished free metal and lightly amalgamated metal surfaces were employed. The billet or foil was amalgamated by rubbing the metal surface with mercury while the surface was submerged in 6M sulfuric acid. A limited amount of mercury was used to ensure that the mercury did not dissolve the entire membrane. It was necessary to amalgamate the membrane after it

was sealed to the glass tube since the amalgamated surface would not adhere to the glue. All experiments were performed at room temperature which was maintained at 22°-27°C. All chemicals employed were of analytical grade.

Silver membrane electrode.—A membrane of silver foil was used. Solutions of silver nitrate in the concentration range of 1 to 1 x 10^{-7}M were placed on the sample side of the membrane. All experiments were conducted in the presence of atmospheric oxygen. The reference electrodes were

$$Ag/AgCl, KCl_{sat.}/3\% \text{ Agar}, NaNO_{3sat.}//$$

Copper membrane electrode.—Both a polished copper foil and a surface amalgamated copper foil membrane were employed. Acidified copper sulfate solutions in the concentration range of 1 to 1 x 10^{-6}M were used on the sample side of the membrane. The effect of oxygen was determined by working in both the presence and absence of air. The reference electrodes were

$$Ag/AgCl, KCl_{sat.}/3\% \text{ Agar}, Na_2SO_{4sat.}//$$

Cadmium membrane electrode.—Polished cadmium metal billets and surface amalgamated cadmium billets were employed as membranes. Cadmium sulfate solutions in the range of 1 to 1 x 10^{-6}M were used on the sample side of the membrane. The effect of acidity was determined by preparing the solutions in the presence and absence of sulfuric acid. The effect of oxygen was studied by making measurements in both the presence and absence of air. Matched Beckman SCE were the reference electrodes employed.

Thallium membrane electrode.—The membranes used in this cell were made of a polished thallium billet and a surface amalgamated billet. The polished thallium billet was stored in 0.1M thallium nitrate solution. The oxide coating is removed by this storage since both thallium oxide and hydroxide are water soluble. Both acidified and neutral solutions of thallium nitrate were utilized. The experiments were conducted in the presence and absence of air. The concentration range of 0.1 to 1 x 10^{-6}M thallium nitrate was put into use on the sample side of the membrane. The reference electrodes used were matched Beckman SCE with an exterior fiber sleeve filled with saturated sodium nitrate.

Results and Conclusions

The silver membrane electrode is characterized by a rapid response. In 1 min the cell is within 0.1 mv of steady-state values. The theoretical concentration dependence is obtained over the concentration range of 1 to 3 x 10^{-6}M. Figure 2 illustrates the Nernst equation type of dependence shown by this electrode.

Cadmium metal is more readily oxidized than silver, and, therefore, greater care must be taken to secure reproducible results from the membrane surface. In the absence of air there is no significant difference between the response of the amalgamated and the pure cadmium metal membranes. In air-saturated solutions the use of the amalgamated electrode is essential if reproducible data are to be obtained. The presence of sulfuric acid in the air-saturated solutions seems to improve the response slightly. However, the main effect is a decrease in the time required to reach steady-state values. The potential was within 1 mv of the steady-state potential in 5 min. Figure 3 shows the range of concentration over which this electrode is applicable.

The requisite conditions for the theoretical response of the copper electrode are even more stringent. Only when the membrane surfaces were amalgamated, oxygen carefully excluded, and 1M sulfuric acid was present in the solution did the cell become capable of providing a theoretical response. Even under these conditions the response of the electrode was sluggish.

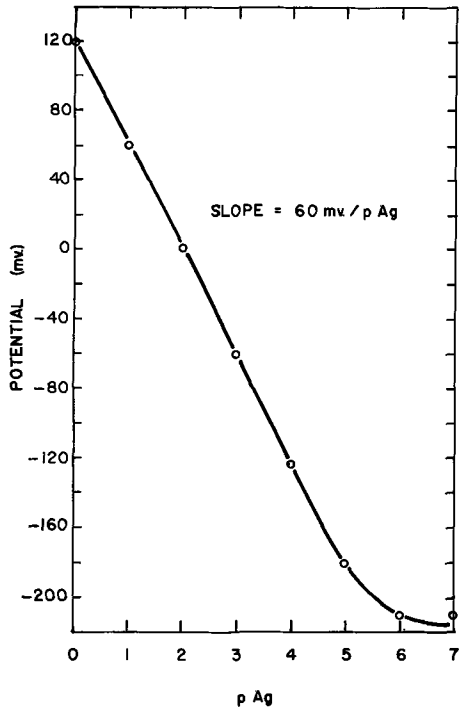

Fig. 2. Silver membrane electrode response

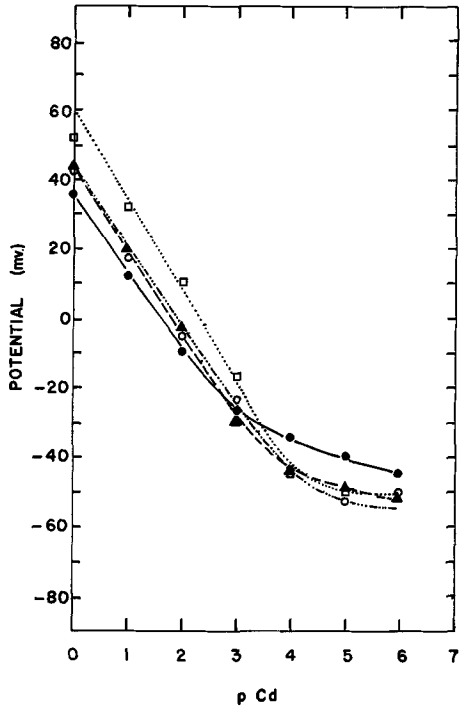

Fig. 3. Cadmium membrane electrode response: ○, cadmium metal membrane, nitrogen atmosphere; □, amalgamated cadmium membrane, nitrogen atmosphere; ●, amalgamated cadmium membrane, air; ▲, amalgamated cadmium membrane, air, 1M H_2SO_4.

Five minutes were necessary for the cell to achieve a potential that was within 1 mv of a steady-state potential. Figure 4 indicates the concentration range over which the cell is capable of producing a theoretical response.

Apparently trace amounts of oxygen catalyze the production of the Cu(I) through the formation of the insoluble Cu_2O. The production of the red oxide is minimized by the conditions which give a theoretical response. This hypothesis is supported by the observation that the copper electrode under no known conditions gives satisfactory results in the presence of

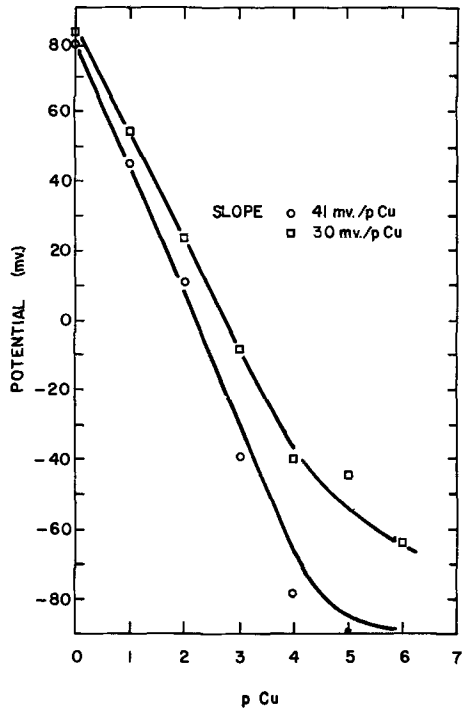

Fig. 4. Copper membrane electrode: ○, copper metal membrane, nitrogen atmosphere, 1M H_2SO_4; □, amalgamated copper membrane, nitrogen atmosphere 1M H_2SO_4.

atmospheric oxygen. Earlier attempts at the use of the copper electrode have involved a pre-equilibration of the Cu(II) solutions with metallic copper before immersion of the copper electrode under experimental conditions which assured the complete exclusion of oxygen (16).

Figure 5 shows the response of the cell utilizing a thallium billet membrane. The theoretical response is only obtained in an oxygen-free atmosphere. This is not surprising as the thallium metal reacts readily with the oxygen of the air forming a yellow oxide coating. Once the coating is removed, and its further formation is prevented, the electrode displays the desired potential. Potential values within 1 mv of steady-state values were obtained in 5 min. Amalgamation of the surface or the presence of 1M sulfuric acid had no effect on the final potential of the cell. However, in the presence of either one or both of these conditions, the response time (±1 mv from steady state) was reduced to 3 min.

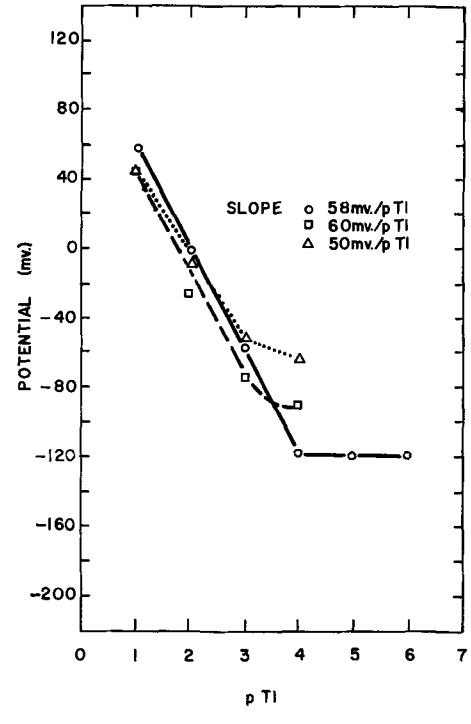

Fig. 5. Thallium membrane electrode response: ○, thallium metal membrane, nitrogen atmosphere, in the absence and the presence of 1M H_2SO_4; □, amalgamated thallium membrane in a nitrogen atmosphere; △, amalgamated thallium membrane, 1M H_2SO_4 in air.

In air, using the surface amalgamated thallium billet and neutral thallium nitrate solutions, no response was obtained. If the thallium solutions were made 1M in sulfuric acid, the amalgamated thallium billet displayed a rapid linear response to a thallium ion concentration of 1×10^{-3}. The slope of the curve was 50 mv/pTl. The authors believe the presence of the sulfuric acid prevents the air oxidation of the thallous ion to the thallic ion. In an alkaline solution the insolubility of thallic hydroxide enhances the ease of this oxidation.

The entire cell may be considered as two cells in series, bridged by an appropriate metal junction. While the membrane is a decided convenience and ensures that the metal has been subjected to the same stresses and distortions, a wire bridging the two cells would give essentially the same results. Each side of the membrane can be thought of as a single electrode which, in conjunction with a reference electrode, produces a potential corresponding to the concentration (activity) of the metal ion in solution. The value of this potential can be obtained from the Nernst equation.

$$E = E^\circ + E_{ref} + \frac{RT}{n\mathbf{F}} \ln C$$

The potential obtained for the entire cell should be the difference in potential calculated for each side of the membrane.

$$E_{cell} = E_{samp} - E_{ref}$$

Substituting the values obtained for each side from the Nernst equation and simplifying gives

$$E_{cell} = \frac{RT}{n\mathbf{F}} \ln \frac{C_{samp}}{C_{ref}}$$

which is the equation for a concentration cell without transference.

From a consideration of the cell, it is apparent that one side of the membrane is acting as an anode while the other acts as a cathode; hence, the term bipolar membrane as used above. In spite of its bipolar character, there can be no potential difference within the membrane itself since a metal cannot show an internal potential difference without a flow of current.

Within the cell there are six sites at which potentials can be considered to arise. Four of these are phase boundaries and two are liquid-liquid junctions. The two connections to the external circuit and the two solution-membrane interfaces constitute the four phase boundaries while the liquid-liquid junctions are found between the reference electrodes and the solution in each side of the cell. The liquid-liquid junction potentials are normally small, and the difference between them results in a still smaller potential. The connection to the external circuit is made through a reference electrode and, therefore, provides a constant potential. The cancellation of the potential due to the external connection and the absence of a potential difference within the membrane causes the measured potential to be a direct measure of the potential difference between the two solutions provided the liquid-liquid junction potentials are neglected. The presence of these liquid-liquid junction potentials even though they are small precludes the use of the cell for the thermodynamic measurement of activities.

The metal membranes are unique in that they involve neither an ionic transport nor the process of diffusion within the membrane. The potential at the metal membrane involves an oxidation-reduction reaction as contrasted to an adsorption or ionic transport mechanism found in other types of ion-responsive membranes. In order to function properly any metal membrane requires reversibility of the oxidation-reduction process. This imposes a serious limitation on the selection of metals as not all will exhibit the degree of reversibility required. Our data indicate that under proper experimental conditions steady-state potentials are achieved very rapidly and are reproducible.

SOLID STATE SCIENCE

The Permeation of Isolated Anodic Zirconium Oxide Films by Potassium Nitrate

A. H. Mitchell

Pitman-Dunn Research Laboratories, Frankford Arsenal, Philadelphia, Pennsylvania

and R. E. Salomon

Department of Chemistry, Temple University, Philadelphia, Pennsylvania

ABSTRACT

The permeation of anodic zirconium oxide films by KNO_3 has been investigated. Dependence of the permeation rate on film thickness, permeant concentration, film area, and temperature was studied. Film thicknesses ranged from approximately 700 to 7000Å. Permeation rates on the order of 10^{-8} moles cm^{-2} sec^{-1} were observed. Rates were found to be directly proportional to KNO_3 concentration and film area and inversely proportional to film thickness. Apparent activation energies calculated from rate constant-temperature data varied with the film thickness. A simple model proposing permeation through a system of cylindrical charged pores is consistent with the data for thin films. The permeation of thicker films may be complicated by additional factors.

Since the advent of the use of zirconium and its alloys in nuclear reactors, the study of oxide films on zirconium has been of considerable interest. A number of investigators have studied both anodic and corrosion formed oxide films on zirconium obtaining information on their formation, structure, and electrical properties (1-8). Evidence has been found to suggest that so-called barrier-type anodic oxide films in contact with electrolyte solutions are penetrated by them (9-12). However, the nature of the flaws allowing penetration and the mechanism by which it might be accomplished remain largely speculative. In this paper, quantitative studies of the penetration of anodic zirconium oxide films by electrolyte are described, and a possible model for the permeation is proposed.

Experimental

The materials, experimental techniques, and equipment used in this investigation have been briefly described in an earlier publication (12). Specimens of chemically polished foil about 50 cm^2 in area were anodized on one side at constant voltage for 18 hr in a boric acid-sodium borate electrolyte buffered at pH 9. The anodization parameters were kept similar to those of earlier investigations (12, 13) so that the growth factor of 27 Å/v over comparable potential ranges could be reasonably assumed. Leakage current densities ranged from 1 μa cm^{-2} for the thinnest films to 4.5 μa cm^{-2} for the thickest. After anodization, the films were washed and stored in a moist atmosphere. Several specimens were anodized at the appropriate voltages to insure a range of oxide thickness for permeation measurements.

Preliminary experiments were made to determine that electrolytes and other species in solution did penetrate the oxide film. In preparation for these experiments, samples of about 1 cm^2 were cut from the anodized specimens and clamped in a simple cell prepared from two Lucite blocks and glass tubing. The isolation of an approximately 3.0 mm^2 area of film was effected with a 0.5% HF solution. The cell was then clamped in a controlled temperature bath, and solutions were carefully added to each side of the cell so that the exposed film area separated them. The cell was then left to stand for periods of from 20 to 72 hr. There was no stirring. Mechanical vibration in the cell supports was relied on to agitate the solutions sufficiently.

Quantitative permeation measurements were made in a Lucite permeation cell described in Fig. 1. Its dimensions are approximately 3.5 x 3.5 x 2 cm. The thickness of the oxide and foil was exaggerated for the sake of clarity.

The anodized foil was clamped between the two blocks, and a small area of oxide film was isolated with a 0.5% HF solution. The area was well washed. The cell was then clamped in a constant temperature bath, and conductance water was slowly added to the

chamber containing the electrodes while electrolyte was simultaneously added to the other chamber. KNO_3 was used in all of the measurements. Stirring was accomplished on the low concentration side with a bent glass rod. Studies were made on 27, 50, 100, 150, 200, and 250v films at temperatures of 15°, 25°, and 35°C. The permeation was monitored by measuring the increase in conductance of the water in the conductance chamber as KNO_3 permeated the exposed film.

Results

The results of the preliminary experiments are presented in Table I. The presence of permeated species on either side of the cell was detected by standard methods of qualitative analysis or by spot tests (14). Flame spectrophotometric checks were made for the presence of the alkali metal ions. All salts permeated the film in either direction. Organic molecules such as methyl orange and sucrose apparently did not penetrate the film at all.

The data resulting from the quantitative permeations consisted of the measured conductance of the water in the conductance cell at several time intervals. The conductances were converted to concentration of KNO_3 and plotted against the time. These curves, after about the first 3 min, proved to be linear. Typical curves for each film thickness are presented in Fig. 2. The rate of permeation was given by the slope and is expressed in moles sec^{-1} cm^{-2}. The permeation rates (average of three or more determinations) for all the films determined at three different temperatures are given in Table II. The rate was found to be proportional to the KNO_3 concentration, to the reciprocal film thickness for thin films, and to the area of film exposed for permeation (Fig. 3-5).

It was previously reported (12) that the permeation rate could be expressed by the empirical equation

$$r = cP = cP_o \exp(-E/RT) \quad [1]$$

where r is the rate, c is the concentration of permeating KNO_3, and P, P_o, and E are constants. With the inclusion of the film thickness and isolated area dependence, the rate for films up to 150v thick can be empirically expressed by

$$r = cP'A/L \quad [2]$$

where A is the area, L is the film thickness, and the other terms retain their identities. The constant P' was calculated. It can be seen, however, (Table III) that P' was not constant, apparently varying with the film thickness. The fact that P' is some function of the thickness was further demonstrated by the constancy of P' when the film thickness remained the same and the concentration was varied (Fig. 3). When the log of P' for films of each thickness was plotted against the reciprocal absolute temperature, straight lines were obtained.[1] The slope gave the apparent ac-

tivation energy, E, listed in Table IV. Although expected, no osmotic phenomena were observed. Permeation rates were affected by the pH of permeating KNO_3, increasing slightly as the pH was lowered.

Discussion

The ease of permeation at low temperatures is an indication that the membrane is broken at intervals by channels or holes. This is not a new concept for many investigators have discussed the origins of flaws that can exist in anodic films (15-17). The rectifying action and the leakage currents exhibited by anodic films have also been variously attributed to the existence of flaws, pores or weak spots (17, 18). Replica electron micrographs at magnifications of 12 to 15 x 10^3 X, however, showed film surfaces to be free of gross flaws.

A simple idea of the size of the holes may be obtained from selectivity observations. For instance (Table I) the sucrose molecule apparently did not penetrate the film. Therefore, the holes must be on the order of the dimensions of the sucrose molecule or smaller. The minimum cross sections of the sucrose molecule have been given as about 8 x 10Å.

Another indication of the pore size is the type of process occurring through the hole. Very large pores would probably be filled with electrolyte, and free diffusion of the salt in the solvent would be a likely penetrating mechanism. The activation energy for free diffusion of KNO_3 has not been reported. However, it should be near the value reported for the free diffusion of KCl which is 4.4 kcal mole^{-1} (19). The apparent activation energy for permeation of the thinnest ZrO_2 films (Table IV) is 9 kcal mole^{-1}, or twice as great. Furthermore, the apparent activation energy for permeation of porous chromic ferro- and ferricyanide membranes by KNO_3 was found to be only 5.3 kcal mole^{-1} (20). Thus, the passage of KNO_3 through ZrO_2 films is greatly restricted, and the holes must be relatively small.

* A corresponding value of 17.1 was found earlier for 100v films (12).

The observed rates for permeation of ZrO_2 films are similar to the rates of diffusion of KNO_3 across porous aluminum oxide films measured by Burwell and May (21). The rates for diffusion of KNO_3 through two portions of a 42μ thick film were 4.1 and 0.49 x 10^{-9} moles cm^{-2} sec^{-1} per molar concentration drop across the membrane. These aluminum oxide films had pores estimated to be 110Å in diameter. The investigators felt that the slow rates indicated a greater resistance than could be exhibited by a simple pore system and suggested that a less porous barrier layer about 0.02μ thick exists at the base of the pores. Considering that the ZrO_2 films are 10^2 to 10^3 times thinner than the aluminum oxide films, their pores must be smaller and less numerous to exhibit similar rates.

Early in this investigation, it was noted that the process under study exhibited certain of the characteristics of steady-state permeation described by Barrer (22). (*A*) The Fick diffusion law appeared to be obeyed in the steady state. (*B*) Steady-state flow was established in a period of minutes. (*C*) The rates were proportional to the concentration and inversely proportional to the film thickness. (*D*) The permeation was temperature dependent. However, the behavior of the rate constant, which appears to be a function of film thickness, implies that the permeation cannot be completely described by a steady-state mechanism.

Another factor which may be considered to determine the permeability of membranes to ions when pores approach molecular dimensions is charges on the membrane pores due either to adsorption or ionization which act as barriers to diffusing ions as postulated by Meyer and Sievers (23). In such a case, the potential barrier may be mainly electrostatic in origin. The criteria for charged pores are the existence of a permselectivity of the membrane and of a membrane potential, the measurable membrane potential being the over-all resultant of the individual pore potentials. In the absence of membrane potential measurements, then, the permselectivity should give an indication of the presence of charged pores. Depending on the membrane potential sign an excess of either cations or anions should be transported. Such a situation would be manifested in a pH change in solution on permeation or in a discrepancy between concentrations of permeated salt as determined by methods depending on measurement of but one ion or of both ions in solution. Based on the data in Table V, there appears to be evidence for permselectivity. At low concentrations of permeant, the agreement between methods is poor while at high concentrations the agreement between the two methods of determining KNO_3 is good. These data match the observation that

Table V. Agreement of methods for determining permeated KNO_3

Sample	Permeant, moles liter^{-1}	Concentration of KNO_3 in cell By flame (moles liter^{-1} × 10^3)	By conductance (moles liter^{-1} × 10^3)
2	1.000	1.20	1.04
3	1.000	1.00	0.98
4	1.000	0.70	0.70
5	0.100	0.18	0.57
6	0.100	0.13	0.30

the permselectivity of membranes is greatest in very dilute solution diminishing and disappearing at higher concentrations (24, 25). Indications are that anion transport is favored. Supporting evidence for the existence of permselectivity is the absence of osmotic effects and the observed pH dependence of the permeation rate.

It is possible to formulate a model for the permeation based on transfer through charged pores with a length much greater than the radius. The membrane may be considered to be completely pierced by an array of cylindrical pores of radii a normal to the surface. The fixed charges, probably adsorbed protons, are confined to a surface layer of density on the inner surface of the pores. Compensating negative charges are assumed to be free. The potential on the pore axis due to the field imposed by the fixed charges can be shown to be

$$v = 2\pi a\sigma \int_{x=0}^{x=L} dx/\sqrt{a^2 + (x - P)^2} \qquad [3]$$

where σ is the surface charge density and the radius a of the cylinder is assumed to be much less than the cylinder length L. P is the distance on the axis from the near end of the cylinder to the point at which the potential is to be found. The cylinder is regarded as a series of hollow disks of thickness dx. Upon performing the integration, expressing P in terms of L and simplifying the ensuing relation by a series expansion, we arrive at the following expression for the maximum potential which from symmetry arguments is at the center of the pore.

$$v = 4\pi a\sigma \ln (L/a) \qquad [4]$$

The apparent activation energy for permeation may not be as readily equated with an activation energy for the process as can the temperature coefficient for diffusion. It may include, in addition to the activation energy for diffusion, the temperature dependence of the number of ions available to enter a hole, heats of sorption or solution of the permeant on or in the membrane, and heats of any phase changes occurring in or at the membrane surface. The rate-determining step is usually considered to be diffusion through the membrane. The observed thickness dependence of the rate constant for the ZrO_2 films may indicate, however, that interface reactions are also important (26). Assuming diffusion through the membrane pores to be the rate-determining step in the case of these ZrO_2 films, the apparent activation energy may be related to the electrostatic potential barrier which must be surmounted by a permeating ion. In this sense, the apparent activation energy may be considered as a true activation barrier.

By Eq. [4], it is evident that the model requires the potential to vary directly as the log of the pore length. A plot of the apparent activation energy for permeation *vs.* log of the film thickness shows (Fig. 7) that for the thinner films there is substantial agreement with the proposed model. Thicker films behave differently since the apparent activation energy begins to decrease. This observation is in accord with the premise that thicker films are under stress during formation and may be more susceptible to formation of microfissures in addition to an established pattern of flaws.

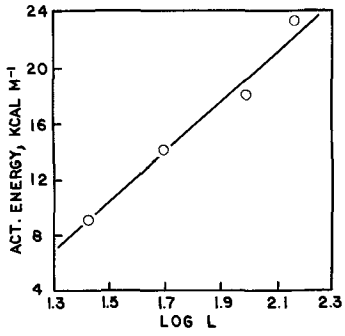

Fig. 7. Plot showing relation between the apparent activation energy, E, and film thickness.

Conversion of Silicon Nitride Films to Anodic SiO_2

P. F. Schmidt and D. R. Wonsidler

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

ABSTRACT

An introduction is given to the principles underlying the anodization of pre-existing dielectric films. In the case of amorphous silicon nitride films on a silicon substrate it is shown that conversion of the nitride film to anodic SiO_2 occurs by oxygen ions reacting with the nitrogen, the latter being evolved from the film as N_2 or as a nitrogen oxygen compound. The process has been applied to the opening of windows in $Si/SiO_2/Si_3N_4$ structures. Nitride films up to 1000Å thick can be rendered soluble by a single anodization step to 350v; thicker films require a repeated anodization. The electric field applied during anodization causes a shift in surface potential of the silicon substrate. The original surface potential can be restored by a bake in forming gas at 500°C. High-resistivity silicon tends to passivate under anodic bias; growth of an oxide film occurs only at very large current densities.

Silicon dioxide films are commonly used for the surface passivation of silicon. Diffusion or field drift of sodium ions through the SiO_2 coating of oxide passivated silicon devices can lead to failure of sodium contaminated devices. Silicon nitride is practically impermeable to sodium ions. Consequently, considerable effort has been devoted to the adaptation of deposited silicon nitride films for surface passivation of silicon devices. The art of depositing silicon nitride films has reached a high level (1).

Once the nitride film has been deposited, it is necessary to open windows in the film for diffusion or contact purposes. Since silicon nitride is soluble in hot phosphoric acid, whereas SiO_2 is very little soluble in this solvent (2), the opening of windows can be achieved by deposition of an SiO_2 film, followed by pattern generation in the SiO_2 layer by photoresist techniques and subsequent etching in hot phosphoric acid.

The present communication describes an alternative approach, in which the insoluble nitride film is converted to easily soluble anodic SiO_2 by anodization in a suitable solvent electrolyte combination. Pattern generation is achieved by the use of an SiO_2 pattern as a dielectric anodization mask; this SiO_2 pattern can be located either above or underneath the nitride film to be anodized.

Principle of the Method

When applying a sufficiently high anodic bias to the system: conductive substrate/dielectric film/electrolyte, either electrons or ions, or both, may be injected into the dielectric film. The substrate forms the cation source and the electrolyte the anion or electron source. Injection of ions can change the chemical composition of a pre-existing dielectric film, and can thus render it more soluble.[1] Injection of electrons is undesirable since it lowers the current efficiency and can damage the dielectric by avalanche formation. Electron injection can be minimized by the choice of a suitable electrolyte. In this study a 7.5 v/o solution of pyrophosphoric acid in tetrahydrofurfuryl alcohol has been used.

In the anodization of pre-existing dielectric films, the interesting feature arises that a change in the chemical composition of the film may depend on whether cations or anions are the mobile species. Thus migration of silicon ions through a pre-existing nitride film would not change its composition, but migration of oxygen ions would. The reverse situation applies, for instance, to the anodization of a pre-existing Al_2O_3 film, where migration of silicon ions changes the chemical composition of the film, whereas migration of oxygen ions does not. The nature of the substrate may thus determine whether a pre-existing dielectric film becomes soluble during anodization.

The degree of crystallinity of a pre-existing dielectric film appears to have a decisive effect on the mobility of the ionic species. The existence of grain boundaries in polycrystalline silicon nitride films favors the mobility of silicon ions and in polycrystalline alumina the mobility of oxygen ions. Thus in the anodization of polycrystalline alpha or beta Si_3N_4 films on silicon substrate, growth of new oxide occurred at the nitride/electrolyte interface, leaving the nitride film unchanged in thickness or solubility. In the anodization of polycrystalline alpha-alumina films on silicon substrate in aqueous borate solution, growth of new oxide occurred at the oxide/silicon interface, increasing the total film thickness but without changing the solubility of the pre-existing outer layer of alpha-alumina.

Amorphous silicon nitride films anodize by migration of oxygen ions, are converted to SiO_2, and become easily soluble in dilute HF. The degree to which oxygen ions migrate in polycrystalline nitride films can be enhanced to some extent by increasing the current density, *i.e.*, the applied field strength, but it is obvious that for purposes of anodization fully amorphous nitride films are preferable. This fact does not constitute an additional requirement in device processing because polycrystalline nitride films are also undesirable for other reasons; for instance, they are not effective barriers to sodium migration (4).

Mechanism of Anodization of Amorphous Nitride Films

Figure 1 shows the changes that occur in the infrared transmission spectrum of a nitride film undergoing anodization. The spectrum of the original nitride film disappears if the film is anodized to completion, *i.e.*, to the point where all of it becomes easily soluble in HF. At incomplete conversion, the spectra of both nitride and of anodic oxide are present, but the oxide spectrum disappears if the soluble outer part of the anodized film is etched in buffered HF.[2] This behavior establishes that oxygen ions penetrate into the nitride film during anodization and replace the nitrogen, but does not rule out simultaneous migration of silicon ions. Absence of silicon ion migration was proven by conversion in the SiO_2 window areas of a nitride film deposited on top of a SiO_2 pattern on a silicon substrate. After anodization and stripping of both nitride and oxide films in concentrated HF, no indication of a step in the silicon

[1] A pre-existing dielectric film may also become more soluble as a function of change in structure or hydroxyl content. This effect was observed in the anodization of thermally grown SiO_2 films (3). The structural effect is very small or absent in the anodization of silicon nitride films.

[2] The transition SiO_2/Si_3N_4 is sharp; thus the method can be used for the controlled thinning down of Si_3N_4 films.

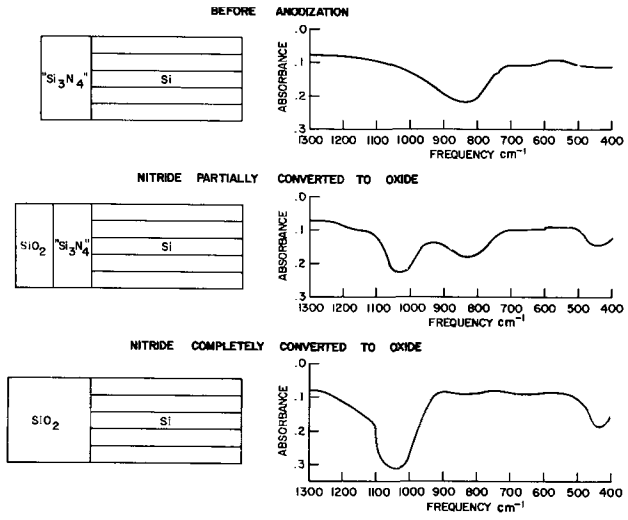

Fig. 1. Shift in infrared spectrum during anodization of silicon nitride film on high resistivity p-type silicon substrate.

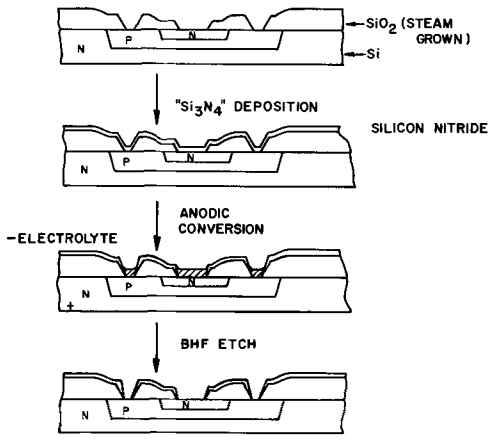

Fig. 2. Sequence of steps used for opening of windows in nitride films.

surface at the position of the former window areas could be detected by interferometry; this proves that no silicon or only very little had been consumed during the anodization.

This observation also clarifies the mechanism of the anodic conversion of the nitride film. Oxygen ions penetrate into the nitride film, yet the electric current through the rest of the nitride film is entirely electronic. Continuity of charge transport and over-all electrical neutrality of the nitride film are possible only if the oxygen ion loses its electrons, which flow off through the nitride film, and replaces the nitrogen which leaves as an electroneutral species, either elemental nitrogen or an oxygen-nitrogen compound. For the case of a Si_3N_4 film, the over-all reaction can be written as

$$6\,O^{2-} + Si_3N_4 \rightarrow 3SiO_2 + 2N_2 + 12\,l$$

The postulated evolution of a gas (nitrogen or an oxygen-nitrogen compound) during anodization also explains the observation that there is no fixed oxide to nitride thickness ratio for a given initial thickness of the nitride film; rather, the ratio appears to depend on the current density during anodization, *i.e.*, the rate of gas evolution. The faster the rate, the more porous and therefore thicker the resulting oxide film.

At a constant current density of 7 ma/cm^2 in the pyrophosphoric acid/tetrahydrofurfuryl alcohol solution it takes about 350v (and about 10 min of anodization) to convert a 1000Å nitride film completely. Complete conversion can also be achieved by anodization at a constant voltage of 215v for 18 hr, and the oxide film formed in this latter case is appreciably thinner than the constant current oxide.

The over-all anodization behavior of nitride films on silicon is not too different from the anodization of a bare Si surface. The electrolytes are the same as can be used for the anodization of silicon, and the current efficiency is similarly low, *i.e.*, a larger percentage of the current is due to oxygen discharge. Silicon nitride is more easily damaged by avalanche formation than is SiO_2, and this fact limits the anodization voltage to about 350v. Nitride films thicker than 1000Å can be rendered soluble by repeating the anodization after stripping the converted surface layer by etching in HF. The etch rate of the conversion oxide is very high, about 100 Å/sec in buffered HF (40g NH_4F + 15 cc conc. HF in 60 cc H_2O).

The process has been applied to the opening of windows in the nitride film of $Si/SiO_2/Si_3N_4$ device structures. Windows are first opened in the oxide film by photoresist techniques, and the nitride film is then deposited over the whole front surface of the wafer, as shown in Fig. 2. During anodization the SiO_2 pattern underneath the nitride film serves as a dielectric anodization mask by reducing the field strength at the location of the SiO_2; anodization thus is confined to the window areas of the pattern.

While the nitride film on top of the SiO_2 is not rendered soluble, the applied field strength at the position of the SiO_2 is usually high enough to cause a shift in surface potential of the silicon substrate, as is also observed in the Si/SiO_2/metal system in the absence of alkali ions (5). A bake in forming gas at 500°C restores the original surface potential of the silicon and the transistor gain (6).

Anodization Behavior of High-Resistivity p-Type Silicon

The spectroscopic work reported above was done on high resistivity (25 ohm-cm) p-type silicon in order to minimize free carrier absorption in the substrate. During anodization of these wafers, an unexpected difficulty was encountered: the bare back surface, instead of forming on oxide film, simply passivated *i.e.*, passed large electronic currents by discharge of oxygen. Strong illumination had no effect in preventing passivation. It was possible to force oxide growth by going to unusually high initial current densities (50-80 ma/cm^2). Once oxide growth had commenced, it was possible to reduce the current density, although it still remained appreciably larger than on lower resistivity wafers for the same rate of oxide growth.

It was of interest to determine whether the electrons were injected into the valence or the conduction band of the silicon. The first case would constitute majority carrier extraction, the second, minority carrier injection. Since the electronic levels of anions in solution are located about 4-5 or more ev below vacuum level, either situation could be realized for the particular system: high resistivity p-type silicon/pyrophosphoric acid in THF.

A distinction between hole extraction or electron injection was possible by means of a transistor configuration, utilizing a n^+p diode, the p-side of which was biased anodically, *i.e.*, in the forward direction *vs.* a platinum wire in the pyro/THF solution, while a reverse bias was applied to the n^+p junction. The resistivity of the p-base was 50 ohm-cm, its thickness 5 mils; the resistivity of the epitaxial n^+ layer was about 1 ohm-cm. Only the p-base made contact to the electrolyte.

It was found that the forward current passed in the p-base/electrolyte circuit appeared almost quantitatively in the base/collector circuit of the "liquid emitter" transistor, thus proving the occurrence of minority carrier injection. After oxide growth had been forced to occur by passage of very large currents in the emitter/base circuit, the transfer ratio was

found to have deteriorated, indicating that now fewer electrons were able to enter the conduction band of of the p-Si.

Determination of the Thickness of Aluminum on Silicon by X-Ray Fluorescence

J. E. Cline and S. Schwartz

Electronics Research Center, National Aeronautics and Space Administration, Cambridge, Massachusetts

ABSTRACT

The thickness of deposited aluminum layers on silicon, in the range from 0 to 4μ, was shown to be determined easily by an x-ray spectrometric technique with much better sensitivity than by the usual optical interferometric measurements. Theoretical curves were calculated for two methods: (*i*) emission of characteristic aluminum fluorescence and (*ii*) absorption of characteristic silicon fluorescence. The first method gave the best results with ultimate thickness sensitivity in very thin layers of $\pm$6Å of aluminum.

In the fabrication of silicon planar transistors, diodes and integrated circuits, vacuum-deposited thin aluminum films are generally used for ohmic contacts to the active devices and for interconnections (1-3). The thickness of this aluminum layer, usually in the range 1000-10,000Å, must be carefully controlled, since too thin a layer will not have sufficient current-carrying capability and too thick a layer can lead to unreliable contacts and excess intermetallic formations. It is possible that future integrated circuit technology will call for even thinner, and more precisely controlled, deposited aluminum as part of multimetal interconnections.

This work was undertaken as a phase of a general research program to improve techniques for failure analysis and process control of microcircuits. Reliability of silicon monolithic circuits depends to a large extent on the thickness of the thin film interconnections and on their uniformity. The strength of the lead-bonding, the reliability for long-term operation, and the ability to carry high currents all depend on the control of the thickness of the aluminum used for the microcircuit interconnections.

The technique described in this paper for determining aluminum thickness has the advantages of being nondestructive, more sensitive, and more reproducible than the commonly used optical interferometric measurements, and of furnishing data in a digital form readily adaptable to automation. The x-ray fluorescence technique is conveniently applied to the entire silicon microcircuit wafer after the evaporation of aluminum and before the interconnection pattern is formed by the photoengraving process.

Experimental

The samples used in this work were polished silicon wafers on which various thicknesses of aluminum were deposited by vacuum evaporation, partly masked to form steps for determination of thickness by a Zeiss interference microscope. Thallium light was used to produce 0.27μ half-wave fringes. On each silicon slice the area of the aluminum film was greater than that of a $\frac{5}{8}$-in. circle for comparison of the thickness of the aluminum by the x-ray fluorescence method.

Two basic techniques were involved in the utilization of x-ray fluorescence for determination of the thickness of the aluminum films. In one technique, emission of the characteristic aluminum K-alpha radiation by the aluminum film, increasing with its thickness, was measured. In the other, measurements were made of the silicon K-alpha radiation emitted by the substrate, decreasing with aluminum thickness due to absorption. In both cases the aluminum and silicon fluorescence lines were activated by x-radiation from a tungsten-target tube in a Norelco vacuum x-ray fluorescence spectrometer. Tube voltages from 15 to 50 kv were used with currents up to 50 ma. The wavelengths of the x-rays (8.320 and 7.111Å for aluminum and silicon, respectively) were analyzed by a flat EDDT (ethylenediamine d-tartrate) crystal with a 2d-spacing of 8.76Å. A flow proportional detector was used with pulse amplitude discrimination to improve the signal-to-background ratio. The spectrometer was operated at a vacuum of less than 0.02 Torr pressure to eliminate absorption of the soft x-rays by the air path.

The four sample holders in the spectrometer could be readily rotated into position in the x-ray beam without breaking the vacuum. In this way several samples or standards could be quickly compared. Each sample holder could accept a wafer up to a diameter of $1\frac{1}{4}$ in. As shown in Fig. 1, a stainless steel mask with opening of 0.625-in. diameter was used in each sample holder to define the area of the aluminum film under examination. Areas of smaller size can be measured with decrease in sensitivity.

In Fig. 2, an enlarged cross section of the aluminum-coated silicon wafer is shown diagrammatically with ϕ

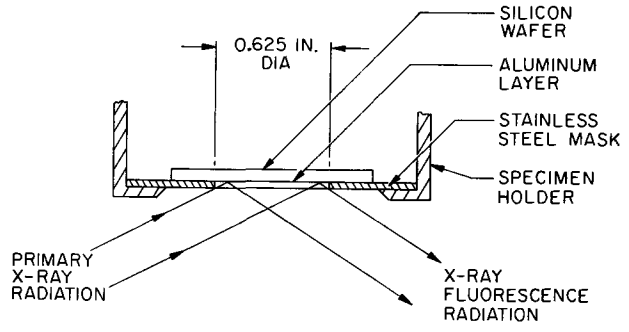

Fig. 1. Position of silicon wafer and stainless-steel mask in specimen holder.

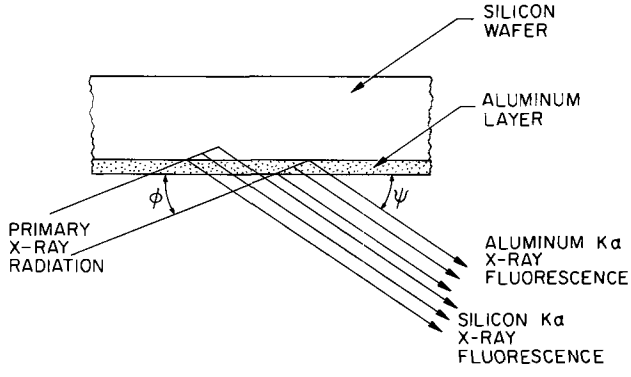

Fig. 2. Angles of incidence of primary and fluorescence radiation, showing paths of x-rays in aluminum film and silicon substrate.

representing the angle of incidence of the primary radiation with the specimen surface and ψ the angle of emission of the fluorescence radiation. These angles are determined by the position of the specimen in relation to the target of the x-ray tube and to the collimator of the spectrometer.

Results and Discussion

Aluminum K-alpha fluorescence.—The dependence of the intensity of the characteristic aluminum K-alpha radiation, I_t, on the thickness of aluminum can be expressed by

$$\frac{I_t}{I_o} = 1 - e^{-At} \qquad [1]$$

where I_o is the intensity limit of fluorescence radiation from thick (over 40μ) aluminum, t is the thickness of aluminum in microns, and A is a constant. The constant A can be calculated (4, 5) from the equation

$$10^4 A = \frac{\mu_p}{\sin\phi} + \frac{\mu_s}{\sin\psi} \qquad [2]$$

where μ_p and μ_s are the linear absorption coefficients of aluminum for the primary and fluorescence radiation, respectively. The second term was calculated from the data of Cooke and Stewardson (6), using the values $\mu_s = 1065$ and $\psi = 35°$. The first term in Eq. [2] cannot be calculated directly since μ_p is uncertain, depending on the average effective wavelength of the primary radiation. In our work the constant A was determined from the experimental data.

Using Eq. [1], a linear relationship between a function of the intensity, $f(I_t)$, and the thickness, t, can be obtained by

$$f(I_t) = -\log_{10}\left(1 - \frac{I_t}{I_o}\right) = \frac{At}{2.3026} \qquad [3]$$

The computation of values of I_t/I_o and $f(I_t)$ for a series of aluminum-coated silicon wafers measured at an x-ray tube voltage of 50 kv and current of 25 ma is shown in Table I. Similar sets of data were also

obtained at 25 and 40 kv. At least five separate counts of 10 sec each were taken on the standard and five on the sample, alternating to minimize error in the ratio due to instrument drift. Since the maximum count rate used was 6400 counts/sec, it was not considered necessary to make any correction in the intensity measurements for the resolving time of the pulse counting circuit.

In columns 2 and 3 of Table I, the relative intensities of the aluminum standard and the sample, respectively, are indicated after correcting for the background measured with the spectrometer setting near the aluminum K-alpha line. In column 4, the blank intensity of an uncoated silicon wafer is shown corrected for variations in count rate from the aluminum standard. Almost all of this blank intensity was shown to be due to aluminum impurities in the stainless-steel mask in the sample holder.

The linearity of $f(I_t)$ relative to t is demonstrated by Fig. 3, plotted for the data in Table I. The slope of the line, 0.151, was computed by the method of best least squares fit. From this slope the constant A in Eq. [3] is calculated to be 0.348. In Table II a comparison is shown between the experimental values of $f(I_t)$ and the best fit values, 0.151 t. The values of t_{calc} (the thickness calculated from x-ray fluorescence data) are also compared in Table II with values of t (measured with the interference microscope). It is believed that most of the difference between experimental and best fit values can be accounted for by experimental error in the interference measurements.

3.58	0.541	0.5461	3.62	0.04
4.18	0.630	0.6269	4.15	−0.03

There was no indication in this set of experiments, or in other sets run at different tube voltages, that a curve other than a straight line would give a better fit of the plot of $f(I_t)$ *vs.* t.

In Fig. 4 a pair of calibration curves are shown for conversion of x-ray fluorescence data at 50 kv to aluminum thickness. It is estimated that the precision of thickness measurement for very thin aluminum films is ± 6Å, limited by the background noise in the x-ray spectrometer. For thicker films the slope of the curve, I_t/I_o *vs.* t, decreases and the precision of the x-ray measurement becomes limited by the stability of the instruments. At 50 kv the best reproducibility of counting rate of the x-ray fluorescence from the same sample was found experimentally to be ± 0.15%. Thus, it was determined from the calibration curves of I_t/I_o in Fig. 4 that the ultimate precision is ± 0.003μ at $t = 1\mu$, and ± 0.2μ at $t = 10\mu$.

The effect of variations in x-ray tube voltage on the intensity ratio, I_t/I_o, was found to be very small. When the voltage was changed from 50 to 25 kv, the slope of the line, $f(I_t)$ *vs.* t, was found to increase only by 3%.

In order to reduce background noise in the x-ray spectrometer, pulse amplitude discrimination was used with peak sensitivity at the energy of the aluminum K-alpha x-ray photons. With a relatively narrow window (energy range) of 5.0v, it was found that I_t/I_o varied significantly when the voltage of the level (bottom of the energy range) was changed. In Fig. 5 the effect of level variations on I_t/I_o measurements taken on a single sample is shown. At the optimum setting

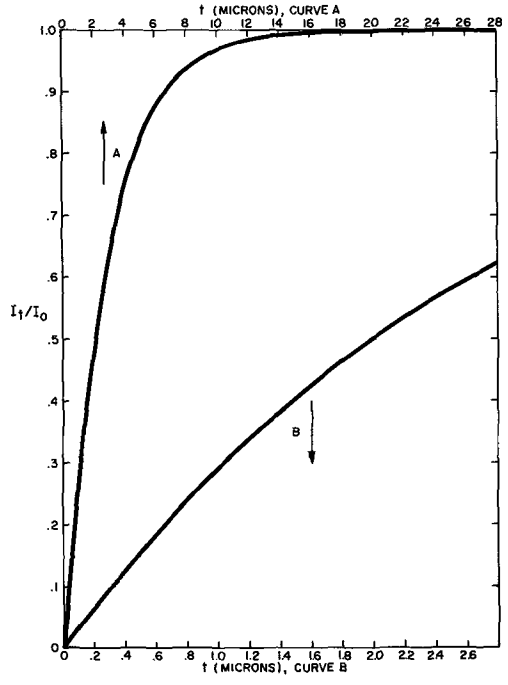

Fig. 4. Calibration curves of I_t/I_o vs. t (Al K-alpha at 50 kv). Top scale is for curve A, bottom scale for curve B.

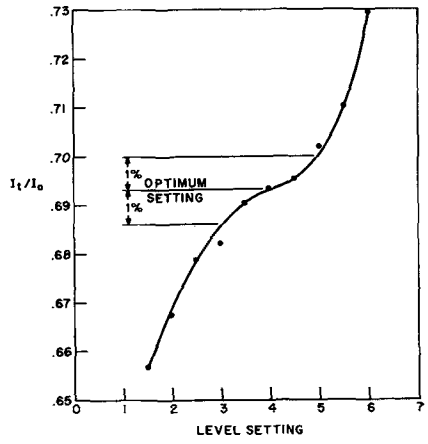

Fig. 5. Effect of level variations on I_t/I_o (Al K-alpha at 50 kv, window setting at 5.0v).

of the level at 4.0v (depending on detector voltage), a change of 0.1v in level results in a 0.07% change in I_t/I_o. For best reproducibility it is advisable to warm up the electronics for stabilization, occasionally check the level for optimum setting, and operate with as large a window that is feasible for the amount of background noise that can be tolerated in order to reduce the effect of level fluctuations.

Silicon K-alpha fluorescence.—Instead of using the aluminum K-alpha fluorescence, the thickness of the aluminum layer on silicon can also be determined by measurement of x-ray fluorescence from the substrate. In this case the maximum silicon K-alpha fluorescence intensity is obtained at zero thickness of the aluminum, and the intensity decreases exponentially as the aluminum thickness increases as shown by the relationship

$$\frac{I'_t}{I'_o} = e^{-Bt} \qquad [4]$$

where I'_t and I^0_o are the intensities of silicon K-alpha fluorescence at aluminum thickness of t (μ) and zero, respectively. The constant B can be expressed by

$$10^4 B = \frac{\mu'_p}{\sin\phi} + \frac{\mu'_s}{\sin\psi} \qquad [5]$$

where μ'_p and μ'_s are the linear absorption coefficients of aluminum for the primary radiation and silicon K-alpha fluorescence, respectively.

From Eq. [4] a linear relationship between a function of the intensity $F(I'_t)$ and t can be obtained by

$$F(I'_t) = -\log_{10}\frac{I'_t}{I'_o} = \frac{Bt}{2.3026} \qquad [6]$$

The values of I'_t/I'_o and $F(I'_t)$ were calculated from measurements at 50 kv for a series of silicon wafers coated with aluminum ranging in thickness from zero to 4.18μ.

In Fig. 6, $F(I'_t)$ *vs.* t is plotted with the slope of the line, 0.769, computed by least squares fit. From this slope the constant B in Eq. [6] is calculated to be 1.771. B is greater than A of Eq. [3] because the linear absorption coefficient of aluminum for silicon K-alpha radiation is much greater than for aluminum K-alpha (9033 and 1065). From experimentally determined constants A and B and published values of absorption coefficients the first terms on the right side of Eq. [3] and [5] are calculated to be 1620 and 2060, respectively. It is possible that this difference can be due to a variation of absorption by aluminum of the primary radiation, which has different effective wavelengths for activating fluorescence in silicon and aluminum.

In Fig. 7 a calibration cone is shown for conversion of the silicon x-ray data to aluminum thickness.

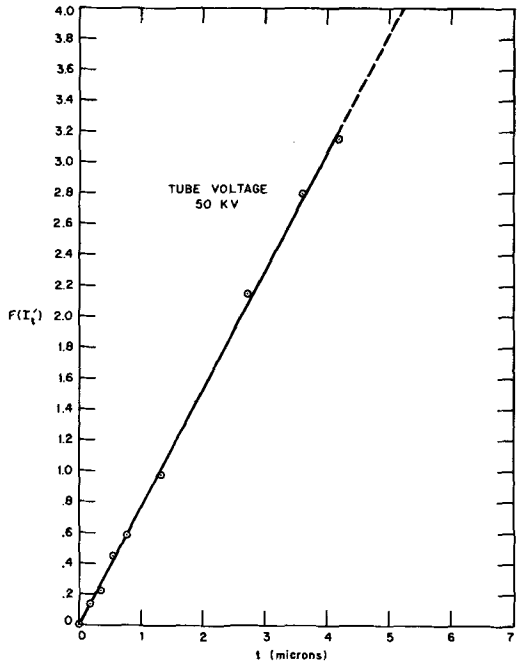

Fig. 6. Plot of $F(I'_t)$ vs. t using silicon K-alpha at 50 kv. Slope of line = 0.769, calculated from least squares fit.

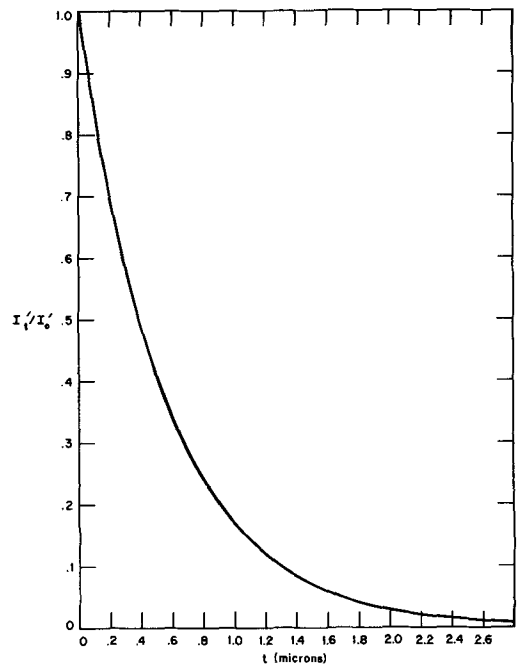

Fig. 7. Calibration curve of I'_t/I'_0 vs. t (Si K-alpha at 50 kv)

For very thin aluminum films a ± 0.3% precision in counting rate would give a precision of ± 24Å in aluminum thickness. At a thickness of 1 micron the ultimate precision is ± 0.003μ. Surface variation and presence of variable silicon dioxide under the evaporated aluminum would decrease the obtainable precision.

Conclusions

The measurement of the thickness of aluminum on silicon by calculation from x-ray fluorescence data is a convenient, nondestructive technique. For very thin films the sensitivity is ± 6Å, obtained with aluminum K-alpha fluorescence. The silicon K-alpha fluorescence can also be used, but is not recommended for measuring aluminum on integrated circuit wafers due to absorption of x-rays by the variable amount of silicon dioxide under the aluminum.

Optical Spectra of Ytterbium in CdF_2

Paul F. Weller

Department of Chemistry, State University College, Fredonia, New York

ABSTRACT

Optical absorption and fluorescence studies were conducted on Bridgman-grown CdF_2 single crystals doped with YbF_3 and with YbF_3 plus codopants such as CdS, NaF, EuF_3, and CaF_2. Generally, the ytterbium absorption spectrum consisted of two lines, a weak line at 9620Å and a strong line at 9760Å. The peak height of the strong line was quite dependent on temperature and codopant. Ytterbium fluorescence lines usually occurred between 9620 and 9700Å and between 9750 and 9800Å and were very dependent on codopant. A possible fit to the experimentally observed absorption and fluorescence data is obtained if the cubic crystal field symmetry at the Yb^{+3} lattice site gives rise to a total splitting of about 475 cm^{-1} for the $^2F_{5/2}$ excited state and about 590 cm^{-1} for the $^2F_{7/2}$ ground state.

Recent EPR studies (1-4) on trivalent rare earth dopants in CdF_2 have indicated that the crystal field symmetry at the rare earth site is largely cubic. This is not the case in CaF_2 where charge compensating ions such as F^- interstitials and substitutional divalent anions such as O^{-2} and S^{-2} and monovalent cations such as Na^+ generally distort the local cubic symmetry around the RE^{+3} ion (5).

Another significant difference between RE doped CaF_2 and CdF_2 is found for Yb^{+3} doping. The cubic crystal field splitting in CaF_2 appears to be about 630 cm^{-1} for the $^2F_{5/2}$ excited state and about 800 cm^{-1} for the $^2F_{7/2}$ ground state as obtained from EPR data (5). The EPR and optical spectra estimates for the Yb^{+3} ground state splitting in CdF_2 range from 12 cm^{-1} (6) to about 110 cm^{-1} (2).

The following optical studies were made on Bridgman-grown CdF_2:Yb^{+3} single crystals in order to obtain more information on the crystal field symmetry and crystal field strength at the Yb^{+3} site in CdF_2. Various codopants such as Na^+, S^{-2}, Eu^{+3}, and Ca^{+2} were added, along with Yb^{+3}, to the CdF_2 and the effects on the Yb^{+3} absorption and fluorescence spectra observed.

Experimental

All of the single crystals reported on in this study were grown via a Bridgman-Stockbarger technique using graphite crucibles, as reported previously (7). The doping concentrations given (mole per cent) are those that were added to the sample charge. In the case of Yb^{+3} and Eu^{+3} these concentrations are reasonably accurate (segregation coefficients near unity). However, for Ca^{+2}, Na^+, and S^{-2} there is considerable segregation in CdF_2. The concentrations listed, therefore, are not the true ones but give the maximum possible values attainable (segregation coefficients less than unity).

CdF_2:Yb^{+3} *Crystals.—Absorption.*—The optical absorption spectra for the "as grown" Yb^{+3} doped CdF_2 crystal shown in Fig. 1, as well as all of the other crystals reported on below, were run on a Cary Model 14 spectrophotometer at 300°, 77°, and 6°K. Several features are of interest. There is only one strong absorption line, 9760Å, which splits into a triplet at 6°K with splittings of 6Å and 8Å from the central line. There are two other weak lines, at 9620 and 9200Å, that are essentially temperature independent. All of these lines are superposed on a broad band absorption, about 9000 to 9700Å. (The reason for this one strong absorption line is not clear. In a cubic crystal field, two absorption lines of approximately equal intensity would be expected. Crystal fields of lower symmetry would give rise to three absorption lines.)

All of the absorption lines detected at 77°K between 0.4 and 2.5μ are listed in Table I, for this

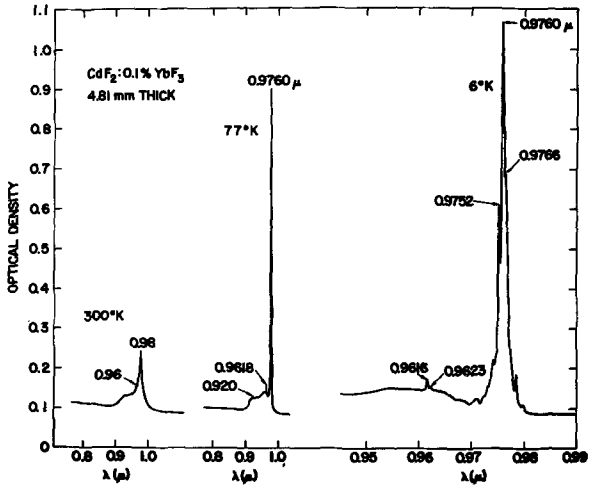

Fig. 1. The optical absorption spectrum of a CdF_2:0.1%YbF_3 crystal at 300°, 77°, and 6°K.

CdF_2:Yb^{+3} sample as well as all others described below. The absorption spectrum of Yb^{+3} in CdF_2 at low temperatures has also been reported by Weakliem (8) and by Banks and Wagner (9). Weakliem found two lines around 9500Å and one around 9200Å. All three lines appeared to be of about equal intensity and were quite weak. The spectrum of Banks and Wagner is very similar to that reported in this study. Konyukhov, Pashinin, and Prokhorov (1) report two absorption lines at 0.961 and 0.972μ for Yb^{+3} in CdF_2 at room temperature.

Fluorescence.—The fluorescence spectra in the region of 1μ were recorded at 77° and 2°K using high pressure mercury lamp excitation with a copper sulfate filter, a Perkin Elmer Model 210 monochromator and a cooled photomultiplier with type S-1 response. Figure 2 shows the emission spectrum at 77°K of the "as grown" CdF_2:0.1% YbF_3 crystal reported on above. Strong lines were observed at 9632 and 9760Å with weaker lines at 9617 and 9755Å. On cooling to 2°K the stronger lines shifted to 9625 and 9767Å and the weaker lines to 9613 and 9750Å. The two lines occurring at 9632 and 9755Å at 77° decreased significantly in intensity on cooling to 2°K. Table II gives the fluorescence lines for this sample as well as all others described below. It should be noted that the fluorescence lines are designated weak and strong in Table II, and throughout the paper, without correction for detector response.

Weakliem (8) has found fluorescence lines for CdF_2:Yb^{+3} samples at 77°K at 9600, 9640, 9705, 10,225, and 10,260Å.

Table I. The observed optical absorption lines and transition assignments at 77°K for Yb^{+3} and for Yb^{+3} plus various codopants in CdF_2 single crystals

The intensities listed as very weak (vw), weak (w), medium (m), strong (s), shoulder (sh) and broad (br) cannot be compared between the various samples. Assigned transitions are given for both strong and weak crystal field splittings and are designated by the Γ level numbers involved.

Crystal treatment and codopants.—Treatment of CdF_2:0.1% YbF_3 crystals in HF gas.—The effects on the absorption and fluorescence spectra were quite pronounced when the "as grown" crystal reported on above was submitted to HF firing. A section of the crystal about 1.2 mm thick, contained in a platinum boat, was fired in flowing HF gas at about 850°C for two days. The resulting absorption spectrum is shown in Fig. 3a and the fluorescence spectrum in Fig. 2, both at 77°K. The broad absorption, between 9000 and 9700Å, of the untreated crystal was noticeably decreased, and a new absorption peak at 9683Å was present in the HF fired crystal. The fluorescence also changed. The two strong lines at 9632 and 9770Å in the untreated crystal disappeared upon HF firing, and new lines appeared around 9671 and 9679Å.

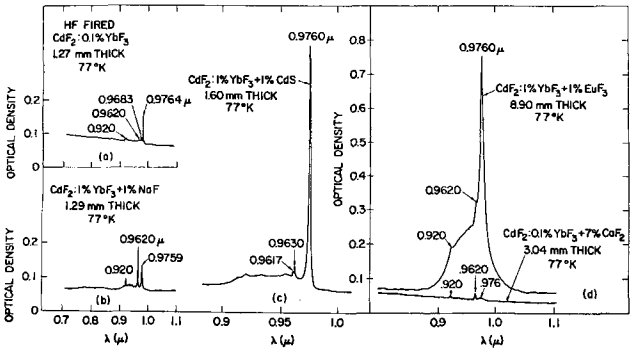

Fig. 3. Optical absorption spectra at 77°K of crystals of CdF_2:YbF_3 + various codopants: *(a)* HF fired CdF_2:0.1%YbF_3, *(b)* CdF_2:1%YbF_3 + 1%NaF, *(c)* CdF_2:1%YbF_3 + 1%CdS, *(d)* CdF_2:1%YbF_3 + 1%EuF_3 and CdF_2:0.1%YbF_3 + 7%CaF_2 (lower curve).

CdF_2:*1% YbF_3 + 1% codopant.*— The effects of Na^+, added as NaF, on the absorption and fluorescence spectrum of Yb^{+3} in CdF_2 at 77°K are shown in Fig. 3b and 4. Of particular note is the drastic reduction in intensity of the 9760Å absorption line, and the loss of the broad, 9000 to 9700Å, absorption. Banks and Wagner (9) discuss the effects of Na^+ on the Yb^{+3} absorption spectrum in more detail.

The 77°K absorption spectrum of CdF_2:Yb^{+3} codoped with CdS shown in Fig. 3c was very similar to the spectrum with no S^{-2} added. The only difference was in the splitting of the 9620Å line. The fluorescence spectrum in Fig. 4 appeared to be similar to that of a composite of the "as grown" and HF fired CdF_2:Yb^{+3} spectra. On cooling from 77° to 2°K the emission peaks shifted slightly in wavelength and became sharper. The 9763Å peak split into two lines of nearly equal intensity at 9771 and 9780Å.

The addition of Eu^{+3} as a codopant appeared to increase the intensity of the Yb^{+3} absorption peak at 9754Å in relation to the 9760Å peak. The general character of the 77°K absorption spectrum, however, did not change as is shown in Fig. 3d. Figure 5 shows the

Assigned transitions are given for both strong and weak crystal field splittings and are designated by the Γ level numbers involved.

fluorescence spectrum at 77°K. No emission was present between 9200 and 9610Å.

CdF_2:1% YbF_3 + 7% CaF_2.—The effects on the Yb^{+3} absorption and emission spectra of adding CaF_2 to CdF_2:Yb^{+3} were large, unexpected, and curious. As shown in Fig. 3d the 77°K absorption changed markedly. The intense line at 9760Å was almost gone. The reason for the drastic decrease in intensity of this absorption peak is not obvious. It is difficult to imagine a large change in crystal field strength or symmetry upon substituting a Ca^{+2} ion for a Cd^{+2} ion at these concentrations.

The fluorescence spectrum at 77°K shown in Fig. 5 revealed intense emission lines, relative to the CdF_2:Yb^{+3} crystals, between 9610 and 9660Å. Other weak lines were observed around 10,220Å but no lines were found in the 9760Å region. On cooling to 2°K only the relative intensities of the emission peaks were changed. The general character of the spectrum was preserved.

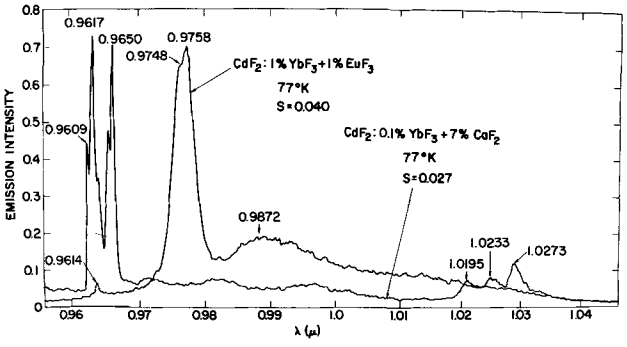

Fig. 5. The fluorescence spectra at 77°K of CdF_2:1%YbF_3 + 1%EuF_3 and CdF_2:0.1%YbF_3 + 7%CaF_2. The slit width, S, is given in mm.

Another interesting observation was the existence of Yb^{+2} as indicated by u.v. absorption bands and yellow fluorescence (10, 11). Divalent ytterbium and its u.v. absorption band might be the reason for the enhanced Yb^{+3} fluorescence at 9610 to 9650Å in the CdF_2-CaF_2 mixed crystals. This would, of course, require energy transfer between the Yb^{+2} and Yb^{+3} ions.

Discussion

Crystal field strength.—As noted above, EPR studies (5) on Yb^{+3} in CaF_2 give a cubic crystal field splitting of about 630 cm^{-1} for the $^2F_{5/2}$ excited state and approximately 800 cm^{-1} total splitting for the $^2F_{7/2}$ ground state. Kiss (12) has studied the optical spectrum of Tm^{+2} (isoelectronic with Yb^{+3}) in CaF_2. He finds a cubic crystal field splitting of 410 cm^{-1} for the excited state and 555.8 cm^{-1} between the Γ_7 and Γ_8 levels of the ground state. Calculations (13) using crystal field parameters derived from these observed optical data yield a total ground state splitting, Γ_7 to Γ_6, of about 588 cm^{-1} (as yet unobserved experimentally).

To a first approximation the crystal fields experienced by Yb^{+3} in CdF_2 and CaF_2 should not be too different. Consequently, a total crystal field splitting of several hundred wave numbers would be expected for the energy levels of Yb^{+3} in CdF_2. However, the estimates for the cubic field ground state splitting, derived from optical and EPR data, have been very much lower, ranging from 12 (6) to 110 cm^{-1} (2).

Two alternatives were selected, therefore, in trying

to fit the above absorption and fluorescence data for Yb^{+3} in CdF_2 to specific transitions on an energy level diagram. In the first case (strong crystal field) a total crystal field splitting of about 600 and 500 cm^{-1} was used for the ground and excited states, respectively. In the second case (weak crystal field) smaller crystal field splittings of about 150 and 140 cm^{-1} were tried.

Strong crystal field.—All of the absorption and fluorescent transition assignments are given in Tables I and II and a summary of the energy level splittings in Fig. 6(a).

The $^2F_{5/2}$ excited state cubic crystal field splitting ($\Gamma'_7 - \Gamma'_8$) of 475 cm^{-1} was given by the weak absorption lines near 9620 and 9200Å (10,395 and 10,870 cm^{-1}, respectively) in all of the samples. In the $^2F_{7/2}$ ground state, the cubic crystal field splittings were found to be $\Gamma_7 - \Gamma_8 = 560$ cm^{-1} using the fluorescent transitions near 9679Å in the CdF_2:YbF_3, HF fired and NaF codoped samples and $\Gamma_8 - \Gamma_6 = 30$-40 cm^{-1} using the emission lines near 9733Å in the HF fired and NaF codoped samples and near 10,195Å in the CaF_2 codoped sample. This gave a total $^2F_{7/2}$ ground state splitting of, $\Gamma_7 - \Gamma_6 = 600$ cm^{-1}.

The absorption data indicated at least two noncubic crystal field splittings for the $^2F_{5/2}$ excited state. In most of the samples the Γ'_7 energy level occurred near 10,250 cm^{-1} and the $\Gamma'_{8(b)}$ level between 10,940 and 10,960 cm^{-1}, giving a total excited state splitting, $\Gamma'_7 - \Gamma'_{8(b)} = 700$ cm^{-1}. The $\Gamma'_{8(a)}$ level was located between 10,680 and 10,718 cm^{-1} in the NaF and CdS codoped samples giving a $\Gamma'_{8(a)} - \Gamma'_{8(b)}$ splitting of about 250 cm^{-1}. In the HF fired sample, however, the Γ'_7 level and $\Gamma'_{8(b)}$ levels were placed at 10,327 and 10,945 cm^{-1}, respectively, giving a $\Gamma'_7 - \Gamma'_{8(b)}$ splitting of about 620 cm^{-1}.

The $^2F_{7/2}$ ground state splittings resulting from crystal fields of noncubic symmetry were more difficult to obtain. In most of the samples, the fluorescence data indicated that the $\Gamma_{8(a)}$ level (probably the first excited level in the $^2F_{7/2}$ ground state) occurred 340-370 cm^{-1} above the Γ_7 ground state level. The relative order of the $\Gamma_{8(a)}$ and Γ_6 energy levels is not known; the assignment in Fig. 6 was chosen arbitrarily. The second excited ground state level ($\Gamma_{8(b)}$?) seemed to lie between 625 and 709 cm^{-1} above the Γ_7 level in the CdF_2:YbF_3, HF fired and CdS codoped samples. No specific transitions were associated with the Γ_6 level, assuming that it lies more than 710 cm^{-1} above the Γ_7 ground state.

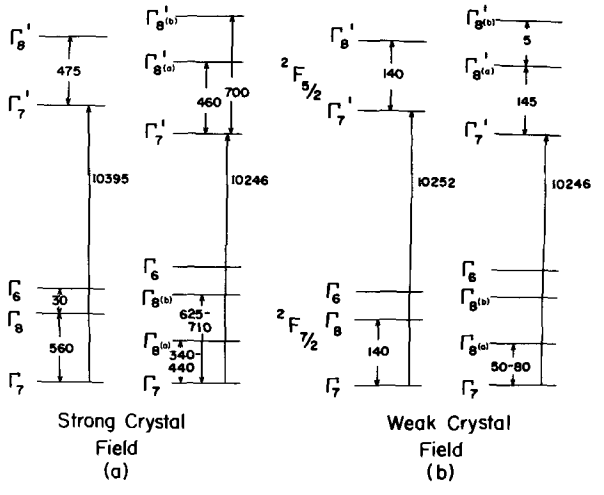

Fig. 6. Crystal field splittings for Yb^{+3} in CdF_2 according to *(a)* strong crystal field and *(b)* weak crystal field. Splittings between energy levels are given in cm^{-1}. Absorption lines between the Γ_7 and Γ'_7 levels are given in cm^{-1}. The ordering of the $\Gamma_{8(a)}$ $\Gamma_{8(b)}$ and Γ_6 ground state levels was selected arbitrarily. In both *(a)* and *(b)* cubic crystal field splittings are given on the left and noncubic crystal field splittings on the right.

There are several difficulties with this strong crystal field scheme. To explain the absorption doublets occurring near 9620 and 9760Å in most of the samples, recourse must be made to a very slight distortion of the crystal fields present at the Yb^{+3} lattice site. These might be caused, for example, by next-nearest-neighbor effects.

The fluorescence lines occurring at 9887, 9944, 10,283, 9872, 10,233, and 10,273Å seem to require a phonon assisted explanation. The fluorescence lines at 9630, 9649, and 9678Å in the CdF_2:YbF_3 + CdS sample cannot be assigned because of their temperature dependence (see Table II).

Weak crystal field.—The assigned transition are given in Tables I and II and a summary of the energy level splittings in Fig. 6(b).

The $^2F_{5/2}$ excited state energy level splitting for Yb^{+3} in a cubic crystal field was estimated to be 140 cm^{-1} for all of the samples. The absorption line near 9752Å (10,251 cm^{-1}) was used along with a line estimated to be at 9620Å (10,395 cm^{-1}) but obscured in the absorption data by the doublet arising from noncubic crystal field symmetry (see below).

The cubic crystal field splitting between the Γ_7 and Γ_8 levels of the $^2F_{7/2}$ ground state was estimated to be 130-140 cm^{-1} from the fluorescence data (the lines at 9887 and 9755Å in the CdF_2:YbF_3 sample, for example). The $\Gamma_8 - \Gamma_6$ splitting was not obtained from the data.

For the case of Yb^{+3} in noncubic crystal fields, the $^2F_{5/2}$ excited state splittings were essentially identical for all of the samples except the HF fired sample. The absorption lines at 9760, 9625, and 9620Å positioned the Γ'_7, $\Gamma'_{8(a)}$, and $\Gamma'_{8(b)}$ levels near 10,246, 10,390, and 10,395 cm^{-1}, respectively, giving the splittings $\Gamma'_7 - \Gamma'_{8(a)} = 144$ cm^{-1} and $\Gamma'_{8(a)} - \Gamma'_{8(b)} = 5$ cm^{-1}. For the HF fired sample the $\Gamma'_{8(a)}$ level was placed at 10,327 cm^{-1} giving a $\Gamma'_{8(a)} - \Gamma'_{8(b)}$ splitting of 68 cm^{-1}.

The splittings of the $^2F_{7/2}$ ground state energy levels, resulting from Yb^{+3} at a site of noncubic crystal field symmetry, were difficult to determine. The fluorescence data on most of the samples indicated that the first excited level, probably the $\Gamma_{8(a)}$, was 50-80 cm^{-1} above the Γ_7 ground state. The positions of the $\Gamma_{8(b)}$ and Γ_6 energy levels were not obtained.

Many difficulties were encountered with the weak crystal field scheme. There was no absorption detected from the Γ_7 to the Γ'_8 level or from the $\Gamma_{8(a)}$ level located only 50-80 cm^{-1} above the Γ_7. No absorption lines with energies greater than 10,400 cm^{-1} could be assigned. In the case of the HF fired sample, the $\Gamma'_{8(a)} - \Gamma'_{8(b)}$ splitting from the Γ'_8 level was quite unsymmetrical.

Several of the fluorescence lines could not be assigned with the 9617, 9630, 9649, and 9678Å lines in the CdS codoped sample and the 9639, 9643, and 9650Å lines with the CaF_2 codopant being most troublesome.

A comparison.—Neither the strong or the weak crystal field spliting model is completely satisfactory for Yb^{+3} in CdF_2. However, when the known data for Yb^{+3} in CaF_2 (6) and Tm^{+2} in CaF_2 (12) are considered along with the apparent "better fit" of the above absorption and fluorescence data to the strong field scheme, it appears that the strong crystal field splitting is favored. With either model many of the strong optical transitions observed for Yb^{+3} in CdF_2 arise from ions at sites of noncubic crystal field symmetry whereas EPR data (1-4) have indicated predominantly cubic crystal field symmetry for Yb^{+3} in CdF_2.

Crystal field symmetry.—One reason for the addition of various codopants to the CdF_2:YbF_3 crystals was to identify specific optical transitions of Yb^{+3} with certain types of local crystal field symmetry. As indicated in the previous section, this was not possible with the data obtained. There were, however, several characteristic Yb^{+3} absorption or emission lines for samples containing various codopants (presumably

Table III. The prominent absorption and fluorescence lines at 77°K for Yb^{+3} and for Yb^{+3} plus various codopants in CdF_2 single crystals

corresponding to at least slightly different crystal field symmetries at the Yb^{+3} lattice site). In Table III the relative intensities of the strongest absorption and emission lines are listed for all of the samples. It can be seen from Table III that the following lines indicate the presence of particular codopants (or impurities) in CdF_2:YbF_3 crystals: (*i*) The emission lines at 9632, 9655, and 9770Å are indicative of "as grown" CdF_2:YbF_3. (*ii*) The absorption line at 9683Å and the emission line at 9671Å correspond to the symmetry in the HF fired crystals (possibly a near neighbor F^- interstitial). (*iii*) The Na^+ codopant is indicated by a, relatively, strong absorption line at 9623Å and fluorescence at 9733Å. (*iv*) The presence of S^{-2} is characterized by the position and relative intensities of the 9617-9630Å absorption doublet and the emission lines at 9649 and 9679Å along with their apparent lack of temperature dependence. (*v*) Two strong fluorescence lines at 9744 and 9760Å indicate Eu^{+3}. (*vi*) Relatively strong emission at 9609, 9617, 9643, and 9650Å is characteristic of CaF_2 codoping.

Acknowledgments

The author would like to thank the following people at the IBM T. J. Watson Research Laboratory: Mr. J. E. Scardefield for help in growing the crystals, Mr. G. D. Pettit for the optical measurements, and Drs. J. D. Axe and P. R. Wagner for interesting and helpful discussions.

Manuscript received Aug. 30, 1966; revised manuscript received Feb. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Rare Earth Cathodoluminescence in $InBO_3$ and Related Orthoborates

F. J. Avella, O. J. Sovers, and C. S. Wiggins

General Telephone & Electronics Laboratories, Inc., Bayside, New York

ABSTRACT

The cathodoluminescence from Eu^{3+} and Tb^{3+} in the orthoborates of In, Sc, Y, La, Gd, and Lu is examined. The host $InBO_3$ is shown to be particularly effective for both activators. Observed spectral details of the luminescence are related to effects of crystal symmetry on electronic transitions.

Reports of photoluminescence from rare earth activated orthoborates of the type $M^{III}BO_3$ have appeared in the literature (1-3); however, little information is available on the cathodoluminescence of those systems. Recently, Avella (4) compared the performance of Tb^{3+} in several orthoborate matrices under cathode-ray excitation and found $InBO_3$ to be an effective host for that activator. In this paper our purpose is (*i*) to report highly efficient cathodoluminescence from Eu^{3+} in $InBO_3$, and (*ii*) to examine the effects of crystal symmetry on the emission processes of Eu^{3+} and Tb^{3+} activated orthoborates of In and the rare earths.

The orthoborates of trivalent In and the trivalent rare earths Sc, Y, La, Gd, and Lu constitute a family of polymorphous compounds with crystal structures at ambient conditions which are related to three crystalline forms of $CaCO_3$: aragonite, vaterite, and calcite (5). The structure which $M^{III}BO_3$ assumes is governed by the size of the cation. Thus La^{3+}, the largest rare earth ion, forms an orthoborate with the orthorhombic aragonite structure having space group V_h^{16}-Pbnm (6), where the La ion is situated in an asymmetric lattice site with point group C_s-m. The orthoborate structures of the smaller Y^{3+} and Gd^{3+} ions are often equated with vaterite; however, Bradley *et al.* (7) have shown that these are not true vaterite isomorphs and have assigned them a probable space group of D_{3h}^2-$P\bar{6}c2$. This pseudovaterite lattice has one cation with twelvefold oxygen coordination for every two

with sixfold coordination. The two sites differ in cation to oxygen distance, but have D_3-32 point symmetry in common. Sc^{+3} and In^{+3} are the smallest ions considered here. They occupy centrosymmetric C_{3i}-$\bar{3}$ lattice sites in orthoborates having the rhombohedral calcite structure with space group D_{3d}^6-$R\bar{3}c$ (6). $LuBO_3$ is a special case having two relatively stable allotropes which crystallize either with the calcite or, if heated above 1310°C, with the pseudovaterite structure. As a group, these orthoborates offer cation environments increasing in symmetry from aragonite to pseudovaterite to calcite.

The orthoborates under consideration are optically inert. Activation occurs when rare earth luminogens are substituted for some of the host cations. Although some emission is obtained from Sm and Dy, the most efficient visible emitters in $M^{III}BO_3$ are trivalent Eu and Tb, both of which form orthoborates of the pseudovaterite type. Therefore, activator incorporation is truly isomorphous only when M^{III} = Y, Gd, or Lu. Nevertheless, with the low activator concentrations considered here, neither the aragonite nor the calcite structured compounds give evidence of lattice distortion after activation when examined by routine x-ray powder diffraction methods. Consequently, the orthoborates offer an opportunity to examine host-activator interaction as a function of cationic species and of lattice symmetry.

Experimental

The orthoborate phosphors were prepared in powder form from stoichiometric mixtures of reagent grade boric acid with the oxides of the host and activator cations having 99.9% purity or better. Optimum Eu and Tb concentrations for maximum cathodoluminescence yield were found to be 0.02 to 0.03 gram atoms/mole of phosphor. The mixtures were fired in air using platinum or fused silica crucibles at two or three intermediate temperatures, and the materials were mortared between firings. The maximum temperatures optimized for cathodoluminescence performance were 1400°C for the In, Lu (pseudovaterite), Y and Gd compounds, 1200°C for the Sc and La compounds, and 1000°C for the Lu calcite polymorph. Compound formation was verified by x-ray powder diffraction analysis.

For measurement of cathodoluminescence the phosphors were settled on 1-in.^{2} sheets of conductive glass. These sheets were positioned in a demountable cathode-ray tube and excited at 15 kv using a 7-in. raster. The luminous output was measured with an RCA 1P21 photomultiplier fitted with a Kodak Wratten 106 filter. The emission spectra were recorded using a ¾-meter Czerny-Turner spectrometer (1200 line/mm grating and 50μ slit width) and an ITT F4013 photomultiplier (S-20 response). A correction function derived from the output of an NBS 1000W quartz-iodine standard lamp served as as internal reference so that spectra were recorded directly in terms of relative energy. The C.I.E. color coordinates and values of lumen equivalent were calculated from these spectra.

Results and Discussion

Eu^{3+} *cathodoluminescence spectra.*—Figures 1a-g present spectral energy distributions for cathodoluminescence emission from Eu in the orthoborates. No provision has been made in these figures for comparison of intensities between phosphors; however, luminosity data will be discussed in a later section. From the spectra it can be seen that the fine structure of the Eu^{3+} emission differs considerably among the three polymorphs but is closely similar among the isomorphs. In the three calcite structures of Fig. 1a-c the two dominant emission lines near 590 and 596 nm can be assigned to magnetic dipole allowed $^5D_0 \rightarrow {}^7F_1$ transitions. The $^7F_1$ level is split into two components as predicted from group theoretical considerations (8). The energy difference between the two Stark levels

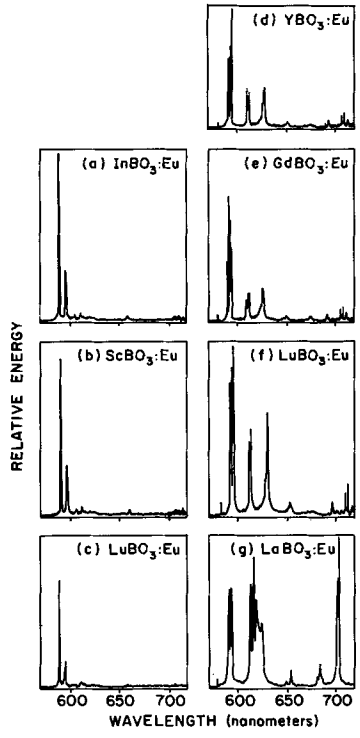

Fig. 1. Cathodoluminescence spectra from Eu activated orthoborates: (a-c) calcite structure; (d-f) pseudovaterite structure; (g) aragonite structure. (Spectra recorded at different instrumental gains.)

of approximately 190 cm^{-1} is larger than that normally observed for this Eu^{3+} multiplet. This splitting decreases slightly from In to Sc to Lu orthoborate. With Eu in the centrosymmetric C_{3i} site, electric dipole transitions are forbidden. Consequently, transitions from $^5D_0$ to the J = 2, 3, and 4 sublevels of ^7F are weak as indicated by the emission groups near 610, 660, and 710 nm, respectively; no emission is observed corresponding to the $^5D_0 \rightarrow {}^7F_0$ transition. It is possible that some of the weak emissions result from transitions which originate in a higher excited level, *e.g.*, $^5D_1$, but such assignments would require detailed studies outside the scope of this paper.

The spectra of Fig. 1d-f were obtained from Eu^{3+} in the pseudovaterite structures. Again emission lines near 590 nm constitute the dominant feature and can be assigned to $^5D_0 \rightarrow {}^7F_1$ transitions. For the D_3 site symmetry a twofold splitting of $^7F_1$ is predicted; however, two distinct types of D_3 sites are involved which make possible a total of four Stark levels and, therefore, as many as four $^5D_0 \rightarrow {}^7F_1$ emission lines. Although not clearly defined in these figures, four such emission lines are indeed observed for each of the three pseudovaterites. In each case the width of the $^7F_1$ multiplet does not exceed 100 cm^{-1}, but there is variation in the energy differences between the four sublevels as well as in the probabilities of transitions to them. As a result of lower site symmetry there is a relaxation of parity forbiddenness, and electric dipole transitions are also possible. At 581 nm a weak line appears that may be attributable to the $^5D_0 \rightarrow {}^7F_0$ transition. The emission groups between 609 and 618 nm probably result from $^5D_0 \rightarrow {}^7F_2$ transitions. These are more intense for the pseudovaterite than for the calcite polymorphs both in relation to other transitions and also on an absolute basis. Of the six lines possible, four distinct ones are observed, with one sublevel (626-628 nm emission) being considerably broadened. Intensity variations among the three pseudovaterites are also evident for these transitions. In these compounds the $^5D_0 \rightarrow {}^7F_3$ transitions give rise to weak emission at about 650 nm *vs.* 660 nm for the calcites. The transitions are about equal in intensity for the

two polymorphs. The $^5D_0 \rightarrow {}^7F_4$ emission lines near 710 nm, however, are more intense for the pseudovaterites.

The spectrum from Eu in the C_s site of the $LaBO_3$ aragonite polymorph is presented in Fig. 1g. It differs from the spectra of Fig. 1a-f mainly in that the magnetic dipole transitions are subordinate to the electric dipole transitions. The dominant group is $^5D_0 \rightarrow {}^7F_2$ with a broad emission band between 610 and 630 nm. Also of relatively high intensity is the emission near 700 nm arising from $^5D_0 \rightarrow {}^7F_4$. However, because the total emitted flux from $LaBO_3$:Eu is considerably smaller than that from the other borates, these transitions are actually no more intense than their counterparts in the pseudovaterites. The magnetic dipole allowed $^5D_0 \rightarrow {}^7F_1$ group is relatively weak here and produces three emission lines between 590 and 594 nm. The $^5D_0 \rightarrow {}^7F_0$ transition is very weakly indicated by the line at 597 nm.

Considered as a group, the spectra from the orthoborates demonstrate that a lowering of site symmetry increases the probability ratio of electric dipole to magnetic dipole transitions. This effect was recently described by Blasse *et al.* (9) using host compounds of several different compositions. On the other hand, the identical site symmetries and closely related lattice parameters of the orthoborate isomorphs combine to produce nearly identical details in the Eu^{3+} radiative transitions.

Tb^{3+} *cathodoluminescence spectra.*—Since in Tb^{3+} all the radiative transitions from the lowest excited state ($^5D_4$) to the J = 3-5 sublevels of the ^7F ground state are allowed by magnetic dipole considerations, the $M^{III}BO_3$:Tb spectra will not bear a similar analysis to that made of the Eu spectra. Also, the multiplicity of Stark levels possible in the pertinent ground and excited levels makes comparison of actual and calculated numbers of components impractical, at least for room temperature spectra. However, some correlations can be made.

Reference to the emission spectra of the Tb activated calcite isomorphs in Fig. 2a-c shows five groups of emission lines which may be assigned to transitions terminating at the following ground levels: for 475-510 nm emissions, $^7F_6$; 535-565 nm, $^7F_5$; 578-600 nm, $^7F_4$; 615-635 nm, $^7F_3$; 650-665 nm, $^7F_2$. Considering their complexity, the spectra are strikingly similar for these three isomorphs, and only small differences appear in the intensities and positions of the lines. The major portion of the emitted energy results from transitions in the $^5D_4 \rightarrow {}^7F_5$ group with the lines at about 542 and 550 nm the most intense. Such a total domination of the Tb^{3+} spectrum by this group of transitions is unusual and has not been reported for other hosts.

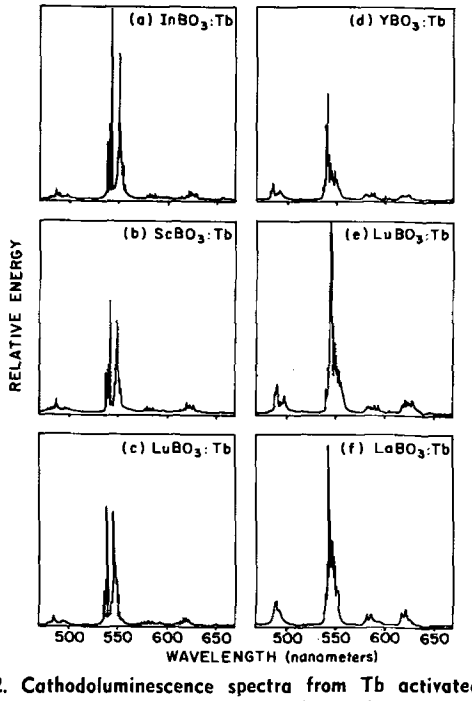

Fig. 2. Cathodoluminescence spectra from Tb activated orthoborates: (a-c) calcite structure; (d & e) pseudovaterite structure; (f) aragonite structure. (Spectra recorded at different instrumental gains.)

Emission spectra of Tb^{3+} in the pseudovaterite structures are given in Fig. 2d and e. $GdBO_3$:Tb has been excluded because of strong interference from Eu^{3+} emission which results from Eu impurity in the Gd_2O_3 starting material. The two pseudovaterite spectra are similar but not identical. The most obvious variation from the calcite spectra occurs in the absence of a strong emission line at 550 nm in the $^5D_4 \rightarrow {}^7F_5$ group. There is an intense emission at about 542 nm, but this is split into two lines in YBO_3 and into three lines in $LuBO_3$. Some of the other lines within this group do have analogues in the calcite spectra. Another variation from the calcites appears in the greater intensity of emission at 478-510 nm (from $^5D_4 \rightarrow {}^7F_6$ transitions) relative to the dominant emission.

The Tb^{3+} spectrum from the aragonite structure in Fig. 2f bears a strong resemblance to the pseudovaterite spectra. The major difference is the absence of splitting in the dominant 542 nm emission line. Other small variations in detail are also seen.

From the above observations it is evident that, just as in the case of Eu^{3+}, the Tb^{3+} emission shows closely similar spectral detail among the orthoborate isomorphs. Among the polymorphs there are spectral differences, but in comparison with the Eu^{3+} ion, it is clear that the radiative transitions in Tb^{3+} are less sensitive to changes in the crystal field.

Cathodoluminescence performance.—Performance data for the cathodoluminescence of Eu^{3+} in the orthoborate hosts are presented in Table I. Also included for comparison are data for Y_2O_3:Eu, YVO_4:Eu and $Zn_{0.21}Cd_{0.79}S$:Ag, all three of which are efficient red-emitting cathode-ray phosphors. In terms of relative luminosity, $InBO_3$:Eu is superior to all the red-emitting phosphors listed. The C.I.E. color coordinates indicate that the emission shifts from red to orange proceeding from the aragonite to the pseudovaterite to the calcite structures. From the values of lumen equivalent it can be seen that this color shift is in the direction of greater eye sensitivity. In order to determine the relative efficiencies with which these phosphors convert the excitation energy into radiant energy, it is necessary to take the emission colors into consideration. Thus, values of relative conversion efficiency were obtained from a ratio of relative luminosity to lumen equivalent, and a value of 1.00 was assigned arbitrarily to the sulfide phosphor. On this basis $InBO_3$ is a more efficient host for Eu^{3+} than any of the other borates and is comparable in efficiency to YVO_4.

The performance of the Tb-activated orthoborates under cathode-ray excitation has been reported elsewhere (4). The superiority of $InBO_3$ over the other orthoborates as a host is even more evident when Tb is the activator, since $InBO_3$:Tb has approximately 300% the conversion efficiency of YBO_3:Tb, the next most efficient $M^{III}BO_3$:Tb. In terms of relative luminosity and conversion efficiency $InBO_3$:Tb is comparable with Zn_2SiO_4:Mn phosphor.

Summary

Orthoborates of type $M^{III}BO_3$, where M^{III} = In, Sc, Y, La, Gd, and Lu, were activated with trivalent Eu and Tb, and their response to cathode-ray excitation was studied. $InBO_3$ proved to be the most effective orthoborate host for Eu^{3+} as well as for Tb^{3+}, and the conversion efficiency of $InBO_3$:Eu was found to be comparable with that of YVO_4:Eu. De-

Table I. Cathodoluminescence data for Eu activated orthoborates

$Cd_xHg_{1-x}Te$ Films by Cathodic Sputtering

Herbert Kraus, Sidney G. Parker, and James P. Smith

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Films of $Cd_xHg_{1-x}Te$ ranging from $x = 0.05$ to $x = 0.15$ were deposited by cathodic sputtering on single crystal substrates of NaCl, Ge, and sapphire. The resulting films were amorphous, but became crystalline on annealing. Optical transmission and electron probe analysis showed a slightly lower Hg concentration in the film than was present in the source material. Although CdTe can be sputtered to give a polycrystalline film, it was not possible to obtain a film by sputtering HgTe.

Reports by several investigators indicate that HgTe and CdTe form solid solutions over the entire compositional range of the alloy (1-4). The location of the absorption edge in this system is determined by the composition of the alloy and is at 0.8μ for pure CdTe and at some value greater than 20μ for HgTe. Compositions ranging from $Hg_{0.80}Cd_{0.20}Te$ to $Hg_{0.95}Cd_{0.05}Te$ are of interest since they exhibit absorption edges beyond 8μ in the electromagnetic spectrum and can possibly be used for fabrication of intrinsic photon detectors.

The phase relationship in this alloy system suggests an equilibrium segregation coefficient greater than three for Cd in the compositional range of interest. This condition makes preparation of highly homogeneous material by conventional melt-growth methods rather difficult. Since the ultimate form of a detector made from this material is to be a layer of the alloy about 10 to 50μ thick attached to an insulating substrate and thin layers of this particular material are usually prepared by cumbersome lapping, polishing, and etching procedures, cathodic sputtering was deemed to be a desirable approach.

This paper describes some of the advantages and disadvantages of cathodically sputtered (HgCd)Te films.

Experimental

Amorphous (HgCd)Te films were prepared by cathodic sputtering from polycrystalline (HgCd)Te sources of several different compositions. Source materials of the desired nominal compositions were made from the purified elements. Appropriate quantities of ultrapure Hg (Hg-9, E. H. Sargent Comany) six-nines Cd (Cominco), and five-nines Te (ASARCO), which was further zone-refined until no impurities were detected by emission spectrography, were placed in a clean quartz ampoule. The ampoule was then evacuated and sealed. The elements were carefully heated in a rocking furnace to 30°-50°C above the liquidus of the alloy for 30-40 hr. Finally, the melt was solidified by air-quenching within 40-50 sec. Electron probe analysis showed the ingots were homogeneous. Emission spectrographic analyses revealed no impurities in samples taken from the compounded ingot. Mass spectrographic analyses were of no use, since the

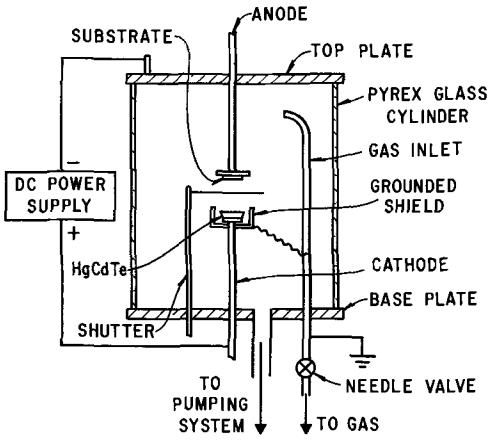

Fig. 1. Sketch of sputtering apparatus

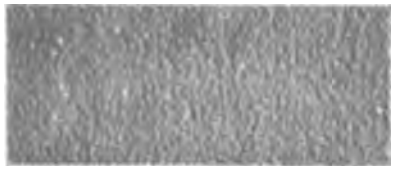

Fig. 2a. Photomicrograph of sputtered unannealed film of $Hg_{0.85}Cd_{0.15}Te$. Magnification 120X.

Fig. 2b. Photomicrograph of sputtered annealed film of $Hg_{0.85}Cd_{0.15}Te$. Magnification 400X.

multiple-charge ions of the major components produced mass interference, masking any possible impurities.

Sputtering was accomplished in a simple apparatus of conventional design, as shown in Fig. 1. All metal surfaces inside the vacuum chamber were cadmium plated to minimize contamination. The anode was a 1½-in. diameter brass disk welded to a stainless steel tube to permit cooling or heating of the substrate. The substrates and growth planes were {1,1,0} NaCl, {1,1,1} Ge, and randomly oriented sapphire, all with a 1μ in. surface finish and a 25 mm^2 surface area.

With the substrate and source material in place, the system was evacuated to approximately 10^{-3} Torr and backfilled with dry, oxygen-free argon. This cycle was repeated several times. The system was then evacuated to 1 x 10^{-5} Torr. The pressure of the system was then adjusted by increasing the argon pressure in the bell jar by use of a micrometer valve. Throughout this study dry, oxygen-free argon was used as the discharge gas to enhance the disintegration rate of the source material and prevent undesirable reactions between the sputtered deposit and the residual gas (5).

It is well known that in the sputtering process the parameters of voltage, current density, pressure, and anode-cathode distance are highly interdependent. Success in obtaining films and the resulting properties of these films differed widely with sputtering conditions. Films of the compositions of interest ranging from $Hg_{0.85}Cd_{0.15}Te$ to $Hg_{0.95}Cd_{0.05}Te$ being relatively free of pinholes and visual defects, sputtered on NaCl, Ge, and sapphire were obtained using the following conditions: voltage, 1500v; current, 470 μa; cathode current density, 0.36 ma/cm^2; anode-cathode distance, 1.0 cm; Ar pressure, 45μ; sputtering period, 4.0 hr; substrate temperature, 25°C.

Results and Discussion

Film characteristics.—Typical film thicknesses were between 30 and 50μ. The films consisted of an amorphous layer interspersed with crystallites. The amorphous and crystalline character of the unannealed films was determined by reflection electron diffraction. Heating the substrates while sputtering, to encourage crystal growth, resulted in poor film adhesion and severe losses of Hg. Cooling the substrate below room temperature during sputtering increased the amorphous character of the deposit. Substrates cooled to near 0°C were invariably 100% amorphous. Figure 2A shows a photomicrograph of the surface of a typical unannealed film of $Hg_{0.85}Cd_{0.15}Te$ sputtered on a randomly oriented sapphire substrate.

Annealing.—Films were annealed under partial Hg-vapor pressures of 3 and 150 Torr, respectively, to obtain crystal growth and to attempt to improve crystalline perfection. The sample was heated to 300°C during annealing. The best crystal growth was obtained when films sputtered on sapphire substrates were annealed for 24 hr under a partial pressure of Hg vapor of 150 Torr with the sample heated to 300°C. Figure 2B shows a photomicrograph of a formerly amorphous $Hg_{0.85}Cd_{0.15}Te$ film exhibiting [1,1,1] oriented crystallites after annealing. Similar results were also obtained with compositions of higher Hg content. Films deposited on NaCl and Ge substrates peeled off when they were annealed or on subsequent handling.

Although CdTe films were readily laid down by sputtering, no HgTe deposit was obtained by cathodic sputtering under any of the conditions attempted. Failure to obtain a HgTe film is probably caused by decomposition of the HgTe by the high energy Ar ions as they bombard the surface and/or by a low accommodation coefficient of the substrates employed. It is apparent that addition of CdTe to HgTe modifies the sputtering properties of HgTe.

Optical measurements.—Transmission measurements were carried out at room temperature with a Perkin-Elmer 337 dual-beam grating spectrometer on unannealed films sputtered on single crystal NaCl. Attempts to measure annealed films were hampered by pinholes in the film which were introduced during annealing. Figure 3 shows the curves of Log I_o/I *vs.* wavelength in microns, where I_o is the incident energy and I the transmitted energy. The absorption curves were de-

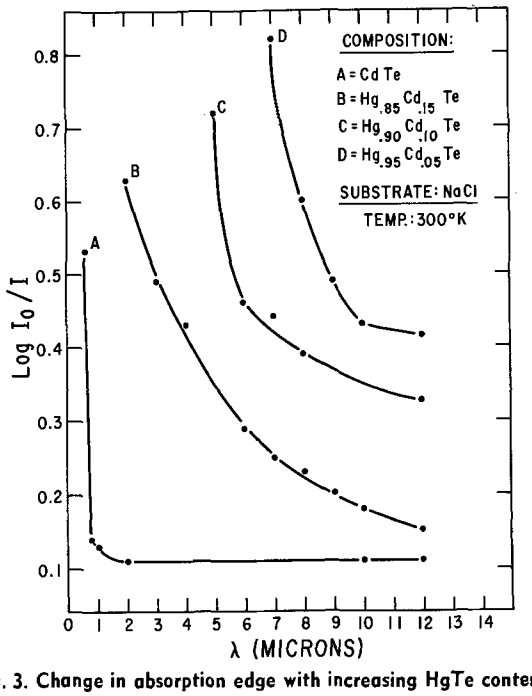

Fig. 3. Change in absorption edge with increasing HgTe content

rived from randomly chosen films whose compositions were established by electron probe analysis. It can be seen that the absorption edge shifts from 0.8μ for pure CdTe to longer wavelengths as the Hg content increases. The exact position of the energy-band edge becomes more difficult to determine from the absorptions curves as the Hg concentration is increased because of free carrier absorption beyond the band edge. However, reasonable estimates of the band gaps can be made by extrapolation.

As mentioned previously, the best films obtained were sputtered on sapphire substrates. These films were less susceptible to peeling and pinhole formation during annealing. Such a film was sputtered from a $Hg_{0.85}Cd_{0.15}Te$ source, annealed for 24 hr at 300°C under a partial Hg vapor pressure of 150 Torr, then measured for photoconductive response at 77°K. Electrical contacts were made with thin-gauge gold wire soldered with pure indium to opposite sides of the film. The final assembly was placed in a Dewar-type flask, cooled to 77°K, and measured for relative spectral response. Figure 4 shows results of the measurements. The peak response was at 3.5μ, which corresponds to an energy gap of about 0.35 ev. This value does not compare favorably with optical transmission data for bulk material of the same composition. Experimental measurements on bulk (HgCd)Te by Blue (6) show the energy gap value for $Hg_{0.85}Cd_{0.15}Te$ to be about 0.14. Because electron probe analysis shows only a small loss of Hg during sputtering, the wider band gap must be attributed to other factors. Chemical analysis data indicate variations in composition in the film, *i.e.*, the value of x in $Hg_{1-x}Cd_xTe$ varies throughout the film, despite the fact that the over-all elemental composition is very near that of the source. Therefore, material of wider band gap is most likely produced along with materials having a wide range of band gaps. It is difficult to determine accurately the band gap in the films from optical data because of scattering (7) and adsorption in the amorphous film. Further, it has been suggested that the adsorption edge position becomes more difficult to determine with increasing HgTe content because of the low values of the energy gap and of the effective electron mass (8).

Chemical composition analysis.—Bulk composition and degree of microscopic homogeneity should be known to correlate the chemical and optical properties of the alloy system. Bulk analysis of the starting material was obtained for cadmium and tellurium with the Jarrell-Ash Model 82-546 Atomic Absorption Flame Spectrometer. The degree of microscopic homogeneity was studied with the Material Analysis Company Model 400 Electron Probe Microanalyzer equipped with three analyzing channels.

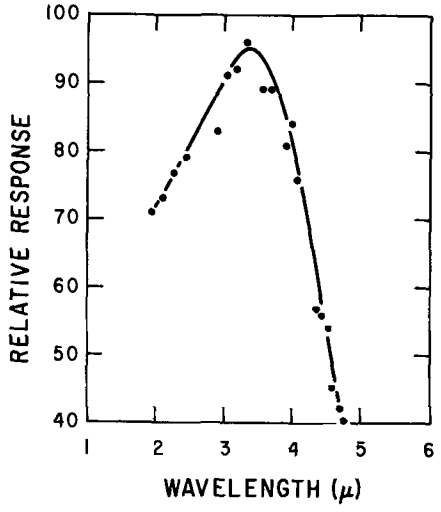

Fig. 4. Relative spectral response curve vs. wavelength of a sputtered film after annealing.

It is not too meaningful to relate analytical results to molar relationships of pseudobinary systems, but we can easily discuss the $Hg_{1-x}Cd_xTe$ compositions in terms of the x value. Of course, the x value assumes a stoichiometric composition, and the fit of the analysis to the stoichiometric composition must be stated. When x is in the range from 0.05 to 0.20, its value in $Hg_{1-x}Cd_xTe$ is very sensitive to the cadmium concentration. Cadmium varies from 1.74 to 7.27 w/o (weight per cent) in this range, whereas mercury varies from 58.86 to 51.61 and tellurium from 39.4 to 41.12 w/o. It appears useful to calculate the x value using the cadmium analysis and to compare the mercury and tellurium concentrations to the theoretical concentrations of a stoichiometric compound. Thus, a cadmium concentration of 1.74% would indicate that x was 0.05. However, if the mercury concentration were only 55.2 w/o, rendering the compound more than 3% deficient in mercury, the end result would hinge again on the assumption that no losses of tellurium occurred during compounding. The electron-probe microanalyzer was used to analyze the three components simultaneously at random 10μ diameter spots over the surface of the sample.

A list of experimental constants is given in Table I. The average of the various electron counts was used for the analysis. The data were computed with the computer program written by Brown (9). This program normalized the three components of the composition to a 100% sum. Before this normalizing step, errors in the sum ranged between —3% and +1% using HgTe and CdTe standards. The use of elemental standards and HgS resulted in errors as large as 10%; these errors were probably the result of absorption uncertainties, atomic number effects, and the creation of Cd L α fluorescence by Te L α radiation. These effects, which are not corrected in the computer program, are minimized by using HgTe and CdTe standards. The cadmium concentrations in the (HgCd)Te compounds under investigation were quite low, and the signal-to-noise ratio was high; therefore, long counting times were required for cadmium. To further eliminate errors, cadmium background counts were taken on the HgTe standard. Table II shows the comparison between theoretical values, given in parentheses, and experimental values found by microprobe analysis.

A significant change in the composition homogeneity was detected by the microprobe analysis. About 100 counts were taken randomly on the starting materials

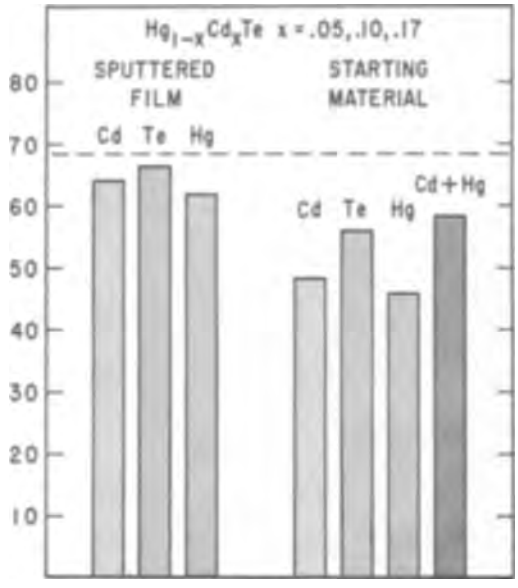

Fig. 5. Per cent of the relative x-ray intensity measurements which were within one standard deviation.

and on the sputtered film. The average count for each element was calculated, and the count deviation ($\sqrt{n}$) was determined. Since experience has indicated that the standard deviation of the x-ray readout of the electron probe microanalyzer is about twice the statistical count deviation, the average count was normalized to 100, and each individual count and the standard deviation were adjusted to fit this new value. The difference between each count and the average was obtained. If the materials analyzed were perfectly homogeneous, 68.3% of the differences would be less than one standard deviation. This statistical analysis is tabulated in Fig. 5 for the three elements in the starting material and for the sputtered films. It is seen that the sputtered films are more homogeneous than the starting material. In the starting material the cadmium and mercury sum[1] places more points in the standard deviation. This indicates that the inhomogeneity consists mainly of $Hg_{1-x}Cd_xTe$ phases rather than elemental phases.

[1] The standard deviation of a sum of two numbers N_1 and N_2 having deviations D_1 and D_2 is $\sqrt{D_1^2 + D_2^2}$.

Conclusion

Nearly homogeneous films of (HgCd)Te can be obtained by sputtering from less homogeneous sources. The slight residual inhomogeneity of the film results mainly from (HgCd)Te phases rather than elemental phases.

The films were predominantly amorphous, but crystal growth was obtained by annealing the films under partial pressures of Hg vapor.

Determining the band edge in the films from optical data becomes progressively more difficult with increasing HgTe content because of the low value of the energy gap and the effective electron mass.

Simultaneous analysis of all the components in this alloy system is essential to avoid errors in interpreting the analytical results. For this purpose, the electron microprobe and computerized computation for compositional analysis of this ternary have been found most useful.

Fused Glass Penetration into Thermally Grown Silicon Dioxide Films

W. A. Pliskin

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

In the manufacture of fused glass protected planar silicon devices having an underlying barrier layer of silicon dioxide, it is desirable to know the degree of penetration of the glass into the underlying layer as a results of fusing the sedimented glass powder. Penetration depths were determined from etch rate plots using P etch which etches most glasses much more rapidly than silicon dioxide. The penetration of low temperature firing lead borosilicate glasses (<600°C for 5 min) can be limited to less than 100Å. For high firing temperature silicate glasses (>1100°C for 5 min), a penetration of a few hundred angstroms is more common. Glasses fired at temperatures significantly higher than their softening points (or minimum firing temperatures) show much greater penetrations. The results are explained on a model based on the fact that the softening point of silicate glasses increases sharply with silica composition. As the glass softens, the lower layer of glass fuses with the upper SiO_2 surface to form a thin boundary glass layer with greater silica composition. As the penetration increases, the silica content of this intermediate layer increases sharply and consequently the effective softening point for the region becomes so high that further penetration is severely limited.

In the manufacture of fused glass protected planar silicon devices which have an underlying silicon dioxide layer, it is desirable to know the amount of penetration of the glass into the SiO_2. This is especially true since in many cases the glass may contain components which should not come in contact with the silicon.

By means of etch rate plots, in which the oxide plus glass film thickness is plotted against the total etch time, glass penetration depths can be determined. For high accuracy with this technique, it is necessary to have (*i*) an etch which will attack the glass much more rapidly than the silicon dioxide, and (*ii*) very accurate techniques for measuring the film thickness. The etch selected for these purposes is "P etch" which consists of 15 parts HF, 10 parts concentrated HNO_3, and 300 parts water (1). This etch is very selective in that its etch rate for thermally grown SiO_2 is only 2 Å/sec, whereas, for Pyrex (Corning 7740) it is 8 Å/sec, and for some lead borosilicate glasses, it can run as high as 500 Å/sec. Film thicknesses were determined very accurately with VAMFO (2), which is a special interferometric microscope, with which thicknesses can be determined to a precision better than 0.1% (3). This microscope is equipped with a monochromatic filter and a stage capable of rotating on an axis normal to the optical axis of the microscope so as to observe the reflected light at various angles. It should be noted that the technique does not require optically flat substrates. The film thicknesses can be determined by equations [7] given in ref. (2) or (3) or by

$$d_T = \frac{N\lambda}{2\mu_g \cos r_g} - \frac{\mu_o \cos r_o}{\mu_g \cos r_g} d_o + d_o \qquad [1]$$

where N is the fringe order for an observed interference minimum at incident angle i; λ, the wavelength of filtered light; μ_g, the glass refractive index at wavelength λ; μ_o, the SiO_2 refractive index at wavelength λ; r_g, the angle of refraction for incident angle i and refractive index μ_g; r_o, the angle of refraction for incident angle i and refractive index μ_o; and d_o, the thermal oxide thickness prior to glassing.

In some cases the thicknesses can be determined most conveniently by (3)

$$d_T = \frac{N\lambda_j}{2\mu_j \cos r} \qquad [2]$$

where μ_j is the average refractive index at λ_j for the composite film of glass and oxide. If the thickness is sufficient for the observation of more than one minimum, then both the average refractive index and d_T can be determined by finding the refractive index for which d_T is the same from sets of tabulated values. If the glass refractive index is not known beforehand, it can be determined by use of the relation

$$\mu_g = \frac{\mu_j d_T - \mu_o d_o}{d_T - d_o} \qquad [3]$$

With thinner films, different filters are used and the sets of tables used in making the interpolation are based on a dispersion system corresponding to the type of dispersion expected for the mixed glass-oxide system (3). If the total film consists of two fairly distinct components of significantly different refractive indices and comparable film thicknesses (and d_o is known) then Eq. [1] is more accurate than Eq. [2]. For example, if the two components had refractive indices of 1.5 and 1.7 and were of comparable thicknesses, then it can be shown that the thickness determined by Eq. [2] is 0.27% greater than that determined by the more accurate Eq. [1]. If the two components are significantly different in thickness or if their refractive indices are not significantly different then the thicknesses determined by the two equations are not significantly different. In those cases where significant interpenetration between the oxide and a high refractive index glass has occurred, thickness measurements in the vicinity of the boundary are more accurately determined by Eq. [2], although Eq. [1] is still sufficiently accurate for all practical purposes.

Experimental

In practice the thicknesses of thermally oxidized wafers were measured prior to glassing. The wafers were then glassed with various glasses by sedimentation techniques (4, 5). The thicknesses were measured after glassing and after various periods of etching. From the etch rate plots, the depth of penetration of the glass was determined.

Results and Discussion

With glasses having a fast etch rate and fired at temperatures close to their softening points, the demarcation is quite sharp. If the glass is fired at a temperature much above its softening point, the demarcation becomes less sharp due to penetration of the glass

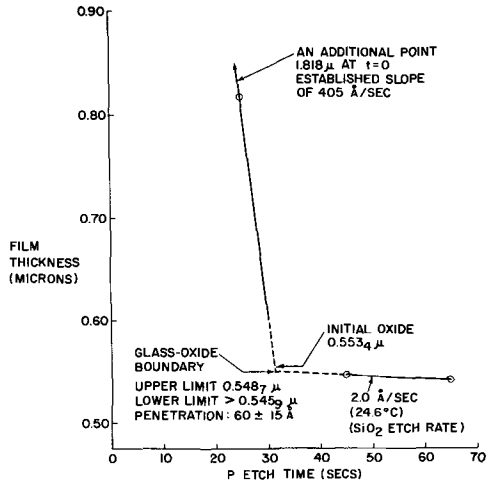

Fig. 1. Etch rate plot of 190B glass fired at 585°C for 5 min in O_2 on SiO_2 film.

into the SiO_2 and consequent formation of an SiO_2 enriched glass layer above and below the initial oxide boundary. If the glass film is formed by firing at the minimum temperature necessary to produce a good glaze, the penetration can be limited to a depth of less than 100Å for glasses whose firing temperatures are less than 600°C. For high temperature glasses (minimum glazing temperature >1100°C), a penetration of a few hundred angstroms is more common. In some cases where glasses are fired a few hundred degrees above the minimum glazing temperature, the overall penetration can be greater than 2000Å in addition to microscopically visible areas where the penetration is much greater. We define the minimum glazing temperature as the minimum furnace temperature necessary for forming a good glazed film of the sedimented powder by 5 min exposure in the furnace. It is usually close to the softening point of the glass.

To show the importance of firing temperature on the degree of glass penetration into the silicon dioxide, results will be given for glasses representing three softening point categories, low (<600°C), intermediate (~800°C), and high (>1100°C). Because of the importance of phosphosilicate glass for device passivation some results are given on the penetration of fused glass into the protective phosphosilicate layer covering the silicon dioxide.

Lead borosilicate glass 190B (low softening point).—In Fig. 1, we have shown an etch rate plot of glass 190B which is a lead borosilicate glass having a softening point of 588°C. The compositions of various glasses is given in Table I. This is a very fast etching glass. The steep slope representing the glass etching was determined by an additional point not shown on the amplified graph of Fig. 1. Because of the very fast etch rate of this glass, the etch times between film thickness measurements must be kept small. The last two points in the figure correspond to silicon dioxide since the P etch rate established by the two points is the same (2.0 Å/sec) as that of thermally grown SiO_2.

If we assume both the glass and oxide continue etching at their respective rates, then the intersection at $0.548_7\mu$ would correspond to the glass-oxide boundary, and we could conclude that the glass penetrated to a depth of about 50Å (47) into the oxide. Actually if we have interpenetration, then the etch rate near the boundary should be intermediate between that of the silicon dioxide and the glass and consequently the actual boundary should be less than $0.548_7\mu$. On the other hand, the point at $0.545_9\mu$ is in the SiO_2 since the etch rate here corresponds to that of SiO_2 and therefore the lower limit is greater than 0.545_9. It is therefore concluded that the glass penetrated 60 ± 15Å of the SiO_2. The penetration determined from these plots is the amount of over-all bulk penetration of the glass and does not show the possible penetration of a small amount of fast diffusing species into the oxide.

An etch rate plot of this same glass when fired at the same temperature (585°C) but for 20 instead of 5 min, showed a bulk penetration of 150 ±15Å. The reason for the small penetration can be explained in terms of the variation of softening point with SiO_2 composition. With most silicate glasses, the softening point increases sharply with silica composition. As the glass softens, the lower layer of glass fuses with the upper SiO_2 surface to form a thin boundary glass layer with greater silica composition. As the penetration increases, the silica content of this intermediate layer increases sharply and consequently the effective softening point for the region becomes so high that further penetration is severely limited.

Lead alumina borosilicate glass Corning X760LZ (intermediate softening point).—With higher temperature glasses, the degree of penetration is increased. This can also be explained in terms of the silica composition. Because of higher silica composition, the softening point is greater and consequently such a glass must be fired at a higher temperature to obtain a good glazed film. Furthermore, since the silica composition is significantly more than that for low temperature glasses, a greater depth of silicon dioxide must be penetrated to make a significant relative difference in the silica composition of the boundary layer and consequently in the difference between the effective softening point of the boundary layer region and the actual firing temperature.

For representation of glasses with an intermediate softening point, we have chosen Corning X760LZ. Although the softening point of this glass is about 785°C, its minimum glazing temperature is approximately 760°-770°C depending on the particle size of the sedimented glass powder (5). In this series of experiments after each etch period, photomicrographs at 400X were taken using monochromatic illumination in addition to measuring the over-all film thicknesses with VAMFO. This process was repeated several times until the oxide etch rate corresponded to that for thermally grown SiO_2. Plots of the film thickness as a function of the etch time show the amount of over-all bulk penetration of the glass into the oxide. Two examples are shown in Fig. 2 and 3 which are for firing temperatures of 770°C for 5 min (Fig. 2) and 760°C for 5 min followed by 1 min at 1100°C (Fig. 3).

Using the same procedure with Fig. 2 as in Fig. 1,

Table I. Approximate glass compositions of principle components (in weight per cent)

Glass	SiO_2	PbO	B_2O_3	Al_2O_3
190B	29	51	9	3
Corning X760LZ	51	29	13	7
General Electric GSC-1	83	0	12	5

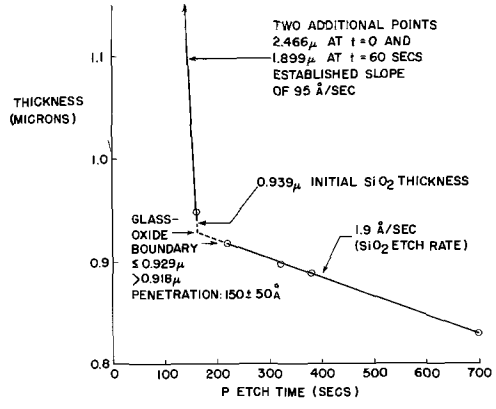

Fig. 2. Etch rate plot of X760LZ glass fired at 770°C for 5 min on SiO_2 film.

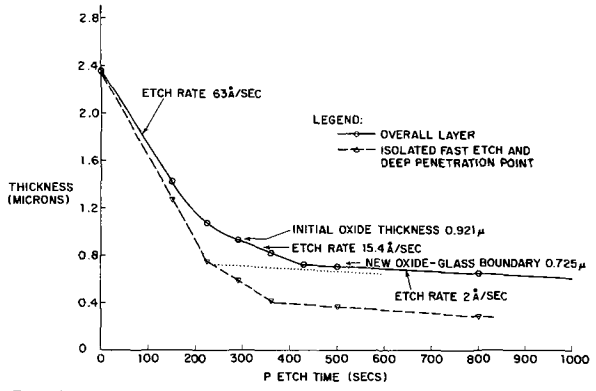

Fig. 3. Penetration of X760LZ glass into SiO_2 (F.T. 760°C—5 min, 1100°C—1 min) penetration: 1960Å (bulk), 5200Å (isolated points).

it is concluded that the penetration is 150 ±50Å. Furthermore, high-power microscopic examination showed the etching to be uniform across the wafer.

From Fig. 3, it is obvious that there has been an over-all bulk penetration into the oxide of about 2000Å. This large penetration also manifests itself in the etch rate reduction for the glass film above the initial SiO_2 film thickness at 0.921μ. In addition to this over-all bulk penetration, as shown by Fig. 3, the monochromatic photographs at high magnification show additional deep penetration into the oxide at isolated spots on the surface. It was observed that the glass over these spots etched much more rapidly than the surrounding glass. The points of deeper penetration into the oxide, observed after the removal of the glass, was not just due to the earlier arrival of the etch solution to the oxide layer at these fast etch points. This can be seen from an examination of Fig. 3 in which the thickness of the underlying film under one of these "pipes" is plotted against the etch time. From the dotted line, it is obvious that for "earlier arrival" to be the explanation, the additional penetration into the oxide must be only a few hundred angstroms rather than the 3600Å observed.

The results of this investigation together with the results obtained from other experiments involving X760LZ glass are summarized in Table II. The main point of these results is that the penetration of the glass into the oxide is minimal when the glass is fired at its minimum glazing temperature, but the penetration becomes significant at higher temperatures and longer firing times.

Table II. Penetration of X760LZ into SiO_2

Wafer	Firing conditions	Over-all bulk penetration	Isolated spot penetration below over-all layer
A	770°C—5 min	~150Å	~300Å (due to penetration through bubbles in glass)
B	760°C—5 min 1100°C—1 min	2000Å	Several 2500-4000Å penetrations and many more 1000-2500Å penetrations
C	1100°C	2000Å	Same as above. See Table III for details.
D	950°C—5 min 1100°C—1 min	2400Å	About same as for B.

Table III. Isolated penetration points in SiO_2 for X760LZ fired at 1100°C

Penetration depth below general penetration	No. in photo	Approx. population (No. per cm²)	Approximate width, μ
3700Å	2	~5 × 10³	~6
2300-3100Å	10	~25 × 10³	~5
1500-2300Å	~90	~200 × 10³	~2-4
500-1500Å	≧500	≧1200 × 10³	~½-2

The extent of the isolated point penetrations can be obtained from Table III in which the number of "pipes" and depth of penetration into the oxide is listed for Wafer C (1100°C fired for 1 min). It is thus concluded that a 1 min firing of X760LZ at 1100°C would require a silicon dioxide film thickness of several thousand angstroms to protect the surface from visible type penetrations, let alone additional penetration due to small amounts of possible fast diffusing deleterious ionic species not detectable microscopically.

High temperature silicate glass (GSC-1).— On high softening point silicate glasses, the penetration into the silicon dioxide can be as high as a few hundred angstroms even when fired at the minimum glazing temperature. With these higher temperature glasses, the glass-oxide boundary is more difficult to determine because the etch rate differential between the glass and oxide is not as great as with the lower temperature glasses. Although in one particular sample (General Electric GSC-1 glass) the firing cycle consisted of 5 min in a furnace maintained at 1190°C, the sample was within a few degrees of temperature for only 3 min. The etch rate plot for this sample showed a penetration of 320 ±100Å. If the firing cycle were altered such as to maintain the same glaze quality, the penetration would be comparable. The glaze quality is determined by the degree of smoothness of the film under microscopic observation. In another case where the wafer was fired for 15 min at 1150°C to obtain the same glaze quality, the penetration was ~400Å. In a third case where the glass was fired for 3 min in a furnace maintained at 1215°C, the penetration was also only 400Å. In this last firing, the wafer was at 1215°C for less than 1 min. It should be noted that thermal oxides which have been heated at temperatures near 1200°C have slightly faster P etch rates.

The penetration of a high temperature borosilicate through silicon dioxide can also be determined from the doping of a silicon wafer by the boron from the glass penetrating through the oxide. The simplest technique is to oxidize a high resistivity N type wafer, step etch the oxide on the wafer so as to have a range of oxide thicknesses, fire the glass, remove the glass and oxide, and then determine the silicon conductivity type with a thermal probe. By such techniques, we found that 4μ of GSC-1 glass fired at 1205°C for 1¾ hr did not penetrate 2500Å of SiO_2, but did penetrate 2400Å of SiO_2. This type experiment can only be used when the glass contains a component which will dope the semiconductor at the firing temperature. The results show only the extent of penetration of the doping material.

Reaction of fused GSC-1 glass with phosphosilicate.—We have also examined the reaction between GSC-1 glass and a phosphosilicate layer on the SiO_2. Figure 4 shows the etch rate plot obtained for a sample in which 1.8μ of GSC-1 glass was fired at 1199°C for 5 min. Prior to the glass deposition, a portion of the wafer was examined with P etch to determine the thickness of the phosphosilicate layer. The over-all film thickness was 0.870μ with 0.175μ of phosphosilicate.

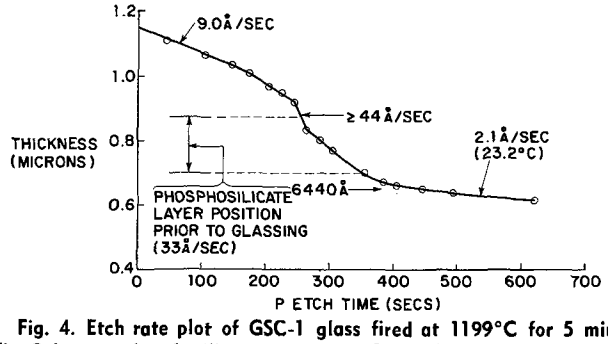

Fig. 4. Etch rate plot of GSC-1 glass fired at 1199°C for 5 min (in O_2) on a phosphosilicate containing SiO_2 film. (The removal of the top 1.5μ of GSC-1 is not shown).

The P etch rate of the phosphosilicate was 33 Å/sec. In a pure phosphosilicate the P etch rate is indicative of the phosphorus concentration.

The P etch rate plot of the sample containing the fired glass showed an unusually fast etch rate (≧44 Å/sec) corresponding to the top region of the phosphosilicate layer and the bottom region of the GSC-1 glass. This etch rate is significantly faster than that of GSC-1 or of the original phosphosilicate. It can be explained as being due to components from the glass combining with the phosphosilicate to form a fast etching glass at the glass-phosphosilicate boundary. This fast etching region is not an experimental artifact. On firing a similar sample at 1219°C for 10 min, as shown in Fig. 5, an even faster (≧65 Å/sec) intermediate etch rate region was obtained.

While the glass is being fired the phosphorus penetrates deeper into the underlying SiO_2 but due to the presence of the GSC-1 glass, the penetration is deeper on a glassed sample than on a nonglassed sample. A nonglassed piece of the same wafer which has been glassed with GSC-1 at 1219°C as shown in Fig. 5 was heated in oxygen for 10 min at 1219°C. P etch rate plots of this portion of the wafer before and after heating are shown in Fig. 6. From the decrease of the maximum etch rate from 33 to 15 Å/sec, it is concluded that the phosphorus concentration has decreased. On the other hand, where GSC-1 glass was applied, glass components combined with the phosphosilicate to give a much faster etch rate region (Fig. 4 and 5). From the "tail" at the lower end of the phosphosilicate region (Fig. 6), it is concluded that the phosphorus has penetrated 350Å of SiO_2 to the 6600Å level. In Fig. 5, with GSC-1 present, the SiO_2 boundary was down to 6300Å. The decreased etch rate at the top few hundred angstroms for the unglassed case is indicative of phosphorus outdiffusion (1). With GSC-1 glass present, the phosphorus tending to outdiffuse would combine with the lower portions of the GSC-1 to help form the very fast etch layer.

We had previously used the etch rate technique for the determination of the presence of phosphosilicate glass beneath other glasses in the failure analysis of devices (6). With faster etch rate glasses, as is the usual case with glasses of lower softening point, no significant reaction or penetration into the phosphosilicate layer was observed.

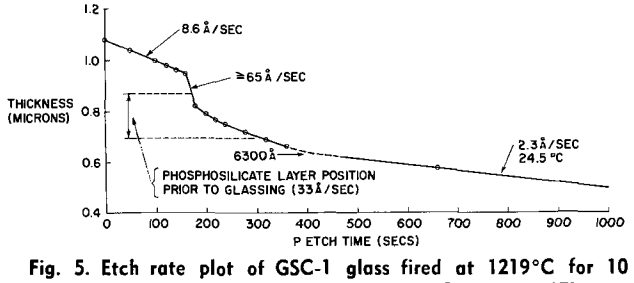

Fig. 5. Etch rate plot of GSC-1 glass fired at 1219°C for 10 min (in O_2) on a phosphosilicate containing SiO_2 film. (The removal of the top 1.6μ of GSC-1 is not shown).

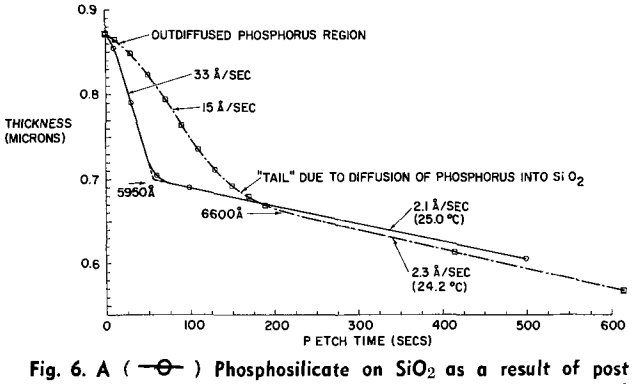

Fig. 6. A (—⊖—) Phosphosilicate on SiO_2 as a result of post oxidation of a P_2O_5 diffused silicon dioxide layer. B (— -□— —) Same wafer after oxygen exposure at 1219°C for 10 min.

Conclusions

1. Glass fused from sedimented powder penetrates into an underlying SiO_2 layer to form an intermediate glass which seals the fused outer glass to the underlying SiO_2.

2. The depth of penetration is dependent on the softening point of the glass and the temperature differential between the minimum glazing temperature (approximated by the softening point) and the actual firing temperature. For silicate glasses with softening points near 600°C, the minimum penetration from a good glazed film is approximately 50Å and for 1200°C softening point silicate glasses, it is about 400Å.

3. High temperature fused glasses penetrate more deeply into phosphosilicate than into silicon dioxide.

Cationic Migration in Silicon Dioxide Films on Silicon

F. C. Collins and M. Schrager

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Earlier calculations of the electrostatic potential and cationic concentration profiles in metal-oxide semiconductor structures on the basis of the Poisson-Boltzmann equation are extended to the case where a maximum in potential exists in the oxide film. The presence of immobile anions terminating the cationic charges does not significantly affect the behavior of the cations if the anions are located in a thin region at the oxide-metal interface. According to this model the currents due to cationic drift in temperature-bias experiments are symmetrical about the contact potential difference between the metal and the semiconductor corrected for the space charge of the immobile anions. For a model involving cationic drift only, the flat band potential of the semiconductor from temperature bias measurements does not display this symmetry about the contact potential difference. Transient nonequilibrium distributions of the cations at low values of the applied potential which may occur because of the existence of the potential maximum in the film are discussed.

The variation of the flat band potential of oxidized silicon surfaces in metal-oxide-semiconductor (MOS) devices following temperature-bias treatments have been interpreted in terms of a drift of mobile cations (1-2). This interpretation is supported by the fact that the charge storage calculated from the ionic current-time integrals in the temperature-bias experiments is in general agreement with the observed shifts of the flat band potential as determined by C-V measurements at room temperature of temperature biased samples (3).

In an earlier paper (2), the electrostatic potential and cationic concentration profiles in a silicon dioxide film under specified values of applied bias at elevated temperatures were developed in terms of a Poisson-Boltzmann distribution of a cationic species. The previous calculations (2) were confined to the case of large values of the applied potential relative to the potential difference arising from the space charge of the cations. The alternative case is treated in the present paper. The solution exhibits a potential maximum at low values of the applied potential compared to the space charge potential.

One of the interesting and well-known characteristics of the silicon dioxide-silicon MOS devices is that while a positive potential applied to the metal electrode in a temperature-bias treatment produces large negative shifts of the silicon surface potential, the application of negative potentials to the metal electrode does not produce a negative shift. This has been shown to be consistent with the presence of mobile cations only (1, 2). In the previous paper the location of the anionic charges terminating those of the mobile cations was not specified. In the present paper, the behavior of a model in which the cations are electrically compensated by immobile anions near the oxide metal interface is investigated. Where the thickness of the sheet of anions is a small fraction of the thickness of the oxide film, it is found that the potential difference arising from the presence of the anions has little effect on the drift of the cations under applied bias.

The currents arising from the drift of the cations under externally applied bias at elevated temperature should be antisymmetrical around zero bias, according to the model. However Tarui (4) has pointed out that the contact potential difference between silicon and the given electrode metal must be added to the applied potential in order to obtain the potential difference across the oxide film. The contribution of the space charge due to the immobile anions must also be included to compute the effective potential difference across the film.

Polarization of the Film by Cationic Migration

It will simplify the presentation to present first the behavior of the model in which no account is taken of the presence of anions. The effect of immobile anions in the region at the oxide-metal interface is later considered. Only a relatively crude treatment of the effect of the anions is justified in any event because of the lack of any detailed information concerning their distribution. To this degree of approximation, the effect of the presence of anions is additive only and its contribution to the behavior of the cations rather simply handled at a later point.

As in the earlier paper (2), the present calculations are confined to the case of thermodynamic equilibrium. The concentrations $c(x)$ of cations in the oxide film is then given by

$$c(x) = c_0 \exp[-qV(x)/kT] \qquad 0 \leq x \leq X' \quad [1]$$

where the silicon-silicon dioxide interface has been selected as the origin of the coordinate x, $c_0 = c(0)$, $V(x)$ is the potential (with $V(0) = 0$) and the other symbols have their usual significance. For simplicity all cations in the system are taken to be univalent. The anions terminating the charges of the cations are assumed to be permanently located in the surface region $X - X'$ of the oxide where $x = X$ at the metal-oxide interface. As the anions are immobile, their distribution will not be governed by the Boltzmann law.

We shall assume that the concentrations of electrons and holes in the oxide are small compared to the concentrations of the ions and may consequently be neglected. Poisson's equation is then given by

$$\frac{d^2V}{dx^2} = -\frac{q}{\epsilon}c(x) \qquad 0 \leq x \leq X' \quad [2]$$

which leads to the usual expression for the Poisson-Boltzmann equation

$$\frac{d^2V}{dx^2} = -\frac{q}{\epsilon}c_0 \exp[-qV(x)/kT] \quad [3]$$

The usual device of multiplying both sides of Eq. [3] by $2(dV/dx)$ enables it to be integrated as follows

$$\left(\frac{dV}{dx}\right)^2 = \mathcal{E}_0^2 - \frac{2c_0kT}{\epsilon}(1 - e^{-qV/kT}) \quad 0 < x < X' \quad [4]$$

where the boundary condition $(dV/dx)_0 = -\mathcal{E}_0$ has been used. The solution to Eq. [4] which was previously obtained for the case that no maximum exists in the potential $V(x)$ within the oxide film is

$$x = \frac{V}{a^{1/2}} + \frac{2}{ma^{1/2}} \ln \frac{a^{1/2} + (a + b\,e^{-mV})^{1/2}}{a^{1/2} + (a + b)^{1/2}} \quad [5]$$

where

$$a = \mathcal{E}_o^2 - \frac{2\,kT}{\epsilon} c_o$$

$$b = \frac{2kT}{\epsilon} c_o \quad [6]$$

and

$$m = q/kT \quad [7]$$

the parameters a and b may be evaluated from the boundary conditions as described in the previous paper. For mathematical simplicity, we shall assume that the cations are confined to the region $0 \leq x \leq X'$. Then the total cationic surface density in the oxide film is given by

$$\sigma = \int_o^{X'} c(x)\,dx = \int_o^{X'} c(V) \frac{dx}{dV} dV \quad [8]$$

Substituting Eq. [1] and [4] into the above yields

$$\sigma = \frac{\epsilon}{q}(a + b)^{1/2} - \left(a + b\,e^{-mV_{X'}}\right)^{1/2} = \frac{\epsilon}{q}(\mathcal{E}_{X'} = \mathcal{E}_o) \quad [9]$$

where the definitions [6] and [7] have been used $V_{X'} = V(X')$ and the relation $\left(a + b\,e^{-mV_{X'}}\right)^{1/2} = \mathcal{E}_{X'}$ has been used.

For practical purposes, the parameters a and b are best evaluated in terms of the potential $V_{X'}$ and the boundary field $\mathcal{E}_o$. The latter is found from the flat band potential of the semiconductor which is experimentally determined from the bias dependence of the capacitance of the MOS structures. The method is described in Appendix (A) of ref. (2) and typical values of a and $c_o = b\epsilon/2kT$ are given in Table I of that paper.

The average distance of the cations from the silicon interface is of some interest. It is given by

$$\langle x \rangle = \frac{\int_o^{X'} x\,c_o\,e^{-mV}\,dx}{\int_o^{X'} c_o\,e^{-mV}\,dx} = \frac{V_{X'} + \mathcal{E}_{X'}X'}{\mathcal{E}_{X'} - \mathcal{E}_o} \quad [9']$$

It will be seen from the previous paper (2) that $-\mathcal{E}_{X'} \approx a^{1/2}$ to an excellent approximation. A few numerical values of the average distance $\langle x \rangle$ are given in Table I corresponding to some typical values of the observable variables. It will be seen that the distance $\langle x \rangle$ is only of the order of one lattice distance.

The solution to the Poisson-Boltzmann equation for the case that a maximum in $V(x)$ exists will now be derived. Let x_m be the point at which the potential maximum $V_{(x_m)} = V_m$ exists. The potential gradient of Eq. [5] is then given by

Table I.

$V_{X'}$, v	$-\mathcal{E}_o \times 10^{-6}$, v/cm	$-\mathcal{E}_{X'} \times 10^{-6}$, v/cm	$\langle x \rangle$, Å
10	1.00	0.3314	8.67
	2.00	0.3299	6.17
	5.00	0.3277	3.62
20	1.00	0.6661	5.01
	2.00	0.6648	4.14
	5.00	0.6627	2.75
30	2.00	0.9989	3.28
	3.00	0.9981	2.85
	5.00	0.9970	2.25

$$\frac{dV}{dx} = (a + b\,e^{-mV})^{1/2} \qquad 0 \leq x \leq x_m \quad [10]$$

$$= 0 \qquad x = x_m \quad [11]$$

$$= -(a + b\,e^{-mV})^{1/2} \qquad x_m < x \leq X' \quad [12]$$

The existence of the maximum V_m with

$$(a + b\,e^{-mV_m})^{1/2} = 0 \quad [11']$$

requires that $a < 0$ because $b \geq 0$ under all conditions as may be seen by reference to Eq. [6]. Under this requirement, the integrals of Eq. [10] to [12] take the forms [5]

$$x = \frac{2}{m(-a)^{1/2}} \left\{ \sin^{-1}\left[\left(\frac{-a}{b}\right)^{1/2} e^{mV(x)/2}\right] - \sin^{-1}\left(\frac{-a}{b}\right)^{1/2} \right\} \qquad 0 \leq x < x_m \quad [13]$$

$$x - x_m = \frac{-2}{m(-a)^{1/2}} \left\{ \sin^{-1}\left[\left(\frac{-a}{b}\right)^{1/2} e^{mV(x)/2}\right] - \pi/2 \right\} \qquad x_m < x \leq X' \quad [14]$$

The position of the potential maximum may be found from Eq. [13] and is

$$x_m = \frac{2}{m(-a)^{1/2}} \left[\frac{\pi}{2} - \sin^{-1}\left(\frac{-a}{b}\right)^{1/2}\right] \quad [15]$$

The total cationic density is again obtained by the use of Eq. [8], but is now given by

$$\sigma = \frac{\epsilon}{q}\left[(a + b)^{1/2} + \left(a + b\,e^{-mV_{X'}}\right)^{1/2}\right] \quad [16]$$

instead of by Eq. [9].

Figures 1 and 2 are plots of the potential profiles $V(x)$ and of the cationic concentration $c(x)$ for two different values of the ratio $(-a/b)^{1/2}$ for the particular case that $V_{X'} = 0$. The methods for evaluating the parameters a and b from experiment for this case is given in a later section of this paper.

Paralleling Eq. [9'], we may define an average distance from the interface for those cations which are on the left hand side of the potential maximum x_m as

$$\langle x \rangle = \frac{\int_o^{x_m} x\,c_o\,e^{-mV}\,dx}{\int_o^{x_m} c_o\,e^{-mV}\,dx}$$

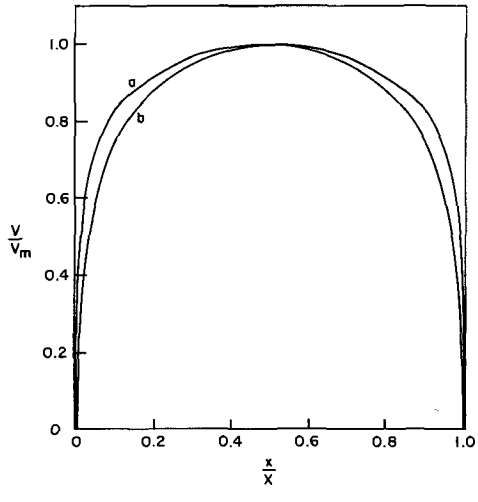

Fig. 1. Normalized potential vs. fractional distance for the symmetrical case of $V_{X'} = 0$ with a film thickness of 5000Å. Two typical values of $(-a/b)^{1/2}$ are plotted: Curve a, $(-a/b)^{1/2} = 10^{-3}$; Curve b, $(-a/b)^{1/2} = 10^{-2}$.

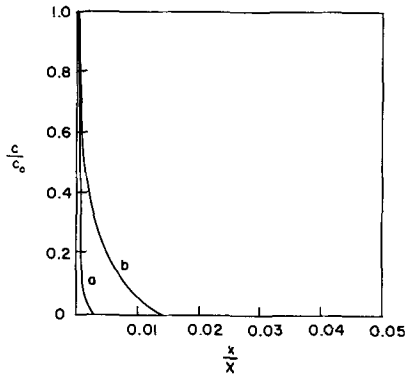

Fig. 2. Normalized cationic concentration vs. fractional distance for the two cases depicted in Fig. 1.

$$= -V_m/\mathcal{E}_0 \qquad [16']$$

Some numerical values of this average distance are given in Table II.

Effect of the Presence of Anions

For the purposes of the present possibly oversimplified analysis, we shall assume that the cations are excluded from the region $X' \leq x \leq X$ and that the anionic concentration is given by

$$C = \text{constant}, \qquad X' \leq x \leq X \qquad [17]$$

Poisson's equation

$$\frac{d^2V}{dx^2} = \frac{q}{\epsilon} C \qquad [18]$$

may now be easily integrated and yields

$$V_X - V_{X'} = \frac{qC}{2\epsilon}(X - X')^2 - \gamma_{X'}(X - X')$$

where $\mathcal{E}_{X'}$ is the field at the point X'.

It is of interest to note that if a constant total density σ_a of anions

$$\sigma_a = C(X - X') \qquad [19]$$

is introduced and the distance $X - X'$ is allowed to approach zero, the potential difference $V_X - V_{X'}$ will approach zero at the same rate. Hofstein (6) has interpreted one aspect of the time dependence of his cationic drift measurements in silicon-silicon dioxide MOS devices in terms of an initial trapping of the cations in a region of 7.5 to 8.0Å thickness at the metal oxide interface. If the trapping in the Hofstein experiments is actually caused by a layer of immobile anions as in the above model, the potential difference $V_X - V_{X'}$ must be very small at typically observed values of the total ionic density σ in accordance with Eq. [18] and [19]. A thickness of the order of 8Å would be consistent with the possible condition that the immobile anions are oxide ions terminating the amorphous silicon dioxide structure.

Table II. Some values of the average distance of the cations on the left hand side of the potential maximum from the silicon-silicon dioxide interface, in the symmetrical case where $V_{X'} = 0$. The film has been taken to be 5000Å in thickness and has been assumed to be equilibrated at a temperature of 250°C

V^0_m, v	$-\mathcal{E}_0 \times 10^{-6}$, v/cm	<x>, A	V^0_m, v	$-\mathcal{E}_0 \times 10^{-6}$, v/cm	<x>, A

The effective potential under which the cations distribute themselves is

$$V_{X'} = V_a + \Delta\phi - (V_X - V_{X'}) \qquad [20]$$

where V_a is the potential externally applied to the metal electrode and $\Delta\phi$ is the contact potential or the difference between the work functions of the metal and the semiconductor.

Currents Arising from Cationic Migration

It is implicit in the foregoing analysis that the shift in the flat band potential of the semiconductor under temperature bias treatment is related to the apparent charge storage. Further, the cationic currents will be antisymmetrical about the point $V_{X'} = 0$. The determination of the applied potential corresponding to the point of symmetry $V_{X'} = 0$ affords a method for obtaining the quantity $\Delta\phi - (V_X - V_{X'})$. Thus a theoretical treatment of the cationic current is of interest.

Calculation of the time-dependent currents arising from cationic migration in the film following changes in the applied bias is extremely difficult and will not be attempted here. Instead we shall compute the time integrals of the current corresponding to the transition of the system from one state of equilibrium to another following a discontinuous change of the applied bias. This requires only the calculations of the mobile electronic charges in the silicon required to terminate the equilibrium distribution of charges in the oxide film. Changes in the electronic charge in the silicon correspond to time integrals of current in the external circuit. We shall assume that the doping is sufficiently high so that the silicon is effectively degenerate at the temperature under which the cationic migration occurs. As the potential increment $\Delta\phi - (V_X - V_{X'})$ in Eq. [20] is effectively a constant, the analysis of the current integrals will be given in terms of $V_{X'}$ for the sake of simplicity.

The surface charge Q_0 in the silicon required to terminate the ionic charges in the oxide film is given by

$$Q_0 = q\int_0^{X'} c(x)\frac{X' - x}{X'}dx \qquad [21]$$

The form of the integration of Eq. [21] depends on whether a potential maximum V_m exists in the region of the integration. Where the potential maximum is absent, Eq. [21] takes the form

$$Q_0 = q\,c_0\int_0^{V_{X'}} e^{-mV}\left[\frac{X' - x(V)}{X'}\right](a + b\,e^{-mV})^{-1/2}\,dV \qquad [22]$$

In the presence of the potential maximum Eq. [21] assumes the form

$$Q_0 = q\,c_0\int_0^{V_m} e^{-mV}\left[\frac{X' - x(V)}{X'}\right](a + b\,e^{-mV})^{-1/2}\,dV - q\,c_0\int_{V_m}^{V_{X'}} e^{-mV}\left[\frac{X' - x(V)}{X'}\right](a + b\,e^{-mV})^{-1/2}\,dV \qquad [23]$$

The last two equations may be integrated by parts and yield respectively in the cases of the absence and the presence of a potential maximum

$$Q_0 = \mathcal{E}_0 - \frac{V_{X'}}{X'} \qquad \text{(maximum absent)} \qquad [24]$$

$$Q_0 = \mathcal{E}_0 - \left(\frac{2V_m - V_{X'}}{X'}\right) \qquad \text{(maximum present)} \qquad [25]$$

The integral of the current $I(t)$ following a discontinuous change of the applied potential V_a is given by

$$\int_0^\infty I(t)\,dt = A[Q_o(V'_{X'}) - Q_o(V^o_{X'})] \qquad [26]$$

where A is the area of the MOS device and $V^o_{X'}$ and $V'_{X'}$ are the potentials before and after the discontinuous change.

Evaluation of System Parameters

The foregoing equations enable the principal variables of the Poisson-Boltzmann distribution model of the cation drift to be quantitatively determined by the separate measurements of the flat band potential and of the current integral. If self consistent, these independent data would lend support to the hypothesis of the Poisson-Boltzmann distribution and to the other assumptions introduced into the model.

The model predicts that the current integrals should be antisymmetrical about the point $V_{X'} = 0$ corresponding to an applied potential

$$V^o_a = \Delta\phi - (V_X - V_{X'}) \qquad [27]$$

Thus we should have

$$Q_o(V_{X'})\ Q_o(0) = -[Q_o(-V_{X'}) - Q_o(0)] \qquad [28]$$

Preliminary measurements indicate that a point of approximate antisymmetry with respect to the current integrals does indeed exist. The applied potential V_a corresponding to the point of antisymmetry is found to be of the order of 1 V.

Where $V_{X'} >> m^{-1}$, Eq. [9] simplifies to that which is customarily used for the experimental determination of the cationic density

$$\sigma = \frac{\epsilon}{q}\mathcal{E}_o \qquad (V_{X'} >> m^{-1}) \qquad [29]$$

At low values of the potential, however, Eq. [29] is no longer valid. In particular, at the point $V_{X'} = 0$, Eq. [16] reduces to

$$= \frac{2\epsilon}{q}\mathcal{E}_o \qquad (V_{X'} = 0) \qquad [30]$$

If the density σ is constant we may conclude that

$$\mathcal{E}_o(V_{X'} = 0) = \tfrac{1}{2}\mathcal{E}_o\,(V_{X'} >> m^{-1}) \qquad [31]$$

Eq. [27] and [31] provide independent methods for determining V^o_a.

The transition between the logarithmic and inverse sine solutions to the Poisson-Boltzmann equation corresponding to the absence and the presence of a potential maximum occurs at the point at which the parameter a passes through zero. In the Appendix the range of values $V_{X'}$ corresponding to the parameter $a = 0$ for various typical values of the density σ and the other variables is evaluated and shown in Fig. 3. It appears that the transition value of $V_{X'}$ is less than 1 V in all cases.

Equation [24] and [25] may be used to determine values of the potential maximum V_m. This is done by measuring the current time integral following a change of the potential $V_{X'}$ from a value above the transition to a value below this transition. The potential maximum V^o_m which exists when $V_{X'} = 0$ is of particular interest. It is given by

$$V^o_m = \frac{V_{X'}}{2} + \frac{X'}{2\epsilon}\left\{\frac{1}{A}\int_0^\infty I\,dt - [\gamma_o(V_{X'}) - \gamma_o(0)]\right\}$$

$$= \frac{X'}{2}\left\{\frac{1}{A}\int_0^\infty I\,dt + 2\mathcal{E}_o(0)\right\} \qquad [32]$$

where here $V_{X'} >> 1$ V. The ratio $(-a/b)$ may now be immediately determined by means of Eq. [11']. From symmetry considerations, the potential maximum V^o_m is located at the point $x_m = X'/2$. The parameter a can now be obtained by the use of Eq. [15], which after the substitution of Eq. [11'], takes the form

$$(-a)^{1/2} = \frac{4}{mX'}\left[\frac{\pi}{2} - \sin^{-1} e^{-mV^o_m}\right] \qquad [33]$$

The parameter b is then determined by Eq. [6].

The determination of the parameters a and b and the point x_m of maximum potential V_m for values of the potential $V_{X'}$ other than $V_{X'} = 0$ in the domain of $a < 0$ requires rather extended numerical analysis. For the purpose of illustrating the quantitative relationships among the parameters for the case where a potential maximum exists, a short tabulation of their numerical values corresponding to typical values of the external variables are presented in Table III. In the calculations, values of the applied potential V_a have been used just balancing the work function difference $\Delta\phi$ so that the effective potential at X is zero. As elsewhere in this paper, the temperature is taken as 250°C.

Transient Nonequilibrium Cationic Distributions

When the applied potential on the MOS structure is abruptly changed the cationic distribution is slow to readjust itself. Immediately after the potential change, the distribution is in a nonequilibrium state with respect to the new applied potential on the MOS structure. It is the drift of the cations toward the thermodynamic equilibrium distribution which produces a current in the external circuit. If a potential maximum exists in the oxide film, it may impede the drift of the cations toward equilibrium.

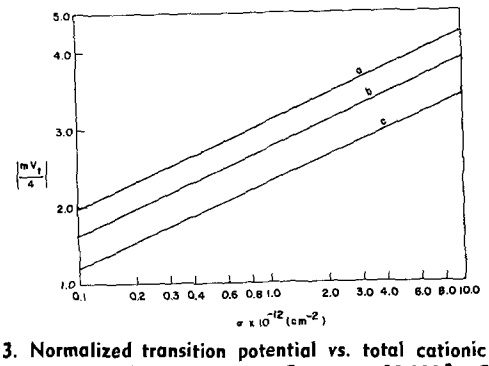

Fig. 3. Normalized transition potential vs. total cationic charge density for three film thicknesses: Curve a, 10,000Å; Curve b, 5000Å; Curve c, 2000Å.

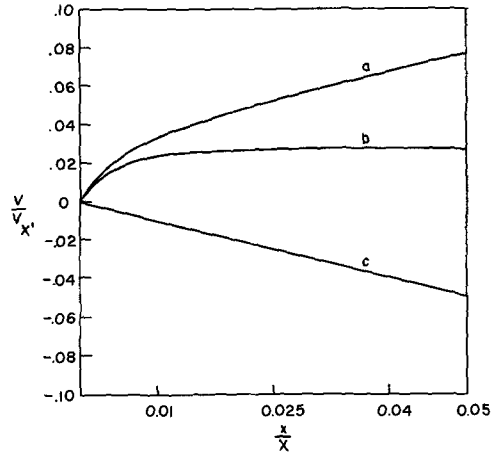

Fig. 4. Potential profile for a transient, nonequilibrium cationic distribution. Curve a represents an equilibrium potential profile corresponding to an applied potential of + 5 V at $t < t_o$. Curve b represents the instantaneous, nonequilibrium, potential profile, after a potential of — 5 V has been applied at $t = t_o$. Note the potential maximum at a fractional distance of about 0.035. Curve c represents the equilibrium potential profile for an applied potential of — 5 V.

Table III. Numeral values of system parameters corresponding to typical values of the observable variables for the case that a potential maximum exists in the film. The applied potential V_a is set opposite and numerically equal to the work function difference $\Delta\phi$. The temperature is constant at $T = 250°C$

Figure 4 shows the equilibrium potential distribution $V(x)$ corresponding to an applied potential of $+ 5V$ at $t = t_0-$ and the potential profile at $t = t_0+$ when the applied potential has been changed to $-5V$ at $t = t_0$. The cationic distribution remains unchanged between t_0- and t_0+. The potential profile $V(x)$ corresponding to the final equilibrium distribution of the cations at $t = \infty$ is also shown.

It is apparent that the cations initially to the left of the potential maximum must pass over the maximum in order to establish the equilibrium distribution. This, however, is a self accelerating process. The cations near the potential maximum and having energies within kT of it will drift over the maximum. In so doing, the transport of the space charge of these cations will lower the potential maximum. Additional cations are now within kT of the lowered potential maximum and will drift over it. The process becomes catastrophic when the potential maximum decreases to within kT of zero.

The net result of the above is that the observed current may not decay monotonically in time but may show a maximum after an initial induction period. The phenomenon of a current maximum has occasionally been observed in this laboratory at high total cationic densities σ. It is not as firm as might be wished for, but the observation is not an artifact.

Manuscript received Aug. 25, 1966; revised manuscript received Feb. 8, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

APPENDIX

Calculation of Transition Potentials for the Case where $a = 0$

The transition between the logarithmic and inverse sine solutions to the Poisson-Boltzmann equation occurs at point $a = 0$. For this case, it can be shown that

$$\mathcal{E} = b^{1/2} = \frac{2}{mX'} [e^{mV_t(x')} - 1] \qquad [34]$$

and

$$\frac{q\sigma mX'}{8\epsilon} = \sinh^2 \left[\frac{mV_t(X')}{4} \right] \qquad [35]$$

where $V_t(X')$ is the transition potential between the two regions.

Figure 3 presents a plot of Eq. [35] for selected values of the experimental variables. It may be concluded from the figure that the transition potential $V_t(X')$ lies between 0.05 and 0.30v over the commonly encountered range of experimental variables where the film is equilibrated at 250°C.

Anodic Oxidation of Silicon in KNO_3-N-Methylacetamide Solution: Interface Properties

Akos G. Revesz

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Silicon was oxidized anodically using constant current and/or constant voltage methods. The Si-SiO_2 interface was investigated with the MOS capacitance method. Constant current anodization results in a high density of surface states. Constant voltage anodization leads to surface state densities that roughly decrease with the final oxidation rate. Short time annealing in He at elevated temperatures removes the states from the Si forbidden band and reduces the density at zero Si surface potential to 2 x 10^{11} cm^{-2}. Positive and negative bias tests at 300°C showed a small positive ion migration effect but no interface instability.

Thermal oxidation of silicon is the most commonly used technique for the passivation of semiconductor devices and for the fabrication of the insulating film in MOS (Metal-Oxide-Semiconductor) devices. Consequently, there are many publications dealing with the properties of the Si-SiO_2 interface obtained by that method. Anodic oxidation of silicon, on the other hand, has been much less explored from this point of view. Only the following has been reported. Dubrowskii *et al.* (1) mentioned in a cursory manner that oxide films produced by anodization in very pure water protected the silicon surface from ambient effects. Boroffka (2) reported recently that anodic oxidation results in a high density of surface states ($\sim 10^{13}$ cm^{-2}) that can be reduced to $\sim$ 3 x 10^{11} cm^{-2} by post-oxidation heat treatment in hydrogen. Jahn (3) reported that the reverse bias characteristics of silicon p-n junctions passivated by thermal oxidation could be improved to a great extent by anodization at constant voltage in a KNO_3-glycol electrolyte.

The primary purpose of this investigation was to compare anodic oxidation with the thermal one on the basis of MOS interface behavior. It is shown here that constant voltage oxidation under clean conditions in a nonaqueous electrolyte followed by a short time annealing in helium at high temperature results in an interface that is comparable with that obtained by thermal oxidation. Especially noteworthy is the fact that no interface instability effects were observed at 300°C and that ion migration under bias at elevated temperature is small and of the voltage-symmetric type.

Experimental

Processing technique.—Chemically polished 10 ohm-cm p-type silicon of (111) and (100) orientations was used (except where otherwise noted). The silicon wafers were cut to a 1 by 1 cm square with a 1 cm long stem that was to be attached to a holder in the anodizing apparatus. The specimens were carefully cleaned, and just before anodization they were submerged in hydrofluoric acid and rinsed with distilled water.

Following the work of Schmidt and Michel (4) the electrolyte chosen was 0.04M solution of KNO_3 in N-methylacetamide (NMA). Since it is known that this electrolyte is hygroscopic and the oxidation process is influenced by its water content (4, 5), fresh electrolyte was used for each oxidation. No attempt was made, however, to avoid water absorption during oxidation. It is not likely that this absorption could cause any serious problem since the observed values of anodization efficiency were below 1.4%. This value is the same as the minimum in the efficiency *vs.* electrolyte water content graph of Duffek *et al.* (5), and according to their observation the most perfect oxides were produced at this water content. Since the electrolyte has a strong tendency for creeping, the upper part of the stem of the silicon specimen together with the holder was masked. The temperature during anodization was about 50°C unless otherwise noted. The cathode was a platinum sheet. The anodization was performed by constant current or constant voltage method, or by a combination of these, that is, constant current oxidation up to a given voltage followed by the constant voltage mode. The constant current density was varied from 5 to 10 ma/cm^2, the highest voltage was 300v, and the lowest current density obtained during the constant voltage mode was 0.04 ma/cm^2 in about 300 min. The range of oxide thickness extended from 160 to 1400Å.

After oxidation the specimens were rinsed in water. Some specimens were then treated in hydrogen at 500°C for 15 min, or in helium at 800°-1000°C. The hydrogen treatment was done in a conventional vitreous silica tube furnace, whereas the helium annealing was performed in an air cooled silica tube with radio frequency (rf) heating. For MOS capacitance measurements with a mercury probe the specimens were provided with nickel back contacts. For stability tests aluminum electrodes were used on the oxide.

Measurement methods.—The interface properties were evaluated on the basis of the MOS capacitance method (6). This gives the density of charges in the states at the Si-SiO_2 interface and within the oxide (lumped together as surface states) as a function of energy in the Si forbidden band. The differential capacitance of the MOS diode as function of bias was measured at 1 MHz with an automatic measuring apparatus, and the data were evaluated with a computer method (7). The results are given as density of surface states at flat band condition, N_o cm^{-2}, and as density of states within the Si forbidden band, dN/dE cm^{-2} $(ev)^{-1}$ (E being the energy, say, above the valence band). Since the distribution of states (energy-wise) was found to be approximately uniform, the value of dN/dE is independent of E. In selected cases the equivalent parallel a-c conductance as a function of bias was also measured (8).

Results

Influence of oxidation and post-oxidation treatments.—*Oxidation.*—The influence of oxidation conditions and post-oxidation treatments on the surface state density is summarized in Table I. It is clear from this table that constant current anodization resulted

Table I. Density of surface states at zero Si surface potential, N_0, 10^{11} cm^{-2} and in the Si forbidden band, dN/dE, 10^{11} cm^{-2} (ev)$^{-1}$

* The data represents the extreme values encountered in a group of 4-7 specimens, except for n-type silicon; in the latter case 2 specimens were measured. About 5 spots were measured on each specimen. The negative sign indicates the presence of acceptor rather than donor states (i.e. negative charge is associated with the interface and/or oxide).

in higher value for both N_0 and dN/dE than the combination of constant current and constant voltage modes. In the latter case the lowest values were usually obtained with relatively long anodization, corresponding to low final current densities and low final oxidation rates. If the contamination level was minimized then both N_0 and dN/dE showed a definite trend to decrease with decreasing final oxidation rate, *i.e.*, with the time of constant voltage anodization. A similar effect of the final oxidation rate for thermal oxidation was previously reported (9, 10); it was attributed to a higher degree of perfection in the interface region of the oxide grown with a lower final oxidation rate. Jahn has also observed that the reverse current of a passivated p-n junction decreased with the time of constant voltage anodization. He has attributed this effect to the removal of positive space charges from the vicinity of the Si-SiO_2 interface in the oxide.

If contamination occurred during anodization, *e.g.*, due to accidental dissolution of the copper holder, then even long time anodization with constant voltage gave rise to high value of N_0 and dN/dE, even though the field across the oxide and electrolyte opposed the entry of positive ions into the oxide.

The behavior of the two n-type specimens was unusual. In the as grown condition negative rather than positive charges were associated with the interface, *i.e.*, acceptor states were present. This situation was unstable, after H_2-treatment the usual positive charges, characteristic of donor states, appeared. This phenomenon should be investigated in greater detail.

Post-oxidation treatments.—In order to decrease the surface state density characteristic of the as grown condition two processes are generally used: H_2-treatment at around 500°C (11) and annealing in helium at 1000°-1200°C (9. 10). Both post-oxidation treatments have been investigated. As we can see from Table I, the annealing in helium is superior to the H_2-treatment from the standpoint of decreasing both N_0 and dN/dE. It is interesting to note that Jahn has found an opposite effect of heat treatment (in unspecified ambient, probably air) after constant voltage anodization of thermally oxidized silicon: the pre-anodization value of the reverse current of the p-n junction was restored. If the magnitude of the reverse current is related to the extent of an inversion layer on the surface of p-type silicon then apparently the nature of the Si-SiO_2 interface in Jahn's case is different from that in the present work.

The effects of H_2-treatment (11) and He-annealing (10) were attributed to a saturation of dangling bonds at the silicon surface and to a decrease of disorder in the oxide at the interface, respectively. Since during anodic oxidation various trapping phenomena can occur, and electrons (holes) can be released from these traps by heat treatment, it is possible that electron (hole) transfer between silicon and traps in the oxide takes place during He-annealing. A mechanism consistent with our observation could be, for instance, release of holes from the traps in the oxide and transfer to silicon. This would reduce the negative space charge there. However, the current decay during constant voltage anodization is usually accompanied by a decrease instead of an increase of the surface state density as would be expected if hole trapping were the predominant process during anodization. If one assumes, on the other hand, that electron trapping occurs during anodization then charge transfer across the interface during annealing (*i.e.*, neutralization of separated charges) would result in more negative charges in the silicon after annealing than before. Just the opposite happens in our case. Evidently, the correlation between current decay during anodization, density of states in the "as grown" conditions, and annealing behavior is not quite clear yet.

The influence of crystallographic orientation of silicon in these experiments was by far not as marked as for thermal oxidation (10). Nevertheless, the lowest values of N_0 and dN/dE after He-annealing were obtained with (100) orientation.

Stability studies.—One of the important aspects of MOS structures is their behavior at elevated temperature under the application of positive and negative bias to the metal electrode (the so-called gate). Only He-annealed specimens were tested for stability. These investigations were performed by S. R. Hofstein. The positive bias was usually 10v, the negative bias varied up to 30v. The tests were carried out in helium ambient at 300°C.

Constant voltage anodization.—A typical result for a specimen oxidized with a constant voltage mode is shown in Fig. 1. Note that the outer surface of the oxide film was not etched before the electrode deposition. It can be seen from this figure that the C-V curves after the bias-heat treatment (2 and 3) are roughly parallel with the original one (curve 1) and that the extent of this shift is comparable with that observed for thermally oxidized and annealed specimens that were prepared by an *in situ* process (12). There the voltage-symmetric nature of the instability was attributed to the migration of sodium or similar ionic impurities in the oxide that are bound to the oxide in a manner that resembles sodium in glass. The sodium was incorporated into the oxide during thermal oxidation in a more or less tightly bound form rather than in the loosely bound one characteristic of sodium associated with the surface region of the oxide (13). It is quite possible that some potassium from the electrolyte was incorporated into the anodic oxide in a similar manner. Indeed, Schmidt *et al.* observed that such an incorporation occurs and that this potas-

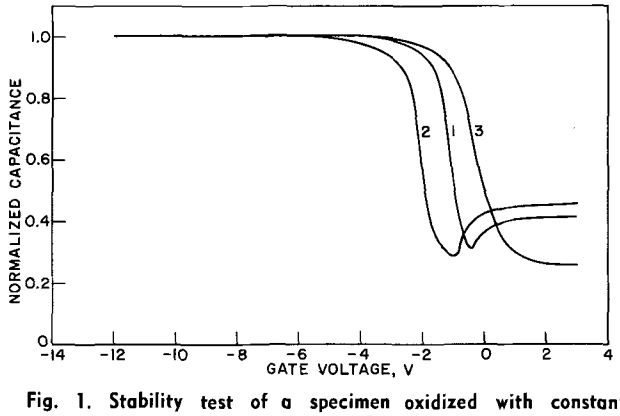

Fig. 1. Stability test of a specimen oxidized with constant voltage mode. Oxide thickness is 1000Å. Curve 1 was taken after the deposition of the aluminum electrode (gate). Curve 2 indicates saturation after applying +10v for 1 hr. Curve 3 was taken after the application of −30v for 3 min corresponding to saturation. (The higher field in the negative direction speeds up the process but does not change the saturation value.)

sium is rather immobile, in contrast to that adsorbed at the surface (14). Since in our studies etching the oxide prior to electrode deposition did not affect the instability behavior, this adsorbed potassium was apparently completely removed by post-oxidation cleaning. Furthermore, it is known that sodium or similar impurities that are associated with the oxide surface lead to a voltage-asymmetric instability behavior (15, 16) that we have not observed. The lack of interface instability (*i.e.*, the C-V curve did not shift to the left under negative bias) in these specimens is an indication of the relatively high perfection of the interface region. As with thermally grown oxides this is due to the elimination of traps in the vicinity of the $Si-SiO_2$ interface by He-annealing. Otherwise these traps could interact electronically with silicon and so cause the so-called interface instability effect (17).

Constant current anodization.—Specimens that were anodized with the constant current mode only showed a different behavior. This is demonstrated in Fig. 2. The shift caused by positive bias is about the same as in Fig. 1 (note, however, that whereas in case of Fig. 1 the time of the test was 1 hr, here it was only ½ min) but the shape of the C-V curve and the minimum capacitance differ considerably from the original ones. Evidently, interface states were introduced during the bias treatment and some of these states could even follow the a-c signal. A similar behavior, but in varying degree, was observed with specimens that were anodized with constant voltage, but became contaminated. Accidental anodic dissolution of the copper holder resulted in very large shifts and distortion of the C-V curves, even though one would think that the high field across the oxide could have prevented the incorporation of Cu-ions into the oxide.

Other properties.—Electronic conduction.—Impedance measurement on MOS capacitors occasionally showed large and asymmetric electronic conduction. Due to the very nature of the growth process anodic oxide films contain less pinholes than thermally grown ones. This has also been demonstrated experimentally (18). Thus, it is not very likely that the observed conduction is caused by simple metal to silicon contacts through pinholes in the oxide. Similar conduction phenomena were also observed with thermally grown SiO_2 films, especially with those processed by an *in situ* method (12). Both the extent of this conductance and the probability of its occurrence was found to be less for thermally grown oxides than for anodic ones even though the opposite behavior is expected. There are indications that both oxides have less conducting spots if some contamination occurred during the processing. The problem of electronic conduction in these films requires more study.

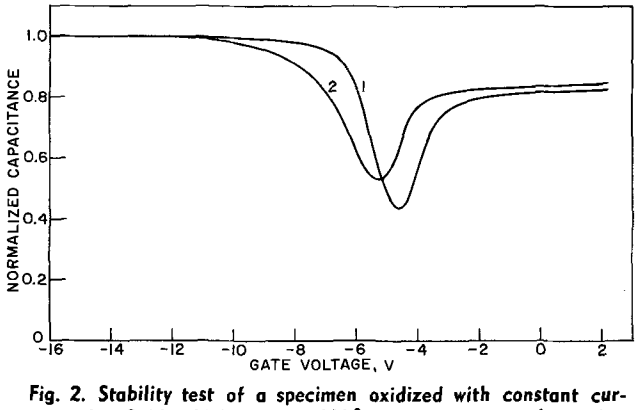

Fig. 2. Stability test of a specimen oxidized with constant current mode. Oxide thickness is 1000Å. Curve 1 was taken after electrode deposition, curve 2 after the application of +10v for ½ min.

Electron bombardment—Preliminary experiments, as performed by K. H. Zaininger, indicated that bombardment by 1 Mev electrons of MOS structures made from anodic oxide films resulted in a parallel shift of the C-V curves. This shift is equivalent to the induction of (0.8 to 4.5) x 10^{11} positive electronic charges/cm^2. This is probably due to ionization of the oxide and predominant hole trapping in the oxide (19). This value is one of the lowest ones obtained in the course of electron bombardment studies.

Interface doping.—Since it was found by Schmidt and Michel (4) that the presence of fluoride ions in the electrolyte drastically modifies the anodization behavior, an experiment was done with $NMA-KNO_3$ electrolyte saturated with NaF. The properties of the $Si-SiO_2$ interface were quite different from those obtained without fluoride. The value of N_o was very high (of the order of 10^{13} cm^{-2}) and, contrary to the usually observed behavior, it remained very high even after He-annealing. Moreover, the value of dN/dE was very high, too, and remained unaffected by the annealing. Although this particular doping is obviously not useful from a practical point of view the experiment nevertheless shows the feasibility of changing the interface properties by doping the anodization electrolyte.

Summary

The density of surface states is determined by the anodization conditions. High values were obtained by constant current anodization. In the case of constant voltage anodization the surface state density generally decreases with the anodization time, *i.e.*, with the final oxidation rate. This is attributed to greater order at the interface, but trapping phenomena can be involved, too. Constant voltage anodization to low final current densities followed by annealing in helium at elevated temperature can result in 2 x 10^{11} cm^{-2} surface state density with no states within the Si forbidden band. The relatively high perfection of this interface is shown by the lack of interface instability effects at 300°C under high field. Under these conditions the shift of the C-V curves is quite small and voltage-symmetric. This may be due to potassium ions incorporated from the electrolyte into the oxide in a relatively strongly bound form. Ions that migrate during positive bias treatment can interact with the $Si-SiO_2$ interface, leading to the appearance of interface states (*i.e.*, $dN/dE \neq 0$). If, however, the interface is relatively perfect then this interaction does not take place. This is in agreement with the concept that cooperative processes play an important role in interface phenomena (10).

Acknowledgments

R. J. Evans assisted in all phases of the work, S. R. Hofstein made the instability investigations, J. Shewchun cooperated in the impedance measurements, and K. H. Zaininger provided the apparatus to measure as well as the computer program to evaluate the MOS capacitance. S. R. Hofstein and K. H. Zaininger of this Laboratory as well as H. Boroffka and M. Zerbst of the Siemens Laboratories in Munich participated in stimulating discussions. P. F. Schmidt made valuable comments on the manuscript. A. M. Goodman and K. H. Zaininger critically read the manuscript. The author wishes to express his gratitude to all.

Manuscript received Nov. 1, 1966; revised manuscript received Feb. 8, 1967. Part of this paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

Technical Notes

A Chemical Polish That Reveals Compositional Variations in $PbSe_{(1-x)}Te_x$

Marriner K. Norr, John V. Gilfrich, and Bland Houston

U. S. Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland

$PbSe_{(1-x)}Te_x$ is single phase with the NaCl structure over the range $0 \leq x \leq 1$ (1). The chemical polish described in this note was used on a single sample in which x was approximately ½. It produced a fairly flat surface except for a network of valleys which covered the surface rather uniformly. Successive applications of the polish resulted in only minor displacements of the valleys, even when the surface was ground between polishings. A dislocation etch, which is also described in this note, revealed that the dislocation density was higher in the valleys than on the plateaus. Electron probe microanalysis revealed a significant drop in the Se concentration in the valleys.

The sample was ground flat on No. 600 grit SiC paper lubricated with water. Next it was finely ground with Carborundum No. 50 Optical Finishing Powder and then polished with Linde A. Both of the latter operations were carried out on a paraffin lap lubricated with an aqueous soap solution.

The chemical polishing solution was prepared by dissolving 0.5g disodium ethylenediamine tetraacetate in 25 ml distilled H_2O and then adding 50 ml 30% H_2O_2 and 25 ml glacial acetic acid. The sample was stuck to a polycarbonate jig with paraffin. It was polished for 5 min with a figure "8" motion on a piece of twill jean cloth[1] which was stretched over a smooth Teflon plate and saturated with the solution. It was then rinsed with distilled water and dried on lens paper. The surface was shiny and free of any films or stains. An "orange peel" structure on the surface which was visible to the naked eye is shown in the slightly defocused photomacrograph (Fig. 1). The chemical polishing procedure was continued for an additional 5 min and the pattern was unchanged. The valleys were removed by repeating the fine grinding operation. When the chemical polishing was repeated, the valleys reappeared in essentially the same positions as were observed after the initial chemical polish.

Fig. 1. Photomacrograph of a chemically polished surface of the $PbSe_{(1-x)}Te_x$ sample.

Detailed information about the topography of the chemically polished surface was obtained from photomacrographs of the interference fringes formed between the surface and an optical flat (2). The flat was coated with a thin layer of metal so that its reflectivity was about 75%. The 4360Å Hg line was used for illumination. White light illumination was used to follow the order of the fringes. The valleys were about ½ μm deep and from 25 to 75 μm across. Most of the plateaus were between 100 and 700 μm across. The tops

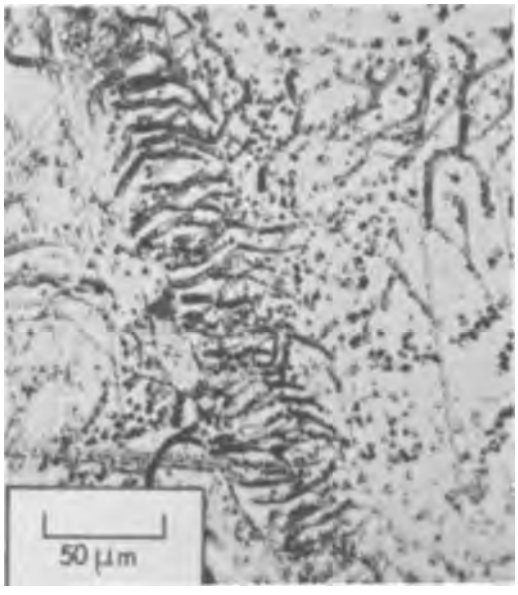

Fig. 2. Photomicrograph of the etched surface of the sample shown in Fig. 1. The distribution of the pits in one of the valleys is shown. The valley runs almost vertically across the photomicrograph. The partially developed pits are due to those dislocations introduced in the mechanical part of the preparation which were not entirely removed by the chemical polish.

of the plateaus were slightly rounded. The changes in height from the high points near the centers of the plateaus to the edges of the valleys were less than 1 μm.

The dislocation distribution in the sample was determined by etching. The etch was prepared by adding 3 ml glycerol to 13 ml 50% KOH, cooling to 25°C, and then adding 1.0 ml 30% H_2O_2. The etching was carried out by immersing the freshly polished sample in the solution for 3 min at 25°C. The etching showed the sample to be polycrystalline. Dislocation etch pits formed only on certain grains. Since the pits looked like pyramids with square bases, the grains on which they appeared probably had {100} planes nearly parallel to the surface of the specimen. The pit density in the valleys was high compared to the pit density on the plateaus. Frequently rows of pits ran across the valleys (Fig. 2).

There are several reasons to believe that these results can be explained by a spatial variation in x. The location of the valleys appears to be associated with variations in the properties of the sample. The pattern formed by the valleys is typical of the cellular structure associated with segregation due to constitutional supercooling (3). The arrangement of the dislocations would reduce the strain energy due to the lattice parameter mismatch which would be associated with variations in x (1). If constitutional supercooling is involved, one would expect the valleys to be rich in the component which lowers the melting point, Te.

Electron probe microanalysis was used to find out whether or not variations in x could be associated with the valleys. First, the sample was chemically polished and mounted in Quickmount together with a piece of PbSe which was used as a selenium standard. The conditions for the electron probe microanalysis were as follows: acceleration potential, 30 kv; specimen current, 3 x 10^{-8} amp; and x-ray wavelength, 1.106Å (Se K_α). A 60 sec point counting technique was used

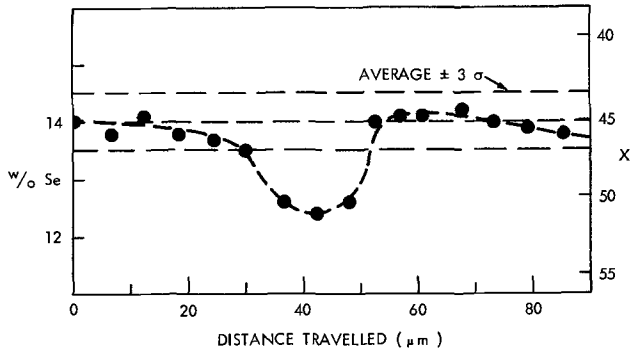

Fig. 3. The Se concentration across one of the valleys in the $PbSe_{(1-x)}Te_x$ sample shown in Fig. 1 from electron probe microanalysis (Se K_α).

in steps of 6-12 μm across two of the valleys. The relative x-ray intensity data were converted into weight per cent (w/o) Se with corrections only for absorption by the method of Birks (4).

Figure 3 is a plot of Se concentration across one of the valleys. The other valley traversed showed the same variation in Se concentration but the lower Se concentration extended over about 50 μm. The analyses indicate that the composition on the plateaus is constant (3σ = 0.5 w/o), but that there is a decrease of about 1.5 w/o in the valleys. On the plateaus the average Se concentration is about 14.0 w/o with a 3σ value of 0.5 w/o, while in the valleys it decreases to a minimum of 12.4 w/o. There is the possibility of some systematic error in these absolute values because of the uncertainties in the conversion from relative x-ray intensities to concentrations, but the relative concentrations are significant, and the lower Se concentration in the valleys is undoubtedly real. The surface topography studies indicate that the steepest slopes on the sides of the valleys are about 2°. A slope of this magnitude would not introduce an appreciable error due to the change in the x-ray "take-off" angle which is nominally 37½°.

The spatial variation in x is consistent with the model for segregation by constitutional supercooling. The preferential attack by the chemical polish could result from the variation in composition or from the strain or the higher dislocation densities associated with the rapid change in lattice parameter associated with a variation in x. Careful metallographic examination revealed no evidence of a second phase. The etch and polish described could probably be adapted to work successfully on samples with x different from ½. Also there is reason to believe that the polish would produce flat, work-free surfaces in homogeneous samples.

Extraction of III-V Intermetallic Compounds from Metallic Matrices

Sylvan Z. Beer

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

Crystals of III-V and other intermetallic compounds are often grown from metallic solutions. The extraction of the desired product from the metallic matrix may prove quite troublesome. While the metal can frequently be dissolved away from the product with aqueous solutions of acids or bases, this is not always possible because of the reactivity of the nonmetallic substance with water. Frequently, the reactivity of the nonmetallics depends, to some extent, on their purity and grain size. This is known to occur in the case of aluminum nitride (1, 2) which, on synthesis, is readily attacked by acids, but which becomes less labile on prolonged heating at high temperature to the extent that it can be extracted with aqueous solutions. This communication describes a nonaqueous method for extracting many water-sensitive compounds from metallic matrices.

Experience with Established Techniques

In the course of aluminum phosphide synthesis in this laboratory, the product was obtained as fine crystals embedded in an aluminum matrix, a highly reactive form which rapidly produces α-alumina and phosphine on contact with moisture in the air. Extraction with inorganic acids or other acids in aqueous solutions was, therefore, impractical. A reagent recommended (3) for this extraction is 1,2-dibromoethane. The aluminum reacts with the reagent to form a brownish tarlike mass from which the phosphide must be extracted. While the procedure is relatively safe, the difficulties in handling and treating the resultant viscous mixture was cause for seeking a simpler process.

Few of the established procedures (4) used for stripping surface films and in the study of nonmetallic inclusions (5) were directly useful or were adaptable for use in nonaqueuos media. For instance, the electrochemical oxidation of the matrix (6), which is used with great success in aqueous solutions, is difficult to adapt to nonaqueous media. Other frequently used extraction procedures are the reactions with halogens in solution or in the gaseous state (2, 4). Chlorine at about 600°C has been used, but it presents problems because of its excessive reactivity which could lead to the destruction of the desired product. Bromine in ethanol or methanol was tried, but was found to react violently with both the aluminum and the phosphide. Similar solutions of iodine also reacted with the phosphide although more slowly. Therefore, these solutions could not be considered suitable extracting agents. Dissolution of the aluminum as an amalgam with mercury as done to extract III-V compounds from indium (7) is impractical here because of the high liquidus temperatures.

Solutions of mercuric salts in N,N-dimethyl formamide (DMF) were found to be excellent extraction reagents. The reaction is the displacement of mercury by the aluminum to form mercury and the corresponding aluminum salt. Mercuric chloride, bromide, iodide, and cyanide were found to be about equally effective. Aluminum bromide, iodide, and cyanide are soluble in hot DMF and are retained in solution, leaving the nonmetallic as the only solid phase, while the less soluble aluminum chloride precipitates out with the nonmetallic phase as a fine powder. Of the mercuric salts listed, the chloride is the least expensive and most easily obtained in pure form; it was used in most of the work reported here.

Recommended Extraction Method

The reagent is prepared by dissolving 85-100g of the mercuric salts in 100 ml of dry DMF at 80°-120°C. The conglomerate mass containing the III-V compound and the metal to be dissolved is then added to the hot solution, or, when using mercuric chloride, can be suspended in a platinum fine-mesh screen which retains the aluminum phosphide and the mercury globules but permits the escape of the aluminum chloride). The product of this reaction is then filtered through a Millipore (8) noncellulosic filter (cellulosic filters dissolve in hot DMF) and washed with additional hot DMF followed by a dry solvent such as carbon tetrachloride. Tapping the filter funnel gently makes the mercury coalesce, which simplifies the mechanical separation of the mercury from the desired product. The mercury can also be removed by distillation under reduced pressure. Finally, the solid is vacuum dried.

Discussion

Solvents other than DMF can be employed in the preparation of this reagent. However, DMF has the advantage of a high boiling point (153°C). By virtue of this property, the solvent can be adequately dried for use in the reagent by heating it at close to 140°C for a short period of time. (Alternately, the solvent can be dried over calcium hydride.) In addition, the reaction can be run at a relatively high temperature if desired, which also permits the preparation of a more concentrated reagent solution.

The relative reactivity of the reagent toward other metals or alloys as a dissolving reagent or etchant can be estimated by their standard aqueous electrode potentials (9). The dielectric constant of DMF is high (36.7), and to some extent one can assume that the relative potentials are independent of the medium. This property also contributes to the high solubility of the mercuric salts as seen in Table I. The nature of the DMF solutions is not fully understood (10), but the rather high solubilities, in the order of decreasing ionic bond, which are closer in value to each other than in the case for the aqueous solutions, indicates that DMF is a highly coordinating solvent, and that anionic solvation plays a smaller role in the dissolution process in DMF than it does in water.

The thermodynamic argument on the reactivity does not always apply as other factors often interfere. For instance, it is found that while the initial reaction of $HgCl_2$ in DMF on aluminum is fairly slow, the re-

Table I. Solubility of mercuric salts in DMF and water

action with gallium and indium is extremely rapid. Yet, the standard potentials for the reactions are —1.66, —0.56, and —0.53v, respectively. The slow reaction of aluminum is no doubt due to the protective oxide coating. In the case of copper, the initial rapid reaction quickly ceases because of the formation of an amalgam coating. Removing the metal from the solution and heating lightly under vacuum removes the mercury film and exposes a vigorously active surface.

A different situation occurs in the reaction with silicon. Although the calculated potential for the reaction is high, the reaction does not take place due, very likely, to a SiO_2 protective film. The reaction can be made to proceed at a reasonable rate, however, by the addition of ammonium fluoride which drives the reaction forward through the formation of a stable fluoride. Mercuric cyanide is the most suitable of the salts for this purpose as it does not form the insoluble mercuric fluoride as readily as the others. Selenium too is attacked in this solution while it does not react with the ordinary reagent.

In general, however, the potential will be a good indicator of the probable reactivity as shown by the listing in Table II of the reactivity of the reagent toward various metals and nonmetals. Thus, mercuric salt solutions in DMF appear to be effective and safe reagents for the extraction of labile nonmetallics from many metallic fluxes, solutions, and parent metals. The highly concentrated form of the reagent which can be prepared in DMF as compared with water and the higher temperature at which the reaction can be run, makes this reagent attractive even in situations (5) where the presence of water is not deleterious.

Acknowledgment

The author wishes to acknowledge the extremely useful discussion on this subject with Dr. L. Mandelcorn of this laboratory, and to thank Mr. R. A. Jox for his assistance in the experimental work.

Table II. Reactivity of selected metals and nonmetals toward DMF-mercuric salt reagent

Attacked:
Indium, gallium, aluminum, iron, nickel, tin, lead, bismuth, antimony, copper, silicon,* selenium*
Not attacked:
Germanium, tellurium, aluminum phosphide, gallium arsenide, gallium phosphide.

* DMF solution of mercuric cyanide and ammonium fluoride.

Manuscript received Oct. 12, 1965; revised manuscript received Dec. 7, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

The Metallic Etching of Indium Antimonide and Germanium

H. D. Barber

Research and Development Laboratories, Canadian Westinghouse Company Limited, Hamilton, Ontario, Canada

and E. L. Heasell

Electrical Engineering Department, University of Waterloo, Waterloo, Ontario, Canada

When the temperature of a semiconductor in contact with a molten metal is raised in such a way that the solid and liquid phases are at all times approximately in equilibrium, the shape of the solid-liquid interface is determined by the ease with which atoms can be removed from the solid. Thus, a concave solid-liquid interface tends to become defined by the most slowly dissolving crystallographic planes during metallic (1) or chemical (2) etching. These planes are also the slowest growing planes (1) and thus define the shape of the growth face when the solid-liquid interface is convex. In the semiconductors silicon and germanium, the {111} planes have long been known (3-7) to be boundary planes or facets in such circumstances.

In the III-V compounds, {111} surfaces display similar behavior (8). However, the lower symmetry of the lattice in III-V compounds leads to two types of {111} surface (9): the A{111} surface terminating in triply bonded group III atoms and the B{111} surface terminating in triply bonded group V atoms. In general the rate of crystal growth on A{111} surfaces is greater than that on B{111} surfaces (10). A polar effect also exists in the reverse case of dissolution or metallic etching (8, 11).

Experiments in both crystal growth (12-15) and metallic etching (16) have given evidence of facet formation on {100} surfaces in III-V compounds. A similar faceting effect does not appear to have been observed in either of the elemental semiconductors, silicon, or germanium. If this is the case, it suggests that the mechanism resulting in polarity dependent effects in III-V compounds in <111> directions has an observable influence in the nonpolar <100> directions.

It is the purpose of this publication to present the results of micro-alloying experiments which demonstrate clearly the development of facet-forming planes in polar indium antimonide and nonpolar germanium under similar conditions of metallic etching; and to consider reasons for the difference in facet development on A{111} and B{111} surfaces, and for the existence of {100} facets in polar compounds.

Experimental Techniques

Crystals of indium antimonide and germanium were cut and polished to give die approximately 2 x 2 x 0.5 mm having their surfaces oriented to within one degree of the {100}, {110}, or {111}. A radiation wetting technique (17) was used to uniformly wet pellets of indium-1% cadmium to these wafers. The pellets were spherical with diameters ranging from 0.2 to 0.5 mm. Following the wetting procedure the wafer and pellet were placed on an enclosed heat sink, to ensure temperature uniformity and stability, and the entire assembly was placed in a temperature programmed furnace. For indium antimonide, the alloying was carried out in an air atmosphere with temperature rates of rise and fall during the cycle kept to about 5°C/min. Previous experiments (8) had shown that temperature rates of change less than 50°C/min were low enough to ensure that the dissolution process was controlled by crystallographic effects and not by diffusion into the solvent. The maximum temperature used was in the region of 400°C. For germanium, alloying was carried out in purified hydrogen and the rate of temperature rise above 500°C was controlled at about 2°C/min. The maximum temperature was 700°C.

After alloying, the shape of the alloyed region in the wafer surface was examined and photographed. The wafers were then encapsulated, sectioned, and etched to determine the shape of the alloyed region in planes perpendicular to the wafer surface. From these observations it was possible to determine the shape of the dissolved volume.

The advantages of the technique described above arise from the limited amount of solvent used (normally less than 400 μg) and the method of examination. When the mass of solvent is small, the mass of solute required to re-establish equilibrium after an incremental change in temperature is also small. Hence, for a given rate of temperature change the dissolution or growth rate in such a "micro-system" is always much less than that in the corresponding large system. (Typical growth rates of 10^{-4} cm/min were involved compared to 10^{-1} cm/min in a typical crystal puller.) As a result, there is no need when microalloying to resort to lengthy temperature cycles to ensure low dissolution or growth rates. Since chemical methods are employed to delineate the dissolution interface, this technique is not effected by the regrowth or residual solvent accumulations which often obscure the results of decanting or rapid quenching experiments. The usefulness of the micro-alloying technique in metallurgical observations has already been demonstrated in studies of polar effects (8) and in liquidus measurements (18).

Observations

{111} Surfaces.—The shape of the alloyed regions observed on A and B{111} surfaces of indium antimonide were with few exceptions almost perfectly hexagonal as shown in Fig. 1(a). Sections taken perpendicular to the surface and to two opposite faces of the hexagon indicated, as shown in Fig. 1(b), a flat {111} bottom, a {111} plane at one side making an angle of ~70.5° with the surface, and a {100} plane at the other side making an angle of ~55° with the surface. It was concluded that the dissolved volume was completely defined by {111} and {100} planes resulting in the shape illustrated in Fig. 1(c).

In the case of germanium, the observations confirmed the reports of other workers (3, 4, 7, 19). The shape of the alloyed region in the {111} surface tended to be hexagonal with three sides rounded and three sides well defined. The rounded sides appeared in the place of the {100} planes in Fig. 1(c) and also appeared rounded in the cross-sections which were in every other respect similar to Fig. 1(b).

{100} Surfaces.—The shape of the alloyed region in {100} surfaces of indium antimonide was invariably

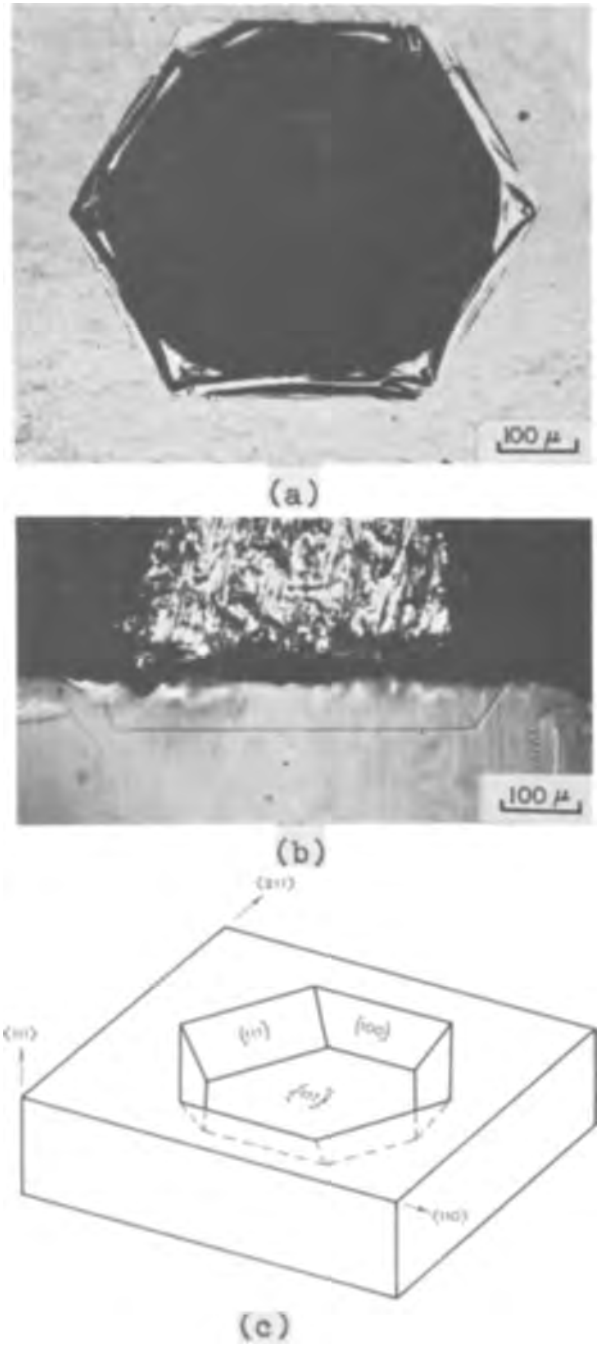

Fig. 1. Metallic etching on the {111} surface of InSb: (a) the shape of the alloyed region in the {111} surface; (b) the shape of the alloyed region in a section perpendicular to the {111} surface and to two sides of the hexagon in (a); (c) the deduced shape of the dissolved volume.

rectangular as shown in Fig. 2(a). Sections perpendicular to the surface and to two sides of the rectangle, such as that shown in Fig. 2(b), have indicated the presence of a crystallographically flat {100} bottom and of sides formed by {111} planes. From evidence presented earlier (8) it was concluded that the long sides of the rectangle were formed by the slower dissolving B{111} planes and thus that the dissolved volume assumed the shape illustrated in Fig. 2(c). It is of interest to note that as early as 1956 Millea and Tomizuka (20) reported the same rectangular morphology appearing in the {100} surfaces of indium antimonide during slow melting experiments, and tentatively attributed this to thermal gradients.

In view of a recent paper (11) giving evidence for greater dissolution rates on B{111} surfaces than on A{111} surfaces of gallium arsenide, a further experi-

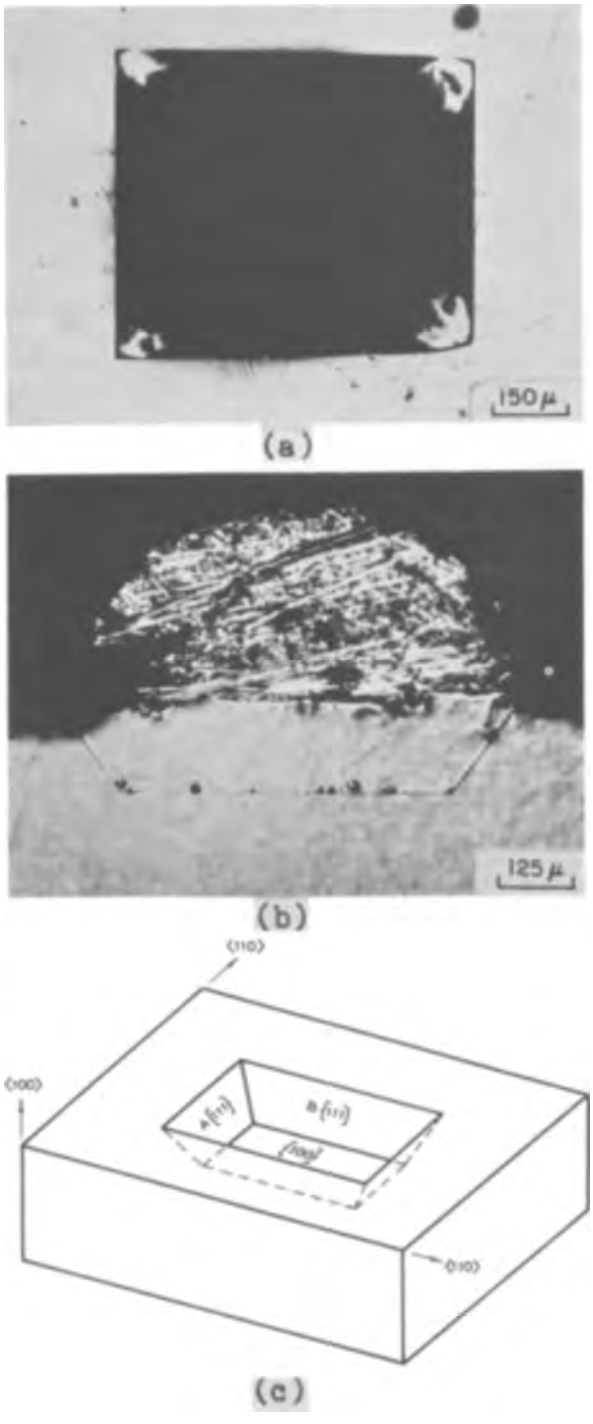

Fig. 2. Metallic etching on the {100} surface of InSb: (a) the shape of the alloyed region in the {100} surface; (b) the shape of the alloyed region in a section perpendicular to the {100} surface and to two sides of the rectangle in (a); (c) the deduced shape of the dissolved volume.

ment was undertaken. Die of {100} oriented indium antimonide were cut to permit identification of the A{111} directions by the presence of etch pits (21) after etching in 5:5:3, $CH_3COOH:HNO_3:HF$. Pellets were alloyed on both top and bottom {100} surfaces. It was observed that the long dimension of the rectangle was always rotated through 90° on one side in comparison to the other, thereby establishing that the difference could not arise from temperature gradients. It was further observed that in ten samples the sides formed by B{111} surfaces were on average 14% longer than those formed by A{111} surfaces and were never less than 5% longer. This would indicate that in indium antimonide the A{111} surface dissolves

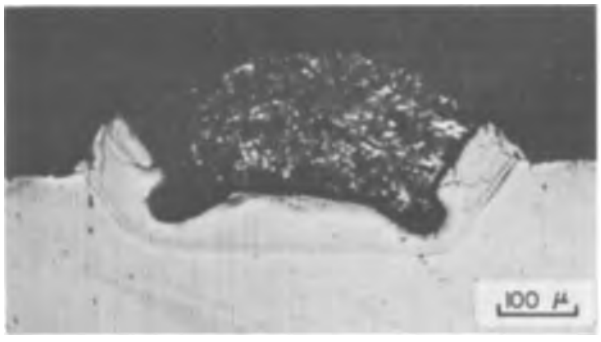

Fig. 3. The shape of an alloyed region in a section perpendicular to the {100} surface in germanium. The sides are formed by crystallographically flat {111} planes but such planarity is not present on the {100} bottom.

more rapidly than does the B{111} and that the configuration illustrated in Fig. 2(c) is accurate.

Alloyed regions on germanium {100} surfaces tended to assume a square shape on the surface and sections such as that in Fig. 3 showed the development of the {111} side planes. Although the alloying cycle was designed so that the dissolution rate was actually smaller than that for indium antimonide, the bottoms of the alloyed regions were in no case crystallographically flat. This observation is supported by those of Eer Nisse and Thompson (22) on both germanium and silicon.

The square, truncated pyramidal shape of the dissolved volume on {100} surfaces was clearly illustrated in an experiment in which indium was sputtered onto a hot germanium surface and the small indium pellets were subsequently removed by chemical etching. Some of the resulting etch pits are shown in Fig. 4.

{110} Surfaces.—For the sake of completeness, alloying on {110} surfaces was also examined. In the case of indium antimonide the shape of the alloyed region on the {110} surface generally tended to assume the form of an irregular octagon as shown in Fig. 4(a). Sections such as that in Fig. 5(b) gave no evidence for faceting on {110} planes. However, the sections did indicate the tendency for the dissolved volume to become bounded by {100} and {111} planes in the configuration illustrated in Fig. 5(c).

In the case of germanium the alloyed regions tended to assume an elongated hexagonal shape with the {100} sides of Fig. 5(a) and (c) absent. This has also been observed by Eer Nisse (19) in silicon and by Faust *et al.* (16) in both silicon and germanium. Sections across the sloping {111} sides were almost identical to that in Fig. 5(b) indicating no tendency for {110} faceting. Other sections confirmed the absence of {100} facets.

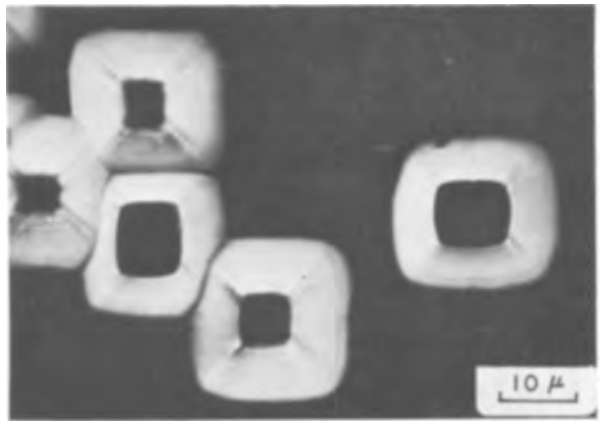

Fig. 4. Etch pits formed by sputtering indium onto a hot germanium surface indicate clearly the truncated pyramidal form of the dissolved volume on {100} surfaces.

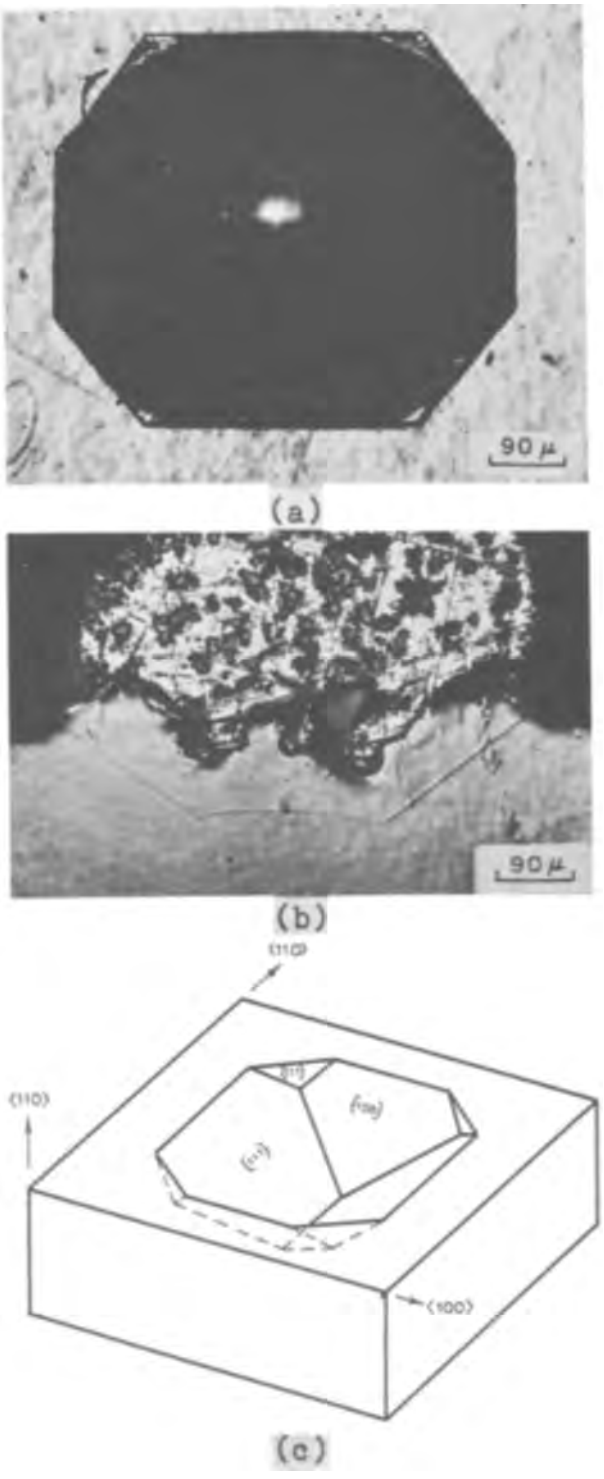

Fig. 5. Metallic etching on the {110} surface of InSb: (a) the shape of the alloyed region in the {110} surface; (b) the shape of the alloyed region perpendicular to the {110} surface and to the well developed sides in (a); (c) the deduced shape of the dissolved volume.

The above describes the results most generally observed. However, it should be added that in the germanium samples examined there were two cases in which the shape of the alloyed region on the surface indicated the possible presence of {100} boundaries: once on a {111} surface, and once on a {100} surface. No detectible {100} faceting was observed in any of the cross-sections.

Discussion

The above observations complement those of Faust *et al.* (16) and indicate that in metallic etching where diffusion effects are negligible the {100} and {111} are dissolution-limiting planes in III-V compounds while the {111} appears as the only dissolution-limiting plane in elemental semiconductors. The experiments also indicate that the A{111} surface dissolves at a greater rate than the B{111}. Since these observations cannot be explained by macroscopic considerations it is necessary to examine the statistics and energy states involved in atomic addition to or subtraction from any atomic configuration on these surfaces before some understanding of the possible forces and mechanisms in these phenomena can be achieved. For this purpose the following highly idealized models for the initial configuration of {111} and {100} surfaces were chosen and it is shown that qualitative agreement with experiment can be obtained.

{111} Surfaces.—In an earlier publication (10) the nature of {111} surfaces in polar III-V compounds was considered and it was concluded that a model for {111} surfaces, similar to that proposed by Gatos and Lavine (21), could be used to explain the differences in growth rates observed between A and B surfaces. This model assumes that A atoms attempt to bond into the A{111} surface in an sp^2 configuration. The A surface becomes more highly strained, therefore, than the B surface where the p^3 bonding tendency is closer to the equilibrium sp^3 configuration. Such a strain difference has been demonstrated experimentally by the spontaneous bending of thin slabs (23). The strain energy in a surface can be shown (10) to assist nucleation and growth and therefore, under identical circumstances, growth on an A surface would be expected to proceed more rapidly than that on a B surface. If dissolution is considered the reverse process to growth it must also proceed more rapidly on the strained A-surface. This conclusion is supported by alloying experiments (4) which have shown that the strain in heavily dislocated materials enhances the etching rate.

Although these conclusions would appear to contradict the observations of Millea and Wilcox (11), it can be shown that there is essential agreement between the experiments. Broadly speaking, crystallographic dissolution is a two-stage process. A difficult stage of atomic removal, analogous to nucleation during growth, is followed by rapid removal of an entire surface layer. It is not difficult to show that the removal of an atom in the first stage may require more than 1.5 times the energy needed for removal of an atom in the second stage. In our experiments the effects of surface strain energy on the first stage are observed. In the experiments of Millea and Wilcox the edge of the crystal provides the starting point for layer removal. Differences in dissolution observed in such experiments reflect differences in propagating a negative step and not in its nucleation. Since propagation on a B-face is typically by an A-faced step (10), layer removal on a B-face could be expected to proceed more rapidly than that on an A-face where B-faced steps develop.

{100} Surfaces.—It would seem reasonable on the basis of the electronic configuration of A atoms to assume that they tend to form sp^2 bonds on any surface in a III-V compound. As a result A atoms could bond stably into the {100} surface in the manner illustrated in Fig. 6. This A{100} surface resembles the {111} surface where the first atoms bonding to the surface can form only one bond. This should be compared to the B{100} surface or the {100} surface of nonpolar semiconductors where all atoms bonding to the surface can form two bonds and no nucleation difficulties would be expected.

If it is assumed the A atoms bond into the {100} surface as shown in Fig. 6, nucleation on such a surface requires that at least two atoms singly bond as close neighbors before growth involving double bonds can occur. Since single bonding is energetically unfavorable and the probability of two atoms single

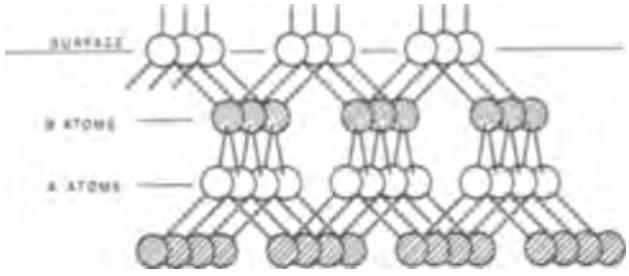

Fig. 6. The bonding configuration of a {100} surface composed of A atoms forming sp^2 bonds with the lower B layer. Only one dangling bond is associated with each A surface atom.

bonding on related sites is low, the formation of a nucleus is difficult. This difficulty in nucleating new layers on {100} surfaces in III-V compounds results in {100} faceting during crystal growth and indicates that a difficult step also exists in dissolution which results again in {100} faceting. The absence of nucleation difficulty on the {100} surfaces in nonpolar semiconductors does not necessarily imply rapid dissolution or growth but it does suggest that crystallographic faceting would be improbable. These conclusions are in agreement with the experimental observations reported here.

A more detailed discussion of possible processes for nucleation and growth on {111}, {100}, and {110} surfaces has been given elsewhere (24).

A Source of Elemental Iodine for Vapor Transport Studies

Samuel E. Blum

IBM Watson Research Center, Yorktown Heights, New York

The use of elemental iodine in vapor transport of semiconductors and other materials is well known. It is, however, difficult to obtain a desired amount of dry iodine in an evacuated sealed system, especially if the system requires a lengthy pumping and outgassing procedure. Generally an elaborate encapsulation technique incorporating break seals is necessary. In his book, Schaefer (1) refers briefly to the production of iodine by heating silver iodide and vanadium pentoxide. Unfortunately, no experimental details are given and the reaction itself could not be found in the literature. The feasibility of using this reaction was investigated.

Experimental

Fisher reagent grade AgI and V_2O_5 were dried at 130°C and used without purification. Mixtures of various mole fractions of the two reagents were prepared and each was intimately mixed. A weighed quantity of each mixture was placed into a tared quartz container and sealed in-vacuo into a quartz tube. The tube was of sufficient length to permit isolation of the liberated iodine from the reactants. The boat end of the tube was heated to about 510°C and held for 1 hr; the other end of the tube was kept in liquid nitrogen to facilitate the condensation of the liberated iodine. After completion of the reaction, the tube end containing the iodine was sealed off from the rest of the system. This iodine ampoule was immersed in aqueous KI and broken. The iodine content of the resulting solution was determined by titration with standardized sodium thiosulfate solution.

Results and Discussion

The yield of liberated iodine was calculated as a percentage of the total iodine in the reaction mixture. A plot of this yield as a function of the V_2O_5/AgI mole ratio is shown in Fig. 1. This curve shows that most of the iodide is oxidized and liberated as free iodine when the mole ratio V_2O_5/AgI is four. At ratios less than four the liberation of I_2 is incomplete.

This would indicate that the following reaction occurs

$$AgI + 4V_2O_5 \xrightarrow{\Delta} \frac{1}{2} I_2 + \text{Residue}$$

An identification of the residue was attempted by conventional Debye-Scherrer x-ray analysis. However, no known compounds of silver and/or vanadium or their oxides could be identified.

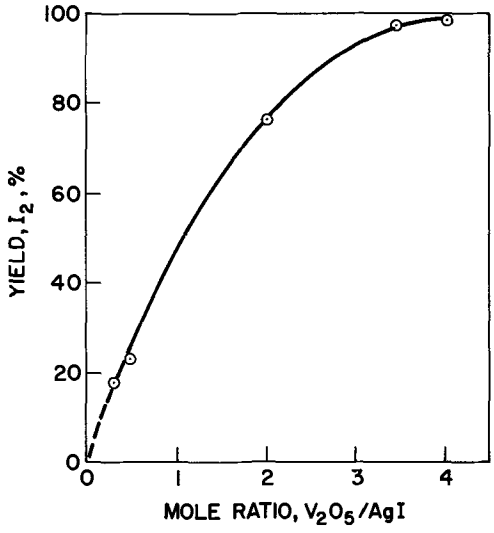

Fig. 1. Iodine yield as a function of V_2O_5/AgI mole ratio

In actual use a stock mixture of V_2O_5 and AgI is prepared and the required aliquot sealed into the vapor transport system. After liberation of the iodine the residue is isolated from the system by a second seal and removed by cutting. Assays of the reacted stock mixture showed that between 95 and 99% of the iodide is liberated as iodine; the major loss of iodine is attributed to some slight volatilization of AgI from the stock during reaction.

Acknowledgments

The author wishes to thank B. Gilbert for the iodine analyses and N. Stemple and J. Angilello for the x-ray analyses.

Thermal Expansion Coefficients and Lattice Parameters between 10° and 65°C in the System GaP-GaAs

M. E. Straumanis and J.-P. Krumme

Graduate Center for Materials Research at the University of Missouri at Rolla, Missouri

and M. Rubenstein

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

The preparation of very homogeneous GaP-GaAs solid solutions was recently described and lattice parameter measurements were made (1). These solid solutions seemed to be very appropriate for the determination of their thermal expansion coefficients and the variation of the coefficient with composition of the solutions. Since the determination of the coefficients, especially within a small temperature range (between 10° and 65°C) requires a high precision in lattice constant determination (2), the measurements were repeated with an x-radiation that produced sharp interference lines at high Bragg angles.

Such an advantageous radiation was produced by a Cr target of the x-ray tube: Cr Kβ, having a wavelength of 2.08059 kX (converted into angstroms by multiplication with factor 1.00202) was used. Lattice constants were calculated from one single back reflection line 511β which appeared at Bragg angles from 83.6° to 75° depending on the GaAs content. Since this line was not very strong, (exact readings were difficult) (2, 3), more patterns were taken at each temperature. The Bragg angles were computed from the obtained asymmetric powder patterns (2-4), after measuring the positions of the lines on them with a comparator by a method described earlier in detail (5, 6). The patterns were made at certain constant temperatures (±0.1°C) in about 10° to 25° increments in a precision camera 64 mm in diameter (2, 4). The powder mounts had a thickness of 0.2 mm so that the absorption correction could be disregarded. The refraction correction was added to the final results (2, 7-9).

The linear thermal expansion coefficients α of the cubic substances were calculated from the a constants obtained at the mentioned temperatures using the relation

$$\alpha = \Delta a/a_{25}\Delta t \text{ in } °C^{-1} \qquad [1]$$

where Δa is the difference in a constants at a temperature difference Δt; a_{25} is the constant at 25°C. The expansivity αa_{25} was obtained from Eq. [1]

$$\alpha a_{25} = \Delta a/\Delta t \text{ in Å } °C^{-1} \qquad [2]$$

The samples were crushed to a fine powder, sieved through 400 mesh screen and, without annealing, were stuck to a Lindemann glass fiber, using vaseline as an adhesive. The fiber was fastened to the adjustable sample holder of the camera.

Figure 1 shows the expansivity of pure GaP. From the inclination of the straight line, using Eq. [1], the thermal expansion coefficient of GaAs was calculated to $\alpha = (4.70 \pm 0.01) \times 10^{-6}$ °C^{-1}. With this coefficient all the lattice constants measured at various temperatures of the sample were reduced to a constant at 25°C (see Table I). The value of the uncorrected constant is

Table I. Reduction of GaP lattice constants to 25°C. Final value of the constant at 25°C.

		a_{25} = 5.45091Å ± 0.00003*

* Standard deviation at 50% confidence limits $S_{50\%}$ (2).

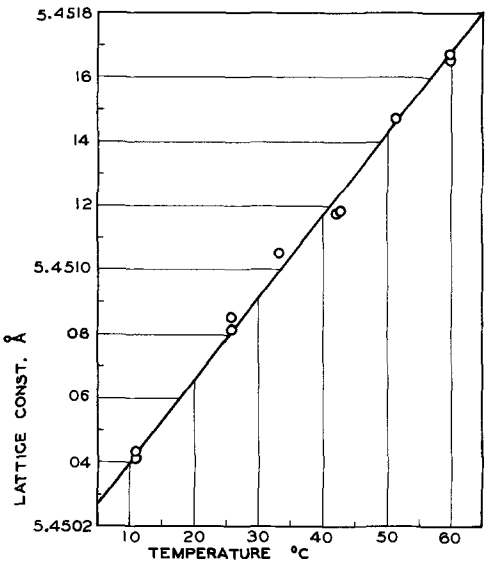

Fig. 1. Lattice parameter in Å of GaP vs. temperature. The standard deviation of ±0.00003Å is represented by the radius of the circles.

in excellent agreement with the previous determination of 5.4508Å (1). If it is desired to have the error (as given in the tables) with confidence limits of 95%, the error $S_{50\%}$ has to be multiplied by 3, or more correctly

$$S_{95\%} = 2.96\, S_{50\%} \qquad [3]$$

The lattice parameters of all other samples were measured in the same way and are listed together with the respective thermal expansion coefficients and refraction corrections added to the constants in Table II. The agreement with previous measurements (1) is good.

In order to see how the measured lattice parameters agree with the Vegard's rule, the constants are plotted against the composition in Fig. 2, which shows that the agreement is perfect within the limits of error. There might be a slight deviation close to the pure components, also observed in some other cases (11). The lattice parameters within the solid solutions a_{ss} in the range from about $x = 0.1$ to 0.9 mole fractions of As can be calculated from

$$a_{ss} = 5.4479 + 0.2023x \text{ Å} \qquad [4]$$

with an average precision of ±0.0004Å, while the outer, pure compounds, fit with a precision of only 0.003Å.

The obtained thermal expansion coefficients are plotted against the mole fraction of As in Fig. 3. There is a slight scatter and the true thermal expansion coefficients can be read from the solid curve of Fig. 3. Taking these coefficients and the constants from Fig. 2, the expansivity of the solid solutions of any composition can be calculated from Eq. [2]. The products obtained are all on a smooth curve similar to that of Fig. 3.

There is no relationship between the energy band gap of the solid solutions (1), and their thermal expansivity.

Closed Tube Apparatus for the Deposition of Silicon Oxide

G. W. Heunisch

Electronic Components Laboratory, U. S. Army Electronic Command, Fort Monmouth, New Jersey

A simple, closed tube method for the deposition of thin, silicon oxide films is presented. The apparatus is primarily designed to deposit silicon oxide by thermal decomposition of tetraethoxysilane. Tetraethoxysilane has received special interest because of its high oxygen content, making possible clear, thick films (1-3) and the low temperature needed for decomposition (4). Carrier gases have been eliminated, bulky furnace apparatus has been reduced, and the unit is safe and inexpensive.

Uses of the method are restricted to those not involving highly accurate film thickness requirements. Film thickness control is within ±200Å.

Apparatus

A top view diagram of the closed tube apparatus is shown in Fig. 1. Pyrex brand glass is used throughout. The pedestal heater, Heater B, consists of a stainless steel core wrapped with nichrome heating wire and insulated from outside ambients. A 1/16 in. hole was drilled through the length of the steel core in order to apply a vacuum for mounting substrates when the heater is inverted. A platinum wire secures the substrate to the heater face when the vacuum is released. Heater A is an oil bath controlled to ±2°C.

To eliminate undesirable convection and "frosting" different heater positions were evaluated. The optimum angle was found when the pedestal heater face and substrate were vertical. This angle is critical for uniformity and is used in all subsequent experiments.

Discussion

The deposition rate of silicon oxide on silicon is linear with time. Figure 2 is a plot of film thickness *vs.* time. The pedestal heater is maintained at 400°C while the liquid tetraethoxysilane is held constant at 105°C. A temperature variation of 3°C exists across the pedestal heater. It should be noted that a pedestal temperature of 350°C results in a waxy film. The length of the tube is approximately 4 in. Longer tubes result in poor reproducibility and nonlinearity because of condensation and reaction within the tube.

At very long deposition times (>8 hr) a decrease in rate occurs, and decomposition at the liquid source becomes important. Increasing the pedestal heater temperature to 500°C does not increase the rate of decomposition appreciably as shown in Fig. 2.

Film thickness measurements are made by lapping a two degree angle across the substrate and oxide coating. The fringes produced by the application of monochromatic light are counted. The refractive index is estimated at 1.4. The low value of refractive index is chosen because of the fast solution rate of the deposited oxide in 4% buffered HF solution. At 25°C the solution rate of thermally grown oxide is 682Å/min while that of the deposited oxide is 1440 Å/min indicating a less dense film.

Films up to 20,000Å have been prepared and show no indication of cracking or other severe stress. Pinholes, however, have been found by high-temperature (1150°C) HCl vapor etch. These number 2 to 3 times those found in thermally grown oxides treated in the same manner.

Electrograph Method for Locating Pinholes in Thin Silicon Dioxide Films

J. P. McCloskey

Autonetics Division, North American Aviation, Inc., Anaheim, California

The electrochemical procedure (1) described in this paper enables simple nondestructive determinations of the precise location of pinholes or other oxide anomalies in thin dielectric material that has been superimposed on and is in contact with a conductive substrate base. The basic principles of the method were first disclosed in a presentation by Besser and Meinhard (2). The particular application presently described relates specifically to a technique used for locating oxide anomalies in thermally grown silicon dioxide passivation layers formed on both phosphorus and boron doped silicon wafers. A need exists in the industry for locating the surface defects at an early stage in production, since electrical failures subsequently occur when vacuum deposited interconnects placed over the holes are short circuited to the conductive substrate beneath. If the faulty areas could be located in the early processing stages, great cost savings and improved reliability would be realized.

An apparatus and technique for carrying out the electrograph method is given in detail in Scott (3). This apparatus could very well be used to advantage for the present application if a sensitive pressure gauge were included to permit accurate control of contact pressure and thereby prevent possible damage to the wafers. The objective of the method, as described in (3), is to obtain qualitative identification of surface components by anodic dissolution in order to chemically transfer small amounts of the surface elements to a suitable medium, usually paper. Distinctive color reactions then occur at specific areas reflecting the compositional differences in the surface. The present electrograph method, however, utilizes a different principle in that a colorless organic reagent, namely benzidine, is anodically oxidized to a colored product only at conductive sites, and does not form a colored compound with any reacting species dissolved from the surface. Since conductive sites represent areas of exposed substrate, the method is conveniently applied to the location of holes in passivation layers.

Experimental

Apparatus.—The apparatus used (see Fig. 1) consists of an electrochemical cell using an aqueous acidified solution of benzidine hydrochloride as an electrolyte. The cell is provided with a supporting stainless steel cathode, 1.5 in. in diameter by 1.5 in. high or slightly wider than the 1.25 in. silicon wafers electrographed,

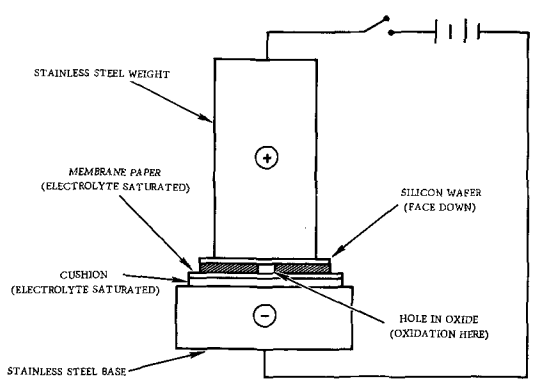

Fig. 1. Electrograph assembly diagram

and an anode of the same material, 1.0 in. in diameter by 6 in. in length, or slightly smaller in diameter than the wafers. As a support pad, a soft cloth such as felt, velvet, certain broadcloths and the like, proved satisfactory. Plain white "Millipore" membrane filter papers were used for recording the electrographs. The 47 mm diameter papers with a 0.45μ pore size furnished excellent results for the 1.25 in. silicon wafers.

Procedure.—Cover the top of the cathode base of the electrograph assembly with a soft cloth pad. Add the benzidine-hydrochloride electrolyte dropwise to the pad until it is completely saturated with the reagent. Immediately place a suitable size membrane filter paper saturated with the electrolyte on top of the pad. The membrane paper may be conveniently saturated by immersing it in a small petri dish containing the electrolyte. Add a few drops of electrolyte to the paper after placing it on the pad to ensure complete saturation. Immediately place the silicon wafer, oxide surface down, on top of the membrane paper. The oxide layer of the wafer should have previously been degassed by immersing, oxide surface up, in a petri dish containing sufficient electrolyte to cover the wafer, and evacuating for 5 min or longer under a vacuum of at least 20 mm of mercury. The evacuation step removes entrapped air from pinholes in the oxide and fills them with electrolyte. Place the anode rod on top of the conductive side of the wafer. Remove all excess electrolyte from around the anode base using an absorbent paper, such as a "Millipore" pad. If the excess electrolyte is not removed, it will tend to cause external short circuits around the wafer. Apply sufficient potential to produce a current of about 1 ma (usually about 5 to 10v) at the start, and maintain at this voltage for 5 to 10 min. Turn off the power supply, disassemble the apparatus, then remove the membrane paper for microscopic examination. Open areas in the oxide will be replicated on the paper with black markings or patterns corresponding exactly in size and shape to a mirror image of the conductive areas present in the wafer.

If repetitive electrographs are to be made of the same wafer, place the previously electrographed wafer in a large plastic beaker cover, preferably Teflon. Cover the wafer with a few ml of 6N HCl and allow 2 to 3 min for reaction. Rinse well with pure water to remove most of the benzidine hydrochloride. Repeat this operation once more. Cover the wafer with a few ml of 0.5% HF etchant and allow to react for exactly 1 min. This treatment removes about 25Å of silicon dioxide in this time period and should be sufficient to remove all of the oxide formed during the electrographing process. Rinse well with pure water to remove the etchant and reaction products. The wafer is now ready for producing another electrograph. If, however, the wafer is now to be returned to the production line, the final pure water rinse must be of 18 megohm or better quality.

Preparation of Reagents

Benzidine-hydrochloride electrolyte.—To a small beaker add 50 ml of pure water, 10 ml of concentrated hydrochloric acid, and 10g of ACS grade benzidine. Warm on a hot plate until completely dissolved. In another beaker prepare a 5% solution by adding 5g of

Fig. 4. Replica electron micrograph of oxide anomaly located by means of the electrograph method.

gelatin to 100 ml of boiling water. Boil for 3-5 min. Combine and mix the contents of the two beakers. Filter through a Whatman No. 40 filter paper into a one liter dark glass bottle. Dilute the filtrate to approximately one liter. Stopper bottle then invert to mix well. The reagent may be used for long periods of time if filtered each time before use.

Hydrofluoric acid etchant.—Prepare an approximately 0.5% hydrofluoric acid etchant solution by diluting 10 ml of 48% hydrofluoric acid to about one liter with pure water in a plastic bottle.

Discussion

Benzidine in acid solution can be oxidized electrochemically to a blue oxidation product (4), in accordance with the following chemical reaction

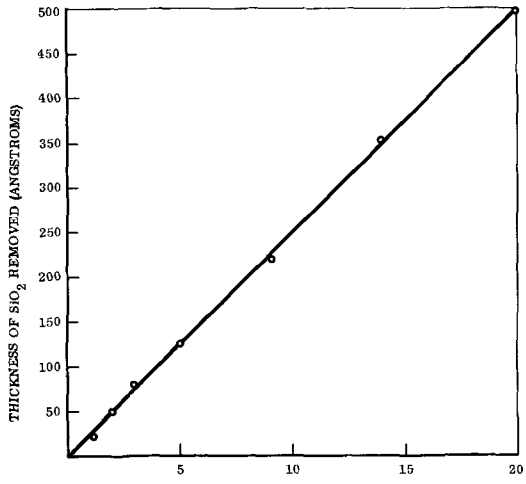

Fig. 5. Etching of silicon dioxide with 0.5% hydrofluoric acid

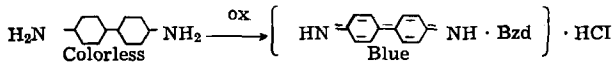

The above sensitive reaction is the basis of the electrochemical method described in this paper.

The simplified drawing of Fig. 1 illustrates the principle of the technique as applied to the determination of the location of conductive areas or holes through the silicon dioxide dielectric of silicon wafers. When a suitable anodic potential is applied to the silicon wafer, oxidation of the colorless benzidine occurs only at conducting areas such as at unwanted pinholes, etched microcircuitry and the like. The dark blue to black oxidation product formed at the conductive sites produces markings or patterns on the paper having the same size, shape, and location as a mirror image of the conductive areas of the wafer electrographed.

Figure 2 is a photograph of an electrograph prepared on a "Millipore" type membrane paper. The silicon wafer electrographed contained 280 complete integrated circuits etched into the silicon dioxide passivation layer. It will be noted that the uniformity of the pattern is broken in two areas, one to the right of center and the other in the upper left hand area. Successive electrographs duplicated the same incomplete pattern in the identical areas. The broken pattern areas represent faulty etching of the microcircuitry patterns in the oxide produced during processing of the wafer. A faulty circuitry pattern, pinhole or other oxide anomaly recorded on an electrographed membrane is not considered as such until it has been duplicated at least once.

Figure 3 is a photomicrograph (50X) of one of the individual integrated circuits selected from the electrograph shown in Fig. 2. The pinhole designated by an arrow illustrates the appearance of an oxide anomaly of this type when observed by microscopic examination of an electrograph.

Figure 4 is an electron micrograph replica of an oxide anomaly on an actual wafer magnified 5000 diameters. The anomaly on the wafer was located by means of the electrograph shown in Fig. 3.

During the course of the development of the electrolyte for the process, the benzidine was first dissolved in a slight excess of acetic acid. It was later discovered that when hydrochloric acid was substituted for the dissolution of the benzidine, a dark blue to black pattern was achieved instead of the light blue color resulting with the former acid. To further improve on the quality of the electrograph produced, a protective colloid such as gelatin was incorporated into the electrolyte to inhibit crystallization of the benzidine and thereby enhance the definition obtained.

Successive Electrographs

When a silicon wafer is electrographed, it is made the anode of an electrochemical cell and therefore some anodic oxidation of the exposed silicon occurs. If a second electrograph of the same wafer is attempted, no dark areas will form on the membrane paper since the formerly conductive sites are now covered with a thin oxide film. Chemical tests indicate that this developed oxide has an approximate thickness of about 25Å. In order that successive electrographs may be processed on the same wafer, a mild etchant was developed which would remove this ultra-thin oxide without serious attack of the main passivation layer. The etchant found suitable was an aqueous 0.5% hydrofluoric acid solution. Figure 5 shows the relationship between the thickness of silicon dioxide removed by the acid per unit contact time. It will be noted that the etching rate was linear in the time interval studied. The data for preparing the graph were obtained by treating a wafer having a silicon dioxide passivation layer of approximately 8500Å thickness, with sufficient etchant to just cover the oxide layer side for successive 1 min intervals. The amount of dissolved silicon in the etchant was then determined by a spectrophotometric chemical procedure developed for this purpose. The thickness of the oxide removed was then calculated from the micrograms of silicon dissolved in the etchant, the measured surface area in square centimeters and an assumed density of 2.15 for the silicon dioxide.

Summary

A simple nondestructive electrograph procedure has been developed for locating pinholes or other oxide anomalies in silicon dioxide passivation layers of silicon wafers. The method is most suitable for the determination of oxide anomalies in silicon wafers that contain etched patterns, such as for microcircuitry, which serve as reference guide lines in establishing the precise coordinates of the defects in the passivation layer. It is estimated that pinholes as small as 1000Å in diameter can be located by the method.

The electrograph procedure described should find applicability in the determination of surface defects in any thin dielectric material that is superimposed on and is in contact with a conductive substrate base. For example, it should be possible to determine surface defects in silicon nitride dielectric over silicon, germanium oxide over germanium, aluminum oxide over aluminum, and many others.

Acknowledgments

The author wishes to acknowledge the help derived from useful discussions with Drs. J. E. Meinhard and P. J. Besser, during development of the process. He also wishes to thank Dr. R. Nolder for the replica electron micrograph shown in Fig. 4. Also, Mr. J. Kersey is thanked for preparing the photomicrographs of the electrographed membrane papers.

Manuscript received Dec. 8, 1966; revised manuscript received Feb. 24, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1967 JOURNAL.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 113, No. 2, 3, 6, 7, 9, 11, and 12 (February, March, June, July, September, November, and December 1966).

Electrical and Structural Properties of Langmuir Films

Robert M. Handy and Luciano C. Scala (pp. 109-116, Vol. 113, No. 2)

J. A. Spink[1]: The inability of the authors to transfer continuous Langmuir-Blodgett monolayers of calcium and barium stearates to gold surfaces raises some important issues regarding the use of the so-called noble metals as substrates for such films. Using ellipsometry to determine film thickness, other workers have also reported difficulties with the transfer of fatty acid and soap monolayers to gold surfaces. Mertens and Plumb[2] found irregularities in the transfer of 30 dynes/cm monolayers to gold films condensed on glass but not to copper and aluminum films. In a more detailed study, Hall[3] observed irregularities due to breakdown and folding of the monolayers at pressures around 40 dynes/cm and incomplete transfer only when the surface pressure was reduced to about 10 dynes/cm.

Already in his early studies in this field, Langmuir recognized the importance of the chemical nature of the solid substrate with regard to the ease with which fatty acid monolayers could be transferred and to the subsequent strength of attachment. In later work, however, Bikerman[4] emphasized the role played by the contact angle that the water made with the solid during the passage of the latter through the air-water interface and concluded: "it is clear that a monolayer on a water surface can only touch and attach itself to the solid surface if the direction of the movement of the slide and that of the water surface near the slide form an obtuse angle so that the monolayer on the water and the . . . metal can approach one another." Subsequent work, discussed below, indicates that both of these factors are important since the chemical nature and even the detailed atomic structure of the solid surface can influence the contact angle in question. Thus, the transfer ratios of unity obtained by Bikerman for chromium and brass surfaces can be explained in terms of the reactivity as well as the wettability of the solids. The concept that under a wide variety of conditions fatty acid and soap monolayers are transferred as a carpet to the solid (*i.e.*, the transfer ratio, ρ, is unity) was maintained for some time until Gaines[5] working with stearic acid, found that at low pressures ($\sim$10 dynes/cm)ρ (compared with an assumed $\rho = 1$ at 30 dynes/cm pressure) never reached unity even for reactive metals such as copper and aluminum. On the other hand, for films transferred at a pressure of 17.5 dynes/cm ρ was found to be unity for glass, mica, Pt, Cr, Cu, and Al.

A more detailed study[6] has shown that with stearic acid ρ depends on a number of factors and for very smooth silver does not reach unity even at a pressure of 30 dynes/cm. At this point it is necessary to make a distinction between solids for which $\rho = 1$ and solids for which subsequent attachment of the transferred monolayer is strong. For example, it has been shown[6] that $\rho = 1$ for mica, glass, and silica although the transferred films are relatively unstable and desorb readily. On the other hand, $\rho < 1$ for silver films condensed on mica, but the monolayer so transferred is more stable and desorbs less readily. This apparent contradiction would appear to arise from several factors. First, the wettability of certain solids during transfer seems to influence the drainage of the water film underneath the transferred monolayer in such a way that some of the molecules are returned to the Langmuir trough. This must occur at the air-water-solid line interface and has been discussed in some detail for smooth silver surfaces.[6] The wettability (or contact angle) can, of course, be influenced by the rate of withdrawal of the solid through the monolayer-covered water surface[4] so that for the silver surfaces mentioned above, ρ depends also on the rate of transfer. Second, the stability of the transferred monolayer must depend not only on the maintenance of the strong lateral Van der Waals interactions between the long hydrocarbon chains but also on the strength of the bonds formed between the polar head groups and the surface of the solid. The latter bonds will, in turn, depend on the outcome of the competition for the solid surface between the polar groups and the film of water transferred together with the monolayer.

Recent unpublished work by this author has shown that gold films ($\sim$1000Å thick) condensed on glass behave similarly to silver films in that $\rho = 0.85$ at 30 dynes/cm and only 0.65 at 10 dynes/cm. On the other hand, the transfer ratio for tin films condensed on glass was found to be equal to unity at both 30 and 10 dynes/cm, which is in agreement with the findings of Handy and Scala. This difference in behavior between metals such as silver and gold on the one hand, and copper, tin, and iron on the other[6] may be explained in terms of the chemical nature of the exposed surfaces. Thus, the principal difference must reside in the fact that, in contact with air, bulk oxide films are readily formed on the latter metals but not on the former. The relative weakness of dipole-metal image forces proposed by Fowkes[7] supports the recent experimental findings[8,9] that oxide-free metal surfaces are not wetted by water. This restricted wettability could then affect the efficiency (at least from the purely geometrical point of view advanced by Bikerman) with which monolayers can be transferred to solid surfaces of the noble metals.

In their discussion Handy and Scala draw no firm conclusions on the true nature of the discontinuities (voids) in their monolayers on gold, *i.e.*, they do not decide whether such discontinuities already exist in the monolayer at the time of transfer or whether they form after transfer because of the low stability of the monolayer on gold substrates.[10] Results obtained by the present author and discussed above suggest strongly that the films transferred to gold surfaces are less closely packed than they were on the water surface and are therefore initially incomplete.

From these considerations it remains to be said that results obtained in various physicochemical studies of Langmuir-Blodgett films transferred to solid surfaces must be treated with extreme caution. It is es-

sential that such films are initially complete and continuous and remain stable under a variety of conditions. To see whether this has been accomplished we have employed techniques using radiolabelled molecules and electron microscopy. The latter technique is useful not only for checking the uniformity and stability of the deposited monolayers but also for revealing the atomic flatness of the metal surfaces.

R. M. Handy and L. C. Scala: The authors are in complete agreement with Dr. Spink's comments, which add to the understanding of the results presented in the paper, and wish to thank him for this contribution.

Red-Emitting Al_2O_3 Based Phosphors

V. D. Mochel (pp. 398-399, Vol. 113, No. 4)

Shannon Jones[11]: The two alumina phosphors, described as new by Mochel, appear to be rediscoveries of phosphors previously described in the literature.

The lithia-iron oxide-alumina phosphor was described by me in 1949.[12] Mochel's blue band in this phosphor is almost surely reflected radiation from the exciting source, and the color coordinates obtained by McAllister allow for no blue emission.

Mochel's calcium aluminate:Mn appears to be of the species described by Kröger in "Some Aspects of the Luminescence of Solids," p. 92 *et. seq.* Kröger studied the ratio $1CaO:6Al_2O_3$, which is within the range covered by Mochel. While Mochel used $MnCl_2$ and Kröger used $Mn(NO_3)_2$, this probably makes little difference after firing at 1450°C in air. The excitation and emission characteristics described by Mochel and Kröger are similar.

V. D. Mochel: I agree with Mr. Jones that the lithia-alumina-iron oxide phosphor I reported is undoubtedly the same as he described.[13] The major contribution of my paper to the description of this phosphor is that I was able to identify the crystalline phase giving rise to the luminescence as lithium zeta alumina ($Li_2O \cdot 5Al_2O_3$) with iron oxide as the activator. This was not done by Mr. Jones.

I am quite sure the blue band at 390 mμ is not due to reflected radiation from the exciting source as Mr. Jones asserts. As explained in my paper the emission spectra were obtained with the Aminco-Bowman Spectrophotofluorometer. With the source grating and the slit systems used, I don't see how a blue band peaking at 390 mμ could arise from the source which is set at 254 mμ. First-order scattering from the grating would center a peak at about 508 mμ, but this is not observed. In addition, blank samples of Al_2O_3 and other types of phosphors did not yield this band. It should be remembered that since there was no calibration between the two photomultiplier tubes used, the intensities of the blue band and the red band in Fig. 1 cannot be compared directly. The curves are normalized. Qualitatively, the blue band was much less intense than the red.

In regard to the calcium aluminate: Mn, Cl phosphors, I did observe luminescence in phosphors with the crystalline phase $CaO \cdot 6Al_2O_3$ as Kröger reported, but in the phosphors I described $CaO \cdot 2Al_2O_3$ was identified as the phase which exhibited the luminescence. I would not rule out the possibility of more than one phase contributing to the luminescence, however. I tried $Mn(NO_3)_2$ and MnO_2 as activators, but neither compound approached the enhancement of luminescence as produced by $MnCl_2$. Apparently the chlorine does make a difference, at least in the intensity of the emission.

Equilibrium Pressures of Oxygen over Oxides of Lead at Various Temperatures

Earl M. Otto (pp. 525-527, Vol. 113, No. 6)

William B. White[14]: Dr. Otto, when searching for previous literature on the system lead-oxygen, apparently overlooked the recent (1964) paper by White and Roy[15] on the high oxygen pressure portion of the system. The oversight was unfortunate in that a comparison of the two sets of results provides some additional insight into the thermodynamics of the system and its phase diagram.

The two experimental techniques are quite different. Otto measured the oxygen pressure over a single phase lead oxide solid under steady-state conditions and obtained his univariant curves directly. White and Roy reacted quite small (50-100 mg) samples of oxide in equilibrium with an externally imposed high oxygen pressure in an open system then determined end product solid phase. Equilibrium univariant curves were obtained by interpolation between the data points which mapped out the bivariant fields.

A comparison of the two sets of data is shown in Fig. 1. Together these compile the most complete phase diagram of the Pb-O system yet presented. Since the vapor phase at these pressures and temperatures is essentially pure oxygen, Fig. 1 is a valid P-T projection for the Pb-O system. Not shown on the diagram are the melting relations, at which temperatures the PbO pressure becomes sufficiently high that oxygen isobars no longer coincide with the univariant curves and the polymorphic relations between the low and the high pressure form of PbO_2[16] which lie above 10,000 atmospheres.

White and Roy, unfortunately, presented their data as linear plots of pressure vs. temperature. The points on the log pressure-inverse temperature plot do not fit a straight line as well as they should. The two curves for the $2Pb_3O_4 \rightarrow 6PbO + O_2$ reaction agree fairly well and have nearly the same slope. The intermediate curve is most interesting. White and Roy could find no evidence for the lower $Pb_{12}O_{17}$ oxide although the x-ray data of Byström[17] and Anderson and Sterns[18] leave little doubt that it exists. Otto finds both phases at low pressures. Otto's $Pb_{12}O_{17} \rightarrow Pb_3O_4$ + oxygen curve agrees fairly well with the extrapolation of the high pressure curve but the low pressure $Pb_{12}O_{19} \rightarrow Pb_{12}O_{17}$ + oxygen curve lies at distinctly lower temperatures than the extrapolated curve. This situation can be resolved by assuming an invariant point of 416°C and 6 atmospheres as indicated in Fig. 1. The exact location of the invariant point is not well-defined but must lie somewhere in this region. A similar situation exists at high pressures where an invariant point at 600°C and 1156 atmospheres marks the lowest P and T at which Pb_2O_3 is a stable phase in the system. Greatest disagreement occurs in the curves describing the decomposition of PbO_2. Each set of data gives good straight lines but the lines have quite different slopes. The calculated heats of reaction are drastically different: 26.8 kcal/mole O_2 from high pressure curve compared with 66.4 kcal/mole O_2 from the low pressure curve. No attempt is made here to prove the correctness of one or the other of these curves. The temperatures are low, reaction kinetics sluggish, and some criticism could be made of either technique. It is necessary to point out, however, that thermodynamic calculations based on this reaction should be suspect.

E. M. Otto: My literature search was made in 1963, the experimental work was completed in the summer of 1964 and the manuscript was written shortly after I presented the paper at the October 1965 Meeting of the Society. Unfortunately, no follow-up literature search was made just before submitting the manuscript for publication.

In the second paragraph of Dr. White's comments it is stated that I measured the oxygen pressure over a single phase lead oxide solid. In dissociation experiments, I invariably produced at least part of the oxygen by partial decomposition of a lead oxide and was careful to satisfy myself that some of the oxide being dissociated remained even after equilibrium had been established; therefore, I always had a two component lead oxide system at equilibrium.

Some Aspects of the Mechanism of Hydrogen Evolution at a Mild Steel Electrode

J. S. Ll. Leach and S. R. J. Saunders (pp. 681-687, Vol. 113, No. 7)

T. C. Franklin[19]: In the article by Matsuda and Franklin[20] the data were treated from the viewpoint that absorption of electrolytically generated hydrogen by iron from sodium hydroxide solutions involved only one mechanism, the migration of adsorbed hydrogen atoms into the interior. This is in apparent contradiction to the conclusions reached in this article. It should, however, be pointed out that several experiments led us to the conclusion, in agreement with Leach and Saunders, that there are two mechanisms of absorption. The most obvious piece of data indicating this in our previous article[20] is shown in plots of rate of absorption *vs.* the amount of adsorbed hydrogen. If hydrogen is absorbed only by the migration of adsorbed hydrogen into the interior, the rate law should be

$$\text{Rate of Absorption} = k(\text{Adsorbed Hydrogen})$$

The experimentally observed rate law for any run was

$$\text{Rate of Absorption} = k(\text{Adsorbed Hydrogen}) + \text{constant}$$

This added constant shows that there is another method of producing absorbed hydrogen.

It was felt that the second mechanism involved the direct electrolytic generation, from water, of hydrogen into the skin of the metal to produce the so called "dermasorbed" hydrogen.[21] It is still felt that this mechanism would explain the data as well as the mechanism proposed by Leach and Saunders. At the time our work was done, it was not felt that enough data were available to reach any definite conclusion as to the process involved in this second mechanism and, since the intercept was relatively small, it was concluded that the primary mode of absorption was through adsorbed hydrogen.

The major point of contradiction between the two articles is our conclusion that the primary source of absorbed hydrogen is adsorbed hydrogen while this piece of work indicates that the primary source of hydrogen comes from a second mechanism. We have concluded that this contradiction arises because of the low current densities (0.83 ma/cm^2) used in our experiments compared with the current densities reported in this article. In recent work sponsored by the Welch Foundation, a study was made of the absorption of hydrogen by nickel in 2*N* sodium hydroxide solutions. These data can be interpreted also in terms of two mechanisms for producing absorbed hydrogen, one of which is potential dependent and one potential independent, in agreement with the present article. The potential independent term would correspond to the absorption of hydrogen from adsorbed hydrogen atoms while the potential dependent term could correspond to the mechanism proposed in this article or to the direct generation of hydrogen into the skin. Using this interpretation, it was determined that the relative contribution of the two mechanisms at the current densities studied was very sensitive to the current density.

Charge-Discharge Mechanisms in Electrolytic Capacitors

W. J. Bernard (pp. 749-751. Vol. 113, No. 7)

A. Dekker, M. G. J. Heijenbrok, and A. Middelhoek[22]: In his paper Bernard gives a new interpretation of the mechanism of oxide formation on the cathode of an electrolytic capacitor during its discharge.

However, it seems somewhat unlikely that prevention of oxidation of the cathode only takes place in a certain limited range of concentration of hydrogen adsorbed at the metal. We believe that the results of Bernard's experiments can be better explained in terms of anodization of the aluminum cathode by a charge larger than its product C_cV_c, where C_c is the cathode capacity and V_c the maximum voltage that can be built up across the natural oxide layer on the cathode just before forming starts. Moreover, Bernard's interpretation disagrees with our experimental results.

Three experimental arrangements are drawn schematically in Fig. 1. Figures 1a and 1b show the same circuits as given in Bernard's Fig. 1 and 2. In Fig. 1b oxidation of the cathode occurs, whereas in Fig. 1a it does not. When the capacitor in Fig. 1a is discharged, the cathode acquires part of the charge located on the anode and when the cathode capacity is large enough, the cathode potential reached is too low to change the cathode capacity by further anodization of the natural oxide layer. When the capacitor is charged again, all the positive charge on the cathode is transported to the anode by means of the battery emf, and the cathode is discharged completely at the same time. The electric

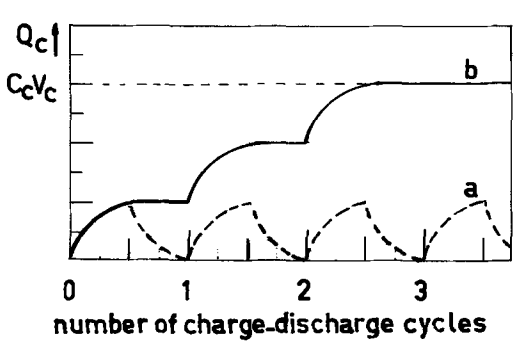

Fig. 2. Charge curve of the cathode C_c vs. number of capacitor discharges. — — — — Q_c from circuit Fig. 1a; ——— Q_c from circuit Fig. 1b.

charge on the cathode *vs.* the number of charge-discharge cycles is shown on Fig. 2, dotted line.

It can be seen from Fig. 2, that when the dimensions of the cathode in circuit in Fig. 1a are sufficiently large, *i.e.*,

$$C_c V_c \geqq \frac{C_a \cdot C_c}{C_a + C_c} \cdot V_{\text{battery}}$$

no oxidation takes place at all. In Fig. 1b however, the cathode capacity cannot discharge during the charging cycle of the anode (assuming that the leakage current is small). Subsequent discharges of the anode will increase the cathodic potential, and formation of Al_2O_3 occurs, until the battery voltage is reached. This formation starts when the cathode charge has attained the value C_cV_c (Fig. 2, curve b). In this case, a large aluminum cathode will anodize, whatever its dimensions are.

In order to discriminate between this interpretation and the hydrogen adsorption theory of Bernard, we performed a third experiment, the principle of which is given in Fig. 1c. This circuit is nearly the same as Fig. 1b, but it has the possibility of discharging the cathode before it is reconnected with the anode for recharging. For the same reason as in Fig. 1b there will be no hydrogen development or adsorption at the aluminum cathode. The counter electrode was not platinum in this case, but an etched Al-foil, having an effective surface area of about 1200 cm^2, in order to avoid the influence of the polarization capacity on the discharge of the cathode. The switching cycle is as follows: S_3 and S_4 go simultaneously to position a for 2 sec, so that the anode is charged *via* the counter electrode; then S_3 goes to position b (discharge of the anode *via* cathode), after 2 sec. S_4 goes to b (discharge of the cathode *via* the counter electrode) and 2 sec afterwards both S_3 and S_4 go to a, etc. The experiments were performed with smooth 99.99 w/o aluminum foil, cleaned by immersion in successively 2% NaOH solution (20°C-9 min), 48% H_2SO_4 (90°C-3 min), and in a mixture of 2.5% CrO_3 and 5% H_3PO_4 in water (85°C-2 min). Both the anode and the cathode surface areas were 40 cm^2. The battery emf was 10v. The anode was anodized to 15v.

The formation of oxide on the cathode was determined from the voltage achieved when the cathode is charged with a small constant current of 1.25 $\mu a/cm^2$; this "control voltage" is plotted *vs.* the number of charge-discharge cycles in Fig. 3. From Fig. 3 one may conclude that the increase of the control voltage with the number of cycles, due to oxide formation on the cathode, occurs only when the charge brought on the cathode is not allowed to leak away.

In our case, where anode and cathode have exactly the same dimensions, there is little difference in cathodic behavior between circuit of Fig. 1a and 1c, whereas adsorption of evolved hydrogen occurs only in 1a. No evidence has been shown that hydrogen evolution has any influence on the oxide formation on the cathode during discharge of the electrolytic capacitor. In fact, in both 1a and 1c the control voltage of the cathode is not zero, but about 2v, independent of

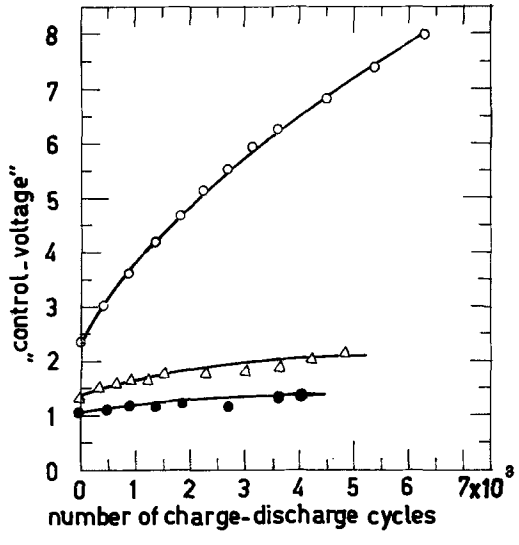

Fig. 3. Cathodic control-voltage *vs.* number of charge-discharge cycles. • result from circuit 1a; ○ result from circuit 1b; △ result from circuit 1c.

the battery emf. This effect can be accounted for quantitatively by the polarization capacity, which reduces the cathode capacity much more than the anode capacity, so that C_aV_a is not equal to C_cV_c.

The Performance of Flooded Porous Fuel Cell Electrodes

R. Brown and J. A. Rockett (pp. 865-870, Vol. 113, No. 9)

H. H. Horowitz[23]: Brown and Rockett have mathematically analyzed flooded porous fuel cell electrodes assuming model cylindrical pores and including activation, ohmic, fuel concentration, and electrolyte concentration polarization. Their calculations fit data obtained on sintered biporous nickel electrodes very well with one exception: the diffusion constants required "were 10^4-10^5 greater than the measured values indicating that a means of diffusive transport other than diffusion through the liquid is a necessary assumption." In connection with the latter point, we wish to offer our experience with another type of porous fuel cell electrode system. We were forced to conclude that the cylindrical pore model needs to be modified somewhat and that the "other means of diffusive transport" was simply gas phase diffusion.

The porous electrodes we were using consisted of platinum black or carbon impregnated with platinum, which was mixed with 15 w/o Teflon in the form of an emulsion and compressed in a 50 mesh screen of platinum or tantalum. Butane was the fuel and 3.7M sulfuric acid was the electrolyte at 95°C. The degree of flooding of the electrodes was controlled, not by the differential pressure, but by the quantity of Teflon used and by the compression step. Under the conditions used, it was found by weighing the electrodes before and after they had been contacted with electrolyte that their pores were over 80% flooded. Decreasing the degree of flooding decreased the electrode activity roughly proportionately. There was little doubt that a high degree of flooding was necessary for activity and that most of the electrode surface was under liquid.

Nevertheless, experimental evidence indicated that most of the surface area was available for reaction and that a solubility-diffusion mode of fuel transport obtained: It was possible to reach the same limiting current per milligram of platinum used by saturating the electrolyte with butane and passing it through a layer of platinum black mounted on a porous tantalum frit. These data have been published.[24]

Using reasonable estimates of the solubility and diffusion constant of butane and the ideal current densities taken from the above experiment, in an equation similar to the present authors' Eq [17] it was calculated that the active area extended only 5×10^{-4} cm from the gas liquid surface. Since the electrodes used were 0.2 mm thick, an apparent enigma arose similar to that presented in the present paper.

This enigma could be resolved by including lateral pores in the model, perpendicular to the "main" pores, and by assuming fingers of gas extending into the depths of the electrode perpendicular to its surface. If these gas filled fingers are small enough and numerous enough they can feed the entire electrode with fuel while occupying less than 20% of its volume. For example, cylindrical holes 2μ in radius in a square array spaced at 8μ on centers, occupy 20% of the total volume. Yet the entire volume of liquid within the remaining pores is within 5μ of one or more gas filled pockets. Thus, the surfaces of granules not directly exposed to gas receive fuel by diffusion through liquid filled pores more or less parallel to the electrode surface, whereas the current lines continue to flow more or less perpendicular to the surface.

We believe the new model offers a greater degree of sophistication than a simple parallel cylindrical pore model, because it makes use of the lateral pores known to be present in the sinter and permits the use of conventional diffusion constants and gas solubilities. A question remains as to the source of the gas filled pores. In Teflon bonded structures it is easy to rationalize pores in the statistical distribution, whose surfaces are so hydrophobic and whose radii are so small that they would not fill with liquid even under a partial vacuum equal to the electrolyte vapor pressure.[25] As to the source of gas filled pores in sintered nickel electrodes, perhaps the authors of the present paper could also rationalize their existence on the basis of inequalities of pore radii in manufacture and inequalities in surface wetting properties due to hydride or other film formation.

The Permeation of Electrolytic Hydrogen through Platinum

E. Gileadi, M. A. Fullenwider, and J. O'M. Bockris (pp. 926-930, Vol. 113, No. 9)

G. Dubpernell[26]: Previous criticisms of the method seem to be largely ignored. The title seems incomplete and not properly indicative, and could include a phrase such as ". . . in Sulfuric Acid Solution Poisoned With Arsenic Additions." Apparently no permeation was observed in pure $0.1N$ H_2SO_4 with platinum membranes as thin as 2×10^{-3} cm (0.0008 in.) unless As_2O_3 was added to the solution. Some explanation should be given for the impermeability, and it would be better to call the effect of arsenic additions an "activation" rather than a poisoning. In previous work membranes which refused to diffuse any hydrogen have generally been called poisoned or passive, and have been discarded rather than accepting them as the norm.

It is good to note that cracks in membranes were easily detected by the immediate effect on the anodic side as soon as the cathodic current was turned on. However, it is not clear that all such membranes were rejected. In Fig. 1, does not the vertical increase in the permeation rate when the current density is increased, indicate such a cracked membrane, and should not this membrane have been rejected instead of using the first transient as acceptable to calculate a diffusion coefficient? Is not this the same membrane with which hydrogen charging is said on page 927 to have caused further cracking?

While the writer believes that all diffusion observed is due to mechanical defects in the metal or pores of one kind or another, the assumption of hydrogen embrittlement in platinum at temperatures of 50°-80°C based on Richardson's observations in the gas phase at 700°-1000°C, does not seem proper. The assumption of a critical low current density between 70° and 80°C on page 928 seems even less in order. It does not seem logical to assume that the permeation process is diffusion controlled at extremely low current densities, and then at a critical current density that ". . . a critical change in the internal structure of the metal takes place."

Aside from taking only first transients at extremely low current densities for the calculations, apparently irregardless of whether or not the membrane was cracked, the authors state that "only transients which have the theoretically expected shape were accepted for the calculation of D." How many transients were rejected for each one accepted?

It would seem that the diffusion of electrolytic hydrogen through carefully handled thin platinum membranes has not been demonstrated, and that the as-

sumption that such a diffusion can occur should be subjected to further scrutiny.

E. Gileadi, M. Fullenwider, and J. O'M. Bockris: Dr. Dubpernell has consistently opposed the notion of hydrogen diffusion through some metals (Fe, Pd, Pt) at or near room temperature, despite clear and unambiguous evidence accumulated at the Electrochemistry Laboratory of the University of Pennsylvania and several other places.

The major point is that the permeation rate J_t is found to follow the equation

$$J_t/J_\infty = \left(\frac{2}{\pi^{1/2}}\right)\left(\frac{1}{\tau^{1/2}}\right) \exp(-1/4\tau) \qquad [1]$$

where

$$\tau = Dt/L^2$$

derived for a diffusion-controlled process with the specified boundary conditions. More conveniently, this gives rise to a half rise time $t_{1/2}$ which is proportional to L^2 (L is the membrane thickness) and a steady state permeation rate J_∞ proportional to $1/L$; both of which have been verified experimentally.

One has yet to devise a pore and crack model that would fortuitously give rise to the same type of transient; give reproducible results for many membranes of the same metal, but widely different diffusion coefficients for membranes of different metals; and, in the case of Pt, yield an apparent energy of activation for diffusion of 9.6 kcal/mole.

One of the advantages of the present method of measurement of hydrogen diffusion is that any pinhole or crack in the metallic membrane is easily detected by an immediate change of current on the anodic side following any change of polarization on the cathodic side. All membranes showing such behavior were discarded. Figure 1 in our paper shows clearly that there was no crack or pinhole in the membrane originally and the diffusion coefficient was accordingly determined from the first transients. A close look will show that subsequent transients in this figure do not rise vertically.

Hydrogen embrittlement of Pt was suggested tentatively and by no means considered proven. The basis for this suggestion is the similarity of permeation transients at high current density to those observed for iron under conditions where embrittlement was shown to occur, combined with the evidence from high temperature work, that hydrogen embrittlement of Pt can indeed occur under certain conditions.

The cathodic current density determines the concentration of adsorbed hydrogen on the surface and hence the concentration c_0 of absorbed hydrogen just under the surface, in equilibrium with it. It was pointed out in the paper that when i increases beyond a particular value, c_0 exceeds the solubility of hydrogen in the metal. Molecular hydrogen can then be formed in crevices or voids inside the metal and the diffusion of atomic hydrogen through the membrane is disturbed. That the critical value of i depends on temperature is hardly surprising. In the case of Pt, it decreases with increasing temperature, indicating that the solubility of hydrogen in Pt decreases with increasing temperature.

Optical Studies of Electrolyte Films on Gas Electrodes

Rolf H. Muller (pp. 943-947, Vol. 113, No. 9)

J. J. Bikerman[27]: The optical measurements of the thickness d of liquid films draining down a vertical electrode, as described in the paper, are in a reasonable agreement with the earlier results[28,29] obtained by weighing the film and with the author's Eq. [5] which is of an older vintage[28] than believed by the author.

The main difference between the older and the new treatment is that the author pays no attention to surface roughness. The thickness d as a function of $\sqrt{t}$, t being the duration of drainage, deviated from the straight line relation (Fig. 5 of the original) when the apparent d was 0.31μ or less presumably because the hills on the electrode surface were approximately 0.31μ tall. It is shown in the earlier papers that a stagnant liquid layer exists next to the solid-liquid interface and that its thickness is nearly equal to the average height of surface hills, as measured by an independent method.

R. H. Muller: I wish to thank Dr. Bikerman for drawing my attention to his interesting work on the effect of surface roughness on gravitational drainage of oil films.

Although it is realized that the quantitative characterization of the smoothness of optically polished surfaces is difficult, indications are that the rugosity of the surfaces employed was considerably lower than the thickness (0.3-0.6μ) of the electrolyte films observed. Examination of the electrode surfaces by double beam and multiple beam interference microscopy showed the largest polishing marks present to be 0.05μ dep and about 0.02μ wide. They were oriented at random and spaced at a mean distance of 20μ with the intervening area filled with progressively finer and more closely spaced grooves. Measurements with a stylus surface tester were found to be below the resolution limit of the instrument of 0.05μ rms.

The regression analysis conducted by Bornong[30] for the dependence of the stagnant oil layer thickness on surface roughness extrapolates to 0.78μ and 0.28μ for zero roughness and, respectively, silver-copper and stainless steel alloys. These figures are surprisingly close to those given in the present work for KOH solution on silver and nickel.

It is felt, therefore, that in the experiments reported, the electrode surface roughness has not been the controlling factor for the formation of stable electrolyte films, although this parameter may be important in an analysis of technical gas electrodes.

The Pressure Coefficients of the Hydrogen Electrode Reaction

G. J. Hills and D. R. Kinnibrugh (pp. 1111-1120, Vol. 113, No. 11)

T. Pyle and C. Roberts[31]: Recent measurements of the pressure coefficient for hydrogen evolution at a mercury surface by Hills and Kinnibrugh have shown that the process has a negative volume of activation. This evidence led them to suggest that the rate-determining step in the reaction is the formation of solvated electrons in the solution adjacent to the metal surface. This proposal has been criticized by Matthews[32] on the grounds that it would lead to negligible rates of hydrogen evolution because of the high heat of activation, ΔH, for the formation of the hydrated electron. Matthews suggested that ΔH would be given by the difference between the work function of the metal ϕ, and the solvation energy of the electron, W_e; for mercury $\phi \sim 4.5$ ev and in aqueous solutions $W_e \sim 1.7$ ev this gives an apparent activation energy >60 kcal/mole which is much greater than that found experimentally, reported values range from 9 to 24 kcal/mole. If ΔH were given by $\phi - W_e$, this would present a powerful argument against the proposed mechanism. However ϕ is the energy required to remove an electron from the metal to infinity; consequently if

Table I. Heats of activation (kcal/mole)

Metal	Cu	Hg	Ni	Pt	Co
Hydrogen evolution	10	9-24	5-16	5	3-5
Solvated electron	7.2	8.3	8.5	27	2.5

$\phi - W_e$ has any meaning at all, it is the activation energy to form solvated electrons at an infinite distance from the metal. Electrons can be solvated rather closer to the metal than this; the activation energy can be expected, therefore, to be rather smaller than that suggested by Matthews.

We believe that the closest point to the metal at which an electron may be considered to be solvated lies in the plane through the center of the first layer of water molecules which are in contact with the metal surface. In this position the electron will lie approximately in the inner Helmholtz plane and the work required to separate an electron from a metal by a distance a, the radius of a water molecule, may be estimated on the basis of a model for the work function of a metal discussed by Loeb.[33] The work required to remove an electron is considered in two parts. (a) at points closer to the metal than a critical distance x_0 the electron moves in a constant field $e/4x_0^2$. The work done in taking an electron from the metal to x_0 is $e^2/4x_0$; (b) at distances larger than x_0 the electron moves against a mirror image force. The work required to take an electron from x_0 to ∞ is $e^2/4x_0$. The work function is the sum of these two parts and equals $e^2/2x_0$. For metals, with $\phi < 5$ ev, $x_0 > a$ and the work required to separate the electron from the metal by a distance a becomes $ae^2/4x_0^2$. The activation energy for the solvation of an electron in this position becomes $ae^2/4x_0^2 - W_e$. Metals with $\phi > 5$ ev have $x_0 < a$ and the activation energy is given by $\phi - e^2/4a - W_e$.

Experimental values of the heats of activation for the deposition of hydrogen at copper,[34] mercury,[34] nickel,[34] platinum,[34] and cobalt[35] surfaces in aqueous electrolytes are compared, in Table I, with values of ΔH calculated on the basis of the model we suggest above.

The agreement between the experimental heats of activation for hydrogen evolution and the calculated heats for the formation of solvated electrons is encouraging. Experimental verification of the role played by the solvated electron in the evolution of hydrogen is only available for mercury, however the calculated values of ΔH do suggest that it may also play a dominant role in the evolution of hydrogen at copper, nickel, and cobalt surfaces. Platinum has a large work function and the activation energy for the formation of solvated electrons at the platinum-electrolyte interface is therefore large. Consequently it appears improbable that hydrogen evolution *via* the formation of solvated electrons will be significant at a platinum surface. However, in general ΔH for the formation of a solvated electron at the inner Helmholtz plane is not large and the formation of a solvated electron as a step in the evolution of hydrogen should not be discounted on the grounds that it will lead to negligible rates of hydrogen evolution.

The Cathodoluminescence of Terbium-Activated Indium Orthoborate

F. J. Avella (pp. 1225-1226, Vol. 113, No. 11)

W. L. Wanmaker and A. Bril[36]: In the paper under discussion it was stated that in one of our papers we described the photoluminescence of Tb^{3+} in alkaline earth borates[37] but did not report on the cathodoluminescence. We should like to point out that in section 5 of the paper cited by the authors we did in fact give cathode-ray efficiencies (p. 491), namely a radiant efficiency (energy conversion efficiency) of about 2%. Moreover in another paper[38] we gave a radiant efficiency of 2.2% for $2CaO \cdot Na_2O \cdot B_2O_3$-0.15 Tb. This means that these phosphors have an efficiency of about 25-30% of that of willemite (Zn_2SiO_4-Mn).[39] They are, therefore, comparable with those described in the paper under consideration.

In a third paper[40] we have given data on more efficient Tb-activated phosphors under cathode-ray excitation, namely on $LnPO_4$-Tb (where Ln = Y, La, Gd). For $GdPO_4$-Tb we found an efficiency of 5%, *i.e.*, about 65% of that of willemite.

F. J. Avella: The author is grateful to Dr. Wanmaker and Dr. Bril for supplying the information on the cathodoluminescence efficiency of their borate as well as their phosphate phosphors. References to the former[37,38] were inadvertently omitted, while the latter reference[40] was not available during preparation of the paper under discussion.

It should be noted, however, that their statement of comparable performance applies only to the Tb-activated borates containing the alkaline earths. The data given in Table I of the paper under discussion show that $InBO_3$:Tb is nearly equal to willemite in cathodoluminescence conversion efficiency and is, therefore, significantly more efficient than the alkaline earth borates as well as $GdPO_4$:Tb.

The Repeatability of the Anode Effect in Cryolite-Alumina Melts

B. J. Welch and R. J. Snow (pp. 1338-1340, Vol. 113, No. 12)

R. Piontelli, B. Mazza, and P. Pedeferri[41]: The recent systematic research work carried out in this Laboratory[42] has thrown much more light on both the overvoltage phenomena and the anode effect conditions at the cryolite-alumina melts.

The influence of the shape, orientation, and size of the anodes has been confirmed for both by investigating the behavior of the anodes represented in Fig. 1.

The apparent overvoltage on these, also before the intervention of the anode effect, includes a large ohmic contribution due to the presence of the gaseous phase in the anodic layer and on the anode surface. This contribution depends (besides on the alumina content of the baths) on the circumstances controlling the gas evacuation and thus on the shape of the anodes (being obviously greater on the anodes of the types: B, C, F, on which the permanence of the gases is favored). This statement is confirmed by the influence of mechanical vibrations impressed on the anode assembly which, by enhancing the gas evolution, reduces the ohmic contribution to the apparent overvoltage. The ohmic character of this contribution is also confirmed by the oscillographic recordings of the electrode voltage at the current inlet and outlet. Thus the amount and configuration of the gaseous phase in the anodic

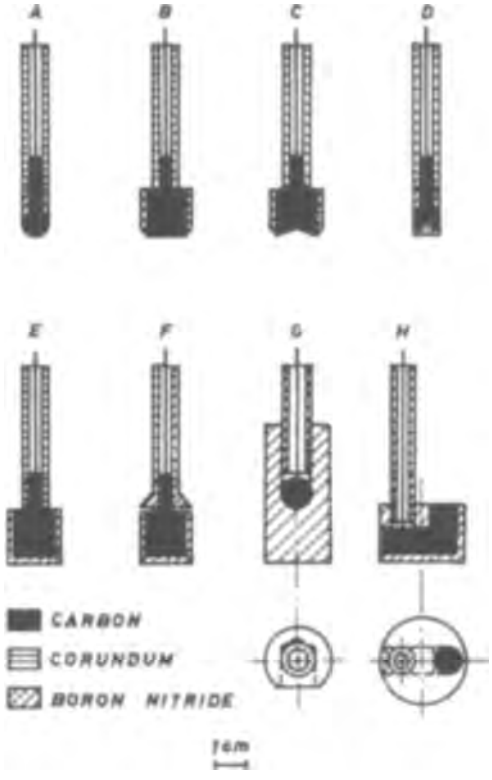

Fig. 1. Types of anodes investigated (sectional views)

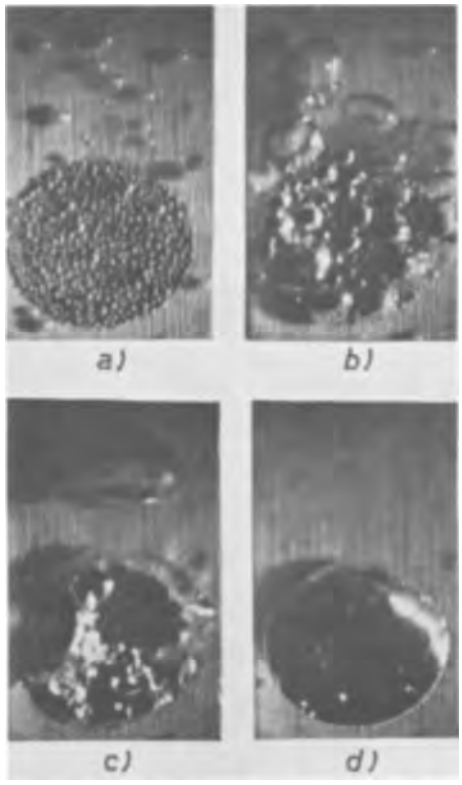

Fig. 2. Chlorine development on carbon anodes from chloride melts. Type G anode, A = 0.5 cm². Bath composition: NaCl + KCl (50 w/o). T = 850°C. G_c = 4.5 amps. (a) nucleate bubbles (G = 0.6 amps); (b) coalescence of bubbles (G = 1.85 amps); (c) transition period; (d) anode effect. Maximum framing rate: 4800 frames/sec.

region appear to be decisive also for the appearance of the anode effect occurring when the gaseous phase prevents any efficient wetting of the electrode surface.

Since this condition is obtained by the coalescence of the bubbles evolved at the electrode surface, a close analogy subsists with the phenomena encountered in the boiling of liquids in contact with a heated solid surface.

Films (up to 5000 frames/sec) on the anode effect phenomena, on carbon anodes in chloride melts, give direct evidence of this point.[43] By increasing the current density one can distinguish three typical regimes in the gas development. In the lowest current density range the gas development takes place in a nucleate form (Fig. 2a). Then coalescence of bubbles occurs (Fig. 2b) and after a transition period, in which the anode surface is covered by irregular gas blankets in violent motion (Fig. 2c), a condition is reached in which the anode is practically insulated from the bath by a permanent continuous gaseous film (Fig. 2d).

As far as the carbon-cryolite alumina melts are concerned, the quoted experiments (see footnote 42) prove that it is more appropriate to define a critical current intensity of appearance of the anode effect (G_c) rather than a critical current density, in so far as the size factor influence does not follow any simple proportionality law. The relationships established (in the laboratory experiments) may be summarized by the formula

$$G_c \simeq \psi \cdot (a + bT) \cdot A^n \cdot \{c + [Al_2O_3]^m\} \qquad [1]$$

where T is the bath temperature, A the apparent anode area, $[Al_2O_3]$ the alumina content of the bath, ψ a factor which depends only on the shape of the anode, and a, b, c, n, m are constants ($n < 1$; $m \simeq 0.5$).

For T in °C, A in cm², $[Al_2O_3]$ in w/o (referred to cryolite), and G_c in amperes, the following expression is obtained in the $[Al_2O_3]$ range 1-10 w/o and in the temperature range 1000°-1150°C

$$G_c = \psi x\{5.5 + 1.8 \cdot 10^{-2} (T - 1050)\} \; x A^{0.9} x\{-0.4 + [Al_2O_3]^{0.5}\} \qquad [2]$$

[43] R. Piontelli, A. Berbenni, B. Mazza, and P. Pedeferri, *Electrochimica Metallorum*, 1, 279 (1966).

ψ being equal to: 1 for type B, 1.4 for type A, about 1.3 for type D, G, E, H, and about 0.5 for type C anodes.

Mechanical vibrations impressed on the anode assembly increase the critical current intensity to a greater extent for type B and C anodes.

Always with reference to the cryolite-alumina melts, the importance in view of the appearance of the anode effect of the change in chemical configuration of the bath in the anodic region, due to current circulation, must be recalled.

As a consequence of the transference processes and of the electrode reaction, the relative content of the aluminum fluoride, as a component of the anodic bath layer, tends to increase.

This phenomenon occurs, magnified, in cells having a soluble anode of metallic aluminum.

In spite of the obvious differences in respect to the usual condition considered above, the study with the soluble anode cells is easier and instructive in showing (magnified again) the possible effects of the accumulation of aluminum fluoride in the anodic region.[44]

With soluble anode one may encounter anomalous voltage increments corresponding to a passivity condition which appears to be chargeable to a separation of aluminum fluoride as a solid phase. Also in this case, as in the one of the anode effect with insoluble anodes, the addition of alumina or also temperature increments[45] displaces the onset of the anomalous anode conditions toward a higher range of current intensity.

The increment of the aluminum fluoride relative content involves strong change in the chemical physical properties of the bath, by lowering conductivity and increasing vapor pressure.

[44] R. Piontelli, B. Mazza, and P. Pedeferri, *Electrochimica Metallorum*, 1, 217 (1966).

[45] It is remarkable that, in chloride melts, the temperature influence is exactly opposite.

In the case of the insoluble anode electrolysis[46], this last effect aggravates the consequences (especially the increase of power dissipation) of the presence of the gaseous products of the electrolysis.

B. J. Welch and R. J. Snow: In the work presented in our paper, we were not concerned with the phenomena associated with the anode effect, but our work was directed toward elucidation of the most reproducible parameter for applications such as *in situ* alumina analysis. We fully acknowledge the great contribution made by Professor Piontelli and his co-workers in shedding light on the phenomena causing the anode effect.

[46] In which also overvoltage phenomena before the onset of the anode effect appear to be influenced by inhibition phenomena at the electrode surface chargeable to fluorine or to some fluorine surface compounds.

It is interesting to note that they have substantiated[47] our observed lack of reproducibility of the critical current density (or intensity). In an extension of our work[48] we have also confirmed the temperature dependence presented above and elsewhere.[49, 50]

In our more detailed study we observed that the point of anode effect, as defined by either cell voltage or critical current density (or intensity), is also dependent on the carbon type used as the anode. Marked differences are observed for carbons that only have small differences in graphitic structure.

ELECTROCHEMICAL SCIENCE

Low-Temperature Battery System Study Using a Mixture of HF and N_2O_4

R. Keller and S. Evans

Research Division, Rocketdyne, A Division of North American Aviation, Inc., Canoga Park, California

ABSTRACT

A battery system using a mixture of anhydrous hydrogen fluoride and dinitrogen tetroxide was evaluated. Dinitrogen tetroxide was the cathodic reactant; the anodes studied were cadmium, manganese, molybdenum, and zirconium. Cadmium exhibited the best anode behavior of the candidates that were evaluated. Typical open-circuit cell voltages were: 1.14v at —40°C and 1.66v at 60°C. Cell polarization at —40°C was moderate and at 60°C was very low. It is predicted that cell voltages of 0.9v at a discharge rate of 100 ma/in.^{2} at —40°C are attainable.

Analysis of basic electrochemical data obtained during a synthesis-oriented program (1) resulted in the proposal for a battery system with a hydrogen fluoride-dinitrogen tetroxide electrolyte. Such electrolyte solutions had shown high conductivities at low temperatures; the electrochemical reduction of N_2O_4 occurred readily.

The objective of this study was to determine the feasibility of a metal anode/HF, N_2O_4/inert cathode system for possible low-temperature, primary battery application.

The discharge of this battery system is based on the anode reaction

$$M \rightarrow M^{n+} + ne^- \quad [1]$$

or

$$M + nHF \rightarrow MF_n + nH^+ + ne^-$$

and the cathodic reaction

$$4H^+ + N_2O_4 + 4e^- \rightarrow 2NO + 2H_2O \quad [2]$$

The over-all cell reaction for a cell with cadmium anode as example is

$$2Cd + N_2O_4 + 4H^+ \rightarrow 2Cd^{2+} + 2NO + 2H_2O \quad [3]$$

or

$$2Cd + N_2O_4 + 4HF \rightarrow 2CdF_2 + 2NO + 2H_2O$$

The anode in contact with the HF-N_2O_4 electrolyte is thermodynamically unstable. A suitable anode should have a low direct corrosion rate, but should undergo reasonable electrochemical dissolution. Tantalum, niobium, and tin react immediately with the solution; zinc, iron, nickel, chromium, cobalt, silver, and copper are stable in HF-N_2O_4, but are passivated by the application of anodic currents. However, zirconium, manganese, cadmium, and molybdenum have been found to be relatively insoluble in HF-N_2O_4, but dissolve electrochemically when anodic currents are applied. These metals were evaluated.

Platinized platinum was selected as the cathode material, since N_2O_4 was reduced with very little overpotential. Nickel was used as the cathode in several experiments.

A special feature of this system is that no cell divider (separator) is necessary, thus allowing for simplified design of a reserve-type cell.

Experimental

The test cell fabricated from Teflon is shown in Fig. 1. The compartment measures 1 by 1 in. with wall thicknesses of ¼ in. Grooves held 1-in.^{2} electrodes in place at opposite walls. The electrolyte covered the electrodes completely, but left a vapor space (approximately 1 in.^{3}) above the liquid. The silver-silver fluoride reference electrode (2) was contained in a sealed Kel-F tube which had an opening approximately ½ in. above the cell bottom. The Teflon cell cover was pressed against the cell body by steel bolts, and the seal was accomplished with a Teflon O-ring. The leads to the electrodes were introduced between the cell body and the O-ring. A perfect seal was not established, but the sealing was found adequate even for high-temperature experiments. Two Monel fittings on stainless-steel tubing allowed for filling and venting of the cell.

The Ag/AgF electrodes were prepared by anodizing silver wire in solutions of 0.5M NaF in anhydrous HF at current densities of approximately 12 ma/cm^2 for 5 min. Electrodes prepared by such a procedure were found (2) to have potentials within 5 mv of each other and to return to their original open-circuit potentials after momentary cathodic or anodic polarization at 0.1 ma/cm^2.

The lower part of the cell was immersed in a constant-temperature bath. A fluorocarbon slush bath was

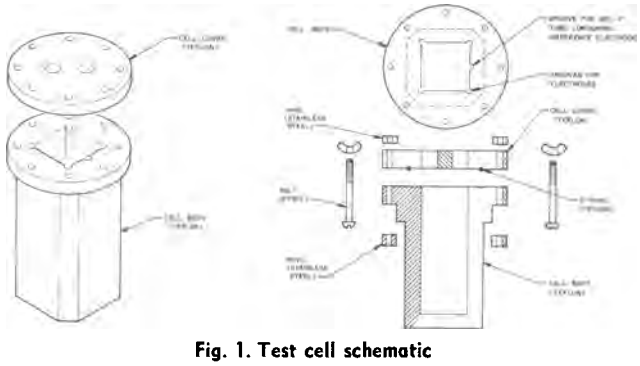

Fig. 1. Test cell schematic

used to maintain —40°C. Freon-113 with a melting point of —35°C was mixed with Freon-11 to achieve a melting point of —40°C. The temperature was normally maintained with an accuracy of ±2°C. A Kel-F oil bath was used for temperatures of 60° ± 1°C. The oil was contained in a 3-liter beaker. An immersion heater was controlled by a relay in conjunction with a contact thermometer.

Liquid anhydrous hydrogen fluoride (3) was quantitatively transferred through Monel tubing and Teflon valves into a Kel-F finger. The hydrogen fluoride was frozen by means of liquid nitrogen, and N_2O_4 was added from a burette. The mixture was allowed to thaw and was then transferred to the cell. During all these procedures, closed systems were used, except for some venting tubes.

Galvanostatic polarization curves were determined by applying a constant current and measuring the resulting potential. The current was usually raised in the sequence 1, 2.2, 5, 10, 22, 50 ma, etc., and each value was maintained for 1 min.

In galvanic studies, constant ohmic loads were applied to the cell, and the potential was recorded as a function of time. The cell currents can be readily determined from the cell voltages.

Vapor pressures were determined by placing a sample of the electrolyte in a stainless-steel bomb and measuring the pressure with a Matheson Monel gauge. The apparatus was kept in a thermostated oven.

Results

Low-temperature galvanostatic anode studies.—Anodic polarization curves of cadmium, manganese, molybdenum, and zirconium, determined at —40°C, are shown in Fig. 2. A cathodic curve for the reduction of N_2O_4 at platinized platinum is also indicated (dashed curve).

Cadmium displayed the most suitable behavior of the anodes tested. The open-circuit potential was —0.48v *vs.* Ag/AgF. The anode polarization was moderate, and the corrosion rate was negligible.

Zirconium exhibited very negative open-circuit potentials; —1.12v in one case, —0.72v in another case. The polarization characteristics were favorable. However, zirconium reacted with the electrolyte and corroded (primarily near the electrolyte surface) at a rate which was fast to moderate. Nevertheless, it may be feasible to use it for short-duration discharge.

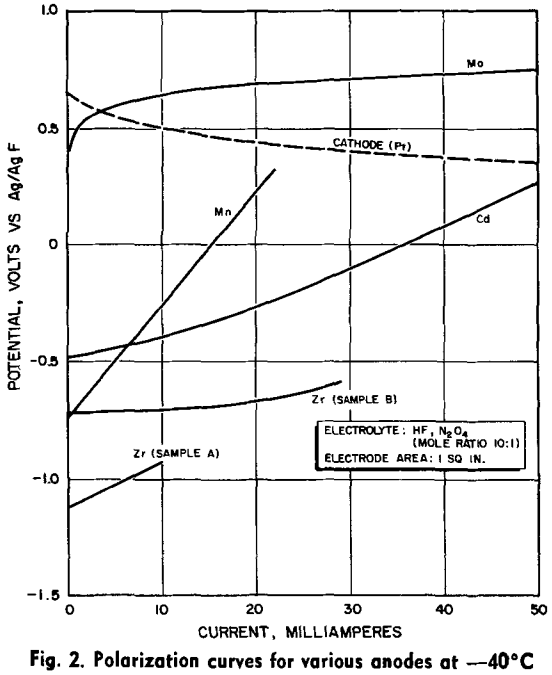

Fig. 2. Polarization curves for various anodes at —40°C

Table I. Specific electrolyte conductance at —40° and 60°C

Electrolyte	Temperature, °C	Cell resistance, ohms	Specific conductance, ohm^{-1} cm^{-1}
0.1*N* KCl	25	24	0.013
HF, N_2O_4	−40	7.6	0.041
HF, N_2O_4	60	1.06	0.18

Table II. Vapor pressure of electrolyte

Temperature		Vapor pressure	
°C	°F	psia	atm
41	106	<15	<1
50	122	20	1.4
60	140	27	1.8
71	160	37	2.5

Manganese polarized fairly severely. The open-circuit potential was somewhat more negative than the value obtained with cadmium.

Molybdenum showed good polarization characteristics but unfavorable potentials.

Cathode studies.—Based on previous experience, nickel had been suggested as electrode material for the reduction of N_2O_4. It was soon noticed, however, that the polarization at smooth nickel was too great for a battery electrode. Although the discharge characteristics were fairly flat, an initial voltage drop of approximately 0.5v was observed at low currents. Platinized platinum electrodes were found to behave very well as cathodes (Fig. 2).

Electrolyte characteristics.—A mixture of HF and N_2O_4 in the mole ratio of 10:1 was used as the electrolyte. Approximate electrolyte conductivities (Table I) were calculated from the measured values of the a-c cell resistance determined in the process of the regular experiments together with a measurement of the a-c resistance of the cell filled with an aqueous 0.1*N* KCl solution.

The results of the vapor pressure measurements are presented in Table II.

Galvanostatic cell discharge.—Galvanostatic polarization curves for the Cd/HF, N_2O_4/Pt and the Cd/HF, N_2O_4/Ni systems at —40° and 60°C are presented in Fig. 3. The potential values were not corrected for iR drops; this correction would total 300-400 mv at the low temperature for 50 ma, and approximately 50 mv at 60°C for the same current.

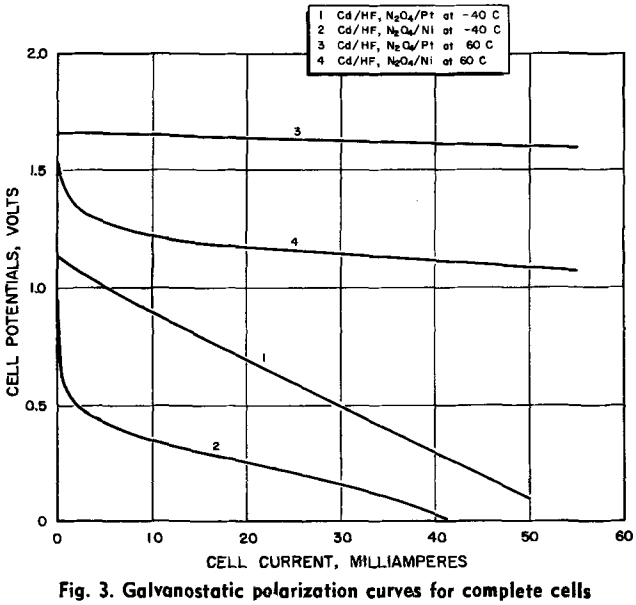

Fig. 3. Galvanostatic polarization curves for complete cells

The potential/current relationship of the cell with a platinized platinum cathode at —40°C (curve 1) was approximately linear; the bulk of the polarization originated at the cadmium anode. With a nickel cathode (curve 2), the contribution from cathode polarization was more substantial.

At 60°C the polarization characteristics of the Cd/HF, N_2O_4/Pt cell were very flat (curve 3). The correction for iR loss in curve 3 would result in practically no polarization up to 1000 ma. If an initial overpotential appearing at low currents is disregarded, the polarization curve for the cell with a nickel cathode at 60°C is flat up to 500 ma (curve 4).

A marked difference of open-circuit potentials was shown at the two different temperatures: 1.66v at 60°C and 1.12v at —40°C (for cells with platinized platinum cathodes).

Galvanic cell discharge curves.—Galvanic discharge curves of the Cd/HF, N_2O_4/Pt cell determined with various ohmic loads are presented in Fig. 4; the temperatures were —40°C (solid lines) and 60°C (dashed lines). Normally, the cell was filled with electrolyte and left on open circuit for 5 to 10 min before discharge was started. For two curves, *i.e.*, for 60 and 10 ohms, the procedure deviated slightly; the load was connected before introduction of the electrolyte or shortly thereafter. Irregularities in such cases occurred because of an adjustment in electrolyte temperature and because of a different behavior of a cell which is only partially filled (the filling procedure covered approximately 1 min). The experiments were not designed to study activation characteristics.

During the course of the experiments, the following two effects can give rise to irregular fluctuations: (*i*) electrode corrosion during the discharge, which increases the surface area and (*ii*) temperature fluctuations of the temperature bath. The main contribution of the cell polarization (disregarding iR drop) resulted from anode polarization. This is evident from galvanostatic data (Fig. 2). The anode and cathode potentials were periodically determined in addition to the continuously recorded cell potential.

At the conclusion of the discharge experiments, grayish, voluminous deposits were observed on the cadmium anodes. These layers, possibly CdF_2, were readily washed away with water.

Direct corrosion of the electrode materials was negligible at low temperature, and the galvanic discharges were all extended over periods of at least 3½ hr. Tests at 60°C were limited to periods of 1 hr because of a uniform attack of the cadmium (0.02-in.-thick sheet) by the electrolyte.

Discussion

The Cd/HF, N_2O_4/Pt system has been established as feasible for a reserve-type primary battery. Experimental discharge rates were moderate at low temperatures (—40°C) and fast at high temperatures (60°C). The use of porous anodes promises substantial improvement of cell characteristics at low temperature because the limitations originated mainly in the anode process. An increase in the active anode surface area by a factor of at least 100 should be readily attainable. Polarization of such an electrode is expected to be less than 100 mv for current densities exceeding 20 ma/cm². A reasonable estimate of the performance which can be achieved with the Cd/HF, N_2O_4/Pt system is summarized in Table III. The observed data (example) have been obtained in the present cell with 1-in.² electrodes. The predicted values are for an improved cell with reduced spacing of the same sized electrodes and with a porous cadmium anode.

The list of possible anode metals has not been exhausted during the present investigation. A more detailed study of anodic characteristics of metals could reveal even better anodes than cadmium. It should be possible to substitute a cheaper electrode material for platinized platinum. Porous nickel, silver, or other metals; carbon, or carbon impregnated with catalysts may allow for a fast electrochemical reaction of the N_2O_4.

The conductivity of the electrolyte at low temperature is sufficient. It should be even higher upon optimization of the HF-N_2O_4 mixture ratio; according to Seel (4) colorless mixtures containing a maximum of 25% N_2O_4 can be prepared. Also, the addition of a salt such as NaF may be beneficial.

No prohibitive corrosion phenomena were observed. Even at high temperatures (60°C), the anode material, which was 0.02-in.-thick cadmium sheet, stood up for at least 1 hr. The vapor pressure of the electrolyte was modest in comparison to some other electrolytes considered for use in low-temperature batteries. Nevertheless, improvements resulting from variation of the electrolyte composition are anticipated (4).

Somewhat less ideal is the temperature dependence of the open-circuit potential; representative measured values for the Cd/HF, N_2O_4/Pt system are 1.14v at —40°C and 1.66v at 60°C. Reversible open-circuit potentials were not measured in all cases, certainly not at nickel cathodes. If the temperature dependence of the cell voltage should prove crucial for certain applications, an improvement should be sought by investigating other anode materials.

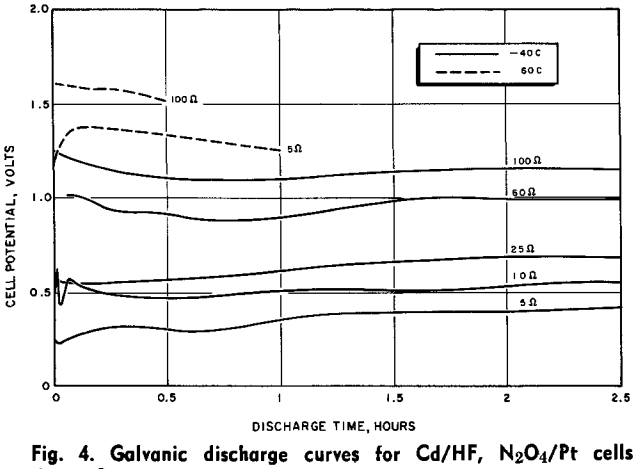

Fig. 4. Galvanic discharge curves for Cd/HF, N_2O_4/Pt cells with 1 in.² electrodes.

Structural Studies of Porous Electrodes

E. Y. Weissman

Research and Development Laboratory, Direct Energy Conversion Operation, General Electric Company, Lynn, Massachusetts

ABSTRACT

Nondestructive techniques are described for the measurement of total electrode surface area, microporosity and pore size distribution, total porosity, and fraction of total porosity consisting of open pores. These measurements have been applied to a class of composite porous electrode structures based on platinum black, Teflon, and a metal screen current collector. They have been shown to correlate with electrochemical performance on the basis of exponential relationships of the type

$$i = a \exp (bS \text{ or } b\Sigma V)$$

where i is the current or limiting current density based on the geometric electrode area, S is the total (BET) surface area, ΣV is the cumulative micropore volume, and a and b are constants depending on the type of electrode and experimental conditions. The electrochemical performance of the electrodes was shown to increase with an increase in the percentage of total open (*i.e.*, accessible) porosity consisting of micropores. It is not clear, at present, whether the relative importance of the micro- and macro-pore structures is actually conducive to maximum or asymptote-type of optimum structure, since no macropore size distribution data are now available. Within the micropore range of 25-350Å pore radius it was shown that the range 25-200 is performance-determining for the class of composite electrode that was studied.

Porous electrode processes, in general, and many aspects of fuel cell investigations, in particular, depend heavily on continued progress in the area of electrode structure optimization. The gradual coming of age of the fuel cell technology has been accompanied by a great variety of theoretical studies attempting to model and to explain quantitatively the operation of porous, catalytic, electrodes.

Since, at least for the time being, porous electrodes are the main workhorse for a variety of fuel cell designs, such studies are entirely justified. Therefore, further clarification as to what constitutes such a structure in any given system becomes of paramount interest; any quantitative geometry measurements could then eventually be applied to existing mechanistic models or to newly derived ones in order to define the electrochemical processes occurring at a typical fuel cell electrode. Design improvements, scale-up data, and adequate quality control would be a natural outcome of such results.

The literature of experimental studies of the geometry of various porous materials, including catalysts, is very extensive. This ceases to be the case, however, when treating the problem of whole, porous, electrodes. Salkind *et al.* (1) reported on a nondestructive method [based on BET (14) gas adsorption measurements] for the determination of surface areas and pore size distributions of porous electrodes; a similar approach was used to study the preparation of platinized-platinum electrodes (2) and to check electrode surface area data obtained also by an electrochemical method (3). Others tried radiographic (4-6), electron microscopic (7), and polarized light microscopy (8) techniques for determination of porous electrode structure and operational parameters.

The importance of the "active porosity spectrum" for the preparation and statistical description of sintered plaque electrodes was described by Feuillade and coworkers (9-10), although the measurements were based on a destructive, mercury intrusion method.

Finally, Paxton *et al.* (11) reported a dependency of the concentration polarization on the micropore structure (again, determined destructively by mercury intrusion porosimetry), while Schwabe (12) indicated the range of pore radii of 100-300Å as determining the current-carrying capability of a certain type of activated carbon electrodes.

In the present paper the technique is described and results are given for a series of nondestructive measurements of surface area, porosity, and micropore size distribution. These tests were conducted on porous platinum black-Teflon-metal screen electrodes of a type previously described (13), and then related to their electrochemical performance.

Experimental

Electrodes were prepared from Teflon and various types of platinum black. The composite structure achieved also included a current collector made of 45 mesh tantalum screen. All electrodes contained 90 w/o (weight per cent) Pt (approx. 34.5 mg/cm^2), were 8.90 x 11.40 x 0.025 cm in over-all size and had an active geometric area of 46 cm^2.

Structural geometry measurements were performed on the finished electrodes at various stages in their preparation (before and after a wetproofing treatment) and evaluation (before and after electrochemical performance testing as anodes). Measurements of the "raw materials" at their various stages of preparation were also made.

Surface areas.—These data were obtained by the BET method (14), using nitrogen adsorption.

The method is based on a generalization of Langmuir's monomolecular adsorption theory, to allow for more than one layer of adsorbed molecules on the surface to be measured. An expression is obtained linking the volume of gas, V, adsorbed at pressure, p, with the saturation pressure of the gas, p_s, the volume of adsorbed gas corresponding to a monomolecular layer, V_m, and a constant, C, which is an exponential function of the heat of adsorption of the first adsorbed layer, E_a, and the heat of liquefaction of the adsorbing gas, E_l, at a given temperature T. This expression can be linearized in the form

$$\frac{p/p_s}{V(1-p/p_s)} = \frac{1}{V_mC} + \left(\frac{C-1}{V_mC}\right)\left(\frac{p}{p_s}\right) \qquad [1]$$

where:

$$C = \exp\left(\frac{E_a - E_l}{RT}\right)$$

The slope, $\frac{C-1}{V_mC}$, and intercept, $\frac{1}{V_mC}$, are obtained from a linear regression of $\frac{p/p_s}{V(1-p/p_s)}$ as a function of the relative pressure of the adsorbate, p/p_s, and the surface area follows from their values plus a knowledge of the molecular area of the adsorbate. For nitrogen, the molecular area, $M.A.$, was calculated as a function of the measured temperature of adsorption (liquid nitrogen temperature), T_s, from existing data (15)

$$M.A. = 3.749\ T_s - 273.850,\ T_s < 77.38°K$$
$$M.A. = 0.0629\ T_s + 11.4020,\ T_s \geq 77.38°K \qquad [2]$$

In general, the molecular area of nitrogen approached the value of 16.2Å².

The equipment used for the BET measurements was a slight modification of the commercially available NUMINCO-ORR Surface Area-Pore Volume Analyzer, Model No. MIC-101.

Figure 1 is a schematic representation of the experimental set-up for gas adsorption measurements. Briefly, the method consists of equilibrating various amounts of adsorbate with the previously cleaned sample (by degassing under heat), at liquid nitrogen temperatures. The necessary material balance data are derived from pressure measurements and from a knowledge of volumes that are either available from calibration values, or from helium displacement measurements. The adsorbate was nitrogen, prepurified grade, filtered through a molecular sieve trap. The helium was filtered through a molecular sieve trap in series with a liquid nitrogen-cooled activated charcoal trap. The saturation pressure of the adsorbate was determined directly, and used also for the calculation of the corresponding temperature of adsorption, according to the relationship (16)

$$T_s = \frac{6.6\ (\log_{10}p_s - 6.49594 - 255.821}{\log_{10}p_s - 6.49594} \qquad [3]$$

The electrodes were contained in specially built stainless steel sample holders. Constructional details for these holders have been given elsewhere (17).

By a judicious choice of the range of relative pressures of the adsorbate, excellent correlatability of the experimental data with the BET equation was obtained. The correlation coefficients for the regression were of the order of 100% and the average deviation (absolute value) less than 1%. Based on standard calibration samples the results were accurate to ± 3% or better, and precise to ± 1.5%.

Pore size distributions.—These data were obtained by a nitrogen capillary condensation method, using the surface area equipment (Fig. 1). The method is based on the assumption of cylindrical, noninteracting, pores and Wheeler's (18) derivation of the pore size distribution expression

$$V_p - V_a = \int_{R_c}^{\infty} \pi\,(r_w - t)^2\,L\,dr_w \qquad [4]$$

where: V_p is the total pore volume, V_a the volume adsorbed, r_w the pore radius, t thickness of the adsorbed layer, function of the relative pressure of the adsorbate, p/p_s, L the pore size distribution function, defined as the total length of all pores of radius r_w per unit weight of adsorbent, and R_c is the critical pore radius, below which all pores are completely filled by adsorbed or condensed gas, function of the relative pressure of the adsorbate p/p_s

The adsorption and desorption isotherms supplying the needed data for this method exhibit a hysteresis. The desorption points are considered to be closer to the true, thermodynamic, equilibrium; they were the only ones taken into account in the present measurements (see Fig. 2 for an example of such a desorption isotherm). Pierce's method (19) has been chosen for the numerical integration of Eq. [4].

By a careful choice of technique, pore radii could be measured covering the range 20-600Å. This covers the entire micropore region[1] and the transition micropore-macropore. A suitable nondestructive method for

[1] Defined as the region where the pore diameters are equal to or smaller than the mean free path of the gas molecule of interest; this is the situation where Knudsen diffusion prevails.

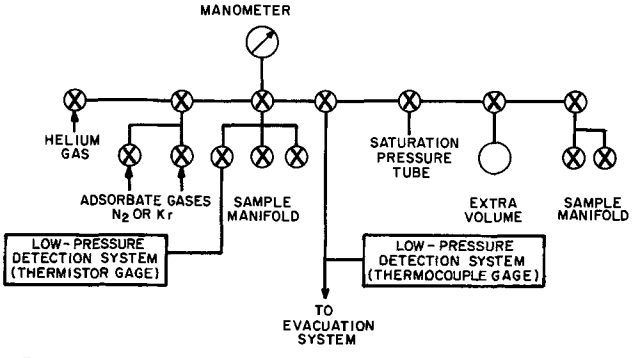

Fig. 1. Diagram of gas adsorption set-up used for surface area and pore size distribution measurements.

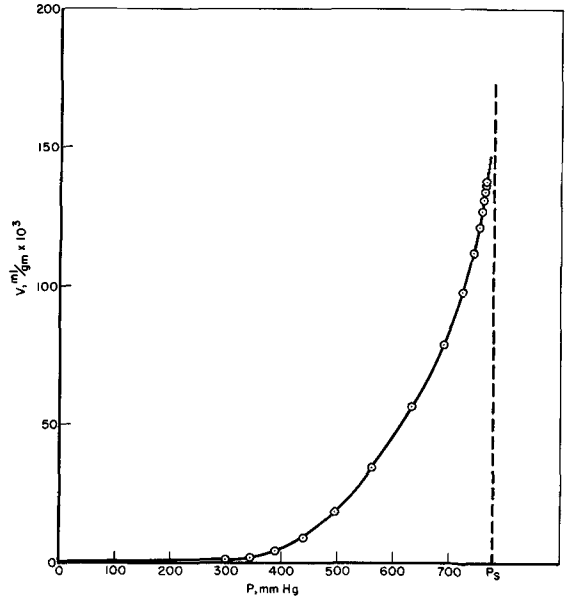

Fig. 2. Nitrogen desorption isotherm for a porous platinum-Teflon electrode.

the balance of the pores of interest, in the macropore region, has yet to be developed.

The processed data were then plotted as cumulative pore volumes *vs.* pore radius, and as pore size distribution curves (derivatives of volume in terms of radius *vs.* the average radius, *e.g.*, Fig. 3) of characteristic multi-modal shape. This afforded a "fingerprinting" of the electrodes or catalytic raw materials of interest.

Porosities.—The total porosity was calculated from measured weights of the various solid ingredients (of known densities) constituting an electrode, and electrode dimensions.

The microporosity, ϵ_μ, for any given range of pore sizes, followed from a knowledge of the cumulative pore volume (as obtained from the pore size distribution measurements) for given weights and dimensions of the catalytic structure.

The fraction of total porosity consisting of open-ended pores, accessible to a fluid phase, was determined by a buoyancy method based on weight data for the electrode in air and in water (after careful and repeated vacuum-impregnation with water).

Calculations.—All the surface area, pore size distribution, and porosity calculations were processed by means of an IBM 7044 digital computer based on FORTRAN IV programs. A CALCOMP subroutine yielded the automatically plotted cumulative pore volume and pore size distribution graphs.

Electrochemical measurements.—Polarization curves were obtained for the oxidation of propane at 150°C with 90% phosphoric acid as an electrolyte. The counter electrodes were structurally similar to the anodes and operated on pure oxygen.

The anode potentials were determined IR-included and IR-free [by means of a Kordesch-Marko bridge (20)] and referred to a reversible hydrogen electrode in the same solution.

Results and Discussion

Two aspects of interest will be covered in this section: (*a*) the structural geometry measurements *per se* and their significance, and (*b*) the relationship between structural geometry and electrochemical data.

While the results have been obtained from a study of specific electrode structures it is felt that the findings and conclusions derived therefrom are sufficiently general to apply, at least qualitatively, to the entire family of porous gas diffusion electrodes based on composite Teflon-metal screen-metal black structures.

Structural geometry measurements.—Figure 2 is a typical representation of a nitrogen desorption isotherm obtained with the type of porous platinum-Teflon composite electrodes under discussion. It clearly exhibits a type 3 shape, characteristic of multi-molecular adsorption. The corresponding pore size distribution is exhibited in Fig. 3.

The first peak, always observed at radii of 20-50Å, is present also in the "raw material" (platinum black) from which the electrode is made; as such, it should mostly be representative of the intra-particle geometry characteristic of the material.

The peaks at higher pore radius values, such as 250 and 575Å in this case, are generally different to a degree from those exhibited by the powdered platinum black; consequently, they are mostly a result of the interparticle configuration obtained as a function of the electrode preparation technique and the ingredients used. The presence of characteristic peaks close to the threshold value of 600Å (radius), beyond which the capillary condensation method breaks down, makes the development of a nondestructive technique for macropore measurements of considerable interest. The need for such additional information is also suggested by the available data on the extent of total, open, porosity consisting of macropores (see Fig. 5).

Pore size distribution calculations are based on the assumption that the pores are cylindrical in shape. This is obviously not the case, and a surface area calculated on this basis (where: surface area = 2 x volume of pores/average pore radius) would be expected to be too low because of irregularities on the walls of the pores, and too high because of pore interactions. In many instances these two separate effects offset each other with a resulting agreement between the BET-calculated area and the area obtained from pore size distribution data.

Such happens to be the case with the platinum and platinum-Teflon samples; however, complete electrodes exhibit a disagreement by a factor of roughly 2, with the BET results being the lower ones. This is represented in Fig. 4 and has also been reported in the

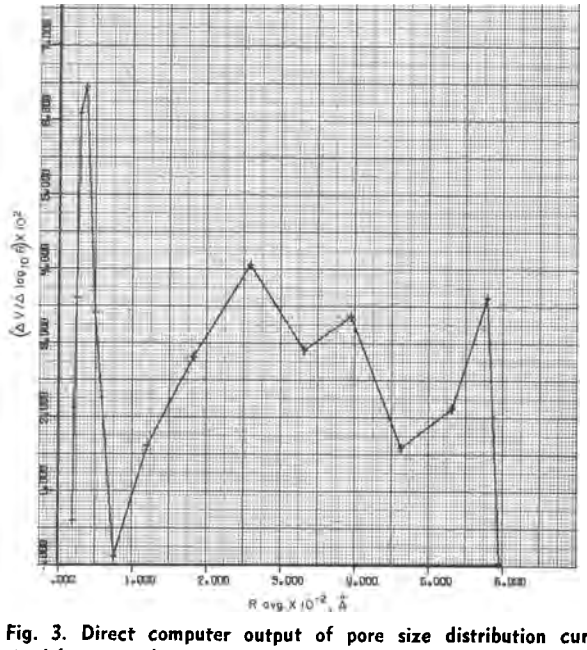

Fig. 3. Direct computer output of pore size distribution curve derived from cumulative nitrogen desorption data (Fig. 2).

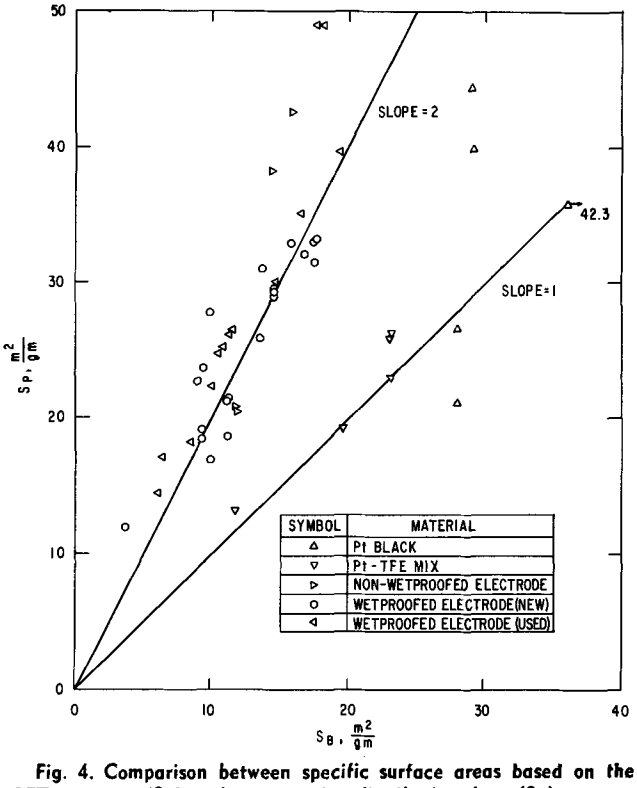

Fig. 4. Comparison between specific surface areas based on the BET equation (S_B) and on pore size distribution data (S_P).

Table I. Effect of electrode manufacturing steps on the measured BET surface areas and cumulative micropore volume for the pore radius range 25-350Å
Data in % of the original platinum black value; in brackets: the cumulative micropore volume

Platinum black type*	Measured surface area, m^2/g	Electrode pressing temperature, °F	Data (%) for: Platinum black powder	Powdered Pt-TFE mix	Finished electrode	No. of electrodes used in study
A	29.11	550	100 (100)	80 (46)	60 (46)	4
		606			52 (40)	2
		650			48 (38)	2
B_1	27.97	550	100 (100)	42 (69)	33 (72)	2
B_2	42.30	550	100 (100)	46 (74)	24 (60)	2

* Type A = Engelhard 25 (*i.e.*, Manufacturer: Engelhard Co.; Nominal specific surface area, as reported by manufacturer: 25 m^2/g); type B_1 = Bishop 24 (same general meaning); type B_2 = Bishop 35 (same general meaning).

literature, for instance for silica-alumina catalyst pellets (21). Thus, the significant geometry changes, interparticle geometry, in this case, coming into play once the electrode is prepared from certain raw materials become evident. In the discussion that follows, the results will be interpreted in terms of the more correct, BET, surface area data.

Another aspect of this geometry change, when passing from a powdered or granular material to a finished electrode structure, follows from an examination of the data in Table I. The sintering process, as evidenced by reductions in the surface area and cumulative micropore volume, is shown to depend on a variety of factors: (*a*) the electrode pressing temperatures, with more pronounced sintering at higher pressing temperatures; (*b*) the catalyst type or manufacturer; and (c) the original platinum black area; the higher the area the more extensive the extent of sintering, everything else being equal.

Further evidence regarding the dependence of electrode structure on the three above-mentioned factors as well as on a fourth one: the history of the electrode (new or used, *i.e.*, before or after electrochemical evaluation), is offered by the graphical representation in Fig. 5.

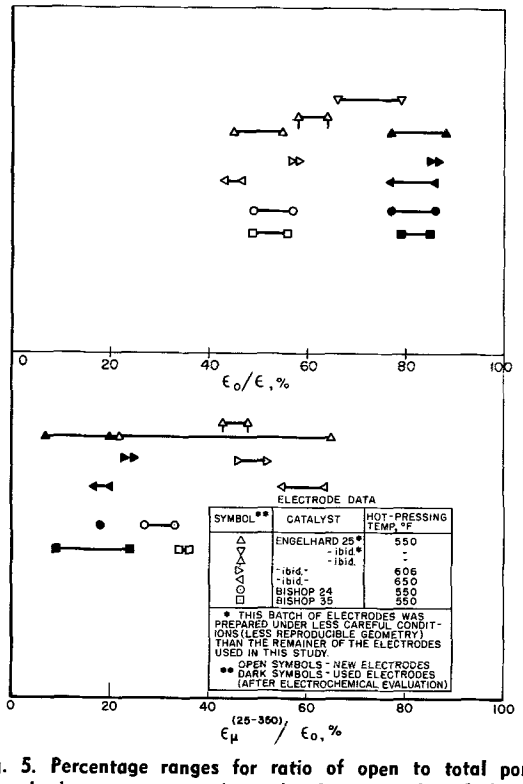

Fig. 5. Percentage ranges for ratio of open to total porosity, ϵ_o/ϵ, and micro-to open-porosity, ϵ_μ/ϵ_o, for new and used electrodes.

One immediately notes that all the electrodes, independent of their history, possess appreciable porosity fractions consisting of macropores; this is indicated by values of the ratio $\epsilon_\mu^{(25-350)}/\epsilon_o$ that are significantly lower than unity. Here, $\epsilon_\mu^{(25-350)}$ represents the microporosity based on cumulative micropore volumes for the pore radius range: 25-350Å, and ϵ_o is the total porosity of the electrode consisting of open pores.

In new electrode structures, this contribution of the macroporosity appears to be not only a function of the type of catalyst used but also of the manufacturing conditions. Thus, it increases with an increase in the hot-pressing temperature, indicating that the probably higher Teflon flow and catalyst pore masking resulting from higher pressing temperatures affect smaller pores to a larger extent.

Another finding that can be derived from Fig. 5 pertains to the fraction open porosity: ϵ_o/ϵ (where ϵ is the total porosity). This appears to become significantly larger for electrodes that have been put on load even for only a few hours. Furthermore, this added open porosity is mainly due to macropores.

The fraction open porosity also appears to change as a function of the type of catalyst used, and it increases when the hot-pressing temperature used in the manufacture of the electrode is decreased. This latter effect can be explained by the correspondingly smaller extent of sintering and of pore masking due to Teflon flow.

Figure 4 indicated a relatively constant correspondence between BET—and capillary condensation—derived values of surface area. On that basis, a correlatability between cumulative micropore volume and BET areas would be expected to follow directly. This is exhibited in Fig. 6 for a great variety of platinum black-Teflon electrodes; the "stray points" are predictably accounted for by the powdered raw material samples which, as was also shown in Fig. 4, obey a different type of relationship between the two kinds of surface area values mentioned above.[2]

The possibility of expressing cumulative micropore

[2] In this and the following figures some of the experimental points have values certain only within a range of several per cent; this is indicated by arrows pointing in the direction corresponding to the range of possible data variation.

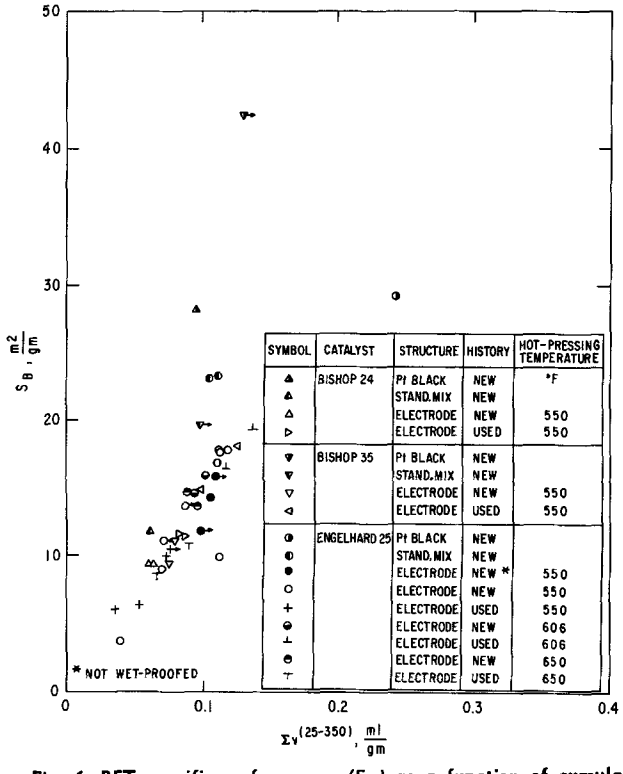

Fig. 6. BET specific surface area (S_B) as a function of cumulative micropore volume for range of pore radii 25-350Å ($\Sigma V^{(25-350)}$).

volumes in terms of BET surface areas, or vice-versa, will have a very pertinent significance in the discussion of performance *vs.* structure results that follows below.

Relationship between structural geometry and electrochemical performance.—A complete picture of the performance dependence on structure for an operating porous electrode has to await pertinent data on the true, electrochemically active area, in addition to the total area described here, as well as some quantitative information on the macropore structure. This would be essential in interpreting existing theoretical models or in deriving modified or new versions. On the other hand, from measurements currently in progress (22) it would appear that total BET areas for porous electrodes of the type considered here are quite representative of true areas as well. The results discussed in this section, while not directly applicable to a rigorous consideration of operating electrode models, are nevertheless adequate to represent characteristic trends in the dependence of electrochemical performance on porous structure.

An examination of how the current density at a chosen anode overvoltage varies as a function of the measured BET surface area suggests either a linear or an exponential type relationship. At this stage, the justification for such relationships is purely empirical; a linear regression analysis of these data, and others to be discussed in what follows, indicates somewhat better correlation coefficients (by about 5%) in the case of the exponential relationship. Accordingly, Fig. 7 is a representation of the logarithm of current density for propane oxidation, measured at an IR-free anode potential of 600 mv *vs.* H_2/H^+, *vs.* the BET surface area of the new electrodes prior to performance evaluation. This corresponds to a relationship of the type

$$i = a \exp(bS) \qquad [5]$$

where i is the current density based on the geometric electrode area, S is the surface area, and a and b are constants depending on the type of electrode and experimental conditions.

If one considers a rate limitation in terms of both activation and concentration polarizations, η_{ac}, with the value of the activation polarization: $|\eta_a| >> (RT/n\mathbf{F})$, which happens to be our case, one obtains

$$\eta_{ac} = A + B \ln i + \frac{RT}{n\mathbf{F}} \ln\left(\frac{i_L}{i_L - i}\right) \qquad [6]$$

where the various symbols have the usual significance; one notes that for an anodic process

$$A = -\frac{RT}{(1-\alpha)\, n\mathbf{F}} \ln i_o \qquad [7]$$

$$B = \frac{RT}{(1-\alpha)\, n\mathbf{F}}$$

One also notes that, for any given current density i referred to the geometric area of the electrode, the over-all polarization η_{ac} is a function of the total available area consisting of active sites and approximated in this case by the BET surface area

$$\eta_{ac} = f(S) \qquad [8]$$

While Eq. [6] is not necessarily valid in each case, particularly for porous electrodes, one observes that by combining [6], [7], and [8] and rearranging on an antilogarithm basis the following relationship is obtained.

$$i\left(\frac{i_L}{i_L - i}\right)^{(1-\alpha)} = i_o \exp[f(S)/B] \qquad [9]$$

It is interesting to note that this implicit expression of i in terms of S is also suggested, admittedly with a certain degree of scatter, by the simple form of empirical Eq. [5].

A similar form is obtained when considering only the limiting current density (again, with respect to the geometric area of the electrode) *vs.* the BET surface area; this is represented in Fig. 8.

Since cumulative micropore volumes were available for all the electrodes investigated over the pore radius range 25-350Å, their values were also considered as an independent variable instead of the surface area. Figures 9 and 10 again demonstrate an exponential dependence of geometric current density and limiting current density, respectively, on the cumulative micropore volume; this is also another way of representing the correspondence between BET surface area and micropore volume (Fig. 6).

Up to this point the treatment and representation of the experimental data would seem to suggest that

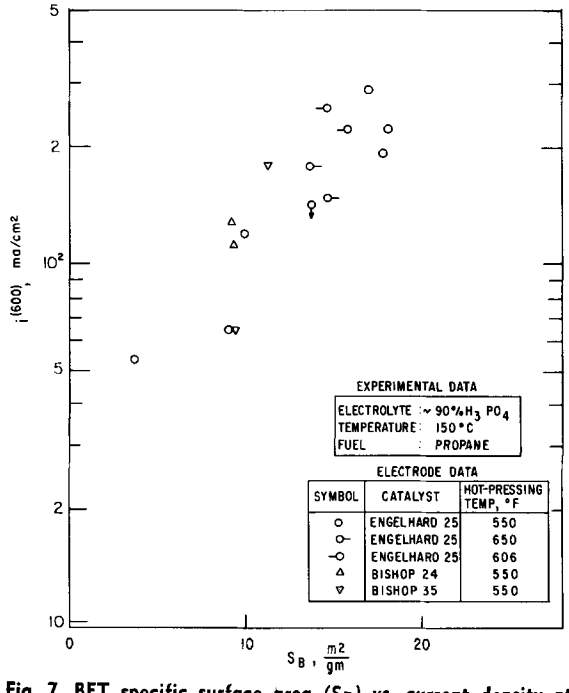

Fig. 7. BET specific surface area (S_B) *vs.* current density at an IR-free anode potential of 600 mv *vs.* H_2/H^+ ($i^{(600)}$).

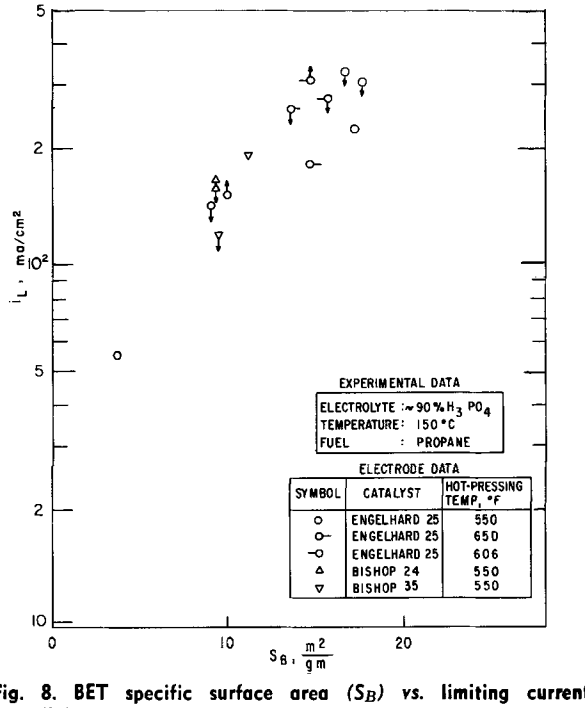

Fig. 8. BET specific surface area (S_B) *vs.* limiting current density (i_L).

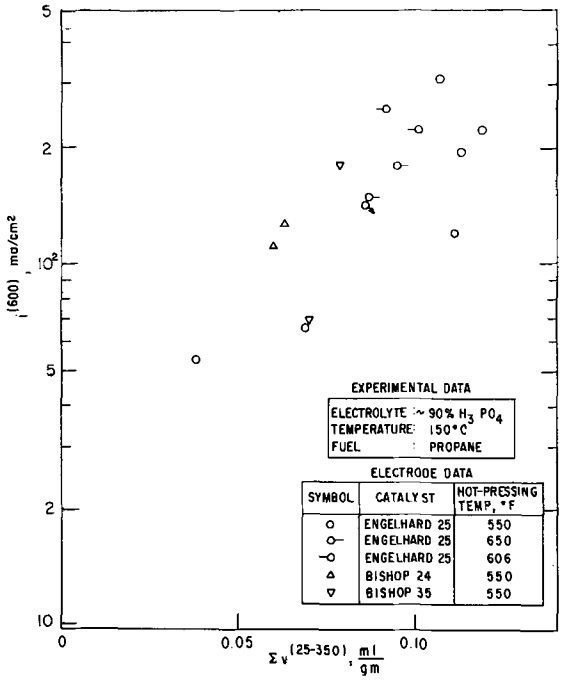

Fig. 9. Cumulative micropore volume for the pore radius range: 25-350Å ($\Sigma V^{(25-350)}$) vs. current density at an IR-free anode potential of 600 mv vs. H_2/H^+ ($i^{(600)}$).

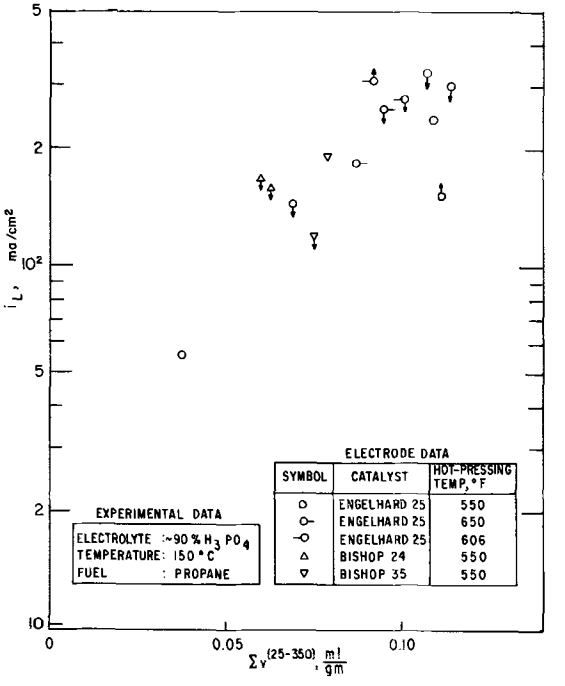

Fig. 10. Cumulative micropore volume for the pore radius range: 25-350Å ($\Sigma V^{(25-350)}$) vs. limiting current density (i_L).

macropore structure effects may not be of great consequence to the electrochemical performance of porous composite electrodes of the type examined here. Indeed, we observe a fair correspondence between the measured micropore volume and the BET surface area, indicating that most of the area is due to the micropores. This in turn is expressed as performance-determining, on an exponential basis.

On the other hand, the bearing that the macropore structure would have in this type of "mixed-pore electrode" on the dynamic capillary equilibria between the electrolyte phase and the reactant phases cannot be ignored. Certainly, on a long-term sustained-operation basis, the degree of utilization of active sites and, as a result, the electrochemical performance and rate of performance decay must be dependent on this macropore-micropore interrelationship. A number of theoretical models derived for porous electrodes are based on a variety of hypotheses on precisely these kinds of pore structure considerations.

On a short-term operation basis, as used in this work for electrochemical measurements, the importance of macroporosity may indeed be unjustifiably subtle. In order to gain some understanding on this point, one can attempt to utilize the only types of pertinent information available at present, namely, nondestructive porosity measurements.

Another aspect of interest, regarding the influence that micropore structure has on electrode performance (11, 12, 23) can be considered in a special sense. This is the question of what portion of the actually measured micropore structure appears to be of greater consequence to performance.

Both of these aspects will now be examined in some detail.

Figure 11 illustrates what happens when current density is referred to specific portions of the micropore structure. In this case, it appears that mostly the pore radius range 25-200Å is performance-determining, out of the total range under consideration, 25-350Å. This examination could conceivably be refined still further, if warranted by additional data, by considering smaller increments of cumulative pore volume. The findings are qualitatively corroborated by similar studies reported for activated carbon electrodes (12).

Figure 12 suggests this dependence on pore radius, in the micropore size range, by examining graphically the relationship between current density or limiting current density and the fraction of the total pore volume (range 25-350Å) consisting of pores in the range 25-200Å. The trend is more obvious for the case where the current density is the dependent variable but, in any case, the data scatter is such as to justify only qualitative conclusions at this point.

The relative importance of micro- and macro-pore structure is graphically represented in Fig. 13 and 14, in terms of measured porosities. A log-log dependence is exhibited between current and limiting current, respectively, and the fraction of the total open porosity consisting of micropores in the range 25-350Å. One

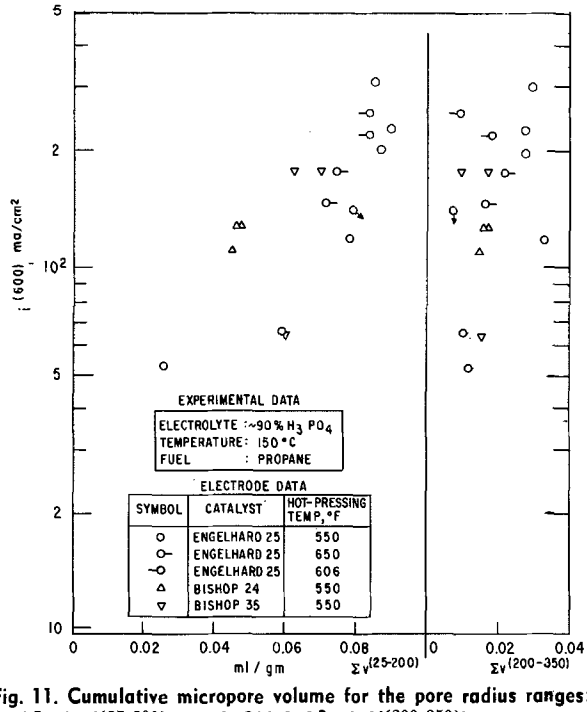

Fig. 11. Cumulative micropore volume for the pore radius ranges: 25-200Å ($\Sigma V^{(25-200)}$) and 200-350Å ($\Sigma V^{(200-350)}$) vs. current density at an IR-free anode potential of 600 mv vs. H_2/H^+ ($i^{(600)}$).

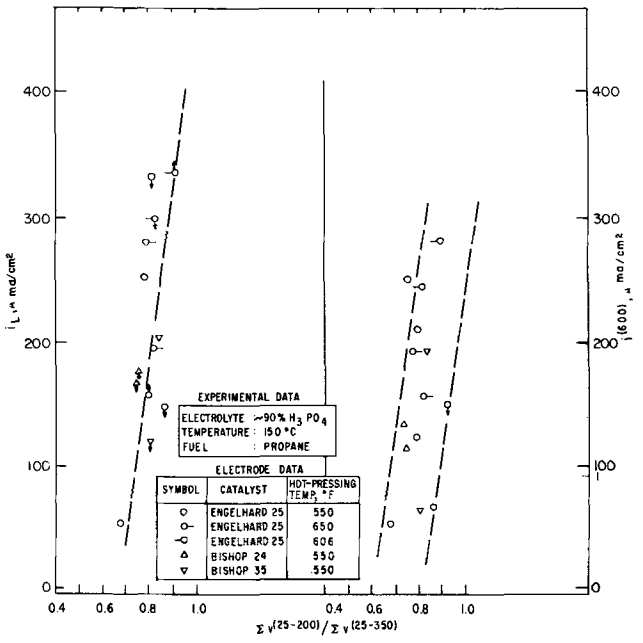

Fig. 12. Limiting current density (i_L) and current density at an IR-free anode potential of 600 mv vs. H_2/H^+ ($i^{(600)}$), as a function of the fraction of the total measured micropore volume composed of pores in the radius range: 25-200Å ($\Sigma V^{(25-200)}/\Sigma V^{(25-350)}$).

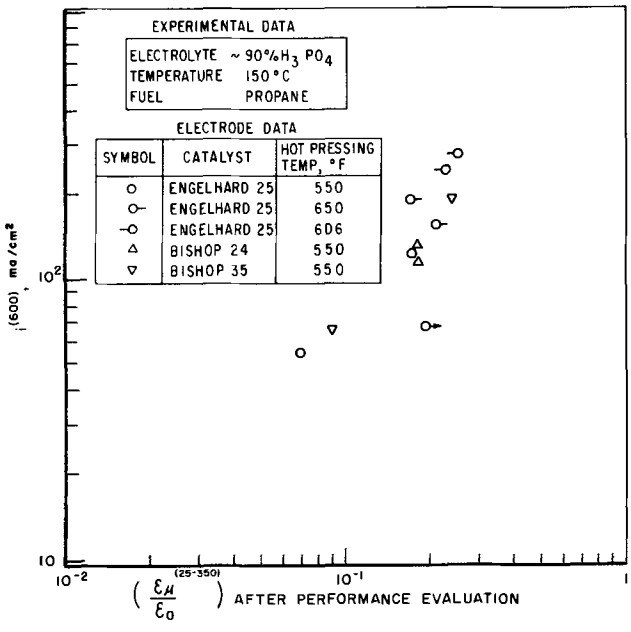

Fig. 13. Current density at an IR-free anode potential of 600 mv vs. H_2/H^+ ($i^{(600)}$) as a function of the fraction of the total open porosity consisting of micropores in the radius range: 25-350Å ($\epsilon_\mu^{(25-350)}/\epsilon_0$).

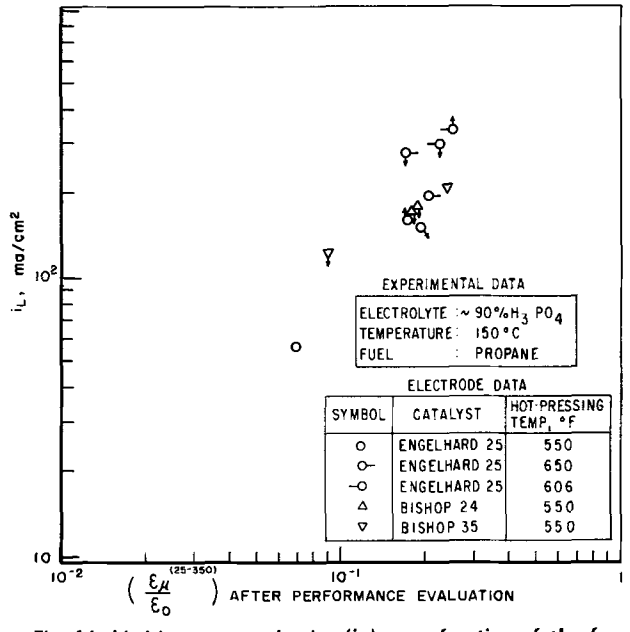

Fig. 14. Limiting current density (i_L) as a function of the fraction of total open porosity consisting of micropores in the radius range: 25-350Å ($\epsilon_\mu^{(25-350)}/\epsilon_0$).

observes the rather interesting fact that, as this porosity ratio increases in favor of more micropores, the performance improves. It is not clear at present whether this relative importance of the micro- and macro-pore structures is actually conducive to a maximum or asymptote type of optimum structure. This type of information would depend on the development of adequate nondestructive methods for the measurement of pore size distributions over a wider range than is presently possible. It is interesting to speculate, however, that in the case of apparent micropore structure control as suggested here the film mechanism used in a variety of electrode models is not necessarily dominating; instead, bulk diffusion into the smaller, flooded, pores may be controlling. Another possibility might be a capillary-type control of the diffusional process in the pores, in terms of film-activated macropores "fed" with fresh liquid surfaces from flooded micropores (23).

Thus, the existing data do seem to demonstrate the importance of extending our present knowledge of performance-structure dependence, while, at the same time, suggesting the possibility of ultimately tailoring optimum configurations from the information at hand. For the time being, any theoretical model describing the operation of the class of porous electrodes covered in the present work will have to take into account the apparent role of the micropore structure, in general, and of certain portions of this micropore structure, in particular. Whether this role will be strictly one of establishing the right electrolyte-reactant phase equilibrium or not, remains to be seen.

Conclusions

1. Nondestructive measurements of structural parameters for porous electrodes of any size are possible, and they offer the advantage of direct correlatability with electrochemical performance. Surface area and porosity can be determined for the whole electrode, the former with a great degree of precision and accuracy. The nondestructive pore size distribution measurements are presently limited to pores 600Å or less in radius, *i.e.*, to that portion of the electrode structure that is mostly in the micropore range where gas molecules would be transported by Knudsen rather than bulk diffusion.

2. Variables such as catalyst type and manufacturer, original catalyst area, electrode manufacturing conditions such as the hot-pressing temperature, and electrode history, all determine to a significant degree the values that the various structure parameters will have.

3. There is a good correspondence between BET-derived electrode surface areas and cumulative micropore volumes. Conversely, the use of electrode surface areas derived from pore size distribution data can lead to values that are higher than the BET results by a factor of roughly 2; these higher figures are believed to be in error due to the assumptions inherent in the integration of the pore size distribution equations.

4. All electrodes possess appreciable fractions of macroporosity; this fraction also appears to be the main contributor to the increase in open porosity characteristic of electrodes that have been put on load.

5. Electrochemical anode performance appears to

increase exponentially or linearly (with slightly more experimental data scatter) with electrode surface area or micropore volume. The micropores themselves play a rather important role when their contribution is compared to that of the entire electrode (in terms of porosities). Furthermore, within the micropore spectrum there are ranges of pore sizes that appear to have more bearing on the electrochemical performance than others. For a porous composite structure of the platinum black-Teflon-metal screen type the more active portion of micropores, consisting of radii in the range 25-350Å, is limited to the range 25-200Å.

Considerably more work is necessary, in terms of more data of total as well as true (electrochemically active) surface areas, and nondestructive pore size measurements encompassing the macropore as well as the micropore spectrum. This should eventually lead to a finalization and generalization of these conclusions and additional ones, as well as to working theoretical models and tailor-made optimum porous electrode geometries.

Electrochemical Studies on Lead in Organic Electrolytes

M. L. Bhaskara Rao

Laboratory for Physical Science, P. R. Mallory & Company, Inc., Burlington, Massachusetts

ABSTRACT

Galvanostatic anodic charge and cathodic discharge curves have been obtained for lead and lead alloys in two organic electrolytes: propylene carbonate, 1M in $LiAlCl_4$, and γ-butyrolactone, 0.5M in LiCl. Charging curves exhibited periodic (oscillatory) voltage phenomena followed by passivation. Discharge curves of pre-anodized electrodes showed a single plateau corresponding to the reduction of $PbCl_2$ to Pb. Utilization efficiencies obtained from charge and discharge coulombs ranged from 10 to 100% depending on the current density, alloy composition, and electrolyte. Differences in observed behavior have been explained, and the suitability of $Pb/PbCl_2$ electrodes for rechargeable organic electrolyte cells is discussed.

During the past few years there has been an increased interest in electrochemical investigations in organic electrolyte media. Most of these efforts have been directed toward the development of high energy density batteries. Analysis of the state of the art reveals that for a success in this endeavor it is necessary to understand more about the chemical and electrochemical behavior of the cathode salts. In the course of developmental work in this field we have earlier reported some observations on the formation and discharge of copper chloride (1). The present paper deals with electrochemical studies on lead leading to the possibility of operation of lead chloride electrodes in an organic electrolyte.

Experimental

The cell.—Electrochemical experiments were carried out in a Pyrex glass H-cell of 50-ml capacity with a sintered glass frit separating the two compartments. The cell had a suitable polytetrafluoroethylene lid with provision for mounting the electrodes and for

admitting dry argon to maintain a moisture-free inert atmosphere over the electrolyte.

Electrolytes.—The electrolytes were 1M $LiAlCl_4$ in propylene carbonate and 0.5M LiCl in γ-butyrolactone. These were prepared by dissolving calculated amounts of the salts in known volumes of pre-purified solvents. The procedures for the purification of the solvents have been described earlier (1).

Electrodes.—Solid lead foil electrodes, amalgamated lead, lead silver (5-15 w/o Ag) and lead-tin (33 w/o tin) were employed in the studies.

The lead foil samples were Fisher test grade, 5-15 mils thick. The foils were degreased in trichloroethylene and treated with 600Å polishing paper or chemically cleaned by immersing the degreased samples in 5*N* aqueous HNO_3 for 2 min at room temperature. The samples were then rinsed with water followed by acetone, and dried. The chemically cleaned electrodes had been etched in the process. Working electrodes of 2-5 cm^2 superficial area were cut from the treated samples.

Lead alloys of silver were prepared in the laboratory. The tin alloy of lead was commercial plumber's solder.

Pasted plate lead chloride electrodes were of the weight composition 9:1:0.5::$PbCl_2$: graphite: ethycellulose. These were made by spreading the mixture of the components as a paste in xylene over graphite cloth and drying the samples in air. The coulombic capacity of the electrodes was between 2.5 and 10 ma-hr/cm^2.

Measuring setup.—The electrochemical measurements were galvanostatic. The constant current was provided from an electronically controlled power supply of Electronic Measurement Inc., Model 620. The counter electrode was a strip of lithium placed in the counter electrode compartment of the H-cell. The potential of the working electrode was measured against a silver reference electrode situated in the same solution at 2 mm from the former. An E-H Labs Electrometer, Model 230, was used for potential measurement. The output from the electrometer was fed to a Mosley Autograph 680 recorder to register the data.

Anodic and cathodic measurements were made at currents between 2.5 and 10 ma cm^{-2} based on superficial area of the electrodes.

The solubility of the lead salt formed during anodization of the lead metal in the organic electrolytes was measured by polarography. Aqueous 1M HCl solutions containing 1-2 v/o (volume per cent) aliquots of the working solution were employed for the purpose. A Metrohm Polarecord Model E-261 unit was used to obtain the polarograms.

A Phillips type 422730 x-ray diffraction unit was employed to identify the electroformed salt. The measurements employed copper radiation with a nickel filter.

Results

Anodic behavior of chemically treated lead in 1M $LiAlCl_4$-P.C.—The galvanostatic anodic behavior of chemically cleaned lead in 1M $LiAlCl_4$-P.C. is shown in Fig. 1. The data in curves 1 to 4 are for apparent current densities of 2.5 to 10 ma cm^{-2}, respectively. It is seen that on anodization the lead electrodes exhibit periodic oscillation in voltage, followed by passivation. In the passive region the electrode potential increased linearly with time and indicated erratic fluctuations above 40v. Analysis revealed that the rate of change of potential with time was directly proportional to the current density in the linear region as is shown in Fig. 2. Current interruption at all stages of anodization resulted in an open-circuit voltage of approximately —0.25v *vs.* Ag. If anodization were continued to passivation, the electrodes exhibited a memory effect in that, following current interruption, the potential after the resumption of anodization rose to the value observed at the point of current interruption. This

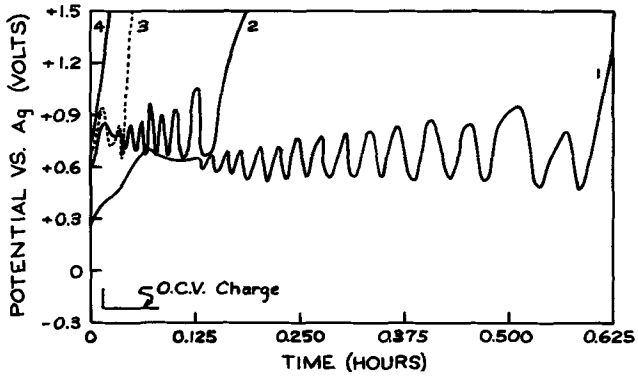

Fig. 1. Anodic charging of chemically etched lead in 1M $LiAlCl_4$-P.C. Curves 1, 2, 3, and 4 are for 2.5, 5, 7.5, and 10 ma cm^{-2}, respectively.

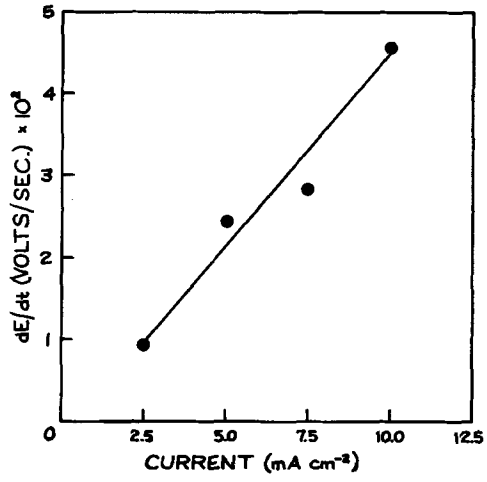

Fig. 2. Plot of (dE/dt) vs. current density

memory effect persisted even when the electrodes were left on open circuit in stirred solution as long as 5 min.

Cathodic discharge curves of electrodes pre-anodized to 40v *vs.* Ag are shown in Fig. 3. In these experiments the cathodic current densities were the same as used for anodization. It is seen from curves 1 to 3 that the electrodes exhibited overshoots in the initial stages of cathodization. However, the overshoot was far less than the potential of 40v reached at the end of the preceding anodization, and the utilization efficiencies were less than 100% at all current densities.

Anodic behavior of polished lead electrodes in 1M $LiAlCl_4$-P.C.—Figure 4 shows the successive anodic

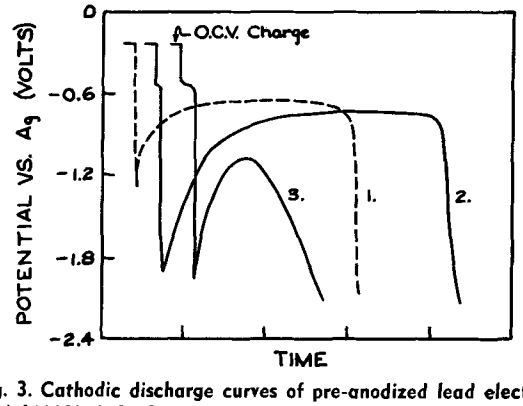

Fig. 3. Cathodic discharge curves of pre-anodized lead electrodes in 1M $LiAlCl_4$-P.C. Curves 1, 2, and 3 are for 2.5, 5, and 10 ma cm^{-2} with time scale 7.5 min, 2 min, and 1 min per division, respectively.

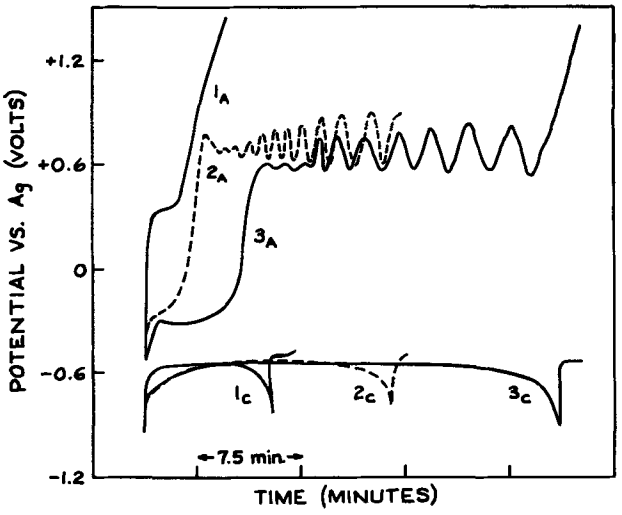

Fig. 4. Anodic charge and cathodic discharge behavior of lead in 1M $LiAlCl_4$-P.C. at current density 2.5 ma cm^{-2}. Curves 1_a and 1_c are charge discharge curves for 0.5 ma-hr cm^{-2} on 1st cycle; curves 2_a and 2_c are charge discharge curves for 1 ma-hr cm^2 on 2nd cycle; curves 3_a and 3_c are charge discharge curves for 2.5 ma-hr cm^{-2} on 3rd cycle.

and cathodic behavior of a polished lead electrode in 1M $LiAlCl_4$-P.C. at 2.5 ma cm^{-2}. Successive cycling of the same electrode increased the anodic charge before passivation from 0.5 to 2.5 ma-hr cm^{-2}. Although potential oscillation occurred during the anodization, the faradaic efficiency of subsequent cathodization was 100%.

Cathodic discharge of pasted plate lead chloride electrodes in 1M $LiAlCl_4$-P.C.—The discharges of typical pasted plate lead chloride electrodes of capacity 7.5 ma-hr cm^{-2} were similar to curves 1_c to 3_c in Fig. 4 in that the open-circuit voltage of the system was close to —0.25v *vs.* Ag. The cathodic discharge efficiency based on the known weight of $PbCl_2$ was greater than 90% at 5 ma cm^{-2}.

X-ray diffraction of the deposit formed on lead electrodes anodized in 1M $LiAlCl_4$-P.C. indicated mostly $PbCl_2$. In case of heavily anodized (>30v) electrodes some PbO_2 was observed in the $PbCl_2$ deposits.

Behavior of lead alloy electrodes.—In the anodization of lead-silver alloys (5-15 w/o Ag) in 1M $LiAlCl_4$-P.C. the oscillatory voltage behavior still persisted very nearly the same as on pure lead. The open-circuit voltages of anodized electrodes were more positive than that of the $Pb/PbCl_2/Cl^-$ system and were unsteady. The lead-tin alloy (33 w/o tin) was capable of supporting 5 ma-hr cm^{-2} anodic charge density (at 5 ma cm^{-2}) before oscillatory voltage behavior ensued. It is interesting to note that under the conditions of experimentation passivation occurred on lead even below 0.5 ma-hr cm^{-2} of anodic charge density. However, from the cathodization experiments, the calculated utilization efficiencies were found to be lower than 80%.

Anodization of the amalgamated electrodes in 1M $LiAlCl_4$-P.C. exhibited neither oscillatory phenomena nor passivation even up to 20 ma-hr cm^{-2} of anodic capacity. X-ray diffraction did not indicate any mercury halide inclusions in the $PbCl_2$ films of the anodized samples. The utilization efficiencies of these electrodes were greater than 90%.

Behavior of lead electrodes in 0.5M LiCl *in γ-butyrolactone.*—Experiments carried out to study the electrochemical behavior of lead electrodes in 0.5M LiCl in γ-butyrolactone showed neither passivation on anodic polarization nor the prepassivation oscillatory voltage behavior in the current density range of 2.5-10 ma cm^{-2}. The faradaic efficiency obtained on subsequent cathodization was less than 10% for 2.5 ma-hr cm^{-2} anodic charge. The working solution was examined to estimate the concentration of dissolved Pb^{++} ions. The analysis indicated a material balance equivalent to 100% anodic efficiency and suggested the dissolution of the electroformed Pb^{++} as the cause of low cathodic efficiency.

Lead chloride solubility.—The solubility of $PbCl_2$ in propylene carbonate, 1M $LiAlCl_4$-P.C. and γ-butyrolactone was low (<0.0005 m/l) at 25°C. However, $PbCl_2$ was soluble in 0.5M LiCl in γ-butyrolactone.

To examine this solubility behavior of $PbCl_2$ in the LiCl in γ-butyrolactone, 0.1 mole equivalent of $PbCl_2$ was added to 100 ml of γ-butyrolactone solutions containing different molarities of LiCl, and the solutions were equilibrated at room temperature by stirring the mixture over a period of a day. A complete dissolution of the lead salt was observed in solutions containing 0.2M LiCl. This indicated the formation of a soluble $PbCl_4^=$ complex.

Discussion

A comparison of the anodic behavior of chemically treated (etched), mechanically polished, and cycled electrodes shown in Fig. 1 and 4 suggests that the differences in the oscillatory voltage behavior for measurements performed at equal apparent current densities may be ascribed to the differences in the true surface area of the three types of electrodes.

Oscillatory phenomena attending electrocrystallization in aqueous media have been described (2-12) earlier. Various mechanisms involving mechanical breakdown and rehealing of anodic films or dissolution and reformation of films due to valence changes of the anodic species have been proposed to account for the oscillatory behavior. By x-ray diffraction we find that $PbCl_2$ is the major product of anodization in the experiments shown in Fig. 1 and 4. Therefore it is presumed that the oscillatory behavior observed in these experiments reflects the particular mechanism by which $PbCl_2$ is anodically formed from the lead metal.

Analysis of the passive region of the heavily anodized (>30v) lead electrodes is shown in Fig. 2. The variation of electrode potential with time follows Eq. [1]

$$\frac{(dE)}{(dt)} = k\, i_a \qquad [1]$$

where E is the electrode potential *vs.* Ag at time t during anodization under the influence of a current density of i_a; k is a proportionality constant. The formulation in Eq. [1], although approximate, is widely discussed (13) in the anodic growth of ionically conducting films. Based on the behavior in Fig. 2, the variation of the electrode potential with time is ascribed to an increase in resistance of the $PbCl_2$ film with increasing thickness. The presence of some PbO_2 in the heavily anodized electrodes is probably connected with parasitic reactions involving the solvent or impurities such as water in the electrolyte.

The cathodic discharge curves of the pre-anodized electrodes as in Fig. 3, curves 1, 2, and 3, do not reflect the IR drop in the electrode observed during anodization except for the overshoot in the initial part of the discharge curves. This is probably due to the generation of a porous conducting matrix of lead from the reduction of lead chloride and the associated large change in the density of the film. The production of large surface area electrodes observed during the cycling experiments substantiates this hypothesis. It is interesting to note from the curves in Fig. 4, 1, 2, and 3, that, provided the electrodes are not heavily pre-anodized, the utilization efficiency of $PbCl_2$ electrodes is nearly 100%. The discharge efficiency of pasted plate lead chloride electrodes was similarly high.

The absence of periodic phenomena and poor utilization efficiencies in the electrochemical behavior ob-

served for lead in 0.5M LiCl in γ-butyrolactone is explained by postulating a soluble lead species formation during anodization as in Eq. [2] and [3]

$$Pb = Pb^{++} + 2e \text{ (electrochemical)} \quad [2]$$

followed by

$$Pb^{++} + 4Cl^{-} = PbCl_2^{=} \text{ (chemical)} \quad [3]$$

The formation of the soluble tetrachloroplumbate complex during anodization and its diffusion away from the electrode accounts for the lack of periodic phenomena, passivation, and low utilization efficiency. The explanation is based on the facts that (*a*) the anodic efficiency is 100% and (*b*) $PbCl_2$, the anodic salt which is inherently sparingly soluble in γ-butyrolactone (0.0005 m/l), dissolves in lithium chloride solutions in $PbCl_2$:2LiCl mole ratio.

It is clear from the above results that of the two organic electrolytes tested, 1M $LiAlCl_4$-P.C. is better suited for the operation of lead chloride cathodes. Pasted plate lead chloride electrodes have shown 90% utilization efficiency in this electrolyte, and hence the suitability of the active material for primary cells has been attested.

The oscillatory voltage behavior and the subsequent passivation reactions of lead during anodization in 1M $LiAlCl_4$-P.C. are rather undesirable characteristics for the application of the $Pb/PbCl_2/Cl^-$ half-cell for rechargeable cells. Hence attempts were made to eliminate or minimize these effects. In one such investigation the electrochemical behavior of lead-silver, lead-tin, and amalgamated lead were studied. Of the lead-silver and lead-tin alloys tested none proved superior to pure lead, but on the other hand, anodization of amalgamated lead electrodes exhibited neither voltage oscillations nor passivation and discharged with utilization efficiency >90%. The formation of a discontinuous $PbCl_2$ film due to the presence of mercury on the surface of lead electrodes is suggested for the observed behavior. Thus the amalgamation technique seems to render the lead chloride electrodes suitable for operation in organic electrolyte secondary cells.

It is interesting to point out that the amalgamation technique has been used to overcome the undesirable characteristics of anodes in aqueous media; herein the process has served to eliminate the problems of a cathode.

Effect of Heating Single Crystal Copper in H_2 and N_2 on Thin-Film Oxidation Kinetics

W. W. Bradley[1] and H. H. Uhlig

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The oxidation rate of spectroscopically pure polycrystalline and single crystal copper at 200°C in 1 atm O_2 was measured by coulometric reduction of the oxide. Growth of Cu_2O films up to 4000Å thick follows two-stage logarithmic kinetics. Pretreatment of filed polycrystalline Cu surfaces in H_2 at 450°C for 30 min decreases by 50% the thickness of oxide forming subsequently in O_2 at 200°C. Similar pretreatment in N_2, on the other hand, has little or no effect. Hydrogen pretreatment of electropolished single crystal Cu decreases oxidation of (100), has no effect on oxidation of (111), and increases oxidation of the (110) face. Pretreatment in N_2 at 450°C has no appreciable effect on subsequent oxidation of (100), contrary to H_2 pretreatment, and it increases oxidation of both (111) and (110) faces.

The oxidation rates of untreated Cu faces decrease in the order (100) > (111) > (110) in agreement with data of Gwathmey and his collaborators. Hydrogen pretreatment leads to oxidation rates, whatever the original orientation, approaching that of the (111) face; N_2 pretreatment leads to rates approaching that of the (100) face. The results appear to be best explained by a rearranged surface or submicroscopic faceting resulting from hydrogen adsorption, the preferred orientation of which approximates the (111) face. Pretreatment in N_2, on the other hand, probably because of adsorbed traces of oxygen in gas or metal, favors rearrangement having the approximate (100) orientation. Observed two-stage logarithmic kinetics for oxidation of rearranged surfaces, and the results by others of low energy electron diffraction, suggest that the first-formed adsorbed oxygen-metal film is extremely stable, maintaining its characteristic structure and orientation throughout the oxidation process. It thereby establishes oxidation rates in the thin film region independent of original crystal face. It is concluded that gaseous or vacuum pretreatment of Cu surfaces can exert a large effect on subsequent oxidation behavior.

Hydrogen annealing of Cu specimens or H_2 reduction of an air-formed oxide film on Cu is often employed as a preliminary step in studying oxidation or measuring oxidation rates (1-6). In the presently described experiments, this procedure was also followed, but it was observed that H_2-pretreated specimens that were oxidized subsequently in 1 atm O_2 at elevated temperatures within the thin film range ($<10^4$Å) reacted to a lesser extent than did the same specimens without pretreatment, or when heated initially in N_2. The obvious immediate explanation was that some hydrogen was dissolved in the metal during the pretreatment procedure becoming available during oxidation to react either with O_2, thereby limiting availability of O_2 for oxidation of copper, or to reduce some of the metal oxide which had already formed. However, calculations showed that the amount of dissolved hydrogen, assuming complete saturation, was appreciably below that required by reduction to explain the observed thinner oxide. For example, the solubility of H in Cu at 450°C, a typical pretreatment temperature, is 6.4×10^{-3} mg/100g Cu (7). Our Cu specimens were 0.6 cm thick, hence assuming saturation at 1 atm H_2, each 1 cm² of the Cu specimen contained

$$\frac{6.4 \times 10^{-3} \times 0.6 \times 8.9}{100} = 3.42 \times 10^{-4} \text{ mg H}$$

where 8.9 is the density of copper. This amount of hydrogen is able to reduce Cu_2O (mol. wt. = 143.1, density = 6.0) equal in thickness to

$$\frac{3.42 \times 10^{-4} \times 143.1 \times 10^8}{10^3 \times 2 \times 6.0} = 408\text{Å}$$

Since dissolved hydrogen is available to reduce oxide on two sides of the Cu specimen, the oxide, therefore, for H_2-pretreated Cu should be thinner to a maximum extent of 204Å. In several experiments using a filed surface of OFHC Cu, 20-min exposure to O_2 at 200°C produced an oxide film averaging 2029Å, whereas after H_2 pretreatment at 450C for ½ hr, the film thickness for the same oxidation conditions averaged 1035Å, the difference being 994Å. Hence the amount of available dissolved hydrogen to account for the thinner oxide was too small by a factor of 994/204 = 4.9, which is well outside present experimental errors.

On the assumption that hydrogen may have dissolved abnormally in our particular copper sample, the solubility was checked by Bohnenkamp at 350°C using standard methods, resulting in a value close to that reported in the literature. Change of roughness factor did not enter the explanation because parallel pretreatment in N_2 at 450°C for ½ hr did not affect subsequent oxide thickness in O_2 at 200°C, contrary to marked reduction caused by H_2 pretreatment.

Further investigation showed that dissolved hydrogen could not be the explanation in any case because, if the copper surface were electropolished after either H_2, N_2, or no pretreatment, the oxide film formed subsequently in O_2 at 200°C was now the same thickness.[2] This experiment, therefore, pointed to an effect occurring at the metal surface. For example, an impurity might diffuse to the copper surface in presence of H_2 but not in presence of N_2. Williams and Hayfield (8), in fact, who observed a lower oxidation rate after vacuum treating copper specimens, suggested that an impurity was involved, such as Fe, which diffused to the surface through grain boundaries. However, our further experiments on spectroscopically pure copper

[1] Present address: Institute of Surface and Colloid Science and Department of Civil Engineering, Clarkson College of Technology, Potsdam, New York.

[2] This was true only when oxidation was carried out at 200°C. At 250°C, the oxide film formed on H_2-pretreated Cu was somewhat thinner than on N_2-pretreated Cu, indicating some reduction of oxide by dissolved H at the higher temperature.

showed the same quantitative effect as for OFHC copper, eliminating impurities as a likely explanation. Attempts were also made to determine any supposed impurities at the surface occurring through pretreatment by machining off a thin portion of the copper surface after both H_2 and N_2 pretreatments and submitting this material for analysis employing a sensitive mass spectrometer. However, the results led to no certain conclusions regarding any one suspected impurity.

Subsequently it was found that the effects of H_2 and N_2 pretreatment were sensitive to crystal face, some faces of copper showing small or no differences in oxidation rate, depending on the gas, whereas others showed a large effect. The details of these experiments are outlined herewith.

Experimental

Specimens of commercial OFHC or spectroscopically pure copper (purchased from American Smelting and Refining Company) measured 2.5 x 2.5 cm (1 x 1 in.) and were 0.6 cm (¼ in.) thick. Single crystals (purchased from Virginia Institute of Scientific Research) cut from a 2.5 cm diameter boule were circular or elliptical in surface dimensions, but otherwise similar. A spiral Nichrome wire heater element made contact with one face of the specimen employing mica sheet insulation and a thin 18-8 stainless steel backing plate. A hole was drilled in the side of the specimen into which a chromel-alumel thermocouple was cemented. The side opposite to that in contact with the heater element was prepared for oxidation studies. Proper surface preparation, as in all thin film studies, was extremely important but was never ideal. Some measurements were made using a filed surface because this preparation was found previously to provide reproducible Volta potentials (9) which are very sensitive to surface preparation. Ten-inch Swiss cut No. 4 steel files were used for this purpose; they were cleaned each time before use by light pickling in nitric acid followed by brushing and washing in water, then immersion in distilled acetone and distilled benzene. Electropolishing, when carried out, was performed on a previously metallographically polished surface. The electrolyte consisted of 70 v/o (volume per cent) orthophosphoric acid to which 100 g/l cupric orthophosphate were added. Initial and final current density approximated 0.04 and 0.02 amp/cm^2 at a temperature of 0°C. More than 10μ of metal were removed totally. The specimen was taken out of the electrolyte without interrupting the current, immediately immersed in 10 v/o orthophosphoric acid (without current) and washed in deaerated distilled water. The acid-water rinse was repeated 4 times, the specimen then being washed in 5 consecutive bottles of deaerated distilled water through which CO_2 passed continuously. The specimens were finally dried in a stream of nitrogen gas. Total rinse time exceeding 20 min was necessary to insure complete removal of copper reaction products remaining on the surface from the electropolishing operation.

For comparison, several specimens were abraded using No. 1 followed by No. 0 grit emery paper. Such specimens were oxidized without further surface treatment.

The assembly for carrying out the oxidation runs is shown in Fig. 1. A spherical Pyrex vessel, which contained the specimen, measured 9 cm diameter; this fitted by means of a ground glass joint (omitting grease) to a glass holder through which thermocouple and heating current wires were connected to tungsten glass seals.

The procedure was to heat the specimen to temperature rapidly (2 min to reach 200°C) in nitrogen previously purified by passing over Cu at 400°C followed by a liquid N_2 cold trap. The heating current was then adjusted to the value required to maintain the specified temperature. Oxygen at 1800 ml/min (dried

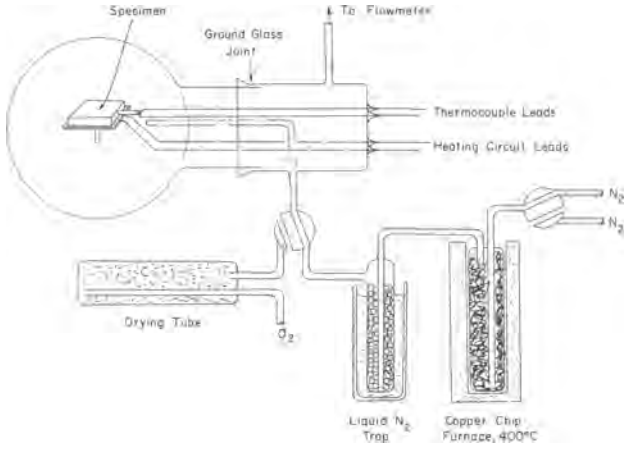

Fig. 1. Schematic diagram of oxidation cell

over $CaCl_2$) was used to flush out the nitrogen rapidly. Its entrance into the cell marked the beginning of oxidation. At the end of the oxidation period the heating current was turned off, the reaction vessel was rapidly flushed with purified N_2 at an initial flow rate of 4000 ml/min, and the specimen allowed to cool in N_2 to room temperature. Hydrogen pretreatment, when carried out, employed purified gas passed over Cu at 400°C followed by a liquid N_2 cold trap. The specimen was first heated to the required temperature in N_2 as outlined previously; the reaction vessel was then flushed out with H_2 and the temperature maintained for a specified time. The specimen temperature was then reduced to the temperature of oxidation, whereupon the vessel was flushed with N_2 for a period of 1 min at 1000 ml/min followed by flushing with O_2 as described previously. Throughout the sequence of operations, based on considerable experience, the temperature of the specimen was maintained by adjusting the heating current manually to within ±1°C of the desired temperature.

Oxide thickness was determined by coulometric reduction in accord with the technique described by Campbell and Thomas (10). The oxidized specimen was attached to a small inverted glass cell by means of a rubber gasket lightly covered with stopcock grease. A silver-silver chloride electrode located near the specimen surface followed potential change of the oxidized Cu surface during electrolytic reduction employing a d-c amplifier and a chart recorder. The cell was filled with deaerated 0.1*N* KCl, and a constant known current of approximately 0.1 ma/cm^2 was maintained with the specimen as cathode, and an auxiliary Ag wire as anode located outside the cell. From the time required to completely reduce Cu_2O of density 6.0 g/cm^3 on the surface of the specimen, the thickness of oxide was calculated to within at least ±10Å.

Results

Figure 2 shows the effect of H_2 pretreatment on oxidation of filed OFHC copper as a function of time in O_2 at 200°C. Oxidation occurs to an appreciably lesser extent after pretreatment of Cu in H_2 at 350°C for 1 hr compared to Cu not pretreated. Two-stage logarithmic kinetics applies in either case, the origin of which is discussed by Nwoko and Uhlig (11). An electropolished Cu single crystal, with exposed (100) face also oxidizes in accord with two-stage logarithmic kinetics as shown in Fig. 3. Since most subsequent comparative oxidation runs were carried out at 200°C for a fixed time of 20 min, it is seen from Fig. 2 and 3 that oxide films formed during this time correspond to second-stage oxidation. The effect of H_2 pretreatment, however, is observed in either first- or second-stage oxidation.

Although H_2 pretreatment lowers by an appreciable factor the oxide thickness formed subsequently on

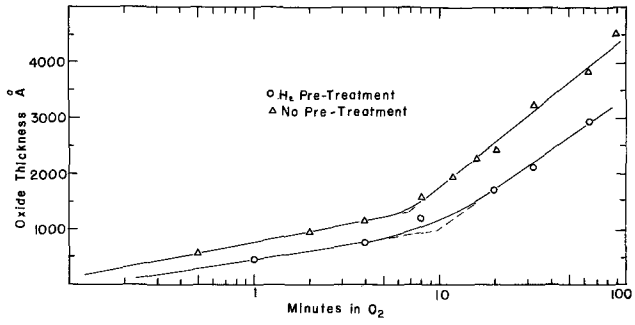

Fig. 2. Oxidation of OFHC polycrystalline copper, filed surface, in oxygen at 200°C. Pretreatment in hydrogen at 350°C, 60 min.

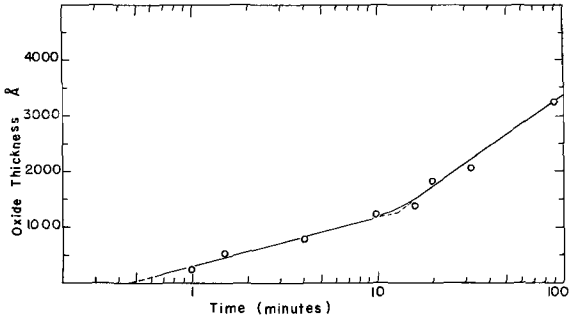

Fig. 3. Oxidation of (100) face of copper, electropolished surface, in oxygen at 200°C.

filed polycrystalline surfaces, a similar large effect is not observed for electropolished polycrystalline specimens nor for abraded specimens. The relevant data are listed in Table I presenting averaged values for the number of given specimens together with averaged deviations from the mean. Pretreatment in H_2 at 450°C lowers oxide thickness formed on filed surfaces by a factor of 0.5. On the other hand, N_2 pretreatment has little or no effect on filed surfaces, but it does increase the oxide thickness formed on electropolished and abraded surfaces by a factor of 3.7 and 1.7, respectively.

The effects of H_2 and N_2 pretreatment are sensitive to crystal face as shown by data of Table II. Further data are needed for adequate quantitative evaluation, but the preliminary results as presented indicate conclusively that the oxide formed on the (100) face is reduced in thickness by H_2 pretreatment (by a factor of 1/3.5), the (111) face is not affected, and the oxide formed on (110) is increased in thickness. Nitrogen pretreatment, on the other hand, has no effect on oxide thickness forming subsequently on the (100) face, but it increases oxide thickness on the (111) and (110) faces (by a factor of 5.4 and 11, respectively).

Specimens not pretreated follow a decreasing oxidation rate in the sequence (100) > (111) > (110) which agrees with previously reported results of Gwathmey and his collaborators (2, 5, 6). It is observed that this sequence and the differences among different faces tend to be obliterated by either H_2 or N_2 pretreatment of the Cu, but with the final oxidation rate for H_2 pretreated faces falling appreciably below that for N_2 pretreated faces. The observation of Rhodin (12) that the (110) face at or below 50°C oxidized more rapidly than did the (111) face, opposite to our results at 200°C, may relate in part to his measuring in some of his experiments a maximum oxide thickness of only 10-15Å which lies in the range of oxide nuclei dimensions. It seems reasonably certain that the mechanism of oxide growth as nuclei differs from that of its growth as a continuous film (13), the latter forming at 200° and 1 atm O_2 pressure from intergrowth of nuclei within fractions of a minute (14).

The effect of temperature and time of H_2 pretreatment of (100) Cu on subsequent oxidation in O_2 for 20 min at 200°C is shown in Fig. 4 and 5. Pretreatment for 30 min is effective above 350°C but not below. On the other hand, pretreatment for 30 min at 450°C achieved almost optimum effect on subsequent reduction of oxidation; longer times had only a slight additional effect.

Discussion

Data of Table II indicate that pretreatment of the three closest-packed faces of copper in H_2 results in an oxidation rate approaching that of the (111) face, whereas pretreatment in N_2 tends toward an oxidation rate approximating the (100) face. These effects are reversible; in other words, an H_2-treated surface subsequently treated in N_2 shows an effect characteristic of N_2 pretreatment and *vice versa*. Comparison of oxidation rates of Table II with those of Table I show that a filed surface appears to exhibit preferred orientation favoring the (100) face whereas an abraded surface favors the approximate (110) face. These orientations are in accord with an effect of H_2 pretreatment to decrease oxidation of filed surfaces but to increase instead oxidation of abraded surfaces. The exposed faces of electropolished polycrystalline OFHC surfaces consist of random orientations of which only those few near (100) are expected to oxidize rapidly. The average behavior corresponds to other orientations which oxidize slowly approximating (111) and (110) for which N_2 but not H_2 pretreatment has a

large effect on subsequent oxidation.

The present results can be explained in at least two ways: (*i*) effect of surface impurities, (*ii*) rearrangement of the copper surface (which may be regarded as submicroscopic faceting). The possibility that the present specimens were surface contaminated by unknown elements, the amount of which varied with N_2 or H_2 pretreatment and with crystal face, cannot be ruled out. This is especially true since only a partial monolayer of contaminant is apparently needed to appreciably change the oxidation rate, as was pointed out by Young *et al.* (5). Such a layer, for example, may change the metal work function, which on one viewpoint of thin film oxidation kinetics, could have a large effect on rate (15). Nevertheless an explanation based on surface rearrangement is also possible and perhaps more probable. For one thing, observed reproducibility of the pretreatment observations from one source of Cu to another is not characteristic of an impurity effect. Furthermore, the effect of pretreatment in N_2 or H_2 is independent of the presence or absence of grain boundaries along which diffusion of any suspected impurity would be enhanced, and also of gas flow rate which would introduce varying quantities of impurities to an exposed metal surface. In addition, the electropolished (100) Cu surface was observed under the electron microscope (60,000X) to roughen after N_2 or H_2 pretreatment corresponding to faceting of the metal surface. A systematic similar observation of other Cu faces (which remains to be done) is undoubtedly desirable for reaching a final conclusion, nevertheless the occurrence of submicroscopic faceting is made plausible on the basis alone of evidence now available.

The effect of gaseous environments at elevated temperatures to produce faceted surfaces of Cu and of other metals has been described previously by several investigators (16-21). Some explanations of the cause are based on preferential evaporation or reactivity of metal atoms, but more recently they have relied instead on variable surface energy of crystal planes. Accordingly, it is suggested that the environment (or gas dissolved in the metal) adsorbs on the metal surface reducing surface energy of some crystal faces more than others. At a sufficiently high temperature, the surface metal atoms bonded to adsorbate are able to rearrange themselves so as to favor the face or faces of lowest surface energy, resulting in microscopic facets or striations. The favored crystal faces vary with environment because adsorption on any given face also varies with environment.

If this explanation is correct, data of Tables I and II can be explained by the ability of H_2 during pretreatment to adsorb on Cu,[3] producing facets which, according to observed oxidation rates, favor the approximate (111) face. Surface diffusion of Cu plus adsorbate atoms probably occurs at an appreciable rate only above 350°C, suggesting this as the reason for an observed effect of H_2 pretreatment for 30 min also beginning at this temperature (Fig. 4). Gwathmey and Benton (16), for example, reported that single crystal Cu exposed at increasing temperatures to H_2-O_2 mixtures began to show facets at or above 360°C. On Ag, appreciable surface migration of atoms is reported to occur beginning at 230°-280°C, and on Au at somewhat higher temperatures (23). Cold working, such as is introduced by filing, would be expected to lower the temperature at which surface rearrangement is first measurable.

Nitrogen, on the other hand, does not chemisorb on copper (24) contrary to oxygen which chemisorbs even at very low partial pressures. A few experiments in the present series in which helium was used instead of N_2 as the pretreatment atmosphere showed the same effect. The influence of N_2, therefore, is probably equivalent to vacuum treatment in low-pressure O_2, the partial pressure of which is established by the dissociation pressure of Cu_2O at 400°C in the copper purification furnace (approximately 10^{-18} Torr O_2). The actual partial pressure of O_2 in our experiments, because of probable nonequilibrium flow rates, was undoubtedly higher. It was never high enough, however, to produce an oxide film showing interference colors on a copper surface maintained in flowing N_2 for 2 hr at 450°C. It is also possible, in fact, that any oxygen required for faceting may have originated not from the N_2 gas but instead from prior lattice dissolution of oxygen or from a previously air-formed oxide film. In this connection Elam (16) showed that faceting of copper in vacuum at 900°-950°C does not occur in absence of oxygen dissolved in the metal. Addition of Cu_2O to the melt or brief previous oxidation of the solid metal was required. In the complete absence of oxygen, therefore, N_2 pretreatment of Cu at 450°C might not produce faceting and, if so, would not affect subsequent oxidation rates. Experiments along these lines are still to be done. On the other hand, pretreatment of specific Cu faces at 450°C in pure H_2 would be expected to result in reproducible faceting although perhaps of submicroscopic dimensions (not visible at 1000X).

Orientation studies also support the occurrence of faceting during gaseous pretreatment. Although faceting is expected to vary with temperature because adsorption is temperature dependent, observed orientation of facets on Cu appearing at about 1000°C are not unrelated to those presumably produced at 450°C the orientation of which is inferred from presently reported oxidation behavior. Robertson (21) found that heating Cu at 1000°C in H_2-H_2O mixtures produces

[3] Although there is difference of opinion as to whether hydrogen chemisorbs on Cu (22), its adsorption in some degree at 450°C is indicated by a measurable interstitial solubility in Cu at this temperature. Alternatively, pretreatment in hydrogen thoroughly removes surface oxygen and may be equivalent in its effect to pretreatment of oxygen-free copper in ultrahigh vacuum.

facets that are thermodynamically stable near the (111) orientation. This is a face of low oxidation rate, and is also the approximate face which we conclude is formed by H_2 pretreatment at 450°C. For Cu heated at about 900°-1050°C in low pressure O_2 (*e.g.*, 10^{-4} Torr) several investigators have reported that resulting facets exhibit (111) and (100) orientation (25-28). The (100) face is rapidly oxidizing, and facets of this predominant orientation are also indicated by the present oxidation rates of Cu pretreated in N_2 (low-pressure O_2) at 450°C.

An important conclusion from the present observations is that gas or vacuum treatment of polycrystalline or single-crystal surfaces prepared in the usual manner can have large effect on subsequent thin film oxidation behavior. Since many previous investigators employed H_2-annealed specimens, the results they reported would be expected to differ from those employing vacuum-annealed specimens, accounting perhaps for initial oxidation rates that are often not in good agreement.

The fact that Gwathmey and co-workers (2, 5, 6) found low-temperature oxidation rates of Cu to vary with crystal face in the same order as for our untreated specimens, despite their use of a previous high-temperature H_2 anneal, suggests that their specimens faceted only incompletely, if at all, during pretreatment. Perhaps exposure of their Cu specimens to low-pressure O_2 during subsequent moderate vacuum outgassing and previous to oxidation counteracted earlier exposure to H_2. Lustman and Mehl's data showing a complicated effect of temperature on low-temperature oxidation rates of single crystal copper (1) may well have been the result of irreproducible faceting during incidental H_2 pretreatment.

Also of interest is the present observation that, assuming a faceted surface, Cu oxidizes continuously in accord with the newly created face or faces and not in accord with that of the original face. This is seen from Fig. 2 for which the oxide reaches a maximum thickness of about 3000Å equivalent to consumption of metal equal to 1800Å. If continuing oxidation gradually caused reversion to the oxidation rate of the original crystal face, the logarithmic equation would not be expected to hold. The speculative explanation that it does hold may reside in the extreme stability of the first-formed adsorbed oxygen-metal atom film on any specific crystal face. Observations of MacRae (29), Farnsworth (30), and others making use of low energy electron diffraction indicate that the first-formed chemisorbed oxygen film on nickel, for example, is thermally stable to a degree that it survives heating in ultra vacuum up to the melting point of Ni (1450°C).[4] Being apparently thermodynamically more stable than the oxide (13), the chemisorbed structure persists at temperatures and pressures that cause NiO to disappear. This unusually stable structure suggests that the adsorbed layer is able to persist or reproduce itself during the oxidation process, maintaining the orientation of the rearranged surface and establishing subsequent thin film oxidation rates. Were it not for this stability, the effect of faceting on thin film oxidation should be temporary and should persist only until most of the metal constituting the facets is consumed by oxidation.

[4] A similar stable chemisorbed oxygen film on Cu can be interpreted as forming on the (100) face in preference to Cu_2O after heating at 800°C in 1×10^{-3} Torr-min O_2 as reported by Mitchell *et al.* (31). The authors assume that absence of oxide is caused by solubility of oxygen in solid Cu.

The Anodic Deposition of Iron Oxide Films on Iron

V. Markovac[1] and M. Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

The anodic deposition of iron oxide films on passive iron polarized at +300 mv in boric acid/sodium borate solutions, at *p*H 7.52, containing ferrous ions has been investigated. The deposition takes place with a current efficiency of 100% based on the reaction $Fe^{++}_{(l)} - e^{-}_{o} \rightarrow Fe^{+++}_{(s)}$. The kinetics of the anodic deposition could be divided into two consecutive regions, an initial stage characterized by the formation of a film with the thickness of a unit cell, followed by a steady growth region where the rate of deposition is dependent on the ferrous ion concentration in the solution and the oxide layer thickness. Both the anodic current densities and the cathodic reduction behavior indicate that the deposited iron oxide film is different from the film formed by anodic oxidation of metallic iron in terms of both electronic conductivity and chemical composition.

In a previous study (1) it was found that iron could be anodically passivated in a neutral borate solution and that the thickness of the film varied from 8 to 30Å. It was also observed (2) that thicker films could be formed if the iron was treated anodically in the neutral borate solution containing ferrous ion.

In this paper a more complete investigation of this process of anodic oxidation of ferrous ion to form a solid film has been made. Similar processes are known for the anodic formation of lead dioxide (3) and manganese dioxide (4) from their respective ions in solution. Our investigations indicate that the kinetics of anodic deposition of iron oxide could be divided into two regions; an initial stage, and the steady growth region, where the rate of deposition depends only on the ferrous ion concentration in solution and the oxide layer thickness. Cathodic reduction experiments indicate that there is a difference in compositions between the deposited oxide and that formed by direct anodic oxidation of metallic iron.

Experimental

Apparatus.—The apparatus (Fig. 1) consisted of an electrolytic cell with storage vessels, nitrogen purification unit, and electrical equipment.

The electrolytic cell was of a cylindrical shape and had a working volume of *ca.* 40 ml. At the bottom of the cell an outlet was provided with two three-way solution lubricated stopcocks for solution transfer from two storage vessels to the cell and for removal from the cell for analysis. The storage vessels had a capacity of 2 liters each, one for standard solution and the other for solution containing ferrous ions. In the side of the cell were two tubes for the inlet of nitrogen. One tube, close to the bottom of the cell, had a sintered glass-disk sealed in its top, providing a fine and uniform bubbling of nitrogen through the solution in order to avoid concentration changes of ferrous ion at the electrode during the electrolysis. The other tube, entering the cell above the surface of solution, enabled the introduction of nitrogen into the cell and electrolysis without stirring. The outlet for nitrogen was built into the ball-joint cap on the top of the cell. The specimen (working electrode) was suspended on a tungsten wire sealed into the middle of a ball-joint cap. A set of four platinum wires 1.5 mm in diameter (counter electrode) with a total area of about 12 cm^2 was placed vertically into the cell surrounding the specimen uniformly. A saturated calomel electrode was used as the reference electrode and was connected with the cell by an electrolytic bridge, filled with the standard solution. The cell was surrounded by a water-jacket through which water at 25° ± 0.2°C was circulated.

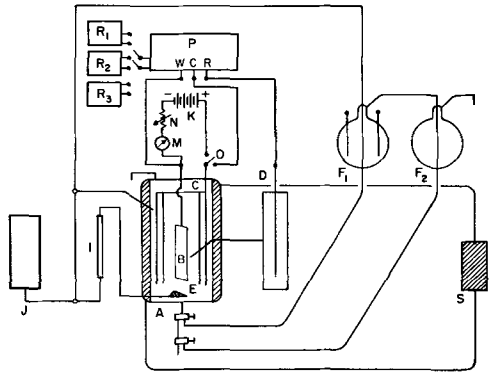

Fig. 1. Schematic diagram of apparatus: A, electrolytic cell; B, specimen; C, counter electrode; D, reference electrode; E, bubbler; F_1, F_2, storage vessels; I, flowmeter; J, nitrogen purification unit; K, battery; M, microammeter; N, variable resistance; O, switch galvanostatic-potentiostatic polarization; P, potentiostat by Wenking; w,c,r, terminals for working, counter, and reference electrode; R_1, R_2, R_3, chart recorders; S, system for water circulation at constant temperature.

The solutions in the cell and in the storage vessels were kept under a stream of purified nitrogen. High-purity tank nitrogen with an oxygen content of less than 20 ppm was further purified by passing through two washing bottles filled with Feiser's solution and a column filled with active copper spread on infusorial earth (5) maintained at 205°C. To obtain reproducibility of stirring by the bubbling of nitrogen through the solution in the cell a flowmeter was inserted in the nitrogen line in front of the cell. The volume of nitrogen passed through the particular sintered glass bubbler was a relative measure of stirring.

A potentiostat, a galvanostat, and recorders were used. Anodic polarization was carried out with a Fast Rise Potentiostat 61 R by Wenking. The voltage amplification factor is 10^4, and internal resistance less than 0.01 ohm (range 0-50 kc), rise time 10^{-6} sec. Limits for output voltage and output current are ±20v and ±300 ma, respectively. For cathodic reduction experiments a galvanostat consisting of a 12v battery and a variable large resistance was used.

The change of current with time during potentiostatic oxidation was recorded as voltage ohmic drop across a resistance of 100 ohms inserted in the current circuit. A Brush Recorder Mark II Model RD 2521 00 with 0.01-sec rise time and chart speed of 125 mm/sec was used for the initial rapid change of current and then recording was switched over to an L&N Speedomax type G recorder (range 0-1.0 mv, rise time

1 sec, chart speed 1.5 mm/sec) with a four-step voltage attenuator (ranges 100-50-10-1), following the change of current very precisely. The potential change with time during galvanostatic cathodic reduction was also recorded by an L&N Speedomax type G recorder (range 0-50 mv, chart speed 0.38 mm/sec) using a corresponding voltage attenuator covering a measuring range 0-1000 mv.

Materials.—Specimens 1x5 cm and 0.0375 cm thick with small handles were cut from Ferrovac E[2] iron sheet and mechanically polished with emery papers through to 4/0. The specimens were then electropolished in an electrolyte containing glacial acetic acid and 70% perchloric acid (20:1) at 0.4-0.5 amp/cm^2, 105 ± 5v d.c. and starting temperature of 15°C (6). To avoid overheating, electropolishing was carried out by 10-sec bursts, and a very smooth surface was obtained usually after 5-6 bursts. Then the specimen was annealed at 700°C in hydrogen and electropolished again by 2-3 10-sec bursts. For the preliminary oxidation and for cathodic reduction of the oxide layer, a standard solution containing 0.15*N* boric acid and 0.15*N* sodium borate (1:1), *p*H = 8.41 was used. Oxygen dissolved in the solution was removed by prolonged bubbling with purified nitrogen in the storage vessel. The solutions containing ferrous ion were prepared in the other storage vessel by potentiostatic dissolution of high-purity iron sheet at −650 to −700 mv in a 5:1 mixture of 0.15*N* boric acid and 0.15*N* sodium borate, *p*H = 7.52. As a counter electrode for iron dissolution, a platinum sheet of the same area was used. To prevent the precipitation of ferric hydroxide even in the presence of traces of oxygen, purified nitrogen was forced through the solution before, during, and after dissolution of iron. The concentration of ferrous ions in solution was estimated approximately from total current passed during electrolysis.

Procedure.—Specimens were prepared for deposition by first cathodically reducing the oxide on the electropolished specimen and then anodically oxidizing at +300 mv for 30 min in the standard solution (7). This forms a film of oxide approximately 25Å thick and provides a uniform reproducible surface for deposition (1). The standard solution was then replaced by the solution containing ferrous ions, and anodic oxidation was continued at +300 mv for 60 min. In order to maintain a constant ferrous ion concentration difference between the bulk of the solution and the metal oxide-solution interface during the oxidation, the solution was stirred by bubbling with a nitrogen flow of 43.0 ml/min, at 1 atm and 21°C. Immediately before and after anodic oxidation a sample of the solution from the cell was taken for analysis. Afterwards the cell and the specimen were washed out at least three times with the standard solution in order to remove any ferrous ion which remained. Cathodic reduction of the iron oxide layer from the specimen was then carried out in the standard solution with a constant c.d. of 10 μa/cm^2, until the second wave of the cathodic reduction curve was completed (2). After any desired period of time of the cathodic reduction, solution could be taken from the cell and analyzed for content of ferrous ion.

All potential data reported in this paper are referred to the saturated calomel electrode. Both change of current with time during anodic oxidation and change of potential with time during cathodic reduction were followed by chart recorders. Iron was analyzed by an orthophenanthroline method (1), the accuracy of which is about ±1%.

[2]Ferrovac E is the trade name of high-purity iron produced by Vacuum Metals Corporation, Division of Crucible Steel Company of America (C—0.007, O—0.015, N—0.0003, Mn—0.005, Si—0.008, P—0.003, S—0.006, Ni—0.005, Pb—0.001, Sn<0.001, Cr<0.003, Va <0.004, Al<0.005, Mo<0.006, Co<0.005, Cu<0.003% by weight).

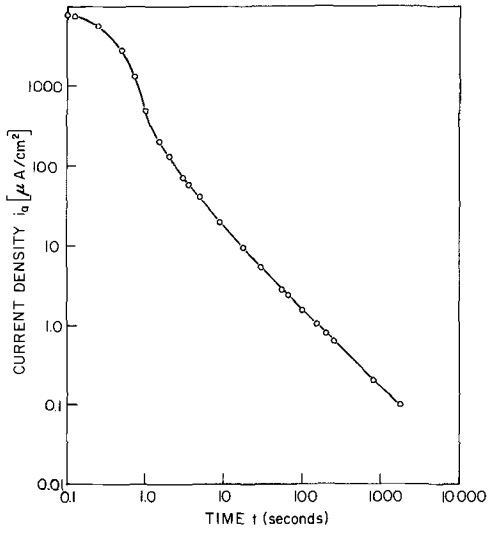

Fig. 2. Change of c.d. with time during preliminary oxidation at + 300 mv.

Results

Preliminary oxidation.—The reduced specimen was oxidized in the standard solution at a constant potential of +300 mv, for 30 min. The change of c.d. with time was recorded (Fig. 2). The total charge passed during oxidation was calculated by graphic integration of the curve and found to be 4.993 mC/cm^2. This value is in a very good agreement with the previous results (7). In order to check the nature of the oxide film, the specimen was reduced with a constant cathodic c.d. of 10 μa/cm^2. A typical cathodic reduction curve obtained (Fig. 4, curve 3a) also indicated that the surface oxide film developed by preliminary oxidation was essentially of the same type as described previously (1, 2, 7). These anodically oxidized specimens, with a film of about 25Å of oxide were used as "standard specimens" for all further anodic deposition work.

Anodic oxidation in solutions containing ferrous ions.—The standard specimens were then anodically oxidized in solutions with various concentrations of ferrous ions, at constant potential of +300 mv.[3] This passive region potential was chosen so that it was high enough to avoid dissolution of oxide or iron, and low enough to avoid oxygen evolution (1). The changes in the anodic current densities with time for eight solutions with various concentrations of ferrous ions are shown in Fig. 3 as log i_a-log t_a curves. It can be seen that a rapid current decrease is immediately followed by an arrest or plateau whose length decreases with increased ferrous ion concentration in the solution. At the end of this period the current then decreases slowly and is dependent on both the total oxide thickness and the ferrous ion concentration in the solution.

The total charge passed during anodic oxidation in solutions containing ferrous ions was obtained by graphic integration of the corresponding curves. Assuming that during anodic polarization the oxidation of Fe^{++} to Fe^{+++} occurs, it is possible, from the decrease in the concentration of ferrous ion in solution, to calculate the amount of charge which should pass during the oxidation. The calculated and the observed amount of charge are in very good agreement (Table I) and thus show that during anodic oxidation in the presence of ferrous ions, the reaction

$$Fe^{++}{}_{(l)} - e^-{}_o \rightarrow Fe^{+++}{}_{(s)} \qquad [1]$$

[3]To check the rise time to the applied constant potential, a Tektronix Model 545 oscilloscope was inserted in the measuring circuit in some experiments, and the rise of the potential was followed using a time sweep of 0.01 sec/cm. A rectangular transient was observed on the screen of the oscilloscope, i.e., a constant potential of +300 mv is reached in a shorter time than the rise time of the recorder.

38.2	575.5	pinkish -violet

takes place with an efficiency very close to 100%. During anodic oxidation no precipitation either in the solution or elsewhere was observed, and the oxide thickness on the iron specimen increased as noted by changes in interference colors. Hence it was concluded that all of the ferrous ion was oxidized to form a solid ferric oxide (not necessarily anhydrous) on the specimen. This process can be described as the electrochemical deposition of iron oxide. The charges passed during anodic oxidation in both the preliminary oxidation and the anodic deposition are proportional to the thicknesses of films formed. The thickness of oxide formed during anodic oxidation of iron ($_PQ_a$) was calculated from the equation

$$2Fe + 3H_2O \rightarrow Fe_2O_3 + 6H^+ + 6e^-_o \qquad [2]$$

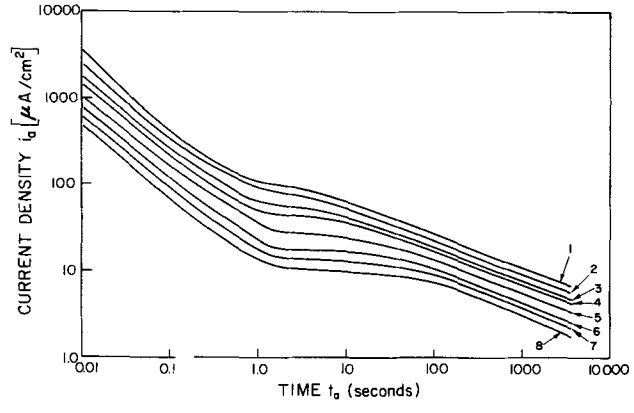

Fig. 3. Changes of the anodic c.d. with time for solutions with various concentration of ferrous ion, E_a = +300 mv.

Experiment No.	Starting [Fe++] mole/l
1	6.030 × 10⁻⁴
2	5.410 × 10⁻⁴
3	3.210 × 10⁻⁴
4	2.490 × 10⁻⁴
5	1.620 × 10⁻⁴
6	0.994 × 10⁻⁴
7	0.835 × 10⁻⁴
8	0.555 × 10⁻⁴

The thickness of oxide formed during anodic deposition ($_DQ_a$) was calculated from Eq. [1] assuming a solid product of Fe_2O_3 with a density of 5. The total oxide thickness ($_TQ_a$) is the sum of these two. The variation of color with thickness is given in Table II.

Cathodic reduction of iron oxide layer.—The iron oxide layers formed on the specimens during anodic oxidation in solutions containing ferrous ions were cathodically reduced in the standard solution at a constant c.d. of 10 μa/cm² The cathodic reduction curves for three specimens with various thicknesses of iron oxide layers are shown in Fig. 4. All curves have two typical arrests, one corresponding to reduction of ferric oxide and the other to reduction of magnetite as was shown earlier (1). The first arrests are very long, depending on the thickness of the oxide layer, *i.e.*, on the amount of ferric oxide in the oxide layer. The cathodic current efficiency for reduction of ferric oxide to ferrous ion (first arrest) for all three experiments is lower than 100% (Table III).

The second arrests show some prolongation in comparison with second arrests obtained by cathodic reduction of the surface oxide film developed by preliminary oxidation on the same specimens (Fig. 4). Assuming that the current efficiency for the reduction of magnetite to ferrous ion is 42% (1), it is possible to calculate the additional amount of magnetite formed during the deposition from the additional charge required to reduce the magnetite. Measured and calculated data are given in Table III.

Discussion

The experimental results show that the anodic deposition of iron oxide at constant potential (Fig. 3) can be divided into two parts. First, an initial region characterized by a rapid current decrease immediately followed by a plateau (arrest), and second, a steady growth region where the logarithm of the current density changes approximately linearly with logarithm of time.

Initial region.—The first step in the initial region (Fig. 5) is the charging of the double layer. With an

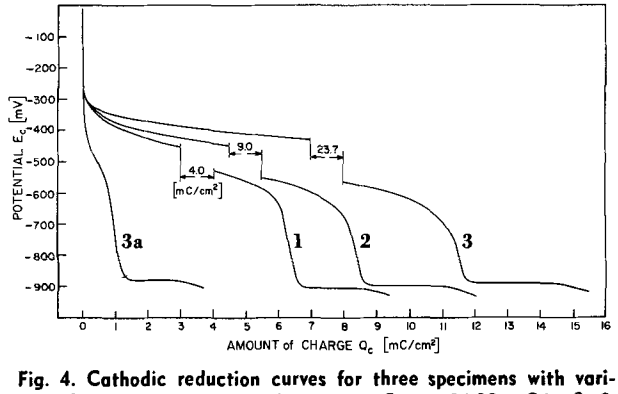

Fig. 4. Cathodic reduction curves for three specimens with various thicknesses of iron oxide layers. 1, $_TQ_a$ = 16.02 mC/cm²; 2, $_TQ_a$ = 25.17 mC/cm²; 3, $_TQ_a$ = 38.24 mC/cm²; 3a, cathodic reduction curve for specimen No. 3 after preliminary oxidation.

Experiment No. 1 is typical of a specimen oxidized by the preliminary oxidation.

efficient potentiostat this process should take place in a short time at high current density (8, 9) and should follow the equation

$$i = C_D \cdot \frac{\Delta E}{\Delta t} \quad [3]$$

$$i \cdot \Delta t = C_D \cdot \Delta E \quad [4]$$

$$\Delta Q = C_D \cdot \Delta E \quad [5]$$

where C_D is the double layer capacity and ΔE the potential change. If we assume a double layer capacity of 20 μF/cm² the corresponding charge is 6 μC/cm². If one takes the maximum current density from Fig. 5, the time required to charge the double layer is 10^{-2} to 10^{-3} sec. This shows that the charging of the double layer takes place at the very beginning of the measuring region and that the number of coulombs required is small in comparison to the total amount of charge used in the initial region.

In the initial deposition region there is a rapid decrease of current density followed by a plateau (Fig. 5). The total charge passed in this period[4] is essentially the same for all concentrations of ferrous ions. However both the current density and the time to pass this constant charge are dependent on the initial concentration of ferrous ion in the solutions. The total charge corresponds to the formation of 4.55 μg Fe_2O_3 and assuming a density of 5 a thickness of 9Å. This corresponds to about 1 unit cell of Fe_2O_3. This amount of deposited iron is insufficient to cause any real change in the concentration of ferrous ion in the solution in the initial region. Hence the rapid decrease in current density must be due to the fact that the resistance of the deposited film is considerably larger (by orders of magnitude) than that of the film formed by anodic oxidation of the metal. The current plateau region which is then followed by a steady growth region, is probably due to the fact that pores in the oxide are not closed until a full unit cell thickness is formed. It should be noted that during anodic deposition the conduction process in the film is electronic, *i.e.*, electrons are transferred across the oxide to the metal. Both the initial and final current densities in the initial growth region are orders of magnitude greater than the final current density during preliminary oxidation (Fig. 2) and hence electronic conductivity of the anodically formed film is much greater than the ionic conductivity.

Steady growth region.—As can be seen in Fig. 3 in the steady growth region the logarithm of the current density varies inversely with the logarithm of time. In Fig. 6 is shown the rate of growth of the film at various starting concentrations of ferrous ion. Although there is a general decrease in the rate of growth of the film with time the curves do not fit any general law. This is probably due to the fact that the current density decreases due to more than one factor. The major decrease in current density is due to an increase in the resistance as the film grows. This increase in resistance leads to a change in potential at the oxide film-solution interface and hence a decrease in current density. A second complicating factor is the decrease in solution concentration during deposition. This decreases the overpotential for the deposition reaction and hence the rate of deposition. The major effect is probably that of resistance of the film and the distribution of potential drops between the metal substrate and the solution.

Cathodic reduction.—The cathodic reduction curves (Fig. 4) show two arrests. The first arrest corresponds to the reduction of "ferric oxide" to ferrous ion in solution following the reaction

$$Fe^{+++}{}_{(s)} + e^-{}_o \rightarrow Fe^{++}{}_{(l)} \quad [6]$$

The current efficiency for the reduction (Table III) of the deposited oxide is less than for the oxide formed by the anodic oxidation of the iron. The current effi-

[4] The intersections of the extrapolated lines from the steady growth region and the prolonged arrest lines are used for the calculation of the amount of charge in the initial region.

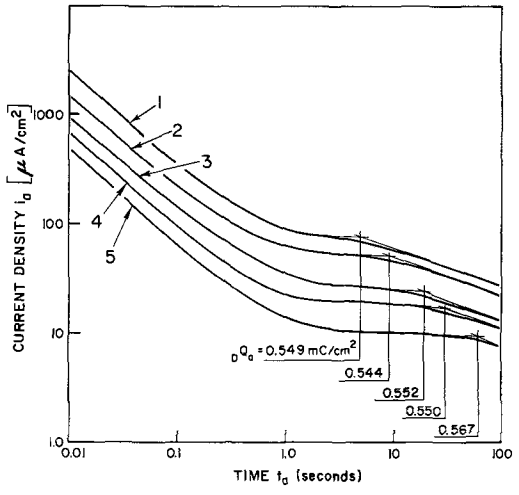

Fig. 5. Change of c.d. with time in initial region. Starting concentration of ferrous ion: 1, $5.410 \times 10^-$ mole/l; 2, $3.470 \times 10^-$ mole/l; 3, $1.620 \times 10^-$ mole/l; 4, $1.000 \times 10^-$ mole/l; 5, $0.555 \times 10^-$ mole/l.

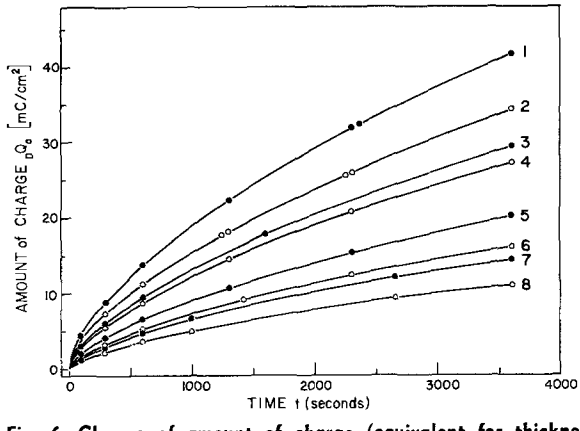

Fig. 6. Change of amount of charge (equivalent for thickness) with time for the same experiments presented in Fig. 3.

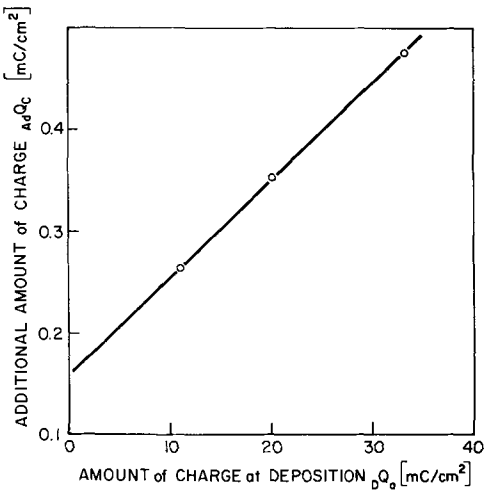

Fig. 7. Relation between the additional amount of charge used for reduction of magnetite and the amount of charge passed during anodic deposition of iron oxide for 60 min.

ciency decreases as the thickness of the film increases. This indicates that the deposited film is different from the preliminary film obtained by the oxidation of iron. This conclusion is also supported by the rapid change in film resistance which is observed during the deposition experiments. A more detailed discussion of the composition of the deposited film will be presented in a subsequent paper (10).

The second arrests of the cathodic reduction curves (Fig. 4) show some prolongation in comparison with the cathodic reduction curves obtained after preliminary oxidation for the same specimens. This means that during anodic oxidation in solutions containing ferrous ion (deposition of iron oxide) an additional amount of magnetite is also formed.

The additional amount of magnetite formed during anodic deposition of iron oxide increases with the amount of charge passed during deposition (Table III). If the additional amount of charge $_{Ad}Q_c$ (corresponding to additional amount of magnetite) is plotted *vs.* the amount of charge passed during deposition $_DQ_a$, a straight line is obtained (Fig. 7). The relation between $_{Ad}Q_c$ and $_DQ_a$ could be expressed

$$_{Ad}Q_c = A \cdot {}_DQ_a + B \qquad [7]$$

where $A = 0.956 \times 10^{-2}$ and $B = 0.159$ mC/cm² are constants obtained experimentally.

The formation of the additional magnetite during the anodic deposition of iron oxide can be explained by a flow of iron from the substrate to the oxide layer where the probable reaction

$$Fe + 4Fe_2O_3 \rightarrow 3Fe_3O_4 \qquad [8]$$

occurs.

The Anodic Deposition of Iron Oxide Films on Platinum

V. Markovac[1] and M. Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

The anodic deposition of iron oxide films on platinum from borate solutions containing various concentrations of ferrous ion was studied. The kinetics of deposition was essentially identical with the kinetics found using passive iron as a substrate. The film is not simple anhydrous or hydrated iron oxide but also contains some borate ion. On heating the film in vacuo hydrated boron complexes are driven off. The residue, after heating to 800°C is α-Fe_2O_3. These facts indicate that the film is formed by the oxidation of a ferrous borate type complex to an insoluble ferric hydroxy borate at the film-solution interface. The anodically deposited film is different both electrically and chemically from the film formed by the anodic oxidation of metallic iron.

It was shown in the previous paper (1) that the anodic oxidation of passive iron in solutions containing ferrous ions leads to the formation of "iron oxide" in which all iron is in the ferric state and originates from the solution. Such an anodic process is the electrochemical deposition of iron oxide, and it should be expected that a similar deposition will also take place on metals or conductors other than iron. The anodic deposition of metallic oxides on metals other than the metallic component in the oxide, has also been reported in the cases of lead dioxide (2, 3) and manganese dioxide (4, 5).

In the present work the anodic deposition of iron oxide on a platinum specimen from solutions containing various concentrations of ferrous ion was studied. These investigations show that the deposition of iron oxide on a platinum specimen takes place in a manner similar to that which was observed on the passive iron (1). The composition of the deposited film was studied using weight increase, mass spectrometry, x-ray diffraction, and chemical analysis.

[1] N.R.C. Postdoctorate Research Fellow. Present address: Scientific Research Laboratories, Ford Motor Company, Dearborn, Michigan.

Experimental

The apparatus consisting of an electrolytic cell with storage vessels, nitrogen purification unit, and electrical devices was the same as that presented in the preceding paper (1).

Smooth platinum sheets of 1 x 5 cm and 0.0127 cm (0.005 in.) thick, with small handles, were used as specimens. After degreasing in methanol and heating for a few seconds, in an ordinary oxidizing flame, the specimens were annealed in a hydrogen atmosphere at 2 Torr, at 900°C, for 24 hr. Before and after annealing there was no change in the weight of the platinum. The electron diffraction pattern after annealing was characteristic of a clean platinum surface.

The specimens were anodically oxidized at a constant potential of +300 mv in a solution of 0.15*N* boric acid and 0.15*N* sodium borate (5:1), pH = 7.52, with various concentrations of ferrous ion. Before and after anodic oxidation, the solutions from the cell were analyzed for ferrous ion. The change in the weight of the specimens resulting from anodic deposition of iron oxide was determined by weighing on a micro balance with an accuracy of $\pm 2 \times 10^{-6}$g. After anodic deposition the specimens were either cathodically reduced or chemically dissolved, or heated in an ultra high vacuum furnace. The cathodic reduction of the deposited iron oxide on the platinum specimen was carried out galvanostatically in the standard solution (equivolume mixture of 0.15*N* boric acid and 0.15*N* sodium borate, pH = 8.41) (1). With some specimens, the iron oxide layer was dissolved in about 60 ml of a mixture of hydrochloric acid and water (1:4). This solution was analyzed for ferrous ion by the o-phenanthroline spectrophotometric method. The heating of the specimen with the iron oxide layer was carried out in an ultra high vacuum furnace by increasing the temperature gradually up to 800°C. The pressure was of the order of 10^{-7} Torr. During the heating, the evolution of some gases was followed by an AEI Mass Spectrometer Type MS 10.

Results and Discussion

Anodic deposition of iron oxide.—The platinum specimens were anodically polarized at a constant potential of +300 mv in solutions containing various concentrations of ferrous ion. The change in the anodic current density with time is shown in Fig. 1. The curves are very similar to those obtained by deposition on passive iron (1) and are characterized by an initial region in which the rapid current decrease is immediately followed by an arrest, and after a transition period, a steady growth region. The total amount of charge passed during anodic oxidation was determined by graphic integration of the experimental curves of current density *vs.* time. The ratio between the calculated amount of charge[2] and that obtained experimentally, is very close to one (Table I). This confirms the fact that the anodic process on platinum at +300 mv in a solution containing ferrous ion is the deposition of an iron oxide in which all the iron

[2] Calculated from the decrease in the ferrous ion concentration during oxidation, assuming the reaction $Fe^{++} - e^-_0 \rightarrow Fe^{+++}$ (1).

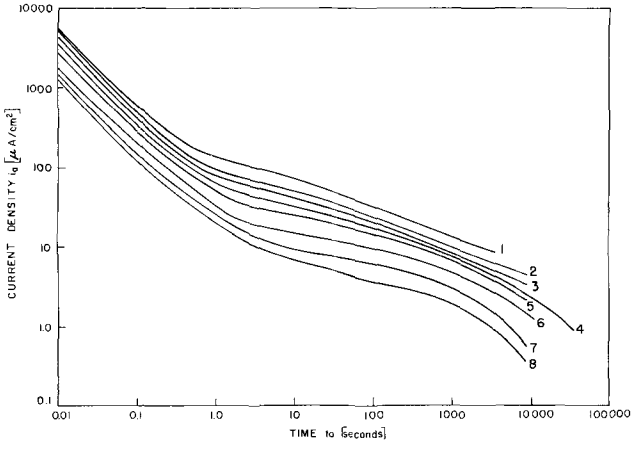

Fig. 1. Changes in the anodic c.d.'s with time during the deposition of iron oxide on the platinum from solutions with various ferrous ion concentration, E_a = +300 mv.

Experiment No.	Starting [Fe^{++}] mole/l
1	6.090×10^{-4}
2	4.980×10^{-4}
3	3.270×10^{-4}

5	1.630×10^{-4}
6	1.164×10^{-4}
7	0.528×10^{-4}
8	0.304×10^{-4}

is in the ferric state (1). Thus the thickness of the deposited layer should be proportional to the total amount of charge passed during the oxidation. The amount of charge ${}_DQ_a$ is

$$ {}_DQ_a = \int_0^t i_D \cdot dt \qquad [1] $$

where i_D is the anodic current density and t the time of deposition.

As pointed out above, the shape of the current *vs.* time curves (Fig. 1) for platinum is almost identical with those obtained with a passive iron substrate (1). In addition there is also a very marked similarity in the current densities observed with various ferrous iron concentrations. As with the iron, it may be concluded that the initial stage comprises the completion of an 8-10Å thick film of oxide. This is followed by a steady-state deposition of oxide where the rate of deposition is dependent on the ferrous ion concentration in the solution and the oxide layer thickness. A more complete discussion of the anodic deposition process is presented in the previous paper (1).

The fact that there is good correspondence between the current densities observed with the platinum and passive iron shows that the resistance of the passive film on iron is low, that is, its electronic conductivity is similar to that of platinum. This would indicate that this anodic deposition process can take place on any conducting surface.

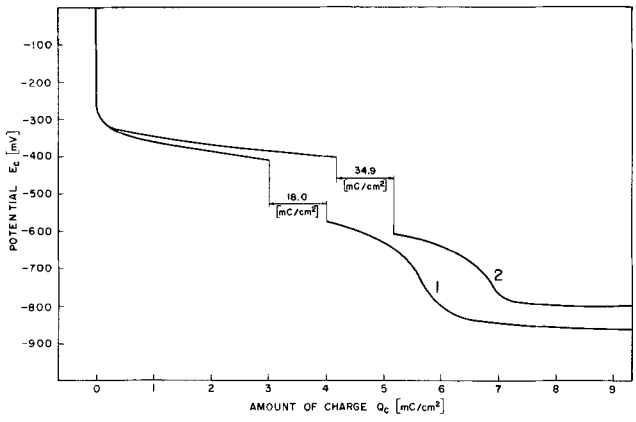

Fig. 2. Curves of cathodic reduction of iron oxide on the platinum specimen. Thickness of iron oxide: 1, $_DQ_a$ = 22.27 mC/cm²; 2, $_DQ_a$ = 47.14 mC/cm².

The growth of the iron oxide layer during the deposition is very easy to observe by the change of interference colors on the surface of the specimen. The relation between the thickness of the deposited iron oxide on the platinum specimen and its color is shown in Table II. It is clearly seen from Table II that the colors of the iron oxide on the platinum specimen are very similar to those observed by deposition of iron oxide on passive iron (1). Moreover, some colors appear several times with increasing thickness of the oxide layer and hence are repeating interference colors.

Cathodic reduction of films.—Some of the specimens were cathodically reduced in the standard solution at 10 μa/cm². Typical cathodic reduction curves are shown in Fig. 2. As can be seen from the curves there are two arrests. The first arrest corresponds to the reduction of the film at a current efficiency of about 65% during which time, from ferrous ion analysis, only about 70% of the total iron in the film is reduced to soluble ferrous iron. The reduction of the film continues during the second arrest, but with a decreasing cathodic current efficiency. The predominant reaction during this latter period is hydrogen evolution. No arrest potential due to magnetite was observed. The low current efficiency of reduction during the first arrest again indicates that the deposited film is different from the film obtained by the anodic oxidation of metallic-iron which cathodically reduces with a current efficiency of about 100% (6, 7). It may be that the low current efficiency during the first arrest is due to a simultaneous reduction of Fe^{+++} to Fe^{++} and protons in the film (present in hydroxyl groups) to hydrogen. The lower current efficiency during the second arrest is probably due to uneven reduction of the film which leads to the exposure of "bare" platinum areas to the solution before all of the film is reduced.

Composition of anodically deposited film.—Both the anodic deposition and cathodic reduction data show that the deposited film is not simply γ-Fe_2O_3. In order to obtain more information about the composition of the film a series of experiments involving material balance, chemical analysis, and heating *in vacuo* were performed.

Material balance and chemical analysis.—Some of the films were dissolved completely in dilute hydrochloric acid (1:4) and the resulting solutions analyzed for iron (Table III). It was found that within the experimental error the iron in the film corresponded almost exactly with that removed from the solution. Also, as noted above (Table I), the current efficiency for the anodic oxidation of the Fe^{++} in solution is 100%. This indicated that all the oxidized ferrous ion is in the film in the ferric state. However, the weight of the film (Table III) as determined by weighing the bare platinum and the coated platinum is substantially greater than the calculated weight of Fe_2O_3 which could be formed from the oxidized Fe^{++}. There appeared to be no simple relationship between excess weight and total amount of film formed, although the excess weight varied mainly between 60-90%.

A few experiments were performed in which the specimens with the deposited film were treated anodically (at the same potential of +300 mv) for extended periods of time in a boric acid/sodium borate standard solution containing no Fe^{++} ion. No change in weight of the specimen was observed. This shows that deposition only takes place in the presence of Fe^{++} ion.

An excess weight of 60-90% cannot be accounted for by any of the simple hydrated oxides of iron. However, it is possible that the iron is deposited, in part at least, as a borohydrate (8). To check this possibility, three specimens were prepared by anodic deposition and the film dissolved and analyzed for boron (9). The results are shown in Table IV. The boron is probably present in the film in the same valence state as in the solution and is co-deposited wtih the iron. The iron in the solution is present in part at least as a complex with the borate ion (8) and some possible

Experiment No.	Amount of Fe++ used in deposition, μg	Corresponding amount of Fe_2O_3, $W_{Fe_2O_3}$, μg	Real weight of iron oxide before heating, μg	Excess weight over stoichiometric Fe_2O_3, %	Weight of iron oxide after heating, W_h, μg	$\frac{W_h}{W_{Fe_2O_3}}$
5	236.0	337.0	623.0	84.8	361.0	1.070
6	490.0	701.0	1231.0	75.6	711.0	1.013
14	260.3	372.4	642.0	72.3	368.0	0.988
15	323.0	462.4	830.0	79.5	500.0	1.081

reactions for the combined deposition of iron and boron are as follows:

$$Fe[B(OH)_4]_2 \xrightarrow{+B(OH)_3 + H_2O} Fe[B(OH)_4]_3 + H^+ + e^-_o \quad [2]$$

$$Fe[B(OH)_4]_2 \xrightarrow{+H_2O} \quad [3], [3a]$$

$$FeOH[B(OH)_4] \xrightarrow{+B(OH)_3 + H_2O} FeOH[B(OH)_4]_2 + H^+ + e^-_o$$

$$FeOH[B(OH)_4] \xrightarrow{+H_2O} Fe(OH)_2[B(OH)_4] + H^+ + e^-_o \quad [4]$$

$$Fe(OH)_2 \xrightarrow{+H_2O} FeO(OH) \cdot H_2O + H^+ + e^-_o \quad [5]$$

If the assumption is made that all of the boron in the film is present as one or more of the above compounds and that the remainder of the iron is present as $FeOOH \cdot H_2O$, then it is possible to account for the total weight of the film. A material balance of this type is given in Table IV.

Effect of heating in vacuo.—Some of the specimens were put into a vacuum chamber and heated at 10^{-7} Torr up to 800°C for as long as 20 hr. During heating the water evolved was monitored with a mass spectrometer. Only minor amounts of water were observed. After cooling the specimens were reweighed. The weight of film now corresponded to Fe_2O_3 (Table V). An x-ray diffraction pattern was obtained and was typical of α-Fe_2O_3. The film was then dissolved in hot hydrochloric acid and analyzed for boron and iron. Only a minor portion of the boron remained. The solution contained 85-95% of the originally deposited iron. This was probably due to the difficulty of completely dissolving the film after heating at high temperature. The boron can sublime from the film at high temperature in the form of various boron hydrates or oxides (10, 11).

Conclusions

1. An iron oxide type film is anodically deposited on either passive iron or platinum by anodic treatment in a neutral boric acid/sodium borate solution containing ferrous ions.

2. All iron in the deposited oxide layer is in the ferric state and originates from the solution.

3. The kinetics of the anodic deposition of iron oxide can be divided into two consecutive regions, an initial state characterized by the formation of "unit cell" thickness, followed by a steady growth region where the rate of deposition is dependent on the ferrous ion concentration in the solution and the oxide layer thickness.

4. The anodically deposited film differs from films formed by the anodic oxidation of metallic iron both electrically and electrochemically. The film is largely composed of a mixture of hydrated ferric oxides and ferric boron hydroxo complexes.

5. The film is deposited by the direct oxidation of the complexed ferrous ion.

6. Since the anodic deposition of the film was obtained on both passive iron and platinum, anodic deposition of this type of film will also take place on any other suitable metal or conductive substrate.

Consecutive Electrode Reactions in the Dissolution Kinetics of Iron

Francis M. Donahue[1] **and Ken Nobe**

Department of Engineering, University of California, Los Angeles, California

ABSTRACT

The qualitative and quantitative behavior of an electrochemical system capable of exhibiting adsorption pseudocapacitance has been examined on a theoretical basis. The analysis was compared with experimental results for the anodic polarization of iron and found to be satisfactory. In addition, a method which allows the estimation of the rate constants for the equilibration step preceding the rate-controlling step for two-step, two-electron transfer processes, was suggested and verified experimentally.

The existence of adsorption pseudocapacitance due to absorbed hydrogen atoms was predicted and demonstrated by Eucken and Weblus in 1951 (1). Subsequently, Bockris and Kita (2) extended the analysis and showed that adsorption pseudocapacitance should be present, although not always measurable, for a consecutive electrode process with the rate-determining step following an electron transfer step in quasiequilibrium. Conway and Gileadi (3) extended the analysis still further by considering non-Langmuir adsorption.

Consider the following generalized reaction scheme

$$A + B \rightleftarrows C \pm e^- \quad [1]$$

$$C \rightarrow D \pm e^- \quad [2]$$

where A and B are reactants, C is an adsorbed species, D is the product, and step [2] is rate limiting. The potential dependent surface coverage of species C, θ_c, may be derived from the analysis of Bockris and Kita for Langmuir adsorption (2). In conformity with the generalized equations given above, it is

$$\theta_c = \frac{1}{1 + \frac{k^o_{-1}}{k^o_1 [A] [B]} \exp\left[\mp \frac{F}{RT}\eta\right]} \quad [3]$$

where k^o_{-1} and k^o_1 are the rate constants for the reverse and forward partial reactions at the equilibrium potential, respectively. All other terms have their usual significance. Likewise, the adsorption pseudocapacitance due to adsorbed C is given by

$$C_{ads} = \frac{F^2 Z}{RT} \frac{\frac{k^o_{-1}}{k^o_1 [A] [B]} \exp\left[\mp \frac{F}{RT}\eta\right]}{\left\{1 + \frac{k^o_{-1}}{k^o_1 [A] [B]} \exp\left[\mp \frac{F}{RT}\eta\right]\right\}^2} \quad [4]$$

where Z is the monolayer coverage feasible for the species (moles cm^{-2}).

Inspection of Eq. [3] shows that for an increasing positive overpotential (*i.e.*, anodic polarization) the surface coverage of anodically generated adsorbed species (plus sign in Eq. [1]) will increase and the surface coverage of cathodically generated species will decrease. Inspection of Eq. [4] on the other hand, reveals that adsorption pseudocapacitance goes through a maximum at the value of η corresponding to $\theta = 0.5$. Working curves of $\theta - \eta$, $C_{ads} - \eta$, and $C_{ads} - \theta$ have been published elsewhere (2-4).

A mathematical analysis or inspection of the working curves (2-4) shows that the adsorption pseudocapacitance and surface coverage are linearly related at very low and very high surface coverages. The linearity extends to values of adsorption pseudocapacitance of about 600 $\mu f\ cm^{-2}$ (3). Therefore, for values of the total measured capacitance of less than 300 $\mu f\ cm^{-2}$, *i.e.*, double layer plus adsorption pseudocapacitance, a linearity between surface coverage and adsorption pseudocapacitance may be assumed.

Previous studies relative to measurements of adsorption pseudocapacitance have been predicated upon quasi-equilibrium or steady-state analyses. However, it should be possible to treat transient phenomena in a similar fashion. It is the authors' intent to investigate theoretically the implications of the steady-state results when applied to transient phenomena and to demonstrate experimentally that the analysis can yield information which may be used independently or to corroborate and complement other experimental techniques.

Theory

Although the subsequent analysis could be presented in a general form, it will facilitate the discussion of the experimental results if the theoretical analysis is tempered by the information available concerning the behavior of iron in acidic solutions. Since measured values of the total electrode capacitance for iron electrodes have been found to be $<300\ \mu f\ cm^{-2}$ (4-7) and have increased on increasing anodic polarization (4, 6), it may be assumed that (*a*) the adsorption pseudocapacitance is a linear function of the surface coverage, and (*b*) the surface coverage is small.

Therefore, the application of an anodic galvanostatic step-function to an iron electrode would cause, after all transients have dissipated, an increased electrode potential and an increased total measured capacitance. However, the transient effects are of greater interest here and will be considered further. Figure 1 schematically represents the transient and steady-state responses. It may be assumed that the surface coverage and capacitance approach steady-state asymptotically as shown in Fig. 1b and 1c. One may then deduce the transient potential response for the assumed variation of θ under the constant current step.

At the steady state, the rate of the reaction step of interest, in terms of current density, has the following form

$$i = k\,\theta \exp[\eta/\beta] \quad [5]$$

where k is a potential independent rate constant (or combination of rate constants), θ is the steady-state coverage of intermediate, and β is the Tafel parameter. If we assume, as suggested above, that the surface coverage during a galvanostatic step approaches the new steady-state value asymptotically, we may deduce the transient potential response of the electrode from Eq. [5]. This requires that Eq. [5] must adequately describe the current, coverage, and overvoltage inter-

[1] Present address: Department of Chemical and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan.

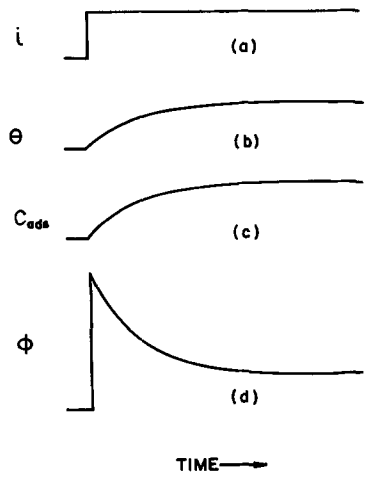

Fig. 1. Transient responses to a current pulse at an electrode exhibiting adsorption pseudocapacitance.

relationships for the transient conditions considered here within experimental error. Therefore, this analysis is precluded for times following the imposition of the step function which are of the same order of magnitude as the relaxation time for double layer charging. As a consequence of these considerations, it is seen that the potential will tend to approach steady state with a negative time derivative as shown in Fig. 1d. Transient phenomena during anodic polarization similar to that shown in Fig. 1d have been observed by many other investigators (5-11). It has been termed "superpolarization" (5). Various explanations have been suggested. Some of the experimental results to be presented below may be utilized to evaluate some of these suggestions.

In the foregoing analysis, it was assumed that the surface coverage and adsorption pseudocapacitance increase monotonically to the steady-state condition as a consequence of an anodic current step function. By a rather simple extension of the steady-state analysis, this can be demonstrated theoretically, and the experimental requirements for verification may be ascertained. The rate of buildup of the intermediate during anodic polarization at any instant is (from the mechanism given by [1] and [2])

$$\left(\frac{d\theta}{dt}\right)_t = k_{1t}[A][B] - (k_{1t}[A][B] + k_{-1t})\theta_t \quad [6]$$

In the present analysis, k_2, the rate constant for the rate-determining step, has been ignored. At the steady state

$$\left(\frac{d\theta}{dt}\right)_{ss} = 0 = k_{1ss}[A][B] - (k_{1ss}[A][B] + k_{-1ss})\theta_{ss} \quad [7]$$

It should be noted that the rate constants here are potential dependent. Hence, if one chooses values of time (t) such that $|\eta_t - \eta_{ss}| < 2RT/\mathbf{F}$, then $k_{jt} \approx k_{jss}$. In this way, [7] may be subtracted from [6] to yield

$$\left(\frac{d\theta}{dt}\right)_t = (k'_1[A][B] + k'_{-1})(\theta_{ss} - \theta_t) \quad [8]$$

where the primed rate constants are now defined as the rate constants at the resulting steady-state potential. Consequently, due to their unique specification, they are potential "independent." They should not be confused with the rate constants used in Eq. [3], which are associated with the reversible potential.

From the discussion above concerning the linear relationship between surface coverage and adsorption pseudocapacitance, one may replace θ with C_{ads} in Eq. [8]. Integration of the resulting equation between the limits of $t = 0$ and $t = t$, yields

$$\ln\left[\frac{(C_{ss} - C_t)}{(C_{ss} - C_o)}\right] = -(k'_1[A][B] + k'_{-1})t \quad [9]$$

From the analysis immediately above, it is seen that the surface coverage does increase monotonically during the anodic step function and further that the pseudo-first order rate constants for the quasi-equilibrium step, *i.e.*, Eq. [1], may be evaluated from measurements of the adsorption pseudocapacitance during the transient potential excursion.

Decay phenomena following anodic polarization may be treated similarly, but the experimental data exhibited considerably more scatter than the charging case (4) and will not be discussed further here.

Experimental

The test cell and the electronic circuitry will be discussed elsewhere (12). The electrode materials used in the present study were zone-refined iron[2] and Armco iron in the form of cylindrical electrodes as before (7). The electrolyte was 1*N* H_2SO_4, and the experiments were performed at room temperature.

Capacitance measurements were made by applying short (~8 msec) galvanostatic pulses to the electrode at open circuit while photographically recording the potential-time trace from an oscilloscope screen as before (7).

Capacitance measurements during anodic polarization were performed as noted above. The one important difference was that the electrode was already undergoing polarization. Consequently, the pulse current was superimposed on the already existing polarizing current. As had been noted previously (13), the measured capacitance during polarization was dependent on the ratio of the pulse to polarizing current (5). However, beyond a certain limiting ratio, the measured capacitance varied little with pulse current. All results listed here were in the latter region.

Results and Discussion

Bockris and coworkers (5) have suggested a mechanism for the active iron electrode which has subsequently been verified experimentally (5, 6, 10). Since the suggested mechanism is similar in form to that of the generalized Eq. [1] and [2] given here, it should be possible to analyze experimental work on the active iron electrode in terms of the treatment given above.

The potential-time behavior of zone-refined iron and Armco iron as a consequence of an anodic current step function is shown in Fig. 2 and 3, respectively. A comparison of the extent and duration of the transient maxima for the two samples indicates that the phenomenon of "superpolarization" is not an unique property of the electrolyte, but is dependent on the electrode material under study. Consequently, analyses predicated on a diffusional process, *e.g.*, hydrogen ion transport (2), fail to explain the discrepancy noted between the two electrodes in the same electrolyte. Suggestions that electrode impurities (8) or electrolyte impurities (10) cause the slow potential transients cannot be evaluated unequivocally. Kelly (10) found that replacement of the electrolyte removed the slow transients for zone-refined iron and concluded that electrolyte impurities were the source of these difficulties. Since slow transients were not noted here for the zone-refined iron, the present work cannot effectively differentiate between electrode and electrolyte impurity as the cause of the transient phenomenon observed for iron. However, it should be noted that none of the solutions tested here were pretreated as stringently as those of Kelly (10). Consequently, the results reported here may be construed as having been taken under "impure" conditions and seem to refute the contention that electrolyte impurities are the source of slow transients in the case of zone-refined iron.

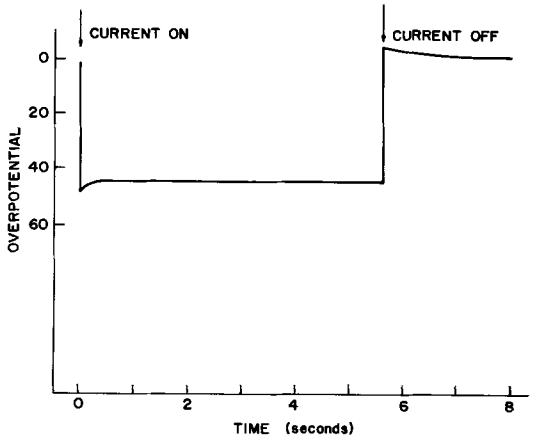

Fig. 2. Typical potential-time behavior of zone-refined iron; current density = 1 ma/cm^2.

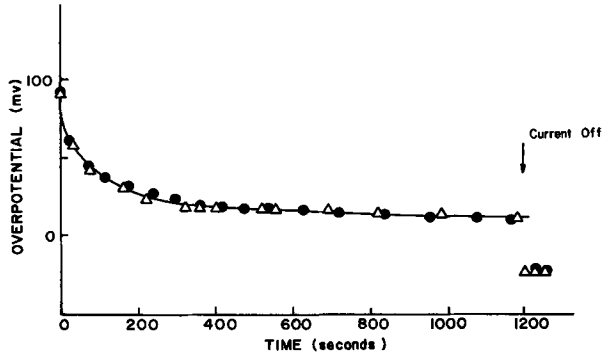

Fig. 3. Typical anodic polarization behavior of Armco iron samples; current density = 1 ma/cm^2.

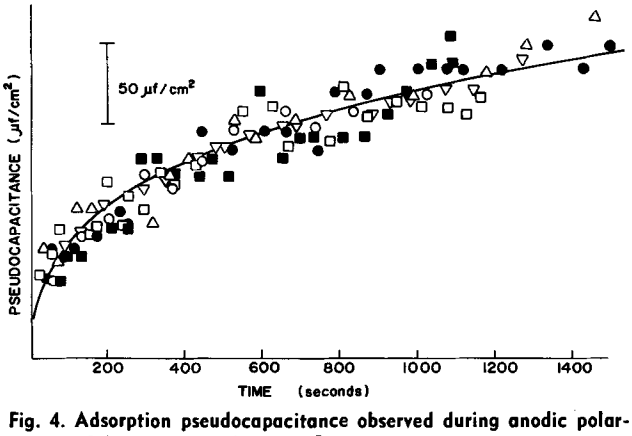

Fig. 4. Adsorption pseudocapacitance observed during anodic polarization of Armco iron at 1 ma/cm^2.

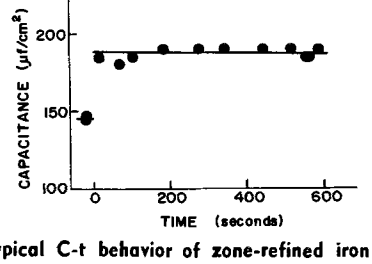

Fig. 5. Typical C-t behavior of zone-refined iron during anodic polarization; current density = 1.0 ma/cm^2.

A comparison of the potential and pseudocapacitance transients for zone-refined iron (Fig. 2 and 5) and Armco iron (Fig. 3 and 4) along with the discussion of these transients earlier in this paper suggest that the rate of equilibration of the first step in the iron dissolution reaction is a function of the bulk purity of the substrate.

* Obtained by extrapolating the cathodic pulse polarization curve back to the corrosion potential.

For the consistency of the kinetic analysis given above, a continuous variation of the measured total capacitance should be noted during anodic polarization until the steady state is reached. However, due to physical limitations of the experimental procedures, capacitance measurements could not be made at times shorter than about 15 sec after the initiation of polarization. Noting the potential-time responses of the two iron samples studied (Fig. 2 and 3), it can be seen that capacitance measurements during the transient are experimentally possible only for Armco iron. Capacitance data are shown for six different Armco iron electrodes in Fig. 4. The pertinent electrochemical data for these electrodes are given in Table I. In order to show the generality of the equations derived above, *i.e.*, that the kinetic analysis is essentially independent of the corrosion potential, corrosion rate, *etc.*, all the data have been normalized: the plotted capacitance values are the measured capacitances at time t minus the measured capacitance prior to polarization. Therefore, the plot shows the variation of the capacitance during anodic polarization and is in agreement with the analysis derived above.

That the increase in value of the capacitance during anodic polarization is not due to surface roughening may be seen from an inspection of Fig. 5 which shows the C-*t* behavior of a zone-refined iron electrode under conditions identical to those for the Armco iron electrodes in Fig. 4. The C-*t* plot is seen to be horizontal. This should not be construed as assuming that the surface does not roughen. It does mean, however, that, if roughening is present, it does not contribute a measurable effect on the C-*t* behavior.

In order to test the validity of Eq. [9], plots of log $(C_{ss} - C_t)$ *vs.* t were made for a number of Armco iron electrodes at current densities of 0.5, 1, and 2 ma/cm^2. A typical example of these plots is given in Fig. 6. The slope of the line shown in Fig. 6 is 1.8 x 10^{-3} sec^{-1}. Data for all three current densities average to a mean slope of 2.0 x 10^{-3} sec^{-1} with a deviation about the mean of about 20%. From the analysis given

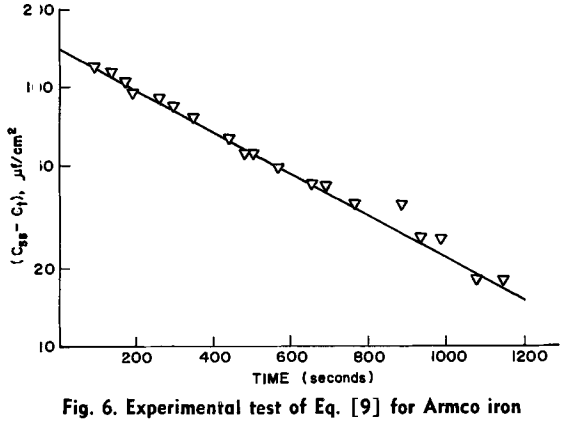

Fig. 6. Experimental test of Eq. [9] for Armco iron

above, this slope is the sum of the respective rate constants at the steady-state polarization potential.[3]

An estimate of the respective rate constants may be obtained from the sum of the rate constants (2×10^{-3} sec^{-1}), C_{ads} (measured), $C_{ads} - \theta$ curves (2-4), and Eq. [3]. Since the reversible potential for a corroding system is quite difficult to specify, one might conveniently refer the data in Eq. [3] to the corrosion potential.

The technique which has been developed here should be useful in future studies of reaction mechanisms and in understanding the role of surface properties on the adsorption of electroactive intermediates. It has already been useful in ascertaining the role of organic corrosion inhibitors (14). A similar analysis, although neglecting the possible application of capacitance measurements has been developed by Conway and Gilroy and applied to the inhibition of surface reactions by oxide formation (15).

[3] Armco iron has been shown to exhibit an anodic Tafel slope of 30 mv under the conditions studied here (7). Consequently, if one assumes that the calculated slopes for all three current densities are referred to the polarization potential for 1 ma/cm² (and thereby, potential "independent"), the expected deviations due to the actual potential dependence would be on the order of ± 20%.

Oxidation of Copper and Copper-Gold Alloys in CO_2 at 1000°C

I. Linear Kinetics

B. Swaroop and J. Bruce Wagner, Jr.

Department of Materials Science and Materials Research Center, Northwestern University, Evanston, Illinois

ABSTRACT

The oxidation rates of copper (99.999 w/o) and copper-gold alloys (Cu-5.32 a/o Au and Cu-10 a/o Au) have been studied as a function of partial pressure of carbon dioxide at 1000°C. The oxidation rates are initially linear. When a certain oxide thickness is attained, there is a decrease in the rate after which the kinetics again become linear. For all the samples the linear rate constant decreases nonlinearly with decreasing partial pressure of CO_2. In addition, the effect of various flow rates of carbon dioxide on the oxidation rate of pure copper has been studied.

The rate of oxidation of a metal may be controlled by one or more of the following processes: (*i*) transport of the gas to the reaction site; (*ii*) dissociation of the gas on the surface (a phase boundary reaction); (*iii*) transport of ions and electrons across an oxide layer; (*iv*) a phase boundary reaction at the oxide-metal interface.

The purpose of the present investigation was to determine the mechanism of oxidation of copper and copper-gold alloys in very low oxygen pressures provided by an atmosphere of carbon dioxide at 1000°C. In the case of the oxidation of copper in carbon dioxide, the oxygen pressure due to the dissociation of CO_2 is very nearly equal to the value of the oxygen pressure for the coexistence of copper and cuprous oxide (see Table I). Consequently, great care must be exercised in interpreting the kinetics, as will be discussed.

Linear oxidation kinetics have been reported for copper in oxygen by Wagner and Grunewald (1) and by Baur, Bridges, and Fassel (2), and in carbon dioxide by Margulescu and Cismark (3).

The oxidation of iron (4) and cobalt (5) in CO_2-CO mixtures has been shown to obey linear kinetics initially and to transform to parabolic kinetics (diffusion controlled kinetics) after a certain initial film thickness was attained. The linear kinetics were inferred to be due to the dissociation of CO_2 into CO and adsorbed oxygen atoms or ions.

Pettit and his co-workers (4) have shown that the linear oxidation of iron in CO_2-CO mixtures obeys an equation of the form

$$K_L \alpha [k' P_{CO_2} - k'' P_{CO}] \qquad [1]$$

Table I. Partial pressures of oxygen in equilibrium with copper and its oxides at 1000°C

Reaction	P_{O_2}, atm
1. $CO_2 = CO + \frac{1}{2}O_2$	1.2×10^{-5}
2. $Cu_2O = 2Cu + \frac{1}{2}O_2$	5.6×10^{-7}
3. $2CuO = Cu_2O + \frac{1}{2}O_2$	1.4×10^{-1}

where K_L is the experimental linear rate constant (g oxygen/cm^2-sec), P_{CO_2} and P_{CO} are the partial pressures of CO_2 and CO, respectively, and k' and k'' are two constants. These constants are functions of the crystal plane exposed to the gas and of the oxide composition, in particular the concentration of excess electrons or excess electron holes. For thin oxide films, Pettit and Wagner (4) inferred that the concentration of excess electrons or holes is virtually constant and does not appear explicitly in the rate equation. The present study involves thin oxide layers (thickness $\leq 5 \times 10^{-4}$ cm) of Cu_2O on copper and on copper-gold alloys.

Experimental

Rectangular coupons, 0.5 x 0.5 in., were prepared from copper and from copper-gold alloys (5.32 and 10 a/o). Both the copper and gold were 99.999+% pure. The alloys were melted in a graphite mold under a vacuum of 10^{-6} mm Hg. In addition, a single crystal of copper in the form of a right cylinder, 3.1 mm thick and 12.6 mm in diameter with the end faces parallel to (100) planes was obtained from Research Crystals, Inc., Richmond, Virginia. The purity of this crystal was listed as 99.999%

The samples were prepared as follows: (*A*) Pure copper rod, 0.360 in. diameter, was cold rolled into sheets about 0.040 and 0.020 in. thick, respectively, in equal reduction passes. (*B*) Samples from these sheets were annealed 24 hr at 1000°C in a sealed quartz tube under a vacuum of 10^{-6} mm Hg. The grain diameter was about 1 mm or larger. (*C*) The copper-gold alloys were cold-rolled to 0.020 in. thickness and annealed as in (*B*). All specimens were polished mechanically on emery paper followed by a polish using Linde "A" alumina powder. In the case of the single crystal and for some of the polycrystalline samples, the specimens were subsequently electropolished and then washed successively in water, acetone, and in ethyl alcohol.

The oxidation rates were measured gravimetrically by methods described previously (5). "Bone dry"[1] CO_2 and CO_2 diluted with argon were used as oxidizing gases. Both the carbon dioxide and the argon were passed through separate columns of copper turnings at 300°-350°C and then through magnesium perchlorate to remove oxygen and water vapor. In order to test whether any residual impurities, especially traces of oxygen, were affecting the observed kinetics, the following experiments were performed. Research grade CO_2 ($O_2 < 10$ ppm, $N_2 < 100$ ppm and $H_2 < 10$ ppm) was used in several runs. No difference in kinetics was observed from those obtained using bone dry CO_2. In addition, pure copper samples were suspended in the purified argon (initial purity >99.998%). No weight change was observed in 24-48 hr. A few runs were carried out in oxygen-argon mixtures. A linear flow rate of 0.9 cm/sec was used for most runs except when the effect of gas flow rate on oxidation kinetics was studied.

Results and Discussion

Figures 1, 2, 3, and 4 show typical oxidation rate curves for the pure copper and the alloys. For all samples, there was an initial linear oxidation rate which was followed by a second linear oxidation rate after a certain critical oxide thickness was attained. This thickness ranged from 0.40 to 0.60 x 10^{-4} cm, assuming a dense layer of Cu_2O. The oxygen partial pressure for the equilibrium dissociation of CO_2 at 1000°C is less than that for the formation of cupric oxide as is shown in Table I. In addition, no CuO was found by x-ray analyses of the oxides. The rate constants for the second linear rate are smaller than those for the first linear kinetics. Pettit and co-workers (4, 5) have shown that the oxidation of iron and cobalt in CO_2-CO mixtures involved two successive stages of linear kinetics.

[1] Bone dry is a trade name of the Matheson Company, Inc. It is 99.8% pure with moisture as the major impurity.

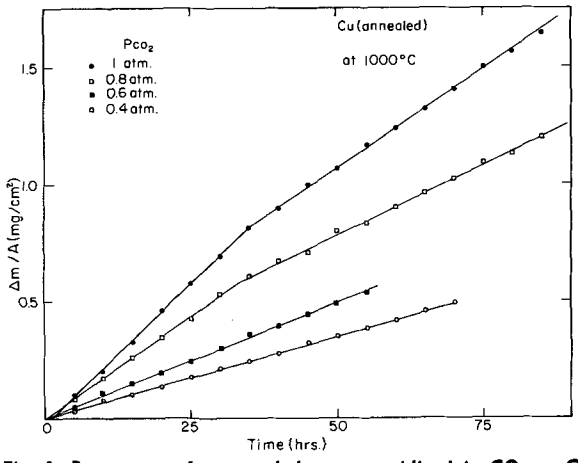

Fig. 1. Rate curves for annealed copper oxidized in CO_2 or CO_2 diluted with argon at a total pressure of one atmosphere. The linear gas flow rate was 0.9 cm/sec.

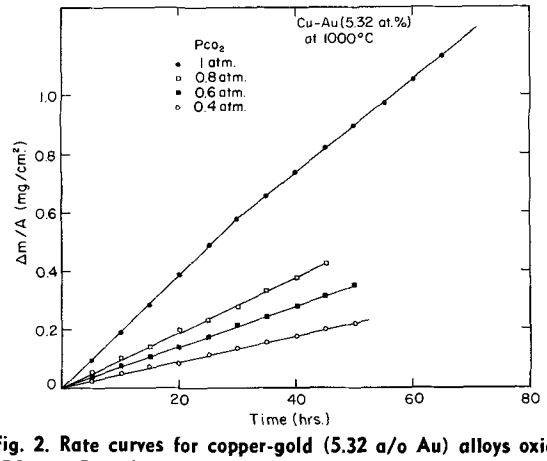

Fig. 2. Rate curves for copper-gold (5.32 a/o Au) alloys oxidized in CO_2 or CO_2 diluted with argon. The linear gas flow rate was 0.9 cm/sec.

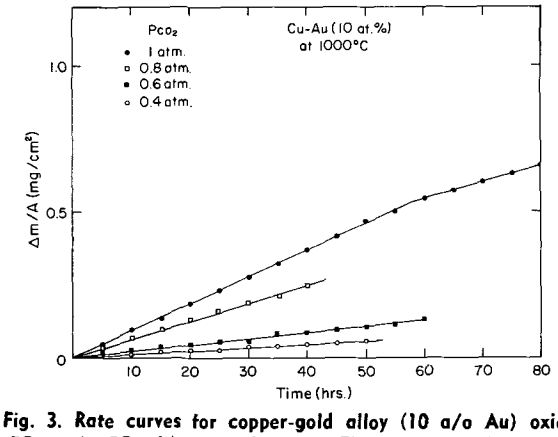

Fig. 3. Rate curves for copper-gold alloy (10 a/o Au) oxidized in CO_2 or in CO_2 diluted with argon. The linear gas flow rate was 0.9 cm/sec.

The linear rates were a function of the oxide planes exposed at the oxide-gas interface. Initially the oxide crystals were epitaxially related to the substrate. As the film thickened, the orientation of the oxide planes exposed to the gas changed. This change was correlated with the change in linear kinetics.

For the present study, the first linear kinetics are discussed. In order to show that gas transport to the samples was not rate determining the following calculation was made for 1000°C. According to Kiukkola and Wagner (6)

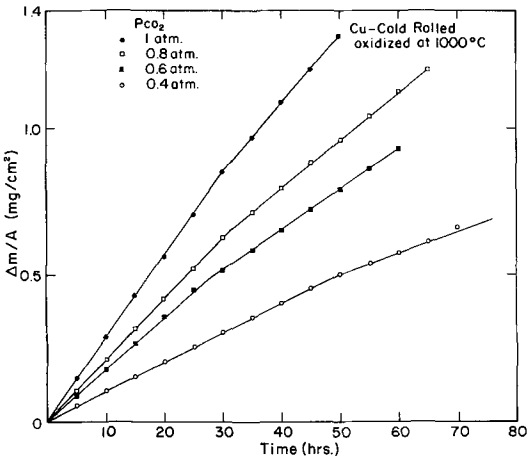

Fig. 4. Rate curves for cold rolled copper oxidized in CO_2 or in CO_2 diluted with argon. The linear gas flow rate was 0.9 cm/sec.

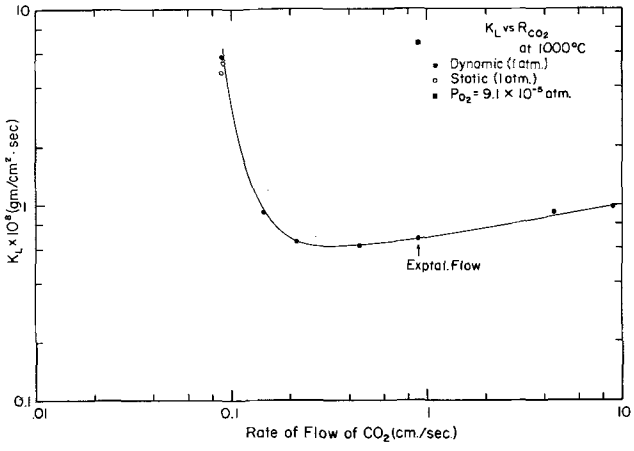

Fig. 5. Effect of linear gas flow rate of CO_2 on the first linear rate constant. The open circles represent data taken in a closed system of static CO_2. The square denotes an experimental result for an argon-oxygen mixture of $P_{O_2} = 9.1 \times 10^{-5}$ atm at a linear flow rate of 0.9 cm/sec.

$$2Cu(s) + \tfrac{1}{2}O_2(g) = Cu_2O(s);\ \Delta G^\circ_1 = -18.2 \text{ kcal} \quad [2]$$

The dissociation of carbon dioxide is given by

$$CO(g) + \tfrac{1}{2}O_2(g) = CO_2(g);\ \Delta G^\circ_2 = -41.0 \text{ kcal} \quad [3]$$

so that

$$2Cu(s) + CO_2(g) = Cu_2O(s) + CO(g);\quad \Delta G^\circ_3 = +22.8 \text{ kcal} \quad [4]$$

from which it follows that

$$\left[\frac{P_{CO}}{P_{CO_2}}\right]_{Cu,\,Cu_2O} = K_3 = \exp\left[\frac{-\Delta G^\circ_3}{RT}\right] = 1.2 \times 10^{-4} \quad [5]$$

If all the carbon dioxide reaching the sample reacted completely to oxidize the copper to Cu_2O then the weight increase per unit time, Δm°, is

$$\Delta m^\circ = M_o\, 1.2 \times 10^{-4}\, n^\circ_{CO_2} \quad [6]$$

where $M_o = 16$ is the atomic weight of oxygen and $n^\circ_{CO_2}$ denotes the number of moles CO_2 passed over the sample per unit time. The usual flow rate was 0.9 cm/sec through a reaction tube of 2.85 cm^2 cross section. During a run lasting 10 hr, the weight change should have amounted to 8 mg if transport of CO_2 to the surface were rate determining. The experimental weight change was 0.25 mg for a run on annealed copper lasting 10 hr in CO_2 at a pressure of 1 atm. The calculation shows that gas transport to the surface was not rate determining. Because the experimental weight change was much less than that calculated for gas transport and because the kinetics were linear, it is concluded that a phase boundary reaction is rate determining. Likewise the total uptake of dissolved oxygen for the size of copper samples used would amount to only 0.015 to 0.025 mg. This weight change is much less than those obtained from the experimental runs so that most of the weight gain resulted from Cu_2O. Furthermore, the change in linear kinetics with time (Fig. 1-4) would tend to rule out gas transport as being rate determining.

Finally, an empirical study of the oxidation rate as a function of the flow velocity of CO_2 was made (see Fig. 5). Between 0.2 cm/sec and 0.9 cm/sec, the oxidation rates were virtually the same. At lower flow rates (<0.2 cm/sec) the oxidation rate increased. An experiment was run at zero gas flow, *i.e.*, in a static system of about 5 liters total volume. This experiment yielded a linear rate constant (K_{L1}) as equal to 4.8 x 10^{-8} g·cm²·sec^{-1}, very nearly that observed for a gas flow rate of 0.09 cm/sec (K_{L_1} = 5.2 x 10^{-8} g·cm^{-2}·sec^{-1}). Probably for the static run and in the runs at low flow rates, the carbon dioxide has time to dissociate in the gas phase according to Eq. [3], whereby the oxygen partial pressure is calculated to be about 1.2 x 10^{-5} atm. To test this assumption, an experiment was run in an oxygen-argon mixture where P_{O_2} = 9.1 x 10^{-5} atm with the mixture flowing over the sample at 0.9 cm/sec. The linear rate constant amounted to 6.84 x 10^{-8} g·cm^{-2}·sec^{-1}. It would be expected that the run in static CO_2 would yield a slightly lower oxidation rate because of the presence of CO in the gas phase, in addition to the lower oxygen partial pressure.

Table II summarizes the data for the initial rates on pure copper as a function of pretreatment of the samples. The relative oxidation rates decrease in the order: cold-worked polycrystalline; mechanically polished and annealed polycrystalline; electrochemically polished and annealed polycrystalline; single crystal which was electrochemically polished and annealed. The relative rates are probably due to the different crystal planes of the oxide exposed to the gas. This explanation is consistent with the results of Pettit and co-workers (4) for the oxidation of iron to wüstite.

The copper-gold alloys exhibited a lower rate of oxidation than did the annealed copper samples. In these cases, gold was inert. The activity of copper coexisting with the Cu_2O was less than that on the pure copper samples. The ratio of the values of the rate constants for the two alloys is almost a constant, approximately 10/5.32 (see Table III). This suggests that the relative amount of copper at the metal-oxide interface

Table II. Linear rate constants (K_{L1}) for copper at 1000°C in 1 atm of CO_2

Pretreatment	K_{L_1} (g/cm²·sec)

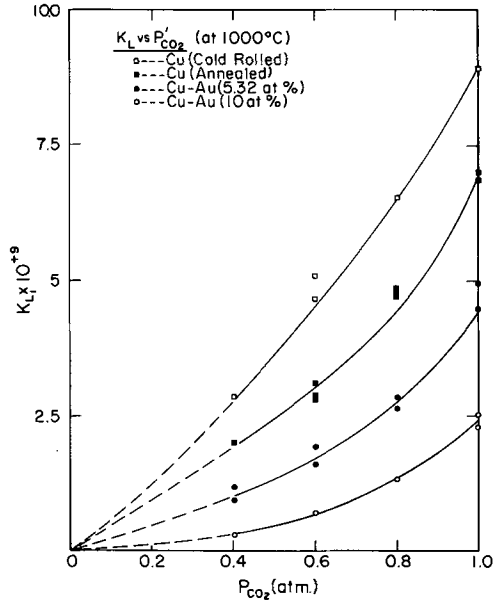

Fig. 6. Dependence of the first linear rate constant, K_{L1}, on the partial pressure of CO_2 in a CO_2-argon mixture. All data were from runs at a linear gas flow rate of 0.9 cm/sec.

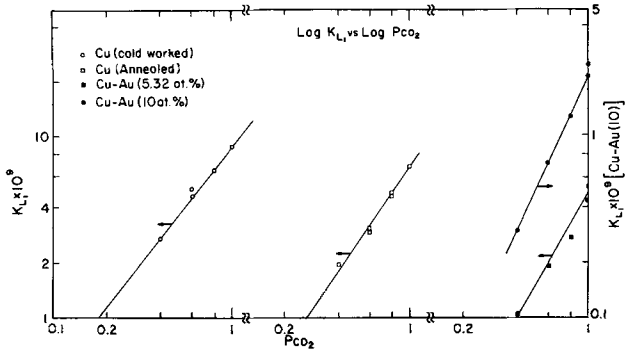

Fig. 7. Graph of log K_{L1} vs. log P_{CO_2}. The slopes of the lines are: (a), cold-rolled copper, 1.3; (b), annealed copper, 1.5; (c), Cu-Au (5.32 a/o), 1.75; (d), Cu-Au (10.0 a/o), 2.06.

and therefore the relative amounts of cuprous oxide are responsible for the difference in rates because the gas presumably dissociates on the cuprous oxide.

Equation [1] could not be tested because of the difficulty in maintaining a CO/CO_2 ratio of the order of one part in 10^4. The dependence of the rate constants on partial pressure of CO_2, using argon as a diluent gas, is shown in Fig. 6 for all the metals studied. The constants obeyed an empirical equation of the form

$$K_{L1} = C P^n_{CO_2} \qquad [7]$$

where C is a constant and n is a number dependent on the metal used. Figure 7 shows a plot of log K_L *vs.* log P_{CO_2}. The values of n for the various metals vary between 1.3 and 2.08. A value of n greater than unity is unusual for oxidation of metals in CO_2. When nickel and a nickel-chromium alloy were oxidized in CO_2, Fueki (7) found that the linear rates were proportional to the partial pressure of CO_2, *i.e.*, $n = 1$ in Eq. [7]. These results were shown to be consistent with the mechanism described in Eq. [1]. Hauffe and Pfeiffer (8) found that the oxidation of iron to wüstite in CO_2-CO mixtures obeyed a pressure dependence of $(P_{CO_2}/P_{CO})^{2/3} \propto P_{O_2}{}^{1/3}$. Pfeiffer and Laubmeyer (9) found the linear oxidation rate of iron to wüstite in low pressures of oxygen obeyed a pressure dependence of $P_{O_2}{}^{0.7}$. The pressure dependences have been inferred to be due to a chemisorption mechanism (10). The pressure dependence observed in the present studies cannot be due to this mechanism since the observed values of n are greater than one. Furthermore, the value of n decreases from those obtained on the copper samples to those of the alloys. The data only show that the reaction occurs at the gas-oxide interface.

It should be mentioned that the present kinetic data do not obey a logarithmic law as has been discussed for thin film oxidation studies on copper and for other metals (10, 11).

Conclusions

The initial growth of an oxide on copper and on copper-gold alloys (5.32 a/o and 10 a/o) in CO_2 at 1000°C is governed by linear kinetics when the linear gas flow is 0.9 cm/sec. Two linear rates are observed. The first linear stage changes to a second linear stage at an oxide thickness of 0.4 to 0.6 x 10^{-4} cm. The linear rates were not proportional to the first power of the partial pressure of CO_2. The rate determining step under these conditions is at the gas-oxide interface. At low flow rates, the oxidation rates are more rapid, presumably due to the CO_2 having time to dissociate in the gas phase prior to a reaction with the sample.

Rate of Solution of Rotating Tantalum Disks in Liquid Tin

T. F. Kassner

Metallurgy Division, Argonne National Laboratory, Argonne, Illinois

ABSTRACT

The dissolution kinetics of tantalum in liquid tin have been investigated under the well-defined hydrodynamic conditions produced by the rotating-disk sample geometry. Dissolution data were obtained under laminar flow conditions (Reynolds No. 1 x 10^3 to 1 x 10^5) for the temperature range 800°-1200°C. Much of the experimental data was found to be in a region of mixed transport control; however, for specific conditions of temperature and velocity, both limiting cases for reaction and diffusion control were also observed. The solubility of tantalum in liquid tin was determined over the temperature range 600°-1200°C. The diffusion coefficient of Ta-182 in liquid tin was also measured at temperatures between 500° and 1100°C by the capillary-reservoir method. These data were used in the convective-diffusion model set forth by Levich to calculate values for the diffusion-controlled dissolution flux. The model was extended to include the range of Schmidt numbers between 4 and 1000. A Schmidt number of ~25 in the tantalum-tin system at 1200°C resulted in a 12% reduction in the calculated dissolution flux. Within the limits of error of the experimental diffusion data, the dissolution flux from the model was in agreement with the experimental values in the region of diffusion control.

The convective-diffusion model for mass transport to or away from a rotating disk first formulated by Levich (1, 2) has been extended (3) to include the range of Schmidt numbers commonly encountered in liquid-metal systems at high temperatures. The purpose of this paper is: (*a*) to give the flux equation for rotating disks applicable to systems in which the Schmidt number, ν/D, ranges between 4 and 1000, and (b) to present kinetic, diffusion, and solubility data that can be used to demonstrate the applicability of the model to a high-temperature liquid-metal system.

When it is assumed that the solute concentration of the liquid is independent of radial and angular position but is solely dependent on the axial distance from the disk surface, and also that steady-state transport across the diffusion layer is achieved rapidly; the convective-diffusion equation in cylindrical coordinates can be written as

$$V_Z(Z)\frac{dC}{dZ} = D\frac{d^2C}{dZ^2} \qquad [1]$$

where V_Z is the axial component of the velocity, D is the solute diffusion coefficient, and C is the solute concentration.

Cochran's (4) exact solution to the Navier-Stokes and continuity equations for fluid motion near a rotating disk yielded a series relationship between V_Z and Z. The first three terms of the series for small values of Z were used with the boundary conditions for a disk undergoing dissolution in a large volume of liquid to obtain a solution to Eq. [1] for the concentration distribution of solute near the disk surface. The maximum (initial) flux of solute from Fick's first law can then be written as

$$J_m = \frac{D(C_{sat} - C_B)}{1.805\,\omega^{-1/2}\nu^{1/6}D^{1/3}I_{(D/\nu)} + 1.124\,D(\nu\omega)^{-1/2}\exp\left[-3.11\,(\nu/D)\right]} \qquad [2]$$

where ν is the kinematic viscosity of the liquid, cm²/sec; ω the angular velocity of the disk, radians/sec; C_{sat} the solubility of the solute in the liquid, g/cm³; and C_B the initial solute concentration in the liquid, g/cm³. $I_{(D/\nu)}$ is the value of an integral in the solution to Eq. [1] and is a function of the reciprocal Schmidt number.

From ref. (3)

$$I_{(D/\nu)} = \int_0^{1.9944(\nu/D)^{1/3}} \exp\left[-X^3 + 0.885\left(\frac{D}{\nu}\right)^{1/3}X^4 - 0.394\left(\frac{D}{\nu}\right)^{2/3}X^5\right]dX$$

The values of $I_{(D/\nu)}$ listed in Table I were determined by a computer integration for the 28 D/ν values between 0.001 and 0.250. Gregory and Riddiford (5) solved the same problem for several D/ν values between 0.001 and 0.004 by a graphical integration method in which the first two terms of the series expansion defining V_Z were used. They showed that when $D/\nu = 0.001$, $I(0.001)$ was 3% greater than the $I(O)$ approximation employed by Levich (1). The

values in Table I result in a 4% correction to the $I(O)$ approximation for $D/\nu = 0.001$ and a 17% correction for $D/\nu = 0.250$.

The convective-diffusion boundary layer, δ_D, is defined by denominator of Eq. [2]. For D/ν values pertinent to this study, the second term in the denominator of Eq. [2] is negligibly small compared to the first so that Eq. [2] can be rewritten as

$$J_m = 0.554\, I_{(D/\nu)}{}^{-1}\, D^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, (C_{sat} - C_B) \quad [3]$$

Equation [3] is applicable to laminar flow which, for a polished and dynamically balanced disk, extends to Reynolds numbers of the order of 10^5. The Reynolds number for a disk of radius R is defined as $Re = \omega R^2/\nu$. For the 5.08 cm diameter disks used in this work, the upper limit for ω was $\sim$ 20 radians/sec at the higher temperatures.

The temperature dependence of the diffusion-controlled dissolution flux was obtained by inserting the following Arrhenius expressions for the temperature dependence of D, ν, and C_{sat} into Eq. [3].

$$D = D_o \exp\left(\frac{-Q_D}{RT}\right) \quad [4]$$

$$\nu = \nu_o \exp\left(\frac{+Q_\nu}{RT}\right) \quad [5]$$

$$C_{sat} = C_o \exp\left(\frac{-\Delta H_{soln}}{RT}\right) \quad [6]$$

The result is given below for the case where the initial concentration of the liquid, C_B, is zero

$$J_m = 0.554\, I_{(D/\nu)}{}^{-1}\, D_o{}^{2/3}\, \nu_o{}^{-1/6}\, \omega^{1/2} \exp\left(-\frac{4Q_D + Q_\nu + 6\Delta H_{soln}}{6RT}\right) \quad [7]$$

For the temperature interval and Schmidt numbers applicable to this work, the temperature dependence of $I_{(D/\nu)}$ becomes negligibly small. From Eq. [7], the temperature dependence of the maximum dissolution flux, Q_{Jm}, is related to the activation energies for solute diffusion, Q_D, and viscosity, Q_ν, and the overall heat of solution of the solute in the liquid, ΔH_{soln} by the relation

$$Q_{Jm} = \frac{1}{6}\,(4Q_D + Q_\nu + 6\Delta H_{soln}) \quad [8]$$

Sufficient experimental data have been obtained to predict the magnitude of the dissolution flux from Eq. [3] and the temperature dependence of the flux from Eq. [8]. These values can then be compared with the experimental dissolution data.

Experimental

The tantalum disks were machined from 0.11 cm thick annealed polycrystalline sheet. The analysis of the material is given in Table II. The disks were ground flat on metallographic paper and then given a light chemical polish in a 50:20:20 sulfuric-hydrofluoric-nitric acid solution. A thin tantalum support rod was electron-beam welded to the disk and the rod was fitted with a quartz protection tube. The support rod was attached to another rod which passed through a rotary push-pull vacuum seal, and the system was dynamically balanced before inserting it into the furnace tube.

The "four-nines plus" purity tin melts were contained in 66 mm ID quartz crucibles. Each melt of about 3200g was deoxidized by bubbling dry hydrogen through it at 500°C in another furnace.

A run was started by lowering the disk into the liquid tin and setting the desired rotational speed. The temperature of the liquid was held to ±2°C and the angular velocity of the disk was maintained to ±1% of the set value. Samples of the tin reservoir were obtained at desired time intervals with quartz sampling tubes.

The following thermal neutron activation method was used to analyze the samples for tantalum. The 0.40 cm diameter by 3.5 cm long cylindrical samples were removed from the quartz sampling tubes and then weighed and capsulated in polyethylene tubes. Samples of pure tin of similar size were also weighed and sealed in polyethylene tubes for use as tin standards. Tantalum standards were prepared by dissolving an accurately tared tantalum wire in a measured volume of a 50:50 HF-HNO_3 solution. One ml quantities of the standard solution were quantitatively transferred to polyethylene tubes and the capsules were sealed. The samples and standards were irradiated for 4 hr in a neutron flux of 1.6 x 10^{11} n/cm^2-sec. A counting system incorporating a large well-type scintillation detector and a pulse height analyzer was used to determine the sample and standard activities in the region of the 1.121, 1.188, and 1.223 mev Ta-182 peaks. Major interference by the 9.4 day half-life Sn-125 peak at 1.07 mev was eliminated by the pulse height analyzer. However, the activity of the Ta-Sn samples was corrected for tin activity with the information from the tin standards. There was essentially no self-absorption within the samples for the sample geometry and gamma-ray energies involved (6). Tantalum concentrations as low as 0.5 ppm could be determined routinely by the method.

Results

Representative concentration *vs.* time plots for two of the runs are shown in Fig. 1. The initial slope of each curve was used along with the area of the disk and the weight of the tin reservoir to obtain the values for the maximum dissolution flux of tantalum. Figure 2 is representative of the type of curve that resulted when trace amounts of air or water vapor were ac-

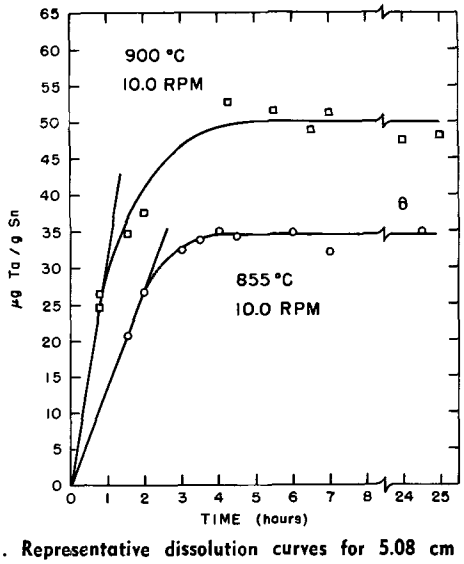

Fig. 1. Representative dissolution curves for 5.08 cm diameter disks in liquid tin.

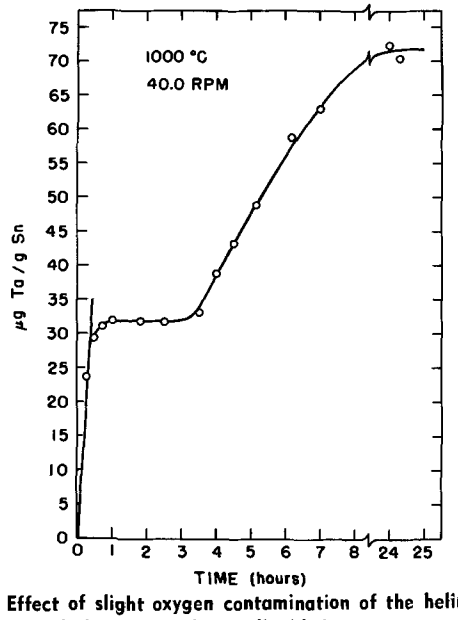

Fig. 2. Effect of slight oxygen contamination of the helium cover gas on the dissolution of tantalum in liquid tin.

cidently introduced into the helium cover gas during the sampling procedure. If the sampling problem was corrected and no additional contaminants were admitted to the system, the system attained saturation.

Dissolution curves similar to the first 3 hr in Fig. 2 were obtained for several runs in which a small air leak developed in the system. The concentration of tantalum in the tin remained at a constant low fraction of the saturation concentration. For the runs where contamination was present, tantalum was selectively oxidized out of solution at the liquid-gas interface. The dissolution process at the tantalum disk-liquid interface proceeded at a rate that could be related to the difference between the saturation concentration and the steady-state concentration of tantalum in the liquid. The latter quantity was determined by the rate of solution of the disk and the rate of removal of tantalum from solution by oxidation.

Figure 3 shows a disk sample at the conclusion of an 1100°C run in which a slight leak had developed. An x-ray powder pattern from a sample of the melt at the conclusion of the run revealed that a large amount of Ta_2O_5 was present along with tantalum. The uniform thinning of the disk substantiates the assumption that the solute concentration in the liquid was independent of radial and angular position and illustrates that the reaction surface was uniformly

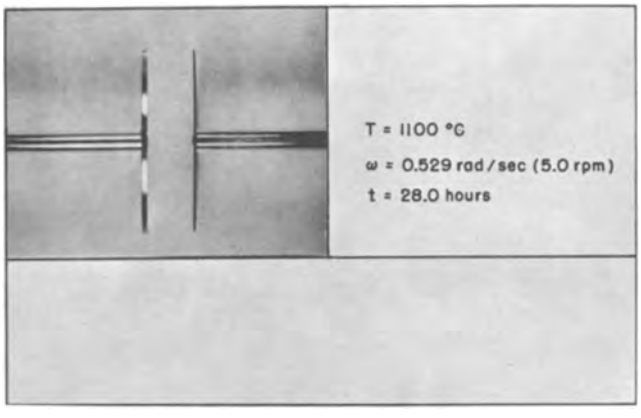

Fig. 3. Disk sample at the conclusion of a run in which the dissolution rate remained near the maximum value because of removal of tantalum from solution by selective oxidation. Uniform thinning of the disk illustrates that the reaction surface was uniformly accessible from the standpoint of diffusion.

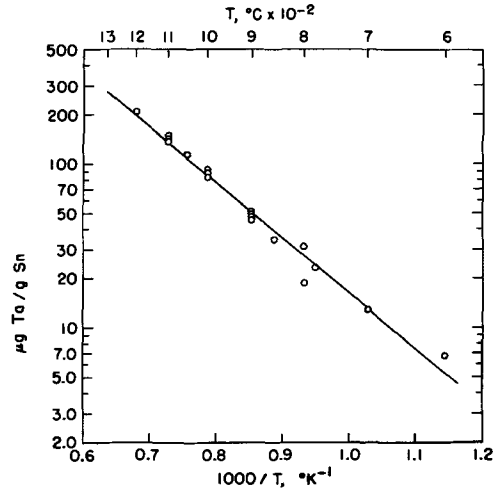

Fig. 4. Temperature dependence of the solubility of tantalum in liquid tin.

accessible from the standpoint of diffusion. Latter data will also show that, for the temperature and velocity of this run, the dissolution process was in a region of diffusion control.

The temperature dependence of the solubility of tantalum in liquid tin is given in Fig. 4. These values were obtained from dissolution curves in which saturation was readily achieved and also from a solubility run in which equilibration times from 48 to 100 hr at each temperature were used. Each point represents the average of a number of analyses. The data can be represented by the relation

$$C_{Sn}^{Ta} = (3.737 \pm 0.254)\ 10^4 \exp\left[\frac{-15{,}390 \pm 1{,}210}{RT}\right] \mu g\ Ta/g\ Sn \quad [9]$$

The over-all heat of solution of tantalum in liquid tin is 15,390 ± 1210 cal/mole at the 95% confidence level.

The results of measurements of the self-diffusion coefficient of liquid tin and tantalum in tin by the capillary-reservoir method are shown in Fig. 5. The diffusivity of Sn-113 in liquid tin was determined to check out the diffusion cell, and these data are in agreement with data of Careri *et al.* (7) and Ma and Swalin (8) for temperatures below 800°C. All of the data below 800°C were used to obtain the following Arrhenius relation for tin self-diffusion

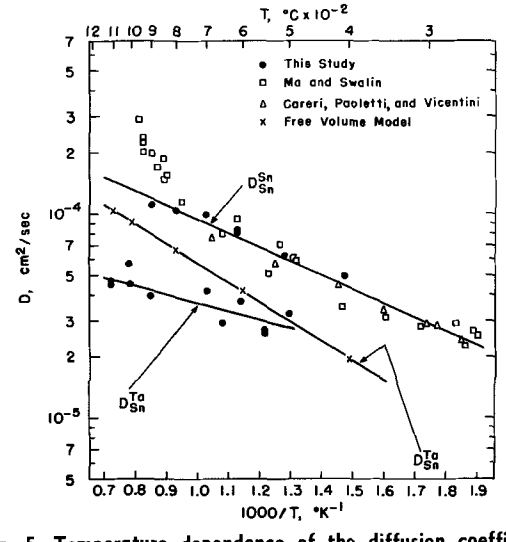

Fig. 5. Temperature dependence of the diffusion coefficient of Sn-113 and Ta-182 in liquid tin; •, x, this study; □, Ma and Swalin (8); △, Careri et *al.* (7).

$$D_{Sn^{Sn}} = (4.59 \pm 0.19)\ 10^{-4} \exp\left[\frac{-3{,}160 \pm 250}{RT}\right] \quad [10]$$

The experimental tantalum diffusion data in Fig. 5 are expressed by the relation

$$D_{Sn^{Ta}} = (9.72 \pm 0.93)\ 10^{-5} \exp\left[\frac{-1{,}930 \pm 900}{RT}\right] \quad [11]$$

at the 95% confidence level. The modified Cohen-Turnbull free-volume model (9) for solute self-diffusion in liquids yielded the following result for tantalum self-diffusion.

$$D_{Sn^{Ta}} = (4.98 \times 10^{-4}) \exp\left[\frac{-4{,}270}{RT}\right] \quad [12]$$

The data for the diffusion coefficient of Ta-182 in liquid tin fall below the tin self-diffusion data. This result is in agreement with the free volume model; however, the experimental activation energy of 1,930 cal/mole is less than half of that predicted by the model in Eq. [12].

The viscosity data for liquid tin in Fig. 6 were taken from the literature (10-13). Gebhardt's (10) data, which were measured over the largest temperature interval, result in the following expression for the kinematic viscosity

$$\nu = (7.83 \pm 0.07)\ 10^{-4} \exp\left[\frac{1190 \pm 40}{RT}\right] \quad [13]$$

Figure 7 illustrates the temperature dependence of the dissolution flux at a rotational speed of 10 rpm (Re ~5 x 10^3). The dashed line gives the temperature dependence of the dissolution flux predicted by Eq. [8]. The experimental activation energy for tantalum diffusion was inserted into Eq. [8] with the over-all heat of solution of tantalum in liquid tin and the activation for viscosity to obtain the value of Q_{Jm} of 16,870 cal/mole.

The velocity dependence of the dissolution flux at four temperatures is shown in Fig. 8. The half-power velocity dependence of the dissolution flux at constant temperature predicted by Eq. [3] is observed at the higher temperatures over an appreciable velocity range.

All of the experimental dissolution data obtained in this study are plotted in Fig. 9. By application of the half-power velocity relationship to the dashed line in Fig. 8 for the 10 rpm data, the high-temperature portion of the curves were generated for the additional velocities. The experimental data points at 1100° and 1200°C are in reasonable agreement with the temperature dependence predicted by the curves.

Discussion

The dissolution data can be examined in terms of the temperature and velocity dependence and the mag-

** The dissolution flux, J_m, is in units of g Ta/cm²-sec.

nitude of the dissolution flux. When the activation energies for competing rate processes in a reaction differ in magnitude by a significant amount, a change in slope in the Arrhenius plot of the rate can occur depending upon the temperature interval that is investigated. Arrhenius plots of this type have been observed for the oxidation of graphite (14, 15), the oxidation of metals which form volatile oxides such as molybdenum (16), and also for the dissolution of metals in acids (17). The decrease in the activation energy with increasing temperature was indicative of a transition from surface or reaction control to transport control. The data in Fig. 7 indicate a similar transition in this system. As the temperature increases, the temperature dependence of the dissolution flux approaches the value of 16.9 kcal predicted by the model for diffusion control. Temperature limitations imposed by the apparatus would not permit a quantitative check of the activation energy over a wider temperature interval. The large activation energy of ~90 kcal at the low temperatures can be associated with the surface reaction for the rate of transport of tantalum across the solid-liquid interface.

Much of the experimental data in Fig. 9 was obtained in a region of mixed transport control. When the dissolution rate is a function of both the rate of the surface reaction and the rate of diffusional transport through the boundary layer, a change in experimental conditions can result in a shift of reaction control toward one of the limiting cases. For example, a decrease in velocity from 150 to 5 rpm at 1100°C shifts the dissolution process from mixed transport control to diffusion control. The effect of temperature on the dissolution process noted earlier for the 10 rpm data in Fig. 7 is also applicable to the other velocities; however, as the velocity increases, the transition from mixed to diffusion control moves to higher temperatures.

A quantitative comparison of the dissolution flux from Eq. [3] and the experimental values in a region of diffusion control is made in Table III. The calculated flux values based on experimental diffusion data are, on the average, about 20% lower than the experimental values. It should be pointed out that this difference would be reduced considerably if the 12% reduction in the calculated dissolution flux due to the $I_{(D/\nu)}$ correction were not applied. The D values for each of the runs in Table III were obtained by inserting the experimental flux values into Eq. [3]. While these D values are approximately 30% higher than the least squares values from the capillary-reservoir method, they fall within the plus two sigma limit of the experimental diffusion data.

The relatively small difference in the diffusion coefficients by the two methods cannot be attributed to the thermodynamic factor in the relationship between the chemical and tracer diffusion coefficients, *i.e.*, $D_{Ta} = D_{Ta}^*\ (1 + d \ln \gamma_{Ta}/d \ln N_{Ta})$. In the event that the tantalum-tin solution deviates from ideal or dilute solution behavior, the diffusion coefficients from the capillary-reservior method become chemical diffusivities since the solute concentrations in the capillaries were near saturation while the solute concentration in the reservoir remained near zero. Thus, the thermodynamic driving force in the diffusion measurements was analogous to that during dissolution in a region of diffusion control.

An experimental problem inherent in the measurement of the diffusion coefficient in this system could easily lead to the low D values. The quartz capillaries were filled from a tin reservoir saturated with high specific activity tantalum at temperatures between 500° and 1100°C. Autoradiographs of the filled capillaries indicated that the activity was distributed homogeneously. The capillaries were subsequently diffused at temperatures from 10° to 20°C above the filling temperature to insure that all of the activity returned to solution. However, in view of the low solute concentrations involved in this study, there is the possibility that the above condition was not completely attained. This factor may be the primary reason for the low diffusion results since the same experimental methods that were employed in the tin self-diffusion measurements were applied to these measurements.

Conclusions

The data presented in this paper provide a critical test of the convective-diffusion model in a high-temperature liquid metal system. The velocity and temperature dependence of the dissolution flux under conditions of diffusion control are in good agreement with the model. The flux values also agree within the limits of error of the experimental diffusion data. The validity of the assumption that the solute concentration is independent of radial position, which leads to the important property that the magnitude of the convective-diffusion boundary layer is constant over the surface of the disk, was evidenced by the uniform thinning of the disk under the laminar flow conditions.

The modified flux relation now applicable to a wide range of Schmidt numbers resulted in a 12% reduction in the calculated dissolution flux in the tantalum-tin system. The correction factors would be significant when diffusion coefficients are calculated from the flux relation in systems with Schmidt numbers below 1000.

A shift in reaction control for the dissolution process

resulting from changes in experimental conditions has been amply demonstrated in a liquid metal system.

Potential of Aluminum in Aqueous Chloride Solutions

T. Hagyard and W. B. Earl[1]

Department of Chemical Engineering, University of Canterbury, Christchurch, New Zealand

ABSTRACT

By using a high-speed technique described in ref. (1), anodic (aluminum dissolution) polarization data have been obtained for aluminum surfaces free from oxide films and from the normal concurrent hydrogen evolution. Similarly cathodic (hydrogen evolution) polarization data have been produced for oxide-free aluminum surfaces on which the usual simultaneous anodic process has been suppressed. These results have been applied to the interpretation of the static "mixed" potential reported in ref. (1). It has been deduced that at the mixed potential the anodic area most probably comprises less than 0.5% and the cathodic area 99.5% of the total surface.

Measurements of anodic and cathodic polarization on highly reactive metals such as aluminum, magnesium, and titanium are commonly made on specimens covered with the usual spontaneously formed oxide film, and it is likely that the effective area for such measurements is that of pores in the film so that conclusions from such measurements are subject to considerable doubt.

These difficulties may be avoided and considerable new insight obtained as to the electrode process if, instead, observations are made on surfaces newly formed in contact with the solution, provided that the experimental method is suited to the very fast processes which then become apparent.

For aluminum it was found (1) that a new aluminum surface, formed sufficiently rapidly under aqueous potassium chloride, underwent first a very rapid fall in potential reaching a minimum value in a few microseconds and that this represented the reversible potential of aluminum uncomplicated by concurrent hydrogen evolution. During the following millisecond, it was found that the potential then increased due to the onset of hydrogen evolution and became stabilized after about 1 msec at a mixed potential which then remained substantially constant in the absence of oxygen. In the presence of dissolved air, the potential rose further, due to oxide film formation, becoming constant after some 5-10 sec at a much more positive value.

The present work was directed at using the large differences in time constants between the first two processes to provide a means of obtaining polarization curves for the anodic dissolution of aluminum and for the cathodic evolution of hydrogen on aluminum. These curves cannot be obtained by normal means for the following reasons. For both processes oxide films must be absent, and so far as the authors are aware no data for such a condition have been published. In the present work, oxide films were certainly absent first because an atmosphere of purified hydrogen (see experimental section) was maintained from the initial cutting of the new aluminum surface, and second because observations were limited to the first millisecond after cutting and contamination of the surface by oxygen or any other trace impurities takes place with time constants that are very long in comparison [see ref. (1), p. 2293]. (Experimentally observed time for effect of oxygen is *ca.* 3 sec, and a simple calculation shows that the time for the arrival of a monolayer of oxygen atoms by diffusion alone in air saturated solutions is *ca.* 5 sec.)

For the anodic dissolution of aluminum, a major difficulty in measurements of the overvoltage by normal techniques is that concurrent hydrogen evolution cannot be prevented. Consequently the total anodic current is greater than the external current. Also since two processes are proceeding simultaneously the area which is actually acting as anode is in considerable doubt. In the present work these difficulties were avoided by observing the potential of a polarized newly cut aluminum surface during the first few microseconds, this procedure being justified in a later section and in ref. (4). For this short time it seemed (1) that the whole of the exposed surface must be anodic and that hydrogen evolution, time constant 1 msec, would contribute negligibly to the current. Consequently it is claimed that the polarization data produced by these means were the first observations in

[1] Present address: Shawinigan Chemicals Limited, Montreal East, Quebec, Canada.

which substantially all the surface was anodic and in which no appreciable hydrogen evolution was taking place.

For the measurements of the polarization of hydrogen discharge, another property of the system had to be used. If an electrode at the mixed potential is cathodically polarized from an external source, then the potential will move in a more negative direction and, if the polarizing current density is continually increased, the "mixed" potential will eventually equal and then become more negative than the reversible potential of aluminum in that solution, and at this point the anodic reaction must cease. By polarizing the newly cut surface at current densities high enough to produce potentials more negative than the normal peak potential, this condition was fulfilled, and the data so obtained therefore referred to an aluminum surface none of which was anodic, *i.e.*, to a wholly cathodic surface on which the only process occurring was the discharge of hydrogen ions.

Experimental

The experimental cell of polyethylene is shown diagramatically in Fig. 1 in which, during use, the electrode, 4, was driven at 1000 cm/sec past a ruby cutter, 8, by the impact of a spring-driven hammer on the anvil, 1, thereby cutting a notch, area some 10^{-3} cm^2, in the flange of the electrode and coming to rest clear of the electrode and embedded in the polyethylene insulation, 9. The electrode, before cutting, was entirely covered by a coating of polyethylene, 9, some 0.5 mm thick providing an insulation resistance around 50 Mohm. By reducing the thickness of the flange which was to be cut to a limit of 0.05 mm, it was possible to reduce the time of cutting to 5 μsec [cutting time in the range 5-100 μsec (5-15 μsec) did not affect the cathodic (anodic) results; although cutting velocity was altered however, the maximum obtainable was always used for obvious reasons]. An antisplash guard of PTFE, 3, was provided. The electrode moved in a duralium bush, 2, which was electrically connected to the electrode so as to avoid electrostatic effects.

Polarizing current was supplied via a platinum wire electrode, 7, purified hydrogen (from "Milton Roy" palladium diffuser, impurity content less than 0.01 ppm), was supplied via 6. The solution was thus saturated with H_2 at a pressure essentially atmospheric. Connection to the *N* calomel electrode was made through a cellophane membrane via 5, it being necessary for high-speed circuitry to provide a salt bridge of large cross section shown so as to keep the resistance of the measuring circuit down to about 1000 ohms. The potential was fed to a cathode follower of impedance 10^9 ohms and thence to the oscilloscope, the total circuit rise time being 6 μsec. [Subsequent experiments performed first using a high-speed cathode follower (rise time 0.1 μsec) and later again without a cathode follower with the cell directly coupled to a high speed oscilloscope (rise time 0.023 μsec) gave the same results.]

The polarizing current was supplied by the transistor circuit, Fig. 2. The latter was necessary because the cathode follower between the test electrode and the oscillograph became deranged if more than 4.5v was applied to it. Nevertheless, it was essential that the chosen polarizing current (0.1 — 1000 μa) must remain constant, starting immediately the cut closed the electrolytic circuit but not imposing more than 4.5v on the cathode follower during the completely insulated period before cutting the specimen. The circuit in Fig. 2 permitted this and had a time constant of <1 μsec.

The above cell differed from that used in ref. (1) because in the latter the electrode was stationary and the cutter moved past it. In doing so it left a cavity, the collapse of which delayed the wetting of the electrode surface. The present design overcame this difficulty and, as will be mentioned, also eliminated possible concentration polarization due to the very high rate of shear produced in the surface film of electrolyte.

Results

Anodic polarization.—A solution 1M KCl + 0.00033M $AlCl_3$ of *p*H 3.2 was used throughout, the aluminum ion being present so that the reversible potential of the aluminum electrode would be defined.

Typical oscillograph traces are shown in Fig. 3. In all traces herein potentials are on the hydrogen scale. In these traces the 1000 Hz sinusoidal trace was used as time base and as the potential calibration. Before the cut, the potential of the still insulated electrode was + 4.5v and on making the cut the trace became more negative due to the ionization of the aluminum. The rate of fall was probably limited initially by the speed of the cathode follower-oscilloscope circuit. The minimum potential was that recorded for the polarization curves. The subsequent rise to the mixed po-

tential is evident from Fig. 3, but is irrelevant to the measurements of anodic polarization. Using various impressed currents and measuring the apparent area of the cut surface gave the polarization plot of Fig. 4.

The justification for using minimum potentials attained during the first 10-30 μsec after cutting the electrode is based on two grounds. When cutting is fast enough (complete in <15 μsec) then the minima occur most often about 20 μsec and independently of cutting time. Observations in the absence of polarizing current gave minimum potentials in this solution ($AlCl_3$ = 0.00033M) of —1.65v, and this may be compared with the calculated E_o = — 1.66v quoted by Latimer (2). If the activity were equal to the concentration, then the measured potential here should in fact have been —1.71. Latimer's value refers naturally to unit aluminum ion activity, but has not been confirmed experimentally nor is the aluminum ion activity known in these solutions. The agreement seems satisfactory for present purposes especially in view of the wide confidence limits at present obtainable. Additional justification for these high-speed potential measurements is provided by similar measurements on cadmium by Chapman (4). In this work 10-30 μsec values of the potential of cadmium in cadmium chloride were compared with the values obtained by standard static potentiometric methods. Cadmium was chosen as being substantially free from concurrent hydrogen evolution. Agreement within some 10 mv was found thus confirming that equilibrium potentials of metals may be measured in the short times used in the present work.

The results in Fig. 4 are more scattered than could be wished, but this is not surprising in view of the experimental difficulties including inevitable scatter due to the roughness of the cut surface not being under control. The plot of potential *vs.* log i is here interpreted, as a first approximation, in terms of a charge-transfer-controlled single step process of the type represented by

$$i = i_o\left[\exp\left(\frac{-\beta n\mathbf{F}\eta}{RT}\right) - \exp\left(\frac{(1-\beta)n\mathbf{F}\eta}{RT}\right)\right]$$

Bockris (5). Where η, as in this work, exceeds + 100 mv, the first term is negligible and a linear Tafel plot of the form $\eta = \frac{RT}{(1-\beta)n\mathbf{F}} \ln \frac{i}{i_o}$ should be obtained. Here $1-\beta$ is the fraction of the interface potential difference effective in the anodic charge transfer process. When the current density is increased to the point where other reaction steps become rate controlling, the linearity is expected to fail, as is normal experience, and these results tend to confirm this.

In Fig. 4 the best straight line has been computed for all points at anodic current densities less than 0.1 amp/cm², above which current density marked deviation is likely. The slope $\frac{RT}{(1-\beta)n\mathbf{F}}$ is found to be 0.18 v/log i with 90% confidence limits 0.12 to 0.24. Hence $\alpha = (1-\beta)n$ = 0.34 with 90% confidence limits 0.53 to 0.25.

The intercept (i_o) of the polarization curve with the reversible potential (our minimum potential —1.65v) is found to be 9 x 10^{-4} amp/cm² with 90% confidence limits 2 x 10^{-4} to 5 x 10^{-3} amp/cm².

Cathodic polarization (hydrogen overvoltage on aluminum).—A solution of 1M KCl pH 3.2 was used throughout, aluminum ion being excluded so that only hydrogen could be discharged.

A typical trace is shown in Fig. 5b. In this trace the electrode potential before cutting is —4.5v, and after cutting becomes more positive very quickly, reaching its most positive value in about 30 μsec at a value appreciably more negative than the reversible potential of aluminum. There follows a slow fall of some 100 mv with a time constant rather less than 1 msec. The potential after 1 msec was that used in obtaining the cathodic polarization curve, Fig. 6, since all observations showed that equilibrium was substantially reached after this time. Concentration polarization, which might have been expected with these unbuffered solutions, was in no case detectable during this short period immediately following the cut even at the highest current densities used. This was apparently due to the extremely effective suppression of the diffusion layer at the electrode surface because of the

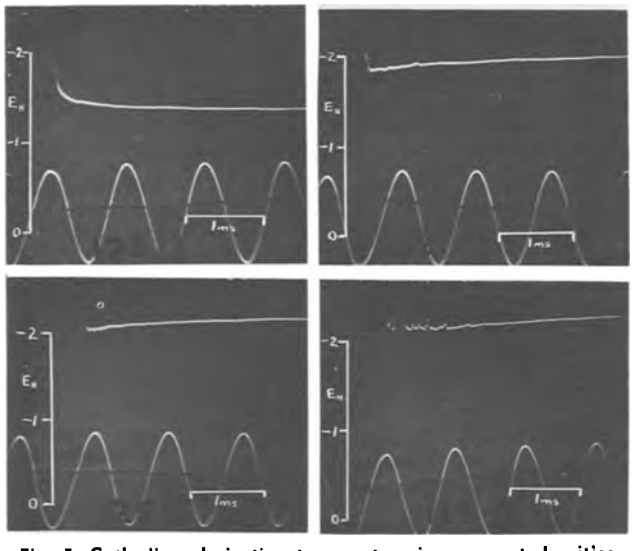

Fig. 5. Cathodic polarization traces at various current densities. Al in 1M KCl, pH 3.2 (a) (top left) $i<10^{-2.2}$ amp/cm² (b) (top right) and (c) (bottom left) $10^{-2.0}<i<10^{-0.2}$ amp/cm² (d) (bottom right) $i>10^{-0.2}$ amp/cm².

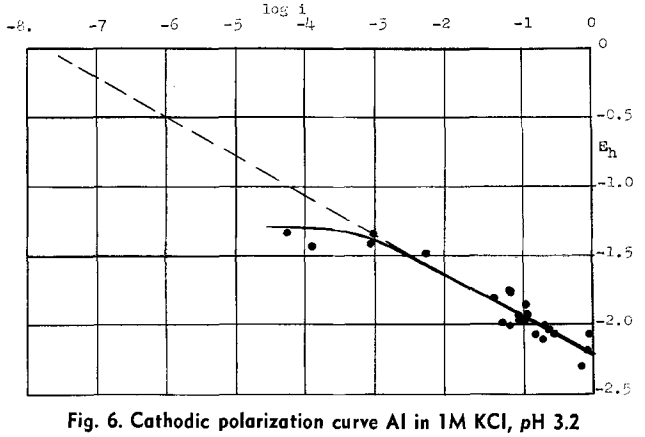

Fig. 6. Cathodic polarization curve Al in 1M KCl, pH 3.2

large velocity difference of 1000 cm/sec between electrode and solution.

Figure 5a shows by contrast that at current densities sufficiently low for the potential to be more positive than the aluminum potential in this solution [see ref. (1), Fig. 5g], then the oscillograph trace is different in form, now rising smoothly to a constant value which is in reality a mixed potential, part of the current being supplied internally from aluminum dissolution at local anodes. The potentials after 1 msec were nevertheless still used for the data of Fig. 6, although it is understood that the points so obtained cannot lie on the correct Tafel line since the measured external current is, in fact, less than the total current in these cases. This accounts for the break in the curve, Fig. 6, at around —1.5v.

The different forms to be observed in the early stages of the traces in Fig. 5 are discussed in a later section. For the present, Fig. 6, derived from the steady potentials after 1 msec, should represent in the lower portion, below —1.6v, the polarization of hydrogen evolution at a wholly cathodic aluminum surface, free from oxide films and at such high overvoltage (more than —1.4v) that the Tafel equation might be expected to be obeyed. Consequently, the best straight line has been computed from those experimental points below —1.67v and is shown in the figure. The straight portion has a gradient of 0.29 v/log i resulting in $\alpha = 0.21$ with 90% confidence limits 0.16 and 0.30 where α is defined by

$$\eta = \frac{RT}{\alpha \mathbf{F}} \ln \frac{i_o}{i}$$

The dotted extrapolation of the straight line to $\eta = 0$ gives $i_o = 7 \times 10^{-8}$ amp/cm^2 with 90% confidence limits 1×10^{-9} and 6×10^{-6}.

Discussion of Results

The mixed potential, in the absence of external current, was observed in these measurements to be —1.30v in substantial agreement with —1.28v recorded in ref. (1). If now the current densities at which the anodic and cathodic Tafel lines reach —1.30v be taken from Fig. 4 and 6, respectively, 1.15×10^{-1} and 5.5×10^{-4} amp/cm^2, then the anodic and cathodic areas operative at the mixed potential are in the inverse ratio, *viz.*, 1:210. Thus, based on the most probable results, represented by the lines in Fig. 4 and 6, only 0.5% of the surface was anodic. Taking into account the standard error on each intercept, the 90% confidence limits for the anodic area are found to be 5% and 0.05% of the total surface. It is quite evident that the anodic is much smaller than the cathodic area at equilibrium.

Obtaining this information was the main object of this work, but the oscillograph traces produced under cathodic polarization, in addition give some hints as to probable electrode mechanisms.

When a new aluminum surface is exposed in the absence of external current, it would be expected that the initial potential would approximate to the (unknown) zero charge potential of aluminum in the solution. All observations made on unpolarized electrodes have indicated that the newly cut surface was initially at a potential lying between +1 and —1v, and it seems likely that the zero charge potential is in this region assuming the equilibrium establishing this occurs in less than a few microseconds. Very quickly thereafter, ionization of aluminum provides the electrons for charging the double layer capacitance to the minimum potential. This process has been shown to be very rapid.

Similar reasoning applies to the anodically polarized surface and explains the shape of the oscillograms.

If the electrode were polarized cathodically, it would still be expected that the double layer on the new surface would act as a capacity initially between +1 to —1v and would draw electrons from the stray capacitance, already at a high negative potential (4.5v), moving the potential in microseconds in a positive direction to a value near the zero charge potential. Since the stray capacitance was in fact only 1% of the usual double layer capacitance of around 20 μF/cm^2, then the potential should first have been driven quite close to that of zero charge before again becoming negative due to the constant impressed cathodic current balanced by hydrogen evolution. This behavior was never observed, and there has never been any sign of a break in the smooth descent of the oscillograph traces. Hence it may be concluded, tentatively, that whereas on open circuit or during anodic treatment a double layer can be formed very rapidly by ionization of the abundant surface atoms of aluminum, this type of double layer cannot be formed when the potential is held initially far above the reversible potential of aluminum. It is presumed that in this case a double layer of quite different properties is formed and that its capacity initially must be very small compared with that of aluminum in equilibrium with its ions, or alternatively that its rate of formation is much slower, otherwise there would be a marked break in the descending trace.

Another property of the cathodic traces is seen clearly in Fig. 5b and c where the trace descends to a minimum and then rises over about 1 msec to an equilibrium value some 100 mv more negative. The minimum in the trace could well represent the formation of adsorbed hydrogen atoms on the aluminum surface, accumulating over about 1 msec to the point where the rate of combination to molecules equals the current. This would imply that combination to molecules is the rate determining process. That the situation is more complicated than this is shown by traces such as Fig. 5d which were repeatedly obtained at current densities exceeding 0.7 amp/cm^2. The initial period of unstable potentials shown in the figure and always lasting approximately 1 msec is intriguing and seems to represent a process of molecular hydrogen formation of an explosive or chain reaction type. Obviously such speculations are premature in view of the paucity of the data, but there seems to be a possibility that oscillograph traces such as these could well be an unusually direct means of investigating the mechanism of hydrogen discharge.

Conclusions

By observations up to 30 μsec after the formation of a new aluminum surface in 1M KCl + 0.00033M $AlCl_3$ an anodic polarization curve for aluminum dissolution, free from simultaneous hydrogen evolution, has been obtained. For that portion to which the Tafel equation could be expected to apply it has been found that the most probable values for α and i_o are

$$\alpha = 0.34$$

and

$$i_o = 9 \times 10^{-4} \text{ amp/cm}^2$$

By observations after 1 msec during cathodic polarization in 1M KCl at such negative potentials that aluminum ion production was not possible, similar data for hydrogen evolution on aluminum have been found. The most probable values are

$$\alpha = 0.21$$
$$i_o = 7 \times 10^{-8} \text{ amp/cm}^2$$

The technique eliminates the possibility of interference by oxide films or trace impurities.

At the open circuit mixed potential on clean aluminum in 1M KCl it follows that, using mean values, 0.5% of the surface is anodic and 99.5% is cathodic.

Transient phenomena were observed which indicate increased complexity in the hydrogen discharge process at high current densities.

Electrolytic Dissolution of Binary Alloys Containing a Noble Metal

H. W. Pickering

and C. Wagner

Max-Planck-Institut für Physikalische Chemie, Göttingen, Germany

ABSTRACT

In the electrolytic dissolution of binary alloys the concepts of ionization and redeposition of a metal, coupling of the anodic reactions in accordance with the concepts of irreversible thermodynamics, and volume diffusion in the presence of given supersaturations of single and double vacancies are analyzed theoretically. The ionization-redeposition mechanism is in principle possible but only if coupling of the anodic reactions occurs. Volume diffusion may be operative *via* divacancies. Results from x-ray investigations and from measurements with a rotating disk-ring electrode for copper-gold alloy indicate that interdiffusion of the constituent metals in the alloy occurs to a significant extent and dissolution of Au does not take place. Electrochemical measurements with a Cu-Zn alloy involving 30 a/o (atomic per cent) Zn give no indication of occurrence of the ionization-redeposition mechanism.

When a single-phase binary alloy A-B is anodically dissolved in an aqueous solution, the mode of dissolution may be (*a*) simultaneous dissolution of the two constituent metals of the alloy, or (*b*) preferential dissolution of the less noble metal of the alloy with the more noble metal accumulating on the alloy surface. For the latter mode it is necessary that the difference between the single electrode potentials of the two constituent metals in the electrolyte involving possibly complexing agents is sufficiently large, *i.e.*, several times greater than $RT/\mathbf{F}$, and that the potential of the dissolving alloy is higher than that of the less noble metal A and significantly lower than that of the more noble metal B. A spongy layer of the remaining more noble metal has been reported especially for Cu-Zn and Au-Cu alloys (1-11). Obviously, there must be a transport mechanism by virtue of which the atoms of the less noble metal A reach the surface and atoms of the more noble metal B aggregate. It is the objective of this paper to discuss pertinent transport mechanisms and to obtain experimental evidence for the occurrence of one or the other of these mechanisms.

Theoretical

When one metal is preferentially dissolved it may be assumed that one or more of three mechanisms operate: (*i*) both metals ionize followed by redeposition of the more noble metal; (*ii*) only the less noble metal ionizes and enters the solution while the atoms of the more noble metal aggregate by surface diffusion; and (*iii*) only the less noble metal ionizes and enters the solution and atoms of both metals move in the solid phase by volume diffusion.

Ionization-redeposition mechanism.—The ionization-redeposition mechanism may be examined by considering, for example, the dissolution of a Cu-Zn alloy. Assume first that the anodic reactions

$$\mathrm{Zn(Cu\text{-}Zn)} = \mathrm{Zn^{2+}\ (aq)} + 2e^- \qquad [1]$$

$$\mathrm{Cu(Cu\text{-}Zn)} = \mathrm{Cu^{2+}\ (aq)} + 2e^- \qquad [2]$$

are independent of each other and also independent of the cathodic redeposition reaction

$$\mathrm{Cu^{2+}\ (aq)} + 2e^- = \mathrm{Cu\ (nearly\ pure)} \qquad [3]$$

Since the activity of Cu in Cu-Zn is less than unity with respect to pure copper, the single electrode potential for equilibrium of reaction [2] in a solution of given Cu^{2+} ion concentration is more noble than that of reaction [3] involving pure copper. Thus, dissolution of copper from Cu-Zn according to reaction [2] can take place only if the electrode potential is more noble than the equilibrium electrode potential for reaction [2] and thereby even somewhat more noble than the equilibrium electrode potential for reaction [3]. Consequently, if a short-circuited couple of Cu-Zn and pure copper is made the anode with a predetermined current, one has to expect that copper ions enter the solution from the Cu-Zn surface and from the pure copper surface as well, provided that there is no coupling between reactions [1] and [2]. However, if in accordance with the principles of irreversible thermodynamics, coupling between reactions [1] and [2] occurs, *i.e.*, the coefficients for cross terms in the general rate equations are finite, the anodic dissolution of copper from Cu-Zn alloy according to reaction [2] may take place at a potential less noble than the equilibrium potential for reaction [3]. The copper ions that enter the solution from the Cu-Zn surface may then be redeposited at the copper surface according to reaction [3]. The occurrence of ionization and redeposition of copper during dissolution of a Cu-Zn alloy may be readily checked with the help of the rotating assembly of a disk of Cu-Zn alloy surrounded by a ring of pure copper described below.

The concept of coupling between reactions [1] and [2] is only a formal description of rate relations which may eventually be found. If the hypothesis of coupling of reactions [1] and [2] is supported by the aforementioned experiment, one may ask for a model in atomistic terms. The following model is suggested. If a Cu-Zn electrode is subjected to anodic dissolution there is the tendency for zinc atoms to enter the solution as ions preferentially and for copper atoms to remain at the surface in the form of adsorbed atoms which migrate at random and may aggregate in order to form grains of virtually pure copper. Since diffusion of adsorbed Cu atoms to grains of virtually pure copper requires an activity gradient, the average activity of copper on the surface may be higher than unity, and thus the steady-state potential for partial equilibrium between adsorbed copper atoms and the solution may be less noble than the equilibrium potential between bulk copper and the solution. If this situation prevails, zinc and copper ions may be dissolved from a Cu-Zn electrode, and copper may be plated out at the same electrode potential on the surface of copper grains where the concentration of adsorbed copper atoms is close to the equilibrium value with the bulk crystal.

Surface diffusion mechanism.—Aggregation of adsorbed atoms of the more noble metal by virtue of surface diffusion leads primarily to the formation of patches of monolayers. In addition, atoms of the more noble metal may pile up on the initial patches of monolayers, and thus small three-dimensional crystals of the more noble metal may be formed. If these crystals grow in all three dimensions, there is the tendency to form finally a dense layer of the more noble metal which prevents further anodic dissolution of the less noble metal. This is to be expected especially if the mole fraction of the more noble metal is high as, *e.g.*, in alpha brass. The significance of surface diffusion has been emphasized most recently by Feller (11), but it has still to be shown that this mechanism accounts for all observations.

Volume diffusion mechanism.—Mechanism [3] involving ionization of the less noble metal and movement of both metals in the atomic state by volume diffusion would normally be considered inoperable on the basis of diffusivities extrapolated from high-temperature measurements. Use of this extrapolation implies that (*a*) equilibrium concentrations of vacancies (and interstitials) are established at room temperature as at elevated temperatures, and (*b*) the contribution of diffusion along small-angle grain boundaries and along dislocations is negligible at room temperature. Many authors have already pointed out that the second condition may not be satisfied and, therefore, the effective (average) diffusion coefficient at room temperature may be considerably greater than the value of the volume diffusion coefficient obtained by extrapolation of high-temperature data. In addition, it is possible that also the first condition is not satisfied as is discussed next.

Anodic dissolution of metal may be considered as an analogue (12) of vaporization of a metal; the latter is assumed to take place in the kink-step-terrace model of a surface after Kossel (13) and Stranski (14) first, by detachment of an atom from a kink corresponding to the formation of an adsorbed atom along the step and then along the terrace, and followed by desorption of an adsorbed atom into the gas phase. Direct vaporization of an atom from a kink or step position is also a possible but rare event. Further, vaporization of an atom from a complete lattice layer (terrace site) acompanied by formation of a surface vacancy may occur, but this would require a high activation energy. These events are, therefore, assumed to be rare events. Likewise, anodic dissolution of a pure metal is assumed to occur with the formation of an adsorbed atom as an intermediate.

A new situation arises when an alloy A-B is subjected to anodic polarization and only atoms of the less noble component A enter the solution as ions. As an example consider a Cu-Au alloy involving 10 a/o Au in H_2SO_4(aq), as investigated by Gerischer and Rickert (6). In this case virtually only copper enters the solution as Cu^{2+} ions. A partial step on the surface with a sequence of Cu and Au atoms is shown in Fig. 1. When a current is passed in the anodic direction, first a copper atom from position 1 may move from its kink position in order to become an adsorbed atom and subsequently to enter the solution as an ion. Then, the gold atom initially at position 2 may also move to become an adsorbed atom. Thus, the Cu atom initially at position 3 becomes the last atom in the step and may be ionized by the same mechanism which has been assumed for the copper atom initially at position 1, as is also true for the copper atom initially at position 4. The gold atom now at the end of the step may also move to become an adsorbed gold atom. In view of the continuous increase of the concentration of adsorbed gold atoms, there is, however, an increased tendency of gold atoms to move back to the kink positions at the end of a step. Thus, after removal of a sizeable fraction of copper atoms from the step, it happens only very rarely that a copper atom occupies the last position in a step and is free to move from its kink position and to be desorbed as an ion. This leads to electrochemical polarization, *i.e.*, the electrode assumes a potential considerably above the equilibrium potential. The increase in the driving force necessary to maintain a constant current may now make it possible that an atom not at the end of a step, *e.g.*, the copper atom at position 8 may enter the solution as a divalent ion. As the driving force is further increased, Cu atoms from complete lattice layers may enter directly the solution as Cu^{2+} ions. In this way, surface vacancies are formed continuously. Surface vacancies in a partially complete step may be filled by lone adsorbed atoms or by a sequence of movements of atoms in a step. Surface vacancies in a complete lattice layer may also be filled by adsorbed lone atoms. In addition, atoms from the lattice layer underneath the surface may fill surface vacancies whereby excess monovacancies and also divacancies in the interior of the alloy may be created. In view of the random walk of these vacancies, excess vacancies will appear not only directly next to the surface, but also in a certain volume of the crystal underneath the surface. Diffusion of monovacancies and divacancies into the interior of the alloy is limited because of the presence of dis-

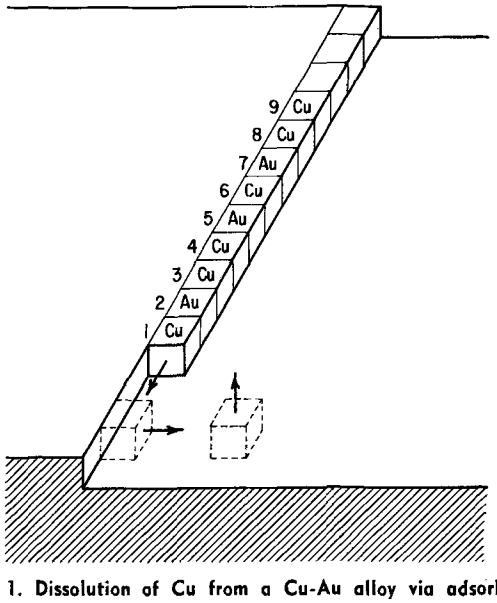

Fig. 1. Dissolution of Cu from a Cu-Au alloy via adsorbed Cu atoms as intermediates.

locations which are sinks for vacancies. In view of the continuous production of vacancies at the surface, the number of available sinks for vacancies in the vicinity of the surface is reduced and subsequently excess vacancies may diffuse to greater distances from the surface while anodic dissolution is continued. The build-up of an excess vacancy concentration in the vicinity of the surface, which has already been considered by Schottky (15) in conjunction with the oxidation of metals at elevated temperatures and suggested by Forty (16) in conjunction with dezincification at room temperature, would also enhance chemical diffusion, *i.e.*, movement of copper atoms from the bulk alloy to the surface and backward diffusion of gold atoms according to the gradient of the Cu/Au ratio. In this way, more and more copper atoms may enter the solution as Cu^{2+} ions, and the alloy next to the surface would become enriched with respect to gold. The removal of copper may be facilitated by roughening of the surface.

Harrison and Wagner (9) have theoretically analyzed diffusion processes during the preferential dissolution of Cu from solid Cu-Ni alloys in liquid Ag at 1000°C and have shown that a plane solid-liquid interface is not stable. In accord herewith they have observed that a highly rugged interface is formed while preferential dissolution of Cu proceeds. In particular, they have observed wedges filled with liquid metal protruding into the interior of the alloys. Similarly, preferential anodic dissolution of Cu from Cu-Au alloys at room temperature may proceed. Primary wedges filled with electrolyte may originate especially at sites where grain boundaries or dislocations reach the surface. Branching of the wedges may occur to form networks. In the case of copper which contains a small fraction of gold, small volume elements can become undermined and eventually lose contact with the sample as is known to occur during electrolytic refining of copper. In copper-gold alloys containing larger fractions of gold, *i.e.*, over 5 a/o, as well as in Cu 30 w/o (weight per cent) Zn, an adherent porous layer results as has been reported by various authors (1-11). One may ask, however, whether diffusion via excess vacancies is sufficiently rapid so that the above mechanism can be operative.

Monovacancies cannot account for diffusion of copper at room temperature because the diffusivity $D_{\square}$ of monovacancies is too low. According to Ramstetter, Lampert, Seeger, and Schüle (17) $D_{\square}$ in pure copper at 25°C equals $3 \cdot 10^{-19}$ cm²/sec. Thus, according to Einstein, the mean square displacement of a monovacancy $\overline{\Delta x^2}$ for $t = 1000$ sec is only $\overline{\Delta x^2} = 2D_{\square}t = 6 \cdot 10^{-16}$ cm² which is of the order of the square of the distance between neighboring Cu atoms. Instead, diffusion of copper atoms via divacancies may be operative because their diffusivity (17), $D_{\square\square} = 1.3 \cdot 10^{-12}$ cm²/sec in copper at 25°C, is much higher, as is shown by the following calculation.

Consider anodic dissolution of copper from a Cu-Au alloy with a plane surface and one-dimensional diffusion normal to the surface. The initial condition is

$$c = c_o \text{ at } x > 0,\ t = o \qquad [4]$$

where c is the local and c_o is the bulk concentration of Cu (mol/cm³) in the Cu-Au specimen and x is the distance from the initial metal surface. Assume that during anodic dissolution the concentration of copper atoms at the surface is virtually equal to zero

$$c = 0 \text{ at } x = x_s \qquad [5]$$

where x_s is the instantaneous distance of the liquid-solid interface from the position of the surface at $t = 0$.

The amount of Cu arriving at the surface of the alloy in mol per unit area per unit time is $D(\partial c/\partial x)_{x=x_s}$. Thus, the rate of recession of the liquid-solid interface equals

$$\frac{dx_s}{dt} = V_m D \left(\frac{\partial c}{\partial x}\right)_{x=x_s} \qquad [6]$$

where V_m is the molar volume whose dependence on composition is disregarded for the sake of an approximation, and D is the interdiffusion coefficient for movement of Cu *vs.* Au atoms. The value of D with due regard to the contribution of excess vacancies is calculated below.

If the interdiffusion coefficient D is independent of composition and location, Fick's second law reads

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \qquad [7]$$

Equations [4] to [7] are satisfied by

$$x_s = 2\gamma (Dt)^{1/2} \qquad [8]$$

and

$$c = c_o \left(1 - \frac{\operatorname{erfc} \dfrac{x}{2(Dt)^{1/2}}}{\operatorname{erfc} \gamma}\right) \qquad [9]$$

where γ is a constant which is calculated below. Substitution of Eq. [8] and [9] in Eq. [6] yields

$$\pi^{1/2} \gamma \cdot \operatorname{erfc} \gamma \cdot e^{\gamma^2} = c_o V_m = N^o_{Cu} \qquad [10]$$

where $c_o V_m = N^o_{Cu}$ is the bulk mole fraction of copper in the Cu-Au alloy. If N^o_{Cu} is close to unity, γ is large. Therefore, one may use the approximation

$$\operatorname{erfc} \gamma \cong \frac{e^{-\gamma^2}}{\pi^{1/2}\gamma} \left(1 - \frac{1}{2\gamma^2} + \dots\right) \text{ if } \gamma >> 1 \qquad [11]$$

Substituting Eq. [11] in Eq. [10] one obtains

$$\gamma \cong \left[\frac{1}{2(1 - N^o_{Cu})}\right]^{1/2} \text{ if } N^o_{Cu} \cong 1 \qquad [12]$$

If $1 - N^o_{Cu} = 0.10$ corresponding to an alloy containing 10 a/o Au, γ equals 2.23.

With the help of Eq. [8] and [9] the flux j_{Cu} of Cu atoms toward the surface is found to be

$$j_{Cu} = D \left(\frac{\partial c}{\partial x}\right)_{x=x_s} = \frac{c_o e^{-\gamma^2}}{\operatorname{erfc} \gamma} \left(\frac{D}{\pi t}\right)^{1/2} \qquad [13]$$

Substituting Eq. [11] and [12] and $c_o = N^o_{Cu}/V_m$ in Eq. [13] one has

$$j_{Cu} \cong c_o \gamma \left(\frac{D}{t}\right)^{1/2} \cong \frac{N^o_{Cu}}{V_m} \left[\frac{D}{2(1 - N^o_{Cu})t}\right]^{1/2} \text{ if } N^o_{Cu} \cong 1 \qquad [14]$$

The corresponding current density i for the formation of divalent copper ions equals

$$i = 2j_{Cu}\mathbf{F} = N^o_{Cu} \frac{2\mathbf{F}}{V_m} \left[\frac{D}{2(1 - N^o_{Cu})t}\right]^{1/2} \qquad [15]$$

where $\mathbf{F}$ is the Faraday constant.

The "effective thickness" δ of the interdiffusion zone may be defined as usual by the relation

$$\delta = \frac{c_o - c(x = x_s)}{(\partial c/\partial x)_{x=x_s}} \cong \frac{c_o}{(\partial c/\partial x)_{x=x_s}} \qquad [16]$$

Substituting Eq. [13] in Eq. [16] and using Eq. [11] and [12] one obtains

$$\delta = [2(1 - N^o_{Cu})Dt]^{1/2} \qquad [17]$$

If interdiffusion takes place essentially *via* divacancies and correlation effects are disregarded, D in the vicinity of the surface may be expressed approximately as

$$D = D_{\square\square} N^s_{\square\square} \quad [18]$$

where $D_{\square\square}$ is the diffusivity of a divacancy and $N^s_{\square\square}$ is the mole fraction of divacancies in the vicinity of the surface. $N^s_{\square\square}$ is supposed to be much higher than the equilibrium mole fraction $N^{Eq}_{\square\square}$ prevailing in the alloy at the beginning of electrolysis.

If annihilation of vacancies during their diffusion into the interior of the alloy can be disregarded and the diffusivity $D_{\square\square}$ is independent of the alloy composition, diffusion of excess divacancies from the surface into the bulk alloy is governed by Fick's second law

$$\frac{\partial N_{\square\square}}{\partial t} = D_{\square\square} \frac{\partial^2 N_{\square\square}}{\partial x^2} \quad [19]$$

with the initial condition

$$N_{\square\square} = N^{eq}_{\square\square} \text{ at } x > 0,\ t = 0 \quad [20]$$

and the boundary condition

$$N_{\square\square} = N^s_{\square\square} \text{ at } x = x_s = 2\gamma (Dt)^{1/2} = 2\gamma (D_{\square\square} N^s_{\square\square} t)^{1/2} \quad [21]$$

where γ is given by Eq. [10] or [12].

Equations [19] to [21] are satisfied by

$$N_{\square\square} = N^{eq}_{\square\square} + (N^s_{\square\square} - N^{eq}_{\square\square}) \times \frac{\operatorname{erfc}[x/2(D_{\square\square} t)^{1/2}]}{\operatorname{erfc}[\gamma (N^s_{\square\square})^{1/2}]} \cong N^s_{\square\square} \operatorname{erfc}\,[x/2(D_{\square\square} t)^{1/2}]$$

$$\text{if } N_{\square\square} >> N^{eq}_{\square\square};\ \gamma (N^s_{\square\square})^{1/2} << 1 \quad [22]$$

From Eq. [22] we calculate the distance at which $N_{\square\square} = \tfrac{1}{2} N^s_{\square\square}$,

$$x(N_{\square\square} = \tfrac{1}{2} N^s_{\square\square}) = 2(D_{\square\square} t)^{1/2} \operatorname{erfc}^{-1} (\tfrac{1}{2}) \quad [23]$$

From Eq. [21] and [23] it follows that the distance between the position at which $N_{\square\square} = \tfrac{1}{2} N^s_{\square\square}$ and the position of the instantaneous surface is

$$x(N_{\square\square} = \tfrac{1}{2} N^s_{\square\square}) - x_s = 2(D_{\square\square} t)^{1/2} [\operatorname{erfc}^{-1} (\tfrac{1}{2}) - \gamma (N^s_{\square\square})^{1/2}] \quad [24]$$

$= 2 \cdot 10^{-5}$ cm for $N^o_{Cu} = 0.90$; $\gamma = 2.23$; $N^s_{\square\square} = 10^{-2}$; $t = 1000$ sec at 25°C. This distance may be used as a measure of the penetration of excess vacancies into the interior of the alloy. Dividing through corresponding sides of Eq. [24] and Eq. [17] and substituting $D = D_{\square\square} N^s_{\square\square}$ according to Eq. [18], one obtains

$$\frac{x(N_{\square\square} = \tfrac{1}{2} N^s_{\square\square}) - x_s}{\delta} = \frac{2^{1/2}}{(1 - N^o_{Cu})^{1/2}} \left[\frac{\operatorname{erfc}^{-1}(\tfrac{1}{2})}{(N^s_{\square\square})^{1/2}} - \gamma \right] \quad [25]$$

If the mole fraction of vacancies near the surface is much less than unity, *e.g.*, $N^s_{\square\square} \leqq 10^{-2}$, and further $N^o_{Cu} \cong 1$, the expression on the left side of Eq. [25] is much greater than unity, *i.e.*, the depth of penetration of the excess divacancies is much greater than the effective thickness of the interdiffusion zone, *i.e.*, the divacancy concentration in the interdiffusion zone does not vary exceedingly and thus, if $D_{\square\square}$ were independent of the alloy composition, the assumption of a constant diffusion coefficient in Eq. [7] would be a reasonable approximation. Actually, $D_{\square\square}$ in Au is higher than in Cu (18). Therefore, interdiffusion may be even faster than estimated in the foregoing calculation.

For these conditions the current density i calculated from Eq. [15] is rather high, *viz.*,

$$i \sim 2 \cdot 10^{-4} \text{ amp/cm}^2 \quad [26]$$

The "effective thickness" of the interdiffusion zone calculated from Eq. [17] is

$$\delta \sim 10^{-6} \text{ cm} \quad [27]$$

The assumption of a mole fraction of vacancies as high as 10^{-2} at and in the vicinity of the surface may be questioned. In particular, divacancies diffusing into the interior may be annihilated at dislocations, or they may aggregate and form quadruple vacancies and further multiple vacancies, *i.e.*, voids. Thus the current density calculated in Eq. [26] represents an upper limit.

The value calculated in Eq. [26] is a true current density. The apparent current density, defined as the quotient of current divided by the geometrical surface area, may be higher if the actual surface area is greater than the geometrical surface area because of roughening of the surface. Thus the apparent current density may be even higher than the value calculated in Eq. [26]. By the same token, an apparent current density of $2 \cdot 10^{-4}$ amp/cm^2 may be obtained with a divacancy mole fraction which is considerably lower than 10^{-2} as assumed for the evaluation in Eq. [26].

The foregoing considerations show that volume diffusion may be instrumental for preferential dissolution of Cu from Cu-Au alloys at room temperature. For acceptance of this mechanism, further experimental evidence is needed. This may be obtained with the help of x-ray investigations of the surface of samples subjected to anodic dissolution.

If gold is redeposited or if adsorbed gold atoms aggregate by virtue of surface diffusion, the lattice constant of these particles or of the sponge would be that of pure gold. In this case an x-ray diffraction pattern would contain rings at the gold positions (which may be broad). If, however, volume diffusion in a region next to the surface takes place as is suggested by the above considerations, a gradual variation in lattice parameter as a function of distance from the electrolyte-alloy interface would exist because of the sharp gradient of the mole fraction of gold between unity and that of the original alloy in a region next to the interface of the order of 10^2 lattice constants. Thus one would obtain a pattern of broad diffraction rings resulting from x-ray scattering of alloy regions of variable composition with a maximum of the intensity at a certain angle.

Investigations of this kind have been conducted already by Graf (19) in 1932. Cu-Au alloys involving 25 a/o Au etched by nitric acid at 25°C showed the x-ray diffraction rings of pure gold. Cu alloys involving 10 a/o Au etched in various solutions with less pronounced oxidizing solutions at 70°C (alcoholic solution of picric acid with or without dissolved oxygen; alkaline solution of sodium tartrate with dissolved oxygen) yielded x-ray patterns with very broad diffraction rings which indicated the presence of alloy crystals with copper contents ranging continuously from 20 to 40 a/o (*i.e.*, 60 to 80 a/o Au). The same is true for Cu-Au alloys involving 15 or 20 a/o Au attacked by sodium polysulfide solution at room temperature. These findings are in accordance with the concept of enhanced volume diffusion. Graf obtained these indicative results by using chemical attack in solutions whose oxidizing power was not well-defined with the help of a photographic technique. More conclusive results were obtained from experiments to be described where alloy samples were treated anodically at well-

defined potentials and were examined by modern x-ray intensity recording methods.

Electrochemical Measurements

General procedure.—Electrochemical measurements were conducted at 23° ± 2°C in order to check whether (*a*) gold is ionized from a Cu 10 Au alloy, or (*b*) copper is redeposited when a Cu 30 Zn alloy is dissolved anodically and both components are ionized.

For these measurements, there was used a rotating disk-ring electrode, which has been introduced by Frumkin and Nekrasov (20) for the detection of intermediates in electrode reactions (see Fig. 2). The theory for the interplay of diffusion and convection has been worked out by Ivanov and Levich (21). The disk electrode was the alloy subject to anodic dissolution at a predetermined current I_d and the resulting potential E_d was measured. The ring electrode was kept at a predetermined potential E_r appropriate for the deposition of the more noble metal with the help of a Wenking potentiostat and the resulting current I_r was measured. The circuit is shown in Fig. 3.

The cell, approximately 5 cm in diameter and 15 cm high, is shown in Fig. 4. A stream of prepurified

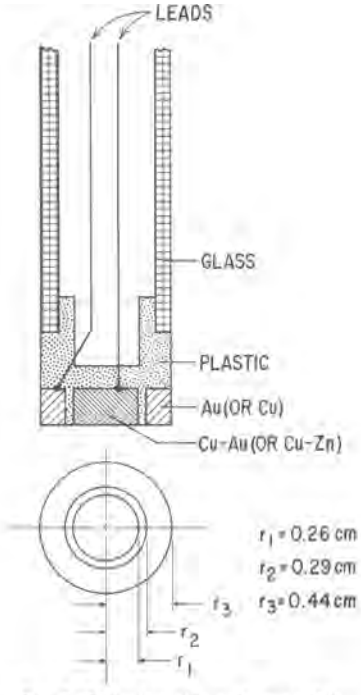

Fig. 2. Disk-ring electrode assembly

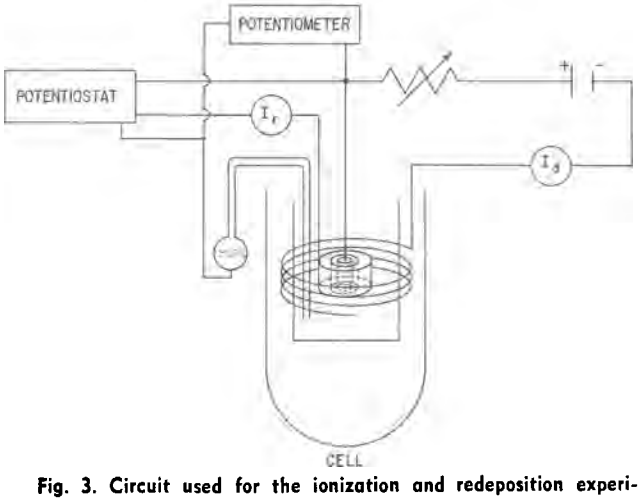

Fig. 3. Circuit used for the ionization and redeposition experiments.

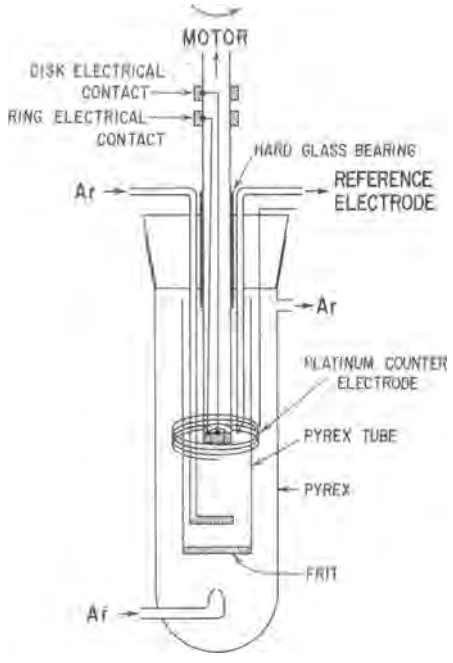

argon was passed through the cell in order to remove oxygen. The reference cell was a mercury-mercurous sulfate electrode in contact with 0.1 or 1.0*N* H_2SO_4 when sulfate electrolytes were used and a 1*N* KCl calomel electrode when a chloride electrolyte was used. The potentials are all reported relative to the standard hydrogen electrode (SHE). To minimize potential differences in the solution, an excess of supporting electrolyte was present in the bulk solution.

Consider conditions where both components of the alloy are ionized to a certain extent. Let j_o be the rate of dissolution of the more noble metal in mol/cm²-sec at the disk electrode. By virtue of rotation of the assembly, the solution in the hydrodynamic boundary layer is swept outward and thus ions of the more noble metal approach the ring electrode and are discharged. If at the potential E_r all ions of the more noble metal approaching the surface of the ring electrode are discharged, the local flux for redeposition of the more noble metal in mol/cm²-sec at distance r from the center is (21)

$$j(r) = \frac{0.4\, j_o}{1 + \frac{k\delta_e}{D}} \frac{r_1^2 r_2}{r^3} \frac{\left[1 - \frac{3}{4}\left(\frac{r_1}{r_2}\right)^3\right]^{1/3}}{\left[1 - \left(\frac{r_2}{r}\right)^3\right]^{1/3}\left[1 - \frac{3}{4}\left(\frac{r_1}{r}\right)^3\right]} \quad [28]$$

$$\text{if } r_2 \leqq r \leqq r_3$$

where r_1, r_2, and r_3 are the radii of the three zones shown in Fig. 2, D is the diffusion coefficient of the ions of the more noble metal, δ_e is the effective thickness of the diffusion boundary layer, and k is the rate constant for electrochemical redeposition of the more noble metal at the disk electrode, the rate being assumed to be proportional to the ion concentration C_s at the surface of the disk electrode, *i.e.*, equal to kC_s.

If only ions of the more noble metal are discharged at the ring electrode, the total current at the ring electrode is obtained by calculating from Eq. [28] the integral over the surface of the ring electrode. This gives for the dimensions reported in Fig. 2

$$I_r = \frac{0.53\, I_o}{1 + \frac{k\delta_e}{D}} \quad [29]$$

where I_r is the current at the ring electrode and $I_o = \pi r_1^2\, n\, j_o$ (with n as the valence of the ions) is the

partial current for the dissolution of the more noble metal at the disk electrode. Thus, I_r/I_o has its highest value, *i.e.*, 0.53, when no redeposition of the more noble metal at the disk electrode occurs, corresponding to $k \to 0$. If redeposition does occur, $k > 0$ and $I_r/I_o < 0.53$. It must be noticed that I_r is always lower than I_o since a certain fraction of the metal ions produced at the disk electrode remains in the boundary layer at the rim of the ring ($r = r_3$) and is swept into the bulk solution. In view of considerations recently published by Riddiford (22), a rigorous validity of Eq. [29] cannot be expected since details of the design in Fig. 2 are not in accord with requirements for ideal hydrodynamic flow. The experiments reported in what follows were made mainly in order to obtain qualitative rather than quantitative information. Minor deviations from Eq. [29] are, therefore, not significant for the evaluation of the experimental data.

Investigations on Cu-Au *alloys.*—The disk electrode was a Cu 10 Au alloy (10 a/o Au) prepared from 99.999% Cu and 99.99% Au, and the ring electrode was pure gold. Immediately prior to a run, the electrodes were polished on fine emery, rinsed in distilled water and dried. The electrolyte was 1*N* $CuSO_4$ + 0.1*N* H_2SO_4, and the rotation speed was 2900 rpm. Oxygen and hydrogen were excluded from the system. Thus at pH $\cong$ 1 only the reaction

$$Au^{3+}(aq) + 3e^- \rightarrow Au(s) \qquad E^o = 1.50 \qquad [30]$$

may occur at the ring electrode if its potential is between 0.5 and 1.2v. Accordingly a potential E_r = 1.1v was selected.

The relation between the observed potential E_d of the disk electrode and the applied current I_d is shown in Fig. 5 for two different runs. At all applied currents I_d, the current at the ring electrode was practically nil, *i.e.*, less than 2 μa. This is an indication that practically no gold is ionized from the Cu 10 Au alloy in accordance with the fact that the potential of the alloy according to Fig. 5 was much lower than the standard electrode potential of gold for reaction [30]. Consequently, aggregation of the remaining gold atoms during the anodic dissolution of copper must occur by surface diffusion, or volume diffusion must be operative as has been discussed already.

Investigations on Cu-Zn *alloys.*—If the Cu 30 Zn alloy (30 a/o Zn) is subjected to anodic dissolution, both components are dissolved according to previous investigations and results reported below. The main purpose of the following experiments was to obtain data for the recovery ratio in conjunction with Eq. [29]. The disk electrode was a Cu 30 Zn alloy prepared from 99.98% Cu and 99.995% Zn, the ring electrode was pure copper, the electrolyte was 1*N* $ZnSO_4$ + 0.05*N* $HC_2H_3O_2$ + 0.05*N* $NaC_2H_3O_2$ of pH $\sim$ 5 and the rotational speed either 290 or 2900 rpm. Preliminary experiments indicated that a potential E_r as low as —0.30v was required in order to discharge all copper ions approaching the surface of the Cu ring electrode. At E_r = — 0.30v and I_d = 0 there was observed a significant residual current at the ring electrode denoted by I_r^o presumably due to hydrogen evolution. Thus the current $I_{r(Cu)}$ for copper deposition at the ring electrode was taken to equal the measured current at the ring electrode I_r less the residual current I_r^o. The latter was necessarily an interpolated value from data obtained intermittently when I_d = 0. The current for dissolution of copper from the Cu 30 Zn disk electrode I_o was taken to equal the impressed current I_d times the mole fraction of Cu in the alloy. Data listed in Table I for a typical run with a rotational speed of 2900 rpm show that the recovery ratios for different impressed currents I_d agree approximately with the value of 0.53 according to Eq. [29] for k = 0, *i.e.*, for vanishing redeposition of copper at the disk electrode. Essentially the same results were obtained for a rotational speed of 290 rpm instead of 2900 rpm. This agreement would be expected only in the absence of redeposition at the disk since δ_e in Eq. [29] is inversely proportional to the square root of the rotational speed (23). These results agree in essence with results most recently obtained by Feller (11).

Table I. Typical potentials of the disk (E_d), measured currents (I_r) and interpolated residual currents (I_r^o) at the ring and recovery ratios $I_{r(Cu)}/I_o$ as a function of the dissolution current (I_d) applied to a Cu 30 Zn disk electrode. The electrolyte was 1*N* $ZnSO_4$ + 0.05*N* $HC_2H_3O_2$ + 0.05*N* $NaC_2H_3O_2$ and the potential of the ring electrode was —0.30v (SHE)

I_d (μa)	50	100	500	1000	3000
E_d (volt)	0.252	0.264	0.301	0.320	0.387
I_r (μa)	62	78	233	435	1239
I_r^o (μa)	43	44	55	80	190
$I_{r(Cu)}/I_o$	0.54	0.49	0.51	0.51	0.50

Data were also obtained for pure copper as the disk electrode with all other conditions the same. The recovery ratio was found in approximate agreement with the theoretical value of 0.53. This is an indication that the setup was functioning properly.

In view of the limited accuracy of the measurements reported in Table I, redeposition of a minor fraction of copper of the order of 10% or less cannot be ruled out. A more definite information was yielded by a second series of experiments where the disk and the ring electrode were practically short-circuited (see Fig. 6). The currents I_d and I_r were obtained by measuring the IR drop across resistors R_1 and R_2 with the help of a galvanometer calibrated before the run. The

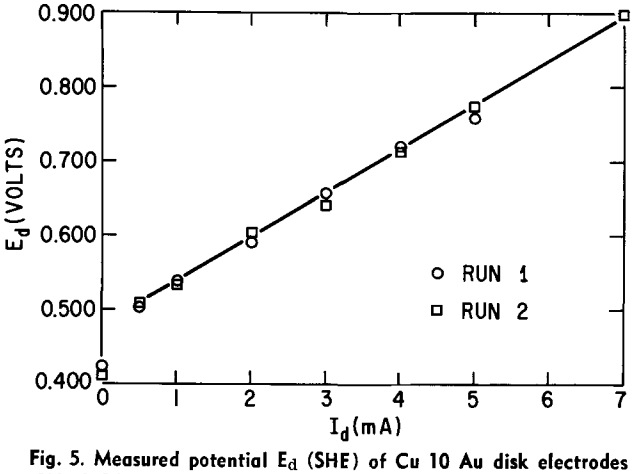

Fig. 5. Measured potential E_d (SHE) of Cu 10 Au disk electrodes in 1N $CuSO_4$ + 0.1N H_2SO_4 vs. the applied current I_d.

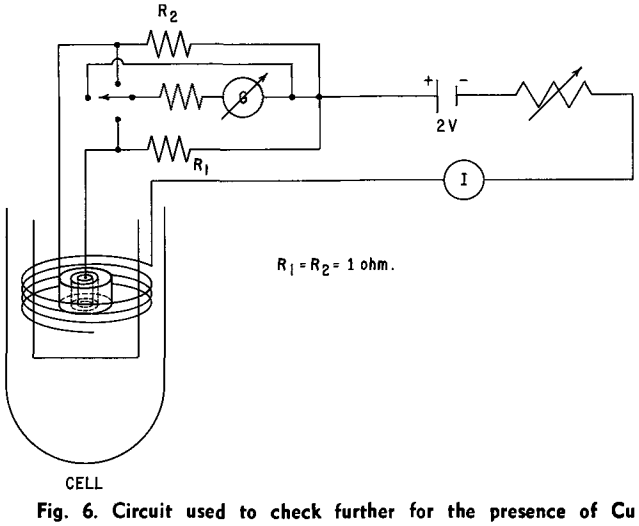

Fig. 6. Circuit used to check further for the presence of Cu redeposition during anodic dissolution of Cu 30 Zn alloy.

Table II. Dissolution currents at the disk (I_d) and at the ring (I_r) electrodes for currents ($I_d + I_r$) applied in the anodic direction on the Cu 30 Zn disk-Cu ring couple in 1N $ZnSO_4$ + 0.05N $HC_2H_3O_2$ + 0.05N $NaC_2H_3O_2$

I_d, μa	I_r, μa
48.3	1.7
96.2	1.7
293	6.9
473	31.6

highest IR drop across the 1 ohm resistors was 0.47 mv. Thus the potential difference between the disk and the ring electrode was always negligible. The electrolyte was the same as for the first series of experiments and the rotation speed was 2900 rpm. In order to eliminate accumulation of copper ions in the bulk solution, fresh electrolyte was used for each run and measurements were begun with the lowest value of the impressed current I_d. Thus the concentration of copper ions at the ring electrode was determined essentially by that prevailing at the disk electrode due to dissolution of the alloy. Results are shown in Table II. The current at the ring electrode was always anodic. Thus no redeposition of copper was found. On the contrary, copper was dissolved at the potential prevailing during dissolution of the alloy.

Discussion.—It is noteworthy that virtually no gold is dissolved from a Cu 10 Au alloy, whereas Cu and Zn are dissolved simultaneously from a Cu 30 Zn alloy. This divergence is understandable since the Cu 10 Au alloy the less noble metal prevails, whereas in the Cu 30 Zn alloy the more noble metal prevails. Preferential dissolution of zinc from the Cu 30 Zn alloy, however, may occur at much lower current densities than used in this investigation in accord with reports that dezincification of brass is observed especially when the supply of oxygen is low (1-3). According to Feller (11), preferential dissolution of zinc does occur when the alloy contains more than 75 a/o zinc.

X-ray Investigations

To test for the occurrence of volume diffusion during the anodic dissolution of Cu-Au alloys, foils of the Cu 10 Au alloy were prepared by rolling, followed by annealing in evacuated quartz capsules at 700°C for 1 hr. For anodic treatment a foil was partially lacquered to expose an area of 3 cm^2 and inserted vertically in place of the disk-ring electrode in the vessel shown in Fig. 3. A platinum wire counter electrode was centered around it in the inner tube. The electrolyte was either 1.0*N* H_2SO_4, or buffered 1*N* NaCl. Current densities of 1, 5, and 20 ma/cm^2 were applied. X-ray diffraction examination of the foils mounted in a diffractometer stage was made with CuK_α radiation.

After dissolution in both solutions broad regions of diffracted intensity occurred over a range of angles θ, extending approximately from the θ value characteristic of pure gold to that of the original alloy. For example in (b) of Fig. 7 and 8, a broad region of diffracted intensity is observable between the {111} diffraction lines of Cu 10 Au and pure gold. At a later stage of dissolution a maximum characteristic of gold-rich alloy is observable (see c of both figures), which as more coulombs are passed shift toward θ values characteristic of alloys richer in gold. For dissolution in 1*N* H_2SO_4 the maximum is seen after 19.2 coulombs/cm^2 have passed to correspond to virtually pure gold (see d of Fig. 7). For dissolution in buffered

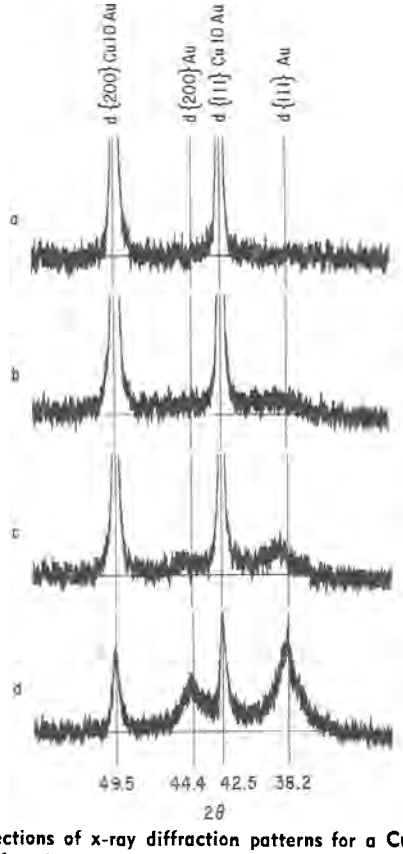

Fig. 7. Sections of x-ray diffraction patterns for a Cu 10 Au foil specimen after increasing amounts of dissolution at 20 ma/cm^2 in 1N H_2SO_4 illustrating increased diffracted intensity over broad ranges of angle θ, e.g., $42.5 > 2\theta > 38.2°$, as would be expected if alloy regions of variable composition were present. a, Prior to anodic dissolution; b, 1.2 coulombs/cm^2 passed; c, 2.4 coulombs/cm^2 passed; d, 19.2 coulombs/cm^2 passed.

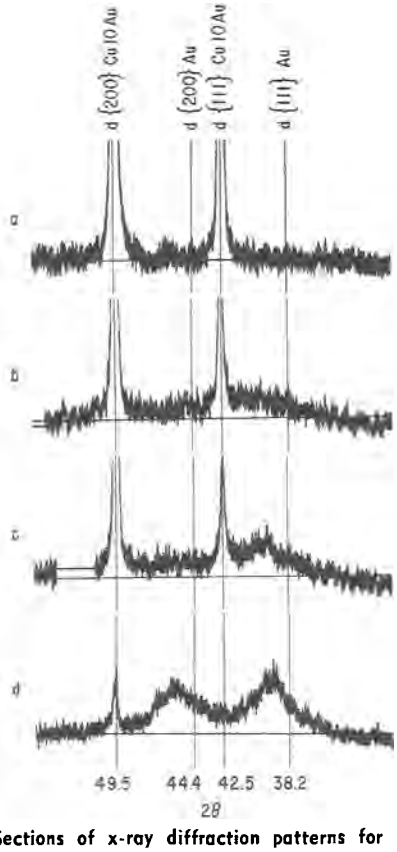

Fig. 8. Sections of x-ray diffraction patterns for a Cu 10 Au foil specimen after increasing amounts of dissolution at 20 ma/cm^2 in buffered 1N NaCl, illustrating increased diffracted intensity over broad ranges of angle θ, e.g., $42.5 > 2\theta > 38.2°$, as would be expected if alloy regions of various composition were present. a, Prior to anodic dissolution; b, 1.2 coulombs/cm^2 passed; c, 2.4 coulombs/cm^2 passed; d, 19.2 coulombs/cm^2 passed.

1*N* NaCl the maximum after the same number of coulombs/cm² have passed is seen to correspond to a gold-rich alloy (see d of Fig. 8). The intensity of the original alloy peak decreases accordingly. Broad regions of diffracted intensity were also observed for the lower current densities, and for all of the first four diffraction lines investigated, although their development occurred to a lesser and lesser extent the higher was the index of the diffracting plane. The latter is in part a result of the fact that the Bragg angle increases as the index of the plane increases, and therefore deeper portions of the specimen contribute more heavily to the diffracted intensity. A calculation of the depth x to which 50% of the diffracted intensity corresponds in the case of pure gold, gives the following values for the first four lines of gold:

Diffraction plane	{111}	{200}	{220}	{311}
x in microns	0.27	0.32	0.45	0.52

This shows that the effective depth of penetration of the incident beam is of the order of 3000Å for the {111} planes, and shows further that it increases sharply as the index of the plane increases. Thus, actual comparisons may be best made for the profile sections corresponding to the {111} planes.

According to Eq. [27] zones of variable composition are fairly thin and, therefore, make a very minor contribution to the x-ray diffraction pattern initially when the alloy has a plane surface. At a later stage of anodic dissolution, however, roughening occurs, *i.e.*, primary, secondary, and tertiary wedges protruding in various directions are formed. Thus the volume of alloy having a variable composition now can make a significant contribution to the x-ray diffraction pattern. Accordingly, the x-ray diffraction pattern shows broad lines characteristic of gold-rich alloy, lines of the bulk alloy and also a significant intensity between the lines.

When more copper is leached out, the depth of the zone of nearly pure gold grows. Thus the intensity of the gold lines increases, whereas the intensity between the lines of gold and the original alloy may decrease because of adsorption. Even under these conditions, however, the lines of the bulk alloy may still be rather strong when there are regions next to the surface of the alloy where protruding wedges filled with electrolyte are not formed.

Metallographic examination of the cross section of the x-ray specimens after the final dissolution corresponding to 19.2 coulombs/cm² shows a "reacted," dark layer extending from the surface to an average depth of about 8 microns for anodic dissolution of the Cu 10 Au foils in both solutions as shown in Fig. 9 and 10. For the sodium chloride solution many large local penetrations were observed within the reacted region as seen in Fig. 10. A few of these penetrations also extended into the alloy both trans- and intergranularly. The presence of a reacted layer is also in accord with results of experimental investigations (1-11). In particular, Pickering and Swann (10) with the help of transmission electron microscopy resolved individual pores (which measured only a few hundred Å in diameter in Cu-Au alloys which had been dissolved

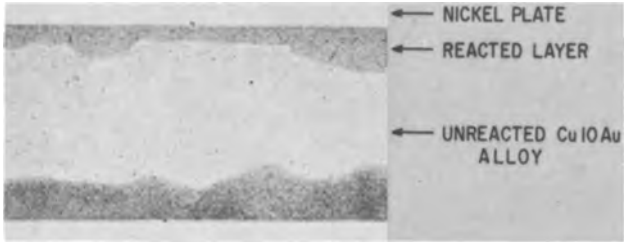

Fig. 9. Cross section of a Cu 10 Au sheet specimen after anodic dissolution of 1 ma/cm² in 1N H_2SO_4 for 320 min (19.2 coulombs/cm² passed). Magnification approximately 340X.

Fig. 10. Cross section of a Cu 10 Au sheet specimen after anodic dissolution at 1 ma/cm² in buffered 1N NaCl solution for 320 min (19.2 coulombs/cm² passed). Magnification approximately 340X.

in certain chloride media containing oxygen). In the present work the number of moles of Cu dissolved per unit area is $it/2\mathbf{F}$. The copper content of a layer of depth δ_p per unit area is $\delta_p N^{o}_{Cu}/V_m$. Assuming complete removal of copper up to depth δ_p as a limiting case, one has

$$\delta_p = \frac{it}{2\mathbf{F}} \cdot \frac{V_m}{N^{o}_{Cu}} \qquad [31]$$

For it = 19.2 coul/cm² one obtains a calculated value $\delta_p = 7\mu$ in approximate agreement with the average measured depth of 8μ.

Concluding Remarks

Further research is needed in order to test whether other alloys exhibiting preferential anodic dissolution of the less noble component behave similarly to Cu-Au alloys. Further, additional research is needed in order to investigate under which conditions Zn may be preferentially dissolved from copper-rich Cu-Zn alloys with formation of a copper sponge.

Acknowledgment

The authors are indebted to Dr. H. Schmalzried of the Max Planck Institut für Physikalische Chemie for many helpful discussions. Appreciation is also expressed to W. F. Kindle of the Edgar C. Bain Laboratory for Fundamental Research for his help in preparing the micrographs. The Cu 30 Zn alloy and Zn metal was kindly provided by Professor P. Haasen of the University of Göttingen. One of us (H.W.P.) gratefully acknowledges the United States Steel Corporation for having sent him to the Max-Planck Institut für Physikalische Chemie, Göttingen Germany for the 1964-1965 year.

Manuscript received Nov. 18, 1966; revised manuscript received March 29, 1967. This paper is based on work performed at the Max-Planck Institut für Physikalische Chemie in 1964-1965 while one of the authors (H.W.P.) was on leave from the Edgar C. Bain Laboratory for Fundamental Research.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Technical Notes

Corrosion Resistance of Platinum, Copper Nickel, and Tantalum in Liquid Oxygen Difluoride

S. M. Toy

Missile & Space Division/Astropower Laboratory, Douglas Aircraft Company, Inc., Newport Beach, California

The corrosion rates of metals and alloys in fluorine-containing oxidizers at cryogenic temperatures are small due to the formation of passive fluoride films (1-3). Low corrosion rates are difficult to measure with conventional methods since the total weight change is very small. In the present study, the corrosion resistance of platinum, copper, nickel, and tantalum in liquid oxygen difluoride is estimated from changes in solution capacitance and conductance between two plates of these materials.

Experimental

Nickel (99.55%; 0.0635 cm thick) specimens, 4.18 x 2.22 cm, were separated at a distance of 1½ mm by glass spacers. Platinum (99.9%; 0.051 cm thick), copper (99.46%; 0.094 cm thick), and tantalum, (99.89%; 0.0254 cm thick) specimens, 2.54 x 5.18 cm, were also separated by 1½ mm glass spacers. Ni was pickled in a nitric acid etch (1 HNO_3/1 H_2O). Ta plates were pickled in a chromic acid solution (saturated chromic acid in sulfuric acid). No etch was used to clean Pt. Cu plates were cleaned with nitric acid etch. The specimens were connected by nickel wires to a four terminal test probe except for Cu specimens where Cu leads were used.

Either a pair of platinum and copper plates or nickel and tantalum plates were inserted into an all-metal test bomb (type 316 stainless steel) which served as a container for OF_2. The two sets were 0.635 cm apart. All parts were in a LOX clean condition (4). The test bomb was checked for leaks at 4 atm with helium at room temperature and overnight at liquid nitrogen temperatures. After the helium was evacuated, OF_2 was introduced and condensed to a liquid at a low temperature (see Fig. 1). The cell constant of each pair of plates was determined by measuring the cell resistance in 0.1*N* KCl. The cell

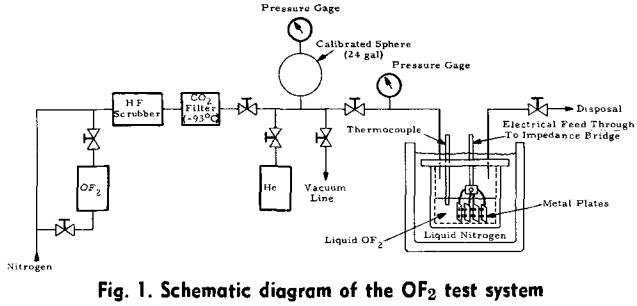

Fig. 1. Schematic diagram of the OF_2 test system

constant for Pt was the same when measured in a glass container or in the metal test bomb.

The capacitance and equivalent circuit parallel resistance were measured by a General Radio Impedance Bridge (1650-A) at 1000 Hz. The specific conductance, k_c was calculated from the resistance and the cell conductance, and the parallel resistance, R_p was calculated from the usual expression, $R_p = (2\pi f C_p D)^{-1}$, where C_p is parallel capacitance, D is dissipation factor, and f is frequency.

Oxygen difluoride (99.5+% purity) was purchased from Allied Chemical Company and was purified by passing the vapor through a column of NaF pellets to remove traces of HF down to 0.02 v/o HF as an acid fluoride. NaF-HF (5). CO_2 (max. 0.5%) was removed by filtering at —93°C. No CO_2 solids were observed in the OF_2 after filtering.

Results and Discussion

Platinum and copper corrosion test.—The capacitances of platinum and copper cells in vacuum were 2.5 pf/cm² and 2.6 pf/cm², respectively. The relative dielectric constant (ϵ) was found to be 2.3 ± 0.1 for

liquid OF_2 at —197° from $\epsilon = C_{pc} + C_t/C_t$ where C_p is the measured capacitance and C_t the theoretical capacitance in vacuum or air.[1]

This value agreed well with the dielectric constant calculated from the corrected capacitance, $C_{pc} = C_p - C_o$, and C_t and the dimensions of the cells. The dielectric constant of liquid oxygen difluoride is calculated to be 2.2 ± 0.1. The dielectric constant of liquid fluorine has been reported as 1.5 (3).

C_{pc} for OF_2 was less than 0.8 pf/cm². The dielectric constant did not markedly change within the investigated temperature range. The C_{pc} of OF_2 *vs.* time measured between the platinum and the copper plates indicates that these metals are passive and do not corrode under these conditions (Table I). Visual examination of the platinum and copper plates supported this conclusion.

The conductance of OF_2 is less than 1.7×10^{-9} ohm^{-1} cm^{-1}, the limit of the present instrumentation.

Nickel and tantalum corrosion test.—The capacitance (C_o) of nickel and tantalum plates in air was 3.3 pf/cm² and 6.3 pf/cm², respectively. In contrast to the platinum and copper test, the specific solution conductance, k_c, was measurable, *i.e.*, 10^{-8} $ohm^{-1}cm$. Table II illustrates the increase of conductance due to

$$^1\epsilon = \frac{C_{pc} + C_t}{C_t} \quad \text{where } C_t \simeq 0.6 \text{ pf/cm}^2 \text{ (theoretical)}.$$

Apparent area, A_{Ta} = 12.47 cm²
Apparent area, A_{Ni} = 8.62 cm².

Table III. Corrosion rate of metals in liquid OF_2 at —110°F in mils per yr (MPY)

Material	Test duration 1 Day	21 Days	4 Months	1 Year
Copper	0.0	0.01	0.005	0.0007
Nickel	0.9	0.02	0.002	0.0007
Tantalum	—	0.02	—	—

solvation of tantalum and nickel ions. The solution resistance for Ta was found to be half that for Ni electrodes. The lower solution resistance for Ta than for Ni indicates tantalum is less corrosion resistant. The fact that the solution conductance for Ni and Ta remains in their own range with time indicates cross contamination is not a problem.

Table II gives capacitance data for Ta and Ni plates in liquid OF_2. C_{pc} measured for Ta was higher than for Ni at both —156° and —92°C.

From the $C_{pc} + C_t$ values, a metal fluoride film capacitance, C_1, can be calculated and differentiated from the solution capacitance, C_2 (6). C_2 for Ta was larger and C_1 smaller than for Ni. A larger C_2 indicates thicker surface film for tantalum. Both comparisons indicate Ta is more susceptible to corrosion than Ni.

A nickel fluoride (NiF_2) film was identified by electron diffraction techniques on corroded Ni specimens.

A marked increase in capacitance and a decrease in solution resistance between Ta electrodes occurred when the temperature of OF_2 was increased from —156° to —92°C. Therefore, an appreciable increase in corrosion attack of tantalum by OF_2 is expected at the higher temperatures.

Corrosion rates of copper, nickel, and tantalum by weight change method are given in Table III for comparison (7). Only the 21-day test indicates copper is more passive in OF_2 than nickel and tantalum.

Vacuum-Deposited Thin Films of the Type PbS_xSe_{1-x}

B. A. Riggs[1]

Physics and Infrared Section, General Dynamics, Pomona, California

Individually, both the lead salt compounds PbS and PbSe have been widely used as radiation detectors sensitive to near-infrared wavelengths. Mixed compounds of the form PbS_xSe_{1-x}, however, offer potentially useful detectors of intermediate wavelength, broad band, and perhaps unique response. As Scanlon (1) has shown, the isomorphism and common cation of the constituent compounds makes possible a complete series of solid solutions. Such synthesis in bulk reactions is difficult however, and most detector applications require thin-film configurations.

Potter and Kretschmar (2) have previously demonstrated the utility of vacuum-deposition in producing thin films of the type $InAs_ySb_{1-y}$. They utilized a so-called, four-temperature evaporation method in achieving the otherwise difficult synthesis of these III-V compounds. The foregoing considerations led to the present efforts relative to formation of mixed-compound lead salt films. In the present case, however, the grain-by-grain, or "flash" evaporation technique (3) was employed.

Depositions were made in a commercial vacuum-evaporation unit (Mikros VE-20) fitted with a rotating-table powder feed device similar to that described by Beam and Takahashi (4). The feed mechanism, unique to the "flash" method, is required to supply a continuous stream of the granulated evaporant to a preheated evaporation source. The latter was a well-type Ta box source with a quartz insert set into the well. The insert was employed to avoid evaporating from the Ta surface (5). Carefully cleaned glass microscope slides were used as substrates and positioned 4 in. above the source heater.

The starting material for each evaporation consisted of mechanical mixtures of accurately weighed portions of sized (100-200 mesh) PbS and PbSe powders. The latter were obtained from Research Inorganic Chemical Company and were of five-nines stipulated purity. Target mixtures consisting of 2:1, 1:1, and, 1:2 PbS:PbSe (mol) were chosen. Individual powder fractions were weighed to the nearest 0.1 mg on a Sartorious balance. The weighed fractions of PbS and PbSe were then mixed mechanically in glass vials.

A typical evaporation utilized about 0.2g of a given mixed-powder sample which was placed in the feed hopper of the evaporation unit. The system was evacuated to about 8×10^{-7} mm Hg and allowed to outgas while heating the glass substrate to 280°-300°C. Depositions were made at a rate of 10-20 Å/sec giving thin-film deposits 1-2μ thick and 1 in. in diameter.

Subsequent to deposition, a diffractometer-profile was obtained by x-ray irradiation of each film on its substrate. Filtered Cu radiation from a Siemens instrument was used to scan 2θ values between 15° and 90°. In addition to the film deposits, a diffraction profile was also made for the individual PbS and PbSe starting materials. This was done by dusting the powder (—200 mesh fraction) over petroleum jelly applied to a microscope slide.

Figure 1 is a schematic reproduction of a portion of the diffraction profiles obtained for the starting PbSe powder and the mixed-film deposit of 16.5 mol % PbS. The latter is representative of the other mixed-compound films. As Figure 1 shows, the starting PbSe powder was not exclusively single phase and this was also true of the PbS starting material. Both the PbS and PbSe diffraction traces showed the (111)

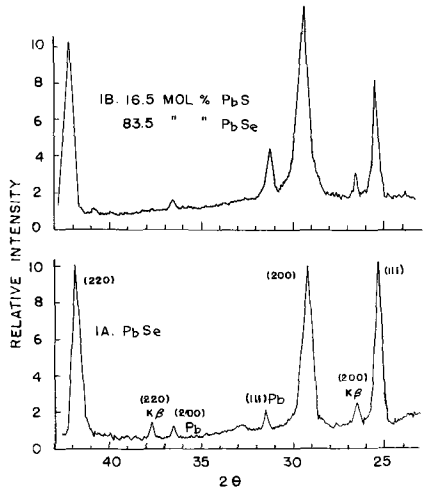

Fig. 1. A portion of the x-ray diffraction profiles for the 16.5:83.5 (mol %) PbS:PbSe thin film (top) and for 99.999% PbSe powder (bottom).

and (200) reflections for Pb superposed on the compound patterns. These "extraneous" lines show that both of the starting materials were Pb-rich non-stoichiometric compounds, and this imbalance was reproduced in the mixed-compound film deposits as illustrated by the 16.5 mol % film of Fig. 1. The diffracted intensity of the (111) Pb peak appears greater in the above film than in the PbSe pattern. This apparent enhancement is believed to be the consequence of the additive effects of the Pb-rich nature of both starting compounds. Some anion loss also may have occurred in the deposition. In addition, some preferred orientation in the film deposits is indicated by the stronger diffracted intensities of (200) and (220).

It was also apparent that the PbS_xSe_{1-x} films were compositionally varying reproductions of the basic PbS-type pattern. As a consequence, it was possible to calculate the lattice parameter for each case as a function of composition. For this purpose (hkl) in the back-reflection region giving the best $K\alpha_1/K\alpha_2$ resolution was used. These data are given in Table I and plotted in Fig. 2.

As Fig. 2 illustrates, the PbS-PbSe system conforms closely to Vegard's law and even the indicated deviation may be more apparent than real. That is, the thin films likely contain stresses and faulting not present in the powder samples used to obtain the terminal a_o values of Fig. 1. The close agreement between the latter and the published (ASTM) values is noteworthy. In view of the demonstrated a_o composition relationship, it is reasonable to expect that other

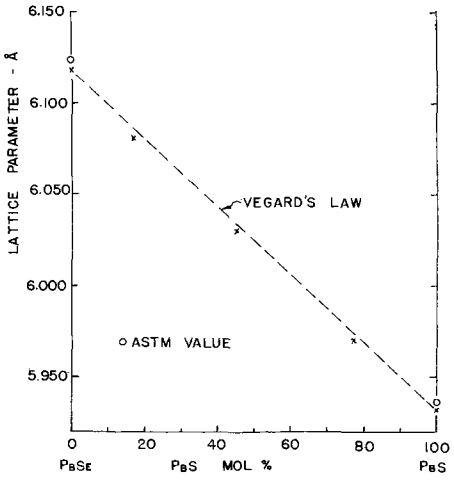

Fig. 2. Lattice parameter (a_o) vs. molar composition for the PbS-PbSe system.

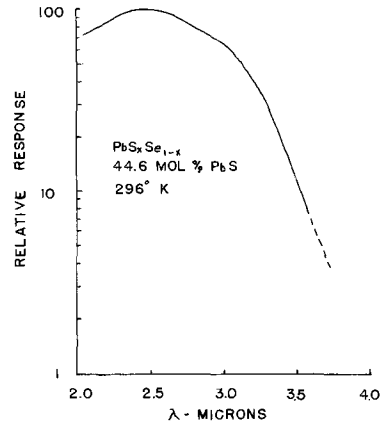

Fig. 3. Spectral response vs. wavelength for a sensitized PbS_xSe_{1-x} (44.6 mol % PbS) detector at room temperature.

physical properties dependent on bonding, such as thermal expansion coefficients, would vary in a similar fashion. This provides the opportunity to match more closely such parameters between film and substrate and thereby attain epitaxial deposits of relatively low defect densities.

In spite of the indicated nonstoichiometry one other deposition was made for purposes of electro-optical evaluation using the 44.6 mol % PbS composition. Several individual films were obtained from this deposition by appropriate masking. These films were rendered photosensitive by heating them in air for a short period subsequent to deposition. Gold electrodes were then deposited so as to define a sensitive area 0.16 cm on a side. Such films exhibited resistances of about 150 kohm.

Signal-to-noise ratios for three such cells were obtained by irradiation with a 600°C black body simulator located 15 cm from the cell and chopped at 1200 Hz. A Hewlett-Packard wave analyzer (5 Hz bandwidth), Perry amplifier, IRI voltage integrator, and Tektronix wave-form monitoring oscilloscope were utilized in the measuring circuit together with a load resistor matching the cell resistance. With this arrangement best- and worst-case signal-to-noise ratios of 770 and 120 were measured at room temperature.

It was also possible to derive a spectral response curve from the best of the above cells by using a Perkin-Elmer Model 13-U spectrophotometer. The relative response as a function of wavelength is shown in Fig. 3. This spectral response suggests the detector is responding as a homogeneous unit rather than as a sum of two separable components. This result then would tend to confirm the x-ray diffraction results presented previously.

The present results indicate that sensitive photodetectors of the PbS_xSe_{1-x} type can be produced by vacuum-deposition techniques. It is believed that improved detectors of this type can be realized by use of selected quality PbS and PbSe starting materials and by optimizing the desposition parameters and sensitization procedure.

Acknowledgment

The assistance provided by Mr. D. E. Wilson in obtaining the x-ray data is most gratefully acknowledged. The writer is also indebted to Mr. G. C. Knight and Mr. J. R. Nelson for their valued contributions relative to the electro-optical evaluation.

Polarization at Impervious and Porous Bromine Redox Electrodes

E. I. Onstott

Los Alamos Scientific Laboratory, Los Alamos, New Mexico

In the original work on desalination by bromine redox (1) a porous carbon anode was used in conjunction with a porous carbon cathode as a method of separating the depleted portion of electrolyte (anolyte) from the enriched portion (catholyte). In principle a single porous electrode in conjunction with an impervious electrode can serve the same useful function of separating the electrolysis products if recombination by convective transfer can be avoided.

Impervious electrodes have some advantages in multistage design, and it was therefore of interest to test the properties of an impervious electrode when used as an anode and also when used as a cathode.

Since dissolved bromine is used as a depolarizer in

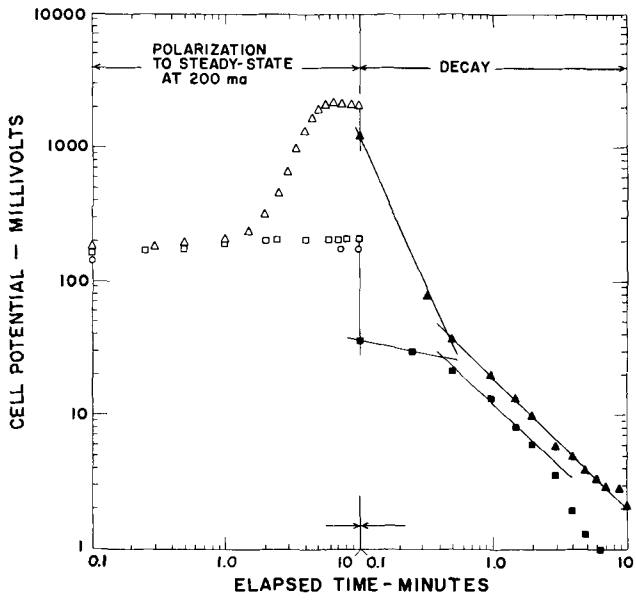

Fig. 1. Electrolysis followed by open-circuit decay of 0.05M NaBr containing about 0.03M Br_2.

the bromine redox method, the most obvious method of testing seemed to be that of measuring electrode polarization at constant current as a function of time, than to observe the decay of the cell potential with time with the driving source removed.

Experimental

Experimental procedures were much the same as reported previously (1). The electrolysis cell was modified by replacing one porous electrode with a high-purity graphite plate about 6 mm thick and having the same geometric surface area. A single exit consisting of a hole about 6 mm in diameter was drilled in the plate in the same position as the exit shown previously for each porous electrode (1). Electrolyte feed flow (countercurrent to the force of gravity) was controlled with a Beckman Model 746 metering pump operated at an input flow rate of 20 ml/min. The anolyte and catholyte flows were approximately equal at 10 ml/min each.

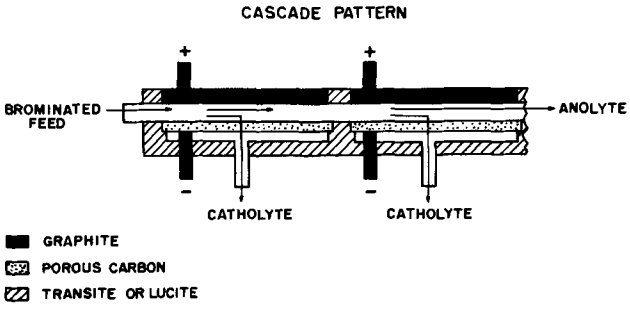

Fig. 2. Practical geometry for cascading cells

Results

The data in Fig. 1 show that an impervious graphite anode behaves very much like a porous carbon anode, but the potential required at steady-state is about 10% higher. With an impervious cathode, however, the potential required at steady state is an order of magnitude higher. These data show clearly that high cathode polarization results from depletion of bromine at the impervious cathode. Use of a porous carbon cathode, however, minimizes polarization by allowing bromine replacement by electrolyte flow through the porous cathode, and the energy requirements for electrochemical desalination are much lower than when an impervious cathode is used.

The data for potential decay indicate also that there are much larger differences in bromine concentration between the anode and cathode when the cathode is made the impervious electrode compared to the converse geometry.

Figure 2 shows a practical geometry for cascading cells. The cathode is placed on the bottom to take advantage of the stabilizing effect of gravity on the electrolyte density gradient. A small pilot plant has been constructed and operated with forty cells in series utilizing this design. Results of this investigation will be reported elsewhere.

Manuscript received March 17, 1967. This work was performed at Los Alamos Scientific Laboratory under the auspices of the Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Brief Communication

The Rotating Disk Electrode, Hydrodynamic Boundary and Diffusion Layers by Laser Interferometry

R. N. O'Brien

Chemistry Department, University of Victoria, Victoria, B. C., Canada

It has recently become possible to build long path interferometers to study concentration contours in electrochemical cells where the path difference between interfering beams in a wedge-type interference cell is 2 cm or greater. Such a cell has been described recently (1) and the theory presented (2). The present cell has been modified from those previously described only in that a disk electrode of the parabolic shape recommended by Riddiford (3) to give stable flow patterns is admitted from the top and a counter electrode from the bottom. The cell as before consists of a Teflon cylinder whose axis is at 90° to the axis of

the electrode, with partially reflecting glass flats in the end and a cylinder insert whose axis coincides with the axis of rotation of the electrode, with its sides sliced off to allow the laser beam to pass through.

The expression for the location of wedge fringes on the interferometer wedge is: $2\mu t \cos\phi = n\lambda$ (μ is the refractive index; t is the thickness of the cell; $\cos\phi$ is about one when ϕ, the angle of incidence, is close enough to zero to give good fringes; n is the order of interference; and λ is the wavelength of the light used). If λ is 6328Å, the common gas laser frequency, the liquid has a refractive index of 1.3540 and t is 1 cm, n is calculated to be 42,810. This means that one fringe shift, that is when the displacement of the fringe brings it to the position where the next fringe would have been if it had remained straight, represents a change of one part in 42,810 in refractive index. If, however, a solution is used, only the part of the refractive index due to the solute will vary and in the case below, one fringe shift is one part in 240. For the present experimental set-up this means one part in 240 change from the bulk concentration of all solutes present.

When a disk is rotated in a liquid the application of the shearing force to the layers of liquid near the disk should result in a change in density; the thermodynamic $P\Delta V$ term that describes the dilation should be proportional to the shearing force applied and hence useful in evaluating liquid viscosities (4). The change in density is related to the change in refractive index by the Lorentz-Lorenz expression $R_M = \frac{M}{p}\left(\frac{\mu^2-1}{\mu^2+2}\right)$, where R_M is the molar refraction, M the molecular weight, p the density, and μ the refractive index. Since it is difficult to see how, in the solution considered, the dilation can occur in anything but the solvent, we will consider only the change in density of water. The molar refraction of H_2O is 1.64624 and detection of one fringe shift due to change in density represents a change in refractive index from 1.33315 at 24°C to 1.33312; consequently, a dilation of one part in 14,875. Since 1/10 of a fringe shift can be detected, the limits of measurement are one part in 148,750 or this is a very sensitive dilatometer.

Figure 1 contains four frames taken from a 16 mm motion picture film taken at 12 fps of a 3.50 mm diameter Ni disk in a 2N NaOH solution which is also 0.1M in $K_4Fe(CN)_6$ and 0.1M in $K_3Fe(CN)_6$ at 24°C. In the first frame a current of 20 μa or 2.5 ma/cm^2 is passing. The disk is not rotating and the apex of the wedge is to the left. The nickel disk is coated with catalyzed polyurethane so that no current passes except on the bottom of the disk. The disk is the cathode and the $K_4Fe(CN)_6$ being generated is more dense than the bulk solution, so natural convection is causing a reversal of the concentration gradient outside the simple diffusion layer, analogous to effects noted in other systems (5). Since the current density is far from the limiting current density in this system, it is assumed [as found to be essentially true in acidified $CuSO_4$ solution (6)] that only the electroactive species change concentration.

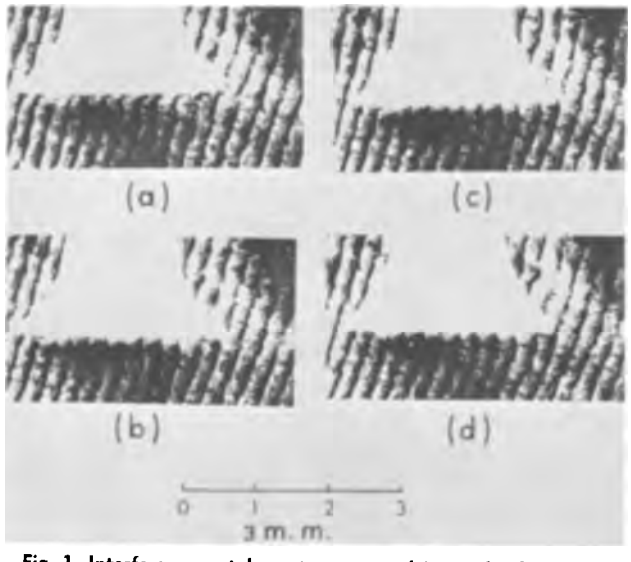

Fig. 1. Interferograms taken at one second intervals of a rotating disk electrode. The current density is 2.5 ma/cm^2 in a 2 NaOH solution which is also 0.1M in each of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ at 24°C. In frame (a) the disk is not rotating and is the cathode, and a diffusion layer affected by natural convection is evident. Immediately following frame (a), rotation was started and reached 250 rpm in (b) and a stable pattern was established by (d). In frame (d) a hydrodynamic shear layer is the only visible feature.

In the second frame, taken one second later, the disk is rotating at about 250 rpm or the rim speed is about 5 cm/sec. Most of the concentration gradient $\left(\frac{\partial[K_4Fe(CN)_6]}{\partial x} - \frac{\partial[K_3Fe(CN)_6]}{\partial x}\right)$ previously established has already been swept away as a much thinner diffusional layer is set up, undetectable by this apparatus. Some convective effects are still evident at the same location in this frame as in the previous one, indicating that the effect of rotation progresses, as expected, through the layers at a finite rate. That is, the previously set up processes relax at a measurable rate. The direction of rotation is such that the rim of the disk nearest the camera is moving from right to left.

The third frame shows a deflection of the fringes in the opposite direction (to the left), except for the solution very close to the electrode. In the last frame, one second later, a hydrodynamic shear zone has been established to the exclusion of any recognizable diffusion layer. The total fringe shift at the center of the disk is again about ¾ of a fringe as in the diffusion layer, but the layer is about twice as thick so the refractive index gradient is only half as steep. A diffusion layer must still exist, but it can be confidently stated that since it cannot be detected by this apparatus (and hence its extent and the concentration gradient in it cannot be determined), its thickness must be less than 0.02 mm since measurements have been made in other systems at this distance (7).

Figure 2 was produced by tracing the center of fringes in a system in which the disk is the anode

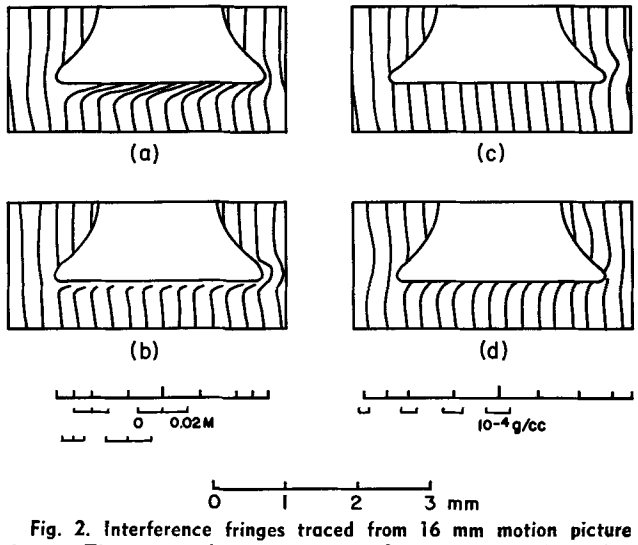

Fig. 2. Interference fringes traced from 16 mm motion picture frames. The current density is 5 ma/cm^2 in the same solution but the disk is now the anode, no convection is occurring, there is only ¼ sec between frames and the dilation in the hydrodynamic shear zone gives a fringe shift in the same direction as the oxidation of $K_4Fe(CN)_6$ in the diffusion layer.

and no natural convection occurs, all other conditions the same except as noted. The frames were taken at ¼ sec intervals. Frame (a) shows a well developed diffusion gradient at twice the current density as in Fig. 1 (5 ma/cm^2), and the apex of the wedge is to the right. Frame (b) shows the diffusion layer set up under nonrotating conditions being swept tangentially outward in accord with Riddiford's theory (3). Frame (c) shows an intermediate regime. In frame (d) the diffusion layer has been established at a thickness undetectable by this apparatus. The hydrodynamic dilation shear gradient is, as expected, in the same direction as the concentration gradient previously established.

Since the effects being viewed in this work are independent of the thickness of the cell (as attested by unperturbed fringes appearing in the edges of the frames), and are the result of viewing a disk of perturbation, the usual formula $2\mu t = n\lambda$ must have a variable t. Now $t = 2d \sin \frac{d}{r}\frac{\pi}{2}$, where d is the distance from the center of the perturbed disk of fluid and r is the radius of this disk. Scales in concentration and density units have been calculated for specific marked points, and are, of course, only applicable to those points. They can only be used as a rough guide to judge as to whether the fringe shift follows the indicated sine function.

Experiments were also performed in which a nickel rod was encased in a Teflon tube. The outside diameter of the Teflon was twice that of the nickel rod, and the Teflon tube outside diameter was 3.5 mm. The surface of the Teflon and nickel were gently polished flat while assembled together and just prior to mounting in the interferometer. The nickel could be rotated while the Teflon remained stationary, or both could be rotated at the same speed. When current was passed in the same electrolyte as above without rotation, then rotation begun after an appreciable diffusion layer was present, the patterns of perturbation to the fringes were similar in both cases to the bell-shaped disk recommended by Riddiford. The configuration in which only the electrode moved showed a slightly better flow pattern (*i.e.*, more closely horizontal, or tangential, motion of the electrolyte away from the electrode). It is thought that both the flow patterns and the dilation in the shear zone will have an effect on current distribution which has recently been the subject of theoretical calculations (8).

Further experiments are planned to firmly establish flow patterns around the rotating disk and to explore the system's usefulness as a dilatometer.

Acknowledgment

The work reported was performed in association with the Inorganic Materials Research Division of the Lawrence Radiation Laboratory while the author was a Visiting Scholar in the College of Chemistry, the University of California, Berkeley. The author is grateful for their support and for valuable conversations with C. W. Tobias.

Manuscript received Jan. 16, 1967; revised manuscript received March 21, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.
