Cd_4SiS_6 crystals annealed in cuprous sulfide for 3 and 6 hr show a broad photoconductivity response in the wavelength region from 4400 to 6200Å with a maximum photoconductivity of $\sigma_{Ph} = 4 \cdot 10^{-4}$ and $4 \cdot 10^{-5}$ ohm-cm^{-1}, respectively, but no uv sensitivity. No further annealing experiments have been made with these crystals.

Preliminary measurements on Cd_4SiSe_6 crystals showed that this material is a good photoconductor. The dark conductivity is similar to that of Cd_4SiS_6. The photoconduction *vs.* wavelength curve shows a broad region of photosensitivity from about 4000 to 7000Å. The photoconductivity reaches values of $\sigma_{Ph} = 3 \cdot 10^{-5}$ ohm-cm^{-1}, and the sensitivity is $S = 10^{-2}$ mho cm^2/w. No photoconductivity was observed for wavelengths shorter than 4000Å.

Undoped Cd_4SiS_6 crystals and those doped with copper, silver, mercury, gallium, indium, thallium, europium, arsenic, niobium, manganese, uranium, and mixed with a powdered Nernst filament (consisting of 85% zirconia and 15% yttrium oxide) were examined for their luminescence properties.

At room temperature, only copper-doped material showed a considerable red luminescence with a broad maximum peaking at 7200Å, the intensity of the peak wavelengths being about one-third of the red commercial RCA ZnCdS : Ag phosphor (33-Z-639*D*) at its peak wavelength (see Table I).

At liquid nitrogen temperature we found the results listed in Table I. All luminescence peaks are shifted to shorter wavelengths in comparison with the peaks at room temperature. Undoped material shows a broad luminescence peak at 6600Å with an intensity about one-third of the mentioned red RCA phosphor. In general the dopant material has only little influence on the luminescence properties of Cd_4SiS_6 at 77°K. Only mercury and copper shift the peak to longer wavelengths, by 200 and 400Å, respectively. The highest intensity is achieved by Cd_4SiS_6 doped with a powdered Nernst filament; the intensity is twice as high as that of the undoped material. Silver, on the other hand, decreases the luminescence intensity to about one-third.

Acknowledgment

The authors wish to thank Dr. G. Harbeke, Dr. H. Kiess, and Dr. R. Nitsche for stimulating discussions, and Mr. E. Meier for taking the reflectivity measurements.

Manuscript received June 22, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Temperature Oscillations in Czochralski Crystal Growth

J. R. Carruthers[1]

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Canada

Temperature fluctuations resulting from thermal convection during crystal growth are known to cause growth rate fluctuations and impurity microsegregation. These fluctuations are normally random in otherwise stationary liquids, although Hurle (1) reports regular periodicities near the surface of liquid gallium at low-temperature gradients. When a liquid with such temperature oscillations is spun about a vertical axis or subjected to a magnetic field (if conducting), additional stabilizing forces are provided which eliminate the oscillations and allow steady flow. With spin, this additional force is the Coriolis force which acts on particles having a horizontal velocity component.

Spin may have a second important effect in addition to the stabilization of flow. When instability does arise under spin, the consequent motion might be oscillatory rather than unidirectional. This type of instability has been termed "overstability" and occurs only in fluids with a low Prandtl number, N_{Pr}, where

$$N_{Pr} = \nu/K < 0.68 \text{ for overstability}$$

where ν is the kinematic viscosity and K the thermal diffusivity. This note reports the existence of overstable oscillations in rotating liquid silicon ($N_{Pr} \approx 0.088$) as observed from a fine set of growth striations appearing on the outer surface of nonrotated silicon crystals.

Chandrasekhar and Elbert (2) define a nondimensional frequency, σ, for overstable oscillations as

$$\sigma = \left[\frac{2}{1+2N_{Pr}}\right]^{1/2}\left[\frac{1+N_{Pr}}{N_{Pr}}\right]^{1/3}\left[\frac{\pi^2}{2}\right]^{1/3} N_{Ta}^{1/3}$$

where N_{Ta} is the dimensionless rotation rate given by

$$N_{Ta} = \frac{4\Omega^2 h^4}{\mu^2}$$

where Ω is the crucible rotation rate and h is the liquid depth. Substitution of N_{Pr} for liquid silicon gives

$$\sigma = 5.15\, N_{Ta}^{1/3}$$

Chandrasekhar and Elbert (2) write the oscillation period; τ, as

$$\tau = \frac{2\pi}{\Omega}\frac{N_{Ta}^{1/2}}{2\sigma}$$

Substituting for σ and using the crucible rotation rate, ω, in revolutions per minute gives

$$\tau = 5.82\,\frac{N_{Ta}^{1/6}}{\omega}\ \text{sec}$$

[1] Present address: Bell Telephone Laboratories, Inc., Murray Hill, New Jersey.

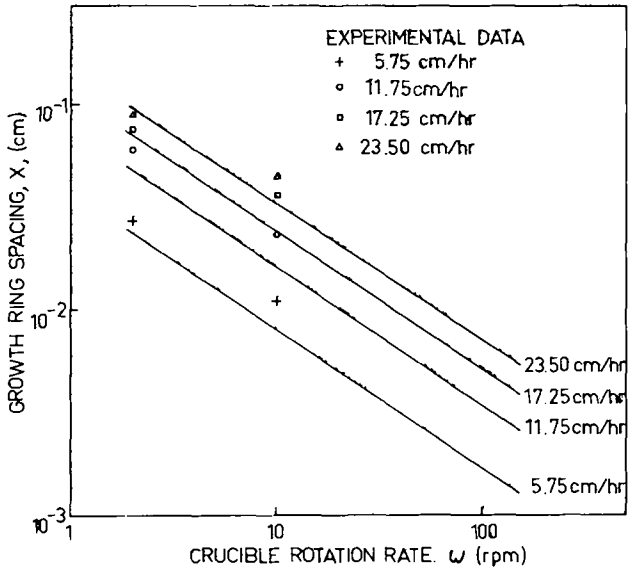

Fig. 1. Variations of growth rate fluctuation spacing caused by overstable oscillations in rotating liquid silicon.

The corresponding spacing period, x, (in growing crystals) of perturbations associated with overstable oscillations for a growth rate, R, will be

$$x = R\tau$$

This relation does not, of course, apply at very low crucible rotation rates. The spacing, x, is plotted as a function of ω for various growth rates, R, in Fig. 1 using $\nu = 0.0125$ cm^2/sec and $h = 4.1$ cm. Experimentally observed points for crystals grown with no crystal rotation are shown for the different growth rates. These crystals were supplied to the author by K. E. Benson of the Bell Telephone Laboratories Inc., The observed spacings were obtained by counting the number of outer growth rings contained in a 1-in. length of the crystal surface. The agreement between theory and experiment is reasonably close, although the slope appears to be somewhat in error. This discrepancy undoubtedly arises because the analysis ignores the additional fluid circulation generated by horizontal temperature gradients and the resultant damping of temperature oscillations.

Epitaxial InAs on InAs Substrates

G. R. Cronin and S. R. Borrello

Texas Instruments Incorporated, Dallas, Texas

Halogen transport and vapor growth of InAs were first reported by Effer *et al.* (1, 2). Epitaxial deposition of pure InAs as well as GaAs-InAs mixed crystals on low resistivity GaAs substrates has also been described by Minden (3), but the net carrier concentration and mobility of the deposits were not reported. By depositing InAs on chromium doped semi-insulating GaAs substrates, electrical measurements on pure epitaxial InAs deposits have been made (4, 5). While these deposits compared favorably with melt grown material in terms of net carrier concentration and mobility at 77°K, electron mobilities at 300°K were on the average somewhat lower than those observed for melt-grown material.

Since defect free deposits were not generally obtained on GaAs substrates, the influence of these defects on electrical properties cannot be ignored. Furthermore, strains in the deposited layer arising from differences in lattice spacing and thermal expansion coefficients may also influence the electrical characteristics of these deposits (6).

In order to avoid these effects as much as possible in the present series of experiments, epitaxial InAs was deposited on undoped InAs substrates. In order to make electrical measurements on the epitaxial layers alone, the deposits were made thick enough (75-100μ) so that the substrates could be removed leaving the deposited layer intact.

The reactor and flow systems are the same as those described previously (4) using elemental indium and arsenic, 99.9999% pure.

InAs substrates were prepared from undoped pulled crystals cut on the (100) orientation. These crystals showed typical excess electron concentrations of 4-5 x 10^{16}/cm^3 at 300°K with dislocation densities ranging from high 10^3 to low 10^4/cm^2. Wafers cut 30 mils thick were chemically polished on a paper pad soaked with a solution of bromine in methanol, 0.5% by volume (7).

Under the operating conditions shown in Table I approximately 6 hr of deposition time are required for a layer of sufficient thickness for substrate removal. The surfaces of these deposits were quite smooth, shiny, and, in general, free of visible defects. In instances where surface imperfections were observed they were identical in appearance with those described previously for deposits on GaAs substrates (4).

Unlike deposition on GaAs where the interface between deposit and substrate is clearly visible due to a slight color difference, epitaxial layers on InAs substrates are virtually impossible to distinguish on a cleaved edge. Growth rates were therefore obtained by using partially masked substrates. Masking is achieved with an SiO_2 film deposited on a portion of the substrate using standard photolithographic techniques. Since no deposit is generally observed on the masked portion of the substrate, deposit thickness is conveniently measured by observing the "step height" revealed on the cleaved edge of the sample (Fig. 1).

Hall measurements were made by the van der Pauw (8) technique on cloverleaf shaped samples 6 mm in diameter. The substrate portion of the specimen was almost totally removed by wet lapping with 5μ alumina abrasive. When the total thickness of the sample (deposit plus substrate residue) measured 125-150μ, the remaining portion of the substrate was removed by etching the sample in a 5% bromine-methanol solution. Approximately 5 min etching time are required to remove 30-50μ of material.

505	75	17	15	30	61
507	75	17	14	28	61
513	100	4.9	3.7	30	112

The final thickness of the sample on which Hall measurements were made was usually about 75-100μ which corresponded to the minimum deposit thickness.

The electron mobility at 300°K for most of the epitaxial InAs crystals measured varies little from approximately 30,000 cm^2/volt-sec. Since the net carrier concentration varies as much as an order of magnitude, the results (see Table II) imply that the mobility at 300°K is probably limited by optical phonon scattering. At 77°K, however, the electron mobility is explicitly related to the carrier concentration (see Fig. 2) for both vapor deposited and melt grown InAs (9). The shift in data points in Fig. 2 represented by the GaAs substrates may be an indirect result of the 7% lattice mismatch between these two materials. The point which noticeably deviates from the best fit curves, we believe, represents rather closely compensated material.

The temperature variation of the electron mobility was determined for two epitaxial crystals and is shown in Fig. 3. These data can be fitted to a fair degree

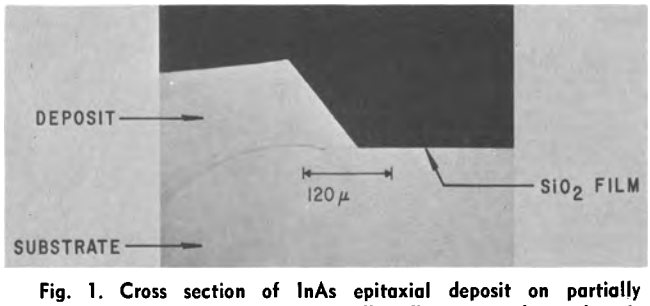

Fig. 1. Cross section of InAs epitaxial deposit on partially masked (SiO_2) substrate. Height of "step" corresponds to deposit thickness. Note also a small amount (approximately 45 μ) of overgrowth. The angle of growth between the surfaces of the masked substrate (100), and the epitaxial deposit corresponds closely to a (111) plane.

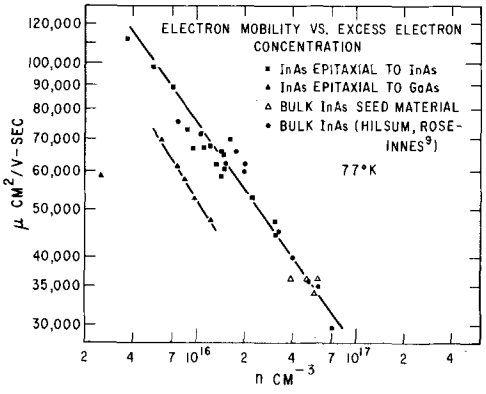

Fig. 2. Electron mobility vs. excess electron concentration for vapor grown and melt grown InAs.

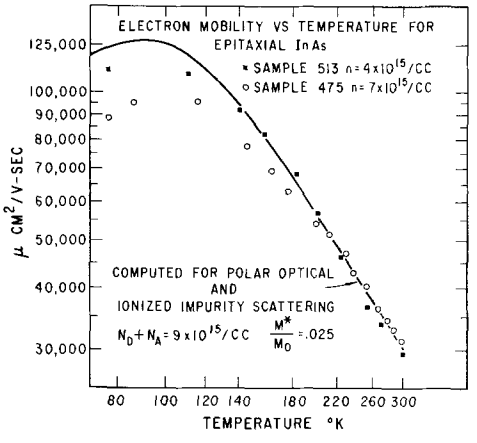

Fig. 3. Electron mobility vs. temperature for InAs epitaxial to InAs.

by a combination of polar optical (10) and ionized impurity (11) scattering and agree well with the results of Chasmar (12). An effective mass ratio of 0.025 and a donor plus acceptor concentration of 9 x 10^{15}/cm^3 were used to obtain the computed curve. The computed curve and the data are in close agreement from 300° to 130°K below which the deviations are less than 30%. Since the assumed value of 9 x 10^{15}/cm^3 for the total ionized impurity concentration produces a good fit for the temperature variation of the mobility and the net carrier concentration is measured at 3.7 x 10^{15}/cm^3, the donor concentration becomes approximately 6.5 x 10^{15}/cm^3 and the acceptor concentration 2.5 x 10^{15}/cm^3. The functional dependence of mobility on net carrier concentration as shown in Fig. 2 is consistent with the ionized impurity scattering model (11) implying that the excess electron concentration is large compared with the acceptor concentration.

The vapor-grown samples shown in Fig. 2 represent an improvement in properties over InAs deposited on GaAs substrates as well as melt grown material. In the former case, it seems reasonable to attribute the increase in mobility to a decrease in the defect density and strains in the deposited layer. In the latter case, it is possible that the impurity segregation coefficients are smaller in this particular vapor-solid growth mechanism than in the liquid-solid. The possibility also exists that the higher excess carrier concentrations normally observed in melt grown InAs are a result of a defect structure introduced at the solidification temperature. We have tried several etchants to reveal differences in the structure of the vapor-grown layer and the InAs substrate but, as yet, without result.

Acknowledgments

Brief Communication

A Chemical Notation for Defect Solid State Chemistry

J. N. Ong, Jr.

College of Applied Science and Engineering and Laboratory for Surface Studies, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin

Communication has been hindered among and between electrochemists, metallurgists, ceramists, and solid-state chemists and physicists, for lack of a consistent or standardized notation to describe chemical reactions in the solid state. This note demonstrates that normal chemical notation is adequate for most purposes and that existing notations are needlessly complicated.

Two familiar reactions are discussed, F-center formation and metal deficit nonstoichiometric oxide formation, (*a*) to illustrate the diversity of symbolism encountered in existing notations to describe vacancies (Schottky-Wagner defects) and charge carriers, (*b*) to suggest an alternate notation, (c) to demonstrate that one common adjustment to the existing notations renders their symbols for vacancies equivalent to each other and to normal chemical notation, and (*d*) to recommend alternate symbols for holes when used in chemical equations.

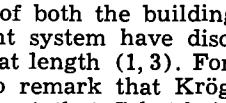
F-Center Formation

Some of the ways in which the reaction of sodium vapor with rock salt to produce F-centers has been symbolized are shown in Table I, reactions (B)-(E). Not shown are another building unit system of notation due to Schottky (2, 8) and a notation of Schmalzried's (9), typographically similar to that of Schottky (1) but considered a structure element system (10). The proponents of both the building unit system and structure element system have discussed their notations elsewhere at length (1, 3). For present purposes it is sufficient to remark that Kröger, Stieltjies, and Vink (3) point out that Schottky's F-center symbol $|Cl|$ in reaction (B) has the operational meaning "take away a chlorine atom" and is in the material balance sense a "negative mass" particle. Schottky (1) objects to the atomic notation because only virtual potentials, $\xi(Na_{Na})$ and $\xi(V_{Cl})$[1] may be assigned to the symbols Na_{Na} (sodium atom at a sodium site) and V_{Cl} (vacancy at a chlorine site).

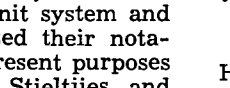
On the other hand Anderson (11, 12) persists in the use of Rees' notation, reaction (D), even though it is less convenient for writing mass action expressions.

The ionic notation, reaction (E), presupposes purely ionic bonding in rock salt. However, the resulting symbol for F-center, $V^{-}{}_{Cl}-$ along with that of Rees, $e|\square-$ represents a more accurate physical picture of the location of the electron than that of Kröger and Vink (2), whose symbol, V_{Cl}, carries zero charge. For future reference and by comparison with Schottky's symbol, observe that the three F-center-symbols in reactions (C), (D), and (E) are essentially "zero mass" particles.

We may view reaction (A) in a more conventional sense and by so doing return to a simple notation, discover one point of difference between the notations, and indicate the procedure by which they may be reconciled on this point. Let us view the F-center as arising from the solution of sodium in NaCl and express the material balance as reaction (F), Table I. Since we know that a sodium atom in solution occupies a lattice site in NaCl normally occupied by sodium and that a chlorine atom is absent from its normal site we may, for purposes of convenience, convey such structural information within the symbol (6) as shown in reaction (G). [The subscripts identify the lattice sites and V denotes absence of matter (2)]. It is frequently desirable to convey polarization information within a symbol. In our example we know that the electron from the sodium atom is localized in the vicinity of the vacancy (6). We may then write the symbol in the form shown in reaction (H). These symbols, Na (identity), $(Na_{Na}V_{Cl})$ (structure) and $(Na^{+}{}_{Na}V^{-}{}_{Cl})$ (polarization) are directly comparable to conventional chemical symbols, for example H_2O,



H, and



H, respectively. To complete the analogy, it is evident that we may solvate the solute atom to any convenient degree, reaction (I), and by incorporating the structure, polarization and solvation refinements to the basic symbol, Na (in solution), we finally arrive at the familiar schematic representation of the F-center (7) shown in reaction (J). In the chemical notation the F-center symbols are

Table I. Comparisons of various notations used to describe dilute solution formation in an ionic crystal

	Reaction	System of notation	Ref.
A.	Sodium vapor + rock salt = rock salt + F-centers	Verbal	
B.	$Na(g) = NaCl + \|Cl\|$	Building unit	(1)
C.	$Na(g) = Na_{Na} + V_{Cl}$	Structure element, atomic	(2-4)
D.	$Na(g) = Na^{+} \|\square\|^{+} + e\,\|\square\|^{-}$	Structure element, Rees	(2,5)
E.	$Na(g) = Na^{+}{}_{Na} + V^{-}{}_{Cl}$	Structure element ionic	(2)
F.	$Na(g) = Na$ (in solution)	Chemical	
G.	$Na(g) = (Na_{Na}\,V_{Cl})$	Chemical, with structure	(6)
H.	$Na(g) = (Na^{+}{}_{Na}\,V^{-}{}_{Cl})$	Chemical, with polarization	(6)
I.	$nNaCl + Na(g) = Na(NaCl)_n$ $Na^{+}\,Cl^{-}\,Na^{+}\,Cl^{-}$	Chemical, with solvation	(6)
J.	$nNaCl + Na(g) = Cl^{-}\,Na^{+} - Na^{+}$ $Na^{+}\,Cl^{-}\,Na^{+}\,Cl^{-}$	Chemical, with structure polarization and solvation	(6,7)

[1] We usually distinguish between chemical potentials (13) of neutral species, $\mu(i)$, whose values are normally experimentally accessible, and electrochemical potentials (13) of charged species (ions), $\mu_{+}(i)$ or $\mu_{-}(i)$, whose values are experimentally accessible only provided that their sum $\sum_j \nu_j\mu_{+} + \sum_k \nu_k\mu_{-}$ in any equilibrium equation is subject to the restriction of electrical neutrality, $\sum_j \nu_j z_j = 0$, where ν is the stoichiometric coefficient and z is the charge number of the appropriate species. Kröger's (3) virtual thermodynamic potentials (virtual potentials), $\xi(i)$, are analogous to electrochemical potentials. The condition that they be experimentally accessible is, however, subject not to electrical neutrality but to a constant ratio between different types of lattice sites. We will write all potentials as $\mu(i)$, $\xi(i)$, etc., instead of μ_i, ξ_i, etc. to avoid typesetting difficulties.

all "positive-mass" particles in contrast to the building unit and structure element symbols.

Mass action expressions relating defect concentrations to vapor pressure present another source of difficulty which is simplified by use of the conventional chemical notation. Experiment shows that the equilibrium number of F-centers formed is directly proportional to the sodium vapor pressure (6). We can obtain this relation by the usual procedure of equating chemical potentials. From reaction (G) for example we have

$$\mu(\mathrm{Na[g]}) = \mu(\mathrm{Na_{Na}V_{Cl}}) \quad [1]$$

from which we get the mass action expression (13)

$$K_G P_{Na} = a(\mathrm{Na_{Na}V_{Cl}}) \simeq [(\mathrm{Na_{Na}V_{Cl}})] \quad [2]$$

where K_G is the equilibrium constant, P_{Na} is the sodium vapor pressure, $a(\mathrm{Na_{Na}V_{Cl}})$ and $[(\mathrm{Na_{Na}V_{Cl}})]$ are the relative activity [ref. (13), p. 226] and concentration, respectively, of the F-center. The concentration is a good approximation to the relative activity when the solution is dilute.

If the same procedure is strictly followed with any of reactions (C), (D), and (E), (C) say, we may equate the chemical and virtual potentials according to

$$\mu(\mathrm{Na[g]}) = \xi(\mathrm{Na_{Na}}) + \xi(\mathrm{V_{Cl}}) \quad [3]$$

from which follows the relation

$$K_C P_{Na} = a(\mathrm{Na_{Na}})a(\mathrm{V_{Cl}}) \simeq [\mathrm{Na_{Na}}][\mathrm{V_{Cl}}] \quad [4]$$

relative activities $a(\mathrm{Na_{Na}})$ and $a(\mathrm{V_{Cl}})$ having been approximated by concentrations in the last term. Since there are equal numbers of excess[2] sodium atoms and vacancies, we have the additional restriction on Eq. [4] of

$$[\mathrm{Na_{Na}}] = [\mathrm{V_{Cl}}] \quad [5]$$

When Eq. [5] is substituted into Eq. [4], we obtain the result

$$(K_C P_{Na})^{1/2} = [\mathrm{V_{Cl}}] \quad [6]$$

which does not agree with experiment.

This conclusion may be avoided by arbitrarily assigning a value of unity to $a(\mathrm{Na_{Na}})$ in Eq. [4]. We may just as readily, and in many respects less arbitrarily, assign unit value to $a(\mathrm{V_{Cl}})$ and regard the changed properties of the crystal as arising from the activity of the excess sodium. A more satisfactory procedure is to regard the excess atom-vacancy pair as inseparable and its symbol accordingly associated, for example (NaCl+|Cl|) reaction (B),[3] ($\mathrm{Na_{Na}}+\mathrm{V_{Cl}}$) reaction (C), *etc.* It is clear from Table I that if the pairs of symbols on the right hand side of reactions (B) to (E) are combined as indicated above, they become equivalent in all but one respect to each other and to the symbols of reactions (F), (G), and (H), *i.e.*

$$(\mathrm{NaCl} + |\mathrm{Cl}|) \equiv (\mathrm{Na_{Na}} + \mathrm{V_{Cl}}) \equiv (\mathrm{Na^+}|\square_+ + \mathrm{e}|\square_-) \equiv$$
$$(\mathrm{Na^+{}_{Na+}} + \mathrm{V^-{}_{Cl-}}) \equiv \mathrm{Na(in\ solution)} \equiv$$
$$(\mathrm{Na_{Na}V_{Cl}}) \equiv (\mathrm{Na^+{}_{Na}V^-{}_{Cl}}) \quad [7]$$

With this one change, all the symbols become "positive mass" particles, all can be assigned normal chemical potentials and all the reactions will lead to the correct equilibrium relationship between vapor pressure and concentration, Eq. [2].

The only difference between symbols lies in the degree of polarization which is implied or assumed. Rather than assign virtual potentials to the separate symbols $\mathrm{Na_{Na}}$ and $\mathrm{V_{Cl}}$ with their respective effective charges, we may assign a chemical potential to the combined symbol ($\mathrm{Na_{Na}V_{Cl}}$) and account for polarization by including an appropriate term in the chemical potential which reflects the contribution to it, due to the presence of the sodium atom in an electric field [ref. (13), p. 415]

$$\xi(\mathrm{Na_{Na}}) + \xi(\mathrm{V_{Cl}}) = \mu(\mathrm{Na_{Na}V_{Cl}}) =$$
$$\mu^\circ(\mathrm{Na_{Na}V_{Cl}}) - \mu^E(\mathrm{Na_{Na}V_{Cl}}) \quad [8]$$

where $\mu^\circ(\mathrm{Na_{Na}V_{Cl}})$ denotes the value of $\mu(\mathrm{Na_{Na}V_{Cl}})$ at zero field strength and where $\mu^E(\mathrm{Na_{Na}V_{Cl}})$ is a function of electric field strength, molecular polarizability, electric moment, and temperature.

Regardless of the merits of the structure element notations for symbolizing polarization, for all other chemical purposes conventional chemical notation is preferable. These purposes include the performance of material balances and thermodynamic and kinetic analyses. The chemical notation can be used for solution, solvation, and ionization reactions, phase transformations or ordering phenomena, and half-cell, electrochemical, and oxidation-reduction reactions.

Table II summarizes the symbols, masses, and thermodynamic potentials associated with the most common defects in solid crystals; interstitial (Frenkel), substitutional, and Schottky-Wagner defects in the building unit, atomic, ionic, and chemical notations. Discussion of Table II is deferred until later.

Metal Deficit Nonstoichiometric Oxide Formation

Both vacancies and positive charge carriers form in some solids. An example, which has been symbolized in Table III in the various notations, is the reaction between cobaltous oxide and oxygen which produces a metal deficit nonstoichiometric p-conducting oxide containing cobalt vacancies. First, I show that the symbols for the vacancies should be modified in a way similar to the F-center example. Second, I point out the differences in and discuss the relative merits of the symbols for charge carriers in the building unit, atomic and Rees notations (holes) and in the ionic, and chemical notations (ions).

Let us reconsider the question of symbolism for vacancies. By arguments similar to those of the preceding section, it is clear that the expected one sixth power oxygen pressure dependency upon equilibrium vacancy concentration (14, 15) cannot be obtained from the structure element notations unless either unit activity is arbitrarily assigned to $a(\mathrm{O^=_O})$ (15), reaction (N) for example, or unless the excess oxygen ion-vacancy pair can be considered associated, $(\mathrm{V_{Co}} + \mathrm{O^=_O})$.

We obtain the proper equilibrium pressure dependency on excess oxygen ion concentration (vacancy concentration) by the normal procedure of equating the appropriate potentials, using reaction (O), say

$$2\mu_+(\mathrm{Co^{++}}) + (\tfrac{1}{2})\mu(\mathrm{O_2,(g)}) =$$
$$2\mu_+(\mathrm{Co^{+++}}) + \mu_-(\mathrm{O^=}) \quad [9]$$

From Eq. [9] we may write for the equilibrium constant, K_O, the expression

$$K_O = \mathrm{a_+{}^2(Co^{+++})\ a_-(O^=)/a_+{}^2(Co^{++})P^{1/2}{}_{O_2}} \quad [10]$$

where $\mathrm{a_+}$ and $\mathrm{a_-}$ are ion activities.

If we make the usual simplifying assumptions of $\mathrm{a_+(Co^{++})} = 1$ and for the mean ion activity coefficient $\gamma_+{}^2(\mathrm{Co^{+++}})\gamma_-(\mathrm{O^=}) \simeq 1$, for the limiting condition of a dilute solution, [ref. (13), Chap. 8], Eq. [10] reduces to

$$P_{O_2}{}^{1/2}K_O = [\mathrm{Co^{+++}}]^2[\mathrm{O^=}] \quad [11]$$

Finally, by noting that $[\mathrm{Co^{+++}}] = 2[\mathrm{O^=}]$, we obtain the correct pressure dependence on either excess

[2] This is clearly a consequence of the precise statement of reactions (C), (D), and (E). If we rewrite reaction (C), say, to include the rock salt: (*m*) NaCl + Na(g) = (*m*) NaCl + $\mathrm{Na_{Na}}$ + $\mathrm{V_{Cl}}$ where usually $m >> 1$, common amounts of NaCl cancel on both sides of the equation leaving only the excess Na on the right-hand side present in equal numbers to vacancies. Alternatively, the activity of the original crystal cancels in the corresponding mass action expression

$$K_C = a^m(\mathrm{NaCl})a(\mathrm{Na_{Na}})a(\mathrm{V_{Cl}})/a^m(\mathrm{NaCl})P_{Na}$$

[3] In the building unit notation, this operation should be regarded as purely formal. It is not to be construed that the notation is inconsistent.

Table II. Symbols, masses, and thermodynamic potentials of typical defects in solids in various notations

Type of defect and example		Notation: Building Unit	Atomic	Ionic	Chemical
Frenkel (Interstitial Zn in ZnO)	Symbol	Zn^x	Zn_i	Zn_i	Zn_i
	Mass	+	+	+	+
	Potential	$\mu(Zn^x)$	$\mu(Zn_i)$	$\mu(Zn_i)$	$\mu(Zn_i)$
Substitutional (Be in Ge)	Symbol	B|Ge|	B_{Ge}	B_{Ge}	B_{Ge}
	Mass	$-$ [a]	+	+	+
	Potential	$\mu(B) - \mu(Ge)$	$\mu(B_{Ge})$	$\mu(B_{Ge})$	$\mu(B_{Ge})$
Schottky-Wagner (F-center in NaCl)	Symbol	|Cl|	V_{Cl}	V^-_{Cl}	Na or $(Na^+_{Na}\ V^-_{Cl})$
	Mass	$-$	O	$O^{(b)}$	+
	Potential	$-\mu(\|Cl\|)$	$\xi(V_{Cl})$	$\xi(V^-_{Cl})$	$\mu(Na)$
Schottky-Wagner (Co vacancy in non-stoichiometric CoO)	Symbol	$\|Co\|''$	V''_{Co}	$V_{Co^{++}}$	O= or $(V_{Co}\ O_O)^=$
	Mass	$-$	$O^{(b)}$	O	+
	Potential	$2\mu_-(e) - \mu(Co)$	$\xi(V''_{Cl})$	$\xi(V_{Co^{++}})$	$\mu_-(O^=)$
Immobile charge carrier (Co^{+++} ion in non-stoichiometric CoO)	Symbol	$\|e\|^\bullet$	h	$Co^{+++}{}_{Co^{++}}$	Co^{+++} or $Co^{+++}{}_{Co}$
	Mass	$-$	$-$	+	+
	Potential	$\mu_+(Co^{+++}) - \mu_+(Co^{++})$	$\mu_+(Co^{+++}) - \mu_+(Co^{++})$	$\mu_+(Co^{+++}{}_{Co^{++}})$	$\mu_+(Co^{+++})$
Mobile charge carrier (Intrinsic conductivity in Si)	Symbol	$\|e\|^\bullet$	h	Si^+	Si^+ or $Si^+{}_{Si}$
	Mass	$-$	$-$	+	+
	Potential	$\mu_+(Si^+) - \mu(Si)$	$\mu_+(Si^+) - \mu(Si)$	$\mu_+(Si^+)$	$\mu_+(Si^+)$

Notes: (a) Mass can also be positive, *e.g.*, Ge|B|.
(b) Mass of electron or effective negative charge excluded.

oxygen ion (metal vacancy) concentration or Co^{+++} ion concentration

$$P^{1/2}{}_{O_2}K_O = 4[O^=]^3 = (1/2)[Co^{+++}]^3 \quad [12]$$

The notation and the thermodynamic formulation employed here is nothing more than that which is normal for strong electrolytes (12). For example, when the reaction is expressed in the form of reaction (Q), we see that the product can be considered a dilute solution of dissociated Co_2O_3 in a CoO solvent. To the extent that association tends to occur with increasing Co_2O_3 concentration, we may represent this by the sum of the association reactions $2(CoO)^+ + O^= = (CoO)^+ + (CoO_2)^-$, and $(CoO)^+ + (CoO_2)^- = Co_2O_3$ and the solvation reaction $Co_2O_3 + CoO = Co_3O_4$.

Because of the associating and solvating tendencies of solutions of this type of reaction, any attempt to relate a definite number of vacancies to the number of excess oxygen ions in solution at high concentrations appears at present to be problematical (12, 16). As before, this difference between the three structure element notations in Table III disappears when the excess ion-vacancy pairs are associated; $(V_{Co} + O_O)''$ (atomic), $(V_{Co^{++}} + O_{O^=})^=$ (ionic) *etc.*, provided, first, that the effective negative charge in the modified atomic notation is interpreted to be a real negative charge and equivalent to the real negative charge associated with the modified ionic and Rees symbols, and, second, that there is a direct correspondence between excess oxygen ions added and metal vacancies created in the crystal.

We now consider the charge carrier symbols. Recalling the equivalence of the vacancy symbols

$$(CoO + |Co|'') \equiv (O_O + V_{Co}'') \equiv (O^=|\square_- + \square_+) \equiv (O^={}_{O^=} + V_{Co^{++}}) \equiv O^= \equiv (V_{Co}O_O)^= \quad [13]$$

we may subtract reactions (K), (L), or (M) from (N), (O), or (P) to determine that the hole symbols, $|e|^\bullet$ and h, represent a difference of two chemical symbols

$$|e|^\bullet \equiv h \equiv (Co^{+++}{}_{Co} - Co^{++}{}_{Co}) \quad [14]$$

Furthermore, since the mass of Co^{++} is greater by one electron than Co^{+++}, holes in both the building unit and atomic notations are "negative mass" particles, and when used in chemical equations, have the operational meaning: "take away an electron" (3). When the thermodynamic potentials of holes are to be considered, Eq. [14] serves to stress that such potentials from a chemical point of view must be regarded as the difference of two potentials, Table II

$$\mu_+(|e|^\bullet) \equiv \xi(h) = \mu_+(Co^{+++}) - \mu_+(Co^{++}) \quad [15]$$

The chemical origin of the hole is frequently of incidental importance for many electrical purposes, and from the electrical viewpoint we can appreciate the practice of representing the charge carrier by a single symbol. Nevertheless distinctions are often made between intrinsic and extrinsic and mobile and immobile holes. In addition to the reactions of Table III which give rise to extrinsic immobile p-conduction due to nonstoichiometry we have, using the chemical notation, extrinsic immobile p-conduction due to impurities, *e.g.*, Fe in MgO

$$(1/2)O_2(g) + 2Fe^{++}{}_{Mg} = (V_{Mg}O_O)^= + 2Fe^{+++}{}_{Mg} \quad [16]$$

intrinsic mobile p-conduction, *e.g.*, Si ionization

$$Si_{Si} = e + Si^+{}_{Si} \quad [17]$$

and extrinsic mobile p-conduction, *e.g.*, B-doped Ge

$$B_{Ge} + Ge_{Ge} = B^-{}_{Ge} + Ge^+{}_{Ge} \quad [18]$$

The last term on the right of the above equations clearly identifies the chemically different charge carriers. On the other hand a single electrical symbol for a hole can represent at least four chemically different conditions

$$|e|^\bullet \text{ or } h = (Co^{+++}{}_{Co} - Co^{++}{}_{Co}) = (Fe^{+++}{}_{Mg} - Fe^{++}{}_{Mg}) = (Si^+{}_{Si} - Si_{Si}) = (Ge^+{}_{Ge} - G_{Ge}) \quad [19]$$

Equation [19] will permit more precise distinctions to be made in the character of the holes where necessary.

Listed in Table II for the various notations are the symbols, masses, and thermodynamic potentials of the defects discussed in this section.

Table III. Comparisons of various notations used to describe metal deficit nonstoichiometric oxide formation

	Reaction	System of Notation
K.	$(1/2)O_2(g) = CoO + \|Co\|'' + 2\|e\|^\bullet$	Building unit
L.	$(1/2)O_2(g) = O_O + V''_{Co} + 2h$	Structure element, atomic
M.	$(1/2)O_2(g) = O^=\|\square_- + \square_+ + 2h$	Structure element, Rees
N.	$2Co^{++}{}_{Co^{++}} + (1/2)O_2(g) = O^={}_{O^=} + V_{Co^{++}} + 2Co^{+++}{}_{Co^{++}}$	Structure element, ionic
O.	$2Co^{++} + (1/2)O_2(g) = O^= + 2Co^{+++}$	Chemical
P.	$2Co^{++}{}_{Co^{++}} + (1/2)O_2(g) = (V_{Co}\ O_O)^= + 2Co^{+++}{}_{Co}$	Chemical; with structure
Q.	$2CoO + (1/2)O_2(g) = O^= + 2(CoO)^+$	Chemical; solution and dissociation of Co_2O_3

Discussion

Two common solid-state reactions have been formulated using a variety of notations. The two reactions discussed were a simple solution of a polarizable sub-

stance (F-center formation, Table I), and an oxidation-reduction reaction (metal deficit p-conducting cobaltous oxide formation, Table III). One simplification of the notations results when properties of nonstoichiometric compounds usually attributed to the presence of vacancies in the lattice are attributed instead to the presence of the excess constituent giving rise to the vacancy. It is shown that structure element notations must be modified to produce correct thermodynamic relationships between the equilibrium concentrations of excess constituents in solution and their vapor pressures. When both building unit and structure element notations are modified in the same way, *e.g.*, Eq. [7] and [18], they become equivalent to each other and to conventional chemical notation in this respect. In the ionic and chemical notations, the identity of the positive charge carrier can be determined, whereas in the building unit, atomic, and Rees notations, which employ the hole symbol, this may not always be done.

Comparing notations in Table II it is important to note that in the chemical notation we may associate not only a positive mass with every symbol but also a single normal thermodynamic potential, a chemical potential for a neutral species and an electrochemical potential for a charged species. In these two crucial respects this notation is identical in form with all chemical notation. The building unit notation although formally correct has both positive and negative masses associated with the symbols and positive, negative, and differences of, thermodynamic potentials associated therewith. Unless one possesses an intimate knowledge of this notation, it is difficult to read and awkward to use (3). The ionic notation has positive and zero masses associated with its symbols. With only one modification, for the vacancy, it becomes equivalent to conventional notation. The symbols in the atomic notation have positive, zero and negative masses associated with them and consequently the gamut of normal, virtual, and differences of, thermodynamic potentials.

Recommendations.—Use the chemical notation to describe reactions in the solid state. No conceptual difficulties will be encountered by its use, and no thermodynamic or chemical confusion can result from its use from the symbols themselves.

If a selection among symbols is to be made, pick the simplest one that will fit your needs. In the F-center example, if the solubility of sodium in rock salt is under consideration, it is unnecessary to use a symbol more detailed than Na(in solution). On the other hand, if defect structure and polarization are under consideration, then use the symbol $(Na^{+}_{Na}V^{-}_{Cl})$. In the cobaltous oxide example the description of cation mobility, diffusivity and oxidation phenomena may require the use of the symbol $(V_{Co}O_O)^{=}$, in reaction (P). However, if the description of the positive charge carrier, Co^{+++} is under consideration, the description of the counter ion, $O^{=}$, need not necessarily convey any structural information.

The use of h (and $|e|^{\bullet}$) as a symbol for positive charge carriers is widespread and a change in usage is unlikely. However, when this symbol is used in chemical equations it is important to keep in mind that it is not a chemical symbol. It describes the operation "take away an electron" and should be represented chemically as a difference of two chemical symbols and thermochemically as a difference of two thermodynamic potentials. When in doubt it is recommended that the use of the symbol h in chemical equations be replaced by an appropriate difference in chemical symbols, Eq. [19].

Low-Pressure Oxidation of Zirconium

J. Levitan, J. E. Draley, and C. J. Van Drunen

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

Low-pressure oxidation of zirconium at high temperatures exhibited a pressure dependence, and several stages of oxidation could be distinguished: an initial period was followed by two periods with a linear rate dependence. Transition from the first linear period to the following linear period was accompanied by increase in oxidation rate. Surface reaction control is suggested for these periods. Linear oxidation was followed by a period when the rate was limited by a protective oxide film.

Low-pressure oxidation of transition metals is receiving increasing attention in connection with vacuum and space applications. There is rather a small number of systematic investigations in the field (2-5). Phenomena observed in low-pressure oxidation reflect specific conditions of lower reacting gas concentration and different sticking probability.

It has recently been reported (1) that the potential recorded across a growing scale on oxidizing zirconium exhibits a dependence on oxygen partial pressure (p_{O_2}) at pressures below 1 mm Hg, remaining constant at $p_{O_2} > 1$ mm. Since the unchanging electric field at $p_{O_2} > 1$ mm corresponds to oxidation kinetics independent of p_{O_2}, a study of low-pressure zirconium oxidation was initiated. Preliminary results (1) stimulated a modification of the existing experimental system in order to run constant pressure and volumetric experiments.

Experimental

The source of material was high-purity zirconium supplied by Materials Research, Inc. Impurity content of the batch, as found by spectrographic analysis was (in ppm by wt):

H	3.3	Al	3.0	Cl	2.0	Ti	1.0
B	0.005	Si	1.5	K	0.004	V	0.05
C	6	P	0.1	Ca	0.04	Cr	0.5
N	2.1	Ni	1.5	Hf	40.0	Fe	30.0
O	25	Cu	0.01				

Specimens were prepared from 1.6 mm thick sheet by punching out disks 12.7 mm diameter. These were wet ground and etched for 2 min at room temperature in a 45:5:50 (by volume) HNO_3 (70%) +HF (49%) + H_2O etchant.

An Ainsworth RV-AU-2S vacuum semimicrobalance (reproducibility ± 0.03 mg) was employed for continuous automatic recording of the weight changes. A Granville-Phillips automatic control valve was used in the experimental system (Fig. 1). Excellent pressure control in the 10^{-5} to 1 mm range was achieved. Pressure control was usually obtained within 1 to 1½ min from the beginning of the experiment and controlled with high precision during the whole run. Temperature was recorded from a thermocouple in a well close to the specimen; this was calibrated to provide actual specimen temperature (controlled to ± 1°C). Experimentally determined corrections were made for buoyancy and thermal convection. Research grade oxygen supplied by Matheson Company was used as-received, with less pure gas (and a desiccant) used for flushing and storage. Oxygen was supplied to the system from a storage vessel through the control valve. Recordings of pressure drop in the storage vessel provided the oxygen consumed in volumetric measurements. The system was built from 304 stainless steel, copper, and brass. Because of variability in initial oxygen adsorption in the system, volumetric results have been only confirmatory in the present study: gravimetric results have been used exclusively.

Results

Zirconium oxidation at different oxygen pressures in the 1 to 400 mm range was found to be essentially independent of p_{O_2}. This is in agreement with results reported by previous investigators (6-10). Slight disagreement with previous data from this laboratory (6) is probably explainable in terms of the degree of purity or of metallurgical history of specimen materials.

However, the oxidation rate exhibited a significant pressure dependence for pressures below 1 mm. This is shown in Fig. 2 for 700°C. Rate of weight gain (per unit area) were considerably lower than that for "standard"[1] oxidation for short times, then increased so that oxidation was more rapid than under standard conditions. Finally, the rate decreased at lower pressures more rapidly than at standard pressures, so that at 1100 min exposure, rates of weight gain were the same at the three lower pressures shown and only about 10% greater than that at 1 mm.

Also notable in Fig. 2 are periods when rates of weight gain remained constant for significant periods of time: the straight line portions such as during the interval 70-240 min at 3 x 10^{-3} mm oxygen pressure.

Behavior during early exposure is not shown clearly in Fig. 2. The weight gain of one specimen is shown on an expanded scale in Fig. 3. It is observed that preceding the linear portion previously noted there is an earlier linear portion at about 8 to 27 min, with a lower slope than that at about 51 to 127 min. This earliest straight line generally did not extrapolate to to origin, as indicated in Fig. 3. The earliest portion of the oxidation curve was rather short and the weight

[1] The term "standard" will be used to refer to oxidation at pressures 1 to 400 mm where oxidation behavior is independent of oxygen pressure.

gains small, so that no accurate curve shape can be described. Generally, the rate decreased during this period.

As can be observed in Fig. 2, the rates of weight gain during the linear portions varied with oxygen pressure. The available linear rate constants are plotted in Fig. 4 as a function of oxygen pressure. (For some runs stage II was not sufficiently clear to justify estimating slopes.) A roughly linear dependence was exhibited both for the first (stage II) and second (stage III) linear portions. The least squares slopes were 42 and 83 mg, dm^{-2}, min^{-1}, $(mm\ Hg)^{-1}$. Their ratio, 2.0, shows the increase in rate which occurred in transition between the first and second linear reaction periods. Degree of reproducibility can be judged in the figure.

Similar behavior was exhibited at other temperatures. At 550°C, only the second linear portion was observed at the higher (than at 700°C) "low pressures" in which pressure sensitivity was evident (see Fig. 5). At 800°C lower "low pressures" were required to display pressure dependence; all stages in the oxidation curve were evident (Fig. 6).

Discussion

The low-pressure oxidation of zirconium can be divided conveniently into four stages as shown schematically in Fig. 7. During the first stage a decreasing rate of oxidation was generally (but not always) observed. During stage II weight was gained at a constant rate, which was approximately proportional to the oxygen pressure. The oxidation rate then increased by a factor of about 2.0, and during stage III

another period of constant oxidation rate was observed. Again the rate was approximately proportional to p_{O_2}. Finally, in stage IV the rate of oxidation continuously decreased with time.

The following explanation seems consistent with the known facts. Before the oxidation experiment, the specimen presumably formed (in air) an oxide film on a surface which was nearly clean (and in which it is hoped the metal structure was not seriously distorted in view of the metal removal during etching). It was then held at oxidation temperature at a pressure low enough for no discernible weight gain to occur. The air-formed oxide film very likely completely dissolved, considering the high rate of oxygen diffusion and the high solubility of oxygen in zirconium (12, 13).

During stage I oxidation, some kind of steady-state situation is being developed on the metal surface. Lack of reproducibility indicates a sensitivity to the original condition of the specimen (oxygen content and disorder in the surface layers of metal?). Perhaps some oxide nuclei form at most susceptible positions on the surface [as observed by Hart in other low-pressure studies (11)], but essentially all the oxygen is presumably dissolving in the metal. The rate of weight gain is substantially less than the expected rate of diffusion of oxygen inward from a saturated surface layer (12).

In stage II, the rate of oxygen uptake is apparently limited by the rate of chemisorption at the metal surface (not by the rate of arrival of oxygen at the surface, since this is calculated to be substantially greater than the oxidation rate). It is difficult to estimate the degree of coverage by oxygen molecules or atoms, but coverage by ions must be rather small because the rate of uptake is still lower than the expected rate of oxygen diffusion inward from a saturated surface. The pressure dependence of the rate is reminiscent of a Langmuir adsorption model. During this stage, local oxygen concentration in surface layers of the metal apparently builds up with time until, at the end of stage II, saturation occurs and surface oxide begins to form.

This surface oxide is not significantly protective; in fact the rate of oxygen uptake increases, perhaps because the ionic crystal surface is more favorable for the formation of adsorbed oxygen ions (as distinguished from uncharged species). As time goes on, more of the surface metal becomes saturated, and more of the surface becomes covered with oxide. Presumably, different grain surfaces become saturated at different times because of their different oxygen diffusion characteristics (12).

In due course the surface is covered with oxide and stage III begins (Table I). Prior to this time it can be expected that the concentration of the oxygen-diffusing species in the surface layers of metal would not have been constant with time, and therefore that the oxygen uptake at this point would be less than that expected if oxygen diffusion had been occurring from a saturated surface. However, during the period between stage II and stage III there often occurred an amount of oxidation which was substantial with respect to that which had occurred by the end of stage II. In order to aid in the development of a model for the processes actually occurring it was decided to compare the experimental results with those which would be anticipated if oxygen diffusion into the metal had been occurring from a saturated surface (such as an oxide-covered surface).

Using this model, the value of the weight gain (W) at the beginning of stage III might approximate $kt^{1/2}$, where k is the diffusion rate constant. Accordingly, the "least squares" optimum value of k was calculated for the nine available low pressure runs at 700°. A kind of rough correlation was observed, with calculated weight gains deviating by amounts up to 38% from those observed. The value of the diffusion rate constant was 1.55 mg dm^2 $t^{-1/2}$, as close to Pemsler's (12) value of 2.0 for polycrystalline zirconium as could be expected in this kind of analysis.

During stage III oxidation the rate is again controlled by the rate of chemisorption, and again Langmuir-like pressure dependence is observed. The oxide film is not thick enough to offer significant impediment to penetration by oxygen. The film continues to thicken, however, and eventually does exhibit protectiveness. Accordingly, the rate decreases (stage IV), slowly at first, and then more rapidly as the rate becomes more and more completely limited by the thickening oxide film. Reaction kinetics then become similar to what is observed in standard oxidation (a rather straight line on a log-log plot of W *vs.* t, with a slope somewhat less than ½).

As an approximation, it might be expected that the film would become significantly protective at about the same thickness (s) for different experiments. Under these circumstances the value of the weight gain at the end of stage III would be expected to equal $s + kt^{1/2}$, where k is again the rate constant for the diffusion of oxygen in zirconium. A least-squares fit provided values for s and k for the same 9 runs used previously. This time the fit was better, with an average deviation in W of 7% (see Table II).

The diffusion rate constant was 1.62, in good agreement with that calculated in connection with the start of stage III, and a bit closer to Pemsler's value for polycrystalline zirconium. At this time no particular significance can be ascribed to the thickness (apparently independent of oxygen pressure in the range studied) at which the oxide film becomes significantly protective. The value calculated was 23.4 mg oxygen/dm^2, or 1.51μ thickness.

Some time after the beginning of stage IV oxidation, the rate of oxidation appeared to be essentially independent of p_{O_2}. Even an oxygen pressure as high as 1 mm caused only about 10% decrease in rate (decrease, rather than increase, because the oxide thickness was greater). It is surprising that the rates were equal at the end of the three low-pressure runs of Fig. 2, although the pressure varied by a factor of 2.0, the weight gains showed about a 60% variation, and the

calculated oxide thicknesses varied by a factor of 2.3. Apparently the reaction rate at this time is limited by the oxide film, but is not in any simple way related to total oxide film thickness. An explanation is not now available.

It is felt that the new data reported here will probably prove valuable in interpreting oxidation mechanisms for zirconium. Certainly, a few new questions have been posed.

Manuscript received Feb. 16, 1967; revised manuscript received July 31, 1967. This work was performed under the auspices of the United States Atomic Energy Commission.

The Oxidation Properties of a Zirconium-2.7 w/o Niobium Alloy in the Temperature Range 300°-500°C

M. G. Cowgill and W. W. Smeltzer

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The reaction kinetics and structures of the alloy/oxide composite system were determined for martensitic and several Widmanstatten-structured alloys oxidized at 300°, 400°, and 500°C in oxygen at 1 atm pressure. At 300° and 400°C, there was little difference between the oxidation rates of the differently structured alloys in the early stages of the reaction. Prolonged exposures illustrated the occurrence of two limiting oxidation curves: martensitic specimens oxidized most rapidly, the oxidation rate decreasing until a transition range was attained in which the rate subsequently increased to a maximum value associated with linear kinetics; on the other hand, Widmanstatten-structured specimens containing equilibrium amounts of proeutectoid alpha-zirconium from the quench temperature oxidized most slowly, the initial decreasing oxidation rates finally approximating to linear kinetics at long exposures. Specimens containing intermediate amounts of proeutectoid alpha-zirconium oxidized at rates between these two limiting cases. At 500°C, the initial oxidation rates for all alloys approximated to parabolic kinetics, the reaction rate constants being directly dependent on the volume fractions of martensite. The oxide was cracked in the range of linear kinetics, but the role of the film as a barrier to oxidation could not be determined. The formation of oxide pustules on martensitic specimens was the only distinct feature indicating a difference in the mode of oxide formation on differently structured alloys. The major product of the reaction at all temperatures irrespective of alloy structure was an oxide whose structure could be indexed as monoclinic zirconia.

Zirconium-niobium alloys containing 2-3 w/o niobium are being utilized in nuclear reactor technology for their desirable mechanical and low neutron absorption properties. A primary disadvantage of poor corrosion resistance for alloys in an appropriate martensitic structure for optimum mechanical behavior has been largely overcome by cold-working and tempering treatments. Dawson (1) has presented a review of the literature on this subject. Although there are many observations on the beneficial effects of tempering on decreasing the corrosion rates of dilute alloys in steam, air, and carbon dioxide atmospheres, studies have not been attempted of structural effects from a fundamental viewpoint. In this investigation, results are reported for the oxidation properties of a Zr-2.7 w/o Nb alloy in both martensitic and Widmanstatten structures exposed to pure oxygen at temperatures in the range 300°-500°C. Alloys of these structures could be readily obtained by vacuum annealing followed by quenching from temperatures in the β solid solution and in the $\beta + \alpha$ phase regions selected from the binary phase diagram (2, 3).

Experimental

The material was a zirconium-2.7 w/o niobium alloy received as 2 mm thick sheet. Analyses for impurities are presented in Table I. Specimens approximately 1 cm^2 were cut from this sheet and subjected to an appropriate annealing and quenching treatment. Several specimens of the above dimensions were received already in a martensitic structure following a vacuum anneal at 960°C for 10 min before water quenching. They were prepared directly for oxidation tests.

Specimens were prepared by annealing and quenching in an all-metal system capable of maintaining a vacuum of 10^{-6} Torr. In order to minimize contamination from residual gas, specimens were wrapped in

platinum foil. In all cases, heat-treatments were carried out by raising the furnace already at 1000°C over the annealing tube containing the specimen. The specimen was held at this β-solution temperature of the alloy for 1 hr, and, if the structure required was that of full martensite, it was then quenched into oil. Specimens were also quenched from 800°C, in which cases a specimen was furnace cooled from 1000° to 800°C, held at this temperature for a predetermined time, then quenched into oil.

The surfaces of specimens were prepared by abrasion on SiC papers from 240 through 600 mesh grit under water followed by polishing for several hours on napped cloths, impregnated with 6 and 1μ diamond paste, respectively, and lubricated with kerosene. Final polishing was obtained with a vibratory polisher using a suspension of 0.3μ alumina powder suspended in water. In addition, several specific preparations involving chemical etching and different types of abrasion treatments were employed to determine possible effects of surface preparation on the oxidation kinetics.

Oxidation kinetic experiments were carried out using a vacuum microbalance apparatus (4). These results were supplemented by a series of experiments in which the specimens were intermittently removed for weighing from a quartz reaction tube. Furnaces were controlled to ±2°C, and the oxygen pressure during reaction was 1 atm. Medical grade oxygen was used which was purified by passage through cupric oxide, phosphorous pentoxide, Linde 5Å molecular sieves, and a trap immersed in solid carbon dioxide to remove traces of hydrogen, water vapor, carbon monoxide, and carbon dioxide.

The surfaces of oxidized specimens were examined microscopically and subjected to nickel filtered copper radiation with a recording x-ray diffractometer in order to identify oxide constituents in the scales. Metallographic examinations were carried out on specimen cross sections mounted in bakelite (4). In some instances, it was possible to delineate the structure of two-phase alloys by relief polishing without etching. When an etchant was needed, the most successful was found to be an aqueous solution containing 30 v/o H_2SO_4, 30 v/o HNO_3, and 10 v/o HF at a temperature in the range 68°- 75°C. The volume fraction of proeutectoid α-Zr in a two-phase alloy structure was readily determined by projecting the microstructure on a calibrated objective screen of the microscope at a magnification in the range 200-600X.

Results

In order to determine the reproducibility of measurements and the influence of surface preparation on the reaction rates, several specimens were prepared with different structures and surface preparations for oxidation at 400°C (Fig. 1). Curves (a) and (b) illustrate the oxidation behavior of martensitic specimens subjected to metallographic and chemical polishes. These different preparations did not influence oxidation at long exposures since the rates were of the same magnitude after transition to linear kinetics. In the early stages of the reaction, a correlation was not found between the methods of surface preparation due to the irreproducibility of measurements. How-

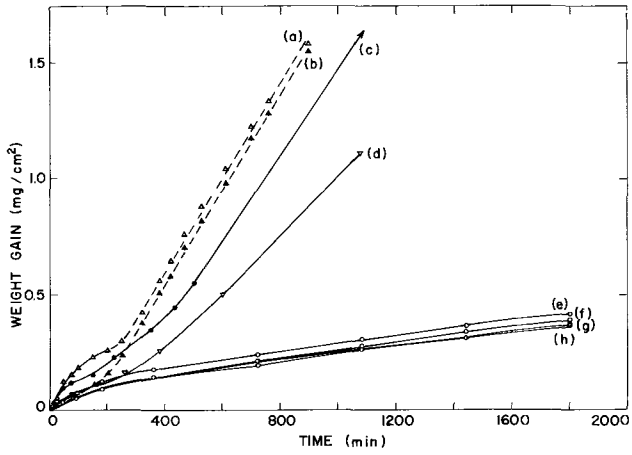

Fig. 1. Oxidation of Zr-2.7 w/o Nb alloy at 400°C in oxygen at 1 atm pressure. (a) anneal 10 min at 960°C, water-quenched, surface chemically polished; (b) anneal 10 min at 960°C, water-quenched, surface metallographically polished; (c) anneal 1 hr at 1000°C, water-quenched, surface metallographically polished; (d) anneal 1 hr at 1000°C, oil-quenched, surface metallographically polished; (e) and (g) anneal 1 hr at 1000°C and 1 hr at 800°C, oil-quenched, surface polished on 0.25μ diamond; (f) and (h) anneal 1 hr at 1000°C and 1 hr at 800°C, oil-quenched, surface polished on 0.3μ alumina.

ever, it was established that the martensitic specimens exhibited oxidation variations dependent upon the heat treatment conditions. This is illustrated by comparing the curves (b), (c), and (d) for specimens quenched into water after vacuum anneals for 10 min at 960° and 1 hr at 1000°C and for the specimen wrapped in platinum foil and quenched into oil after a vacuum anneal of 1 hr at 1000°C, respectively. These oxidation curves are of the same form with the latter specimen exhibiting the slowest rate. This behavior with the platinum-wrapped specimen would be associated with less impurity pickup from the residual gas or the slower rate of cooling during quenching. Martensitic specimens used in this investigation were prepared by both methods and are specified in the results.

Possible effects on the oxidation rate due to variations in the final stage of mechanical polishing were also investigated by oxidizing Widmanstatten structured specimens from the same batch heat-treatment (Fig. 1). Curves (e) and (g) were obtained from specimens after a polish with 0.25μ diamond paste on a selvyt cloth, whereas, curves (f) and (h) were obtained from specimens polished on a vibratory pol-

isher using a suspension of 0.3μ alumina in water. Apparently, the oxidation rate is not influenced by the type of abrasive employed in the final polishing stage.

Typical measurements of oxidation rates at 300°, 400°, and 500°C for various alloys prepared by metallographic polishing are shown in Fig. 2, 3, and 4. Although the kinetics were characterized by a certain degree of irreproducibility in the initial stages, the large variations in the oxidation rates could be correlated with the structures of the specimens. It is apparent from the volume fraction of α-Zr in the alloy listed with each kinetic curve that the oxidation rates at all investigated temperatures decrease with increasing amount of this phase.

Two examples of specimen microstructures obtained by quenching from 800° and oxidized at 400°C are shown in Fig. 5. If the anneal was carried out for only 5 min, structures containing 10-15 v/o α-Zr were obtained. Upon equilibrating an alloy at 800°C, the structure would contain about 50 v/o proeutectoid α-Zr. This condition was found after an anneal for 1 hr. Specimens containing contents of this phase between these two extremes were obtained by annealing within the above time periods.

The topography of an oxidized specimen was dependent on the alloy structure, the reaction temperature, and the time of exposure. A martensitic structured specimen, oxidized at 300° or 400°C, exhibited interference colors to film thicknesses of approximately 2000Å with color tints varying from grain to grain. At about the time of transition from an initial decreasing rate to a more rapid approximately linear rate, isolated growths of pustular shape were observed. The densities of these pustules varied with alloy grain orientations (Fig. 6a). These growths spread with lengthening exposure to cover most of the surface, although complete coverage was never observed in the exposure periods of the present experiments (Fig. 6b). On viewing the surface of a pustule at high magnification, fine cracks were observed which appeared to emanate from the tip. These pustules protruding above the main oxide surface only accounted for a relatively small amount of oxide as they were not observed at the surface of metallographic cross sections.

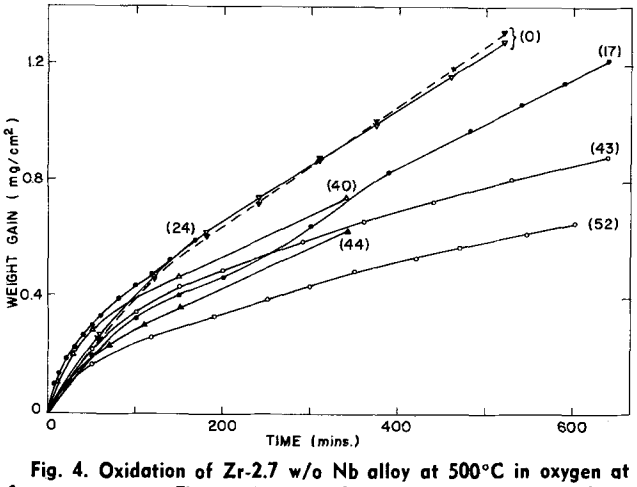

Fig. 4. Oxidation of Zr-2.7 w/o Nb alloy at 500°C in oxygen at 1 atm pressure. Figures in parantheses are approximate volume fractions of α-Zr in the alloys. Martensitic specimens oil-quenched.

Martensitic specimens oxidized at 500°C did not exhibit pustules even at brief exposures of 10 min. The oxidized specimens exhibited a gray rippled surface (Fig. 6c). This external appearance indicated that a very large number of small pustules had formed in close proximity without a large degree of lateral growth before their coalescence.

Oxidation of an alloy obtained by quenching from the (α + β) alloy region gave rise to rates of film growth dependent on the phase on which the oxide was growing. The growth of oxide on the α-Zr platelets was much less than on the α'-Zr regions. For the conditions and exposures examined, the former film never exhibited other than interference colors. The film on the α' structure gave rise initially to interference colors, but its growth rate was estimated to be at least triple that of the film on α-Zr. The film eventually became gray, and small cracks appeared running parallel to the direction of the α-Zr plates (Fig. 7a). Eventually, these cracks became more extensive and developed into intricate networks (Fig. 7b). Such observations applied to all specimens in this alloy condition, irrespective of the reaction temperature, when reaction had proceeded to linear kinetics. No oxide pustules were observed at any time for this alloy condition by light microscopy.

Cross sections of all oxidized specimens revealed an uneven metal/oxide interface. Martensitic-structured specimens exposed to the transition range for linear kinetics exhibited fine microscopic irregularities

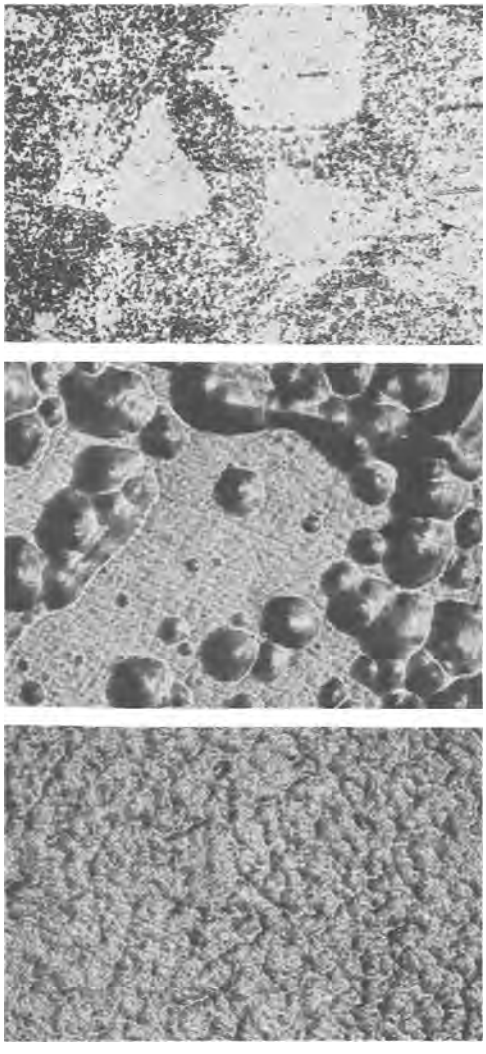

Fig. 6. Topographies of oxidized specimens with martensitic structure. a (top), 400 min at 400°C, oxygen uptake 0.07 mg/cm^2, magnification 150X; b (center), 1330 min at 400°C, oxygen uptake 1.9 mg/cm^2, magnification 100X; c (bottom), 300 min at 500°C, oxygen uptake 0.8 mg/cm^2; magnification 150X.

and also much larger undulations representing areas, rather than points, of larger oxide penetration (Fig. 8a). At long exposures, the larger variations almost disappeared to leave a relatively uniform thick scale containing cracks, many of which appeared to follow the contour of the metal/oxide interface (Fig. 8b).

The topographical observations on oxidized specimens in the two phase ($\alpha + \alpha' - Zr$) structure were confirmed by the examinations of cross sections (Fig. 9); that is, the rate of oxide growth was greater on the α' structure. This behavior was most vividly illustrated by specimens exposed for long times at 300°C where the oxide formed on the α'-regions had selectively penetrated to the extent that it appeared pinned by the unoxidized α plates (Fig. 9a). This degree of selective penetration became less pronounced with increasing temperature, and the oxide in the external film appeared less cracked at the highest temperature of 500°C (Fig. 9c).

Detailed examination of the metal/oxide interface of all specimens oxidized for relatively long time periods demonstrated that localized points of oxide penetration occurred at the lines of martensitic transformation in the α'-Zr microstructure. This is illustrated by the etched microstructure of the martensitic alloy (Fig. 10a), and by the Widmanstatten-structured alloys (Fig. 9a, 10b) where the fine degree of oxide penetrations into the martensitic structure between the α-Zr plates is readily apparent.

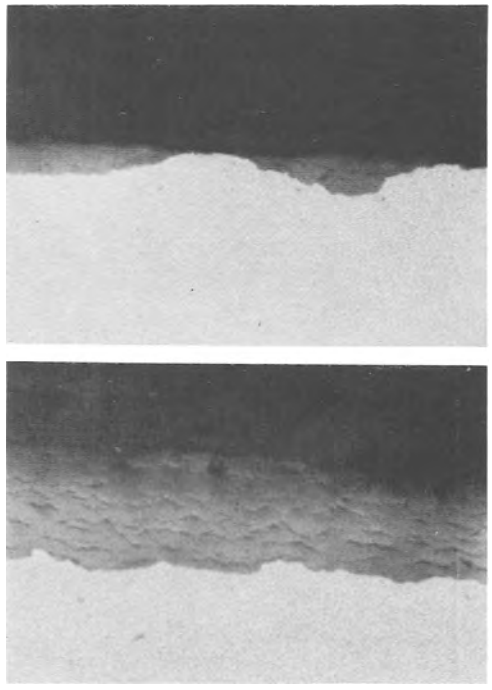

Fig. 8. Cross sections of oxidized specimens with martensitic structures. a (top), 1030 min at 400°C, oxygen uptake 1.1 mg/cm^2, magnification 675X; b (bottom), 1380 min at 500°C, oxygen uptake 2.0 mg/cm^2, magnification 675X.

X-ray analyses revealed that the major oxidation product could be indexed as monoclinic zirconia. Occasionally a weak reflection was observed which could be interpreted as either the cubic or tetragonal form of zirconia. Oxides of niobium were not detected. However, the technique is limited and monoclinic zirconia may not be the only reaction product.

Discussion

An attempt has been made to elucidate more fully the oxidation mechanisms of a Zr-Nb alloy by deter-

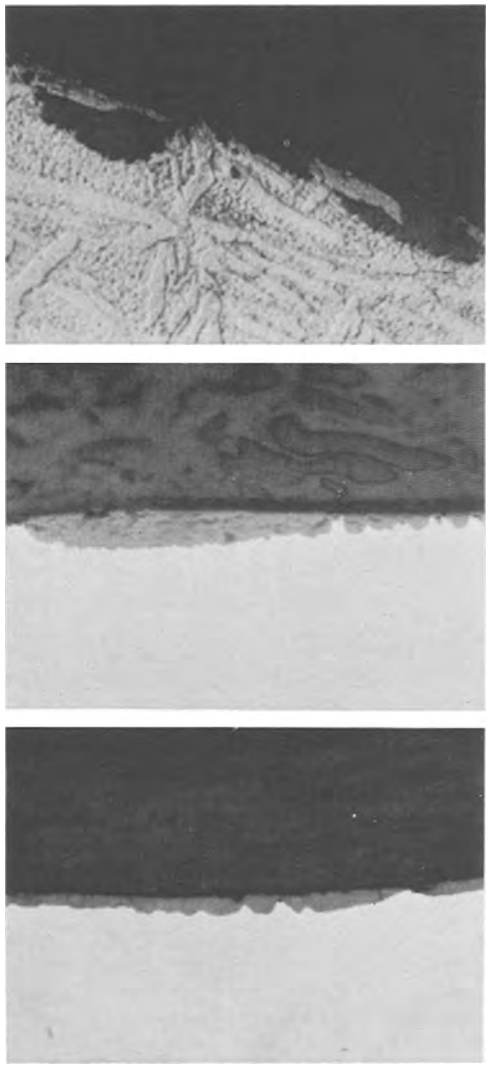

Fig. 9. Cross sections of oxidized specimens with Widmanstatten structures. a (top), 19,300 min at 300°C, oxygen uptake 0.23 mg/cm^2; b (center), 485 min at 400°C, oxygen uptake 0.5 mg/cm^2; c (bottom), 150 min at 500°C, oxygen uptake 0.5 mg/cm^2. Magnification 675X.

mining the effects of alloy structures on the oxidation kinetics. The results available at 300° and 400°C (Fig. 2 and 3) gave two limiting oxidation curves for the alloy under examination. A distinct transition was shown in the oxidation curves of the martensitic alloy, prepared by quenching from a β-solid solution temperature. The rate decreased until a transition range was attained in which the rate increased again to a maximum value associated with approximately linear kinetics. The other limiting oxidation curve was shown by alloys with Widmanstatten structures produced by quenching from 800°C and containing approximately 50 v/o proeutectoid α-Zr, the equilibrium amount for this temperature. These curves exhibited a decreasing rate, which, in the later stages, approximated to linear kinetics.

In the early stages of the reaction at 300° and 400°C, there was little difference between the oxidation rates for the two alloy structures. However, the reaction rate at long times of a Widmanstatten-structured alloy was much less than the linear rate of the martensitic alloy. Specimens with intermediate amounts of proeutectoid α-Zr exhibited oxidation rates between these two limiting cases, the over-all rate increasing with decreasing amount of α-Zr.

A direct relationship between the magnitude of the reaction kinetics and the amount of α-Zr in an alloy could not be demonstrated from the present results

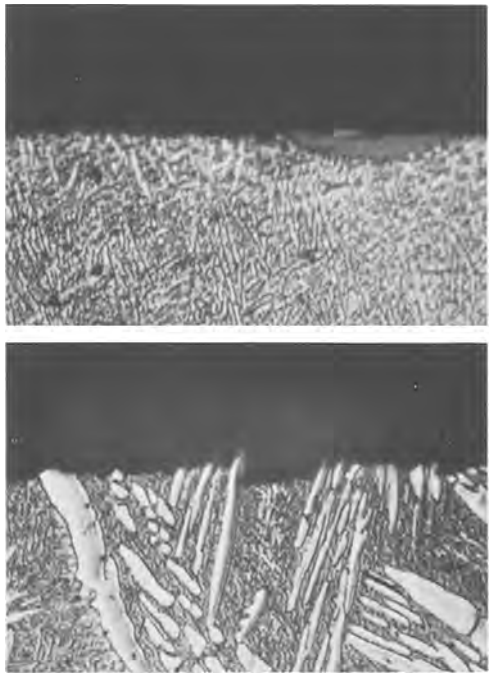

Fig. 10. Etched structures of oxidized specimens. a (top), martensitic structure, 7130 min at 300°C; b (bottom), Widmanstatten structure, 485 min at 400°C. Magnificaion 675X.

at 300° and 400°C. In the initial stages, the oxidation rate of α'-Zr was at least three times faster than α-Zr, while in the final stages of the exposures, the contribution of film growth on the α-Zr plates was of minor significance to the over-all film growth. Moreover, the oxide film on α'-Zr at long exposures was cracked and porous. These observations suggest that the linear oxidation kinetics at 300° and 400°C would be largely dependent on the amount of α'-Zr in the alloy.

Plots of the linear rate constants *vs.* the amount of α'-Zr are shown in Fig. 11 and 12. At 300°C, the kinetic curves were irregular and the rate constants are only approximations. The martensitic specimens reacted rapidly at this temperature, the rate decreasing markedly over the range to 85 v/o martensite. At 400°C, the decrease in rate was proportional to the amount of α'-Zr from full to approximately 80 v/o martensite. A smaller dependence of the oxidation rate on the contents of α'-Zr less than 80 v/o appeared to be associated with the morphological development of the oxide film.

Chemical composition is a major difference between martensite formed by quenching from 1000° and 800°C. α'-Zr formed under the latter condition would contain twice as much niobium. At small niobium contents, alloys with larger niobium concentration exhibit more rapid oxidation (5, 6). Thus, α'-Zr would possibly oxidize more rapidly in the specimens quenched from 800°C. The observations from this investigation do not support this consideration. Accordingly, any variations to be expected from increased niobium concentration in the martensitic phase were suppressed by possible variations in the structure of this phase or its mechanism of oxidation in the presence of proeutectoid α-Zr.

It has been shown that the oxide on the martensitic phase was subject to constraint by α-Zr plates and was pinned beneath the metal/oxide interface, Fig. 9(a). The oxide under such circumstances was less porous and the oxidation rate showed a smaller dependence on the amount of α'-Zr at percentages less than 80 v/o (Fig. 11 and 12). Thus, the over-all oxidation rate became dependent on two factors: the amount of α'-Zr and the penetration depth of oxide into the metal. With low percentages of proeutectoid

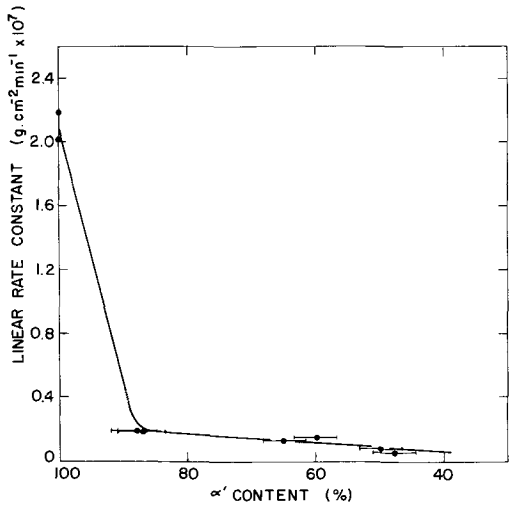

Fig. 11. Plot of linear oxidation rate constants vs. amount of α'-Zr at 300°C.

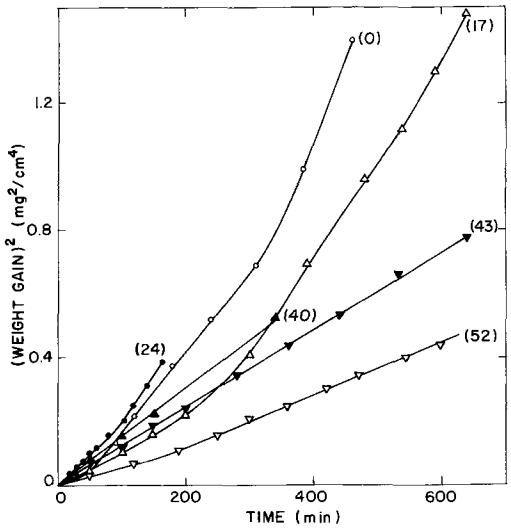

Fig. 13. Oxidation kinetics at 500°C represented by parabolic plots.

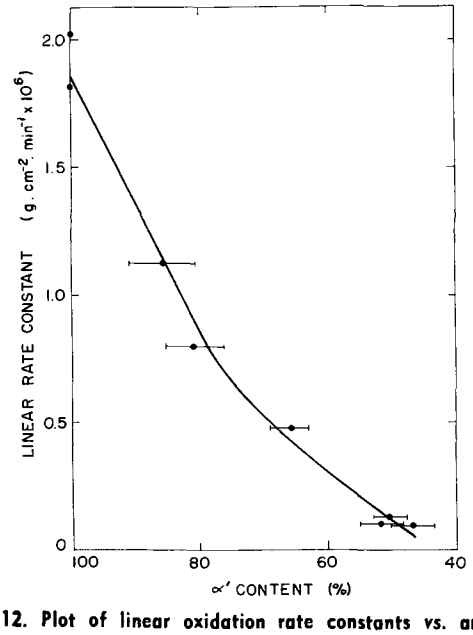

Fig. 12. Plot of linear oxidation rate constants vs. amount of α'-Zr at 400°C.

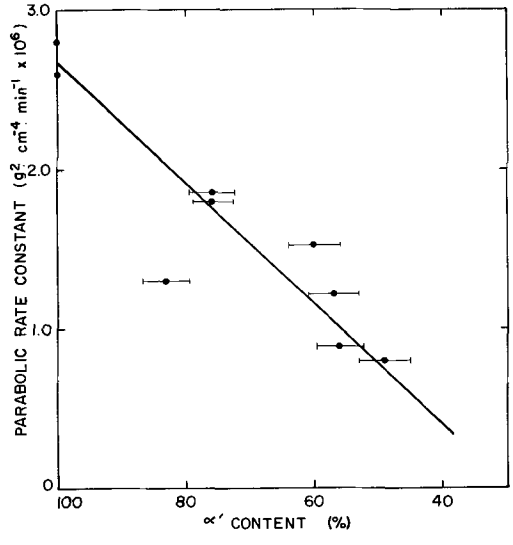

Fig. 14. Plot of parabolic oxidation rate constants vs. amount of α'-Zr at 500°C.

α-Zr, this latter factor was less important, and the over-all rate varied almost linearly with the amount of martensite. However, at large percentages of the proeutectoid phase, oxide on martensite penetrated selectively between plates of the former phase, and the oxidation rate was much slower than to be predicted by a direct proportionality between oxidation rate and amount of α'-Zr.

Oxidation curves at 500°C did not exhibit transitions to more rapid linear kinetics as observed at the two lower temperatures. Although the films on α-Zr were characterized by interference colors, those on the α'-phase were invariably gray at all observed times in contrast to results at the lowest temperatures. Though the oxidation properties were dependent on alloy structure at this highest temperature employed, the kinetics could be represented by parabolic plots for relatively long exposures (Fig. 13). Moreover, a plot of the parabolic constants *vs.* the amount of α'-Zr demonstrated a direct proportionality from full martensite to 50 v/o proeutectoid α-Zr (Fig. 14). This behavior appears reasonable since pronounced selective penetration of oxide between plates of this phase did not occur as at lower temperatures. Tempering of martensite occurs at this temperature and α-Zr would exhibit a larger niobium solubility. The influence of these parameters on oxidation processes in a manner not understood at present may account for the smaller degree of selective phase oxidation.

In view of the fact that the form of the oxidation curve is dependent on both alloy structure and temperature, conclusions drawn from comparisons of results obtained under different exposure conditions must be accepted tentatively. The major product of the reaction of all temperatures, irrespective of alloy structure, was an oxide whose structure could be indexed as monoclinic zirconia. However, it is interesting to compare the differences in surface topography and cross sections of oxidized specimens (Fig. 6-9). At 500°C and while the rate curve was parabolic, the gray oxide which formed did not exhibit cracks distinguishable by light microscopy. The oxidation rate would be possibly controlled by diffusion processes in the oxide film during this stage of the reaction. Cracking of such oxide, however, was noted at 300° and 400°C for all alloys in early periods of exposure at small film thicknesses and parabolic kinetics were not obeyed. On the other hand, the oxide was cracked in the range of approximately linear kinetics at all temperatures, but its role as a barrier to oxidation could not be interpreted by using standard metallographic techniques.

The formation of oxide pustules was the only distinct feature indicating a difference in the mode of oxide formation on different structured alloys. The pustules, moreover, were only observed at the temperatures 300° and 400°C on martensitic specimens and appeared on the surface during the transition to linear kinetics. These specimens were the only ones to exhibit the type of oxidation curve where there was a very pronounced transformation in the kinetics from a small initial rate to a much more rapid rate at long exposures. This behavior, involving pustule formation and cracking, may be associated with interfacial stress between the alloy and the oxide film. At 500°C, such stress might be relieved by tempering of the alloy at the reaction temperature and thus allow a more compact film to form. The presence of the proeutectoid α-Zr plates could similarly aid stress relief and so reduce the possibility of pustule formation, but no substantiating evidence could be found in the present results.

Acknowledgments

The authors were indebted to B. Cox for supplying the Zr-Nb alloy sheets and several specimens in prepared metallurgical structures. This research was completed under auspices of the Atomic Energy of Canada Limited and the Defence Research Board of Canada.

Manuscript received June 2, 1967. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Electrochemical Reduction of Cyanoalkyldimethylsulfonium Ions

John H. Wagenknecht and Manuel M. Baizer

Central Research Department, Monsanto Company, St. Louis, Missouri

ABSTRACT

The polarographic and coulometric reduction of cyanomethyldimethylsulfonium ion (I) in anhydrous dimethylsulfoxide occurs in a single apparent one-electron reduction. Evidence from polarography in the presence of acetic acid and from macroelectrolyses leads to the interpretation that I probably actually undergoes a two-electron reduction to form the cyanomethyl anion which reacts at the electrode surface with a second parent ion. This result is another example of a concealed limiting current in the reduction of compounds $(LCH_2E)^+X^-$. Cyanoethyldimethylsulfonium ion and cyanopropyldimethylsulfonium ion each have an initial one-electron reduction wave followed at more negative potentials by reduction to form cyanoalkyl anions which react with the parent sulfonium ion. Products obtained from macroelectrolyses are consistent with those predicted from the mechanisms proposed from the polarographic data.

As part of a study of the follow-up reactions of species formed by the electrochemical reductive cleavage of compounds $[L(CH_2)_nE]^+X^-$ (when L is a "leaving group" and E is an electron-withdrawing group), we recently reported the electrochemical reduction at mercury of triphenylcyanoalkylphosphonium ions and the reaction of the cleaved cyanoalkyl groups with styrene (1). This paper is a report of the results of a similar study of cyanoalkyldimethylsulfonium ions, $(CH_3)_2S^+(CH_2)_nCN$ (n = 1, 2 or 3; I, II, and III, respectively).

Calculations based on polarography and coulometry of I in aprotic solvents give a value of $n = 1$. We report evidence which strongly suggests that a two-electron reduction is involved to form the cyanomethyl anion which then reacts with another I to form a nonreducible product.

The polarograms of II and III obtained in aprotic media contain an initial one-electron reduction wave followed by a maximum. The diffusion current is the same before and after the maximum. Evidence from polarograms of II and III obtained in the presence of phenol indicates that at the potential of the maximum a wave is repressed by reaction of the reduction product with the parent sulfonium ion. Previous reports on sulfonium ion reductions (2-8) have indicated only that various β-ketosulfonium ions have unusual maxima (4-7). These do not appear to arise from the same phenomena as those occurring in the polarograms of II and III.

Attempts to trap the electrochemically cleaved cyanoalkyl fragments by *in situ* reaction with styrene were of limited success, but the identification of the products obtained in the macro electrolyses was helpful in rationalizing the course of the electrochemical-chemical reactions.

Experimental[1]

The polarographic data were obtained using a Sargent Model XXI Polarograph. Electrode constants were m = 2.216 mg/sec, t = 3.43 sec, and $m^{2/3}t^{1/6}$ = 2.08 $mg^{2/3}t^{-1/2}$ at a mercury column height of 90 cm. The polarographic cell was immersed in a thermostated water bath at 25° ± 0.1°C. A Chemical Electronics Corporation (Newcastle, England) potentiostat and an electrometer operational-amplifier integrator[2] were used to obtain microcoulometric data. The coulometry was carried out on 0.1 to 0.2 mmole of sulfonium compound at a mercury pool cathode in a divided cell with a SCE reference electrode and silver wire secondary electrode. The solvent was dimethylsulfoxide containing 0.1*M* tetrabutylammonium bro-

[1] Boiling points are not corrected.
[2] Built by Dr. John M. Fritsch at our laboratories.

mide. Nuclear magnetic resonance analyses were carried out with a Varian A-60 n.m.r. spectrometer. Analytical gas chromatography was carried out with a F&M Model 300 Gas Chromatograph with 3m, ¼ in. columns packed with 18% Carbowax 20-1% $AgNO_3$ on Chromosorb W, 3% XE-60 on Teflon, 3% Flexol 8N8 on Teflon or silicone grease on Chromosorb W. Vpc analyses were obtained from two or more columns to insure the identity of the peaks.

The dimethylsulfoxide (Matheson, Coleman & Bell) was distilled at reduced pressure from a small amount of sodium hydride, bp 58°-60° (5 mm). The dimethylformamide (DMF) was distilled from barium oxide before use. Styrene (Eastman) was distilled *in vacuo* just before use and stabilized with hydroquinone. Tetra-*n*-butylammonium bromide (Eastman) was recrystallized from ethyl acetate before use. Tetraethylammonium *p*-toluenesulfonate (Alfred Bader Chemical Company) was recrystallized from acetone.

The electrolytic cell used for macro electrolyses has been described (9). The cathode potential was monitored with a SCE and vacuum tube voltmeter. The power supply was a Nobatron RC150-7.5, and the cell voltage was adjusted so that the cathode potential was near the first wave, half-wave potential of the compound being reduced. The cell voltage was manually controlled later in the run to prevent a large rise in cathode potential. The electrolysis was stopped when the cathode potential would no longer remain near the half-wave potential at a cell current of 0.25 amp indicating that nearly all of the starting material had been consumed. An Analytical Instruments, Inc. current integrator was used to determine the total amount of electricity passed.

The anolyte in each case was a solution of tetraethylammonium *p*-toluenesulfonate in DMF. Styrene was present in the catholyte in each case to trap reactive intermediates.

Macroelectrolysis of I.—The catholyte consisted of 20.5g (0.075 mole) of cyanomethyldimethylsulfonium *p*-toluenesulfonate (10), 200 ml of DMF, 30g of tetraethylammonium *p*-toluenesulfonate and 30 ml of styrene. The electrolysis was carried out at 10°-15°, 1.0-0.25 amp and a cathode voltage of —1.0 to —1.13v (*vs.* SCE). The total quantity of electricity was 0.096**F**. After the electrolysis, the solvent was removed from the catholyte by distillation at reduced pressure. The strong odor of dimethyl sulfide was present. Vpc analysis of the distillate showed the presence of 2.15g (70% based on starting material) of acetonitrile. The residue after solvent removal was extracted with ether. The residue after removal of the ether from the ether extract contained no 4-phenylbutyronitrile by vpc analysis. Traces of DMF were removed from the residue by distillation at 0.1 mm leaving a black, gummy residue.

A second electrolysis of I was carried out using a glass frit divided H cell with a 20 ml catholyte capacity. The cathode was a 2 cm diameter mercury pool. The anode was platinum foil. The catholyte consisted of 19 ml of 0.915*M* cyanomethyldimethylsulfonium *p*-toluenesulfonate in dimethylsulfoxide. The anolyte consisted of 27 ml of 1*M* tetra-*n*-butylammonium bromide in dimethylsulfoxide and 1.5 ml of cyclohexene. The catholyte was deaerated with N_2 before the electrolysis and then was sealed. The anolyte was swept with N_2 during the electrolysis. The cathode potential was not monitored. Only a thermometer was in contact with the catholyte. The catholyte was maintained at 20°C during the run by immersing the cell in an ice-water bath. The electrolysis was carried out at 50-60 ma until 8.7 m**F** of current was passed. After the electrolysis, polarographic analysis of the catholyte and anolyte[3] indicated 8.53 mmoles of I had been consumed. Vpc analysis of the catholyte showed the presence of 3.9 mmoles of acetonitrile (90% yield based on 2 **F**/mole).[4] No acetonitrile was detected in the anolyte.

Macroelectrolysis of II.—The catholyte was identical to the previous run except that the sulfonium salt (22g, 0.078 mole) was cyanoethyldimethylsulfonium *p*-toluenesulfonate. The electrolysis was carried out at 0°, 1.0-0.25 amp, and a cathode potential of —1.74 to —1.89v (*vs.* SCE).[5] The total quantity of electricity was 0.097**F**. The electrolysis was stopped at this point because more than 1**F** of electricity per mole had been passed, and it was suspected that II had been decomposed[5] to form acrylonitrile, the reduction of which would require 2**F**/mole. The workup was as described for the previous run and yielded 1.0g (37%) of propionitrile, 0.54g (21.6%) of acrylonitrile and a trace of adiponitrile (all by vpc analysis). No 5-phenylvaleronitrile or mercurials were detected.

A second electrolysis was carried out in a glass frit divided H-cell with a mercury pool cathode and platinum foil anode. The catholyte consisted of 150 ml of dimethylsulfoxide containing 0.1*M* tetra-*n*-butylammonium bromide, 40g (0.14 mole) of dimethylcyanoethylsulfonium *p*-toluenesulfonate, 30 ml of styrene, and a trace of hydroquinone. The anolyte was dimethylsulfoxide containing 0.1*M* tetra-*n*-butylammonium bromide and saturated with cyclohexene. The cell was maintained at 15° by a water bath. The electrolysis was carried out for 24.25 hr with a cell voltage of 150v, a curernt of 0.2 amp, and at a cathode potential of —1.6v (*vs.* SCE). A total of 0.167**F** of electricity was passed. The cathode potential did not increase as the 1**F**/mole of II point was passed, and it was again suspected that decomposition of II had occurred.

After the electrolysis, the catholyte was evacuated to 30 mm through a dry-ice, acetone-cooled trap overnight. The trap overnight collected about 1 ml of a mixture of acrylonitrile, propionitrile, and dimethylsulfide.

Attempts to get a quantitative analysis of acrylonitrile in the catholyte by vpc analysis were futile because II decomposes in the injection port to form acrylonitrile. Attempts to determine the amount of acrylonitrile present in the catholyte by polarography were also unsuccessful because the waves of it and II were too close together.

The catholyte was then mixed with 500 ml of water, and this mixture was extracted with three 200-ml portions of ether. The combined ether extract was back-extracted with water and dried over anhydrous magnesium sulfate. The ether solution was concentrated on a rotary evaporator. The concentrated solution was cooled in dry-ice whereupon 1.2g (5.5%) of biscyanoethylmercury, mp 46°-48° (17), precipitated.

The remainder of the ether was stripped from the solution, and the styrene was removed at reduced pressure (0.3 mm). The residue was distilled at 0.2 mm giving a single cut from 50°-80° (2.0g). Nmr analysis of this indicated 1.0g each of 3-thiomethylpropionitrile (7.1%) and methylcyanoethyl mercury (5.3%). Vpc analysis of the pot residue which contained all the hydroquinone used to prevent styrene polymerization showed the presence of 0.012g of 5-phenylvaleronitrile. (The standard sample of 5-phenylvaleronitrile was obtained from 5-phenylvaleric acid by the usual methods.)

The mixture of 3-methylthiopropionitrile and methylcyanoethyl mercury was redistilled in a micro apparatus. The 3-thiomethylpropionitrile distilled at 50°-60° at 0.2 mm. Two small cuts were then taken at 70° and 71°. The first was used for nmr analysis and

[3] A small amount of I had been forced by hydraulic pressure into the anode compartment.

[4] Due to decomposition of I in the vpc injection port to unknown products which emerge in the dimethyl sulfide region, it was impossible to determine dimethyl sulfide by this method. However, nmr analysis of the solution indicated the presence of 7.3 mmoles of dimethyl sulfide in the catholyte (168% base on 2 **F**/mole). See Discussion.

[5] This electrolysis was carried out at a lower temperature than the others, so that over the duration of the electrolysis (*ca.* 4 hr) the base catalyzed Hofmann elimination reaction of II could be minimized.

the second for mass spectral analysis of the methylcyanoethyl mercury.

The nmr spectrum of methylcyanoethyl mercury consists of a singlet at $\tau = 9.68$ for the methyl with its Hg^{199} side bands at $\tau = 8.75$ and 10.56. The triplets for the methylenes α and β to the mercury occur at $\tau = 8.92$ and 7.31, respectively. Hg^{199} side bands occur as triplets at $\tau = 6.51$ and 9.78 and a multiplet between the major α and β methylene triplets. The nmr spectrum contained small peaks due to thiomethylpropionitrile and 5-phenylvaleronitrile.

The vpc analysis of the second cut indicated the presence of small amounts of thiomethylpropionitrile and 5-phenylvaleronitrile along with what were probably decomposition products of the methylcyanoethyl mercury. Mass spectral analysis of this cut showed small parent ion peaks for thiomethylpropionitrile at $m/e = 101$ and 5-phenylvaleronitrile at $m/e = 159$. The parent ions for the methylcyanoethyl mercury were obtained in the correct ratios for all the naturally occurring mercury isotopes, the major ion being at $m/e = 271$ corresponding to the parent ion containing Hg^{202}, the major naturally occurring isotope.

The nmr spectrum of biscyanoethyl mercury consists of triplets for the methylene α and β to the mercury at $\tau = 8.64$ and 7.18, respectively. The Hg^{199} side bands occur as triplets at $\tau = 6.25$ and 9.55 and a multiplet between the major methylene triplets.

Macroelectrolysis of III.—The catholyte was identical with that used for I except that now the sulfonium salt was 30g (0.1 mole) of cyanopropyldimethylsulfonium p-toluenesulfonate. The electrolysis was carried out at 20°-25°, 1.0-0.25 amp, and a cathode potential of —1.90 to —2.05v (*vs.* SCE). The total quantity of electricity was 0.123F.

Vpc analysis of the catholyte indicated a trace of butyronitrile. The catholyte was then distilled at 5.0 mm to remove solvent (warning: dimethyl sulfide). The nmr spectrum of the material trapped in a dry ice-acetone cooled trap during the solvent removal distillation showed a singlet at $\tau = 9.82$ suggesting the presence of dimethyl mercury (11).

The residue remaining after the solvent was removed from the catholyte was treated with 250 ml water and extracted with dichloromethane. The dichloromethane was removed by distillation from the extract. A trace of 6-phenylcapronitrile was detected in the residue by vpc. Distillation of the residue at 0.005 mm gave three fractions (*a*) mostly DMF, bp < 25°, (*b*) 3.0g, bp 55°, (c) 3.1g, bp 145°-155°. Fraction (*b*) contained 4-methylthiobutyronitrile by vpc analysis. The nmr spectrum of fraction (*b*) suggested the presence of methyl-3-cyanopropyl mercury giving singlets at $\tau = 9.77$ and $\tau = 8.95$ and $\tau = 10.57$ (satellites due to Hg^{199} splitting) for the methyl group attached to mercury. Fraction (c) appeared to be nearly pure biscyanopropyl mercury by nmr analysis which showed a complex multiplet at $\tau = 7.85$ due to the methylenes alpha and beta to the nitrile and triplets at $\tau = 8.94$ and $\tau = 9.78$ due to the methylene alpha to the mercury and one of its Hg^{199} satellites. The area ratio was 2:1 for the multiplet and major triplet. A portion of fraction (c) was dissolved in ether and treated with anhydrous HCl. From this solution cyanopropylmercuric chloride crystallized. It was recrystallized from ether cooled in dry ice giving white crystals, mp 109°-110°.

Anal. Calcd. for C_4H_6ClHgN: C, 15.79; H, 1.99; Cl, 11.66; Hg, 65.95; N, 4.61. *Found*: C, 15.70; H, 2.04; Cl, 11.41; Hg, 66.19; N, 4.64.

The ether solution, after removal of the solid, was found by vpc to contain butyronitrile.

Preparation of cyanoethyldimethylsulfonium p-toluenesulfonate.—3-Methylthiopropionitrile (12) was quaternized with methyl p-toluenesulfonate at room temperature. Crops were removed from time to time. After four weeks, 78.5% of crude product was obtained which, after recrystallization from ethanol, melted at 110°-111°.

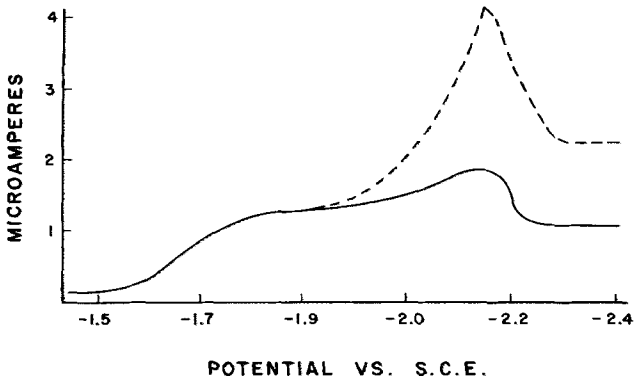

Fig. 1. Polarogram of cyanoethyldimethylsulfonium p-toluenesulfonate in dimethylsulfoxide containing 0.2M tetra-n-butylammonium bromide. Dashed line represents the effect of adding phenol to the solution.

Anal. Calcd. for $C_{12}H_{17}NO_3S_2$: C, 50.14; H 5.96; S, 22.32. *Found*: C, 50.12; H, 5.62; S, 22.43.

Preparation of dimethylcyanopropylsulfonium p-toluenesulfonate.—A mixture of 17.4g of sodium hydroxide in 200 ml of ethanol was saturated with methanethiol. To this solution was added 45g of 4-chlorobutyronitrile, and the solution was stirred for 2 hr at 10°C. The mixture was poured onto ice and then extracted with ether. Evaporation of the ether and distillation of the residue yielded 32g (64%) of 4-methylthiobutyronitrile, bp 85° (9 mm), $n^{25}D$ 1.4777. The 32g of thionitrile was mixed with 52g of methyl-p-toluenesulfonate and allowed to stand at room temperature. After 4 days, the mixture was filtered and the solid recrystallized from CH_3CN yielding 30g (36%) of dimethylcyanopropylsulfonium p-toluenesulfonate, mp 142.5°-144°.

Anal. Calcd. for $C_{13}H_{19}NO_3S_2$: C, 51.80; H, 6.35; N, 4.64; S, 21.28. *Found*: C, 51.96; H, 6.14; N, 4.43; S, 21.46.

Results and Discussion

The values of $E_{1/2}$ (*vs.* SCE) and I_d[6] (in parentheses) for I, II and III were —1.04 (1.04), —1.69 (1.08), and —1.76 (1.06), respectively, for 1 mm solutions in dimethylsulfoxide containing 0.2*M* tetra-n-butylammonium bromide. In addition, the polarograms of II and III each contain an unusual maximum (Fig. 1) occurring from —2.05 to —2.35v and —2.15 to —2.45v, respectively. Microcoulometry gave values of $n = 0.945$, 0.98, and 1.03 for I, II, and III, respectively, on exhaustive reduction at a potential just past the half-wave potential. By inference the values of I_d must correspond to a one-electron reduction when taken in conjunction with evidence from microcoulometry and comparison with values obtained with similar phosphonium ions (1). Dimethylsulfoxide was used for polarographic studies because traces of dimethylamine, which abstract a proton from I, could not be removed from DMF.

The addition of a small amount (less than 1%) of acetic acid[7] to the polarographic solution of I caused the value of I_d to double. Addition of more acetic acid caused no change. This parallels the behavior of triphenylcyanomethylphosphonium ion (1) and can be explained similarly. The reduction of I is most easily understood as a two-electron reduction (reaction [1]). In the absence of another proton source the cyano-

[6] $I_d = i_d/C_m^{2/3}t^{1/6}$.

[7] Phenol did not effect the polarogram. The phenol was apparently not acidic enough to compete effectively with the very acidic I for protonation of the cyanomethyl ion. The strong acidity of I is not surprising in view of the acidity of the methylene hydrogens in compounds such as cyanoacetic esters, malononitrile, etc.

methyl anion

$$\underset{\text{I}}{(CH_3)_2\overset{+}{S}CH_2CN} \xrightarrow{2e} (CH_3)_2S + (CH_2CN)^- \quad [1]$$

abstracts a proton from an unreduced I (reaction [2]). The

$$I + (CH_2CN)^- \rightarrow (CH_3)_2\overset{+}{S}-\overset{-}{C}HCN + CH_3CN \quad [2]$$

net result is that two electrons effectively consume two of the sulfonium ions giving an apparent one-electron reduction. However, when acetic acid is present, the cyanomethyl anions are protonated by the acetic acid and all the sulfonium ions that diffuse to the mercury drop are available for reduction, giving a two-electron reduction wave. Khaikin and Feoktistov (13) recently published a theoretical treatment of a general system which would include the above example.

Gerdil (14) recently reported that certain sulfides ($C_6H_5S\ CH_2X$, X = CN, $CO_2C_2H_5$, CO_2H) gave one-electron reduction polarograms in anhydrous DMF, but that the wave height doubled on addition of phenol. These results may also be explained by reaction of the anion formed with the depolarizer.

$$C_6H_5S\ CH_2X \xrightarrow{2e} C_6H_5\overset{+}{S}(-) + (-)CH_2X$$

$$C_6H_5S\ CH_2X + (-)CH_2X \rightarrow CH_3X + C_6H_5S\overset{(-)}{C}HX$$

The results of the macroelectrolyses of I give further evidence for the reactions shown in Eq. [1] and [2]. If the reduction of I were a true one-electron reduction, the products would be dimethylsulfide and cyanomethyl radicals. The reduction carried out in DMF in the presence of styrene would have been expected to give the product of attack on styrene by cyanomethyl radicals (reaction [3]).

$$\cdot CH_2CN + C_6H_5CH = CH_2 \rightarrow$$

$$C_6H_5\dot{C}H(CH_2)_2CN \xrightarrow{\text{solvent}} C_6H_5(CH_2)_3CN \quad [3]$$

No γ-phenylbutyronitrile was detected in the electrolysis products. The only products detected in either electrolysis were acetonitrile and dimethylsulfide.[8] It may be calculated from the yield of acetonitrile that about half the cyanomethyl anions formed in the electrolysis of I in DMF were protonated by sources other than I. Since the electrolysis was carried to completion, it is not surprising that as the concentration of I became lower other sources of protons such as water and dimethylamine could effectively compete with I to react with cyanomethyl anions.

The electrolysis of I in dimethylsulfoxide in the absence of styrene was carried to only about 50% completion. Since there was still a high concentration of I at the end of the run, little competition by other proton sources was observed. The values of 1.02 **F**/mole of I consumed and a 90% yield of acetonitrile based on 2 **F**/mole are in accord with reactions 1 and 2. The higher than theoretical yield of dimethylsulfide can be explained by the fact that the sulfur ylid decomposes to form dimethylsulfide.[9]

[8] The other product expected would be the sulfur ylid in reaction [2]. Since simple sulfur ylids are very reactive (16), the ylid shown presumably led to the intractible material formed in this electrolysis. Triphenylcyanomethylphosphonium ion behaves similarly to I, but in that case the more stable phosphorus ylid survived the electrolysis and reacted with water in the workup to give triphenylphosphine oxide which was isolated and identified (1).

[9] A 1*M* solution of cyanomethyldimethylsulfonium *p*-toluene-sulfonate in dimethylsulfoxide was treated with an equivalent amount of potassium *t*-butoxide in dimethylsulfoxide. The nmr spectrum of I in this mixture immediately disappeared and a small adsorption for dimethylsulfide appeared indicating that displacement of dimethylsulfide from I by nucleophilic attack by *t*-butoxide is not a major contributing reaction. Over a period of 6 hr the dimethylsulfide concentration increased at least tenfold; therefore, it must have arisen by decomposition of the sulfur ylid since no more I was present. No acetonitrile could be detected in the reaction mixture.

The first polarographic waves of II and III are not effected by the addition of phenol indicating a true one-electron reduction (reaction [4]). However, the addition of phenol does affect the unusual maximum for II or III

$$(CH_3)_2\overset{+}{S}(CH_2)_nCN \xrightarrow{1e} (CH_3)_2S + \cdot(CH_2)_nCN\ (n = 2 \text{ or } 3) \quad [4]$$

changing it to an ordinary maximum preceding a wave (Fig. 1). Since the second waves for II and III occur only in the presence of a proton donor, a reaction similar to that of I is suggested. Thus, at the potential of the second wave, a two-electron reduction occurs leading to the cyanoalkyl anion (reaction [5] or [6]).

$$(CH_3)_2\overset{+}{S}(CH_2)_nCN \xrightarrow{1e} (CH_3)_2S + \cdot(CH_2)_nCN \xrightarrow{1e^-} (-)(CH_2)_nCN \quad [5]$$

$$(CH_3)_2\overset{+}{S}(CH_2)_nCN \xrightarrow{2e} (CH_3)_2S + (-)(CH_2)_nCN \quad [6]$$

The reduction at the second wave may be a direct two-electron reduction (reaction [6]), or a one-electron reduction-disproportionation—one-electron reduction pathway (reaction [5]).

In the presence of phenol the cyanoalkyl anion is protonated by phenol, and both waves are observed. In the absence of phenol the second wave does not appear because the cyanoalkyl anion formed reacts with unreduced sulfonium ion (reaction [7] or [8]) so that two electrons effectively remove two sulfonium ions. This then gives the

$$(-)(CH_2)_nCN + \overset{+}{(CH_3)_2S}(CH_2)_nCN \rightarrow (CH_3)_2S + CN(CH_2)_{2n}CN \quad [7]$$

$$(-)(CH_2)_nCN + \overset{+}{(CH_3)_2S}(CH_2)_nCN \rightarrow CH_3(CH_2)_{n-1}CN + (CH_3)_2\overset{+-}{S}CH(CH_2)_{n-1}CN \quad [8]$$

same wave height as the original one-electron reduction. Although the diffusion current is prevented from increasing at the potential of the second wave by reaction [7] or [8], the maximum associated with the change in electrode mechanism still occurs giving the unusual polarogram. The maxima observed for β-ketosulfonium ions (4-9) have a similar appearance, but, since they occur in aqueous solution, they probably cannot be explained by similar reactions.

The macroelectrolysis of II was complicated by the ease of base catalyzed decomposition of II (reaction [9]).

$$(CH_3)_2\overset{+}{S}CH_2CH_2CN \xrightarrow{B:} (CH_3)_2S + CH_2 = CHCN + BH \quad [9]$$

It has been mentioned (15) that the region next to the cathode is very basic during electrolysis even if the bulk solution is neutral. It is not surprising then that the products obtained from the reduction of II in DMF appear to arise from the reduction of acrylonitrile. The products identified were acrylonitrile, propionitrile, and adiponitrile and are visualized as being formed by reactions [9]-[11].

$$CH_2 = CHCN \xrightarrow[2H+]{2e} CH_3CH_2CN \quad [10]$$

$$2CH_2 = CHCN \xrightarrow[2H+]{2e} CN(CH_2)_4CN \quad [11]$$

Since even traces of base can catalyze reaction [9], the second electrolysis of II was carried out in a more acidic medium, dimethylsulfoxide. In this run, tetra-*n*-butylammonium bromide was used so that bromine would be liberated at the anode. Cyclohexene was added to the anolyte to react with the bromine. This was done in an attempt to eliminate the possibility of acidic material formed at the anode from entering the cathode compartment. All the components of the catholyte were rigorously purified. These precautions, however, did not prevent the decomposition of II to acrylonitrile. However, it was possible in this case to reduce enough II to allow products of that reduction to be isolated. In addition to dimethylsulfide, acrylonitrile, and propionitrile there were also obtained thiomethylpropionitrile, methylcyanoethyl mercury, biscyanoethyl mercury, and 5-phenylvaleronitrile.

The products of the macroelectrolysis of III were butyronitrile, dimethylsulfide, thiomethylbutyronitrile, 6-phenylcapronitrile, and biscyanopropyl mercury, with evidence of dimethyl mercury and methylcyanopropyl mercury. The biscyanopropyl mercury was identified by its nmr spectrum (described in the experimental section) and its reaction with HCl to form butyronitrile and cyanopropylmercuric chloride (reaction [12]).

$$(CNCH_2CH_2CH_2)_2Hg + HCl \rightarrow CH_3CH_2CH_2CN + CNCH_2CH_2CH_2HgCl \quad [12]$$

The products from the reductions of II and III are visualized as being formed by the following scheme

$$\text{II or III} \xrightarrow{1e} (CH_3)_2\dot{S}(CH_2)_nCN \qquad (n = 2 \text{ or } 3)$$

(IV)

$$IV \rightarrow (CH_3)_2S + \cdot(CH_2)_nCN$$

$$IV \rightarrow CH_3S(CH_2)_nCN + \cdot CH_3$$

$$\cdot(CH_2)_nCN \xrightarrow{\text{Styrene}} C_6H_5\dot{C}H(CH_2)_{n+1}CN \xrightarrow{\text{Solvent}} C_6H_5(CH_2)_{n+2}CN$$

$$\cdot(CH_2)_nCN \xrightarrow{\text{Solvent}} CH_3(CH_2)_{n-1}CN$$

$$\cdot(CH_2)_nCN \xrightarrow{Hg} [\cdot Hg(CH_2)_nCN] \rightarrow \tfrac{1}{2}[CN(CH_2)_n]_2Hg + \tfrac{1}{2}Hg$$

$$\cdot CH_3 \xrightarrow{Hg} [\cdot HgCH_3] \rightarrow \tfrac{1}{2}(CH_3)_2Hg + \tfrac{1}{2}Hg$$

$$[\cdot HgCH_3] + [\cdot Hg(CH_2)_nCN] \rightarrow CH_3Hg(CH_2)_nCN + Hg$$

The electrolyses were carried out at the potential of the first wave in each case, and the products are those expected from a one-electron reduction. Compounds of the series $(CH_3)_2\overset{+}{S}(CH_2)_nCN$ fall into three categories: (*a*) $n = 1$, (*b*) $n = 2$, (*c*) $n = 3$ or greater. The primary chemical consequence of the electron transfer is cleavage of the starting material between the sulfonium group and the adjacent carbon. The —CN group has a decreasing influence on the fate of the cyanoalkyl fragment. When $n = 1$, further reduction of the initial cyanomethyl radical to the relatively stable cyanomethyl anion is a very favorable process. The relatively anodic cathode voltage required reflects this ease of reduction. The cyanomethyl anion abstracts a proton from the most acidic substrate present, namely I. When $n = 2$ or 3 the —CN group has a much weaker (inductive) stabilizing influence upon the cyanoalkyl fragment. Reduction to the cyanoalkyl carbanion is decreasingly favored, and reactions deriving from the initial cyanoalkyl radical predominate. When $n = 2$, further complications arise from the ease of decomposition of II in a Hofmann-type degradation to yield an additional electro-reducible material (acrylonitrile).

Manuscript received Dec. 27, 1966; revised manuscript received *ca.* July 24, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Nuclear Activation Technique for Detecting Nitrogen-15 Tracer in Solids

Ralph H. Condit, J. Birch Holt, and Lawrence Himmel

Lawrence Radiation Laboratory, University of California, Livermore, California

ABSTRACT

A technique for studying the transport of nitrogen in solids is described which makes use of the nuclear activation, $N^{15}(\alpha,n)F^{18}$. The radioactivity of the product, F^{18}, can be used to deduce the location of the original N^{15} tracer by autoradiographic methods. Requirements for the success of this technique are discussed, and its application to the study of nitrogen diffusion in uranium mononitride is outlined. Other possible uses, *i.e.*, the analysis for nitrogen or the identification of nitride inclusions in solid, are also mentioned.

Radiotracers have proven useful in many areas of solid-state research, particularly in diffusion and other material transport studies. Unfortunately, two of the most important elements, oxygen and nitrogen, do not have radioisotopes with convenient half-lives, and for them it has usually been necessary to use stable isotope techniques which employ sources of the elements enriched in one of their less abundant species, O^{17}, O^{18}, or N^{15}. These have generally involved a procedure wherein a solid specimen is annealed in a gaseous environment containing the isotopically enriched element, and the depletion of this enrichment in the gas has been followed by mass spectrometric analysis. Alternatively, the solid may be sectioned and the sections subjected to atomic mass analysis. These two methods have been compared (1). Interpretation of the data in order to derive values for the diffusion within the solids in these ways is often obscured by (*a*) uncertainties regarding the surface exchange rate between gas and solid, (*b*) the possibility of diffusion along defects such as grain boundaries or dislocation lines, and (*c*) the frequent need for fine particle materials to insure sufficient area of solid for adequate exchange, because determination of the surface area requires an added experimental step. Special techniques such as internal friction (2) or nuclear magnetic resonance (3) have been used to give an indirect indication of diffusion coefficients, but these are often limited to special crystallographic species such as the bcc metals for internal friction or special isotopes for NMR. With radiotracers, however, it is possible to use autoradiography which has proven versatile in pin-pointing the location of a tracer in solid specimens. This can reveal segregation at microinclusions of an impurity or preferential diffusion along grain boundaries.

We have previously described a means for circumventing this problem in the case of oxygen (4). This involves the proton bombardment activation of O^{18} according to the nuclear reaction, $O^{18}(p,n)F^{18}$, leading to the production of a radioisotope of fluorine in those areas in which the oxygen tracer had migrated. This means that one can make use of O^{18} almost as if it were a radiotracer. The only difference from the usual radiotracer experiment is that the O^{18} is made radioactive after the experiment rather than having been active from the start. In locating the F^{18}, we have relied on autoradiography which provides an indication of the distribution of O^{18} at the surface of the irradiated specimen.

This technique has been used in the study of oxygen diffusion along dislocations and microcracks (5) and grain boundaries (6) in MgO, and marker-type experiments have been carried out with O^{18} tracer used in the reaction between CoO and Al_2O_3 (7). It is currently being used in studies of the mechanism of iron oxidation (8). A related technique has been developed to study silicon self-diffusion (9), the stable isotope, Si^{30}, being allowed to penetrate into silicon and then subsequently being activated by neutron irradiation to give 2.6-hr Si^{31}. However, we are using charged-particle irradiations rather than neutrons. A general review of charged-particle activation techniques has been prepared by Tilbury (10). It is the purpose of this paper to describe an ion bombardment procedure for following the nitrogen isotope, N^{15}, which makes such studies as those in oxides also possible in nitrides.

Experimental Requirements

For the nuclear activation of stable isotopes to be of practical interest in transport studies in solids, it is necessary that the following conditions be met:

1. The necessary stable isotopes must be available in sufficient degree of enrichment over the natural concentration. This is clearly essential if self-diffusion measurements are contemplated.

2. The activation reaction must give enough activity for it to be measurable by counting methods or autoradiographic procedures.

3. Nuclear reactions involving other elements must not give rise to the same radioisotope as does the element of principal interest, and other radioactive species which are produced must not interfere with the detection of the principal one. Additionally, secondary reactions between constituents of the material under study and the products of the primary reaction, such as neutrons produced by (p,n) or (α,n) reactions, must not yield interfering activities.

4. The specimen must be able to withstand the irradiation conditions. In the case of ion bombardment this will normally mean some increase in temperature under vacuum conditions, although setups usually can be designed to avoid this.

5. The activity must be produced in the same position as that occupied by the tracer. The product radioisotope must not recoil appreciably from the point of reaction, and it must not diffuse away before its position is determined.

6. The resolution of the detector, such as autoradiographic emulsions or counters, must be adequate for the purposes of the experiment.

7. It must be possible to relate some measurement of activity to the amount of stable tracer present. This means that there must be control over the homogeneity of flux of the bombarding particles and their energy. Given a homogeneous beam, the effect on nuclear reaction rates of variations in density and crystal orientation must be understood, because these affect the depth of penetration of the beam. There must also be a relatively simple relationship between the geometry of the product activity and the detector, and it must be possible to calibrate the detector so that its response can be related to the activity.

Experimental Results

The ways in which α-particle irradiation of N^{15} can be used to satisfy the above conditions are described in the following sections:

1. Nitrogen-15 is present in 0.37% concentration in natural nitrogen and can be purchased in enrichments up to 99%, a factor of almost 270. Under α-particle bombardment, it is converted to fluorine-18 via the nuclear reaction $N^{15}(\alpha,n)F^{18}$. The radioactive F^{18} has a half-life of 110 min (11) and decays with the emission of a 0.6-Mev positron but without any accompanying nuclear γ-ray. This means that γ-spectroscopy cannot be usefully employed to distinguish this isotope from others which might also be produced.

2. The cross section of the $N^{15}(\alpha,n)F^{18}$ reaction has not been measured experimentally, but the energy has been calculated as —6.41 Mev (12), *i.e.*, it is endothermic and this energy is required to drive the reaction. Therefore, taking into account the momentum correction for the participants $(15 + 4)/15$, the threshold energy for the reaction should be about 8.1 Mev. In a preliminary attempt at estimating the cross section, we have irradiated specimens of uranium nitride with 9.6-, 10.4- and 12.9-Mev α-particles and have then removed a series of parallel slices by grinding and taking counts of residual fluorine-18 activity remaining after each slice. The observed activity density increases to a peak at a point below the surface and then falls off to zero at the depth into the UN specimen where the energy of the α-particles had been reduced to 8.1 Mev (see Fig. 1). On the basis of this measurement, it appears that there is a resonance peak in the cross section between 9.5 and 10.0 Mev.

The cross section at the resonance peak can be estimated as being roughly 100 mb on the basis of the radiochemical yield of fluorine-18. The amount of activity produced in a specimen is about 3×10^5 disintegrations per minute for each minute of irradiation with a 1-μa bombardment current. Even so, during a 10-min irradiation, only about one N^{15} atom in 3×10^6 undergoes reaction, so that chemical alteration of the sample is negligible. Any further reaction between this product isotope and the bombarding α-particles can also be neglected. In a 10-min irradiation with a current of 1 μa over a square centimeter area, a generous amount of activation is obtained with a pure N^{15} target; exposures of less than a minute with Kodak Autoradiographic Plate, Type A, or 20 min with Kodak AR-10 stripping emulsion will give images of good film density. Of course, this is equally true for small amounts of tracer concentrated at a few points. More dilute tracer requires longer irradiation, and times up to about one half-life of the F^{18} may prove worthwhile.

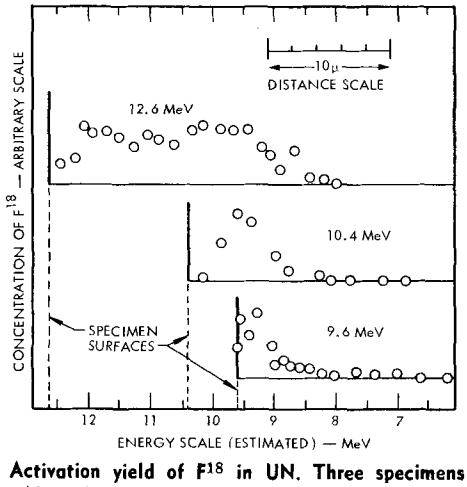

Fig. 1. Activation yield of F^{18} in UN. Three specimens of UN containing N with natural isotopic abundance were bombarded with α-particles having energies of 9.6, 10.4, and 12.6 Mev. The density of F^{18} produced from N^{15} as a function of depth below the surface was determined by sectioning the specimens. Yields are shown as a function of energy, i.e., the initial surfaces are displaced so as to align the three yield curves as a function of energy. Near-surface values are normally suspect because of slight surface roughness of about 1 μ.

3. The activation of elements other than N^{15} has not been found to be serious with most materials we have studied thus far. However, unwanted activation is more frequent than for the corresponding $O^{18}(p,n)F^{18}$ activation method mentioned above. Our usual bombardment energy of 10 Mev is relatively low as far as reactions involving α-particles are concerned, because the doubly charged α-particle must overcome the electrostatic repulsion of the target atom. This means that most reaction cross sections under our bombardment conditions should fall off quite rapidly after atomic number 40, and become negligible after number 50. Among the majority of those elements which can be activated with 10-Mev α-particles, the resultant half-lives will either be short compared with the 110-min half-life of F^{18}, so that these unwanted products can be allowed to decay away before analyzing a sample, or the half-lives are relatively long; in this case, the specific activity will be low compared with that of the F^{18}, and the autoradiographic exposures of less than a few hours will not register them strongly.

To obtain a rough measure of interferences to be expected from various elements, a number of targets have been irradiated and counted with an end-window β counter. The activities in these targets 1 hr after irradiation with 10-Mev alphas are compared in Table I with that of a pure nitrogen target of natural isotopic composition. The activation ratios have been normalized so that they correspond to equivalent irradiations. Product isotopes have been identified in most cases from an analysis of their half-lives. The activation ratios listed in Table I should be used only for rough comparison because they do not take into account such important variables as differences in sensitivity of different detectors, *i.e.*, film *vs.* counters, and the effect of target density on the depth of activation. Also, the ratio is a function of time after irradiation and, indeed, on the duration of the irradiation. In summary, it appears that there is no nitrogen compound in which nitrogen diffusion could not be studied by this activation technique, provided high enrichments, greater than about 50% of N^{15} were used.

The product neutrons carry off several Mev energy, and the secondary reactions produced by them may have to be considered in some experiments. The lowest energy neutrons produced by this reaction still have energies above 1 Mev when α bombardment energies are just above the threshold for reaction and the cross sections for most elements with such neutrons are generally small. Thus, a typical 0.1-barn cross section in a 0.3-cm-thick specimen will give 0.1% of the activity which one would obtain in a target of a nitride of pure N^{15} or 1/3 of that produced in a target of natural nitrogen composition.

4. Under ion bombardment the specimen must be protected against heating. A 10-Mev, 1-μa beam delivers 10w, or 2.4 cal/sec. Therefore, the specimen must be mounted on a cooled support. We have normally employed a water-cooled target specimen holder and have placed a thin layer of a nonvolatile, heat-resistant silicone grease between the back of our specimens and the holder as an aid to heat conduction from the specimen. On the basis of the thermal conductivity of a material such as uranium nitride, 0.17 w/cm/°C (13), having 0.3 cm thickness and an area of 1 cm^2, one would expect to impose a temperature differential of 18°C. In other materials with lower conductivities the surface temperature will be greater, and fracturing of a specimen under the temperature gradient may occur. The fact that such heating takes place in the vacuum of the cyclotron or Van de Graaff beam pipe may result in the deterioration of the specimen by vaporization or pyrolysis when less stable

Table I. Ratio of activity produced in elements under α bombardment to that produced in nitrogen of natural isotopic abundance (0.37% N^{15})

Element	Z	Remarks	Activity ratio (measured 1 hr after bombardment)
H	1		0*
He	2		0*
Li	3		0
Be	4		0
B	5	Rich yield of N^{13}, $t_{1/2}$ = 10 m.	0
C	6		0
N	7		1.00
O	8		0
F	9	Rich yield of Na^{22}, $t_{1/2}$ = 2.6 y.	0.2
Ne	10		0*
Na	11		0
Mg	12		0
Al	13	Rich yield of P^{30}, $t_{1/2}$ = 2.6 m.	0
Si	14		0
P	15	Cl^{34}, $t_{1/2}$ = 32 m, to be expected	>1*
S	16	Ar^{37}, $t_{1/2}$ = 34 d., to be expected	1*
Cl	17		0
Ar	18		0*
K	19	Good yield of Sc^{44}, $t_{1/2}$ = 3.9 h.	20
Ca	20	Good yield of Ti^{45}, $t_{1/2}$ = 3.1 h.	0.3
Sc	21	V^{48}, $t_{1/2}$ = 16 d, to be expected	<1
Ti	22	Rich yield of Cr^{49}, $t_{1/2}$ = 42 m.	40
V	23		0
Cr	24	Good yield of Fe^{53}, $t_{1/2}$ = 8.4 m.	1
Mn	25	Fair yield of Co^{58m}, $t_{1/2}$ = 9 h.	0.1
Fe	26	Fair yield of Ni^{57}, $t_{1/2}$ = 37 h.	0.1
Co	27	Fair yield of Cu^{62}, $t_{1/2}$ = 10 m.	1
Ni	28	Good yield of Cu^{61}, $t_{1/2}$ = 3 h.; Zn^{63}, $t_{1/2}$ = 38 m.	20
Cu	29	Good yield of Ga^{68}, $t_{1/2}$ = 68 m.; Ga^{66}, $t_{1/2}$ = 10 h.	30
Zn	30	Mixed products	1
Ga	31	As^{72}, $t_{1/2}$ = 26 h., to be expected	<1*
Ge	32	Some yield of Sc^{73m}, $t_{1/2}$ of 44 m.	0.3
As	33	Br^{76}, $t_{1/2}$ = 64 m., to be expected	0.0*
Se	34	Mixed products to be expected	1*
Br	35	Fair yield of Rb^{84m}, $t_{1/2}$ = 21 m.	0.3
Kr	36	Mixed products to be expected	10*

Re	75		0.05

* Estimated ratios not based on actual measurements.

compounds are studied. Protective foil coverings are possible, provided the beam energy is boosted to compensate for its energy degradation in the foil. This procedure may give unwanted neutrons, however.

5. The excess energy of the nuclear reaction, that is, the bombardment energy minus 6.41 Mev, appears afterward as kinetic energy of the two products. It is divided between the F^{18} atom and the neutron roughly in the ratio 1:18, depending on the directions in which they recoil. The few hundred kilovolt F^{18} recoil distance will be less than a few tenths of a micron in typical solids (14), a distance smaller by at least a factor of ten than the resolving power of standard autoradiographic techniques.

It should be recognized that the F^{18} may be able to diffuse in the target material at the temperature to which it is heated in the beam. We have not checked this in the case of F^{18} in UN, but it seems improbable that diffusion over measurable distances will occur at temperatures below the few hundred degrees to which a specimen may be heated if a 10-μa beam is used or if the specimen is not perfectly cooled.

6. Although the most sophisticated autoradiography which makes use of the electron microscope to examine the photographic emulsion may give resolutions of the order of 0.1μ (15), resolutions of little better than 10μ can normally be expected with commercially available stripping films (16, 17).

7. The α-particle beam may not be homogeneous over the 1 cm^2 circular target area which we generally employ. However, the shape of the beam normally remains fairly constant with time and the beam homogeneity can be checked with a fluorescent quartz disk (available in many irradiation facilities). Alternatively, a standard target having a uniform distribution of N^{15} may be irradiated and autoradiographed to serve as a reference against which other specimens can be compared. Then the concentration of N^{15} at one point can be related to that at another in a straightforward way if the material is chemically and physically homogeneous. For determining the amount of nitrogen in solution in a specimen the absolute amount of bombardment must be known, and the total charge of α particles injected can usually be measured within a few per cent by current integration.

One precaution which should be observed in ion bombardment activation is to check the effect of crystal orientation. The bombarding ions travel in closely parallel paths, and entry into a crystal along certain low-index crystallographic directions may permit channeling through lines of interstitial sites which do not block the ions in the usual way (18). The activation in such cases might be expected to be significantly different from that in randomly oriented crystals.

A unique feature of ion bombardment activation is that, unlike neutron or γ-activation, the nuclear reactions take place within a region close to the surface rather than throughout the volume of the specimen. The range of penetration of 10-Mev α-particles in UN may be 25μ, but they only have sufficient energy to induce the reaction with N^{15} to a depth of about 9μ (Fig. 1). If the target specimen were to be mounted so that a beam strikes the surface at a shallow or grazing angle, the depth of activation could easily be reduced to about 1μ.

Production of such a thin active layer can serve the same purpose as does the thinning of metallurgical specimens before an autoradiograph is taken, and makes it possible to achieve maximum resolution of features of activity at or near the surface (19). The distance within which a flux of F^{18} positrons in UN would drop to $1/e$ would be close to 100μ. Therefore, if F^{18} were present throughout the sample, subsurface activity would tend to obscure surface details. In thicknesses of a few microns, on the other hand, the flux from one point as measured at another on the surface falls off as the reciprocal of distance squared. Therefore, ion bombardment activation combined with autoradiography can almost be thought of as metallographic technique for looking at details of a surface. This can be important in measuring the diffusion coefficient if the mean penetration of N^{15} is small. Variations in activity as revealed from densitometer scans of the autoradiograph can then be related to variations in surface concentration of the N^{15} tracer. The photographic emulsion can be calibrated by making a series of different exposures with the same sample so that the characteristic curve, *i.e.*, the optical density of the film *vs.* exposure time, can be used to translate film density into specimen activity.

Discussion of Applications

We have been applying these techniques in the study of the diffusion of nitrogen in uranium mononitride. In our exploration of the use of this activation technique we have used UN, because (*a*) its preparation and properties have been described (13); (*b*) it is suitable for our purposes because it is available in dense, coarse-grained form; (c) there are no competing reactions under our α bombardment energies; and (*d*) the rate of diffusion of nitrogen in the material has been measured previously by gas exchange (20).

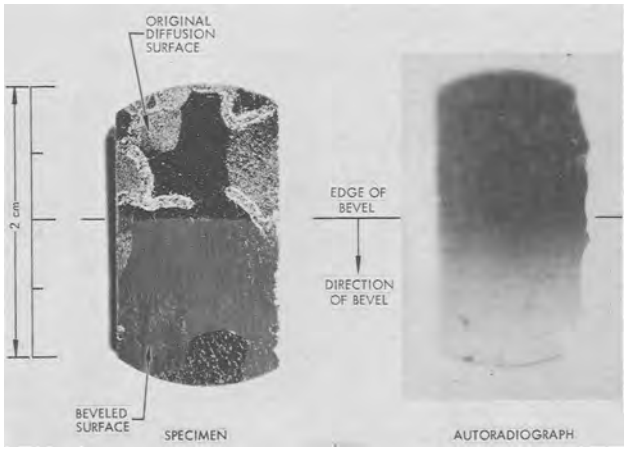

Fig. 2. Beveled UN and autoradiograph. A specimen after a diffusion anneal in enriched N^{15} gas as described in the text was beveled, the surface irradiated with α-particles, and an autoradiograph taken. Note the decreased concentration of N^{15} with depth below the original surface as revealed in the autoradiograph. Note, also, the preferential diffusion along grain boundaries.

Specimens were prepared by hot-pressing UN, obtained by arc-melting metallic uranium in a nitrogen atmosphere. The material had a density about 97% of theoretical, and average grain diameter of about 2 mm. Porosity visible under the microscope was confined mostly to grain boundaries (see Fig. 2), and there did not seem to be many open connecting pathways between the pores. The specimen surfaces were ground flat and parallel, and one surface was polished through 4/0 emery paper. The sample was then annealed in an atmosphere of nitrogen enriched to 35% N^{15} at a pressure of 129 Torr for 23.6 hr at 1792°C.

After this diffusion anneal, the specimen was prepared for irradiation by grinding a shallow bevel on the previously polished surface of the material, so as to spread out the view of the region below the original interface as one scans away from the intersection of the bevel plane with the original surface plane. In the specimen shown (Fig. 2), this was a 16-μ increase in depth per millimeter of traverse. The specimen was then irradiated for 40 min in a 1.0-μa beam of 10-Mev α-particles. Within an hour after irradiation an autoradiograph was taken, with a 6-min exposure on autoradiographic plate type A (Eastman Kodak Co.). This autoradiograph shows the activity due to F^{18}. The activity, which can be taken proportional to the N^{15} concentration at the surface, falls off from the original diffusion interface as shown in the densitometer trace (Fig. 3). Comparison with the grain structure (Fig. 2) shows that this corresponds to bulk penetration of the nitrogen. On the basis of the anneal time and the penetration as determined from the calibration of this autoradiograph, the diffusion coefficient of N in UN at 1792°C is approximately 8.1 x 10^{-11} cm²/sec. This is smaller than the value measured by Sturiale and De Crescente (20) who monitored the isotopic content of the gas phase as it exchanged with a UN specimen by diffusion. The apparent discrepancy between the two sets of measurements will not be discussed here, since our diffusion work will be reported in detail at a later time. However, it is possible that grain-boundary diffusion may have been an important but neglected factor in the earlier study. It can be seen in Fig. 2 that enhanced penetration has occurred at the boundaries. Some of the rapid diffusion paths are actual cracks while others appear to be microscopically sound boundaries. Apart from trying to decide at this time the exact nature of the preferred paths of penetration, the importance of this observation to the present discussion is that such paths can be made apparent by this activation and autoradiographic detection technique.

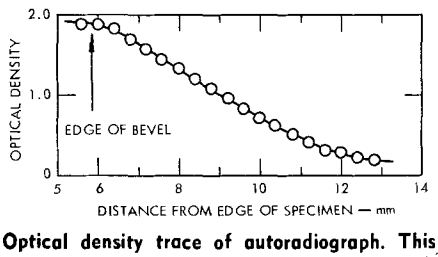

Fig. 3. Optical density trace of autoradiograph. This measurement of the optical density of the autoradiograph, Fig. 2, was obtained in the direction of the bevel. From this, a calibration of the film density in terms of activity and a relationship between distance along the surface of the specimen and depth below the original diffusion interface (16μ increase in depth per mm of traverse) it is possible to obtain the N^{15} penetration profile.

The N^{15} activation procedure may also find other applications. It can serve as an analytical tool for determining nitrogen in solids due to the 0.37% of N^{15} present in the natural element. Of course, this is only possible for those materials for which the activity ratio (Table I) is not much greater than 1.0, or unless the half-lives are clearly separable. Even the high Z elements, for which this method is attractive, are likely to contain impurities which could give a mixed yield of half-lives, thereby obscuring the F^{18} activity. However, taking a favorable element, hafnium, with an apparent activity ratio of 0.01, it would appear possible to detect 1% natural nitrogen. If one wished to carry out solubility studies using 100% N^{15} it should be possible to detect about 40 ppm N.

For the purpose of identifying nitride inclusions in a metal it is necessary that the irradiation be followed by taking an autoradiograph on the specimen. This should prove successful if

$$\frac{E\,d^2}{RS^2} > 1$$

where E is the atomic fraction of nitrogen in the inclusion (normally about 0.5), d is the diameter of the inclusion, R is the activation ratio, and S is the minimum distance resolvable by the film. With films having resolutions of 10μ it should therefore be possible to identify nitride particles in hafnium having diameters of 1-2μ, provided they are separated by distances greater than the film resolution. This is a sensitivity which is comparable with standards achieved with the electron beam microprobe. If studies were to be carried out with enriched N^{15} and high-resolution autoradiographic techniques, much greater sensitivity and resolution would be possible.

Conclusion

The activation reaction, $N^{15}(\alpha,n)F^{18}$ appears to have significant potential value in the study of nitrogen self-diffusion in nitrides and other solids, for the identification of nitride inclusions in a number of materials, and the analysis for nitrogen in solids. The ion bombardment with α-particles can be designed to yield activity within a micron of the surface of a specimen, and therefore this activation, when coupled with autoradiography of the irradiated surface, can serve as a technique for resolving features of the distribution of the nitrogen-15 tracer.

Acknowledgments

The authors are indebted to Dr. Charles Engelmann at the Center for Nuclear Studies, Saclay, France, for suggesting the use of the α activation of N^{15}. The irradiations were carried out with the staff of the 90-in. cyclotron at the Lawrence Radiation Laboratory, Livermore. Mr. Frank Vanderhoofven and Mrs. Marcia Almassy carried through several of the experimental steps.

This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript received May 15, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Impurity Effects in the Pre-Electrolysis of Caustic Electrolytes

Paul Malachesky, Raymond Jasinski, and Brian Burrows

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

Pre-electrolysis is a common purification technique for aqueous solutions. However, detectable quantities of dissolved anode metal are found in caustic electrolytes, if one of the pre-electrolysis electrodes is allowed to reach the oxygen evolution potential. The reduction of O_2 on oxidized cadmium and the displacement of the H_2 evolution potential on gold are useful tests for this phenomenon. Holding the Pt anode at +500 mv (*vs.* DHE) or less prevents dissolution. Significant purification is accomplished on a high surface area platinum fuel cell electrode held $\leq$ +300 mv (*vs.* DHE). Some of the impurities adsorbed by the electrode are desorbed at +500 mv. In the purified electrolyte little activity for oxygen reduction was found on oxidized cadmium; the reaction on reduced cadmium is diffusion limited.

It is well established that aqueous solutions of high purity must be employed when studying charge transfer processes on smooth electrodes. A common *in situ* purification technique is pre-electrolysis between "inert" noble metal electrodes, primarily platinum. The beneficial effects of this technique on the H_2 oxidation reaction on platinum has been recently discussed in some detail by Kronenberg (1). This approach to purification is not without its pitfalls, however. Although impurities are indeed removed, it is also possible simultaneously to contaminate the electrolyte. Such effects have been observed, for example, by Giner (2) in acid solutions. This paper discusses a similar contamination problem in caustic electrolytes, particularly with regard to the oxygen reduction reaction on cadmium.

Experimental

2*N* KOH was made up from Baker Analyzed Reagent pellets and triply distilled water. Most of the electrolysis experiments were carried out in an L&N coulometry cell (No. 7961). This cell had a Teflon cover which was attached to a 100 ml Pyrex tall-form beaker by a polyethylene ring. Openings of various sizes in the cell cover allowed the insertion of electrodes and a gas bubbling tube. A 100 ml capacity cell, with ground glass connections, was used for experiments requiring more efficient exclusion of atmospheric impurities. Argon was used to purge the system; the residual oxygen concentration in the gas was given by the manufacturer as 0.1-0.5 ppm. All potentials were measured *vs.* the dynamic hydrogen electrode (DHE) (3). The DHE electrodes were enclosed in a glass shield. This device successfully inhibited diffusion of soluble platinum from the anode of the DHE couple to the test electrode.

A Wenking potentiostat was used to obtain current-time curves. For the galvanostatic charging experiments, the potential step sequence for the electrode cleaning was obtained from the "set" and "output"

positions of a laboratory constructed, step function generator. Switching from potentiostatic to galvanostatic operation was carried out with a mercury relay (Potter-Brumfield). A battery pack (90v) with appropriate resistors was used to supply the constant current pulse. Potential-time curves were photographed on a Tektronix Type 651A oscilloscope equipped with a Type 2A63 differential amplifier and a Type 2B67 time base.

Purity monitoring techniques.—The purity monitoring techniques can be broadly classified into two categories: (*i*) methods which are sensitive to the presence of electroactive organic compounds, dissolved oxygen, and heavy metal ions, and (*ii*) methods which are selectively sensitive to the presence of trace noble metals.

In the first category are the following: (*a*) residual currents, (*b*) the stability of hydrogen oxidation on platinum, (c) the stability of O_2 reduction on platinum or gold, and (*d*) galvanostatic charging. The residual, or background current method is probably the least sensitive; furthermore, it is affected by residual oxygen, which is not of particular concern in this study. The H_2 oxidation method has been described by Kronenberg (1); the O_2 reduction method is similar in concept. A recent paper indicated that organic rather than inorganic impurities altered the oxygen reduction activity of a noble metal probe electrode (4).

The galvanostatic charging method (5-9) assumes the formation of a monolayer of atomic hydrogen (or oxygen) on a platinum electrode before molecular hydrogen (or oxygen) is evolved. The predominant face on polycrystalline platinum is the (100) plane which adsorbs 1.3 x 10^{15} atoms/cm^2 or 210 μcoulombs/cm^2 in the deposition of a monolayer of H atoms or 420 μcoulombs for a monolayer of O atoms. In the presence of an absorbate, these sites are "poisoned," and the charge required for the formation of the Pt-H monolayer (Q_H) or the Pt-O monolayer (Q_O) decreases in proportion to the surface coverage. In addition, if the absorbate itself is oxidizable, it can cause an apparent increase in Q_O.

The two methods used to detect the presence of trace noble metals are based on (*a*) O_2 reduction on cadmium and (*b*) H_2 evolution on gold. The cadmium was used as a rotating disk electrode in a solution saturated with oxygen. These results are discussed in detail below.

Results and Discussion

It was observed that pre-electrolysis of 2*N* KOH at *ca.* 10 ma/cm^2, in the usual manner (1, 10) removed impurities as judged by the monitoring techniques described above. However, it was also found that O_2 reduction activity was induced on an oxidized cadmium electrode. Curve A of Fig. 1 is a slow sweep (100 mv/min) cyclic voltammogram of such an electrode immersed in a nitrogen-saturated solution; curve B is for an oxygen saturated solution. Negligible activity for the reduction of oxygen at positive potentials was obtained; the reaction on cadmium metal is diffusion limited. Pre-electrolysis with Teflon-bonded platinum fuel cell electrodes led to a substantial increase in O_2 reduction activity on oxidized cadmium (Fig. 2).

This activated cadmium electrode was then removed from solution, washed thoroughly with distilled water, and placed in fresh, nonelectrolyzed electrolyte saturated with oxygen. The results were identical to those shown in Fig. 2. Thus the electrode had been permanently altered by the pre-electrolysis procedure. The same phenomenon was observed when palladium, gold, or silver were used as pre-electrolysis electrodes, but not when cadmium itself was used. Traces of platinum and silver added to the electrolyte in the form of chloroplatinic acid or silver oxide also induced oxygen reduction activity.

Another technique sensitive to the presence of trace platinum is the potential of the H_2 evolution reaction

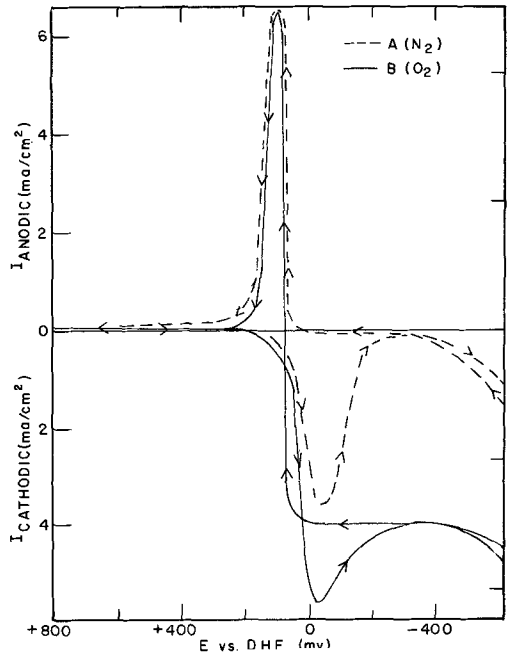

Fig. 1. Cyclic voltammograms (100 mv/min) of a rotating cadmium disk electrode in nonpre-electrolyzed 2*N* KOH under N_2 (curve A) and O_2 (curve B).

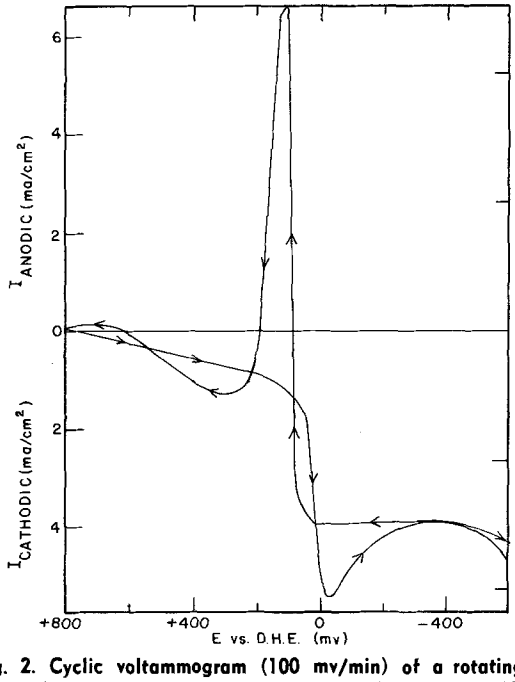

Fig. 2. Cyclic voltammogram (100 mv/min) of a rotating cadmium disk electrode in Pt electrode pre-electrolyzed 2*N* KOH under O_2.

on gold. Brummer (11) has observed, when working with acid solutions, that if a platinum counter electrode was used in conjunction with a gold working electrode, the gold electrode became covered with what appeared to be a monolayer of platinum. Giner has observed similar effects in studies of H_2 oxidation on gold in dilute acid (2). Apparently the same phenomenon can take place in aqueous caustic. Figure 3 shows results for hydrogen evolution on gold before and after pre-electrolysis with platinum. There is little doubt that trace noble metals can be introduced into a caustic electrolyte after conventional pre-electrolysis. However, as will be shown, this effect is potential dependent and, if proper precautions are ob-

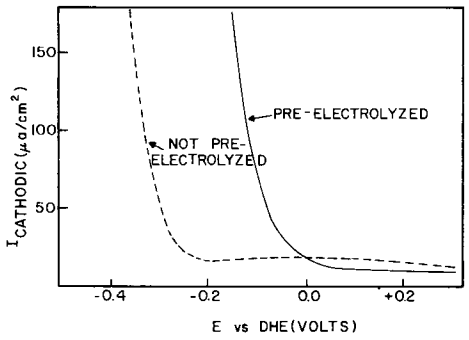

Fig. 3. Variation of the potential of H_2 evolution on a gold electrode in Pt-electrode pre-electrolyzed and nonpre-electrolyzed 2N KOH.

served, significant purification can be obtained without simultaneous contamination.

High surface area, electroplated platinum electrodes have often been used for pre-electrolysis. Teflon-bonded platinum fuel cell electrodes are more convenient and were used in the experiments described below. Some success has been achieved with this configuration in acid electrolytes as well (2).

The specific criteria of purity were the stability of the H_2 oxidation reaction on platinum in 2N KOH and the value of Q_H as a function of time. The criteria for contamination of the solution by dissolved platinum was the activity of anodized cadmium electrode toward oxygen reduction. The platinum test electrode was a wire of fixed area; the same electrode was used throughout the experiments reported below. Its real area, based on 210 μcoul/cm^2 for Q_H, was approximately 0.25 cm^2.

In an unpurified solution the value of Q_H on the probe is as shown in Table I. The test electrode was first cleaned by holding at +1.35v and taken to the potential of interest. The oxide formed at +1.35v is reduced within the first 10 msec. After holding for the time specified, the electrode is pulsed to hydrogen evolution and the quantity of hydrogen deposited on the surface during this pulse computed.

Purification was first carried out with a platinum fuel cell electrode at approximately +1200 mv *vs.* DHE. Although the solution was purified, this procedure was unacceptable because significant noble metal contamination took place as judged by oxygen reduction on oxidized cadmium. The effectiveness of purification at less positive potentials was then explored.

The platinum fuel cell electrode was taken to +300 mv and held for 24 hr to allow adsorption of impurities. A cathodic current was observed during this time. The palladium counter electrode, previously charged with hydrogen, was at +500 mv, where presumably the oxidation of adsorbed hydrogen took place. The quantity of hydrogen then adsorbed on the platinum probe at +300 mv was 38.5 ± 1.2 μcoul at t = 3 sec and 32.7 μcoul at 300 sec. Thus considerable improvement on the untreated solution was noted. Trace noble metals were not present as indicated by the Cd/O_2 test. A triangular voltage sweep on a cadmium electrode operated in the purified electrolyte gave curves essentially as shown in Fig. 1.

Table I. Platinum in untreated 2N KOH at 25°C

E of adsorption (mv *vs.* DHE)	Q_H* (μcoul)
+500	35.9
+400	23.0
+300	17.3
+200	9.7

* Measured with t_{adsp} = 3 sec.

Table II. Platinum charging in purified 2N KOH at 25°C

t (sec) at +300 mv	Q_H (μcoul)
2	45.5
5	44.6
10	40.3
30	41.4
60	
120	39.8
300	39.2
	$\overline{Q_H}$ ave = 41.3 ± 1.6

Considerable purification can in fact be achieved without pre-electrolysis. A platinum black electrode immersed in the solution will adsorb impurities extensively as shown by the following results. A Teflon-bonded fuel cell electrode was immersed in a hydrogen saturated, 2N KOH solution for 24 hr. The dissolved hydrogen maintained the electrode potential at +55 mv *vs.* DHE. Cathodic galvanostatic charging curves were then carried out on the platinum wire probe and Q_H determined for E = +300 mv *vs.* DHE. The results are shown in Table II. The current-time curves for the oxidation of H_2 on the probe in untreated electrolyte and after purification by adsorption on Pt are shown in Fig. 4. Obviously, a significant amount of impurity has been removed from the electrolyte.

The same fuel cell electrode was then held potentiostatically at +500 mv for 24 hr in the purified solution now saturated with argon. A small anodic current was observed; the Pt counter electrode was at +35 mv *vs.* DHE. After this period Q_H on the probe at t = 300 sec was 24 ± 0.5 μcoul, a marked decrease from its previous value of 39.2 μcoul. Thus, some of the impurities adsorbed by the platinum electrode can apparently be desorbed at +500 mv.

Summary

The presence of trace platinum in the electrolyte induces O_2 reduction on cadmium hydroxide and decreases the overpotential for H_2 evolution on gold. Conventional pre-electrolysis between platinum, palladium, gold, or silver electrodes introduces detectable quantities of metals into a 2N KOH electrolyte. Noble metal dissolution occurs at high positive potentials; it can be avoided by holding the platinum electrodes at lower potentials. At 500 mv, dissolution does not take place but there is no purification. At ≤300 mv, there is no dissolution and considerable purification of the caustic solution.

The Mechanism of Oxygen Reduction at Platinum in Alkaline Solutions with Special Reference to H_2O_2

A. Damjanovic, M. A. Genshaw, and J. O'M. Bockris

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

A rotating disk electrode with a concentric ring has been used to determine the role of hydrogen peroxide in the reduction of oxygen at platinum electrodes in alkaline solution. Oxygen reduction proceeds along two parallel reaction paths with comparable rates. In one of the paths, hydrogen peroxide is a reaction intermediate which is partially reduced to water. In the other, oxygen reduces to water without hydrogen peroxide as an intermediate. In the path with hydrogen peroxide intermediate, the first part of the probable sequence of reaction steps is shown to be

$$O_2 + e^- \rightleftarrows O_2^-$$

$$O_2^- + H_2O \rightarrow HO_2^- + OH$$

$$OH + e^- \rightleftarrows OH^-$$

The peroxide anion is thereafter reduced to water in a path which does not involve an electron transfer before or in the rate-controlling step. Possible paths for oxygen reduction to water without peroxide intermediates are discussed in the light of already proposed mechanisms for the reduction at prereduced and preoxidized electrodes.

It has often been reported that H_2O_2 is formed in O_2 reduction at platinum electrodes in alkaline solutions (1-12). It was not clear, however, whether H_2O_2 is an intermediate in a reaction path and reduces further to water or a product in a reaction path parallel to that in which oxygen is reduced to water without hydrogen peroxide as an intermediate. The rotating disk electrode with a concentric ring proved to be suitable for detecting H_2O_2 formed in a reaction path (13). Using a diagnostic equation, which was previously developed to distinguish between reaction intermediates and products in a parallel reaction (14), it has recently been shown that in oxygen reduction at oxide free platinum in acid (H_2SO_4) solution no H_2O_2 forms either as a reaction intermediate in the over-all reduction to water or as a product in a parallel path, providing the solution is sufficiently "pure" and electrode potential is anodic to 0.15v in respect to the hydrogen electrode in the same solution. In impure or in insufficiently purified solution H_2O_2 is formed in a reaction path parallel to that in which oxygen is reduced to water without H_2O_2 as an intermediate (15).

In this paper, the role of H_2O_2 in the reduction of oxygen at Pt electrodes in alkaline solution is analyzed. The mechanism of O_2 reduction is discussed in the light of the available experimental data.

Experimental

The cell is shown in Fig. 1. It is the same cell used in a previous study (15). It consists of a spherical main compartment with a side compartment for a hydrogen reference electrode. Between experiments the cell was washed with a mixture of HNO_3 and H_2SO_4. The details of the cell and of the rotating disk electrode with the concentric ring are given in a previous paper (15).

KOH solutions (0.1*N*) were prepared from Baker Analyzed Reagent grade KOH and conductance water. Solutions were not purified by electrochemical means as no time dependent effects on electrodes were observed attributable to the residual impurities in the solutions. This is a notable contrast to the behavior in sulfuric acid solutions where the current is strongly time dependent (15).

The electrode was washed with acetone, conductance water, concentrated sulfuric acid, and again with conductance water. To remove $SO_4^=$, the electrode was then immersed for 15 min in the KOH solution used

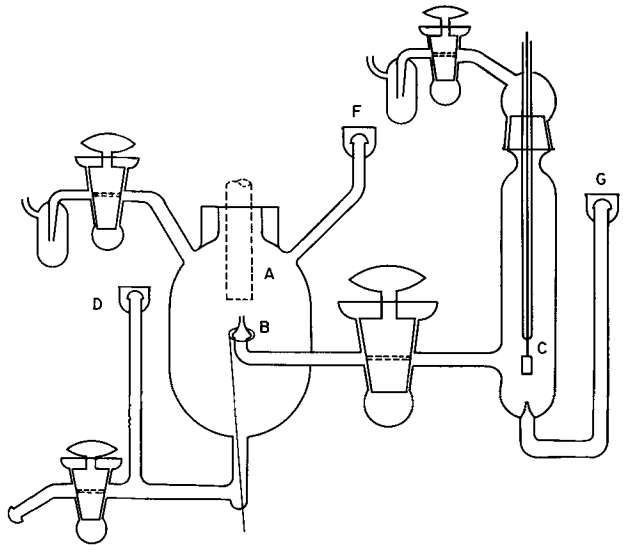

Fig. 1. Drawing of the cell: A, position of the rotating disk electrode; B, counter electrode and Luggin capillary; C, reference electrode; and D, F and G, gas inlets.

in the measurements. Measurements were taken by increasing electrode potentials in steps starting from 0.00v at which potential[1] the electrode was kept for 1 min before the measurement. These electrodes are called here prereduced. In some experiments, measurements are taken by decreasing electrode potential in steps starting from the rest potential (not prereduced electrodes).

Electrical circuit and the procedure of measurements were the same as described in an earlier paper (15). For any given potential of the disk electrode, currents both at the disk and the ring electrodes were measured. To ensure that all hydrogen peroxide which diffuses from the disk electrode to the ring electrode is oxidized and hence detected, the ring electrode is kept at 1.4v.

Results

Potential-current relationships are shown in Fig. 2. At high potentials, Tafel slope is close to 0.06v either for prereduced or not prereduced electrodes. The same value of the slope was previously reported by other workers (2, 5, 10, 16, 17). The average exchange current density from 6 measurements is 5 x 10^{-11} amp/cm^2.

A second Tafel region with a slope of $2RT/F$, which has not previously been reported in alkaline solution, appears at more cathodic potentials. To eliminate the effect of mass transfer so that Tafel lines at higher current densities can be obtained, plots (18) of $1/J$ *vs.* $\omega^{-1/2}$ were extrapolated to $\omega \to \infty$. Here, ω is the rate of disk rotation, and J is the total (current) flux of oxygen reacting at the electrode. To make this plot, the flux of oxygen is obtained from measured currents at the disk and ring electrodes.

The flux to the disk electrode is given by

$$J = I_1 + I_2 + I_3 + I_4 \qquad [1]$$

where I_1 is the partial current due to the reduction of oxygen to water in the path without peroxide intermediate, I_2 is the partial current due to the reduction to hydrogen peroxide, I_3 is the partial current for the further reduction of hydrogen peroxide to water, and I_4 is the flux of hydrogen peroxide, expressed as current, which diffuses away from the disk electrode. Now, with (14)

$$I_1 + I_2 + I_3 = I_d \qquad [2]$$

and with (14)

$$I_4 = I_r/N \qquad [3]$$

the flux to the disk electrode becomes

$$J = I_d + I_r/N \qquad [4]$$

Here I_d is the current at the disk electrode, I_r is the current at the ring electrode, and N the geometric factor of the electrode which depends on the radii of the disk and ring electrodes (19, 20).

The linearity of the $1/J$ *vs.* $\omega^{-1/2}$ plot (Fig. 3) with the slope predicted from the mass transfer considerations (18), indicates that the reaction is first order in oxygen.

In Fig. 4 and 5, the dependence is given of I_d/I_r *vs.* $\omega^{-1/2}$ for the prereduced electrodes. For a given electrode potential, I_d/I_r is linearly dependent on $\omega^{-1/2}$. In the potential range 0.30-0.60v, the slopes of the I_d/I_r lines increase with increasing potential. Above about 0.60v, they decrease. The intercept of these lines with the I_d/I_r axis cluster around the value of 10 (*cf.* Fig. 4 and 5).

The dependence of I_d/I_r on $\omega^{-1/2}$ for the not prereduced electrodes at potentials cathodic to about 0.65v is basically the same as for the prereduced electrodes. The intercepts with the I_d/I_r axis are again close to

[1] All potentials are given with respect to the reversible hydrogen electrode in the same solution.

Discussion

It is possible to distinguish whether in the electrode reduction of oxygen, hydrogen peroxide is an intermediate in a single reaction path, or it is a product in a path parallel to the main path in which oxygen is reduced to water without hydrogen peroxide as an intermediate. For this distinction the equation (14)

$$\frac{I_d}{I_r} = \frac{x+1}{N} + \frac{x+2}{N}\,\frac{1.61\,k_3\nu^{1/6}}{D^{2/3}\,\omega^{1/2}} \qquad [5]$$

is used. In this general equation, I_d and I_r have the same meanings as given above, N is a calculable geometric factor for the given electrode assembly (19, 20), k_3 is the rate constant for the further reaction of an intermediate at the disk electrode, ν is the kinematic viscosity, and D is the diffusion coefficient of the intermediate. The ratio of the current at the disk electrode due to the reaction which does not result in the

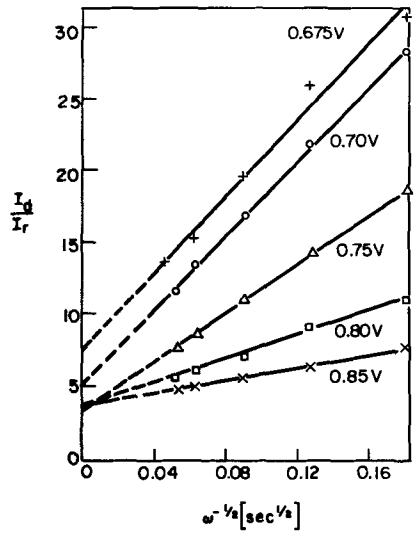

Fig. 6. Plot of I_d/I_r *vs.* $\omega^{-1/2}$. Pt electrode is not prereduced. Potentials of the disk electrode are marked in the figure.

formation of intermediates, to the current at the same electrode due to the formation of intermediates is given by x. From the intercept of an I_d/I_r *vs.* $\omega^{-1/2}$ line with the I_d/I_r axis, x can be obtained. From the slope of this line, k_3 can be calculated.

For oxygen reduction, the intercept of straight lines in the plots of I_d/I_r *vs.* $\omega^{-1/2}$ is given by

$$\text{intercept } \frac{x+1}{N} = \frac{I_{H_2O}/I_{H_2O_2}+1}{N} \qquad [6]$$

Here, I_{H_2O} is the partial current at the disk, due to the reduction of oxygen to water in a path without hydrogen peroxide as an intermediate, and $I_{H_2O_2}$ is the partial current at the same electrode due to the reduction of oxygen to hydrogen peroxide. For the present electrode assembly, N is 0.38, as calculated from the dimensions of the electrodes (21), and checked by a redox reaction ($Fe^{+++} \rightarrow Fe^{++}$).

The intercepts of the plots of I_d/I_r *vs.* $\omega^{-1/2}$ are all greater than $1/N = 2.6$. Thus $x > 0$, and two paths of oxygen reduction must be present, with hydrogen peroxide produced as an intermediate in one of them.

Rates for individual reaction paths.—For each potential of the disk electrode, the individual rates of the two partial reactions, I_{H_2O} and $I_{H_2O_2}$, can be obtained from the disk and ring currents if the value of x can be obtained with sufficient accuracy [*cf.* Eq. (19) and (20) of ref. (14)]. For the prereduced electrodes the dependence of these partial currents on potential are given in Fig. 7. For the not prereduced electrode, in the Tafel region x is less than 1, and the separation

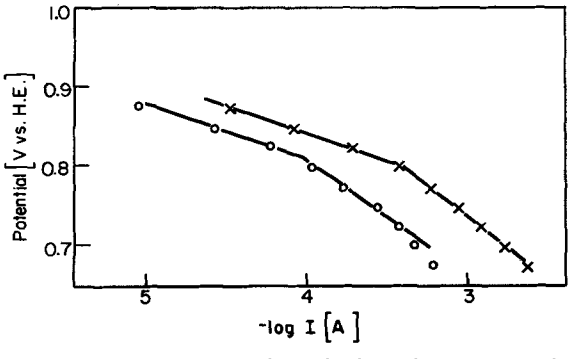

Fig. 7. Partial currents at the disk electrode. o, current due to the formation of hydrogen peroxide; x, current due to the reduction of oxygen to water without peroxide intermediate. Prereduced electrode. The area of the electrode is 0.18 cm^2.

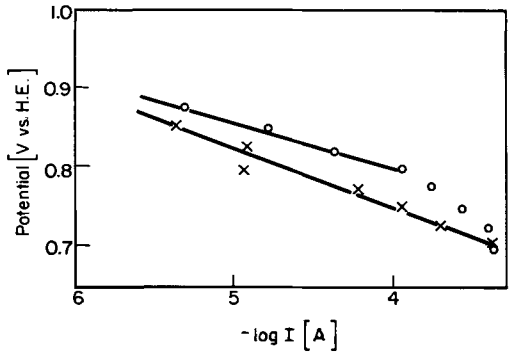

Fig. 8. Same as in Fig. 7, but electrode is not prereduced

of partial currents I_{H_2O} and $I_{H_2O_2}$ is rather uncertain. Nevertheless, from the best estimated values of x, these partial currents are calculated (Fig. 8).

For the prereduced electrode (Fig. 7), the slope of the log $I_{H_2O_2}$ — V line is about 0.070v at higher, and 0.140v at lower potentials. For I_{H_2O}, the corresponding slopes are 0.070 and 0.150v.

For the not prereduced electrode (Fig. 8), the slope for the log $I_{H_2O_2}$ line is about 0.050v, and it increases at higher cathodic overpotentials. The slope of the log I_{H_2O} line is 0.070v. Here, no change in the slope with potential is observed. $I_{H_2O_2}$ appears to be independent of the electrode pretreatment, while the I_{H_2O} changes with the pretreatment by about factor 10. being larger at the prereduced electrodes.

The change in the rate of oxygen reduction (Fig. 2, 6, and 7) with electrode pretreatment is not surprising, as the amount of oxides at the surfaces of these two electrodes are probably very different. Ellipsometric studies (22) in sulfuric acid solutions have shown that an air oxidized electrode is covered by an oxide layer of average thickness of ~6Å. It has also been shown that in sulfuric acid solutions the kinetics and the mechanism of oxygen reduction at the bare and oxide covered Pt surfaces are different (17, 23, 24), the activity at the bare electrodes, at 0.9v for instance, being higher than at an oxide covered electrode by more than a factor 10. A similar situation exists in alkaline solutions; activity at bare electrodes (17) is about a factor 10 higher than at oxide covered electrodes (24). Thus, an increase in the reaction rate by an order of magnitude when the oxides at the Pt surface are reduced is expected.

Reaction path followed in oxygen evolution.—Since for the same electrode, two paths for oxygen reduction are found, the question arises: "Which path is followed in oxygen evolution?" Tafel lines for oxygen evolution and reduction at oxide covered[2] Pt electrodes intersect at the reversible potential (16, 24, 25), and thus a common path is probably followed for the evolution and reduction reactions at these electrodes. A simple argument is presented here to show that the path with the hydrogen peroxide intermediate is not involved in oxygen evolution, and hence also in the reduction at oxide covered electrodes at potentials close to the reversible oxygen potential.

Were H_2O_2 an intermediate, then at the reversible oxygen potential the oxygen electrode reaction is in equilibrium. The rate of each stage of the reaction must be equal to or greater than the (observed) exchange current density ($\sim 10^{-10}$ amp/cm^2). For the stage of reduction of hydrogen peroxide to water, the rate of the reaction may be written as

$$i = nFkc_{H_2O_2} \geqq i_o \sim 10^{-10} \text{ amp/cm}^2 \qquad [7]$$

The concentration of hydrogen peroxide, $c_{H_2O_2}$, at the electrode surface as calculated from the Nernst's equation for two electron reduction of oxygen is 10^{-21} moles/cm^3. Substituting this value into [7], it is found that

$$k \geqq 10^6 \text{ cm/sec} \qquad [8]$$

This rate constant is 8 orders of magnitude larger than that experimentally observed for the reduction of H_2O_2 to H_2O in the potential range 0.90-0.00v (see later). It is unlikely that the rate would increase so greatly when the potential is made 0.30v more anodic (from 0.9 to 1.2v). Also, the anodic reaction would have to occur with an equal rate constant. From experimental data on hydrogen peroxide oxidation (26, 27), the rate constant at 1.23v is about 10^{-2} cm/sec. It is much lower than that required for the model in which, at potentials close to the reversible oxygen electrode potential hydrogen peroxide is an intermediate in a reaction path. Hence, the path which does not have hydrogen peroxide intermediate must predominate near the reversible potential and in oxygen evolution.

The mechanism in the path with peroxide intermediate.—For analyses of this path, the following diagnostic data are available. The Tafel slope is $-RT/F$ at low overpotentials and changes to $-2RT/F$ at more cathodic potentials. Under Langmuir conditions of adsorption[3]

$$b_c = -\frac{\nu RT}{(n_c + \beta n^*)F} \qquad [9]$$

where b_c is the cathodic Tafel slope, ν the stoichiometric number, n_c is the total number of electrons transferred before the rate-controlling step, β is the symmetry factor ($= \frac{1}{2}$), and n^* is the number of electrons transferred in the rate-controlling step. With $b_c = -RT/F$ for low current density region

$$n_c + \beta n^* = \nu \qquad [10]$$

Thus, since

$$n_c + n^* \leqq 2 \qquad [11]$$

either

$$n_c = 1,\ n^* = 0,\ \text{and}\ \nu = 1 \qquad [12]$$

or

$$n_c = 0,\ n^* = 2,\ \text{and}\ \nu = 1 \qquad [13]$$

or

$$n_c = 2,\ n^* = 0,\ \text{and}\ \nu = 2 \qquad [14]$$

Since a simultaneous transfer of two electrons ($n^* = 2$) is improbable, the second case may be rejected. The third case requires two identical species for the rate-determining step. This would require a dissociation of the oxygen-oxygen bond followed by a recombination in the rate-determining step which is highly improbable. Thus, the path must consist of an electron transfer step followed by a rate-controlling step which does not involve an electron transfer.

Two such paths may be suggested. The first is

$$O_2 + e^- \rightleftarrows O_2^- \qquad [15]$$

$$O_2^- + H_2O \rightarrow HO_2^- + OH \qquad [16]$$

$$OH + e^- \rightleftarrows OH^- \qquad [17]$$

The second is

$$O_2 + H_2O + e^- \rightleftarrows HO_2 + OH^- \qquad [18]$$

$$HO_2 + H_2O \rightarrow H_2O_2 + OH \qquad [19]$$

$$OH + e^- \rightleftarrows OH^- \qquad [20]$$

These mechanisms may be distinguished by their different pH dependences. In respect to a potential of a pH independent electrode, the first is pH independent, while the second has the dependence given by $\partial V/\partial \text{pH} = -RT/F$. The experimental pH dependence of —26 mv/pH for the prereduced electrodes in alkaline solution (28) reflects most probably the dependence on pH of the parallel reaction leading to H_2O without peroxide intermediate. This is because the rate of the reaction for the latter path is higher by at least a factor 3 than that for the path in which

[2] In evolution, a Pt electrode is expected to be oxide covered.

[3] See ref. (17) and (25).

peroxide in an intermediate. Hence, a clear distinction between the proposed reaction paths may not be made.

The region of Tafel slope of $-2RT/F$ is consistent with either path and corresponds to a change of the rate-controlling step to the first, charge transfer step (Eq. [15] or [18]). A point in favor of the first path ([15], [16], and [17]) is that this is the path followed in the reduction of oxygen to peroxide at gold electrodes, which behaves kinetically, in the $-2RT/F$ Tafel region, like platinum (29)

A possible path with a peroxide intermediate under Temkin conditions.—If the rate-controlling step is

$$O_2 + e^- \rightarrow O_2^- \qquad [21]$$

the rate expression under Temkin conditions of adsorption is

$$i = k[O_2] \exp(-\beta VF/RT) \exp[-\beta f(\theta)] \qquad [22]$$

With (15)

$$f(\theta) = VF/RT - \ln [H^+] \qquad [23]$$

and $\beta \approx \frac{1}{2}$, the rate expression becomes

$$i = k[O_2][H^+]^{1/2} \exp(-VF/RT) \qquad [24]$$

At higher cathodic overpotentials, $\theta \rightarrow 0$ and Temkin conditions no longer hold. Then, the rate expression becomes

$$i = k[O_2] \exp(-\beta VF/RT) \qquad [25]$$

and the Tafel slope for the same rate-controlling step changes from $-RT/F$ for Temkin to $-2RT/F$ for Langmuirian conditions.

Thus, the experimental results are consistent with either Temkin or Langmuirian conditions. However, a similar behavior of platinum, and gold, in respect to oxygen reduction in alkaline solution (29), favors the interpretation in terms of Langmuirian conditions with the same path followed at these electrodes. This is because at gold the adsorption must be Langmuirian as coverage by oxygen is low.

The mechanisms in the paths with no hydrogen peroxide as an intermediate.—For the parameters available in the literature ($\partial V/\partial \ln i \approx +RT/F$ and $-RT/F$, for anodic and cathodic reaction at low overpotentials (16, 24), respectively, and $+2RT/F$ for high anodic overpotentials (24), and for (24) $\partial \log i/\partial \log p_{O_2} \approx 0.5$), two paths were suggested in the literature for the reduction at preoxidized electrodes. These are first path (30)

$$O_2 \rightleftarrows 2\,O \qquad [26]$$

$$2(O + e^-) \rightleftarrows 2\,O^- \qquad [27]$$

$$2(O + H_2O) \rightleftarrows 2(OH^- + OH) \qquad [28]$$

$$2(OH + e^-) \rightleftarrows 2\,OH^- \qquad [29]$$

and second path (24)

$$O_2 \rightleftarrows 2\,O \qquad [30]$$

$$2(O + H_2O) \rightleftarrows 2\,O\text{-}H\text{-}OH \qquad [31]$$

$$2(O\text{-}H\text{-}OH + e^-) \rightleftarrows 2\,O\text{-}H\text{-}OH^- \qquad [32]$$

$$2(O\text{-}H\text{-}OH^-) \rightleftarrows 2(OH + OH^-) \qquad [33]$$

$$2(OH + e^-) \rightleftarrows 2\,OH^- \qquad [34]$$

In the first path, step [28] is the rate-controlling at low overpotentials with step [27] and [29] becoming the rate-controlling at high cathodic and anodic overpotentials, respectively. In the second path, which is basically a hydrated version of the first path, step [33] is rate-controlling at low overpotentials with [32] and [34] becoming rate-controlling at more cathodic and anodic overpotentials, respectively.

It is suggested that at the not prereduced electrodes of the present work, which are likely to be partially oxide covered, the mechanism for oxygen reduction to water is as that for the preoxidized electrodes.

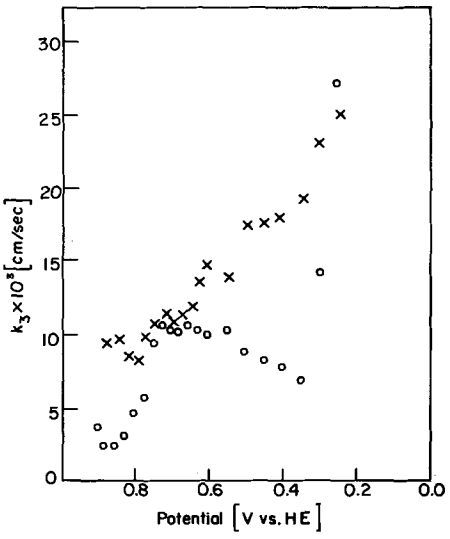

Fig. 9. Plot of the rate constant for hydrogen peroxide reduction, k_3, vs. disk potential. Two measurements.

The kinetics at the prereduced electrodes of the present work corresponds to that at the oxide free electrodes for which the mechanism has recently been discussed in some details (17). For these prereduced electrodes, oxygen partial pressure ($\partial V/\partial \log p_{O_2} \approx RT/F$) and pH dependence ($\partial V/\partial pH \approx -RT/2F$) were accounted for if Temkin conditions of adsorption by intermediates are considered. The rate-controlling step was suggested (17) to be the first discharge according to either [15] or [18]. The observed order of the reaction with respect to O_2 of the present work[4] is in agreement with this mechanism.

The change of slope from $-RT/F$ at low overpotentials to $-2RT/F$ at high overpotentials, as observed in the present work, is then accounted for by the change of the conditions for adsorption of intermediates from Temkin, at low overpotentials, to Langmuirian at high overpotentials.

The situation in which for oxide free electrodes Langmuirian conditions are favored for the path in which peroxide is an intermediate, and Temkin (at low overpotentials, at least) for the path in which no peroxide is formed, is not an impossible one. Thus, this situation may arise whenever there is a heterogeneity of the electrode surface. If, for instance, a part of the surface is still covered by oxides, these may serve as sites at which reduction occurs under Langmuirian conditions while at oxide free electrode Temkin conditions may prevail with a different reaction path. It seems probable that the O_2^- in a hydrogen peroxide path is not chemisorbed at the electrode surface. This view lends support from an analysis that in acid solution H_2O_2 appears to form only at sites at which residual impurities from the solution are already adsorbed (15), and, hence no chemisorption of O_2^- at these sites is possible.

The reduction of hydrogen peroxide.—From the diagnostic Eq. [5], the slope of I_d/I_r *vs.* $\omega^{-1/2}$ plots is given by (14)

$$\text{slope} = \frac{(x+2)}{N} 1.61\, D^{-2/3} \nu^{1/6} k_3 \qquad [35]$$

From this relationship, the rate constant for the further reduction of hydrogen peroxide to water, k_3, is obtained for each electrode potential (Fig. 9). The change in k_3 is less than two orders of magnitude for the potential change of 0.9v. In Fig. 10, the log of k_3 is plotted as a function of potential. If a straight line were drawn through the points, the slope would be about 0.6v. This unusually high slope probably indi-

[4] For these prereduced electrodes the observed order of the reaction corresponds to the path in which O_2 is reduced to water.

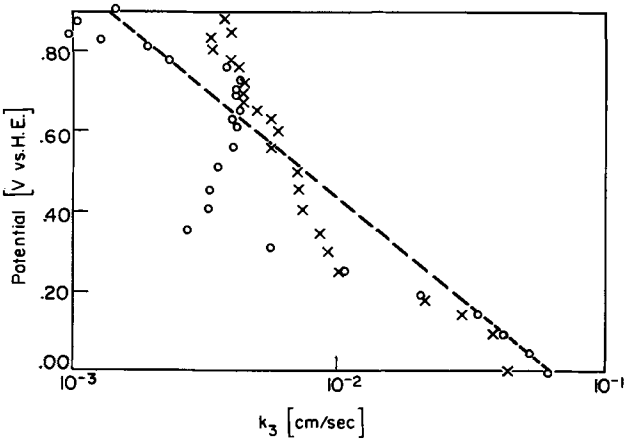

Fig. 10. Same as in Fig. 9, but with k_3 on a log scale

cates that the reduction of hydrogen peroxide is controlled by a chemical step, rather than a step involving an electron transfer.

The value of k_3 was previously determined by Muller and Nekrasov (31) to be $8.9 \pm 0.8 \times 10^{-2}$ cm/sec at 0.5v, and $3.6 \pm 0.5 \times 10^{-2}$ cm/sec at 0.1v. Jacq and Bloch (8) have determined the rate constant in 1*N* KOH to be 2.3×10^{-2} cm/sec at platinized platinum at −0.5v *vs.* NHE. These values are somewhat higher than those in Fig. 9. Considering the differences in the techniques used, the agreement of three independent sets of data for the rate constants of the reduction of hydrogen peroxide is good.

The mechanism of hydrogen peroxide reduction at platinum.—The rate constant for the reduction of hydrogen peroxide shows only a small dependence on potential between 0.90 and 0.00v (*cf.* Fig. 10). Since in this potential region, the coverage by OH and hydrogen varies from zero to appreciable values without a major change in the reaction rate, Temkin kinetics will not be considered.

Several paths for hydrogen peroxide reduction, which do not involve electron transfers before or in the rate-controlling step, have been proposed. In the path (32)

$$H_2O_2 + OH \rightarrow HO_2 + H_2O \qquad [36]$$

$$HO_2 + H_2O_2 \rightarrow O_2 + H_2O + OH \qquad [37]$$

oxygen is formed which is then reduced to hydrogen peroxide.

In another path hydrogen peroxide is dissociated in the rate-controlling step which is then followed by a charge transfer (33)

$$H_2O_2 \rightarrow 2\,OH \qquad [38]$$

$$OH + e^- \rightleftarrows OH^- \qquad [39]$$

Finally, in the path (34)

$$H_2O_2 + Pt \rightarrow PtO + H_2O \qquad [40]$$

$$PtO + H_2O + 2e^- \rightleftarrows Pt + 2\,OH^- \qquad [41]$$

hydrogen peroxide is decomposed into water and an oxygen atom which then reduces to OH^-.

Since the coverage with adsorbed OH is known to be potential dependent, it seems unlikely that the path according to [36] and [37] can be followed. The other two paths involve dissociation of hydrogen peroxide. No distinction between these paths by electrochemical methods can be made.

Acknowledgments

The authors wish to thank the sponsor of this work, the U.S. Army Electronics Materials Laboratory, Fort Monmouth, N. J. (Contract No. DA-36-039-Sc88921) for financial support, and Dr. H. F. Hunger and Mr. J. Wynn for their advice during this work. They also thank Mr. O. Shannon for machining the disk electrode assembly, and Mr. J. Dawson for glassblowing the cell.

The Electrochemical Activation of Platinum Electrodes

S. D. James[1]

Brookhaven National Laboratory, Upton, New York

ABSTRACT

The various mechanisms proposed for the electrochemical activation of platinum electrodes are reviewed. Experimental results are described showing impurity desorption to be by far the most important result of conventional brief activation treatments. Literature evidence is cited for the view that a second type of activation exists produced by prolonged preoxidation and characterized by an exceptionally stable activity. This latter activation is probably associated with an oxide quite distinct from that formed in conventional brief anodizations.

It is well known that an electrical oxidation-reduction (anodization-cathodization, A-C) pretreatment applied to smooth Pt electrodes in aqueous solution usually causes a marked improvement in the reversibility and reproducibility of electrode processes subsequently studied at the electrode. Equally well known is the fact that this increase in electrode activity is only transitory and decays at rates varying widely according to experimental conditions. This appears to have been first noticed by Hammett (1) who observed that the activation effect was obtained even if a long time separated "A" from "C" but that it disappeared quickly after "C" (2). Various explanations have been advanced for these observations. The impurity theory (3-7) supposes that the A-C treatment causes desorption of adsorbed surface-active contaminants which were poisoning the electrode. These impurities may be traces of organic matter or of certain cations which, at sufficiently negative potentials, are very strongly adsorbed on Pt (6). Desorption might be effected either by the surface disruption involved in the formation and dissolution of the oxide film or by the general tendency of organic or cationic adsorbates to be desorbed during large positive excursions from the potential of zero charge ($\approx +0.2$v, NHE for Pt in 1M $HClO_4$ or H_2SO_4). In addition, destructive oxidation of organics might produce simpler and less adsorbable products. The initially high activity then decays as fresh contaminant adsorbs on the electrode.

The platinization theory (8-13), on the other hand, attributes the increased activity to a change in the nature of the surface layers of Pt consequent on the successive formation and reduction of a superficial oxide. Anson regards the A-C treatment as effecting a light platinization of the electrode. This is supported by the fact that the surface texture is visibly coarsened by repetitive A-C treatments (11, 14). One hundred such cycles removed the luster from a bright Pt electrode in 1M H_2SO_4 and 600 cycles resulted in a dark surface resembling that of a conventionally platinized electrode (11). According to Will and Knorr (9) the A-C procedure results in the formation of a very thin layer of unstable atoms having a high electrochemical activity. This activity is supposed to decay as the active disturbed structure gradually relaxes into a relatively stable and inert state.

A third interpretation of the effect of A-C treatments on electrode activity was given by Feldberg *et al.* (15). From their measurements in $HClO_4$ they inferred that a fully oxidized Pt surface suffered cathodic reduction (at constant current) rapidly to a half-reduced state but only very slowly beyond this to the fully reduced state. They imply that the half-reduced state is produced under the conditions of most A-C treatments and that this state is one of very high electrochemical activity. However this explanation is untenable because (a) a rapid decay in activity can be observed at a potential of about +0.8v, NHE [cf. Fig. 1 referring to Fe(II)-(III) in 1M $HClO_4$] where, on their own testimony, the half-reduced state should be quite stable and (b) under appropriate conditions, quite long-lived activations of the hydrogen evolution reaction can be obtained, at 0v, NHE in acid where the half-reduced state should be quite unstable. These arguments also dispose of the basically similar mechanism proposed by Davis (16), *viz.*, that the A-C treatment gives rise to a partially reduced oxide film which facilitates electron transfer *via* oxygen bridges between electrode and reactant.

A special mechanism, sometimes invoked for the hydrogen electrode, is related to the so-called "hydrogen poisoning" effect. It has been observed [see ref. (17) for summary] that hydrogen electrodes are subject to fatigue on prolonged cathodization or exposure to hydrogen. It is postulated that this decay in activity is associated with a slow attainment of equilibrium adsorption of atomic hydrogen into the bulk platinum (18). Anodization, according to this idea, activates the electrode by stripping the surface layers of dissolved hydrogen.

Time variations, after activation, in the activity of smooth Pt cathodes reducing O_2 in acid solutions have been attributed to progressive deactivation by adsorption of anions (19). This correlates with a pronounced shift in $E_{1/2}$ for O_2 reduction towards negative values in the series $HClO_4 < H_2SO_4 < HCl < HBr$, *i.e.*, the shift increases with anion adsorbability (20-22).

The present study indicates clearly that the removal of adsorbed impurities is by far the most important result of conventional brief activation treatments.

Since one of the major themes of this article is the overriding importance of solution purity in solid-electrode studies, a brief discussion of this subject is in order.

Workers in Frumkin's laboratory (23, 24) first realized the significance of capillary-active poisons under conditions of low electrode-area to solution-volume ratio and long electrode-solution contact time. The effect of these contaminants is minimized at the DME by the short ($\approx$4 sec) contact time. However, at a hanging drop or small area solid electrode, removal of adsorbable impurities is of paramount importance in obtaining reproducible and meaningful results. In some cases Frumkin utilized platinized platinum as a purifying adsorbent. Bockris and Conway (25) recommended preelectrolysis on auxiliary platinum electrodes as a method for cleaning a solution. However as Barker pointed out (26) preelectrolysis on an auxiliary cathode, while capable of removing reducible impurities like oxygen or some of the metal ions, leaves organic contaminants virtually untouched. Furthermore, exhaustive preelectrolysis at an auxiliary Pt anode is likely to do more harm than good, since oxidized Pt is quite inert as a material for the electrooxidation of most organic compounds over a wide range of potentials (27) while, during the preelectrol-

[1] Present address: Electrochemistry Division, Chemistry Research Department, United States Naval Ordnance Laboratory, White Oak, Maryland.

ysis, appreciable amounts of Pt can leave the anode and deposit on other cell surfaces. This can be a fruitful source of confusion, especially when electrode materials other than Pt are under study (28). Vahramian (29) showed that impurities responsible for the passivation of silver electrodes in $AgNO_3$ solutions could be eliminated by bubbling oxygen through for 2 hr at 60°C in the presence of platinized platinum. Vermilyea (30) confirmed this and established that both platinized platinum and O_2 were necessary for the cleansing effect. No effect was obtained with Pt alone, or with activated carbon or alumina, with or without oxygenation, *i.e.*, the effect was primarily one of oxidation rather than adsorption of impurities. In a study of the $Cu\text{-}Cu^{2+}$ reaction by an impedance technique in molar KNO_3, Hillson (31) found that it was impossible, by repeated recrystallizations, to purify his reagent-grade salts sufficiently to prevent electrode contamination during the course of an experiment. He eliminated surfactants and obtained stable impedances by a batch treatment of his 200-ml cell solutions with 5g of λ, a chromatographic alumina adsorbent. Although quite effective in this case the procedure in general is severely limited by the unacceptable solubility levels of high-area alumina in many aqueous solutions.

In connection with his studies on single-drop polarography, Barker (26) developed an adsorption purification technique, a simplified version of which was used in the present work. In view of the effectiveness and versatility of this method and the relative inaccessibility of the original publication (26), this work will be briefly described. The adsorbent column used contained a mixture of active charcoal and silica gel. The charcoal was purified by extraction for several weeks in a Soxhlet apparatus, first with 2*N* HCl and then with water. Granulated silica gel, formed by treating sodium silicate solution with dilute HCl, was washed repeatedly with water. Before use both materials were roasted in air then boiled with water to ensure thorough wetting. The small adsorbent column containing 5g of charcoal-silica mixture was an integral part of the polarographic cell and, in the *in situ* purification, a nitrogen lift circulated the cell solution (≈100 ml) through this column for about an hour. An additional effort to eliminate reducible cations involved circulating the solution for 15 hr past a 30-cm^2 Hg pool cathode maintained at —0.8v, NHE.

By following the double-layer capacity of a Hg drop formed in his solutions (molar KCl, analytical reagent) Barker was able to demonstrate the radical improvement effected by his cleansing procedure. In a cleansed solution the high initial capacity after drop formation was maintained with a fall of <1% in 24 hr. On the other hand, in untreated KCl, the capacity had fallen to 40% of the high value only 4 min after drop formation, due to the adsorption of surface-active impurities. Barker's method of solution purification, although used in British electrochemistry laboratories for over a decade (32) still appears relatively unknown in the United States. This is unfortunate as the method seems unrivalled in its general efficacy, *e.g.*, Parsons (33) obtained stable impedances in a study of V^{3+}/V^{2+} at a hanging Hg drop only in charcoal-treated solutions. Other standard purification techniques like distillation, recrystallization, and preelectrolysis proved quite unsatisfactory. The charcoal adsorbent is inexpensive and chemically resistant to all but the most strongly oxidizing solutions.

Experimental

Solution cleansing.—To cleanse solutions from surfactants, Barker's method was subjected to a drastic simplification. Both the silica half of the adsorption treatment and the preelectrolysis at a Hg cathode were dispensed with, and solutions were merely passed through a column of purified active charcoal. The charcoal employed was Nuchar C-115 (granular), a

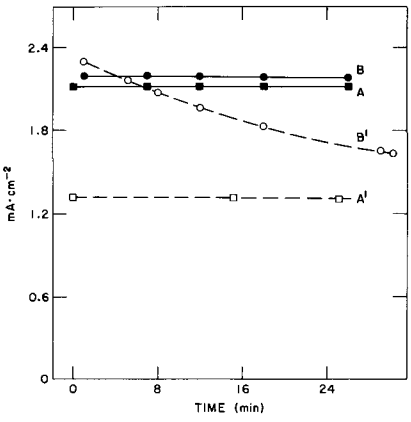

Fig. 1. Effect of A-C pretreatment (1 min at 2.34 then 1 min at 0.1v, NHE) on current-stability during the anodic oxidation of Fe(II) at a constant voltage of 30 mv applied to a Pt rde. All curves in 1M $HClO_4$, 1.06 x 10^{-2}M in Fe(II) and (III) and at 1500 rpm. A and B: Before and after A-C in charcoal-cleansed solution; A' and B': before and after A-C in uncleansed solution.

decolorizing carbon from the West Virginia Pulp and Paper Company, having a specific surface of 800 m^2 (BET). This carbon was sieved, retaining the 16-40 mesh particles which constituted about 70% of the whole. After boiling with water for about 2 hr, that portion still floating was discarded and purification commenced in an extra large Soxhlet apparatus. The ground surfaces of the large (103/60) tapered joint in this apparatus were coated with a thin Teflon layer to prevent freezing and a special Pyrex, fritted extraction thimble was made, capable of holding nearly 1000 ml of carbon. Extraction with constant boiling HCl (6*N*) was carried out for 2 weeks using successive charges of fresh HCl for 2-, 4-, and 8-day periods. Drainage of HCl from the thimble occurred every 30 min. Before the first and second changes of HCl the boiler solution had a strong green and a pale green color, respectively, while at the end of the extraction this solution was quite colorless. After the HCl extraction, the whole apparatus, including carbon, was rinsed with twice-distilled water and then a similar water-extraction was done with daily charges of fresh water. Extraction for 5 days sufficed for the complete removal of HCl (boiler solution tested with $AgNO_3$). The purified carbon was stored under distilled water in Pyrex jars. Solutions to be cleansed (about 300 ml in volume) were percolated at 3 ml/min through a 2.4 x 18-cm column of charcoal (this 80 ml of column contained 20g of dry carbon[2]) *via* a ground joint directly into the Pyrex electrochemical cell which was continuously purged with pure N_2.

In the case of the Fe(II)-(III)-$HClO_4$ system the solution was percolated as Fe(II)-1M $HClO_4$, since Fe(III) was very strongly adsorbed by the charcoal. After percolation, half of the Fe(II) was anodically oxidized *in situ* at a 40-cm^2 Pt electrode. For the study of the hydrogen evolution reaction, no such problem existed, and 2*N* H_2SO_4 was filtered directly into the cell.

The effectiveness of the charcoal treatment is obvious in Fig. 1 from the complete elimination of current-instability (at ≈0.8v, NHE) following the A-C treatment. The charcoal used to cleanse this solution had been purified the previous week. After a year of storage under distilled water, some of this carbon was lent to a colleague who had found it impossible to reproduce voltammograms for $Ag^+ \rightarrow Ag$ at a rotating

[2] This amount of carbon has a BET surface area of ≈2 × 10^6 cm^2, i.e., monolayer adsorption would involve 10^{-2} to 10^{-1} moles of a molecule occupying say 50A^2. This is 10^6-10^9 times the amount of contaminant likely to exist in 1 liter of, *e.g.*, reagent grade H_2SO_4 solution which is thought to contain about 10^{-7} M of impurity (34-36). Thus, even allowing for the specificity of adsorption and a wide heterogeneity of adsorption sites, it seems likely that such a column could be re-used many times to cleanse solutions of normal, reagent-grade purity.

disk electrode. After charcoal-cleaning the molar $HClO_4$ supporting electrolyte, his scans (between 0.8 to 0.5v, NHE) became quite reproducible (37). Thus the year's storage under water had left the charcoal's cleansing ability unimpaired. The charcoal used to cleanse the H_2SO_4 used for Fig. 4 (h.e.r. at Pt) had been stored under water for 2 years. Comparing curves A and C, it is clear that, while considerably reducing current-instability, the charcoal treatment by no means eliminated it. That the residual instability was still largely due to solution impurities is shown by its pronounced dependence on rpm. It is probable that the smaller success of charcoal cleansing in stabilizing the h.e.r. is connected with an inherently greater sensitivity of this reaction to impurities rather than with a degradation of the carbon during storage. This greater sensitivity may be linked with the relative rational potentials (ϕ = deviation of electrode potential from its zero charge value) in the different systems. The potential of zero charge for Pt in H_2SO_4 or $HClO_4$ is about +0.2v, NHE (38) and that for Ag in $HClO_4$ is probably close to +0.05v, NHE (39). Thus, in Fig. 1, $\phi \approx +0.6$v; for the $Ag\text{-}Ag^+$ study mentioned above, ϕ was between +0.75 to 0.45v whereas in the h.e.r. study, $\phi \approx -0.2$v. Figure 2 reveals, as is discussed below, that on Pt at 0v, NHE, there is a wide spectrum of adsorbed impurities which are progressively removed at increasingly positive potentials. Thus, because of the more positive ϕ's in the first two systems, even at open circuit, they are already activated relative to the hydrogen electrode in that they are sensitive to a smaller range of impurities. The few direct measurements made, *e.g.*, for Cd^{2+} and Tl^+ (40), support the expectation that, at least in this range of potential, the adsorbability of cations on Pt falls as ϕ rises. Also, as a general rule, ions are not well adsorbed on activated charcoal (41). Hence it is likely that the impurities responsible for the instability of current in Fig. 4 are metallic cations which passed through the charcoal column.

Thus it appears that purified charcoal may be stored for long periods under water with little or no loss in effectiveness and is therefore always ready for immediate use. While excellent for the removal of organic contaminants it appears much less so for metallic cations and where sensitivity to cations is anticipated (at low values of ϕ) it should be supplemented by cathodic preelectrolysis at Hg, as recommended by Barker (26). Actually, for Pt electrode studies the simplest way to clean a solution involves prolonged exposure to a large-area auxiliary Pt electrode held at the most negative potential of the projected study (34). A periodic brief anodic cleaning of this auxiliary electrode in another solution would enhance its effectiveness.

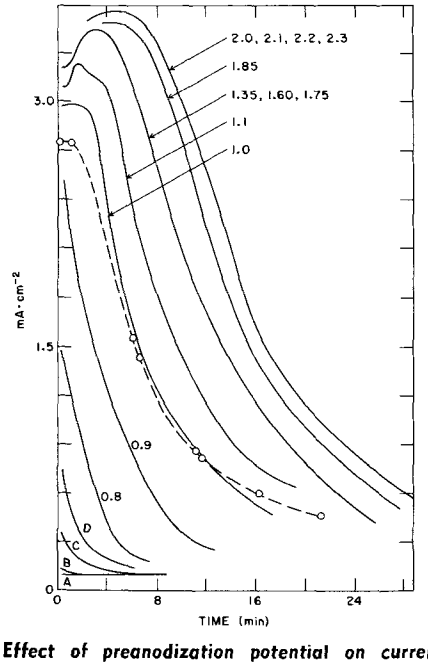

Fig. 2. Effect of preanodization potential on current-stability for h.e.r. at Pt rde. All curves at 1200 rpm in uncleansed 2N H_2SO_4 and constant cathodic applied voltage of 14.7 mv, RHE. Each curve labelled with potential (vs. RHE) of its 1 min (1200 rpm) pre-anodization except curves A, B, C, and D where these potentials were 0.0, 0.25, 0.5 and 0.7v, RHE, respectively. Broken curve: see text.

Apparatus and procedure.—Electrode activity was followed by recording the current at a given small overpotential under well-defined and constant mass-transfer conditions. This latter situation was achieved at a rotating disk electrode of Pt ($\approx$0.03-cm^2 area) spinning at a constant rpm ($\pm$1%) in an all-glass air-thermostatted cell at 25° $\pm$ 1°C. This apparatus has been described elsewhere (42).

In the case of the Fe(II)-Fe(III) system, voltages of $\pm$10 and $\pm$30 mv (constant and reproducible to within 0.1 mv) were applied between the rde and a large (40 cm^2) unpolarized Pt counter electrode in oxygen-free molar $HClO_4$, equimolar in Fe(II) and (III) at about 10^{-2}M. The general procedure was as follows. After the rde had been quiescent in the solution, under pure nitrogen, for a few hours or more, a small constant voltage was applied at 1500 rpm and the resulting current recorded for about 20 min. Then the still spinning electrode was given an A-C activation comprising 1 min at +2.34v, NHE (plating out oxygen at 120 ma · cm^{-2}) and 1 min at +0.1v, NHE. After 1 min at open-circuit the current was again recorded at the same rpm and applied voltage. All these electrical operations were done with a Sargent model XXI polarograph and potentials are given on the Stockholm sign convention. The results of the above procedure were compared in two different solutions. The first solution contained chemicals of the reagent-grade purity customary in most electrochemical studies. The second solution employed the same source of Fe(II) and $HClO_4$, but it was cleansed from surface-active contaminants by the charcoal treatment described above. The unpurified solution was made up with Fe(II) and (III) equimolar at 1.06 x 10^{-2}M in 1M $HClO_4$. From limiting currents at the rde in this solution, diffusion coefficients of 6.12 and 4.66 x 10^{-6} $cm^2 \cdot sec^{-1}$ at 25°C were calculated for Fe(II) and (III), respectively. Using these data, by a reverse process, the composition of the purified solution after half-oxidation was calculated as 1.32 x 10^{-2}M for both ferrous and ferric in molar $HClO_4$. Currents observed in the purified solution were multiplied by 0.80 to allow for this concentration difference and facilitate the comparison, in Fig. 1, of behavior in the two solutions.

In the h.e.r. study illustrated in Fig. 2 to 4, the same Pt rde was used in N_2-saturated molar H_2SO_4. However, this time, the counter and reference electrode was a reversible hydrogen electrode in the same solution separated from the main compartment by a fine frit. During these hydrogen deposition experiments, H_2 formed at the Pt disk was continually swept by the motion of the rde into a fringe of bubbles on the Teflon nonworking surface leaving the Pt surface perfectly bright. At rpm's above 1500 these H_2 bubbles were swept entirely away from the rde. The time-zero in Fig. 2 to 4 coincides with the end of the preanodization. Although the results of Fig. 2 to 4 were all obtained at the same constant applied voltage of about 14.6 mv, RHE, a substantially varying iR drop (R = 65 ohm) is included in this figure. For instance, in curve A of Fig. 2, η = 14.5 mv, RHE, whereas at the highest i in this figure, η = 5.5 mv. This fact, while causing the curves of Fig. 2 to 4 significantly to understate both the initial activation levels achieved and the rate of their decay, does not vitiate the discussion, in which only the relative shapes of these curves are invoked.

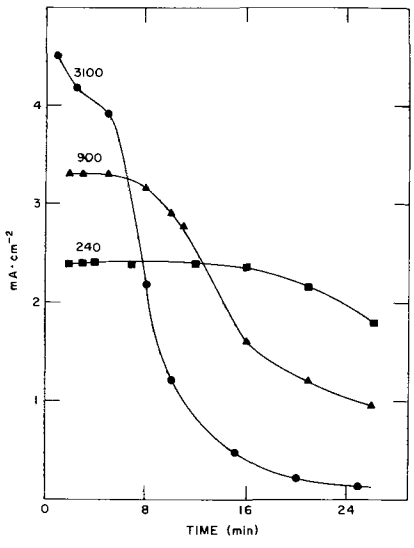

Fig. 3. Effect of stirring-rate on current-stability for h.e.r. at Pt rde. All curves, at labelled rpm's, in uncleansed 2N H_2SO_4 and constant cathodic applied voltage of 14.6 mv, RHE, were preceded by 1 min of preanodization at 2.0v, RHE (at 1200 rpm).

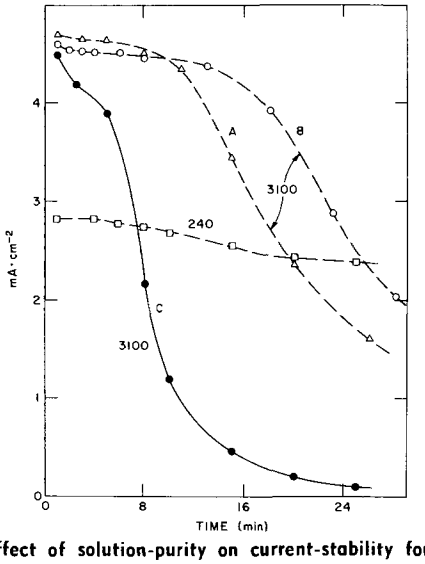

Fig. 4. Effect of solution-purity on current-stability for h.e.r. at Pt rde. All curves, at labelled rpm's and constant cathodic applied voltage of 14.6 mv, RHE, were preceded by 1 min of anodization at 2.0v, RHE (at 1200 rpm). Broken curves in charcoal-cleansed 2N H_2SO_4. Curve C in uncleansed 2N H_2SO_4. Before B, solution subjected to additional cleaning described in text.

Results and Discussion

Ferrous-Ferric.—Figure 1 shows the effect of the A-C treatment on current and its time-dependence for the oxidation of Fe(II) at the rde. (After correction for iR drops, the actual anodic η operating in this case was 27.4 mv and at 2.1 ma · cm^{-2}, the anodic i was about 40% of its limiting value.) In the unpurified solution (A', B') the A-C treatment caused an initial boost of about 70% in the current which then sank back quite rapidly toward its original level. On the other hand, in the purified solution (A, B) the A-C treatment raised i by only about 3%, and this increase took hours to recede. A' and B' were only approximately reproducible, but A and B in the purified solution were precisely reproducible, *e.g.*, even after eight days at open-circuit under pure N_2 curves A and B could be duplicated exactly.

Comparable behavior to that illustrated in Fig. 1 was obtained for both anodic and cathodic currents at ±10 and ±30 mv applied voltage. Thus the charcoal-cleansing treatment of the solution virtually nullified the effect of an A-C pretreatment on electrode activity. The "active-electrode" behavior obtained initially in B' following the A-C treatment was produced in A, B merely by the cleansing procedure. This is conclusive evidence for the impurity theory as opposed to the other theories concerning the mechanism of electrochemical activation. The 3% increase in current following A-C in the purified solution may arise from the presence of residual surfactants or from a small "platinization" effect.

Hydrogen evolution.—Figure 2, referring to uncleansed molar H_2SO_4, illustrates the activation levels achieved and their stability as a function of the potential (E_A) of the 1-min preanodization. All preanodization and the subsequent recording of current were done at 1200 rpm. Prior to curve A, the stationary rde was shorted to the reversible hydrogen electrode for 2 hr with N_2 bubbling through the solution. Then the other curves were obtained after 1-min anodizations at the potentials listed. The maximum activation effect, both in terms of the initial current and its stability, was achieved after E_A = 2.0v, RHE. Raising E_A to 2.3v, RHE, effected no greater activation. Taking rough account of the differing η's prevailing in the two cases, the initial current after E_A = 2.0v, RHE, was about one hundredfold greater than that after prolonged maintenance at the equilibrium potential (curve A). This is a much greater effect than the 70% increase in current observed in the Fe(II) $\rightleftarrows$ (III) system. As discussed in the experimental section, this is probably caused by the much lower (by 0.8v) rational potential in the h.e.r. study and its consequently greater sensitivity to surfactants in general and metal cations in particular. A significant feature of Fig. 2 is the fact that substantial levels of activation were attained even when $E_A < 0.9$v, RHE, where it is quite unlikely that the Pt surface is oxidized to any appreciable extent (43-45). The unlabeled broken curve of Fig. 2 is also relevant to this point. The pretreatment here was 24-hr soaking of the previously reduced rde in the cell at open-circuit under flowing N_2. The equilibrium potential just before recording of the curve was 0.95v, RHE. Since a 24-hr soaking in molar H_2SO_4 has been employed to completely free Pt electrodes from surface oxides (46), it is obvious that the recent reduction of a surface oxide had nothing to do with the considerable activation evident in this broken curve. Thus the platinization theory of activation is untenable for this system.

In the subsequent work illustrated in Fig. 3 and 4 a 1-min preanodization at 2.0v, RHE, was invariably used as this achieves maximum activation without an inconveniently high anodic current (actual anodic $i \approx 5$ ma · cm^{-2}). Employing this 1-min prepolarization at 1200 rpm, Fig. 3 shows the rpm dependence of current-stability for h.e.r. in uncleansed molar H_2SO_4. The radically faster decay at higher rpm shows the deactivation to be largely caused by mass transfer controlled adsorption of solution impurities and hence the activation must have been due mainly to the reverse process, *viz.*, impurity desorption. It is difficult to imagine how any structural change in the electrode surface, *e.g.*, recrystallization or oxide reduction could be affected by angular velocity of the electrode. Also, at this large concentration of H_2SO_4 (2*N*) adsorption of ions from H_2SO_4 could not be limited by mass transfer, *i.e.*, the gradual deactivation is not related to anion adsorption from the supporting electrolyte. The large increase in initial current with rpm, evident in Fig. 3, shows considerable control of the h.e.r. by concentration polarization of dissolved H_2. The polarization resistance R_η for the over-all process of hydrogen evolution, calculated from the initial current at 3100 rpm was ≈0.9 ohm · cm^2 (i = 4.5 ma · cm^{-2} at η = 4.0 mv). This would be somewhat lower after correction for residual concentration polarization, and thus the electrode is quite active (47). As the current diminished, during deactivation, so also did its rpm

dependence which eventually changed sign, *e.g.*, at the end of the 3100-rpm curve of Fig. 3; when i, η had changed from their initial values of 4.5 ma · cm^{-2} at 4.0 mv to 0.125 ma · cm^{-2} at 14.5 mv, lowering rpm from 3100 to 1200 boosted i to 0.2 ma · cm^{-2}, *i.e.*, nearly 100% increase. Obviously, the deactivation had caused a change in mechanism of the h.e.r. It is well-known that, at contaminated Pt electrodes, the combination of adsorbed H is inhibited, *e.g.*, (18b). Hence it seems possible that, at the deactivated (contaminated) electrodes, electrochemical desorption becomes rate-limiting, *viz.*, $H_{ads} + H^+ + e \rightarrow H_2$. An increase of stirring, by tending to clear the surface of H_{ads}, might then cause a decrease in current.

Figure 4 shows the effect of solution purity on the stability of the h.e.r. current after a 1-min (1200 rpm) preanodization at 2.0v, RHE. A greatly enhanced stability in the charcoal-cleansed solution (broken curves) is further support for the idea that the activation effect is primarily one of impurity desorption. That the residual instability in the cleansed solution is still largely due to solution impurities is shown by its pronounced dependence on rpm. Curve B, like A, was in a charcoal-cleansed solution at 3100 rpm but, before B, the solution was given an additional cleansing as follows. As an integral part of the cell it contained a 40 cm^2 auxiliary smooth Pt electrode which, during every curve of Fig. 2-4 excepting B of Fig. 4, was standing idle in the solution at an open-circuit potential of $\approx$ + 0.9v, RHE. However, before B, this large electrode was shorted to the RHE for 40 min with N_2 bubbling through the solution. Since Fig. 2 showed that Pt is very much more heavily contaminated at 0.0v than at 0.9v, RHE, it was anticipated that this procedure would significantly improve solution cleanliness. The higher stability of current in B shows this was true although not quite to the extent hoped for. (The open-circuit potential of the large electrode rose slowly during the recording of B, but even at the end of B it was only $\approx$0.1v, RHE.)

Thus, Fig. 2 to 4 show that, at least in 2*N* H_2SO_4, the decay in activity of Pt electrodes for h.e.r., following activation, is due mainly to the readsorption of solution impurities, not to the relaxation of a disturbed structure in the Pt surface, to the readsorption of anions from H_2SO_4, nor to a gradual "hydrogen poisoning" effect. H_2SO_4 contains a wide spectrum of surface-active poisons which are progressively desorbed with increasing potential between 0.0 to 2.0v, RHE.

Oxygen reduction.—The present study of electrochemical activations was about to be concluded by examining oxygen reduction in acid when this was made unnecessary with the publication of the work of Damjanovic, Genshaw, and Bockris (34). They investigated O_2 reduction in 0.1*N* H_2SO_4 at a Pt rde. After an activation treatment comprising 1.4 and 0.0v, RHE, for 1 min each, it was found that, while potentiostatting at potentials <0.8v, RHE, the cathodic current decayed at a rate which increased greatly with rpm but was greatly lessened (by × 10-100) after purifying the solution. The purification involved circulating the solution for 5 to 10 hr through a platinized Pt gauze adsorbent maintained at 0.3v, RHE. Thus their activation effects were caused mainly by impurity desorption. They also found that, at potentials anodic to 0.15v, RHE, H_2O_2 was produced only in a dirty solution. In a purified solution at these potentials, O_2 was reduced wholly to H_2O, the limiting current being attained at 0.5v.

In unpurified solutions, after activation, scanning at constant rpm cathodically from 0.9v, RHE, produced a maximum current at 0.6v, RHE, in their manual voltammograms. With further cycling of potential between 0.9 and 0.0v, the height of this maximum fell radically as time elapsed, *e.g.*, 20 min after the activation the maximum current was only 7% of its initial value. They associated the maximum with the idea that, as the potential falls during a cathodic scan, a progressively more extensive contamination of the electrode occurs producing a type of site where O_2 is reduced only as far as H_2O_2 (at least if $E > 0.15$v, RHE). They also postulated that the reduction to water occurs on a different type of site, not subject to the influence of contaminants and does not have H_2O_2 as an intermediate. Apart from the inherent improbability of these postulates, if this latter type of site is uninfluenced by contaminants then contamination can reduce the current only insofar as O_2 reduction is diverted to the 2-electron process at the contaminated sites, *i.e.*, a maximum lowering of 50% as compared with the factors of 10 or more by which currents in the later stages of their Fig. 5 differ from those immediately following the activation.

There seems no justification for their identification of impurities as exclusively or even mainly organic in character. After activation at 1.4v, RHE, the gradual diminution of current during successive cycles between 0.9 and 0.0v could, as they say, be due to the partial oxidation of organic impurities to even more tenaciously adsorbable products. However their alternative explanation, in terms of a wide spectrum of impurities, a fraction of which desorbs only above 0.9v, seems just as cogent. If, after an activation at 1.4v, the potential is not allowed to exceed 0.9v, then this fraction will gradually readsorb in a pseudoirreversible manner causing the gradual reduction in peak current which they obtained. They advance no reason why various metallic cations could not form part of this spectrum of impurities.

Thus, for the three electrode reactions described in this paper it has been shown that impurity desorption is by far the most important result of brief electrochemical activations. Other effects like the creation of a disturbed Pt surface, the desorption of ions derived from the supporting electrolyte, or, in the case of the h.e.r., the stripping of absorbed H from surface layers may quite possibly be present but appear inconsequential to the electrode kinetics.

Activations involving protracted preanodizations.—In contrast to the conclusion, expressed in the preceding paragraph, that brief activations act merely by impurity desorption, the work of Shibata (12) contains evidence linking activations produced by protracted preanodization with a change in structure of the superficial layers of Pt atoms, and this work merits further discussion. He found that, although a wide variety of preoxidation treatments resulted in the same high, initial value of electrode activity for H^+ reduction, the stability of this activity differed profoundly according to the nature and duration of the pre-oxidation procedure. Assuming that each preoxidation completely desorbed impurities and that electrode activation was due solely to this desorption, he reasoned that a similar time-decay of activity should be observed, as contaminant readsorbs from bulk solution, irrespective of the detailed nature of the preoxidation. Hence he discarded the impurity theory and supposed the activation to originate in a superficial structural change whose lifetime increased with severity of the preoxidation. Shibata's quite complicated pretreatments, applied to a number of 1-cm^2 Pt foil electrodes included aging for 2 weeks in a hydrogen atmosphere at room temperature followed by a preoxidation (*a*) by soaking in chromic acid at 80°C for 1, 15, or 60 min, or (*b*) by anodization in 1*N* H_2SO_4 at 100 ma·cm^{-2} for 0.25, 1, or 28 hr. After washing in water followed by cathodization at 20 ma·cm^{-2} for 200 sec, the electrodes were placed in H_2-saturated 1*N* HCl for a definite time before measuring their activity in this solution.

In all cases the electrode activity fell off with time from roughly the same initial high value. The various preoxidations yielded activities increasing in stability along the series listed above. In the least stable case, after chromic acid pretreatment for 1 min, the activity

in HCl dropped a hundredfold in 3 hr. At the other extreme, 28 hr of preanodization produced a high activity that had diminished only 10 to 20% after 30 hr in HCl. His initial activity corresponded to an over-all R_η for h.e.r. at 15°C in 1*N* HCl of ≈50 ohm·cm². This relatively large value [cf. ref. (47)] is probably due, not to a relative inactivity of Shibata's electrodes but to the fact that his measurements were made in unstirred, H_2-saturated solution, *i.e.*, the 50 ohm·cm² figure must contain a large contribution arising from concentration polarization of dissolved H_2. Considering the fact that his solutions were not particularly pure with respect to surface-active material (no preelectrolysis or adsorption technique was used) the activation produced by his extended anodization was unprecedentedly stable.

Another striking feature of Shibata's results are the two arrests in cathodic chronopotentiograms of his anodically activated electrodes. The first arrest at 0.6v, NHE, corresponded to a surface charge of 4 mC·cm^{-2}. Similarly high charges have been observed previously at this potential (43, 48). The second arrest at 0.3v, NHE, lengthened with duration of the preanodization (after an induction period of about 30 min) and was 36 mC·cm^{-2} for an electrode which had been preanodized at 0.1 amp·cm^{-2} for 28 hr. The only arrest previously described in the literature at this potential is that caused by monolayer hydrogen adsorption, accounting for 0.5 mC·cm^{-2} at the most (49). $i\tau$ for the second arrest was independent of cathodic i over at least 10 to 600 μa·cm^{-2} (50) and this arrest thus arises in a surface film of some kind. Even allowing a roughness factor of 2.5 (49) a film equivalent to 36 mC·cm^{-2} corresponds to associating 40 oxygen atoms with each surface Pt. Shibata attributed the second arrest to the reduction of such a "thick" surface oxide and the stable high activity persisting after this reduction to residual strain remaining in the surface layers. If the temperature of Shibata's preanodizations was <21°C, irrespective of the severity or duration of the anodic treatment, the second arrest was never observed in subsequent cathodic chronopotentiograms (50). Shibata's discovery of this low-potential arrest during the reduction of Pt electrodes subjected to excessive prior anodization was confirmed and extended by Kozawa (20b). After constant current anodization in 1*N* H_2SO_4, Kazawa recorded voltammograms in N_2-saturated 1*N* H_2SO_4 from 0.9 to 0.0v, NHE. As well as the normal cathodic peak at 0.6v he got a second peak at 0.2v the height of which increased with the duration, current-density, and temperature of the anodic pretreatment. As in Shibata's experiments, the charge corresponding to this low-potential peak, under extreme conditions, greatly exceeded that of the first peak. During anodization at 300 ma·cm^{-2} at 40°C in 1*N* H_2SO_4 a Pt anode acquired, after 3 hr, a yellow film whose color deepened with continued electrolysis.

This Japanese work, indicating as it does the existence of an electrochemically well-differentiated second oxide formed at very severely oxidized Pt, is very interesting and appears to be unique. The latter is certainly due to the fact that with the notable exception of the persulfuric acid manufacturers, extended anodization of Pt is rarely practiced by electrochemists. In view of the innumerable papers published on the 0.6v oxide, the deafening silence with which electrochemists have greeted the 0.2v oxide is surprising.

The work of Hoare (51, 52) has some similarity to that of Shibata in that an extended period of preoxidation was employed resulting in a stable high activity. After preoxidation by immersion in concentrated HNO_3, Hoare measured the activity of an electrode by its ability to retain an open-circuit potential of 1.229v, NHE, in oxygen-saturated acid solution (51), or to catalyze the reduction of oxygen in acid (52). Hoare's activities were significantly less stable than Shibata's probably because of the greater severity of the latter's preoxidations. An important feature of Hoare's results is the fact that the development of a stable activity depended on an immersion in HNO_3 for a minimum of about 50 hr, a much greater time than that needed to free the electrode surface from adsorbed contaminants. This fact argues for Hoare's contention that his activation was caused by some change extending several monolayers into the platinum. He identifies this change with the formation of a "Pt-O alloy" layer (53). Cathodic chronopotentiograms on Hoare's activated electrodes revealed only the single arrest customarily obtained at about 0.7v, NHE, in acid (54). However, in acid solution swept with H_2 gas, Hoare's activated electrodes took about 40 min to arrive at the same potential as reduced platinum compared to 4 min for electrodes oxidized by conventional anodization (51, 53). Assuming that Hoare had carefully removed adsorbed nitrogeneous species after the HNO_3-soaking, this would indicate that the HNO_3-soaking yielded an oxide more stable or more extensive than that obtained conventionally. This then is another significant similarity to Shibata's results as opposed to those normally obtained.

To sum up, both Hoare and Shibata activated platinum electrodes under conditions which appear to exclude impurity desorption as the cause of activation. Both employed protracted preoxidations and attributed the resulting activation to the presence (Hoare) and recent presence (Shibata) of a surface oxide qualitatively different from that rapidly reduced at 0.6v, NHE, in acid solution. It appears likely therefore that the electrochemical activation of platinum electrodes must be divided into two classes: (*a*) conventional anodizations of the order of a minute in duration which merely clean the electrode surface by desorbing impurities, and (*b*) severe oxidations extending over periods of many hours which appear to effect a more penetrating oxidation and an activation which is very stable, even in solutions not particularly clean with respect to adsorbable impurities.

Apart from the work of Shibata and Kozawa already cited, other evidence exists for postulating a qualitative change in the nature of the anodic film on Pt under extreme conditions of oxidation. For instance, several workers (43-45) have found definite changes in slope in plots of mC·cm^{-2} *vs.* *E* at about 1.8v, NHE, in acid solution. (mC·cm^{-2} is the charge required for the galvanostatic reduction of an electrode after its potentiostatic oxidation at potential *E*.) Mayell and Langer (43) observed a distinct maximum in such plots at 1.8v followed by a plateau. These authors proposed a series of platinum-oxygen couples culminating in a "tight" platinum oxide at potentials above 1.8v. Also, in Tafel plots for the oxygen evolution reaction at Pt in $HClO_4$ or H_2SO_4, a rapid transition toward higher overvoltages is observed at high current densities (55). This transition is associated with the incipient participation of anions in the electrode reaction caused perhaps by a qualitative change in the nature of the oxide film. It is relevant here to mention that, in 1922, by fusing $NaNO_3$ with chloroplatinic acid, Voorhees and Adams (56) arrived at a platinum oxide which is readily reduced by hydrogen giving a Pt black of unprecedentedly high and reproducible activity. This Pt black is still the best Pt catalyst available to the organic chemist for hydrogenations (57). In view of all the foregoing, it does not seem unlikely that the prolonged maintenance of platinum electrodes in a severely oxidizing environment might produce the more penetrating oxidation envisaged by Shibata and Hoare and hence a type of activation quite distinct from that associated merely with "anodic cleaning" of electrodes.

Manuscript received Feb. 1, 1967; revised manuscript received June 22, 1967. This work was performed under the auspices of the United States Atomic Energy Commission. The paper was presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Correction

The following corrections are indicated for "Electrochemical Reduction of Aromatic Hydrocarbons in Ethylenediamine" by H. W. Sternberg, R. E. Markby, I. Wender, and D. M. Mohilner, **143**, 1060-1062 (1966).

In the text to Fig. 3, ref. (6) and (10) should be replaced by (1) and (3).

The subscripts s in e^-_s should be omitted in the equations on the second column of page 1062. If any subscript is to be used, it should indicate the phase in which the electron occurs. For example, e^-_{pt} indicates the electron in the platinum. The equations should read

$$\begin{array}{rl} Li^o_s = Li^+_s + e^-_{pt} & E_i = 1.1 \\ B_s + e^-_{pt} = B^-_s & E_i = -1.4 \\ \hline B_s + Li^o_s = Li^+_s + B^-_s & E_o = -0.3 \end{array}$$

Li^o_s stands for $Li^+ \ldots e^-_s$ and e^-_s signifies the solvated electron in contrast to the electron in the platinum e^-_{pt}.

A simpler and perhaps more informative formulation would be the following

$$\begin{array}{rl} e^-_s = S + e^-_{pt} & E_i = 1.1 \\ B_s + e^-_{pt} = B^-_s & E_i = -1.4 \\ \hline B_s + e^-_s = S + B^-_s & E_o = -0.3 \end{array}$$

Here S indicates the solvent molecules required to solvate an electron.

On the Activity of Platinum Catalysts in Solution

I. Effects of Thermal Treatment and Chemical Etching on the Pt-O/Hydrogen Specific Reaction Rate

Theodore B. Warner, Sigmund Schuldiner, and Bernard J. Piersma[1]

Naval Research Laboratory, Washington, D. C.

ABSTRACT

The effects of thermal treatment and chemical etching of platinum on the specific rate of the chemical reaction of chemisorbed oxygen with hydrogen were determined. The hydrogen was present in electrochemically clean 1M H_2SO_4 and in the derma of the metal. On successive thermal treatments of bright Pt beads, which were heated to the melting point and then slowly recrystallized under high temperatures, the specific rate varied randomly from trial to trial. Where heating was more uniform, and the cooling rate slower, reaction of hydrogen with Pt-O was usually faster. Repeated aqua regia etching of a given Pt bead caused monotonic improvement until a rate between 0.014 and 0.021 amp/cm^2 was attained. Rates on Pt wire electrodes, which probably differed from the flame-formed Pt beads both in average crystallite size and in number of defects (created by the drawing process and only partially removed by subsequent annealing), were highly variable, but considerably lower than on beads. Surfaces whose activity for the Pt-O/hydrogen reaction differed manyfold showed no differences in anodic charging curves nor did electrochemical rates of water oxidation at +0.617 and +0.587v (NHE) or reduction of hydrogen ions at +0.300v differ. It appears that many electrochemical reactions are insensitive to these differences in surface condition. Because of its great sensitivity to catalyst pretreatments, the Pt-O/hydrogen reaction is identified as a "demanding reaction," especially useful for identifying and examining certain variables affecting contact catalysis in solution. Since impurity sorption is one such variable, the rate of this reaction is one of the most responsive cleanliness tests available.

Boudart *et al.* (1) have pointed out that the rates of some catalyzed reactions are much more sensitive to subtle nonuniformities of solid surfaces than others. They suggested that it may be important to distinguish between these different types of reactions, and proposed the terms "demanding" and "facile" reactions. They define a facile reaction as one for which the specific activity of the catalyst is practically independent of its mode of preparation. The selection and use of demanding reactions to monitor effects of changes in catalysts should offer considerable advantages in precision and discrimination.

It was previously found (2) that the rate of chemical reaction of oxygen chemisorbed on a smooth platinum electrode with hydrogen present both in 1M H_2SO_4 solution and dissolved in the electrode was very sensitive to changes in the composition of the surface. In particular, absorption of a monolayer of oxygen atoms in the top few atomic layers of the metal caused a change in the reaction mechanism and a sixfold reduction in rate, *i.e.*, the Pt catalytic activity depended on the amount of dermasorbed oxygen, even when the amounts were much less than a monolayer. This reaction rate could be measured simply, quickly, and fairly precisely by observing the time required for potential decay after depositing known amounts of adsorbed and/or dermasorbed oxygen with an anodic current pulse. It appeared to be a demanding (1) reaction, well suited to the study of other factors important in catalysis.

A study of catalysis must have as one prerequisite a way to eliminate effects due to impurity sorption. The responsiveness of the rate of the Pt-O/hydrogen reaction to surface variations made it more sensitive to trace impurities than any other rapid test we have had available, and accordingly the investigation was divided into two main sections. First, the effects of varying degrees of solution and metal cleanliness on rate were examined to determine under what conditions platinum could be considered sufficiently clean so that changes in catalytic behavior due to metallic factors were not obscured. The usefulness of this reaction rate as a cleanliness test was concurrently examined. Second, having established these criteria and while maintaining the necessary conditions, the effect on rate of changing the atomic arrangement and/or the surface condition of the metal was determined. This study was not designed to identify which types of surface conditions are the most active, although inferential evidence was obtained, but rather to demonstrate that subtle metal phase changes in a clean catalyst surface can have large effects on some reaction rates. The sensitivity of the studied reaction makes it a particularly useful experimental probe. Finally, the question was examined, will surface morphology changes that affect the catalytic activity for this chemical reaction necessarily cause changes in electrochemical reaction rates?

Apparatus and General Procedure

The gas-tight electrochemical system, He and H_2 purification trains, solutions, and general procedures were essentially the same as previously used (2, 3). The cell contained a large platinum gauze counter electrode (about 80 cm^2 wetted geometric area), a Pt wire reference electrode 0.064 cm diameter extending about 3 cm into the solution, a miniature glass reference electrode, and two bright Pt bead working electrodes with areas about 0.1 cm^2. The beads were formed by melting the end of 99.99% pure Pt wire. One bead was mounted by sealing the wire into a Pyrex tube, the other was mounted in a Teflon tube and sealed with molten polyethylene. True electrode areas were determined from the amount of oxygen deposited in an anodic charging curve (3) and all areas given are true areas unless otherwise specified. The oscilloscope was a Tektronix Type 547 with Type 1A1 preamplifier; the electrolyte was 1M H_2SO_4

[1] National Academy of Sciences Postdoctoral Resident Research Associate at NRL. Present address: Eastern Baptist College, St. Davids, Pennsylvania.

at 25° ± 1°C, and all potentials are given *vs.* the normal hydrogen electrode.

The cell was cleaned at different times in two different ways. The first method (5) was with hot HNO_3 followed by numerous rinses with triply distilled water. In the second method, the reference electrode and polyethylene-sealed bead were removed, and after cleaning with hot nitric acid the cell and remaining electrodes were steamed for several days while carrying the condensate out a side arm in a constant stream of purified H_2. Periodically the cell was allowed to fill; on one such filling, NaOH was added to make hot 1M NaOH and the cell was soaked for 1 hr, and then rinsed by further steaming. Finally, condensate was again allowed to collect and concentrated reagent grade H_2SO_4 was added to make up the electrolyte. In this cleaning technique, the cell is isolated from the room atmosphere at all times except when adding the NaOH or H_2SO_4, or when replacing the electrodes. Laboratory air was continuously purified (4).

Solutions were cleaned by electrolysis under H_2 or He at 50 to 250 ma with the Pt wire electrode as cathode and all other electrodes as anodes, the wire subsequently being cleaned with HNO_3 and an H_2/O_2 flame. Any electrode removed was rinsed with concentrated HNO_3 and water before reinsertion.

Electrodes in the cell were cleaned by one or more of the following anodic treatments, listed in order of increasing severity and effectiveness: level 1, single anodic pulses just up to O_2 evolution region, as in Fig. 1; level 2, multiple pulses as in 1 with partial recovery of potential between pulses; level 3, d-c anodization at 3 amp/cm²; level 4, repeated (200/min) 7 amp/cm² pulses for periods of 1 to over 10 min.

Two classes of impurities could be distinguished by their influence on charging curves and by the difficulty of their removal from an electrode surface or from solution. Their exact natures are unknown; they will be defined as "readily oxidizable" or "difficultly oxidizable" impurities as follows. The first category could be removed from an electrode by level 1 or 2 anodization and could be removed from solution by extended electrolysis. The "difficulty oxidizable" could be removed slowly and sometimes only partially with level 3 or 4 treatment, and they could not be removed from solution by electrolysis; they could be eliminated by cleaning the cell and charging with fresh solution.

The strength of the bond between a foreign substance and a platinum lattice may vary continuously from weak physisorption to lattice incorporation. Impurities will be arbitrarily and operationally divided into those removable by the cell and cleaning techniques used, and those not, with the former being called "sorbed impurities" and the latter "lattice impurities." It should be understood that under this division a sufficiently tightly sorbed species could be classed as a lattice impurity and would be experimentally indistinguishable from one.

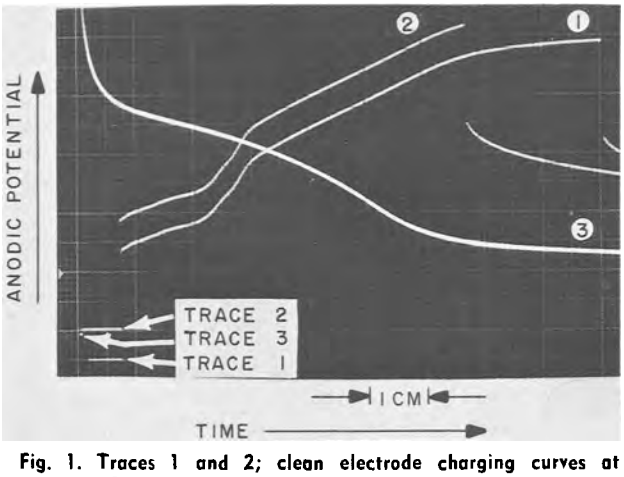

Fig. 1. Traces 1 and 2; clean electrode charging curves at 2.3 amp/cm², 25°C; time = 50 μsec/cm, voltage = 0.5 v/cm. Trace 1 shows a full charging curve up to and into the O_2 evolution region, used to determine how much charge was required to deposit a monolayer of Pt-O. Trace 2 represents the pulse, adjusted in length such that just one monolayer of Pt-O was deposited, whose decay time was subsequently measured. Trace 3 is the subsequent decay curve; time = 5 msec/cm, voltage = 0.2 v/cm. Decay time ≈ 30 msec. The starting point of each trace is 0.000v. The end point of trace 2 is 1.68v, just below the 1.76v normally associated with the beginning of the O_2 evolution region (3).

Measurement of Decay Times

The Pt electrode was exposed to one-atmosphere hydrogen-saturated electrolyte until an equilibrium H^+/H_2 potential was reached. The electrode was then anodized with a single constant-current pulse such that just one monolayer of atomic oxygen was deposited. Current densities of 2.5 to 7.0 amp/cm² were used to avoid dermasorption of oxygen in the metal lattice. Also, because of these high current densities and since the pulses were terminated before the O_2 evolution region was reached, an insignificant amount of O_2 was formed. At pulse cut-off, the electrode potential became less positive as Pt-O was reduced by reaction with hydrogen. The time required for the potential to drop to a plateau at about 0.3v is defined as the decay time. At 0.3v, the electrode is virtually free of O_{ad} and significant H sorption commences. Figure 1 shows a typical display; for details see ref. (2). In ref. (2) varying amounts of oxygen q_o were deposited on the electrode, and the observed decay times t_{decay} were converted to reaction rates i_r where

$$i_r(\text{amp/cm}^2) = \frac{q_o(\text{coul/cm}^2)}{t_{decay}\ (\text{sec})} \qquad [1]$$

In this study, the t_{decay} resulting during removal of one monolayer of oxygen (420 μcoul/cm²), deposited on the electrode in the manner described above, was defined as t_o and reaction rates are frequently discussed in terms of the corresponding t_o. This procedure eliminates need for *a priori* knowledge of electrode area; it measures a quantity related to specific reaction rate, automatically adjusted for surface area changes. In these terms, the i_r previously found for a clean system of 0.014 amp/cm² [from Fig. 4a of ref. (2); blank correction requires that ordinate values of Fig. 4 and 5 be divided by 2] is equivalent to a monolayer decay time, t_o, of 30 msec.

During pulse cut-off and potential decay, the impedance between the working electrode and any other cell component must be high enough so that an insignificant current flow results. This is achieved by using a 10 megohm probe [for circuit see Fig. 3, ref. (3)] and adding blocking diodes to the pulse generator output to impede back flow of current after the pulse terminates [as in Fig. 2, ref. (6)]. Long decay times of over 100 msec that later decrease with additional purification are excellent evidence for the absence of significant current leakage. Absence of long t_o in less active systems would indicate undetected leakage paths.

Previous results (2) showed that decay times in clean solutions are not a function of hydrogen stirring rate from 0 to 560 ml/min, nor of current density in the range used. The t_o values are independent of soak time (time elapsed since last polarizing pulse) from 1 min to many days; temperature is not important, nor is hydrogen partial pressure (although longer soak times are required at lower partial pressures).

Cleanliness Criteria

For the purposes of this paper an electrode or a solution has been called clean if the following criteria were met. These criteria were monitored during the course of the experiments and were also used to estimate relative amounts and types of contaminants, when present.

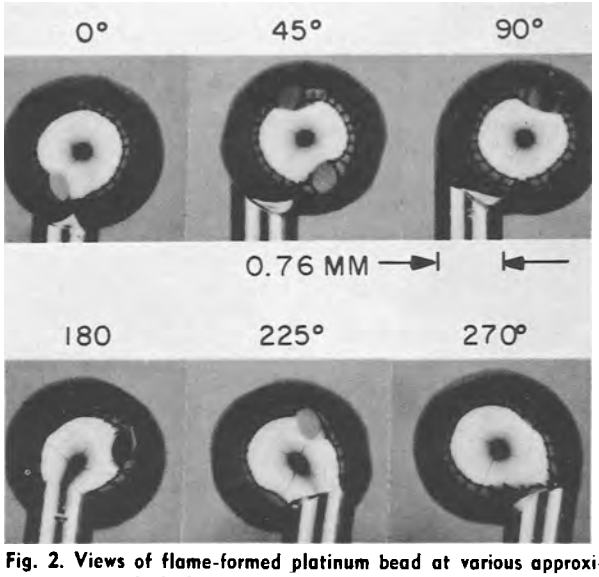

Fig. 2. Views of flame-formed platinum bead at various approximate amounts of clockwise rotation. Magnification ≈ 12X. Photos by A. C. Simon.

Hydrogen electrode potentials.—For a clean system, at $P_{H_2} = 1$ atm, the potentials of the four smooth platinum electrodes differed by no more than 0.1 mv.

Current-voltage relations.—Recent (7) measurements in He-saturated solution in a separate "improved gas-tight system" showed that in that system the rate of electrode recontamination with oxidizable or reducible species was no more than one millionth of the surface area per second, roughly equivalent to contamination rates in a 10^{-12} Torr vacuum system. Further, there was no indication of the presence of any nonoxidizable electrode poisons. Certain of the present experiments were carried out in this improved gas-tight system immediately after termination of the previous work (7).

Anodic charging curves.—Figure 1 represents curves typical of a clean system (8). They show detail in the hydrogen region, a small plateau in the double layer region, and a linear oxygen region. To test system cleanliness with charging curves, it is first left under flowing hydrogen at open circuit for extended periods (usually 16-64 hr, sometimes longer). Polarization resulting from the very first pulse applied is photographed. After several intermediate charging curves to clean the surface, followed by a soak time of no less than 4 min, an additional pulse is photographed without changing trace position. If the two superimposed traces are essentially the same, and if they meet the above criteria concerning shape, the system is judged clean. If the pulses do not coincide, the differences in pulse shapes when correlated with soak time can give information on the type and amounts of contaminants present.

Decay time.—In the course of this work it was found that a low decay time together with a linear O_{ad} formation region is a dependable measure of cleanliness of an electrode and its associated electrolyte. Whenever possible, one electrode with a t_o below 30 msec was obtained and used as a probe for solution condition while the other electrode was treated in varying ways. So long as the solution probe electrode retained its t_o, short and unchanging, the solution was considered clean and unchanging.

Results

Effects of impurities.—Decay times are directly related to solution and/or platinum cleanliness. Given an imperfectly cleaned solution, as shown by charging curve tests, newly prepared Pt electrodes generally showed relatively high t_o of over 100 msec. This initial value was dependent on a number of variables. Repeated solution and electrode cleaning caused a steady reduction of t_o to some limiting value, which will be called the "base value" of t_o. When this base value was reached, further cleaning of solution and electrode had no effect on t_o, and unchanged values of t_o could then be observed over time periods of many weeks. When a base value was attained, other tests indicated a clean solution. Base values attained on different electrodes differed considerably, ranging from 25 to over 100 msec.

Factors other than solution or platinum cleanliness influence decay times. Two Pt electrodes, nominally the same and in the same solution at the same time usually showed different initial values of t_o, differing on occasion by almost two orders of magnitude. Extended cleaning generally yielded base values of t_o that also differed, a typical pair being 32.7 ± 3.2 and 100 ± 15 msec (all errors given for t_o are standard deviations). Previous work[2] indicated that t_o of 29.6 ± 3.0 msec could be attained in clean solution, so that Pt with a significantly higher t_o was assumed to be capable of increased catalytic activity. Of the pair of electrodes mentioned above, the one with an invariant t_o of 33 msec indicated that the solution was clean and unchanging. The other was unaffected by any of the above cleaning techniques up to and including level 4 anodization while simultaneously boiling the solution. Other tests gave no evidence of impurity present. It was concluded that some factor other than solution cleanliness or undesired sorbed species also influenced t_o. In a series of experiments, the higher base value t_o of a given pair was independent of type of electrode mounting (glass or Teflon-polyethylene) eliminating that variable. The two-electrode studies described above also showed, that given a clean solution, as indicated by the solution probe electrode, a newly prepared Pt electrode could be inserted into the cell without detectable solution contamination. This result was a necessary precondition to experiments described below. Such a newly inserted electrode would sometimes have sorbed impurity on it, as indicated by high initial t_o, that could be removed by the cleaning techniques used. The resulting base value t_o varied over wide limits.

Decay time on "active" platinum in a clean solution increases on introduction of impurities to the solution. Active Pt is here defined as that with $t_o < 35$ msec in clean solution. The amount of impurity required to cause a detectable change in t_o is related to the base value of t_o originally shown; the lower the base value t_o, the more sensitive it is to traces of impurities. Clean solutions containing two active electrodes were observed over long periods under conditions, such as frequent opening of the cell for short periods to insert or remove one electrode, where gradual solution recontamination from impurities in the room atmosphere was expected to occur. The presence or absence of impurity was estimated from charging curves, the relative amounts of impurity from amount accumulated in a given soak time. Simultaneously, the base values of t_o were monitored as well as the amount and level of electrode cleaning required to reattain the base value after long times on open circuit.

In solutions believed to be very clean, the decay time from the very first charging curve applied after 12 days soak time was the same as the base value. With continued use, however, the "first decay time" after a given soak time became higher and higher and successively more severe electrode cleaning was required to bring t_o back to the base value. Finally, the original base value became unattainable, and "apparent base values" were observed that rose as more impurity collected in solution. These apparent base values were unaffected by electrode cleaning up to level 4, or by extended preelectrolysis of solution. Under these conditions, both the solution probe

[2] Data taken from that used in ref. (2), Fig. 4a, and i_r values converted to corresponding t_o.

electrode and the working electrodes would show similar rises in apparent base value t_o, that is, they both appeared to be controlled by some external factor and took essentially the same value as they slowly rose together.

Rising apparent base values were connected with difficultly oxidizable impurities described more fully below. The point in this sequence at which such an impurity could be observed on the electrode using the charging curve test was highly variable, but, in general, first decay times observed after a few minutes soak that were higher than the base value would signal the presence of difficultly oxidizable impurity under conditions where a charging curve after 8 to 24 hr frequently would not. On the other hand, when impurity level in the solution was high enough to cause apparent base values to rise, its presence could be confirmed *via* charging curves after 8-hr soak periods.

This difficultly oxidizable impurity had a number of interesting properties. It was classed as difficultly oxidizable because it could not be removed from solution by extended electrolysis, and because, when present in sufficient concentrations, it could not be removed from the electrode by anodization, as indicated by charging curves and by the rising apparent base values. Yet after long standing in H_2-saturated solutions, charging curves showed a species on the electrode surface that was oxidized at about 1v. After this readily oxidizable species was removed, the electrode still had impaired catalytic activity, yet charging curves gave no indication of any remaining impurity. It was tentatively concluded that this was some nonvolatile, oxidized form of an impurity that could interact only slowly with H_2 to give an oxidizable product on the electrode surface yet was itself not removed with anodic treatment. Note the interesting similarities between this substance and CO_2, which, when present in solutions containing H_2 also causes anodic charging curves showing something being oxidized at around 1v (9).

The importance of these observations is that difficultly oxidizable impurities might accumulate in any real system under prolonged use. Even if the amount of surface covered with these impurities were too small to influence charging curves, demanding reactions such as the Pt-O/hydrogen reaction could be affected. Hence, to study such demanding reactions the usual kinds of anodic cleaning may not suffice.

The above results indicated that the increasing t_o were due to impurity sorption. However, it was also possible that some other process, such as a slow change in the catalyst lattice, could be affecting the base t_o. If the increase in t_o had been due to sorption of some impurity very resistant to removal by anodic polarization, then recleaning the solution and cell should cause the original value of t_o to be regained. These treatments would not affect a changed catalyst structure, however. Experimentally, the original base value could be regained by recleaning the cell, recharging with fresh solution, and again cleaning solution and electrodes *in situ*. In a typical case, the initial base value was 23 msec, the highest apparent base value was 55 msec, and the regained base value after recleaning was 25 msec. It might be argued that the solution electrolysis following recleaning of the cell would once again modify the base lattice to make it active again; however, the results in the paragraphs on Thermal Annealing below show that anodization of a surface is not a necessary prerequisite for an active surface, and further, that anodization of an inactive but clean surface will not affect its activity in the least.

Behavior of platinum with high t_o in clean solutions.—If under the treatments described, the only variable causing changes in t_o were sorbed impurity, and if a system were sufficiently clean initially, then the initial value t_o should be the same as the base value. It was desirable to obtain evidence in a system whose cleanliness was measured by an independent method. The improved gas-tight system (7) was such a system. The initial value of t_o was 270 msec; it was unaffected by increasingly severe anodic treatment up to level 4 while simultaneously boiling the solution.

Variables intrinsic to platinum.—Different Pt electrodes, nominally the same, showed widely differing t_o even when clean and in clean solutions. The variables that could affect the catalytic activity for the Pt-O/hydrogen reaction five or tenfold appeared to be fixed in the platinum when the electrodes were frozen. The following experiments were primarily designed to show that this was the case. The Pt surfaces were rearranged by remelting and by different heat-treatments, and the effect on decay time was observed. Surfaces were also etched with aqua regia. In the following work, unless otherwise specified, solutions were clean as indicated by an active solution probe electrode with unvarying decay time, usually less than 25 msec, as well as all other tests. Effects due to impurities introduced into the cell on a newly inserted electrode were eliminated, and all t_o under these conditions are necessarily base values.

Thermal annealing.—Platinum beads were melted and recrystallized repeatedly with determination of t_o between subsequent treatments. They had highly variable decay times on successive trials. Figure 2[3] shows typical appearance of a well-annealed Pt bead before mounting. It is nominally spherical with a number of well-developed flat regions that may have crystallographic significance. Not only are the developed flats regularly arrayed, but emerging flat regions are also part of the pattern, for example, the emerging regions at 2 and 8 o'clock in the 45° view are spaced between the large flats at 11 and 5 o'clock. A similar emerging flat can be seen in the 225° view. Under proper conditions, an entire bead could be held molten for as long as desired in a relatively large flame whose temperature was adjusted by changing the H_2/O_2 ratio. By reducing temperature gradually the bead could also be kept indefinitely just below the crystallization temperature and then slowly cooled from there. Beads so formed had variable t_o ranging from 20 to over 100 msec; they were highly reflective and, in general, would have no visible (10X optical) surface irregularities other than the flats. Beads made with smaller flames or cooled rapidly from a molten condition frequently showed fissures due to contraction on cooling, and flats were neither so numerous nor well-formed. Their t_o were also variable on repeating reforming of the same bead; they were frequently much higher, a typical series being 550, 200, 600, and 650 msec.

Typically, on inserting a newly formed bead, it was repeatedly anodized to oxygen evolution (in such a way as to introduce dermasorbed O) to remove surface impurities. Usually this caused t_o to fall to a value lower than the initial value. It was possible that the repeated introduction of oxygen into the lattice followed by its removal with hydrogen was alternately expanding and contracting the Pt surface layers and that this was the essential process in changing t_o. However, on several occasions, the initial t_o before any anodic polarization other than the single charging curve was less than 30 msec and was also the base value, *i.e.*, heavy anodic polarization in clean solutions is not a prerequisite for low t_o. Furthermore, heavy anodization of an originally clean electrode does not affect t_o even when it is as high as 270 msec (cf. section on behavior of Pt with high t_o in clean solutions, above). Anodization is presumed to reduce t_o primarily by removing sorbed species.

Chemical etching.—Decay time on a given Pt bead decreased monotonically with time etched in hot aqua

[3] Photographs were obtained by surrounding the bright, reflective bead with a white right circular cylinder marked with a black grid of parallel lines. Illumination was projected downward through a translucent planar surface, also marked with a rectangular grid, that appears as a bright circle in the photographs.

regia until a t_o was reached matching that of the solution probe electrode (between 20 and 30 msec). Further etching caused no change in t_o, and it would then remain unchanged as long as the solution remained clean. Since it remained unchanged over long periods it was concluded that contamination by Cl_2 or Cl^- had been avoided. Microscopic examination showed that etching occurred first in the regions between flats and, as etching continued, less and less area was unattacked, but the centers of many of the flats remained bright even after 15 min etching. Since attack is expected to take place at the most highly strained areas first, this supported the hypothesis that the flats might be crystallographically significant.

Platinum wires vs. platinum beads.—If the structural form of the underlying crystal lattice is significant, then rates on wires should be different from rates on beads, for the drawing process introduces large numbers of defects and possibly also surface impurities that can only be removed partially by annealing. Furthermore, a wire is unquestionably composed of many small crystallites. Wire electrodes under extended aqua regia treatment could not be brought down to active bead values; the lowest wire decay time achieved was 120 msec.

Electrochemical rates on different Pt electrodes.—Previous measurements in this laboratory of hydrogen overvoltage, anodic charging curves, etc., have not shown any detectable variation when measured on different electrodes, yet the foregoing indicates that substantial differences in catalytic activity for the chemical Pt-O/hydrogen reaction are the general rule. This suggested that these electrochemical reactions may be facile reactions, *i.e.*, independent of Pt pretreatment.

Rates of oxidation and reduction of water were measured in an improved gas-tight system (7) with a t_o = 270 msec electrode. Brief aqua regia treatment reduced t_o to 50 msec, and three representative points were redetermined. Data are shown in Table I; the currents were measured under He stirring rates of 350 ml/min, and the currents given for the t_o = 270 msec electrode are mean values taken from Fig. 1 of ref. (7). Current uncertainty at a given potential is about ±30%. Etching the Pt bead did not affect these rates within experimental error, although it increased the rate of the Pt-O/hydrogen chemical reaction involved in the decay fivefold.

Discussion

The results show that each Pt electrode as formed has some intrinsic activity for the chemical reaction

$$Pt\text{-}O_{ad} + \text{hydrogen} = Pt + H_2O \qquad [2]$$

Hydrogen is available from solution as H_2 and from the Pt metal as dermasorbed H. The intrinsic activity, that is, the catalytic activity of the clean metal, varied widely depending on how the metal was originally crystallized, worked after crystallizing, or etched. These treatments should affect the state of the surface, possibly by changing the type and number of grain boundaries exposed at the surface, by changing the number and distribution of crystal defects at or near the surface, or by changing the number and distribution of impurity atoms in the lattice and exposed at the surface. Carbon is one such impurity persistently present in trace amounts in platinum, and the platinum atoms surrounding such an impurity are expected to be quite different energetically. Previous work (2) indicated that oxygen present as an impurity in the lattice would change activity. Which are the more important variables cannot be established on the basis of these experiments.

Table I. Reaction rates on different electrodes

Potential in volts *vs.* NHE	Current amp/cm² t_o = 50 msec	Current amp/cm² t_o = 270 msec
+0.617	$+2.0 \times 10^{-8}$	$+2.0 \times 10^{-8}$
+0.587	$+1.2 \times 10^{-8}$	$+1.2 \times 10^{-8}$
+0.300	-4.5×10^{-8}	-6.0×10^{-8}

Since the detailed mechanisms of the chemical Pt-O/hydrogen reaction and of the electrochemical reactions investigated are not known, it is not possible to establish why the former should be so sensitive to surface changes while the latter are unaffected. However, it may be suggested that one way that these reactions differ is in the extent that surface diffusion of reactant is rate limiting. Notwithstanding the many differences between gas and solution phases, diffusion over the surface of a metal is expected to be very sensitive to structural differences. For example, in the gas phase, Ehrlich and Hudda (10) observed that surface diffusion of tungsten adatoms on tungsten occurred at different rates on different single crystal planes, that migrating atoms were reflected at boundaries of certain planes, and that in some planes motion along atomic rows was favored over diffusion across lattice steps. The thermal and chemical treatment used could act in a way to remove barriers to rapid surface diffusion. It was previously concluded (1) that the probable rate-determining process in the decay reaction was diffusion of either O_{ad} or H_{ad} over the surface to an active site.

It is not appropriate to speak in general about active or inactive electrodes, for one may be more active than the other for a demanding reaction, but both be equivalent and as active as possible for a facile reaction. If the reaction that defines the activity is explicitly given, then such ambiguity is avoided. This obviously also applies to such terms as electrode activation. One aspect of this investigation should be stressed. Anodic pretreatment of clean electrodes, for extended periods at up to 7 amp/cm², changes neither the surface area nor the Pt activity for the $Pt\text{-}O_{ad}/H_2$ reaction. If, however, Pt electrodes have impurities sorbed on them, anodization can improve such activity. Platinum electrodes equal in activity to the best obtained could be achieved with no initial anodic treatment. Such active surfaces stay active and unchanged indefinitely on open circuit, as long as they remain clean.

The combination of a charging curve and its subsequent decay curve gives extensive information concerning solution and electrode cleanliness. Charging curves are extremely sensitive to chemisorbed oxidizable substances (9) whereas this work shows that they may fail to signal presence of traces of difficulty oxidizable impurities. On the other hand, decay curves may not be influenced by trace amounts of easily oxidized species, which would tend to be removed by the preceding charging curve, but they are dependably influenced by difficultly oxidizable species present in quantities too small to be detected by any other technique. Experience indicates that these difficultly oxidizable impurities are more prevalent than heretofore expected and, while they require demanding reactions to detect when present in trace amounts, they can seriously affect catalysis. Experience also suggests, however, that the electrochemical reactions previously studied in this laboratory to date are relatively facile and unaffected by Pt surface structure.

Conclusions

The specific rate of the chemical reaction of oxygen chemisorbed on platinum with hydrogen is particularly sensitive to metallic pretreatment. Under clean conditions, certain thermal, chemical (etching), and physical treatments can modify this rate manyfold while several electrochemical reaction rates monitored concurrently are unchanged.

This demanding reaction is proposed as especially useful for identifying and examining certain variables affecting catalysis. Because impurity sorption is one

such variable, the rate of this reaction is one of the most responsive cleanliness tests available. It is quickly and easily applied and is a convenient way to monitor solution purity.

Anodization of a platinum surface is not a necessary prerequisite for maximizing its catalytic activity either for the Pt-O/hydrogen reaction or for the electrochemical reactions investigated. Under clean conditions, anodization of Pt that has low activity for this reaction does not affect its activity in the least. When sorbed impurities are present, anodic treatment can improve activity by removing these sorbed species, but such anodization cannot do more than bring activity up to that intrinsic to the clean metal itself.

Acknowledgments

The authors wish to thank Mr. A. C. Simon for devising the technique and obtaining the photographs shown in Fig. 2, and to thank him, Mrs. J. B. Burbank, and Dr. R. L. Jones for fruitful discussions concerning crystallography.

Electrochemical Formation and Dissolution of Different Types of Copper Layers on Platinum

M. W. Breiter

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The formation of adsorbed layers of Cu atoms and of thin and thick copper patches was studied at constant potential between 0.6v and 0.1v on smooth platinum in acidic solutions containing between 10^{-5}M to $5 \cdot 10^{-4}$M $CuSO_4$. After an activation procedure copper deposition was allowed for different times up to 1600 sec. The copper layers were characterized by the waves in the current-potential curves during their anodic stripping by a linear potential sweep at 30 mv/sec. Adsorbed layers alone are produced between 0.6 and 0.4v. Sites for weakly and strongly bonded Cu atoms may be distinguished as for H adsorption. At potentials between 0.4 and 0.1v the adsorbed layer is formed first, followed by the formation of thin and thick copper patches. The production of thin patches that do not yet possess the bulk properties of thick patches could be investigated at 0.3v. The extent of the formation of thin patches is small.

The first studies (1-4) of the deposition and dissolution of very small amounts of metals on inert electrodes were made with radioactive tracers. In general, deposition of fractions of monolayers was observed to occur at a certain "undervoltage" with respect to the equilibrium potential of the reaction

$$M^{z+} + 2e^- = M \qquad [1]$$

Here, M^{z+} designates the metal ion, and M, the metal atom in a lattice position.

It was recognized (3) that the undervoltage results energetically from the contribution of the heat of adsorption of the metal atoms on the inert metal surface to the energy of activation of the discharge reaction. Electrochemical studies of undervoltage phenomena were carried out with different trace metals on electrodes of Au (5), Ag (5-7), and Pt (8). A comprehensive paper involving Au, Ag, Cu, Bi, Pb, and Sn as inert electrodes and Bi, Pb, Sn, Tl, and Cd as deposited atoms was published (9) recently. Adsorption of polarized adatoms or adions is widely assumed (10, 11) to play an important role in the deposition of metal ions on electrodes of the same metal.

The decrease of hydrogen adsorption on smooth platinum in the presence of traces of copper ions was studied previously (12). The present investigation is much more comprehensive. It was carried out for three reasons. First, the properties of the platinum surface have been characterized by extensive studies (13) of the adsorption of H atoms. Sites for the adsorption of weakly bonded H-atoms may be easily distinguished (14-16) from sites on which H atoms are strongly bonded. It was of interest to see if two types of sites are involved in the adsorption of Cu atoms.

Second, the transition from the formation of an adsorbed layer to the formation of thick copper layers may be investigated in a simple way. The growth of thick layers need not be uniform across the surface. Thin layers ($\leq$20Å) of oxides or metals do not yet possess (17) the properties of the bulk phase. The free energy of formation approaches (17) that of the bulk phase with increasing layer thickness. Thus the initial formation of thin copper layers may be expected at potentials more anodic than the equilibrium potential of reaction [1], but less anodic than the potentials at which adsorbed layers are produced. Ex-

perimental evidence for the behavior of thin layers is scarce. The deposition and dissolution of small amounts of metals on inert electrodes seems to offer an opportunity to find out if and to what extent thin films exist as an intermediate stage in metal deposition in these systems.

Third, the formation of the described layers, especially of the adsorbed layer of Cu atoms should depend strongly on potential. It is the purpose of the paper to establish this dependence for the system Pt/Cu.

Experimental

The experiments were made in a Pyrex glass vessel of standard design at 20° ± 1°C. The electrolytic solutions (XM $CuSO_4$ + 0.5M H_2SO_4 or XM $CuSO_4$ + 1M $HClO_4$, $X = 10^{-5}$ to $5 \cdot 10^{-4}$M) were prepared from double distilled water and Analytical Reagent chemicals. Purified helium was used to remove molecular oxygen from the solutions and for stirring. The glass vessel was in an atmosphere of nitrogen inside a plastic dry box. The electrode potential, U, was measured *vs.* a hydrogen electrode in 0.5M H_2SO_4 or 1M $HClO_4$, respectively.

The following procedure which is similar to procedures (18) for the study of the adsorption of organic species on platinum was adopted. The platinum wire electrode (0.5 cm^2 geometric surface area) was kept for 5 min under He stirring at 1.4v. The stirring was stopped. Two minutes later, the electrode potential was switched potentiostatically to the desired potential ($0.1v \leq U \leq 0.6v$). The oxygen layer is reduced rapidly at these potentials. Deposition of copper atoms was allowed for different times up to 1600 sec. Subsequently, the copper layers were removed by anodic potential sweeps of 30 mv/sec. In a given solution, the copper deposition was carried out for different times at 0.5v first, then at 0.4, 0.3, 0.2v, and finally at 0.1v. The subsequent series of runs was made in a fresh solution with increased copper sulfate concentration.

The Wenking potentiostat 6 IRS, the Type 255 Function Generator of Exact Electronics, a Western Electric 275C Relay, and suitable potentiometers formed the electronic circuit. The current, I, was measured as voltage drop across standard resistors. The voltammetric I-U curves were recorded by the Varian F 80 X-Y recorder or the Tetronix 502 Oscilloscope. Cyclic I-U curves were also taken under different experimental conditions.

Results

Anodic I-U curves that were obtained after different times of deposition at 0.5v in 10^{-5}M $CuSO_4$ + 0.5M H_2SO_4 are replotted in Fig. 1. The curves are shifted against each other. A wave that is absent in 0.5M H_2SO_4 appears between about 0.6 and 0.9v. It was

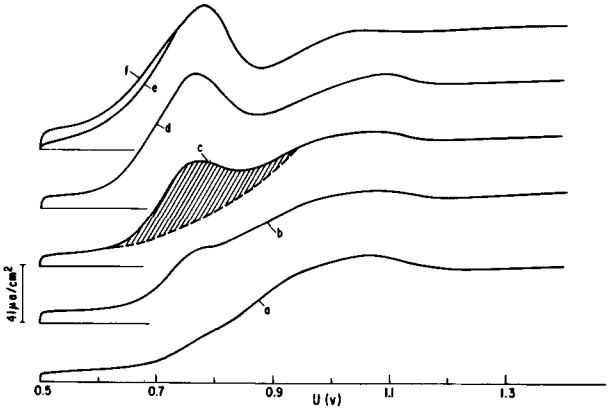

Fig. 1. Anodic I-U curves at 30 mv/sec after different times of copper deposition at 0.5v in 10^{-5}M $CuSO_4$ + 0.5M H_2SO_4: a, 50 sec; b, 100 sec; c, 200 sec; d, 400 sec; e, 800 sec; f, 1600 sec.

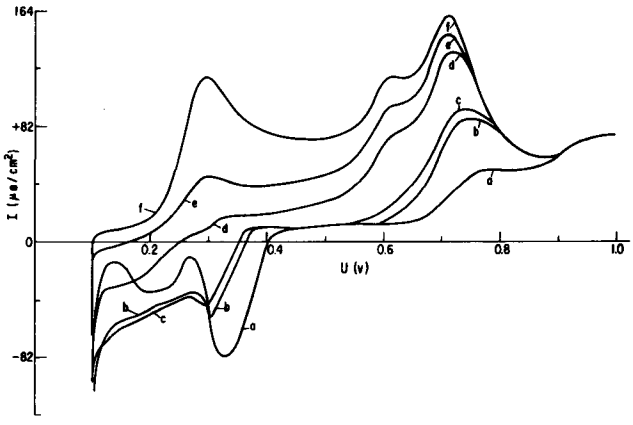

Fig. 2. Anodic I-U curves at 30 mv/sec after different deposition times at 0.1v in 10^{-5}M $CuSO_4$ + 0.5M H_2SO_4: a, 50 sec; b, 100 sec; c, 200 sec; d, 400 sec; e, 800 sec; f, 1600 sec.

verified by the corresponding experiments in 0.5M H_2SO_4 alone that this wave is not due to the slow adsorption of traces of organic impurities. The height of the wave increases with time. It tends to a limiting value in Fig. 1 after 1000 sec. The charge equivalent used up by the process that causes the appearance of the wave may be estimated by integrating the dashed area (sec curve c) between the I-U curves with and without this wave. It was 0.16 mcoul/cm^2 for curve c. As will be discussed later in detail, the wave is attributed to the anodic removal of adsorbed Cu atoms. The deposition of Cu atoms on a Rh electrode has been postulated (19) previously at potentials $U \leq 0.4v$ on the basis of the inhibition of the anodic dissolution of molecular hydrogen in 0.5M H_2SO_4 in the presence of traces of copper ions.

The I-U curves taken after different deposition times at 0.1v in 10^{-5}M $CuSO_4$ + 0.5M H_2SO_4 are replotted in Fig. 2. Curve a exhibits two minima of the cathodic current between 0.1 and 0.3v and the above described anodic wave between 0.6 and 0.9v. The two minima of the cathodic current are due to the superposition of the partial anodic current of reaction [2]

$$H_{ad} = H^+ + e^- \qquad [2]$$

to the limiting diffusion current of copper ions between 0.1 and 0.3v at small coverage with Cu atoms. The agreement of each of the potentials of the two minima with the corresponding potentials of the hydrogen peaks in 0.5M H_2SO_4 [see Fig. 1 in ref. (15)] demonstrates this. While the H layer is formed rapidly at 0.1v, only a small amount of Cu atoms is deposited in 50 sec because of mass transport control. The increase of the height and the broadening of the anodic wave between 0.6 and 0.9v is paralleled in curves b and c by a decrease of the partial anodic currents of reaction [2]. It is concluded that H atoms are replaced by Cu atoms that are more strongly bonded than hydrogen atoms.

Two new features are observable in curves d, e, and f. The broadening of the anodic wave between 0.6 and 0.9v leads to the appearance of another peak. The two peak potentials differ by about 0.1v. Simultaneously, an additional anodic wave with the peak at about 0.3v increases in height with time. The development of the described features is accompanied by the disappearance of hydrogen adsorption. It will be shown in the discussion that the wave with peak at about 0.3v may be ascribed to the anodic dissolution of thick copper patches.

While it is possible to determine the charge equivalent of the wave between 0.6 and 0.9v (compare curve c in Fig. 1) for $U \geq 0.4v$ at deposition times up to 1600 sec, the curves in Fig. 2 are an example for the fact that the integration can only be made with certainty at shorter times for $U \leq 0.3v$. The overlapping

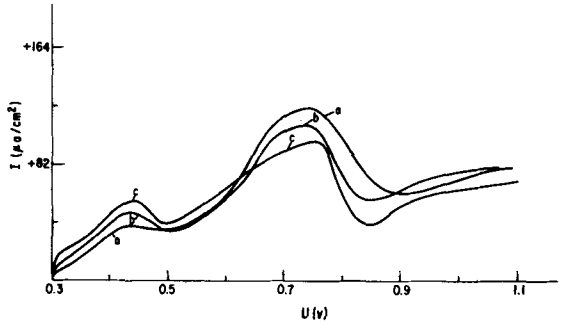

Fig. 3. Anodic *I-U* curves at 30 mv/sec after 1600 sec at 0.3v in XM $CuSO_4$ + 0.5M H_2SO_4: a, $X = 10^{-5}$M; b, $X = 3 \cdot 10^{-5}$M; c, $X = 10^{-4}$M.

of the different waves makes it difficult to find the integration limits at larger times. There is also the possibility that an additional anodic wave which is masked by overlapping effects exists between 0.35 and 0.55v in curves d, e, and f of Fig. 2. The actual presence of this wave is demonstrated by the *I-U* curves in Fig. 3. These curves were taken after a deposition of 1600 sec at 0.3v in *X*M $CuSO_4$ + 0.5M H_2SO_4 ($X = 10^{-5}$M, $3 \cdot 10^{-5}$M, 10^{-4}M). The wave with the peak potential at about 0.43v increases only slightly in height with the concentration of copper ions. It could not be detected after deposition at potentials $U \geqq 0.4$v.

The expected influence of mass transport processes is demonstrated by the cyclic *I-U* curves of Fig. 4 in XM $CuSO_4$ + 1M $HClO_4$ ($X = 4 \cdot 10^{-5}$M, 10^{-4}M, $5 \cdot 10^{-4}$M). Stirring increases the height of the anodic wave between 0.6 and 0.9v (compare curves a and a'). The wave between 0.35 and 0.55v appears in addition to the adsorption wave at $X = 10^{-4}$M in curve b'. An increase of the sweep rate has the same effect as a decrease of the rate of stirring, *i.e.*, the height of the waves decreases (compare curve b with b' and c with c'). All three waves are present in curve c'. The splitting of the adsorption wave is visible in curves b' and c'.

Discussion

Conclusions on electrode reactions from the formation of thick films.—The thermodynamic aspects and steady-state kinetics of the copper electrode have been discussed (20) recently. Three electrochemical net reactions, the standard potentials (21) U_o of which are given on the side of the equations, have to be considered

$$Cu^+ + e^- = Cu \qquad U_o = 0.522\text{v} \quad [3]$$

$$Cu^{++} + 2e^- = Cu \qquad U_o = 0.346\text{v} \quad [4]$$

$$Cu^{++} + e^- = Cu^+ \qquad U_o = 0.170\text{v} \quad [5]$$

Thick copper layers could be built up by three different mechanisms (a) by reaction [3]; (b) by reaction [4]; (c) by a net local cell represented by reactions [1] and [2]. The contribution of reaction [3] is negligible because of the small concentration of Cu^+. The thermodynamics demonstrate that the formation of thick layers according to reaction [4] is not feasible at $U \geqq 0.20$v for $X = 10^{-5}$M and at $U \geqq 0.23$v for $X = 10^{-4}$M. The results in Fig. 5 suggest that only reaction [4] contributes to the formation of thick copper layers because of the occurrence of a peak at 0.3v in the region of correct thermodynamics for Eq. [4] and by its absence when the thermodynamics indicate that reaction [4] will not go.

Curve d taken after 1600 sec of deposition at 0.1v and $X = 10^{-4}$M coincides practically with curve c between 0.23 and 0.30v. The peak of curve d appears at a more positive potential than that of curve c. This is interpreted as a combined influence of activation polarization and resistance overvoltage during the final depletion of the thick copper layer. Curves b, c, and d show the presence of the wave between 0.6 and 0.9v, in spite of the considerable charge equivalent corresponding to the dissolution of the thick layer. This is considered experimental evidence that the thick layer grows nonuniformly in patches on the Pt surface.

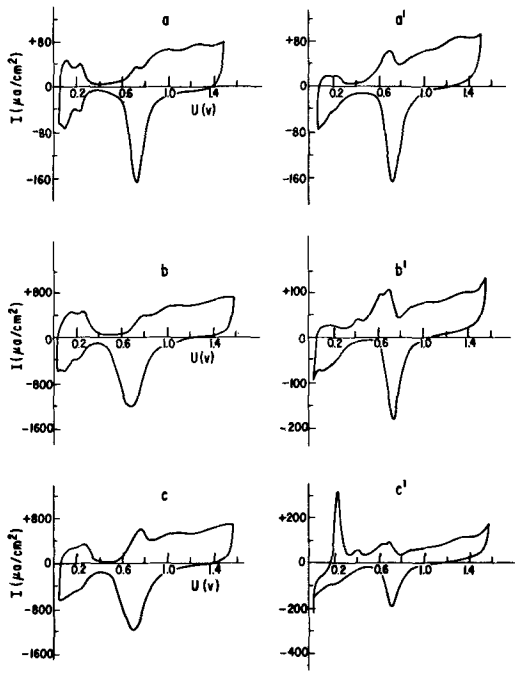

Fig. 4. Cyclic *I-U* curves at 30 mv/sec (a, a', b', c') or 300 mv/sec (b, c) in unstirred (a, b, b', c, c') and stirred (a') solutions of XM $CuSO_4$ + 1M $HClO_4$: a, a', $X = 4 \cdot 10^{-5}$M; b, b', $X = 10^{-4}$M; c, c', $X = 5 \cdot 10^{-4}$M.

Curves a, b, c and d in Fig. 2 demonstrate that the formation of the adsorbed layer takes place first at 0.1v. After nearly a monolayer exists, the other copper layers begin to form. The same statement holds for deposition at 0.2v.

Formation of thin layers.—After deposition at 0.3v the small wave between 0.35 and 0.55v is found for

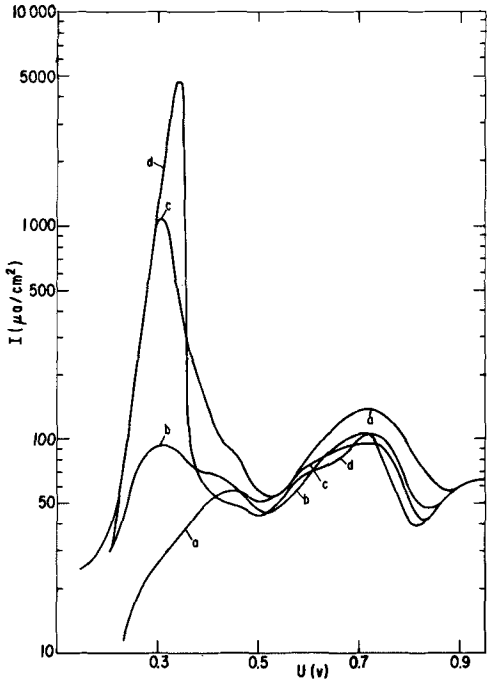

Fig. 5. Anodic *I-U* curves at 30 mv/sec after 1600 sec at 0.2v (a, b, c) or 0.1v (d) in XM $CuSO_4$ + 0.5M H_2SO_4: a, $X = 10^{-5}$M; b, $X = 3 \cdot 10^{-5}$M; c, $X = 10^{-4}$M; d, $X = 10^{-4}$M.

deposition times larger than 400 sec at $X = 10^{-5}$M, than 200 sec at $X = 3 \cdot 10^{-5}$M, and than 100 sec at $X = 10^{-4}$M. In contrast, the wave between 0.6 and 0.9v is largely developed when the small wave begins to appear. This result and the value of the peak potential of the small wave suggest that a few patches of thin films with intermediate behavior between adsorbed layers and thick layers are formed. Weak adsorption of Cu atoms in a second layer on top of the first layer might be another interpretation of the origin of the small wave. However, a larger dependence of the height of the small wave on the concentration of Cu^{++} than that in Fig. 3 would be expected in this case.

Curve a in Fig. 5 shows that the small wave is also present after deposition at 0.2v if the concentration of Cu^{++} is sufficiently small to rule out the formation of thick layers. Humps in curves b, c, and d of Fig. 5 indicate the existence of the wave in the presence of thick patches. It appears that the thin patches have not been converted into thick patches under the given conditions.

A simple calculation demonstrates that the small wave cannot result from the formation of a few thick patches according to reaction 3. In this case the concentration of Cu^{+} ions would have to be $1.6 \cdot 10^{-4}$M at least. This is not possible for curves a and b in Fig. 3 with $X = 10^{-5}$M and $3 \cdot 10^{-5}$M, respectively.

Formation of adsorbed layers.—The wave between 0.6 and 0.9v can only be attributed to the removal of adsorbed Cu atoms. Deposition of Cu atoms, according to reactions 3a and 4a

$$Cu^{+} + e^{-} = Cu_{ad} \qquad [3a]$$

$$Cu^{++} + 2e^{-} = 2Cu_{ad} \qquad [4a]$$

may occur at potentials more positive than the equilibrium potentials of reaction [3] and [4] at $X \leq 10^{-4}$ M, since the free energy of activation of reactions [3a] and [4a] is smaller than that of reactions [3] and [4] because of the influence of the free energy of adsorption. The situation is similar to that of reaction [2] for which the effect of the free energy of hydrogen adsorption has been discussed (22) in detail.

The charge equivalent ${}_sQ_H$ corresponding to a monolayer of H atoms was determined from *I-U* curves in 0.5M H_2SO_4 at the beginning of each series of deposition runs in the usual way (23). It was found to decrease slowly with the number of runs. The charge equivalents Q_{Cu} of the anodic wave between 0.6 and 0.9v were obtained for deposition at 0.4, 0.5, and 0.6v in the way shown for curve c in Fig. 1. Table I contains ${}_sQ_H$, Q_{Cu}, and $\theta_{Cu} = Q_{Cu}/2 \cdot {}_sQ_H$ at a deposition time of 1600 sec for the different concentrations.

The error in the determination of ${}_sQ_H$ and Q_{Cu} is estimated as 5% leading to an error of about 10% in θ_{Cu}. Overlapping prevents a reliable determination of θ_{Cu} for $U \leq 0.4$v.

In agreement with the results on the formation of thick layers, it had been assumed in the definition of θ_{Cu} that reaction [4a] is involved in the formation of the adsorbed layers of Cu atoms. The θ_{Cu} values in Table I support this assumption since θ_{Cu} is larger than 0.5 at 0.4v. The results in Table I demonstrate that the adsorption depends strongly on potential. As for the adsorption of organic substances (18, 24), the coverage decreases at constant bulk concentration in the potential region of oxygen adsorption on platinum. Oxygen atoms are more strongly bonded than Cu atoms. Monolayer formation is not yet achieved at 0.4v in 10^{-4}M $CuSO_4$ + 0.5M H_2SO_4 according to Table I. The appearance of a second peak in the desorption wave is just noticeable after deposition at 0.4v and $X = 10^{-4}$M.

Table I. Characteristic values for adsorption of Cu atoms at 0.4, 0.5, and 0.6v

	${}_sQ_H$ mcoul/cm²	0.4v Q_{Cu} mcoul/cm²	0.4v θ_{Cu}	0.5v Q_{Cu}	0.5v θ_{Cu}	0.6v Q_{Cu}	0.6v θ_{Cu}
10^{-5}M $CuSO_4$	0.59	0.66	0.56	0.42	0.36	0	0
$3 \cdot 10^{-5}$M $CuSO_4$	0.52	0.60	0.60	0.41	0.39	0.05	0.05
10^{-4}M $CuSO_4$	0.46	0.64	0.64	0.38	0.41	0.11	0.12

The anodic removal of Cu_{ad} occurs in a potential region of about 0.35v. This width corresponds approximately to that of the ionization of H_{ad} on smooth platinum in 0.5M H_2SO_4 at room temperature. Similarly, the desorption wave consists of two overlapping waves (see curves d to f in Fig. 2). A distinction between loosely and strongly bonding sites may be made for Cu_{ad} as well as for H_{ad}. However, while the number of strongly and weakly bonding sites is approximately equal for H_{ad} in 0.5M H_2SO_4, there are more strongly bonding sites than weakly bonding sites for Cu_{ad}. Since the adsorption experiments with H_{ad} and Cu_{ad} involve the same anions and the same concentration of anions, the latter difference is attributed to the specific influence of the adsorbed species on the surface states in the sense of an induced effect.

Comparison of the preceding conclusions with the results of cyclic voltammetry.—The conclusions on the formation of thick and thin copper layers and of adsorbed layers of Cu atoms are confirmed by the results obtained by cyclic voltammetry. Deposition of Cu atoms starts during the cathodic sweep after the oxygen layer has been reduced.

The hydrogen waves are well pronounced in curve a of Fig. 4, and the desorption wave of Cu atoms is small in unstirred $4 \cdot 10^{-4}$M $CuSO_4$ + 1M $HClO_4$. Stirring of the solution decreases the thickness of the diffusion layer. More Cu atoms were deposited in the case of curve a' than in curve a. The desorption wave is large. The cathodic current of Cu^{++} deposition is superimposed to that of the deposition of the H layer during the cathodic sweep. This effect is clearly pronounced for curve a' taken in the stirred solution. Owing to blocking of sites for H adsorption by adsorbed Cu atoms, the hydrogen wave is small in curve a'. The sweep rate and the concentration of Cu^{++} are such that formation and removal of only the adsorbed layer are observable.

The desorption wave of Cu atoms is small in curve b of Fig. 4 because of the short deposition time at a sweep rate of 300 mv/sec. At 30 mv/sec monolayer formation can be considered complete as indicated by the presence of the two peaks of the desorption wave. The small wave at the foot of the desorption wave shows that a few patches of thin films are dissolved there.

As to be expected the height of the desorption wave in curve c' increases with the Cu^{++} ion concentration above the height of the corresponding wave in curve b. Simultaneously hydrogen adsorption decreases. The relatively large cathodic current between 0.4 and 0.05v in curve c' indicates that formation of the thick layer occurs in $5 \cdot 10^{-4}$M $CuSO_4$ + 1M $HClO_4$ at 30 mv/sec. The presence of the first anodic wave confirms this conclusion. In addition, the waves corresponding to the removal of the thin layer and of the adsorbed layer are well pronounced.

It is clear from the preceding discussion that the same conclusions that were obtained in a quantitative manner from the results in Fig. 1 to 3 may be drawn in a qualitative manner from the curves in Fig. 4.

Brief Communications

Use of Nonlinear Circuits for the Acquisition of Electrode Kinetic Data

S. D. James[1]

Brookhaven National Laboratory, Upton, New York

A wide variety of relaxation methods has been devised to measure the parameters characterizing the kinetics of electrode processes. The usual single-pulse techniques involve recording transient i, η, or Q (charge) *vs.* time, immediately following the imposition of a galvanic step-function to the cell (1-5) or recording η *vs.* t after the completion of a very abrupt increment in electrode charge density (6, 7).

In the potential-step (1), potential-step-integral (2), voltage-step (3), and small amplitude current-step or galvanostatic (4) methods, the required parameters are obtained from the slope and intercept of plots of i, η, or Q *vs.* $t^{1/2}$. In the charge-step method (6) and its derivative current-impulse method (7), η is abruptly changed with a slug of charge. The double layer then relaxes by discharging through the electrode reaction, and kinetic parameters are extracted from plots of ln η *vs.* t. In the large amplitude current-step or chronopotentiometric method (5) the required plot is η *vs.* ln $(1 - At^{1/2})$, where $A = \tau^{-1/2}$, τ = transition time.

It appears that much more attention has been paid to the imposition of the electrical perturbation than to the read-out of cell response (8). The usual data acquisition method in these studies has been to photograph an oscilloscopic record of the electrical variable *vs.* time and then replot the data in the form designed to achieve linearity. Apart from the time consumed (especially in chronopotentiometry) and the errors introduced by this replotting, the experimentation lacks fluency, punctuated as it is by hiatuses for the replotting. This is especially true in the η or i *vs.* $t^{1/2}$ experiments where the linearity with $t^{1/2}$ is often rather brief and elusively sandwiched between the decay of capacitative current on the one hand and the onset of pure diffusion control on the other. The examination of a few time scales is always desirable to locate the one best displaying the linear region. In the opinion of the present author, these difficulties may, at least in part, explain the relative paucity of applications of these methods (9).

The use of nonlinear circuits is recommended for the direct display of the desired linear relations. Devices possessing a logarithmic response have been on the market for about five years and appear well adapted for the direct display of ln η *vs.* t curves (6, 7) by interposition between the cell output and the y-plates of the CRO. About three years ago many other nonlinear devices became available in the form of plug-in units which can perform a broad spectrum of mathematical operations on an electrical signal (these devices are the building bricks of the more advanced analogue computers). There seems no reason why a direct read-out of, *e.g.*, the chronopotentiometric linearity between η and ln $(1 - At^{1/2})$, could not be obtained with a combination of four of these devices: a quadratic for $t^{1/2}$, linear for A, differential amplifier to get $(1 - At^{1/2})$, and finally a logarithmic device.

Of particular use in electrochemical kinetics is the square-rooting circuit or "quadratic transconductor," which can convert an input V into an output proportional to $V^{1/2}$. By diverting the ramp voltage which drives the time base of an oscilloscope through one of these circuits, the time base can be made to displace

according to $t^{1/2}$ instead of t. Thus a direct display of the commonly useful $t^{1/2}$ linearity is secured. A circuit designed to effect and illustrate the square-rooting of an oscilloscope's time base is shown in Fig. 1. PSQ-N is the quadratic device. Its input is 0-10v, and the accuracy of the square-rooted output is 0.1% of full scale. The response, in terms of a settling-time to within 10% of its final value, is 1 μsec. Thus it is already suitable for most applications and further improvement in both accuracy and response time is to be expected. Figure 2 is a photograph of 1-msec markers on a total time-base interval of 10 msec. The time base was square-rooted with the circuit of Fig. 1. If a cell output instead of the time markers were applied to the y-plates, a direct recording of output *vs.* $t^{1/2}$ would be obtained with an abscissa dimension of 10^{-2} $sec^{1/2}/cm$.

Charge-Transfer Coefficients for Aqueous Cd (II) Evaluated by Large Amplitude A-C Polarography

J. D. McLean and Andrew Timnick

Department of Chemistry, Michigan State University, East Lansing, Michigan

This article is an extension of the initial work on large amplitude a-c polarography of aqueous Cd(II) (1). The purpose of this work is to test the extent of applicability of existing equations developed for low amplitude a-c polarography by determining the effect of large amplitudes of the applied a-c potential on experimentally determined charge-transfer coefficient (α) values for Cd(II) in aqueous solutions.

The solutions and chemicals employed in this work were described previously, as well as the instrumentation and experimental techniques (1).

Charge-transfer coefficients can be evaluated from cot ϕ *vs.* $\omega^{1/2}$ plots of a-c polarographic data, where ϕ is the corrected phase-angle between the applied a-c potential and the measured a-c current from the polarographic cell, and ω is the angular frequency of the applied a-c potential. The phase-angles are corrected for uncompensated solution resistance and double-layer charging current of the supporting electrolytes according to the method of Bauer and Elving (3). The experimental constants necessary for these corrections are listed in Table I. To calculate values for α, it is necessary to obtain the slopes of cot ϕ *vs.* $\omega^{1/2}$ plots evaluated at two different d-c potentials. The following equation is used for this calculation (2)

$$\alpha = \frac{2.303}{(j_2 - j_1)} \left\{ \log \left(\frac{1 + e^{j_2}}{1 + e^{j_1}} \right) - \log \left(\frac{\text{slope 1}}{\text{slope 2}} \right) \right\} \quad [1]$$

where

$$j_1 = \frac{n\mathbf{F}}{RT} (E_{\text{d.c.1}} - E_{1/2^R}) \quad [2]$$

$$j_2 = \frac{n\mathbf{F}}{RT} (E_{\text{d.c.2}} - E_{1/2^R}) \quad [3]$$

In these equations the subscripts, one and two, refer to the two d-c potentials, $E_{\text{d.c.1}}$ and $E_{\text{d.c.2}}$, respectively, and $E_{1/2^R}$ is reversible half-wave potential. The slopes listed in Tables II and III are the least squares slopes of cot ϕ *vs.* $\omega^{1/2}$ plots evaluated at 15 frequencies be-

tween 30 and 1100 Hz, at d-c potentials of $E_{1/4}$, $E_{1/2}{}^R$ and $E_{3/4}$. The various supporting electrolytes were used to obtain a range of values for the apparent heterogeneous rate constant (k_h) since the accuracy of the determination of α depends on the magnitude of k_h.

Table II lists the variation of values of α with increasing amplitude of the applied a-c potential for Cd(II) in 1.0M Na_2SO_4, for which k_h = 0.06 cm/sec. Table III lists similar variations of α for Cd(II) in 1.0M H_2SO_4 for which k_h = 0.14 cm/sec. From Tables II and III it is apparent that α values, as determined by the low amplitude equation, do not vary markedly up to an amplitude of 80 mv peak to peak. Although the α values show good agreement, some deviations in the plots become apparent above 40 mv. These deviations occur as a distinct falling off from linearity in the cot ϕ *vs.* $\omega^{1/2}$ plots at frequencies above 600 Hz, with the magnitude of the error increasing directly with the frequency. For typical plots, see Fig. 1 of the previous paper (1). In all of these plots the intercept is one on the cot ϕ axis at zero frequency, as predicted by low amplitude theory.

The changes in the slope of the cot ϕ *vs.* $\omega^{1/2}$ plots with increasing amplitudes are smaller at $E_{1/4}$ and $E_{3/4}$ than at $E_{1/2}{}^R$. This leads to the conclusion that acceptable values of α can be evaluated at large amplitudes even though α is more sensitive to changes in the slope of these plots, than is k_h. Smith's (4) theoretical plots of cot ϕ *vs.* $E_{d.c.}$ for a hypothetical system at amplitudes of 10, 40, 60, and 80 mv peak to peak, predict smaller slope changes at $E_{1/4}$ and $E_{3/4}$ than at $E_{1/2}{}^R$, in agreement with the results obtained in this study.

The conclusions of this study are only valid for charge-transfer coefficients for systems having apparent heterogeneous rate constants in the range 0.01 to 0.20 cm/sec, as is the case for Cd(II) in the various sulfate media. When employing large amplitudes, charge-transfer coefficients should only be evaluated with low amplitude equations at potentials near $E_{1/4}$ and $E_{3/4}$ or from averages of data obtained at $E_{1/4}$ and $E_{1/2}{}^R$ and at $E_{1/2}{}^R$ and $E_{3/4}$, since the larger variations in the slopes of cot ϕ *vs.* $\omega^{1/2}$ plots at $E_{1/2}{}^R$ are eliminated in this manner.

Transfer coefficients for Cd(II) in 1.0M KNO_3 could not be evaluated due to the large value of the heterogeneous rate constant of 0.67 cm/sec. This caused the ratio of the uncertainties in the slopes of cot ϕ *vs.* $\omega^{1/2}$ plots to become competitive with the values of the ratio of the slopes.

The results obtained for the aqueous Cd(II) system indicate that, if the apparent heterogeneous rate constant for electron transfer is between 0.05 and 0.20 cm/sec, low amplitude equations can be used to calculate α values for applied a-c potentials of up to 80 mv peak to peak, which is considerably beyond the previously predicted limit of 16/n mv which would be 8 mv for Cd(II).

Gas Phase Anodization of Tantalum

T. A. Jennings and W. McNeill
Frankford Arsenal, Philadelphia, Pennsylvania
and R. E. Salomon
Department of Chemistry, Temple University, Philadelphia, Pennsylvania

ABSTRACT

The anodic oxidation of tantalum in the gas phase was studied using an electromagnetic ion cathode. The anodic films were prepared at constant current densities of 1.0 and 2.0 ma/cm^2. The growth characteristics of anodic tantalum oxide films, in the gas phase, were found to be similar to films prepared in liquid electrolytes. A comparison is made between the results of this study and other reported gas phase reactions with various anode surfaces. The tantalum oxide growth, for the experimental conditions reported here, is shown to be linearly dependent on the total charge passed in the anode circuit during the reaction up to a formation voltage of 200v.

Tantalum oxide films prepared by anodic reactions in aqueous and nonaqueous electrolytes have been shown to contain impurities from the solution (1-3). Anodic oxide films prepared in an oxygen discharge (4-7) have been found to exhibit physical and electrical properties analogous to those found with films formed in liquid electrolytes. Certain aspects of the growth of films by anodization in liquid electrolytes are similar to those observed during gas phase anodization. Examples are the relationship between thickness and the formation voltage and the current decay at constant voltage.

Some authors (5) report the presence of a large electron population in the gaseous electrolyte and anode temperatures as high as 200°C during anodization. This paper reports the use of an electromagnetic ion cathode which was designed to limit the electron and positive ion concentration in the gaseous electrolyte. Separation of the ion cathode from the anode reduces heating effects of the anode and allows for the observation of the anode reaction without the masking effects of a general discharge. Results are compared with anodic oxidation of tantalum in aqueous electrolytes and with gas phase anodization of various materials as reported by others.

Experimental

The gas phase electrochemical cell is illustrated in Fig. 1. Part of the cell (see Fig. 2) consists of an electromagnetic ion cathode. The primary function of the ion cathode is to serve as a source of negative charge carriers. The ion cathode consists of a permanent magnet (1400 gauss), a tantalum cylinder which serves as a cathode, and a tungsten coil which serves as a positive electrode. The tantalum cylinder (cathode) was held at 500 to 1000v negative with respect to ground while the tungsten coil was maintained at ground potential. The magnetic field served to restrict the motion of the electrons to the space defined by the tungsten coil and thereby enhance the probability of electron capture by the oxygen. The oxygen is introduced at the base of the ion cathode through a variable leak.[1]

The anode consisted of a tantalum sheet, 0.010 in. thick, which was connected to an electrically insulated lead. The tantalum anodes were constructed from metallurgical grade (99.90% min) tantalum sheet supplied by the Fansteel Metallurgical Company. The anodes were prepared by cleaning in a hot detergent solution for several hours, followed by rinsing in freshly distilled water. After drying, an anode area of 3.6 cm^2 was defined by masking the rest of the anode with vinyl insulating tape. Electrical contact to the anode was made by contacting a wide strip of thin tantalum sheet to the back of the anode to serve as a low resistance contact. Only the 3.6 cm^2 anode area was exposed to the gas electrolyte.

The pressure of the cell, determined by a discharge gauge located in the base plate, was first reduced to 5 x 10^{-5} Torr and was maintained at this pressure for less than 1 hr in order to limit possible contamination due to backstreaming of the diffusion pump oil. The cell was then backfilled with oxygen to a pressure of 70 mTorr.

One of the operating characteristics of our gas phase anodizing cell was that no significant anode current was measured when the anode was negative with respect to ground. This was taken as evidence for a low concentration of positive ions leaving the ion cathode. The presence of positive ions in the gas phase cell was investigated using a probe fashioned after that described by Barnes (8). Positive ions were

detected only when the anode was positive with respect to ground and only when the probe was in a zone characterized by a pale green glow immediately adjacent to the anode surface.

Anodic reactions were carried out at anode current densities of 1.0 and 2.0 ma/cm². The anode temperature, which was measured by a thermocouple attached to the metal back of the anode, did not exceed 40°C for the anodic reactions performed at 1.0 ma/cm² and 70°C for reactions at 2.0 ma/cm².

All films were grown at a constant current density and to a predetermined voltage. This voltage is defined as the formation voltage and is measured between ground and the metal anode. Figure 3 illustrates the voltage-time dependency for films formed at current densities of 1.0 and 2.0 ma/cm². It will be noted that in Fig. 3 the voltage-time curves do not intersect the ordinate at zero time. This is because it was observed experimentally that in a time of about 1 sec or less the anode voltage would rise to about 45-50v for current densities of 1.0 and 2.0 ma/cm²

In Fig. 4, the anode current is plotted as a function of time for a 100v gas phase anodic Ta_2O_5 film. It is seen that the relationship is nonlinear, while the reciprocal current-time function is linear.

Figure 5 is a plot of the anode current in the gas electrolyte as a function of the applied anode voltage for a constant film thickness. In order to study this effect a 100v film was first prepared by gas phase anodization at a constant current density of 2.0 ma/cm². The applied voltage was reduced to zero and then increased in small increments. The current was measured after each increment. Since there was no noticeable change in the interference color of the film it is assumed that there was not a significant increase in the film thickness. Figure 5 reveals a relationship between the anode current density and the applied voltage which is probably due to simultaneous changes in the electrical characteristics of both the gas electrolyte and the oxide film. It is of interest to note that the steep rise in the current density between 32

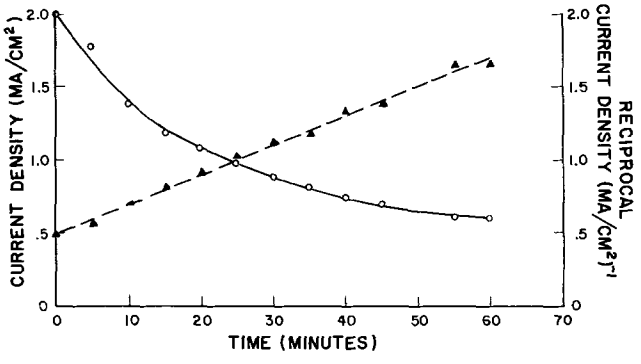

Fig. 4. Time dependence of anode films form at a constant formation voltage. ○, current density vs. time; ▲, reciprocal current density vs time.

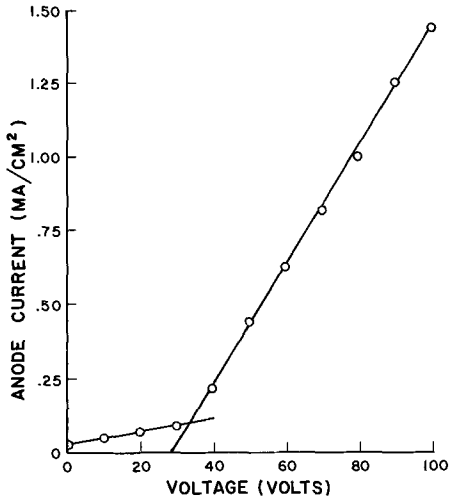

Fig. 5. Anode current as a function of anode voltage at constant film thickness.

and 50v is in the same region as that where film growth begins.

Film thickness was determined by capacitance measurements and by comparison with an optical step gauge. In the capacitance measurements eighteen gold contacts, measuring approximately 0.020 cm², were deposited on the oxide film. Electrical contact to the gold film was made with a smaller spot of conductive silver paint. After the silver paint had dried, the capacitance of the films was measured using a type 716-C General Radio Capacitance Bridge. Capacitance values measured at 1 kc/sec are shown in Table I. Thicknesses were calculated assuming a dielectric constant of 27.6 (9). The possible presence of αTa_2O_5, which Pavlovic (10) showed to have a much larger dielectric constant, was discounted by the observation that the capacitance and the dissipation factor of our films remains nearly constant from 77° to 300°K, while the dielectric properties of αTa_2O_5 are reported to be strongly temperature dependent.

Thickness measurements were also made by comparison with an optical step gauge (11). The gauge was prepared by anodization of a chemically polished strip of tantalum in a 0.1 w/o solution of Na_2SO_4 at 48°C. Anodization was carried out in 15v steps, and for each increase in voltage a portion of the tantalum strip was removed from the solution. The current density was 2.0 ma/cm² maximum and was allowed to decay to 0.1 ma/cm² which was used as the end point for each step. The films prepared by gas phase anodization were compared with the step gauge, and by matching the number of fringes and the color it was possible to estimate film thickness.

The thickness-voltage values determined by both the capacitance and optical techniques are plotted in Fig. 6. One should note that the voltage-thickness plots are linear for our gas phase films and have slopes close to that reported by Vermilyea (11) for

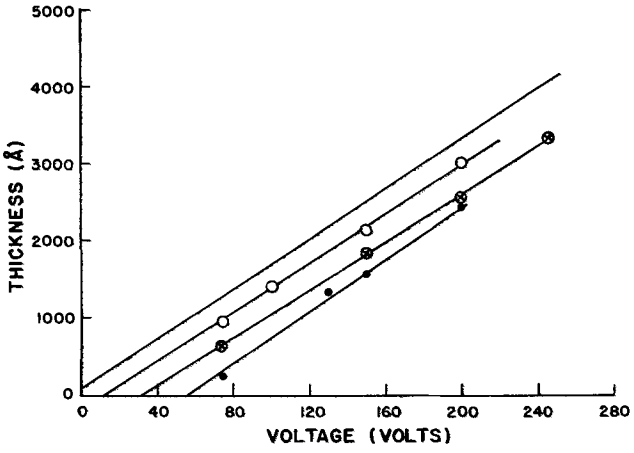

Fig. 6. Thickness as a function of voltage at a constant current density. ———, data from ref. (11); ○, 1.0 ma/cm², thickness determined by capacitance; ⊗, 2.0 ma/cm², thickness determined by capacitance; ●, 1.0 ma/cm², thickness determined by optical step gauge.

Ta_2O_5 films grown in liquid electrolytes. The slopes for the gas phase film grown at 1.0 ma/cm² is 16.5 Å/v and for the 2.0 ma/cm² films it is 15.7 Å/v. There are differences due to measurement techniques and anodization conditions. However, a strong similarity between the thickness-voltage relationship for the liquid and gas phase films is evident. It is also noted that extrapolation to zero thickness leads to voltage intercepts that are larger than zero.

The efficiency of film growth was determined by calculating the mass of the Ta_2O_5 produced for each set of anodization conditions and comparing them with the quantity of charge that had passed through the anode circuit. For these calculations a density of 8.0 g/cm³ was assumed for Ta_2O_5 (12). The Faraday efficiency calculated for films grown at applied anode voltages of 200 or less is 17%. Figure 7 is a plot of the measured thickness values as a function of the total charge that passed through the anode circuit. Although there is a difference between the intercepts of the plots from the capacitance and the optical data (the latter are believed to be more accurate and have a slope of 256 Å/coul/cm²), both are linear for films grown up to 200v. It is also evident that film growth efficiency is independent of the current density and anode temperature in the limited range of the variables studied, since the points for 1.0 and 2.0 ma/cm² films fall on the same line. The extrapolation of the optical plot in Fig. 7 to zero charge leads to an intercept on the ordinate that corresponds to a film thickness of 57Å.

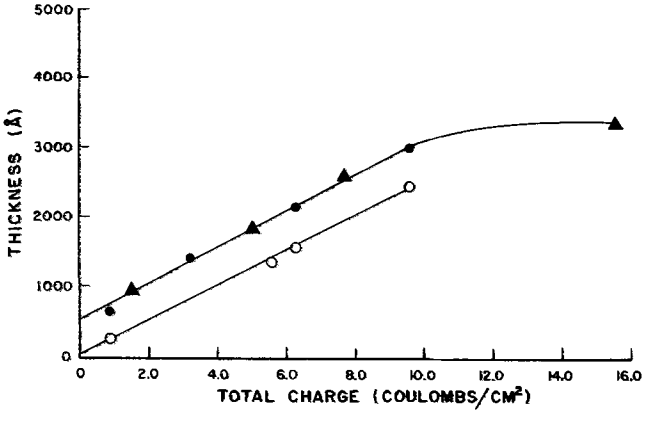

Fig. 7. Total charge dependence of total film thickness. ●, film formed at 1.0 ma/cm², thickness determined by capacitance; ▲, films formed at 2.0 ma/cm², thickness determined by capacitance; ○, films formed at 1.0 ma/cm², thickness determined by comparison of interference colors with an optical step gauge.

The results of the x-ray diffraction studies on the gas phase anodic films did not indicate the presence of crystalline Ta_2O_5. A vacuum fusion analysis was conducted on both anodized and unanodized tantalum. The results of these analyses showed a significant increase in the oxygen concentration and no significant increase in the hydrogen and nitrogen concentration as a result of the gas phase anodization of tantalum. These results indicate that the film was free from hydrocarbon contamination due to the vinyl tape and the diffusion pump oil.

Discussion

The nature of the interference colors, the apparent temperature independent dielectric constant, the low dielectric loss of the films, and the fact that these films were insoluble in all common acids and alkali, except HF, is in accord with the assumption that the composition of these gas phase anodic films is Ta_2O_5.

It is of interest to compare the growth characteristics of the films formed by the gas phase and by liquid phase anodization of tantalum.

The voltage-time curves shown in Fig. 3 for the gas phase anodization exhibit similarities to those for liquid phase anodization (11) except for a brief initial period in which the voltage rise is exceptionally rapid in the gas phase process.

The thickness-voltage relationship for gas phase anodic Ta_2O_5 films plotted in Fig. 6 is not only a straight line, but matches very closely the slope of the plots for comparable films grown in liquid solutions (11). The intercepts on the voltage axis are substantially above zero.

The decay of the anode current measured as a function of time at constant current voltage is nonlinear and, in addition, the plot of the reciprocal current *vs.* time (Fig. 4) is linear and agrees with the experimental observations by Dreiner (13) for anodic Ta_2O_5 films grown in liquid electrolytes.

The current-voltage relation for a film pre-formed at 100v is more complex than that for film growth in liquid electrolytes. It can be represented as two straight lines intersecting at about 32v. This voltage value is near the point at which film growth appears to begin in the plot of Fig. 3 and also coincides with the region of the voltage intercepts in Fig. 4. These results suggest that there may be an induction period required before Ta_2O_5 film growth can proceed in the gas phase system. This latter observation may well be associated with the build-up of reactive species in the vicinity of the anode or may be due to the initial presence of a thin oxide film on the anode surface as in Vermilyea's experiments and as suggested by the plot of our data in Fig. 7. The localization of reactive species in the vicinity of the anode is consistent with the observation of a glow near the anode, but further experimental work will be required to determine adequately the composition of the gaseous electrolyte.

It is also of interest to compare our results with those of Miles and Smith (4), Tibol and Hull (5), Ligenza (6), and Weinreich (7), who have investigated gas phase anodic processes with various materials.

Miles and Smith (4) and Tibol and Hull (5) observed a linear dependence of film thickness on applied voltage with aluminum anodes. The latter also reported a nonlinear decay of the anode current with time at constant anode voltage, but their results for aluminum differ from ours for tantalum in that a plot of the reciprocal of the current *vs.* time for aluminum is nonlinear.

The maximum applied anode voltage in this work was 250v while in Miles and Smith's paper the maximum voltage reported is 9v for aluminum, and in the work of Tibol and Hull the maximum is 90v for aluminum. Ligenza (6) reports a maximum voltage of 90v for silicon anodes and Weinreich (7) reports a

maximum voltage of 50v for GaAs anodes. Ligenza (6) and Miles and Smith (4) also noted that oxide films grew on their anode surfaces when no voltage was applied, and this is probably due to the presence of high energy species in the gaseous electrolyte.

Ligenza reported a white glow on the surface of the anode during anodization. We also observed a glow, which was, however, pale green. In both cases the intensity of the glow was associated with an increase in the rate of oxide formation.

In summary, we have investigated the gas phase anodization of tantalum and observed that films obtained in this manner bear a close similarity in growth characteristics and optical and dielectric properties to those films obtained by anodization in the liquid electrolyte. We believe that this observation is made possible by the design of the anodization cell in which the anode surface is not exposed to the high energy species present in the conventional discharge. It is furthermore considered significant that the quantity of Ta_2O_5 produced in the gas anodization process is a linear function of the charge passed through the anode surface up to a formation voltage of 200v.

We suggest that the gas phase anodization process described here offers a means of preparing Ta_2O_5 films which are comparable to those obtained in liquid systems, but which are free of impurities deposited from the solution.

Manuscript received Dec. 8, 1966; revised manuscript received May 29, 1967. This research was supported by the U. S. Army Research Office, Durham, North Carolina, Intra-Army Order No. ARO-D-7 and is part of a dissertation submitted by one of the authors (T.A.J.) to Temple University Graduate Board in partial fulfillment of the requirements for the M.A. degree.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Luminescent Behavior of Bismuth in Rare-Earth Oxides

R. K. Datta

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

Activation of rare-earth oxides by ions other than rare earths is successfully attempted in the present investigation. Bi^{+3} is incorporated in yttrium, gadolinium, and lanthanum oxides by solid state reaction. Probably a charge-transfer mechanism involving bismuth and oxygen introduces an absorption band at about 3200Å region. Under 3650Å radiation R_2O_3:Bi (R =Y, Gd, La) shows Bi^{+3} emission (blue) with a broad-band spectrum extending from 4500 to 6000Å and peaking at 5000Å. When incorporated in R_2O_3:Eu phosphors, Bi^{+3} acts as a sensitizer for Eu^{+3} emission under 3650Å radiation. Energy absorbed by bismuth-oxygen component is transferred by a radiationless process to Eu^{+3} resulting in the final emission from excited Eu^{+3} ($^5D_0 \rightarrow {}^7E_2$). However, under 2537Å radiation Bi^{+3} in R_2O_3:Bi acts as a "killer." Among the three oxide matrices studied, the fluorescence of Bi has been found to be most efficient in Y_2O_3 host. Reflectance, emission, and excitation spectra of the phosphors are discussed with special reference to Y_2O_3:Bi and Y_2O_3:Eu:Bi.

Activation of rare-earth oxides by various rare-earth ions has drawn much attention in recent years. The phosphor R_2O_3:Eu (R = Y,Gd) (1) shows narrow-band, Eu^{+3} emissions in the region 5900-7000Å, a very strong maximum occurring at about 6100Å. Although efficient under cathode-ray and short wavelength (2537Å) u.v. excitations, this phosphor has very poor response to long wavelength (3650Å) u.v. radiation. Borchardt (2) studied the mechanism of absorption and emission in Y_2O_3:Eu from empirical observations. Wickersheim *et al.* (3) studied the same phosphor and interpreted its photoluminescence in terms of crystal-field theory. Ropp (4) studied different rare-earth oxide phosphors activated by rare-earth ions and generalized that except for Gd_2O_3, where special stability of Gd^{+3} is obtained due to half-filling of inner 4f shell, fluorescence occurs only in those oxides where the cation possesses no unpaired electron, *i.e.*, in Y_2O_3 and La_2O_3. Although various rare-earth ions are used to activate these oxides and other rare-earth compounds (5), only one published report (6) has come to the present author's attention where ions other than rare earths have been used to activate rare-earth compounds, especially the oxides. Bi^{+3} ion is well known as an activator and sensitizer in several particular phosphors (7). In addition, on the basis of ionic size Bi^{+3} (radius = 0.96Å)[1] is very close to Y^{+3} (r = 0.92Å), Gd^{+3} (r = 0.97Å), and La^{+3} (r = 1.14Å). On the basis of these arguments, Bi^{+3} is used in an attempt to activate Y_2O_3, Gd_2O_3, La_2O_3 (the most promising rare-earth oxide matrices known) and various solid solutions of these oxides. It has been found in the present investigation that Bi^{+3} can activate Y_2O_3, Gd_2O_3, La_2O_3, and sensitize the Eu^{+3} emission of Y_2O_3:Eu, Gd_2O_3:Eu, and La_2O_3:Eu phosphors under 3650Å excitations and possibly under cathode-rays. Thus, two different groups of phosphors are obtained. (*i*) R_2O_3:Bi (R = rare earth, Table I) and (*ii*) R_2O_3:Eu:Bi. R_2O_3:Bi shows weak blue emission under cathode rays and 3650Å radiation, whereas R_2O_3:Eu:Bi phosphor shows strong red Eu^{+3} emission under cathode rays, 2537 and 3650Å excitations.

[1] Ahrens revised figure (1953).

It should be noted that the former group does not show any Bi^{+3} fluorescence under 2537Å excitation, and although sensitized Eu^{+3} emission is observed in the latter group of phosphors under 3650Å excitation, only usual unsensitized Eu^{+3} fluorescence is shown under 2537Å radiation.

This paper describes the mechanism of photoluminescence in terms of absorption, emission, and excitation of the phosphors with special emphasis on Y_2O_3:Bi and Y_2O_3:Eu:Bi.

Experimental Procedure

Sample preparation and composition.—The raw materials used in this investigation consisted of luminescent grade (99.99-99.999% pure) oxides, such as yttrium oxide, Y_2O_3, gadolinium oxide, Gd_2O_3, lanthanum oxide, La_2O_3, europium oxide, Eu_2O_3, and bismuth trioxide, Bi_2O_3.

Appropriate amounts of Y_2O_3, Eu_2O_3, and Bi_2O_3 were mixed together and dissolved in dilute nitric acid. Eu and Bi were incorporated in yttrium (gadolinium, lanthanum) oxide by co-precipitation as the oxalates from the nitrate solution. The oxalate was ignited to oxide at temperatures from 900° to 1000°C[2] for 1 or 2 hr depending on the size of the charge. The firings of the phosphor were done in covered, fused-silica containers. Samples consisting essentially of Gd_2O_3 required a second firing at about 650°C for complete conversion to the low temperature, cubic form which is the most efficient matrix among Gd_2O_3 polymorphs.

Samples having general composition $(R_{1-y}Bi_y)_2O_3$ and $(R_{1-x-y}Eu_xBi_y)_2O_3$ with x and y varying from 0.005 to 0.06 and 0.001 to 0.02, respectively, were synthesized. Composition of the finished phosphors were periodically analyzed by wet chemical method in order to determine the loss of bismuth during firing. A loss of 2-6% of Bi was noticed in the analyzed samples; however, the amount of bismuth in the phosphor described throughout this report is based on the formulated compositions.

To assure that all bismuth-activated compositions studied in the present investigation were single phases, the preliminary step involved in activating rare-earth oxides was to study the solubility of Bi_2O_3 in the rare-earth oxide lattices. Bi_2O_3 has two stable polymorphs. The high temperature cubic form shows a reversible transition to the low temperature monoclinic form at 730°C. Levin and Roth (8) studied the phase equilibrium relationship of the bismuth-rich side [100-85 m/o (mole per cent) of Bi_2O_3] of the systems Bi_2O_3-M_aO_b (M stands for cations having charge from one to five). Since a detailed study of the phase equilibrium relationships between the rare-earth oxides and Bi_2O_3 is beyond the scope of the present program, only the subsolidus solubility of Bi_2O_3 in the rare-earth oxide lattices at 1050°C was studied. It has been found that at least 50, 35 and 15 m/o of Bi_2O_3 is soluble in Y_2O_3, Gd_2O_3, and La_2O_3, respectively, at 1050°C. These amounts are well beyond the range of concentration of activators in usual phosphors. Nevertheless, phase purity of the phosphors prepared was checked by x-ray diffraction analysis. CuKα radiation from a G. E. diffractometer with a nickel filter was used to investigate all compounds.

Spectroscopic measurements.—Diffuse reflectance spectra of the samples within the range 2500-7000Å were obtained using CaF_2 as standard in a Cary Recording Spectrophotometer, Model No. 14. The emission spectra from phosphor plaques, excited under different u.v. sources, were obtained by a direct-recording spectroradiometer (9) adapted with a grating monochromator with nearly constant dispersion. Maximum sensitivity in the spectral region from 2500-7000Å was obtained with a quartz-windowed, S-20 response photomultiplier. The total band pass was kept about 30Å. The spectra were calibrated against a standard tungsten filament lamp reflected from a magnesium-oxide plaque. Photoluminescent-brightness data given throughout this report were measured from the height of the main peak (in case of narrow emission), or from the area (in case of broad emission) of the emission spectra. The excitation spectra were measured using sodium salicylate as standard.

Cathodoluminescence spectra were obtained using a demountable cathode-ray tube operating at 20 kv anode potential at 17.5μ a beam current over a standard scan TV raster of 35 cm^2 area. Brightness and color points of emission under these conditions were measured using an eye-corrected Weston foot-Lambert meter and G. E. colorimeter (JB1E), respectively.

Results and Discussions

The subsequent discussion on optical properties will pertain to the optimized phosphors, *i.e.*, $(Y_{0.995}Bi_{0.005})_2O_3$ and $(Y_{0.946}Eu_{0.05}Bi_{0.004})_2O_3$, unless otherwise stated. However, spectra of phosphors having other compositions are presented in many figures to emphasize the role of Bi.

Excitation spectra.—The excitation spectra of Y_2O_3:Bi (Fig. 1) and Y_2O_3:Eu:Bi (Fig. 2 and 3) are shown.

Y_2O_3:Bi has a spectrum with narrow responses at about 2000 and 3650Å regions. Y_2O_3:Eu:Bi has a broad excitation spectrum with responses to 2000, 2537, and 3650Å excitations. This spectrum, divided into two parts, is shown in Fig. 2 and 3. Y_2O_3:Eu has a very poor response to 3650Å excitation. However, incorporation of Bi enhances its response to 3650Å excitation markedly with a simultaneous, but small decrease in its response to both 2000 and 2537Å radiations. The

[2] Commercial grade Y_2O_3:Eu phosphor is usually fired at about 1200°C or higher. The lower temperature of firing, as followed in the present investigation, was necessitated due to high volatility of Bi_2O_3. This low temperature of firing also explains the lower brightness of the standard sample (see Tables II and III).

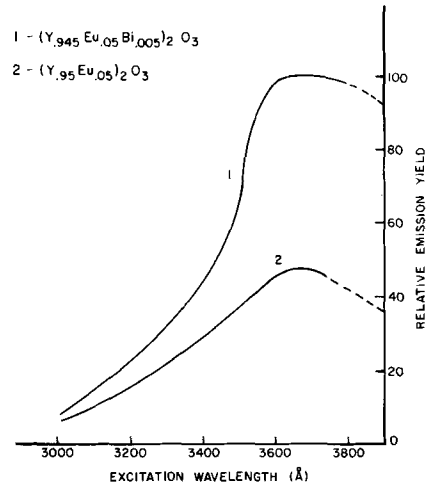

Fig. 3. Excitation spectra of Y_2O_3:Eu and Y_2O_3:Eu:Bi (3000-3800Å).

implication of these excitation data will be discussed later in conjunction with emission and reflectance spectra.

Emission spectra and plaque brightness.—Bi^{+3} activated rare-earth oxides do not show any emission under 2537Å radiation (Table I). However, when excited by 3650Å radiation, they emit broad-band spectra in the region of 4500-6000Å with a peak at about 5000Å. Most of the Bi^{+3}-activated phosphors (sulfides, selenides, carbonates, oxides, silicates, etc.) emit in the blue region, although other emissions, such as green, yellow, red, etc., are known (7). No simple correlation between the Bi^{+3} emission and composition and structure of the matrices could be obtained. Bi^{+3} fluorescence is suggested to be due to $6s6p \rightarrow 6s^2$ transition (10). These outer sp orbitals of Bi^{+3} ions are also actual bonding orbitals which are influenced by the neighboring anions. It may be generalized that in all these phosphors Bi^{+3} ions act as emission centers, although the nature of the emission is highly influenced by the environment of Bi^{+3} ion. Pure rare-earth oxides, such as Y_2O_3 and Gd_2O_3, do not show any emission under cathode-ray and u.v. excitations. Hence, on the basis of their blue emission under cathode-ray and 3650Å excitations, it may be postulated that Bi^{+3} ions in R_2O_3:Bi act as primary activators, although indirect involvement of oxygen ions in the emission process cannot be ruled out.

The emission spectra of Y_2O_3:Bi under 3650Å excitation are shown in Fig. 4. Normalized plots of plaque brightness against logarithm of Bi^{+3} concentration in Y_2O_3 and Gd_2O_3 are shown in Fig. 5. The optimum ranges of concentration of Bi^{+3} in Y_2O_3 and Gd_2O_3 are found to be about 0.5-2 and 0.5-1 m/o, respectively, of total yttrium (gadolinium) and bismuth present.

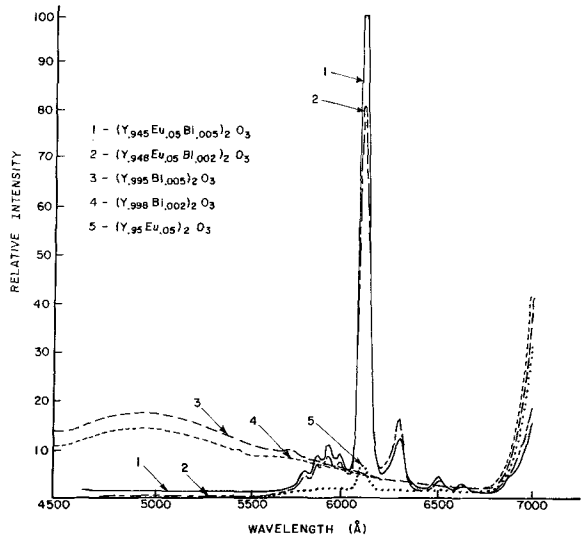

Fig. 4. Emission spectra of $(YEuBi)_2O_3$ under 3650Å excitation

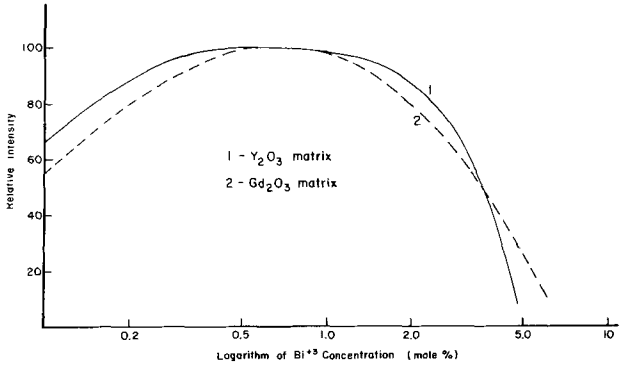

Fig. 5. Plaque brightness vs. Bi^{+3} concentration in Y_2O_3 and Gd_2O_3 (3650Å excitation).

Y_2O_3:Eu:Bi samples show essentially Eu^{+3} emission under cathode rays (Fig. 6), 2537Å (Fig. 7), and 3650Å radiations (Fig. 4). Under 2537Å radiation, as Bi^{+3} is added to Y_2O_3:Eu, the plaque brightness gradually decreases, whereas under 3650Å excitation the brightness shows a sharp rise with increase in Bi^{+3} content (Fig. 8, Table II). This is also demonstrated in the emission spectra of the samples.

Under 3650Å excitation Y_2O_3:Eu has very weak emission. As Bi^{+3} is incorporated in the lattice, the narrow-band Eu^{+3} emission with a maximum at 6110Å ($^5D_0 \rightarrow {}^7F_2$ transition) is enhanced considerably. On the other hand, the band shape of the Bi^{+3} emission in Y_2O_3:Bi is generally unchanged, although the intensity of the luminescence of Bi^{+3} is strongly quenched by incorporating europium in the phosphor (Fig. 4). This indicates that Bi^{+3} is acting as a sensitizer for Eu^{+3} emission and the major portion of the energy, which would have otherwise been emitted as Bi^{+3} emission (as in Y_2O_3:Bi), is transferred by a radiationless process (11) to Eu^{+3} resulting in excitation of the latter among levels of the $4f^6$ configuration. The final emission originates from these excited Eu^{+3} ions. The situation is quite different under 2537Å excitation. Bi^{+3} in Y_2O_3:Bi does not show any emission, whereas Y_2O_3:Eu shows Eu^{+3} emission corresponding to $^5D_0 \rightarrow {}^7F_2$ transition. As Bi^{+3} is gradually

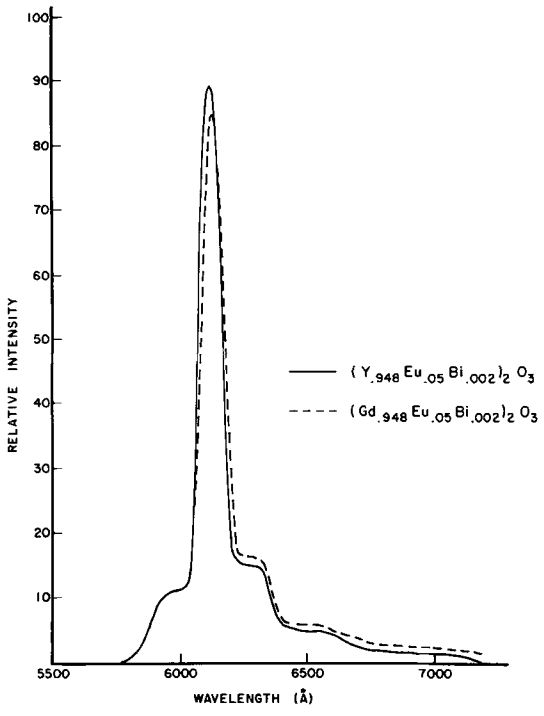

Fig. 6. Emission spectra of R_2O_3:Eu:Bi phosphors (R= Gd, Y); cathode ray excitation.

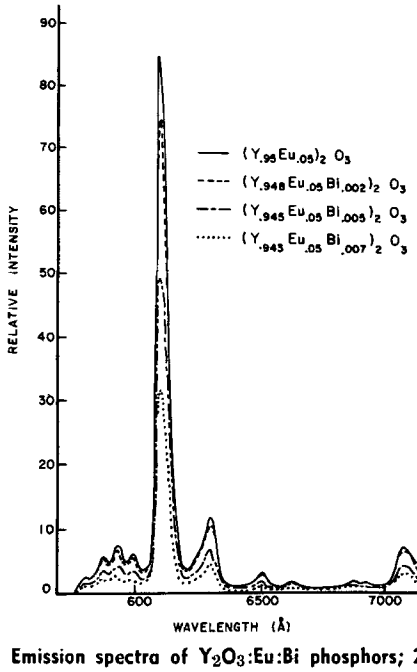

Fig. 7. Emission spectra of Y_2O_3:Eu:Bi phosphors; 2537Å excitation.

incorporated in Y_2O_3:Eu, Eu^{+3} emission is gradually reduced without any noticeable emergence of Bi^{+3} emission.

These observations indicate that Bi^{+3} in Y_2O_3:Eu:Bi acts as "killer" and sensitizer for Eu^{+3} emission under 2537 and 3650Å excitation, respectively.

The cathode ray brightness of Y_2O_3:Eu:Bi as function of Bi^{+3} concentration is shown in Fig. 9. Because of instrumental limitations, the cathode-ray spectra (Fig. 6) could not detect any Bi^{+3} emission. However, weak Bi^{+3} emission under cathode-ray excitation, as indicated by shift in color point (Table III) with increase in Bi^{+3} content, is inferred. This bismuth emission, although undetected, may also explain the increased brightness of the phosphor Y_2O_3:Eu:Bi with

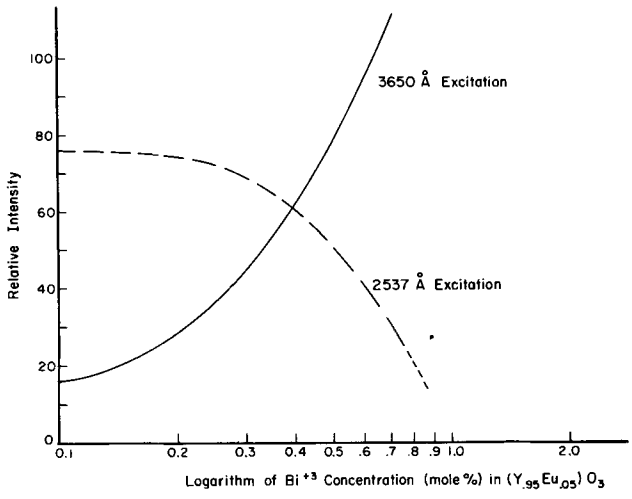

Fig. 8. Plaque brightness vs. Bi^{+3} concentration in Y_2O_3:Eu:Bi

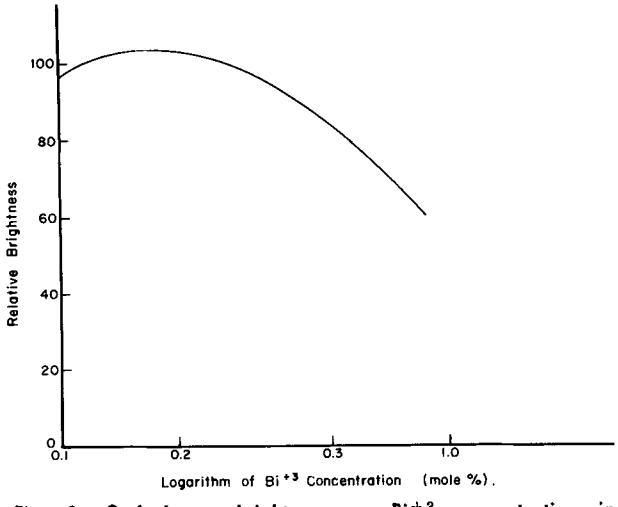

Fig. 9. Cathode-ray brightness vs. Bi^{+3} concentration in Y_2O_3:Eu:Bi.

very litle change in the Eu^{+3} emission peak under cathode-ray excitation.

Reflectance spectra.—Y_2O_3:Bi.—The reflectance spectra of the Y_2O_3:Bi samples studied are shown in Fig. 10. Gd_2O_3, Y_2O_3, and La_2O_3 show broad u.v.-absorption bands at wavelengths less than 2300Å. Addition of Bi^{+3} to these oxides introduces two broad absorption bands, namely, at 2500 (or lower wavelengths) and 3200Å regions. Pure Y_2O_3 has about 90 and 100% re-

flectance at 2500 and 3600Å, respectively, whereas $(Y_{0.995}Bi_{0.005})_2O_3$ has about 20 and 60% reflectance at the corresponding wavelengths. The u.v.-absorption bands (below 2300Å) of pure rare-earth oxides are attributed to charge-transfer absorption states involving the rare-earth ion and oxygen (2). A similar absorption band is seen in Bi_2O_3, except that it extends to longer wavelength (to 4200Å) as shown in Fig. 11. Absorption of u.v. radiation due to charge-transfer processes involving Bi^{+3} is known (10). The question now arises if Bi^{+3} is excited directly, or bismuth-oxygen states are involved during such absorption. The reflectance spectrum of a non-oxidic bismuth compound, such as BiF_3 (Fig. 11), shows absorption around 2500Å only. This suggests that u.v.-absorption of Y_2O_3:Bi at about 3200Å may well be due to charge-transfer states involving bismuth and oxygen, whereas the absorption at about 2500Å is caused by excitation of Bi^{+3} ion.

The essential mechanism of fluorescence in Y_2O_3:Bi under 3650Å excitation is, therefore, suggested to be absorption of long wavelength (3650Å) u.v. radiation by the bismuth-oxygen component resulting in the excitation of charge-transfer states and the final emission from such excited states. The excitation band of Y_2O_3:Bi at around 2000Å (Fig. 1) may be due to fundamental absorption by Y_2O_3. The failure of Y_2O_3:Bi to emit under 2537Å excitation, in spite of its high absorption of this radiation, is not understood yet.

Y_2O_3:Eu:Bi.—Y_2O_3:Eu has about 15 and 95% reflectance around 2500 and 3600Å, respectively, and it shows strong Eu^{+3} emission under short wavelength (2537Å) u.v. radiation. From a study of the reflectance and excitation spectra of many Eu^{+3}-activated phosphors,

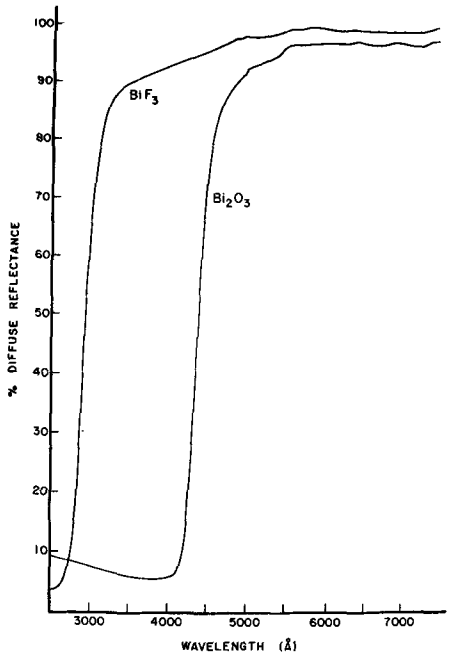

Fig. 11. Diffuse reflectance spectra of BiF_3 and Bi_2O_3

Borchardt (2) suggested that excitation is due to charge-transfer absorption involving Eu-O components, and wavelengths anywhere below 2800Å would cause such absorption and efficiently excite Eu^{+3} ions to fluoresce.

When Bi^{+3} is incorporated in Y_2O_3:Eu, a new, broad absorption band is introduced at about 3200Å, although little change in absorption at about 2500Å is observed. The band extends well up to 4000Å, and incorporation of 0.5 m/o of Bi^{+3} in $(Y_{0.95}Eu_{0.05})_2O_3$ causes a reflectance of about 60% at 3650Å, whereas $(Y_{0.95}Eu_{0.05})_2O_3$ with no Bi^{+3} has a reflectance of about 95% at the same wavelength (Fig. 12). This new absorption, on the basis of arguments presented earlier, might well be due to absorption by bismuth-oxygen components of the phosphor. Furthermore, this new absorption band is responsible for the enhanced Eu^{+3} emission of Y_2O_3:Eu:Bi under 3650Å excitation. It

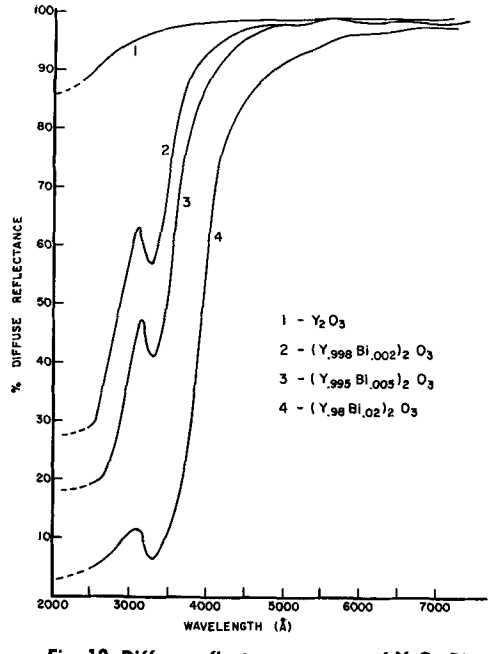

Fig. 10. Diffuse reflectance spectra of Y_2O_3:Bi

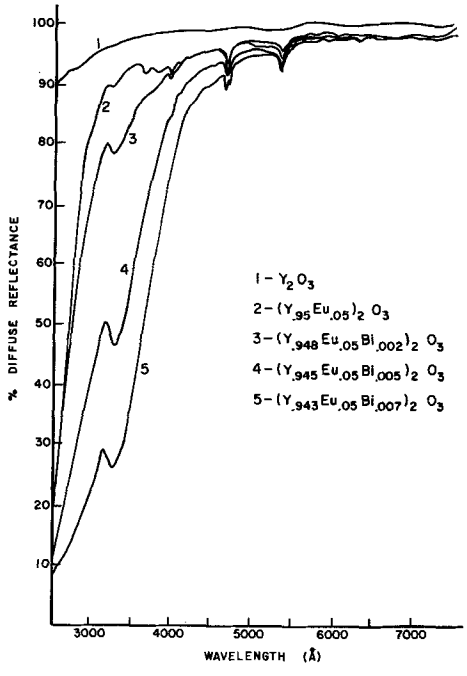

Fig. 12. Diffuse reflectance spectra of Y_2O_3:Eu:Bi

may be recalled here again that under 3650Å excitation Y_2O_3:Eu:Bi phosphor shows Eu^{+3} emission much more intensely than that shown by Y_2O_3:Eu under similar conditions. This contradicts Borchardt's (2) suggestion that the minimum energy required for Eu^{+3} fluorescence in any host is about 2800Å radiation. His observation is true in cases where absorption is caused essentially by Eu-O components of the phosphors.

The inferences drawn from the emission and reflectance spectra can be combined and the postulated mechanism of fluorescence in Y_2O_3:Eu:Bi restated. Eu^{+3} emission of Y_2O_3:Eu:Bi under 3650Å excitation is due to charge-transfer absorption involving Bi-O components of the phosphor resulting in the excitation of charge-transfer states, relaxation of these giving rise to Bi^{+3} in the excited states, transfer of energy from Bi^{+3} to Eu^{+3} and the final emission from the excited states of Eu^{+3} among levels of the $4f^6$ configuration. Although incorporation of Bi^{+3} does not decrease the absorption of Y_2O_3:Eu around 2500Å region, Eu^{+3} emission of Y_2O_3:Eu is gradually reduced under 2537Å excitation as Bi^{+3} is gradually incorporated in the lattice (Fig. 7). Probably, under 2537Å radiation Bi^{+3} acts as a "killer" in the phosphor Y_2O_3:Eu:Bi.

Summary

Oxides of yttrium, gadolinium, and lanthanum show extensive solid solution with Bi_2O_3. However, when incorporated in small amounts (0.1-2 m/o) in these oxides, Bi^{+3} introduces broad absorption bands at about 3200Å. By analogy, as well as by independent evidence, this absorption band is attributed to charge-transfer states involving bismuth and oxygen. By virtue of such broad absorption, R_2O_3:Bi (R = Y, Gd, La) show Bi^{+3} emission (blue) under 3650Å excitation. When incorporated in R_2O_3:Eu phosphor, Bi again introduces a new absorption band around 3200Å which extends well up to 4000Å. This enhances the Eu^{+3} emission of R_2O_3:Eu:Bi under 3650Å radiation; on the other hand, the emission under 2537Å excitation is reduced. Bi^{+3}, therefore, acts as a sensitizer and "killer" for the Eu^{+3} emission in R_2O_3:Eu:Bi under 3650 and 2537Å, respectively. In the former case, energy absorbed by bismuth-oxygen component is transferred by a radiationless process to Eu^{+3} resulting in the sensitization of Eu^{+3} ions and their excitation between states of the $4f^6$ configuration. Final emission takes place from the excited Eu^{+3} ion ($^5D_0 \rightarrow {}^7F_2$).

Of the three oxide matrices studied, Y_2O_3 has been found to be the most suitable matrix for Bi^{+3} activation.

Acknowledgment

The author acknowledges the assistance of Dr. R. L. Brown in obtaining emission and excitation spectra, of Miss M. Brines and F. Geraghty who measured cathodoluminescent properties. The author also wishes to express his thanks to L. S. Staikoff for x-ray measurements, to T. Luscher for preparing the phosphor and measuring u.v. brightness and to Dr. E. F. Apple for many helpful discussions. The quantitative analyses of Bi in the samples were done by N. Braun.

Manuscript received April 27, 1967; revised manuscript received July 17, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

The Role of Copper in the Transformation of Hexagonal Zinc Sulfide

Gleb Gashurov[1] and Ephraim Banks

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The mechanism of the copper-induced transformation of hexagonal zinc sulfide was investigated. High-temperature x-ray studies and rate experiments suggest that the transformation is characterized by a one-dimensional recrystallization process, initiated by nuclei of cubic ZnS which precipitate from a solid solution of ZnS in cuprous sulfide under gross isothermal conditions. This solid solution is formed at elevated temperatures, and at 800°C the concentration of ZnS that can be dissolved in cuprous sulfide lies in the neighborhood of 8 mole per cent.

Well crystallized hexagonal ZnS is known to be exceptionally stable toward the transformation to its cubic modification. The temperature of transition between hexagonal ZnS (high temperature form) and cubic ZnS is around 1020°C (1, 2), but highly perfect crystals of hexagonal ZnS show no change in structure even after annealing at 975°C for 504 hr (3).

When hexagonal ZnS (wurtzite) is fired in the presence of small amounts of copper, the transformation to the cubic phase (sphalerite) is found to begin at a temperature as low as 350°C (4). It appears that there exists a minimum concentration of copper that will initiate the wurtzite-sphalerite transformation at a given temperature within a reasonable period of time. Nickerson, Goldberg, and Baird (5) found that when a given hexagonal ZnS:Cu,Cl sample was fired in H_2S, above its critical temperature, appreciable amounts of both copper and chloride were ejected from the ZnS lattice. They speculate that the H_2S serves to remove copper as copper sulfide, and that it is the physical presence of copper sulfide as a separate phase that triggers the observed transformation. This hypothesis is strongly supported by their experiments in which a small amount of copper sulfide was added to samples containing certain amounts of incorporated copper. Complete transformation occurred at a temperature 100°-200° below the temperature at which the transformation would occur without additional copper. These samples showed no significant changes in incorporated copper content.

Aven and Parodi (6) have also proposed that the hexagonal to cubic transformation of ZnS:Cu is initiated by the formation of a separate phase of copper sulfide. They observed that, in ZnS:Cu samples synthesized at 1100°C in H_2S and then cooled to room temperature, the wurtzite-sphalerite transition become detectable when the concentration of incorporated copper was increased to about 5×10^{-4} atom fraction. However, in the presence of small amounts of aluminum, which has been shown to increase the solubility of copper in ZnS (7), a higher concentration of copper was necessary to trigger the transformation. In fact, the change became appreciable when the Cu-concentration in excess of that of aluminum was about 5×10^{-4} atom fraction.

The effect of copper on the transformation of hexagonal ZnS has also been discussed by Ballentyne (8), Gobrecht *et al.* (4), and by Presland *et al.* (9).

The experiments by Nickerson *et al.*, as well as those by Aven and Parodi, indicate then that it is the external (unincorporated) copper sulfide phase that initiates the ZnS transition. It was decided therefore to carry out a detailed study of the zinc sulfide-copper sulfide interaction. Particular emphasis was placed on a high temperature x-ray study of the system. The investigation also included a study of the kinetics of the copper-induced ZnS transformation.

Experimental

Materials.—Hexagonal ZnS was prepared by firing ZnS precipitate in an atmosphere of hydrogen sulfide at 1200°C for 2 hr. The resulting hexagonal ZnS showed no detectable transformation to the cubic phase when fired at 800°C for 2 hr in H_2S,N_2, vacuum or sulfur vapor. $Cu_{1.8}S$ was prepared in two steps. Spectroscopically pure copper was fired in H_2S at 800°C for 1 hr. Chemical analysis showed its copper content to be 78.36% by weight (the theoretical content is 79.88%). This impure $Cu_{1.8}S$ was then fired in a sealed, evacuated vial containing a small amount of CuS at 800°C for 4 hr. (CuS was separated from $Cu_{1.8}S$ by means of a quartz partition as shown in Fig. 1). The x-ray pattern of the resulting sulfide was in excellent agreement with that of Djurle's $Cu_{1.8}S$ (10). The preparation of Cu_2S was also carried out in two steps. First, CuS was fired in nitrogen at 800°C for 1 hr. This treatment produced $Cu_{1.96}S$ together with a small amount of Cu_2S. The mixture was then fired in a sealed, evacuated vial containing a small amount of copper (Fig. 1) at 800°C for 4 hr. The resulting material was examined with x-rays and found to be essentially pure Cu_2S with a trace of $Cu_{1.96}S$. Single crystals of zinc sulfide were kindly supplied by Dr. H. Samelson of General Telephone & Electronics Laboratories. The preparation of these crystals is described in ref. (11).

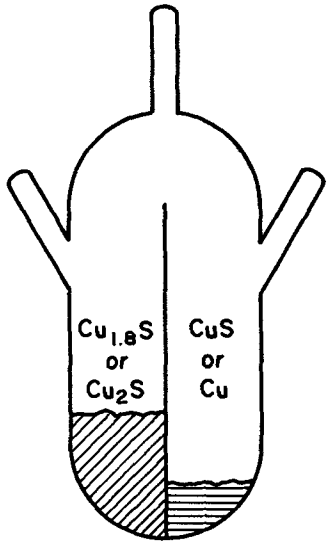

Fig. 1. Quartz vial used for preparation of cuprous sulfides

[1] Present address: General Telephone & Electronics Laboratories, Incorporated, Bayside, New York.

X-ray measurements.—X-ray measurements were made on a Philips wide range goniometer using a Geiger tube as a detecting source. The degree of the ZnS conversion was calculated by measuring the integrated intensity of the (200) cubic reflection and normalizing it with respect to the intensity for a completely converted sample. The (200) peak was chosen because it is the strongest cubic reflection which is not overlapped by hexagonal peaks. The (200) peak was scanned at the rate of 1/8°/min using a time constant of 4 sec. To minimize preferred orientation, the following technique was used. Specimens were moistened with a dilute solution of castor oil in xylene and gently pressed into the specimen holder which was in the form of a machined recess in an aluminum disk. The specimen was then rotated about an axis at right angles to the diffractometer axis and normal to the plane of the specimen. This technique reduced the mean deviation in the (200) integrated intensity to a few per cent. In those cases where only a qualitative x-ray identification was desired, the scanning speed was increased to 1°/min. Nickel filtered CuKα was used in all x-ray measurements.

High temperature x-ray measurements were made in a special high temperature diffractometer attachment (model X-86G, MRC Corporation) used with a Philips wide-range goniometer. The specimen stage in most experiments was a Pt-40% Rh ribbon which also served as a heating element, with a Pt/Pt-13% Rh thermocouple welded to the specimen stage. High temperature runs were made in a nitrogen atmosphere. The zero positioning in the attachment is possible only by using actual Bragg reflections as a gauge. The Bragg reflections of the powder specimen were determined at room temperature prior to the high temperature measurements. The room temperature reflections served as the basis for correcting the high temperature peaks.

Results

According to Djurle (10) there are four compositional forms of copper sulfide: Cu_2S, $Cu_{1.96}S$, $Cu_{1.8}S$, and CuS. Since preliminary experiments showed that firing of hexagonal ZnS with CuS produces no detectable transformation in the ZnS phase until CuS is decomposed into cuprous sulfide, investigation of the relative efficiencies of copper sulfides in transforming hexagonal ZnS was limited to cuprous sulfides.

First, experiments were carried out to determine conditions under which firing of ZnS with cuprous sulfides produces no change in the copper sulfide phase. ZnS was mixed with $Cu_{1.8}S$ (in the ratio of 2 to 1 by weight) and fired in a sealed, evacuated quartz vial containing a small amount of CuS (not in physical contact with the mixture) at 800°C for 1 hr.[2] A similar experiment was carried out with a mixture of ZnS and Cu_2S, except that in this case copper metal was used instead of CuS. In both cases ZnS was completely converted to the cubic form but no changes could be detected in the copper sulfides. These experimental conditions appear then to preserve the identities of copper sulfides. Next, ZnS was fired in sealed vials at 800°C for 1 hr with 1% by weight of Cu_2S or $Cu_{1.8}S$ under conditions stabilizing the respective cuprous sulfides. Conversion was found to be complete in the case of ZnS-$Cu_{1.8}S$, and nearly complete in the case of ZnS-Cu_2S. Similar firings were carried out at lower temperatures (700° and 600°C). In all cases the degree of transformation was only slightly higher for the ZnS-$Cu_{1.8}S$ combination. Similar experiments were carried out with ZnS-$Cu_{1.96}S$. Unfortunately, attempts to prepare pure $Cu_{1.96}S$ (free of Cu_2S) were not successful. Experiments with cuprous sulfide consisting of predominantly $Cu_{1.96}S$ (with some Cu_2S) showed that this mixture was essentially as effective as pure Cu_2S. One may conclude, then, that at least when present in amounts exceeding 1%, all forms of cuprous sulfide, namely, Cu_2S, $Cu_{1.96}S$, and $Cu_{1.8}S$, are nearly equally effective agents in ZnS transformation.

[2] In this experiment as well as in all experiments except the high temperature x-ray studies, samples were cooled by removing the combustion tube from the furnace. This resulted in a cooling time of about 5 min.

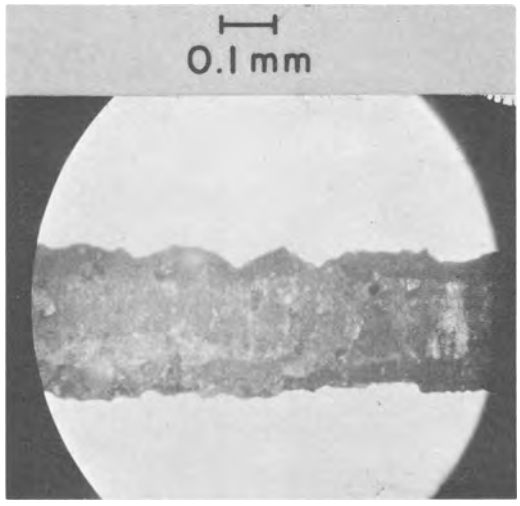

Fig. 2. Photomicrograph of ZnS single crystal treated with CuS at 800°C.

In the course of studies with single crystals, it was found that heat treatment of ZnS single crystals embedded in copper sulfide leaves marked signs of chemical attack on ZnS. For example, a "thick" crystal of hexagonal ZnS (3 mm long and 0.2 mm thick) was fired together with two "thin" ZnS crystals (2 mm long and slightly less than 0.1 mm in thickness) in H_2S at 800°C for 1 hr. The crystals were embedded in CuS powder. After the treatment, the thin crystals could not be detected; microscopic examination of the thick crystal (after KCN-washing) showed that the crystal had been heavily attacked by CuS as can be seen in Fig. 2. A rotation photograph of this crystal was that of a heavily faulted cubic ZnS with just a trace of coherent hexagonal ZnS. In addition, a polycrystalline pattern of cubic ZnS was superimposed on the single crystal photograph.

Additional single crystal experiments gave similar results. Of particular interest is the experiment in which two single crystals of hexagonal ZnS were placed on a pressed pellet of $Cu_{1.8}S$ and fired in H_2S at 900°C for 1 hr. Figure 3 shows the photographs of one of the crystals before and after firing. One can see that as a result of this treatment, the ZnS crystal has been covered with a very thick coating of $Cu_{1.8}S$ (the cross-section has increased by a factor of almost two). The crystal was then treated with KCN solution for a few minutes and photographed again. In Fig. 3c small ZnS crystallites are seen dispersed in $Cu_{1.8}S$. Complete KCN treatment left only polycrystalline ZnS together with a very thin ZnS plate containing fairly large portions of monocrystalline cubic ZnS. The plate was found below the original ZnS crystal and since its dimensions were longer than the cross-section of the original crystal, it is possible that it crystallized on cooling.

A possible explanation for the result of the above experiments is that zinc sulfide and copper sulfide interact to form a compound or a solid solution. X-ray examination of quenched ZnS-CuS samples showed no phases other than those of pure ZnS (hexagonal or cubic) and cuprous sulfide. It was decided therefore to use high temperature x-ray techniques in our further study of the ZnS-copper sulfide interaction.

High temperature x-ray studies.—The following experiment shows a typical course of the ZnS-CuS interaction at elevated temperatures. A 1 to 1 mixture (by weight) of ZnS and CuS was x-rayed in N_2 atmosphere on a high-temperature diffractometer. The temper-

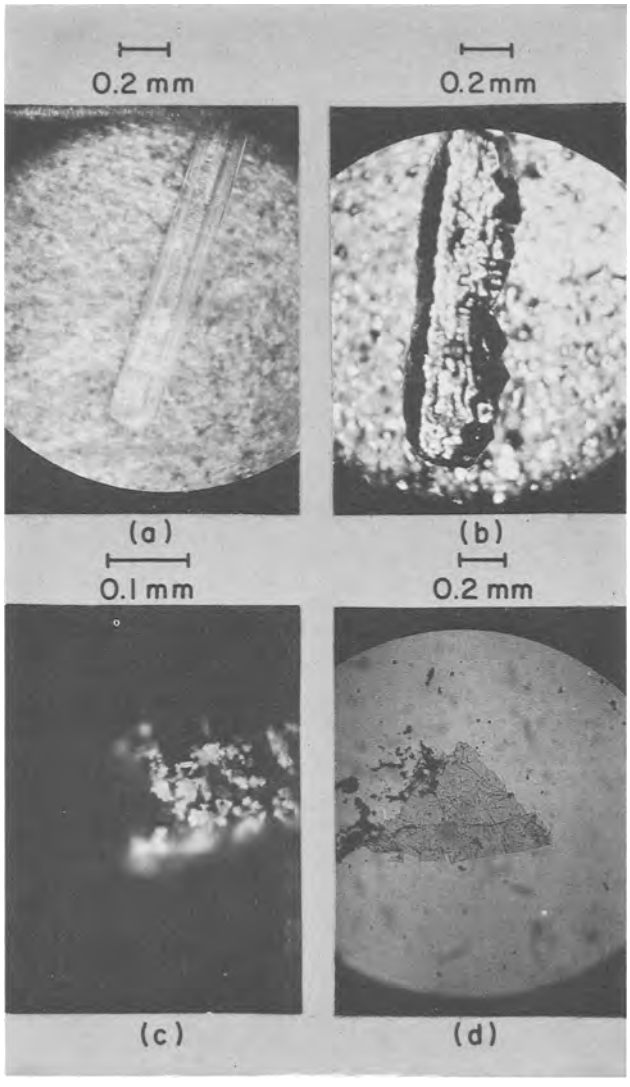

Fig. 3. Photomicrograph of ZnS single crystal treated with cuprous sulfide: (a) before copper treatment, (b) after copper treatment, (c) copper treated crystal after KCN etching, (d) ZnS plate (see text).

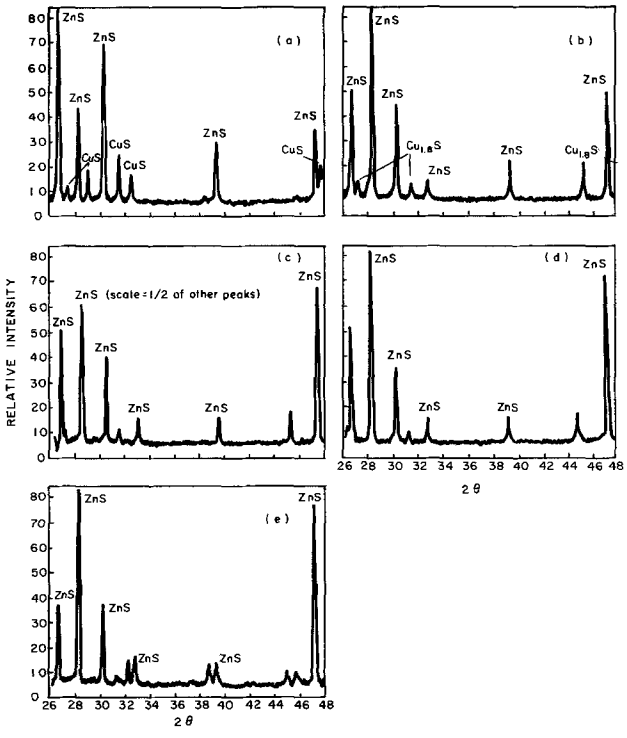

Fig. 4. High temperature diffractometer traces of ZnS + CuS: (a) at 300°C, (b) at 350°C, (c) at 350°C, (d) at 400°C, (e) at room temperature following high temperature run.

ature was raised from room temperature to 300°C within 15 min, and 30 min later an x-ray trace was taken. The x-ray pattern, Fig. 4a, is that of well-crystallized hexagonal ZnS and CuS. The temperature was raised to 350°C, and a few minutes later an x-ray trace was taken. CuS was found to be converted to $Cu_{1.8}S$, while a substantial fraction of the ZnS was transformed to the cubic form (Fig. 4b). The temperature was kept constant, and 30 min after the first run at 350°C a second trace was taken. As can be seen from Fig. 4c, the ratio of cubic to hexagonal ZnS increased still further. A slight shift may be detected in the cuprous sulfide peaks indicating transition from $Cu_{1.8}S$ toward $Cu_{1.96}S$. The temperature was next raised to 400°C, and after about 20 min an x-ray trace was taken. Figure 4d shows that the cubic to hexagonal ratio increased still further, while the cuprous sulfide peaks diminished slightly in intensity (the intensity decrease in cuprous sulfide peaks has been found to be quite general for the ZnS-cuprous sulfide system at elevated temperatures). The temperature was lowered to room temperature within a few minutes. Apart from a slight thermal shift, the ZnS pattern can be seen to be essentially unchanged as compared with that at 400°C. The cuprous sulfide is found to consist of low-temperature forms of $Cu_{1.96}S$ and $Cu_{1.8}S$ (Fig. 4e).

In some high temperature experiments the conversion of CuS has been found to precede the transformation of ZnS. The temperature of the incipient ZnS transformation was usually around 350°-400°C. Certain important facts emerge from these experiments. First, the conversion of ZnS occurs at the firing temperature and not during the cooling process. Also the transformation of ZnS appears to be preceded by the conversion of CuS. It appears then that copper sulfide must be in the form of the high temperature modification of cuprous sulfide in order to exert its catalyzing effect.

Experiments were then carried out to determine changes in lattice constants of ZnS and Cu_2S. The lattice determination of the high temperature Cu_2S form was based on its (220) peak since this is the strongest peak of high Cu_2S and, except for the (311) peak [which is only 4° above the (220) peak], is the peak with the highest θ value. For the sake of consistency, the lattice determination of ZnS was also based on its (220) peak, both (220) of ZnS and (220) of Cu_2S occurring in the 22°-24° θ range. Since in the high temperature diffractometer the flat surface of the specimen did not usually pass through the rotation axis of the instrument, the following procedure was adopted. The pure samples of ZnS and Cu_2S were first run on the regular wide range diffractometer at room temperature, and the (220) peak of ZnS (cubic), as well as the (3.12.0) peak of room temperature Cu_2S, was calibrated against the (220) peak of a National Bureau of Standards silicon sample. The difference between the correct value of the peak (of either ZnS or Cu_2S) and the room temperature value of the same peak recorded on the high temperature diffractometer was used to correct the high temperature (220) peaks of both ZnS and Cu_2S. This procedure is permissible since all the pertinent peaks occur in the 22°-24° θ region. The angular shift due to displacement of the sample from the instrument axis is proportional to $\cos\theta$ (12), and this means that in the 22°-24° region the shift varies by less than 1.4%.

Table I gives the calculated lattice parameters for ZnS and Cu_2S. The values were based on three independent runs. According to Djurle (10) the value of a for Cu_2S is 5.735 ± 0.010Å at 500°C which is seen to

Table I. Lattice parameters of ZnS and Cu_2S

Sample	a, Å
Pure ZnS at 500°C	5.434 ± 0.010
ZnS in ZnS + Cu_2S mixture at 500°C	5.437 ± 0.010
Pure ZnS at 800°C	5.448 ± 0.010
ZnS in ZnS + Cu_2S mixture at 800°C	5.450 ± 0.010
Pure Cu_2S at 500°C	5.725 ± 0.010
Cu_2S in ZnS + Cu_2S mixture at 500°C	5.720 ± 0.010
Pure Cu_2S at 800°C	5.762 ± 0.010
Cu_2S in ZnS + Cu_2S mixture at 800°C	5.736 ± 0.010

be quite close to the value obtained in our investigation, 5.725. If one assumes a linear relation between unit cell parameter and concentration, one obtains a value of 8 m/o (mole per cent) of ZnS in Cu_2S at 800°C. The lattice parameter of ZnS, in the presence of Cu_2S at high temperatures, seems to show a slight trend indicating solid solution of Cu_2S in ZnS. However, these shifts are within experimental error. No such apparent shift was detectable in ZnS at room temperature. In all cases, analysis of cooled and cyanide washed samples showed retained copper concentrations of the order of a few hundred parts per million.

The results of the experiments described so far point very strongly to the existence of a solid solution between ZnS and cuprous sulfide. These results are thus in basic agreement with those of Novoselov (13). Novoselov's value for the concentration of ZnS dissolved in Cu_2S at 800°C is about 12 m/o (as estimated from his diagram). His results were obtained by means of differential thermal analysis.

Experiments were carried out to obtain additional evidence for solid solution formation between ZnS and Cu_2S.

A mixture of 0.95 mole of Cu_2S and 0.05 mole of cubic ZnS was deposited on Pt-Rh holder. The temperature was raised quickly (2 to 3 min) to 800°C. The (111) peak of cubic ZnS could not be detected. The 30°-28° region was scanned for 38 min more but no indication of the (111) peak was obtained. The temperature was then lowered to 500° and a small though rather broad (111) peak was recorded. This peak became sharper with time at 500°C, indicating a crystallization process of ZnS. The temperature was raised to 800°C again and the (111) peak disappeared. A similar experiment was made with a mixture containing 8 m/o of cubic ZnS. The results were essentially the same as in the preceding experiment. In a mixture containing 15 m/o of ZnS, however, the ZnS phase could be detected at both 500° and 800°C.

The last three experiments allow one to set approximate limits on the solid solubility at 500° and 800°C. The ZnS phase in the 5% ZnS mixture was detectable at 500°C. The ZnS concentration in Cu_2S is therefore less than 5 m/o at 500°C. At 800°C the ZnS phase disappears in both 5 and 8% ZnS mixtures. It is significant that in the 8% mixture the position of the (200) Cu_2S peak reached what appears to be an equilibrium 2θ value at 800°C. The ZnS concentration at 800°C then does not exceed 8 m/o.

The following experiment is quite indicative of solid solution formation. A layer of hexagonal ZnS was deposited on a Pt-Rh strip and Cu_2S was then placed on top of the ZnS. The diffractometer trace taken at room temperature showed weak reflections of hexagonal ZnS. This probably indicates that the Cu_2S layer was not thick enough to stop the x-ray radiation used. The temperature was raised to 800°C and the scanning of the 31-28 2θ region was begun. The x-ray trace showed no hexagonal ZnS. The cubic (111) peak was initially quite broad; it grew steadily with time, reaching what appeared to be an equilibrium intensity after about 80 min at 800°C. At no time was the hexagonal phase detectable. It appears that hexagonal ZnS forms a solid solution with Cu_2S and the cubic ZnS precipitates in the cooler portion of the layer.

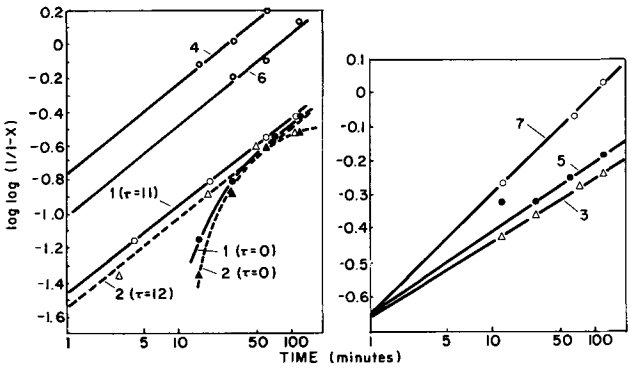

Fig. 5. Plot of log log (1/1—x) against log t. Sample numbers refer to Table II.

Rate experiments.—In these experiments two different preparations of hexagonal ZnS and two CuS reagents were used. CuS was used, rather than any form of cuprous sulfide because the former was available as very fine powder, while the Cu_2S prepared here was very coarse-grained. To have ground the Cu_2S materials might have introduced unwanted contamination. The crystallite size in both CuS reagents was about the same (below 1μ); however, in CuS-2 the crystallites were frequently sintered together, forming somewhat coarser particles than in CuS-1. All experiments in this section were carried out by mixing 4 parts of hexagonal ZnS and 1 part of CuS and firing the mixture in nitrogen atmosphere for various periods of time. It was found that the above ratio of the reactants was sufficient to provide intimate contact between the reacting particles and that no change in the ZnS transformation rate would result on increasing the CuS to ZnS ratio. The degree of conversion to the cubic form of ZnS was determined on the basis of the integrated intensity of the cubic (200) ZnS peak, measured at room temperature.

The experimental data have been found to fit the so-called sigmoidal rate equation.

$$x = 1 - \exp(-bt^n)$$

where x is the fraction of the transformed phase, t the total transformation time, n a constant determined by the shape of the growing particle, and b is a constant related to the rate constant.

In numerous instances the sigmoidal equation has been found to describe the kinetics of various phase changes (14). A plot of ln ln(1/1—x) against ln t should yield a straight line, and Fig. 5 shows that good straight lines are indeed obtained for the data of our experiments. The failure to obtain a straight line relation between ln ln(1/1—x) and ln t for samples fired at 500°C indicates that at this temperature the induction period, τ, is relatively long. In this case ln ln(1/1—x) was plotted against ln(t—τ) for a series of τ values, and the value of τ which gave a straight line was taken as the induction period.

Table II lists the values of the constants n and b, as well as the rate constants $k = nb$ obtained from Fig. 5.

Table II shows that for samples treated with CuS-1, as well as for samples fired at 500°C (with either CuS-1 or CuS-2), the value of n is very nearly 1/2.

Table II. Rate parameters of ZnS transformation

	Series	Temp, °C	n	b	k (min^{-n})
1	(ZnS-2 + CuS-2)	500	0.51	0.078	0.040
2	(ZnS-1 + CuS-1)	500	0.53	0.064	0.034
3	(ZnS-2 + CuS-2)	600	0.205	0.51	0.10
4	(ZnS-2 + CuS-1)	600	0.54	0.39	0.21
5	(ZnS-2 + CuS-2)	700	0.225	0.51	0.11
6	(ZnS-1 + CuS-1)	700	0.54	0.22	0.12
7	(ZnS-2 + CuS-2)	800	0.325	0.51	0.17

A departure from $n = 1/2$ is observed for samples fired with CuS-2 at temperatures above 500°C. This may be attributed to the fact that, owing to the coarser particles of CuS-2, an appreciable number of ZnS crystallites may have escaped attack by CuS. This effect, however, would be of relatively minor importance at 500°C where the transformation rate is not fast. Also it may be noted that the two preparations of ZnS transformed at different rates; this may be attributed to slight differences in their stoichiometry or crystalline perfection.

Discussion

It has been shown that the copper phase effecting the ZnS transformation is the high temperature modification of cuprous sulfide and that, at least when present in sufficiently large amounts (1% or more), all compositional forms of cuprous sulfide, *i.e.*, Cu_2S, $Cu_{1.96}S$, and $Cu_{1.8}S$, are nearly equally effective at elevated temperatures. It has also been shown that at elevated temperatures ZnS and cuprous sulfide interact to form a solid solution having a composition in the neighborhood of 8 m/o ZnS at 800°C. The high temperature x-ray evidence for the solid solution is based on experiments involving Cu_2S. Other forms of cuprous sulfide, in particular $Cu_{1.8}S$, undoubtedly form solid solutions also, as has been shown in experiments with single crystals. This is understandable since the high temperature modifications of all cuprous sulfides appear to be isostructural (10). In this structure the sulfur atoms form a close-packed cubic arrangement, and the copper atoms are statistically distributed in the tetrahedral sites (15). The structure of high cuprous sulfide is thus seen to be related to that of cubic ZnS, in which the positions of the sulfur atoms are also those of face-centered cubic close packing with the zinc atoms occupying one-half of the tetrahedral holes. It appears that it is the structural similarity between cubic ZnS and high cuprous sulfide that enables the two sulfides to form solid solution. The (Cu,Zn)S solid solution cannot be preserved by quenching to room temperature, and this again is understandable since on cooling the high temperature form of the cuprous-sulfides is transformed into low symmetry structures (10).

One may assume then that the first step in the ZnS transformation (copper induced) is formation of the (Cu,Zn)S solid solution. The high temperature x-ray results show that in a thoroughly mixed sample of ZnS and cuprous sulfide (containing comparable amounts of both sulfides) this process is quite rapid at 800°C. The rapid rate of the solid solution formation is illustrated by the fact that the shift in the (220) peak of Cu_2S in ZnS-Cu_2S mixture appears to reach an equilibrium value within the first 1 or 2 min at 800°C (with a total heating-up period of only 2-3 min). At this temperature then, solid solution formation is not a rate determining step. The fact that the transformation rates are quite close in the 600°-800°C range suggests that all the steps in the transformation, including that of solid solution formation, are rapid in the 600°-800°C range.

There is no direct evidence on which one could draw conclusions regarding the rate of nucleation, but the kinetic data suggest that, in the 600°-800°C range, nuclei are formed in a time that is negligible compared to the time required for particle growth. Rapid nucleation rates have been established (by inference from over-all rate) in a number of precipitation reactions (14), as well as in many recrystallization processes (16). It is reasonable to assume then that in the 600°-800°C range the formation of ZnS nuclei is not a rate determining process.

The over-all transformation rate of ZnS has been found to obey the sigmoidal rate equation

$$\frac{dx}{dt} = k(1-x)\ t^{n-1}$$

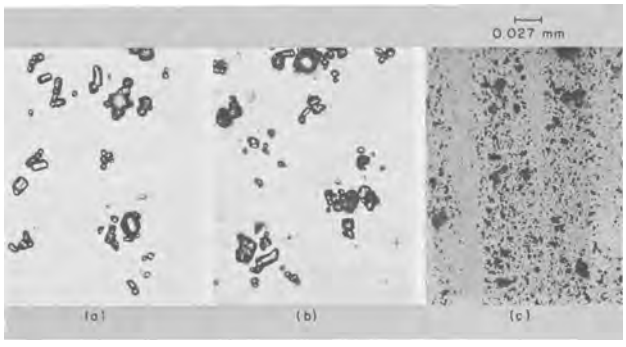

Fig. 6. Photomicrographs of (a) starting hexagonal ZnS, (b) hexagonal ZnS treated with CuS at 800°C (after KCN wash), (c) precipitated ZnS fired at 800°C.

with n lying in the neighborhood of 1/2. This value of n may be explained either in terms of a one-dimensional growth mechanism which is determined only by processes occurring at the interface of the growing phase, or in terms of a one-dimensional precipitation model proposed by Roberts *et al.* (17). The essential difference between these two models lies in the fact that in the latter model (precipitation) the growth of the particle is diffusion controlled. It has been shown by Zener (18) that the rate of linear growth in this case is proportional to $(Dt)^{1/2}$, where D is the diffusion coefficient of the diffusing species. Assuming a linear concentration gradient, it is then easy to show (17) that the growth rate of a particle in one dimension (*e.g.*, a platelet which thickens with time) should be proportional to $t^{-1/2}$.

If one assumes that the growth of cubic ZnS is diffusion controlled, it follows that the ZnS transformation proceeds by dissolution of hexagonal ZnS in Cu_2S, followed by precipitation and subsequent crystallization of cubic ZnS. In Fig. 6 are shown photomicrographs of the starting hexagonal ZnS, hexagonal ZnS treated with CuS at 800°C for 1 hr, and ZnS precipitate crystallized for 1 hr at 800°C. It is seen that the copper-treated sample (which was almost completely converted to the cubic form) is essentially similar to the starting hexagonal ZnS. Crystallization of ZnS precipitate, on the other hand, yielded crystallites considerably smaller in size. Crystallization of ZnS precipitate at temperatures lower than 800°C would be expected to produce even smaller crystallites, yet the crystal size of ZnS samples treated with CuS even at 350°C shows no detectable difference from that of the starting material (although considerable conversion to the cubic form may be achieved after 1 hr at 350°C). One may then reject the diffusion-controlled mechanism, though as pointed out earlier it has been found operative under certain conditions.

We shall now examine a one-dimensional growth mechanism which is controlled primarily by processes occurring at the phase interface. It may be recalled that the ZnS structure can be regarded as being composed of ZnS layers stacked in the direction normal to the layer plane. The forces holding each layer together are apparently considerably stronger than those holding the separate layers together. This is evidenced by the fact that the mechanical or thermal treatment very often produces one-dimensional faulting, but there is no detectable sign of disorder within individual layers. It is significant that mechanical or thermal treatment of hexagonal ZnS (without copper) produces usually little or no coherent cubic ZnS. For example, Smith and Hill (19) found that impact comminution of hexagonal ZnS results in a heavily faulted structure which is neither coherent cubic nor coherent hexagonal. They obtained similar results for thermally treated ZnS (prolonged sintering with NaCl at 850°-970°C). Short and Steward (20) describe similar experiments on grinding hexagonal ZnS. They report a

decrease in the proportion of hexagonal stacking as the grinding time is increased. However, there is no evidence in their paper for the appearance of a coherent cubic phase, as can be seen from the absence of any intensity in the cubic (200) reflection. Extensive faulting with little or no coherence in either cubic or hexagonal phases was reported in the case of thermally treated hexagonal ZnS in the absence of copper (21). In the single crystal experiments carried out as part of this investigation it was also observed that in the absence of copper, thermal treatment produces faulting but little or no coherent cubic ZnS.

The theory of one-dimensional disorder, as developed by Wilson (22) and Jagodzinski (23), which proved to be successful in interpreting stacking fault disorder in certain layer structures (cobalt, graphite, ZnS, etc.), assumes that whenever growth or deformation faulting occurs, the position which will be taken by a given layer depends on the positions of the preceding layers. In Wilson's theory the "sphere of influence" was restricted to two preceding layers. This model proved to be inadequate in certain cases (including ZnS) and better agreement with experiment was achieved by extending the sphere of influence to 3 layers (23). A more adequate description of one-dimensional disorder would probably have to extend the interaction range to more layers (24).

It is proposed that the failure of thermal treatment (no copper) to transform hexagonal ZnS into coherent cubic phase lies in the fact that for such transformation to occur one needs nuclei of coherent cubic ZnS which could guide the transformation wave. Such nuclei appear to form in copper-treated ZnS as a result of precipitation of cubic ZnS from the (Cu,Zn)S solid solution. When the nucleus attains a certain critical size (perhaps a few tens of layers thick), it may start to reorder the hexagonal layers, provided the nucleus happens to grow on certain specific hexagonal faces, for example, (0002). The transformation of hexagonal ZnS may then be characterized by a progressive movement of the hexagonal-cubic interface, the driving force being a decrease in the free energy associated with the transition to the stable cubic phase. In this case the transformation mechanism amounts to a one-dimensional growth process. Now, assuming that the linear growth rate is proportional to $t^{-1/2}$, which according to Loria *et al.* (16) appears to hold for many recrystallization processes, and further assuming that the nucleation period is negligible compared with the time required for growth (which also seems to be a very reasonable assumption) (16), one may set the over-all transformation rate proportional to $t^{-1/2}$. Making allowance for mutual interference of growing domains by introducing a factor $(1-x)$, one obtains

$$\frac{dx}{dt} = k(1 - x)t^{-1/2}$$

which is the rate equation describing our kinetic data.

Influence of Carbon Transport Kinetics on Solution Growth of β-Silicon Carbide Crystals

R. W. Bartlett, W. E. Nelson, and F. A. Halden

Stanford Research Institute, Menlo Park, California

ABSTRACT

Twinned β-silicon carbide platelets with a (111) habit were grown from the walls of graphite crucibles in liquid silicon solutions with carbon concentrations below 0.1 a/o (atomic per cent). The observed crystal growth effects resulting from increasing the carbon solute transport rate by stirring the solution are described and correlated with boundary layer theory. Both forward growth of platelets into the solution and lateral growth of platelets were accelerated by stirring. However, crystal growth in the forward direction was eventually limited by a boundary layer region, beyond which the solution was no longer supersaturated. Because of the decrease in boundary layer thickness with increasing stirring speed, the terminal lengths of silicon carbide platelets decrease with increasing stirring speed.

Cubic β-silicon carbide crystals have been grown from carbon-saturated liquid silicon solutions (1, 2). These crystals normally occur as vicinal platelets with a (111) habit. They nucleate on walls of the graphite crucible and extend into the solution with their major faces normal to the wall. The crystals are usually twinned on the (111) planes (3), and the twin plane re-entrant edge formed when at least two (111) twin planes occur in the crystal is believed to cause more rapid growth at the edge of these platelets than in a direction normal to their habit faces (4, 5). This anisotropy in growth kinetics accounts for the platelet morphology. However, modifications in this general form have been observed under different growth conditions. Stirring the solution causes a reduction in platelet length and an increase in platelet thickness, and rapid stirring leads to approximately equidimensional twinned crystals (see Fig. 1 where cross sections of partially leached crucibles are shown). Untwinned crystals are also polyhedral and quite small unless the solution is rapidly stirred to increase the rate of transport of carbon across the boundary layer.

Although there is considerable experimental evidence to support the twin plane re-entrant edge mechanism of platelet crystal growth for silicon carbide (see Fig. 2) there are no data on the kinetics of solute attachment to the crystal (sticking coefficients) as a function of crystal habit that would permit an analytical treatment of this aspect of the crystal growth rate. It would be exceedingly difficult, if not impossible, to devise suitable experiments to secure these data because of the high crystal growth temperatures and highly reactive growth environment. Consequently, the present study was confined to an analysis of carbon transport in the solution adjacent to the growing crystal platelet and the effect of carbon transport on crystal growth rates. Both forward, <110>, and lateral, [111], growth directions of platelets were considered, but primary attention was placed on the forward growth rate.

Experimental

The method of growing β-silicon carbide from solution in a molten silicon solvent has been described previously (1, 2). Silicon is melted in a graphite crucible and is held in a thermal gradient, which permits solution of carbon at the upper walls and growth of silicon carbide crystals on the base and lower walls of the crucible. The solubility of carbon in liquid silicon (6) is only about 0.03 a/o at 1600°C. Carbon transport

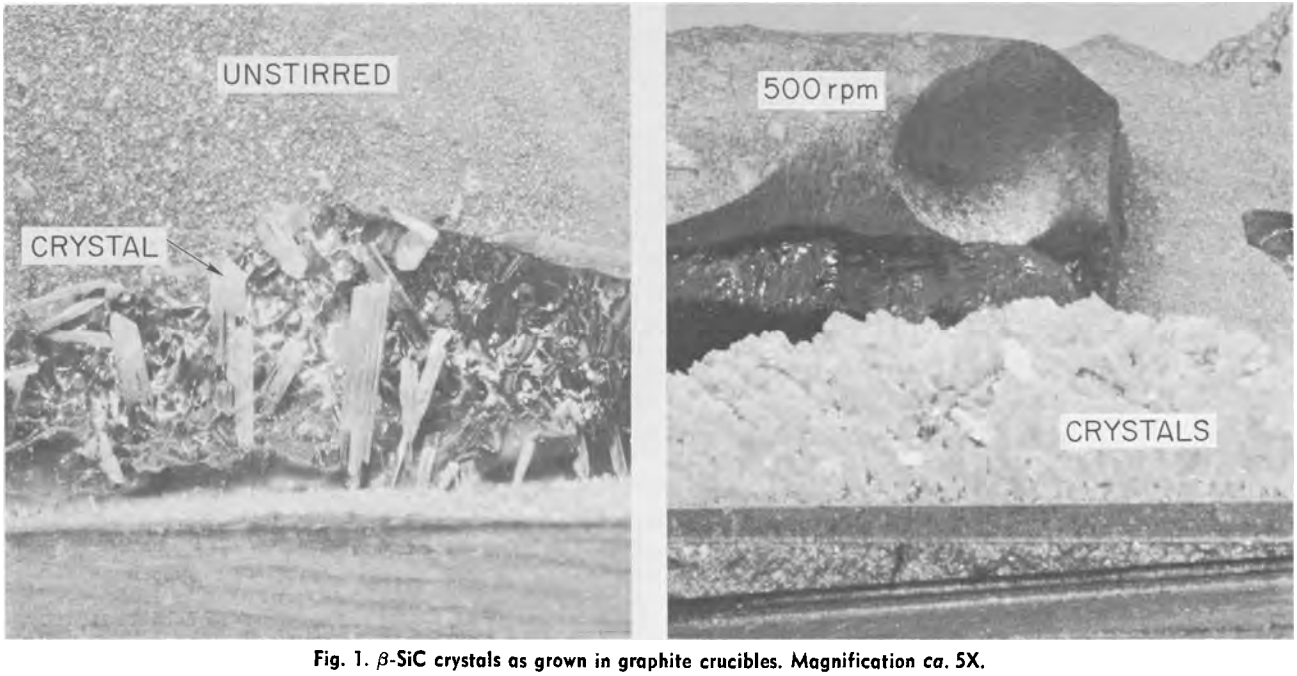

Fig. 1. β-SiC crystals as grown in graphite crucibles. Magnification *ca.* 5X.

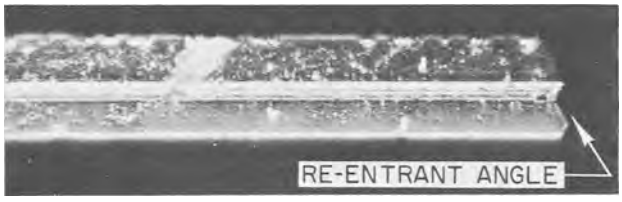

Fig. 2. Edge view of twinned β-silicon carbide crystal showing the re-entrant angle. Magnification 235X.

within the solution normally occurs by free convection and diffusion. In the present study, carbon transport was accelerated by stirring the solution with a graphite impeller. The crucible diameter was 50 mm and the impeller diameter was 38 mm. The impeller was separated 15-20 mm from the crucible base. Crystal growth experiments were conducted at impeller speeds varying from 0 to 500 rpm.

Although more crystals were formed with increasing impeller speed, platelet length decreased. The terminal length of platelets grown in 24 hr decreased from 8-10 mm to about 1 mm as the stirring speed was increased from 0 to 500 rpm (see Fig. 1). Platelet thickness increased with stirring speed, and at 500 rpm crystal thickness approached crystal length.

Theory

Latent heat effect.—The effect of the latent heat of formation of the growing silicon carbide crystals on the growth mechanism is insignificant. This fact can be confirmed by examining the diffusion-controlled rate of growth of silicon carbide in a perfectly quiescent solution with the following typical experimental conditions: a temperature difference ΔT of 100°C and a carbon mole fraction difference $X_{c_\infty} - X_{c0}$ of 2 x 10^{-4} (2 x 10^{-2} a/o) from source to sink, and a distance Δy of 3 cm between the source and sink. $T_\infty - T_0$ and $X_{c_\infty} - X_{c0}$ correspond to a growth temperature of 1530°C and a source temperature of 1630°C, based on Scace and Slack's data (6) for carbon solubility in silicon.

For steady-state diffusion, the carbon flux J (moles cm^{-2} sec^{-1}) is given by

$$J = C_0 D(X_{c_\infty} - X_{c0})/\Delta y \qquad [1]$$

where C_0 is the total molar concentration of the dilute solution (0.0768 mole cm^{-3}), and D is the diffusivity of carbon in the solution. The physical properties of liquid silicon $\overline{C}_p$, D, K_L, μ, and ρ, required for this and subsequent analyses are listed in Table I. Estimates were made for μ, K_L, and D. The diffusion coefficient for carbon, D = 1.7 x 10^{-4} cm^2 sec^{-1}, was estimated using the generally accepted empirical equation for self-diffusion in liquids shown in Table I. The growth rate $\dot{y}$ is related to the carbon flux in solution by the expression

$$\dot{y} = J(M/\rho)_{SiC} = 12.5J \qquad [2]$$

Table I. Properties of liquid silicon

Property	Value
Specific heat, $\overline{C}_p$	0.182 cal g^{-1} $°C^{-1}$
Viscosity, μ	1 x 10^{-2} poise (est.)*
Thermal conductivity, K_L	0.08 cal sec^{-1} cm^{-1} $°C^{-1}$ (est.)*
Density, ρ	2.55 g cm^{-3}
Diffusion, D	1.7 x 10^{-4} cm^2 sec^{-1}†
Kinematic viscosity, $\nu = \mu/\rho$	3.92 x 10^{-3} cm^2 sec^{-1}
Prandtl number, $Pr = \overline{C}_p\mu/K_L$	0.023
Schmidt number, $Sc = \mu/\rho D$	23

* Liquid silicon is metallic rather than semiconducting; estimates for thermal conductivity and viscosity are based on values for other liquid metals, particularly tin.

† Diffusion coefficient calculated from liquid silicon properties using the following formula

$$D = (kT/2\pi\mu)(N_0\rho/M)^{1/3}$$

For the selected conditions previously mentioned, $\dot{y}$ = 8.3 x 10^{-3} mm/day, or conversely, 121 days are required to increase the crystal length by 1 mm.

The heat flux q_f associated with this simple diffusion-controlled growth can be calculated from the heat of formation of silicon carbide from liquid silicon saturated with carbon

$$q_f = \dot{y}\rho(-\Delta H_f) \qquad [3]$$

where ΔH_f is the heat of formation of SiC at 1580°C; ΔH_f = −1470 cal/g (−59,000 cal/mole). The heat flux transferred through the liquid solution, q_L, is given for the convectionless case

$$q_L = K_L(T_\infty - T_0)/\Delta y \qquad [4]$$

The ratio q_f/q_L is the ratio of heat flux originating from crystallization to heat flux arising from transfer through the solution. This ratio is very small for the selected condition, q_f/q_L = 1.6 x 10^{-5}, and consequently the heat of crystallization will not significantly affect heat transfer or temperature distribution within the solution or at the crystal solution interface. Stirring the solution will increase both q_f and q_L, but the ratio q_f/q_L will remain negligibly small for the growth of silicon carbide.

Boundary layer profiles.—Boundary layer theory (7, 8) is used to describe the silicon solution adjacent to the crucible wall under defined stirring conditions. This analysis proceeds as follows. Dimensionless profiles of the mass (carbon concentration), fluid velocity, and temperature are calculated as functions of a dimensionless distance from the cold wall. These calculations are made without regard to the presence of silicon carbide crystals, which are considered to be too few in number to alter the boundary layer profiles. Physical constants for liquid silicon or estimated physical constants based on properties of other similar liquid metals are used. The thermal boundary layer is much thicker than the mass boundary layer, leaving a supersaturated region near the cold wall, even if equilibrium is attained at the cold wall surface. The converse is true near the hot wall, where an undersaturated region will be found even though equilibrium with respect to carbon solubility is attained at the hot wall. These results are a consequence of the thermal diffusivity being much larger than the mass diffusivity. The situation is shown schematically in Fig. 3. The linear gradients in this figure represent molecular diffusion and thermal conduction in a quiescent liquid.

Consider solution flow around a flat disk that rotates about an axis perpendicular to its plane with uniform angular velocity ω in a fluid otherwise at rest. Because of friction, a boundary layer of fluid is carried by the disk and thrown outward by centrifugal forces. This flow is compensated for by an influx of fluid in the axial direction toward the disk. The axial and radial flow are shown in Fig. 4. This case permits a solution

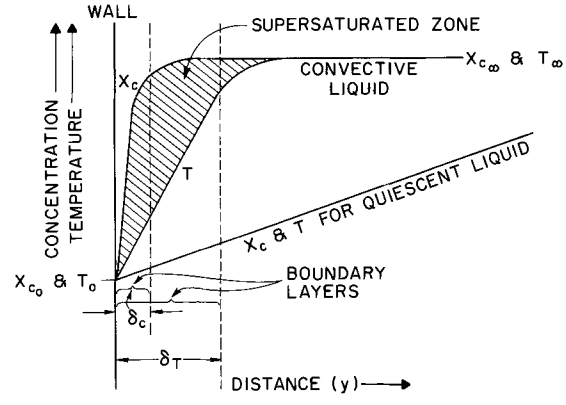

Fig. 3. Schematic diagram comparing the temperature and carbon mole fraction profiles near the crucible cold wall.

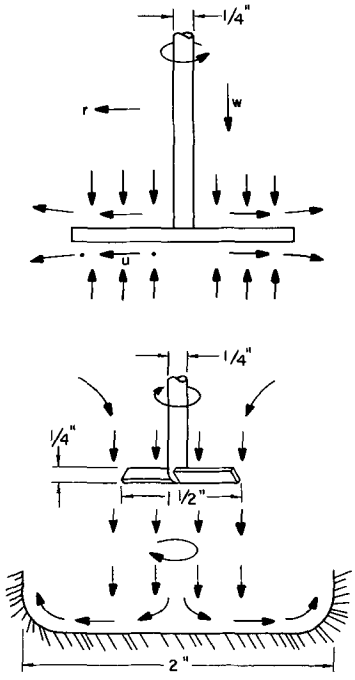

Fig. 4. Axial and radial fluid flow for a rotating flat disk in an otherwise quiescent liquid and for a crucible base in a stirred liquid.

of the Navier-Stokes equations for flow (7) and, with some modification, provides a good analogue of the conditions existing at the bottom of an impeller-stirred crucible. The thickness δ of the layer carried by the disk is

$$\delta \cong (\nu/\omega)^{1/2} \quad [5]$$

Dimensionless velocity profiles for tangential (circumferential), radial, and axial flow are shown in Fig. 5(a) as functions of a dimensionless distance ξ from the disk, where $\xi = y/(\nu/\omega)^{1/2}$. The actual velocities, v in the tangential direction, u in the radial direction, and w in the axial direction, are obtained from the dimensionless velocities by the following defining equations

$$G = v/r\,\omega\,\xi \quad [6]$$

$$F = u/r\,\omega\,\xi \quad [7]$$

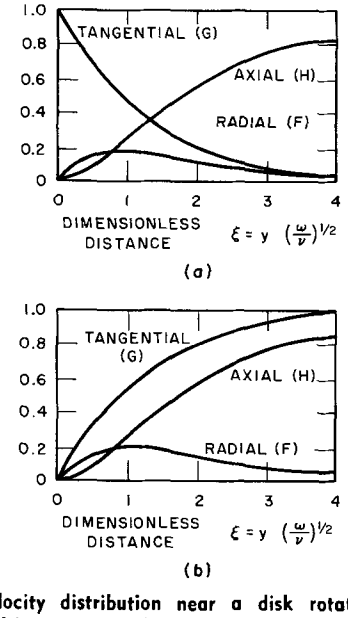

Fig. 5. Velocity distribution near a disk rotating in a fluid at rest (a) and in a rotating fluid near a disk at rest (b).

$$H = w/(\nu\,\omega\,\xi)^{1/2} \quad [8]$$

where r is the local radius of the disk where the velocity values are being determined. The velocity profiles for a stationary disk, *e.g.*, with the reference coordinates rotating with the disk, are shown in Fig. 5(b). The tangential flow is zero at the surface and increases in the direction away from the surface. This situation corresponds closely with that in the base of a stirred crucible when the impeller forces fluid down onto the crucible base. The curves of Fig. 5 are for an infinite disk, but they are not altered for a finite disk, or a finite crucible diameter, provided that the disk or crucible radius $R >> \delta$. The tangential velocity for rotating coordinates is defined as

$$|G| = 1 - (v/r\omega\,\xi) \quad [9]$$

Although the axial flow component is essential for permitting the introduction of enriched solution into the boundary layer, it is not significant in terms of flow over the surface of a platelet protruding into or through the boundary layer. This is because of the much smaller absolute magnitude of the axial flow compared with tangential flow, *i.e.*, $r > (\nu/\omega)^{1/2}$ and therefore $v >> w$ at all but very small values of r, $(r \to 0)$. Furthermore, the region beyond the velocity boundary layer $y > (\nu/\omega)^{1/2}$, is of primary interest because the thermal boundary layer is much thicker than the velocity boundary layer. Since flow in the radial direction does not increase beyond $y = (\nu/\omega)^{1/2}$, flow past a platelet growing in the region to the limit of the thermal boundary layer (supersaturated region) can be described to a good approximation with only the tangential velocity component.

The temperature and mass (carbon) boundary layer thicknesses depend on the velocity boundary layer, δ. Figure 5(b) shows that an exact definition of δ is impossible, because the velocity is a continuous function of y. Boundary layer theory can be used to calculate the temperature and concentration profiles as functions of η, where $\eta = y/\delta$. These dimensionless temperature and concentration profiles also depend on the Prandtl (Pr) and Schmidt (Sc) numbers, respectively (see Table I). In the limit as the net mass transfer rate approaches zero, which is a valid approximation because of the slow growth of silicon carbide, the profile equations are

$$\frac{T - T_0}{T_\infty - T_0} = \frac{\int_0^\eta \exp(-1.328Pr\,\eta^3/3!)\,d\eta}{\int_0^\infty \exp(-1.328Pr\,\eta^3/3!)\,d\eta} \quad [10a]$$

$$\frac{X_c - X_{c0}}{X_{c_\infty} - X_{c0}} = \frac{\int_0^\eta \exp(-1.328Sc\,\eta^3/3!)\,d\eta}{\int_0^\infty \exp(-1.328Sc\,\eta^3/3!)\,d\eta} \quad [10b]$$

For a derivation of these equations, the reader is referred to Bird *et al.* (8), chap. 4 and 19, or to Schlichting (9), chap. 7.

The general profile from Eq. [10] is plotted in Fig. 6, which is taken from Bird *et al.* (8). By letting $\delta = 1.3\ (\nu/\omega)^{1/2}$, the curve of Fig. 6 fits well with the tangential curve of Fig. 5(b). In effect, curve fitting has been used to select the constant, 1.3, in Eq. [5] in order to match all of the profiles appropriately. Using the values for Sc and Pr listed in Table I and the curve from Fig. 6, the temperature and carbon concentration dimensionless profiles were calculated and plotted in Fig. 7. It is readily seen that the mass transfer boundary layer is thinner than the velocity boundary layer and very much thinner than the temerature boundary layer. Since equilibrium (carbon-saturated solution) occurs in the silicon solution beyond the boundary layers, a supersaturated region must occur within the thermal boundary layer. Crystal growth is enhanced in this region in direct proportion to the separation between the mass transfer profile

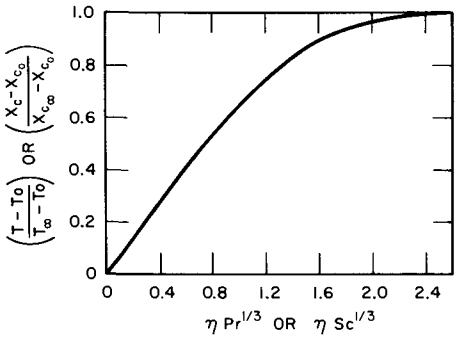

Fig. 6. Temperature or concentration profiles for high Prandtl or Schmidt numbers.

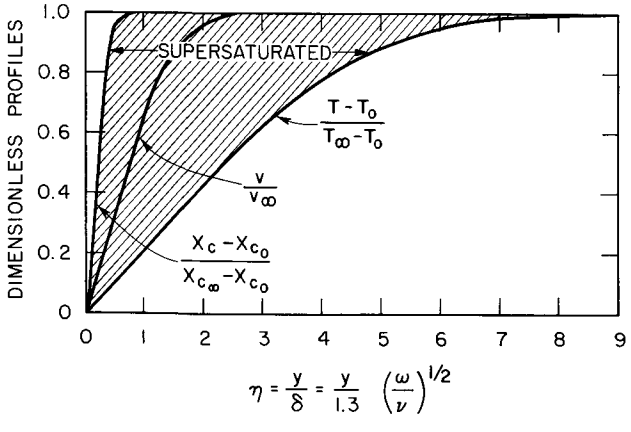

Fig. 7. Dimensionless temperature, velocity, and carbon mole fraction profiles in a stirred crucible of liquid silicon.

and the temperature profile, since this is a measure of the degree of supersaturation. The boundary layer thickness is proportional to $(\omega^{-1/2})$ (see Eq. [5] and Fig. 7).

This pronounced difference in profiles is a direct consequence of the disparity in Schmidt and Prandtl numbers; more particularly, the thermal diffusivity, $K_L/\rho\overline{C_p}$, is very much higher than the mass diffusivity, D. Thus, mass transport is very dependent on stirring, whereas thermal transport is always rapid and is accelerated only slightly by stirring.

Calculated platelet growth rate.—Calculation of the platelet growth rate involves two major terms: (*i*) the excess carbon mole fraction, $\overline{\Delta X_c}$, in the supersaturated (boundary layer) region, and (*ii*) an appropriate mass transfer coefficient, k_m. The velocity profiles for the silicon carbide growth conditions have been described and used to determine temperature and concentration profiles that define the supersaturated region. Over all of this region, except very close to the wall, the carbon mole fraction X_c is equal to the level within the solution, $X_c \approx X_{c_\infty}$, and the tangential fluid velocity v is equal to the velocity of the bulk of the solution, v_∞. Consequently, the critical carbon mole fraction $\overline{\Delta X_c}$ in excess of equilibrium is a function of distance into the boundary layer, y, as follows

$$\overline{\Delta X}_{c(y)} = \left[1-\left(\frac{T-T_0}{T_\infty-T_0}\right)\right]_{(y)} (X_{c_\infty}-X_{c0}) \quad [11]$$

where $(T-T_0)/(T_\infty-T_0)$ is given by Fig. 7.

The carbon flux J to the surface and the reaction rate to form silicon carbide, assuming a sticking coefficient $\sigma = 1$, are proportional to the carbon mole fraction in excess of equilibrium $\overline{\Delta X}_{c(y)}$ as follows

$$J_{(y)} = k_m \overline{\Delta X}_{c(y)} \quad [12]$$

where k_m is the mass transfer coefficient, which will now be discussed.

In general, k_m is a function of the fluid properties and velocity of flow. The Nusselt number (Nu_m) for mass transfer, which is a dimensionless group defined as

$$Nu_m = k_m d/C_0 D \quad [13]$$

where d is a characteristic dimension of the system, is often used in treating mass transfer problems in fluid systems. Empirical correlations have been made to evaluate the Nusselt numbers for forced flow around a few simple shapes. The tangential flow of silicon over the tip of a platelet affects its forward growth rate. Flow over the minor dimension (thickness) of a platelet can be approximated by viscous flow around a submerged rod (transverse direction) or sphere. The resulting Nusselt numbers using the sphere correlation differ little from the Nusselt numbers for the rod. The calculated Nusselt numbers for rods or spheres of the same diameter in identical fluids and flow velocities are usually within 20% of each other, which is adequate for our purpose. Adopting the simple sphere correlation (10)

$$Nu_m = 2.0 + 0.6\, Re^{1/2}\, Sc^{1/3} \quad [14]$$

where Re is the Reynolds number for flow over the tip of the platelet

$$Re = d\, r\omega/\nu \quad [15]$$

In Eq. [15] d is the minor dimension (thickness) of the platelet, and r is the radial distance from the center of the crucible to the platelet. From Eq. [13] and [14] the mass transfer coefficient is

$$k_m = (C_0 D/d)\,(2.0 + 0.6\, d^{1/2}\, r^{1/2}\, \omega^{1/2}\, \nu^{-1/2}\, Sc^{1/3}) \quad [16]$$

Combining Eq. [2], [11], [12], [13], and [14] yields the following relation for the rate of forward platelet growth (sticking coefficient $\sigma = 1$)

$$y = (M/\rho)_{SiC}\,(C_0 D/d)\,(2.0 + 0.6\, d^{1/2}\, r^{1/2}\, \omega^{1/2}\, \nu^{-1/2}\, Sc^{1/3}) \left[1-\left(\frac{T-T_0}{T_\infty-T_0}\right)\right]_{(y)} (X_{c_\infty}-X_{c0}) \quad [17]$$

where $[1-(T-T_0/T_\infty-T_0)]_{(y)}$ is a function of y determined from Fig. 7. Because of this term the growth rate $\dot{y}$ decreases as y increases.

The effects of the radial location of the platelet in the crucible, r, and the minor dimension, d, of a platelet on forward growth velocity and terminal thickness of the platelet are also obtained from Eq. [17], or the Reynolds number. Increasing r increases the growth velocity, but does not affect terminal length. The growth rate decreases slightly as d increases (decrease in aspect ratio).

Results and Discussion

Equation [17] was integrated by successive approximations to obtain growth curves for SiC platelets at various stirring speeds. The following parameters were used in Eq. [17]: the minor platelet thickness, d, is 10^{-2} cm (typical of observed values of d); $(X_{c_\infty}-X_{c0}) = 1 \times 10^{-4}$; and the radial platelet location is $r = 3$ cm. The calculated growth curves are shown in Fig. 8. Results of crystal growth experiments for $(X_{c0}-X_{c_\infty}) = 1 \times 10^{-4}$ are also presented in Fig. 8 as bars. The number adjacent to each data bar indicates the stirring speed, in rpm rather than ω, associated with the crystal lengths observed in that run. The data consensus of more than 30 unstirred experiments is shown as a dashed zone. The terminal crystal lengths are in good agreement with observed values for various stirring speeds, except at the lowest stirring speed, 1 rpm. Crystals longer than 10 mm are usually thin whiskers, and none greater than 15 mm has been grown. Several factors, in addition to some lack of precision in determining the boundary layer thickness, may contribute to this small discrepancy: (*A*) A stirring speed of 1 rpm is very slow, and free convection in an unstirred nonisothermal solution

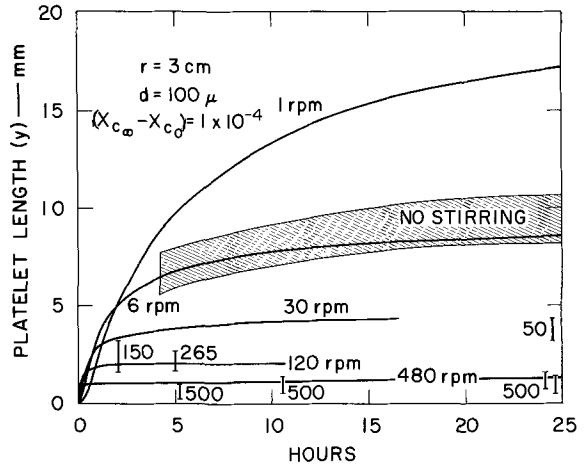

Fig. 8. Calculated growth (length) of silicon carbide platelets at various stirring speeds.

may actually provide more mixing than is secured from stirring at this speed, and consequently may reduce the boundary layer thickness. (*B*) The sticking coefficient in the forward growth direction may be less than $\sigma = 1$. (*C*) As growth progresses, impurities may strongly adsorb on the surface, blocking reactive sites and slowing or even halting further growth. Support for impurity poisoning is found in the fact that crystals longer than a few millimeters have only been obtained in an environment without nitrogen or oxygen. Iron and other metals, when added to the solution in sufficient quantity, have been observed to repress the forward growth of platelets.

Thus far no attempt has been made to analyze the free convection situation where fluid motion is induced because of gravitational forces and the differential specific gravity of a nonisothermal solution. The results in Fig. 8 indicate that free convection mixing is approximately equivalent to stirring at 5 rpm.

The lateral growth direction, [111], of β-silicon carbide can be discussed only qualitatively. The sticking coefficient on the (111) habit is undoubtedly $\sigma << 1$, and because surface active sites for carbon attachment are probably kinks, edges, or other surface anomalies, the effective sticking coefficient probably varies with the surface roughness. Considerable variation in thickness of crystals within a single melt has been observed. Nevertheless, the effect of stirring on the relative rate of lateral growth is of interest because significantly thicker crystals are obtained as a result of stirring. The mass transfer coefficient for growth in the lateral direction can also be expressed as a function of an appropriate Nusselt number, and it can be shown by dimensional analysis that $Nu_m = f(Re^n)$. For simple shapes $n \approx 0.5$. Thus the lateral growth velocity ($\dot{z}$) is a function of stirring velocity, $\dot{z} = f(\omega^n)$. Assuming n = 0.5, untwinned polyhedral crystals grown at a stirring speed of 480 rpm should be 22 times larger than untwinned crystals grown at 1 rpm over the same growth period. A marked increase in the size of untwinned crystals was observed as a result of stirring the solution.

Summary

The case of a rotating impeller inside a large crucible has been treated using boundary layer theory for laminar flow, and the calculated crystal growth results are similar to experimental results obtained using a crucible stirred with a thin impeller. Stirring creates a region of quasi-uniform temperature and carbon concentration throughout most of the solution. However, near the cold base of the crucible where growth occurs, the solution temperature, carbon concentration, and the fluid velocity decrease as the crucible wall is approached. Within this gradient zone, or boundary layer, supersaturation and crystal growth occur. At higher stirring velocities, crystal growth is more rapid, but the boundary layer is also thinner. Consequently, growth in the forward direction quickly terminates at a shorter total platelet length than is eventually attained by slower growing crystals in less rapidly stirred solutions. Growth in the lateral direction, [111], which is the slow-growth direction, is increased by stirring and proceeds without impediment until, given sufficient time, adjacent crystals come in contact. Because higher stirring speeds cause greater supersaturation at the crucible wall, the number of stable nuclei is probably increased by stirring. At higher stirring speeds, these phenomena, coupled with the greater lateral growth velocity of twinned crystals, eventually produce a compact mass of adjacent, approximately equidimensional crystals, rather than the widely separated platelets obtained at low stirring speeds, or without stirring. The agreement between calculated and observed lengths for twinned crystals is satisfactory at all stirring speeds. Agreement is poorest at low velocities: at 1 rpm, the calculated platelet lengths obtained in 24-48 hr are about twice the maximum observed length.

In a perfectly quiescent solution there is no boundary layer limit on the crystal length, but the rate of growth becomes extremely slow. In reality, a quiescent solution is never attained, even without stirring, because of the free convective mixing of the nonisothermal solution. A description of free convection in a hot-top, cold-bottom large crucible has not been attempted. This situation causes much less mixing than the opposite thermal gradient, but the problem is too complex for analysis at this time. The modest free convective mixing obtained in large crucibles, such as those used currently, is probably a good compromise between adequate growth velocity and adequate terminal length of the crystals.

Behavior of Large-Scale Surface Perturbations during Silicon Epitaxial Growth

W. R. Runyan and Earl G. Alexander

Texas Instruments Incorporated, Dallas, Texas

and S. E. Craig, Jr.

Arizona State University, Tempe, Arizona

ABSTRACT

The behavior of relatively large surface depressions and protrusions was studied as a function of various epitaxial growth parameters. It is shown that at high concentrations of silicon-bearing species, surface stability occurs which cannot be explained solely on the basis of gas phase diffusion and capillarity.

The effects of various process variables on the growth rate of silicon over large relatively flat areas have been studied extensively and are reasonably predictable. The differences to be observed between the infinite plane case just mentioned and one in which only small areas of silicon are exposed has also been treated (1, 2). In addition, the general problem of the stability of very small surface perturbations during diffusion controlled growth was examined in terms of the relative effects of the diffusion gradient and capillarity (3-5). The behavior of rather large individual surface depressions or protrusions during vapor phase growth is also of considerable importance and is the subject of the present investigation. It will be shown that, by the proper choice of gas stream composition, large initial variations in the surface contour can be made to disappear, remain, or grow in amplitude.

This particular study was initiated originally because of the possibility of studying growth rates as a function of orientation by examining the behavior of different sides of small holes. Initial work, however, showed that in the silicon system other features of the deposition process were usually dominant and should be further investigated. From a more practical standpoint, the desire to construct commercial semiconductor devices which require far more complex structures than the original n on n+ material has added considerable impetus to confined growth. As examples of structures requiring this type of growth there are field effect transistors using channels etched and refilled, the polycrystalline silicon deposition required in making dielectric isolation networks, the n- and p-type local areas used for complementary structures in p-n junction isolated integrated circuits, and the etch-refill process often used in conjunction with dielectric isolation. Even though the results have not been fully verified for other systems (such as germanium and gallium arsenide), it is felt that the study and interpretation of such confined growth can materially aid in the understanding of vapor deposition processes.

Experimental

While the majority of the data taken related to silicon, the $GeCl_4$-H_2 system was briefly examined and found to behave in a roughly analogous manner.

The experimental arrangement used for the silicon growth studies has been described previously in some detail (6). Substrates of single crystal (111) oriented silicon approximately 2.5 cm in diameter were first polished chemically to produce damage-free planar surfaces. One side of each slice was then selectively masked and further etched to produce hills or holes approximately 125 μm in diameter and 25 μm deep spaced

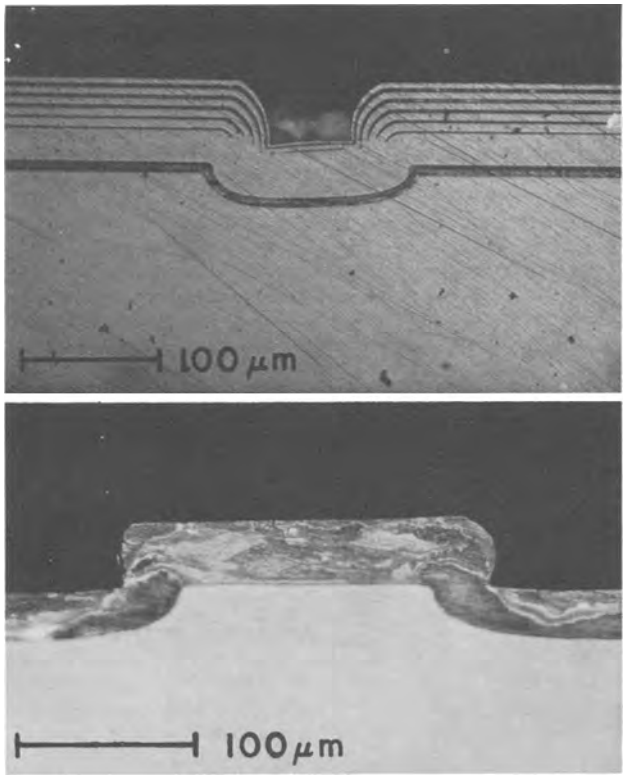

Fig. 1. Cross section of a depression and a hill overgrown at 1270°C while using a mole fraction of 0.006 $SiCl_4$ in hydrogen. During growth in the depression, alternate p- and n-type dopants were introduced at equal time intervals. This produced, after subsequent staining, the banding visible in the photograph.

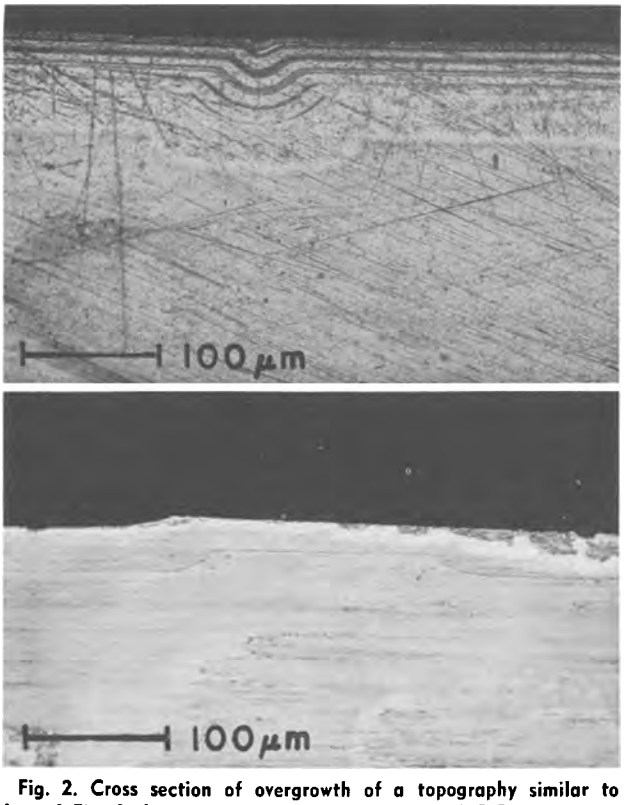

Fig. 2. Cross section of overgrowth of a topography similar to that of Fig. 1, but using a mole fraction of 0.06 $SiCl_4$ in hydrogen (growth at 1270°C).

on 1.25 mm centers, after which the masking material was removed. Reactant gases were fed through a conventional flow system and delivered at atmospheric pressure to a single-slice, vertical-flow epitaxial reactor. The surface was *in situ* vapor etched and the silicon grown epitaxially by either the hydrogen reduction of $SiCl_4$ or by the pyrolysis of silane diluted with hydrogen. During growth, p- and n-type dopants were sometimes alternately introduced so that by staining a perpendicular section, the growth interface at any given time could be approximately determined. The germanium was deposited via the hydrogen reduction of $GeCl_4$ at 900°C onto (111) oriented, *in situ* vapor etched germanium substrates.

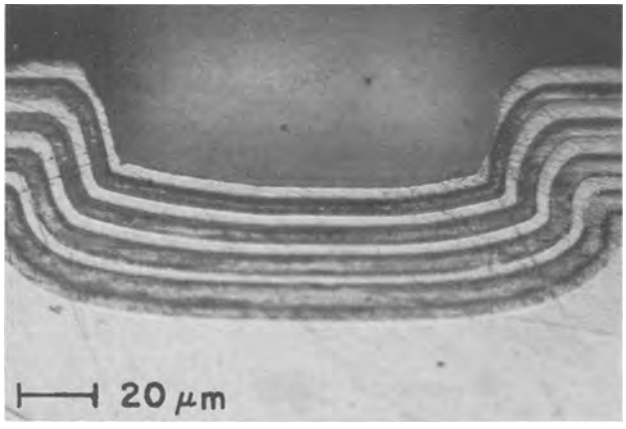

Fig. 3. Detail of the overgrowth of a hole using a $SiCl_4$ mole fraction of 0.01 (growth at 1270°C). Time dependence of the growth interface is revealed by staining the layers of alternating dopant types.

The photographs of Fig. 1-3 are typical of the behavior observed during the silicon deposition from $SiCl_4$ at temperatures of 1270°C. Figure 1 is a cross section of a hole and a hill overgrown while using a mole fraction of 0.006 $SiCl_4$ in H_2. These are the conditions often used during silicon growth and are the ones which give unstable growth.[1] Figure 2, which shows silicon grown using a mole fraction of 0.06 $SiCl_4$ in H_2 (which produces, on a flat surface, the same deposition rate as the 0.006 $SiCl_4$ case), represents a stable system, *i.e.*, the holes fill up and the hills level out. Comparable experiments using the silane-hydrogen system failed to show any region of stability. Detail of the growth interface, as delineated by the alternating dopant technique, is shown in Fig. 3 for the intermediate mole fraction of 0.01 $SiCl_4$ in H_2.

Figure 4a plots the observed growth rate *vs.* mole fraction $SiCl_4$ for a flat surface at both 1130° and 1270°C. In Fig. 4b the ratio of the growth rate on the perturbation (hill or hole) to that on the flat surface is plotted as a function of y, the reactant gas stream mole fraction of $SiCl_4$ in hydrogen. Since the rate on the perturbation is time-dependent, the numbers presented are estimated initial rates. Figure 5 shows germanium growth cross sections for $GeCl_4$ mole fractions 0.0005 and 0.005, respectively. Figure 6, analogous to Fig. 4, shows that for germanium the conversion from unstable to stable growth occurs before the maximum deposition rate, whereas for silicon, the transition appears quite close to the maximum.

Discussion

Because of the observations just mentioned, it is tempting to postulate a mechanism based on simple diffusion through a boundary layer of thickness w over the unperturbed portion of the slice. Then, if a small depression of depth δ occurs, in that depression the boundary layer thickness will be approximately $w + \delta$, and the rate will be correspondingly reduced since all silicon-bearing species are required to diffuse through a larger distance. If growth conditions are such that the deposition rate J decreases as the gas stream concentration y increases (*i.e.*, $\partial J/\partial y$ is negative), increasing the layer width might lead to an

[1] A stable system is defined as one in which the amplitude of surface discontinuities decreases with time.

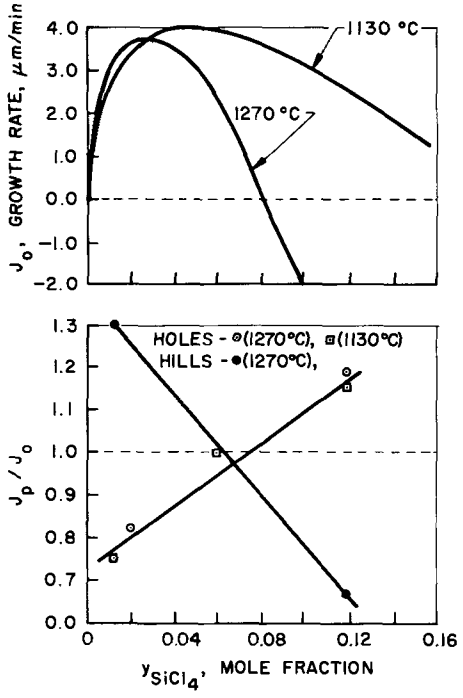

Fig. 4a. (top) Observed silicon growth rate for a flat surface versus mole fraction $SiCl_4$ (growth at 1130° and 1270°C). Fig. 4b. Ratio of silicon growth rate on the perturbation (J_p) to that on the flat surface (J_o) as a function of mole fraction of $SiCl_4$ in hydrogen.

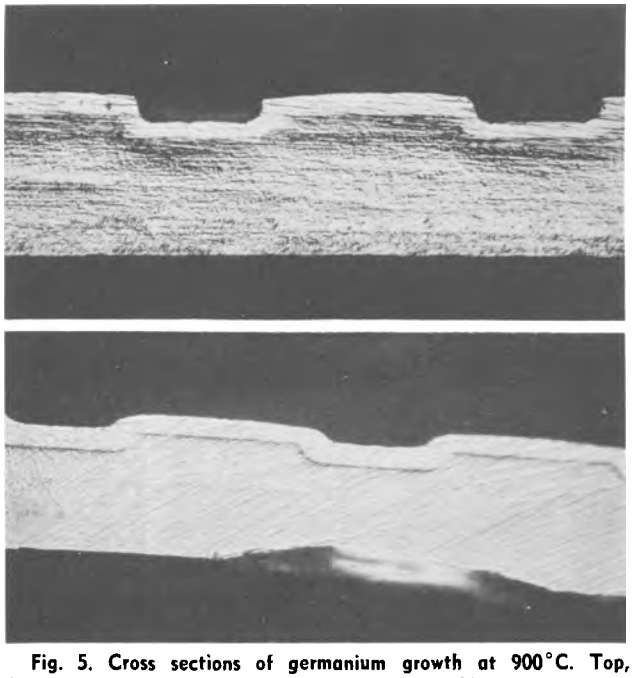

Fig. 5. Cross sections of germanium growth at 900°C. Top, 0.0005 mole fraction $GeCl_4$ in H_2; bottom, 0.005 mole fraction $GeCl_4$ in H_2. Hole diameters are 200 μm.

increased deposition rate in the hole. Such an argument is difficult to deal with even qualitatively because of the inability to actually determine whether or not a change in y occurred. Despite the previous discussion it cannot be said that the surface concentration changed since there appears to be considerable evidence that very close to the surface, equilibrium occurs [*e.g.*, (7, 8)]; surface concentration is thus independent of local diffusion layer thickness. Similarly, the inlet gas stream concentration is clearly independent of surface fluctuations.

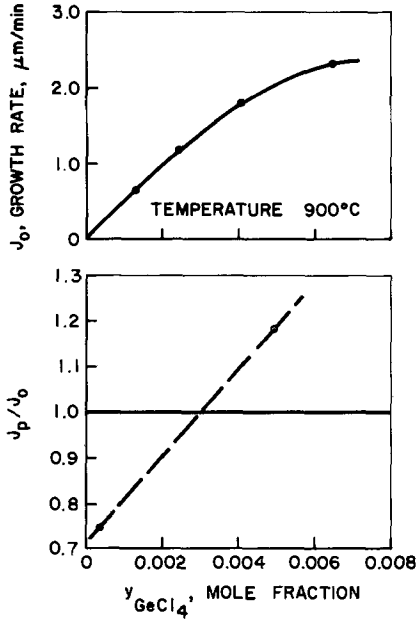

Fig. 6. Observed germanium growth rate for a flat surface vs. mole fraction $GeCl_4$. Growth at 900°C.

There are actually several formulations of J *vs.* y, depending on the assumptions made and boundary conditions chosen. The growth rate may be considered in terms of thermodynamics, surface kinetics, mass transport, or a combination of these concepts (*9*). The mass transport formulation can in general be reduced to the form

$$J = k(y - y_o^*) \qquad [1]$$

where k is a mass transfer coefficient (which involves appropriate diffusion coefficients and is inversely dependent on the boundary layer thickness), y is the summation of the mole fractions of all silicon-containing species (*i.e.*, SiH_4, $SiCl_4$, $SiCl_2$, etc.) in the bulk gas, and y_o^* is the value at equilibrium with a flat surface. From this,

$$dJ = dk(y - y_o^*) + k dy - k dy_o^* \qquad [2]$$

If surface energy effects are neglected, dy and dy_o^* are zero as the surface is traversed. A depression will cause an increase in the boundary layer thickness and dk will be negative. The consequent negative dJ leads to a hole deepening for all values of y. The inclusion of surface energy terms changes the equilibrium surface concentration y_o^* to y^* at the perturbation, given by

$$y^* = y_o^* (1 + \Gamma K) \qquad [3]$$

where K is the curvature determined by the geometry of the hole or hill, $\Gamma = (\gamma\Omega/RT)$, γ is the surface energy, Ω is the molar volume of the solid, and RT is the gas constant times absolute temperature. The curvature is positive for a convex surface (hill) and negative for a concave surface (hole). With this addition, Eq. [1] becomes

$$J = k\,[y - y_o^* (1 + \Gamma K)] \qquad [4]$$

and

$$dJ = [y - y_o^* (1 + \Gamma K)]\, dk - k\Gamma y_o^* dK \qquad [5a]$$

or

$$\Delta J = J_p - J_o = (y - y_o^*)\,(k_p - k_o) - y_o^*\,\Gamma k_p K_p \qquad [5b]$$

since dy, dy_o^*, $d\Gamma$,[2] and $K_o = 0$. The subscript p denotes in the perturbation and the subscript o denotes on the flat surface.

Note in Eq. [5b] the term involving the surface energy is negative while the term involving Δk, *i.e.*, $(k_p$

[2] $d\Gamma$ is probably not zero since γ is orientation dependent. However, the change should be small and can be neglected as a first approximation.

$- k_o$), is positive. Note also that Δk and K have the same sign (positive quantities for a hill, negative for a hole). Thus, if Γy_o^* is sufficiently large, the system is stable. For the silane system y_o^* is extremely small over the useful range of inlet silane concentrations. No range of stability would then be expected, and as previously indicated none was observed. The behavior of the silicon tetrachloride-hydrogen system is decidedly different however, in that as the inlet $SiCl_4$ concentration increases, so does y_o^* [see *e.g.*, Fig. 7 and ref. (10)].

This fact does provide for a range of stability, but the formulation is not completely satisfactory because a substitution of appropriate numbers does not agree well with measured dJ's. This can most easily be shown by examining Eq. [5b] for the case of the hole neither deepening nor filling. Thus,

$$y - y_o^* = \frac{y_o^* \Gamma k_p K_p}{k_p - k_o} \qquad [6]$$

Unstable growth should result if the right-hand side of Eq. [6] is smaller than the left. Conversely if the right-hand side is larger than the left, the growth should be stable.

From Eq. [1], values of k_o and k_p may be calculated for the case of small y (and accordingly, small y_o^*). y_o^* can be obtained from Fig. 7, which was plotted from Lever's data (10). The curvature term K_p may be estimated from the appropriate photograph, and from Fig. 4b the value of y for $\Delta J = 0$ can be determined. Alternatively, the average value of the ratio of transport coefficients may be obtained from the boundary layer theory as

$$\frac{k_p}{k_p - k_o} = -\frac{w}{\delta} \qquad [7]$$

while the average K may be obtained from the definition $K_{avg} = (dA/dV) \cong 4/D$, where A is the surface area, V is the volume of solid, and D is the perturbation diameter. The parameter Γ, involving the surface tension γ, is the only term not experimentally observable, but by substitution of the values into Eq. [6], γ must be at least 20,000 ergs/cm^2, as compared to a reported value of 1230 ergs/cm^2.

While some uncertainties exist in the values of K, k, y_o^*, and γ, these uncertainties cannot explain the discrepancies noted above. Also, two-dimensional computer solutions and three-dimensional electrical analog solutions of the diffusion equation were obtained which confirmed the general finding that, for gas phase diffusion to explain the observed phenomena, the surface energy of silicon would need to be at least an order of magnitude greater than its known value.

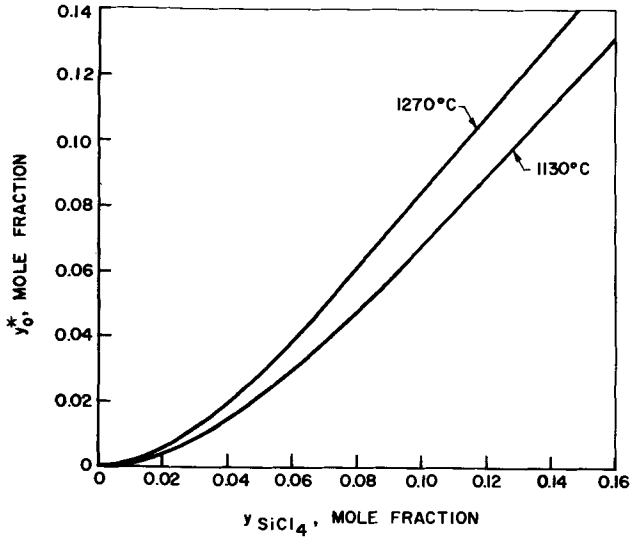

Fig. 7. Equilibrium surface concentration of silicon-containing species, y_o^*, as a function of mole fraction of $SiCl_4$ in incident reactant gas stream, y.

The diffusion equation assumes a stagnant film through which mass is transported and this certainly is not true. However, the concentration field in the gas is distorted by the perturbations for only a very small distance into the gas as compared to the total apparent film thickness. In this distorted region the velocities are very low and the standard diffusion equations should be an excellent approximation. We are strengthened in this conclusion by noting that the deposit shapes and local deposition rate around the perturbation are not a function of the direction of flow.

Departures of the gas phase concentrations from the equilibrium values of y_o^* exist, but these cannot explain the observed results. Since all areas of the sample surface are undergoing deposition, the concentrations must be equal to or greater than the values given by the equilibrium equation corrected for capillarity in order to have the small positive δy's required for a driving force. One would expect these δy's to be generally proportional to rate of growth. Therefore, such δy's would be in the wrong direction to explain the observed results. Also in cases where the perturbation bottoms (or tops) remain flat and grow at the same rate as the main flat surface, δy in the center of the perturbation should equal δy on the main flat surface, and any deviations from equilibrium would cancel.

Diffusion of possible unknown species in the gas phase has already been taken into consideration in our development. We have added the gradients of all silicon-containing gas species to obtain the total gradient of silicon in the gas phase. We have assumed that all gas phase species have the same diffusivities and have neglected the total flow of gases away from the surface. This treatment may result in an error of a few per cent, but cannot result in an error of a size needed to explain the observed results.

It appears that theory based on gas phase diffusion and capillarity cannot be used alone to explain the details of growth on perturbed surfaces of silicon. An additional mode of mass transport of silicon is required. Since volume diffusion of solid silicon is extremely slow, the only possibility seems to be surface diffusion. If this is true, several conclusions can be drawn about the diffusing surface specie. First and most obvious is that such a specie is not silicon adatoms. The concentration of silicon adatoms on the surface is believed to be mainly a function of temperature, growth rate, and crystal orientation. However, deposits which have approximately the same concentration of adatoms have growth characteristics that differ widely. Also, the surface species cannot be composed of only silicon and hydrogen, for the sample deposited from silane would then be expected to exhibit the same type growth phenomena as that observed for $SiCl_4$ reduction. It is concluded therefore that the species diffusing on the surface must also contain chlorine. They may be chemically adsorbed $SiCl_4$, $SiHCl_3$, or $SiCl_2$, etc., or perhaps an adsorbed radical such as SiCl.

Conclusions

While most of the studies reported were for the specific case of silicon, and while explanations of the observations are not complete, the results should be directly applicable to systems which exhibit a y_o^* that varies appreciably with inlet gas concentration. If a substrate etch is used which produces surface asperities, growth conditions can be chosen to eliminate them. This explanation could, for example, be applicable to GaAs where the vapor etching prior to deposition often produces a rough surface which after deposition is again found to be smooth. However, if

a faithful replica of the original surface is desired, this can also be approximated.

It is observed that even if the system is unstable, *i.e.*, a hole gets deeper, the walls often gradually close in. If small areas are initially masked, perhaps by unintentional foreign matter, a well may be formed which can close over to give a continuous surface with holes beneath. It is suggested that this is the mechanism which gave rise to the interface voids observed during some of the early work with silicon and germanium epitaxy. Even though such a system is not desirable, it may still be preferable to one which allows direct overgrowth of the impurity with the attendant high probability of polycrystalline growth.

Finally, it should be remembered that while all of the discussion has been based on single crystal growth, most of the observations should apply directly to polycrystal growth as well. For the specific case of silicon we have verified that the polycrystalline filling or deepening of holes directly parallels the single crystal behavior.

Some Properties of Vapor Deposited SiC

Kenneth E. Bean and Paul S. Gleim

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

A process for the vapor deposition of silicon carbide films on silicon substrates using the hydrogen reduction of silicon tetrachloride and the pyrolysis of a hydrocarbon such as toluene was developed. At the optimum deposition temperature of 1075° ± 10°C, the deposition rate using 0.89% silicon tetrachloride and 0.18% toluene was 1.6 μ/min. Films deposited at less than 0.18% toluene, with a fixed silicon tetrachloride concentration of 0.89%, were attacked by "Planar etch," while those deposited at or above 0.18% toluene were not; the electrical resistance decreased, however. When the silicon tetrachloride concentration was varied from 0.7 to 0.9% at 0.18% toluene, the electrical resistance of the films was greater than one hundred megohms. The thermal coefficient of expansion was tailored to be less than, equal to, or greater than that of silicon by changing the concentration of silicon tetrachloride from 0.6 to 1.2% at 0.18% toluene. The refractive index of the films also changed with the change in silicon tetrachloride concentration. Infrared transmission data on films deposited at 0.18% toluene and 0.89% silicon tetrachloride were identical to those for bulk silicon carbide. X-ray diffraction studies showed that the films were normally polycrystalline and consisted of both alpha and beta phases, however, epitaxial silicon carbide was observed in some cases.

Considerable work has been done on the growth of SiC crystals for various purposes. Also, work has been reported both in the open literature and in government reports on the vapor deposition of thin SiC films (1-10). The work to be discussed in this paper covers the vapor deposition of polycrystalline SiC films which were very hard, had high electrical resistivity, and were chemically resistant to standard silicon etchants.

The process used was the hydrogen reduction of silicon tetrachloride and the pyrolysis of a hydrocarbon. The flow system employed was a conventional vapor deposition unit. Silver palladium purified hydrogen was used as the reducing agent for the silicon tetrachloride and as the carrier gas for the silicon halide and the hydrocarbon, toluene. Other hydrocarbons, both liquid and gaseous, were also used successfully. Constant temperature baths were used to control the vapor pressure of the silicon halide and hydrocarbon. A liquid nitrogen trap was employed to prevent back streaming of the hydrocarbon into the pure hydrogen source. Anhydrous hydrogen chloride was used for *in situ* vapor etching (11) of the substrates prior to silicon carbide film deposition. Forming gas was used as the purge gas. The reactor was a horizontal, resistance-heated, cold-wall unit utilizing a water cooled quartz reaction chamber. Water cooled Hastelloy B electrodes were used to carry current to the silicon carbide (TI-Kote)®[1] coated graphite strip heater. The deposition temperature was monitored and controlled by a radiation detector and feedback controller.

The substrates used for film deposition were single crystal silicon. The (111), (110), and (100) orientations (both on and 1½° off) were examined. Very

[1] (R) U.S. Patent Office.

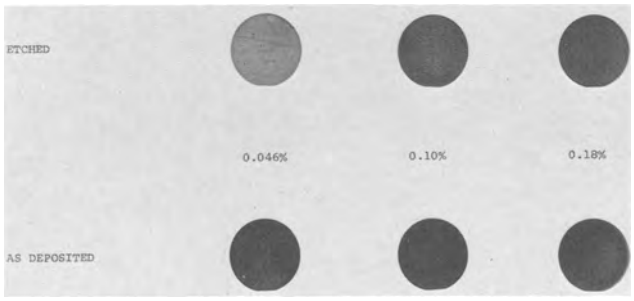

Fig. 1. SiC etch resistance vs. per cent toluene in source

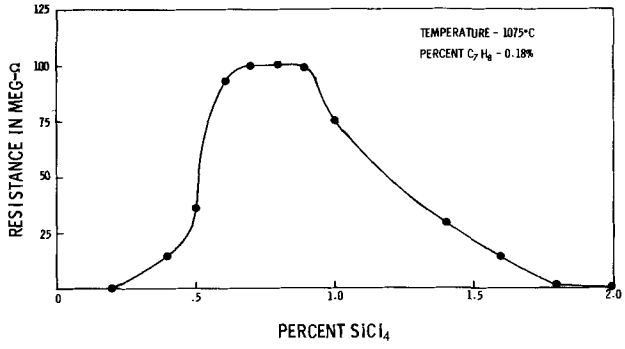

Fig. 2. Electrical resistance vs. per cent silicon tetrachloride

little difference in film quality was observed, however, films deposited on substrates oriented 1½° off the (110) were consistently haze free and had mirror like surfaces. It should be noted that the visual appearance of the film is also dependent on substrate surface preparation.

Experimental

Experiments were carried out to determine the optimum deposition temperature to give the desired film characteristics. Investigations were made at 25° increments between 800° and 1300°C. The optimum temperature for producing films that had mirror-like planar surfaces was found to be 1075° ± 10°C.[2] At this temperature, the deposition rate was 1.6 μ/min at 0.89% silicon tetrachloride and 0.18% toluene.

Silicon carbide films were deposited on silicon substrates (in groups of two) at a constant temperature of 1075°C, 0.89% silicon tetrachloride and a total flow rate of 50 l/min. The per cent toluene was varied from 0.046 to 0.28%. One slice from each group was subjected to a planar etch[3] while the other was kept as a standard. Figure 1 is a photographic comparison of the slices. As is evident from the figure the films deposited at less than 0.18% toluene were attacked (note discoloration) by planar etch while those deposited at or above 0.18% toluene were inert to planar etch. Films deposited at 0.28% toluene and 0.89% silicon tetrachloride were completely inert to planar etch but had an electrical resistivity substantially below that of films deposited at 0.18% toluene.

To determine the effect of changing the concentration of silicon tetrachloride on the film's electrical resistance and resistivity, the silicon tetrachloride concentration was varied from 0.2 through 2.0%. Resistance measurements were made by a two-point probe technique on 20.0μ films on silicon substrates. The relative values obtained are plotted in Fig. 2. The resistance of the films from 0.7 to 0.9% was at least one hundred megohms, which is the upper limit of the test equipment used. Resistance values of films deposited with silicon tetrachloride concentrations below 0.7 and above 0.9% drop off markedly perhaps due to a change in the stoichiometry of the films. Evidence of this change, which produces a silicon rich or carbon rich film is apparent from the data in Fig. 1, 3, and 5. For example in Fig. 1, as the toluene concentration is decreased below 0.15% a silicon rich film results which is more soluble in the common silicon etchants. Resistivity measurements were made by Hall mobility studies using low resistivity silicon as contacts and values of approximately 6000 ohm-cm were obtained. Resistivity values on samples deposited with different concentrations of silicon tetrachloride were calculated from sheet resistance measurements on thick films (> 20 mils) using a four-point probe and values of approximately 8000 ohm-cm were obtained. This resistivity is adequate for the isolation of components in some integrated circuits.

The reported value for the thermal coefficient of expansion of SiC (4.4×10^{-6}) (20) closely matches that of silicon (4.2×10^{-6}) (12, 13) (see Table I). A series of runs was conducted to determine the effect of varying the concentration of silicon tetrachloride in the reactant gases on the thermal coefficient of expansion of the deposited films. Films 50.8μ thick were deposited with silicon tetrachloride concentrations from 0.6 to 1.2% on 1 in. diameter, 14 mil thick silicon substrates. The relative change in the thermal coefficient of expansion was determined by measuring the amount of curvature[4] of the silicon slice after film deposition. These measurements were made by using a Taylor-Hobson Talysurf and the data are shown in Fig. 3. From the data it may be observed that the coefficient of thermal expansion of the SiC films can be changed or tailored to be equal to, greater than, or less than that of silicon by changing the per cent silicon tetrachloride in the reactant gas stream.

An experiment was conducted to compare the curvature of like silicon substrates having silicon carbide films with those having silicon dioxide films. Silicon carbide films 10.0μ thick were deposited (one side only) at 1075°C with a deposition rate of 1.6 μ/min on 1-in. diameter 14 mil thick silicon substrates, using 0.89% silicon tetrachloride and 0.18% toluene. Films of SiO_2

[2] Optical pyrometer.
[3] Planar etch, 15-HNO_3, 5-HAc, 2-HF.
[4] Curvature is defined herein as the variation from planarity across a 1 in. diameter substrate and is expressed in mils.

Table I. Some properties of Si, SiC, Si_3N_4, and SiO_2

	Si	SiC	Si_3N_4	SiO_2
Thermal expansion	4.2×10^{-6}/°C (0-1000°C) (13)	4.8×10^{-6}/°C (2) α 4.3×10^{-6}/°C (20) β 4.5×10^{-6}/°C (20) (0-1000°C)	α : 2.87×10^{-6}/°C β : 2.25×10^{-6}/°C (25-1000°C) (19)	(Fused silica) 0.58×10^{-6}/°C (0-1200°C) (15)
Thermal conductivity	0.30 cgs @ 20°C (12)	1.17 cgs @ 20°C (21)	0.035 cgs (22)	0.0021 cgs @ 20°C (23)
Resistivity @ 25°C	$>10^5$ ohm-cm (12)	$6\text{-}8 \times 10^3$ ohm-cm (text, also) (see Fig. 4)	$>10^{13}$ ohm-cm (25) 5×10^{14} ohm-cm (24)	10^{15}-10^{17} ohm-cm (27)

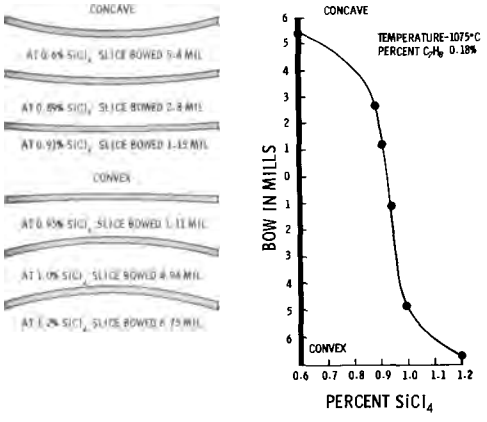

Fig. 3. Slice curvature vs. per cent silicon tetrachloride

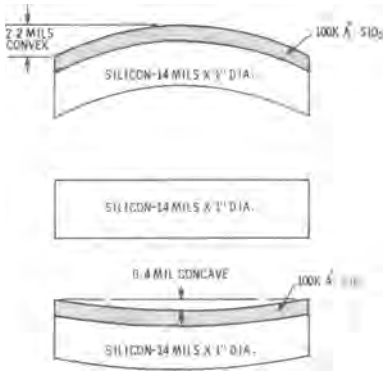

Fig. 4. Curvature of silicon slice, with SiO_2 vs. SiC film

(10.0μ thick) were deposited from silicon tetrachloride, CO_2 and H_2 at 1250°C with a deposition rate of 0.34 μ/min. The SiC films produced a 10.0μ curvature, concave to the top or SiC surface. The SiO_2 films produced a 56.0μ curvature, convex to the top or SiO_2 surface. This indicates a 5.5 times greater bowing or curvature in the opposite direction in the case of the SiO_2 films (see Fig. 4). The reported thermal coefficient of expansion of fused silica (SiO_2) is 0.58 x 10^{-6}/°C (14).

A series of runs was made, varying the per cent silicon tetrachloride, to determine the refractive index of the deposited films as a function of per cent silicon tetrachloride in the reactant gas stream. The per cent toluene was 0.18 and the deposition temperature was 1075°C. These data were taken at 5461Å using the ellipsometer technique (15, 16) and are plotted in Fig. 5. It should be noted from Fig. 5 that the curve passes through 2.6, the reported value (17) for the index of refraction of SiC, at approximately 0.9 and again at approximately 0.15% silicon tetrachloride.

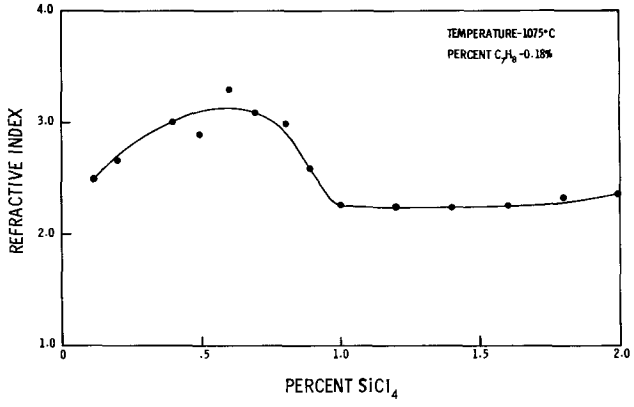

Fig. 5. Refractive index vs. per cent silicon tetrachloride

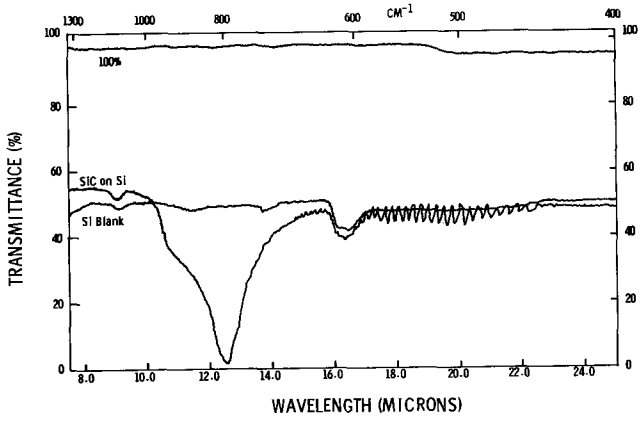

Fig. 6. Infrared transmission curve for SiC on silicon

Infrared transmission data were obtained on films deposited at 1075°C with a toluene concentration of 0.18% and silicon tetrachloride concentration of 0.89%. These data show the transmission of the films is the same as for bulk SiC (18). The infrared transmission curve for a SiC film on silicon is shown in Fig. 6.

Attempts to measure hardness as a function of the per cent toluene in the gas stream are incomplete; however, from observations during sawing, lapping, and polishing of the films, the hardness increases with increasing toluene.

X-ray diffraction studies show the films are alpha and beta SiC. Single crystal epitaxial SiC was observed in some cases but the growth of very hard, chemically stable, high resistivity films was the objective of this program.

Summary and Applications

The chemical, physical, and optical properties of silicon carbide films can be tailored by changing the deposition temperature, volume per cent silicon tetrachloride and or toluene. The optimum conditions for deposition were 1075°C at 0.89% silicon tetrachloride and 0.18% toluene in hydrogen with a total flow of 50 l/min. At these conditions a deposition rate of 1.6 μ/min was obtained. Infrared transmission data on the polycrystalline (alpha and beta) films agree with that reported for bulk silicon carbide.

The films were used as the isolation medium in dielectric isolation type structures. They are superior to SiO_2 films from the standpoint of hardness or abrasive resistance thus providing an excellent lap stop or wear resistant surface. They are also superior to SiO_2 films with respect to etch resistance thus providing an excellent etch stop. The thermal conductivity of silicon carbide (see Table I) is much greater than that of silicon dioxide and other common insulating materials. In general the dielectric properties of the films are inferior to those of SiO_2. However, a thin oxide or nitride film can be used in conjunction with the SiC film to give good dielectric isolation.

The Ga-P-Te System

Morton B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Differential thermal analysis, x-ray, and electron beam microprobe studies of melts cooled from the liquid in the Ga rich region of the Ga-P-Te system have been done, and a part of the ternary condensed phase diagram has been drawn on the basis of the experimental data. GaP does not form continuous or extensive solid solutions with Te containing phases. The possible existence of a ternary compound in the P rich region is discussed.

This work is part of a series of studies of the phase systems and phase fields encountered when GaAs or GaP are present in equilibrium with other phases containing elemental impurities which are of general interest in semiconductor studies.

The most extensive work with III-V-VI systems has been done for the $A^{III}B^{V}$—$A_2^{III}C_3^{VI}$ binary systems (1) where there is particular interest in the $A_2^{III}C_3^{VI}$ compounds, which crystallize in a tetrahedral lattice with built-in vacancies. These compounds might be expected to have extensive solid solubility with $A^{III}B^{V}$ compounds. In addition to solid solution formation, III-V-VI systems are likely to be complicated by ternary compound formation such as has been suggested by Hahn and Thiele (2) for In_2AsSe and demonstrated for $InAs_3S$ by Luzhnaya *et al.* (3). Liquid immiscibility has been observed in the InSb-InSe system by O'Kane and Stemple (4). The Ga-P-Te system appears to be most closely related to the Ga-As-Te system which was recently studied in this laboratory (5).

In this work we have observed thermal effects by differential thermal analysis when cooling several molten mixtures through phase transitions. Compositions were along selected cuts in the ternary system. Because of the high pressure and temperatures encountered in this system we were able to study in detail only mixtures with compositions in the gallium rich region of the ternary.

Samples obtained after cooling ternary mixtures from the melt were examined by electron beam microprobe and x-ray techniques.

Experimental

Semiconductor grade Te with purity better than 99.999% and reclaimed Ga and GaP with purities better than 99.99% were used in this work. The use of GaP rather than the elements was necessary in order to prevent explosions resulting from the exothermal reaction of the elements.

Fused silica capsules with a volume of about 2 cc which were about 2/3 filled with melt were used for the differential thermal analysis experiments. The experimental details are very similar to those which have already been described for the study of the Ga-As-Zn ternary (6) and several other systems

(5, 7). The precision to which thermal effect temperatures are reported is about ±5°K.

For all of the runs it was necessary to heat the cells above 1250°C and in some cases to about 1350°C. These temperatures are above the softening point of fused silica and in general the cells expanded. Expansion of the DTA cell resulted in poorer contact of the liquid to the thermopile well. The precision of the temperature-thermal effect data in these studies is therefore somewhat poorer than in previous studies. In some cases only the highest temperature transition could be obtained before the cell became useless. In these cases other transitions were obtained by heating the cell to 1200°-1250°C and then allowing it to cool without attempting to study the first transition.

X-ray analysis of the DTA samples was done by standard powder techniques, and electron beam microprobe analyses were obtained for several of the samples.

For several compositions along the GaP-Te cut at which we were unable to obtain DTA curves, mixtures were heated in heavy (1/8 in.) walled fused silica capsules which were only about 1/5 filled with the molten mixture. These samples were heated very slowly to about 1250°C and then allowed to cool at about 1°C/min.

The Binary Phase Systems

Ga-P.—Gallium and phosphorus form a single congruently melting compound GaP, with a melting point of 1465°C (8). Thurmond (9) has utilized the solubility data of Rubenstein (8) and Hall (10) along with an adaptation of the regular solution treatment of Vieland (11) to construct the binary phase diagram.

Ga-Te.—Gallium and tellurium form two congruently melting compounds, GaTe and Ga_2Te_3. The melting point of Ga_2Te_3 has been reported as 792°C (12) and 790°C (13) and that of GaTe as 835° (12) and 824°C (13). In recent work on the Ga-As-Te system (5) the melting points of Ga_2Te_3 and GaTe were found to be 789° ± 3°C and 827° ± 3°C, respectively. Two other tellurides, Ga_3Te_2 and $GaTe_3$, have been suggested on the basis of thermal analysis studies (12). These compounds were reported to decompose below their melting points. A phase corresponding to $GaTe_3$ has been identified in a metallographic study (14), but in the same study Ga_3Te_2 was not identified. A region of liquid immiscibility on the gallium rich side of the binary phase diagram has been reported but not confirmed (12).

Te-P.—There is no phase information available for the Te-P system. One compound, P_2Te_3, has been reported (15).

Results

The temperatures at which thermal effects were observed and the phases obtained when various compositions were cooled are given in Table I, and some of the data are plotted in Fig. 1 and 2.

In each case T_1 represents the temperature at which the surface of primary crystallization was reached, and T_2 represents the temperature of the first appearance of a second phase. GaP was found by powder

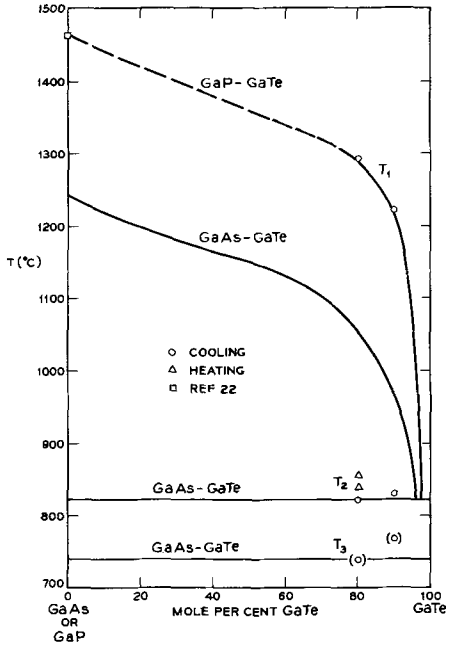

Fig. 1. Thermal effects for samples with composition along cut B (the GaP-GaTe cut) of Fig. 3.

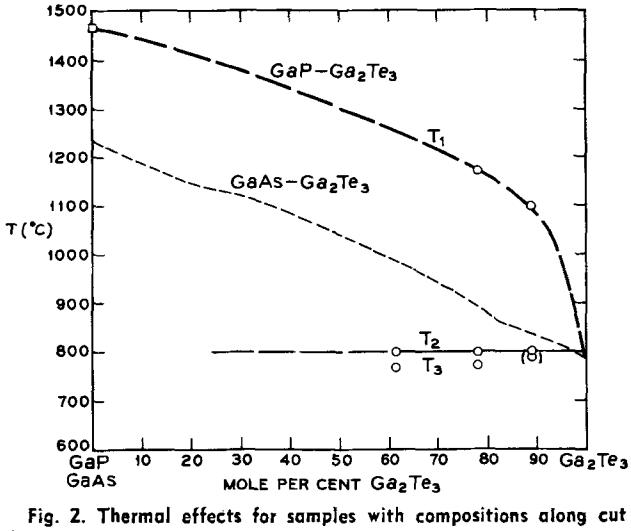

Fig. 2. Thermal effects for samples with compositions along cut C (the GaP-Ga_2Te_3 cut) of Fig. 3.

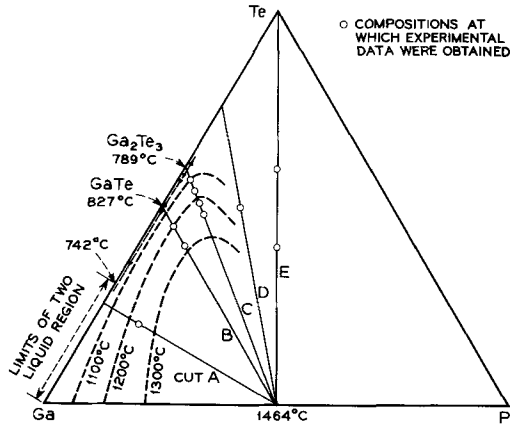

Fig. 3. Portion of the Ga-P-Te ternary phase diagram. Compositions are in atom per cent.

x-ray and microprobe studies to be present in all samples. By analogy with the Ga-As-Te system we take this to indicate that, since GaP is the highest melting compound in the system and since T_1 is quite high in all cases, all the mixtures studied were in the GaP primary phase field.

The x-ray patterns for GaP were sharp and unshifted. This indicates that GaP crystallized in this system did not form extensive solid solutions with Te.[1]

Cut A.—Only one experimental point was obtained along cut A of Fig. 3. Except for the higher value of T_1, the DTA and the x-ray data are essentially identical with the data from a similar point in the Ga-As-Te system (5). When cooling, GaP precipitates first; then as the liquid composition moves along cut A toward the Ga-Te binary, a two liquid region is encountered (no thermal effect observed) and finally at 740°C GaTe precipitates.

Cut B (the GaP-GaTe *system).*—Several DTA runs with samples at two compositions on this cut were done. As above, except for the higher temperature of the T_1 transition, the DTA data and the x-ray data are similar to the data previously obtained in the Ga-As-Te system (5). The suggested liquidus curve is given in Fig. 1 along with that for the GaAs-GaTe cut for comparison. The T_2 and T_3 transitions obtained when cooling are at approximately the same temperature as transitions obtained in the Ga-As-Te system. Several DTA points for T_2 were obtained from slow heating cycles and yielded a somewhat higher temperature. It is not clear whether T_2 is a eutectic or peritectic transition from this data. As with the GaAs-GaTe system, the occurrence of the T_3 transition, which in this case is very slight, is an indication that the liquid has reached the composition of the start of the two liquid region and therefore that the GaTe phase precipitating must be somewhat rich in Te.

Cut C (the GaP-Ga_2Te_3 *cut).*—Transitions observed by DTA for two compositions along this cut are shown in Fig. 2. The suggested liquidus curve is shown along with that for the GaAs-Ga_2Te_3 cut for comparison. Examination of the cooled samples with the electron beam microprobe showed large crystals of GaP present, and this is again interpreted to show that GaP is present as the primary phase formed at T_1. X-ray and microprobe examination showed the second phase (which we suggest starts to precipitate at T_2) to be Ga_2Te_3. In contrast to the GaAs-Ga_2Te_3 cut, in this case the x-ray lines from the Ga_2Te_3 phase are moderately sharp and unshifted. Since T_2 is above the melting point of pure Ga_2Te_3 it appears that as in the GaAs-Ga_2Te_3 case a solid solution containing excess P, and Te is found, but to a much more limited extent, and below the limits of detectibility (~5-10 a/o P) in the x-ray powder photographs.

Unfortunately, the second order L_{β_1} line of Te interferes with $K\alpha_1$ line of P and therefore reduces the sensitivity of the electron beam microprobe to P in the presence of Te. It was therefore not possible to determine the amount of P in the Ga_2Te_3 phase. Goryunova and Radautsan (16) have, however, reported an approximate solubility of about 6 a/o P in Ga_2Te_3.

The T_3 transition is interpreted here as a ternary eutectic or peritectic which occurs near the Ga-Te binary between the GaTe and Ga_2Te_3 compositions.

Cut D.—DTA, x-ray, and electron beam microprobe data have been obtained for one point along cut D of Fig. 3. Again the high T_1 value and the presence of large crystals of GaP are taken to show that the over-all composition is in the GaP primary phase field. The T_2 and T_3 transitions are due to the formation of phases in the Te rich portion of the phase diagram.

It is instructive to inspect three electron beam microprobe photographs of the surface of a polished sample from the DTA run of cut D taken by scanning the fluorescence radiation from each of the elements (Fig. 4). Several features of this system are demonstrated. There is a large region (lower left corner) of GaP and a large region which is high in Te as shown by the Te fluorescence photograph but which contains at least three different intensities of Ga fluorescence radiation. The P fluorescence radiation photograph contains an over-all haze of interference from the Te second order L_{β_1} line as mentioned above, but also has a few bright zones in the Te rich region. It thus appears that there are at least two tellurium containing phases other than the Ga_2Te_3 phase identified by the x-ray powder patterns. The bright regions on the P photograph indicate that at least one of these Te containing phases may be associated with P, and there is some x-ray evidence that one of the phases may be principally Te. The powder patterns for this sample were too complicated, however, to permit definite identification of anything other than the GaP and Ga_2Te_3 phases.

Cut E (the GaP-Te *pseudobinary).*—Only x-ray and electron beam microprobe studies were done with mixtures with compositions on this cut. DTA studies

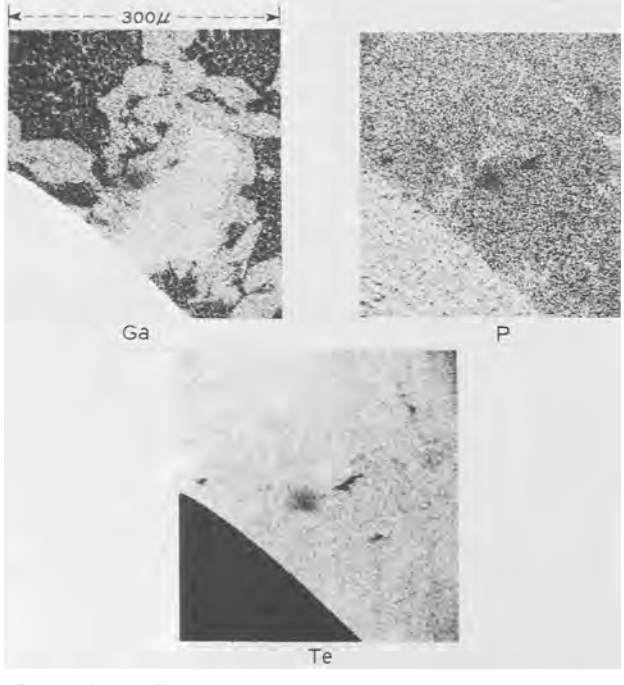

Fig. 4. X-ray fluorescence photographs of a sample from cut D of Fig. 3.

[1] It should be noted that the precision of the powder x-ray data is such that solid solutions with less than several per cent of impurity would not be detected.

were attempted but the relatively thin walled (1 or 2 mm) fused silica cells charged with Te and GaP always exploded during the heat-up period. Explosions occurred at temperatures as low as 800°C if the cells were heated at about 5°C/min and in the 1200°C range when heated much more slowly.

It was possible to prepare molten mixtures which were then slow cooled for subsequent examination by using relatively large heavy walled cells which were only about 1/5 filled with the mixture. These cells also exploded occasionally at about 800°C during the heat up, and on several occasions cells exploded at about the same temperature on cooling when too full or when too rapidly cooled.

The x-ray and microprobe examinations both revealed the presence of GaP and Ga_2Te_3 in addition to other phases. Again, the x-ray patterns were too complicated to permit identification of the other phases, and the Te interference with the P radiation prevented accurate analysis for P. There is, however, at least one phase containing Ga other than Ga_2Te_3. Furthermore, there is evidence for a phase very rich in P (probably elemental P) from the microprobe studies. In Fig. 5 the Ga, P, and Te radiation photographs of a small region of the sample containing 60 a/o Te are shown. Figure 5 shows a dendrite like structure which is essentially all P in a matrix which is principally Ga_2Te_3 with some small areas containing a phase with Te and probably some P.

On the basis of the small amount of data obtained for this cut, it appears that the primary phase is GaP at the compositions studied. The explosion of cells at about 800°C on heating indicates that an exothermic reaction (probably occurring suddenly due to a phase change in a protecting layer) occurred to form an unknown new phase. The presence of elemental phosphorus can be explained if we assume that a compound or compounds decomposed at a ternary peritectic at a relatively low temperature. [This is reminiscent of the Ga-As-Te system (5) in which there was evidence that a ternary compound decomposed at a low temperature (~340°C) to yield elemental arsenic and a phase based on the Ga_2Te_3 structure.]

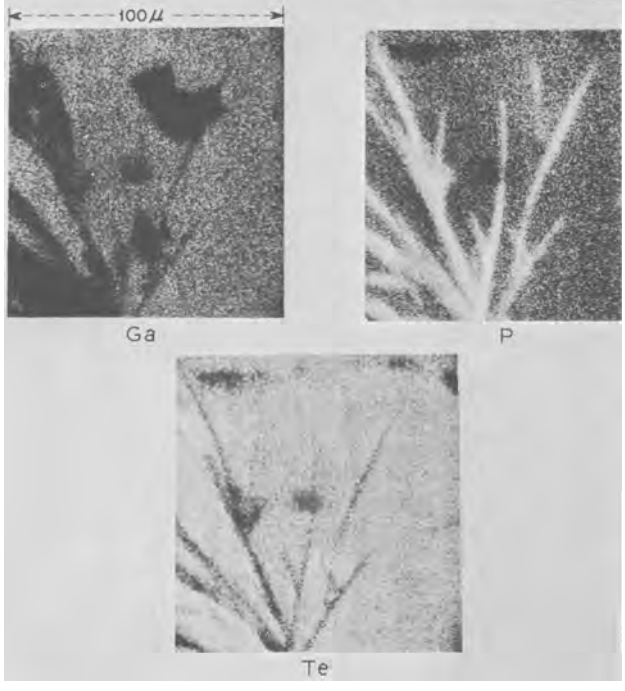

Fig. 5. X-ray fluorescence photographs of a sample from cut E of Fig. 3.

The ternary phase diagram.—The ternary diagram (Fig. 3) is drawn in such a manner as to be consistent with the DTA, x-ray, and microprobe data for the cuts indicated. No data were obtained in the Te and P rich regions of the system.

Conclusion

Part of the condensed ternary phase diagram for the Ga-P-Te system has been constructed on the basis of data obtained from differential thermal analysis, x-ray, and electron beam microprobe studies. Unlike several other III-V-VI systems (17-21), no regions of extensive solid solubility of tellurium in GaP or GaP in Ga_2Te_3 were observed. The gallium rich part of the phase diagram appears to be similar to that found earlier for the Ga-As-Te system (5) except that the primary phase formation of GaP occurs at higher temperatures than the formation of GaAs, as would be expected from the higher melting point of GaP.

DTA data were not obtained for mixtures on the GaP-Te cut. X-ray and microprobe data for samples prepared along this cut yield data which indicate that a ternary compound may exist in the P rich region which decomposes to yield P and Ga_2Te_3 on cooling.

Acknowledgments

The author would like to acknowledge useful discussions with C. D. Thurmond. H. Schreiber performed the electron beam microprobe analyses and aided in their interpretation. Powder x-ray analyses were done by M. Leung. S. Sumski prepared the DTA samples.

Manuscript received May 26, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Properties of Gold Doped MOS Structures

S. F. Cagnina and E. H. Snow

Research and Development Laboratory, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

The theoretical capacitance-voltage characteristics of gold-doped metal-oxide-silicon structures have been calculated and compared with experiment for both the high and the low frequency cases. It is found that gold diffused from the back side causes a negative interface charge Q_{Au} in addition to the usual positive Q_{ss}. Evidence is presented to show that the gold responsible for Q_{Au} is located in the silicon very near the oxide silicon interface. Gold diffused from the top side (through the oxide) results in a positive Q_{Au} indicating that gold in the oxide near the interface is positively charged. Temperature-bias tests showed that Q_{Au} was stable under conditions which mobile alkali ions such as sodium drift rapidly. In addition, an MOS capacitance-voltage method is described for determining diffusion coefficients and solid solubilities in the oxide layer. Values of $D \cong 3 \times 10^{-3}$ μ^2/hr and $N \cong 3 \times 10^{18}$ cm^{-3} were obtained for gold in SiO_2 at 1100°C.

The introduction of gold into silicon devices is an effective and commonly used method for controlling minority carrier lifetime. Because of this practical application, the properties of gold in bulk silicon have been studied extensively (1). It has been found that gold diffuses rapidly in silicon, but that its diffusion depends in a complicated way on the defect structure of the crystal (2, 3). It has also been found that each gold atom in a substitutional site gives rise to two energy levels located within the silicon forbidden band: one of these is a donor level 0.35 ev above the valence band edge; the other is an acceptor level located 0.54 ev below the conduction band edge (4).

Because of the current importance of planar silicon technology, a knowledge of the effects of gold on oxidized silicon surfaces would be desirable. Such surfaces can be studied effectively using the capacitance-voltage characteristics of metal-oxide-semiconductor (MOS) structures. Theoretical C-V characteristics have already been calculated for nongold doped devices and successfully compared with experiment (5). The most important conclusion of these studies is that the oxidized silicon surface is characterized by a fixed positive surface-state charge Q_{ss} which tends to deplete or invert p-type silicon and accumulate n-type silicon. These theoretical C-V characteristics, however, are valid only for the case of silicon doped with shallow donors or acceptors such as phosphorus and boron for which complete ionization throughout both the neutral semiconductor and the surface space-charge region can be assumed. The charge state of the deep gold levels, on the other hand, will depend strongly on the electrostatic potential within the silicon. Thus, before one can effectively study the surface characteristics of gold doped silicon, the corresponding theoretical C-V characteristics must be developed. In the following sections these characteristics are calculated for both the high and the low frequency cases and are compared with experimental measurements. Such comparisons reveal the presence of an excess interface charge in addition to the normal Q_{ss}. The interface charge density is determined for various gold diffusion conditions and an attempt is made to determine the physical location of the gold responsible for the excess charge. Finally, the MOS method is used in a novel way to determine the diffusion coefficient and solid solubility of gold in SiO_2.

Theory

We shall now proceed to calculate the theoretical capacitance-voltage characteristics of gold doped MOS capacitors using the same procedure and notation as were used in ref. (5) for the nongold doped case.

The introduction of gold into the silicon substrate will affect the C-V characteristic because of the presence of the gold energy levels lying deep within the forbidden gap, the charge state of which will depend on the potential within the depletion region. Thus the space-charge density and hence the depletion region width and the resultant high frequency capacitance will be dependent on the gold concentration. At sufficiently low measurement frequencies, the charge in the gold levels will also respond to the a-c signal, giving an additional contribution to the semiconductor capacitance (6).

The charge state of a gold atom in silicon is not related to the potential by the usual Fermi factor because each gold atom introduces both a donor level and an acceptor level and the two are not independent; *i.e.*, a gold atom cannot be both a positively charged donor and a negatively charged acceptor at the same time. Taking this into account, the expressions for the concentration of gold atoms in each charge state become (2, 7)

$$N_{Au-} = \frac{N_{Au}}{1+2\exp(u_F+u-u_{Au-})\,[1+\tfrac{1}{2}\exp(u_F+u-u_{Au+})]} \quad [1]$$

$$N_{Au+} = \frac{N_{Au}}{1+2\exp(u_{Au+}-u_F-u)\,[1+\tfrac{1}{2}\exp(u_{Au-}-u_F-u)]} \quad [2]$$

where N_{Au} is the total gold concentration, u_{Au-}, and u_{Au+} are the potentials of the gold acceptor and donor levels, respectively, u_F is the Fermi potential in the bulk and u is the electrostatic potential or band bending.[1] Note that when the Fermi level lies above the gold acceptor level most of the gold atoms are negatively charged; when the Fermi level is between the two gold levels most of the gold atoms are neutral; and when the Fermi level is below the gold donor level most of the gold atoms are positively charged.

Potential and charge distributions in the vicinity of an inverted n-type silicon surface are shown in Fig. 1 and 2. The band diagrams are drawn to scale and were obtained from a computer solution to Poisson's equation, which will be described in detail later. Figure 1 corresponds to a sample doped with 1.0×10^{16} shallow donors/cm^3 and shows the usual uniform charge distribution and parabolic potential distribution within the depletion region. Figure 2 shows the same sample but with the addition of 0.98×10^{16} gold atoms/cm^3 to the silicon. Note that the bulk Fermi level has moved toward midgap due to compensation by the gold atoms. Note also that the depletion region is considerably wider and no longer contains a uni-

[1] All potentials are measured in units of kT/q with the potential at the intrinsic Fermi level in the bulk of the semiconductor taken as reference. Note that the energy levels in the lower half of the band gap correspond to positive potentials while energy levels in the upper half of the band gap correspond to negative potentials.

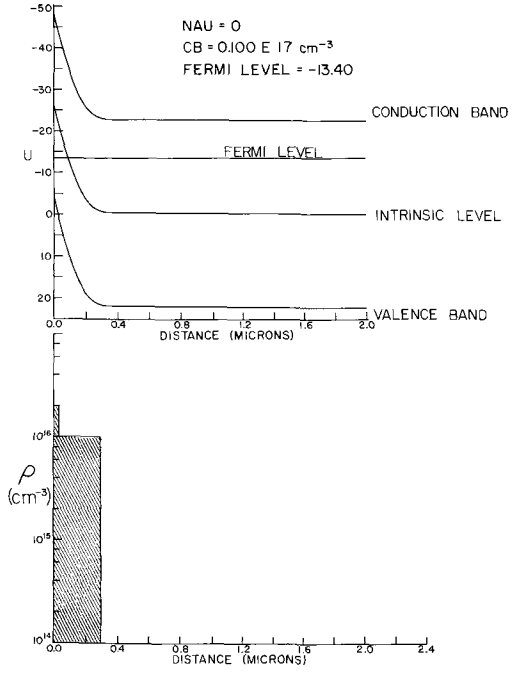

Fig. 1. Approximate charge density ρ (electronic charges/cm^3) and energy band diagram near an inverted n-type silicon surface ($N_D = 1.0 \times 10^{16}$ cm^{-3}, $u_S = -26.8$). The charge in the depletion region consists of positively charged ionized donors. The thin layer of added charge at the surface is due to accumulated minority carriers (holes).

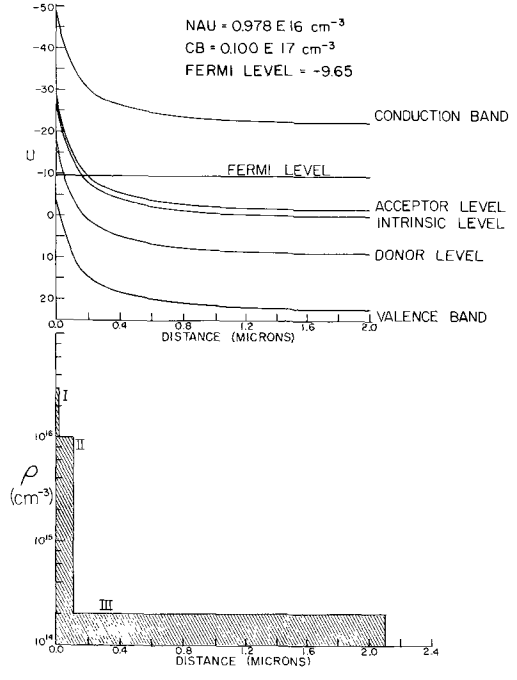

Fig. 2. Approximate charge density ρ (electronic charges/cm^3) and energy band diagram near an inverted surface of gold-doped n-type silicon ($N_D = 1.0 \times 10^{16}$ cm^{-3}, $N_{Au} = 9.8 \times 10^{15}$ cm^{-3}, $u_S = -26.8$). The charge in region I consists of minority carriers (holes) plus positively charged ionized donors plus positively charged gold atoms. The charge in region II consists of positively charged ionized donors (the gold is neutral). The charge in region III consists of positively charged ionized donors plus negatively charged gold atoms.

form charge density. In fact the depletion region can be divided into three regions corresponding to the three charge states of the gold. In region I the charge density is given approximately by $q(N_D+N_{Au})$, in region II by qN_D and in region III by $q(N_D-N_{Au})$. It is because of the charge compensation in region III that the band bending extends farther into the silicon than in the nongold doped case. This is true for all gold concentrations $N_{Au} \leqq N_D$. For gold concentrations substantially above N_D, the gold donor ions in region I will contribute approximately N_{Au} positive charges whereas the compensation effect in region III will diminish because the Fermi level will lie close to (or even below) the gold acceptor level.[2] The silicon depletion region will then consist of two regions: one of charge density $N_{Au} + N_D$ and the other of density $\sim N_D$. Effectively, the silicon will have an average donor concentration greater than N_D, thereby resulting in a smaller maximum depletion region width than is obtained on the nongold doped case [see ref. (5)].

The above figures and discussion were based on the calculated variation of the space charge in the silicon with potential. We shall now discuss these calculations using gold-doped n-type silicon as an example. The theory applies equally well for p-type silicon, but different characteristics are obtained because of the asymmetry of the gold levels about the center of the forbidden band. The charge density in the silicon is given by

$$\rho = q(p - n + N_D - N_A + N_{Au+} - N_{Au-}) \quad [3]$$

where p and n are the equilibrium electron and hole concentrations, N_D and N_A are the densities of shallow level donor and acceptor impurities, and N_{Au+} and N_{Au-} are the densities of charged gold atoms in donor and acceptor states respectively as given by [1] and [2]. Assuming that the semiconductor is nondegenerate, the carrier concentrations are given by

$$p = n_i \exp(u_F - u)$$

and

$$n = n_i \exp(u - u_F) \quad [4]$$

The Fermi potential is determined from the condition of charge neutrality in the bulk (far from the surface); there $u = 0$ and

$$n + N_{Au-} + N_A = p + N_{Au+} + N_D \quad [5]$$

In terms of the normalized potential u, Poisson's equation is given by

$$\frac{d^2u}{dx^2} = \frac{-q\rho}{kTK_S\epsilon_0} \quad [6]$$

Substituting [3] into [6], defining the intrinsic Debye length

$$L_D \equiv \left(\frac{kTK_S\epsilon_0}{2q^2n_i}\right)^{1/2}$$

and noting that

$$\frac{d^2u}{dx^2} = \frac{du}{dx}\frac{d}{du}\left(\frac{du}{dx}\right) = \frac{1}{2}\frac{d}{du}\left(\frac{du}{dx}\right)^2 \quad [7]$$

we obtain

$$\frac{d}{du}\left(\frac{du}{dx}\right)^2 = \frac{2}{L_D^2}\left\{\sinh(u-u_F) - (N_D - N_A)/2n_i - \frac{N_{Au}/2n_i}{1+2\exp(u_{Au+}+u-u_F)[1+\frac{1}{2}\exp(u_{Au-}+u-u_F)]} + \frac{N_{Au}/2n_i}{1+2\exp(u_F-u_{Au-}-u)[1+\frac{1}{2}\exp(u_F-u_{Au+}-u)]}\right\} \quad [8]$$

The above expression can be integrated in closed form from $u = 0$ (far in the bulk) to $u = u_s$ (at the silicon surface). The net charge per unit area in the silicon is then given by

$$Q_S = \frac{kT}{q}K_S\epsilon_0\left.\frac{du}{dx}\right|_{x=0} \quad [9]$$

[2] Adding gold to n-type silicon will progressively move the Fermi level toward the center of the band gap and will ultimately assume a position midway between the two gold levels.

This charge is made up of two parts: (*i*) minority carriers (holes) in a narrow inversion layer near the surface, and (*ii*) ionized gold and shallow donor and acceptor ions within a depletion region of width x_d. The part of Q_s which is due to holes in the inversion layer can be calculated from

$$Q_p \equiv q\int_0^{x_d} p(x)\,dx = q\int_{u_s}^{0} \frac{p(u)}{du/dx}\,du \qquad [10]^3$$

Similarly, that part of Q_s which is due to uncompensated ions within the depletion region may be calculated from

$$Q_B = q\int_0^{x_d} [N_{Au^+}(x) - N_{Au^-}(x) + N_D - N_A]dx$$

$$= q\int_{u_s}^{0} \frac{[N_{Au^+}(u) - N_{Au^-}(u)]}{du/dx}\,du + q(N_D - N_A)x_d \qquad [11]$$

where x_d is the effective depletion region width. This useful quantity may be determined from the relation

$$Q_s = q\int_{u_s}^{0} \frac{p(u)}{du/dx}\,du + q\int_{u_s}^{0} \frac{[N_{Au^+}(u) - N_{Au^-}(u)]}{du/dx}\,du + q(N_D - N_A)x_d \qquad [12]$$

Once a surface is strongly inverted, x_d rapidly approaches a maximum value with further increase in surface potential, corresponding to the fact that the added potential variation causes a very large increase in Q_p without substantially affecting Q_B.

In an MOS capacitor, the gate voltage V_G applied to the metal electrode is related to the silicon surface potential ϕ_s and the net charge in the silicon Q_s by (5)

$$V_G - \Phi_{MS} + Q_{ss}/C_o = \phi_s - Q_s/C_o \qquad [13]$$

where Φ_{MS} is the metal-semiconductor work function difference, C_o is the oxide capacitance per unit area, and Q_{ss} is the surface-state charge density which for nongold doped samples was shown to be independent of surface potential over the observable range.

If the charge in surface states is independent of surface potential, the small signal MOS capacitance per unit area can be calculated from the relation

$$C = \frac{1}{(1/C_o) + (1/C_s)} \qquad [14]$$

where $C_o = K_o\epsilon_o/x_o$ is the oxide capacitance per unit area and C_s is the silicon space charge capacitance per unit area. The latter must be calculated separately for the two cases of high and low measurement frequency. At sufficiently low frequencies, the minority carriers, the majority carriers, and the charge on the gold atoms within the space-charge region can follow the applied a-c measurement signal and contribute to the capacitance. The silicon capacitance can thus be determined from the relation

$$C_s = -\frac{dQ_s}{d\phi_s} = -\frac{d}{d\phi_s}\int_o^{\infty} \rho(x)\,dx = -\frac{d}{d\phi_s}\int_{\phi_s}^{0} \frac{\rho(x(\phi))}{d\phi/dx}\,d\phi = \frac{\rho(x=0)}{\left.\frac{d\phi}{dx}\right|_{x=0}} \qquad [15]$$

where the surface charge density $\rho(x = 0)$ is given by Eq. [3] evaluated at $u = u_s$, and the potential gradient at the surface follows directly from the first integration of Poisson's equation [8].

[3] Though the inversion layer does not, of course, extend throughout the depletion region, the expression for $p(u)$ decreases exponentially and the integral may be extended to $u = 0$ without serious error.

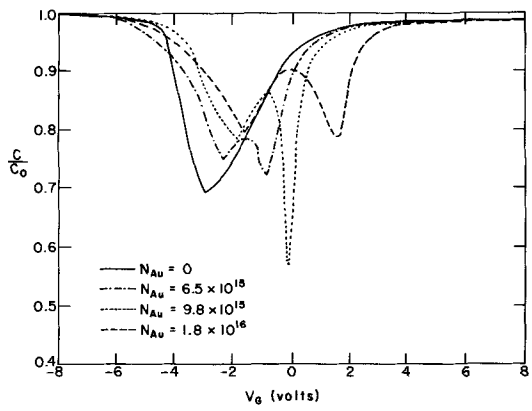

Fig. 3. Theoretical low frequency MOS C-V curves for a constant donor density of 1 x 10^{16} cm^{-3} and various gold concentrations ($x_o = 0.2\mu$).

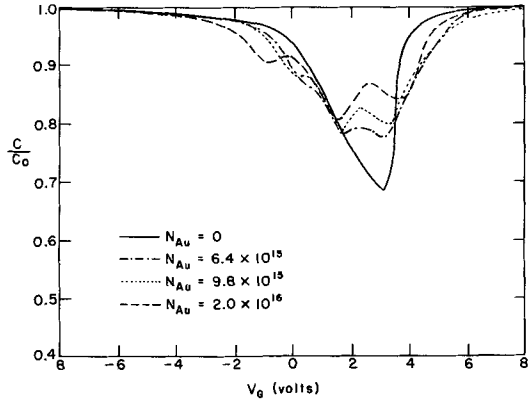

Fig. 4. Theoretical low frequency MOS C-V curves for a constant acceptor density of 1 x 10^{16} cm^{-3} and various gold concentrations ($x_o = 0.2\mu$).

For particular values of $N_D - N_A$, various Fermi levels were fed into an IBM 1130 computer. Gold concentrations were calculated for each Fermi level from the equation of charge neutrality [5]. For each gold concentration, the silicon capacitance C_s was computed for values of surface potential spanning most of the band gap. The MOS capacitance was then determined as the series sum of the oxide and silicon capacitances [14]. Finally, each surface potential was related to the effective applied gate voltage $V_G - \Phi_{MS} + Q_{ss}/C_o$ by Eq. [13]. Families of calculated C-V curves for 10^{16} doped n-type and 10^{16} doped p-type material with gold concentration as a parameter are shown in Fig. 3 and 4. These particular curves are for an oxide thickness of 0.2μ.

The presence of gold within the depletion region results in a peak in the C-V curve in the depletion-inversion range of the characteristic. This peak is similar to what would be obtained if surface states localized in energy within the forbidden band could follow the a-c measurement signal and contribute to the capacitance. As an example, a low-frequency MOS C-V characteristic was calculated for the case of nongold doped n-type silicon in the presence of 5 x 10^{10} cm^{-2} fast donor states located 8.88 kT units below the intrinsic level and 5 x 10^{10} cm^{-2} fast acceptor states located 1.54 kT units above the intrinsic level, corresponding to the energy levels of gold. The doping was chosen such that the Fermi level was the same as that for the sample, doped with 9.8 x 10^{15} gold atoms/cm^{-3}, whose C-V characteristic is shown in Fig. 3. The results are shown in Fig. 5, where two sharp peaks can be seen in the depletion-inversion region, corresponding to the Fermi level crossing each of the surface state levels. In the case of gold-doped silicon, those gold atoms that are located at the point where either

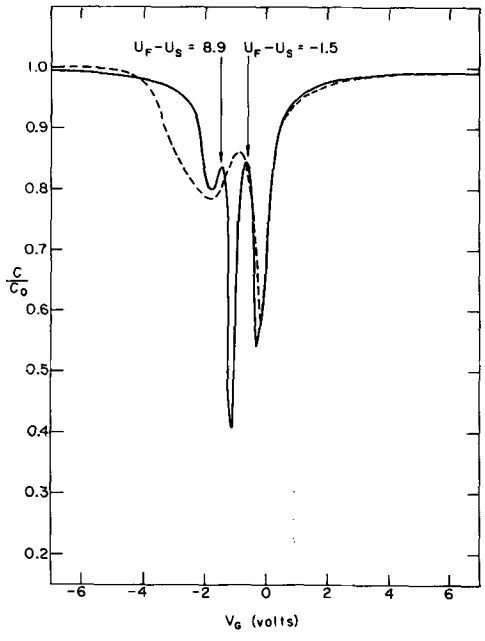

Fig. 5. Comparison of the effects of surface states and deep bulk levels on low frequency MOS C-V characteristics. The solid line corresponds to the case of 5 x 10^{10} cm^{-2} fast acceptor states at $u = -1.5$ and 5 x 10^{10} cm^{-2} fast donor states at $u = +8.9$. The dotted line corresponds to gold doped silicon (N_{Au} = 9.8 x 10^{15} cm^{-3}). In each case N_D = 1 x 10^{16} cm^{-3} and x_o = 0.2μ.

gold level crosses the Fermi level will contribute to the capacitance in the same way. However, the gold will continue to contribute even after the gold levels at the surface cross the Fermi level, since the crossover point then simply moves back into the bulk with increasing surface potential. Thus, the discrete gold levels behave qualitatively like fast surface states that are distributed in energy, resulting in a smearing of the two peaks into the single broader peak which is actually obtained.

At sufficiently high frequencies only the majority carriers can respond to the a-c signal; the minority carriers and the charge on the gold within the depletion region do not contribute to the capacitance. For this case the silicon capacitance is obtained by differentiating Eq. [12] keeping the first two terms on the right constant. This results in

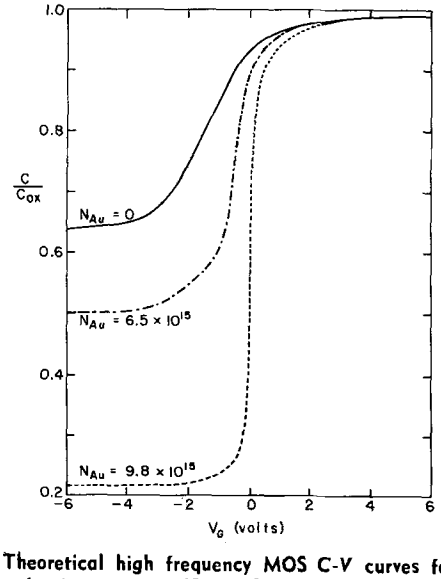

Fig. 6. Theoretical high frequency MOS C-V curves for a constant donor density of 1 x 10^{16} cm^{-3} and various gold concentrations (x_o = 0.2μ).

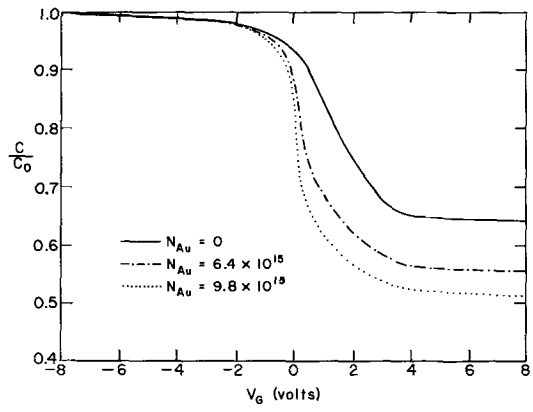

Fig. 7. Theoretical high frequency MOS C-V curves for a constant acceptor density of 1 x 10^{16} cm^{-3} and various gold concentrations (x = 0.2μ).

$$C_s = q(N_A - N_D)dx_d/d\phi_s \quad [17]$$

where $dx_d/d\phi_s$ can be calculated on the basis of the idealized charge distribution shown in Fig. 2. This results in

$$C_s = K_s\epsilon_o/x_d \quad [18]$$

Thus for each value of surface potential, an x_d, and hence a C_s, is obtained. C_s is related to the MOS capacitance by Eq. [14] and surface potential is related to gate voltage by Eq. [13], as in the low frequency case.

High frequency curves for n-type ($N_D = 10^{16}$ cm^{-3}) and p-type ($N_A = 10^{16}$ cm^{-3}) silicon doped with varying amounts of gold are shown in Fig. 6 and 7. Note that the MOS capacitance levels off at a minimum value in the inversion range corresponding to a maximum value for x_d. We shall refer to this limiting value of the effective space-charge width as x_{dmax}. The effect of increasing gold concentration on x_{dmax} is shown in Fig. 8. Here the calculated ratio of x_{dmax} with gold to the corresponding value without gold is shown as a function of normalized gold concentration.

Comparison of Experimental and Theoretical Characteristics

Gold doped MOS capacitors were fabricated in order to compare the calculated C-V characteristics with experiment. n-type units were made using (100) surface oriented silicon wafers doped with 1.0 x 10^{16} phosphorus atoms/cm^3. The wafers were chemically polished to 150μ and oxidized in dry O_2 to form a 0.2μ thick oxide layer. The oxide was then removed from one side; 500Å of gold was deposited on this side and then diffused for 1.5 hr at 1000°C in a nitrogen ambient. Aluminum was then evaporated onto the oxide

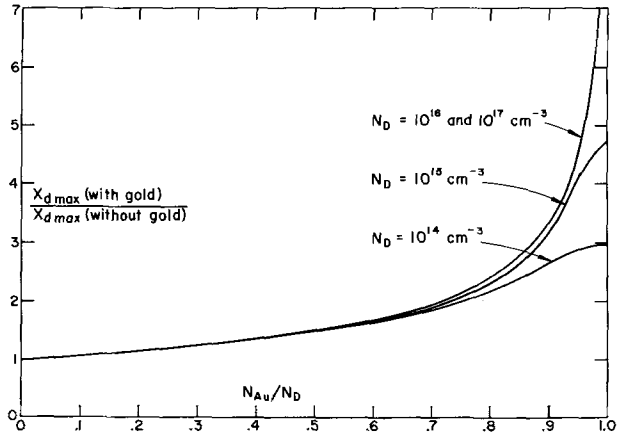

Fig. 8. Theoretical gold concentration N_{Au} (normalized to N_D) as a function of x_{dmax} (normalized to x_{dmax} without gold) for various values of N_D.

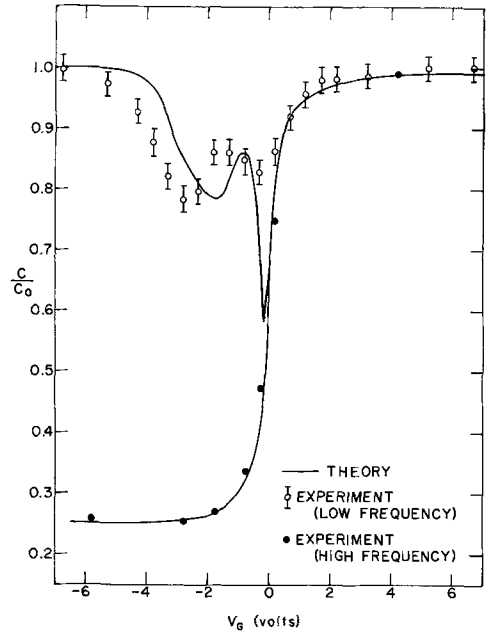

Fig. 9. Comparison between theoretical and experimental MOS C-V characteristics for n-type silicon gold-diffused at 1000°C ($x_o = 0.2\mu$, $N_D = 1 \times 10^{16}$ cm^{-3}, and $N_{Au} = 9.8 \times 10^{15}$ cm^{-3}, low frequency: 73 Hz, high frequency: 100 kHz). Experimental curves are shifted to the left to account for a fixed negative interface charge.

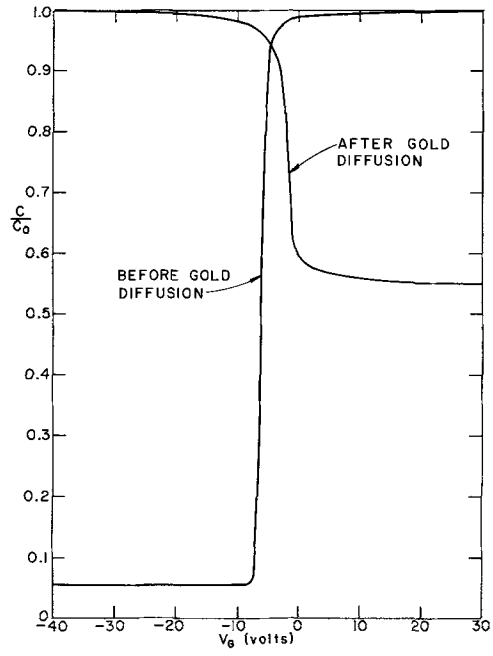

Fig. 10. Experimental C-V characteristic of a lightly doped n-type sample overcompensated with gold (gold diffused 40 min at 1200°C). Also shown is the C-V characteristic on the same sample before gold diffusion.

side and etched to form the field plates of MOS capacitors. Finally, the sample was heat treated at 565°C in nitrogen.[4]

High frequency C-V characteristics (100 kc/sec) were obtained using a Boonton model 74C-S8 capacitance bridge, and low frequency characteristics (73 Hz) were obtained using a Wayne-Kerr model B221 bridge. The transition between high and low frequency type characteristics [see Ref. (5)] was about 100 Hz for these devices. The results for a typical device are shown as the data points in Fig. 9. Reproducibility of both high and low frequency characteristics from device to device was good. The theoretical characteristics (solid lines), to which the experimental points are compared, were chosen so as to match the minimum capacitance of the high frequency measurements. The theoretical curves thus obtained correspond to a gold concentration of 9.8×10^{15} cm^{-3}, a value in good agreement with the solid solubility of gold at the 1000°C diffusion temperature. Agreement between theoretical and experimental curve shapes is excellent in the high frequency case and fairly good in the low frequency case.[5]

The possibility of over-compensation of n-type material with gold was also demonstrated using the MOS technique. For this purpose MOS capacitors were fabricated with starting material phosphorus doped to a concentration of only 10^{13} cm^{-3} and with gold diffusion taking place at 1200°C. Controls were fabricated similarly but without the gold diffusion step. High frequency (100 kHz) capacitance-voltage measurements made on the resulting devices are shown in Fig. 10. Note that the characteristic of the gold-diffused device corresponds to a p-type silicon substrate. Although the silicon substrate is nearly insulating (the Fermi level is a few kT units below the intrinsic level), the minimum-to-maximum capacitance ratio corresponds to a relatively large substrate impurity concentration. As the bands are bent downward (corresponding to a positive voltage on the gate electrode), the gold acceptor level is brought below the Fermi level and hence the gold near the surface becomes negatively charged. Thus, the charge density in the surface space-charge region is equal to the gold concentration which is $\sim 10^{16}$ cm^{-3} in this case.

[4] The above MOS processing was used throughout the course of this work unless otherwise noted.

[5] For this comparison the experimental characteristics were shifted horizontally along the voltage axis by a constant amount ΔV to bring them into alignment with the theoretical curves. The magnitude of ΔV can be used to calculate interface charge densities, as will be described in the next section.

Interface Charge Densities

The surface-state charge density Q_{ss} of oxidized silicon can be evaluated from capacitance-voltage characteristics by comparing an experimental plot of C *vs.* V_G with a theoretical plot of C *vs.* $V_G - \Phi_{MS} + Q_{ss}/C_o$. If Φ_{MS} is known, the displacement between the two curves yields Q_{ss}. For nongold doped silicon, Q_{ss} is normally positive and of the order of several times 10^{11} electronic charges per cm^2, its exact value depending on orientation (8) and on oxidation and annealing conditions (9). In the present study, high frequency capacitance-voltage characteristics were measured on both control and gold diffused samples and were compared with the appropriate theoretical curves. The controls yielded Q_{ss} values in general agreement with those previously reported, but the apparent Q_{ss} of the gold-diffused samples was less positive than that of the controls and in many cases it was actually negative. This indicates the presence of a gold-related effective interface charge in addition to the normal Q_{ss}. We shall refer to the density of this gold related interface charge as Q_{Au}. Thus the displacement ΔV between theoretical and experimental C-V curves is given by $\Delta V = Q_{ss}/C_o - \Phi_{MS}$ for the control samples and by $\Delta V = (Q_{ss} + Q_{Au})/C_o - \Phi_{MS}$ for the gold diffused samples. After back side gold diffusion, Q_{Au} was always negative. Its magnitude increased with diffusion time reaching a steady state value after about 10 min at 1000°C. To assure that this steady state had been reached, standard diffusion times of 1 hr were used for comparing samples processed in various ways. In each case it was demonstrated that Q_{Au} was stable under fields of ± 50 v/μ at 250°C, a condition under which mobile oxide impurities such as sodium migrate rapidly (10).

Effect of doping and conductivity type.—Negative Q_{Au} shifts are observed on both p- and n-type silicon; neither type nor doping seem to have an important

Table I. Values of Q_{ss} and Q_{Au} for a set of n- and p-type samples

Doping	$(Q_{ss} + Q_{Au})$/(gold)	Q_{ss}/q (control)	Q_{Au}/q
5×10^{15} cm^{-3}, n	-3×10^{11} cm^{-2}	2×10^{11} cm^{-2}	-5×10^{11} cm^{-2}
1×10^{17} cm^{-3}, n	-1.5×10^{11} cm^{-2}	2×10^{11} cm^{-2}	-3.5×10^{11} cm^{-2}
1×10^{16} cm^{-3}, p	-3×10^{11} cm^{-2}	3×10^{11} cm^{-2}	-6×10^{11} cm^{-2}

Table II. Values of Q_{ss} and Q_{Au} for (100) and (111) orientations

Orientation	$(Q_{ss} + Q_{Au})/q$ (gold)	Q_{ss}/q (control)	Q_{Au}/q
(100)	-1×10^{11} cm^{-2}	1×10^{11} cm^{-2}	-2×10^{11} cm^{-2}
(111)	-3×10^{11} cm^{-2}	3×10^{11} cm^{-2}	-6×10^{11} cm^{-2}

effect. Values of -5×10^{11} electronic charges/cm^2 are typical for both p- and n-type samples of (111) orientation which have been diffused 1 hr at 1000°C. Values of Q_{ss} and Q_{Au} for a set of n- and p-type samples with 0.2μ oxides and various doping concentrations are shown in Table I.

Effect of orientation.—There appears to be a definite orientation effect on the magnitude of the gold-related interface charge. Values of Q_{ss} and Q_{Au} for (100) and (111) orientations are shown in Table II. All were n-type ($\sim 10^{16}$ cm^{-3}) with 0.2μ oxide and were gold diffused for 1 hr at 1000°C.

Effect of dislocation density.—To determine the effect of dislocation density on Q_{Au}, the following experiment was performed. Three different sets of wafers, one with low dislocation count (<100 cm^{-2}), another with intermediate dislocation count ($\sim$3000 cm^{-2}), and the third with high dislocation density (>10,000 cm^{-2}) were gold diffused 1 hr at 1000°C in N_2. Control samples were fabricated similarly but without the gold diffusion step. In agreement with an earlier study (11) the controls all showed identical Q_{ss}, approximately 2.5×10^{11} cm^{-2} independent of dislocation count. The gold diffused samples all showed negative Q_{Au} of about -6.0×10^{11} cm^{-2}, independent of dislocation density.

Effect of ambient.—To ascertain the effect of the diffusion ambient, Q_{Au} was compared for samples gold diffused at 1000°C in nitrogen and in oxygen. The sample that had been oxygen diffused was subjected to an initial 15 min in nitrogen to ensure that a sufficient quantity of gold entered the silicon before an oxide layer began to form on the back side. Capacitance-voltage measurements revealed Q_{Au}/q values of -5×10^{11}/cm^2 on both samples, suggesting that the negative shift due to gold is independent of the gaseous ambient (inert or oxidizing) in which the gold diffusion takes place.

Physical location of the negative interface charge.—In this section we describe experiments that are aimed at locating the region of the oxide-silicon system that is responsible for the negative Q_{Au} observed after back-side gold diffusion.

In the first of these experiments, gold diffused wafers and controls were split into three groups. Group A received no additional treatment. The existing 2000Å of thermal oxide was etched off group B and 2000Å of SiO_2 was vapor deposited by reacting SiH_4 and O_2 at $\sim$400°C. The deposition time was about 20 sec. In the case of group C, the thermal oxide was etched off and, in addition, the silicon surface was given a light etch to remove $\sim 1\mu$ of silicon. A 2000Å film of SiO_2 was then vapor deposited on these samples also. The average Q_{ss} and Q_{Au} values and the spreads in each group are shown in Table III. Although the Q_{Au} values in this experiment are smaller than typical values, they are clearly evident. Note that approximately the same Q_{Au} is observed on all three groups, indicating that the gold responsible for the shift either is not located within the oxide or it diffuses back into the new oxide during the short heat treatments at 400° and 565°C that occur during processing.

Table III. Average Q_{ss} and Q_{Au} values in gold diffused wafers

Group	$(Q_{ss} + Q_{Au})/q$ (gold)	Q_{ss}/q (control)	Q_{Au}/q
A	$0.9 \pm 0.2 \times 10^{11}$ cm^{-2}	$3.1 \pm 0.5 \times 10^{11}$ cm^{-2}	-2.2×10^{11} cm^{-2}
B	$1.7 \pm 0.3 \times 10^{11}$ cm^{-2}	$3.8 \pm 0.1 \times 10^{11}$ cm^{-2}	-2.1×10^{11} cm^{-2}
C	$1.5 \pm 0.1 \times 10^{11}$ cm^{-2}	$2.9 \pm 0.6 \times 10^{11}$ cm^{-2}	-1.4×10^{11} cm^{-2}

Radiotracer studies have shown that back-side gold diffusion results in a large gold concentration (in excess of the solid solubility in silicon) at the Si-SiO_2 interface (12). Since the observed negative Q_{Au} could be related to this interfacial gold, an experiment was performed in which an attempt was made to introduce gold only at the interface but not in the bulk silicon or in the oxide. Chemically polished n-type ($\sim 10^{16}$ cm^{-3}) silicon wafers were subjected to the following treatment: A thin layer of gold was evaporated onto the top surface and the wafers were heated for 10 min at 565°C in nitrogen. They were then immersed in an aqua regia bath to remove any unalloyed metallic gold from the surface. After this treatment the surface had lost its initially shiny appearance and appeared dull. A 0.2μ film of SiO_2 was then vapor deposited on the surface. C-V measurements revealed very large negative Q_{Au} values for the gold-alloyed samples (from about -1.5×10^{12} cm^{-2} and upward in magnitude), whereas the control sample had a Q_{ss} value of approximately $+8 \times 10^{11}$ cm^{-2}. From the capacitance minimum of the gold-alloyed samples, a bulk doping value was calculated which agreed well with the known initial resistivity of the n-type wafer. This shows that negligible gold was present within most of the depletion region of the MOS devices ($x_{dmax} = 0.3\mu$).

The above two experiments show that the gold responsible for the negative Q_{Au} is at or near the interface. Also, they indicate that the negatively charged gold atoms probably reside in the silicon. If the species causing the negative Q_{Au} is in the silicon, then it should be possible to obtain gold-induced C-V shifts on MOS structures using dielectrics other than SiO_2. For this reason, a third experiment was performed in which gold was diffused for 1 hr at 1000°C into silicon upon which a layer of silicon nitride had been previously deposited in place of the usual thermally grown SiO_2. The silicon nitride was deposited on n-type ($N_D = 5 \times 10^{15}$ cm^{-3}) silicon slices at 900°C utilizing an ammonia and silicon tetrachloride process. Capacitance-voltage measurements on control samples showed large positive Q_{ss}/q values of about 10^{12} cm^{-2}. However, in every case, negative Q_{Au} shifts of about -6×10^{11} cm^{-2} were obtained for the gold-diffused samples. This value of Q_{Au} is very typical of what is observed on oxidized samples for the same gold diffusion temperature and time.

Gold Diffusion through SiO_2

In this section we describe the results of experiments to determine the charge state of gold in SiO_2, and a novel method for determining the diffusivity and solid solubility of gold in the oxide. These experiments were performed as follows: n-type silicon was initially oxidized to form oxide layers 0.1, 0.2, and 0.5μ thick. A single dot of gold approximately 0.75 cm^2 in area was then evaporated onto the oxide. The back side was covered by a thicker oxide to ensure that any gold "breaking through" the oxide and entering the silicon during diffusion had entered through the top oxide layer. The samples were diffused in nitrogen for varying lengths of time at temperatures between 800° and 1100°C.

Q_{Au} shifts.—Positive Q_{Au} shifts were observed after gold diffusion through the oxide, corresponding to the apparent introduction of positive charges into the

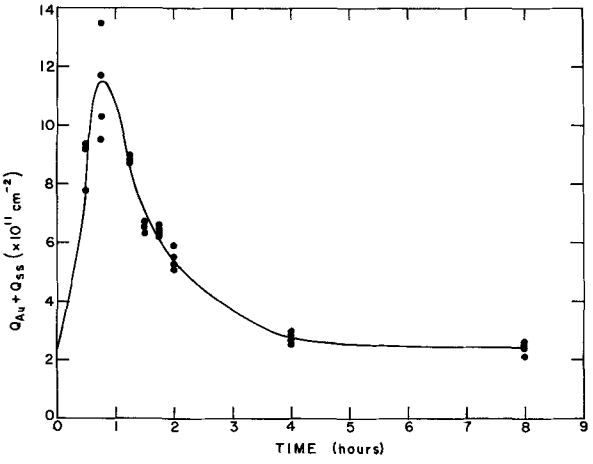

Fig. 11. Total interface charge $Q_{Au} + Q_{ss}$ vs. top side gold diffusion time [(111) surface oriented sample, $N_D = 2 \times 10^{15}$ cm^{-3}, $x_o = 0.2\mu$].

oxide. Temperature-bias tests (10) were used to demonstrate that these positive shifts were stable and were not due to contamination by mobile alkali ions.

The Q_{Au} shift at first increases with diffusion time, reaching a maximum value of about 10^{12} electronic charges/cm^2. It then decreases with longer diffusion time and approaches zero. An example of the time dependence is shown in Fig. 11 for the case of diffusion at 1000°C. That this type of behavior is due to evaporation of the gold from the wafer is considered unlikely, since a layer of gold remained atop the oxide surface after all high temperature treatments.

In an effort to determine the charge distribution in the oxide, the excess charge induced in the silicon due to gold (Q_s') was measured as a function of oxide thickness as the oxide was etched away in steps [see ref. (9)]. After each etching step, C-V curves were measured using a mercury probe as the metal electrode. The excess charge per unit area induced in the silicon Q_s' was determined from the relation

$$Q_s' = \Delta V \cdot C_o \qquad [19]$$

where ΔV is the voltage shift between the C-V characteristics of the gold-diffused and nongold-diffused devices and C_o is the oxide capacitance per unit area. Samples of 0.5μ oxide thickness, diffused varying lengths of time, were etched to as thin as 0.15μ, and 0.2μ samples were etched to about 0.12μ. No decrease in Q_s' was observed. This indicates that most of the positive charge Q_{Au} is located within 500Å of the interface and is not distributed throughout the oxide.

Diffusion coefficient of gold in SiO_2.—In addition to the positive Q_{Au} shifts, it was observed that after a sufficiently long diffusion time the capacitance minimum decreased over the entire gold-covered area. This is interpreted as being due to gold which had diffused through the oxide into the silicon so as to compensate the original n-type doping. C-V characteristics or oxides gold-diffused at 1000°C in a nitrogen ambient for 2 and 4 hr, respectively, are shown in Fig. 12(a) and (b)

The diffusion of gold through a film of SiO_2 is analogous to the permeation of a gas through a membrane. The solution to the latter problem is available in the literature (13). If the diffusivity of gold in the silicon is much larger than in the oxide (an assumption which we shall verify) and the gold concentration in the silicon remains smaller than the solid solubility limit, it can be shown that the concentration of gold in the silicon (N_{Au}) as a function of time is given by

$$N_{Au} = \frac{D_o N_o t}{W x_o} + \frac{2N_o x_o}{\pi^2 W} \sum_1^\infty \frac{(-1)^n}{n^2} \left[1 - \exp\left[-\left(\frac{n\pi}{x_o}\right)^2 D_o t\right]\right] \qquad [20]$$

In this expression D_o is the diffusivity of gold in the oxide, N_o is the gold concentration at the outer surface of the oxide (presumed equal to the solid solubility), x_o is the oxide thickness, and W is the silicon wafer thickness. For times sufficiently large, this expression reduces to (13)

$$N_{Au} \cong \frac{D_o N_o t}{W x_o} - \frac{N_o x_o}{6W} \qquad [21]$$

Equation [21] can be rearranged and put in the form

$$\frac{x_o^2}{6t^*} = \frac{D_o}{(1 + 6N_{Au}^* W/N_o x_o)} \qquad [22]$$

where t^* represents the time required for the gold concentration in the silicon to reach its minimum detectable value ($N_{Au}^* \sim 10^{14}$ cm^{-3} in our experiment). If $N_o x_o >> 6N_{Au}^* W$, then $x_o^2/6t^*$ will be independent of x_o and just equal to D_o.

In Fig. 13, measured values of $x_o^2/6t^*$ for various oxide thicknesses are shown (all samples diffused at

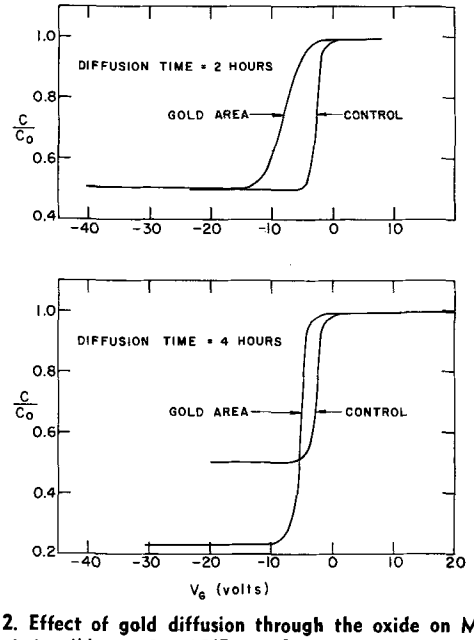

Fig. 12. Effect of gold diffusion through the oxide on MOS C-V characteristics ($N_D = 2 \times 10^{15}$ cm^{-3}, $x_o = 0.2\mu$, diffusion temperature = 1000°C). Breakthrough occurs between 2 and 4 hr as is evident from the change in capacitance minimum.

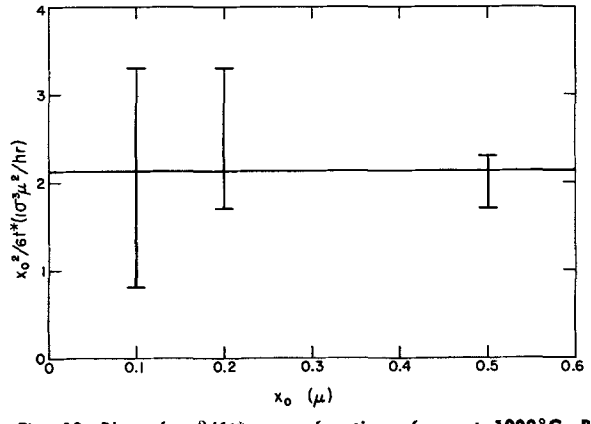

Fig. 13. Plot of $x_o^2/6t^*$ as a function of x_o at 1000°C. Best fit appears to be a horizontal line (independent of x_o) corresponding to a diffusivity $D_o \simeq 2 \times 10^{-3}$ μ^2/hr.

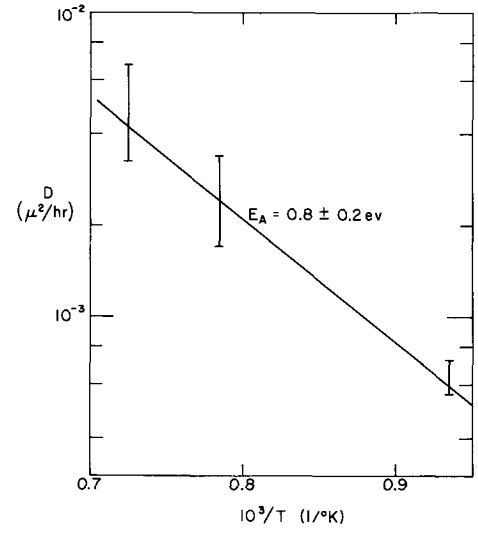

Fig. 14. Gold diffusivity in SiO_2 as a function of temperature

1000°C). The best line fit through the data appears to be horizontal, corresponding to a diffusivity $D_o \cong 2 \times 10^{-3}$ μ^2/hr and placing a lower bound on the solid solubility of gold in SiO_2 of about $N_o \gtrsim 10^{18}$ cm^{-3} at this temperature.

Data on gold diffusivities at 800° and 1100°C were also determined for 0.1μ oxide films, using the expression $D_o \cong x_o^2/6t^*$. These data are plotted in Fig. 14 as a function of reciprocal temperature. An activation energy of 0.8 ± 0.2 ev is indicated.

From Eq. [21] it can be seen that a plot of N_{Au} *vs.* diffusion time should be a straight line with intercept on the N_{Au} axis proportional to N_o and slope proportional to both N_o and D_o. Thus by plotting the gold concentration as a function of time after the breakthrough time t^*, it is possible to determine the gold solubility N_o and the diffusivity D_o independently. Such a plot is shown in Fig. 15 for the case of gold diffusion at 1100°C. In this case the oxide thickness was 0.1μ and the silicon wafer thickness was 150μ. The best straight line through the data points indicates a solubility of $N_o \simeq 3 \times 10^{18}$ cm^{-3} and a diffusivity $D_o \simeq 3 \times 10^{-3}$ μ^2/hr.

Collins, Schroder, and Sah (14) have inferred diffusivity values for gold in Si and SiO_2 from their measurements of the dependence of Q_{Au} on gold diffusion time. Their analysis was based on several assumptions including the supposition that the gold in the oxide is negatively charged. Since this is in conflict with the present findings, it is not surprising that their results ($D_o = 4.8 \times 10^{-4}$ μ^2/hr at 1100°C and $E_a = 2.14$ ev) are in substantial disagreement with ours.

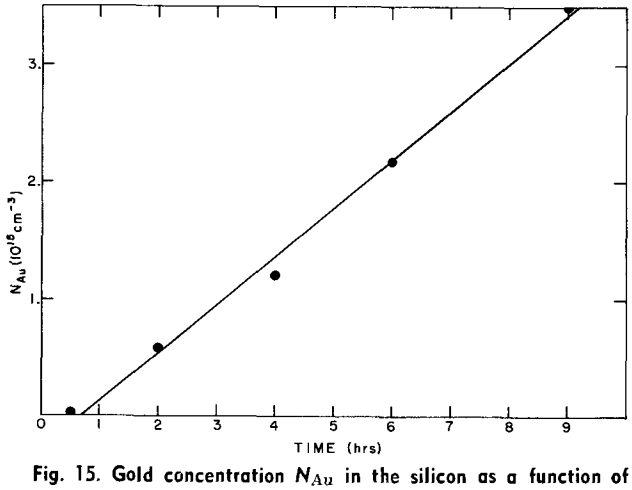

Fig. 15. Gold concentration N_{Au} in the silicon as a function of total diffusion time through the oxide ($x_o = 0.1\mu$, $T = 1100$°C). These data indicate a diffusivity $D_o \simeq 3 \times 10^{-3}$ μ^2/hr and a gold solubility in the oxide $N_o \simeq 3 \times 10^{18}$ cm^{-3}.

Conclusions

The theory of the MOS capacitance-voltage method has been extended to the case of gold-doped silicon and has been verified experimentally. Using this method, it was shown that back-side gold diffusion into an oxidized silicon wafer causes an apparent negative shift in the interface charge density. A series of special experiments indicated that this negative charge is localized in the silicon very near the oxide-silicon interface.

Why such interfacial gold should have a fixed negative charge is not understood. It is known that substitutional gold in the silicon bulk gives rise only to the pair of deep levels discussed previously (4). However, it has also been reported that gold piles up at the oxide-silicon interface reaching concentrations far in excess of the solid solubility (12). One can speculate that this excess interfacial gold has energy levels quite different from those of the bulk substitutional gold. A high concentration of shallow acceptor levels localized at the interface could account for the observed results.

Gold diffused into an MOS structure from the top side through the oxide gives a positive contribution to the interface charge density indicating that gold in the oxide near the interface may be positively charged as is sodium (10). However, it is immobile at temperatures ~250°C at which sodium drifts rapidly under an applied field.

Finally, the MOS method has been used to measure the diffusion coefficient and solid solubility of gold in SiO_2. This method should be applicable to many other impurities. It is as sensitive as the p-n junction method which has been used for phosphorus (15), boron (16), and gallium (17) and it has the additional advantage that it can be used with impurities such as gold which do not form p-n junctions in silicon, but merely compensate the initial doping.

Acknowledgments

The authors wish to thank K. M. Cooper for his assistance with the measurements and A. S. Grove for many stimulating and helpful discussions throughout the course of the work.

Chemistry and Electrical Properties of the Interface Between ZnSe and an Electrolyte

Richard Williams

RCA Laboratories, Princeton, New Jersey

ABSTRACT

The interface between n-type ZnSe and electrolyte solutions has been investigated. A summary discussion of the properties of a Schottky barrier under these conditions has been given with reference to the experiments which are reported here. For the interface, ZnSe: 1.0M HCl, barrier height is from 2.0 to 2.6 ev for different crystals. These results are obtained from capacitance measurements and compared with photovoltage measurements. Current-voltage curves for forward and reverse bias are shown. For forward bias the current-voltage curve for the hydrogen evolution reaction has been measured. Results emphasize the difficulty of distinguishing between cases where the current is controlled by the properties of the Schottky barrier and those where it is controlled by the electrochemical kinetics. With high electric fields there is electron multiplication in the ZnSe. An efficient photochemical decomposition of the ZnSe is observed in which the net reaction is to deposit free selenium on the surface of the crystal and to liberate Zn^{++} ions into the solution.

The interface between a semiconductor and an electrolyte combines the behavior of electrochemical and semiconductor systems. The special features of such an interface are emphasized when the semiconductor has a high band gap. With high band gap materials electrolyte contacts have provided a unique tool for studying surface properties and obtaining high electric fields in the semiconductor (1-7). In addition, study of the photochemical decomposition of binary compounds in contact with an electrolyte (8) shows an important link between structure, charge transport, and chemical reaction. In this article a summary discussion is given of the semiconductor-electrolyte interface for high band gap materials. Emphasis is on physical concepts rather than detailed theory and equations are given which are applicable to the experimental results of this study. Use is made of the simple diode rectifier theory which has been applied to metal-semiconductor contacts (9). Experimental results are reported which give a survey of the general properties of the interface between ZnSe and an electrolyte.

Semiconductor-Electrolyte Interface

Reviews of the semiconductor-electrolyte interface have been given by Dewald (10), Green (11), and Gerischer (12). In general there is separation of charges at equilibrium and corresponding potential differences develop in both semiconductor and electrolyte. For high band gap materials it is common for a Schottky barrier to form in the semiconductor, within which there is a space charge of ionized donor or acceptor ions. If the band gap is 2 ev or more, minority carriers are present in concentrations too small to be significant through most of this barrier region. The thickness of the barrier region is typically around 1μ. By way of contrast the Helmholtz layer, the corresponding region in the electrolyte in which charge separation and space charge are important, has a thickness of several angstroms. Hence the capacitance of these two regions in series is effectively the capacitance of the Schottky barrier alone. Measurement of the small signal a-c capacitance of the barrier as a function of d-c bias voltage gives information about bending of the bands in the semiconductor at the interface. An ideal Schottky barrier for an n-type semiconductor is one in which the donors are completely ionized and uniformly distributed, and in which the minority carrier concentration is small compared to the donor concentration. For this system the relation (9) between the carrier capacitance, C, the ionized donor concentration, N, the dielectric constant, ϵ, the diffusion voltage, V_d, and the applied voltage, V, is

$$\frac{1}{C^2} = \frac{8\pi(V_d + V)}{\epsilon e N} \qquad [1]$$

This can be put into practical units, using the value (13) of 9.1 for the dielectric constant of ZnSe. Equation [1] becomes

$$\frac{1}{C^2} = 1.9 \times 10^7 (V_d + V)/N \qquad [2]$$

Here C is in pF/cm^2, N in cm^{-3}, V and V_d in volts. The sign convention used is that V has positive values for reverse bias and negative values for forward bias. Measurements of C as a function of V can be plotted to give a straight line. The slope of the line gives N and the intercept with the horizontal axis gives V_d.

An alternative formulation of Eq. [2] has been given (14) which takes account of the reserve region at the inner edge of the barrier where ionization is incomplete. This gives a correction of kT/e or 0.026 ev at room temperature to the voltage sum in [2]. This has not been used in the present work but can easily be used wherever the barrier is low or the accuracy of the measurements warrants. It will be emphasized in what follows that, for the electrolyte-semiconductor system, capacitance measurements can give values for V_d which include a contribution from two electrolyte half-cells in series with the barrier. When this is the case, as it is in this work, the capacitance measurements give a value of V_d which is not a fundamental property of the semiconductor. In this it differs fundamentally from the metal-semiconductor system.

The relation between current and applied voltage may be determined by the transport of electrons to or from the surface or, alternatively, by the electrochemical reaction which is going on. Since charge transport in the semiconductor is entirely electronic and that in the electrolyte is entirely ionic there must be a change in the mechanism of transport at the interface. Whether transport to the interface or the reaction at the interface is slower depends on the details of the reaction and the supply of carriers. It is conceivable that, for a given system, charge transport is dominant at one current density and electrochemical reaction at a different current density. For a Schottky barrier, transport of carriers to the surface is most simply described by the diode rectifier theory. This is oversimplified for many systems but its simplicity commends it for describing the general properties which are the subject of this article. A band picture diagram for a Schottky barrier at the interface between an n-type semiconductor and a high work function metal is shown in Fig. 1. At equilibrium, equal and opposite exchange currents, j_o, flow over the barrier between metal and semiconductor. These are thermionic emission currents due to electrons having energies equal to or greater than the barrier energy, $\Delta\phi$, above the Fermi level. The magnitude of j_o is related (9, 15) to the effective mass, m^*, electron charge, e, absolute temperature, T, Boltzmann constant, k, and Planck's constant, h.

$$j_o = \left(\frac{4\pi m^* ek^2T^2}{h^3} \right) e^{-\Delta\phi/kT} \qquad [3]$$

In practical units, for room temperature, this becomes

$$j_o = 1.0 \times 10^7 \ (m^*/m) \times 10^{-17\Delta\phi} \text{ amp/cm}^2 \qquad [4]$$

$\Delta\phi$ is in ev.

For the current-voltage relation the diode theory gives

$$j = j_o \ (1 - e^{-eV/kt}) \qquad [5]$$

This has been put into a form which is consistent with the convention introduced. Reverse bias voltages are taken as positive. This governs the transport of electrons to and from the surface. For reverse bias when the barrier voltage is more than a few times kT/e (26 mv at room temperature) the current is equal to j_o, independent of voltage. For forward bias voltages greater than several times kT/e, j becomes

$$j = j_o \, e^{-eV/kT} = j_o \times 10^{17 \ {}^{V}f} \text{ amp/cm}^2 \qquad [6]$$

Here the last expression is in practical units for room temperature; ${}^{V}f$ is the absolute magnitude of the forward bias voltage. The minus sign has been dropped for simplicity. It is often found in practice that the exponential relation of Eq. [6] is obeyed but the factor multiplying the voltage is not 17. The equation in this case is commonly written as

$$j = j_o \times 10^{17 \ {}^{V}f/\beta} \qquad [7]$$

β is independent of voltage and is usually between 1 and 2. Typical experimental values are given in ref. (15).

Equations [6] and [7] are valid as long as the current flow across the interface is limited by the transport of carriers up to the interface. In the metal-semiconductor system the density of unoccupied electron states in the metal is comparable to that in the semiconductor at the same energy and does not limit transport of electrons across the interface. Replacing the metal by an aqueous solution may provide a smaller density of states. This would limit transport and may be a factor in the current-voltage curve for forward bias which departs appreciably from Eq. [6].

As long as the electrochemical reaction is using up electrons as fast as they arrive at the surface then Eq. [6] will give the current-voltage relation, subject to a possible restriction by the density of states. This means that the potential across the Helmholtz layer

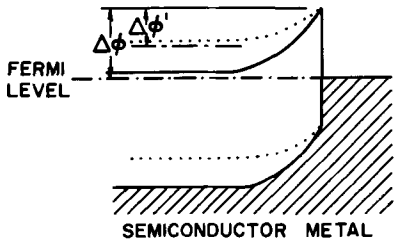

Fig. 1. Energy band diagram for the interface between a metal and an n-type semiconductor with high band gap. Solid lines indicate the energy band edges in the dark with no applied voltage. The dotted lines show the band edges under illumination with a high resistance external circuit.

does not depart significantly from its open circuit value for which there is no current flow. Under these conditions there is no significant departure from equilibrium of the concentrations of any charged species on the surface. If the discharge of such species becomes the rate limiting step then the rate of their arrival at the surface determines the current and the voltage dependence of this rate determines the current-voltage curve.

A specific example of such a process is the transfer of a surface electron, e_s, to an adsorbed hydrogen ion, $H^+(s)$.

$$e_s + H^+(s) \rightarrow H(s)$$

This would give a current-voltage relation determined by the rate of formation of $H^+(s)$. The Tafel equation (16) is appropriate for an electrode reaction under these conditions. In a clearcut case it may be possible to infer from the experimental current-voltage relation whether it is transport of electrons to the surface or reaction at the surface which determines the current. The Tafel equation has the form

$$j = j_o \, e^{e\alpha\eta/kT} = j_o \times 10^{17\alpha\eta} \qquad [8]$$

Here η is the overpotential, *i.e.*, the departure of the potential drop in the electrolyte from the equilibrium potential drop, and α is the fraction of the overpotential which assists the forward reaction. The proper experimental determination of α and η is complicated for a semiconductor system and will not be taken up here. We wish to note here only the similarity between Eq. [7] and [8] and to emphasize the difficulty in assigning unique values to the constants involved from the analysis of experimental current-voltage data.

A useful tool for determining properties of a Schottky barrier is the photovoltaic effect. Consider the band picture diagram of Fig. 1. The metal-semiconductor interface is illuminated with light which is absorbed near the interface, producing hole-electron pairs. The barrier field separates the pairs drawing the holes into the metal and the electrons through the barrier in the opposite direction. If the diode is short circuited there is a current, $j(I)$ which is proportional to the light intensity, I. The number of electrons flowing per unit time is equal to the number of photons absorbed per unit time, providing the quantum yield for creation of hole-electron pairs is unity. If the diode is operating under open circuit conditions the electrons which flow to the left and the holes which flow to the right do not recombine through the external circuit. Instead the separated charges create a field that opposes the barrier field. This is equivalent to applying forward bias from an external voltage supply. As a result there is a current, j, of electrons from left to right. When equilibrium is reached there is no net flow of charge and

$$j = j(I) \qquad [9]$$

Using Eq. [7] we see that this happens when

$$j_o \times 10^{17 \ {}^{V}f/\beta} = j(I) \qquad [10]$$

Since $j(I)$ is directly proportional to I Eq. [10] gives the logarithmic relation between photovoltage and light intensity which is commonly observed. (The observed photovoltage will be ^{V}f). It is not usually possible to use a light intensity high enough to flatten the bands in the semiconductor. It is possible to estimate the total barrier height without flattening the bands from the following argument. Consider the open circuit photovoltage produced by a light of intensity, I, which gives the value, $j(I)$, for the short circuit current. At open-circuit equilibrium the forward bias current of electrons toward the metal must be equal to the current, $j(I)$, of electrons away from the metal. This is just the thermionic emission current over that part of the barrier, $\Delta\phi'$, which still remains at the given level of illumination. This is the j_0 of Eq. [4] for a barrier equal to $\Delta\phi'$. If a photovoltage, V_{ph}, is measured for a light intensity given a short circuit current, $j(I)$, then $\Delta\phi'$ is obtained by equating the right side of Eq. [4] to $j(I)$. The total barrier in the diode at equilibrium in the dark is then $(V_{ph} + \Delta\phi'.)$ Similar considerations hold for the Schottky barrier in a semiconductor in contact with an electrolyte. This method will be used here for estimating the total barrier height, as a check on the barrier height determined from capacitance measurements. This assumes that the photovoltage is a semiconductor property and not an electrochemical property. The chemical properties of the electrode are not irrelevant, however, They may determine whether a given semiconductor undergoes dissolution in the dark or only under illumination. The foregoing is a summary of basic relations for the simplest possible model for the semiconductor electrolyte interface.

Experimental

The crystals of ZnSe used were grown by Fischer and DeMeis in this laboratory, using a vapor growth technique (17). To obtain n-type conductivity they were doped after growth with aluminum under excess zinc pressure at 1030°C, followed by quenching. Before use, the crystals were etched in hot concentrated KOH solution to remove about 0.1 mm of the surface. Ohmic contacts of indium were applied by heating in nitrogen atmosphere to 300°C. The final specimens had dimensions of about 5 x 5 x 1 mm. In one specimen the area in contact with the electrolyte contained a twin boundary. The others were single crystal. Crystals were mounted as shown in Fig. 2. A round hole was drilled in the bottom of a small lucite box and the crystal cemented over this polystyrene cement. The working electrode in the electrolyte was a sheet of platinum with a geometric area of 2 cm² which had been sandblasted to increase its effective surface area. Preliminary experiments with two such platinum electrodes in 1.0M HCl solution showed that there is no significant cathodic polarization up to currents of 10^{-4} amp and no significant anodic polarization up to currents of 10^{-6} amp. For all experiments shown except that in Fig. 7 the working platinum electrode is not polarized and the voltages shown are the externally applied voltages. This gives potentials at the ZnSe electrode relative to the potential in the dark with no externally applied voltage. For the data of Fig. 7 a saturated calomel reference electrode was used to obtain potential differences.

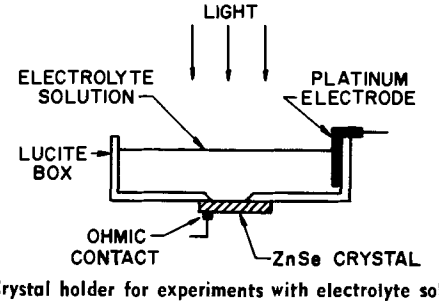

Fig. 2. Crystal holder for experiments with electrolyte solutions.

The potential difference between the ohmic contact on the ZnSe and the calomel reference electrode was measured as a function of current using a Keithley 610B electrometer. The platinum still served as a working electrode. Potentials were plotted relative to that with no externally applied voltage, as was done for the other data.

Measurements of the small signal a-c capacitance were made as a function of d-c bias using a Boonton 74D bridge in which the measuring signal has a frequency of 100 kHz. Photovoltage and current measurements were made with a Keithley electrometer.

General Behavior

The general behavior of the system ZnSe-1.0M HCl is that to be expected for a Schottky barrier in an n-type semiconductor, according to the discussion given above. The following observations are consistent with the energy diagram of Fig. 1. There is a high degree of rectification for current flow in the dark. The polarity for easy current flow is with the ZnSe negative. On illumination a photocurrent and photovoltage are generated for which the direction of electron flow is from the surface of the ZnSe crystal toward the interior.

Figure 3 shows current-voltage curves for forward and reverse bias. Reverse bias is with the ZnSe positive. Under illumination there is a saturation current for reverse bias, independent of voltage but proportional to light intensity. This is due to collection of all hole-electron pairs by the barrier field. Similar reverse saturation currents have been reported by Brattain and Garrett (18) for the germanium electrode in KOH solution, by Beck and Gerischer (19) for germanium in various electrolytes and by the author (8) for CdS in KCl solution. For the ZnSe the reverse bias dark current is very small. At 2v, for example, the dark current is 2×10^{-11} amp/cm². For forward bias the magnitude of the current grows rapidly with increasing voltage.

The spectral response data for the back bias saturation current support the idea that the current is due to the collection of free hole-electron pairs by the barrier field. Figure 4 shows the current per incident photon as a function of photon energy for a back bias of 1v. The current is excited almost exclusively by light of energies greater than 2.6 ev. The band gap (20) of ZnSe is 2.6 ev so the exciting light is restricted to energies sufficient to create hole-electron pairs.

Capacitance Measurements

Figure 5 shows capacitance as a function of d-c bias for four crystals, plotted in the form, $1/C^2$ *vs.* V, suggested by Eq. [2]. The intercept, on the voltage axis, of the extrapolated straight line gives an experimental value of V_d. These vary over a range of more than 1v. Values for N, the ionized donor concentra-

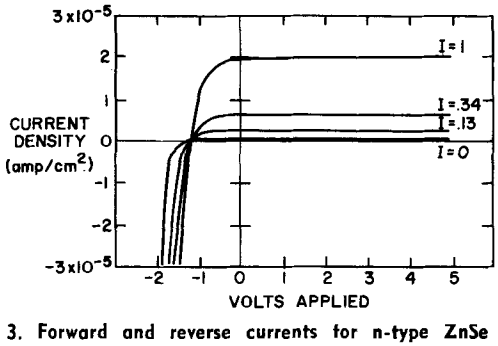

Fig. 3. Forward and reverse currents for n-type ZnSe crystal in 1.0M HCl solution. The relative light intensity is indicated for each curve. As an example of the magnitude of the reverse dark current, the current at 2v in the dark is 2×10^{-11} amp/cm². Positive values of voltage mean that the positive terminal of the external voltage source goes to the ZnSe crystal.

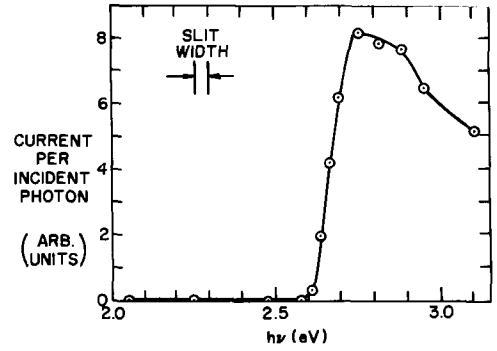

Fig. 4. Spectral response of the saturation photocurrent: 1v reverse bias. The band gap for ZnSe is 2.6 ev.

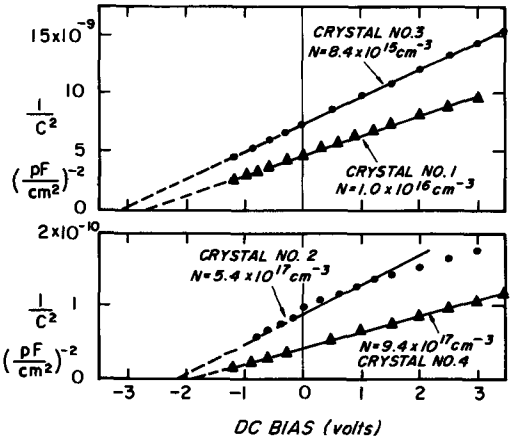

Fig. 5. $1/C^2$ vs. d-c bias voltage for four different crystals. Note that the voltage scale is the same for both parts of the figure.

tions, obtained from the slopes of the lines, are shown for each crystal. V_d decreases monotonically as N increases. For crystals 1 and 3, V_d is larger than the band gap of ZnSe. This never happens at a metal-semiconductor interface but can take place at a semiconductor-electrolyte interface under certain conditions which seem to be fulfilled here. There must be an electrochemical reaction at the semiconductor-electrolyte interface and the dark resistance of the barrier must be very high. The half-cell formed at the semiconductor-electrolyte interface can act together with the half cell at the platinum electrode as a battery in series with the ZnSe crystal. The dark current through the ZnSe barrier at low applied voltages is of order 10^{-11} amp/cm^2 so that a very slow electrode reaction is sufficient to build up a charge on the surface faster than it can leak through the barrier. Since, under these conditions the barrier region is acting as a capacitor, the charge builds up a voltage. This is equivalent to putting a battery in series with a metal-semiconductor Schottky barrier. Thus we may anticipate that, for a semiconductor-electrolyte interface, the band bending under short-circuit conditions may exceed the band gap by as much as 1v or so. An example of an appropriate electrochemical reaction would be the reaction described below for the photochemical dissolution of ZnSe. This might go fast enough, even in the dark, to maintain a significant potential difference across the Schottky barrier. It is emphasized that the amount of reaction required is very small. To maintain a potential difference in this way across a barrier in which the leakage current is 10^{-11} amp/cm^2 requires the dissolution of about one monolayer of the surface per month. To summarize the capacitance results, apparently the barrier height under short circuit conditions depends significantly on both an electrochemical cell of which the crystal forms one half-cell and all the normal

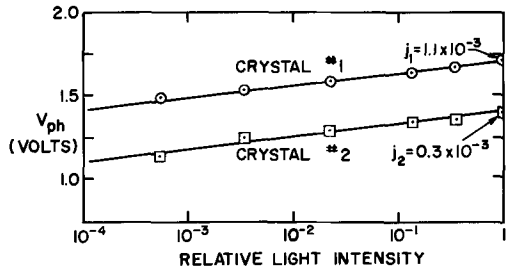

Fig. 6. Open circuit photovoltage as a function of relative light intensity for two crystals with 1.0M HCl solution. Short circuit current is indicated for the highest light intensity in each case. Note that the vertical scale does not begin at zero.

semiconductor interface properties which ordinarily determine the barrier height in nonelectrolyte systems.

Photovoltaic Effect

Analysis of photovoltage and photocurrent measurements confirms that barriers are high but the barrier heights obtained in this way are not as high as those obtained with capacitance measurements. The difference, apparently, is that photovoltage measurements are made under open circuit conditions as opposed to the closed circuit conditions used for capacitance measurements. The battery effect described in the preceding section is not operating here. A battery in series with a Schottky barrier does not establish any potential difference across the barrier if there is an open circuit. For this reason the barrier heights estimated by the photovoltage method do not exceed the band gap of the ZnSe. Figure 6 shows typical photovoltage data for two of the crystals used to obtain Fig. 5. The data give straight lines on a logarithmic plot and the slope in each case is 78 mv/decade. This gives a value of 1.3 for β in Eq. [7]. The short-circuit currents for the highest light intensity were used to estimate the remaining barrier height, $\Delta\phi'$, at this light intensity. This is added to the photovoltage at this light intensity to obtain the total equilibrium barrier height for open-circuit conditions. This is compared with the barrier heights for the capacitance measurements in Table I. The consistently higher values obtained from capacitance data are apparently a result of the battery effect.

Forward I-V Curve and Hydrogen Evolution

Due to the limited number of crystals available the electrochemical data are necessarily of a preliminary nature. The current-voltage relation has been measured over 8 orders of magnitude in current for ZnSe in 1.0M HCl. At the higher current densities, the electrode reaction is clearly hydrogen evolution. The similarity between the Tafel equation, [8], describing electrochemical reaction, and the diode rectifier equation, [7], describing charge transport in a Schottky barrier has been pointed out. The difficulty of determining which of these equations is appropriate may be seen by examining the data of Fig. 7. Here V is the potential of the ohmic contact of the ZnSe relative to its potential when the cell is short circuited

Table I. Crystal measurements and concentration

Crystal No.	$\Delta\phi$ (ev) capacitance measurements*	$\Delta\phi$ (ev) photovoltaic measurements	N (cm^{-3}) ionized donor concentration
3	3.1	2.2	8.4×10^{15}
1	2.7	2.3	1.0×10^{16}
2	2.2	2.0	5.4×10^{17}
4	1.9	2.2	9.4×10^{17}

* This is the energy difference between the conduction band edge in the interior of the crystal and that at the surface. This differs from $\Delta\phi$ defined in Fig. 1 by the difference between the Fermi level and the conduction band edge in the interior of the crystal which is of order 0.1 ev.

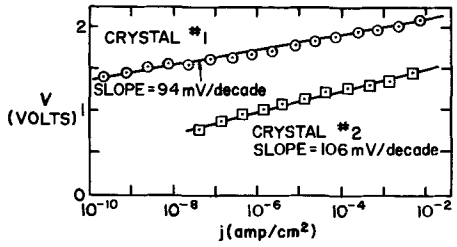

Fig. 7. Dark current for forward bias for ZnSe in 1.0M HCl on a logarithmic plot.

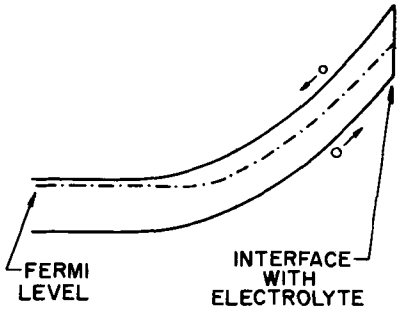

Fig. 8. Band diagram for Schottky barrier and electrolyte contact with high reverse bias. The variation of the Fermi level from the interior of the crystal, which is field free, to the interface is shown. The Fermi level in the barrier region is determined by thermally generated hole-electron pairs.

(*i.e.*, zero applied voltage). The corresponding dark current densities for cathodic bias fall on a straight line on the logarithmic plot. The data fall on two separate lines. These are separated on the voltage axis by 0.6 to 0.7v. This is comparable to the difference in barrier heights in going from one crystal to another. However, the slopes are different from those obtained by the photovoltage technique. This fact suggests that the slopes in Fig. 7 may be determined by electrochemical considerations and that these are Tafel plots. It is also possible that the current is actually limited by transport in the Schottky barrier, though neither case is proven at this point. We stress that in a system of this kind additional evidence other than current-voltage data is probably necessary to analyze the electrochemical reaction.

High Electric Fields and Electron Multiplication

At high reverse bias the region of the semiconductor including the Schottky barrier becomes a layer of insulating material. To the extent that no electrons are injected from the electrolyte (perfect blocking contact) the only carriers in the barrier region are those thermally generated. This means that electrons and holes are present in equal numbers and the Fermi level is in the middle of the forbidden gap.[1] This is illustrated in the band diagrams of Fig. 8. Hence, by application of modest voltages it is possible to obtain very high fields in the barrier region. Quantitatively the field may be obtained from the capacitance as follows. The capacitance, C, in pF/cm^2 is related to d, the thickness of the barrier in centimeters, by the equation

$$C = 1.1\ (\epsilon/4\pi d) \qquad [9]$$

$$Cv = 1.1\left(\frac{\epsilon}{4\pi}\right)\left(\frac{V}{d}\right) \qquad [10]$$

$$v = V + V_d = E_{av}\, d \qquad [11]$$

E_{av} is the average field in the barrier since it is the total voltage drop across the barrier divided by the total thickness. In a Schottky barrier the field is a linear function of distance increasing from zero at the inner face of the barrier to a maximum value, E_{sur}, at the surface next to the electrolyte. $E_{sur} = 2E_{av}$. Hence

$$E_{sur} = 2.5\ Cv \qquad [12]$$

The value of the dielectric constant for ZnSe has been put into Eq. [12].

[1] This idea about the location of the Fermi level was suggested during conversation by A. Rose.

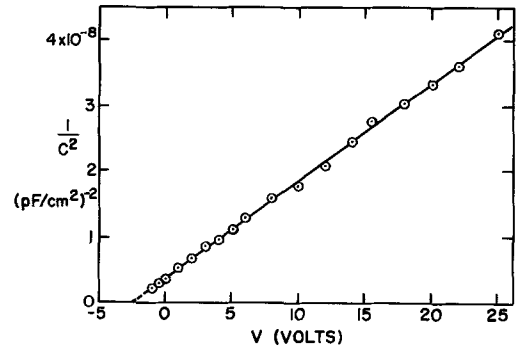

Fig. 9. Capacitance-voltage plot for voltages up to that where there is dielectric breakdown, crystal No. 1.

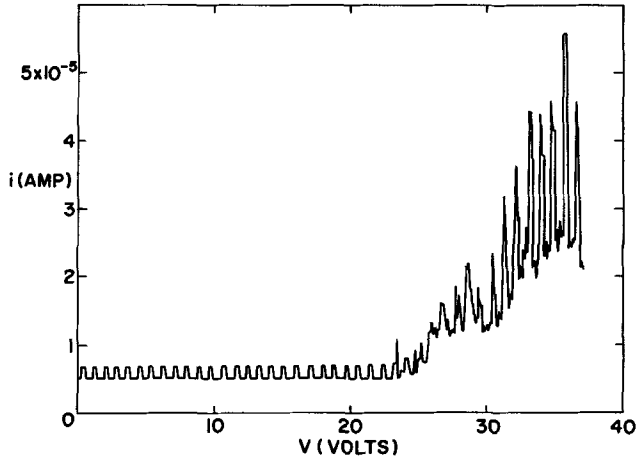

Fig. 10. Recorder tracing showing a long region of saturated photocurrent followed by multiplication of the carriers which are injected by the light. Intermittent light is obtained with a 1 cps chopper. Voltage is increased smoothly with a motor driven Helipot potentiometer. Multiplication of about 15 is seen at the highest voltage. The light was strongly absorbed blue light obtained from a W lamp and Corning 5-58 filter. Note that the current zero is displaced from the horizontal axis so that it may be seen clearly.

A plot of $1/C^2$ *vs.* V up to high reverse bias is shown in Fig. 9 for crystal 1. It is seen that the Schottky relation is maintained over a wide range of voltage. The voltage is indicated where E_{sur} becomes equal to 1 x 10^5 v/cm. At higher fields there is electron multiplication in the barrier due to impact ionization. This is shown by the recorder tracing of Fig. 10. Here a back biased ZnSe crystal is illuminated with strongly absorbed light, made intermittent by interposing a 1 Hz mechanical chopper between light source and crystal. The photocurrent and dark current are displayed alternately on the vertical channel of a pen recorder. At the same time the applied voltage is increased steadily by a motor driven potentiometer and this voltage drives the horizontal channel of the recorder. Thus at low voltages the photocurrent has a constant magnitude, independent of voltage. After a long range of constant photocurrent there is a noisy but steeply increasing photocurrent beyond about 23v. This shows that the carriers injected by the light are being multiplied by impact ionization in the high field of the barrier. From the capacitance data it is inferred that impact ionization begins when E_{sur} reaches 2.5 x 10^5 v/cm. This experiment provides direct support for the mechanism advanced by Fischer (21-23) for electroluminescence in ZnSe. This mech-

anism is based on the creation of hole-electron pairs by impact ionization of free carriers in a high electric field with subsequent recombination through luminescent centers.

It is interesting to note that attempts to observe electron multiplication in CdS by this technique have given negative results and it has been concluded that the ultimate dielectric breakdown in CdS is due Zener tunneling of electrons from valence band to conduction band (24). The band gap and electron mobility for CdS (2.5 ev and 300 cm^2/v-sec) are remarkably similar to those for ZnSe (2.6 ev and 260 cm^2/v-sec). Hence the difference in high field behavior must reflect some more subtle aspect of electron transport.

Photochemical Dissolution of ZnSe

The photochemical dissolution of ZnSe follows an interesting pattern which has been found earlier for CdS. In the cell shown in Fig. 2, short circuited, behavior in light and dark were compared. In the dark, in contact with an inert solution such as 0.1M KCl, ZnSe does not undergo any visible reaction even after standing for days. It does not appear to be attacked even by concentrated HCl at room temperature. In light there is a rapid photochemical reaction. After several minutes of illumination by a tungsten microscope lamp the surface is noticeably changed. After about half an hour of illumination there is a layer of a deep red solid on the surface of the crystal. This solid is readily soluble in CS_2. From this (25) it is concluded that the red material is elemental selenium, probably amorphous. At the same time that selenium is depositing on the surface, zinc ions are going into solution. A ZnSe crystal was mounted in contact with 0.1M KCl acidified with a drop of HCl solution to avoid possible precipitation of Zn^{++}. The solution was allowed to stand in contact with the crystal for 1 hr in the dark. There was no visible decomposition of the crystal. The solution was removed and replaced by another solution. This was allowed to stand for 1 hr in contact with the crystal under illumination. The light intensity was not high enough to raise the temperature of the crystal significantly above room temperature. The photovoltaic current was measured as a function of time. The total charge flowing during 1 hr was 1.5×10^{-2} coulomb. After this time the characteristic deposit of selenium was on the surface of the crystal. The solution was removed and, both this and the above solution analyzed by emission spectroscopy for zinc. In the solution which stood in the dark the zinc content was less than the limit of detectability which was 0.5 μg. In the solution which stood in the light the zinc content was (4.0 ± 1.2) μg. If one zinc ion requires two electrons then 1.5×10^{-2} coulombs should give 4.9 μg zinc in the solution. Thus, within the limits of error of the analysis, the photovoltaic current is accompanied by the dissolution of one zinc ion for every two electrons which flow in the external circuit. Rough estimates of the amount of selenium deposited are consistent with the interpretation that to within an order of magnitude, one selenium is deposited for each two electrons flowing in the external circuit.

This reaction is similar to the photochemical decomposition of CdS under similar circumstances. The mechanism can be understood from Fig. 11. Here the band structure is shown. For ionic crystals such as alkali halides the conduction band can be identified with the positive ions and the valence band with the negative ions (26). This is less true for materials such as ZnSe which are not strongly ionic but appears to retain some validity as a qualitative guide (8). A possible mode of dissolution of such a crystal is the unsymmetric one in which a zinc ion goes into solution as Zn^{++}, leaving a negatively charged $Se^{=}$ attached to the crystal. The resulting separation of charge prevents any appreciable amount of dissolution unless the excess negative charge on the selenium ions can be transported out of the crystal and through the external circuit. For an n-type semiconductor this provides difficulties because the charge is at an energy near that of the valence band and can be transported out of the crystal only through the conduction band, which lies 2.6 ev higher in energy. Thermal excitation is too slow to support significant reaction at room temperature. Optical excitation greatly speeds up reaction by providing hole-electron pairs. The holes come to the surface and neutralize the excess charge on the $Se^{=}$ and the electrons leave through the external circuit. In this way the excess charge is removed and further reaction can take place. According to this mechanism the passage of two electrons through the external circuit should be accompanied by the deposition of one selenium atom on the surface and the passage of one Zn^{++} into the solution in agreement with the observations. This appears to confirm the connection between semiconductivity type and photochemical reaction which has been suggested earlier (8).

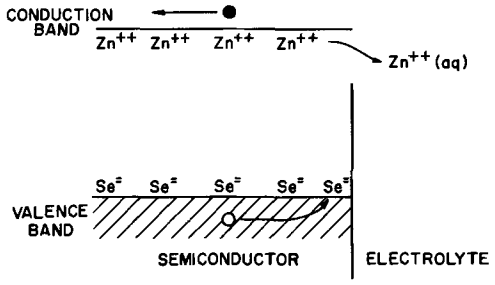

Fig. 11. Illustration of the mechanism suggested to explain the photochemical decomposition of ZnSe in solutions of inert electrolytes such as 0.1M KCl. The conduction band is associated with Zn^{++} ions and the valence band with $Se^{=}$ ions. A Zn goes into solution as Zn^{++} (aq) leaving a negative charge behind on a $Se^{=}$ at the surface. To remove this excess charge from the crystal requires light which produces a hole-electron pair. The hole neutralizes the charge on $Se^{=}$ and the electron goes through the external circuit to complete the electrochemical reaction. For simplicity the Schottky barrier field at the surface has not been indicated in this diagram though it is essential for efficient utilization of hole-electron pairs in this way.

Summary

Several properties of the ZnSe-electrolyte interface have been examined experimentally. Capacitance measurements, which are, of necessity, done under short-circuit conditions, show that the barrier height for these conditions is determined by both the semiconductor properties and by an electrochemical half-cell at the interface. It is possible for the band bending at the interface to be larger than the band gap under short-circuit conditions. Photovoltage measurements, which are ordinarily done under open-circuit conditions, give lower values for the barrier height which are not larger than the band gap. The general features of the current-voltage data for forward and reverse bias can be explained by the diode rectifier model. For the hydrogen evolution reaction there is ambiguity and it cannot be stated with certainty whether the current-voltage relation is determined by electrochemical kinetics or by electron transport to the surface. Multiplication of electrons by impact ionization was observed in high electric fields and provides direct confirmation for the mechanism which has been proposed by Fischer for electroluminescence in ZnSe. There is an efficient photochemical decomposition of ZnSe in contact with an electrolyte. The over-all reaction is

$$ZnSe(s) \xrightarrow{h\nu} Zn^{++}(aq) + Se(s) + 2e$$

Thermodynamic and Transport Properties of Stoichiometric and Nonstoichiometric Nickel Oxide

S. Pizzini and R. Morlotti

Electrochemistry Group, Euratom C.C.R., Ispra, Italy

ABSTRACT

Electrical conductivity and emf measurements on polycrystalline NiO, as functions of the partial pressure of oxygen, at temperatures ranging between 800° and 1100°C, are used to study some transport and thermodynamic properties of nearly stoichiometric and nonstoichiometric NiO. Due to the localized character of electrons in ionic, hopping-type semiconductors, results are discussed with a chemical approach, in terms of the dependence of the activation enthalpy for the electrical conductivity and of the activity coefficients of Ni^{3+} on the partial pressure of oxygen. A defect model for nonstoichiometric NiO is given, which involves the presence of defect clusters (microdomains) with an inverse spinel structure. Furthermore, electrical conductivity results in nearly stoichiometric NiO are presented and discussed, which show straightforward evidence of the influence of iron doping in the range 100-500 ppm on the "intrinsic" character of the electrical conductivity.

Nickel oxide is a well-known metal-deficit semiconductor. Since the pioneering work of Baumbach and Wagner (1) a great deal of information has been obtained on its defect structure, the type of electrical conductivity (it is well established that the charge transport in NiO, as in other transition metal oxides, is of the thermally activated hopping-type and electron holes are localized at cation lattice sites), and the influence of different dopants on electrical and galvanomagnetic parameters (2-22).

The present investigation deals with results of electrical conductivity and emf measurements on solid galvanic couples of nearly stoichiometric and nonstoichiometric NiO. It is intended primarily as a contribution to the knowledge of the interactions between points and electronic defects within the lattice and their influence on the thermodynamic and transport properties of NiO. In addition we consider the nature of defect clusters and complexes in metal-deficit NiO, as well as the role of specific impurities, which are shown to influence remarkably the activation enthalpy for the electrical conductivity of the nearly-stoichiometric NiO.

Experimental Procedures

NiO *sample preparation.*—The preparation of NiO samples has been carried out according to standard ceramic procedures. Manyfold recrystallized reagent grade pure $Ni(NO_3)_2$ [1] has been used as the starting material. Nickel oxalate was first precipitated from nitrate solutions, decomposed at about 450°C, and finally fired at 700°-1200°C to yield a rather active, green NiO. The oxide was first pressed to pellets 12 mm diameter, 2-4 mm thick at a pressure of about 10 metric tons/cm^2 at room temperature and then sintered in air at 1500°C in a Superkanthal furnace.

[1] (Cl 30 ppm, SO_4 100 ppm, Cu 20 ppm, Fe 50 ppm, Co 100 ppm, Zn 50 ppm).

In the powders obtained by decomposing and firing in air at temperatures lower than 700°C, nickel metal at concentrations between 10-40% was found which, however, disappears during the sintering process. Nickel metal is also present in pellets sintered in vacuum at temperatures of 1100°-1200°C.

Table I shows the relevant characteristics of different samples which have been prepared and tested for impurity content and density. Density has been measured by means of a mercury pycnometer.

Furnace and cell for electrical conductivity measurements.—The furnace used is of the resistance type and was supplied with rectified current. Figure 1 shows the furnace and the measuring cell. A NiO pellet is pressed between two spectropure Pt-13% Rh electrodes. The electrodes are arranged at the ends of two vertical silica tubes. The tube at the bottom of the cell is externally supported by a clamp, the upper one is held in position by spring pressure. The measuring Pt, Pt-10% Rh thermocouple is placed very near the pellet (0.5 mm) and the temperature is continuously recorded by means of a potentiometric recorder.

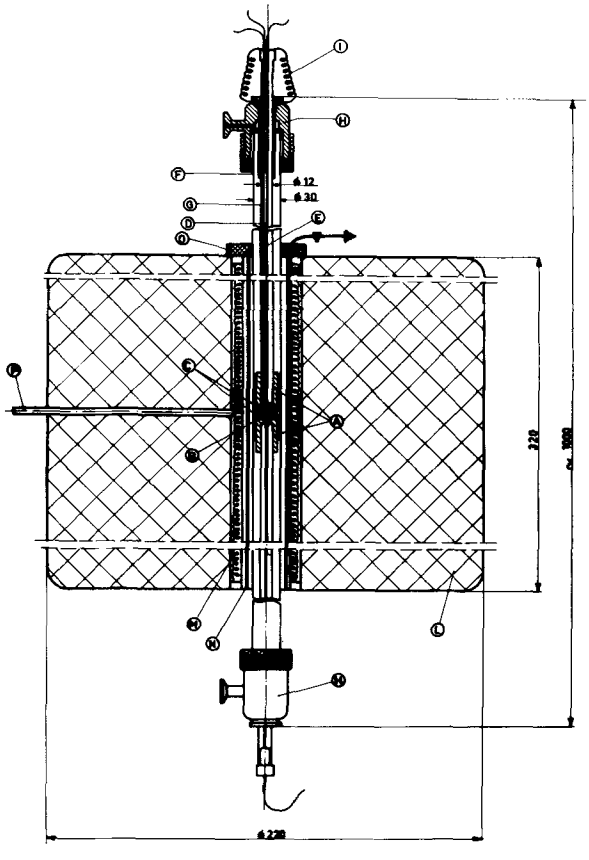

Fig. 1. Assembly of oven and cell for electrical conductivity measurements. A, fused silica holders; B, sample; C,Pt-13% Rh electrodes; D, Pt, Pt-10% Rh thermocouple for temperature measurement; E, leads from the electrode; F, outer silica tube; G, silica pressing tube; H, Inox cover; I, springs; L, furnace; M, resistance heaters; N, platinum tube; O, refractory cover; P, Pt, Pt-10% Rh thermocouple for temperature control.

Oxygen-free nitrogen or nitrogen-oxygen mixtures are allowed to flow through the silica tube at a rate of few cubic centimeters per minute. A slight overpressure is maintained in the cell, and partial pressures of oxygen are varied by varying the oxygen and nitrogen flows, measured with conventional laboratory rotameters. Mass spectrometrically standardized O_2-N_2 mixtures have been used as well. Thermal diffusion effects have been calculated to be negligibly small, and no correction due to these effects has been applied to the measured values of gas composition.

NiO pellets, to be used for electrical conductivity measurements, were coated with a thin Au or Pt layer to avoid contact resistances and to insure that the measurements give results significant for volume conductivity. The Au was evaporated and the Pt was sputtered in a conventional high vacuum evaporation unit. Direct-current resistance measurements have been carried out with the two terminal method. In order to tell whether contributions by Seebeck voltages due to small temperature gradients across the pellet were present, readings were also taken with voltage or current flow reversed.

A platinum tube inside the furnace acts as an electrostatic shield to avoid spurious stray-voltage effects when measurements were made on very high resistance samples. No such contributions were found. Moreover no significant polarization effects have been observed on imposing a total potential drop across the pellet as high as 1.35v over the whole experimental temperature range.

Furnace and cell for emf measurements.—The same type of furnace and shielding has been used for emf measurements as for conductivity measurements.

The cell, which may be represented as

$$Pt/NiO(p'_{O_2})/ZrO_2 + CaO/NiO(p''_{O_2})/Pt$$

consists essentially of a zirconia tube (Zr 23 Degussit), to the bottom of which a pellet of ZrO_2-18% CaO is sealed with a high-temperature ceramic cement, obtained from Melpar Inc. Two oxide electrodes are in contact with the faces of the zirconia pellet, the electrical contact being ensured by means of Pt-30% Rh electrodes. The arrangement is shown in Fig. 2. The oxide electrodes (in the present case two NiO pellets) are kept under different oxygen partial pressures by sweeping gas mixtures of known oxygen content through each compartment by means of Vycor tubes. Temperature is measured by means of Pt, Pt-10% Rh thermocouples, placed very near the Pt electrode. Failures due to imperfect tightness of the ceramic seal are easily monitored by the sudden change in the emf of the cell, which drops to zero, when there is a leak.

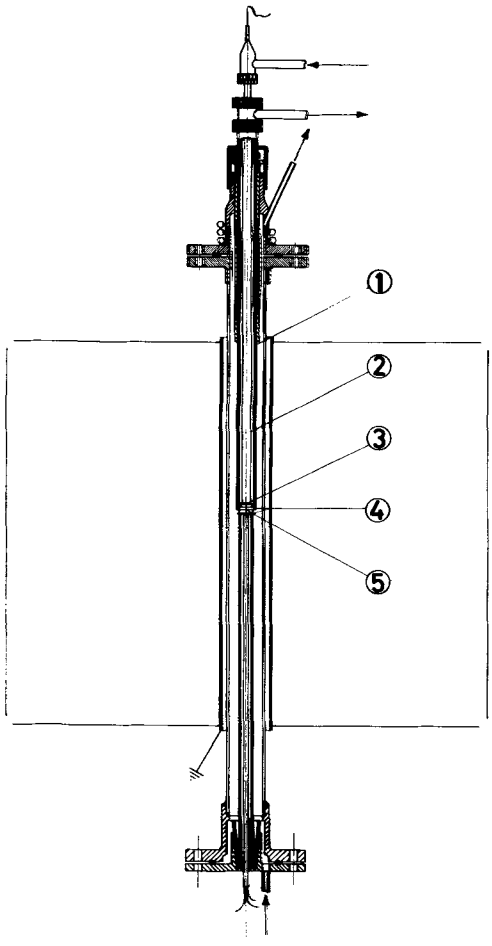

Fig. 2. Assembly of oven and cell for EMF measurements. 1. Zirconia tube; 2, silica electrode holder; 3, NiO pellet; 4, intermediate electrolyte; 5, NiO pellet.

The electrolyte has been previously tested for 100% ionic conductivity by using it for the emf determination of the solid galvanic cell

$$Pt/Fe/w\ddot{u}stite/ZrO_2 + CaO/NiO,Ni/Pt$$

the emf of which is well known from the literature (23). Results of this test are given in Fig. 3, which indicates the correct working of the electrolyte.

(oxygen-free argon or nitrogen)[2] on samples C_1 to C_8 of Table I (where preparation and analytical data are summarized). The samples were subjected to a high-temperature anneal to remove the excess oxygen dissolved in the samples during the preparation processes.

Figure 4 shows the effect of annealing with stepwise increasing temperatures; the break at about 850°C is taken to indicate the evolution of the excess oxygen. When the annealing is carried out carefully at temperatures higher than 850°C the break is no longer observed during successive cooling and heating cycles.

For each homogeneous sample a linear relationship is obtained by plotting the logarithm of the experimental d-c conductivity χ *vs.* $1/T$ as shown in Fig. 5. Breaks in the curves log χ *vs.* $1/T$ are, however, observed when Ni metal is present as a second phase (see sample C_1).

In Table I the values of the slope of the curves of log χ *vs.* $1/T$ are reported as "activation energy" values, as calculated from the relationship $\chi = \chi^\circ \exp -(E/2\,kT)$. It can be deduced from the table that there is a certain relationship between the activation energy, the firing temperature, and the iron content of the samples.

[2] The residual partial pressure of oxygen is of the order of 10^{-6} atm, as determined by mass spectrometric analysis, and it has been demonstrated that, within the limits of experimental accuracy, variation of p_{O_2} in this range does not affect the experimental results.

Electrical conductivity of NiO in oxygen atmosphere.—Electrical conductivity measurements have been carried out on samples C_6, C_7, and C_8 (see Table I) at partial pressures of oxygen ranging between 10^{-3} and 1 atm. Results are given in Fig. 6, 7, and 8 in log χ *vs.* $1/T$ plots.

In agreement with the results of Mitoff (6), Herbst (15), Thorton (16) and Snowden (17), experiments carried out at temperatures lower than 750°C show that the equilibration time is very long (hours or days) and that breaks appear in the curves log χ *vs.* $1/T$.

Moreover the temperature of the break, which should represent the lowest temperature at which thermodynamic equilibrium is established between the gaseous atmosphere and the crystal, depends on the cooling and heating rate of the sample. In the present experimental temperature range (800°-1050°C) the equilibration times are orders of magnitude lower than those measured at low temperature, and the electrical conductivity is a function of the temperature and partial pressure of oxygen, according to the relationship (5, 6)

$$\chi = \chi^{\circ}\, p_{O_2}^{1/n} \exp -\left(\frac{\Delta H}{RT}\right) \qquad [1]$$

where ΔH is the over-all activation enthalpy.

In Fig. 9, 10, and 11, log χ *vs.* log p_{O_2} plots are presented, from the slopes of which values of n can be derived, assuming the activation energy in the exponential term of Eq. [1] does not depend on the partial pressure of oxygen. At partial pressures of oxygen $<10^{-1}$ atm a value of n close to 6 is obtained ($5.7 \leq n \leq 6.4$).

In Fig. 12, 13, and 14, where the present experimental results are plotted in terms of resistivity, ρ *vs.* $p_{O_2}^{1/6}$, it is apparent that, within the limits of the experimental accuracy, Eq. [1] is satisfied for an n value of 6 up to partial pressures of oxygen of about 10^{-1} atm, where a remarkable deviation from linearity is observed.

EMF measurements.—Emf measurements have been carried out on low-density NiO samples for ensuring better and faster equilibration with the external atmosphere. As reference pressure a partial pressure of oxygen not lower than 10^{-3} atm has been chosen to avoid complications due to iron contamination which, as will be shown in the following discussion, has a noteworthy influence on the Ni^{3+} concentration at very low partial pressures of oxygen.

Five isotherms are shown in Fig. 15. The electrochemical "n" value, as determined from the slope of

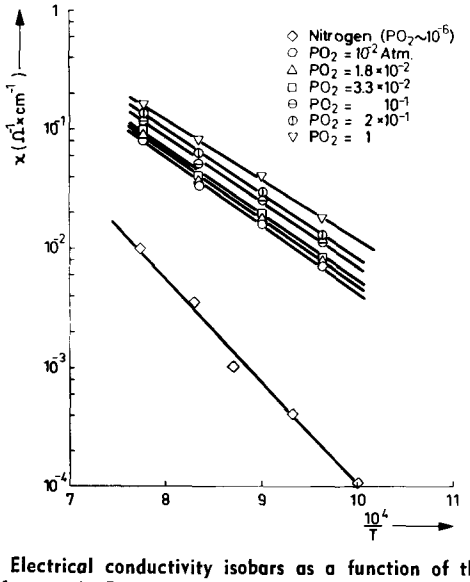

Fig. 6. Electrical conductivity isobars as a function of the temperature for sample C_6.

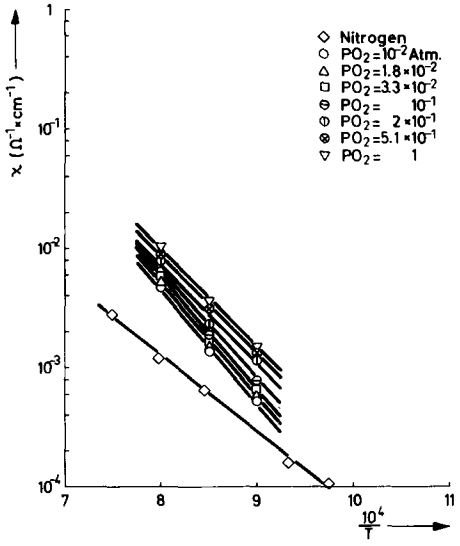

Fig. 7. Electrical conductivity isobars as a function of the temperature for sample C_7.

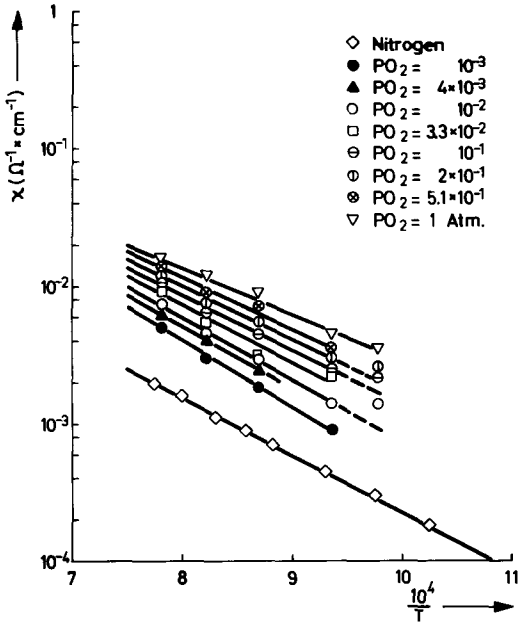

Fig. 8. Electrical conductivity isobars as a function of the temperature for sample C_8.

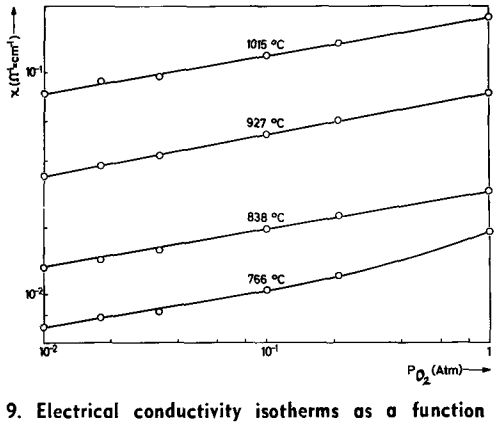

Fig. 9. Electrical conductivity isotherms as a function of the partial pressure of oxygen for sample C_6.

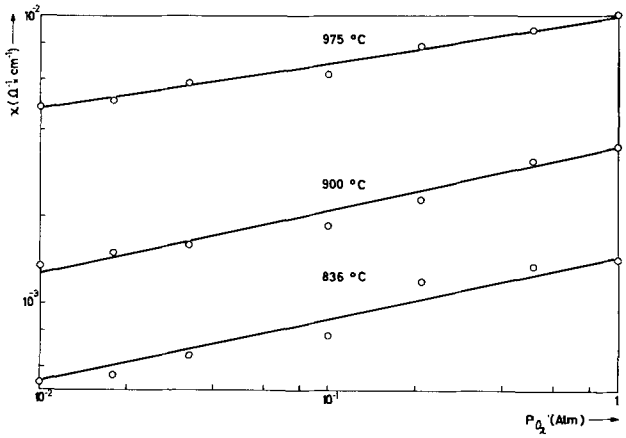

Fig. 10. Electrical conductivity isotherms as a function of the partial pressure of oxygen for the sample C_7.

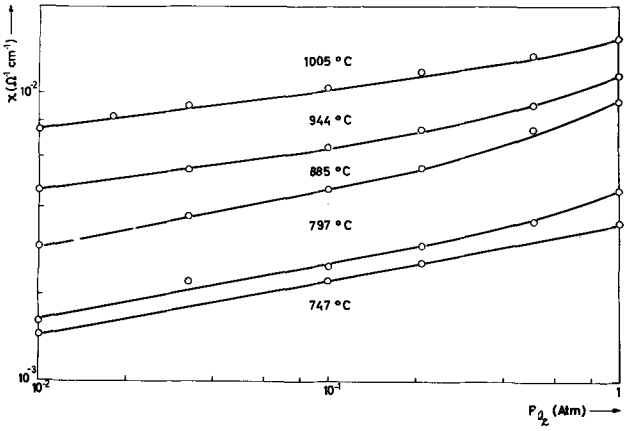

Fig. 11. Electrical conductivity isotherms as a function of the partial pressure of oxygen for the sample C_8.

the linear part of the E *vs.* log p'_{O_2}/p''_{O_2} plots according to the relationship

$$E = \frac{RT}{n\mathbf{F}} \ln \left(\frac{p'_{O_2}}{p''_{O_2}} \right) \qquad [2]$$

is shown in Fig. 16. It can be seen that n depends strongly on temperature, shifting continuously from 2 to 6 as temperature increases.

Since in the case of an oxygen cell we should observe slopes which equal $RT/4\mathbf{F}$, the emf of the cell

$$\mathrm{Pt} \mid \mathrm{Ni}_{1-x}\mathrm{O}(p'_{O_2}) \mid \mathrm{ZrO_2} + \mathrm{CaO} \mid \mathrm{Ni}_{1-y}\mathrm{O}(p''_{O_2}) \mid \mathrm{Pt} \qquad [3]$$

reflects, under equilibrium conditions, the changes in activity of electron-holes localized at cationic sites (*i.e.*, the activity of Ni^{3+}) as a function of the oxygen pressure.

In fact, NiO is a metal-deficient p-type semiconductor for which the electron-hole concentration is dependent on the partial pressure of oxygen (see below) according to the relationship[3]

$$\tfrac{1}{2}\,O_2 \rightleftarrows O_O + 2h^{\bullet} + V''_{Ni} \qquad [4]$$

By assuming the activity of oxygen ion in the anionic sublattice is constant and independent of the partial pressure of oxygen (it is generally recognized that ionic defects occur almost exclusively in the cationic sublattice), the electrode reaction at the metal (I) NiO(II) phase boundary is

$$_{II}Ni^{3+} + {}_{I}e \rightleftarrows {}_{II}Ni^{2+} \qquad [5]$$

[3] The Kröger and Vink symbols will be used throughout in this paper.

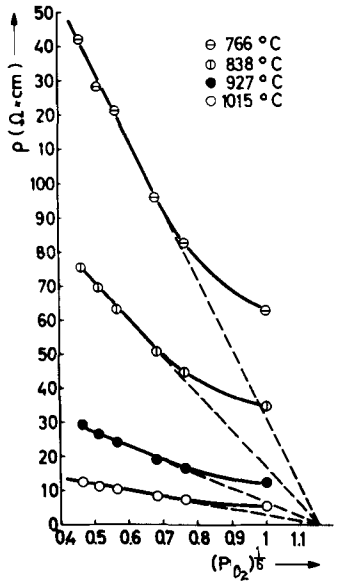

Fig. 12. Electrical resistivity isotherms for the sample C_6 as a function of the sixth root of the partial pressure of oxygen.

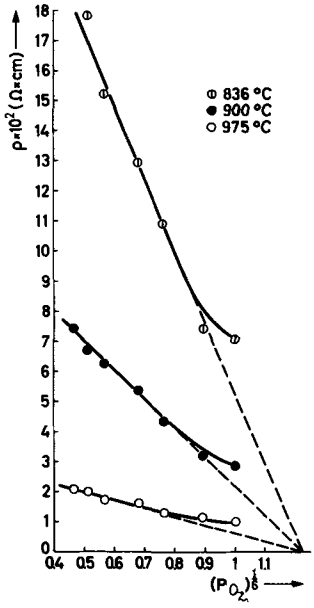

Fig. 13. Electrical resistivity isotherms for the sample C_7 as a function of the sixth root of the partial pressure of oxygen.

and that at the oxide (II)-zirconia (III) phase is

$$_{II}O^{2-} \rightleftarrows {}_{III}O^{2-} \qquad [6]$$

where CaO-doped ZrO_2 works, as is well known, as a purely anionic membrane ($t_{O^{2-}} = 1$).

From the condition of electrochemical equilibrium between phases of different composition we obtain

$$_{I}\tilde{\mu}_e = {}_{II}\tilde{\mu}_h \qquad [7]$$

$$_{I}\phi - {}_{II}\phi = \frac{1}{\mathbf{F}} ({}_{I}\mu_e + {}_{II}\mu_h) \qquad [8]$$

and

$$_{II}\tilde{\mu}_{O^{2-}} = {}_{III}\tilde{\mu}_{O^{2-}} \qquad [9]$$

$$_{II}\phi - {}_{III}\phi = g_{II,III} = \frac{1}{\mathbf{F}} ({}_{III}\mu_{O^{2-}} - {}_{II}\mu_{O^{2-}}) \qquad [10]$$

where $\tilde{\mu}_i$ is the electrochemical potential of the i^{th}

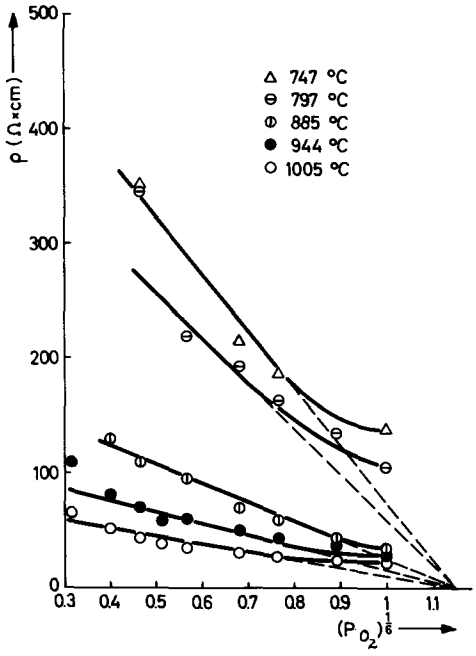

Fig. 14. Electrical resistivity isotherms for the sample C_8 as a function of the sixth root of the partial pressure of oxygen.

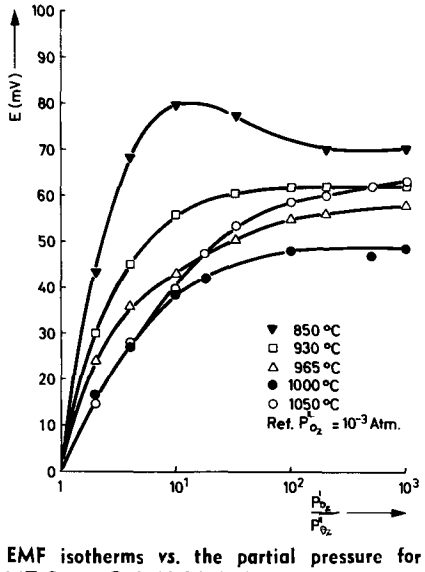

Fig. 15. EMF isotherms vs. the partial pressure for the cell: $Pt/NiO(p'_{O_2})/ZrO_2 + CaO/NiO(p''_{O_2})/Pt$.

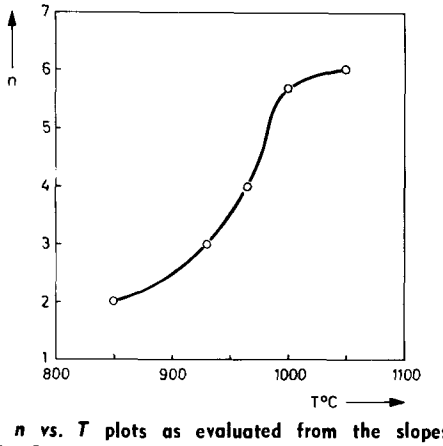

Fig. 16. n vs. T plots as evaluated from the slopes of the curves of Fig. 15 at very low partial pressures of oxygen.

species in the α phase and is defined as

$$\tilde{\alpha\mu_i} \equiv \alpha\mu_i + \mathbf{F}\phi \qquad [11]$$

$\alpha\mu_i$ is the chemical potential of the i^{th} species in the α phase, ϕ is the internal potential of the phases and g is the Galvani potential difference.

Moreover, since the chemical potential of O^{2-} in the NiO phase is independent of the oxygen partial pressure, we can write

$$g_{II,\,III} - g_{III,\,II} = 0 \qquad [12]$$

and the emf of the cell [3] may be written

$$E = {}_I\phi' - {}_I\phi'' = \frac{1}{\mathbf{F}}({}_I\mu''_e - {}_I\mu'_e = \frac{1}{\mathbf{F}}({}_{II}\mu'_h - {}_{II}\mu''_h) \qquad [13]$$

where the symbols (') and (") refer to the left-hand and right-hand compartments of cell [3]. Equation [13] reduces to the explicit equation

$$E = \frac{RT}{\mathbf{F}} \ln \frac{a'_{Ni3+}}{a''_{Ni3+}} \qquad [14]$$

when the emf of the cell is expressed in function of Ni^{3+}.

Discussion

Electric conductivity of NiO *in inert gas atmosphere.*—In spite of the fact that a great deal of experimental and theoretical information is available on charge transfer processes in both stoichiometric and nonstoichiometric NiO, it seems questionable if one could succeed in measuring the properties of pure and stoichiometric NiO. We shall indeed restrict our discussion to the influence of the environmental conditions and the impurity content of NiO on the activation energy for the conductivity, which is generally assumed to represent a bulk property of a material, even when measured in polycrystalline samples. In the present case it is well to emphasize that the excellent agreement of our results with those obtained by different authors on single crystals indicates a negligible effect of surface conductivity on the measured activation energy.

The accurate determination of the impurity content of sample C_2 (which is representative of samples from C_1 to C_6) and of sample C_8 has been carried out by means of neutron activation analysis and is reported in Table I. It is apparent that the alkali metal content is very low and comparable in both series and that the samples differ mainly in the iron content. The chromium and aluminum contents remain low and constant in all the samples, apart from the case of sample C_7.

Insofar as the nickel metal content is considered, sample C_1, the only one which has a rather high nickel metal content, exhibits an anomalous behavior. Moreover, electron microprobe experiments on samples where x-ray powder diffraction measurements did not reveal the presence of nickel metal seem to indicate no apparent segregation of minute amounts of nickel metal at the grain boundaries. However, these experiments are not conclusive, as the resolution power of the electron microprobe used is relatively low (about 2μ).

The experimental activation energies, as calculated from the slopes of the log χ *vs.* $1/T$ diagrams (see Fig. 5 and Table I) indicate that samples from C_1 to C_6 exhibit very large values of activation energy, as compared with those of ref. (3-5, 17), whereas the values for samples C_7 and C_8 are in satisfactory agreement.

According to Van Houten (8) Mitoff (6), and Morin (4b) an activation energy of about 2 ev (from a slope $E/2k$) as we observe in samples C_7 and C_8, is to be accounted for by an extrinsic conduction process, which is associated with the change of carrier concentration due to the excess oxygen dissolution.

According to the results of the investigations of Newman and Chrenko (24) and, more recently, of Ksendzov and Drabkin (25) on epitaxially grown NiO single crystals, the optical absorption spectrum and the dependence of the photocurrent on the incident radiation energy, indicate that the wide absorption band observed at 4 ev (24) is associated with a photoionization process and that the energy gap calculated from the slope $E/2k$ [for the relationship between thermal and optical activation energies, see ref. (26)] of a log χ *vs.* $1/T$ plot agrees well with the red edge value of the photocurrent, which lies at 3.7 ev. This indicates that we are dealing with intrinsic behavior.

Results of experiments on samples C_{1A}, C_2, C_4, C_5, and C_6 indicate that the values of the activation energy obtained from electrical conductivity measurements in inert gas with an oxygen partial pressure less than 10^{-5} atm, agree within a few 0.1 ev with those of Ksendzov and Drabkin, as is shown in Table I. We might assume as did Ksendzov and Drabkin that samples from C_1 to C_6 exhibit intrinsic behavior. Our results indicate, however, that by greatly improving the purity of the samples (Fe $\leq$ 100 ppm) the activation energy drops to values which are well accounted for by an extrinsic conduction process (see Eq. [18] and [19]).

We would like to stress, however, that at constant temperature and partial pressure of oxygen (*i.e.*, at a certain fixed electron-hole and vacancy concentrations) the equilibrium involving a redox impurity such as iron

$$Fe^{2+} + Ni^{3+} \rightleftarrows Fe^{3+} + Ni^{2+} \qquad [15]$$

is strongly shifted to the right [from the difference in the third ionization potentials of Ni and Fe, which equals 5.5 ev (27)]. The resulting situation can be described according to the following equations

$$\mu^\circ_{Fe^{2+},Fe^{3+}} + RT \ln \frac{a_{Fe^{3+}}}{a_{Fe^{2+}}} = \mu^\circ_{Ni^{2+},Ni^{3+}} + RT \ln \frac{a_{Ni^{3+}}}{a_{Ni^{2+}}} \qquad [16]$$

and

$$\mu^\circ_{Ni^{2+},Ni^{3+}} >> \mu^\circ_{Fe^{2+},Fe^{3+}} \qquad [17]$$

(where μ° redox are the standard chemical potentials for the redox couples Fe^{3+}/Fe^{2+} and Ni^{3+}/Ni^{2+}, which are identical with the electronic energy levels generally used in discussing the properties of semiconductors).

If holes at localized iron extra levels are to be considered as trapped holes, then at a particular temperature, oxygen partial pressure, and iron concentration, the concentrations of holes and electrons provided by intrinsic ionization predominate, and we have

$$n \simeq p$$

Moreover, if the difference between the value of the μ's (μ° Fe^{2+}, Fe^{3+} — μ° Ni^{2+}, Ni^{3+}) is greatly in excess of the difference in the chemical potentials of oxygen obtained by varying the oxygen pressure over few orders of magnitude, it is apparent that the value of the ratio $(a_{Ni^{3+}})/(a_{Ni^{2+}})$ is practically unaffected by the partial pressure of oxygen, as long as the concentration of the excess holes introduced by oxygen dissolution is lower than, or, in the limiting case, equal to the iron content.

It has been tacitly assumed that conditions of complete equilibrium with the gas phase exist, but it is apparent that Eq. [15] and [16] hold even when only internal electronic equilibrium exists between the iron impurities and defects frozen in the lattice.

In strong support of this suggestion, we quote the results of Richards *et al.* (27) who demonstrated that the high diffusivity of iron in NiO (which is appreciably greater than that of Ni) could be accounted for, by realizing that, while the total concentration of vacancies and holes is fixed at constant temperature and p_{O_2}, the specific concentration of Fe^{3+} (bound holes) would always be higher than that of Ni^{3+} (quasi-free holes) because of its lower ionization potential.

As to the influence of monovalent impurities, it is apparent that, at sufficiently high temperatures, doping in the ppm range is of little significance. Recent investigations (13-29) demonstrated the restricting role of steric parameters on the solubility of several monovalent oxides in NiO, such as K_2O and Na_2O, which seem to be almost insoluble.

Electrical conductivity measurements in oxygen atmosphere.—The plots of Fig. 9, 10 and 11, which show the log χ *vs.* p_{O_2} relationships and those of Fig. 12, 13, and 14 which show the ρ *vs.* $p_{O_2}^{1/6}$ relationships, indicate that, at least at pressures lower than 10^{-1} atm, the value of n equals 6 over the whole experimental temperature range.

This value of n reflects, in good agreement with the results of Mitoff (6), Petitt (7), and Herbst (15), the presence of doubly ionized cation vacancies at a concentration largely in excess over that of singly ionized ones. Each atom of oxygen in stoichiometric excess introduces a cation vacancy and two electron holes, according to the following equations

$$\tfrac{1}{2}\, O_2 \rightleftarrows O_o + 2h^\bullet + V''_{Ni} \qquad [18]$$

or

$$\tfrac{1}{2}\, O_2 + 2Ni_{Ni} \rightleftarrows O_o + 2Ni^\bullet_{Ni} + V''_{Ni} \qquad [19]$$

where electron holes in their state of lower energy are localized at lattice sites (*i.e.*, corresponding to Ni^{3+} at octahedral sites); the cation vacancies bear a $-2e$ charge.

$$K_1 = \frac{a^2_{Ni^\bullet_{Ni}}\, a_{V''_{Ni}}}{P_{O_2}^{1/2}}$$

is the equilibrium constant of Eq. [19] and

$$a_{Ni^\bullet_{Ni}} = a_{h^\bullet} = K_1^{1/3} p_{O_2}^{1/6} \qquad [20]$$

The electron hole concentration is of course fully determined by the electroneutrality requirements within the crystal.

Trivalent nickel ions may be localized at interstitial positions as well, just as in the case of trivalent iron in ferrous oxide, according to Roth's paper (30) on neutron diffraction of $Fe_{0.87}O$. When this is the case, we should express the equilibrium between Ni^{3+} at octahedrally and tetrahedrally coordinated sites by the following equations

$$V''_{Ni} + Ni^\bullet_{Ni} + V_i^* \rightleftarrows (V_{Ni}\, Ni_i\, V_{Ni})' \qquad [21]$$

and

$$\tfrac{1}{2}O_2 + 2Ni_{Ni} + V_i^* \rightleftarrows Ni^\bullet_{Ni} + (V_{Ni}\, Ni_i\, V_{Ni})' + O_o \qquad [21']$$

and we remark, according to Anderson (31) that the defect complex $(V_{Ni}\, Ni_i\, V_{Ni})'$ and its immediate environment (which includes one Ni^{3+} in octahedral position) behaves like a microdomain of inverse-spinel structure, with 0.5 of the total Ni^{3+} at octahedral positions and 0.5 at tetrahedral sites. We assume on steric grounds that positive holes are trapped at tetrahedrally coordinated sites (31). It appears that the microdomain behaves as a neutral species and that its activity a^* depends on the partial pressure of oxygen as

$$a^* = K_2\, p_{O_2}^{1/2} \equiv a_{Ni^\bullet_{Ni}} \equiv a_{h^\bullet} \qquad [22]$$

where K_2 is the equilibrium constant of reaction [21']

By considering that only holes at octahedral positions behave as free current carriers, we obtain

$$\chi = \overline{K_2}\, p_{O_2}^{1/2} \qquad [22']$$

It is well to emphasize that we assume here that the defect complex $(V_{Ni}\, Ni_i\, V_{Ni})'$ of Eq. [21] can never trap a second hole according to the equation

$$(V_{Ni}\, Ni_i\, V_{Ni})' + h^\bullet \rightleftarrows (V_{Ni}\, Ni_i\, V_{Ni})^* \qquad [23]$$

inasmuch as this process of trapping requires the stability of singly ionized vacancies, whereas, in the temperature range here considered, doubly ionized vacancies are shown to be largely in excess of the singly ionized ones.

Deviations of conductivity isotherms from the theoretical plot should indeed indicate that the reaction [21] participates or is predominant in determining the concentration of the free-current carriers. The isotherms of Fig. 12, 13, and 14 suggest a significant contribution of reaction [21] only at high partial pressures of oxygen and at temperatures lower than about 1200°K. At higher temperatures, deviations from the theoretical plot (indicated by a dotted line) are negligibly small at the higher partial oxygen pressures too.

The plots of Fig. 6, 7, and 8 have been used for the evaluation of the activation enthalpy for the conductivity and its dependence on the partial pressure of oxygen. In order to discuss the experimental results, we will use the equation

$$\chi = (C/T)x \exp - (\Delta G/RT) \qquad [24]$$

where (C/T) is nearly a constant, x is the concentration of current carriers, ΔG is the free energy of activation, and the other symbols have their usual significance. This is the same equation Heikes and Johnson (5) used for discussing the electrical conductivity in transition metal oxides. If, now the concentration x which enters Eq. [24] is expressed as a function of the partial pressure of oxygen, according to Mitoff (6), we obtain, by assuming [19] to be the predominant contribution

$$\chi = (\overline{C}/T)\ p_{O_2}{}^{1/6} \exp - \left(\frac{\Delta H^{\neq}}{RT} + \frac{\Delta H_f}{3RT} \right) \qquad [25]$$

In this equation the ΔG terms are split in their enthalpy and entropy contribution and ΔS terms are included in the preexponential $(\overline{C}/T)$. ΔH_f is the enthalpy of formation for the reaction of Eq. [19] and $\Delta H^{\neq}$ is the activation enthalpy for the mobility.

The calculation of the enthalpy of formation has been accomplished according to Mitoff by assuming that the activation enthalpy $\Delta H^{\neq}$ is constant and independent of the partial pressure of oxygen, *i.e.*, independent of the composition. The results are given in Table II. It is apparent that the over-all activation enthalpy and therefore the enthalpy of formation is a function of the partial pressure of oxygen, as also results from the data of Takeuchy and Igaky (22) and as has been recently demonstrated for CoO as well (32).

By assuming for $\Delta H^{\neq}$ a value of 5500 cal/mole as used by Mitoff (6) or of 6900 cal/mole as used by Herbst (15) the values of the enthalpy of formation of defects have been calculated and are reported also in Table II. It results that the ΔH_f values for sample C_6 are very near to the Mitoff values (measured at 1 atm O_2) whereas those for sample C_8 are in very good agreement with the Herbst results. (Results for sample C_7 are not reported, as it is apparent that spurious contributions due to the high aluminum content lead to anomalously high ΔH_f values. Results for sample C_6 should be treated carefully, as the iron content of the sample could be of significant importance). Mitoff reports that the sample used was of reagent grade purity, *i.e.*, about 1000 ppm total impurities, and quotes the lithium content as below the limits of detection. Herbst's data for impurity content closely approach those of our sample C_8.

It appears however, that the above mentioned arguments give only a fictitious solution of the problem. If we assume that $\Delta H^{\neq}$ remains constant (and independent of the concentration of current carriers) and if we used a value of $n=6$, the ΔH_f values are unambiguously determined. Nevertheless, we cannot suppose that the activation enthalpy for the mobility $\Delta H^{\neq}$ remains constant unless the carrier concentration changes negligibly with the partial pressure of oxygen. As the dependence of the activation enthalpy for the mobility on the carrier concentration is known from the literature for Li-doped NiO, the results from such experiments may be compared with the results on samples C_6 and C_8, and those of Takeuchy and Igaky (22), if the Li_2O concentration scale is arbitrarily related to the p_{O_2} scale. We observe that at pressures between 10^{-2} and 10^{-1} atm. the slope changes, namely, if b_1 is the slope at high pressures and b_2 is the slope at low pressures:

$$b_2 = 1/3\ b_1$$

In order to account for this change of slope, we recall the dependence of carrier concentration on the partial pressure of oxygen for Ni^{3+} in lattice positions alone and for holes distributed over both lattice and interstitial positions (see Eq. [19] and [21'])

$$x_{h^{\bullet}} = K_1{}^{1/3}\, p_{O_2}{}^{1/6} \qquad [20]$$

$$\frac{\partial \Delta H}{\partial \ln x} = 6 \frac{\partial \Delta H}{\partial \ln p_{O_2}} \qquad [26]$$

$$x_{h^{\bullet}} = K_2\, p_{O_2}{}^{1/2} \qquad [22]$$

$$\frac{\partial \Delta H}{\partial \ln x} = 2 \frac{\partial \Delta H}{\partial \ln p_{O_2}} \qquad [27]$$

when electron holes are distributed across lattice and interstitial nickel sites and, as before, holes at tetrahedral nickel positions behave as bound-holes.

It appears that the change of slope observed in Fig. 17 only reflects the transition from Eq. [19] to Eq.

[21'] due to the different dependence of the free carrier concentration on the partial pressure of oxygen. Unfortunately, as is shown in the same figure, it seems to be rather difficult to correlate the Li_2O concentration dependence of the ΔH of lithium doped NiO with our results, as the slopes obtained from the literature values are not very consistent. Moreover, as Van Houten and Bosman (33) observed, it is not certain that the activation energy for the jumping of a hole around a lithium ion is the same as for the hopping of a free hole through the NiO lattice, although the difference is not expected to be very large. Nevertheless, Koyde's data (21) express a slope b which is approximately twice the slopes observed by us (or deduced from the Takeuchy data) at high partial pressures of oxygen.

It results that the experimental dependence of the over-all activation enthalpy on the partial pressure of oxygen roughly corresponds to the dependence of the activation enthalpy for the mobility of the current carriers on the concentration of the free carriers over the whole concentration range considered.

EMF measurements.—Due to the composite character of the electrical conductivity as a function both of the concentration and of the mobility of the current carriers, only indirect evidence has been drawn from the dependence of the electrical conductivity or of its activation energy on the partial pressure of oxygen about the occurrence of defect association reactions in nonstoichiometric NiO.

In the absence of direct structural information, emf measurements, which allow the measurement of the activity of Ni^{3+} introduced by excess oxygen dissolution in the NiO lattice, should be used to test the validity of the defect model proposed with Eq. [21] and [21'], involving interstitial nickel at the higher oxygen partial pressures.

We will choose as an ideal solution model that solution where Ni^{3+} behaves as a free, independent ion [*i.e.*, the partial molar enthalpy of mixing or, according to Guggenheim (35) the interchange energy w, equals zero] and in which the concentration (= activity) of Ni^{3+} depends on the partial pressure of oxygen according to the formal equilibrium constant

$$K_1 = \frac{a_{Ni^{3+}}\, a_{V''_{Ni}}}{p_{O_2}{}^{1/2}}$$

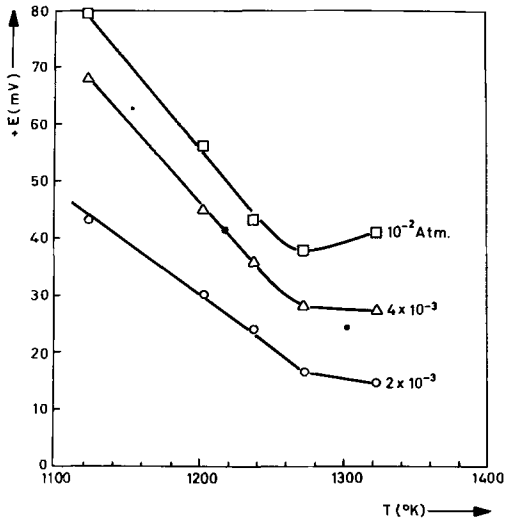

Fig. 18. EMF isobars as a function of the temperature for the cell: $Pt/NiO(p'_{O_2})/ZrO_2 + CaO/NiO(p''_{O_2})/Pt$ at low oxygen pressures.

and

$$a_{Ni^{3+}} = K_1{}^{1/3}\, p_{O_2}{}^{1/6} \qquad [20]$$

Since it would be unnecessarily restrictive, we will not consider here the condition of undistinguishability of Ni^{3+} and Ni^{2+} (35) that could be supposed to hold, due to the continuous exchange of electrons between altervalent metal ions (36). We have first to remark that the isotherm at 1323°K of Fig. 15 fits this model quite well at least at pressures lower than about 10^{-2} atm. Furthermore, from the isobars of Fig. 18, we observe that a kink is present at 1273°K in the E *vs.* T plots, in a range of pressures where the isotherms of Fig. 15 indicate the presence of a purely monophasic system. Finally, it is worthwhile to remark that, the E *vs.* p_{O_2} plots indicate, at temperatures lower than 1273°K and at pressures higher than about 5 x 10^{-2} atm, the existence of a two-phase system (from the constancy of the chemical potential of Ni^{3+}).

The segregation of a second phase could be easily accounted for by considering that the occurrence of reaction [21'] involves the presence of microdomains of the inverse spinel Ni_3O_4, which apparently is soluble in the NiO phase only to a very limited extent at temperatures lower than 1273°K, which can be considered as the temperature of critical mixing (35). Above this temperature, the emf isotherms indicate the presence of a purely monophasic system up to the higher pressures; therefore the discontinuity at 1273°K in the emf *vs.* T plot indicates also an order-disorder transition which reflects the randomization of the point and electronic defects within the crystal.

From the difference between the experimental (E) and the theoretical ($E°$) emf of the cell

$$Pt/NiO(p'_{O_2})/ZrO_2 + CaO/NiO(p''_{O_2})/Pt \qquad [3]$$

we calculated the activity coefficients of Ni^{3+}

$$E - E° = \frac{RT}{F} \ln \left(\frac{\gamma C_{Ni^{3+}}}{C_{Ni^{3+}}} \right)_{p'_{O_2}} = \frac{RT}{F} \ln (\gamma)_{p'O_2} \qquad [28]$$

where the $E°$ values have been calculated according to the following equation

$$E° = \frac{RT}{6F} \ln \frac{p'_{O_2}}{p''_{O_2}} = \frac{RT}{F} \ln \frac{C'_{Ni^{3+}}}{C''_{Ni^{3+}}} \qquad [29]$$

assuming that at the reference pressure ($p'' = 10^{-3}$ atm) the solution is nearly ideal. The latter is a very crude approximation, which nevertheless is helpful in the evaluation of the activity coefficients as well as of the enthalpies of mixing.

Experimental values are reported in Table III. It may be stated that at temperatures lower than 1273°K

Table III. Activity coefficient values as obtained from emf measurements on cell of Eq. (3)

4×10^{-3}	28.0	26.33	1323	0.006	1.015
10^{-2}	40.0	43.73	1323	0.014	1.033
3.3×10^{-2}	53.5	66.38	1323	0.048	1.119
10^{-1}	58.5	87.46	1323	0.110	1.290

the activity coefficients are well accounted for only in the range of compositions corresponding to the solid solution. At higher concentrations their value is only fictitious. It is nevertheless quite evident that at temperatures < 1273°K γ diverges rapidly from 1 at pressures slightly increasing from the reference one, whereas at higher temperatures the deviations from ideality are also relatively low at the higher pressures.

As this behavior (at temperatures lower than that of critical mixing) reflects the properties of a regular solution (35) we may calculate the partial molar enthalpy of mixing of Ni_3O_4 in NiO, $\Delta\bar{H}$, from the temperature dependence of the activity coefficients of Ni^{3+} at 2×10^{-3} atm and at 4×10^{-3} atm according to the relationship

$$\ln \gamma = -\frac{\Delta \bar{H}}{RT} \qquad [30]$$

which describes the ln γ *vs.* $1/T$ plots of Fig. 19.

We thereby obtain a value for the partial molar enthalpy of mixing equal to 5.46 kcal/g ion at $p_{O_2} = 2 \times 10^{-3}$ and 7.46 kcal/g ion at 4×10^{-3} atm; thus, indeed, the solution cannot be considered as a strictly regular one (35).

Conclusions

1. Intrinsic semiconductivity has been observed in fully compensated polycrystalline NiO. The activation energy for the intrinsic process corresponds to half of the energy gap value as obtained from optical measurements. It seems moreover that surface conductivity does not affect our results in the temperature range of our experiments.

2. Nickel vacancies are fully ionized over the entire experimental temperature range. Literature data which indicate the existence of partially ionized vacancies suffer from errors attributed to the effect of unknown impurities.

3. In nonstoichiometric (metal deficit) NiO a second phase segregates at temperatures lower than 1300°K which has an inverse spinel structure. The existence of inverse spinel microstructures has been tentatively inferred, at partial pressures of oxygen lower than that corresponding to the segregation of a second phase, from the dependence of the activation energy for the conductivity on the partial pressure of oxygen.

4. From emf measurements the activity coefficients of Ni^{3+} and the partial molar heat of mixing of Ni_3O_4 in NiO have been calculated and an order-disorder transition temperature of 1273°K has been inferred.

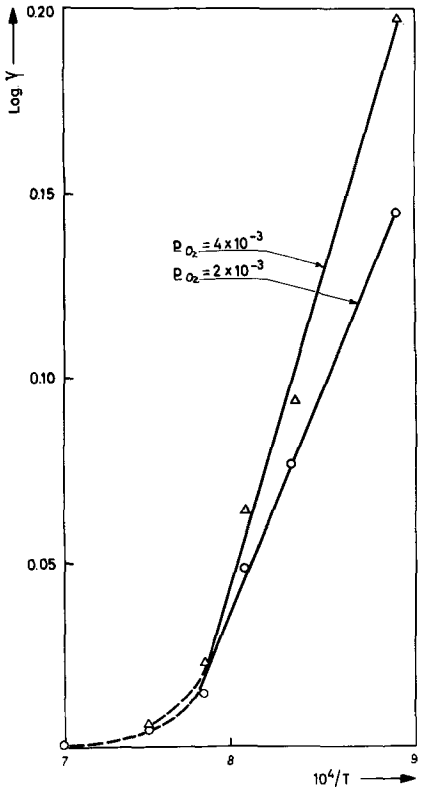

Fig. 19. Log γ *vs.* $1/T$ plot for the activity coefficients γ as obtained from Eq. [17] at 2×10^3 and 4×10^{-3} atm of oxygen.

Acknowledgment

The authors are greatly indebted to Mr. C. Geel for the preparation of samples, to Dr. Vos and Mr. Toussaint of the Analytical Chemistry Group, and to Dr. Girardi and Mr. Sabbioni of the Nuclear Chemistry Group for their analytical support, and to Dr. R. Kelly of the Solid State Physics Group for helpful discussions. They would like, moreover, to acknowledge Dr. J. H. Westbrook, who substantially improved the text and to Dr. N. Hackerman and Mrs. R. G. Sterns for their helpful suggestions.

Technical Note

The Si-WSi_2-Si Epitaxial Structure

Norikazu Hashimoto and Yasushi Koga

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

Chemical vapor deposition of metals on single crystal silicon has received increasing attention in the fabrication of devices with a metal-semiconductor contact, such as the Schottky barrier diode. There are the following problems: (*a*) morphology and crystallinity of the deposited metal layer, and (*b*) silicide formation at the interface between the deposited metal and the silicon substrate.

Deposition of molybdenum on silicon has been reported by Casey *et al.* (1) and Lindmayer (2). The latter author reported that 100Å thick molybdenum layers on silicon were not single crystals. Kano *et al.* (3) have studied the molybdenum-silicon Schottky barrier formed by chemical vapor deposition in which a special technique (preactivation of reaction) was employed to prevent the formation of the silicide. Crowell *et al.* (4) have reported deposition of polycrystalline tungsten layers on silicon, germanium, and gallium arsenide substrates. Deposition of vanadium on silicon has been reported by Miller *et al.* (5) where no evidence of the silicide formation was observed.

Very recently, the silicide formation on deposition of molybdenum has been reported by Casey *et al.* (6). The orientations of molybdenum silicides with respect to the silicon substrates have been determined to (001) $MoSi_2$ // (100) Si with (110) $MoSi_2$ // (010) Si and (110) Mo_3Si // (111) Si with [335] Mo_3Si // [$10\bar{1}$] Si.

This paper reports on deposition of tungsten and the formation of its silicide layer by hydrogen reduction of the hexachloride on single crystal silicon substrates. The orientation relations between the silicide layer and the substrate are analyzed by electron diffraction and x-ray diffraction. Furthermore, we are concerned with epitaxial growth of the silicon layer on the grown silicide layer.

Experimental

Materials.—Commercial tungsten hexachloride, WCl_6 (99% min) was purified by sublimation. The resultant impurity contents in the chloride (in weight per cent) were as follows: Ca, Mg, and Cu 1 — 5 × 10^{-4}; Al 1 — 5 × 10^{-3}; Fe and Si 5 — 10 × 10^{-3}. Tungsten oxychlorides ($WOCl_4$, WO_2Cl_2) were eliminated by preliminary sublimation.

Hydrogen (99.9%) used as a carrier gas was passed through a "Deoxo" and then through a two-stage liquid nitrogen trap.

The silicon substrates used were circular slices, 25 mm diameter, 0.2 mm thickness, with (111), (110), and (100) faces.

Apparatus.—The apparatus used for deposition is shown schematically in Fig. 1. It consisted of a hydrogen purifier, quartz evaporator, and a quartz reaction chamber. A high-frequency induction heater was used.

Operation.—The substrate was etched with HF (46%) for 1 min and then set on the silicon pedestal. After preliminary purge of the reaction chamber with hydrogen gas, the substrate surface was treated with hydrogen stream at *ca.* 1200°C. A gaseous mixture of WCl_6 and hydrogen was produced by passing dry hy-

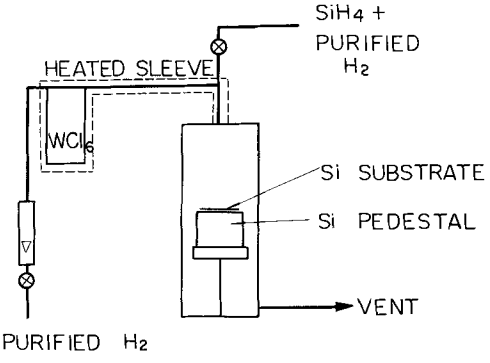

Fig. 1. Schematic diagram of the vapor deposition apparatus

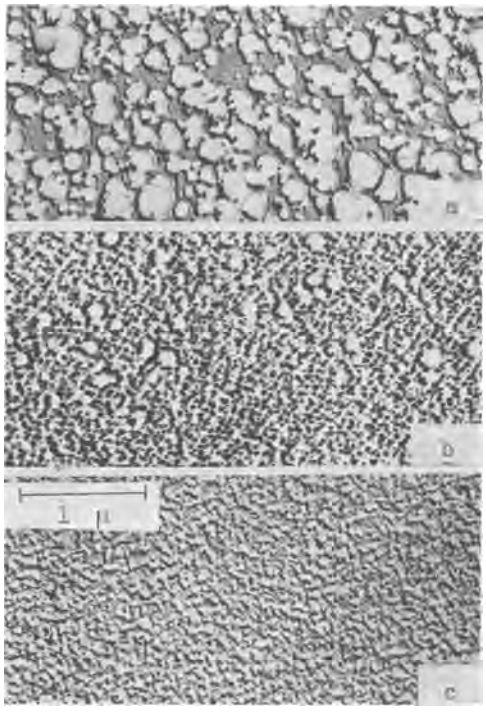

Fig. 2. Replica electron micrographs of the tungsten surfaces deposited (a) at 650°C, (b) at 750°C, and (c) at 840°C.

drogen at a flow rate of 5 l/min over the solid chloride heated at 200°C in the evaporator and was introduced into the chamber. The chloride was reduced and tungsten was deposited onto the substrates which had been heated to a temperature in the range from 650° to 1250°C.

Presence of oxygen in the deposition system resulted in formation of oxides on the silicon substrate. Since this affects deposition processes markedly, care should be taken to remove trace amount of oxygen.

In the case of silicon deposition on the silicide layer, the reaction chamber was first purged with hydrogen. The monosilane gas was then introduced directly into the hydrogen stream, and silicon was deposited on the silicide by thermal decomposition of the gas.

Results and Discussion

Deposition of W *on* Si, *and formation of* WSi_2—Figures 2a, b, and c illustrate typical deposits of the polycrystalline tungsten on the single crystal silicon at 650°, 750°, and 840°C, respectively. The surfaces become smoother on increasing the deposition temperature.

According to the measurements of the photoelectric response, the barrier height between the deposited tungsten and n-type silicon was higher than that of tungsten and n-type silicon which was formed by vacuum deposition by about 0.20 ev. This result has been attributed to the existence of tungsten silicides between the deposited tungsten and the silicon substrate; nevertheless the deposition temperatures are 400°C or more lower than the W-Si eutectic temperature (4, 7).

Compositions of the deposited tungsten layers at higher temperatures were determined by electron diffraction and x-ray diffraction analyses. Results are given in Table I. The deposition time was 5 min. With electron diffraction, we can observe thin surface films, because penetration of the electron beam is slight. On the other hand, the main composition of the deposited layer can be determined with x-ray diffraction. At 1065° and 1087°C, the thin surface films of the deposited layer were polycrystalline tungsten, although the main composition was tungsten disilicide (WSi_2). The deposited layers at 1120° and 1180°C were WSi_2 throughout. The thickness of the WSi_2-layer was estimated by the angle lapping method as about 5000Å.

Table I. Analyses of deposited layers on Si substrates by hydrogen reduction of tungsten hexachloride

Substrate temperature, °C	Electron diffraction analysis	X-ray diffraction analysis
1065	W	WSi_2
1087	W	WSi_2
1100	W or WSi_2	WSi_2
1120	WSi_2	WSi_2
1180	WSi_2	WSi_2

The growth of WSi_2-layer with respect to time followed to the well-known parabolic relationship, and the activation energy for the growth was 22 kcal/mole (8). This indicates that WSi_2-layer growth is controlled by a solid-state diffusion mechanism.

Epitaxial growth of WSi_2 *on* Si *substrates.*—At higher deposition temperatures, orientation of the grown silicide layers were found by reflection electron diffraction analysis. Figure 3 shows the electron micrograph of the grown layer on the (110) Si surface at 1200°C. One of electron diffraction patterns showing the WSi_2 (110) plane parallel to the Si (110) substrate plane are shown and analyzed in Fig. 4. Patterns for WSi_2 crystal grown on Si (111) and Si (100) planes are shown in Fig. 5 and 6. The extra spots in the patterns which are not explained as due to the orientated WSi_2 crystals probably come from multiple twins in the WSi_2 crystals or other tungsten silicides on the surface.

Epitaxial Si *growth on the grown* WSi_2*-layer on* Si. —Silicon was deposited on the epitaxially grown WSi_2-layer by the thermal decomposition of monosilane (SiH_4). The epitaxial growth of silicon was achieved at 1100°-1150°C with a mole ratio of SiH_4/H_2 of 0.0001-0.001.

Figure 7 shows the reflection electron diffraction pattern and the replica electron micrograph of the epitaxially grown Si-layer on the WSi_2-layer which has

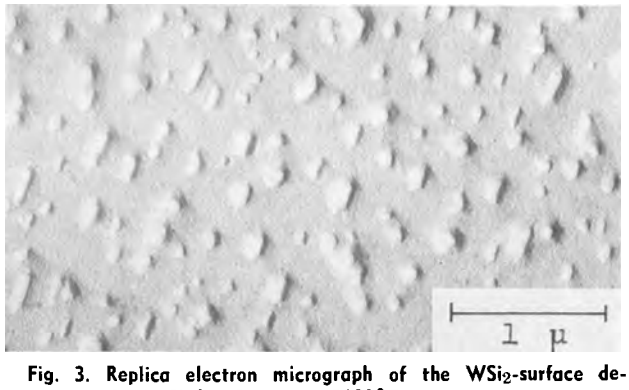

Fig. 3. Replica electron micrograph of the WSi_2-surface deposited on the (110) Si substrate at 1200°C.

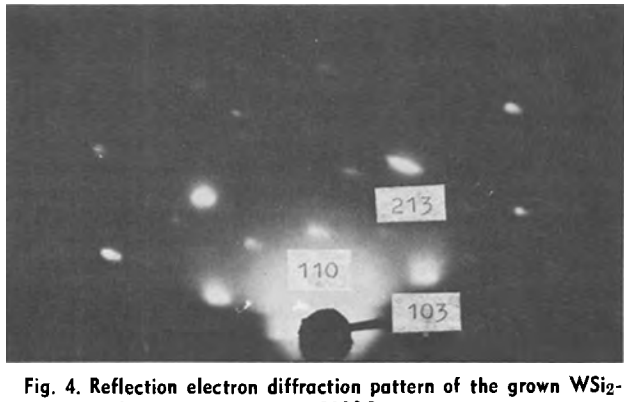

Fig. 4. Reflection electron diffraction pattern of the grown WSi_2-layer on the Si (110) substrate at 1200°C.

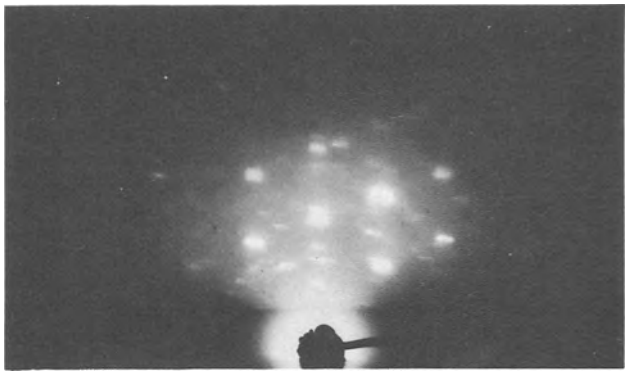

Fig. 5. Reflection electron diffraction pattern of the grown WSi_2-layer on the Si (111) substrate at 1200°C. WSi_2(101) is parallel to Si (111).

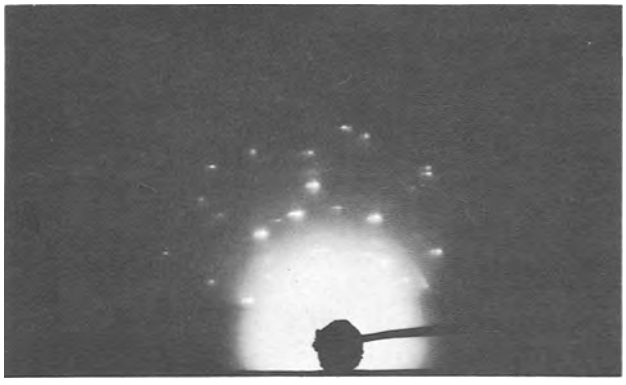

Fig. 6. Reflection electron diffraction pattern of the grown WSi_2-layer on the Si (100) substrate at 1200°C. WSi_2 orientation can not be determined.

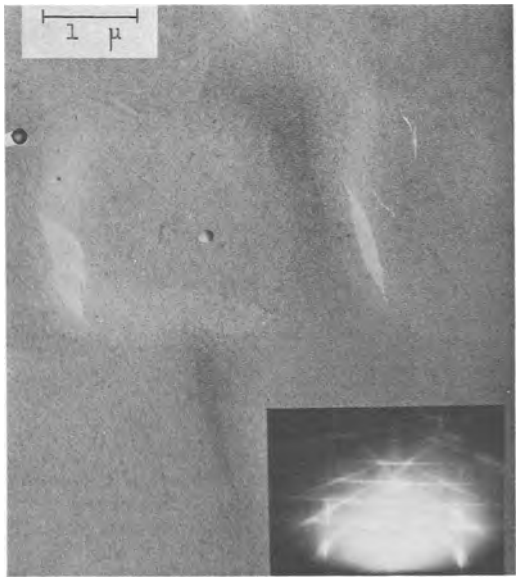

Fig. 7. Replica electron micrograph and reflection electron diffraction pattern of epitaxially grown Si-layer on the WSi_2-layer which has been grown on the Si (110) substrate.

been epitaxially grown on the (110) Si substrate. The Kikuchi lines appear clearly in the diffraction pattern.

On measurement of tungsten silicide and n-type Si barriers, aluminum films of approximately 1000Å were evaporated in a vacuum on the WSi_2-layers. When the WSi_2-layers are fragmentary, Al films become ohmic contacts to the substrate. The WSi_2-layer between the thin deposited Si-layer and the substrate was confirmed by x-ray diffraction analysis and the existence of a Schottky-type metal-semiconductor barrier (9). The epitaxy of the second Si-layer may

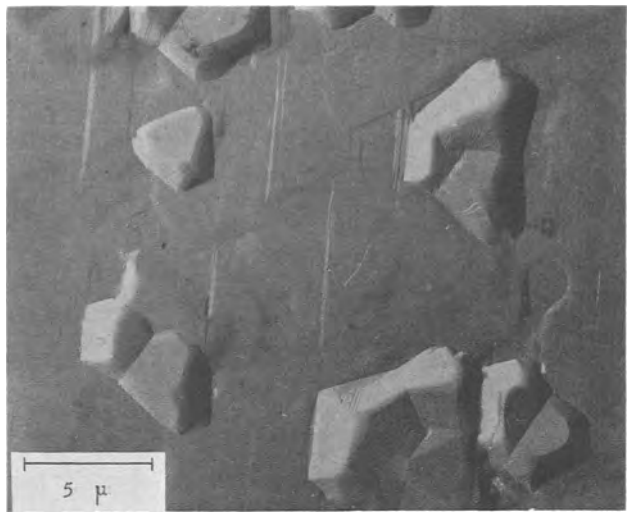

Fig. 8. Replica electron micrograph of epitaxially grown Si-layer on the WSi_2-layer which has been grown on the Si (111) substrate.

not raise direct nucleation on exposed Si substrate at holes in the WSi_2-layer.

The epitaxial relationships for the "three-layer" structures such as the above were found to be (110) Si // (110) WSi_2 // (110) Si substrate and (111) Si // (101) WSi_2 // (111) Si substrate from electron diffraction patterns and photomicrographs of the deposited Si-layer.

At higher temperature and the thicker deposited Si-layer the deposited silicon atoms diffuse into the orientated WSi_2 substrate during the deposition and so the WSi_2-layer deteriorates. On the other hand, lower temperatures generally increase the nucleation rate of the deposit and hence cause the growth of polycrystalline silicon.

The crystallographic texture of silicon was more evident in deposits on thicker ($>$ *ca.* 1μ) WSi_2-layers. Tripyramids on an epitaxial (111) Si-layer are shown in Fig. 8.

When the WSi_2-layer was very thin ($<$ *ca.* 0.1μ), however, single crystal silicon grew epitaxially on the WSi_2-layer as well as on the Si substrate, although the epitaxial Si-layer had many faults. The fact indicates that a continuous WSi_2-layer free of microholes cannot be formed when the WSi_2-layer is thin. These holes may become preferred or nonpreferred sites for the nucleation of deposited silicon close to the substrate silicon and act as the origin of many faults.

Brief Communication

Infrared Spectra of Silicon Nitride Deposited on Gallium Arsenide

R. S. Levitt[1] and W. K. Zwicker

Philips Laboratories, Briarcliff Manor, New York

Considerable interest exists (1) in using silicon nitride (Si_3N_4) films as a passivating or protective insulating coating for semiconductor surfaces and devices. We have been investigating methods of preparation of such films, using various techniques to characterize their properties. In this note we report on the infrared transmission spectra of a mechanically good Si_3N_4 film deposited on a gallium arsenide substrate which exhibits several characteristics of "pure" (nonoxygen contaminated) nitride.

The characteristic infrared absorption of Si_3N_4 occurs in the 8-14μ wavelength region (2, 3). In order to be able to record definitive spectra in this region it is best to use as a substrate a material which is both optically nonabsorbing and chemically stable. The most useful semiconductor, silicon, unfortunately fails the first criterion, having a complex spectrum of lattice absorptions throughout this region. Only with careful optical compensation can good spectra be recorded. (Germanium, while better satisfying the first criterion, its lattice absorption spectrum starts at 11.5μ, appears to be severely attacked during the deposition process.) Gallium arsenide (GaAs) more particularly high resistance GaAs, however, appears to be an excellent substrate material. The normalized infrared "transmission" spectrum through a 25 mm path length of high resistivity GaAs is shown in Fig. 1. Absorption due to free carriers is almost completely absent, and the transmittance is constant out to at least 12μ. The lattice band absorptions which occur toward longer wavelengths can be nicely balanced out by simply inserting a similar plate of equal path length in the reference beam of our double-beam, ratio-mode spectrometer, the details of which have been described elsewhere (4). The normalized transmittance (I/I_o) through the ~1 mm thick plate of high resistivity GaAs which was subsequently used as the substrate is also shown in Fig. 1.

The substrate was mechanically polished on all surfaces and carefully cleaned prior to deposition. The silicon nitride film was deposited pyrolytically by the reaction of silicon tetrachloride with ammonia. The apparatus for this deposition was very similar to that generally used for silicon epitaxial growth. The deposition was performed in a quartz reaction chamber. The sample was heated to 700°C by being placed on a quartz pedestal which enclosed an RF heated high-purity graphite core. The reaction was completed in only a few minutes resulting in a film ~1250Å thick, pale bluish-green in color.[2] The film appeared to be adherent, uniform, continuous, and nonporous over the entire exposed surface of the sample. It was subsequently found that the film was much more slowly attacked by concentrated hydrofluoric acid than the GaAs substrate. It was therefore necessary to remove by mechanical means the imperfect and nonuniform

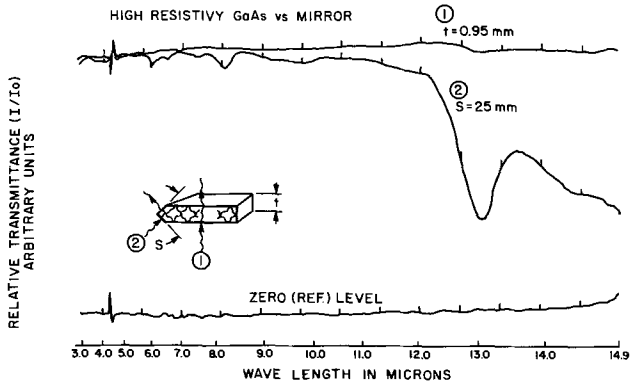

Fig. 1. Infrared optical absorption characteristics of high resistivity GaAs used as substrate material. Curve 1 refers to transmission transversely through a 0.95 mm plate. Curve 2 refers to transmission via internal reflections through the same plate but with a path length of 25 mm. In both cases reflection off of a highly polished mirror constituted the reference beam.

film from the surface which was in contact with the quartz pedestal. The refractive index of the film was determined by the liquid immersion method (5) and found to be 1.98 ± 0.02. The refractive index determined by the ratio of optical thickness to actual thickness (interferometrically determined) is in excellent agreement with this value.

The transmission spectrum of this film is shown in Fig. 2.[3] (With the double-beam, ratio-mode technique reflection and insertion losses are automatically compensated so that what is recorded is I/I_o *vs.* λ. This is shown schematically in the insert.) A second trace is also shown which was obtained by increasing the gain by a factor of 3 and suppressing the zero by a like amount. The characteristic heavy, broad absorption centered about 11μ is easily observed. At 11.35μ we determine the absorption coefficient to be 1.7×10^4 cm^{-1}. The asymmetry of the line and the suggestion of structure on both the short and long wavelength shoulders are to be noted.

Several observations lead us to conclude that this film is relatively uncontaminated by oxygen. The high value of refractive index we measure is characteristic of the "pure" silicon nitride. It is our experience that the refractive index is greatly influenced by the presence of oxygen, and that films with a refractive index as high as this are not easily prepared consistent with the difficulty of excluding oxygen from the system. Even the native oxide film on the substrate surface is a source of oxygen contamination. The use of GaAs

[2] The optical thickness of the film determined from its color is 2500Å (±10%). Optical thickness is the product of actual thickness and refractive index of the medium.

[3] Internal reflection spectra (6) could not be satisfactorily recorded due to the unexplained appearance after deposition of a large number of "scratches" and other imperfections on the GaAs surface under the Si_3N_4 film. These gave a large scattering loss at short wavelengths and severely distorted the internal reflection spectrum at longer wavelengths so as to make a quantitative interpretation impossible.

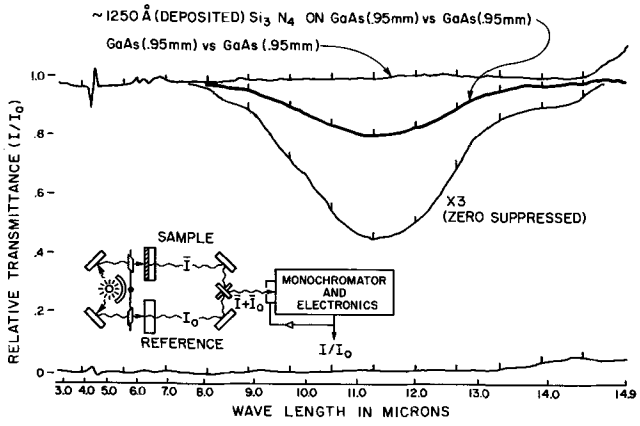

Fig. 2. Infrared transmission spectrum of vapor deposited silicon nitride film on GaAs substrate. The upper curve which represents 100% transmission, neglecting reflectance losses, was obtained prior to the deposition by placing the uncoated plate in the sample beam (I). For the lower curve the gain is increased 3-fold and the zero suppressed an equal amount. In all cases the reference beam (I_0) was transmitted through a GaAs plate of the same thickness. A schematic of the double-beam, ratio-mode, constant energy infrared prism spectrometer is shown in the insert.

should have eliminated this source. Further evidence is the lack of any observable SiO_2 structure in the transmission or internal reflection spectra. The high resistance to etching by HF is also typical of films with low oxygen contamination. Based on these optical and chemical properties of this film, we feel that Fig. 2 represents the characteristic spectrum of relatively uncontaminated, deposited silicon nitride.

Silver Oxide Electrode Processes

Thedford P. Dirkse, David DeWit, and Richard Shoemaker

Calvin College, Grand Rapids, Michigan

ABSTRACT

The cathodic and anodic overvoltages at a silver electrode were measured in a range of KOH concentrations of 20-45%. The values of these overvoltages undergo a change in 30-35% KOH. Similar changes or maxima or minima have been observed for other phenomena in KOH solutions, *e.g.*, double layer capacitance. An attempt to account for these changes is made in terms of ion-pair association in concentrations greater than 35% KOH. This association is due to insufficient solvent for the normal hydration of the ions.

Occasionally, in studying various phenomena taking place in alkaline solutions, it has been observed that these phenomena have a maximum or a minimum value at about 30-35% KOH. For example, the hydrogen overvoltage at a zinc electrode shows a minimum at about 10M in both KOH and NaOH (1); the parameters associated with the anodic passivation of zinc have a maximum at about 9M KOH (2); and the rate of decomposition of silver oxide dissolved in KOH solutions has a minimum at 7-9M KOH (3). Sometimes these maxima or minima can be explained in terms of the net effect of increasing OH^- ion concentration and increasing viscosity (or decreasing mobility) as the KOH or NaOH concentration increases. However, this does not offer a satisfactory explanation for all these phenomena. Consequently, the work reported here was undertaken with a twofold objective: (*a*) to see whether any silver electrode processes exhibited maxima or minima; and (*b*) to seek an explanation for any such phenomena. Similar work on the zinc electrode is also in progress at our Laboratory.

Experimental

The method selected to look for maxima and minima involved the use of the sine wave tester described by Kordesch and Marko (4). The IR-free overvoltage of the silver electrode was measured as the current was increased anodically and then as it was increased cathodically. The silver electrode was a piece of silver foil of which only a circular area of 0.32 cm^2 was exposed to the electrolyte. The counter electrode was a sintered Ag-Ag_2O plate, 4 x 5 cm; the reference electrode in most runs was $Hg/HgO/OH^-$. The OH^- concentration was the same in the cell as in the reference electrode.

Readings were taken at 1-min intervals during each run. A typical set of results is given on Fig. 1. The anodic run was carried out first. Then the electrode was allowed to remain on open circuit for about an hour before the cathodic run was made. During the open-circuit period some of the AgO may have decomposed to Ag_2O, and some Ag_2O may have dissolved off the electrode. Figure 2 shows the pattern of the open-circuit voltage after the anodic run was terminated. The voltage holds at the AgO/Ag_2O level for some time and then, because of decomposition of at least the surface layer of AgO, falls to the Ag_2O/Ag level. The cathodic run was begun only after the open-circuit voltage had fallen to that of the Ag_2O/Ag level.

Results and Discussion

In analyzing the results, emphasis was placed on changes rather than absolute values because the values obtained are, to some extent, time dependent. Consequently, only comparisons are significant. In the anodic process three values were compared: (*a*) the overvoltage at the Ag_2O/Ag level at 1.3 ma/cm^2; (*b*) the overvoltage at the AgO/Ag_2O level at 9.5 ma/cm^2; (*c*) the current density at which the voltage changes from the lower to the higher value. A summary of these three values is given on Fig. 3. Each point is the average of at least two runs. Of interest is the fact that the overvoltage at the Ag_2O/Ag level increases much more slowly beyond 30% KOH than in more dilute solutions; the overvoltage at the AgO/Ag_2O level has a maximum at about 35% KOH, and the current density at which the voltage transition occurs decreases rapidly beyond 30% KOH. Qualitatively, this last phenomenon can be accounted for by the increased viscosity of the KOH solutions as the concentration increases beyond 30%. This reduces the mobility of the OH^- ions markedly and the anodic processes do require these ions, *e.g.*

$$2Ag + 2\,OH^- \rightarrow Ag_2O + H_2O + 2e$$

Cathodically, the points of interest are: (*a*) the overvoltage at the Ag_2O/Ag level at 1.3 ma/cm^2, and (*b*) the current density at which the overvoltage decreases rapidly. A summary of the cathodic results is given on Fig. 4. Again the current density falls rapidly beyond 30% KOH while the overvoltage has a minimum at about 35% KOH. The current density

variation can perhaps be accounted for in terms of the increasing viscosity of the more concentrated KOH solutions, but this does not account for the overvoltage behavior. While the line drawn for overvoltages on Fig. 4 connects all the data points, this line does not necessarily give a complete description of the overvoltage behavior between 35 and 45% KOH. More data would be needed for this. But the data do show a minimum in the vicinity of 35% KOH.

Double Layer Capacitance.—The foregoing results suggested that with some of the silver electrode processes in alkaline solution, a change takes place as the concentration of the KOH solutions becomes about 35% or 8.5M. Consequently, still further work was attempted. Because these processes are associated with an electrode, it is possible that changes in the processes could be due to changes in the adsorption at the electrode-electrolyte interphase or in the composition of the double layer. One way to determine this is to measure the differential double layer capacity (dlc) of the electrode and note any changes in it. This measurement is made from the slope of the voltage-time curve during the charging of the double layer. This requires a constant current density, and here one encounters difficulty with the silver electrode. The current can be kept constant, but because the electrode is active, it undergoes a chemical change which changes the surface area and, consequently, the current density. Furthermore, the current may be used to bring about chemical change as well as to charge the double layer.

With these difficulties in mind, attempts were still made to get some sort of value for this double layer capacity. Because of this difficulty, only changes, and not absolute values, were considered significant. In the first attempt, the method of McMullen and Hackerman (5) was used. The counter electrode was a 3 x 6 cm platinized platinum screen. The reference electrode, kept in a separate compartment, was a partially charged cadmium electrode, and the silver electrode was either a 0.3 cm^2 circular area of a silver foil, or a half of a small bead of silver with about 0.1 cm^2 area exposed. The silver electrode was placed against the capillary from the reference electrode. The frequency of the square wave was 20 or 50 kHz.

In each run the silver electrode was cleaned by dipping it in dilute HNO_3, then in dilute NH_4OH, and then rinsing in deionized water. This electrode was allowed to stand in the cell for about an hour before any runs were made. During this time, the potential of the silver electrode became constant. The potential of the electrode was always allowed to reach a constant value before any measurements were made. The results were surprisingly reproducible. A representative set of results is given on Fig. 5. Similar results were obtained in 30, 35, and 45% KOH. The sudden drop in the "capacitance" is attributed to the formation of an oxide layer. (The terms capacitance or dlc refer to the calculated values. They are not intended to mean actual double layer capacitance values.)

For purposes of comparison, the dlc at 1.0-1.1v was considered to be that of the silver surface before any appreciable oxide formation took place. This value, it was found, does vary with KOH concentration, Fig. 6. The value is high at 35% KOH and decreases on either side of this concentration. No attempt will be made here to give a mechanistic interpretation of Fig. 6, but the results do show that some type of change occurs at the electrode surface at about 35% KOH. This same behavior was noted a year earlier by another student in connection with another research project.

In order to verify the relationships described above, the differential double layer capacity and the over-

voltage for the anodic process were measured using the single pulse technique described by Hoare (6). The silver electrode was a circular area, 0.32 cm^2, of a silver foil, the counter electrode was a commercial sintered AgO electrode, and the reference electrode was Hg/HgO having the same KOH concentration as that being used in the cell. All runs were made at room temperature and, unless otherwise noted, only anodic pulses were used. In one series of runs the electrode was treated anodically until its potential, compared to the reference electrode, was 0.55v, including IR drop. At this point the voltage was rising from that of the Ag_2O/Ag level to the AgO/Ag_2O level. By treating all the electrodes this way it was assumed that the surface condition and area would be fairly similar in all runs. The electrode was then given a single pulse and the voltage-time curve was photographed from an oscilloscope.

In another series of runs, the silver electrode was treated anodically for varying lengths of time before it was subjected to the single pulse. All overvoltages reported are corrected for IR drop.

Figure 7 shows a typical set of results for an electrode that was charged to 0.55v with respect to Hg/HgO before measurements were made. The calculated dlc does vary with the current density of the anodic pulse used, but appears to approach a constant value as the current density increases. A comparison of the values at two current densities is shown on Fig. 8. Again there is evidence of a maximum in these values for the Ag_2O electrode. Because of uncertainties with respect to the surface, however, this comparison is, at best, qualitative in nature.

That the nature of the surface has a definite bearing on the dlc is well known and is illustrated on Fig.

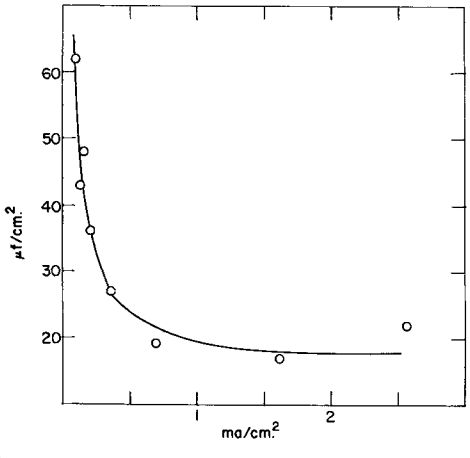

Fig. 7. Double layer capacitance calculated for silver electrode in 30% KOH at room temperature.

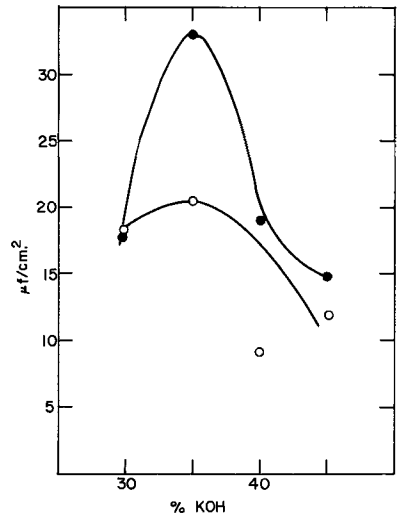

Fig. 8. Variation of dlc of an Ag_2O electrode with KOH concentration. ○ current density of 2 ma/cm^2; ● current density of 1 ma/cm^2.

9. Here the silver electrode was treated anodically for different lengths of time, or to different voltages with respect to the reference electrode. The higher the voltage reached, the more current has been passed, and the thicker the Ag_2O coating produced. The electrode was then subjected to an anodic pulse of 2 ma/cm^2 and the dlc was calculated from the voltage-time trace. The dlc decreases rapidly as the thickness of the Ag_2O layer increases and again appears to approach a limiting value. The overvoltage increases as the Ag_2O layer increases.

Exchange Current.—In the course of this work with the single pulse technique, the activation overvoltages were measured. These, however, could not be measured with a great degree of accuracy because of the uncertainty in estimating the IR drop. No Tafel slopes were drawn because the overvoltages used (< 40 mv) are not beyond the limits where the cathodic process can be neglected in the general current-overvoltage equation. Instead, since the overvoltages are small, the approximate form of the equation can be used

$$\frac{\eta}{i} = \frac{RT}{i_0 F}$$

A plot of overvoltage *vs.* current is given on Fig. 10. The slope of this line gives a value of 2 ma/cm^2 for

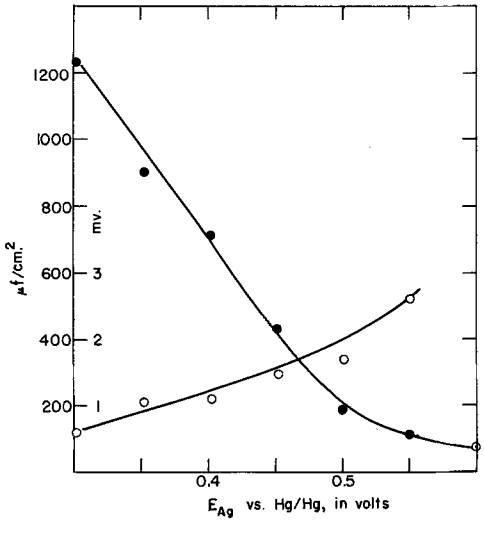

Fig. 9. Values for an Ag_2O electrode in 35% KOH as a function of the thickness of the Ag_2O layer. ○ overvoltage; ● dlc.

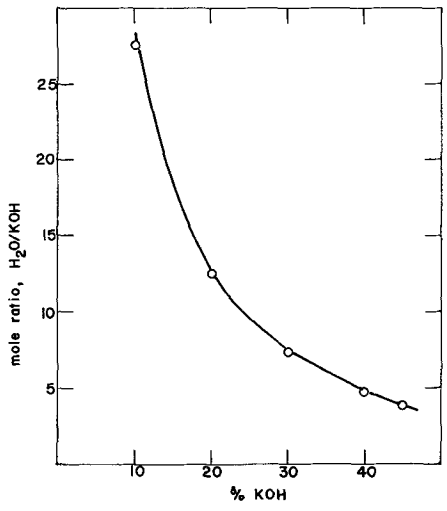

Fig. 11. Mole ratio of H_2O/KOH in aqueous KOH solutions

i_O. Others (7) have determined i_O for the cathodic process and obtained a value of 50 ma/cm². Considering the difficulties involved in either case, the agreement is reasonably good. In our work we made only a few cathodic pulse measurements, but they are unsuitable for calculating i_O.

All these results show that several values associated with the silver electrode processes have a maximum, a minimum, or undergo some alteration at about 35% KOH. Probably the most significant of these is the differential double layer capacity. It too shows a maximum at this KOH concentration both for a silver electrode and an electrode having a layer of Ag_2O. Regardless of the precise physical significance of these results, they suggest some change in electrode behavior and/or double layer composition. It is possible that this factor may account for the maxima and minima that cannot be explained in terms of the trade-off between increasing OH^- ion concentration and decreased mobility as the KOH concentration increases.

Effect of Electrolyte.—A possible interpretation of the variations noted in Fig. 6 and 8 follows. In a water solution, water molecules cover the surface of the electrode. As the KOH concentration increases, these are replaced by OH^- ions which are attracted to the electrode (positive charge) and increase the dlc. [At the potentials used here the silver electrode is almost 1v anodic to its potential of zero charge (8).] The OH^- and the K^+ ions are hydrated. It has been estimated that the K^+ ions have 4 water molecules associated with them (9). The OH^- ions may have 1 or 2 water molecules of hydration. Thus, hydration of the ions requires about 5 or 6 moles of water per mole of KOH. This is the ratio that prevails in about a 35% KOH solution, Fig. 11. Therefore, in KOH solutions more concentrated than 35% there is insufficient water for normal hydration of ions. This leads to a competition for water molecules and perhaps the OH^- ions at the electrode surface are, in effect, neutralized by ion-pair formation with K^+ ions. This could occur by means of bridging water molecules. As a result, the dlc decreases again. The possibility of ion pair formation in these solutions has also been suggested recently by Lander (10).

Electrode processes.—If this explanation is correct, then it should also be applicable to the overvoltage behavior observed in this work. Anodically the overvoltage increases rapidly at about 30-35% KOH, Fig. 3. A possible explanation is that the OH^- ions needed for the anodic process are then more closely bound to the K^+ ions and hence more energy is needed to pry these OH^- ions away.

An alternate explanation assumes that these silver electrode reactions proceed by way of a species in solution (11, 12), *e.g.*,

$$Ag(s) \rightarrow Ag^+_{sol'n} + e \quad [1]$$

$$Ag^+_{sol'n} + OH^- \rightarrow \tfrac{1}{2}Ag_2O(s) + \tfrac{1}{2}H_2O \quad [2]$$

In the anodic process the OH^- ions are needed to react with the Ag^+ ions in solution. However, the overvoltage then is that of reaction [1] and would likely be due to concentration polarization of the Ag^+ ions in solution. An increase of 20 mv in the overvoltage would correspond to a Ag^+ ion concentration of about 2M. This seems inordinately high in view of the relative insolubility of Ag_2O even though this would be but a local interfacial concentration. The OH^- concentration in this area would then be of the order of 10^{-4}M.

Cathodically, there is a lowering of the overvoltage in 35% KOH, Fig. 4, *i.e.*, the process takes place more easily in this concentration of KOH. This is consistent with a proposed mechanism suggested earlier (13). Hydrated K^+ ions are involved in this process. As the concentration of these ions increases, the process proceeds more easily (overvoltage decreases). But beyond 35% KOH, the incipient ion-pair formation changes this relationship and the OH^- ions in solution now also compete for the water of hydration of the K^+ ions. As a result, the overvoltage for the reduction of silver oxide increases.

A somewhat similar explanation has been offered for the minimum in the hydrogen overvoltage curve at a zinc electrode (1). It was suggested that beyond about 35% KOH there is a decrease in cation hydration in the double layer. These less-hydrated cations then have a greater screening effect on the electrical force lines, making it more difficult for the water molecules to discharge.

It is also possible to assume that the cathodic process proceeds by way of a species in solution, *e.g.*,

$$Ag_2O(s) + 2\,OH^- + H_2O \rightarrow 2Ag(OH)_{2(sol'n)}^- \quad [3]$$

$$2Ag(OH)_{2(sol'n)}^- + 2e \rightarrow 2Ag + 4\,OH^- \quad [4]$$

Again the overvoltage and its changes would likely be due to the concentration of $Ag(OH)_2^-$ and this would be governed by the availability of both H_2O and OH^- ions to dissolve the Ag_2O. However, other evidence suggests that it is more likely that the cathodic process takes place on the electrode (13).

The dlc data on Fig. 5 have a close resemblance to similar data obtained for the cadmium electrode (14). Superimposed on Fig. 5 is a part of the voltage-cur-

rent trace obtained by using a sweeping voltage technique at a rate of 20 mv/sec. The current becomes anodic at potentials cathodic to the $Ag_2O/Ag/OH^-$ electrode in that solution. The beginning of this anodic current coincides with the slight rise in the dlc. It may be associated with the formation of a strongly adsorbed layer of OH^- ions or of OH radicals (14), but not with the formation of Ag_2O (15). As the potential increases anodically, the anodic current also increases, corresponding to the formation and growth of the Ag_2O layer. The dlc then also decreases because this film or layer of Ag_2O introduces a parallel capacitance at the electrode-electrolyte interphase (14).

If this model has any validity, then it should also be applicable to other electrode processes occurring in KOH solutions. Further work is now in progress to make this test of the model.

Low-Temperature Intermediate pH Fuel Cell Electrolytes

M. Beltzer

Esso Research and Engineering Company, Linden, New Jersey

ABSTRACT

Expressions are developed to compare the efficiency of buffers with strong acids or bases in minimizing concentration polarization. The effect of electrode structure on electrolyte efficiency is also considered. The expressions are tested experimentally. In certain cases, practical current densities can be obtained with buffer electrolytes at sufficiently low concentration polarizations. It is possible therefore to supplant, *e.g.*, strong acids in some fuel cell systems. Unlike acid electrolytes, the performance of buffers is markedly dependent on electrode structure.

Sulfuric and phosphoric acid electrolytes are frequently used in fuel cells because these systems reject carbon dioxide, have high ionic conductivity, minimize concentration polarization, and allow attainment of high activity levels. The corrosiveness of these acids, however, restricts choice of electrode catalysts to noble metals. Auxiliary cell components must also be composed of noble metals or expensive nonnoble corrosion resistant metals such as tantalum. The use of noble metal catalysts and costly cell components constitutes the major obstacle to the development of a practical economical fuel cell.

One approach to this problem would be to investigate inexpensive alloys which would be acid resistant and possibly catalytic. An alternative approach, which will be the theme of this article, is the use of less corrosive electrolytes to replace sulfuric acid in low-temperature fuel cells.

Acids can be conveniently grouped into three types according to how they partake in the corrosion reaction (1). There are strong acids such as sulfuric and hydrochloric acids, weak acids such as acetic acid, and oxidizing acids such as nitric acid. Excluding oxidizing acids, hydrogen ion is the principal and most universal factor in corrosion phenomenon. Alkaline electrolytes are, therefore, not nearly as corrosive as acids. When corrosion does occur in alkaline electrolytes, it is usually the result of particular reactions such as formation of anionic metal complexes. Although it is difficult to generalize about the corrosiveness as a function of electrolyte *p*H, neutral and alkaline *p*H electrolytes are normally not as corrosive as acids (1,2). The requirement that the electrolyte reject carbon dioxide sets an upper limit to the alkalinity. Accordingly, a study was undertaken to determine if electrolytes in the neutral to weakly alkaline *p*H range would be suitable as fuel cell electrolytes. The potentials of the electrodes are *p*H dependent which means that any electrolyte used in a fuel cell must have buffering action.

Invariance Requirement Sets Upper pH Limit of Buffer System

The necessity for electrolyte invariance sets the upper limit to the *p*H range and, therefore, the buffer systems that can be used. Whether a buffer system or electrolyte in general is carbon dioxide rejecting or not depends on the extent of the reaction

$$CO_2 + H_2O + 2H_{N-1}A^{-(M+1)} \rightarrow 2H_NA^{-M} + CO_3^{-2} \quad [1]$$

where $H_{N-1}A^{-(M+1)}$ is an anionic basic buffer component and H_NA^{-M} the anionic acidic buffer component. Anionic buffer components were chosen for illustration simply because the components of the so-called practical buffer systems are anions, *e.g.*, as in phosphate and carbonate buffers. All charge types of course are possible.

The equilibrium constant for the reaction with carbon dioxide is

(III)
$$\begin{cases} H_{N-1}A^{-(M+1)}{}_{\{\text{bulk solution}\}} \xrightarrow[\text{Diffusion, Migration, Convection}]{\text{Slow}} H_{N-1}A^{-(M+1)}\ (\text{electrode}) + H_2O \\ H_NA^{-M}{}_{(\text{electrode})} \xrightarrow[\text{Diffusion,Migration}]{\text{Slow}} H_NA^{-M}\{\text{bulk solution}\} \end{cases}$$

$$K = \frac{[H_NA^{-M_2}]^2[CO_3^{-2}]}{[H_{N-1}A^{-(M+1)}]^2[CO_2]} = \frac{K_1K_2}{K_A^2} \qquad [2]$$

where K_1 and K_2 are the first and second ionization constants of carbonic acid, and K_A the ionization constant of the buffer acid (H_NA^{-M}). It can readily be shown that carbonate formation becomes appreciable when K_A is of the order of 10^{-10} for finite carbon dioxide partial pressures. Extensive formation of carbonate means that the buffer has been quantitatively converted to its acid form and therefore no longer can function as a buffer.

The resultant electrolyte reacts further with carbon dioxide as shown below

$$H_2O + CO_2 + CO_3^{-2} \rightarrow 2\ HCO_3^{-1} \qquad [3]$$

The equilibrium constant for the above reaction is K_1/K_2. This is also the equilibrium constant when the buffer system is a carbonate-bicarbonate buffer, *i.e.*, $H_NA^{-M} = HCO_3^{-1}$, $H_{N-1}A^{-(M+1)} = CO_3^{-2}$ and $K_A = K_2$. It has been shown that at the contemplated fuel cell conditions, in particular the operating temperatures and carbon dioxide partial pressures, the equilibrated carbonate-bicarbonate mixture will be constituted so that it is capable of functioning as a buffer (3, 4). Complete conversion of carbonate to bicarbonate would result in a solution of low buffering capacity. If this occurred, then the upper pH limit of suitable fuel cell electrolyte would be less than pK_2; *i.e.*, only a buffer whose pK_A was one to two units lower than pK_2 would be suitable. The carbonate-bicarbonate carbon dioxide equilibrated electrolyte is a buffer system because conversion is not complete. Consequently, no buffer system whose acid component is a weaker acid than bicarbonate ion can be an invariant electrolyte. Thus, the upper pH limit for electrolyte invariance is approximately equal to pK_2.

Theoretical

Buffers are the only possible substitute electrolytes for fuel cells if it is desirable not to use either strong acids or bases. It is therefore of interest to compare the efficiency of buffers with that of acids and bases in minimizing electrolyte concentration polarization. It is also of interest to determine the effect of electrode structure on the ability of the buffers to support practical current densities. To this end it was necessary to develop the expressions for concentration polarizations incurred with buffers as a function of their mass transfer characteristics.

Consider a fuel cell operating in a neutral Na_2SO_4 electrolyte. When current is drawn, anodically produced hydrogen ions cause a precipitous pH decrease at the anode. At the cathode a large pH increase occurs simultaneously due to hydroxide ion production. To prevent the occurrence of large pH changes at the electrodes, agents are needed to remove anodically produced hydrogen ion and cathodically produced hydroxide ion. These agents are the basic and acidic components of what constitutes a buffer system.

The sequence of reactions occurring at an anode of fuel cell employing a buffer electrolyte is given below.

(I) $$\tfrac{1}{2}\ H_2 + H_2O \xrightarrow[\text{Discharge}]{\text{Anodic}} H_3O^+ + E^-$$

(II) $$H_{N-1}A^{-(M+1)}{}_{(\text{electrode})} + H_3O^+{}_{(\text{electrode})} \xrightarrow[\text{Recombination}]{\text{Fast}} H_NA^{-M}\ (\text{electrode})$$

Hydrogen ions produced by the anodic current are removed by reaction with the basic buffer component. It is well known that the recombination steps are very rapid and many have recently been measured (5). The rate-limiting steps are replenishment of the basic component in the unstirred layer from the bulk electrolyte by diffusion and migration, and mass transfer of the acidic buffer component out of this region.

If a linear concentration gradient for each species is assumed to exist across the boundary layer, and if Fick's law is applicable to each diffusing species, the steady-state concentration of the buffer components at the electrode electrolyte boundary can be calculated. In turn, the change in pH at the boundary and, therefore, the concentration polarization as a function of the current density, can be calculated.

At steady state, consumption of the basic component is equal to the rate at which it is replaced by mass transfer.

$$\frac{I}{\mathbf{F}} = D_B\frac{(C^o_B - C_B)}{\delta} + t_B\frac{I}{\mathbf{F}} \qquad [4]$$

Here C^o_B is the bulk concentration of the basic component in eq/cm^3, C_B the concentration at the electrode due to a current density I (amp/cm^2), t_B and D_B the transference number and diffusion coefficient, respectively, of the basic component, and δ the boundary layer thickness. Rearrangement of the above expression gives the limiting anodic current density I_{LA}

$$\frac{C_B}{C^o_B} = 1 - \frac{I(1-t_B)\delta}{C^o_B D_B \mathbf{F}} = 1 - \frac{I}{I_{LA}};$$

$$I_{LA} = \frac{D_B \mathbf{F} C^o_B}{(1-t_B)\delta} \qquad [5]$$

By similar reasoning, the concentration at steady state of the acidic component at the electrode can be calculated where the

$$\frac{I(1+t_A)}{\mathbf{F}} = \frac{D_A(C_A - C^o_A)}{\delta} \qquad [6]$$

subscripts refer to the acid component and its parameters. The concentration of the acidic buffer component may also be cast in terms of a limiting current by appropriate rearrangement.

$$\frac{C_A}{C^o_A} = 1 + \frac{I(1+t_A)\delta}{C^o_A D_A \mathbf{F}} = 1 + \frac{I}{I_{LC}} \qquad [7]$$

That $I_{LC} = D_AC^o_A\mathbf{F}/(1+t_A)\delta$ is the limiting cathodic current density will be shown when considering concentration polarization at the cathode.

When the relative concentrations of the basic and acid components are such that the electrolyte acts as a buffer, the pH of the solution may be expressed by the Henderson-Hasselbach approximation

$$pH = pK_A + \log\frac{C^o_B}{C^o_A}$$

The pH change at the electrode-electrolyte boundary may be calculated by appropriate substitution into this equation. Thus, the pH change due to current at the anode is

$$\Delta pH_{Anode} = \log \frac{[1 - I/I_{LA}]}{[1 + I/I_{LC}]} \quad [8]$$

The anodic concentration polarization is simply

$$\eta_{Anode} = -2.3 \frac{RT}{F} (\Delta pH) \quad [9]$$

At the cathode, the hydroxide ions produced are removed by reaction with the acidic buffer component. Here too, mass transfer of the buffer components into and out of the boundary layer is rate determining.

The concentration of the acidic buffer component at the electrode-electrolyte boundary can be calculated in a similar manner as shown at the anode, where I_{LC} is the limiting cathodic current density.

$$\frac{I(1 + t_A)}{F} = \frac{D_A(C^o_A - C_A)}{\delta} \quad [10]$$

$$\frac{C_A}{C^o_A} = 1 - \frac{I}{I_{LC}} \quad [11]$$

The basic buffer component concentration at the electrode is similarly calculated.

$$\frac{I}{F} = \frac{D_B(C_B - C^o_B)}{\delta} + t_B \frac{I}{F} \quad [12]$$

$$\frac{C_B}{C^o_B} = 1 + \frac{I(1 - t_B)_\delta}{D_B F C^o_B} = 1 + \frac{I}{I_{LA}} \quad [13]$$

The pH change at the cathode due to current flow is

$$\Delta pH_{cathode} = \log \frac{\left[1 + \frac{I}{I_{LA}}\right]}{\left[1 - \frac{I}{I_{LC}}\right]} \quad [14]$$

and the polarization,

$$\eta_{cathode} = 2.3 \frac{RT}{F} [\Delta pH \text{ cathode}] \quad [15]$$

Comparison of buffers with strong acids and bases.— Williams and Gregory (6) have shown that, in strong acids, limiting current densities are encountered at the cathode. Cathodic current decreases the hydrogen ion concentration at this electrode and since the concentration cannot drop below zero, a limiting current will be attained. The limiting current expressed in amp/cm^2 is given by the expression

$$I_{LC(acid)} = \frac{D_{H+} C^o_{H+} F}{(1 - t_{H+})\delta} \quad [16]$$

where t_{H+}, C^o_{H+}, and D^o_{H+} are the transport number, bulk concentration, and diffusion coefficient of hydrogen ion.

In strong base, hydroxide ion is decreased at the electrode-electrolyte boundary of the anode so that it is at this electrode that limiting currents are attained. The limiting current in base is given by the expression

$$I_{LA(base)} = \frac{D_{OH-} C^o_{OH-} F}{(1 - t_{OH-})\delta} \quad [17]$$

where t_{OH-}, C^o_{OH-}, and D_{OH-} are the equivalent parameters for a strong base.

As shown previously, buffers exhibit limiting currents at both electrodes due to decrease of the basic component at the anode and of the acidic component at the cathode. In addition to exhibiting limiting currents at both electrodes, the limiting currents in buffer are considerably less than those attained in acid and base. The limiting current ratios are given below

$$\frac{I_{LC(acid)}}{I_{LC(buffer)}} = \left(\frac{D_{H+}}{D_A}\right)\left(\frac{C^o_{H+}}{C^o_A}\right)\left[\frac{(1 + t_A)}{(1 - t_{H+})}\right] \quad [18]$$

$$\frac{I_{LA(base)}}{I_{LA(buffer)}} = \left(\frac{D_{OH-}}{D_B}\right)\left(\frac{C^o_{OH-}}{C^o_B}\right)\left[\frac{(1 - t_B)}{(1 - t_{OH-})}\right] \quad [19]$$

A sample calculation using reasonably accurate values for diffusion coefficients and transference numbers would show that the limiting current densities attainable in acids or bases are much larger than what can be attained in buffer. Using the literature values given below, plus some reasonable estimates where data are not available, shows that the limiting cathodic current density in acid is more than 40 times greater than that in buffer

$$D_{HCl} \simeq 4 \times 10^{-5} \text{ cm}^2 \text{ sec}^{-1} \quad 7$$

$$t_{H+} \simeq 0.8 \quad 8$$

$$D_{NaH_2PO_4} \simeq 0.5 \times 10^{-5} \text{ cm}^2/\text{sec} \quad 8$$

$$t_{H_2PO_4} \simeq 0.1 \text{ (estimated)}$$

$$\frac{I_{LC(acid)}}{I_{LC(buffer)}} \simeq 44, \text{ for } C^o_{H+} = C^o_A$$

The abnormally high ionic diffusivities and mobilities of hydrogen and hydroxide ion allow much greater limiting currents to be reached. This does not mean that buffers are unsuitable. The limiting current in 3M strong acid for example assuming a boundary layer thickness of 10^{-2} cm is about 6000 ma/cm^2. This means that in the practical current density range, *i.e.*, 100-400 ma/cm^2, concentration polarization in acid would not be discernible. In buffer, the limiting current density would be about 120 ma/cm^2 which is in the range of practical fuel cell loads.

It can be shown that the concentration polarization with a buffer electrolyte at less than the limiting current densities is much greater than what would be incurred using an acidic or basic electrolyte, at identical current densities. A comparison can be readily made by using the expanded form of logarithm in Eq. [8] or [14] and neglecting the higher order terms.

$$\underset{(buffer)}{\Delta pH_{anode}} \simeq -0.43I\left[\frac{1}{I_{LA(buffer)}} + \frac{1}{I_{LC(buffer)}}\right] \simeq -\underset{(buffer)}{\Delta pH_{cathode}} \quad [20]$$

Assuming that $I_{LA(buffer)} \simeq I_{LC(buffer)}$

$$\Delta pH_{anode} \simeq -2(0.43)\frac{I}{I_{LA(buffer)}} \quad [21]$$

The following expression is obtained

$$\underset{(base)}{\Delta pH_{anode}} \simeq -0.43\frac{I}{I_{LA(base)}} \simeq \frac{-0.43(I)(1 - t_{OH-})\delta}{D_{OH-} C^o_{OH-} F} \quad [22]$$

by expanding the logarithm of the expression for concentration polarization in strong base (6).

Comparing concentration polarization at the anode for example in buffer and in base at the same current density

$$\frac{\underset{(buffer)}{\Delta pH_{anode}}}{\underset{(base)}{\Delta pH_{anode}}} = 2\frac{I_{LA(base)}}{I_{LA(buffer)}} = 2\frac{(C^o_{OH-})D_{OH-}(1 - t_B)}{(C^o_B)D_B(1 - t_{OH-})} \quad [23]$$

As the pH changes vary inversely with the limiting current density, it is obvious that concentration polarization in buffers will be considerably greater than that incurred in acids or bases.

If we consider the case of a buffer system equimolar in each component having a stoichiometric concen-

tration equal to the hydroxide ion concentration, the ratio of the pH changes becomes

$$(4)\quad \frac{D_{OH^-}\,(1-t_B)}{D_B\,(1-t_{OH^-})} = \frac{\eta\text{anode(buffer)}}{\eta\text{anode(base)}} \qquad [24]$$

The factor 4 reflects the fact that the maximum buffering capacity of a buffer solution, one containing equimolar amounts of each component, is only ¼ that of a solution of strong base or acid having a hydroxide or hydrogen ion concentration equal to the stoichiometric buffer concentration.[1] Thus, completely exclusive of mass transfer considerations, the lower inherent buffering capacity of buffers means that greater pH changes would occur with this electrolyte than with strong acids or bases. It is the cooperative coupling of the greater inherent buffer capacities of strong acids and bases with the abnormally high mobilities of hydrogen and hydroxide ion that make these markedly superior electrolytes in minimizing concentration polarization.

A sample calculation shows that if an electrode exhibited a concentration polarization of, *e.g.*, 50 mv in buffer, the same electrode in base would be polarized about 1 mv.

Using $t_{OH^-} = 0.74$ and $D_{KOH} = 2.2 \times 10^{-5}$ cm^2 sec^{-1} and the appropriate values for the buffer system

$$\frac{\Delta pH_{\substack{\text{anode}\\(\text{buffer})}}}{\Delta pH_{\substack{\text{anode}\\(\text{base})}}} = 4\,\frac{(2.2)\times 10^{-5}\,(1-0.3)}{(0.5)\times 10^{-5}\,(1-0.74)}$$

$$\simeq 50 = \frac{\eta\text{anode(buffer)}}{\eta\text{anode(base)}}$$

Tests were conducted on platinum electrodes using hydrogen as the test reactant because of its negligible activation polarization. Galvanostatic performance curves were obtained using a Kordesch-Marko bridge (9). Consequently, the measured polarization under load is strictly concentration polarization. Because of the necessity for maintaining an interface to insure an unimpaired supply of hydrogen, it is not possible to use the idealized electrode model of the calculation. This structure can be approached by using an extremely thin porous electrode such as that manufactured by the American Cyanamid Company (10). It has been shown that practically all of the electrode catalyst surface area is available for reaction. As these electrodes are too porous to maintain a stable interface, it was necessary to clad the electrodes. The cladding material was a Gelman Acropor Battery Separator (11) which has microscopic porosity ($\sim 0.5\mu$).

A material of microscopic porosity rather than submicroscopic porosity was chosen to simulate more closely, the situation where the electrode is wetted by a stagnant film that is in contact with a bulk electrolyte, *i.e.*, the Nernst boundary layer conditions.

Comparison of the hydrogen performances in phosphate and carbonate buffers, with that in sulfuric acid and potassium hydroxide, Fig. 1 shows that the results are in good agreement with what Eq. [18], [19], and [25] predicted.

It is readily seen that there is no sensible polarization in 3M KOH or 30% H_2SO_4 at 100 ma/cm^2, for example, as opposed to 40 mv in buffer. The fact that no polarization occurs in base or acid is taken to mean that these electrode structures are not hydrogen limited and that the polarization in the buffer systems is due to ionic mass transfer limitations. Although finite polarizations occur with buffers, practical current densities can be attained.

Effect of electrode structure.—It is of interest to determine if buffers are suitable electrolytes for the electrode structures commonly employed in fuel cells.

[1] Buffer capacity is defined as the number equivalents of strong base or acid per liter required to produce a unit change of pH in the solution.

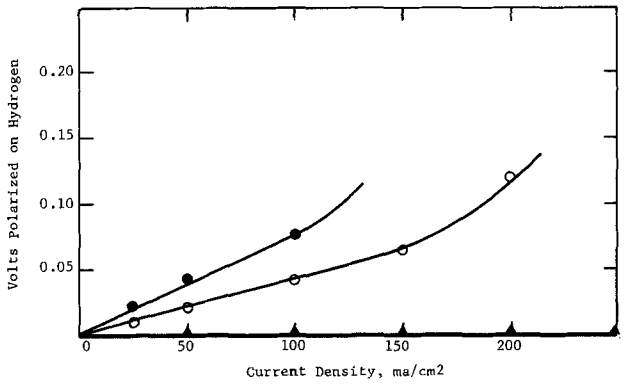

Fig. 1. Unlike strong acids and bases, buffers exhibit finite concentration polarizations at practical current densities. Temperature 80°C, Electrode type AA-1 Cyanamid clad with Gelman Acropor membrane. ● 1M each KH_2PO_4, K_2HPO_4; ○ 2M each RbH_2PO_4, Rb_2HPO_4; ▲ 30% H_2SO_4 or 3M KOH.

For example, fuel cell electrodes using gaseous reactants cannot have the active catalytic surface in direct contact with the bulk electrolyte and attain adequate performance levels. If the dissolved gas molecules are forced to diffuse through a thick liquid interface to reach the catalyst surface, the supply of reactant to the electrode will be insufficient to maintain the electrochemical reaction, and thereby become rate controlling. Only if very thin electrolyte films wet the catalyst surface can this rate limitation be removed, *i.e.*, the electrode must be interface maintaining. It will be shown, however, that with buffer electrolytes, practical current densities cannot be attained at the usual interface maintaining electrode structures without incurring large ionic concentration polarizations.

An example of an interface maintaining a structure is the membrane electrode (12). This generally consists of thin electrode bonded to a membrane. The membrane is a thin sheet or film having submicroscopic pores and is usually organic in nature. The electrode cladding the membrane may be powdered metal directly bonded, or may consist of catalyst and binder spread uniformly on to a metal gauze which in turn is bonded to the membrane.

As used in most applications, the uncatalyzed side of the membrane contacts the bulk electrolyte. Electrolyte is imbibed by the membrane although bulk flow through the membrane does not occur because it is a structure of submicroscopic porosity. The electrolyte layer on the catalyzed side of the membrane is regulated by the properties of the membrane as well as being stabilized at the junction between a fine pore layer and a coarse pore layer of the catalyst. Teflon may also be mixed with the catalyst to regulate the gas-electrolyte interface further.

In the following discussion, it will be assumed that the membrane electrode is planar, that all fluxes are normal to the electrode, and that the steady state can be attained. A membrane electrode as now constituted can be considered to consist of three barriers to ion transport either toward or away from the electrode surface. The sequence of these barriers considering ionic mass transfer from the bulk of solution through the membrane to the electrode surface are as follows; the stagnant electrolyte film on the side of the membrane contacting the electrolyte, the membrane, and the electrolyte film wetting the catalyst.

When a steady-state current is attained, the value of each ionic flux across all planes parallel to the interfaces is constant. It is assumed that a linear concentration gradient exists across each barrier. In addition, the membrane is assumed to be uncharged so that the distribution coefficient of both electrolytes and nonelectrolytes is unity. This coefficient is defined as the ratio of the concentration of a species in the membrane to that in the external solution at equilibrium.

The concentration of the buffer components at the electrode electrolyte interface is calculated from the flux equations. Thus for a membrane electrode functioning as an anode, the interfacial concentration of the basic component C'''_B is

$$C'''_B = C^o_B - \frac{I}{\mathbf{F}}\left[\frac{(1-t_{B1})\delta_1}{D_{B1}} + \frac{(1-t_{B2})\delta_2}{D_{B2}} + \frac{(1-t_{B3})\delta_3}{D_{B3}}\right] \quad [25]$$

Where D_{B1}, D_{B2}, and D_{B3}, are the diffusion coefficients of the basic buffer component in the stagnant electrolyte film, the membrane and the electrolyte film wetting the electrode, respectively. The corresponding transport numbers in each phase are t_{B1}, t_{B2}, and t_{B3}; δ_1, etc., the corresponding diffusion barrier thicknesses and C^o_B has its previous meaning.

This may be generalized for both components in an n-barrier system so that

$$C_B{}^{n'} = C^o_B - \frac{I}{\mathbf{F}}\sum_{i=1}^{n}\frac{(1-t_{Bi})\delta i}{D_{Bi}}, \text{ and}$$

$$C_A{}^{n'} = C^o_A + \frac{I}{\mathbf{F}}\sum_{i=1}^{n}\frac{(1+t_{Ai})\delta i}{D_{Ai}} \quad [26]$$

The concentration polarization at the anode is given by the equation

$$\eta\text{anode} = \frac{2.3\,RT}{\mathbf{F}}\log\left[\frac{1-\frac{I}{C^o_B\mathbf{F}}\sum_{i=1}^{n}\frac{(1-t_{Bi})\delta i}{D_{Bi}}}{1+\frac{I}{C^o_A\mathbf{F}}\sum_{i=1}^{n}\frac{(1+t_{Ai})\delta i}{D_{Ai}}}\right] \quad [27]$$

and the limiting current density by

$$I_{LAM} = \frac{\mathbf{F}C^o_B}{\sum_{i=1}^{n}\frac{(1-t_{Bi})\delta i}{D_{Bi}}} \quad [28]$$

Similar equations are obtained for the case of a membrane electrode cathode.

It has been generally assumed that material transport across a membrane resembles diffusion in bulk solutions with the following differences. Only the void volume, *i.e*, that volume not occupied by the membrane matrix, is available for solute transport. The tortuosity of the pores makes the average distance traveled by the ions in traversing the membrane greater than the average distance traveled in crossing the same thickness of pure water by random Brownian displacements. In addition, the actual mobility of the diffusing species may be reduced by interactions with the pore walls. The retarding effect of the membrane matrix can be taken into account by using an effective membrane diffusion coefficient $\overline{D}$ which must obviously be lower than the diffusion coefficient $\overline{D}$ of the species in free solution. Thus, $\overline{D}$ refers to both D_{A2} and D_{B2}.

There are various models which attempt to relate the diffusion coefficient in the absence of a matrix with that of the effective intra-particle diffusion coefficient of the species in an ion exchange particle (12, 13). These treatments can be applied to diffusion through porous membranes. Helfferich (14) has estimated $D/\overline{D}$ as approximately 5. Most membranes are thicker than the adherent film wetting their external surfaces. The quotient $D\delta_2/\overline{D}\delta_1$, where δ_2 is the membrane thickness, δ_1 that of the adherent film, ranges from 10 for very thick membranes to 200 for a relatively thick one, *e.g.*, 0.1 cm. Consequently, it would be expected that even with very thin membranes, the membrane will determine the over-all rate of transport.

Therefore, the anodic concentration polarization is given by the expression

$$\eta\text{anode} = \frac{2.3\,RT}{\mathbf{F}}\log\frac{\left[1-\frac{2I\delta_2(1-t_{B2})}{C^oD_{B2}\mathbf{F}}\right]}{\left[1+\frac{2I\delta_2(1-t_{A2})}{C^oD_{A2}\mathbf{F}}\right]} \quad [29]$$

and the limiting anodic current density by

$$I_{LAM} \simeq \frac{C^oD_{B2}\mathbf{F}}{\delta_2(1-t_{B2})} \quad [30]$$

The limiting current density (I_{LAM}) at a membrane electrode is therefore only about 1/10 to 1/200 that which can be obtained in the absence of a membrane since, *e.g.*,

$$\frac{I_{LAM}}{I_{LA}} \simeq \frac{D_{A1\,2}}{D_{A2\,1}}$$

Since the range of the buffer region is inversely proportional to the limiting current density, Eq. [21], it follows that the buffer range with a membrane electrode is so compressed as to make this structure entirely unsuitable for use in a practical fuel cell.

Using the same experimental set up previously described, membrane electrode systems were tested with hydrogen in phosphate buffer, carbonate buffer, sulfuric acid, and potassium hydroxide. The membrane used was a Nalfilm D-30 membrane made by the National Aluminate Company. A description of its properties is available (15). This membrane has a fractional void volume as measured by water content of 65% and pores ranging from 30 to 60Å in diameter; too small to allow convection. Figure 2 shows that the retarding effect of the membrane matrix is to reduce severely the limiting current density attainable with phosphate buffers to impractically low levels. Similar results were obtained with carbonate buffers and with both buffers on various types of porous diffusion electrodes.

No structure effect is evident with sulfuric acid or potassium hydroxide. This is because the high efficiency of hydrogen ion and hydroxide ion in minimizing concentration polarization obliterate the effect of structure at practical current densities. Thus for example, if the effect of a membrane is to reduce the limiting current density in acid by a factor of 10, it would still be as high as 600 ma/cm^2 based on previous calculations. Consequently, in the practical current density range of 100-400 ma/cm^2 concentration polarization would still be small.

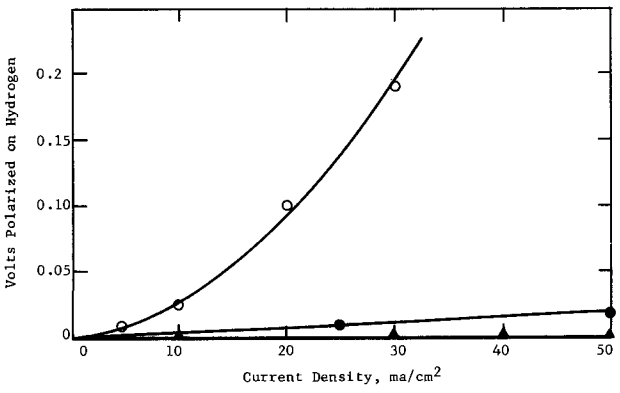

Fig. 2. Dependence of buffer efficiency on electrode structure. Temperature 60°C, Electrode type AA-1 Cyanamid; ○ Electrode clad with Nalfilm D-30 in 1M each KH_2PO_4, K_2HPO_4 buffer; ● electrode clad with Gelman Acropor battery separator in phosphate buffer; ▲ electrode clad with either backing material in 30% H_2SO_4 or 3M KOH.

Electrode structure is, therefore, critical only when the electrolyte is a buffer. Strong acids and bases can be used with a variety of structures because of their high buffering capacity and abnormally high ionic mobilities. Concentration polarization with buffer systems is markedly sensitive to electrode structure because they do not have these rather unique properties of acids and bases.

Buffers and electrolyte soluble fuel systems.—With an electrode that does not have to maintain an interface, a more favorable situation for buffer ion mass transport exists. For example, when a soluble fuel such as methanol is oxidized, a relatively nonporous electrode structure can be used. The working area of the electrode is immersed in and completely wetted by the fuel containing electrolyte. The active electrode areas are subject to natural convection which would be augmented by carbon dioxide evolution, when the electrode is under load.

Methanol runs were carried out using platinum black anodes. The catalyst was made by reduction of chloroplatinic acid with potassium borohydride. Electrodes were fabricated by pressing the freshly precipitated platinum into 80-mesh platinum or gold support screens. Anodic activity runs were obtained in neutral phosphate and in weakly alkaline carbonate buffers, each 1M in each buffer component and containing 1M in each buffer component and containing 1M methanol. Steady-state current-voltage curves were obtained with quiescent solutions, and with the electrolytes stirred magnetically at 200 rpm.

Suppression of ionic concentration polarization by stirring allows a more accurate measurement of the true catalytic activity, as well as a way to measure the major portion of the concentration polarization itself. At 60°C for example, stirring either buffer solution produces a polarization decrease of 50 mv when the anode is operating at 100 ma/cm^2. That the reductions in anode polarization obtained by stirring are solely that due to lowering of ionic concentration polarization, and not to fuel transport limitations can readily be shown.

It is known that stirring sulfuric acid solutions containing 1M methanol has no effect on anode performance (16). Studies have also shown that with methanol concentrations as low as 0.1M, identical steady-state current-voltage curves are obtained in quiescent as well as stirred solutions in strong acid (16) and strong base electrolytes (17). The difference between the results obtained in strong acids or bases and buffers can, therefore, be only due to the concentration polarization in buffers. The use of buffer solutions of increased capacity would, as expected, lower concentration polarization still further. This can be accomplished by simply increasing the buffer concentration, or without changing concentration, employ buffers that are salts of polybasic acids having successive ionization constants that overlap sufficiently so that they do not differ appreciably in magnitude.

Methanol performances were obtained in stirred and unstirred solutions of 2M each RbH_2PO_4, Rb_2HPO_4, and 1M each $K_3HP_2O_7$, $K_4P_2O_7$ solution as an example of the latter system. The performance improvements obtained in the unstirred higher capacity buffer solutions were similar to those obtained by stirring the more dilute buffer systems. Consequently, agitating the higher buffer capacity solutions had little influence on activity. The comparative results showing the decreased effect of stirring with increased buffering capacity is given in Table I, demonstrating the virtual elimination of concentration polarization.

Figures 3 and 4 show that methanol activity on platinum in the intermediate pH range is comparable to or considerably better than that exhibited in strong acid medium. That there is a pH effect on activation polarization can be readily seen by the markedly superior activity in carbonate bicarbonate buffer. The influence of pH on activation polarization will not be considered in this communication, however. In all cases, carbon dioxide evolution was observed in the buffer electrolytes at current densities as low as 5 ma/cm^2. This is also about the lowest current density at which evolution can be visually ascertained in acid electrolytes. No electrolyte pH changes were observed despite high loads sustained for time intervals of sufficient length to alter the electrolyte composition if it was not invariant.

Table I. Effect of stirring and buffer capacity on anode performance

Current density, ma/cm^2	Reduction of polarization (volts) at 60°C by stirring		
	1M KH_2PO_4 1M K_2HPO_4	2M RbH_2PO_4 2M Rb_2HPO_4	1M $K_3HP_2O_7$* 1M $K_4P_2O_7$
25	0.020	0.010	0.010
50	0.040	0.010	0.015
100	0.050	0.015	0.015
150	0.050	0.015	0.015

* Pyrophosphate hydrolyzes to phosphate, but at 60°C and neutral pH, hydrolysis is slow enough that steady-state current-voltage data can be obtained with negligibly low conversions to orthophosphate.

Conclusions

Compared to strong acids and bases buffers are inferior fuel cell electrolytes. They exhibit considerably greater concentration polarizations than, *e.g.*, acids and cannot be used with typical interface maintaining fuel cell electrodes. Limiting current densities are exhibited at both anode and cathode, unlike acids or bases. As buffer ions do not have the high conduc-

tivities of hydrogen or hydroxide ion, ohmic losses would be higher in a buffer fuel cell. Where electrode structure is unimportant, as in the case of electrolyte soluble fuels, buffers are comparable to strong acids or bases.

Practical current densities have been attained however at novel interface maintaining electrode structures with finite but tolerable concentration polarizations. The justification for buffer systems is that cheaper nonnoble catalysts unstable in acid can be assessed for activity in less corrosive media. Buffers therefore present the opportunity to construct practical economical fuel cells.

The Kinetics of the Fluorination of Beryllium

Patricia M. O'Donnell

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio

ABSTRACT

The kinetics of the reaction of sheet beryllium and gaseous fluorine to form beryllium fluoride were studied by means of the pressure drop method over the temperature range of 125°-775°C and at pressures from 20 to 700 Torr. The reaction followed the parabolic rate law. Parabolic rate constants were calculated, and activation energies are given. The pressure dependence is approximately first order with respect to the fluorine pressure. A change of slope in the plot of the rate constant against reciprocal temperature suggests a change in the nature of the reaction near 525°C. Above 525°C the crystal structure of the film changes from α-quartz hexagonal to rhombic tridymite. Beryllium is identified as the diffusing species.

Beryllium, because of its light weight, high-temperature strength, thermal conductivity, and neutron-moderating characteristics, is of interest for application in reactors, satellites, and future supersonic aircraft. The beryllium-oxygen reaction has been extensively studied, and it involves the outward diffusion of beryllium ions (1). At high temperatures the initially protective oxide film is no longer protective (2) because of the onset of breakaway oxidation. Several other beryllium-gas reactions have been investigated (3) including the reactions of beryllium with carbon monoxide and with carbon dioxide (4). Although data appear in the literature (5, 6) concerning the thermodynamic properties of beryllium fluoride, little is reported on the kinetics of the beryllium fluorine reaction. This work presents the kinetics of the reaction of fluorine with beryllium and the effect of temperature and pressure on the reaction rate.

Experimental

The experimental apparatus and the procedure used to measure the rate of fluorination are described in (7). The high-purity beryllium test pieces were strips measuring 1.27 x 15.24 x 0.012 cm with a 0.5 cm diameter hole drilled in one end for handling. The strips were treated with a solution of $HF\text{-}HNO_3$ during manufacture by the supplier. Immediately before being inserted into the fluorine system the strips were washed with detergent (8), distilled water, and finally an acetone rinse. This procedure was followed as a safety measure in order to avoid any possibility of contamination. The strips were preheated for 0.5 hr at 525°C. After reaction the products were characterized by x-ray diffraction and cross-section metallography.

Results and Discussion

In Fig. 1 and 2 the reaction is shown to follow the parabolic rate law $y^2 = kt$, where y is the amount of fluorine consumed (at STP) per unit area of beryllium surface (ml/cm^2), k is the parabolic rate constant, and t is the time (min). All the data over the temperature and pressure ranges studied can be described by this parabolic rate law. Solid symbols represent duplicate runs and show the reproducibility of the data. A reaction similar to breakaway oxidation was not found with fluorine; the film continued to be protective.

The values of the parabolic rate constants are listed in Table I. The parabolic rate constant is plotted as a

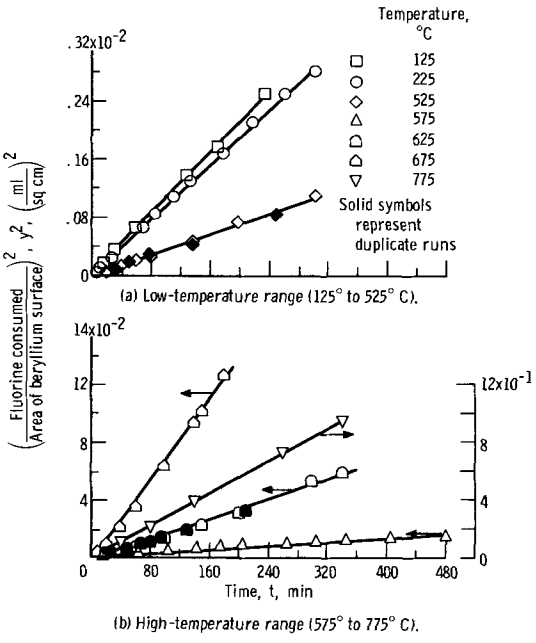

Fig. 1. Effect of temperature on fluorination of beryllium. Pressure, 200 Torr.

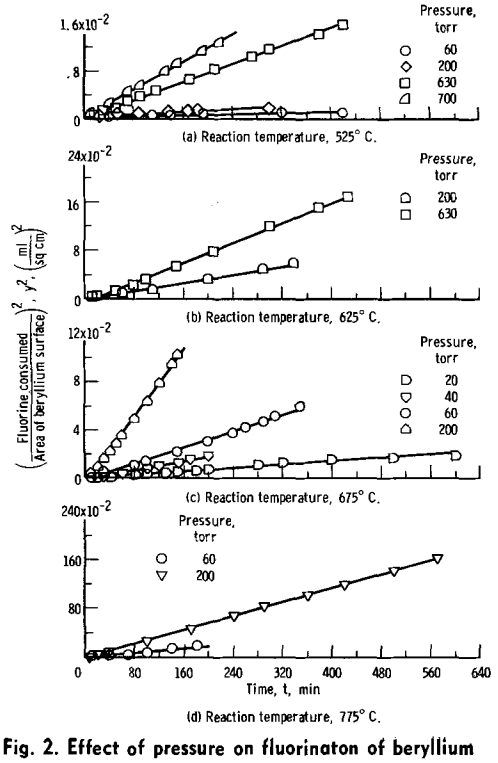

Fig. 2. Effect of pressure on fluorinaton of beryllium

function of temperature at a pressure of 200 Torr in Fig. 3. In this figure the rate of reaction shows a negative temperature dependence in the low-temperature range. This behavior is not unique because in heterogeneous systems where the rate of reaction is determined by diffusion in a solid layer a simple temperature dependence of the net process is not always found. Reactions of this type are complex processes involving the diffusion of at least one ion and electrons across the film through accessible diffusion sites. The number and accessibility of these sites can change at different temperatures; thus, the rate of reaction can decline with rising temperature. The effect shown in this region is not due to the experimental error. A variation of this amount in k would represent greater than a 60% error in determining the amount of fluorine consumed. This is far outside the precision of

Table I. Summary of temperature and pressure conditions and calculated parabolic rate constants

Temperature, °C	Pressure, Torr	Parabolic rate constant, k, $(ml/cm^2)^2/min$
125	200	1.05×10^{-5}
225	200	0.94×10^{-5}
525	60	0.20×10^{-5}
	200	0.69×10^{-5}
	630	3.77×10^{-5}
	700	5.70×10^{-5}
575	200	3.30×10^{-5}
625	200	17.0×10^{-5}
	630	41.0×10^{-5}
675	20	4.03×10^{-5}
	40	9.70×10^{-5}
	60	16.30×10^{-5}
	200	69.20×10^{-5}
775	60	130×10^{-5}
	200	280×10^{-5}

the determination. From duplicate runs in the low-temperature region the average deviation in k is (0.03 x 10^{-5} $ml/cm^2)^2/min$. There are many examples in the literature where oxidation rates have been found to decrease with increasing temperature so that the equation $k = a \exp-(\Delta H/RT)$ yields an apparent negative activation energy. A good explanation for this is not available. It could be suggested that the effect is due to changes brought about possibly by ageing or sintering of the reaction film. A break in the curve appears at 525°C. At this point the activation energy (ΔH_a) changes from —0.8 kcal/mole at the low temperatures to 8 kcal/mole at the high temperatures. Although this value for the activation energy appears low when compared to oxidation reactions it is not low when compared to the ΔH_a values of other fluorination reactions reported in the literature. An example is the fluorination of nickel with a reported activation energy of 5 kcal/mole (9). The following equations define the variation of the rate constant in the two temperature ranges

$$k = .0.4\text{x}10^{-5} \exp(800/RT) \quad (ml/cm^2)^2/min \text{ for } 125°—525°C \quad [1]$$

$$k = 1.5\text{x}10^{-2} \exp(-8000/RT) \quad (ml/cm^2)^2/min \text{ for } 525°—775°C \quad [2]$$

where k is the rate constant, R is the gas constant, and T is the absolute temperature.

A log-log plot of the rate constant as a function of the fluorine pressure is shown in Fig. 4. The reaction is approximately first order with respect to the fluorine pressure. The values are $k = 7.404\text{x}10^{-9}\ P^{1.3}$ at 525°C and $k = 1.019\text{x}10^{-6}\ P^{1.2}$ at 675°C.

The low-temperature film is identified as α-quartz hexagonal BeF_2, and the high-temperature film is

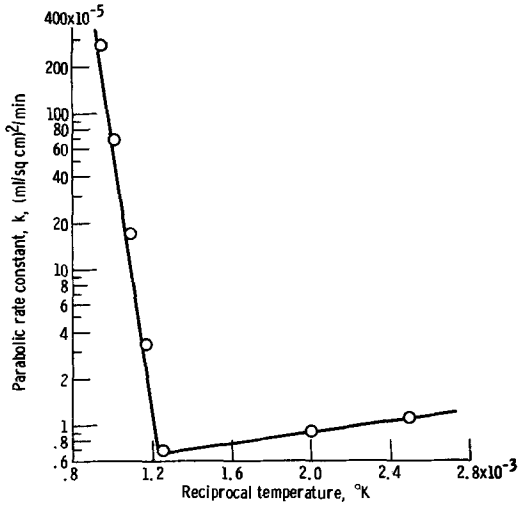

Figure 3. - Effect of temperature on parabolic rate constant. Pressure, 200 torr.

Fig. 3. Effect of temperature on parabolic rate constant. Pressure, 200 Torr.

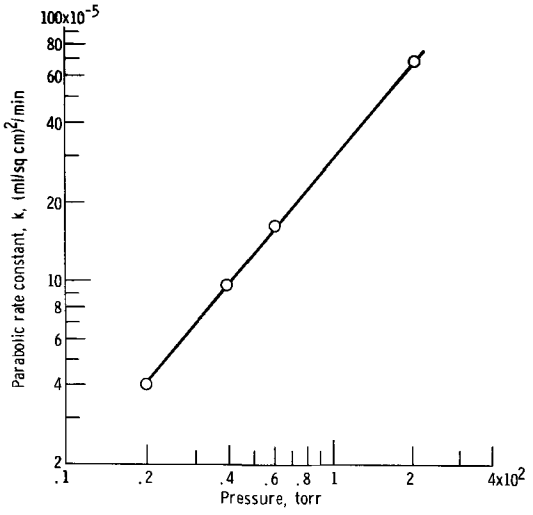

Fig. 4. Effect of pressure on parabolic rate constant. Temperature, 675°C.

identified as rhombic tridymite BeF_2 (10). A study was made of the reaction of α-quartz BeF_2 with fluorine gas at a temperature of 675°C and a fluorine pressure of 200 Torr. No apparent change was observed in that no rhombic tridymite form was found. This observation would lead to the assumption that for the high-temperature reactions the α-quartz hexagonal BeF_2 is not formed first and then converted to the tridymite form but that the tridymite BeF_2 is formed directly. Films formed at low temperatures were dull, nonreflecting surfaces, while those produced at high temperatures resembled shiny mirrors. Reacted metal strips are shown in Fig. 5 and 6. Figure 5 shows a reacted metal strip after fluorine exposure at a temperature of 625°C and a pressure of 630 Torr.

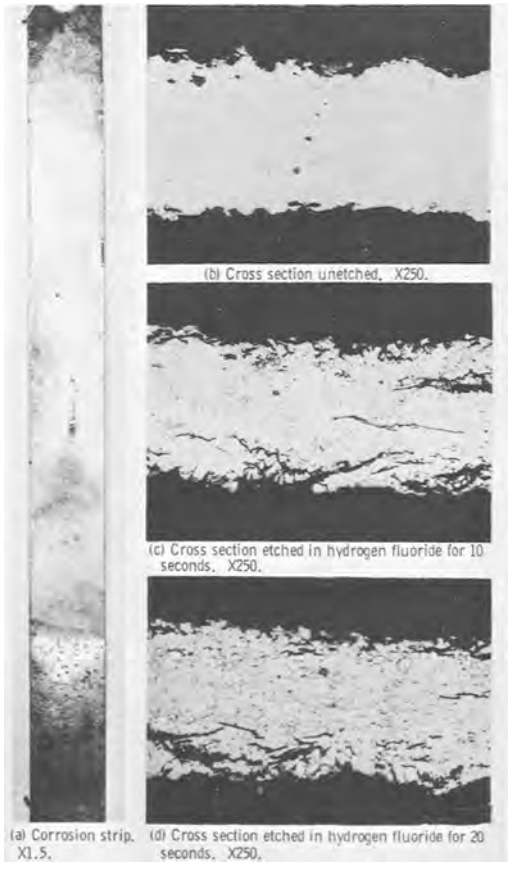

Fig. 5. Reacted metal strip after fluorine exposure. Temperature, 625°C; pressure, 630 Torr. (Reduced 40% in printing.)

Fig. 6. Cross section showing beryllium fluoride coating. X500. (Reduced 50% in printing.)

Etched cross sections of the strip show that the reaction is not a grain boundary attack but is a transgranular attack. The photomicrograph in Fig. 6 is a cross section showing the BeF_2 coating. The boundary between the beryllium and the BeF_2 is not well defined, but beryllium is seen as light areas extending into the film. If the gas was the primary diffusing species, one would expect a sharp, well-defined interface as was observed previously in the fluorination of iron (11). The appearance of Be in the film could suggest that outward diffusion of beryllium is taking place. Another experimental technique used to determine which species, metal or nonmetal, was the principal diffusing species was to determine whether two films of the same material, beryllium fluoride in this case, growing toward each other would fuse into one continuous film or whether there would be an interface formed between the films (12). If the metal were the principal diffusing species and the reaction site was at the gas/film interface, the two surfaces would fuse together as the metal species from one film migrated into the other film. If however the nonmetal were the principal migrating species, the two films would come together but would not fuse resulting in an interface between the two films. Two beryllium strips were clamped together along the 1.27 cm side with a 0.012 cm thick Monel ribbon inserted between the plates to form a small wedge angle. The sample was fluorinated at 675°C at 400 Torr. Figure 7 shows a cross section of the polished sample which reveals that the surfaces have fused together, suggesting that the metal rather than the nonmetal is diffusing during fluorination at high temperature. The approximate first order pressure relationship associated with a parabolic rate law is unusual and could be explained by suggesting that the diffusing species is an interstitial fluorine molecule; however, present experimental evidence does not indicate this.

Manuscript received April 5, 1967; revised manuscript received July 28, 1967. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Infrared Studies of Protective Films Formed by Acetylenic Corrosion Inhibitors

G. W. Poling

Research and Technical Department, Texaco Inc., Beacon, New York

ABSTRACT

Infrared spectra of surface films formed on iron and steel mirrors by propargyl alcohol. acetylene, and ethynyl-cyclohexanol acid corrosion inhibitors were recorded using a multiple reflectance technique. These spectra showed that the acetylenic molecules reacted at the metal surfaces in HCl solutions to produce protective polymer film coatings. Corrosion protection increased markedly as the polymer coatings grew from nearly two-dimensional, adsorbed layers to films 20°-200A° thick. Saturated hydrocarbon material composed the majority of these films. Hydrogen evolved by the acid corrosion reaction probably participated in hydrogenating adsorbed acetylenic species. The polymer also contained several polar species including hydroxyl and carbonyl groups. Increased carbonyl content appeared to decrease the protectiveness of these films.

Acetylenic alcohols effectively inhibit the acid corrosion of metals such as iron, aluminum, and zinc. The carbon-carbon triple bond has been shown (1) to act as the focal point in the inhibiting action of acetylenic derivatives. Several investigators (1-3) have proposed that the acetylenic molecules chemisorb on the metal surface to form a protective film one monolayer thick. This chemisorption is believed to involve sharing of π electrons in the triple bond with metal atoms at the surface. Recent studies have indicated that the protective films may instead consist of products of the reaction of these inhibitors at the metal-acid interface. Duwell, Todd and Butzke (4) found hydrogenation and dehydration reaction products in heptane extracts of acid-iron powder-ethynylcyclohexanol ($C_6H_{10}OHC{\equiv}CH$) reaction mixtures. Putilova, Rudenko, and Terentev (5) used a similar solvent extraction technique to show that acetylene reacted at iron-HCl interfaces to form thick polymolecular films on the iron. Electrochemical studies by Duwell (3) and Froment and Desestret (6) indicate that acetylenic compounds act primarily as cathodic inhibitors in acid solutions. Opposing results have been published by Okamoto *et al.* (7) who found that propargyl alcohol inhibited primarily the anodic reaction of steel in HCl solutions.

This paper describes an infrared study of the surface films formed by propargyl alcohol ($HC{\equiv}CCH_2OH$), acetylene ($HC{\equiv}CH$) and 1-ethynylcyclohexan-1-ol ($C_6H_{10}OHC{\equiv}CH$) inhibitors on iron and steel mirrors in HCl solutions. A multiple reflectance technique has been used so that spectra of films left intact on acid-exposed metal mirrors could be recorded. These spectra have provided direct evidence on the composition, structure, and thickness of the protective films. Determinations of mirror corrosion rates have enabled correlation of the infrared data with corrosion inhibition efficiencies. Our results indicate that acetylenic inhibitors react at iron or steel-HCl interfaces to form polymer film coatings that can grow to several hundred angstroms thickness. The protectiveness of these films increased markedly as they grew in thickness.

Experimental

Recording infrared spectra.—Figure 1 shows a schematic drawing of the multiple reflectance accessory that was used with a Beckman IR-12 spectrophotometer to record the spectra of thin films formed on two metal-mirror corrosion test specimens, M_4 and M_5.

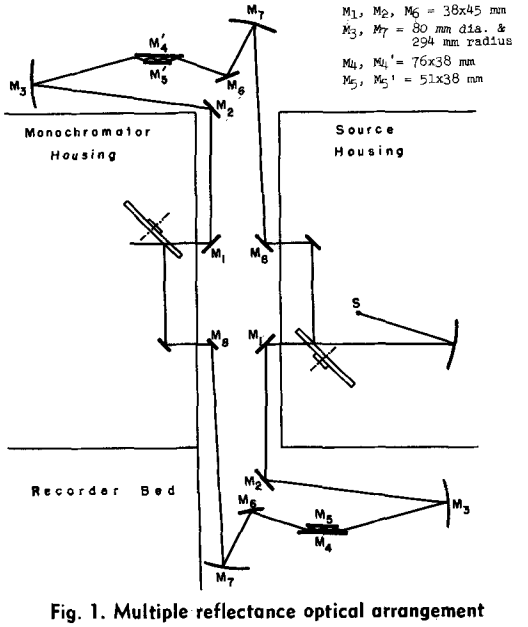

Fig. 1. Multiple reflectance optical arrangement

This accessory produced seven reflections at 73° incidence from the two metal sample mirrors. All other mirrors in the sample beam path were front-surfaced aluminum. Mirror-imaged but otherwise identical optics were provided in the reference beam path to maintain optical balance in the double-beam spectrophotometer. Spectra of surface films formed on the two sample mirrors M_4 and M_5 were, therefore, recorded differentially to two similar reference mirrors M_4' and M_5'. These reference mirrors were maintained in their freshly polished condition throughout the experiments. The reflectance accessory was enclosed in a plexiglas cover so that the entire optical path could be purged free of interfering water vapor using dry air or nitrogen. The accessory was designed to enable the IR-12 to record spectra of surface films as thin as one monolayer on sample mirrors that had sometimes become slightly roughened due to their exposures to the test solutions. Achieving monolayer-detecting sensitivity also required the installation of an efficient infrared polarizer in the monochromator section of the IR-12. Use of ordinate scale expansion facilities up to 20X expansion was also necessary. Details of the theory and practice of the multiple reflectance infrared technique have been clearly presented in papers by Francis and Ellison (8) and by Greenler (9).

Multiple reflectance spectra could not be recorded while the sample mirrors M_4 and M_5 were immersed in the acidic test solutions due to intense absorption of the infrared light by such solutions. Instead spectra from these mirrors were recorded before and after their exposure to the inhibited acid test solutions. Differences between these spectra were due mainly to absorption of the infrared light by thin surface films that the acetylenic inhibitors had formed on the sample mirrors. The ability to record spectra of films as thin as one monolayer was demonstrated by recording a recognizable spectrum of a single monolayer of barium stearate. This monolayer film had been deposited on two aluminum sample mirrors using the Langmuir-Blodgett technique.

Materials and procedures.—Two Armco iron or mild steel (1020) sample mirrors (3 x 1½ in. and 2 x 1½ by ⅛ in. thick) were used in each inhibitor test. Mirrors were prepared from metal plates either by mechanical lap polishing, using αFe_2O_3 polishing grit or by electropolishing (10), in a 20/1 glacial acetic acid to 70% perchloric acid solution.

Propargyl alcohol and acetylene were obtained from Matheson, Coleman and Bell. The acetylene was purified before use by passing it through H_2SO_4 and then through a column of activated alumina. 1-ethynylcyclohexan-1-ol was obtained from Air Reduction Company. No significant impurities were detected in the infrared spectra of these pure inhibitors.

Multiple reflectance spectra of freshly polished sample mirrors were first recorded to serve as background spectra. These were flat and featureless since spectra of the two sample mirrors were recorded differentially to two similarly prepared reference mirrors. The two sample mirrors were then immersed in the inhibited acid test solution in a 1-liter Pyrex reaction flask. All joints to this flask used Viton-A O-ring seals. A bubbler-tube extended to the bottom of the flask for purging the solution. The solution was magnetically stirred. Normal use of 500 ml of acid solution provided 4.6 ml acid/cm² of exposed metal specimen.

Most inhibitor tests were conducted in 10% HCl (3.3*N*) at 65° ±2°C with the solutions deaerated by continuously purging with helium or argon. Exposure times varied from a few minutes to several days. Inhibitor concentrations of *ca.* 9 x 10^{-2}M were generally used. In testing acetylene as an inhibitor, the acid was maintained saturated with this gas. After the desired exposure, the sample mirrors were removed from the flask, immediately rinsed in distilled water, and dried at room temperature. Their multiple reflectance spectrum was then recorded and compared with the original background spectrum to detect any organic film formation.

In most tests, corrosion by the inhibited HCl was so uniform that the sample mirror reflectivities were practically unaffected by exposures lasting several hours. When the mirror surfaces were roughened, increased light scattering caused loss of infrared energy over the entire spectral region (4000-400 cm^{-1}). This energy loss was more pronounced at the higher frequencies (cm^{-1}) which was characteristic of a light scattering phenomenon. These energy losses were therefore readily distinguished from the sharp absorption bands due to an organic film on the mirrors. The spectra presented in this paper were replotted to subtract spectral changes due to increased light scattering.

Corrosion rates of the metal mirrors were determined by periodical removal of 3-5 ml aliquots of the acid solution for atomic absorption spectroscopic analysis for iron.

Inhibitor tests were also made at other than the "standard" conditions cited above. These included HCl concentrations from 1.7 to 12N, temperatures from 22° to 93°C, and exposure of the acid solution to air.

Film thickness calculations have been based on application of the Beer-Lambert law to the measured intensity of the C-H stretching bands in the organic films. Estimation of appropriate absorption coefficients were derived from Greenler's (8) data. Random orientation of the C-H groups, with respect to the incident and reflected infrared beam, was assumed. Even if the C-H groups were preferentially oriented with respect to the metal surfaces, microroughness of these surfaces would probably produce random orientation with respect to the infrared beam.

Results

Propargyl alcohol inhibitor.—Spectra of films.—Figure 2A shows an infrared spectrum of pure liquid propargyl alcohol inhibitor together with assignments (11) of its major absorption bands. Figure 2B shows a spectrum of the film formed on Armco iron mirrors during their 23-hr exposure to helium purged 3.3*N* HCl solution at 65°C containing 8.7 x 10^{-2}M propargyl alcohol. The zero absorbance level in this figure represents the initial "background" spectrum of the mirrors prior to their test exposure. Spectrum B is typical of many spectra that resulted from similar tests of propargyl alcohol for exposure times ranging from 15 min to several days. Absorption band intensities, which were directly proportional to film thicknesses, increased with the length of the exposure. Based on the intensity of the 2930 cm^{-1} CH_2 band in spectrum

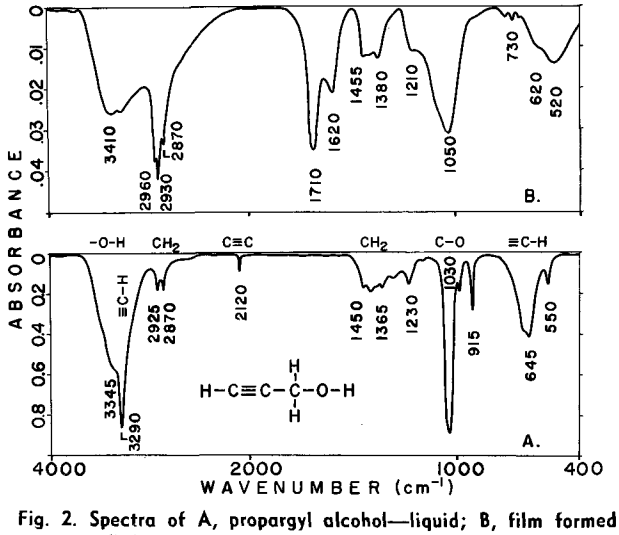

Fig. 2. Spectra of A, propargyl alcohol—liquid; B, film formed on iron in HCl by propargyl alcohol.

B, this organic film was calculated to be about 60Å thick. This would be equivalent to nearly 15 monolayers thickness of the added inhibitor molecules.

Direct comparison of spectra A and B of Fig. 2 indicates that the organic film consisted of reaction products of propargyl alcohol rather than chemisorbed inhibitor molecules. Acetylenic (H—C≡C—) groups were not present in the film as evidenced by absence of characteristic bands at 3290, 2120, and 645 cm^{-1}. In addition, the film exhibited bands that were not present in the spectrum of the inhibitor (A). These new bands and their assignments are as follows

2960 cm^{-1}	— CH_3 stretch (11)
1710 cm^{-1}	— $\geq C=O$ stretch
~1620 cm^{-1}	— overlapping { $\geq C=C\leq$ stretch; H—O—H bend; COOFe stretch
520-620 cm^{-1}	— Fe—O stretch

The above assignments are based on reference to characteristic group frequencies (11) and on the following tests of the films. Reacting amines with the films decreased the intensity of the 1710 cm^{-1} band and confirmed its assignment to carbonyl groups; *i.e.*, $\geq C=O+H_2NR \rightarrow \geq C=NR+H_2O$. Contribution of a small amount of residual olefin ($\geq C=C\leq$) to the ~1620 cm^{-1} band was indicated by the observation that exposure to ozone decreased the 1620 cm^{-1} band intensity while the ~1710 cm^{-1} carbonyl band was markedly enhanced, *i.e.*, 3 [$\geq C=C\leq$] + 2 $O_3 \rightarrow$ 6($\geq C=O$). Evidence for contribution of iron carboxylate (—COOFe) groups to the ~1620 cm^{-1} band is presented later. Assignment of the 520-620 cm^{-1} bands to Fe-O stretching modes is based on reference to spectra (12) of iron oxide compounds.

Physical properties of films.—Protective films formed by propargyl alcohol on iron proved to be highly insoluble, nonvolatile, and strongly adhering. Solvents tested included n-heptane, benzene, acetone, chloroform, pyridine, and 3.3*N* HCl solution. Of these, only acetone and chloroform dissolved appreciable film material. These solvents were able to extract only about one-third of the film. A 1-hr exposure of film-covered mirrors to uninhibited 3.3*N* HCl at 22°C did not remove appreciable film material. No significant evaporation of film material to vacuum was detected below a temperature of approximately 250°C. At 350°C most of the film was removed within 1 to 2 hr. The small amount of residual film exhibited broad bands at 1, 1590 cm^{-1}, 2, 1430 cm^{-1}, 3, 1070 cm^{-1}, and 4, 400-600 cm^{-1}. Bands 1 and 2 are characteristic of iron carboxylate (—COOFe) species. Band 3 is believed due to C-O stretch in iron alkoxide groups (—COFe) (13). Bands in the 400-600 cm^{-1} region are ascribed to Fe-O stretching modes in iron alkoxide and iron oxide groups. These stable species thus appear to have been concentrated at the organic film-iron (iron oxide) interface.

The film coated iron mirrors were observed to be hydrophobic on their removal from the helium purged HCl test solutions. After a short rinse in distilled water, the mirrors became hydrophilic even though the organic film persisted on the mirror surfaces. This indicated that air oxidation could have caused this conversion by the production of polar groups at the surface of the organic films. To test this theory, an experiment was conducted in which air contact of the mirrors was eliminated. The acid-exposed mirrors were transferred from the reactor flask to an infrared gas cell within a helium-filled dry box. The spectrum of this film was similar to that shown in Fig. 2B (which was recorded in air) except that the 1710 cm^{-1} carbonyl band was about 50% less intense. Subsequent addition of oxygen to the gas cell, containing the iron mirrors, resulted in an immediate 50% increase in the intensity of the carbonyl band. The spectrum did not change further on exposing the mirrors to air for several days. This experiment indicated that approximately one-third of the carbonyl content of films that were exposed to air was probably due to air oxidation reactions.

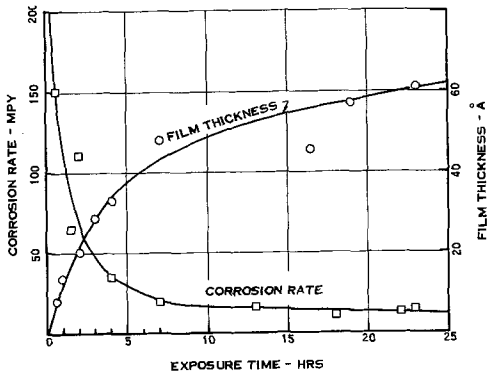

Fig. 3. Time dependence of protective film growth and corrosion rates, for iron in 10% HCl at 65°C with 8.7 X 10^{-2}M propargyl alcohol.

Corrosion rate vs. film thickness.—Figure 3 shows how the corrosion rate decreased as the thickness of an organic film formed by propargyl alcohol increased. A replot of these curves has shown that the logarithm of the corrosion rate exhibited a linear dependence on film thickness up to 50Å which was near the limiting film thickness. Under similar conditions (helium purged 3.3*N* HCl at 65°C) but with no inhibitor present, the corrosion rate steadily increased with exposure time. A rate of 10,000-12,000 mils per year (mpy) was attained within a few hours exposure of the "blank" iron specimens.

Figure 4 shows how the corrosion protection increased as the organic film grew in thickness.

$$\text{Per cent protection} = 100\left(\frac{\text{uninhibited rate-inhibited rate}}{\text{uninhibited rate}}\right)$$

Results are shown for tests of propargyl alcohol in both helium purged and air-exposed 3.3*N* HCl solutions. These curves show that the organic films became highly protective (*i.e.*, >99%) only after they had grown to thicknesses equivalent to many molecular layers. Near one monolayer thickness, the films appeared to confer 80-90% protection. Figure 4 illustrates that, at equal thicknesses, films formed in air-exposed HCl solutions were less protective than those formed in solutions free of oxygen. Differences in the compositions of these films are described in the following section.

Effects of varying exposure conditions.—Acid exposure conditions such as concentration, temperature, and oxygen availability have been varied to study their effect on the composition, growth rate, and pro-

[a] Uninhibited corrosion rates were not determined for these conditions.

tectiveness of the organic films. Results have also been obtained using both mechanically and electrolytically polished Armco iron and mild steel sample mirrors. Table I summarizes these results. Typical data for the standardized exposure conditions (test 1 of Table I) are included for comparative purposes. The growth rates of the films were highly dependent on the exposure conditions. Film compositions were found to be relatively independent of changing conditions. Test 4, with the HCl test solution exposed to the air, was the exception. The films from this test exhibited considerably higher carbonyl content than those formed in oxygen-free solutions. In spite of the fact that the test No. 4 film grew to be thicker than the others, it was less protective as shown in Fig. 4.

Acetylene inhibitor.—Infrared analyses of films formed on iron by acetylene in HCl solutions were made to help elucidate the film formation mechanisms. Figure 5 (A and B) shows spectra of the acetylene gas that was used as an inhibitor. The three major bands in these spectra are due to ≡C-H stretching and bending modes in the C_2H_2 molecule. Exposure of Armco iron mirrors to an acetylene saturated, 5% HCl solution (~1.7*N*) for 4¼ hr at 47°C followed by an additional 1¼ hr at 57°C produced a film which exhibited spectrum C of Fig. 5. This film was calculated to be about 40Å thick.

The differences between the spectra of the acetylene inhibitor and the film that it formed on iron are very striking. There is, however, a close similarity between the spectrum of the acetylene-formed film (Fig. 5C) and the spectrum of the film formed from propargyl alcohol (Fig. 2B). Comparison of these spectra shows differences only in relative band intensities. This indicates that the compositions of the films formed by these two inhibitors were very similar, *i.e.*, both films contained the following groups: —OH (3410 cm^{-1}); CH_3 (2960 cm^{-1}); CH_2 (2930 and 2870 cm^{-1}); >C=O (1705 cm^{-1}); —COOFe (~1600 cm^{-1} shoulder); —C—O—Fe (1010-1100 cm^{-1}) and Fe-O (400-600 cm^{-1}).

Benzene extraction of the organic film succeeded in removing about one half of the original film material. No appreciable decrease in bands attributed to iron carboxylate (~1600 and 1430 cm^{-1}), iron alkoxide (1000-1100 cm^{-1}) or iron oxide (400-600 cm^{-1}) resulted from this extraction.

In the 47°C exposure described above, the iron mirrors corroded at a rate of 12 mpy. The subsequent 10°C temperature rise to the 57°C exposure did not alter this corrosion rate.

Ethynylcyclohexanol inhibitor.—Films formed on iron by this cyclic acetylenic alcohol were much more readily extracted by solvents than those previously mentioned. By observing the infrared spectra of the residual films after successive extractions, we have obtained information on variations of composition through the film. Figure 6 presents typical spectral results. Spectrum A is that of the pure ethynylcyclohexanol inhibitor. The films, formed by exposing two mechanically polished Armco iron mirrors for 16 hr to an oxygen-free 3.3*N* HCl solution at 65°C with 7.2×10^{-2}M ethynylcyclohexanol, exhibited spectrum B. This film was calculated to be about 470Å thick.

Comparison of spectra A and B of Fig. 6 indicates that the relatively thick organic films consisted of products of the reaction of ethynylcyclohexanol at the surface. Similarity of the C-H stretching bands (2940 and 2860 cm^{-1}) and C-H bending bands (1450-900 cm^{-1}) in these two spectra suggested that the cyclohexyl ring structure was retained in the organic film. Apart from this feature and the absence of CH_3 groups

E	After HCl extr. % original intensity	—	5	5	—	—	—	—	—	29	40

(no bands at 2960 and 1370 cm^{-1}), the composition of these films appears similar to those formed by propargyl alcohol (Fig. 2B) and by acetylene (Fig. 5C).

Spectra C, D, and E of Fig. 6 were exhibited by residual films after successive extractions in n-heptane, acetone and 10% HCl solutions, respectively. Spectra C and D were recorded after the mirrors had been immersed in each organic solvent until no further dissolution occurred at 22°C. Exposure to 10% HCl (at 22°C) lasted 10 min. Table II summarizes the results of these extractions. The tabulation of spectrum C shows that n-heptane removed about two thirds of the C–H, C=C, and C=O content of the original film. The bands attributed to —OH, —COOFe, —COFe, and Fe-O were relatively unaffected. After the acetone extraction, the film was only about one tenth of its original thickness of 470Å. Again the four bands just mentioned were left relatively unaffected. The HCl treatment left a film only about 25Å thick based on the residual 2940 cm^{-1} CH_2 band in spectrum E. The C-H, C-O, and Fe-O bands retained in spectrum E are believed due to several monolayers of iron alkoxide (RCOFe) on a thin layer of iron oxide that was retained on the iron surface. The above results indicated that the composition of the organic film was uniform throughout its thickness apart from concentration of iron carboxylate and iron alkoxide species at the organic film/iron oxide interface.

Discussion

Structure and properties of protective films.—These infrared studies have shown that the acetylenic corrosion inhibitors propargyl alcohol, acetylene, and ethynylcyclohexanol reacted at HCl-exposed iron and steel surfaces to form organic film coatings. These surface reactions were not limited to the formation of "adsorbed layers" since the organic films grew to thicknesses equivalent to many molecular layers.

The films were composed primarily of fully saturated hydrocarbon material. Hydroxyl, carbonyl, carboxylate, and alkoxide groups were also present in all films studied. The —OH content, which varied considerably, is believed due mainly to retention of absorbed water and to presence of hydrated or hydroxylated iron oxide species. Even in the films formed by acetylenic alcohols (Fig. 2B and 6B) the OH bands did not appear to be due to retained —C—O—H groups. This was indicated by the fact that the relative intensities of the —C—O (~1070 cm^{-1}) and —O—H (~3400 cm^{-1}) bands varied widely (see for example Table II). Therefore these bands could not have been due to one species. These results indicate that the acetylenic alcohol inhibitors must have been dehydrated at the surface. Most of the carbonyl content of films formed in absence of oxygen is believed to have resulted from hydration of the acetylenic bond followed by isomerization. This is discussed in the following section. Some carbonyl also originated from air oxidation after the films were formed, as described above. Evidence has been presented (*i.e.*, in Table II) that the carboxylate and alkoxide groups were concentrated at the organic film-iron oxide interface. These stable species probably contributed to strong adhesion of the organic film to the iron.

The infrared spectra, low solubility, low volatility, and high thermal stability of these organic films indicate that they were composed of polymeric material. Spectra of the films formed by propargyl alcohol (Fig. 2B) and by acetylene (Fig. 5C) are similar to spectra (14) of oxidized polyethylenes, for example. The films exhibiting these particular spectra were about 60 and 40Å thick, respectively. Much weaker but otherwise similar spectra were recorded when these films were of the order of one monolayer thick. Therefore, even in the early stages of growth, the films are best described as being nearly two dimensional or adsorbed polymer layers. A simplified model of the structure of the protective films formed by acetylenic inhibitors is presented in Fig. 7. In films formed by ethynylcyclohexanol, the hydrocarbon would consist primarily of cyclohexyl rings instead of as shown in Fig. 7.

Film forming reactions.—Polymerizations of acetylenic hydrocarbons are common reactions, particularly when they are surface catalyzed. For example, infrared studies (15) (16) of surface species resulting from hydrogenation of acetylene adsorbed on nickel, palladium, and copper metals have shown that polymerization produced n-alkyl hydrocarbons. A reaction involving hydrogenation and dehydration of acetylenic alcohols has been used in the commercial production of 1,3-butadiene and buna rubber (17). The iron-HCl-acetylenic inhibitor system offers the possibility for similar surface catalyzed reactions for the formation of protective polymer films. Hydrogen evolution from the acid-exposed metal surface was found to be necessary for the formation of polymer films by these inhibitors. Polymer films did not form on copper, silver, and platinum in 3.3*N* HCl at 65°C, where no hydrogen was evolved. When the HCl concentration was increased to greater than 6.7*N* (>20%) so that hydrogen was evolved from copper, the acetylenic inhibitors then formed relatively thick polymer films on this metal. Apparently, hydrogenation of adsorbed acetylenic inhibitor species by cathodically liberated hydrogen participated in the polymer film formation.

Some of the oxygenated groups found in films formed in oxygen-free acid solutions probably resulted from the following types of reactions:

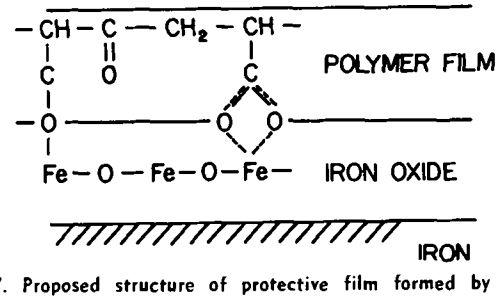

Fig. 7. Proposed structure of protective film formed by acetylenic inhibitors.

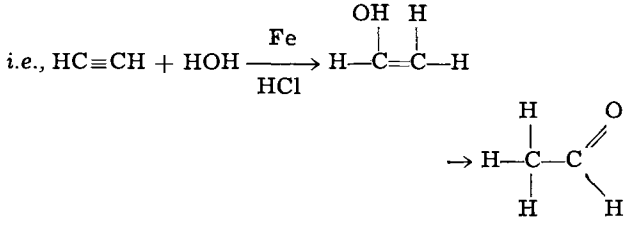
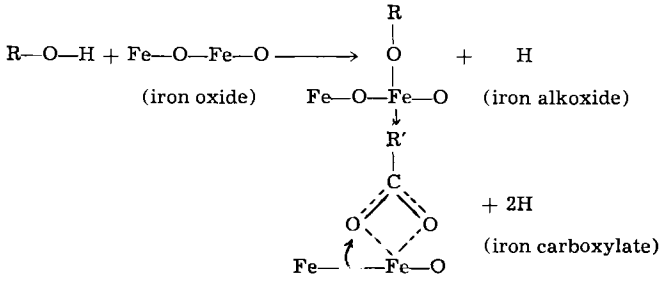
1. *Hydration of the C≡C*



In a similar process, used for the commercial production of acetaldehyde, formation of tarry condensation products are troublesome. Similar condensation products probably contribute to polymer film formation in use of acetylenics as corrosion inhibitors. The strongest evidence for this type of reaction comes from the composition of the films formed by acetylene (Fig. 5C). Although this inhibitor contained no oxygen and the acid was well purged with helium, the polymer films exhibited a strong carbonyl band at 1705 cm^{-1}. Most of this carbonyl content probably derived from hydration of the C≡C.

2. *Formation of Alkoxides and Carboxylates*



Adsorption of alcohols on Al_2O_3 was shown to result in the formation of similar aluminum alkoxide and carboxylate species (18). The alcohol for the above reaction could be an acetylenic alcohol inhibitor or it could be the intermediate product in hydration of C≡C groups as shown above. Hydrogen released by the above reactions could have participated in the hydrogenation of acetylenic species or it could have been evolved as a gas. According to the above reactions, alkoxide and carboxylate species would be formed only at the surface of an iron oxide film on the iron or steel specimens. Our infrared results agree with this mechanism since these species were found concentrated at the organic film-iron oxide interface.

Corrosion inhibition mechanisms.—Acetylenic corrosion inhibitors effectively prevent the acid corrosion of iron and steel by the formation of polymer film coatings on the exposed metal surface. The protection afforded by these films increased markedly as they grew from near two-dimensional, adsorbed polymer networks (~4A° thick) to films of up to several hundred angstroms thickness. This is illustrated in Fig. 4 for films formed by propargyl alcohol inhibitors. Similar results have been obtained from our study of other acetylenic inhibitors including acetylene, 1-ethynylcyclohexan-1-ol, 1-hexyn-3-ol, and 2-butyn-1,4-diol. Production of polymer film coatings, therefore, appears to be the general mode-of-action of acetylenic corrosion inhibitors. Rapid chemisorption of these inhibitors to form metal-acetylene surface complexes is probably a crucial step in initiating the formation of protective polymer films. The ability of acetylene to act as an efficient inhibitor provides indirect evidence of this mechanism. Films in the chemisorbed or monolayer thickness range appeared capable of decreasing the uninhibited acid corrosion rate by about 10 times (*i.e.*,~90% protection). This rapid reduction in corrosion rate probably enabled subsequent growth of relatively thick polymer films that remained strongly adhering to the surface. These thicker films often resulted in 1000 times reduction of the uninhibited corrosion rate (*i.e.*, ~99.9% protection).

The protectiveness of the polymer films depended on both the thickness and composition of the polymer films as indicated in Fig. 4. In general, the corrosion rate was found to vary linearly with the exponential of the film thickness (*i.e.*, mpy=exp. $K \times$ Å thickness $+C$). This relationship was often obeyed from the monolayer stage to bulk films approaching limiting thicknesses. Therefore, the protective mechanism did not appear to change markedly throughout this film growth interval. Availability of oxygen resulted in growth of a thicker film (*i.e.*, 100Å in Fig. 4) than in its absence (*i.e.*, 60Å in Fig. 4), but the thicker film was less protective. The thicker film contained about three times as much carbonyl content as the thinner film. This increase in content of polar carbonyl species could have facilitated charge transfer through the film and thus decreased its protectiveness. Studies are planned to correlate infrared structural studies of films with electrochemical polarization data to help elucidate the effects of composition and thickness on the rate controlling corrosion reactions.

Acknowledgments

The author expresses appreciation to H. Macy and D. Bauer for help with the experimental work, to R. P. Eischens, B. C. Lippens, and L. C. Roess for stimulating discussions and helpful suggestions and to the management of Texaco Inc. for support of this research.

Oxidation of Nickel by Carbon Dioxide

J. E. Antill and J. B. Warburton

Metallurgy Division, Atomic Energy Research Establishment, Harwell, Berkshire, England

ABSTRACT

Two studies have been carried out, one to determine the conditions for the equilibrium between nickel, nickel oxide, carbon dioxide, and carbon monoxide, and the second to determine the kinetics of the oxidation of nickel in carbon dioxide and in CO_2/CO mixtures. The equilibrium conditions determined over the temperature range 580°-1016°C are given by the equation

$$\log_{10}\left(\frac{p_{CO}}{p_{CO_2}}\right) = -\frac{2381}{T} - 0.025$$

The kinetic study covered the behavior of pure nickel, commercial impure nickel, and nickel dispersion strengthened with alumina or thoria within the temperature range 700°-1100°C. The reaction rates were significantly reduced by the normal impurities in commercial nickel and by water vapor in the carbon dioxide. It was deduced that the oxidation rate was at least partially governed by a reaction at the oxide/gas interface and that considerable plastic flow occurred in the oxide scales.

The present paper covers the oxidation of nickel and oxide dispersion strengthened nickel by carbon dioxide and CO_2/CO mixtures at elevated temperatures. Examination of the relevant thermodynamic data reveals that the concentration of carbon monoxide necessary to prohibit the formation of nickel oxide in CO_2/CO mixtures is small, but considerable scatter exists in the values which can be calculated or have been determined directly for this concentration. The first studies in the present work involved therefore an accurate determination of the conditions for equilibrium between nickel, nickel oxide, carbon dioxide, and carbon monoxide

$$Ni + CO_2 \rightleftarrows NiO + CO$$

These studies were followed by kinetic studies of the oxidation of four grades of nickel, including oxide dispersion strengthened nickel, in primarily carbon dioxide over the temperature range 700°-1100°C, although some work was also carried out with CO_2/CO mixtures and oxygen. By comparison with previous work the exposure times were long (*e.g.*, 1000 hr). The data obtained in the equilibrium studies were in the midst of most of those published previously, while the kinetic studies extended previous work.

Thermodynamic Study

The conditions for the equilibrium have been studied previously by four major groups of workers (1-4) and may be calculated from a summary of the thermodynamic data (5) for the four components. The various sets of work are not in good agreement as the values for the ratio of the partial pressures of the two gases at equilibrium at a given temperature can vary by up to a factor of 10. In the present work the equilibrium was studied directly over the temperature range 580°-1016°C.

Experimental

A standard technique was used in which a CO_2/CO gas mixture was circulated round a closed loop containing a heated mixture of nickel and nickel oxide. When equilibrium was established samples of the gas mixture were taken and analyzed by two methods, one in which the total pressure and the carbon monoxide partial pressure were measured manometrically and with a McLeod gauge, respectively, and the other using the tracer ^{14}C in the gas and a Geiger-Mueller end window counter attached to the gas circuit. In both methods the carbon monoxide partial pressure was measured after the carbon dioxide had been removed by a small liquid nitrogen trap, but the trap and the size of the sample were different in the two cases. The second method had the advantage that erroneous results could not arise from the inadvertent presence of an inert gas such as nitrogen. The p_{CO}/p_{CO_2} ratios obtained by the two methods agreed to within 4%. The total pressure varied during the series of experiments within the range 0.34-0.66 atm. The temperature of the solid mixture was measured with a Pt/PtRh thermocouple in a pocket in the reaction tube adjacent to the mixture. The values were accurate to ±3°C. The solid mixture weighed approximately 5.5g and consisted of equal amounts of an intimate mixture of nickel and nickel oxide powders.

The nickel and nickel oxide were spectrographically standardized and obtained from Johnson Matthey Company. The major impurities were 75 ppm carbon, 2 ppm silicon, and 1 ppm iron in the nickel, and 60 ppm carbon, 5 ppm silicon, 3 ppm iron, and 1 ppm magnesium in the nickel oxide. The initial charge of gas was spectrographically standardized carbon dioxide supplied by BOC to which was added some $^{14}CO_2$ made from barium carbonate. It was dried over phosphorous pentoxide before use.

Results

The results are summarized in Fig. 1 and by the equation

$$\log_{10}\left(\frac{p_{CO}}{p_{CO_2}}\right) = -\frac{2381}{T} - 0.025 \quad \ldots [1]$$

The experimental values for the p_{CO}/p_{CO_2} ratio agree with Eq. [1] to within ±3%. The gas flow rate for the majority of the experiments was 220-240 cm^3/min. It was shown that there was no thermal segregation of the gases or cooling of the solid mixture as the p_{CO}/p_{CO_2} ratio at equilibrium was unaffected by flow rate over the range 100-500 cm^3/min. Also the results were unaffected by the direction from which the equilibrium was approached. However it is noteworthy that reproducible results could not be obtained until the solid mixture had been outgassed at 900°-1000°C; the reason for this behavior is not known. Fricke and Weitbrecht (4) have reported complications arising from the deposition of carbon by the Boudouard reaction

$$2CO \rightarrow C + CO_2$$

but this reaction did not occur in the present work as the carbon content of the nickel-nickel oxide mixture at the end of the experiments was only 30-100 ppm, and hence comparable with the initial content.

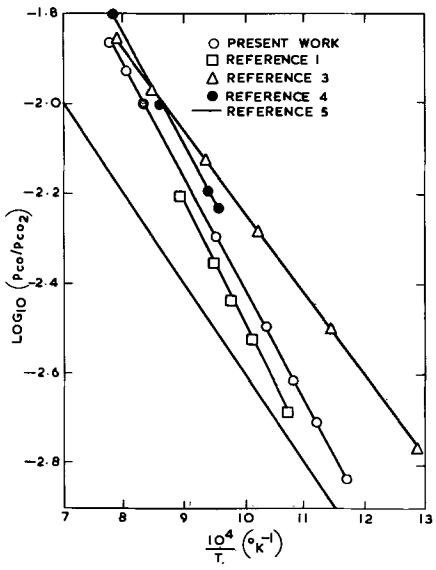

Fig. 1. Summary of thermodynamic data

Discussion

The data obtained in the present work are compared with the results of three of the direct studies (1,3,4) carried out previously and the compiled data of Kubaschewski, Evans, and Alcock (5) in Fig. 1. The compiled data used the standard free energy equations for the reactions

$$Ni + \tfrac{1}{2}O_2 \rightarrow NiO \quad (a)$$
$$C + \tfrac{1}{2}O_2 \rightarrow CO \quad (b)$$
$$C + O_2 \rightarrow CO_2 \quad (c)$$

Other thermodynamic data obtained for these reactions have not been included because direct studies of the equilibrium are of most interest and the compilation of data for several reactions leads to comparatively large limits of error. The data from the direct study by Kapustinsky and Silberman (2) have not been included in Fig. 1 because the equilibrium p_{CO}/p_{CO_2} ratios differ markedly from the other values, being greater than those obtained in the present work by at least a factor of five.

The agreement with the data of Watanabe (1) and of Fricke and Weitbrecht (4) is good especially as the small discrepancies with the German work could be due to the better precautions taken in the present work against separation of the gases by thermal diffusion. No firm explanation can be offered for the significant disagreement with Bogatski's data at low temperatures although it is noteworthy that the purity of the nickel and nickel oxide used in the present work was superior to that used by Bogatski (3) or any of the other workers.

The free energy equation obtained from Eq. [1] for the formation of nickel oxide from carbon dioxide

$$Ni + CO_2 \rightarrow NiO + CO$$

is

$$\Delta G^\circ = 10890 + 0.11T \text{ cal/mole } (853°\text{-}1289°K) \quad \ldots [2]$$

The free energy values obtained from Eq. [2] are within 2 kcal/mole of the compiled data of Kubaschewski, Evans, and Alcock (5) which is within the limits of error given for this data, the limits being ±2 kcal/mole for reaction (*a*) and ±1 kcal/mole for reactions (*b*) and (*c*).

When Eq. [2] is combined with the data of Kubaschewski, Evans, and Alcock (5) for reactions (*b*) and (c) the following equation is obtained for the free energy of formation of nickel oxide from oxygen [reaction (*a*)]

$$\Delta G^\circ = -56600 + 20.9T \text{ cal/mole } (853°\text{-}1289°K)$$

Kinetic Study

The oxidation behavior of nickel and thoria dispersion strengthened nickel has been covered by several previous publications. Most of the studies have been concerned with oxidation by oxygen (6-16) although two pieces of work have covered carbon dioxide and CO_2/CO mixtures (16, 17). While the subject has received considerable attention several complicating features have not been fully explained, and the rate-determining processes have not been clearly identified. In oxygen at temperatures of 500°-1400°C the over-all attack may be approximated to a parabolic law although deviations are in general obtained with the nickel oxide being either more or less protective than required by the law. Cation diffusion via cation vacancies in the nickel oxide is normally accepted as the rate-determining process. Consistent with this view, the parabolic rate constant is increased by impurities in the metal such as iron, manganese, and chromium and is proportional to $p_{O_2}^{1/4}$ up to an oxygen pressure of 1 atm. Complicating features are that the parabolic rate constant is independent of the pressure of oxygen above 1 atm, that in one study on thoria dispersion strengthened nickel it was deduced that some control of the oxidation rate was exercised at 950°-1000°C by a surface reaction at the oxide/gas interface (14), and that the oxide film may consist of two layers with markers positioned within the scale between the two layers. The inner oxide layer is porous and is usually assumed to grow with the transfer of oxygen gas across the pores. The formation of the two oxide layers is facilitated by the presence of impurities in the metal.

The two previous studies (16, 17) with carbon dioxide and CO_2/CO mixtures were carried out at temperatures of 900°-1300°C. A linear rate law was obeyed initially, and this was followed by a period in which the rate continuously decreased according approximately to a parabolic law. It was deduced that during the linear period the rate of oxidation was controlled by the dissociation of carbon dioxide on the surface of the nickel oxide while latterly ionic diffusion was rate controlling. However the dependence of the linear rate constant on the carbon monoxide concentration did not agree with theoretical predictions which held in the case of the analogous oxidation of iron (18). In contrast to the behavior for oxygen only one layer was observed in the oxide film with markers being situated at the oxide/metal interface.

Experimental

Four types of nickel were investigated, spectrographically standardized pure metal from Johnson Matthey Company, an impure commercial grade containing appreciable amounts of manganese and iron, and metal dispersion strengthened with approximately 2 vol % of either alumina or thoria from Henry Wiggins Company and E. I. du Pont de Nemours & Co., respectively. Detailed analyses are given in Table I. The particle sizes of the oxide in the alumina and thoria strengthened materials were 500-5000 and 100-400Å, respectively. The first three types were tested in the form of 500μ thick sheet while the last was as sections of tube 1.5 cm diameter with a wall thickness of 750μ. Before testing all the specimens were annealed for 15 min at 900°C and then pickled in a mixture of nitric, sulfuric, orthophosphoric, and acetic acids to obtain a bright smooth surface. The carbon dioxide and oxygen were the spectrographically standardized grades supplied by BOC. They were dried over phosphorus pentoxide before use.

Oxidations were carried out on vacuum microbalances by a procedure described previously (19). Specimens were outgassed at room temperature and then at the reaction temperature before the admission of the reactant gas. There was no carrier gas or continuous gas flow through the apparatus. Carbon monoxide formed by the oxidation with carbon dioxide was continuously reconverted to carbon di-

oxide by two beds of cupric oxide, one in the reaction vessel beneath the specimen and one in a thermal convection loop attached to the balance. The temperature of the beds was 350°-400°C for all the experiments. Analysis of the gas at the end of the experiments established that the beds worked efficiently and the final carbon monoxide pressure in the apparatus was $<10^{-5}$ atm. The experiments with the CO_2/CO mixtures were carried out in a gas circuit similar to that used for the thermodynamic study but containing a microbalance and a bed of nickel and nickel oxide powders, the temperature of which fixed the p_{CO}/p_{CO_2} ratio.

Information on the mechanisms of oxide film growth was obtained from marker studies employing platinum deposits on preoxidized surfaces, and the alumina particles in the alumina dispersion strengthened material. The deposits were prepared from a product supplied by Engelhard Industries containing a platinum compound in a hydrocarbon solvent. The specimen was painted with the product and then given the normal high-temperature outgassing treatment on a microbalance to decompose the platinum compound and thereby produce a fine dispersion of metallic platinum.

Results

The primary experiments were carried out in carbon dioxide at 0.1 atm pressure at 700°, 800°, 900°, 1000°, and 1100°C. All four batches of metal were tested at the four latter temperatures, but only the pure nickel was investigated at 700°C. As the results from these experiments were in some respects unexpected, further experiments were carried out with pure nickel in oxygen at 0.1 atm and in carbon dioxide at 1 atm to provide reference data which overlapped published work. Experiments were also carried out with the pure nickel in CO_2/CO mixtures at 0.1 atm at 900° and 1000°C.

With carbon dioxide and CO_2/CO mixtures the kinetics were complex and varied to a significant extent in duplicate runs but allowed firm conclusions to be reached. The weight gain-time curves for carbon dioxide are given for the four higher temperatures and a gas pressure of 0.1 atm in Fig. 2-5, respectively. The degree of irreproducibility is demonstrated in the figures by duplicate runs for pure nickel. The initial rate of oxidation decreased and then became linear or continued to decrease. After very long exposures a linear rate would change to a steadily decreasing rate. At 700°C the oxidation of the pure metal was very slight with the weight gain amounting to only 0.1 mg/cm² after 1000 hr exposure. With oxygen the rate steadily decreased during the course of the experiment. Decreasing rates obeyed in general a parabolic law as demonstrated by the data for carbon dioxide at 1000°C in Fig. 6. The parabolic rate constants obtained initially for the pure metal in carbon dioxide and oxygen are summarized together with those for the relevant published data in Fig. 7. The following conclusions were drawn from an analysis of the results:

(*A*) The data for carbon dioxide at 1 atm and for oxygen are in good agreement with the comparable published data.

(*B*) With a pressure of 0.1 atm the extent of the oxidation by carbon dioxide is almost independent of temperature over the range 900°-1100°C and is decreased by the impurities in commercial nickel. This latter conclusion is in general supported by the results of the dispersion strengthened materials.

(*C*) An increase in the gas pressure from 0.1 to 1 atm increases significantly the oxidation by carbon dioxide particularly at the higher temperatures of 1000° and 1100°C.

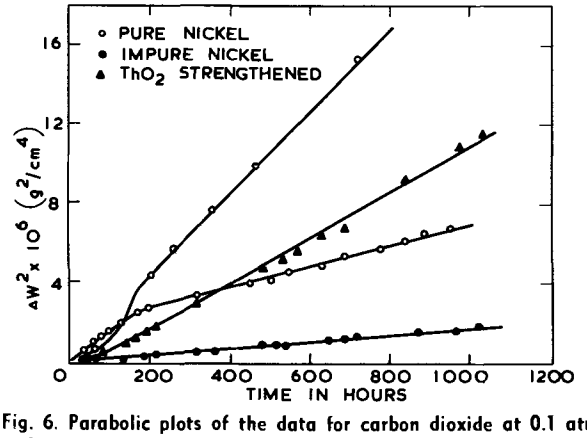

Fig. 6. Parabolic plots of the data for carbon dioxide at 0.1 atm at 1000°C.

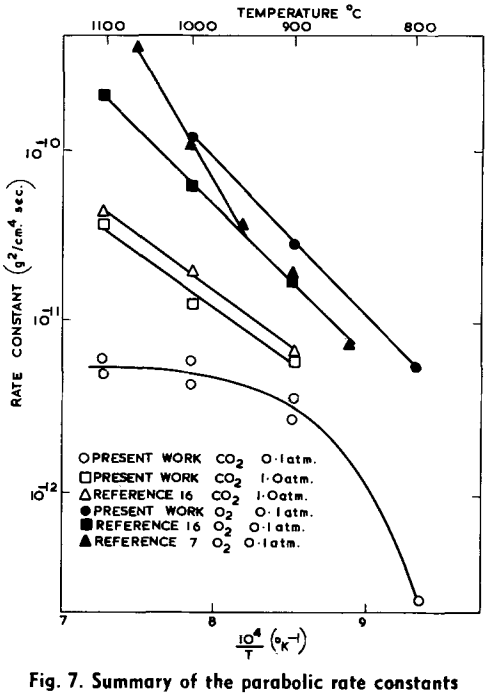

Fig. 7. Summary of the parabolic rate constants

The addition of carbon monoxide to the carbon dioxide at 0.1 atm pressure decreased the extent of the oxidation. At 900°C a linear law was obeyed after the initial oxidation, and a series of experiments was carried out on one specimen in which the carbon monoxide level was varied over the range 0.16-0.7% such that a rate constant was determined for each of 5 carbon monoxide concentrations. The results are summarized in Fig. 8 which shows the rate constant varied linearly with the percentage of carbon monoxide in the gas. At 1000°C two experiments were carried out with 0.91 and 0.94% carbon monoxide. In both cases a parabolic law was obeyed over the 300-1200 hr exposure period, the respective rate constants being 2.1×10^{-13} and 4.9×10^{-13} g²/cm⁴ sec.

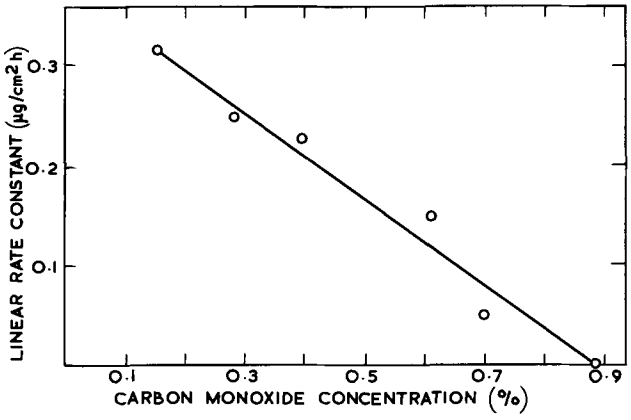

Fig. 8. Influence of carbon monoxide on the linear rate constant for CO_2/CO mixtures at 0.1 atm at 900°C.

Metallographic examination of the specimens established that for the pure and impure grades of metal the extent of the attack differed on different metal grains at 700° and 800°C and for some but not all specimens at 900°C. This phenomenon was obtained also for pure nickel in oxygen at 700° and 900°C but was absent for oxygen at 800°C and for both carbon dioxide and oxygen at temperatures ≧ 1000°C. During the oxidation of the pure metal in carbon dioxide pores were formed on grain boundaries within the metal at 700° and 800° and in some specimens at 900°C, but not at higher temperatures or in oxygen at any temperature. With the impure nickel, pores were not formed within the metal, but internal oxidation was obtained at all test temperatures; this oxidation was more pronounced the higher the temperature and resulted in the formation of oxide particles primarily on the grain boundaries but also within the grains at the higher temperatures. Electron microprobe analysis showed that the internal oxide was enriched in manganese. Internal oxidation was not obtained for any other metal-environment combination other than for one anomalous pure metal specimen oxidized in carbon dioxide at 1 atm at 1000°C. With the two oxide dispersion strengthened materials there was no pore formation within the metal or internal oxidation although the oxide/metal interface was very uneven at the higher experimental temperatures, indicating preferential attack of certain grains. The oxide scales formed on all, but possibly one specimen, were single layered and contained pores of various sizes (Fig. 9); these pores appeared closed and hence did not provide access for the gas to the oxide/metal interface. The possible exception was the alumina strengthened material oxidized in carbon dioxide at 1000°C, which had an outer dense layer and an extremely porous inner oxide with a pronounced tendency to separate from the metal substrate on cooling of the specimen.

All the experiments with a platinum marker were carried out at 1000°C and with the surface of the metal slightly preoxidized in carbon dioxide at 1000°C before application of the marker. The preoxidation amounted to a weight gain of 18-30 μg/cm² and stopped interaction of the marker with the metal. A separate experiment in which the marker was applied to a heavily oxidized specimen which was subsequently heat-treated *in vacuo* at 1000°C for 478 hr confirmed that the marker did not interact with the oxide. Three experiments were carried out with pure nickel for varying oxidation times. The majority of

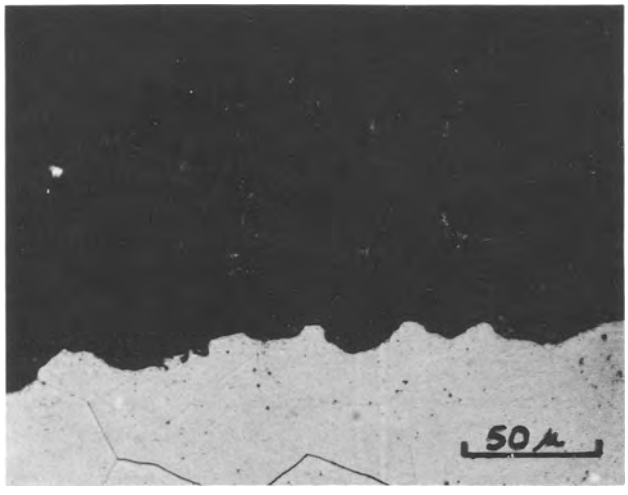

Fig. 9. Section of the scale formed on pure nickel after 6000 hr oxidation in carbon dioxide at 1 atm at 1000°C.

the platinum was found in approximately the middle of the scale although appreciable amounts were distributed randomly throughout the oxide between the two interfaces (Fig. 10). One experiment was carried out on the alumina strengthened material and the majority of the platinum was found at the boundary between the dense and porous regions of the scale, although in contrast electron probe analysis of this and other alumina strengthened specimens indicated that little or no alumina was incorporated into either region of the oxide, instead there was an accumulation of alumina at the oxide/metal interface.

Discussion

For the experiments with carbon dioxide, the oxygen potential of the gas should have been determined by the experimental temperature according to the equilibrium

$$CO_2 \rightleftarrows CO + \tfrac{1}{2} O_2 \qquad \ldots [d]$$

but as the partial pressures of carbon monoxide and oxygen will have been low consideration should be given to the effects of carbon monoxide produced by the oxidation of the metal. First, it may be deduced that changes in the carbon monoxide content of the main gas stream could not have invalidated the essential kinetic results for temperatures of 900°-1100°C as (*a*) reaction rates differed considerably between the different batches of metal; (*b*) there was only a slight effect of temperature on the kinetics with a total pressure of 0.1 atm; (*c*) there was only a slight effect of total pressure on the kinetics at 900°C, the temperature within the 900°-1100°C range at which the maximum effect of carbon monoxide should be obtained at 0.1 atm from considerations of the reaction rates and carbon monoxide contents produced by reaction [*d*].

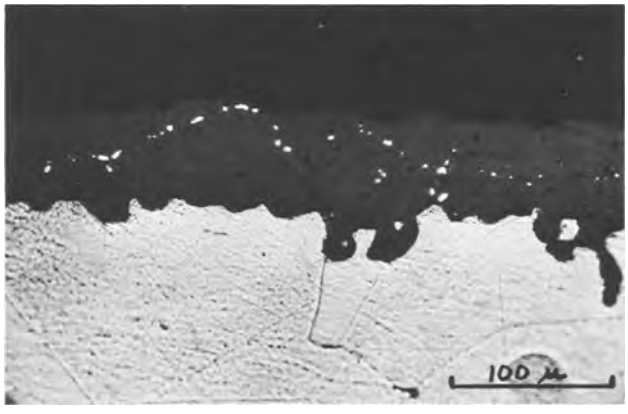

Fig. 10. Platinum marker in oxide formed on pure nickel after 1500 hr oxidation in carbon dioxide at 0.1 atm at 1000°C.

Regarding points (*b*) and (*c*), if the CO_2/CO ratios had been altered significantly by the oxidation, high reaction rates would have been expected at 1100°C 0.1 atm and 900°C 1 atm by comparison with 900°C 0.1 atm because the proportionate contributions to the carbon monoxide content of the gas from the oxidation would have been greatly reduced in the former instances. Also with particular relevance to the data for 1000°-1100°C the carbon monoxide pressures produced by the oxidation were shown at the end of the experiments to be $< 10^{-5}$ atm, a pressure comparable with or less than that obtained from reaction [*d*] at temperatures $\geq$ 1000°C. It may be deduced that the oxidation had no significant influence on the CO_2/CO ratios below 900°C because at these temperatures the decrease in the reaction rate with temperature was greater than that for the carbon monoxide produced by reaction [*d*]. Further to the above points interdiffusion rates between carbon dioxide and carbon monoxide are fast by comparison with the reaction rates from which it may be shown that changes in carbon monoxide concentration across a diffusion barrier layer next to the metal would have been small. Considerations of the kinetic data and the thermodynamics of reaction [*d*] show that the maximum effect of the barrier layer would have been obtained at 900°C with a total pressure of 0.1 atm. With the maximum reaction rate obtained initially at 900°C, an interdiffusion coefficient of 1 cm^2/sec and a barrier layer thickness of $<$ 1 mm it may be calculated that the change in carbon monoxide concentration across the barrier layer would have been $< 1.5 \times 10^{-6}$ atm. By comparison the carbon monoxide concentration in the main gas stream at 900°C and 0.1 atm total pressure according to reaction [*d*] was 1.2×10^{-6} atm. Under the worst possible conditions, therefore, the oxidation of the metal could have only doubled the carbon monoxide content of the gas next to the metal. This increase would have only decreased the cation defect concentration in the oxide at the oxide/gas interface by 30% assuming the defect concentration is proportional to $p_{O_2}^{1/4}$. Also it would have been unlikely to have affected surface reaction rates appreciably, and therefore it is concluded that the carbon monoxide produced by the oxidation had no significant influence.

Nickel oxide is a p-type semiconductor from which it is assumed throughout the remainder of this discussion that nickel is the predominant diffusing ion in the oxide and that the position of markers within the oxide scale in both this and other work must be explained by mechanisms other than the diffusion of oxygen ions. The temperature dependence of the kinetic data for pure nickel in carbon dioxide clearly indicates that the oxidation rate was at least partially governed by a process other than the diffusion of nickel across the oxide scale. At 0.1 atm pressure the parabolic rate constant was almost independent of temperature over the range 900°-1100°C and at 1 atm pressure the activation energy was only 29 kcal/mole. In contrast the activation energy for reaction by oxygen was 42 kcal/mole and the values reported for the diffusion of nickel in nickel oxide are within the range 44-62 kcal/mole (13). For pure diffusion control the activation energy for oxidation by carbon dioxide should be slightly greater, not less than these values because the oxygen potential of the environment rises with temperature according to reaction [*d*]. As already discussed the kinetics cannot be explained in terms of the carbon monoxide produced by the oxidation but instead it is considered that the oxidation rates are at least partially governed by a surface reaction at the oxide/gas interface. This view is supported by a linear rate law being obeyed in several instances. In particular the data obtained for the CO_2/CO mixtures at 900°C obey an equation shown by Pettit *et al.* (18) to hold when a linear rate law

is obeyed and reaction is controlled by the dissociation of adsorbed carbon dioxide, namely

$$\overset{o}{n} = k'P'(1 + K)[N'_{CO_2} - N'_{CO_{2(equil)}}] \quad \ldots [3]$$

where $\overset{o}{n}$ = number of equivalents of oxide formed/sec/cm² area; k' = rate constant of the phase boundary reaction; P' = total pressure; K = equilibrium constant between metal, metal oxide, and gas mixture; N'_{CO_2} = mole fraction of carbon dioxide in gas; and $N'_{CO_{2(equil)}}$ = mole fraction of carbon dioxide in CO_2/CO gas mixture in equilibrium with metal and oxide. In contrast this relationship did not apply to the data of Fueki and Wagner (17) for temperatures within the range 1100°-1300°C.

In addition to the linear regions, interface control is believed to apply to at least a limited extent during periods in which the reaction rate continuously decreases with time, thereby explaining the low activation energies for the parabolic rate constant for carbon dioxide at both 0.1 and 1 atm pressure. Also it could explain the pronounced pressure dependence of the parabolic rate constant at 1000°-1100°C. For example at 1100°C oxidation controlled by cation diffusion should result in the rate constant being increased by a factor of 1.5 for a total pressure increase from 0.1 to 1.0 atm assuming the rate constant is proportional to $p_{O_2}^{1/4}$, while in fact the constant increased by a factor of 6.4. Interface control could apply during an extended period in which the over-all reaction rate was decreasing if it was assumed that the interface reaction was linked to the diffusion of nickel in the oxide and decreased with time, with for example the rate of the interface reaction being coupled to the defect concentration of the nickel oxide at the oxide/gas interface. A mechanism consistent with the data would be that the rate of adsorption or dissociation of carbon dioxide decreased as the concentration of cation vacancies increased. By such a mechanism both the interface and diffusion processes would be linked to give a continuously decreasing over-all rate of oxidation, and the concentration of cation vacancies at the oxide/gas interface would gradually increase. Thickening of a thin oxide film initially in equilibrium with the metal would increase the diffusion path for nickel ions and thereby tend to increase the concentration of nickel ion vacancies at the oxide/gas interface, but this would be partially counteracted by a slowing of the interface reaction. For pure diffusion control the oxide at the oxide/gas interface would be in equilibrium with the gas while for complete interface control this oxide would be in equilibrium with the metal; it follows that in the present case an intermediate situation is envisaged in which the oxide at the interface is in equilibrium with neither the underlying metal nor the gas.

The proposed mechanism would be consistent with the low rates of oxidation obtained for the impure nickel, the impurities in which should increase the concentration of nickel ion vacancies as shown by the high rates of attack obtained in oxygen with metal contaminated with iron and manganese (15), the main impurities in the commercial grade of metal. Also it is consistent with the work of Jones and Westerman (14) on the reaction of TD nickel with oxygen in that these workers deduced that the partial interface control for this reaction resulted from the adsorption of oxygen (reaction [e]) being decreased by the

$$O_2 + \text{site} + 4e^- \rightarrow 2\,O^{--}\ (\text{ads}) \quad \ldots [e]$$

presence in the oxide of foreign cations with a valency > 2 (*i.e.*, thorium).

Further support for interface control was obtained from experiments aimed at explaining the significant irreproducibility in the kinetics by determining the influence of water vapor in the carbon dioxide. The experiments were carried out at 800°, 900°, and 1000°C with a total pressure of 0.1 atm. Oxidation started in dry carbon dioxide, water vapor at a pressure of 3.5 x 10^{-2} atm was subsequently added, and then finally the water vapor was removed and the oxidation concluded in dry carbon dioxide. The results demonstrated that at the three temperatures water vapor inhibited the reaction. Results for 900° and 1000°C are summarized in Fig. 11. The free energies of formation of carbon dioxide and water vapor at these temperatures are such that the water vapor could not have significantly altered the oxygen potential of the gas, and hence diffusion rates in the nickel oxide, and therefore the results can only be explained by the water vapor modifying the surface reaction and being adsorbed in preference to carbon dioxide. It is relevant to note that the water vapor exerted its effect at 800°C, although the preferential attack of certain metal grains obtained at this temperature would indicate that processes at the metal/oxide interface were of prime importance.

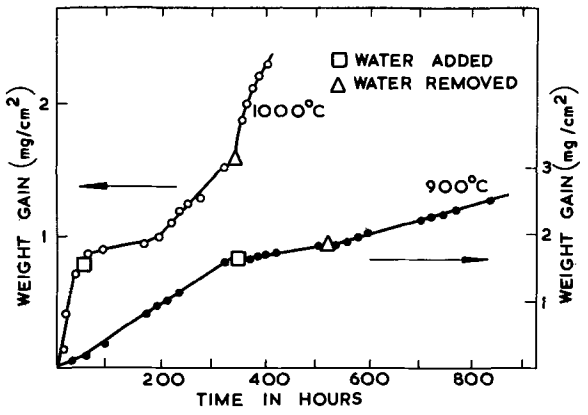

Fig. 11. Influence of water vapor on oxidation of pure nickel by carbon dioxide at 0.1 atm at 900° and 1000°C.

Consideration of the parabolic rate constants obtained for oxygen and CO_2/CO mixtures at 1000°C showed that the rate constant was proportional to $p_{O_2}^{1/4}$, but in view of the influence of interface control for pure carbon dioxide no conclusions can be drawn from this relationship as to the defect structure or diffusion processes in the nickel oxide. The observance of a parabolic law is therefore considered incidental and of no particular significance.

As in other work it was observed that the color of the oxide could vary considerably from bright green to black. Films which were black in reflected light were shown to be green in transmitted light, and therefore in contrast to previous work (8) it was concluded that the color was not dependent on the composition of the oxide, but rather was a measure of the surface roughness and the proportion of transmitted light reaching the eye. Also supporting experiments could obtain no correlation between color and stoichiometry.

The metallographic examination clearly established that the internal oxidation was associated with impurities in the metal. The one anomalous result, with internal oxidation of a pure nickel specimen at 1000°C, is not understood, but may have resulted from surface contamination during specimen preparation. The pores formed in pure nickel are believed to have resulted from the condensation of vacancies produced by the outward diffusion of nickel ions through the oxide film. The penetration of the vacancies was reduced by high temperatures and by the presence of the alumina and thoria particles, or the fine grain size resulting from the particles in the oxide dispersion strengthened materials. These factors would have facilitated the nucleation and growth of the pores at the oxide/metal interface. The absence of pores in the impure nickel specimens is probably due to the internal oxide facilitating condensation of vacancies as in the dispersion strengthened materials and to the reverse process of embryo pores acting as nuclei for internal oxidation

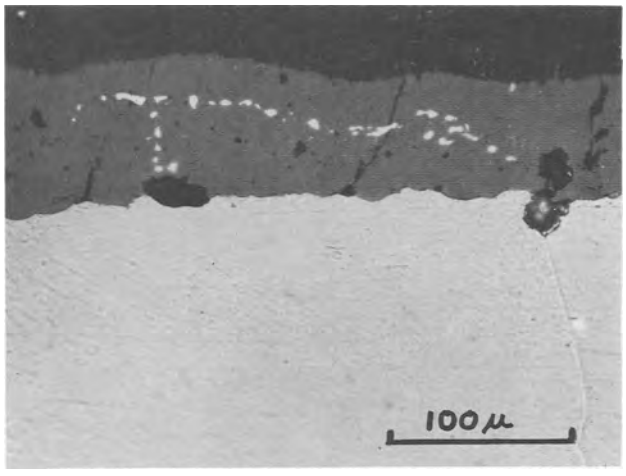

Fig. 12. Platinum marker neighboring a pore in a scale formed on pure nickel after 1500 hr oxidation in carbon dioxide at 0.1 atm at 1000°C.

such that oxide fills the vacancies as they condense. The pores within the oxide scale could have been formed by a variety of mechanisms which cannot be discussed profitably on the basis of the available data. However, it should be noted that the distribution of the pores was random.

With one possible exception the double layered scales obtained in previous studies with oxygen were not obtained. In particular the scales formed on impure nickel in carbon dioxide were single layered. To ensure consistency on this subject with previous work additional experiments were carried out with the impure nickel in oxygen at 1100°C. In agreement with the previous work the impurities led to the formation of a double layered oxide at a weight gain similar to that for the single layered scale formed in carbon dioxide (6 mg/cm^2). Double layered scales appear therefore to be associated with a high oxygen potential in the environment or the associated fast growth rates as well as impurities. Also in agreement with other work these experiments demonstrated that the impurities enhanced the attack in oxygen as distinct from carbon dioxide.

Considerable plastic flow of the oxide caused by pore formation and/or other factors was deduced from the photomicrographs. In particular the platinum markers were broken up and distributed across the oxide scale and the oxide usually kept in close contact with uneven metal surfaces (Fig. 9 and 10) resulting from preferential attack of certain regions (*e.g.*, grain boundaries). The behavior of the platinum adjacent to pores was consistent with considerable flow (Fig. 12) in these regions which would be expected as flow should be accentuated by the pores acting as barriers to ionic diffusion in the oxide, thereby tending to produce a scale of uneven thickness. The behavior of the platinum will have been facilitated by placing it on a preoxidized surface. In contrast, with the alumina strengthened material, the alumina did not pass into the oxide confirming that little or no diffusion of oxygen ions occurred in the nickel oxide and indicating that flow of the oxide did not extend to the oxide/metal interface.

The notable disagreements with previous work arise from the work of Fueki and Wagner (17) in that Eq. [3] was obeyed at 900°C although it should be noted that the other work referred to 1100°-1300°C, and in that partial interface control was believed to apply in carbon dioxide at 1 atm as well as at lower pressures. Also partial interface control is believed to apply in many instances over protracted periods when the reaction rate continuously decreases. In other respects the data are in good agreement with the previous work and extend previous knowledge in the areas covering in particular the influence of impurities in the metal, of water vapor in the gas, and the physical structure of the oxide scale.

The Effect of Anodic Films on the Gaseous Oxidation of Tantalum

II. Films Formed in Phosphoric Acid Solutions

R. E. Pawel

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The high-temperature oxidation characteristics of tantalum specimens anodized in phosphoric acid solutions were studied. The anodic oxide films containing phosphorus were found to be considerably more effective in limiting oxygen access to the metal and in postponing breakaway oxidation than phosphorus-free anodic films of the same thickness. Thickness-voltage calibrations were obtained for anodization in 0.9M and 14M H_3PO_4 electrolytes allowing quantitative measurements and comparisons of oxidation behavior to be made with that previously found for plain tantalum and for tantalum specimens anodized in dilute aqueous solutions.

In a previous paper (1) it was indicated that thin anodic films can exert a significant influence upon the subsequent gaseous oxidation characteristics of tantalum. Briefly, at temperatures up to about 600°C, the anodic films were observed to decrease the oxygen consumption rate and to postpone the occurrence of the "breakaway" increase in the oxidation rate common to this metal. While during the protective stage of oxidation the amorphous anodic films passed oxygen to the metal at a rate inversely proportional to their thickness, they appeared not to change in thickness or to crystallize. Loss of the protective properties of the films was associated with the formation of crystalline oxides, proposed to originate at the anodic oxide-metal interface, which physically ruptured the overlying film at isolated points. The purpose of the present paper is to present and discuss some of the differences in these effects when the anodic films are formed in phosphoric acid solutions rather than in dilute aqueous solutions of Na_2SO_4 and KF.

Many effects on the formation characteristics and film properties associated with anodizing in concentrated and nonaqueous electrolytes have been reported in the literature (2). In particular, anodization in phosphoric acid solutions has produced some interesting results. Vermilyea (3) concluded from his experiments that films formed in phosphoric (or sulfuric) acid electrolytes consist of two layers: a layer of normal Ta_2O_5 next to the metal and a layer of unspecified composition having different properties next to the electrolyte. Randall *et al.* (4) investigated quantitatively the composition of the films formed over a wide range of conditions. By a radiotracer technique, they confirmed the "two-layer" model, showing that the inner layer (approximately half the total thickness except for those formed in concentrated acid) was essentially stoichiometric Ta_2O_5, with the outer layer containing up to about 18 mole % phosphorus depending on the phosphoric acid concentration of the electrolyte. The relative thickness of the phosphorus-rich layer increased with increasing current density and electrolyte concentration. Smyth and his coworkers (5, 6) have made extensive measurements of the dielectric behavior of such films, particularly after mild heat-treatments, and found significant differences from those properties exhibited by phosphorus-free anodic films. The irregular distribution of phosphorus in the anodic film was found to become still more irregular upon annealing. For 1-hr anneals in air at 500°C, the "interface" separating the two layers of film moved away from the tantalum, resulting in a large phosphorus concentration increase in a narrow zone within the phosphorus-containing layer. In addition, Smyth reported several observations which indicated that mass transport, particularly of oxygen, is more difficult in phosphorus-containing anodic Ta_2O_5 films, a behavior consistent with that observed for several other metal-oxide systems where phosphorus is involved. It is also interesting to note that thin phosphide layers, formed by holding specimens in phosphorus vapor, have been reported to decrease the rate of high-temperature (800°C) oxidation of several refractory metals (7, 8).

Since the early stages of gaseous oxidation of tantalum involve the dissolution of comparatively large quantities of oxygen with the attendant development of both stress and mechanical-property gradients in addition to oxide formation, it is anticipated that devices which decrease oxygen access to the metal through decreasing oxygen mobility in oxide films might be especially effective in combating otherwise poor oxidation resistance. Therefore, the extent of protection during subsequent oxidation afforded by anodic films formed in phosphoric acid was studied and compared with the previous results on tantalum anodized in dilute aqueous solutions. The manner in which the films eventually break down during oxidation was also investigated.

Experimental Procedure

The tantalum[1] specimens were prepared from 0.020- and 0.050-in. sheet in the form of 1- × 2-cm coupons. The coupons were annealed in vacuum at 1600°C for 2 hr, mechanically polished through 0.3-μ alumina, and electropolished in a 90% H_2SO_4-10% HF solution. A short length of 0.010-in. electropolished tungsten wire was spot welded to the specimen to serve as electrical contact and support during anodization. The electropolished tungsten did not interfere with the anodization of the tantalum and, during oxidation, proved to be more "inert" than fine tantalum wire which sometimes exhibited premature breakdown of the anodic film.

Since the H_3PO_4-anodized specimens oxidized very slowly compared to unanodized tantalum, it was important to reduce spurious oxygen consumption sources to a minimum in order for the kinetic studies to be meaningful. The specimens were carefully electropolished to avoid as much as possible physical surface flaws such as pits or fine scratches which serve as sources for breakdown. The 0.050-in.-thick specimens appeared to exhibit less severe edge and corner effects, perhaps due to the rounding that occurred at these

[1] Nominal analysis is 99.7-99.8% Ta with Nb, Fe, W, and Si being major metallic impurities; interstitial content after vacuum anneal is 200-300 ppm.

points during extended electropolishing, and most of the data presented in this paper were obtained on such specimens.

The specimens were anodized at room temperature to a given voltage in a simple cell in which the initially high rates of film formation were limited by a variable series resistor. The series resistance was reduced to zero and the specimen held at full voltage for a "standard" time, in this case 2 min, such that the final thickness was relatively insensitive to small differences in the anodization sequence or time.

The specimens were heated quickly in dry oxygen to the desired reaction temperature in a high sensitivity manometric oxidation rate apparatus, and the rate of oxygen consumption was followed as a function of time. Specimens for metallographic examination were similarly oxidized for various times in a quartz apparatus.

Results and Discussion

Film formation.—Generally, the anodic films formed on electropolished tantalum surfaces in dilute electrolytes are of very uniform thickness and consist of amorphous layers or very small crystallites of material having pentoxide stoichiometry. The anodization efficiency is virtually 100%, and suitable thickness-voltage calibrations can be obtained with a simple constant-voltage power supply using the procedures outlined above. The measurement of the weight changes of a 450 cm^2 tantalum sheet specimen during stepwise anodization in 0.2% KF to 200v resulted in a linear relationship between weight gain and voltage of 0.2399 $\mu g/cm^2$-v. Recent measurements (9, 10) indicate that the density of the amorphous oxide formed under these conditions is approximately 8.03 g/cm^3, which leads to an oxide thickness calibration value of 16.5 Å/v.

Anodizing tantalum in phosphoric acid solutions also produces uniform amorphous layers of oxide; however, the effect of included phosphorus on the physical properties of these layers is not well established. The problem is magnified because of the apparent duplex nature of the films, and an accurate thickness-voltage calibration in this case is difficult to obtain. In Fig. 1, the weight gain as a function of applied voltage is presented for anodization in 0.9M and 14M H_3PO_4. These data were obtained with a standard laboratory microbalance using polished tantalum sheet specimens having surface areas of approximately 500 and 600 cm^2, respectively. In 0.9M H_3PO_4, the tantalum anodized very much in the same manner as in dilute solutions: that is, a critical examination of interference colors, weight gain data, and electrical breakdown voltages is necessary to distinguish this film from one formed, for example, in 0.2% KF. On the other hand,

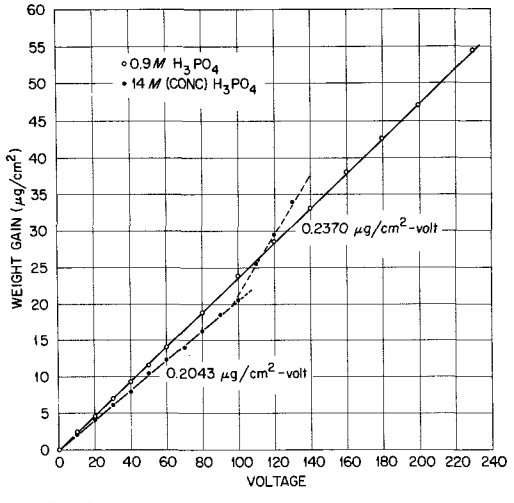

Fig. 1. Anodization of tantalum in H_3PO_4 solutions. ○ 0.9M H_3PO_4; ● 14M H_3PO_4.

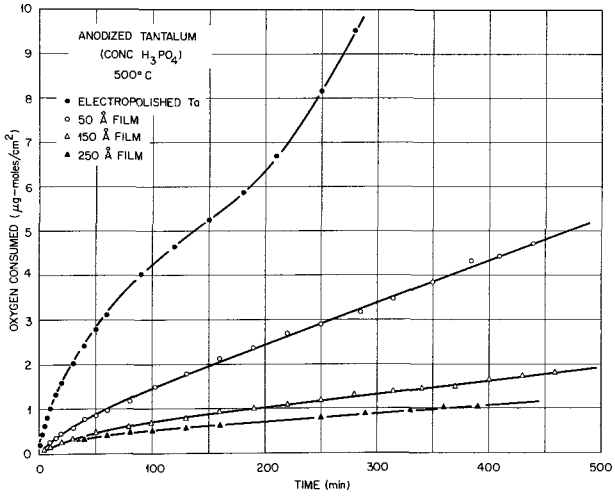

Fig. 2. Effect of anodic film thickness on the oxidation rate of polycrystalline tantalum at 500°C. Electropolished tantalum anodized in concentrated (14M) H_3PO_4 electrolyte. ● plain electropolished tantalum; ○ 50Å anodic film; △ 150Å anodic film; ▲ 250Å anodic film.

in the case of concentrated (85.3%, 14M) H_3PO_4, it is much more obvious that the process results in films of different properties.

The weight gain data of Fig. 1 are well described by a linear function of the voltage up to the breakdown voltage for each of the electrolytes. In 0.9M H_3PO_4, the specimen gained weight at a rate of 0.2370 $\mu g/cm^2$-v which was very close to that measured for tantalum in dilute KF, 0.2399 $\mu g/cm^2$-v. However, for our anodization procedures, about 10-12% additional voltage was required for 0.9M H_3PO_4 electrolytes to match interference colors with films formed in the dilute electrolytes. The breakdown voltage in this electrolyte was in excess of 220v.

In 14M H_3PO_4, the rate of weight gain of the specimen with voltage was appreciably less, 0.2043 $\mu g/cm^2$-v. The film suffered a self-healing dielectric breakdown and partial crystallization at about 95v resulting, among other things, in an increase in the rate of weight gain. In the concentrated acid, about 50% higher voltage was required to produce the same interference color as that formed in the dilute solution: for example, 49.5v films in 0.2% KF matched those formed to 75v in 14M H_3PO_4.

In order to establish a suitable thickness-voltage calibration for the phosphorus-containing films, it would be desirable to have an estimate of the density or at least information regarding the composition, structure, and refractive index of the films. While only limited direct data are available, some indirect measurements permitted a reasonable value to be estimated from the weight gain measurements. As indicated in detail in the Appendix, the most probable values were determined to be 13.2 Å/v for 14M H_3PO_4, and 15.7 Å/v for 0.9M H_3PO_4.

Kinetics.—Electropolished tantalum specimens anodized to a given film thickness in concentrated phosphoric acid (14M) were found more resistant to subsequent gaseous oxidation at elevated temperatures than specimens anodized in dilute aqueous solutions. While there were differences in the degree of protection depending on the phosphoric acid concentration of the electrolyte, the maximum effect seemed to occur for specimens anodized in the concentrated acid, and these results only will be considered in this paper.

The oxidation kinetics of plain tantalum and several anodized specimens[2] during the early stages of oxidation at 500°C are shown in Fig. 2. At this temperature,

[2] The thickness of the anodic films reported in Fig. 2-5 were calculated on the basis of a 14.0 Å/v calibration and are thus considered to be an upper limit of the actual thickness (see Appendix).

compared to the plain tantalum specimen, the anodized specimens consumed oxygen at a much slower rate: films as thin as 50Å exerted a considerable effect; films thicker than 250Å reduced the oxidation rate to very small values. By comparison with our previous work (1) it was apparent that these films were considerably more efficient in reducing the oxidation rate than those formed in dilute electrolytes. Smyth *et al.* (5, 6) previously reported that the over-all oxygen uptake of anodized tantalum while being annealed in air was less for the phosphorus-containing films. Smyth also concluded that the mobilities of the diffusing species, both high-temperature and field-driven, were decreased by the presence of phosphorus.

As further discussed below, the rate of oxygen permeation through the films was found to be inversely proportional to their thickness. This indicated that, as in the case of films formed in dilute electrolytes, oxygen diffused through the film and dissolved in the metal without an appreciable change in the film thickness. After a period of time in which oxygen solution in the metal was the primary event, the oxidation rate suddenly increased in a manner similar to the "breakaway" observed in the case of pure metal. The effect of temperature on the oxidation kinetics of tantalum specimens anodized in 14M H_3PO_4 to film thicknesses of 250 and 1000Å is shown in Fig. 3 and 4. The behavior was qualitatively the same as that shown previously (1) for conventional anodic films. However, for a given film thickness and temperature, the oxidation rate and time-to-breakaway were greatly different. It should be pointed out that the occurrence of breakaway of the oxidation rate curves for anodized specimens usually represents the start of film breakdown on an extremely local scale and not a general degradation of the protective properties of the film.

It was also possible to compare quantitatively the oxygen flux through these films with the corresponding flux observed during oxidation of tantalum specimens anodized in dilute solutions. The oxygen flux or permeation rate was taken as the slope of the almost-straight-line portion of the oxidation rate curve which existed immediately prior to the breakaway inflection. In order to check our results and to make use of some improvements in technique, our measurements for specimens anodized in 0.5% Na_2SO_4 solution were repeated and extended to higher temperatures. Figure 5 is a plot of the permeation rate as a function of reciprocal temperature for the four sets of specimens having two different film thicknesses. The data for 250 and 1000Å films formed in the dilute Na_2SO_4 solution are slightly higher than those presented in our earlier work (1); however, within experimental error the slopes of the lines describing the present data are the same as those found previously.

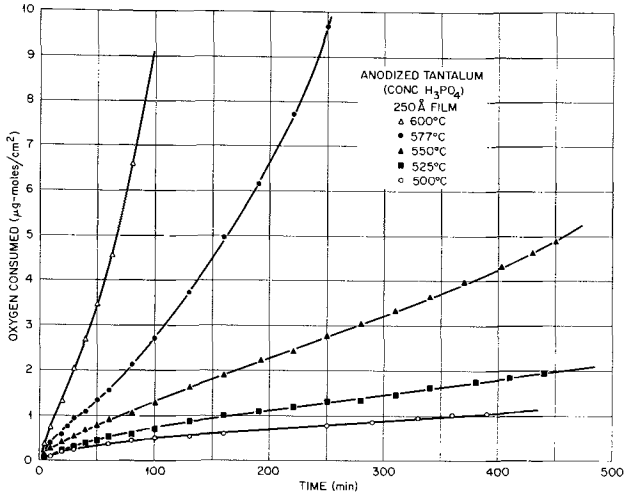

Fig. 3. Effect of temperature on the oxidation rate of anodized polycrystalline tantalum. Specimens anodized in concentrated (14M) H_3PO_4 to a film thickness of 250 Å. ○ 500°C; ■ 525°C; ▲ 550°C; ● 577°C; △ 600°C.

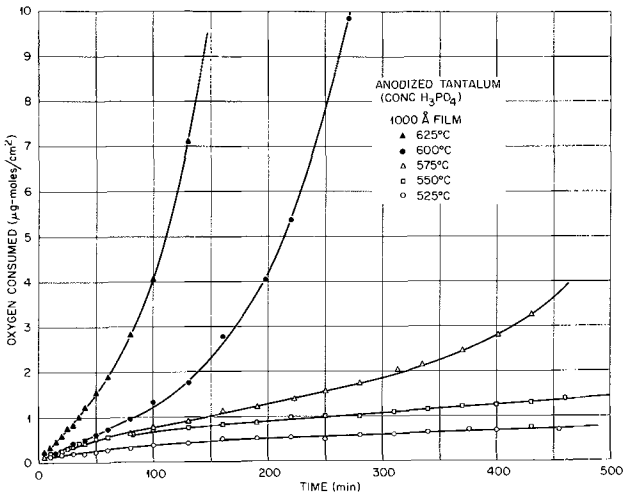

Fig. 4. Effect of temperature on the oxidation rate of anodized polycrystalline tantalum. Specimens anodized in concentrated (14M) H_3PO_4 to a film thickness of 1000 Å. ○ 525°C; □ 550°C; △ 575°C; ● 600°C; ▲ 625°C.

The data of Fig. 5 show that at a given temperature the oxygen permeation rates through films formed in dilute Na_2SO_4 were roughly five times greater than those for films of equivalent thickness formed in concentrated H_3PO_4. For films formed in either electrolyte, the permeation rates were inversely proportional to the film thickness, indicating that transport within the film was rate controlling. The activation energies for oxygen transport in both types of films, determined from the slopes in Fig. 5, were only slightly different: about 43 kcal/mole for plain Ta_2O_5 and about 46 kcal/mole for the phosphorus-containing films. Obviously, the error limits of these values overlap so it is impossible to tell unequivocally if the differences in rate were simply due to differences in activation energy

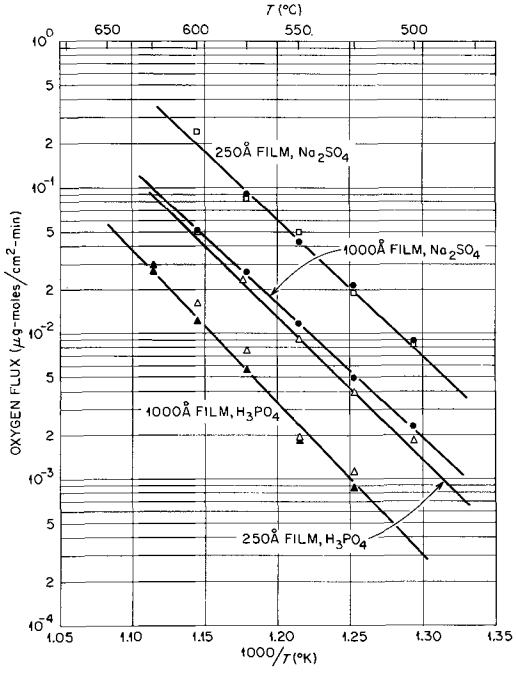

Fig. 5. Oxygen permeation rates through anodic films on polycrystalline tantalum. ● and ▲ specimens prepared from 0.050-in. Ta sheet. □ and △ specimens prepared from 0.020-in. Ta sheet. Anodic film thickness and electrolyte specified on figure.

rather than concentration differences or preexponential factor effects. However, a difference of this magnitude in activation energy could indeed account for the observed difference in rate in this temperature range.

Breakdown of the films.—Visual and microscopic observations of the topography of anodized specimens during oxidation emphasized, perhaps even more than the oxidation rate curves, the differences in protection afforded by the anodic oxide films. For all tantalum specimens anodized in concentrated H_3PO_4 (with the possible exception of specimens having film thicknesses of 150Å or less) virtually no changes in surface topography of the oxide were observed until localized regions of accelerated attack appeared. The onset of this localized attack correlated well with the beginning of the "breakaway" stage of oxidation as indicated by the oxidation rate curve. As in the case of the type of film breakdown reported for plain anodic films (1), it appears that the oxygen content in the metal at the anodic oxide-metal interface increased until crystalline oxide formed which in turn physically disrupted the overlying anodic film or promoted its crystallization. The presence of flaws in the anodic oxide films such as those described by Vermilyea (11) would probably determine to a large extent the limit of protection afforded by an anodic film of a given thickness and also account for the local nature of the accelerated attack, particularly at the higher temperatures. It may be that the role of phosphorus in increasing the over-all oxidation resistance is to change the nature of the flaws as well as to decrease the rate of oxygen permeation. It is also tempting to speculate that an unusual rearrangement of the available phosphorus, such as that described by Smyth (6), may be responsible for the large effects. Obviously, considering the film to be of uniform composition is a dangerous oversimplification.

A comparison of the topography of plain and anodized tantalum after oxidation is presented in Fig. 6-11. Figure 6 shows the oxide texture on plain electropolished tantalum after 4 hr in oxygen at 500°C. Oxidation has proceeded into the breakaway stage, and the surface has become at least partially covered with the crystalline pentoxide. In contrast, Fig. 7 shows that a similar specimen, anodized to a film thickness of only 250Å in dilute KF, was virtually unchanged by 8-hr exposure. However, 48 hr at 500°C produced serious breakdown over most of the specimen. Figure 8 shows the type of breakdown which occurred: the dark regions in the micrograph are areas exhibiting high oxidation rates where voluminous crystalline pentoxide existed; the light regions are areas still protected by the anodic oxide film. That there was an orientation effect on the morphology of film breakdown at least for the thinner films is obvious from the figure. It is possible that this is caused by the fact that formation of one or more of the suboxides of tantalum which may develop prior to the breakdown of the overlying amorphous film is orientation dependent. As these high-rate regions grew in size, the measured oxidation rate continued to increase, and "breakaway" was thus rather sluggish compared to that for plain tantalum.

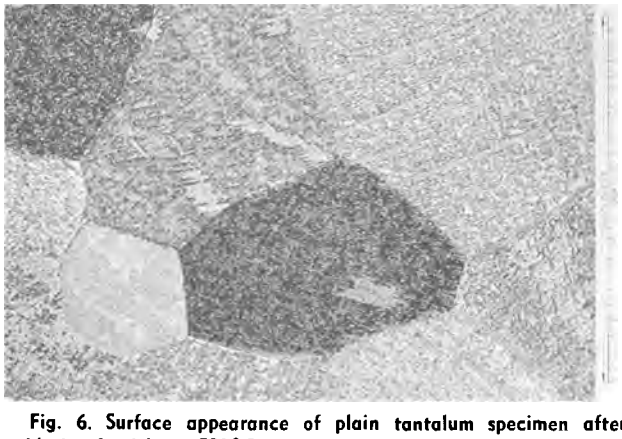

Fig. 6. Surface appearance of plain tantalum specimen after oxidation for 4 hr at 500°C.

Fig. 7. Surface appearance of anodized tantalum specimen after oxidation for 8 hr at 500°C; 0.5% Na_2SO_4 electrolyte; 250Å film thickness.

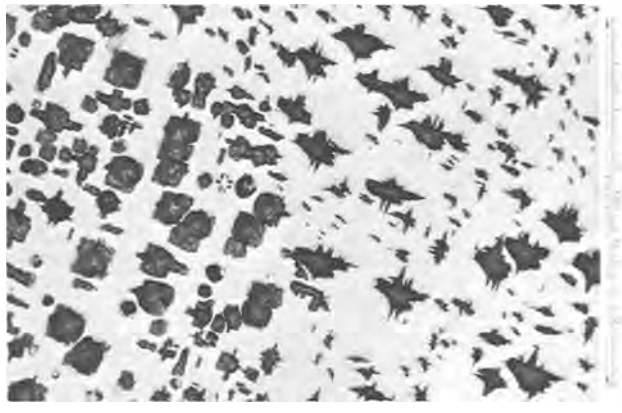

Fig. 8. Surface appearance of anodized tantalum specimen after oxidation for 48 hr at 500°C; 0.5% Na_2SO_4 electrolyte; 250Å film thickness.

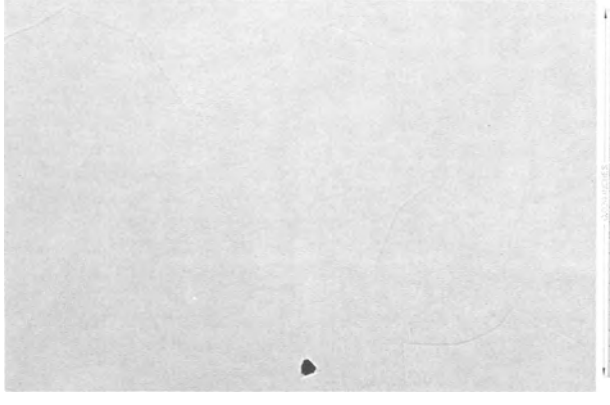

Fig. 9. Surface appearance of anodized tantalum specimen after oxidation for 48 hr at 500°C; 14M H_3PO_4 electrolyte; 250Å film thickness.

On the other hand, films of a given thickness formed by anodizing in H_3PO_4 were considerably more resistant to this sort of breakdown than those formed in dilute solutions. For example, Fig. 9 shows the surface of a specimen anodized to a film thickness of 250Å after 48 hr at 500°C in oxygen. The film was still protective to the extent that the observation of a small "breakdown" area such as that seen in the figure was a rare event. Specimens anodized to this film thickness were held in oxygen for over 100 hr at 500°C

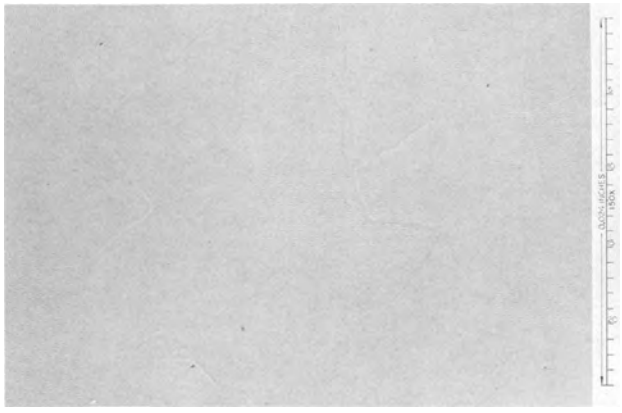

Fig. 10. Surface appearance of anodized tantalum specimen after oxidation for 6 hr at 600°C; 14M H_3PO_4 electrolyte; 1000Å film thickness.

with only few such areas observed. Even after 500 hr, large areas of film were still protective on an otherwise heavily attacked specimen. Thicker anodic films furnished an increased degree of efficiency in postponing breakaway. Figure 10 shows a typical surface area showing no breakdown of a 1000Å phosphorus-containing film after 6 hr in oxygen at 600°C, a rather severe oxidation treatment for tantalum. Of course, when a flaw in the film breaks down when the oxidation temperature is 600°C, the result is catastrophic. Figure 11 shows such a surface region from the same specimen as that of Fig. 10. The large, thick oxide patch has resulted from the consumption of practically the entire thickness of the metal at that point. While perhaps 1 or 2% of the surface area is oxidizing at a rate comparable to that of the plain metal, the rest is still being well protected by the film. The high degree of physical distortion of the film and metal around the oxide patch suggests that stresses associated with the volume change when tantalum is converted to oxide may play an important role in the lateral propagation of the fast-rate regions.

Conclusions

Anodic oxide films formed on electropolished tantalum specimens serve as protective oxide films during subsequent gaseous oxidation in the sense that they decrease the early-stage oxygen consumption rate and postpone the breakaway increase in oxidation rate associated with voluminous pentoxide formation. In agreement with the observations of Smyth *et al.* (5, 6), the presence of phosphorus in the anodic films, brought about by anodizing the specimens in phosphoric acid electrolytes, was shown to be especially effective in increasing the protective properties of the films. Compared to the behavior exhibited by films formed in dilute electrolytes, the oxygen permeation rates through films formed in concentrated phosphoric acid were shown to be decreased by a factor of five; however, the data were not sufficiently accurate to ascertain if the indicated increase in the activation energy for oxygen transport were solely responsible.

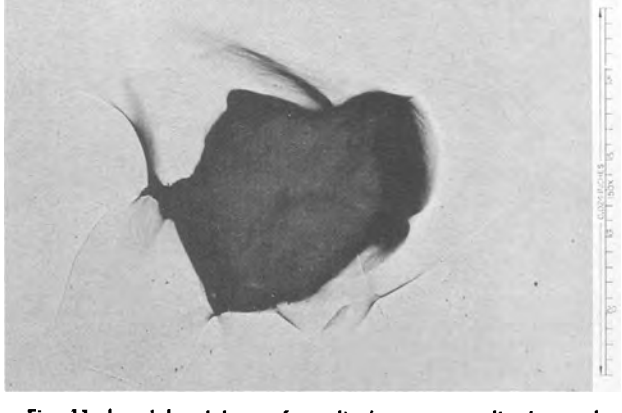

Fig. 11. Local breakdown of anodic layer on anodized tantalum specimen oxidized for 6 hr at 600°C; 14M H_3PO_4 electrolyte; 1000Å film thickness.

The characteristics of the eventual breakdown of the phosphorus-containing anodic films were shown to be similar to that observed for films formed in dilute solutions (1). Breakdown appeared to be initiated at isolated points in the film. At these points, which may be associated with any of several types of flaws in the anodic films, it appeared that crystalline oxide is nucleated either via oxidation of the metal or crystallization of the amorphous layer, or both. The resulting physical disruption of the film leads to a locally high oxidation rate. The density of activated flaws seemed to depend particularly on film thickness. For specimens with thick anodic films oxidizing at high temperature, oxidation generally proceeded from a small number of fast-oxidizing regions which consumed the specimen mainly by lateral growth.

Acknowledgments

The author is indebted to J. V. Cathcart for his helpful suggestions during the course of this work and preparation of the manuscript. Thanks are also extended to D. M. Smyth at Sprague Electric Company for communicating some of his results prior to publication, and to J. J. Campbell for a large contribution to the experimental work. Research on this paper was sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

Manuscript received June 7, 1967. A portion of this paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

APPENDIX

Establishment of the Thickness-Voltage Relationship for Tantalum Films Formed in Phosphoric Acid Solutions from the Weight Gain Measurements

On the assumption that the film is amorphous, stoichiometric Ta_2O_5 only, having a density of 8.03 g/cm³ (9, 10), the thickness-voltage relationship is given by

1. for anodization in 14M H_3PO_4

$$0.2043 \frac{\mu g O_2}{cm^2 - v} \times \frac{441.76}{80} \frac{g Ta_2O_5}{g O_2} \times \frac{1}{8.03} \frac{cm^3 Ta_2O_5}{g Ta_2O_5} \times 10^8 \frac{Å}{cm} = 14.05 \frac{Å}{v}$$

2. for anodization in 0.9M H_3PO_4, $0.2370 \frac{\mu g O_2}{cm^2 - v}$, the above expression yields 16.30 Å/v.

We can make the assumption that the film is a uniform layer of PTa_9O_{25}. According to Roth and his coworkers (12, 13), this compound is tetragonal. A theoretical density of 7.424 g/cm³ can be calculated on the basis of the x-ray data. Thus, if this assumption is correct, the thickness-voltage relationship is

1. for anodization in 14M H_3PO_4:

$$0.2043 \frac{\mu g (O_2 + P)}{cm^2 - v} \times \frac{2058.9}{431} \frac{g PTa_9O_{25}}{g (O_2 + P)} \times \frac{1}{7.424} \frac{cm^3 PTa_9O_{25}}{g PTa_9O_{25}} \times 10^8 \frac{Å}{cm} = 13.16 \frac{Å}{v}$$

2. for anodization in 0.9M H_3PO_4, $0.2370 \frac{\mu g (O_2 + P)}{cm^2 - v}$, the above expression yields 15.25 Å/v.

We could also make the assumption that phosphorus is included in the film so that the general formula $P_xTa_{2-x}O_5$ is applicable. The criterion that phosphorus

substitute for tantalum in the amorphous pentoxide without a volume change leads to a density for PTa_9O_{25} of 7.485 g/cm³. This figure is in reasonable agreement with that calculated for the crystalline material, and gives an additional degree of credence to this method of estimating the density. It is significant also to note that the density of oxide formed in 50% H_2SO_4 has been determined as 7.87 g/cm³ (9). The mole ratio of phosphorus to tantalum in the outer part of the anodic layer has been found (4) to be about 0.18 and 0.09 for 14M and 0.9M H_3PO_4 solutions, respectively. The effective density of the films can then be calculated as 7.59 and 7.79 g/cm³ corresponding to the compositions $P_{0.16}Ta_{1.84}O_5$ and $P_{0.09}Ta_{1.91}O_5$. These compositions approximate the average composition expected in the films. Therefore, on the above basis, the thickness-voltage relationship becomes

1. for anodization in 14M H_3PO_4:

$$0.2043 \frac{\mu g(O_2 + P)}{cm^2 - v} \times \frac{417.8}{85} \frac{gP_{0.16}Ta_{1.84}O_5}{g(O_2 + P)} \times \frac{1}{7.59} \frac{cm^3 P_{0.16}Ta_{1.84}O_5}{gP_{0.16}Ta_{1.84}O_5} \times 10^8 \frac{Å}{cm} = 13.23 \frac{Å}{v}$$

2. for anodization in 0.9M H_3PO_4

$$0.2370 \frac{\mu g(O_2 + P)}{cm^2 - v} \times \frac{428.3}{82.8} \frac{gP_{0.09}Ta_{1.91}O_5}{g(O_2 + P)} \times \frac{1}{7.79} \frac{cm^3 P_{0.09}Ta_{1.91}O_5}{gP_{0.09}Ta_{1.91}O_5} \times 10^8 \frac{Å}{cm} = 15.74 \frac{Å}{v}$$

Randall *et al.* (4) report a decrease of about 24% in the dielectric constant for the phosphorus-rich portion of the anodic film formed in 14M H_3PO_4 solutions. This change implies a decrease in the index of refraction and, all other things being equal, an increase in the thickness at which a given interference color appears.

The thickness, t, at which destructive interference of a wavelength, λ, occurs due to multiple reflection from a film-covered metal surface at near-normal incidence is

$$t = (2m - 1) \frac{\lambda}{4n} + C$$

where m = 1,2,3, ---, n = refractive index of the film, and C a constant reflecting the difference in the phase retardation at the metal-film interface from π. Young (14) reported that C varies from —100 to —200Å; our data favor the latter value for C for λ near 6500Å.

For two films, A and B, which exhibit the same interference color (in the same order) the following expression is applicable

$$t_B = \frac{t_A - C_A}{n_B/n_A} + C_B$$

By noting that a film anodized by the procedure outlined in the text to 75v in concentrated H_3PO_4 exhibited a color identical to that of a specimen anodized to 49.5v in dilute KF (817Å), an additional means to estimate the film thickness is obtained. Since $C_A \cong C_B$ for the films under consideration, a lower limit (when $n_A = n_B$) for the thickness-voltage ratio is found to be 10.9 Å/v. How much higher the actual value will be depends on how much the refractive index has been changed. If it is assumed that the ratio of the refractive indices of films A and B is equal to the square root of the ratio of their dielectric constants, about 0.88, (an assumption requiring that the frequency dependence of the dielectric constant of each be similar), a value of 12.8 Å/v is obtained for films formed in the concentrated acid.

Despite the various assumptions made in the above calculations, the range of values obtained for the thickness-voltage relationship is relatively narrow. For anodization in concentrated H_3PO_4 and 0.9M H_3PO_4, 13.2 and 15.7 Å/v, respectively, have been chosen as the "best" values based on present information.

Crystal Morphology and Mechanisms of Growth of Alpha-Fe_2O_3 Whiskers on Iron

Richard L. Tallman and Earl A. Gulbransen

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

ABSTRACT

The morphology of α-Fe_2O_3 whiskers formed on iron at 400°-500°C in dry oxygen was studied. Diffraction patterns of individual whiskers and texture patterns of oxidized surfaces showed the whisker axis to be $[\bar{1}\bar{1}20]$. The axial rotation indicated by the pattern is that resulting from an axial twist. This is good evidence that the most simple oxide whiskers have a single axial screw dislocation. Arguments are presented for the view that growth of the whisker occurs by diffusion of iron atoms or ions through the dislocation and reaction with oxygen at the tip.

When iron is heated in oxidizing atmospheres, localized oxide growths form on the oxidized iron surface (1-3). The crystal habit of these oxide growths and the extent of oxide growth depend on many factors, including temperature, time of reaction, internal or external stress, impurities in the metal, pretreatment of the metal, and the composition of the oxidizing atmosphere (3).

Oxide whiskers formed on pure annealed iron at 400°-500°C in dry oxygen have diameters of about 150Å or more, lengths up to 4 x 10^5Å, and whisker densities on the surface up to $10^8/cm^2$ (3). Electron diffraction studies show that the most simple whiskers are single crystals of α-Fe_2O_3.

This paper presents: (*i*) new selected area electron diffraction studies on single iron oxide whiskers formed during the oxidation of iron in dry oxygen, (*ii*) morphological evidence for screw dislocations in oxide whiskers, and (*iii*) a growth mechanism for oxide whiskers on iron.

Experimental

A large file of carefully oxidized pure iron wires were available from earlier studies (3). Before oxidation, the iron wires had been carefully annealed and cleaned. The iron wires were then oxidized in dry and purified oxygen under controlled temperature and time conditions.

An RCA EMU-3D electron microscope with selected area diffraction was used at 100 kv electron energy. The relative rotation of the selected area electron diffraction pattern was determined by use of the selected area images and the selected area diffraction patterns of asbestos fibers.

Structural Information

α-Fe_2O_3 crystal structure.—Pauling and Hendricks (4) determined the crystal structure to be trigonal or rhombohedral, space group R $\bar{3}$ c. This structure was confirmed by Blake *et al.* (5) in 1966. The latter authors give the following structural hexagonal dimensions: $a = 5.038 \pm 0.002$Å, $c = 13.772 \pm 0.012$Å, and $c/a = 2.733 \pm 0.015$Å. We have calculated the corresponding structural rhombohedral dimensions to be $a = 5.469$Å and $\alpha = 55°13.9'$. The natural hematite used contained, with lesser impurities, sufficient aluminum to fill 2.8 ± 0.6% of the iron positions. The dimensions we have chosen (6) are sufficiently accurate for this work.

Unit cells and indices.—Figure 1 shows top and front views and dimensions (6) for the unit cells for α-Fe_2O_3 and its isomorphs. Four unit cells are in common use. The conventional structural hexagonal and rhombohedral unit cells are shown at the left. Four indices are used to describe a set of lattice planes in terms of the hexagonal cell. The conventional morphological rhombohedral unit cell is shown at the right. The face-centered rhombohedral F unit cell has an *a* value of twice that for the conventional morphological rhombohedral unit cell. This cell is shown at the center. The rhombohedral F cell angle α is nearly 90°. It is this relationship to the face-centered cubic cell which makes the rhombohedral F cell convenient for indexing. Directions are nearly normal to lattice planes with the same indices. This cell is used in indexing all of our selected area diffraction patterns and is referred to wherever the unit cell is not identified. Conventional structural hexagonal and rhombohedral indices are also given.

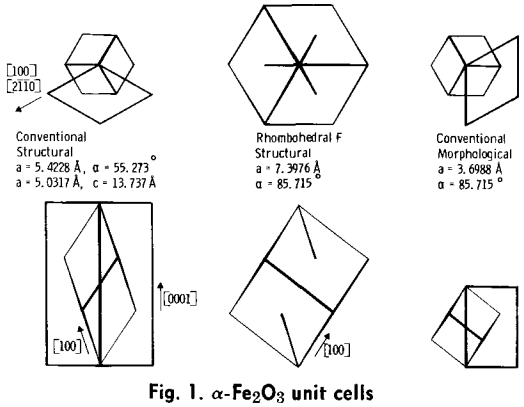

Fig. 1. α-Fe_2O_3 unit cells

Results and Discussion

Figure 2 shows a selected area electron diffraction pattern from an iron oxide whisker measuring 1.5μ in the selected area image. Indexing was made using the rhombohedral F unit cell. The orientation of the projection of the axis of the whisker lies normal to the layer lines of the pattern shown in Fig. 2, *i.e.*, in the [$\bar{2}$20] direction. This whisker axis is [$1\bar{1}$20] and [$\bar{1}$01] in the conventional structural hexagonal and structural rhombohedral indices, respectively.

An analysis of the diffraction spots in Fig. 2 shows two nets, the first is a net normal to the [111] direction and the second is a net normal to the [110] direction. The angles between rows of spots are within 1° of the angles between rows of index points in the reciprocal lattice of α-Fe_2O_3. The sections of whisker giving the two reciprocal lattice nets lie at 32.4° to one another.

Both nets of Figure 2 include the origin, $\bar{2}$20, and 220. We conclude, therefore, that the rotation axis of the pattern is [$\bar{2}$20]. The same conclusion results from the fact that the spots of each layer line are indexed by points in a corresponding reciprocal lattice net normal to [$\bar{2}$20].

Two additional oxide whiskers which have been studied satisfactorily by selected area electron diffraction are of interest. In one, two new nets of spots, normal to the [001] and [$\bar{1}\bar{1}$2] directions, respectively, were found. The rotation axis of the oxide whisker was [$\bar{2}$20]. The whisker axis was proved to be the rotation axis as follows: The whisker axis lies in a plane normal to the pattern of the second oxide whisker different from the plane of the whisker axis for the whisker giving the pattern shown in Fig. 2. These two planes intersect in the [$\bar{2}$20] rotation axis.

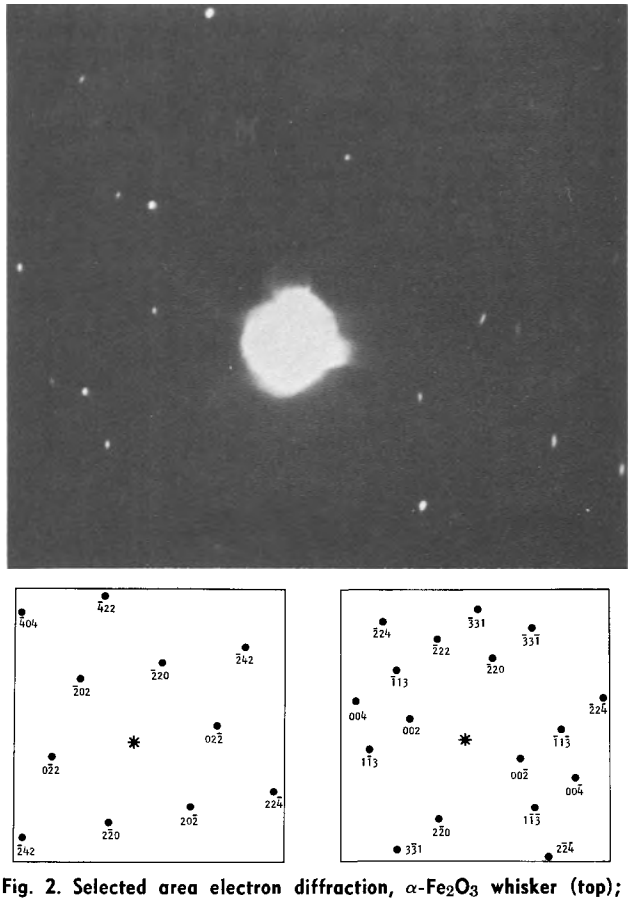

Fig. 2. Selected area electron diffraction, α-Fe_2O_3 whisker (top); 1.5μ long, 10^{-15}g; indexed with a face-centered rhombohedron, $\alpha = 85.7°$. Nets normal to [111] and [110] included (bottom).

If the whisker axis is the same in the two cases, it is $[\bar{2}20]$.

For the third indexed pattern, the same rotation axis was found, but not close to 90° to the beam direction. Again the projections of the whisker and rotation axes coincide in the pattern. This is a more common type of diffraction pattern than that shown in Fig. 2. Bent, kinked, and apparently multiple whiskers introduce further complications.

The three different selected area patterns which were indexed include very weak extra anomalous diffraction spots on the layer lines. Some of the spots correspond in position in the pattern to the systematically absent diffraction from planes of the form $\{11\bar{1}\}$, but most of the spots could not be indexed. The anomalous spots were also found by Takagi (2).

Since the whisker axis and the rotation axis coincide we are led to hypothesize that the whisker is twisted. This is consistent with the diffraction patterns of individual whiskers, in that they show a limited rotation by including diffraction represented by appropriately limited sectors of the reciprocal lattice. All of the selected area diffraction patterns of individual whiskers obtained for this work, about forty, are composed of rows of spots (layer lines) normal to the projection of the whisker axis. It appears certain that axial twist was at least common to whiskers sufficiently long to be selected separate from other whiskers.

Since no grain boundaries are commonly revealed by diffraction contrast in the micrographs, any grain boundaries which may exist must be such that the contrast is difficult to observe. The probability that a small number of untwisted crystals might lie in the special orientations in the beam indicated by the diffraction patterns of individual whiskers is negligible.

In addition to evidence in the selected area diffraction patterns of individual whiskers, we find evidence of axial twist in the electron diffraction patterns of whiskers growing from a surface. These patterns contain long, straight streaks which include elongated spots on arcs of several rings of the pattern between 400 and $42\bar{0}$, ($02\bar{2}4$ and $12\bar{3}2$ in structural hexagonal indices).

The angles of the streaks on the pattern and the positions of the spots on the streaks show that each streak is the second layer line for limited rotation about the whisker axis. That is, the streaks correspond to diffraction represented by the plane of the reciprocal lattice normal to the whisker axis, $[\bar{2}20]$, and passing through $\bar{2}20$ (or $2\bar{2}0$). The rotation of the crystal about $[\bar{2}20]$ is evidenced further by the continuity of the streaks, as follows: the intensity between the spots results from integration over the sector of the reciprocal lattice plane by rotation through the reflecting sphere.

Axial Twist Calculations

The axial twist α can be calculated from an equation given by Eshelby (7), $\alpha = K\,b/A$. Here b is the length of the Burgers vector, A is the cross section area, and K is a constant which depends on the shape of the cross section. $K = 1$ for an elliptical cross section with central dislocation. If we approximate the cross-sectional area A with the area of a circle of the whisker image diameter, we can calculate the axial twist and compare this with the observed twist. The full length of whisker in the selected area image for the pattern of Fig. 2 was 1.5μ. The diameter, including contamination, was about 300Å. Assuming the smallest Burgers vector, *i.e.*, the minimum repeat distance along the whisker axis, 5.03Å, the axial twist is calculated to be 41°/μ. The sections of whisker giving the two reciprocal lattice nets of Fig. 2 are at 32.4° to one another by rotation about the whisker axis. If at most these two sections lie at the ends of the 1.5μ whisker section, the axial twist is not less than 22°/μ; thus the 5.03Å Burgers vector is likely.

There are many reasons for a discrepancy between the calculated and observed axial twist: (*i*) both the cross section and the axial twist were difficult to determine; (*ii*) the elastic anisotropy of α-Fe_2O_3 may be important and should be included in the theory; (*iii*) the dislocation strain may have a planar character which would alter the strain distribution near the core; (*iv*) the discrete atomic structure and the decreased stress at high strain near the dislocation may result in a smaller twist than that calculated by the simple formula of Eshelby (7); and (*v*) surface stresses may decrease the axial twist.

Comparison with Previous Morphological Studies

Miyake (8) reported in 1937 a preferred orientation in the electron diffraction pattern of α-Fe_2O_3 formed on an oxidized iron specimen. He stated that the $(10\bar{1})$ structural rhombohedral plane was parallel to the surface. Apparently, lack of knowledge of the existence of oxide whiskers precluded a complete interpretation. The $(10\bar{1})$ structural rhombohedral plane given by Miyake is normal to the whisker axis we have determined.

Takagi (2) determined the growth axis of localized α-Fe_2O_3 growths using diffraction patterns of individual growths. That Takagi's work preceded the general recognition of axial twist apparently explains his failure to recognize the rotation pattern. Takagi oxidized pure iron in flowing dry oxygen, but not so dry as to prevent the formation of oxide platelets. He observed that whiskers and sometimes smaller blades grew from broken bases of blades. This and other observations suggested that growth is from the top. Takagi postulated a screw dislocation mechanism for the localized growths. He considered surface diffusion to provide the transfer of metal.

Bigot (9) and Talbot and Bigot (10) failed to analyze correctly their selected area electron diffraction patterns of α-Fe_2O_3 whiskers and platelets. They give no indexing for their whisker rotation patterns. Instead they determine the whisker axis on the basis that the most intense spots are aligned parallel to the smallest dimension of the crystal. They give incorrectly the structural hexagonal direction $[10\bar{1}0]$ as the whisker axis without supporting data. The most intense arc in the fiber texture pattern for whiskers on an oxidized iron surface is at 90° to the surface in the $11\bar{2}0$ ring. This results from the preferred orientation of the $(11\bar{2}0)$ planes, which are normal to the $[11\bar{2}0]$ whisker axis. Thus, the most intense arc is on a normal to the $[10\bar{1}0]$ direction, but this is not the whisker axis.

Transport Mechanisms of Whisker Growth

Three mechanisms have been put forward for the growth of oxide whiskers: (*i*) surface diffusion to the tip of the whisker, (*ii*) extrusion from the oxide, and (*iii*) growth by internal diffusion in a hole or screw dislocation.

The possibility that α-Fe_2O_3 whiskers result from some extrusion process seems unlikely because the growths are so uniform and are apparently of high crystalline perfection.

It is also unlikely that α-Fe_2O_3 whiskers could grow by a surface transport mechanism as suggested by Takagi (2) from a surface with competing α-Fe_2O_3 surface growth mechanisms. The hypothesis of a surface growth mechanism would require that other growth mechanisms or the existence of α-Fe_2O_3 crystals growing by only mechanisms other than the mechanism of whisker tip growth be very limited. The existence of species and mechanisms for surface transport of iron sufficient to produce the rapid growth rates and the extreme lengths of the α-Fe_2O_3 whiskers is not known and is unlikely because of the stability of

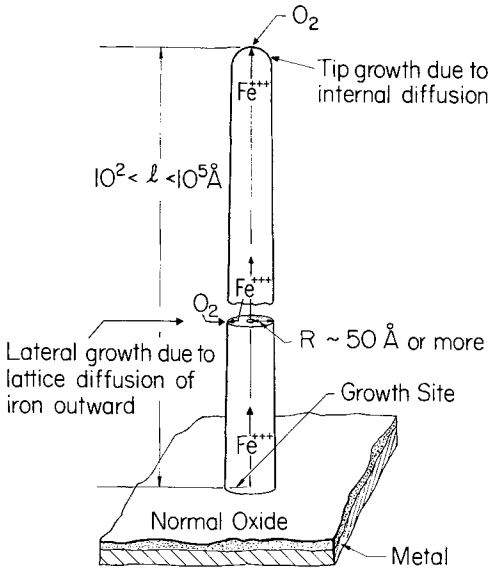

Fig. 3. Model of whisker growth during oxidation of iron, 400°C, dry O_2.

the Fe_3O_4 from which the iron would be transported. Furthermore, the nucleation of α-Fe_2O_3 on Fe_3O_4 is a common phenomenon and involves only a change from cubic close-packing to a distorted hexagonal close-packing of oxygen in the α-Fe_2O_3 lattice together with a change in the iron positions. One cannot readily propose that the driving force for rapid diffusion to the α-Fe_2O_3 whisker tips can be provided by high concentrations of iron species mobile on the Fe_3O_4 surfaces.

Gulbransen (11) has proposed a model for the growth of oxide whisker assuming the whiskers are hollow or contain a screw dislocation at the center. The essential feature of this model is that this internal defect allows rapid diffusion of iron to occur compared to normal lattice diffusion. The morphological studies presented demonstrate that oxide whiskers are single crystals of high crystalline perfection and show axial twist. The latter property is strong evidence for a screw dislocation at the center of the whisker.

Figure 3 shows a model for the whisker growth on iron. The whisker contains an internal hole or screw dislocation where dislocation core or internal surface diffusion of iron occurs along a gradient in chemical potential.

Most of the growth occurs by reaction with oxygen atoms or ions at the tip of the whisker. Since the diameter is nearly uniform during growth it follows that cationic mobility is much smaller in the lattice than along the dislocation.

Good measurements of the growth rates of oxide whiskers are not yet available. Pease and Ploc (12) have observed initial growth rates at 500°C of over 0.2 μ/min, an average rate over 5 min. Takagi (2) observed growth rates up to 2 μ/min at 700°C in the first minute. Whether the growth observed in these cases should be classified as whiskers or platelets cannot be determined from the information given.

The structures of the sections where the cation diffusion rate is high cannot be given at this time. It may be that information on these structures is contained in the anomalous diffraction. The structure in the immediate vicinity of the screw dislocation must show ions either displaced by the strain into some distortion of the α-Fe_2O_3 structure, or otherwise positioned, possibly in some disordered structure. In either type of structure, diffusion coefficients would be expected to be different from those in the much less distorted structure of more than half of the cross section of the whisker. This outer region probably exhibits the bulk or lattice ionic diffusion coefficients.

The Chemical Vapor Deposition of Titanium Carbide Coatings on Iron

Takehiko Takahashi, Kohzoh Sugiyama, and Kensuke Tomita

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

When titanium tetrachloride carried by argon is reduced by titanium sponge and the product flows over a carbon steel at 850°-1000°C, a titanium carbide film is formed on the steel surface, and the thickness can be related linearly with the square root of time. If a mixture of hydrogen and propane is used as carrier, the carbide film grows linearly with time. Pre-electrodeposition of cobalt on low carbon steel is effective to obtain good titanium carbide coatings.

Titanium carbide is known as a refractory, very hard, and corrosion resistant material. If titanium carbide coating could be deposited on various materials, the coated materials would be widely used. Titanium carbide has been plated on graphite at 1200°-1300°C (1) and also on carbon or tungsten

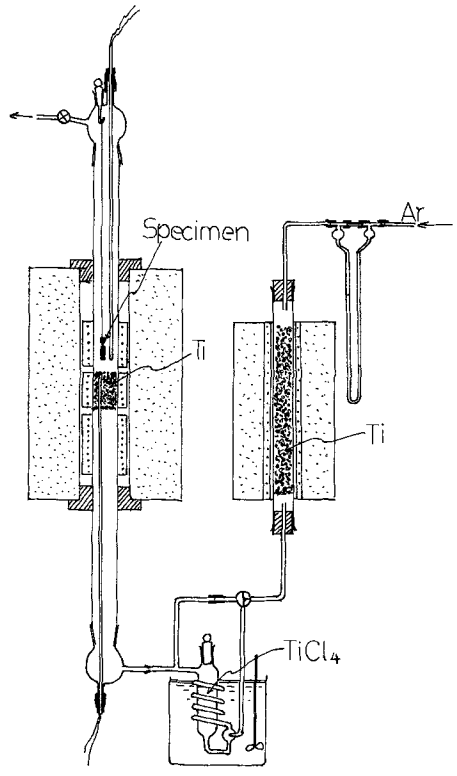

Fig. 1. Apparatus for the vapor plating with titanium sponge as reductant.

filament from a gas mixture of hydrogen, hydrocarbon, and titanium tetrachloride at temperatures between 1300°-1700°C (2-4). Ruppert and co-workers reported on titanium carbide coated on carbon and/or chromium containing iron at above 800°C (5-8). Semenova and Minkevich have investigated titanium carbide coatings on 12% chromium steel at 1100°C (9). When the base material is iron, especially, thick coatings of titanium carbide may spall off for the thermal expansion coefficient of titanium carbide is much smaller than that of iron. Further it would be advantageous to cover iron with a thick titanium carbide layer without restriction of the composition of the base material.

Apparatus and Experimental

In the present work, two kinds of experiments have been carried out. In the first, carbon was supplied from high carbon steel substrate, and titanium sponge was used as reductant of titanium tetrachloride. In the second experiment, carbon was supplied by gaseous hydrocarbons, and hydrogen was chosen as reductant and carrier gas.

The apparatus used for the first kind of experiment is shown in Fig. 1. Argon, the carrier gas, was flowed through a deoxygenerator filled with titanium sponge heated up to 800°C, before bubbling into the titanium tetrachloride saturator, then passing into the quartz tube reactor, 27 mm ID, for which three zones, each of which were 80 mm long, were provided for preheating and for heating the titanium sponge and specimen. The temperatures of these three zones were controlled independently. The specimens were connected to the top of the quartz tube by means of a platinum or high carbon steel wire. After a certain time, the gas stream was changed to pure argon, then the specimen was raised to the upper cool part of the tube where it was cooled, thereafter taken out, and washed with ether. The specimen was of cylindrical shape, 3 mm OD and 20 mm long. The carbon content of the specimen was 0.80 w/o (weight per cent), and α-iron structure was confirmed by the x-ray diffraction pattern.

In the experiment, the growth rate of titanium carbide was too low to coat iron with a thick film. For this reason, in the second experiment, carbon was supplied by gaseous hydrocarbons, and the reductant was changed to hydrogen. The apparatus is shown in Fig. 2. The coating chamber was quartz tube, 220 mm long and 27 mm ID. Three iron specimens, 20 x 10 x 1 mm^3, were connected to a balance. The carbon content in the specimen was 0.035%. In this case, the direct coating of titanium carbide on low carbon steel was found to be hopeless due to severe weight loss of iron and its cementation both of which cause weakening of the adherence of titanium carbide on iron. Preplating of the low carbon steel with a cobalt layer was found to be of use to suppress the weight loss of iron.

Results and Discussion

Type 1 experiment (carbon supplied by the base).—Changes in weight of the specimen.—In the preliminary experiments, the weight changes of various materials were measured with no titanium sponge layer in the reactor. Titanium, wrought iron, platinum, copper, and quartz underwent considerable weight loss, but with the high carbon steel the decrease was relatively slight. From these facts, it is concluded that the titanium tetrachloride stream causes a loss of base materials probably due to the formation of chlorides of the respective metals. The small change in weight of high carbon steel suggests the formation of corrosion resistant surface film. When titanium sponge was used as shown in Fig. 1, the weight of the specimen increases with time. Based on x-ray analysis, this weight increase was attributed to the formation of titanium carbide film on the specimen.

Dependence of the growth rate.—The temperature of titanium sponge and of the titanium tetrachloride saturator and the flow rate of argon showed minute effects, but the temperature of the specimen was the dominant factor for the deposition of titanium carbide layers. Weight increase was observed at above 800°C.

Figure 3 shows the relation between the titanium carbide thickness and the square root of time at various temperatures. In this experiment, the temperatures of titanium sponge and of the titanium tetrachloride saturator were held at 900° and 40°C, respectively, and the flow rate of argon was 5 cc/sec. The titanium carbide thickness was calculated from the weight increase considering the specific gravity of

titanium carbide layer to be 4.94. The linear relation between the thickness of the titanium carbide layers and the square root of time suggests the rate-determining process is not the surface reaction but a diffusion process in the titanium carbide layer or in the base. From a plot of the logarithm of the gradient at various temperatures against the reciprocal absolute temperature, the activation energy was calculated to be 48 kcal/mole, which is supposed to be that for carbon diffusion in titanium carbide (10).

Microstructure of the titanium carbide coatings.—Figure 4 shows the cross section of titanium carbide coated on iron. The middle layer consists of titanium carbide which was applied at 900°C in 170 min. The upper layer is copper plated for protection of the edge break while being polished. A tight and nonporous titanium carbide layer is seen in this figure.

Figure 5 shows a cross section through a titanium carbide coating which was deposited at 1000°C in 225 min. The higher the temperature the looser the contact between the titanium carbide layer and the high carbon steel. Titanium carbide formed at 1000°C was gray colored and had a metallic luster, but below 900°C a blue-black-colored dull surface was obtained.

Interdiffusion between titanium carbide layers and iron.—Figure 6 shows the profiles obtained by means of an electron-probe microanalyzer at the interface of iron and titanium carbide formed at 900° and 1000°C. The intensities of titanium correspond roughly with those of pure titanium carbide. In the profile, the carbon intensities are recorded by two magnifications, and the proportionality of the carbon concentration to that of titanium can be seen; however, the absolute carbon concentration cannot be estimated because the neighboring atoms show the high extinction coeffi-

cient of carbon Kα x-ray. The concentration of iron in the titanium carbide layer amounts to 2-7%, the value of which depends on the thickness of titanium carbide layer and the coating temperature.

Figure 7 shows the x-ray diffraction profiles of titanium carbide deposited onto iron at 1000°C in 225 min. The peaks obtained are in accord with the superposition of those of titanium carbide (11) and α-iron. The intensity of {200} plane is relatively high. The lattice constant was calculated as $a = 4.33$Å from the 2θ value.

Type 2 experiment (carbon supplied by hydrocarbons).—Dependence of weight increase on time.—Cobalt was plated from a sulfate bath at 25°-40°C, and at a current density of 4 amp/dm², within 40 min. The bath contained in 1 liter solution; 450g $CoSO_4 \cdot 7H_2O$, 32g H_3BO_3 and 13g NaCl. Figure 8 shows the sum of the weight increases of three specimens. The temperature of the titanium tetrachloride was 60°C. The flow rate of propane and hydrogen were 0.08 and 2.80 cc/sec, respectively. These curves show a linear

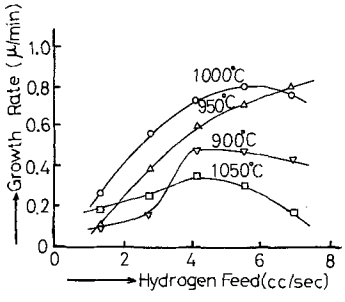

Fig. 10. Effect of hydrogen feed rate on growth rate

relation between the weight increase and time; the highest increase was found at 1000°C.

Dependence of weight increase on the position of specimen.—Figure 9 shows the influence of the specimens position (as illustrated in Fig. 2) on weight increase. The coating time is 150 min. The total weight increase has a maximum at 1000°C, while the weight increase of the specimens at the upper, middle, and lower position have the maxima at 850°, 950°, and 1000°C, respectively. The temperature at the upper position was nearly equal to that of the middle position, while the temperature of the lower position was somewhat less than that of the middle position. The influence of position may be attributed to variations of titanium subchlorides, or to the state of unstable hydrocarbons or of soot formed by thermal decomposition of propane.

Dependence of growth rate on hydrogen supply and on temperature.—In Fig. 10 a relation between the growth rate and the rate of hydrogen supply is shown. The maximum growth rate was obtained at 1000°C, while at the higher flow rate of hydrogen, it was obtained at 950°C. The propane flow rate was held at 0.08 cc/sec. The maximum of growth rate was 0.8 μ/min. Figure 11 shows the relation between the

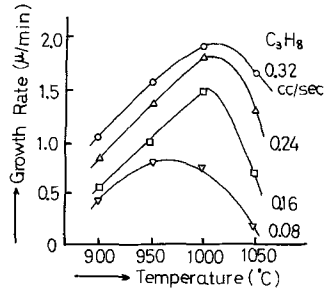

Fig. 11. Relations between growth rate and temperature as a parameter of hydrocarbon feed rate.

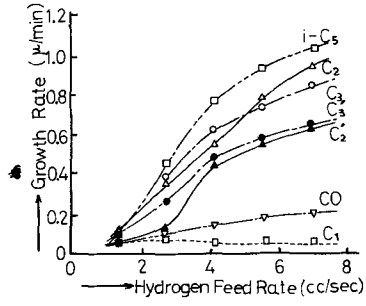

Fig. 12. Dependence of growth rate on the kinds of hydrocarbons

growth rate and the coating temperature with the flow rate of propane as a parameter. The hydrogen feed was held at 7 cc/sec. The higher the propane feed rate, the higher the growth rate. A saturating tendency was found at 0.32 cc/sec where the atomic ratio of titanium in titanium tetrachloride carried by hydrogen to carbon in propane was roughly unity.

Surface appearance.—The surface appearance of the specimen formed by high feed rate of propane was black and coarse which suggests that the saturating tendency arises from the covering by soot.

Effect of hydrocarbon species.—Figure 12 shows the effect of hydrocarbon species. The coating temperature is 950°C. In the figure, x in C_x and C_x' is the carbon number of paraffins and olefins, respectively. From the results obtained, it may be derived that paraffins such as i-pentane, propane, and ethane show high coating growth rate up to 1 μ/min on the average of three specimens, but methane and carbon monoxide show very low rates, and olefins such as propylene and ethylene are placed on intermediate positions between the former two groups. These relations are in accord with the thermal stabilities of the respective hydrocarbons. In other experiments, interruption of titanium carbide growth was observed when the surface was covered with soot. Therefore it is considered that solid carbon may react with titanium chloride to form titanium carbide only at relatively high temperatures, such as 1300°-1700°C, which were chosen by other investigators. Hydrocarbons are considered to decompose to hydrogen and soot at the surface of specimen or at the wall of the reactor. Only the atomic carbon formed at the titanium carbide surface may react to form titanium carbide crystals at relatively low temperature. The soot which has been deposited cannot react in accessible rate, but it interferes with the adsorption and desorption of titanium subchlorides.

Microstructure and microhardness of the titanium carbide coatings.—The microscopic cross section of a cobalt-titanium carbide double layer is seen in Fig. 13. The starting thickness of the cobalt layer was 8.5-10μ and that of titanium carbide was about 17μ. This coating was deposited at 950°C in 35 min. The upper layer is titanium carbide under which the cobalt interlayer is unified with the base material. Figure 14 shows the surface appearance of titanium carbide formed at

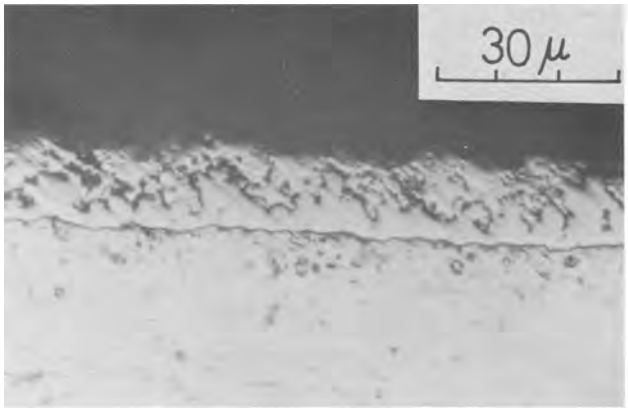

Fig. 13. Micrograph of the cross section of the specimen obtained at 950°C in 35 min. The thickness of the precoated cobalt layer, 8.5 — 10μ.

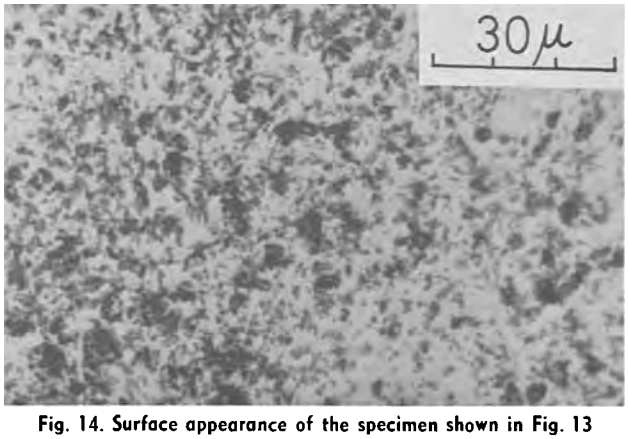

Fig. 14. Surface appearance of the specimen shown in Fig. 13

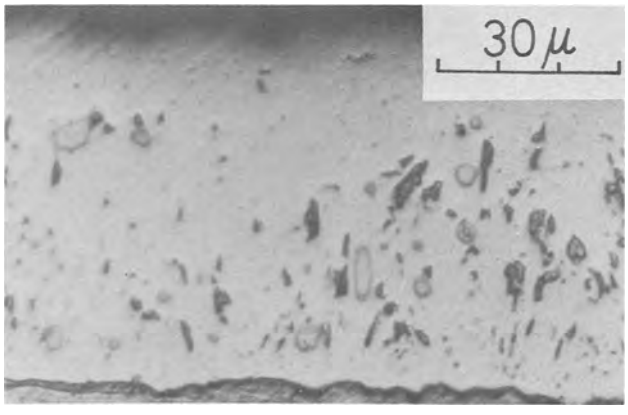

Fig. 15. Profile of the cross section of the specimen deposited at 1100°C in 160 min.

950°C. Micropores can be seen. Figure 15 shows the cross section of a titanium carbide coating applied at 1100°C in 160 min. The thickness is about 80μ.

The microcrystalline coating in Fig. 16 was deposited at 950°C while holding the temperature of titanium tetrachloride at 90°C. The crystal size was roughly estimated to be 4-6μ. Figure 17 shows the cross section.

Microhardness measurements were carried out using a load of 50g. The values are gathered in Table I. The high hardness values are nearly equal to that of pure titanium carbide (12). The hardness of the thin titanium carbide layers seems to be lower than that of the thick coatings. This is probably not due to an influence of the cobalt layer.

Figure 18 shows the effect of the thickness of cobalt on the x-ray diffraction patterns. Titanium carbide was deposited at 950°C in 72-92 min under the flow

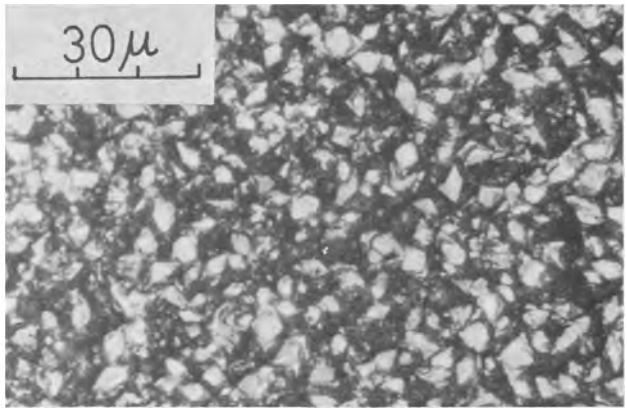

Fig. 16. Microcrystalline coating obtained under a partial pressure of $TiCl_4$ of 0.24 atm at 950°C.

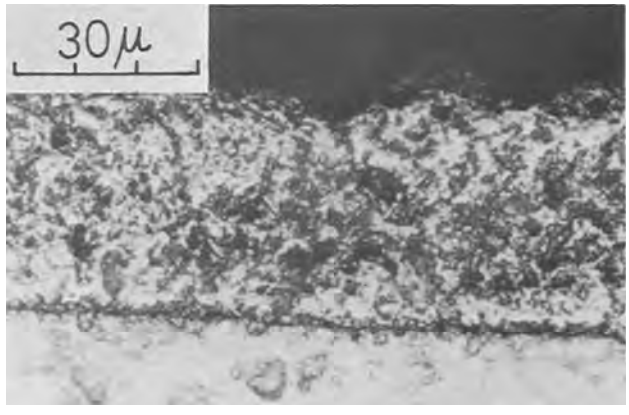

Fig. 17. Micrograph of the cross section of the specimen in Fig. 16.

rates of 2.8 cc/sec for hydrogen and of 0.08 cc/sec for propane, the partial pressure of titanium tetrachloride being 0.079 atm. Peaks of titanium carbide and α-iron diffractions can be seen, if the thickness of cobalt interlayer was only 4-5μ. In case of the thicker cobalt layers, the peaks of α-iron were weakened, and those of titanium carbide were sharpened. If the thickness of cobalt was 33-40μ, γ-Co-Fe phase appeared, and that of titanium carbide was weakened.

The crystallization of titanium carbide which was deposited above 950°C can be estimated from Fig. 19. The crystal grain size did not change much at 950°C. The two profiles at the bottom of the figure are those of titanium carbide for keeping the temperature of titanium tetrachloride at 90° and 75°C. The abnormal growth of {220} and {111} planes can be seen.

Table I. Microhardness

Specimen	TiC plating conditions: Temperature, °C	Partial pressure of $TiCl_4$, atm	Plating time, min	Thickness of TiC layer, μ	Microhardness, kg/mm²
Cobalt plated on iron	—	—	—	—	220
TiC plated on cobalt layer (thickness of cobalt layer; 20μ)	900	0.079	205	11	145
	950	0.079	170	35	2400
	950	0.14	200	24	2300
	950	0.24	220	33	3200
	1050	0.079	142	67	3300
	1100	0.079	160	64	3700

Specimen	TiC plating time, min	Thickness of cobalt layer, μ	Thickness of TiC layer, μ	Microhardness, kg/mm²
TiC plated at 950°C and under the partial pressure of $TiCl_4$ of 0.079 atm	72	4-5	17-20	147
	80	8.5-10	17-20	1470
	92	13-15	22-25	1040
	78	33-40	17-20	1380

(50g load)

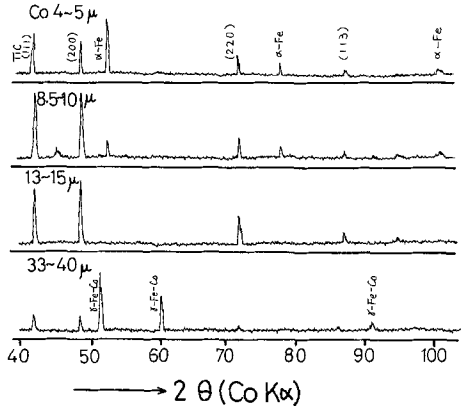

Fig. 18. X-ray diffraction patterns for the specimens precoated with cobalt in various thickness.

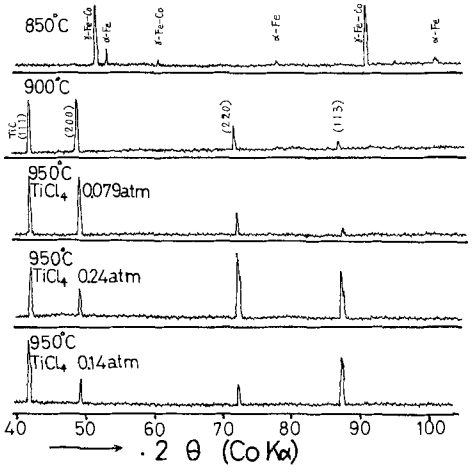

Fig. 19. X-ray diffraction patterns for the specimens obtained at various temperatures and under various partial pressures of $TiCl_4$.

Solid phase reaction at the interfaces.—Figure 20 shows the microanalyzer profiles of titanium carbide coated on the cobalt interlayer of 4-5 and 33-40μ. The cobalt contents at the interface are 58% for thin cobalt interlayers and 82-90% for thick cobalt interlayers. The diffusion layer thicknesses at thin and thick cobalt interlayers were 2.0 and 10-12μ, respectively. The iron and cobalt contents in the titanium carbide layer at a distance of 17-20μ from the TiC-Co alloy interface are 0.65 and 0.23 w/o for thin cobalt interlayer and 0.29 and 0.34 w/o for thick cobalt.

Conclusions

From these results, it is concluded that thick cobalt layer, transformed to γ-Co-Fe phase by the interdiffusion of cobalt and iron, and the thin cobalt interlayer favor the formation of α-Fe solid solution in spite of taking an arrangement of γ-phase at coating temperature.

Up to present, the effects of cobalt layer are considered to improve the adherence of the titanium carbide layer to iron and to suppress the interdiffusion

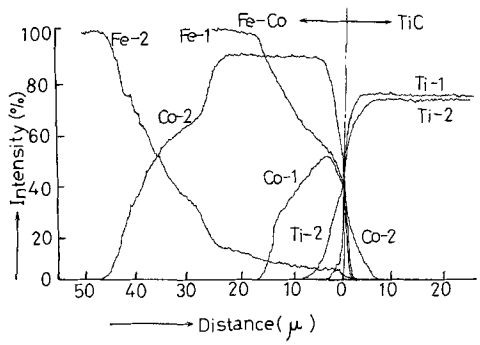

Fig. 20. Profiles of the concentration of iron, cobalt, and titanium obtained by electron probe microanalyzer. The thickness of precoated cobalt: 1, 8.5 — 10μ; 2, 33 — 40μ.

of iron and carbon. The former effect appears to arise from the affinity of cobalt to titanium carbide as is known from the sintered carbide alloys which consist of titanium carbide powder and cobalt binder. The reason for the good adherence of titanium carbide layers to the base, in spite of the large difference between their coefficients of expansion, cannot be explained here. However the titanium carbide layers sometimes spalled off at the part of edge, especially from those specimens which were coated at high growth rates. Annealing of the contact layer might improve the adherence of the coatings, and it is now under investigation. Materials other than cobalt have also been sought, but no further favorable material has yet been found.

Torsion-Effusion and Torsion-Langmuir Studies of Zinc Telluride

William T. Lee and Zuhair A. Munir

Department of Materials Science, School of Engineering, San Jose State College, San Jose, California

ABSTRACT

The vapor pressure of polycrystalline zinc telluride was measured by the torsion-effusion and torsion-Langmuir methods. The pressure, in atmospheres, measured by the torsion-effusion method between 888° and 1150°K is given by the equation: $\log P = 6.18 - 1.065 \times 10^4/T$. Third-law calculations of the heat of sublimation for the reaction 2 ZnTe (s) = 2 Zn (g) + Te_2 (g) gave a value of $\Delta H°_{298} = 156.3 \pm 3.0$ kcal. The free-surface vapor pressure, in atmospheres, measured by the torsion-Langmuir method between 800° and 1015°K is given by the expression: $\log P = 7.89 - 1.283 \times 10^4/T$. The energy of activation for this sublimation process, $\Delta H^{\ddagger}_{298}$, was calculated to be 178.6 ± 4.2 kcal, and the evaporation coefficient, α, was found to vary from 0.155 at 807°K to 0.294 at 953°K.

Thermodynamic properties of zinc telluride were first investigated by McAteer and Seltz (1) by the application of reversible galvanic cells. Korneeva *et al.* (2) made vapor pressure measurements on zinc telluride at relatively high temperatures. More recently, Goldfinger and Jeunehomme (3) made rather extensive vaporization studies of Group IIB-VIA compounds by mass spectrometric and Knudsen-cell methods. Their work showed that the vaporization process of ZnTe is

$$2ZnTe\ (s) = 2Zn\ (g) + Te_2\ (g) \qquad [1]$$

The existence of such gaseous diatomic molecules in the sublimation products has been shown to give rise to a slow step in the sublimation mechanism and, hence, low apparent vapor pressure (4, 5).

The use of the torsion-Langmuir method (4) has provided an effective way for apparent pressure measurements, and, when combined with Knudsen-cell techniques, values of accommodation coefficients can be determined.

None of the vapor pressure studies of zinc telluride has incorporated both torsion-effusion and torsion-Langmuir experiments. Free-surface evaporation studies to establish activation energies and sublimation coefficient as a function of temperature are therefore highly desirable.

Apparatus

The torsion-effusion method has been described in several publications (4-7).

Figure 1 shows a schematic diagram of the torsion apparatus. The lower portion of the apparatus consists of a stainless steel vacuum chamber 35.6 cm in diameter and 45.7 cm high. Situated in the center of this chamber is an 11.4 cm diameter and 17.8 cm high cylindrical tungsten mesh heating element. Several layers of curved tantalum radiation shields are wrapped around the oustide of the heating element to insure black body conditions. Mounted within the heating element and close to its center is a graphite "dummy" cell identical to the cell used for measurements. A 10v secondary of a 50 kva transformer supplies power to the heating element. Water cooled, heavy-walled 0.64 cm copper tubing carries power to the heating element.

The upper portion of the torsion apparatus consists of a Pyrex glass housing 10.2 cm in diameter and 91.5 cm long. This detachable glass tubing is joined to the vacuum chamber by two rubber O-rings. At the top of this tube, a goniometer acts as the anchor point for the entire suspension system by means of a 0.64 cm diameter copper rod which enters the top of the Pyrex tubing through an O-ring joint to insure a good vacuum. Attached to the end of the copper rod is a 2 mil diameter annealed tungsten wire, approximately 35.6 cm long. From the other end of the tungsten wire, a 0.64 cm diameter aluminum rod is suspended. To this rod is glued a 1.27 cm diameter circular mirror which during operation hangs directly behind an optically flat window in the vertical glass tube. A circular aluminum disk 4.75 cm in diameter and 0.64 cm thick attached to the rod about 7.62 cm below the mirror serves as a damper when a permanent magnet is placed near it outside the glass housing. The lower part of the suspension system is a 0.25 cm diameter, 33.0 cm long tantalum wire which is attached to the aluminum rod below the mirror. The torsion cell, made of National Carbon ZT101 grade graphite, is fastened to the lower end of this tantalum rod. During a run, the torsion cell hangs free in the center of the heating element about 1.9 cm above the dummy cell.

Torsion cells are made from cylindrical pieces of graphite approximately 4.5 cm long and 2.5 cm in diameter. Sample cavities were drilled into both ends of the cell and tightly fitting lids were used to seal off the sample cavities. One of the cells used in this investigation was tested for leakage before its effusion holes were drilled. No deflections were observed while heating tin samples over the entire experimental temperature range. Effusion holes drilled at diagonally opposite locations into the sample cavities had diameters ranging from 1 to 3 mm for various cells.

The torsion-Langmuir cells used in this work were made of graphite blocks. Two wells 1.27 cm in diameter and 0.32 cm deep were drilled into opposite sides of these blocks. Sample wafers, 0.16 cm thick, were

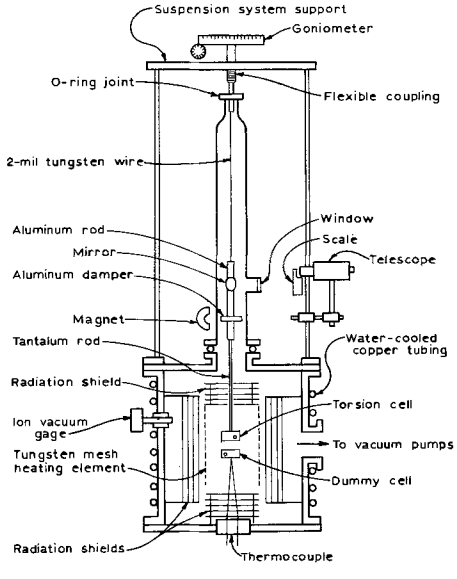

Fig. 1. Schematic diagram of torsion apparatus

placed inside these recessions and were secured there by specially designed graphite washers. Each washer had one flat surface that fit snugly against the sample wafer, with a concave surface on the other side. When the washer was in place, the effective sublimation area of the sample was defined by the 0.64 cm diameter opening through each washer. To prevent vapor that sublimed from the rear faces of the wafers from escaping in a manner that might contribute to the torque, a pair of holes were drilled on top of the cell into cavities behind the two samples. Due to relatively large sizes of the holes (3 mm in diameter), any vapors subliming from the rear face of a sample would escape through the holes in the top of the cell and give rise to no angular deflection.

Vacuum was maintained by a duo-seal Welch forepump and an NRC H56-1500 oil diffusion pump with 300 liter per second capacity placed beneath a liquid nitrogen cold trap. A CVC Phillips ionization gauge was used to measure pressure below one micron. During any run a background pressure of less than 2×10^{-5} Torr was maintained in the chamber.

Temperatures were measured by means of a calibrated 20 mil Pt/Pt-10% Rh thermocouple. Calibration of the couple was accomplished by measuring the apparent melting points of copper, gold, silver, aluminum, and zinc inside the dummy cell. The thermocouple leads were inserted in a small hole in the bottom of the dummy cell. Temperature was measured using an L&N potentiometer, Model 8662.

Methods of Operation

Torsion-effusion.—After loading about 1.5g of ZnTe 99.99% pure) powder in each sample compartment, the torsion cell was attached to the suspension system. With the torsion cell hanging free in the middle of the heating element, the system was closed and pumped. Power was introduced when the ambient pressure had reached 2×10^{-5} Torr or lower. Vapor pressure measurements were made only after the system had come to an equilibrium condition, as indicated by the constancy of temperature as a function of time. The temperature in the torsion cell was assumed to be equal to that in the dummy cell, which was read from the potentiometer during each torsion run. This assumption is based on findings which will be discussed later.

The torque resulting from the effusion of vapor through the cell orifices was determined from the angle through which the wire had twisted. Angles of deflection were determined by returning the suspension system to its original (null) position. Proper alignment was ascertained by viewing through the telescope on the mirror, which reflects a scale placed outside the vacuum system. Vapor pressure values were then calculated from deflection angles.

Torsion-Langmuir.—Deflection measurements were made in a similar fashion to those described above. Readings were taken at progressively higher temperatures until deflections began to decrease either with further increase in temperature or with increased time at constant temperature. Examination of the wafers after apparent pressures had departed from the straight line portion of a plot of log P *vs.* $1/T$ always revealed that holes had developed completely through one or both wafers in at least one region. Only those points measured before the apparent pressures began to decrease systematically with time were used in the calculations of apparent pressures, since the rest represented deflection due to sublimation from a surface with an unknown area.

X-ray analysis.—To determine the congruency of the evaporation of zinc telluride crystals, two samples, one before and one after heating in vacuum at 1160°K for 30 min in a graphite torsion cell with an orifice of 3 mm, were analyzed by the Debye-Scherrer powder method, using Cu K_α radiation with an Ni-filter. The power setting (in G.E. XRD-6) used was 30 kv and 18 ma, and the exposure time was 5 hr for each film.

Results

Congruency of sublimation.—X-ray patterns of the heated samples were compared to those of the unheated sample. All lines of the heated sample corresponded to those of the unheated zinc telluride. Furthermore, the lines of the heated sample were compared to those of zinc, tellurium, zinc oxide, and tellurium dioxide with negative results of correspondence.

Torsion-effusion studies.—Vapor pressures were calculated from the torsion-effusion and torsion-Langmuir data by means of the equation

$$P = 2D\phi/(f_1 q_1 a_1 + f_2 q_2 a_2) \qquad [2]$$

where P is the pressure in atmospheres, D is the torsion constant of the wire in dyne-centimeter per radian, ϕ is the angle of deflection of the cell in radians, q_1 and q_2 are perpendicular distances in centimeters from the center of the effusion holes to the axis of rotation, a_1 and a_2 are the areas of the effusion orifices in square centimeters, and f_1 and f_2 are Searcy's force correction factors (8, 9).

The vapor pressure of tin (99.99% pure) was measured as a check on the validity of the experimental results obtained with this apparatus. Tin was chosen as the calibration material because previous investigations (7, 10, 11) indicated it to be a well-behaved and uncomplicated material. Vapor pressure values from 1.1×10^{-6} to 6.3×10^{-5} atm were obtained from the temperature range 1378°-1640°K. From these measurements the third-law heat of sublimation at 298°K was found to be 72.8 kcal/mole compared to 72.2 kcal/mole calculated by Hultgren *et al.* (12) from results of earlier studies.

The results of the torsion-effusion studies on zinc telluride are plotted in Fig. 2. Figure 2 also shows previous results obtained by Goldfinger and Jeunehomme (3). All calculated thermodynamic functions were based on the reaction $2ZnTe\ (s) = 2Zn\ (g) + Te_2(g)$. Calculations of the heat of sublimation are tabulated in

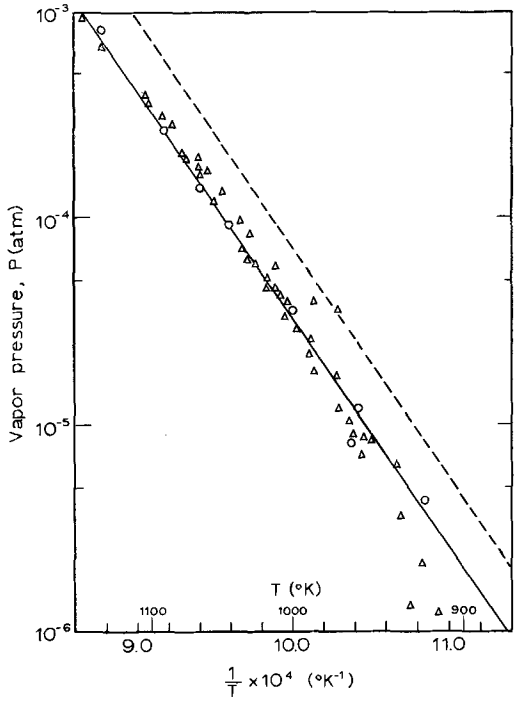

Fig. 2. Vapor pressure of zinc telluride (s), torsion-effusion method: △, this work, orifice $d \simeq 2$ mm; o, this work, orifice $d \simeq 1$ mm; —, this work, least-square fit; . . ., Goldfinger and Jeunehomme (3).

Table I. From this table an average of $\Delta H°_{298}$ of 156.3 ± 3.0 was obtained.

A least-square fit of the data gives an equation for log P at any temperature between 800° and 1150°K for the sublimation of zinc telluride

$$\log P = 6.18 - 1.065 \times 10^4/T \qquad [3]$$

From the second-law method, the heat of sublimation of zinc telluride at 298°K, $\Delta H°_{298}$, was found to be 150.4 ± 1.0 kcal.

Torsion-Langmuir studies.—Figure 3 shows a plot of the logarithm of the free-surface vapor pressure of polycrystalline zinc telluride *vs.* $1/T$. When experimental total pressures were expressed in the form $\log P = a + (b/T)$ with the aid of the least-square method, the following expression for the free-surface sublimation resulted

$$\log P = 7.89 - 1.283 \times 10^4/T \qquad [4]$$

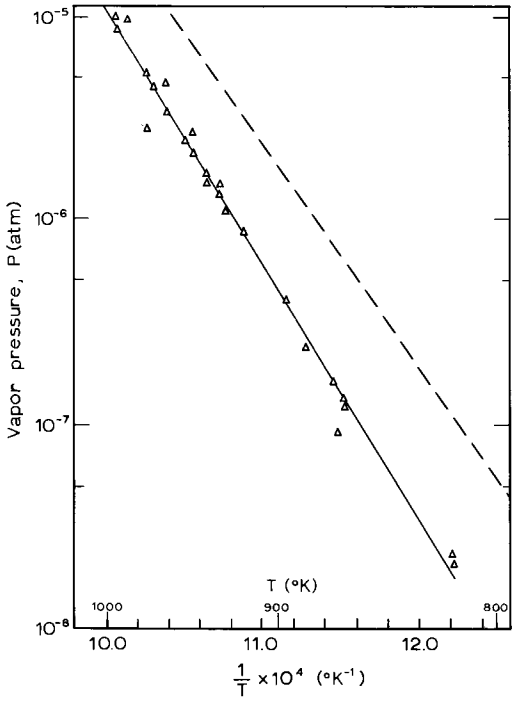

Fig. 3. Vapor pressure of zinc telluride (s), torsion-Langmuir method: △, this work; —, this work, least-square fit; . . ., this work, torsion-effusion method.

where P is the free-surface vapor pressure of zinc telluride in atmospheres between 810° and 1013°K.

By defining $K = (P_{Zn})^2(P_{Te_2})$, where K is the apparent equilibrium constant of the dissociation, Eq. [4] can be expressed

$$\log K = 22.78 - 3.849 \times 10^4/T \qquad [5]$$

From Eq. [4] the second-law heat of actiyation at 298°K was calculated to be 178.6 ± 4.2 kcal.

Discussion

X-ray analysis of zinc telluride samples heated in vacuum at 1160°K for 30 min showed no change in composition. Therefore, it was concluded that the sublimation of zinc telluride is congruent. No diffraction lines belonging to zinc, tellurium, zinc oxide, or tellurium dioxide were observed. Hence, the sublimation of zinc telluride could have occurred by means of one of the following evaporation processes

$$ZnTe\ (s) = ZnTe\ (g) \qquad [6]$$

$$2ZnTe\ (s) = 2Zn\ (g) + Te_2(g) \qquad [1]$$

Mass spectrometric studies have confirmed that the reaction defined by Eq. [1] is predominant for the sublimation of zinc telluride (3).

Nearly all of the torsion-effusion data for zinc telluride were obtained using a 2-mm diameter orifice. A torsion-effusion cell with 1-mm orifice gave vapor pressure data in line with those obtained previously with the 2-mm orifice cell, thus indicating that the assumption of the existence of equilibrium conditions inside the cell with a 2-mm orifice is valid.

The value for the heat of sublimation of zinc telluride polycrystal calculated by the second-law method from torsion-effusion studies is $\Delta H°_{298}$ = 150.4 ± 1.0 kcal. This value is in good agreement with 151.8 kcal reported by Goldfinger and Jeunehomme (3). However, it is somewhat lower than the value of 154.2 kcal calculated by Goldfinger and Jeunehomme when their data were combined with those of McAteer and Seltz (1). Based on Cp data estimated by Goldfinger and Jeunehomme using Kubaschewski's procedure (13), third-law calculations of $\Delta H°_{298}$ gave a value of 156.3 ± 3.0 kcal. This value is in reasonable agreement with the second-law value given above.

Thermodynamic calculations were made to determine the entropy of sublimation for zinc telluride. The second-law entropy was found to be 83.9 ± 1.4 eu at 298°K, which is in reasonable agreement with the value $\Delta S°_{950}$ = 86.2 eu reported by Goldfinger and Jeunehomme (3).

Temperature measurements have been a source of conflict between investigators working in this area. The present research uses a thermocouple calibrated *in situ* using the fusion points of several metals as standard points. Furthermore, with a similar torsion-effusion apparatus, Munir and Searcy (4, 6) have shown that the temperature of the dummy cell is the same as that of the effusion cell for a given power input to the heating element.

From apparent pressure measurements obtained by the torsion-Langmuir method, the free-surface activation energy for the sublimation of polycrystalline zinc telluride was calculated to be 178.6 ± 4.2 kcal at 298°K. The apparent equilibrium constant for the dissociation reaction of Eq. [1] was calculated to be K = 4.62 x 10^{-16} at 1000°K as compared to 3.5 x 10^{-15} at 1000°K obtained by the torsion-effusion method. This difference between the apparent equilibrium constants for sublimation measured under Langmuir conditions and those measured in Knudsen cells demonstrates the existence of free energy barrier to the sublimation process. The evaporation coefficient of zinc telluride appears to vary from α = 0.298 at 953°K to α = 0.155 at 807°K if the Langmuir data are compared to the pressures measured with the torsion-effusion cell.

Since the composition of solid zinc telluride is not changed by heating, therefore it would seem that solid-state diffusion is not a necessary step in the process. Accordingly, the free-energy barrier must be imposed either by a step involved in the transfer of Zn and Te atoms from lattice positions in the surface layers to adsorption sites on the surface, by the desorption of Zn atoms, or by the step of formation and desorption of Te_2 molecules from two adsorbed tellurium atoms.

Acknowledgments

The authors extend their appreciation to Mr. Dennis W. De La Roca for his help in the computation of some of the data and to Mr. Walter Mounts for his technical assistance. Special thanks are extended to Dr. Alan W. Searcy who provided valuable counsel.

Manuscript received May 12, 1967; revised manuscript received Aug. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Performance of Silver-Palladium Alloys in a Concentrated Caustic Electrolyte

Paul Malachesky and Raymond Jasinski

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

The anodic oxidation of silver and a series of palladium-silver alloys, all in the form of smooth rotating disk electrodes, has been studied in 36% KOH. The total charge accepted by silver and the alloys is a pronounced function of current density. Charge acceptance at the Ag(I) level is enhanced with the palladium-silver alloys in agreement with existing data on porous electrodes. Maximum charge acceptance on the first cycle was accomplished with the 1% Pd-Ag alloy. Cycling increased both charge acceptance capacity and surface roughness (as measured by double layer capacitance), being more pronounced for the alloys than for pure silver. However, the increase in surface roughness (area) did not lead to a totally commensurate increase in the total charge accepted with all materials studied.

One approach to altering the charge acceptance properties of silver is to modify the electronic conductivity of Ag_2O. This can be done by alloying silver with minor impurities. Addition of metals of the same group as Ag (*e.g.*, Cu) or of anions (*e.g.*, $S^=$) can promote vacancy formation, presumably due to the lowering of the energy necessary for the creation of vacancies. Impurities which change the concentration of holes in the oxide crystal are metals to the left of silver in the periodic table (*e.g.*, Pd) or metals of high ionization potentials (*e.g.*, Au).

Indeed, the use of palladium as an additive to the silver plate has been reported to increase charge acceptance, particularly at the Ag(I) level (1). Some problems are also reported for electrodes of this type. For example, these same plates did not accept charge efficiently at the Ag(II) level (2). Studies of separator deterioration in cells containing Pd additions showed significant amounts of this additive in the separators (3). The concentration of Pd in positive plates of this type appeared to stabilize at 0.1-0.2%. Generally, cells designed to operate at the Ag(I) level containing such additives had good recharge properties, but discharge characteristics were poor, especially with respect to initial capacity and capacity maintenance (4).

The experiments described in this paper are concerned with changes in the charge acceptance of silver resulting from alloying with varying amounts of palladium. Smooth electrodes were used in order to avoid the complications of mass transport processes within porous plate structures.

Experimental

The palladium-silver alloys (10, 1, and 0.1 a/o) were prepared by direct fusion of the elements. All alloys, in the form of cylinders, were mounted by threading onto a ¼ in. metal shaft. The cylinder sides were coated with Kel-F wax so that only the cylinder face was exposed; the metal shaft was encased in heat-shrinkable Teflon tubing. A Sargent synchronous motor was used to rotate the electrode at 30 rps. All potentials are reported with respect to the dynamic hydrogen electrode (DHE) (5). All runs were made in N_2-saturated 36% KOH at 35° ± 2°C.

A freshly coated and polished (with successively finer alumina powders) electrode was used for the determination of the charge-discharge curves on the first charging cycle. The electrodes were cathodized to H_2 evolution before taking measurements in order to reduce any surface oxide formed during handling.

On successive cycling some etching occurred at the edges of the disk electrodes causing minor leakage between the cylinder sides and the wax. This contribution to an increase in effective electrode area generally proved to be negligible in comparison with that resulting from oxide formation and dissolution on the surface disk. However at low current densities (*i.e.*, longer charge-discharge periods) on the single cycle experiments, this erratic leakage effect did cause some scatter in the charge acceptance capacities. The data reported are the averages of 3-6 determinations made at each current density.

A possible experimental complication in studies using rotating disk electrodes is that of unequal current distribution across the surface of the disk (6). This effect could, in principle, give rise to premature oxygen evolution before the disk electrode was completely charged at the Ag(II) level. Experimentally, it was observed that rotating the electrode had no effect on the observed charge acceptance values and, when charging was continued into the O_2 evolution plateau, no additional oxide was formed. Thus at the beginning of the O_2 evolution potential step the silver electrode had accepted its maximum charge.

Potential-time curves were recorded on a Houston Instruments X-Y recorder (x-axis on time base) or a Tektronix type 561A oscilloscope with a type 2A63 differential amplifier and a type 2B67 time base. An operational amplifier-based voltage follower was used as an impedance matching device in the potential measuring circuit. A Wenking potentiostat operated in the galvanostatic mode or an Electronic Measurements and Control constant current power supply was used as the current source.

The double layer capacity measurements were made using the method of Will and Knorr (7), employing a triangular wave of 100 Hz and an amplitude of *ca.* 25 mv (*i.e.*, a sweep rate of 5 v/sec), biased by a d-c voltage.

Results

The data for the initial charge-discharge cycle will be considered first, followed by the effects of cycling.

The total charge accepted (Q_T) as a function of current density for silver and the palladium alloys is plotted in Fig. 1. The scatter in data can be due in part to the leakage effect described above. Some "natural" scatter is also to be expected due to the inherent irreproducibility of the oxidation of metals. This has been attributed to the erratic or irreproducible creation of grain and strain points in the metal lattice during the working of these metals (8, 9). Because of the pronounced sensitivity of Q_T to current density, slight uncontrolled variations in charging current could also result in scatter of the data.

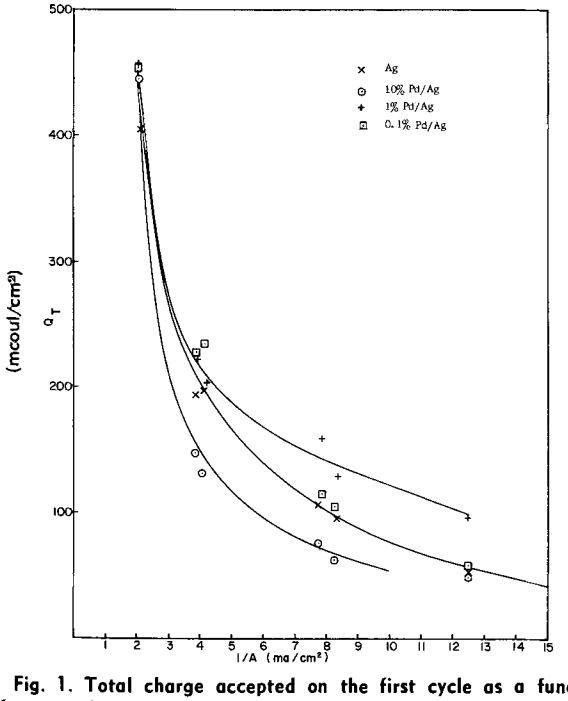

Fig. 1. Total charge accepted on the first cycle as a function of current density for silver and silver palladium alloys.

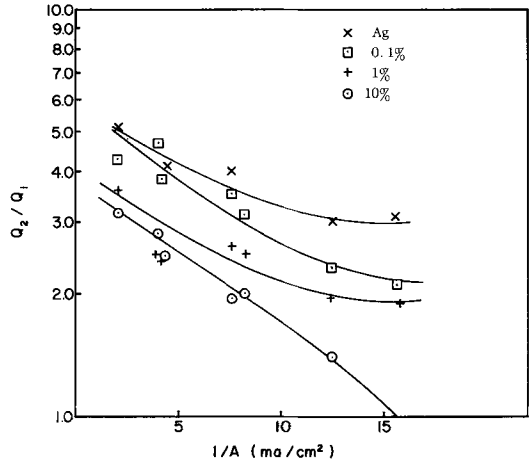

Fig. 2. Ratio of the charge passed at the Ag_2O/AgO potential level (Q_2) to that passed at the Ag/Ag_2O level (Q_1) on the first charge cycle as a function of current density.

At all current densities, the charge accepted on the first cycle by silver and the 0.1% alloy are only marginally different. The sensitivity of Q_T to charging rate at the lower current densities obscures the effect of alloy composition. At high current densities (> 4 ma/cm²) maximum charge acceptance was accomplished with the 1% alloy. This is in agreement with data on porous battery structures (1). No difficulty was experienced in charging to the Ag(II) level, in contrast to data in the literature (2).

The ratio of the charge accepted at the AgO potential level (Q_2) to that passed at the Ag_2O potential level (Q_1) on the first cycle is plotted in Fig. 2 as a function of current density. As can be seen, this ratio (Q_2/Q_1) decreases with increasing current density and also with increasing palladium content. This dependence on composition is consistent with results reported on porous electrodes (1). The charge passed to the Ag_2O/AgO potential is given in Table I for silver and the alloys.

Discharges of the electrodes were carried out at the same current density as used in the charging cycle. The discharge efficiencies were in the range of 90-95%. The ratio Q_1/Q_2 for the first discharge cycle is plotted as a function of current density in Fig. 3.

On cycling, the charge accepted and delivered by all materials increases. The total charge acceptance, at a constant current density of 3.87 ma/cm², is plotted *vs.* the number of cycles in Fig. 4. The ratio of charge accepted at the AgO potential level to that accepted at the Ag_2O level decreases as the electrodes are cycled (Fig. 5); the ratio Q_2/Q_1 on discharge is essentially independent of cycling. The relative change in double layer capacitance is shown in Table II. There is a significant increase in all cases; eventually a leveling off is approached.

The ratios of total charge accepted (Q_T) to the double layer capacitance (C_{dl}), as measured at +300

Discussion

As shown in Fig. 1, the total charge accepted on the first cycle is a pronounced function of current density for all materials, particularly at the lower charging rates. These results are similar in form to those obtained by Wales (10) on porous battery electrodes. This improved charge acceptance at low rates was attributed (10) to greater time for diffusion of electrolyte into the pores of the electrode and reaction of the divalent silver with metallic Ag according to

$$AgO + Ag \rightarrow Ag_2O$$

Since the electrode is oxidized more completely before barrier layers are formed, the lower charging rates are more effective.

This bulk diffusion explanation is inconsistent with the present measurements on smooth rotating disk electrodes since no macropore structure exists. Furthermore, the results were relatively independent of stirring rate. However, it is not possible on the basis of those results to discount diffusion phenomenon within the micropores, *i.e.*, the volume of electrolyte between the crystallites of oxide within the diffusion layer.

The discharges were all 90-95% efficient. Essentially all charge delivered to the electrode was recoverable; the slight deviation from 100% can be explained in terms of solubility of the oxides in the large volume of bulk electrolyte.

Consider next the distribution of charge between divalent and monovalent silver. The ratio of the coulombs passed into the two silver plateaus (Q_2/Q_1) on charge is dependent on current density, alloy composition and the number of cycles, while the ratio (Q_1/Q_2) for the discharge process is independent of these variables.

As shown by Langer and Patton in a coulogravimetric study of a sintered silver electrode (11), both Ag_2O and AgO are formed at the Ag(II) plateau on charge. The x-ray diffraction study of Wales and Burbank (12) indicated that a similar situation prevailed on discharge, *i.e.*, the lower potential discharge plateau arises from AgO as well as Ag_2O. The constancy of Q_1/Q_2 on discharge, in the present work, implies either that the high potential discharge plateau arises solely from the total discharge of AgO or, to be consistent with ref. (12), that the discharge of AgO at the higher potential level comprises a constant fraction of the total discharge capacity. It is not possible, at this time, to suggest a simple mechanism other than coincidence for the constant fraction interpretation of the constancy of Q_1/Q_2 with current density and with alloy composition.

The alloys are all more effective than silver in charge acceptance and delivery of the Ag(I) level, 1% Pd/Ag showing the largest value (103 mcoul/cm²), (Table I). With this alloy, at 2.08 ma/cm, an additional 107 mcoul/cm² of Ag_2O is formed at the Ag(II) level. Thus a possible procedure to obtain the maximum charge of Ag_2O in a working plate is to charge fully and then bleed off the AgO charge (13).

The anomalous behavior of the 10% Pd alloy in total charge accepted may be explained in terms of a passivating oxide film. With the 10% Pd-Ag alloy, the contribution of a lower palladium oxide on discharge at +700 mv was particularly evident. In addition, the formation of a higher oxide of palladium at $E \cong +1600$ mv *vs.* DHE must also be considered (14). The palladium oxides formed on charge are apparently 3-10 monolayers thick. Silver, on the other hand, forms oxide layers of approximately 300 monolayers at 2.08

* Cycling carried out at 2.08 ma/cm².

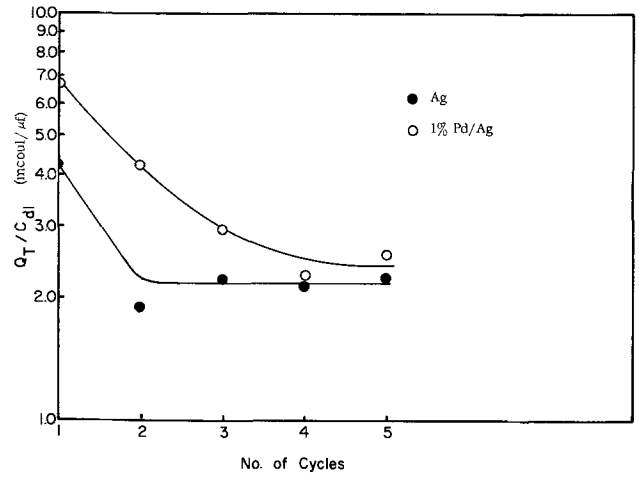

Fig. 6. Ratio of the total charge accepted (Q_T) to the double layer capacitance (C_{dl}) as measured before each charging cycle.

ma/cm^2. This lower depth of oxidation of palladium thus can result in the formation of thin, isolated palladium oxide deposits on the alloy surface, obscuring some silver from the charging reaction. A very similar explanation has been advanced (15) in the high-temperature oxidation of alloys containing a solute which has less affinity for oxygen than the solvent metal.

Cycling the electrodes increased substantially the quantity of charge accepted. As shown in Table II, the double layer capacity of all the electrodes also increased with cycling. Since C_{dl} is proportional to surface roughness, this implies that the increase in capacity is due primarily to an increase in the area of the electrode accepting charge. In Fig. 6 the ratio of the total charge accepted to C_{dl} is plotted as a function of cycles for Ag and 1% PdAg. A decrease is observed rather than an increase, *i.e.*, the surface appears to roughen faster than the coulombic capacity increases. As shown in Fig. 2, the ratio of the amount of charge accepted on the first cycle at the Ag_2O/AgO potential level to that at the Ag/Ag_2O level increased with decreasing current density. However, on cycling, this ratio decreased with increasing double layer capacitance values, *i.e.*, decreasing real current densities. Therefore, as implied by the double layer data, the effect of cycling on charge acceptance is not solely a matter of decreasing the effective current density.

There are at least two alternative explanations: (*i*) part of the roughened surface, as measured by C_{dl}, is not available to the charging reaction or (*ii*) the crystal structure of the surface of the electrode is different from that of the smooth electrode, alloy or silver. (Such a change could also affect C_{dl}.)

It is not possible with the present data to resolve these alternatives. The fact that there is a second alternative is based on the work of Wales and Burbank (12), who observed that prior to cycling, a smooth rolled silver sheet showed a strong preferred orientation. On cycling x-ray diffraction patterns revealed a gradual increase in the amount of randomly oriented polycrystalline silver, as well as surface roughness.

Conclusions

1. The total charge acceptances for silver and palladium-silver alloys are all a pronounced function of current density. Differences between materials at low current densities are obscured by this high sensitivity to charging rate. Since this effect, first reported for porous electrodes, is also observed on smooth electrodes, the mechanism must involve processes taking place at or near the electrode surface, rather than diffusion into and out of large pores.

2. No difficulty was experienced in introducing charge at the Ag(II) level in palladium-silver alloys, contrary to data reported for porous electrodes.

3. While palladium-silver alloys may accept more charge at the Ag/Ag_2O potential level, the relative amount of charge delivered at the two discharge potential levels after a complete charge is constant and independent of current density and alloy composition.

4. The total charge accepted and the double layer capacitance (proportional to surface roughness) for the palladium-silver alloys increase more with cycling than for pure silver, accounting for most of the improvements noted in charging cells containing palladium as an additive. The double layer capacitance of all electrodes increased on cycling, but this increase does not result in a completely proportional increase in total charge accepted. Thus, some other factor besides surface area and/or surface orientation is probably involved in the charging process.

Acknowledgments

The authors wish to acknowledge the assistance of Miss Susan Carroll in carrying out the experimental work and the support of the U.S. Naval Air Systems Command (Contract No. W66-0621-C).

Manuscript received Aug. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Electrochemical and Related Phenomena under Weightless Conditions

I. Flowing Electrolyte Thermocells

Minas Ensanian

Physical Chemistry Group, Textron's Bell Aerosystems Company, Buffalo, New York

ABSTRACT

A flowing electrolyte thermogalvanic cell (Cu, $CuSO_4$) has been studied under weightless conditions via drop-tower experiments. Unexplained perturbations have been observed in the output potential in both the time-dependent (emf build-up) and quasi-stationary state regions over a wide range of experimental conditions. Exhaustive control experiments as well as the general and over-all reproducibility of perturbations *per se* in a large number of trials rule out oscillations in the hydraulic system as well as random transients as factors responsible for the observed phenomena. Stationary electrolyte systems including thermocells, concentration cells, and a Daniell cell, exhibited similar perturbations during the 1-*g* to 0-*g* transition.

The addition of urea was found to dampen the marked oscillations normally shown by a copper thermocell at the same output potential. The result is important in view of the known decreased ultrasonic attenuation and increased sound velocity caused by urea addition to water. At ambient temperatures the electrolytic conductivity of freshly prepared urea-cupric sulfate solutions gradually increases and in subsequent drops the zero-gravity induced oscillations reappear.

Copper thermocells utilizing nonaqueous solvents (acetonitrile or absolute methanol) exhibit a voltage decrease (several millivolts) but the time/potential curve continues on its original course after impact. The potential of concentration cells (with linear and nonlinear gradients) increases (several millivolts in 0.7 sec), then decays to its initial value prior to impact; cells with linear gradients exhibit relatively larger changes. Inversion tests are also described. Daniell cells (1.09v at 20°C) show a similar behavior except that the voltage increase is about 40 mv.

To understand better the influence of the 1-*g* to 0-*g* transition on physicochemical processes, the electrochemical measurements were supplemented (with the appropriate controls) by a study of diffusional phenomena, heterogeneous and homogeneous chemical reactions. In all cases increased rates were observed and are attributed to enhanced ion mobility during weightlessness. On the basis of these experiments it must be concluded that an interaction exists between chemically reacting systems and gravitational fields.

In recent years the question of an interaction between gravitational fields and chemically reacting systems (1) has become increasingly important. From the experimental viewpoint, the unevacuated drop tower conveniently provides a weightless environment for periods of 1 or 2 sec.

This paper reports the results obtained in the first of a series of studies concerned with the behavior of flowing and stationary electrolyte thermocells (including nonaqueous systems), concentration cells, and galvanic cells during the 1-*g* to 0-*g* transition.[1]

In a previous communication (2) it was reported that partially frozen thermocells exhibited oscillations and a potential decay with the reduction of gravity. A similar "zero-gravity effect" has now been observed in a thermocell in which the electrolyte is under forced flow during the free fall period.

The results which demonstrate the perturbation of an electrochemical system with the sudden removal of the gravity field are of considerable interest in view of the reported physiological effects of weightlessness during space flight (3, 4), the theory of coupled transport processes (5, 6), and theoretical electrochemistry (7).

Concurrently, the effects of free fall on the boundary between concentrated copper sulfate solutions and water, the solubility of copper sulfate crystals in water, the reaction between triphenylchloromethane (in benzene) and a zinc surface, the stress corrosion of Plexiglas by a (KI, I_2, $ZnCl_2$, HCl) reagent, and the rate of the "iodine clock reaction" were investigated.

These studies were initiated in order to gain insight on the influence of a weightless environment (and or memory) on diffusion, wetting, heterogeneous and homogeneous reactions. Although some of the work reported here is preliminary in nature, the indications are nevertheless, that the zero gravity drop tower may become an important tool for electrochemical investigations.

Experimental

Flowing electrolyte thermocells.—The effect was demonstrated and studied in the apparatus (8) shown in Fig. 1. The inflation of a collapsed bottle against the sides of the reservoirs (T_1 and T_2) forces electrolyte past the electrodes into the containers (R_1 and R_2) below. The electrical circuit is completed via a pinhole (1 mm diam) located an inch below the tips of the electrodes.

The reservoirs and containers (500 ml polyethylene bottles, squeeze type with screw caps) are connected by 3/16 in. ID Tygon tubing (1/16 wall) 25 in. in length properly aligned and taped at the position indicated. The electrodes are a 4 mm OD coil of copper wire (B & A reagent, B & S No. 24) 1 in. long (10 turns/in.) having a geometrical surface area of 0.361 in.^{2} and located midway along the Tygon tubes. After degreasing they were immersed for several hours in

[1] As used here the term (1-*g* to 0-*g* transition) or simply the transition means going from a state of rest (normal gravity) to free fall (reduced gravity).

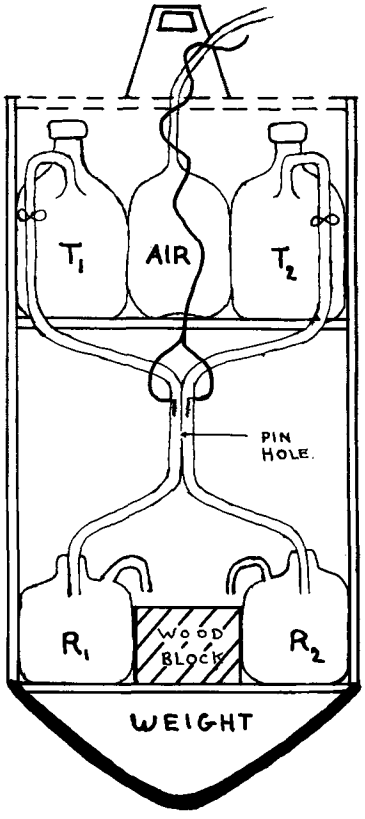

Fig. 1. Schematic diagram of flowing electrolyte thermocell and Zero Gravity Drop Capsule. The usable time of cell depends on the volume of fluid that can be discharged as well as the rate. The single air bottle (actually lying on its side) shown can discharge up to 250 ml from each of the 500 ml reservoirs at rates up to 25 ml/sec. Three or four smaller bottles (500 ml) inserted symmetrically enable 350 ml at rates up to 35 ml/sec. When the warmer reservoir is properly wrapped with rubber tape, the amounts of fluid released by the reservoirs will normally differ by less than 20 ml. Pressures within the bottles (2-10 psig). Cell continues to operate after impact.

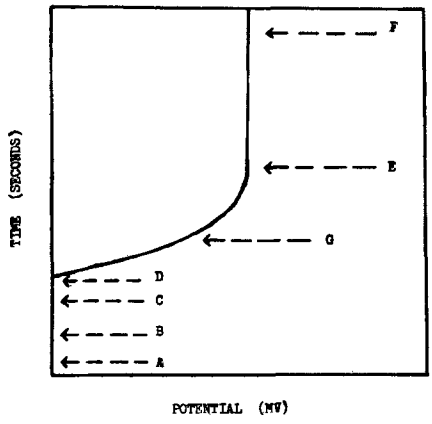

Fig. 2. The experimental sequence shown in terms of the time/potential profile. A—recorder chart on, B—pressure adjustment begun, C—pinch clamps opened, and D—electrolyte flows past the pinhole region. The regions D-E and E-F represent time dependent and stationary states respectively, and cell behavior during the reduction of gravity was studied in both of these regions. Practical limitations prevent a drop test before the point G has been reached. As used here, output voltage refers to the emf at drop-time, *e.g.*, the points G or F. The polarity of the cold electrode is negative with respect to the potentiometer terminal.

hot electrolyte (cupric sulfate, Baker reagent) of identical composition to that found in the reservoirs prior to their being used.

Shielded lead wires (30 ft long) attached to the electrodes and taped to the rubber hose were connected to a recorder which had a balancing and chart speed of 1-sec and 24 in/min. The hose (30 ft of 5 mm ID blk gum rubber) attached to the air bottle (1 liter) was connected to a source of compressed gas (N_2) and the pressure monitored by a Will (15292) regulator.

Two drop capsules (I and II) were used (constructed of wood/plastic) having aerodynamic cross-sections of 113 and 50 in.^{2} and weighing 13 and 15 lb, respectively. In view of drag forces, the attainment of true zero gravity (10^{-3}-10^{-5}-g) for durations of 1 to 2 sec can only be achieved in an evacuated tower or by means of the encapsulated cell method (9). An unguided capsule dropped through air requires a high ratio of weight to frontal area ($\sim$ 1 to 2 psi) in order to overcome this resistance (10, 11). The preliminary work was done with the lighter capsule and the second used in an attempt to amplify the discovered effect.

The experimental procedure is as follows; after the capsule is positioned (17 ft above a sand pit), the electrical circuit is checked, and the reservoirs nearly filled with cold (T_1) and hot (T_2) electrolyte and temperature readings taken, whereupon they are filled to overflow and the screw caps replaced and taped. Some gas is then introduced into the air bottle ($<$ 1 psig) causing electrolyte to flow past the upper pinch clamps which are then closed, thus permitting an opportunity to inspect the system, making minor adjustments, as well as putting the release mechanism (essentially a wire cutting tool) in the "on" position. The drop capsule was released in less than 2 min after temperature readings were taken. The recording chart is turned "on," the gas pressure is rapidly adjusted to the desired value as the clamps are opened, and after a short count-down (during which the flow system is still under visual observation) the capsule is released. The sequence is shown in Fig. 2.

Control experiments fell into three main categories, viz., mechanical, electrical, and chemical. In the mechanical tests the electrolyte flow rate was varied, pulsated, restricted, and reversed, and as in all control tests effects on the time/potential curves were noted. Beginning with a gravity flow of 9 ml/sec the gas pressure could be adjusted to enable flow rates in excess of 30 ml/sec. In the pulsated flow tests a rate in the above range was selected and one or both of the Tygon tubes at a point midway between the electrodes and the upper reservoirs was manually constricted once or twice a second. Restricted flow refers to closing the pinch clamps when they are positioned between the electrodes and the lower reservoirs. In the reverse flow tests the fluid in one of the tubes was flowing in the normal direction while in the other tube it was being forced to flow at the same rate in the opposite direction, thus changing the vorticity in the pinhole.

Vibration, impact, and rotation tests were made on a loaded capsule to ascertain the effects (if any on the output potential) of handling and minor changes in capsule orientation during flight.

In the electrical category the following tests were made; swinging and twisting of the lead wires, controlled streams of air bubbles of various sizes being forced over the electrode surfaces as well as through the pinhole, and eliminating the pinhole and allowing the liquids to empty onto a common surface (8) or into a single reservoir.

In the chemical tests, thermal and concentration shock experiments were performed, *i.e.*, in the flowing electrolyte thermocells and the more recently studied flowing electrolyte concentration cells (to be discussed in another report), precise amounts (Cornwall syringe) of hot or cold electrolyte of identical composition, or in the case of the concentration cells at the same temperature but different concentration, were injected at definite intervals at distances of 0.75-1.5 in. upstream from the electrodes as well as through the pinhole area and the response noted.

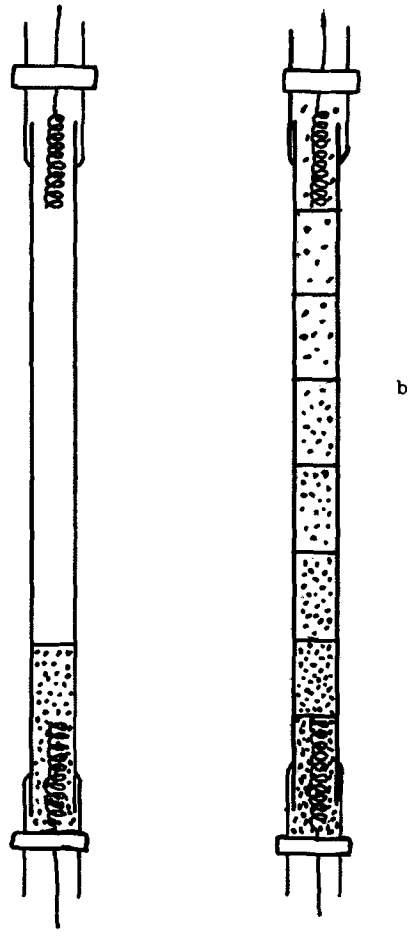

Fig. 3. Concentration cells with nonlinear (a) and linear (b) gradient used in this study. Cells (a) and (b) are made from glass and Tygon tubing, respectively. Cell (b) can also be made from glass which means either a very long tube in order to accommodate a certain amount of uncontrollable mixing or successively freezing each addition in the tube which may not always be practical. In cell (a) the height of the 1.0M cupric sulfate solution (dotted region) can be varied at will provided the lower electrode is completely covered. Tygon tubing is attached to the ends of the cells which are sealed by means of pinch clamps. The polarity of the lower electrodes is positive with respect to the potentiometer terminals. Concentration cells with membranes have also displayed perturbations and will be considered in another report.

Finally, the behavior of a flowing electrolyte system was observed (during free fall) when there was no temperature difference (No, dT) between the fluids in the reservoirs (T_1 and T_2), in other words, identical solutions. The output voltages observed under these conditions are due to microscopic differences (surface conditions, stored energy, etc.) between the electrodes.

Stationary electrolyte thermocells and concentration cells.—The thermocells (not shown) and concentration cells with nonlinear gradients (Fig. 3a) were made by inserting the coiled wire electrodes through Tygon attached to the ends of a Pyrex tube and sealed by means of a pinch clamp. In the case of the thermocell the tube was filled to overflow with a homogeneous solution of 0.005M cupric sulfate. Urea-cupric sulfate electrolyte was prepared by adding 1g of urea (Baker reagent, mp 132°-133°C used without further purification) to 50 ml of 0.005M cupric sulfate, mixed and poured immediately into the cell.

Thermocells were also made with nonaqueous electrolytes, 0.5g of $CuCl_2 \cdot H_2O$ (Baker reagent, as received) was dissolved in 25 ml of acetonitrile (Fisher reagent, bp 81.5°-82.0°C) or 40 ml of absolute methanol (Baker reagent, 99.8% purity).

Concentration cells with multiple lines of demarcation, *i.e.*, with a linear gradient (Fig. 3b) were made by taking a Tygon tube (8 mm ID) with a sealed electrode at the bottom and pouring in as many as eight different concentrations (equal volume) of decreasing strength by pinching the plastic tubing just above the last entry and pouring in the next volume of electrolyte and releasing the pressure and carefully allowing the fluids to come into contact. The following values refer to the ratio (in milliliters and beginning from the bottom of the cell) of 1.0M cupric sulfate to water in eight stock solutions used to prepare a typical gradient: 50/0,43/7,36/14,29/21,22/28,15/35,8/42, and 1/49. The total length of the tube was 63.5 cm and each of the eight additions was approximately 3.8 ml. The interelectrode distance (tip to tip) was 58 cm. These cells exhibit remarkable stability, however, they are supported (jacketed) before being placed into the drop capsule.

The voltage of a cell depends on its construction, for example, in the nonlinear case on the respective heights of the 1.0M cupric sulfate and the water above it, and likewise, in the linear case on (dc/dx). These factors can be varied at will, provided both electrodes are covered by a homogeneous phase.

In addition to drop tests the cells were also subjected to inversion tests, *i.e.*, rotating the cell 180° (in a time of the same duration as free fall).

Diffusion.—The effect of weightlessness on ion diffusion was investigated by measuring the optical density across an aqueous interface in a column of fluid before and after free fall and by observing the output potential of a concentration cell or a Daniell cell (Fig. 4) during the 1-*g* to 0-*g* transition. Fifteen milliliters of 1.0M cupric sulfate was pipetted into a 12 mm ID Pyrex tube and 55 ml of distilled water carefully added so as to obtain a clear line of demarcation and the system sealed by means of Tygon tubing and a pinch clamp. The tubes were then dropped from a height of about 22 ft and scanned in a photometer developed in this laboratory. Stationary control tubes were subjected to simulated impact by means of a spring-driven sandbucket propelled upward toward the tubes (equal penetration depth) and were likewise scanned. The drop-tower and photometer reading room temperatures were 15° and 20°C, respectively.

In a single low temperature experiment (no controls) of another type (Liesegang phenomena) concentrated solutions of KI and $CuSO_4 \cdot 5H_2O$ (1 gram each in 10 ml of water) were very carefully placed in the positions shown (Fig. 5) and covered with dilute starch solution and the system sealed. The tube was then dropped nine times at intervals of 2 min from a height of 24 ft (drop-tower temperature 9°C) and was then set aside in a room where the temperature varied from 15° to 21°C.

At a higher temperature a total of six tubes have been evaluated including two sets of controls, viz., simulated impact and those left alone. The drop-tower temperature was 21°C while the room temperature averaged 25°C.

Solubility.—Crystals of cupric sulfate (Fisher Tech. Crystal) weighing approximately 1.30g were wrapped in cotton cloth and suspended a distance of 3.75 cm from the top of 38 cm Pyrex tubes. The cloth passed through a small piece of Tygon tubing which again was sealed by a pinch clamp. Eight pairs of crystals (a drop and a control) were selected and the individual volumes noted by immersion in acetone at 20°C. The tubes (12 mm ID) were dropped 3 times from 22 ft and photometer readings taken after each drop. The reference point was 11 cm from the lower end of the tube. The drop-tower and photometer reading room temperatures were 15° and 20°C, respectively.

Adsorption.—Triphenylchloromethane (Fisher reagent) was dissolved in carbon dioxide saturated benzene (Baker reagent) and the solution poured into a Pyrex tube into which was placed a mirror-like sheet of zinc (ribbon, Baker reagent) and the system hermetically sealed. The drop samples and controls

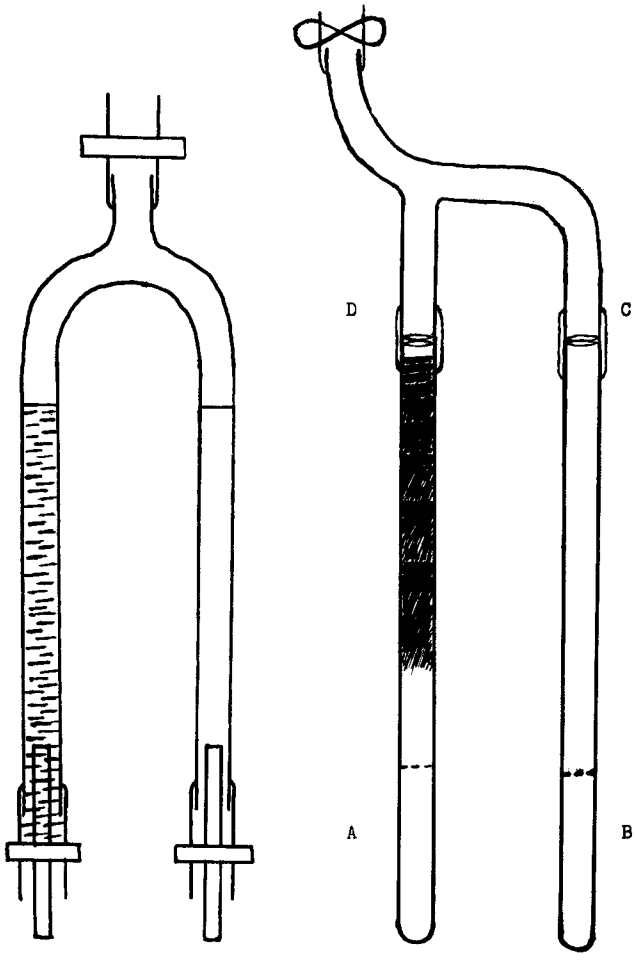

Fig. 4 (left). Daniell cell used for zero-gravity investigations. Several cells of this type were constructed and showed a very large perturbation (40 mv) of the type shown in Fig. 7 during free fall. 1.0M solutions of cupric sulfate (dotted region) and zinc sulfate are introduced to the levels shown and the remaining volume carefully filled to overflow with distilled water. The electrodes are made from thin sheets of copper and zinc and held in position by means of pinch clamps as shown. The emf of the cell is about 1.09v at 20°C. In work of this kind Tygon tubing is a very useful material for making impact proof seals.

Fig. 5 (right). Glass apparatus used to demonstrate Liesegang bands in an aqueous system. Solutions of potassium iodide and cupric sulfate are contained in tubes (A) and (B) respectively at the levels indicated by the broken lines which are 11 cm from the bottom. Arm (A) is 44.5 cm long and the parallel tubes (8 mm OD) are 4 cm apart. After 32 days (in the low temperature experiment) a purple color began to develop in the region shown (tube containing the potassium iodide) and by the 41st day 9 distinct bands or rings had formed. It required 72 days before the liquid in region (C) assumed a light blue color. Eventually, the darkest color developed in the region (D). Although at higher temperatures ring formation is much more rapid it is not as well defined. The tubes were connected by Tygon at the positions shown.

were compared with regard to the golden color of the triphenylmethyl free radical which develops on the zinc surface. A total of eight tubes were evaluated, each being dropped 5 times from a height of 22 ft. The drop-tower temperature was 15°C. The reduction of gravity in the solubility and adsorption studies was estimated at 10^{-3}-*g*.

Stress corrosion.—The corrosive reagent consisted of 4g of potassium iodide, 1g of iodine, 25 g of zinc chloride, 25 ml of HCl and 50 ml of water, mixed and stored in a glass stoppered bottle. Plexiglas samples 62 mm in length and 17 mm wide were bent in a wooden vise to an angle of about 44° and the vise placed in a small plastic box which served as the drop capsule. One drop of the reagent was then placed at the point of greatest tension (eyes must be protected) and followed by a small pinch of zinc dust (12). The box was then closed and dropped from a height of about 24 ft and subsequently the time to failure noted. A clearly visible iodine stain marks the initial position of the drop and the effects of minor variations in the amounts of zinc are negligible. Thirty samples (0-*g*) were dropped and 30 others (static) acted as controls. This work was preceded by an exploratory investigation during which over a hundred test specimens were evaluated. Every attempt was made to duplicate in the controls everything which a dropped sample experienced except the momentary reduced gravity state. This included impact, the spreading, and rolling, etc. of the corrosive droplet. The drop-tower temperature was 9°C.

Homogeneous reaction.—Fresh iodic acid solution was prepared by dissolving 5g of iodine pentoxide (K & K crystal) in one liter of triple distilled water; iodine pentoxide is a powerful oxidizer and must be kept away from flammable vapors, etc. Five milliliters of water was saturated (slow bubbling) for 10 min with anhydrous sulphur dioxide from a Matheson cylinder and then added to a liter of water. The starch solution was prepared by making a paste of 12.2g (Baker reagent) with chilled water and then adding one liter of boiling water.

Fifty milliliters of the iodic acid solution was poured into a beaker and 15 ml of starch solution added; 50 ml of the sulfurous acid solution was poured into a beaker and enough water added to make 300 ml of solution. Water was also added to the iodic acid starch mixture to give a final volume of 300 ml. Both solutions were stirred and then poured into a 2000 ml beaker and the reaction mixture stirred for 15 sec. Each of eight 2-oz bottles were then filled in two steps in a sequence that was empirically determined to insure standardization.

In order to keep the temperature as uniform as possible during the experiments, the solutions as well as the reaction mixtures were prepared near the drop tower where temperatures averaged 9°C. The 2-oz vessels were filled to overflow and attempts were made to minimize the entrapment of air bubbles which were measured and recorded after the experiment and subsequently taken into consideration.

A photometer was constructed which contained two chambers that could accommodate four bottles each and the photometric readings were an indication of the average radiant energy (light) that was transmitted through the row of four bottles simultaneously. The light source was a 150w 120v flood lamp (Sylvania) and the radiation intensity measured by two calibrated Soligor meters which were found to be satisfactory. Although the geometry of the system was rigid and the bottles locked in numbered positions, the positions of the meters as well as the bottles (rows) were switched separately during the course of the investigation and the results were found to be nearly identical.

The reaction is very concentration dependent and reaction time is defined as the interval between the initial mixing and when the bottles first begin to turn blue. In addition to the bottles that were dropped there were two sets of controls; one set was left alone after the bottles were closed and the other was subjected to simulated impact at the same time the zero-gravity bottles were dropped. All bottles were, at all times, exposed to the same amount of light. The experimental procedure was as follows: A total of four drops were made from a height of 24 ft, viz., at 3 min and 40 sec (after mixing), 4 min, 4 min and 20 sec, and 4 min and 40 sec. The four drop bottles as well as the four simulated impact bottles were always placed into the photometer at 5 min and 10 sec and the flood lamp turned on at 7 min and 30 sec. The distance between the lamp and the lightmeters was

Table I. Flowing electrolyte thermogalvanic cell stationary state potentials

67 cm. Two sets of experiments were done (the only alternative would have been to build a photometer with three chambers in order to accommodate the twelve 2-oz bottles) viz., where the simulated impact set was compared with the initial controls as well as those which experienced free fall. The reduction of gravity was estimated at 10^{-3}-*g*.

Results

Flowing electrolyte thermogalvanic potentials are difficult to reproduce, *e.g.*, if a dozen or more cells are constructed in identical detail and evaluated and, although each produces a curve similar to that shown in Fig. 2, nevertheless, the range of their respective voltages at point F may be as high as 10 mv or more. Some data are shown in Table I, and the values represent the average of four experiments.

The apparatus can easily be converted into a flowing electrolyte concentration cell (also exhibit zero-gravity oscillations) and by proper adjustments of concentration differences, flow rate, and cell temperature a wide range of reasonably controllable voltages can be obtained and will be discussed in another report.

During the course of 107 drop tests (with flowing electrolyte thermocells), three general types of zero-gravity effects (Fig. 6) have been observed over a wide range of conditions; concentrations (0.005-0.35M) ΔT (T_1 from 2 to 13; T_2 from 25° to 65°C), flow rates (from 12 to 30 ml/sec), and output voltages (from 10 to 70 mv); viz., oscillations (6a, 6c), potential decay (6b) and combinations (6d) in both the time dependent (D — E) and stationary state (E — F) regions.

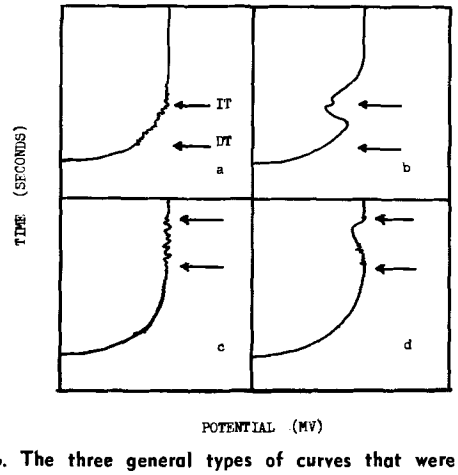

Fig. 6. The three general types of curves that were observed over a wide range of experimental conditions. The oscillatory curves exhibited as many as nine deflections during the free fall interval and whose amplitude varied as much as ± 1 mv. Potential decays of 4 mv have been seen with a semblance of recovery prior to impact. Curve 6b appears at 0.01M, when $T_1 < 10$°C, $\Delta T > 47$°C and the output voltage > 35 mv, at a flow rate of 21 ml/sec when a preliminary study was made of the time dependent region (D-E). DT and IT refer to drop time and impact time, respectively.

A large number of experiments would be required to characterize these curves and, although the evidence is limited, an output voltage of 35 mv in the time dependent region appears to be a transition range, *i.e.*, below this value we see curve 6a and above it curve 6b.

The control experiments showed that the observed effect was due to the sudden reduction in gravity and in particular those concerned with pulsated or variable flow rates, proved that the perturbations cannot be due to oscillations in the hydraulic system, in fact, on the basis of their frequency alone it is a physical impossibility with the apparatus shown. The only way to change the potential of a flowing electrolyte thermocell or concentration cell in this manner is to either suddenly and completely restrict all fluid flow or attempt to rapidly increase the air bottle pressure and even then there is a lag-time of at least 0.6 sec before a smooth transition is registered by the recorder. Streams of bubbles (some as large as the coils) passing through the electrodes or the pin-hole region had no effect on the potential either under gravity or forced flow in a normal 1-*g* environment. No perturbations were observed during the thermal and concentration shock experiments.

In the (No, dT) experiments, at very low flow rates, there are oscillations in polarity, but as soon as the flow rate increases (5-30 ml/sec) one of the electrodes becomes anodic and the other cathodic. At various times and under different conditions during the course of this investigation, 18 drop tests have been made with electrolyte concentrations of 0.005, 0.01, 0.1, and 0.3M cupric sulfate and at temperatures ranging from 17° to 34°C. In spite of the fact that comparisons are difficult in view of varying temperatures, flow rates, etc., the following conclusions can nevertheless be drawn. The potential increases with time, in other words, there is a build-up curve (Fig. 2) and output voltages range from 0.5 to 11 mv, although one occasionally observes higher potentials momentarily and the lower concentrations give higher output potentials. In all cases during free fall the cells exhibited perturbations and continued to operate after impact.

In marked contrast to the behavior of partially frozen (upper electrode) thermocells previously reported (2), when the upper electrode region is heated with air instead of being frozen, pronounced saw-toothed oscillations are observed during weightlessness with the time/potential curve resuming its initial course after impact. It has been found that the addition of urea substantially dampens the zero-gravity induced perturbations when the cell is dropped at the same output potential. The electrolytic conductivity of freshly prepared urea-cupric sulfate solutions gradually increases (at ambient temperatures) and in subsequent drops (after 3-4 sec of weightlessness, corresponding to a drop-tower operating time of about 25-35 min) the zero-gravity induced oscillations reappear. The principle characteristic of the time/potential curves of thermocells employing acetonitrile or absolute methanol, is potential decay during the 1-*g* to 0-*g* transition. However, as in all decay curves under these circumstances some type of oscillation (spiked or smooth) is always present.

During the course of about 70 experiments it has been observed (at least in 50% of the cases) that the output voltage (cells shown in Fig. 3) will increase during free fall (otherwise some type of perturbation is observed, oscillations or potential decay), *e.g.*, if the initial emf is 28 mv (in a cell with a linear gradient) it may increase as much as 2.5 mv during weightlessness in the manner shown in Fig. 7. In some cases a cell will show a similar but weaker increase when dropped a second or third time. If instead of dropping a cell it is rotated 180° (inversion test)[2] in a time of the same duration as free fall, then,

[2] In inversion tests the recorder chart is left on until zero output potential.

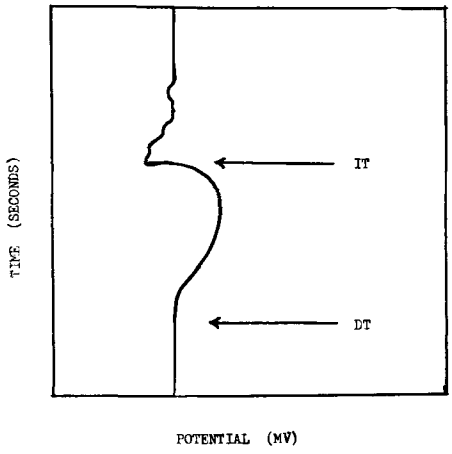

Fig. 7. A time/potential curve of the type frequently observed with the cells shown in Fig. 3. Cells with linear gradients show a larger potential increase during the free fall period. Cells that are rotated 180° (turned upside down) display similar behavior however, there is a lag-time of about a second or more after the cell is in the new orientation before a potential change is indicated; the voltage increments, however, are similar, viz., 0.5-2.5 mv. Although the evidence is limited since almost all of this work has been done with coiled wire electrodes, the indications are that electrodes made from metal sheet will behave in a like manner. Concentration cells (Fig. 3b) of identical construction but slightly different emf's have been connected in series and parallel and in both cases have acted as expected. They have exhibited a small increase in emf when dropped.

for reasons as yet unknown to the author, one may either see a brief increase in the emf before potential decay or an immediate decay, in either case the curves are smooth.

Some preliminary work has been done with nonlinear gradient concentration cells where the internal diameter of the tubes varied from 2 to 25 mm with cell length from 12 to 36 in. On a relative basis for example, if a 2 mm ID cell is rotated 180°, depending on the initial gradient, it may take 30 sec or more before there is any indication of potential change and as may be expected, this type of cell did not exhibit any perturbations during the first second of free fall. However, in subsequent drops the same cell exhibited perturbations, an indication of an additive or memory effect. The ratio of the inversion time to 0-g time, for indications of potential change, (neglecting any contributions due to impact) can be used to obtain a rough estimate of diffusion rates under weightless conditions and the calculations show it to be four to six times faster. Contributions due to impact could be readily determined experimentally. If the glass wall near the lower electrode of the cell shown in Fig. 3a is uniformly heated, a smooth non-oscillatory voltage build-up will be observed.[3] Conversely, if the upper electrode area is warmed, there will be a smooth potential decay, nevertheless, under either condition, the cell exhibits oscillations and potential decay during free fall. The curves are shown in Fig. 8 and 9. The diffusion experiments have shown that during weightlessness the line of demarcation (now faint but still visible) between the colored and colorless solution (cupric sulfate/water) has advanced about 0.70 cm while that of a control (as nearly well-defined as before) has only advanced about 0.25 cm. Some typical curves are shown in Fig. 10 and 11.

The results of the Liesegang experiments are interesting but complicated, suggesting a large number of trials before the zero-gravity samples and the controls can be characterized and compared. However, in spite of the limited evidence the following observations have been made. Two kinds of rings or bands are formed, viz., horizontal and inclined (~45°), the latter are formed first and, although all tubes have one or two such rings, the simulated impact samples have the most. Rings eventually grow into one another and disappear. The zero-gravity samples display more even spacing as well as the greater ring stability and

[3] The experiment is important in that it offers another method of studying the effects of weightlessness on build-up and decay curves. The potential increase or decrease continues on its original course after impact indicating that heat losses during the course of the experiment are unimportant.

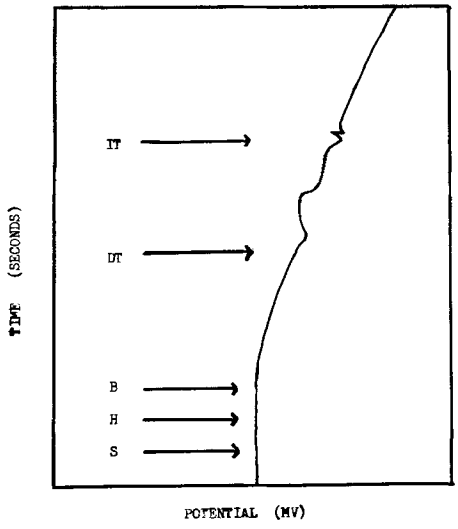

Fig. 8. A typical time/potential curve for a concentration cell of the type shown in Fig. 3a (nonlinear gradient) when the region at the lower electrode is heated with air at 78°C. S—steady state potential, H—warm air applied to glass wall near electrode, B—beginning of build-up curve. In the systems studied the average time between points H and B was 6.53 sec and the voltage increment between point B and drop time, 7 mv. The rate of change was 0.27 mv/sec. Although only four cells of identical construction have been evaluated, the zero-gravity perturbations of these systems are remarkably reproducible in general detail. The system is referred to as a delta "T" concentration cell, (ΔT, ΔC).

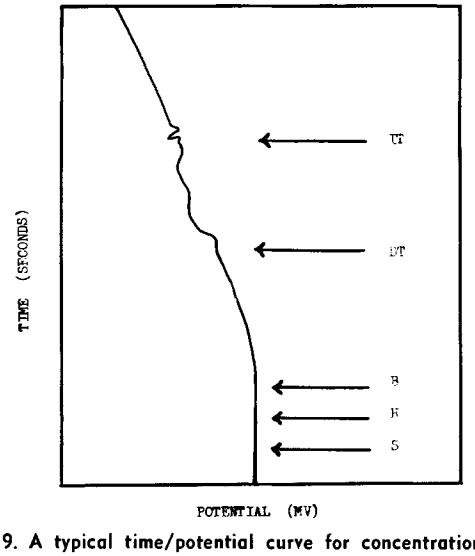

Fig. 9. A typical time/potential curve for concentration cell of the type shown in Fig. 3a (nonlinear gradient) when the region at the upper electrode is heated with air at 78°C. S—steady state potential, H—warm air applied to glass wall near electrode, B—beginning of the decay curve. The average time between points H and B was 5.56 sec and the potential decrease between point B and drop time, 7 mv. The rate of voltage decay was 0.62 mv/sec. These systems likewise exhibit nearly reproducible curves during the brief period of weightlessness and merit serious consideration. The electrodes were made from coiled copper wire (4 mm OD and previously described) and the initial cell temperature and voltage (point S) were 20° and 44 mv, respectively. The effective cell length (6 mm ID Pyrex) was 42 cm and the tubes filled to the 13 cm level with 1.0M cupric sulfate. The interelectrode distance (tip to tip) was 33 cm.

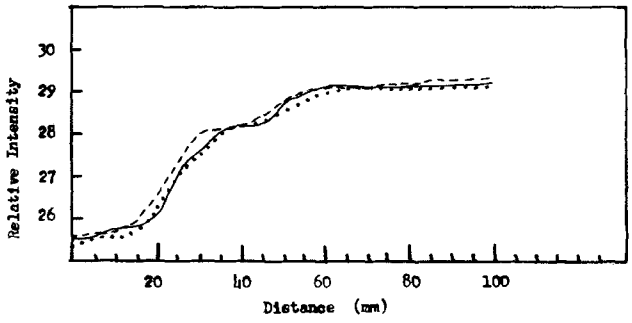

Fig. 10. Photometric curves showing the relative amount of light from a tungsten lamp passing through a 12 mm ID Pyrex tube containing 15 ml of 1.0M cupric sulfate and 55 ml of distilled water when the tube which has been subjected to simulated impact is lowered through the instrument in 5 mm increments. The solid line refers to initial conditions and the dot and dash lines to conditions following the first and second simulations (impact), respectively.

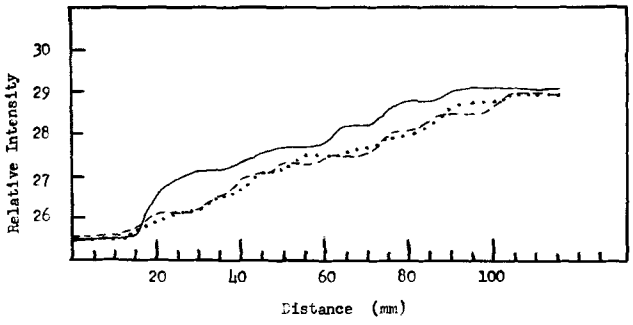

Fig. 11. Photometric curves showing the relative amount of light passing through a 12 mm ID Pyrex tube containing 15 ml of 1.0M cupric sulfate and 55 ml of distilled water when the tube which has been subjected to weightlessness (22 ft drop) is lowered through the instrument in 5 mm increments. The solid line refers to initial conditions and the dot and dash lines to conditions following the first and second weightless periods respectively. The nonsuperimposition of the solid lines of Fig. 10 and 11, of little consequence here, reflects, nevertheless, the inherent experimental difficulty and or limitations in attempting to reproduce gradients. The air drag on the drop capsule was estimated to be between 10^{-2} and 10^{-3}-g.

increased rates of diffusion, *e.g.*, the diffusion of the iodide ion and or the rate of formation of the blue color in the arm (Fig. 5) containing the cupric sulfate. The average number of rings formed in the 6 tubes was seven. These experiments are best performed at lower temperatures (15°C or less) where individual ring formation can be more easily followed. There is no immediate explanation for the greater ring stability of the samples with a weightless memory.

The indications are that, although polycrystalline material was evaluated (and thus the crystals differed in weight, volume, shape, and structure), weightlessness enhances the rate of crystal solubility. The zero-gravity samples dissolved approximately 1.5 times faster than the controls. In a similar vein drop tests indicated that the golden color of the triphenylmethyl free radical which develops on the zinc surface (adsorption experiments) is more intense than for the controls.

Concerning the free fall stress corrosion studies the statistics are as follows: average angle of the drop samples, 43.5°, static samples, 43.8°. The average thicknesses were the same, viz., 1.42 mm. The average time for failure was 67.4 sec for the zero-gravity samples and 82.9 sec for the controls. The average place of failure (see Fig. 12) for the dropped samples were 2.3 and 2.5 for the controls.

A total of 109 experiments were performed during the study of the "iodine clock reaction," although the reported averages concern only 60 of the trials. The

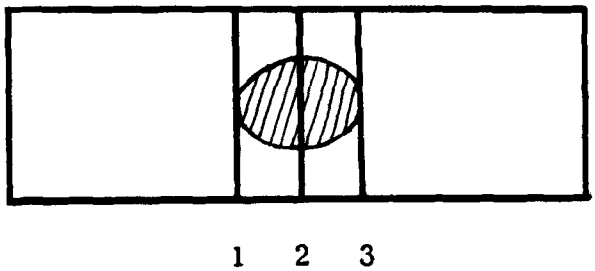

Fig. 12. Plexiglas sample used in the zero-gravity stress corrosion study showing the regions relative to the liquid where the specimen could fail. A drop of the corrosive liquid was placed at the point of greatest tension as shown. The zero-gravity samples and the controls failed at the positions 2.3 and 2.5, respectively, indicating more extensive wetting near the plane of greatest tensile strain in the samples subjected to weightlessness.

reaction time for the zero-gravity bottles was found to be 13.8 min compared to 14.6 min for the simulated impact bottles. Likewise, the latter differed by about 3.5 sec (earlier) from the initial controls.

It was of considerable interest to notice that, although in all cases the zero-gravity bottles had a shorter reaction time than either set of controls, nevertheless, with respect to the time required to reach maximum color intensity once the bottles began to change color, the initial controls reached maximum intensity in less time than the bottles experiencing weightlessness.

Discussion

The main observation on the time/potential curves of flowing electrolyte thermocells due to the sudden reduction of gravity has been the appearance of oscillations. Except for an earlier paper (2) the literature concerning the behavior of electrochemical systems during the 1-g to 0-g transition is essentially nonexistent and since this is the first paper in a long range study a detailed analysis would be premature, however, in view of the concurrent studies, there is some basis for speculation and it may be helpful in some cases to indicate a possible explanation. In essence the concurrent studies suggest that ion mobility is enhanced under these conditions.

In the thermocell shown (Fig. 1) there are three regions that may possibly be influenced by the transition, viz., the electrode surface, the bulk electrolyte, and the liquid-liquid interface within the pinhole region. With respect to the latter, regardless of the initial vorticity, and in view of the existence of quasi-stationary or slow moving layers of fluid, there is the remote possibility of perturbing mass transport through this region during the sudden transition. However, in the control experiments bubbles of air were forced through the pinhole region and which obviously changed the vorticity, likewise, concentrated solutions of copper sulfate as well as water were forced through this region, again with no observable effect on the output potential of the cell. If the reservoirs (R_1 and R_2) and the pinhole are removed and the streams of electrolyte allowed to impinge or mix above or upon a flat glass surface 5 or 6 in. below, there are no effects; the same holds true if the Tygon tubes are separately or simultaneously rotated or swung back and forth like a pendulum. These experiments appear to rule out any contributions from this source.

Although the question of dissolved gases in the electrolyte being adsorbed or the expansion or contraction of gas films on the electrode surface during weightlessness cannot be answered at this time, it is doubtful the oscillations could be explained on this basis.

The behavior of various electrochemical systems during the 1-g to 0-g transition is summarized in Table II and in those cases where the data is preliminary and work is currently in progress it is so indicated. Turning our attention to the electrode surface, one

may expect a gravitational field effect even in a dynamic system (fluid flow) for the following reasons. When a body is being acted upon by the earth's gravitational field, there is no weakening of the field in the region of this body at any time, in other words, the process is void of energy transfer and is the only known interaction of this kind, therefore, whether we have a rotating disk in a fluid or a fluid flowing over a plate, there are in either event quasi-stationary fluid layers near the solid surface and if these encompass the reaction zone, then a true gravitational field effect would be independent of fluid motion.

In a discussion of periodic processes, Frank-Kamenetskii (13) points out that besides purely kinetic oscillations, there is the possibility of a periodic course of a chemical reaction due at the same time to both the kinetics of the reaction and to the evolution and removal of the heat and refers to this kind of oscillation as thermokinetic.

Returning to the flowing thermocells and neglecting any effects associated with enhanced wetting, the hydration and dehydration of ions at electrode surfaces involves the evolution and adsorption of heat, and one might envision the oscillations as being due to a Lotka-Volterra (14, 15) type mechanism (ecological oscillation)[4]; in other words, we assume that the sudden zero gravity induced increase in the mobility of ions gives rise to a situation where the interaction of the three principle rates, viz., arrival, departure, and change within the reaction zone, is such that the time/potential curve becomes periodic[5]. However, to draw upon such an analogy, *e.g.*, the Ross malaria equation (14) touches upon a fundamental question, viz., that such systems operate without benefit of the principle of microscopic reversibility.

With regard to the bulk electrolyte, it is not possible at this time in the absence of significant experiments to speculate on internal changes within a flowing electrolyte during the 1-*g* to 0-*g* transition, however, this is not the case for cells with stationary fluids.

Although the theory of the liquid state (structure of pure liquids and solutions) is incomplete, it is generally assumed (with the exception of the hydrogen and hydroxyl ions) that ions pass through a liquid (the solvent is not a continuous medium) by jumping from one hole to another.

The dampening of the oscillations by urea additions is important and deserves serious attention, *e.g.*, Hammes and Schimmel (17) have reported decreased ultrasonic attenuation and increased sound velocity as a result of urea additions to water, and is thought to be due to an increase in the population of unbonded water molecules which pack more tightly than molecules which are hydrogen bonded in the water clusters. In the present work the reappearance of the zero gravity induced oscillations is due to the chemical degradation of the urea (conversion to ammonium cyanate) and efforts are presently being made to determine if the reappearance of the oscillations coincides (time-wise) with any significant change in the slope of the conductivity curve.

Although a limited number of thermocells have been made with nonaqueous solvents, the observed potential decay curves somewhat resemble in form and magnitude the curve shown in Fig. 7, (but going in the opposite direction) *i.e.*, with a semblance of recovery prior to impact. It is not known whether the cooperative relaxation of the nonaqueous solvent (during the transition) can momentarily trap or retard any of the migrating ions[6].

The question of a change in the structure of a solvent during the transition is presently being considered by two types of studies, viz., a straightforward electrical conductivity measurement and the transmission or scattering of polarized light. Theoretically, in a weightless environment temperature is the driving force for molecular distribution since molecular matter has an equal probability of distributing in one direction as in another; thermal and concentration gradients in static systems are expected to be perturbed during free fall.

Finally, with regard to the observed increase in ion mobility in the various concurrent studies the possibility arises that the cooperative relaxation of the solvent (aqueous solutions) during the transition could momentarily reduce the frictional force on the ions. On this basis one would expect the conductance at high dilution to increase during the transition since the asymmetry and electrophoretic retarding effects under these conditions are at a minimum and the remaining retardive influence, viz., the frictional force of the solvent, may be further reduced by the 1-*g* to 0-*g* transition. Efforts in this direction are currently in progress.

Conclusion

The following conclusions are based on the observed behavior of flowing and stationary electrolyte electrochemical cells and a number of physicochemical systems during and after the 1-*g* to 0-*g* transition.

1. An interaction exists between chemically reacting systems and gravitational fields.

2. Ion mobility increases suggesting structural changes within the solvent. Further work is indicated, *e.g.*, electrical conductivity measurements on pure solvents and very dilute electrolytes, systems with nonaqueous solvents and in aqueous systems the utiliza-

[4] The relationship between chemical mechanisms and kinetic oscillations has recently been reviewed by Higgins (16).

[5] The observation that an output potential of 35 mv may be a transition point in going from oscillations to potential decay in the time-dependent region is important, however, more experimentation is necessary.

[6] Theoretically a local interaction of this kind could give rise to a space charge.

tion of structure-forming and structure-breaking additives.

3. Oscillatory time/potential curves may be due to the mechanics of energy dissipation processes at the electrodes initiated by increased ion mobility. Other possibilities that may explain zero-gravity induced perturbations concern the disruption of thermal and concentration gradients and interrupted ion transport through the bulk electrolyte.

4. These experiments suggest that the behavior of electrochemical systems during the transition is a manifestation of relaxational forces and indicate that the Zero Gravity Drop Tower can be utilized for fundamental investigations in electrochemistry.

Acknowledgment

The author wishes to thank his colleagues in the Engineering Laboratories and the Chemistry Section for their encouragement and generous cooperation, in particular G. Kappelt, W. C. Schulte, M. Taylor, and H. Ph. Heubusch.

He also thanks B. N. Ensanian and A. O. Ensanian for their assistance in the construction of the drop-capsules and numerous cells and E. Rogers for several useful suggestions.

Thanks also are due to J. W. Useller, W. J. Masica, and E. L. Corpas of the NASA-Lewis Zero Gravity Research Facility for a penetrating discussion of zero-gravity phenomena and assistance in calculating gravitational accelerations, the staff of the Bell Technical Library for their generous assistance as well as the Leeds & Northrup Company, The Falls Welding and Supply Company, and the Great Lakes Plastics Company for supplying instrumentation and materials.

Manuscript received March 22, 1967; revised manuscript received July 5, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Catalytic Decomposition and Anodic Current-Potential Characteristics of Methanol on Active Palladium in Alkaline Solution

Tsutomu Takamura and Fusako Mochimaru

Central Research Laboratory, Tokyo Shibaura Electric Company, Ltd., Komukai, Kawasaki-shi, Japan

ABSTRACT

Methanol was found to decompose into hydrogen and CO_3^{2-} on active palladium immersed in alkaline solution containing methanol. The hydrogen evolution rate was examined by using a hydrogen permeating foil electrode. From the concentration dependency of the evolution rate, the catalytic decomposition was found to proceed through the reaction, $CH_3OH + 2\,OH^- \rightarrow CO_3^{2-} + 6H_{ad}$ (liquid-solid interface) and $2H_{ad} \rightarrow H_2$ (gas-solid interface). The current-potential characteristics during anodic polarization recorded in the low current-density region showed two steps, which could be elucidated by taking the above mechanism into consideration. Decomposition mechanism also dealt with standard potential.

Recent studies of the electrocatalytic oxidation of methanol at platinum electrode have been concentrated in acidic media (1-4). Podlevchenko and Gorgonova pointed out that methanol in acidic media adsorbs on Pt/Pt surface and decomposes into adsorbed hydrogen and a fragment such as COH, which are then oxidized into H_2O or CO_2 during anodization (1).

On the other hand, a few papers have treated the surface fragment formed during the electrooxidation of methanol in alkaline media (5, 6). During the course of the present study, Pringent and Bloch reported on the hydrogen evolution of Raney nickel powder immersed in methanolic alkaline solution at about 120°C (7). In connection with the results of

anodic oxidation, they showed that the hydrogen evolution proceeds through Eq. [1]

$$CH_3OH + 2\,OH^- \rightarrow CO_3^{2-} + 3H_2 \qquad [1]$$

but their conclusion does not seem to be on the quantitative analysis of reaction mechanism.

The anodic oxidation of methanol on palladium in alkaline solution was investigated by one of the present authors who suggested that the reaction involves a formation of intermediates such as $(H)_{ad}$ and $(CO_2^-)_{ad}$ (6). Since palladium, like Raney nickel, has considerable affinity for hydrogen, it is plausible that the palladium takes hydrogen away from the methanol molecule which is going to be oxidized. Experimental indication of this reaction has been observed for the metal at higher temperature. The initial open-circuit voltage at active palladium in methanolic solution was about —0.75v *vs.* HgO electrode, while it shifted gradually to a more negative value and finally reached a saturation value of about —0.85v which is close to the hydrogen potential at the electrode. The reversible potential calculated for the over-all oxidation, Eq. [2], is —0.99v *vs.* HgO electrode, which is higher than the observed value.

$$CH_3OH + 8\,OH \rightarrow CO_3^{2-} + 6H_2O + 6e \qquad [2]$$

The actual initial voltage is considered to be controlled by some rate-determining reactions, and the final higher negative voltage would depend on the amount of the adsorbed hydrogen formed by a catalytic decomposition of methanol at palladium. In the present investigation, the rate of hydrogen formation was determined quantitatively by the method in which the hydrogen was taken into a vacuum cell through a thin palladium plate electrode, one side of which was contacted with the solution. The evolution rate was observed to depend on both methanol and alkali concentrations, respectively, the reaction being confirmed to proceed through reaction [1].

Experimental

All the reagents used and the method of measurements of the current-voltage curve were the same as described in a previous paper (6), but care was taken to measure the very low current density region.

Measurement of the rate of hydrogen evolution.— Hydrogen formed by the decomposition of methanol at the solution side of palladium plate was taken through the plate into a vacuum compartment, and the evolution rate was measured as a pressure increase. An outline of the measuring cell is sketched in Fig. 1. A thin palladium plate (0.1 mm thick, 3 cm diameter) was soldered to cover one end of a Kovar ring, and the other end was air-tightly joined to a glass tube. An ionization gauge was attached to the tube which was connected to a vacuum line through a stopcock. The palladium plate was palladized electrolytically on both sides. Lead wires were soldered at an appropriate position of the Kovar ring the outer bare part of which was coated with polyethylene. The cell was immersed in the electrolyte solution, and the pressure inside the cell was read with an ionization gauge. Electrolytic voltage was read by referring to HgO electrode through a Luggin capillary. The counter electrode for applying the anodizing voltage to the Pd electrode was faced through a cylindrical separator. Total volume inside the cell (to the stopcock) was about 400 ml. Galvanostatic potential transient was traced on a Toshiba oscilloscope, the constant current being supplied from a high potential source.

Results and Discussion

Current-voltage characteristic at 60°C is shown in Fig. 2, where each point was read 10 min after the setting at the desired current. At room temperature a stable voltage more negative than —0.75v was hard to obtain whereas at 60°C, high negative value of —0.85v could be obtained easily.

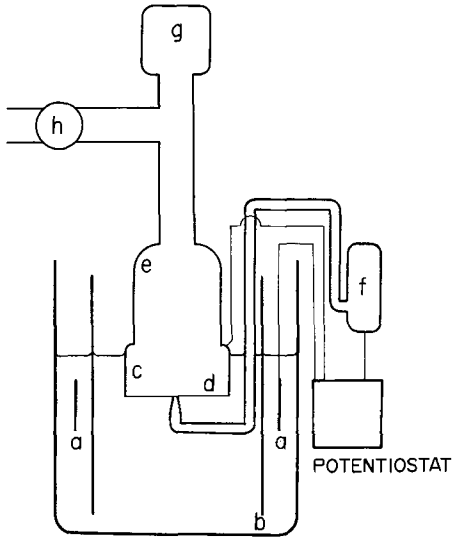

Fig. 1. Cell for measuring the rate of catalytic formation of hydrogen at Pd electrode: a, Pt counter electrode; b, glass cylindrical separator; c, Kovar tube; d, Pd foil electrode; e, glass tube; f. HgO reference electrode; g, ionization gauge; h, vacuum stopcock.

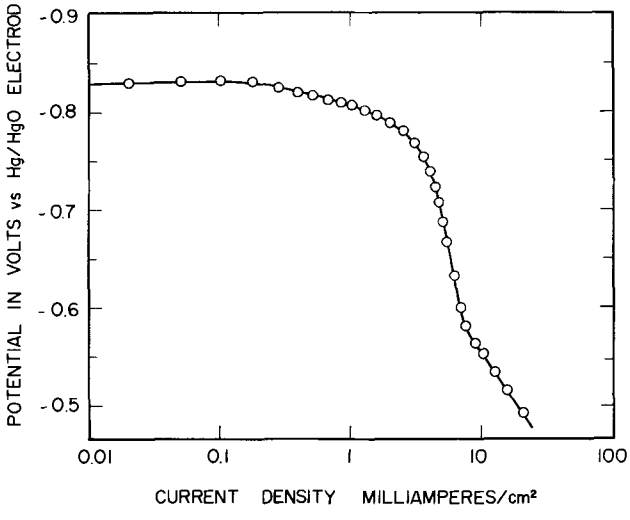

Fig. 2. Anodic current-voltage characteristic for Pd immersed in the alkaline solution in the presence of CH_3OH. [KOH] = 1.6M, [CH_3OH] = 3M, 60°C.

At high temperature the initial open-circuit voltage of a newly immersed test electrode was about —0.75v, and the voltage shifted gradually to a more negative value, reaching a final limiting value of —0.86v within 10 min. In the very low current density region of the polarization curve, the voltage was found to be independent of the current density giving a flat characteristic. In the region of more increased current density, slow increase in current gave a gentle downward slope where the voltage was unstable and shifted very slowly to a positive side during the measurement. After this slope, the curve falls rapidly to about —0.6v where direct electrooxidation of methanol begins to take place and the current-voltage relation fell on the Tafel line.

Since the high negative voltage at very low current density region nearly coincides with the reversible hydrogen potential at the electrodes, methanol is supposed to decompose adsorbed hydrogen. The current-voltage characteristics can be elucidated with this assumption. At constant temperature and at fixed concentrations of all species the rate of the hydrogen formation reaction will reach a stationary state because the formed hydrogen will be absorbed into a large reservoir of palladium lattice without remain-

ing at the surface site. When the rate of oxidation of hydrogen due to anodic polarization is slow compared with the catalytic formation rate of hydrogen, the observed potential will be constant irrespective of anodic current density because the exchange current density for the hydrogen oxidation is sufficiently high at the electrode.

On the other hand, when the increased anodic current overcomes the rate of the hydrogen formation, the electrode potential will shift to the positive side. The observed slow downward region will correspond to this situation. The rate of anodic oxidation of methanol in this region, however, is still not as rapid as that of hydrogen oxidation. The limiting current in the downward region is explained by the restricted supplying rate of hydrogen. Under the sufficient overvoltage thus reached, the rate of direct anodic oxidation of methanol becomes fast enough to fall on the Tafel line.

The evidence of hydrogen formation was found as a pressure increase in the cell shown in Fig. 1. In the absence of methanol, the alkaline solution gave no pressure increase in the room separated from a pumping line by a closed stopcock. This indicates no observable gas leakage through any connection or palladium foil. Some 10 min after methanol was added to the solution, the pressure began to increase, the increasing rate being slow at first but more rapid with the lapse of time. But this increased pressure was found to decrease under anodic polarization at about —0.4v, where the formed hydrogen was consumed at the electrode before being absorbed. Contrary to this, even in the absence of methanol, the pressure increase was found when the electrode was polarized cathodically.

The dependency of the rate of this catalytic hydrogen formation reaction on the concentration of reacting species was examined by varying the concentrations of methanol and hydroxyl anion. As shown in Fig. 3, the rate was proportional to the concentration of methanol at fixed hydroxyl concentration. On the other hand, increased concentration of hydroxyl at fixed methanol concentration resulted in the rate increase depending on the square of hydroxyl concentration, which is given in Fig. 4.

Galvanostatic traces were obtained for two cases: the one was traced in the base solution with the palladium containing absorbed hydrogen; the other was traced with the test electrode immersed for sufficient time in methanolic alkaline solution. Two traces are depicted in Fig. 5 (curves a and b), which shows the two traces are identical in feature and give a wave at

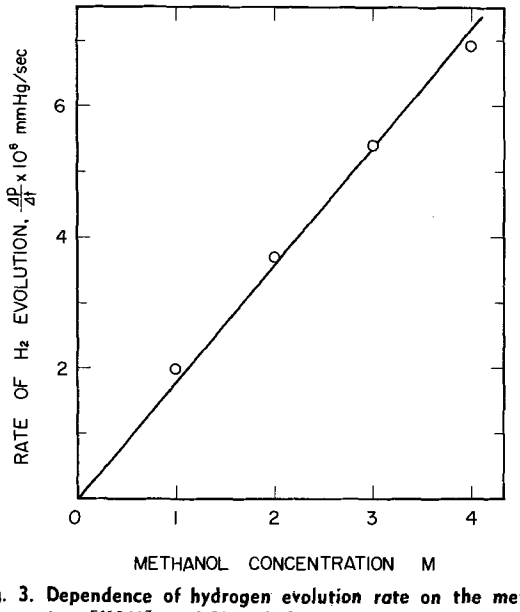

Fig. 3. Dependence of hydrogen evolution rate on the methanol concentration. [KOH] = 1.0M, 60°C.

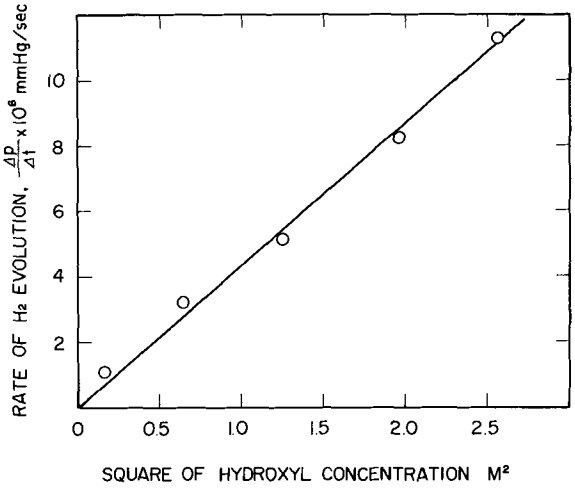

Fig. 4. Dependence of hydrogen evolution rate on the hydroxyl concentration. [CH_3OH] = 3.0M, 60°C.

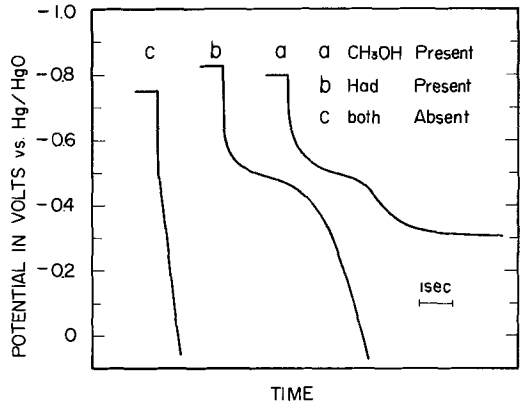

Fig. 5. Galvanostatic transients obtained during anodic polarization for Pd in alkaline solution. [KOH] = 2.0M.

—0.48v due to the oxidation of absorbed (or adsorbed) hydrogen. A trace immediately after the first trace, however, gave no indication of hydrogen wave, (Fig. 5, curve c). The amount of surface hydrogen estimated from the transition time for the two cases was far less than the value expected for full coverage. This indicates that the amount of hydrogen staying at the surface is very small, and a major part of hydrogen formed at the surface is immediately absorbed in the palladium lattice. Consequently the rate of the hydrogen formation reaction of methanol is difficult to estimate from the galvanostatic trace. The increasing rate of hydrogen pressure in the gas phase of the cell was far slower than the diffusing rate of methanol to the electrode in solution (see later). Accordingly, the adsorption of methanol (methoxyl) or hydroxyl ion at the electrode surface would be in an adsorption equilibrium. If the equilibrium amount of adsorption were near the saturation and accordingly, the amount is independent of concentration, the rate of hydrogen evolution is expected to be independent of the concentrations. The experimental rate, however, was proportional to the methanol concentration and to the square of hydroxyl concentration, respectively, indicating the actual amounts of adsorption to be far from the saturated amounts. These features may be written as follows.

$$[CH_3OH_{ad}] = K_1\,[CH_3OH] \qquad [3]$$

$$[OH^-{}_{ad}] = K_2[OH^-] \qquad [4]$$

$$\frac{dp_{H2}}{dt} = k[CH_3OH_{ad}][OH_{ad}{}^-]^2 \qquad [5]$$

$$= k\,K_1K_2[CH_3OH][OH^-]^2 \qquad [6]$$

where [ad] denotes surface amount of adsorption, K_1 and K_2 the equilibrium constants of adsorption, dp_{H_2}/dt the rate of hydrogen pressure increase, and k the appropriate rate constant. When active palladium was immersed in the test solution which contained barium hydroxide, a white precipitate of barium carbonate was found to be formed on the palladium as the hydrogen gas evolution proceeded. On the other hand, if we use formate or formaldehyde instead of methanol, the more rapid hydrogen evolution accompanied by the formation of carbonate can be observed at the elevated temperature. These findings indicate that the decomposition product of methanol is not the species like formaldehyde or formate but carbonate. Although the quantitative coulometry for the formation of carbonate was failed because of its very small amount, we infer that the decomposition of methanol proceeds through the reaction [1] which contains two steps

$$CH_3OH + 2\,OH^- \rightarrow CO_3^{2-} + 6H_{ad} \text{ (liquid solid interface)} \quad [7]$$

and

$$2H_{ad} \rightarrow H_2 \text{ (gas solid interface)} \quad [8]$$

Open-circuit voltage at room temperature was about —0.75v, and it was not possible to shift the voltage to the higher negative value of hydrogen equilibrium potential which could easily be realized at higher temperature. The rate of hydrogen evolution reaction [5] was evaluated in two different ways; from the observed dp_{H_2}/dt and from a limiting current in the flat region of high negative voltage in the current-voltage curve. The estimated rates at 60°C by the two ways coincided, and it was about 10^{-9} mol/sec cm^2, showing that the rate at room temperature would be too slow to give a hydrogen equilibrium potential in the presence of some species having inhibit action.

Several electrode reactions which give a equilibrium potential of —0.75v were examined by considering the conception given by Spiro and Ravno (8). Formation reaction of formaldehyde and water such as

$$CH_3OH + 2OH^- \rightarrow HCHO + 2H_2O + 2e \quad [9]$$

gives a higher negative value than —0.75v *vs.* HgO electrode. Similar results are given for the formations of formate or carbonate.

On the other hand, formation reaction of adsorbed hydrogen may be classified into three possible categories. The first is related to the formation of $(CO_2^-)_{ad}$ such as

$$CH_3OH + l\,OH^- \rightarrow (CO_2^-)_{ad} + (6-l)H_{ad} + (l-1)H_2O + (l-1)e \quad [10]$$

where $l = 2$ to 5.

The second is related to the formation of $(CO)_{ad}$ like

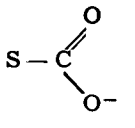
$$CH_3OH + mOH^- \rightarrow (CO)_{ad} + (4-m)H_{ad} + mH_2O + me \quad [11]$$

where $m = 1$ to 3.

The third is related to the formation of $(CO^-)_{ad}$ like

$$CH_3OH + nOH \rightarrow (CO^-)_{ad} + (4-n)H_{ad} + nH_2O + (n-1)e \quad [12]$$

where $n = 2$ and 3. In these three mechanisms, $(CO_2^-)_{ad}$, $(CO)_{ad}$, and $(CO^-)_{ad}$ are supposed to be chemisorbed species like



, S = C = O and S = C — O$^-$,

respectively, where S denotes surface site.

In order to calculate standard potentials for these reactions, we should know the values of free energy of formation of all the species appearing in the reaction. Since we have no data for $(CO_2^-)_{ad}$, $(CO)_{ad}$, and $(CO^-)_{ad}$, tabulated values of similar stable species were used as substitutes: As a rough approximation, we assumed that the binding energy of C-Pd bond in the adsorbed form does not differ seriously from that of C—H bond. Then for $(CO_2^-)_{ad}$, the value of HCO_2^-, for $(CO)_{ad}$, that of formaldehyde, and for $(CO^-)_{ad}$, that of CH_3O^- in aqueous solution were used, respectively. The free energy of formation of CH_3O^- was evaluated from that of CH_3OH in aqueous solution and pk_a of it (9). The free energy of H_{ad} was estimated experimentally. If the test electrode is cathodically polarized in alkaline solution in the absence of alcohol and is brought to $\alpha\beta$ coexistence phase, the open-circuit voltage will give the value in question, since the voltage is due to the reaction [13].

$$H_{ad} + OH^- \rightarrow H_2O + e \quad [13]$$

The actual value was —0.87v *vs.* HgO electrode, from which standard free energy of formation of H_{ad} was calculated to be —1.3 kcal/mole. The standard free energy of formation of stable species used for calculation were of the values cited in Latimer's text book (10). All the equilibrium potential calculated for various cases are very high negative values except for reaction [11] with $m = 1$ and 2 whose $E°$ are —0.63 and —0.75v *vs.* HgO electrode, respectively. If the surface concentrations of $(CO)_{ad}$ and H_{ad} can be assumed to be far lower than those of reactant species, the mechanism of $m = 1$ is more probable. This mechanism agrees with the mechanism proposed by the present author (6) in which three H_{ad} are formed from one mole of methanol, but differs in the contribution number of hydroxyl ion. In the previous paper, the author mistook the rate-determining mechanism to be reaction [14].

$$CH_3O\cdot + 2\,OH \rightarrow (CO_2^-)_{ad} + 3H_{ad} + H_2O + e \quad [14]$$

with the assumption that equilibrium exists between methanol and methoxyl anion from which $CH_3O\cdot$ is formed. In this equilibrium one hydroxyl takes part, and accordingly, concentration of $CH_3O\cdot$ will be represented by the product of original methanol and hydroxyl concentrations, respectively. Therefore the electrochemical reaction order for OH^- in reaction [14] is not 2/3 but 1 as represented by reaction [10] with $m = 3$. But this mechanism is rejected in the present consideration on the basis of equilibrium potential. The reaction order of OH^- for the accepted present mechanism [11] is 1/3, which differs from the preceding observed value of 2/3. Precise reinvestigation should be carried out to explain this point.

Technical Notes

Electrolytic Reduction of Acrylonitrile to Allylamine

Tsutomu Nonaka and Kiichiro Sugino

Department of Applied Electrochemistry, Tokyo Institute of Technology, Tokyo, Japan

The electrolytic reduction of acrylonitrile in sulfuric acid[1] was found to occur smoothly at a lead cathode, for example, when the cathode potential reached — 1.3 ~ 1.5v (*vs.* SCE). In this case, the reduction product consisted mainly of allylamine. A small amount of propylamine was produced as by-product, but formation of secondary amines was present only in trace amounts if at all. The current efficiency for allylamine was above 50%. Cadmium and zinc were found to be effective but at lower efficiency. On the other hand, mercury was seen to be inefficient for this reduction as was palladium. The latter fact indicated that the nature of the reduction is not a catalytic one.

It is interesting to note that the selective reduction of the nitrile group in acrylonitrile could be performed in acidic medium. The detailed results of the electrode process will be reported later.

Experimental

An H-type cell, similar to that described earlier (2), was used with a sintered glass diaphragm. Cathode was lead (treated with dilute nitric acid); area, 12.0 cm^2; anode, platinum disk. The electrolysis was carried out by controlling the cathode potential at —1.45v (*vs.* SCE). The electrolysis conditions were: catholyte, 10g acrylonitrile, 25 cc methanol, 50 cc 10% sulfuric acid; anolyte, 10% sulfuric acid; amperage, 1.30 ~ 0.27 amp; cathodic current density, 12 ~ 2 amp/dm^2 (average, 3.9 amp/dm^2); temperature, about 20°C; amount of current, 3.99 amp hr (about 20% of the theoretical amount for allylamine).

After the reduction, the catholyte was neutralized with a 50% solution of sodium hydroxide in water. The resulting solution was extracted with ether. The ether extract was analyzed by gas chromatography for propionitrile and unreacted acrylonitrile. The aqueous solution was evaporated to dryness at reduced pressure, and the residue was thoroughly extracted with ethanol. The ethanol extract was evaporated to dryness at reduced pressure leaving pale yellow hygroscopic crystals. These were found to consist mainly of allylamine sulfate as described below: mp 230°-235°C (after purification); analysis, calculated for $C_3H_7N \cdot \frac{1}{2}H_2SO_4$; N, 13.2; SO_4, 45.3; found: N, 12.4; SO_4, 45.3. By paper chromatography of the crystals[2] only two spots corresponding to allylamine and propylamine were obtained. No spot was found for secondary amines. Using this information, the amount of allylamine in the crystals was determined by titration with a mixed solution of potassium bromide and potassium bromate in the presence of sulfuric acid. Secondary amines could hardly be obtained even from a large amount of samples obtained by a separate run. Also, it should be noted that polymerization of acrylonitrile itself could hardly occur during the electrolysis.

The amounts of products identified were as follows: allylamine, 1.16g; propylamine, 0.18g; ammonia,[3] 0.12g; propionitrile, 0.07g; hydrogen, 58 cc. Current efficiency was 55% for allylamine and 13% for propylamine. The formation of propionaldehyde was also confirmed.

Identity was then confirmed by the preparation of several compounds from free amine which was obtained by distillation of the sulfate with alkali. Crude allylamine thus obtained boiled at 52°-55°C (3), its hydrochloride and picrate melted at 105°-110°C (4), and at 140°-141°C (5), respectively. It gave propylamine, which was identified as N-n-propylbenzamide, mp 83°-84°C (6) and picrate, mp 132°-134°C (7), by catalytic hydrogenation over nickel catalyst in acetic unhydride at 50°-60°C under 100 atm. Bromination of the crude allylamine in hydrobromic acid gave 2,3-dibromopropylamine hydrobromide as precipitate, mp 164°-165°C (8). After removal of the precipitate, the mother liquor was distilled with alkali to obtain propylamine which was identified as picrate, mp 132°-135°C (7).

These compounds were further identified by IR spectroscopy and also by a mixture melting point test with authentic sample.

A scale-up preparative study was made by using forty times the amount of sample for the run and using lead. This gave almost the same result as in the small scale experiment. Thus: catholyte, 400g acrylonitrile, 2000 cc 10% sulfuric acid, 1000 cc methanol [during the electrolysis four portions (50 cc each) of 50% sulfuric acid were added]; anolyte, 1600 cc 10% sulfuric acid; cathode, lead (treated with dilute nitric acid); anode, lead; amperage, 55 amp; cathodic current density, 5.8 amp/dm^2; temperature, 20°C; amount of current, 247 amp hr (30% of the theoretical amount for allylamine).

The products obtained (current efficiency) were: allylamine sulfate 137g (56%), propylamine sulfate 31g (19%), ammonium sulfate 30g (10%), propionitrile 2.4g (1%).

Acknowledgment

This investigation was promoted by a grant for fundamental and developmental scientific research from the Ministry of Education of Japan and also a grant from Nippon (Japan) Carbide Industries Inc., for which the authors wish to express their deep appreciation.

Manuscript received July 10, 1967; revised manuscript received Sept. 12, 1967. This paper was presented at the Annual Meeting of the Chemical Society of Japan, Tokyo, March 31-April 4, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

[1] At about the same time that the authors conducted their research, S. L. Varshavskii *et al.* (1) also carried out the same investigation and obtained allylamine.

[2] Before use, the original sulfate was converted to hydrochloride.

[3] This might result from the hydrolysis of a reduction intermediate, $CH_2 \cdot CH_2 \cdot CH{=}NH$, taking the formation of propionaldehyde into consideration.

On the Ratio Method of Analysis of Potentiostatic Current-Time Curves for Planar Electrodes

Charles A. Johnson and Sidney Barnartt

E. C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Monroeville, Pennsylvania

Potentiostatic current-time curves for a simple first-order electrode reaction of the type: $O^{z+} + ne^- = R^{(z-n)+}$, coupled with semi-infinite linear diffusion, are described by the theoretical equation (1)

$$i_{(t)}/i_{(t=0)} = \exp(\lambda^2 t)\ \mathrm{erfc}\ (\lambda\sqrt{t}) \qquad [1]$$

Here $i_{(t)}$ is the current at time t, and the initial current $i_{(t=0)}$ is the desired charge-transfer current corresponding to the applied potential step. λ is a diagnostic constant, dependent on the charge-transfer mechanism as well as on reactant concentrations and diffusivities; we need not know its components for the purpose of this note.

At short times such that $1 > i_{(t)}/i_{(t=0)} > 0.85$, Eq. [1] reduces to

$$i_{(t)}/i_{(t=0)} = 1 - \frac{2}{\sqrt{\pi}}\lambda\sqrt{t} \qquad [2]$$

so that $i_{(t=0)}$ is readily obtained by linear extrapolation of an $i - \sqrt{t}$ plot back to zero time. For cases where experimental data are not available at such short times, we have proposed (2) a simple "ratio method" of analyzing the longer-time data. This utilizes the ratio

$$R = \frac{i_{(t)}}{i_{(4t)}} = \frac{\exp(\lambda^2 t)\ \mathrm{erfc}\ (\lambda\sqrt{t})}{\exp(4\lambda^2 t)\ \mathrm{erfc}\ (2\lambda\sqrt{t})} \qquad [3]$$

From the "master" curve of R against $\lambda\sqrt{t}$, the value of $\lambda\sqrt{t}$ corresponding to any measured R may be read. This value yields λ, and then Eq. [1] gives $i_{(t=0)}$. Methods of obtaining the charge-transfer parameters from λ and $i_{(t=0)}$ have been described (1-3) and will not be repeated here.

The master curve of R *vs.* $\lambda\sqrt{t}$ has been published (2), and this curve is adequate for approximate analyses. For accurate analyses, a numerical table of the function exp (x^2) erfc (x) given to at least four significant figures and at intervals $\Delta x \leq 0.01$ is required. Such an extensive table of this function is not generally available. We have succeeded, however, in obtaining a sufficiently precise and useful analytical relation between R and $\lambda\sqrt{t}$, such that tables of the function exp (x^2) erfc (x) are no longer required. Our relation gives $\lambda\sqrt{t}$ as the rational polynomial

$$\lambda\sqrt{t} = \frac{a_0(R-1) + a_1(R-1)^2}{1 + a_2(R-1)} \qquad [4]$$

$$a_0 = 0.8827,\ a_1 = -0.45387,\ a_2 = -0.907113$$

For $1.15 < R < 1.67$, which covers the range $0.14 < \lambda\sqrt{t} < 1$, Eq. [4] yields $\lambda\sqrt{t}$ with an accuracy better than ±0.05%. The current-time curve beyond $\lambda\sqrt{t} \simeq 1$ contains no appreciable kinetic information (1, 3) and therefore is not considered in the present analysis.

Table I. Analysis of data by Gerischer (4) in the intermediate-time range

t, (sec) × 10^3	$i(t)/i(4t)$	λ, $(\mathrm{sec})^{-1/2}$	$i_{(t=0)}$*
0.25	1.22_9	14.3	8.28
0.50	1.33_2	15.6	8.55
0.75	1.39_6	15.9	8.63
1.00	1.44_5	16.0	8.66
1.25	1.48_3	16.1	8.69
1.50	1.51_5	16.2	8.73
1.75	1.54_6	16.4	8.80
2.00	1.56_2	16.1	8.71
2.25	1.58_0	16.0	8.67
	Mean :	16.1	8.70
	σ :	0.16_3	0.05_4

* Unit current is one division of the ordinate scale, Fig. 6 of ref. 4.

A good illustration of the precision obtainable using this ratio method is afforded by experimental data of Gerischer (4) for potentiostatic deposition of cadmium from cyanide solution. In this paper Gerischer proposed an analytical procedure based on the measured slope of the current-time curve, but his procedure gave scattered results. Oldham and Osteryoung (3) devised an improved method also based on the slope of the current-time curve, which was applied to a particular experimental curve from Gerischer's paper and yielded $i_{(t=0)}$ with a standard deviation $\sigma = 4\%$. We have now applied our ratio method to the same experimental curve and the results (5), which span the entire experimental curve, are listed in Table I. The standard deviation[1] is less than 1% in $i_{(t=0)}$; the mean value and standard deviation exclude the data for $t \leq 0.5$ msec, since Gerischer noted that the currents at such short times included spurious transient components.

Table I illustrates both the high precision obtainable with the ratio method of analysis, and the good conformity of Gerischer's experimental current-time curve with Eq. [1].

Glass-Membrane Potentials in Mixed Anion Melts

Kurt H. Stern

Electrochemistry Section, National Bureau of Standards, Washington, D. C.

In a previous study of membrane potentials (1) at molten salt-fused silica interfaces it was shown that the emf of the cell

$$\text{Ag}|\text{AgCl, NaCl}|\text{glass}|\text{AgBr, NaBr}|\text{Ag} \qquad (A)$$

could be calculated by a straight-forward thermodynamic method if it was assumed that the only equilibrium at the glass-melt interface involved sodium ions. The cell reaction then is

$$\text{AgBr} + \text{NaCl} = \text{AgCl} + \text{NaBr} \qquad [1]$$

Calculated and experimental results were in good agreement when $X_{AgCl} = X_{AgBr} = 0.99$, $X_{NaCl} = X_{NaBr} = 0.01$. For equal sodium concentrations below ~1 m/o (mole per cent) the emf depends only on the $E°$ values of the above four salts and is independent of the concentration. (However, the emf can neither be calculated nor measured for zero sodium concentration since there would then exist no equilibrium at the glass-melt interface.) Since no extrathermodynamic assumptions about anion-glass interactions were made in the derivation of the cell emf it was tentatively assumed that such interactions were absent.

Nevertheless, it seems that mixed anion cells might offer a more sensitive tool for detecting possible anion-glass interactions, particularly since sulfate and nitrate ions have been found to inhibit the potential response of the glass to changes in sodium ion concentrations (1, 2). Moreover, the thermodynamic interpretation of such cells is of some interest. The mixed chloride-bromide analog to cell (A) was therefore studied. Since the thermodynamic derivation of the cell has not previously been worked out it is presented first.

Consider the concentration cell

$$\underset{\text{I}}{\text{Ag}|\text{Ag}^+, \text{Na}^+, \text{Cl}^-, \text{Br}^-|\text{glass}|\text{Ag}^+, \text{Na}^+, \text{Cl}^-, \text{Br}^-}\underset{\text{II}}{|\text{Ag}}$$

Since only the cations are involved in the cell reaction this can be written as

$$\text{Ag}^+(\text{II}) + \text{Na}^+(\text{I}) = \text{Ag}^+(\text{I}) + \text{Na}^+(\text{II}) \qquad [2]$$

However, the corresponding E or ΔG can only be expressed in terms of the thermodynamic components (cation-anion pairs) of the reciprocal salt system. Writing the cell in this manner gives

$$\underset{\text{I}}{\text{Ag}|\text{AgBr}(X_\text{I}), \text{AgCl}(X'_\text{I}), \text{NaCl, NaBr}|\text{glass}|}$$
$$\underset{\text{II}}{\text{AgBr}(X_\text{II}), \text{AgCl}(X'_\text{II}), \text{NaCl, NaBr}|\text{Ag}} \qquad [3]$$

Since activity coefficients of all the components are not known over the entire concentration range we restrict the derivation to the case $X_{Na+} << X_{Ag+}$. We now assume that the chemical potentials are additive functions in the mole fractions of the components. For example,

$$\mu_{\text{Ag}^+(\text{I})} = X_\text{I}\,\mu_{\text{AgBr(I)}} + X'_\text{I}\,\mu_{\text{AgCl(I)}} \qquad [3a]$$

$$\mu_{\text{Na}^+(\text{I})} = X_\text{I}\,\mu_{\text{NaBr(I)}} + X'_\text{I}\,\mu_{\text{NaCl(I)}} \qquad [3b]$$

The Gibbs energy change for reaction [2] then is

$$\begin{aligned}\Delta G = (\mu_{\text{Ag}^+(\text{I})} + \mu_{\text{Na}^+(\text{II})}) - (\mu_{\text{Ag}^+(\text{II})} + \mu_{\text{Na}^+(\text{I})}) \\ = [X_\text{I}(\mu°_{\text{AgBr}} + RT\ln a_{\text{AgBr(I)}}) \\ + X'_\text{I}(\mu°_{\text{AgCl}} + RT\ln a_{\text{AgCl(I)}}) \\ + X_\text{II}(\mu°_{\text{NaBr}} + RT\ln a_{\text{NaBr(II)}}) \\ + X'_\text{II}(\mu°_{\text{NaCl}} + RT\ln a_{\text{NaCl(II)}})] \\ - [X_\text{II}(\mu°_{\text{AgBr}} + RT\ln a_{\text{AgBr(II)}}) \\ + X'_\text{II}(\mu°_{\text{AgCl}} + RT\ln a_{\text{AgCl(II)}}) \\ + X_\text{I}(\mu°_{\text{NaBr}} + RT\ln a_{\text{NaBr(I)}}) \\ + X'_\text{I}(\mu°_{\text{NaCl}} + RT\ln a_{\text{AgCl(I)}})] \qquad [4]\end{aligned}$$

Combining terms and using $\Delta G = -n\mathbf{F}E$, $n = 1$, gives

$$\begin{aligned}E = [(X_\text{I} - X_\text{II})\,E°_{\text{AgBr}} + (X'_\text{I} - X'_\text{II})\,E°_{\text{AgCl}} \\ + (X_\text{II} - X_\text{I})\,E°_{\text{NaBr}} + (X'_\text{II} - X'_\text{I})\,E°_{\text{NaCl}}] \\ + RT/\mathbf{F}\left[X_\text{I}\ln\frac{a_{\text{AgBr(I)}}}{a_{\text{NaBr(I)}}} + X'_\text{I}\ln\frac{a_{\text{AgCl(I)}}}{a_{\text{NaCl(I)}}}\right. \\ \left. + X_\text{II}\ln\frac{a_{\text{NaBr(II)}}}{a_{\text{AgBr(II)}}} + X'_\text{II}\ln\frac{a_{\text{NaCl(II)}}}{a_{\text{AgCl(II)}}}\right] \qquad [5]\end{aligned}$$

Since the melts are very dilute in Na^+ we assume

$$a_{\text{NaCl}} = X_{\text{Na}^+}\,X_{\text{Cl}^-} = X_{\text{Na}^+}\,X_{\text{AgCl}} \qquad [6a]$$

$$a_{\text{NaBr}} = X_{\text{Na}^+}\,X_{\text{Br}^-} = X_{\text{Na}^+}\,X_{\text{AgBr}} \qquad [6b]$$

where X_{Na+} is the cation fraction of Na^+. Substituting [6] into [5] and rearranging gives

$$\begin{aligned}E = [(X_\text{I} - X_\text{II})\,(E°_{\text{AgBr}} - E°_{\text{NaBr}}) \\ + (X'_\text{I} - X'_\text{II})\,(E°_{\text{AgCl}} - E°_{\text{NaCl}})] \\ + RT/\mathbf{F}\ln[X_\text{I}\ln\gamma_{\text{AgBr(I)}} + X'_\text{I}\ln\gamma_{\text{AgCl(I)}} \\ - X_\text{II}\ln\gamma_{\text{AgCl(II)}} - X_\text{II}\ln\gamma_{\text{AgCl(II)}} \\ + (X_\text{II} + X'_\text{II} - X_\text{I} - X'_\text{I})\ln X_{\text{Na}^+}] \qquad [7]\end{aligned}$$

where the activity coefficient $\gamma_i = a_i/X_i$. If the sodium concentrations on both sides of the membrane are equal the last term in the second bracket becomes zero. The entire second bracket is a correction term for the nonideality of the AgCl-AgBr solutions. For the limiting case $X_\text{I} = 1$, $X'_\text{I} = 0$, $X_\text{II} = 0$, $X'_\text{II} = 1$ Eq. [7] reduces to the equation derived previously for the cell Ag|AgCl, NaCl|glass|AgBr, NaBr|Ag. For very low and equal concentrations of sodium on both sides of the membrane the entire second bracket becomes zero and the cell emf then depends only on the relative chloride-bromide composition. Since the activity coefficients of all the components in Eq. [5] are not known over the entire range of composition the experiments were restricted to cells in which the cation fraction of sodium was 10^{-2} in each compartment. It was then assumed that the activities of AgCl and AgBr in the resulting solution are the same as in the absence of sodium and could be obtained from the data of Murgulescu and Marchidan in AgCl-AgBr mixtures (3). The general experimental procedures have been described previously (1).

Experimental.—In order to ensure that the mixed melts would retain equal sodium ion concentration 1 m/o NaCl in AgCl and 1 m/o NaBr in AgBr melts were prepared first and subsequent melt compositions made by mixing these.

Table I. Experimental and calculated emf's for cell (B) at 525°C

X_I	X'_I	X_{II}	X'_{II}	$-E_{calc.}$ (mV)	$-E_{exp}$ (mV)
0.490	0.500	0.489	0.501	0	4
0.454	0.536	0.489	0.501	9	10
0.407	0.583	0.489	0.501	16	30

0.331	0.659	0.489	0.501	37	37
0.293	0.697	0.489	0.501	46	49
0.263	0.727	0.489	0.501	53	56
0.263	0.727	0.515	0.475	53	55
0.263	0.727	0.560	0.430	60	62
0.263	0.727	0.596	0.394	67	70
0.263	0.727	0.630	0.360	73	78
0.263	0.727	0.660	0.330	79	87
0.263	0.727	0.700	0.290	87	92
0.263	0.727	0.726	0.264	92	100
0.263	0.727	0.757	0.233	99	107
0.263	0.727	0.791	0.199	107	117

In contrast to experiments in which the new equilibrium potential is established almost immediately after the addition of a sodium salt to a silver halide, in the present case steady potentials were obtained much more slowly, frequently several hours after a change in melt composition. In every case steady emf's were eventually obtained, however. Two runs were made. In the first of these, at 525°C, both compartments initially contained a nearly equimolar AgCl-AgBr mixture. The composition of the compartments was then altered by increasing the AgCl concentration of one, and the AgBr concentration of the other.

Results

Table I shows the comparison of the experimental results with those calculated from Eq. [7]. The term in the second bracket is small ($\leq$3 mv) compared to the first. The source of the $E°$ values has been discussed elsewhere (1).

Since $E_{calc.}$ is essentially equal to the first bracket of Eq. [7] which consists of a small difference between two large terms (and thus is very sensitive to small changes to the choice of the $E°$'s and small errors in concentration) the agreement between calculated and experimental values must be considered excellent. Except for four points agreement is within 5 mv.

The second experiment was similar except that one compartment initially contained only the AgCl-NaCl mixture and the AgBr-NaBr mixture was added to it. Results were similar but ($E_{calc.} - E_{exp}$) was somewhat larger, ~15 mv.

In view of these results it appears that Eq. [7] correctly gives the emf of cell B and that the assumption implicit in Eq. [3] is justified.

Performance of a Silver-Gold (10%) Alloy in a Concentrated Caustic Electrolyte

Paul Malachesky and Raymond Jasinski

Tyco Laboratories, Inc., Waltham, Massachusetts

Silver oxide, Ag_2O, is a p-type semiconductor of low electronic conductivity, ~10^{-8} ohm^{-1} cm^{-1} (1). In principle, this conductivity can be increased by the addition of minor impurities which change the concentration of holes or which promote the formation of vacancies. Impurities of the former type are metals to the left of silver in the periodic table (*e.g.*, Pd) or metals of high ionization potential (*e.g.*, Au). An increase in electrical conductivity of Ag_2O can be expected to result in an improvement in the charge acceptance characteristics of silver when anodized in a concentrated caustic electrolyte. The performance of silver-palladium alloys has been discussed elsewhere (2). This paper is concerned with the electrochemical characteristics of an Ag/10% Au alloy. The oxidation behavior of a 2% gold-silver alloy has been reported, but no quantitative data were given (3).

Experimental

The apparatus and approach employed to investigate this effect, have already been described (2). Briefly, the system consists of a polished gold-silver alloy electrode mounted in a rotating disk assembly. The electrolyte was 35% KOH saturated with nitrogen. The electrode was cathodized before using and freshly polished between each galvanostatic charging experiment.

The electrode was anodized at varying current densities, and the charge accepted on the Ag (I) and Ag (II) plateaus was measured. During cycling, the double layer capacity was measured after each total discharge step. Details are given elsewhere (2).

The data on charge acceptance and delivery on all cycles are the average of at least triplicate runs. The total charge accepted in millicoulombs/square centimeters is designated as Q_t; the charge accepted on the Ag (I) level and the Ag (II) level are designated as Q_1 and Q_2, respectively.

Results and Discussion

The total charge accepted by the 10% Au sample is compared in Fig. 1 with the charge acceptance for silver. The form of the curve is identical for both materials and for silver-palladium alloys as well (2). The quantity of total charge accepted is particularly sensitive to current density at and below 3 ma/cm^2. At all current densities the alloy shows a greater charge acceptance than pure silver.

Also significant is the difference between the alloys in the quantity of charge accepted on the Ag (I) plateau. As shown in Fig. 2, the alloy will accept approximately 2.5 times as much charge at this level as will silver itself. Furthermore, this effect is maintained over the entire current density range surveyed.

The ratio of charge accepted on the Ag (II) level to that on the Ag (I) level is shown is Fig. 3 for the 10% Au alloy. As observed with silver and silver-palladium alloys (2), there is a relative increase in the Ag (I) plateau with increasing current density. Comparing this curve with Fig. 1 implies that de-

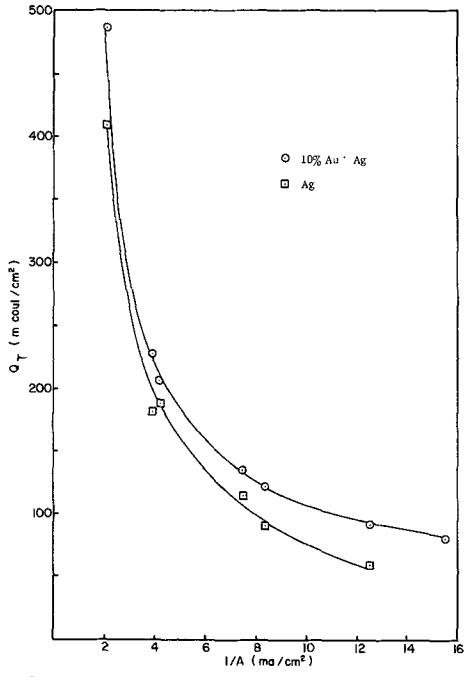

Fig. 1. Total charge accepted (Q_T) on the first cycle as a function of current density for pure silver and the 10% Au-Ag alloy.

Table I. Relative variation in C_{dl}* on cycling at 2.08 ma/cm²

Cycle	Ag, 91 μf/cm²	Ag/10% Au, 100 μf/cm²
0	1	1
1	3.8	3.2
2	3.6	3.9
3	3.8	4.3
4	3.8	4.0
5	4.3	4.2

* Normalized to C_{dl} before cycling.

creasing current density will increase charge acceptance at both oxide levels, although Q_2 increases somewhat more rapidly than Q_1.

The inverse ratio (Q_1/Q_2) is also shown for the discharge of this alloy at the same current density as the charging process. There is a slight dependence on current density, as the relative length of the Ag (II) plateau increases with increasing current density.

This electrode was then cycled at a number of current densities. The relative change in double layer capacitance (C_{dl}) is shown in Table I for silver and the 10% Au alloy cycled at 2.08 ma/cm².

The higher charge acceptance of the alloy on the first cycle does not appear due to a higher roughness factor. Although it is not possible to deduce values rigorously for the initial surface roughness from the double layer capacitances, the values observed, 91 μf/cm² for Ag and 100 μf/cm² for Au, imply that the alloy does not have a markedly greater roughness than silver. The variation of C_{dl} on cycling is most likely due to surface roughening. Thus, for both materials there is a significant change in electrode surface area for the first two cycles, approaching a steady state of about 4/1. The change in total charge acceptance on the first five cycles for silver and the 10% Au alloy is shown in Fig. 4 at a current density of 4.2 ma/cm². Similar data for the alloy up to 15 cycles are presented in Fig. 5. The effect of cycling on the ratio Q_2/Q_1 is shown in Fig. 6.

The charge acceptance curves show the same general features as the C_{dl} data of Table I. Q_t for the alloy reaches a relatively constant value after the first two cycles, while the charge accepted by the silver electrode continues to increase slowly as, apparently, the surface continues to roughen. The change of Q_t for the 10% Au alloy after 10 cycles is believed due to leakage about the Kel-F seal on the rotating disk electrode.

The relative quantity of charge accepted at the Ag (I) level is higher for the alloy initially and after the fourth cycle. As shown in Fig. 6 the curves for the two materials are parallel after these few cycles, showing no tendency to approach one another.

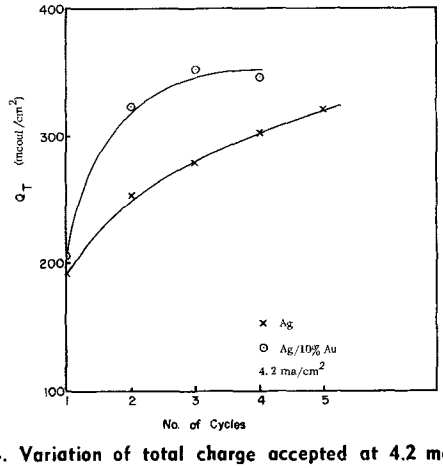

Fig. 4. Variation of total charge accepted at 4.2 ma/cm² with cycle number for silver and the gold-silver alloy.

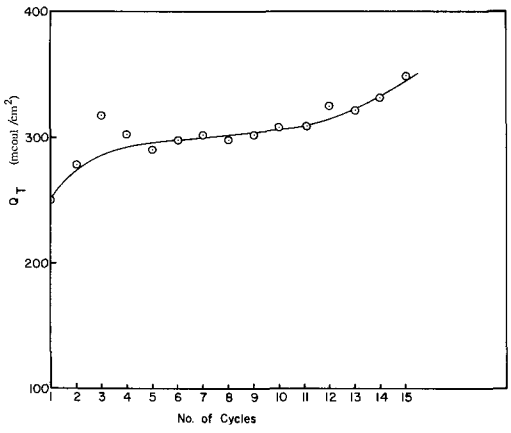

Fig. 5. Variation of the total charge passed for the gold-silver alloy with cycle number on extended cycling at 3.9 ma/cm^2.

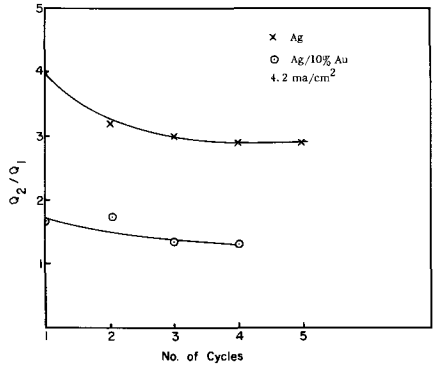

Fig. 6. Variation of Q_2/Q_1 on charging with cycle number

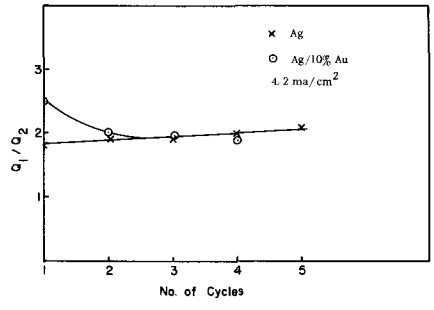

Fig. 7. Variation of Q_1/Q_2 on discharge with cycle number

This relative increase in Q_1 on cycling (Fig. 6) must involve more than a decrease in current per real surface area. As shown in Fig. 3 for charge acceptance as the first cycle, a decrease in current density decreases the relative amount of Q_1. A similar effect was noted for the Pd/Ag alloys (2).

The electrodes were discharged at the same current density as used in the charging portion of the cycle. The Q_t-cycle curves parallel the charge acceptance curves. In Fig. 7 is shown the variation of Q_1/Q_2 on discharge at 4.2 ma/cm^2. After this first discharge, both materials discharge with the same relative lengths of Ag (I) and Ag (II) plateaus. This characteristic was also noted for silver-palladium alloys (2).

Discharge efficiencies for the Au-Ag alloy were 80-85% in comparison to the value to 90-95% observed for silver and silver-palladium alloys (2). On stand at full charge for 5 min, efficiency was reduced to 62% for the Au-Ag alloy in comparison to a decrease in efficiency to 83% for a fully charged silver electrode over the same time period. The AgO plateau on discharge for the gold alloy became much shorter than usual. The length of the Ag (I) plateau remained essentially unchanged. This behavior can be explained in terms of the corrosion of AgO to Ag_2O; the anodic reaction is the gold catalyzed evolution of oxygen.

This decomposition of AgO to Ag_2O on the gold-silver alloy can explain the small decrease in Q_1/Q_2 with increasing current density (decreasing charging time) in Fig. 3. Similar data for pure silver showed no such variation in Q_1/Q_2 (2). The effect of this decomposition process on the charging data is less clear since both silver and the gold alloy show a decrease in Q_2/Q_1 with increasing current density. Thus, since the relative amount of decomposition is small during the duration of the experiments, the data for Q_t *vs.* current density (Fig. 1) probably represent true differences in the charge acceptance properties of silver and the silver-gold alloy.

Conclusions

1. The Ag/10% Au alloy will accept more charge than pure silver over the current density range studied.
2. The relative amount of charge accepted on the Ag (I) level is substantially greater for the alloy than for pure silver.
3. Both materials show a pronounced dependence of charge acceptance on current density.
4. Both materials show an increase in total charge acceptance on cycling. However, this increase is not commensurate with the increase in surface roughness as measured by double layer capacitance. The gold alloy reached a steady state after two cycles; the silver alloy continued to roughen on repetitive cycling.
5. After the first cycle, both materials discharged with the same relative lengths of the Ag (I) and Ag (II) plateaus.
6. The presence of gold apparently accelerates the decomposition of AgO; the charge delivered at the Ag_2O/Ag level was unaffected.

Brief Communication

Area Changes of a Smooth Platinum Electrode

T. Biegler

Division of Mineral Chemistry, Commonwealth Scientific and Industrial Research Organization, Port Melbourne, Victoria, Australia

The problem of whether or not a smooth platinum electrode maintains a constant "real" surface area has arisen mainly in connection with studies of the nature of the process of activation of such electrodes by anodic-cathodic pretreatment [see *e.g.*, (1) and (2) and references therein]. Since areas are measured by means of an electrode reaction (generally deposition or ionization of a monolayer of hydrogen atoms), which must be sensitive to contamination of the surface, there is no immediate way of separating "area" and "activity" effects without establishing independent criteria. However, there is a good deal of evidence that activation by the usual means is essentially a cleaning procedure (2, 3) and that the platinized active surface state proposed by Anson (4) is simply a clean surface. French and Kuwana (1), who supported Anson's concept of a distinct surface state, found that deactivation obeyed first order kinetics with a half-life of 46 min. In contrast, Bagotskii and Vasil'ev (5) reported that they could maintain a fully active electrode surface for at least 20 min in 1*N* H_2SO_4. Gilman (3) was able to reproduce the hydrogen area of an electrode over several weeks' use and concluded from this and from stirring effects that deactivation is a result of adsorption of impurities. On the other hand, modifications of platinum electrode surfaces have been observed (6-8) under sufficiently severe conditions. Blackening of the surface was found (6, 7) when electrodes were polarized with a.c. into the oxygen evolution region. Gilman (8) showed that at 120°C in 85% phosphoric acid the surface area of a smooth electrode was modified by treatments involving formation and reduction of an oxide layer.

This communication describes observations of what are believed to be true area changes found during a study of adsorption of methanol on a smooth platinum electrode (9). Area changes were also noted with two other platinum electrodes used in this work, but these were not followed systematically. Full details of the types of experiments carried out with the electrode will be found in ref. (9). Briefly, current/time curves for adsorption of methanol from 1M H_2SO_4 were determined by the potential step technique described earlier (10). Charges needed to oxidize layers of chemisorbed methanol were measured by a technique in which methanol was adsorbed, the solution was replaced by supporting electrolyte, and the adlayer stripped off during a linear anodic potential sweep. During use, the electrode potential was normally within the range 0.04-1.55v *vs.* reversible hydrogen electrode in 1M H_2SO_4; occasionally a potential of 1.8v was used for vigorous anodic cleaning. Between runs the electrode was stored in distilled water. No significant area changes were observed in the periods between sets of experiments (up to two weeks). Each series of runs was preceded by a period of anodic-cathodic cleaning in 1M H_2SO_4, using pulses and/or sawtooth scanning between 0.08 and 1.55v. Since the changes in surface properties described below were of a long term nature there was no problem in judging

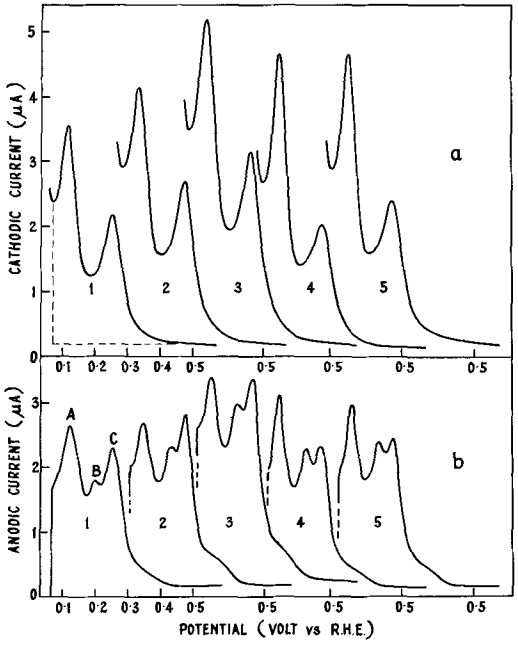

Fig. 1. Current-voltage curves (a, cathodic, b, anodic) in the hydrogen region for a platinum electrode at various stages of its life (see text). Solution, 1M H_2SO_4. Curves displaced horizontally for clarity. Broken lines on curve 1a indicate limits for integration to obtain $Q_H{}^S$. Sweep rate 37 mv/sec.

electrode cleanliness from the reproducibility of successive area determinations and anodic scans in the oxide region. Experiments were carried out at 22° ±2°C.

Figure 1 shows anodic and cathodic sweeps for 1M H_2SO_4 in the hydrogen region at various stages of the life of the electrode (34 gauge Pt wire, geometric area 0.042 cm^2). Anodic sweeps were obtained by cleaning the electrode with anodic pulses from 0.08 to 1.55v, then holding at 0.08v for 10 sec before starting the anodic scan. For the cathodic curves, cleaning was achieved by anodic pulses between 0.58 and 1.55v, the potential was held at 0.58v for 10 sec, and the cathodic sweep started. These curves were integrated according to Gilman's procedure (3) in order to obtain the saturation hydrogen coverage, $Q_H{}^S$. The solution was unstirred during these measurements. Sweep rate was 37 mv/sec.

The history of this electrode is as follows. After sealing into soft glass it was washed in cleaning solution, rinsed, and set up in the cell with degassed 1M H_2SO_4. Repetitive sawtooth scanning between 0.08v 1.55v was then commenced. Voltammegrams assumed the shape expected for a clean, active electrode after about 60 cycles [*cf.* (2)] when $Q_H{}^S$ was 10.7 μcoul. Curves 1a and b were taken after some 1700 cycles

and are qualitatively much the same as those after 60 sweeps; Q_H^S had, however, increased by 6%.

The electrode was then put into use for the methanol adsorption experiments. Curves 2a and b were obtained after a number of such runs by which time Q_H^S had increased to 14.8 μcoul. The electrode area continued to increase steadily with use and when the series of experiments with methanol was completed curves 3a and b were recorded. Q_H^S was now 19.2 μcoul, almost double the original value. It was then decided to examine the effects of further prolonged cycling in 1M H_2SO_4 and curves 4a and b were obtained after about 5900 sawtooth sweeps between 0.08v and 1.55v. There was a dramatic fall in Q_H^S to 13.4 μcoul as well as a marked change in the shapes of the curves. At this point, the solution was replaced with 0.5M methanol in 1M H_2SO_4 and 2200 cycles over the same potential range were applied, after which Q_H^S had increased to 15.2 μcoul (curves 5a and b). Only a slight change in the shapes of the curves accompanied this increase.

From the above, it appears that area changes occurred more rapidly during methanol stripping runs than in the separate experiment in which cycling in 0.5M methanol, 1M H_2SO_4 was carried out for an extended period. Quantitative comparison is difficult because no record was kept of the number of anodic excursions of the electrode during the methanol adsorption experiments. However, to give a rough comparison, in runs on a single day during which an estimated total of 600 potential steps and sweeps (mainly the former) was applied, Q_H^S increased by 23%. This compares with the 13% increase found after 2200 cycles in 0.5M methanol. Although we cannot explain the dependence of rate of area change on the type of experiment, it seems clear that the presence of methanol is necessary for the large area increases observed.

Comparison of the curves in Fig. 1 with the work of Will (11) strongly suggests that the present results reflect changes in the platinum surface structure. Will used linear sweep voltammetry to study hydrogen adsorption on platinum single crystal electrodes cut to expose each of the three low index crystal planes. Three peaks for anodic sweeps over the range 0.05-0.4v were found for each face and these were attributed to adsorption of hydrogen on the three crystal planes. The relative peak heights depended on the face used and Will concluded (11) that his technique had produced polycrystalline electrodes with a predominance of the nominal crystal face. Furthermore, he found that triangular cyclic voltammetry (0.05-1.55v) with a freshly cut face resulted in an over-all change in electrode area together with a change in relative peak heights. Will interpreted these effects as indicating etching of the surface and development of facets during repeated anodic-cathodic cycling.

There is a sufficient analogy between Will's observations (11) and the present results to indicate that the surface structure of a polycrystalline platinum electrode has been influenced by the electrode reactions which occurred on it during the course of this work. Accepting Will's assignment of the peaks in the anodic scans,[1] one concludes that the experiments with methanol caused a small decrease in the [110] plane (peak A) relative to the [111] (peak B) and [100] (peak C) planes which retained about the same relation to each other; at the same time there was an overall increase in area. After cycling in sulfuric acid, Q_H^S fell, peak A became predominant, and the heights of the other two peaks were now equal. It is a striking result that curves 2 and 4, representing similar electrode areas, indicate such different surface structures. Here, curve 2 was recorded before maximum expansion of the surface had occurred and curve 4 after it had been returned to around its former area. The surface changes are clearly not reversible.

A few general conclusions can be drawn from the few results available. We have found that a platinum surface is slowly altered by electrochemical processes occurring on it at ambient temperatures. This response depends on the nature of the reaction and the history of the electrode. Thus, examples have been found of both an increase and a decrease in Q_H^S after cycling in 1M H_2SO_4, *i.e.*, the same electrode reactions (hydrogen adsorption/desorption, oxide formation/dissolution) cause different effects depending on electrode prehistory. The observed changes in the electrode surface are considered to result from an increase in surface mobility of platinum atoms brought about by formation of bonds between surface atoms and chemisorbed reactants, with a consequent weakening of adjacent Pt-Pt interactions. In this connection, structural changes have been reported (12) for evaporated silver films on which formic acid vapor has been decomposed catalytically, but conclusive evidence that the catalyzed reaction is solely responsible does not appear to be available.

[1] Note that cathodic scans have only two peaks so that factors other than the reversible adsorption equilibrium of hydrogen must influence the current-voltage curves, *e.g.*, molecular hydrogen forms slowly and leaves the surface by diffusion in this potential region. The electrode at any potential therefore "sees" a different H_2 concentration depending on the direction of scan and this factor could possibly account for the observed difference. Association of peaks with crystal faces must be considered tentative.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 113, No. 8 and 11 (August and November 1966) and Vol. 114, No. 1 and 3 (January and March 1967).

Studies of the Electrochemical Kinetics of Indium, III. Systems In + $InCl_3$ and In + Combined Sulfate-Chloride Electrolyte

V. Markovac and B. Lovrecek (pp. 838-841, Vol. 113, No. 8)

G. A. Wright[1]: Steady-state Tafel lines for the polarization of the indium amalgam electrode have been obtained by using galvanostatic pulses. Markovac and Lovrecek have interpreted the Tafel slopes by using the following equations for cathodic and anodic reactions, respectively.

$$\frac{\partial \log_{10} i_-}{\partial V} = -\frac{z\mathbf{F}}{2.303\,RT}(n_c^* - \alpha) \qquad [1]$$

$$\frac{\partial \log_{10} i_+}{\partial V} = \frac{z\mathbf{F}}{2.303\,RT}(n_a^* - 1 + \alpha) \qquad [2]$$

n_c^* and n_a^* are the ordinal numbers of the slowest reaction steps for cathodic and anodic polarization, $(1 - \alpha)$ and α are the transfer coefficients for the cathodic and anodic reactions, and z is the number of electrons transferred in the rate-determining step. Other symbols have their usual meanings.

These formulas are incorrect and should be replaced by

$$\frac{\partial \log_{10} i_-}{\partial V} = -\frac{\mathbf{F}}{2.303\,RT}(n + z - \alpha z) \qquad [3]$$

$$\frac{\partial \log_{10} i_+}{\partial V} = \frac{\mathbf{F}}{2.303\,RT}(n + \alpha z) \qquad [4]$$

Here n is the number of electrons involved in a rapid equilibrium which precedes the rate-determining step, and the other symbols have the same meaning as before. The derivation of these equations is quite straightforward.[2] Thus for a cathodic reaction

$$0 + ne^- = \mathrm{P}, \text{ equilibrium}$$

$$\mathrm{P} + ze^- \rightarrow \mathrm{R}, \text{ rate determining}$$

the first step is an electrochemical equilibrium

$$a_p = \mathrm{K}\, a_o \exp\left[-\frac{n\mathbf{F}V}{RT}\right] \qquad [5]$$

The second step obeys the usual rate equation of electrode kinetics

$$i_- = (n + z)\mathbf{F}\, k\, a_p \exp\left[-\frac{z(1-\alpha)\,\mathbf{F}V}{RT}\right] \qquad [6]$$

$$= (n + z)\mathbf{F}\, k K\, a_o \exp\left[-\frac{(n + z - \alpha z)\mathbf{F}V}{RT}\right] \qquad [7]$$

This leads directly to Eq. [3]. Lovrecek[3] originally derived Eq. [1] and [2] by considering only 1-electron steps, and the correct result was obtained for that case. Generalization of his result for reaction steps with more than 1-electron has led to the error.

The difference between the equations can be seen by considering the following hypothetical mechanism of cathodic reduction of the indium ion.

$$\mathrm{In}^{3+} + e^- = \mathrm{In}^{2+} \quad \text{equilibrium}$$

$$\mathrm{In}^{2+} + 2e^- \rightarrow \mathrm{In} \quad \text{rate determining}$$

Equation [1] predicts $\partial \log_{10} i_-/\partial V = -(4 - 2\alpha)/0.059$ v^{-1} at 25°C, whereas the correct result from Eq. [3] is $-(3 - 2\alpha)/0.059$ v^{-1}. It is however fortunate that for all the mechanisms proposed by Markovac and Lovrecek, Eq. [1] and [2] yield the same parameters as would be obtained from Eq. [3] and [4]. Thus the tables of transfer coefficients are consistent with the mechanisms proposed, and the same is true for an earlier paper in this series.[4]

I would also like to point out that the use of Tafel slopes as a criterion of mechanism can be ambiguous, even when supported by additional evidence as discussed by Markovac and Lovrecek. In the case of the anodic dissolution of indium amalgam in a chloride electrolyte, it was found that $\partial \log_{10} i_+/\partial V = 11.95\ \mathrm{v}^{-1}$. Markovac and Lovrecek propose that the rate-determining step is $\mathrm{In} \rightarrow \mathrm{In}^+ + e^-$ with $\alpha = 0.69$. But the same Tafel slope is consistent with $\mathrm{In} \rightarrow \mathrm{In}^{2+} + 2e^-$ with $\alpha = 0.35$, and this rate-determining step seems to be equally probable.

V. Markovac and B. Lovrecek: Actually Eq [1] and [2] from the quoted paper are valid generally in case of electrode reactions with 1-electron steps. In the case of a rate-determining step with more than 1 electron they will hold only if the first reaction step is rate determining. All our results and kinetic parameters really relate to the above cases.

Formulas given by Wright, [3] and [4] are certainly correct. (We would only suggest the form

$$\frac{\partial \log_{10} i_-}{\partial V} = -\frac{\mathbf{F}}{2.303\,RT}(n_c^* - 1 + z - \alpha z)$$

and

$$\frac{\partial \log_{10} i_+}{\partial V} = \frac{\mathbf{F}}{2.303\,RT}(n_a^* - 1 + \alpha z)$$

with usual meaning of symbols.)

As to the question of ambiguity of Tafel slopes as a criterion for mechanism it would certainly be wrong to claim its absolute validity in every case. But in many cases, cautiously applied it can give suggestions on mechanism, especially if combined with other evidences.

Some Problems in Electrodeposition

J. A. Harrison, S. K. Rangarajan, and H. R. Thirsk (pp. 1120-1133, Vol. 113, No. 11)

B. Behr, W. Kemula, and J. Taraszewska[5]: At the Symposium on Electrode Processes held in Cleveland in May 1966 an interesting discussion followed this paper. The important points of this discussion, concerning the mechanism of the anodic oxidation of mercury in the presence of chloride ions, were the following:

(A) Which stage of the process of calomel-layer formation corresponds to the "induction time" determined ellipsometrically by Bockris *et al*?[6]

(B) Which is the primary product of anodic oxidation of mercury?

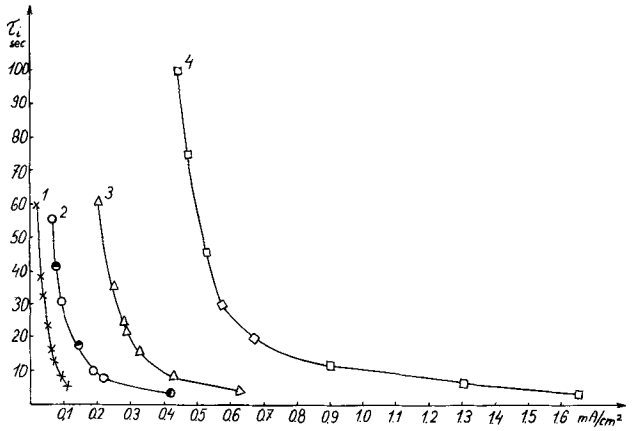

Fig. 1. Induction times measured in KCl solutions by the method of reducing the volume of the mercury drop, in dependence on current density: 1-0.1M, 2-1.0M, 3-1.5M, 4-2.0M. Black points taken from Bockris et *al.*[6]

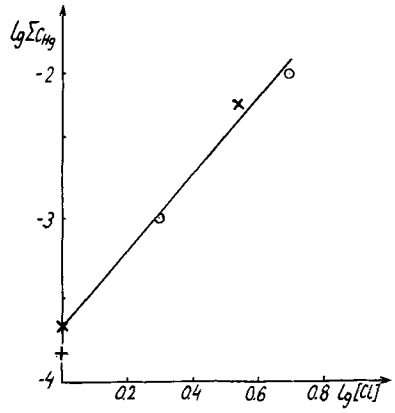

Fig. 2. X, Total mercury concentration in equilibrium with Hg and Hg_2Cl_2, determined polarographically; +, from the data of Sillen;[10] o, the concentration of electroactive species calculated by Armstrong, et *al.*, [11] from the Warburg impedance.

The first question is important because of its relation to the mechanism of calomel crystallization: is calomel the primary product of the electrode reaction or a secondary product formed by crystallization from the solution? In view of the high-sensitivity of the ellipsometric method Bockris *et al.* assumed that the induction time corresponds to the first moment of crystallization of calomel. However it was generally agreed during the discussion that this should be checked also with another method. Some of our experiments[7] may be helpful in discussing this question.

Our results were obtained as follows: we have measured under galvanostatic conditions the shortest time τ_i after which a calomel layer can be detected on the hanging mercury drop electrode. This can be made simply by reducing the volume of the mercury drop electrode by taking most of mercury back into the capillary and observing the shape of the drop showing the formation of the stiff layer.[8] The results obtained by this method (Fig. 1) in the case of 1M KCl solution, are identical with the induction times determined ellipsometrically by Bockris *et al.*[6] Our measurements of the potential-time relationship confirmed also the results of these authors. Investigating the 0.1M KCl solution we have recorded oscillographically similar potential-time curves as described by Ives *et al.*,[9] and we were able to correlate the induction times measured by us with the results of the authors. The induction time always corresponded to a point well after the hump on the V-t curve. According to the microscopic observations of Ives *et al.*[9] crystals of calomel could be seen on the electrode surface when the hump was reached. This may be considered as an argument against the supposition of Bockris *et. al.*[6] that before the induction time is reached there exists no precipitate at the electrode surface.

A similar conclusion (also for 1M KCl solution) could be obtained by considering the equilibria between mercury electrode and all soluble mercuric species formed as a result of electrolysis and their diffusion rate toward the bulk of the solution. We have calculated the minimal quantity of mercury in the calomel layer formed by subtracting the maximal quantity of mercuric species which could diffuse away from the electrode till the induction time was reached from the total quantity of mercury being oxidized galvanostatically.

The participation of the diffusion of mercuric species in studied processes has been calculated as follows. The actual surface concentration of dissolved mercuric ions was estimated using the V-t curves and equilibrium data. The equilibrium concentrations of chloromercuric complexes formed in the presence of Hg and Hg_2Cl_2 in a solution of ionic strength of 0.5 are given by Sillen.[10] Polarographic determination of total concentration of mercury (II) in the bulk of solution being in equilibrium with Hg and Hg_2Cl_2 was done for 1M and also for saturated KCl (Fig. 2). Our result for 1M KCl was slightly higher than that of Sillen. We assumed that for 1M KCl solution the surface concentration of the potential-determining species corresponding to the experimentally found overvoltage of 14 mv is equal to thrice of the equilibrium value. Thus, we have used for calculating the diffusion of mercuric species from the electrode, the total mercury surface concentration as equal to $3x2.2x10^{-4} = 6.6x10^{-4}$M. From thermodynamic considerations it is impossible to expect that higher concentrations of soluble species are formed at the electrode surface. The maximal possible charge transported from the electrode into the solution by soluble mercuric species formed has been calculated by integrating over the induction time the equation for linear diffusion at a constant potential and applying the value of the diffusion coefficient equal to 10^{-5} $cm^2\ sec^{-1}$ and $n=2$ (practically only the Hg^{II} complexes are formed). The quantities thus obtained and the resulting minimal values of charge consumed in formation of the calomel layer are presented in Table I. The real value of the charge corresponding to the calomel layer formed, would be higher if there were any slow homogeneous reaction in solution.

The large amount of soluble mercuric complexes in the solution which may correspond to a threefold supersaturation with calomel (η = 14 mv) may produce significant contribution to further calomel growth after switching off the current. This effect should not

66	55	3630	3050	580

be observed in 0.1M KCl. As follows from our calculations based on equilibrium concentrations given by Sillen, the contribution of the diffusion process is in this case insignificant, amounting only to a few per cent of the total charge. Therefore we could expect that the induction time in this case will be independent of stirring, contrary to the 1M KCl solution. This conclusion has been confirmed experimentally.

The results given above may be regarded as an evidence that the induction time, measured both ellipsometrically and determined by reducing the mercury drop volume, corresponds to some particular stage in the crystallization process at which the average thickness of the layer is already polymolecular. In view of microscopic observations of Ives *et al.*,[9] it may be the stage of secondary growth of calomel crystals.

It seems that the problem of the primary electrode reaction cannot be solved at present owing to the lack of necessary additional information. There is no evidence for any slow homogeneous reaction occurring in solution. Our considerations based on equilibrium data are rather consistent with the model in which the overvoltage observed during the galvanostatic process is due to crystallization only. Also the concentrations of the electroactive form present in solution calculated from the impedance data by Armstrong *et al.*[11] in 2M and 5M HCl are consistent with experimental equilibrium concentrations obtained by us as is shown in Fig. 2. This only means that there exists an equilibrium between the mercury electrode and the soluble mercuric species and not that the $HgCl_4^{2-}$-ion is the primary product of the electrode reaction.

Studies of Hydrocarbon Fuel Cell Anodes by the Multipulse Potentiodynamic Method, III. Behavior of Saturated Hydrocarbons on Conducting Porous Teflon Electrodes with a Phosphoric Acid Electrolyte

L. W. Niedrach and M. Tochner (pp. 17-22, Vol. 114, No. 1)

J. A. Shropshire[12]: I think the authors are to be commended for having turned their attention to the study of a catalyst and electrode system which bear some relationship to a realistic fuel cell electrode. Although the MPP technique falters somewhat in the face of the high surface area catalyst, the comparison of the C_1-C_4 paraffins is still of considerable interest.

In the discussion, the authors repeatedly state that the initial adsorption rates of the paraffin fuels are: butane>propane>ethane. This is not at all clear from the data available in the paper. For instance, in their Fig. 11, if one takes the (low coverage) 15-sec adsorption, the accumulated charge ($Q_{E_{tot}}$) is exactly what one expects for equal moles of the various fuels having adsorbed on the surface. Thus, the accumulated charge ratios (at 15 sec) are approximately

$$C_3/C_2 = 1.45; \quad C_4/C_2 = 1.84; \quad C_4/C_3 = 1.27$$
(measured from graph)

If one assumes oxidation to CO_2, the ratios of the required number of electrons per mole for the three fuels are

$$C_3/C_2 = 1.43; \quad C_4/C_2 = 1.86; \quad C_4/C_3 = 1.30$$

a remarkable agreement under the circumstances.

Since according to the authors' data, the steady-state oxidation current at $U = 0.3$v (the potential of the above measurements) is relatively minor, the above values should represent a fairly realistic relative accumulation rate. On this basis then the adsorption rates appear to be substantially equal for the three fuels.

L. W. Niedrach and M. Tochner: We appreciate Dr. Shropshire's communication and agree that we have overstressed the relative order of the initial adsorption rates for ethane, propane, and butane. Actually, as emphasized in the paper, it was not possible to perform measurements at short enough equilibration times to obtain highly accurate estimates for the adsorption rates on the clean surface. In addition, such estimates are further complicated by the presence of several species in the ad layer. In any event we agree with Dr. Shropshire that the three adsorption rates are of the same order of magnitude, and indeed quite close.

With regard to the remarkable agreement among the accumulated charge ratios at 15 sec and the electron ratios for oxidation of the individual fuels, this must be considered fortuitous in the light of the variety of derived species that are present on the surface. Further, the accumulated charge ratios change considerably with the time of the equilibrations. For the precise relationships quoted by Dr. Shropshire to have direct meaning, it would be necessary to assume physical adsorption of the fuel entities themselves, although one or two site attachment through dissociative adsorption would not markedly affect the ratios. This appears quite unreasonable in the light of available evidence concerning the ad layer. That it consists of a variety of species including an appreciable fraction of partially oxygenated material as well as alkyl radicals is adequately supported by many investigations.[13-17] It should also be noted that although the steady-state currents in our experiments at 0.3v were small, sizable currents did flow during the initial stages of adsorption. These currents were, of course, associated with the oxidation of dissociated hydrogen as well as the formation of the partially oxidized species.

That the rates of adsorption of these saturated hydrocarbons are not markedly different undoubtedly reflects the structural similarity among them and hence a similarity of behavior in the adsorption step itself. Coupled with this would be regular, but small, trends among solubilities and diffusion coefficients, both of which control mass transport to an electrode. These are undoubtedly important during the early stages of adsorption. Some suggestions bearing on these latter points have been discussed recently.[18]

Ellipsometric-Potentiostatic Studies of Iron Passivity, I. Anodic Film Growth in Slightly Basic Solutions

J. Kruger and J. Calvert (pp. 43-49, Vol. 114, No. 1)

H. H. Uhlig[19]: The results presented by the authors eloquently describe the process of film growth on iron anodically polarized in a buffered borate solution. They demonstrate and further confirm that the ellipsometric technique is a sensitive method for studying growth of films *in situ*. Unfortunately, ellipsometry inherently provides no information regarding the composition and structure of such films. Hence it is not clear whether the anodic films measured in the authors' experiments are ferrous or ferric hydroxide, ferrous borate, or indeed anhydrous iron oxides as they hypothesize.

It is also not clear whether such films, the thickness of which they report, are justifiably called passive films. For example, it has been established by previous investigators that several metals in the passive state are often covered by films which are equivalent to no more than a monolayer of oxygen. On the other hand, many metals in the active state, including iron, which do not show passive behavior may be covered by adherent oxide films 30-100Å thick. Discussions

along these lines are of long standing. U. R. Evans[20] in 1927 succeeded in isolating thin oxide films from passive iron, but significantly he also succeeded in isolating similar oxide films from active iron.[21]

It is perhaps relevant to any discussion of passivity to remind ourselves of certain properties that apply to passive but not to other-type films on iron. (A) Thermally produced films of Fe_3O_4, or duplex Fe_2O_3 overlying Fe_3O_4 films on iron do not result in any of the usual passive film characteristics, no matter how thin or how thick such films may be. (B) The potential of iron in equilibrium with any of the known iron oxides is about 0.6v too active to account for observed passive potentials. Hypothesizing a cation-defect iron oxide, as was done by Nagayama and Cohen[22] in order to bridge the gap, is hardly acceptable because any such defect oxide would by definition allow rapid ion diffusion and would be a relatively poor diffusion barrier film in a corrosive environment. Alternatively, the hypothesis of a potential drop through an insulating iron oxide runs into the serious problem that no insulator could readily sustain the required potential gradient. Even if all of the film thickness (30Å), as measured by the present authors, were insulating (which passive film conductivity measurements contradict) an over-all potential of 0.6v requires a potential gradient of 2×10^6 v/cm, which value can be compared with the dielectric breakdown of glass equal to 0.7 to 1.5×10^6 v/cm or of mica equal to $1.5\text{-}2.2 \times 10^6$ v/cm. The potential gradient in an insulating film thinner than 30Å, as would be required by any oxide model, would exceed 2×10^{-6} v/cm. (C) The passive film on iron is able to oxidize chromites to chromates[23] in accord with 3 O (in passive film) + Fe + OH^- + CrO_2^- + $H_2O \rightarrow CrO_4^{--}$ + $Fe(OH)_3$. Passive iron which has been activated by mechanical shock does not have similar oxidizing properties. None of the known iron oxides is able thermodynamically to effect the above reaction, hence it is not likely that the usual iron oxides can in fact constitute the passive film.

Present viewpoints on structure of the passive film on *e.g.*, iron, nickel, chromium, and the stainless steels usually resolve themselves into two categories: *i.e.*, the passive film is either (a) an ion diffusion barrier or (b) it acts instead to increase anodic overvoltage for metal dissolution (decreases the exchange current density i_0 in the Tafel equation). Difficulties in the way of successfully assuming an ion diffusion barrier for iron are contained in some of the points raised above. In addition the observed limited dimensions of passive films suggest that they are protective by some other mechanism. Air-formed films on iron, as measured by ellipsometry,[24] in time reach 30Å or more, but these films are not protective to chemical environments and hence are not the same as the passive films. On the other hand, anodic overvoltage for metal dissolution can in principle be raised appreciably by oxygen adsorbed on the metal surface, and an assumed passive film of this kind also meets other requirements. Such a film by increasing the activation energy for hydration and ionization of metal atoms (or ions), parallels the well-known properties of many adsorbed organic and some inorganic species to increase either hydrogen or anodic overvoltage at metal electrodes. Oxygen is one of the most effective substances able to chemisorb on transition metals, but other compounds like CO (on stainless steels) and in some cases iodine (on iron in H_2SO_4) can also do so, and they similarly increase corrosion resistance in aggressive media.

Low energy diffraction data of metals like Ni[25] have disclosed that the first-formed chemisorbed layer of oxygen is extremely stable, resisting thermal decomposition even up to the melting point of Ni (1450°C). Multiple adsorbed layers which may form by anodic polarization at noble potentials, are less energetically bonded to the surface than is the first layer and are easier reduced. Depending on the metal, they may reduce more readily than the metal oxide (*e.g.*, Fe_3O_4). Hence adsorbed films of this kind, either easier or more difficult to reduce than the metal oxide depending on structure and thickness, and perhaps not easy to detect by ellipsometry, more readily fit the description of films accounting for passive phenomena. Such adsorbed films slow down corrosion processes but the rate of chemical reaction remains finite nevertheless, particularly in aqueous media or at elevated temperatures. Thick oxide films eventually grow which may behave as diffusion barrier layers, but their protective qualities, in aqueous media at least, remain inferior to the first-formed passive films at the immediate metal surface.

The thicker films described by the authors, if the above viewpoint has any merit, are probably iron compounds of unspecified composition which grow on top of the passive film. These thicker films presumably confer secondary protective qualities; but acting alone they would not be expected to account for recognized passive properties (*e.g.*, resistance to concentrated HNO_3).

In this connection, R. Frankenthal,[26] employing quantitative coulometry, has recently demonstrated that a primary passive film first forms on a 24% Cr-Fe alloy which is less than an equivalent monolayer of close-packed oxygen ions. This film itself in H_2SO_4 accounts for observed very low anodic current densities in the passive potential range. He finds a secondary thicker film to form subsequently at more noble potentials, which perhaps is constituted of hydrous metal oxides. The hydrous oxide film, however, has little or no influence on the passive current density (and hence on corrosion rate) in H_2SO_4. If the situation is similar for iron, as seems likely from the accumulated evidence, the primary passive film is the first-formed adsorbed structure. This film remains thin, being followed by a thicker stoichiometric iron compound film which grows on top of the passive film, the latter however having only secondary protective qualities.

J. Kruger and J. P. Calvert: We appreciate Professor Uhlig's interest in our paper. The main gist of his arguments is that the origin of the passivity of iron resides in a very thin film, presumably a chemisorbed monolayer of oxygen, next to the metal surface, and that any films that may be detected above this thin film are incidental to the phenomenon of passivity.

It is difficult to understand how this can be the correct picture of passive film on iron, when one considers, for example, the recent work by Nagayama and Cohen[27], using the same borate solutions as we do. (Some recent results of ours which are to be published as Part II of the series of which the paper under discussion is part, provide ellipsometric verification for their coulometric measurements.) These results show that when one reduces the outer layer of the passive film, the one that Professor Uhlig feels is incidental to the phenomenon of passivity, one then has a surface which exhibits an active potential and is no longer passive. However, at this point in the process, Nagayama and Cohen and our own work show that there still exists a film on the iron surface. Therefore, it is difficult to understand how Professor Uhlig's picture can be correct, because his picture would require that when the metal surface becomes active, the all-important oxygen monolayer slips out from between the metal surface and the oxide. This seems highly unlikely.

That there is indeed an oxide film on the iron surface, even in the active region, and that this film is as shown by others[27] Fe_3O_4, is further supported by electron diffraction studies.[28] These studies, moreover, show that when one forms a passive surface, besides Fe_3O_4 there are found extra spots due to γ-Fe_2O_3. In other words, when a passive potential is observed, both Fe_3O_4 and γ-Fe_2O_3 are present. At an active potential, only Fe_3O_4 spots are observed. Does it not then seem more reasonable to associate passivity with an outer layer and an active surface with Fe_3O_4 alone?

The fact that "thermally produced films of Fe_3O_4 or duplex Fe_2O_3 overlying Fe_3O_4" do not result in the usual passive film characteristics, really has no relevance to the present argument. The Fe_2O_3 in films formed at temperatures a few hundred degrees above room temperature is α-Fe_2O_3 and not γ-Fe_2O_3 Also, recent work of Okamoto[29] on passivation of stainless steel in aqueous solutions and our own on iron[30] indicate that hydrogen may play a role in the formation of a passive film. This is explained in a paper by Bloom and Goldenberg[31] as being due to the difficulty of obtaining γ-Fe_2O_3 without having hydrogen present in the lattice. Thus, some sort of aqueous environment may be necessary to form passive films on iron. Interestingly enough, films formed on iron at room temperature in oxygen containing small traces of water do indeed produce films that have different characteristics from those formed in pure oxygen alone.[32]

The important point to make here, however, is that one should not compare the film formed in aqueous solution with that formed in gaseous environments, even though we may nominally have the same kind of oxides from a bulk standpoint. Also, oxide in the form of very thin films may have quite different properties than bulk oxides because of the big influence of small amounts of impurities such as hydrogen, or because of a nonstoichiometry that may exist which produces cation or anion defects. The new thin film electronic devices depend on the very fact that large changes in properties can be produced by fantastically small changes in composition. It is for this reason, also, that one should not make predictions as to what potential the iron should exhibit in equilibrium with known iron oxides, because only the known bulk values for the iron oxides can be used, while thin film oxides may give entirely different values. Thus, one does not really know that a potential calculated using bulk values is "0.6 volts too active to account for observed passive potentials," when very thin films are involved. If one wants to hypothesize, one can by suitable models using the properties of bulk oxides, as Vetter[33] has done, account for the passive potentials. We think this is a dangerous game to play, however.

Likewise, it is difficult to predict what the breakdown potentials of these films are and, hence, to say that it is not possible to have the kind of potential drop that we speculate about in the paper. Whitehead's monograph[34] on dielectric breakdown of solids makes the point that as a film gets thinner, the electric strength can actually increase. He quotes breakdown values for some oxide films that are much higher than those given in our paper, thereby making our values quite possible. By the same token, one cannot assume that the oxidation of chromite to chromate can or cannot occur on the surface of thin oxide films from thermodynamic considerations because the thermodynamic data for the oxides (as very thin films) are not known.

We fail to see the relevance of low energy electron diffraction data for a metal like nickel on a discussion of the passivity of iron. Granted that the monolayer formed on nickel may be quite stable; this may not say anything about such a monolayer formed on iron. Assuming that the results for Ni are relevant, the films formed by gas-metal reaction must also start with this very stable initial monolayer. If this monolayer were the passive film, are room temperature formed films, which start with this monolayer, passive? You cannot have it both ways. You cannot have a film formed by gaseous oxidation in a low energy electron diffraction experiment be passive, while one formed by gaseous oxidation in a non-low energy electron diffraction experiment, not be passive.

Just as one cannot extrapolate gas-metal results to aqueous solution, one cannot take the data of an entirely different kind of material, such as 24% chromium-iron alloy, and expect that the results found there are applicable to pure iron. Thus, the results of Frankenthal may or may not be relevant. An indication that this is so can be found from some of our own work[35] that indicates that at 24% chrome-iron concentration, the film formed on such an alloy does not exhibit any crystallinity; it is amorphous. Our own work shows that, although optically we can detect films that are as thick as 20Å at a concentration of 18% chromium, an amorphous film is observed. Surely such a film can be expected to behave differently than the highly crystalline film that one observes on passive iron[27,28]. Hence, one cannot argue that because one kind of film found in the case of chromium-iron alloys may exhibit passivity, that such a film is responsible for the passivity of iron.

Surface Roughness Effects in the Electrodeposition of Copper in the Limiting Current Range

N. Ibl and K. Schedegg (pp. 54-57, Vol. 114, No. 1)

R. Piontelli, B. Mazza, and P. Pedeferri[36]: This paper gives very interesting information on some of the problems involved by the formation of powdery deposits.

The authors[37] consider the decisive condition to be that of reaching the limiting current of mass transport. As a matter of fact this is often a sufficient condition. It does not appear, however, to be a necessary one. Moreover, the mere statement that in the limiting current range, powdery deposits are often encountered, does not appear to throw sufficient light on the mechanism of the phenomena itself. Like the whole field of electrocrystallization this problem is still wanting a satisfactory solution.

Some suggestions arising from the systematic work carried out in this laboratory[38] on the powdery-deposits formation from sulfamate baths[39] may be recalled here. The incoherent deposits of the various classes (spongy, coarse-powdery, blacks) are formed in any case, starting from tridimensional nuclei, mutually independent and in respect to the basis metal.

The possibility of formation and the kind of the incoherent deposit depends on the relative formation rate of the nuclei themselves, which must be high enough, and on the distribution in space of their

Siniscalco, *Electrochimica Metallorum*, 1, 441 (1966); *ibid.*, 1, 449 (1966); see also "Proceedings of the Symposium on Sulfamic Acid and its Electrometallurgical Applications (Milan, May 1966); Associazione Italiana di Metallurgia, Editor; Milan (1967).
[39] Also in this field the sulfamate baths appear to be especially interesting in view of their versatility and capacity to give powders (of Cu, Ag, Zn, Cd, Ni, Co, Pb, Sn and others) free from inclusions and contamination.

growth rate, which must be tendentially isotropic.[40]

In this sense a very essential role is played by the throwing power at the microscopic scale, largely decided by the rate of change of the overvoltages with current density, the contribution of the concentration polarization included. In this general frame the importance of the limiting current conditions, in view of the separation of powdery deposits, may find a reasonable interpretation, when one considers that everywhere the ratio: current density/activity of the metal ions attains high enough values; also the ensuing concentration polarization may be sufficient to deviate the cathodic metal separation, thus promoting a tendentially isotropic growth.

On the other hand also the intervention of factors, which appear to be rather underestimated by the "limiting current theory" of the powdery deposits formation, must be taken into account. This, especially in view of the study of the formation conditions of powdery deposits from complex-salt baths or from melts, and of explaining the transition from dendritic or spongy to powdery-deposits.

Among these factors one may recall: (A) the nature of the metal, as far as the exchange overvoltages, their dependence law on current density, the influence of the lattice forces on the properties and behavior of nuclei are concerned; (B) factors influencing the secondary inhibition effects by hydrogen, colloidal products, but also by anions, secondary constituents of the baths, *etc.;* and (C) the physical and mechanical conditions (also apart from their direct influence on the mass transfer).

As in many other fields of the theory of electrode processes, the models which do not explicitly acknowledge the direct influence of the nature of the metal and of the bath constituents, are at least incomplete.

N. Ibl[41]: The remarks of Piontelli *et al.*, are very pertinent. Reaching the limiting current is indeed in general a sufficient, but not always a necessary condition for the formation of a very rough or powdery deposit. We have discussed this question in more detail in a previous review paper[42]. Powdery or spongy deposits can be obtained well below the limiting current. A well-known case is the formation, at lower currents, of spongy Zn or Cd deposits from nonacidified sulfate solutions, a phenomenon which is very probably not due to mass transfer effects[42]. However, if no other causes of powder formation are operative at lower currents, the deposit, as a rule, becomes very rough or powdery when the limiting current is reached.

But the properties of the powders obtained at the limiting current are also affected by other factors[42] beside mass transport. For instance, we have found that copper powder deposited from a nonacidified copper sulfate solution containing gelatin is very finely divided and almost black, whereas the powder obtained without addition of gelatin is much coarser and reddish in color.[43] But in both cases powder formation starts at the limiting current. As pointed out by the authors, the structure of electrodeposits depends in general on a number of factors and their interaction. One of these factors is mass transport. Its role can be more or less important, depending on the circumstances. Sometimes it is negligible, but in certain cases it is predominant.

Undoubtedly, many factors finally contribute to shape the structure and the properties of an electrodeposit, but the main fact which I would like to point out here is that we can visualize a pure transport mechanism which should, in a very general way, cause the formation of a very rough deposit, at the limiting current as a rule, and, under certain circumstances, already below the limiting current. The leading ideas, which have been developed in more detail in a recent review paper[44], are as follows:

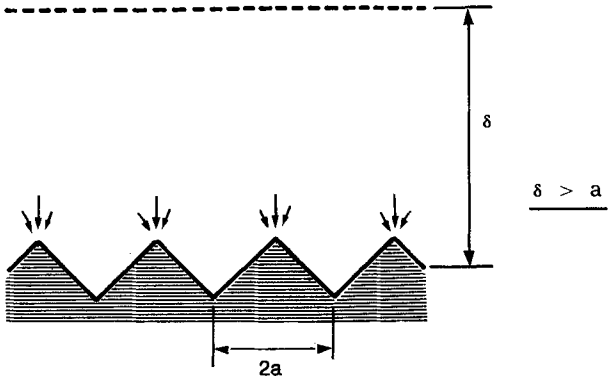

Fig. 1.

Let us consider a metal surface which has some initial roughness, with small crests and recesses, as shown schematically in Fig. 1. We will now discuss the question under which conditions certain factors tend to enhance the irregularities of the surface, and how they operate. This is a problem of current density distribution.

If the characteristic length a of such a profile is small as compared to the thickness of the diffusion layer δ (Fig. 1), the crests of the profile are privileged from the viewpoint of mass transport, because the free cross section for diffusion increases with increasing distance from the crest: the crest is more accessible for mass transfer than a recess. However, this does not yet mean that the local current density is necessarily larger at the crest, because the current density distribution depends not only on the transport of mass but also on the transport of charges through the solution and through the electric double layer at the interface, *i.e.,* it also depends on electric quantities (conductivity of the solution, overvoltage). Depending on the conditions, the current distribution is governed mainly by the transport of mass, or of charge, or by both simultaneously to a comparable degree.

Let us now consider the simple case that the current distribution is given solely by the geometry of the system and by the conductivity of the solution. We then have what is called in plating primary current distribution. Under these conditions, the local current density is larger at a crest than in a recess because the crest is privileged from the viewpoint of the transport of charges through the solution: the lines of electric flux converge toward the crest (Fig 1). Now, if we take into account overvoltage, the situation is changed: the overvoltage tends to make the current distribution more uniform (secondary current distribution). The decisive quantity is the polarization parameter P defined as the product of the specific conductivity of the solution κ and the slope of the current voltage curve, $d\eta/di$: $P = \kappa d\eta/di$. If P is large as compared to the characteristic length a of the profile, the current distribution is virtually uniform over the profile[45], in spite of the influence of the serrated geometry. This can be interpreted, at least qualitatively, in a simple manner. Along the interface, between crest and recess (Fig. 1), there is, in the solution, an ohmic potential drop ΔE_R, which must be compensated by the difference $\Delta\eta$ between the overvoltage at the crest and in the recess

$$\Delta E_R + \Delta\eta = 0 \qquad [1]$$

[40] A predominating growth-rate parallel to the basis metal may lead to compact deposits, while one normal to the cathode enhances the dendritic or acicular growth.

If the overvoltage η increases rapidly with increasing current density i ($d\eta/di$ large), a negligible increase in current at the crest will be enough to create an increase in overvoltage which is sufficient to compensate ΔE_R, and the current density is virtually the same at the crest and in the recess.

Let us now consider separately concentration and activation overvoltage, which we denote by η_c and η_a, respectively; we therefore split the total overvoltage difference $\Delta\eta$ in two parts, $\Delta\eta_c$ and $\Delta\eta_a$, which correspond to concentration and activation overvoltage, respectively. Equation [1] thus takes the form

$$\Delta E_R + \Delta\eta_c + \Delta\eta_a = 0 \qquad [2]$$

In this equation, $\Delta\eta_c$ and $\Delta\eta_a$ have not the same sign. This can be seen as follows. If the current distribution is virtually uniform, the lines of the electric flux and those of the flux of mass do not converge toward the crests as indicated in Fig. 1, but are essentially parallel, vertical lines. The concentration c_i of the metallic cations at the interface electrode-solution is then larger at the crest than in the recess; the difference Δc_i between the interfacial concentration at the crest ($_cc_i$) and in the recess ($_rc_i$) is given by

$$\Delta c_i = {}_cc_i - {}_rc_i = h\, dc/dy \qquad [3]$$

where h is the vertical distance between crest and recess and dc/dy the concentration gradient in the vertical direction[46]. We see that the concentration overvoltage is larger in the recess than at the crest; therefore, $\Delta\eta_c$ is of the same sign as ΔE_R but has the opposite sign of $\Delta\eta_a$. We thus come to the important conclusion that only activation overvoltage necessarily tends to flatten the current distribution; in the case of a microprofile ($a<\delta$), concentration overvoltage cannot contribute to making the current distribution more uniform than would correspond to primary current distribution; to the contrary, it counteracts the equalizing action of activation overvoltage and tends to make the current distribution nonuniform. The extent of the departure from an even distribution depends on the relative values of ΔE_R, of $\Delta\eta_c$ and of $d\eta_a/di$, *i.e.*, of the variation of the activation overvoltage with current density. If $\Delta\eta_c$ is large, the current distribution will be nonuniform even if the slope of the current voltage curve, $d\eta/di$, is large. An extreme case is that of the limiting current. It can be easily shown that $\Delta\eta_c$ is proportional to $\ln({}_cc_i/{}_rc_i)$; at the limiting current, or close to it, $_rc_i$ tends to zero, whereas $_cc_i$ is still finite; the value of $\Delta\eta_c$ thus tends to be exceedingly large. Under these conditions, the influence of concentration overvoltage is overwhelming and the current distribution is controlled by mass transport. Since the crests of a microprofile are privileged from the viewpoint of diffusion, under mass transport control, the local current density is larger on a crest than in a recess. Geometric irregularities of the surface will then tend to grow.

The surface of a polycrystalline metal is usually heterogeneous. This causes local variations of the activation overvoltage, and therefore of the current density, which are, in general, randomly distributed, both in location and in time. There is thus a natural tendency for the formation of small, geometric irregularities in the deposit. Below the limiting current, the concentration overvoltage changes only slowly, and the influence of activation overvoltage on the current distribution at a microprofile is often predominant. If the polarization parameter P is sufficiently large, the small protuberances of the surface, randomly distributed in space and in time, are, on the average, not privileged; the local current density tends to be the same on the crests and in the recesses and, on the time average, peaks do not grow faster than the rest of the deposit. At the limiting current, however, the situation is very different. According to the above discussion, the current distribution is mass transport controlled and the current density is larger at the peaks, which thus grow faster; the irregularities of the surface are strongly amplified: there is, at the limiting current, a sort of instability with respect to small protuberances present by chance on the surface, and a very rough or dendritic deposit results.

Let us note that, under certain circumstances, a similar situation prevails even below the limiting current, or at least already when the limiting current is being approached. The essential condition is that the rate of change of activation overvoltage with current density, $d\eta_a/di$, is sufficiently small. If this is the case, the current distribution over a microprofile is nonuniform, and the deposit tends to become very irregular even at low currents. The activation overvoltage is usually very small in the deposition of metals from fused salts, because the high temperatures involved much accelerates the ion exchange at the interface. But it is sometimes also very low at room temperature in aqueous solutions, for instance, in the deposition of Ag from aqueous $AgNO_3$. It is well known that it is indeed very difficult to get even deposits in molten salt electrolysis, and that metals of an irregular, dendritic form are usually obtained. Similarly, in the deposition of silver from an aqueous $AgNO_3$– solution there is a marked tendency for the formation of long dendrites and needles which grow outward into the solution. This is in qualitative agreement with the above discussion.

Generally speaking, the formation of very rough or dendritic deposits is necessarily linked with nonuniform current distribution. It is therefore to be expected that the factors which govern current density distribution (conductivity of the solution, overvoltage, and mass transport) have a very great influence on the structure of electrodeposits. It was the main purpose of the paper under discussion, and of some of our earlier articles, to stress these aspects which have been hitherto rather neglected in the literature. Undoubtedly, factors such as the formation of new nuclei and the rate of growth of already existing crystals play an eminent role in electrocrystallization. But they have been already studied by quite a number of authors.

[46] A more quantitative treatment along these lines has been developed and compared with experiment (unpublished calculations of J. Levkov and N. Ibl). The results will be published later.

Surface Tensions of Co-Ce and Pu-Co-Ce Alloys as Determined from Frozen Menisci

J. C. Biery (pp. 225-231, Vol. 114, No. 3)

P. D. Ownby and B. C. Allen[47]: Interest in Biery's surface-curvature technique of measuring surface tensions was generated when his first paper[48], which forms the basis of his present one, appeared.

There is some similarity between his technique and that used recently at the Columbus Laboratories of Battelle Memorial Institute[49,50] to determine the surface tension of reactive materials. Chromous iodide[49] and boron triiodide [50] have been allowed to rise in 0.02 to 0.2-cm ID capillary tubes in evacuated quartz or Pyrex containers. The liquid surface tension, γ_{LV} was determined from the capillary-rise height, h, using the capillary-rise equation

$$\gamma_{LV} = \frac{g\rho_L r h}{2\cos\theta}$$

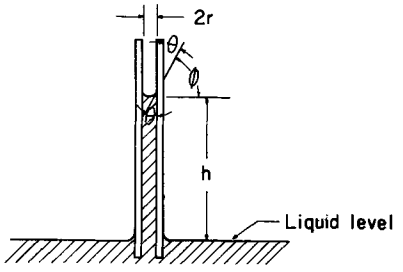

Fig. 1. Schematic diagram of capillary and height of rise measured to determine surface tension.

where g = 981 cm/sec^2, ρ_L = liquid density, r = capillary radius, and θ = contact angle (Fig. 1).

In the case of CrI_2, where the quartz view window was clouded, h was measured by radiographic methods. In the case of BI_3, h could be viewed and measured directly and/or photographed. Both contact angles used in Eq. [1] were determined independently by the sessile-drop method *in vacuo*. In an attempt to compare the results of the two techniques, a photograph[50] of the 0.052-cm ID capillary containing BI_3 was enlarged, and the Biery technique applied to the meniscus shape.[51] Although the photograph was grainy, a modification of the technique described was reported to correlate favorably[51] with the surface-tension value obtained by the capillary-rise technique. However, the contact angle determined by the Biery technique was 52°. The sessile-drop method yielded a contact angle less than 5°, and 0° was used in the capillary-rise calculation

In an attempt to resolve this discrepancy, the question of capillary-diameter measurement arose. It was found that diameter measured by viewing through the capillary wall was somewhat larger than that measured from the capillary cross section. That is, a magnification effect enlarged the apparent capillary diameter when viewed through the capillary. This same effect distorted the apparent meniscus shape, so that the angle obtained by smoothing or extrapolation to the wall was consistently larger than the actual value. This can be seen by referring to Biery's data[48] on water, where "the sine of the outside angle at contact" ϕ, or the cosine of the contact angle θ (see Fig. 1) was between 0.50 and 0.65. This gave a contact angle of 30°-40°. The contact angle for water in preliminary experiments using the capillary-rise technique was found to be ~0°.[50] Using a zero contact angle, the surface tension of water by capillary-rise was found to correlate with the accepted value of 72 dynes/cm at 25°C.[52]

Biery's method of photographing meniscus shapes through a glass tube inaccurately determines the contact angle, and the shape itself appears distorted because of the lens effect. Because the lens effect is one dimensional, no distortion of the capillary-rise height is experienced in either photographing or radiographing the liquid. Therefore, Biery's complex calculations seem to have little advantage over the more straightforward and reliable capillary-rise technique.

In his present paper, Biery has presented surface-tension results on alloys that have not been studied previously. Except for one capillary-rise value, there are no standards with which to compare his elevated-temperature results. Since surface contours of a solidifying metal distort by differential contraction or expansion, curvature measurements based on solidified metals are not recommended.[53] In fact, the resulting surface tensions can be 50-70% low.[54] In spite of the methods presented for arbitrary mathematical selection of solidified menisci, the validity of the reported surface tensions appears questionable. It seems as though the results would be greatly enhanced by (*a*) correlation with a metal of known surface tension, using similar experimental techniques; (*b*) measurements on unalloyed cerium to provide base-line surface-tension data for the alloys; and (*c*) correlation with radiographs taken with the alloy liquid.

The computational method is presented as being capable of determining contact angle as well as surface tension. In the capillary-rise result presented for 57.7 w/o Pu-9.4 w/o Co-32.8 w/o Ce, a contact angle of 0° was assumed. It would be enlightening to see an explicit comparison between the assumed value and that observed and/or calculated from menisci shape.

It appears that the "usual methods of determining surface tension" would be applicable to plutonium alloys. For example, a simple technique could involve the capillary-rise method [49,50] in an inert atmosphere, since a nonreactive capillary material, tantalum, is available. Small-diameter tantalum capillaries could be tack welded to the inside of the tube containing the alloy. When melted, the alloy would form a reservoir on the bottom and rise up the tubes. A radiograph at temperature would provide an accurate measure of capillary-rise height. Values of the height from radiographs in the solidified alloy could then be calibrated and used for most of the determinations.

J. C. Biery: The surface tension generation technique as outlined in footnote 55 was applied by the author to the BI_3 meniscus of Ownby and Allen. However, the method was found to be unworkable with such a meniscus formed in a capillary rise experiment where the meniscus rise height was very small as compared to the capillary rise itself. The shape of the meniscus did not vary sufficiently with changes in surface tension in this case to overcome the inaccuracies and distortions involved in photographing the meniscus.

The technique that was utilized was a new one[56] which the author derived by assuming a mathematical form for local sections of the meniscus. Parameters in the assumed equations, when utilized with the Laplace-Young equation and physical data from the meniscus, generated surface tensions as a function of radius. An interesting result from this development was that $\sin\theta$, where θ was the angle between a horizontal line and a line tangent to the meniscus curve, was a linear function of the radius when the capillary rise was many times greater than the height of the meniscus. Thus, in principle, the contact angle at the wall of a capillary rise experiment could be obtained by making a linear extrapolation of the $\sin\theta$ data obtained from a photograph of the meniscus. This procedure was followed with the BI_3 meniscus of Ownby and Allen, and the $\sin\theta$ at the wall was found to be 0.62 and θ to be 38° (the contact angle as normally defined was then 52°).

As indicated by the communication of Ownby and Allen, the 52° angle did not agree with the 5° angle that they measured from sessile-drops. Three possibilities exist to explain the discrepancy. (A) The actual contact angle in the capillary tube was not the same as the sessile-drop contact angle. The change in angle could result from impurities and contamination on the inside of the capillary. In capillary rise experiments, the contamination of the inside surface is a common malady. (B) The distortion from the curvature of the glass tube in a small capillary may have made the photograph unusable for determination of the $\sin\theta$ versus radius curve. (C) In the work done in footnote 55 and the present article, the menisci were magnified approximately 20x while

the BI_3 capillary meniscus had to be enlarged 260x. The large magnification definitely produced additional uncertainty. In the BI_3 case, there was no positive check as to which of the three possibilities was causing the disagreement. Possibly, all factors were contributing. Further work with liquids of known surface tension is required to define the causes for disagreement between the two contact angle procedures.

Distortion near the tube wall was very evident in the photographs of the water and mercury menisci formed in glass tubes which were analyzed and reported in footnote 55. Because of this distortion, as noted in that paper, the full meniscus up to the wall could not be utilized. As a result, $\sin\theta$ at the outside of the meniscus section studied was not the sine of the tangent angle at the wall. Therefore, the statement made by Ownby and Allen about water contact angles at the wall has no validity since contact angles at the wall were not determined in the work presented in footnote 55. Also, in that work the $\sin\theta$ data could not be linearly extrapolated to the wall since the capillary rise was small as compared to the rise in the meniscus.

The comments of Ownby and Allen concerning the use of the solidified menisci and the possible distortions involved are well taken. The procedure developed in footnote 55 and used in the paper under question was designed to detect distortion. Still the possibility exists that distortion which changed the meniscus to another mathematically consistent meniscus shape would not be detected by the procedure. To check data from this procedure, data from other methods certainly are necessary. However, because of the check with the one capillary rise experiment, and also because of the fine agreement of the surface tensions of the same alloy in containers of different diameters where distortion effects should have been considerably different, the author believes that the data presented for Pu-Co-Ce and Co-Ce do give good indications of the surface tensions of the alloys at their freezing points.

In reference to their comment about use of radiographs of the liquid, some work with radiographs of liquid menisci has been done. The menisci in all cases were too fuzzy to produce good data with this technique. To be successful, very sharp radiographs of the meniscus must be made.

Ownby and Allen raised the question of contact angles for the Pu-Co-Ce and Co-Ce alloys. Both alloy systems completely wet the insides of the capsules above the meniscus. This creeping phenomenon would indicate a 0° contact angle at the wall. Also, the computational method indicated $\sin\theta = 1.0$ or 0° wall contact angles for menisci analyzed. Figures 5 and 6 of the article being considered show $\sin\theta$ equal to 1.0 at the outside of the 25th increment which in these cases was coincident with the wall.

Hydrogen Absorbed by Clean Platinum Electrodes

Fritz G. Will and David J. BenDaniel

General Electric Research and Development Center, Schenectady, New York

Rebuttal on Comments by S. Schuldiner (Vol. 114, 916 (1967))

In a paper published in the September issue of this *Journal* (1), we presented a mathematical analysis of the effect of hydrogen absorbed by electrode and electrolyte on the hydrogen surface coverage as determined by nonsteady-state methods. Using reliable experimental values of the hydrogen diffusivity and solubility in platinum, we were both able (*i*) to establish systematic errors in the widely used charging curve and sweep methods due to these effects, and (*ii*) to show quantitative agreement between predictions of our analysis and other workers' measurements of surface coverage on platinum. In a comment published in the same issue of the *Journal*, S. Schuldiner attacked our analysis on a variety of points. We present now a point-for-point reply to those comments in sufficient detail such as to prevent any ambiguity from existing with respect to our work.

We quote our critic on his major objections.

1. "Slow phase boundary reactions cannot be ignored for studies of the permeation rates of hydrogen through metals."
2. "BenDaniel and Will cannot assume that slow phase boundary reactions did not affect the H permeation rate found by Vetter and Knaack, or that the Vetter and Knaack Pt electrode was clean."
3. "On a clean Pt surface hydrogen diffusion through Pt is immeasurable."
4. "BenDaniel and Will confuse the issue of electrode cleanliness and activity for hydrogen permeation."
5. "The assumption used by BenDaniel and Will that the rate of diffusion through a Pt electrode is dependent on the square root of the hydrogen partial pressure in the gas phase above the solution is not applicable to a polarized electrode."
6. ". . . the solubility and diffusion coefficients for hydrogen in Pt by BenDaniel and Will are much larger than would be reasonably expected."

In summary of our comments to be presented below, we find that the overwhelming evidence in the literature establishes the inapplicability of each of these criticisms.

1. Regarding his first and main objection, that slow phase boundary reactions cannot be ignored in H permeation studies, our critic cites only a single reference (2), and this single reference is misinterpreted.[1] On the other hand, we wish to point out that the fast rate of phase boundary reactions on clean, active platinum electrodes has been well documented (3-10). These rates are by 3 to 5 orders of magnitude larger than the permeation rates of H through Pt found by Vetter and Knaack and other authors. Thus, Bodenstein (11) found a permeation rate of $1.1 \cdot 10^{-12}$ moles H/cm/sec at 40°C, Vetter and Knaack (12) found $6.6 \cdot 10^{-13}$ at 25°C, and Gileadi *et al.* (13), on Pt intentionally poisoned with As_2O_3, found a rate of $3.5 \cdot 10^{-14}$ at 70°C. Note that the current density, equivalent to a permeation rate of $6.6 \cdot 10^{-13}$ moles H/cm/sec is only 22 μa/cm^2 for a 30μ thick Pt foil (12), while the equilibrium rates of the H discharge and the H_2 dissociation on active Pt are several hundred milliamperes per square centimeter (3-6) and several milliamperes per square centimeter (7-9), respectively. It is evident from a comparison of these numbers that for active surfaces the diffusion of H through Pt solely determines the over-all permeation rate, *i.e.*, phase boundary reactions have no effect on the permeation rate.

Furthermore, there is ample experimental evidence that, even for the H-Pd system with its large permeation rates [$4 \cdot 10^{-9}$ (14) to $1.2 \cdot 10^{-8}$ (15) and $1.6 \cdot 10^{-8}$ (16) moles H/sec/cm, *i.e.*, about 4 orders of magnitude larger than for H-Pt], the effect of phase boundary reactions has been successfully eliminated, for example, by "activation" of the surface by oxidation and subsequent reduction (17). Nevertheless, with such high permeation rates, as for H-Pd, one has to be careful to obtain results which are free of the effects of the processes occurring on the phase boundary or in the electrolyte.[2]

2. With regard to our critic's second assertion, we can verify in a straightforward and well-known way that the H-permeation rate found by Vetter and Knaack (12) was indeed not affected by slow phase boundary reactions. The permeation transients obtained by these authors uniquely meet the two sufficient criteria for diffusion through the metal as determining the over-all permeation rate, *i.e.*, (*i*) the diffusion distances (membrane thicknesses) are proportional to the square root of the diffusion times, and (*ii*) the steady-state permeation rates are inversely proportional to the diffusion distances.

Incidentally, we did not assume in our analysis, as asserts our critic, that the Pt electrode of Vetter and Knaack was particularly "clean." The 0.12v slope on the polarization side of their electrode signifies that H_2 diffusion in the electrolyte was not rate determining; in fact, it shows that the H^+ discharge determined the rate of the hydrogen evolution on their Pt electrode. However, since the rate of H diffusion through Pt was much slower than any of the processes on the polarization side, the question which one of these determined the rate of H_2 evolution is irrelevant. Moreover, while the Pt electrode of Vetter and Knaack was not very "active," it was clean enough to establish the reversible hydrogen potential.

3. We now concern ourselves with our critic's third claim, that no H permeates through clean Pt or that the surface has to be poisoned to observe permeation. We find that contrary to his claim, it was not demonstrated in the two references cited by him (13, 19) that the surfaces were free of adsorbed impurities, *i.e.*, clean. Hence, we are inclined rather to accept the evidence of the overwhelming majority of investigators who were able to demonstrate H permeation into Pt, without finding it necessary to poison their Pt surfaces intentionally (11, 12, 20-23) [compare also Smith (24) and more references cited there].

Parenthetically, in a later paper (25) our critic himself provided convincing experimental evidence that hydrogen is absorbed by

[1] It suffices to say that Ash and Barrer (2) present a theory in which they merely show how the permeation rate would be affected if phase boundary reactions were slow.

[2] Thus, Schuldiner *et al.* (18) obtained permeation data which are about an order of magnitude lower than those by Wicke *et al.* (15) and Barrer (16) and which fail to show the inverse proportionality between permeation rate and membrane thickness characteristic for slow diffusion through the solid. Indeed, LaPietra (14) showed that Schuldiner's data were affected by slow transport of the ceric-cerous couple in solution.

Pt whose surface was proven to be clean by showing H coverage to the extent of a full monolayer. In fact, it was this very paper we used to verify successfully our analysis. Conversely, the fact that the experimental results follow the predictions of our diffusion analysis for current densities from 0.78 to 203 ma/cm^2 is clear evidence in itself that H diffusion into clean Pt occurs and that phase boundary reactions are not rate determining in this range of currents.

Last, it is also interesting to note that with his third assertion our critic directly refutes own statements in the mentioned paper (25) in which he writes, and we quote, "that platinum electrodes in sulfuric acid solution can absorb considerable quantities of oxygen and hydrogen."

4. Our critic states that we "confuse electrode cleanliness and activity for H permeation." However, established views of permeation and adsorption clearly favor such "confusion." It is well documented that (i) adsorption is a prerequisite for permeation (26), and (ii) commonly adsorbed impurities interfere with H adsorption (10). In other words, the cleaner and more active the Pt electrode, the more it will favor H permeation.

Further, we find our critic's claim "that for clean Pt electrodes with high activity for H_2 evolution, the H-permeation is negligible" plainly incompatible with a later statement in the same Comments "that the atomic hydrogen activity on the . . . electrode surface is the primary factor controlling the rate of solution and migration of H through the metal."

5. Our critic also believes that we set the rate of H diffusion through Pt proportional to the square root of the H_2 partial pressure above the solution and argues that we should have used the "effective H_2 partial pressure" instead. But, in fact, this is exactly what we have done (compare Eq. [3a] and [4] in our analysis).[3]

6. Our critic states that our values for the diffusivity ($3\cdot10^{-8}$ cm^2/sec) and solubility $2.2\cdot10^{-5}$ moles H/cm^3) derived from Vetter and Knaack (12) are "much larger than would be reasonably expected."

Again, he bases this opinion on two obviously inapplicable studies while not quoting the work of a larger number of investigators whose values are comparable with ours. Our critic quotes data obtained by Sieverts (27) at temperatures between 409° and 1342°C. If one would extrapolate Sievert's data, one would find a solubility of 10^{-16} moles H/cm^3 at 25° (and 10^{-14} at 70°C). These values are clearly much too low to be reasonable. In fact, they are by 8 orders of magnitude lower than even the values obtained in the second study, quoted by our critic (13), which was done on Pt intentionally poisoned by As_2O_3. Obviously, we favored the values of Vetter and Knaack which were obtained on Pt that established the reversible hydrogen potential. Furthermore, Vetter's permeation rates at 25°C agree well with data of Bodenstein (11), who found rates twice as large at 40°C. Also, careful studies by Graham (20) and Thiel *et al.* (21) result in solubilities of $4.9\cdot10^{-4}$ and $7.9\cdot10^{-4}$ mole H/cm^3 both at 25°C. Their Pt electrodes had been thoroughly outgassed by heating *in vacuo*, then cathodically polarized for several hours, and finally heated *in vacuo* again to remove and measure all of the absorbed hydrogen. If, as our critic recommends, one applies Gileadi's *et al.* (13) finding that only 5-15% of this hydrogen is "free to move" at ordinary temperatures, the solubilities of mobile hydrogen in Graham's and Thiel's studies would be $2.4\cdot10^{-5}$ to $1..2\cdot10^{-4}$ moles H/cm^3. The lower of these values agrees very well with Vetter's value.

Finally, the diffusivities of hydrogen in metals in general make it clear that our value for the diffusivity in Pt is well in order. Thus, by extrapolation of Eichenauer's *et al.* data obtained between 200° and 900°C we find H diffusivities of $2.4\cdot10^{-9}$ cm^2/sec for Al (28), $1.0\cdot10^{-5}$ for α-Fe (20), $2.3\cdot10^{-9}$ for Cu (28), $9.8\cdot10^{-9}$ for Ag (29), and $4.5\cdot10^{-8}$ for Au (30), all at 25°C. Diffusivities of H in Pd measured near room temperature by three investigators are $2.4\cdot10^{-7}$ cm^2/sec at 37°C (16), $2.7\cdot10^{-7}$ (16), $2.2\cdot10^{-7}$ (14), and $1.6\cdot10^{-7}$ (15), all at 25°C.

In conclusion, the assumption in our diffusion analysis that the rate of the phase boundary reactions is fast compared to the rate of permeation into the metal is fully justified in the case of hydrogen diffusing into clean platinum and beyond that, is expected to hold in a variety of other cases. The values by Vetter and Knaack on the diffusivity and solubility of hydrogen in platinum, which we use in our analysis, are valid and reliable. They were clearly obtained under conditions of diffusion control through the platinum. These values compare favorably with values obtained by other authors on platinum and on a variety of other metals. Our quantitative interpretation of recent transient measurements on evidently clean Pt electrodes, based on the simple and sole process of diffusion, is sufficient proof in itself for the applicability of our analysis. We feel that the burden of proving otherwise now falls on the proponent of the unusual hypothesis of "dermasorption" which has recently been invoked (31).

[3] One could, however, argue that the use of a square root relationship in itself is not a good approximation in the limiting case of large surface coverages.

Hydrogen Evolution on Single Crystal GaAs Electrodes

Kathleen D. N. Brummer

Tyco Laboratories, Inc., Waltham, Massachusetts[1]

ABSTRACT

Hydrogen evolution from 0.1*N* $HClO_4$ at 23°C on the Ga (111) and As ($\bar{1}\bar{1}\bar{1}$) faces of single crystals of GaAs has been studied using current-potential curves, differential capacity measurements and anodic charging curves. The irreproducible results frequently found are shown to be the result of surface corrosion, and it is shown that great care must be taken to preserve the crystal surface. A freshly etched and washed electrode can be taken from −1.2v to −0.3v (*vs.* RHE), and reproducible hydrogen evolution measurements can be obtained at both Ga and the As faces. Current-potential curves on the Ga face show two regions: positive to ~ −0.6v (*vs.* RHE) the current is almost independent of the potential; negative to ~ −0.6v, Tafel behavior is found with a slope of 180-200 mv/decade; n-type and p-type electrodes show similar behavior, and there are no photoeffects.

Differential capacities on the Ga face indicate substantial space charge effects at potentials positive to −0.7v, but suggest degeneracy at more negative potentials. A substantial frequency dispersion is found in the range 0.5-20 kHz and is shown to originate from surface states. The variation of the surface state contribution with potential suggests that some of them arise from adsorbed hydrogen. After allowance for space charge effects, made from the differential capacity data, the Tafel slope for the reaction in the region above −0.6v is shown to be $\leq 2\ RT/\mathbf{F}$.

Anodic charging curves show a change from high to low hydrogen coverage at ~0.7v.

It is suggested that the reaction path is discharge ($H^+ + e \rightarrow H_{ads}$) followed by recombination ($2H_{ads} \rightarrow H_2$) where discharge is rate limiting over the range investigated, −0.4 to −1.2v. This mechanism is quantitatively consistent with all the experimental data.

The object of the work reported in this series of papers was to investigate the hydrogen evolution reaction on a number of single crystal III-V semiconductors with a view to understanding the properties of the electrode material which determine the kinetics of electrochemical processes.

The hydrogen evolution reaction was chosen for this study, partly because of its relative simplicity and partly because it should be possible to study it on these electrode materials without undue competition from corrosion reactions. III-V semiconductors, *e.g.*, gallium arsenide, were chosen for this purpose because of their unusual crystal structure. Gallium arsenide, a typical III-V semiconductor, crystallizes in the zinc blende structure, so that each atom is surrounded tetrahedrally by four atoms of the other kind (1). Each (111) crystal surface comprises atoms of entirely one kind or the other. It follows that atoms of gallium exposed at the arsenic surface by the removal of the surface atoms are unstable. So too are atoms of arsenic exposed at the gallium surface by the removal of the surface atoms. This description of the crystalline properties of III-V semiconductors is idealized in that there is probably minor surface faceting on the atomic level. Nevertheless a series of III-V semiconductor electrodes offers an opportunity to compare an electrochemical reaction at each of the (111) surfaces of such a compound with the same reaction at the surface of each constituent pure element.

Because of their unusual structure, these compounds have been the subject of a number of investigations. Their etching behavior (2) and anodic dissolution (3, 4) have been studied in detail. The hydrogen evolution reaction at the surface of single crystal samples of gallium arsenide has been investigated by Harvey (4), Pleskov (5), and Gerischer and Mattes (6).

Pleskov (5) found that for strongly doped materials there was substantially no difference in behavior between p-type and n-type electrodes. In the range 10^{-4} to 5×10^{-2} amp/cm^2, he found Tafel behavior with a slope of 0.12 v/decade in *N* H_2SO_4. Below 10^{-4} amp/cm^2, he found a "knee' which was attributed to semiconductor properties of the electrode. This knee was unstable and the H_2 overpotential tended to become larger with time in this region. Considerable hysteresis between ascending and descending (cathodic) current regimes was reported.

The results of Gerischer and Mattes (6) are in sharp contrast to the results of Pleskov. They did find a limiting current for H_2 evolution on p-type electrodes. This limiting current increased with illumination. These observations suggested that the reaction consumes electrons from the conduction band. On n-type electrodes in 2*N* H_2SO_4, Gerischer and Mattes found a Tafel slope of ~200 mv/decade. Thus a considerable part of the p.d. across the interface must be across the Helmholtz double layer rather than across the space charge in the electrode. They were unable to decide whether the electron transfer is rate limiting, however. They found AsH_3 in the gas phase during H_2 evolution and suggested that the surface is saturated with hydride. Cyclic voltammetry indicated an approximate monolayer of this material ($\equiv H_{ads}$). They did not report any hysteresis effects nor whether they distinguished the crystal faces.

Harvey (4) reported considerable hysteresis between increasing and decreasing cathodic currents. This he attributed to changes in surface condition. His cathodic curves were obtained after anodic polarization thus the hysteresis may relate to changes in the surface produced both by this treatment and also by subsequent treatment at very cathodic potentials; the latter particularly on the As ($\bar{1}\bar{1}\bar{1}$) face. Indeed, Harvey reported great sensitivity of his cathodic data to the anodic pretreatment. He carefully distinguished between the Ga (111) and the As ($\bar{1}\bar{1}\bar{1}$) faces, but found no difference either in NaOH or in $HClO_4$. He also found no difference between n-type and p-type electrodes and, specifically, found no limiting current

[1] Present address: 31 Oak Hill Road, Wayland, Massachusetts.

for the latter out to 100 ma/cm^2. With repetitive anodic-cathodic cycles, the surface condition of the electrode was modified such that the hysteresis effects disappeared; then, he found a Tafel slope of 300 mv/decade.

It is clear from the above that considerable disagreement and uncertainty exists about the H_2 evolution reaction on GaAs. In particular, the effects of prior anodic treatment and of careful orientation have not always been appreciated. Because of this uncertainty, there is very little evidence concerning the mechanism of the reaction. In the present investigation, it was desired to carry out experiments bearing these factors in mind in order to clarify the mechanism of the reaction. This paper describes procedures which were developed to investigate the H_2 reaction on the faces of single crystals of GaAs while preserving their chemical identities. In this context, a detailed study of the mechanism of the reaction on the Ga (111) face was carried out. In a further paper (7), we have compared the H_2 reaction on a number of III-V semiconductor electrodes.

Experimental

Electrodes.—Single crystal samples of gallium arsenide, cut into flat plates along the (111) crystal surface, were obtained from Monsanto Chemical Company, St. Louis, Missouri. The plates were about 0.5 cm^2 in area and about 0.1-0.2 cm thick, the resistivity of different samples was: 1.1 ohm cm and 0.0075 ohm cm for n-type material and 0.004 ohm cm for p-type. Each sample was soldered to the end of a steel rod, with which it made ohmic contact, and with the flat area parallel to the axis of the rod. The reason for this was to hold the electrode vertically in the cell. The steel rod was then inserted in a glass tube, which was ground on the outside, and sealed at the ends with a tapered Teflon stopper similar to that described in ref. (8). The soldered joint between the rod and sample and the edges of the sample were sealed with Kel-F wax. Only one side of the sample was therefore exposed to the solution. The exposed electrode surface was chemically polished in a 4:3:1 mixture of distilled water, nitric acid and hydrofluoric acid (2) and then washed in distilled water.

The cell.—Measurements were made in a conventional, three electrode cell. The center compartment, which contained the gallium arsenide electrode, was made so that the ground glass tube of the electrode fitted through a long tube at the top of this compartment. At the top of this tube there was a cup, which was filled with electrolyte, to make an air-tight seal. The purpose of the long tube was to allow the electrode to be raised and lowered in and out of the electrolyte, without breaking the air-tight seal. During the measurements the working electrode was clamped close to the Luggin capillary. The counter electrode, a large platinized wire, was separated from the working electrode by a glass frit, and a copious supply of hydrogen was maintained in this compartment to ensure that the current could be carried by the hydrogen reaction at a voltage close to the reversible potential. This was done to ensure that no platinum dissolved from the counter electrode, as it might have been plated out on the working electrode.

Solutions and cleaning procedures.—Measurements were taken in 0.1*N* perchloric acid, obtained by diluting 70% acid with triple distilled water (one distillation from alkaline permanganate) at room temperature (23° ± 2°C).

Since it was desired to measure the capacity at the GaAs electrode, special solution-cleaning procedures were adopted. Each experiment was preceded by prolonged electrolysis with a platinized platinum electrode, and a hydrogen lift pump was included in the cell.[2] By means of this, the electrolyte was percolated through platinum black for several hours to remove adsorbable impurities. This procedure was repeated periodically during the course of each experiment. The platinum black for the lift pump was first cleaned in a Soxlet distillation apparatus with hydrochloric acid for two days to remove base metal impurities and then with distilled water for at least a week. As an example of the effect of this treatment, the electrode capacity at 10 kHz between —0.80 and —1.00v was 20-50 μF/cm^2 with the lift pump and 8 μF/cm^2 without it. The reproducibility of the capacity was 10-15% in any one experiment, over a period of several days, and within a factor of two between different experiments.

Measurement procedures.—Most of the measurements were made potentiostatically using a Wenking "fast rise" potentiostat. Some experiments were carried out galvanostatically, and the constant current pulses were obtained using a high voltage battery with a bank of resistors. Current-time traces were recorded on a Sargent S. R. recorder *via* a high input-impedance amplifier.

Capacity measurements were made by balancing the impedance of the electrode solution interface against a variable capacity and resistance in series, using a bridge similar to that described by Parsons (9). The galvanostatic circuit was used for these measurements.

The reference electrode was a reversible hydrogen electrode, and the data are reported with respect to the hydrogen electrode.

The reproducibility of the measurements varied with the circumstances of the experiment, as is discussed below. It was found (see below) to be necessary to put the gallium arsenide electrode into the solution at a certain cathodic potential, and the following procedure was therefore adopted for the final measurements: The cell was cleaned and assembled and the electrode lowered through the neck in the cell to a position above the electrolyte. The cup was then filled with electrolyte to make an air seal. Hydrogen was then bubbled through all three cell compartments for an hour to remove oxygen and to bring the reference electrode to the required potential. The connections were then made to the potentiostat, which was set at —1.20v. At this point the gallium arsenide electrode was lowered into the electrolyte to its position near the Luggin capillary, thus completing the circuit.

Results and Discussion

Establishment of conditions for preserving the crystal surfaces.—The hydrogen overvoltage has been measured at both the gallium and the arsenic (111) surfaces of gallium arsenide. The measurements taken initially were very irreproducible, and it was observed that the behavior of the electrode was complicated by its corrosion. At potentials more positive than —0.24v the electrode dissolves as an anodic current is measured. However, since this is a mixed potential between hydrogen evolution and electrode dissolution, the latter process must also occur at more negative potentials than —0.24v.[3] After allowing some electrode dissolution, a different hydrogen overvoltage was observed. A systematic investigation was carried out of these effects. The results for the two (111) faces were very different and are discussed separately.

[2] The H_2-lift pump comprised a special side-compartment of the cell. This consisted of a glass tube (12 mm OD) with a fritted disk at the bottom containing platinum black. A narrow glass tube looped from the bottom of this chamber and re-entered it at the top. H_2 was admitted near the bottom of this narrow tube and each gas bubble, as it rose, drew solution from the main compartment of the cell and dropped it into the Pt. The use of this device was suggested by Dr. R. Payne.

[3] It is not certain at what potentials gallium and arsenic dissolve from gallium arsenide. The standard potentials have been calculated (4) as +0.11 and −0.05v for gallium arsenide and the trivalent gallium ion and as −0.69 and −1.47v for gallium arsenide and arsine. The standard potentials of the pure elements are −0.46v for gallium and its trivalent ion, and −0.60v for arsenic and its hydride (10).

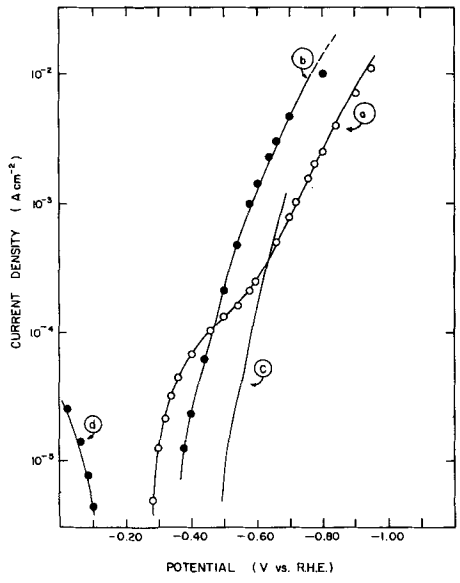

Fig. 1. Current *vs.* potential in 0.1N $HClO_4$ at: curve a, the gallium face of single crystal gallium arsenide; curve b, an electroplated gallium surface; curve c, pure liquid gallium, in H_2SO_4 (11); curve d, anodic current at gallium arsenide electrode.

The gallium (111) face.—The gallium surface was investigated first, the results are shown in Fig. 1; two extreme situations are given in curves a and b. Curve a was obtained in the following manner. A freshly polished and washed electrode was lowered into the electrolyte at a potential of —1.20v, as described in the experimental section. No solution of the electrode was allowed, and the current quickly reached a steady value. The overpotential curve was then measured at successively less negative potentials. The current at each potential showed no tendency to drift, and at potentials more negative than —0.60v the line a was reproducible to ±10 mv from one experiment to another. In this straight line portion of a the Tafel slope was 0.19 ± 0.01v, and the line could be reproduced on increasing or decreasing the potential. Anodic to —0.60v, the overvoltage curve a showed a knee, where the current was larger than would have been expected from the results at more negative potentials. These results were less reproducible than those obtained below —0.60v, by about a factor of two, i.e., ±20 mv. The current did not drift with time, however.

The rest potential occurred at —0.24v and at less negative potentials than this the anodic current represented by line d was obtained. This represents electrode dissolution. Having undergone anodic dissolution, this electrode was then taken back gradually to —1.20v. At each potential more negative than about —0.20v a much larger cathodic current was observed than in line a. This current decreased rapidly at first and then more slowly and did not become steady, even after an hour at a given potential. These high currents were as much as fifty times greater than those represented in line a. At —1.20v, the current became sensibly steady after about 2 hr, and subsequently, on increasing the potential, line b was obtained. These measurements did not vary with time and were reproducible to within ±20 mv from sample to sample; the rest potential occurred at —0.35v. Line b could be repeated with this electrode for measurements made at succesively increasing potentials, as before. In order to obtain line a again, the electrode was removed from the cell, repolished and washed and then returned to the cell at —1.20v, as described above.

Intermediate treatment of the electrode produced measurements intermediate between lines a and b; that is to say an electrode could be taken down line a to some point just above —0.60v, say to —0.50v, and subsequently, on decreasing the potential, a large but decreasing current was observed. This settled down to a steady value after the electrode was kept for some time at —1.20v. Then, on increasing the potential again, a line between lines a and b was obtained. Above —0.60v a knee occurred, smaller than in line a, and the rest potential of the electrode (a mixed potential of course) was between —0.24 and —0.35v. The longer the electrode was kept at a less negative potential than —0.60v and/or the more positive the potential to which the electrode was taken, the nearer the measurements came to line b.

The following interpretation of these differences in the hydrogen overvoltage is suggested. Line a corresponds to hydrogen evolution on the gallium face of gallium arsenide, but line b and the curves intermediate between lines a and b correspond to hydrogen evolution on a partly dissolved and subsequently gallium-plated surface. That is, at relatively anodic potentials, greater than —0.60v, the electrode dissolved. Then, as the potential subsequently decreased, some replating of one or both of the constituent elements occurred, and a steady state for hydrogen evolution was not obtained. At high negative potentials the replating process was more or less completed. Both elements could have been plated on the electrode, but it appeared probable that any arsenic plated out would have been reduced to the hydride, so that whatever actually occurred initially, a plated gallium surface remained on the electrode. Line b therefore, represents the hydrogen overvoltage on plated gallium. The results intermediate between lines a and b were obtained on a partially gallium plated electrode.

Two tests were made to corroborate this picture. First, the results of Sabo and Bagotskaya (11) were plotted for comparison in Fig. 1, line c. Their results were made in sulfuric acid using a liquid gallium electrode. The difference in roughness between a solid plated surface and liquid surface may account for some of the observed difference in the results represented by lines b and c, and therefore the comparison is not entirely conclusive. However we note that there is no knee in either line b or c. In order to make a better comparison, a freshly etched and washed gallium arsenide electrode was cathodized at —1.20v, for 5 to 10 min in a solution of gallium ions in perchloric acid in a separate cell from the one used in the overpotential experiments. This electrode was then washed and put into the other cell at —1.20v. Then a curve indistinguishable from line b, to within ±20 mv, was obtained. It is concluded from this that line a represents the hydrogen overvoltage on the gallium face of gallium arsenide and that line b, like line c, represents the hydrogen overvoltage on pure gallium.

The arsenic (111) face.—Measurements made of the hydrogen overvoltage at the arsenic surface of gallium arsenide were more complex, Fig 2. When the hydrogen reaction was measured at a freshly polished electrode, beginning at the open-circuit potential and decreasing the potential to more negative values, line c was obtained. The current first became unsteady at —0.58v, when it oscillated slowly between the two currents shown at this, and more negative potentials. There was no over-all increase nor decrease with time, just an oscillation.

The hydrogen evolution reaction was also measured, as before, beginning at —1.20v and proceeding to less negative potentials. The results shown in line a of Fig. 2 were obtained. The currents at potentials positive of —0.80v fluctuated, but no long term increase nor decrease with time was observed. Line a was reproducible, even after the electrode was kept as long as 10 min at —0.35v. This is in sharp contrast to the corresponding results at the gallium surface, see line a of Fig. 1, and probably reflects the fact that gallium from solution is not plated out onto the arsenic surface at —1.20v as it was onto the gallium surface.

Different results were obtained after holding the electrode at a very negative potential, *e.g.*, —2.00v for

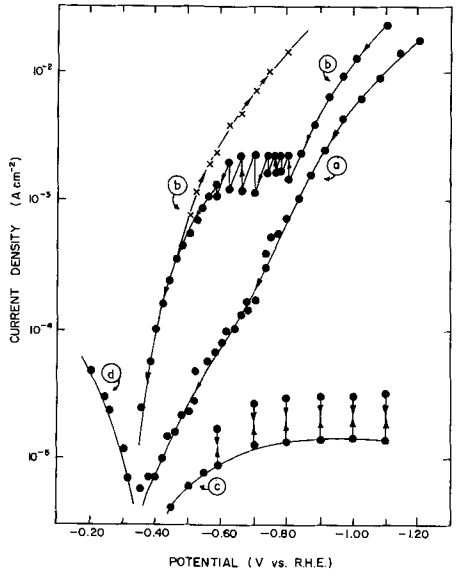

Fig. 2. Current *vs.* potential in 0.1*N* $HClO_4$ at the arsenic face of gallium arsenide: curve a, potential increasing from —1.20 to —0.30v; curve b, potential increasing from —1.20v after being held at —2.00v, and subsequently decreasing as indicated; curve c, potential decreasing from —0.40v; curve d, anodic current at gallium arsenide electrode.

about an hour, line b. Then, at potentials increasing from —1.20 to —0.80v, the current was steady, but higher than that represented in the same potential region by line a. Between —0.80 and —0.58v the current changed with time as indicated. The current did not fluctuate erratically in this potential region, but systematically. An increase in potential produced an initial decrease in the current, and a larger increase in potential produced a larger initial decrease in the current. However, after each change in potential, the current then increased slowly to a constant value independent of time and potential, taking about 10 min after a 40 mv increase in potential and about 5 min after a 20 mv increase in potential. Above —0.58v the current potential curve was closely similar to that of the hydrogen reaction at an electroplated, pure gallium surface. If the potential were then made more negative, after being above —0.58v, the experimental points again followed the curve representing the hydrogen reaction at a pure gallium surface, that is line b of Fig. 1. The lines b of Fig. 2 were only obtained after the electrode was held for some time at a high negative potential (—2.00v). If the electrode were held at —1.20v, even overnight (about 16 hr) line a was still obtained.

These results are rather unusual, but were obtained repeatedly, with various samples. All the reported features of them were reproducible at least to 20 mv, but the sections of lines b and c where the current oscillated were only reproducible to within about 50 mv. Also lines a above —0.80v was only poorly reproducible.

The objective as before had been to measure a steady hydrogen evolution curve, but at the arsenic surface of gallium arsenide and to define the conditions necessary for keeping the surface constant. In view of the possibility of hydride formation from arsenic below —0.69v [3] the measurements were first made beginning at the rest potential and proceeding to more negative potentials, line c. This was clearly unsatisfactory as the measurements were unsteady. Instead the current potential curve was started at —1.20v in an analogous manner to that for the gallium face; line a was obtained. This was reproducible, within the limits given above, and it was concluded that the results represent the hydrogen evolution reaction at the arsenic face. Analysis of the effluent gases showed no evidence of hydride formation, nor was there any undue corrosion of the surface.

Hydride formation evidently occurs only at much more negative potentials, *e.g.*, —2.00v, for the results in line b are probably the results on a surface which has undergone cathodic corrosion. A suggested interpretation of line b is as follows. At a large negative potential the hydrides of both gallium and arsenic may be formed. These hydrides are both volatile. The corroded surface must then consist of gallium and arsenic patches no longer part of an orderly crystal structure. Line b, between —0.80 and —1.20v, represents the hydrogen reaction on a mixed polycrystalline surface. Since the section of line b obtained after taking the electrode to more positive potentials than —0.58v is very close to the results obtained at a gallium plated electrode, we must conclude that the section of line b between —0.58 and —0.80v represents the region where the patches of arsenic are removed, leaving a disordered gallium surface.

We can see that in order to measure meaningful H_2-evolution rates on the single faces of GaAs, great care must be taken to avoid corrosion of the surface. This can occur at low cathodic potentials, near to the rest potential, and at high cathodic potentials, for example at —2.0v. Thus the data must be taken, at each electrode, by changing the potential from a large cathodic value of about —1.20v to the rest potential at —0.20 to —0.30v, but not in the reverse direction. Particular care must be taken to avoid redeposition of the dissolved Ga after any corrosion has been allowed. In these circumstances, both the Ga (111) and As ($\bar{1}\bar{1}\bar{1}$) faces of GaAs give reproducible behavior.

Further studies to elucidate the mechanism of the H_2 evolution reaction were carried out on the Ga (111) face of the crystals.

Current-potential curves on the Ga(111) *face of* GaAs.—Details of the current potential curve for hydrogen evolution on GaAs are shown in Fig. 1. The main features, as indicated, are that negative to $\sim$ —0.6v a stable and reproducible (<10 mv) current-potential curve is found with a Tafel slope of 180-200 mv/decade. Positive to —0.60v, the Tafel slope is much less steep (350-420 mv/decade). In this region the current at a fixed potential tends to decay because of destruction of the surface. The rest potential is $\sim$ —0.3v.

These current-potential curves are similar in general shape to those reported by Pleskov (5). The Tafel slope in the high overpotential region is similar to that found by Gerischer and Mattes (6) on n-type material although the overpotential is about 0.3v less here. The present overpotentials are, however, fairly close to those reported by Harvey (4) in the same current range.

Similar features were found for both p-type and n-type samples (Fig. 3), and no significant difference in behavior was ever found between p-type and n-type materials except perhaps in the region of the knee positive to —0.6v. Here, currents for p-type were possibly a little higher than for n-type (Fig. 3). This observation of similarity for the two conductivities and the failure to observe a limiting current for p-type material agrees with the observations of Pleskov (5) and Harvey (4) but disagrees with Gerischer and Mattes (6).

One possibility to account for the absence of a limiting current with p-type electrodes is to assume that H_2 evolution generates holes in the valence band rather than consuming electrons from the conduction band. Gerischer and Mattes' (6) observations show quite clearly, however, that the reaction must occur *via* the conduction band. It is evident then that their material was more perfect, *i.e.*, had fewer generation and recombination centers, than that used in this investigation. Finding a similarity of behavior between p-type and n-type suggests that the present samples

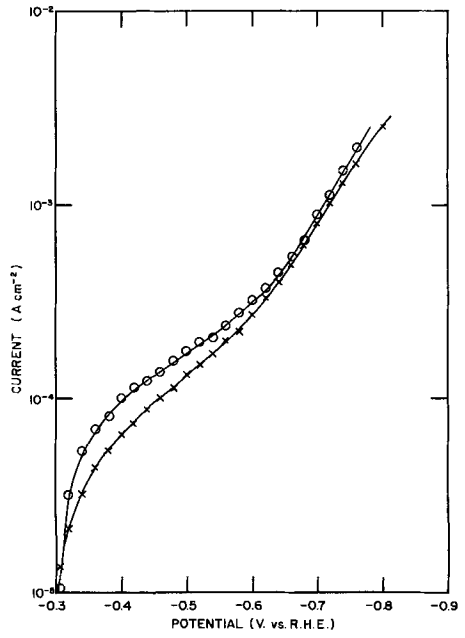

Fig. 3. Comparison of Tafel plots for p-type and n-type GaAs. x, 1.1 ohm cm n-type; O, 0.004 ohm cm p-type.

were more or less degenerate, certainly in the more cathodic region.

This conclusion is reinforced by the absence of a photoeffect on the H_2 evolution rate and by the differential capacity data presented later. We will proceed on the basis that below ~ —0.6v the semiconductor properties are not important and that the electrode is essentially a metal, *i.e.*, the space-charge region in the electrode is inconsequential in magnitude or at least independent of applied potential.

According to the analysis of Parsons (12), the following mechanism could lead to a Tafel slope of ~180 mv on a metallic electrode

$$H^+ + e \rightarrow H_{ads} \quad [1]$$

$$2H_{ads} \rightarrow H_2 \quad [2]$$

Here, H^+ discharge is followed by atom combination and the discharge is rate limiting. The combination step is not in equilibrium and the H_{ads} coverage, θ, is in the middle range of coverage, *i.e.*, Temkin (13) adsorption conditions apply. Then the Tafel slope is

$$b = \frac{RT}{\mathbf{F}}\left(\frac{2\gamma + \alpha}{2\alpha\gamma}\right) \quad [3]$$

Here α is the transfer coefficient of the discharge step and γ that of the combination step, if we take $\alpha = \gamma = 0.5$, b is $3RT/\mathbf{F}$, *i.e.*, 177 mv at 25°C.

If θ is small at low overpotentials, as is likely since reaction [1] will be relatively slower than reaction [2], this mechanism predicts that b should become smaller. In the limit of $\theta \rightarrow 0$, b should tend to $RT/\alpha\mathbf{F}$, *i.e.*, 118 mv if $\alpha = 0.5$. The mechanism also predicts that there should be pseudocapacity since θ changes with potential. In order to obtain evidence for this mechanism, the differential capacity of the electrode was investigated as a function of potential.

Differential capacity data on the Ga (111) *face of* GaAs.—The impedance of the electrode was measured with a series combination of resistance (R_s) and capacitance (C_s). Results are shown in Fig. 4 and 5. The most remarkable feature of the results is the large frequency dispersion. Thus the resistance part of the impedance increases from a limiting value of ~80 ohms (~ the solution resistance) at 20 kHz and —1.0v to ~700 ohms at 2 kHz and —0.45v. Similarly, the capacity increases from about 0.25 μF/cm² at 20 kHz and —0.46v to about 300 μF/cm² at 0.5 kHz and —0.62v. As

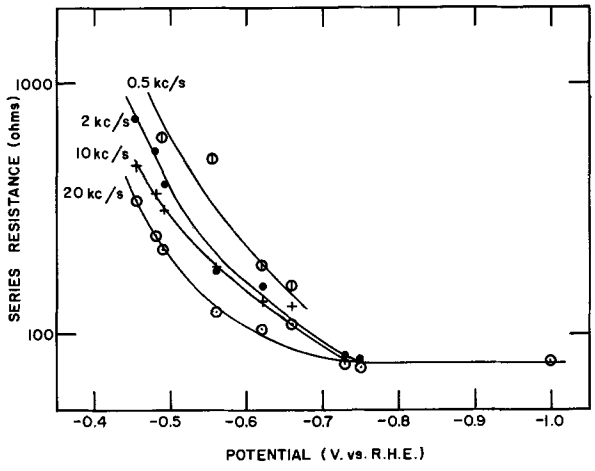

Fig. 4. Series resistance as a function of the frequency and the potential.

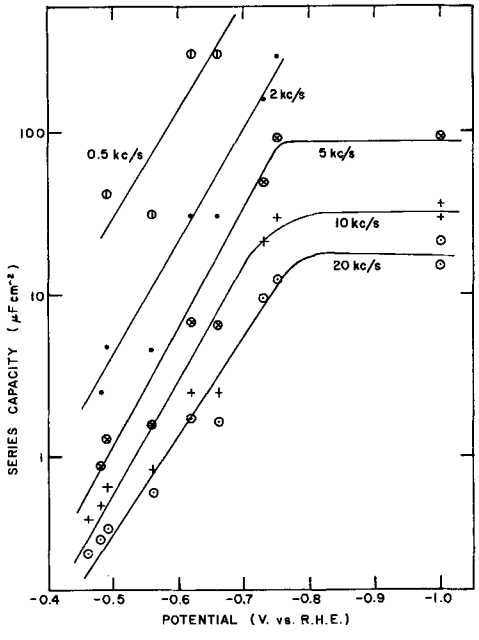

Fig. 5. Series capacity as a function of the frequency and the potential.

an example of the effect of frequency at a single potential, we note that C_s increases from 0.36 to 42 μF/cm² at —0.49v when the frequency decreases from 20 to 0.5 kHz.

The capacity of GaAs electrodes has been investigated also by Birintzewa and Pleskov (14). Their studies were mostly carried out in 1M KOH, and they also found considerable frequency dispersion which they attributed to Faradaic effects.

The large frequency dispersion suggests the possibility of the presence of the large adsorption capacity required by the postulated mechanism, reactions [1] and [2]. Thus the equivalent circuit for the Faradaic reaction might, following Parsons (9), be depicted by the circuit shown in Fig. 6(a). Here, R_e is the solution resistance, C_d the capacity of the double layer, R_r the reaction resistance, and C_a the postulated pseudocapacity. W is the Warburg diffusional impedance, negligible in this instance. In the limit of high frequency, the series capacitance and resistance elements should approximate R_e (~80ω) and C_d (~20 μF/cm²).

The data of Fig. 4 indicate that even at 20 kHz the resistance at low overpotentials is considerably higher than the solution resistance (*viz.*, 350ω at —0.46v). With any "normal" (*e.g.*, ~20 μF/cm²) value of C_d this is unlikely. This is because the impedance

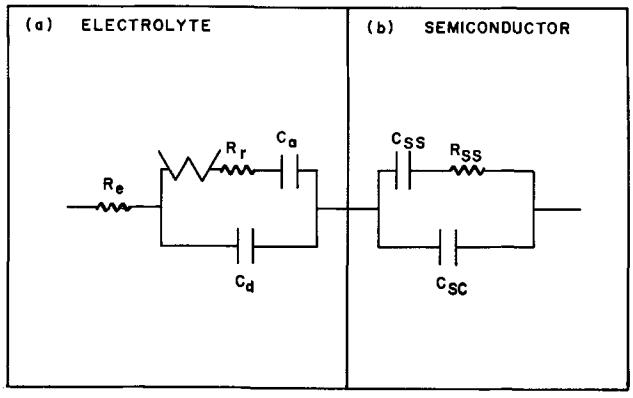

Fig. 6 (a). Equivalent circuit of the H_2 evolution reaction after Parsons (9). Fig. 6 (b). Equivalent circuit of semiconductor with surface states, after Gerischer (15). Combination of (a) and (b) is the postulated electrode-solution interface.

of such a value of C_d at this frequency is only about 0.5ω, which would shunt out R_r. Even more significant, the high-frequency values of C_s, particularly at less cathodic potentials, are already much too low to be equal to C_d. Thus at —0.46v, C_s is only 0.25 μF/cm^2 at 20 kHz. Yet even this low value is higher than the infinite frequency value.

These low values of C_s suggest that certainly at less cathodic potentials we may not treat the semiconductor electrode as a metal. The capacity in this region is apparently largely determined by the space charge in the semiconductor. If this is so, it is impossible to find the large values of C_{sc} that we do find at lower frequencies solely as a result of a series combination of the space charge capacity, C_s, and any capacity on the solution side of the interface, say C_a. This is because in these circumstances

$$\frac{1}{C_s} = \frac{1}{C_a} + \frac{1}{C_{sc}} \qquad [4]$$

and C_s would always be lower than either C_{sc} or C_a.

It follows that at low frequencies there must be an admittance parallel to C_{sc} on the semiconductor side of the interface. Such an admittance could be contributed by surface states (15). An equivalent circuit, after Gerischer (15), for such surface states is represented in Fig. 6b. The surface states contribute a relaxation term, C_{ss}, and a resistance term, R_{ss}. At low frequencies the large value of C_{ss} provides a path for charge redistribution at the interface as the potential is altered. At very high frequencies the surface states cannot follow potential changes and the charge variations we see are distributed *via* C_{sc}. The analogy with the solution side of the interface is plain.

So the frequency dependence of the observed capacity must originate largely on the semiconductor side of the interface and gives little information about the H_2 evolution reaction directly. It may be argued that the surface states originate (at least partly) from H-atoms adsorbed on the surface, but this is somewhat speculative since we do not know exactly how GaAs interacts chemically with aqueous solutions. Gerischer and Mattes (6) reported some AsH_3 evolution from their samples and suggested that the surface is saturated with AsH_3. This gas could contribute surface states although in the present work very careful examination showed that no AsH_3 is evolved out to —1.2v from the Ga (111) face. Thus the presently found surface states might originate from H_{ads}, but there is no evidence that they are from AsH_3.

We may note that the frequency dispersion is still large in the very cathodic region where the capacity is reasonably high and fairly independent of potential (Fig. 5). In this potential region, the capacity-potential relation suggests that the surface has become degenerate, as assumed in the previous section, *i.e.*, the surface charge density has become almost independent of the applied potential. It is likely that the frequency dependence in this region arises substantially from adsorbed H effects.

Important evidence that some of the observed surface states are associated with H_{ads} was obtained from anodic charging curves.

Anodic charging curves on the Ga (111) *face of* GaAs.—Anodic galvanostatic transients were applied to the electrode to analyze for the removal of H_{ads}. The electrode was potentiostated at —1.00v before application of each anodic pulse. A typical chronopotentiogram is shown in Fig. 7. We see that the potential increases rapidly until at ~0.7-0.55v, depending on the current density, there is a plateau. The anodic process involved in this plateau consumes about 2 x 10^{-4} coulombs cm^{-2} (Fig. 8). After this plateau, the potential increases again until it reaches a second plateau region in which much more charge is consumed than in the first plateau. Finally, the potential reaches a steady value corresponding to steady-state dissolution of the GaAs.

It is postulated that the first plateau corresponds to the oxidation of H_{ads} while the later processes correspond to electrode oxidation. We may note that the first plateau occurs at just about the region where the knee in the current-potential relation starts (Fig. 1 and 3). The charge consumed in the plateau is of the

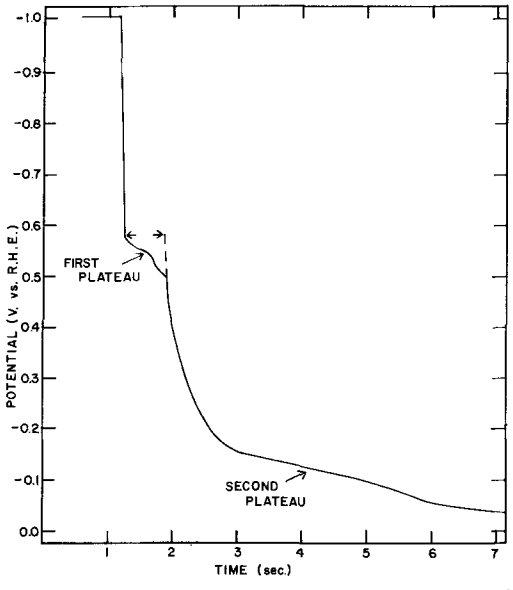

Fig. 7. Typical anodic charging curve taken from —1.00v vs. RHE on a p-type sample at 1.3 x 10^{-4} amp/cm^2.

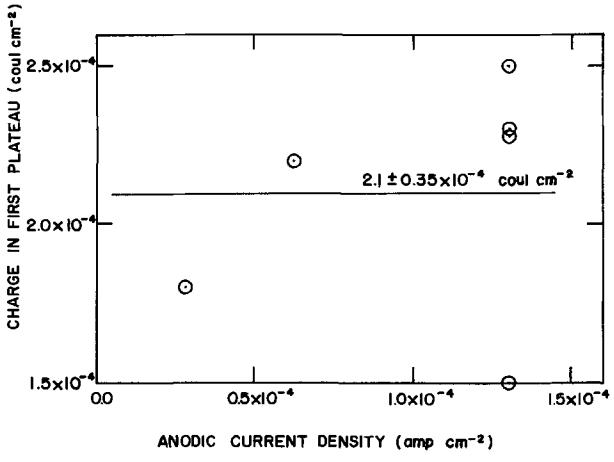

Fig. 8. Charge in the first plateau in the anodic charging curves as a function of anodic current density.

order of monolayer. It is possible that this plateau does in fact correspond to some kind of electrode oxidation. It seems unlikely, however, that such a clean separation between the two plateaus would be found in that case. Gerischer and Mattes (6) have also reported an extra charge in this potential region during an anodic sweep. This they also attributed to oxidation of about a monolayer of adsorbed H atoms or hydride.

The interpretation of these data then is that below $\sim$ —0.7v the electrode is covered with a substantial amount of adsorbed hydrogen. Above —0.7v the electrode is thought to be virtually bare. Further qualitative evidence for this latter view can be found from further consideration of the differential capacity curves.

Potential distribution in the electrode.—In the discussion of the current-potential data, it was assumed that the electrode could be treated as a metal. That is to say that there is either no space charge or a constant space charge, independent of applied potential. The evidence for this followed from the similarity between p- and n-type electrodes (Fig. 3) and the absence of a photoeffect. Further evidence that this is reasonable in the far cathodic range follows from the capacity data which show typical degenerate behavior in this region (Fig. 5).

However, these same capacity data indicate that positive to $\sim$ —0.6v it is not possible to treat the electrode as having no space charge since the low values of C_s at high frequencies must be associated with space charge effects. Indeed the region of high Tafel slope in the current-potential curves could be associated with the space charge. This is particularly probable since a similar, almost symmetrical potential-independent region was found for the anodic dissolution of the electrode. It is of some interest then to estimate the space charge potential from the capacity data.

In the absence of surface states, for space charge potentials with respect to the electrode bulk $>3RT/\mathbf{F}$, we may approximate C_{sc} for an n-type semiconductor as (15)

$$C_{sc} \simeq A \exp (\psi_s \mathbf{F}/RT)^{1/2} \quad [5]$$

where A is a constant and ψ_s is the potential drop across the space charge. Experimentally (Fig. 5), at high frequencies where the contribution of surface states to the measured capacity is small, we find that

$$C_s \simeq B \exp (-E\mathbf{F}/2.7RT) \quad [6]$$

Here B is a constant and E is the measured potential *vs.* RHE. Equating C_s with C_{sc} and taking $\exp(\psi_s \mathbf{F}/RT) >> 1$, we obtain

$$-2.7 \frac{RT}{\mathbf{F}} \ln \frac{A}{B} = \text{const} = 1.35\, \psi_s + E \quad [7]$$

However

$$E = \eta - \psi_s \quad [8]$$

where η is the potential available to drive the reaction. Hence we obtain the desired relationship between observed potential, E, and the driving potential η

$$\eta = \text{const} + 0.26E \quad [9]$$

Using Eq. [9], we can allow for the space charge potential in the region above —0.60v. Experimentally, above 0.60v for n-type material, we find approximately a 340 mv slope, *i.e.*

$$i = \text{const} \exp \left(- \frac{E\,\mathbf{F}}{5.75\,RT} \right) \quad [10]$$

Using [9] and [10], the relationship i and η is

$$i \simeq \text{const} \exp \left(- \frac{\eta\,\mathbf{F}}{0.24 \times 5.75\,RT} \right) = \text{const} \exp \left(- \frac{\eta\,\mathbf{F}}{1.4\,RT} \right) \quad [11]$$

For p-type, with a 450 mv slope

$$i \simeq \text{const} \exp \left(- \frac{\eta\,\mathbf{F}}{1.9\,RT} \right) \quad [12]$$

In either case, the important point is that this approximate calculation of ψ_s gives a lower Tafel slope between i and η than that found in the more cathodic region. This is expected from the mechanism of reactions [1] and [2] if the coverage is low at potentials positive to —0.6v. These calculations substantiate in some measure the requirement of the mechanism particularly in conjunction with the anodic charging data.

Further evidence on the hydrogen coverage in the region above —0.6v can be found from reconsideration of the capacity data. Ignoring the solution side of the interface and assuming that $R_{ss} < 1/\omega\, C_{ss}$, we may write the capacity as

$$C_s = C_{sc} + C_{ss} \quad [13]$$

Thus in the region near the space charge minimum, C_s will be given essentially by C_{ss}. We will consider a low frequency, say 0.5 kHz, where the impedance of R_{ss} is less significant. Since C_s at this frequency is much lower at —0.46v than at more cathodic potentials, it follows that C_{ss} increases sharply as we go more cathodic. Such an increase must be associated with increase in the number of surface states as we go cathodic and presumably this results from an increase in θ. The degeneracy exhibited below —0.75v would on this view, reflect saturation coverage with H_{ads}, although other explanations are possible (16).

Summary and Conclusions

1. Meaningful H_2 evolution rates at the Ga (111) and As ($\bar{1}\bar{1}\bar{1}$) faces of single crystals of GaAs may be obtained if care is taken to avoid corrosion of the surface. This corrosion can occur either at relatively anodic potentials or under very cathodic conditions. Most of the previously reported hysteresis is the result of changes of the condition of the surface due to corrosion and replating processes following corrosion. The procedure for preserving the chemical integrity of the faces is never to allow the electrode to rest at potentials more positive than $\sim$ —0.3v or at very negative potentials. It is safe to work as low as —1.2v. Satisfactory data are then obtained by raising the potential from —1.2v in the positive direction.

2. The current-potential curves for H_2 evolution from 0.1*N* $HClO_4$ on the Ga (111) face of single crystal GaAs show two distinct regions: At potentials positive to $\sim$ —0.6v *vs.* RHE, the current is almost independent of potential. More negative than $\sim$ —0.6v, Tafel behavior with a slope of 180-200 mv/decade is found.

3. Similar behavior is found on n-type and p-type samples and no limiting current is found on the latter. No photoeffect on the rate of H_2 evolution was found. These results suggest that the space charge regions in the electrodes are not important and that they can be treated as metals for purpose of mechanistic analysis of the reaction.

4. Differential capacity measurements indicate substantial space charge effects at potentials positive to $\sim$ —0.7v, however. They confirm degenerate behavior at more negative potentials.

5. A large frequency dispersion is shown to arise from the contribution of surface states to the bulk properties of the semiconductor. The variation of these surface states with potential suggests that some of them originate from adsorbed hydrogen.

6. Further evidence for considerable hydrogen adsorption is found from anodic charging curves. They indicate a transition from high coverage to low coverage at about —0.7v.

7. The following mechanism is suggested

$$H^+ + e \xrightarrow{\text{slow}} H_{ads} \quad [1]$$

$$2H_{ads} \rightarrow H_2 \qquad [2]$$

Here discharge is rate limiting over the whole range from —0.4 to —1.2v. This mechanism is consistent with the current-potential behavior and with the coverage data.

Phase Equilibria in the Zinc-Tellurium System

Richard A. Reynolds,[1] David G. Stroud,[2] and David A. Stevenson

Materials Science Department, Stanford University, Stanford, California

ABSTRACT

The Knudsen effusion cell method was used to determine the free energy of formation of subliming ZnTe between 650° and 830°C. The values of $\Delta H°$ and $\Delta S°$ for the reaction $ZnTe_{(s)} = Zn_{(g)} + \frac{1}{2}Te_{2(g)}$ were found to be 79.1 kcal/mole and 45.0 e.u., respectively. The calculated minimum total vapor pressure over congruently subliming ZnTe using these data is significantly lower than the values calculated from earlier vapor pressure data. The solubility of Te in liquid Zn was measured in the temperature range 500°-900°C using weight loss and chemical methods. The mole fraction of Te in the Zn-rich liquidus is given by

$$\log N_{Te(l)} = \frac{-3320 \pm 738}{T°K} - 0.67 \pm 0.50$$

A pressure-temperature diagram showing the range of stability of solid ZnTe was constructed using the vapor pressure data and the temperature-composition diagram for ZnTe. The pressure-temperature diagram and the measured solubility of Te in liquid Zn were used to calculate the activity coefficient of Te in liquid Zn. At 1000°K the calculated activity coefficient is 10^{-2}, the small value being due to a large, negative deviation from ideality in the Zn-Te binary system. The compositional limits of the ZnTe phase field were calculated using the pressure-temperature diagram and data giving the high temperature conductivity of ZnTe in Zn vapor. The calculations suggest the existence of a retrograde solubility of a native double acceptor defect on the Te rich side of the ZnTe phase field.

The point defect concentrations in solid crystalline compounds are significantly influenced by the high temperature equilibrium between the solid and the vapors of its components. These defects in turn are important in controlling the physical properties of the compounds. A quantitative description of the high temperature solid-vapor equilibrium, therefore, is significant in describing the variation in physical properties of compounds treated in different crystal environments. In addition, such information is valuable in selecting the optimum conditions for crystal growth and also in the calculation of the standard free energy, enthalpy and entropy of formation of the compound.

Zinc telluride (ZnTe) is a II-VI compound of interest for its potentially useful electrical and optical properties. The solid-vapor equilibrium, which has been shown to influence the high temperature defect equilibrium (1), has been the subject of two previous investigations. Korneeva *et al.* (2) have measured the decomposition pressure from 518° to 715°C using a free sublimation method; occasional reference points using a Knudsen cell were obtained to determine the evaporation coefficient. In interpreting their results, they assumed that the vapor was exclusively molecular ZnTe. Goldfinger *et al.* (3) determined the decomposition pressure of ZnTe from 553° to 837°C using a Knudsen cell technique, and in their study, the vapor species were identified by mass spectrometric techniques and found to be predominantly Zn and Te_2; no significant amount of the molecular species ZnTe was observed. The absence of molecular vapor species such as ZnTe is general of all the II-VI compounds and is further evidenced by the vapor transport characteristics of the II-VI compounds (4). The two investigations are not in satisfactory agreement, even when the results of Korneeva *et al.* are recalculated

(5) using the observed vapor species. As a consequence, additional experimental information is needed.

The present work describes investigations of the solid-vapor equilibrium of ZnTe from 650° to 830°C using a Knudsen cell technique and of the solubility of ZnTe (or Te) in liquid Zn between 500° and 900°C. The Knudsen effusion data were used to calculate the enthalpy and entropy of formation of ZnTe and to calculate the pressure-temperature diagram for ZnTe by using the existing information concerning the temperature-composition diagram and the thermodynamic properties of the elements. The total pressure over congruently subliming ZnTe reported here is lower than that found in the previous studies (2, 3), and the range of component pressures over which solid ZnTe is stable is calculated to be greater than expected on the basis of previous studies.

The liquidus of the Zn-Te system has recently been redetermined by means of DTA calorimetry by Kulwicki (6) and by Carides and Fischer (7). Their results are shown in Fig. 1. In the region of low tellurium concentration, the dashed line represents an estimate of the liquidus curve. Since the liquidus curve in this region is important for estimating the pressure-temperature diagram, an experimental determination of this line was made for the temperature range of 500°-900°C. The data giving the solubility of ZnTe in liquid Zn and the pressure-temperature diagram were combined to calculate the activity coefficient of Te, γ_{Te}, along the Zn-rich liquidus line. At 1000°K, γ_{Te} is about 10^{-2}, this small value being due to the large, negative deviation from ideality in the Zn-Te system.

Finally, the compositional limits of the ZnTe phase field were calculated using a model of the dominant defect in ZnTe (a Zn vacancy or Te interstitial acceptor defect), data giving the high temperature conductivity of ZnTe in Zn vapor (1), and the pressure-temperature diagram. Results of this calculation suggest that the Te-rich composition limit is nearly independent of temperature and that a retrograde solubility of Te in ZnTe may occur at 800°-900°C. The Zn-rich composition limit shows a continuously increasing solubility of Te in ZnTe as the temperature is increased.

Experimental Procedure and Results

Vaporization of ZnTe.—The ZnTe used for this study was synthesized from the pure elements (purity of 99.999% or better) and the resulting compound was sublimed in a dynamic vacuum for further purification and compositional control. Optical microscopic examination and x-ray diffraction analyses confirmed that the ZnTe was single phase and contained no voids, precipitates, or inclusions of Zn or Te. Mass and emission spectrographic analyses showed that the total impurity content was about 1 x 10^{17}/cm^3 to 5 x 10^{17}/cm^3 with the principal impurities being Si, Fe, and Cu.

The Knudsen cell method is described in detail elsewhere (8). In the present study, a graphite cell was used and a molybdenum jacket served as a thermal mass around the cell to minimize temperature gradients. The radius of the orifice of the cell was measured with a traveling microscope to be 0.052 cm, and the thickness of the orifice was measured with a micrometer to be 0.122 cm. The cell and its molybdenum jacket were contained in a quartz tube which was heated by a resistance furnace. The temperature of the cell was measured with a chromel-alumel thermocouple in a well which protruded into the cell. The measuring thermocouple was periodically calibrated with a platinum-platinum + 13% rhodium thermocouple calibrated by the National Bureau of Standards. The background pressure of the system was kept between 10^{-5} and 10^{-6} Torr during effusion. During heating of the cell, however, the system was backfilled with argon to minimize weight loss prior to the effusion measurement.

The mass of the ZnTe efflux was determined by two methods: direct weight loss of the cell, and the measurement of the Zn^{65} radioactive tracer activity of the entire efflux from a radioactive ZnTe source. The former method is discussed in detail elsewhere (8). The latter method was particularly sensitive and was used for the lower temperature measurements. A liquid nitrogen cooled stainless steel cup was used to collect the efflux, which was then dissolved in nitric acid, and the resulting solution was evaporated until a convenient volume was obtained for counting. In order to determine the weight of ZnTe in the efflux, the solution was placed in the well of a gamma ray spectrometer and the activity of the 1.1 Mev $Zn^{65}\gamma$ radiation was compared with that of a standard ZnTe sample having the same specific activity as the ZnTe contained in the cell.

In all cases the efflux was assumed to be stoichiometric for purposes of calculating the pressures of Zn and Te_2. In order to verify this assumption, and to compare the results obtained from the weight loss and tracer methods, the following experiment was performed. An effusion experiment which produced a large, easily measured weight loss was done using radioactive ZnTe. The Zn tracer activity was determined in the usual manner and converted into a weight of Zn. The weight of Te in the efflux was then taken as the difference between the total weight loss and the weight of the Zn calculated from the Zn tracer activity. The efflux was found to be stoichiometric and the vapor pressure determined by the two methods agreed within the experimental scatter of 5%. It should be emphasized that this is not a check on the precise stoichiometry related to the concentration of defects, but rather a justification of assuming stoichiometry for relating weight loss to the effusion pressure of Zn and Te.

The Knudsen effusion weight loss is related to the pressure of the vaporizing species i by the equation

$$P_i = Z_i\,(M_iT)^{1/2}/(44.33\,W_o \cdot A \cdot t) \qquad [1]$$

where P_i is the pressure of species i in atm, Z_i the efflux of i in moles, M_i the molecular weight of species i, T the absolute temperature, W_o the Clausing factor (calculated to be 0.48 from the orifice dimensions), A the orifice area in cm^2, and t the time in seconds. This representation of P_i is appropriate as long as the mean free path of the gas molecules is large compared to the orifice dimensions. The vaporization reaction is

$$ZnTe_{(s)} = Zn_{(g)} + \tfrac{1}{2}\,Te_{2(g)} \qquad [2]$$

for which the vaporization constant is

$$K = P_{Zn}\,P_{Te_2}^{1/2} \qquad [3]$$

responding calculated values of P_{Zn}, P_{Te_2}, and K. Figure 2 shows a plot of log K *vs.* $1/T$ for the results reported here as well as those of Korneeva *et al.* (2) [recalculated (5) assuming the vapor species to be Zn and Te_2], and of Goldfinger and Jeunehomme (3). A least squares fit of our data gives

$$\log K\ (\text{atm}^{3/2}) = \frac{-17{,}270}{T_{°K}} + 9.84 \qquad [4]$$

Possible sources of error in our measurements are in the (*i*) weighing and/or radiotracer counting procedures, (*ii*) temperature measurement, and (*iii*) Clausing factor calculation. The agreement between the data of the weight loss method and that of the radioactive tracer method suggests that the first source of error is not larger than about 5% in this study. We believe the uncertainty of the temperature inside the effusion cell is the largest source of error. Since the collection cup above the Knudsen cell was at liquid nitrogen temperature for runs using radioactive ZnTe, temperature gradients within the cell were likely. A conservative estimate of the temperature error, however, would not exceed 5°C. This error in temperature would not cause an error of greater than 30% in the value of pressure calculated from the least squares fit of the experimental data.

Finally, in order to verify the Clausing factor and to check the apparatus, an effusion experiment was performed at 1051°K with KCl and the results compared with previous work. A value for the vapor pressure of KCl of 0.36 Torr was obtained from the present work (assuming the vapor to be 100% KCl molecules). This may be compared with 0.41 Torr obtained from the equation of Treadwell and Werner (9), 0.46 Torr from the equation of Zimm and Mayer (10) and 0.48 Torr from the equation of Pugh and Barrow (11). This corresponds to a difference of approximately 15-25%, suggesting that in our measurements errors from all sources were in the range 15-30% at a maximum.

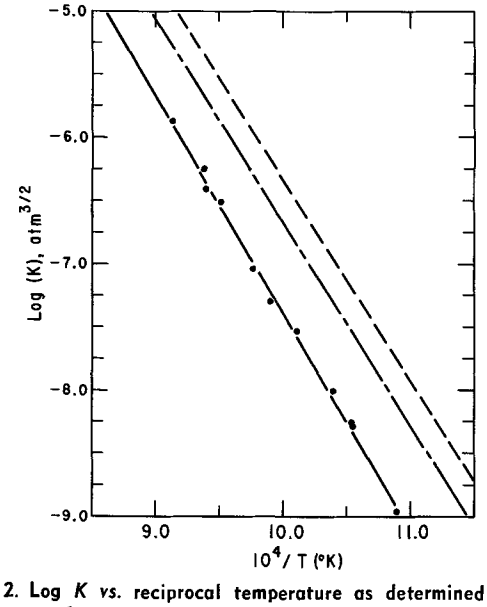

Fig. 2. Log K *vs.* reciprocal temperature as determined in this work (———O———); by Korneeva *et al.* (2) (- - - -); and by Goldfinger and Jeunehomme (3) (——— — ———).

Determination of the Zn-ZnTe *liquidus in the 500°-900°C range.*—A determination of the liquidus composition was made by equilibrating zinc telluride crystals with liquid zinc followed by separation of the solid and liquid at temperature. The liquidus composition was then determined in two ways: chemical analysis of the material that was liquid at temperature; and measurement of the weight loss of the solid crystals.

Quartz ampules (17 mm diameter and containing two doubly connected compartments) were charged with approximately 20g of zinc shot (purity of 99.999% or better) and 0.5g of a zinc telluride crystal, evacuated to 5×10^{-6} Torr and sealed. Initial weights of Zn and ZnTe were measured to ± 12 and ± 3 μg, respectively, with a Mettler microbalance. The ampules were annealed in a resistance wound furnace. A nickel jacket minimized temperature gradients and the samples were rotated during annealing to speed the attainment of equilibrium. Temperature was controlled to within ± 1/2°C with a Barber-Coleman 293C controller and temperature was monitored with a chromel-alumel thermocouple that was periodically compared with a thermocouple calibrated by the National Bureau of Standards.

At the end of the annealing time, the ampules were tilted and shaken to separate the solid from the liquid at temperature and then quenched. The portion of the sample that was liquid at temperature was analyzed for tellurium content gravimetrically. The remaining ZnTe crystals were etched with HCl to remove excess zinc (HCl attacks ZnTe at a rate negligible compared to that for Zn metal), reweighed, and the solubility computed from the weight loss.

The experimental results are summarized in Table II. As is evident from the data, there is rather poor agreement between the weight loss points and the results obtained from chemical analysis. For dilute solutions such as the liquidus in this region of the T-X diagram, one expects Henry's law to apply and the liquidus composition to follow the relation

$$\ln X_{Te}^{L} = \frac{m}{T} + b \qquad [5]$$

where X_{Te}^{L} is the mole fraction of Te in the liquid, T the temperature of the liquid, and m and b are constants. Treating the present data, one obtains

$$\ln X_{Te}^{L} = -\frac{7.63 \times 10^3}{T} - 1.55 \qquad [6]$$

with the probable error values of m and b of ± 1.16 x 10^3 and ± 1.16, respectively. While these error values are large in comparison to m and b (15% and 75%, respectively), they are not unreasonable in view of the small solubilities measured. The data are useful for semiquantitative estimates (as below); however,

they are not adequate for obtaining excess heats and entropies of solution.

Discussion

Enthalpy and entropy of formation of ZnTe.—The vaporization constant (Eq. [3]) is related to the change in standard enthalpy ($\Delta H°$) and entropy ($\Delta S°$) for the vaporization of ZnTe by the equation

$$R \ln K(T) = \frac{-\Delta H°(T)}{T} + \Delta S°(T) \qquad [7]$$

For the temperature ranges covered by the three vaporization studies the dependence of $\Delta H°$ and $\Delta S°$ on temperature may be neglected[3] so that $\Delta H°$ and $\Delta S°$ can be calculated directly from the analytical expressions for K. Table III lists the values of $\Delta H°$ and $\Delta S°$ calculated from our results and from the results of Korneeva *et al.* and of Goldfinger and Jeunehomme. The differences in the values of ΔH and $\Delta S°$ listed in Table III are small, but they result in significant differences in the calculated total pressure over congruently subliming ZnTe. At 1000°K, for example, the calculated pressures are 1.6 x 10^{-2} Torr, 9 x 10^{-2} Torr, and 5 x 10^{-2} Torr using our data, the data of Korneeva, *et al.*, and the data of Goldfinger and Jeunehomme, respectively. The differences in the calculated pressures are due to differences of the same magnitude in the experimental values of the vapor pressure.[4] Considering the major sources of experimental error, those in the weighing and/or counting operations would be random, and any error in the Clausing factor would be constant, independent temperature, and hence neither would influence the calculated enthalpy. An error in temperature, however, would probably be systematic and result in an error in the enthalpy. Since the data of each investigation are self-consistent but there exist small but significant differences in the enthalpy values, an error in the measurement of temperature is probably the major reason for the discrepancies between the present study and previous investigations. As discussed above, a conservative estimate of the error in pressure due to the experimental error in temperature in the present study is placed at 30% which is less than the observed differences.

The values of $\Delta H°$ and $\Delta S°$ for the reaction

$$Zn_{(s)} + Te_{(s)} = ZnTe_{(s)} \qquad [8]$$

have been determined at lower temperatures by McAteer and Seltz (13) and by Pool (14). Values of $\Delta H°$ and $\Delta S°$ for the vaporization of ZnTe can be calculated from these data and compared with the values determined from the vapor pressure studies. Because of the large temperature difference between these investigations and the vaporization investigations one must estimate ΔC_P for Eq. [2] and also insure that the standard state of the ZnTe is the same in all the investigations. An estimate of C_P for ZnTe can be made using the empirical methods discussed by Kubaschewski and Evans (15) and gives

$$C_P(\text{ZnTe}) = 11.5 \text{ cal/°K mole} + 2.8 \times 10^{-3} T \qquad [9]$$

Other required values of C_P are in the literature (16-18). The standard state chosen for ZnTe is the pure, stoichiometric compound, and since the phase field of ZnTe is very narrow, it is assumed that negligible deviation from this standard state can be achieved experimentally. In other words, it is assumed that the phase field of ZnTe is so narrow in terms of its composition limits that the difference between the free energies of formation of ZnTe saturated with Zn and ZnTe saturated with Te cannot be detected experimentally. This assumption has been shown to be valid for CdTe as discussed by Brebrick and Strauss (12).

McAteer and Seltz (13) used a reversible galvanic cell to study the reaction of Eq. [8] and found $\Delta H°$ = — 28.2 kcal/mole and $\Delta S°$ = —2.9 e.u. at an average temperature of 658°K (385°C). Pool (14) used tin solution calorimetry to determine $\Delta H°_{273°K}$ for the same reaction and obtained a value of —28.5 kcal/mole. Since ΔC_P is expected to be negligible for Eq. [8] [Neumann and Kopp's law (16)], the agreement between these two values of $\Delta H°$ is expected despite the difference in temperatures of measurement. Combining these data with the thermodynamic data for the vaporization of a solid Zn and Te (17) and the heat capacities of $Zn_{(s)}$(18), $Te_{(s)}$(15), $Zn_{(g)}$(17) and $Te_{2(g)}$(17) enables one to calculate $\Delta H_{658°K}$ = 79.1 kcal/mole and $\Delta S°_{658°K}$ = 51.3 e.u. for the dissociation of ZnTe into $Zn_{(g)}$ and $Te_{2(g)}$ (Eq. [2]). Using the estimated heat capacity of ZnTe, one calculates further that ΔC_P for Eq. [2] is —2.5 cal/mole °K, leading to $\Delta H°_{1000°K}$ = 77.6 kcal/mole, and $\Delta S°_{1000°K}$ = 49.5 e.u. These values are in good agreement with those derived from the vapor pressure studies (Table III) when one considers the approximations and extrapolations required for the calculation. Previously, Kröger (19) has concluded that the data of McAteer and Seltz yielded calculated vapor pressure values in conflict with those measured directly and with the maximum melting point (6, 7) of ZnTe (Kröger's Figure I indicates a $\Delta H°$ derived from data of McAteer and Seltz which is about 25% larger than those determined by vapor pressure measurements).

Pressure-reciprocal temperature diagram.—The pressure-reciprocal temperature (P-1/T) diagram for compounds describes the component pressures along the liquidus line of the temperature-composition (T-X) diagram and shows the range of component pressures at a given temperature for which the solid

[3] In the present and two previous studies a plot of $\ln(K)$ *vs.* $1/T$ is well represented by a straight line, indicating that a Σ function analysis over these temperature ranges is not necessary. Furthermore, the estimated value of ΔC_P of —2.5 cal/mole °K for the reaction in Eq. [2] (see below) would produce a change of less than —1.0 kcal/mole in $\Delta H°$ and less than 1.0 e.u. in $\Delta S°$ between the minimum and maximum temperatures of each investigation.

[4] The composition of ZnTe inside the effusion cell is very near that of congruently subliming ZnTe (12). Hence, the measured vapor pressures are very near the minimum total vapor pressure, which occurs over congruently subliming ZnTe.

phase is stable. The (P-1/T) diagram is used to determine the range of component pressures under which the compound can be annealed without melting, and to predict the extrema in defect concentrations for those crystalline defects in equilibrium with the external component pressures.

An experimental determination of the (P-1/T) diagram for the Zn-Te system has not been made; however, one can construct a diagram by combining the vapor pressure data with the T-X diagram which was recently redetermined by two investigators (6, 7) and is shown in Fig. 1. Studies of the P-T-X diagrams for the Cd-Te (20), Cd-Se (21), and Hg-Te (22) systems show that Raoult's law can be applied to liquids except for compositions in the region of the compound. Assuming that Raoult's law also may be applied to liquids in the Zn-Te system, the partial pressures of Zn over the Zn rich liquidus and of Te over the Te rich liquidus are given by

$$P_{Zn} = P^{\circ}_{Zn} N_{Zn(l)} \qquad [10]$$

and

$$P_{Te_2} = P^{\circ}_{Te_2} N^2_{Te(l)} \qquad [11]$$

respectively, where P°_i is the vapor pressure of pure Zn or Te, and N_i is the mole fraction of Zn or Te in the liquidus composition at temperature T as shown by the T-X diagram.[5] The vapor pressures of Zn over the Te rich liquidus and of Te over the Zn rich liquidus can be calculated from the vaporization constant of ZnTe (Eq. [3]) and the vapor pressure of the major component in the liquid phase, if it is again assumed that the phase field of ZnTe is so narrow that free energy of formation (*i.e.*, the vaporization constant) of ZnTe is independent of changes in the solid composition. A P-1/T diagram constructed in this manner is shown in Fig. 3 using the values of the vaporization constant from this work. Both the Zn and Te vapor pressures are shown in Fig. 3 in order to emphasize that over the Zn rich liquidus the Zn pressure is orders of magnitude higher than the Te_2 pressure, and that over the Te rich liquidus the Te_2 pressure is orders of magnitude higher than the Zn pressure. Consequently there exists a composition of solid ZnTe between those corresponding to saturation with Zn or Te whose total vapor pressure has a minimum value. The solid composition having the minimum total vapor pressure is known as the congruently subliming composition because it and its equilibrium vapor have precisely the same composition (which may also be a function of temperature). Deviations from stoichiometry in ZnTe are small, however, so that both the congruently subliming solid and its equilibrium vapor may be considered to be stoichiometric for purposes of chemical analysis. The total vapor pressure over congruently subliming ZnTe is related to the vaporization constant by (4)

$$P_T(\text{Torr}) = 3/2^{2/3} K^{2/3} \times 760 \qquad [12]$$

and is also shown in Fig. 3. Due to the lack of sufficient thermodynamic data at temperatures above about 1000°C for extrapolation purposes, the portion of the P-1/T diagram above this temperature must be considered to be approximate.[6]

[5] A significant discrepancy exists between the two experimental Te-rich liquids lines above 1000°C (Fig. 1). The causes of this discrepancy are not readily apparent, especially since the data agree well along the Zn-rich liquidus where pressures are higher and the DTA experimentation more difficult. Average values for $N_{Te_{(l)}}$ were used to calculate the P-1/T diagram above 1000°C, since the major sources of error in the calculation at these temperatures are in the use of Raoult's law and the lack of experimental values of C_p for ZnTe.

[6] In Fig. 3 the liquidus lines near the maximum melting point have been constructed so that the maximum melting composition also sublimes congruently (*i.e.*, $P_{Zn} = 2P_{Te_2}$ at T_{max}). This assumed coincidence has not been demonstrated experimentally.

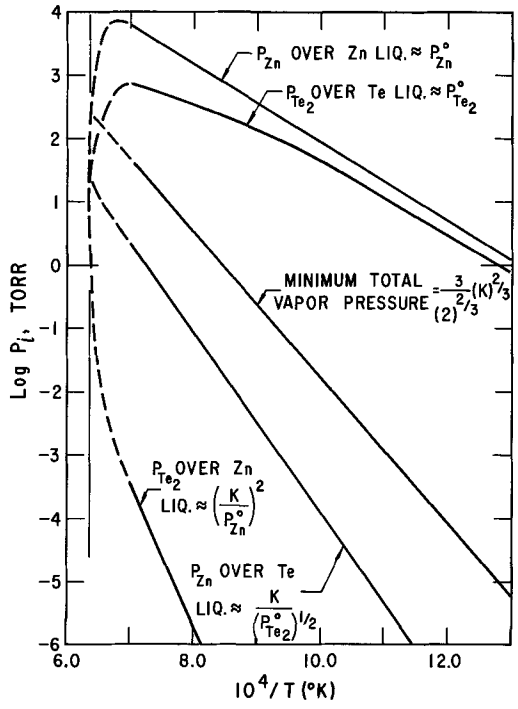

Fig. 3. Pressure-reciprocal temperature diagram showing the Zn and Te_2 partial pressures along the liquidus of the T-X diagram (Fig. 1), and the minimum total vapor pressure over congruently subliming ZnTe. Above about 1000°C the diagram is tentative because of the lack of heat capacity data for proper extrapolation of the vapor pressure of ZnTe, and possible deviations from ideality in the liquid phase.

Activity coefficient of Te *in liquid* Zn.—An estimate of the activity coefficient of Te in liquid Zn can be made by combining the data giving the solubility of Te (or ZnTe) in liquid Zn with the vapor pressure of Te_2 over ZnTe saturated with Zn, which is given by the P-1/T diagram of Fig. 3.

The activity coefficient γ_{Te} of Te in liquid Zn-Te alloys is given by

$$\gamma_{Te} = \frac{1}{X_{Te(l)}} \left(\frac{P_{Te_2}}{P^{\circ}_{Te_2}} \right)^{1/2} \qquad [13]$$

where $X_{Te(l)}$ is the mole fraction of Te in the liquid, P_{Te_2} is the vapor pressure of Te_2 over the liquid, and $P^{\circ}_{Te_2}$ is the vapor pressure of pure Te. The value of $P_{Te_2}{}^{1/2}$ is given by

$$P_{Te_2}{}^{1/2} = \frac{K}{P_{Zn(l)}} \qquad [14]$$

where K is the dissociation constant for ZnTe and $P_{Zn(l)}$ is given by Eq. [10]. Using Eq. [6] for $X_{Te(l)}$, the vapor pressures of pure Zn and Te, and our vaporization constant for ZnTe to evaluate Eq. [13] gives

$$\log \gamma_{Te} = -4800/T + 2.86 \qquad [15]$$

where γ_{Te} is explicitly for the Zn-rich liquidus. The calculated value of γ_{Te} is 10^{-2} at 1000°K and 6 x 10^{-2} at 1173°K. These small values arise due to the large, negative deviation from ideality in the Zn-Te system. They can be compared to the value of 5 x 10^{-4} calculated (21) for Se along the Cd rich liquidus of Cd-Se alloys between about 1200° and 1400°K. Since the melting points and free energies of formation for CdSe and ZnTe are very comparable (3, 21), one might expect that the activity coefficients of the group VI elements would be of more comparable magnitudes in these two alloy systems.

Compositional limits of the ZnTe *phase field.*—Undoped ZnTe is a p-type semiconductor, presumably

due to the presence of a native defect which acts as a double acceptor. The defect is believed to be due to the incorporation of excess Te and generally has been attributed to be a zinc vacancy (1, 24, 25). Self-diffusion data (26) for Zn and Te, however, suggest that the acceptor defect is an interstitial Te atom. Thomas and Sadowski (1) have measured the high temperature hole concentration in ZnTe as a function of temperature and zinc partial pressure and found that

$$p \propto (P_{Zn})^{-n} \quad [16]$$

where n varied from 0.44 at 700°C to 0.30 at 950°C. Thomas and Sadowski interpreted their data to show that doubly ionized zinc vacancies dominate the defect equilibria at high temperatures according to the reaction

$$Zn_{(ZnTe)} = Zn_{(g)} + V_{Zn}^{-2} + 2p \quad [17]$$

where V_{Zn}^{-2} is a doubly ionized Zn acceptor vacancy. This reaction and the presumed charge neutrality condition of

$$p = 2[V_{Zn}^{-2}] \quad [18]$$

predict that

$$p \propto P_{Zn}^{-1/3} \quad [19]$$

which approximates the experimental results at the higher temperatures. The double acceptor model would predict the same electrical behavior regardless of whether the defect was assumed to be a zinc vacancy or an interstitial Te atom.

If one combines the experimental data of Thomas and Sadowski, an appropriate model of the defect equilibria, and the P-$1/T$ diagram previously constructed for the Zn-Te system, it is possible to calculate the compositional limits of the ZnTe phase field. The composition limits on the zinc rich side of the ZnTe phase field are determined by extrapolating the data of Thomas and Sadowski to zinc pressures corresponding to zinc saturation, while the composition limits on the Te rich side are determined by extrapolating their data to the zinc pressures corresponding to Te saturation, as read from the P-$1/T$ diagram. The double acceptor defect model described above has been used by Reynolds (27) and Kroger (19) to calculate the limits of the ZnTe phase field. Both authors assumed that the acceptor defect was doubly ionized for all relevant values of temperature and Zn partial pressure; hence, their calculations of the Te-rich boundary of the ZnTe phase field employs an extrapolation of the hole concentration at all temperatures on the basis that $p \propto P_{Zn}^{-1/3}$. However, if the acceptor defect were singly ionized for some values of temperature and Zn pressure, the defect model would predict $p \propto P_{Zn}^{-1/2}$. The data of Thomas and Sadowski, which give $p \propto P_{Zn}^{-0.44}$ at 700°C and $p \propto P_{Zn}^{-0.38}$ at 750°C, indicate that this is the case. Both lower temperatures and lower Zn partial pressures will favor single over double ionization of the defect. Even at a constant temperature the defect may become singly instead of doubly ionized as the Zn pressure is reduced because the crystal is becoming more p-type (Fermi level of energy moving closer to the valence band). Hence isotherms giving the hole (or defect) concentration as a function of Zn partial pressure may be analytically complex and show some "irrational" average dependence on Zn pressure lying between $P_{Zn}^{-1/3}$ and $P_{Zn}^{-1/2}$. In order to demonstrate the effect of the possible change in charge state on the calculated limits of the ZnTe phase field, Fig. 4 shows the Te-rich limit calculated using both Eq. [19] and the experimental pressure dependencies for extrapolation purposes. A decrease in hole concentration with increasing temperature at low temperatures is suggested when the experimental hole concentration-P_{Zn} relations are used. This tendency would be reduced if the data at the higher temperatures were extrapolated according to $P_{Zn}^{-1/3}$ near Zn saturation and according to $P_{Zn}^{-1/2}$ near Te saturation, due to a decrease in charge of the acceptor defect as the Zn pressure is reduced. Nevertheless, the use of the experimental pressure dependencies would suggest that the Te-rich solidus is nearly temperature independent and perhaps exhibits a retrograde solubility limit. In fact, the suggestion of retrograde behavior persists even using the pressure dependence of $P_{Zn}^{-1/3}$. The temperature range over which the retrograde behavior is suggested is in qualitative agreement with the range suggested by the theory of Miller and Komarek (28) which (for the Zn-Te system) relates the temperature of the maximum in the retrograde solubility to the temperature of the inflection in the Te-rich liquidus line in the T-X diagram (Fig. 1). Further evidence suggesting retrograde behavior is the pronounced precipitation which occurs in ZnTe crystals annealed at high temperatures in Te-rich atmospheres (26, 29). Finally, a nearly temperature independent Te-rich solidus is in agreement with the Hall effect measurements of Larsen (30) who found that the net acceptor concentration in ZnTe annealed in excess Te was nearly independent of annealing temperature (the net concentration in crystals annealed in excess Zn increased rapidly as the annealing temperature was increased).

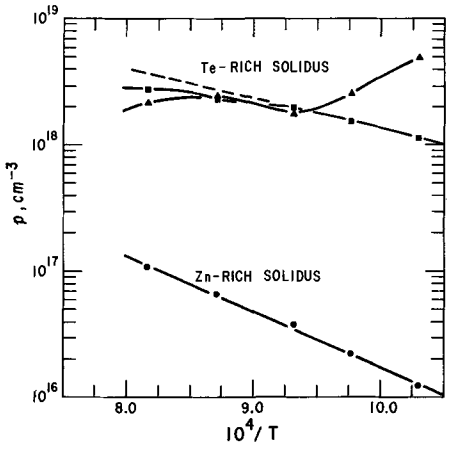

Fig. 4. Free hole concentration in ZnTe vs. reciprocal temperature for the conditions of Zn saturation (1) (———●———); for Te saturation as calculated using the P-$1/T$ diagaram (Fig. 3) and Eq. [19] for extrapolation (———■———); and for Te saturation as calculated using the P-$1/T$ diagram and the experimentally determined hole concentration vs. P_{Zn} relations (———▲———). The dotted line is a straight line extrapolation using the three low temperature points at Te saturation as computed assuming Eq. [19].

An alternative defect model which also would predict that $p \propto P_{Zn}^{-1/2}$ at the lower temperatures postulates that charge neutrality is given by

$$\tfrac{1}{2}[A^{-2}] = [D^{+}] \quad [21]$$

where A^{-2} is the double ionized acceptor native defect and D^{+} is a donor impurity. When the temperature is made sufficiently high the thermally generated concentration of A^{-2} would exceed the concentration of D^{+} and the charge neutrality condition would become that given in Eq. [19] so that $p \propto P_{Zn}^{-1/3}$. Analysis of the data of Thomas and Sadowski using this model of the defect equilibria would suggest that their crystals contained about $5 \times 10^{16}/cm^3$ donor impurities. This model, however, is difficult to reconcile with the good reproducibility from crystal to crystal observed by Thomas and Sadowski because it infers all crystals have the same donor content.

Formation of Precipitates in Gold Diffused Silicon

E. D. Wolley and R. Stickler

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

ABSTRACT

Gold was diffused into silicon wafers with a variety of surface treatments and doping conditions by a sealed tube $AuCl_3$ process. Transmission electron microscope examinations of the wafers showed that precipitates were formed at or near dislocations, at loop-type defects, and at the $Si-SiO_2$ interface. In one case of a slow-cooled diffusion run very large precipitates which were formed at the $Si-SiO_2$ interface were identified as Au_2P_3.

Wilcox, LaChapelle, and Forbes (1) found that the increase in resistivity of uniformly gold diffused silicon was not as much as expected from the gold concentration determined by tracer techniques. These results lead to a conclusion that not all of the gold is present as substitutional atoms in the silicon lattice but that some gold may be present as precipitates. These investigators also found that the solubility and diffusion constant of gold were higher in silicon which was highly doped with phosphorus. They concluded that one possible explanation of these results was the formation of a gold phosphide compound Au_2P_3. Sprokel and Fairfield (2) showed by means of autoradiographs that the concentration of gold was increased in regions of high phosphorus concentration. By x-ray diffraction microscopy these investigators also found precipitates in highly phosphorus-doped silicon samples which had been gold diffused (3). Joshi and Dash (4) recently reported transmission electron microscope observations on the precipitation of a not-further-identified "Au-Si-P" compound in gold- and phosphorus-diffused silicon.

All these investigators used elemental gold deposited on silicon surfaces as diffusion sources. In the present investigation silicon wafers were gold diffused by using a volatile gold compound as a diffusion source. The diffusion was carried out in a sealed tube process with small amounts of $AuCl_3$ as a source.

We have examined the gold diffused silicon wafers by transmission electron microscopy (TEM) and electron diffraction (ED) in order to ascertain if any precipitation does occur and to identify the precipitate, if present. Precipitation was observed, and some of these precipitates have been identified as gold phosphide, Au_2P_3 (5). The Au_2P_3 was observed at or near the silicon-silicon dioxide interface. Other precipitated particles were also detected which could not be identified because they were too sparse and electron diffraction patterns were inconclusive. Some of these particles could be gold. On some specimens a finely dispersed surface precipitate could be identified as SiC.

Experimental Procedures

Materials and wafer preparation.—Wafers of 250 μm (1 μm = 10^{-6} m) thick silicon of several different resistivities both n-type (phosphorus-doped) and p-type (boron-doped), as well as relatively perfect and highly imperfect material were diffused. The material,

treatment before diffusion, and diffusion conditions are listed in Table I.

The wafers referred to in the table as "Deformed" were slightly deformed in a quartz tube so that the wafers were suspended on the edges by the tube walls. A quartz rod was placed on top of the wafers, the tube was evacuated to 10^{-5} Torr, back-filled to 1/5 atm with argon, and sealed off. Then the tube was heated at 1275°C for 24 hr. Only 2×10^5 dislocations cm^{-2} were introduced by this treatment, however.

Since a relatively high dislocation density ($> 10^6$ cm^{-2}) is required in order to observe dislocations readily by TEM, wafers of the two subsequent gold diffusions were lapped with 600 mesh Al_2O_3 and given only a light polish with 0.25 μm diamond powder before diffusion. This treatment is referred to in Table I as "lapped." The dislocations were introduced by the abrasion treatment and rearranged during heat-treatment by the relief of lapping stress (6).

Gold diffusion.—The Si wafers were oxidized in wet argon at 1200°C to produce surface oxide films ranging from 7000 to 12,000Å in thickness. Prior to the Au-diffusion treatment, the oxide was removed from one side of the wafers, and the wafers were sealed in quartz tubes (20-60 cm^3 volume) together with approximately 0.1 mg of $AuCl_3$ (supplied by Engelhard Industries). The $AuCl_3$ was held at a low temperature during pump-down to 10^{-5} Torr and seal-off to prevent decomposition. The $AuCl_3$ is somewhat hygroscopic with the result that a small amount of H_2O and perhaps other adsorbed gases might have been introduced into the diffusion tube. The diffusions were carried out at 885°C for 16 hr or at 1235°C for 2 hr. For these diffusion conditions, the distribution of gold through the 250 μm samples should have been relatively uniform at the end of the diffusion time. Wafers were both slow cooled and fast cooled from the diffusion temperature. For the slow cooled wafers the average cooling rates were 10°C/min to 1000°C, 5°/min to 800°C, and 1°C/min to 400°C. Fast cooling was accomplished by removing the diffusion tube from the furnace and placing it under running tap water. The time required to cool the tube to room temperature was 5-10 sec.

During the sealed-tube gold diffusions, a thin oxide layer of a thickness varying from a few to several hundred Angstroms formed on the side from which the thick oxide film had been removed. Nevertheless, in the following this side will be called the "free" surface and the side with 7000 to 12,000Å the "oxidized" surface.

Transmission electron microscope examinations.—After gold diffusion the wafers were divided into pieces small enough to be mounted on the specimen stage of the electron microscope. They were chemically thinned from one or both sides, to obtain areas transparent to the electron beam (6). Both the free and the oxidized sides of the wafers were examined. When the samples were examined near the surface region by thinning from one side only, they were examined first through the oxide and the silicon. Then, the oxide was removed in HF and the Si samples were re-examined.

Determination of electrically active gold.—In order to compare the amount of the electrically active gold obtained by the $AuCl_3$ sealed tube diffusion process to that obtained by other investigators by the use of deposited gold sources, the change in resistivity of various silicon wafers after the gold diffusion was determined.

Since gold introduces both a deep donor and acceptor (7) in silicon, it decreases the net carrier concentration in both p-type and n-type material. Thus the amount of electrically active gold introduced by diffusion can be determined by measuring the change in resistivity in either p-type or n-type material. Several resistivities in both conductivity types covering a range of concentrations from 3×10^{15} to 6×10^{17} cm^{-3} were diffused with gold at 1235° and 885°C for 2 and 31 hr, respectively. The diffusion time was presumably long enough to diffuse completely through the wafers, and hence a relatively uniform distribution of gold was obtained. After diffusion the wafers were fast cooled to prevent appreciable redistribution or precipitation of the gold.

The resistivities and conductivity type of the wafers were measured before and after diffusion. The carrier concentrations were determined from the resistivities and the data of Irving (8).

Results

Electrical data.—The results of the 1235 and 885°C diffusions are given in Table II and Table III, respectively. From Table II it is apparent that the amount of electrically active gold which was obtained at 1235°C is approximately 1×10^{16} cm^{-3}. Note that for concentrations above 10^{16} cm^{-3} the change in resistivity corresponded to an active Au concentration of about 1×10^{16} cm^{-3}. For concentrations below 1×10^{16} cm^{-3} the resistivity became very large as a result of complete compensation. This value of 10^{16} cm^{-3} is less than the solid solubility of gold in silicon reported by Collins *et al.* (9), who reported a value of about 10^{17} cm^{-3} at 1235°C. The concentration of gold in the gaseous phase in our diffusion experiments was of the order of 10^{15} cm^{-3} which probably accounts for the value lower than the solid solubility.

From Table III it appears that the amount of gold diffused at 885°C depended on the concentration in

the starting material. Other investigators have found that the diffusion rate and the solubility of gold in silicon depends on the quantity and type of impurities present in the silicon (1, 2).

Electron microscope examinations.—Description of the results of electron microscopic examinations will be made of the groups of diffusions listed in Table I in the order in which they appear in the table.

Float-zone material (Group 1).—Figure 1 is composed of TEM's taken about 100 μm below the surface. Figure 1a is a TEM of a typical undiffused starting wafer showing loop-type features (10, 11), which are often found in starting material. In the gold diffused and fast-cooled wafer from group 1 the loops remained substantially unchanged. In the slow cooled specimen shown in Fig. 1b, there is evidence of precipitate formation or change in the nature of the loop-type features. An ED pattern could not be obtained from these precipitates.

Deformed material (Group 2).—As stated above, this material was only slightly deformed so that the effect of deformation was not apparent in the TEM's. These wafers were, however, substantially different from those of group 1. Figure 2a shows the surface region of a fast cooled wafer with the oxide film removed in HF. There are more small precipitates near the surface than were evident in the fast-cooled wafers of group 1. A TEM of a slow cooled specimen is shown in Fig. 2b.

The large regular-shaped particles were located near the silicon-silicon dioxide interface. A spotted ED ring pattern was obtained from these particles. The d-spacings determined from the ED pattern did not match those of Au which lead us to postulate the precipitate was a gold-phosphide compound. However,

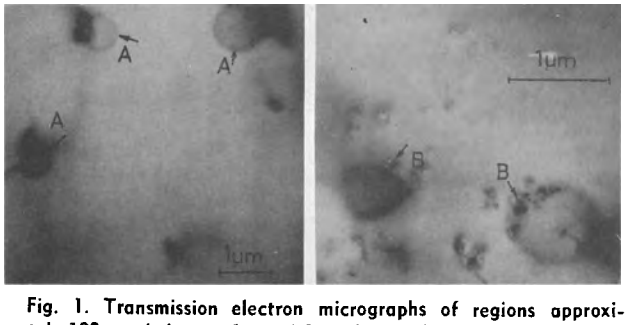

Fig. 1. Transmission electron micrographs of regions approximately 100 μm below surface of Si-wafers: a (left) untreated wafer, 20 ohm-cm, n-type, loop-type defects (A); b (right) portion of same wafer, Au-diffused at 1235°C for 2 hr and slow cooled, formation of precipitate near loop-type defects (B).

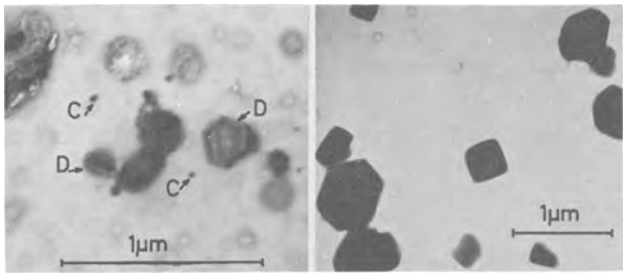

Fig. 2. Transmission electron micrographs of surface regions of Si-wafers (20 ohm-cm, n-type) heat-treated at 1275°C for 2 hr in vacuum prior to Au-diffusion at 1235°C for 2 hr: a (left) wafer fast cooled after diffusion treatment, surface oxide film removed with HF, fine precipitated particles (C) and thin plate-like precipitate (D); b (right) wafer slow cooled after diffusion treatment, oxide film removed with HF, massive particles identified as Au_2P_3.

there is little crystallographic data on gold-phosphide compounds. In order to obtain accurate structural data on Au_2P_3, a 40 a/o (atom per cent) gold, 60 a/o phosphorus alloy was prepared as follows. Gold powder was put into a Vycor glass ampoule, the P was placed upright in the glass ampoule in a small quartz phial (10% over the stoichiometric amount). Thus, only P vapor could reach the Au powder. The ampoule was then evacuated to better than 10^{-5} Torr, sealed off, and placed in a furnace. After several hours heating at 600°C the ampoule was removed and allowed to cool to room temperature. The reaction product appeared as a dark gray powder. Unreacted P was driven off by gently heating the sample by flaming the ampoule with a Bunsen burner, while cooling the other end of the ampoule. The tube was then opened. A chemical analysis of the reaction product revealed a P content of 60.4 a/o which is very close to the stoichiometric composition of Au_2P_3. X-ray diffraction data were obtained from Debye-Scherrer patterns; the measured d-values are listed in Table IV and compared with electron diffraction data obtained from

* Structure of the bulk Au_2P_3 was determined to be hexagonal, a_o = 6.13 Å, Co = 11.08 Å (5).

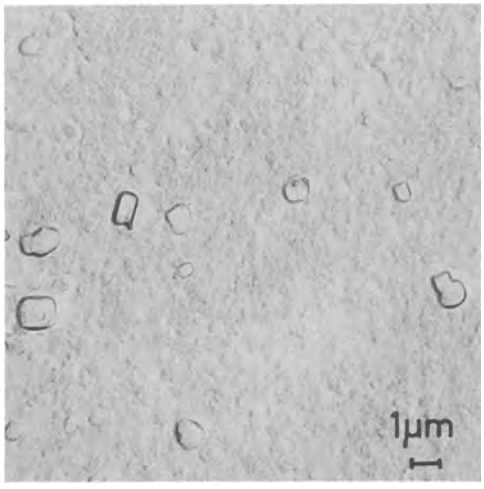

Fig. 3. Electron micrograph of direct-C replica of surface of same wafer as shown in Fig. 2b after extended etching in HF.

the precipitate by electron diffraction. The crystal structure has been reported elsewhere (5). Electron microscope examination of the bulk prepared Au_2P_3 showed it to be unstable in the vacuum under intense electron beam irradiation, leaving Au as residue after a short time exposure in the electron beam. A similar instability was noted also for the precipitate in the diffused wafers.

In addition, the bulk prepared Au_2P_3 and the precipitates both were soluble in HF. The similarity in decomposition under electron irradiation and the dissolution in HF and, particularly, the similarity of the d-spacing as shown in Table IV in the bulk prepared Au_2P_3 and the precipitates of Fig. 2b indicate that these precipitates are indeed Au_2P_3.

Further evidence that these precipitates were located near the Si-SiO_2 interface is that on extended etching in HF the particles disappeared leaving depressions in the silicon. Most of the precipitates consisted of platelets, as is evident from the carbon replica which was made of the surface after the particles were removed on extended etching in HF, Fig. 3.

Lapped material (Group 3).—The TEM's of the fast cooled wafer, Fig. 4, show tangles or networks of dislocations. ED patterns sometimes show extra diffraction spots; however, no positive identification of any other phase was possible. Small precipitated particles can be seen at some dislocation lines, especially close

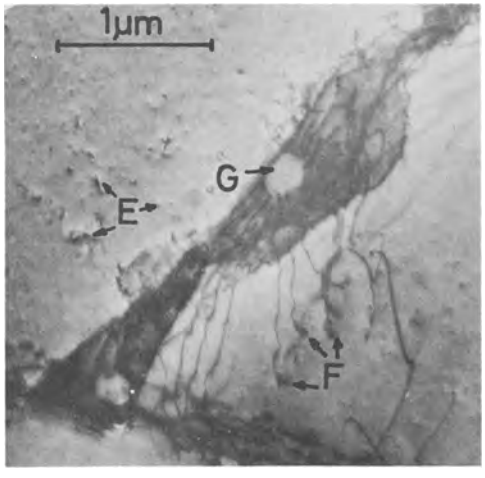

Fig. 4. Transmission electron micrograph of surface region of "damaged" Si-wafer, Au-diffused at 1235°C for 2 hr and fast cooled. Fine precipitate at E could be identified as SiC. Small particles at the emergence points of dislocations (F) and massive particles within dislocation networks (G) could not be identified.

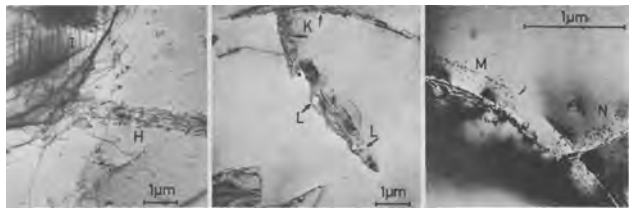

Fig. 5. Transmission electron micrographs of surface regions of damaged Si-wafers, Au-diffused at 1235°C for 2 hr and slow cooled: a (left) high phosphorus doped Si, 0.06 ohm-cm, note precipitated particles in dislocation network intersecting the wafer surface (H), while no precipitate is evident in the dislocation networks parallel to the wafer surface (I); b (center) low phosphorus doped Si, 150 ohm-cm, note precipitate in dislocation networks intersecting the wafer surface (K) and in the oxide platelets (L); c (right) high boron doped Si, 0.08 ohm-cm, note precipitate in regions close to dislocation network (M) and crack (N).

to the wafer surface. Some dislocation lines appear as broad bands of different contrast. Fine particles are distributed all over the surface, which yield a sharp electron diffraction ring pattern for cubic SiC.

Heavily damaged material with high doping (Group 4).—In order to observe the effect of high phosphorus and boron doping on the gold diffusion, the wafers of group 4 were prepared and examined. TEM's typical of the samples from this group are shown in Fig. 5. In the phosphorus-doped specimens of both high and low concentrations, Fig. 5a and b, precipitates were found at dislocations inclined to the surface while there was little or no precipitation evident at dislocation networks parallel to the surface. Precipitation was also observed near or at the oxide platelets shown in Fig. 5b. The formation of these oxide platelets has been described by Stickler and Booker (6).

Many fine particles were observed near dislocation networks inclined to the silicon surface and near cracks in the wafer with high boron doping as is shown in Fig. 5c. Although the gold diffusion was the same there was a striking difference in the highly boron-doped and phosphorus-doped specimens. In the boron-doped silicon the precipitates were formed not only in the dislocation networks but also in the bulk near these networks. In the phosphorus-doped wafers precipitates occurred only at the dislocation networks. The precipitates in either the boron-doped or the phosphorus-doped samples could not be identified.

Phosphorus diffused material (group 5).—Wafers of group 5 were phosphorus diffused in order to obtain higher doping than was available in the uniformly doped material in group 4 and to make a preliminary investigation of the mechanism of P_2O_5 gettering. TEM examination of the phosphorus diffused material showed the diffusion induced dislocation networks (12), but relatively few precipitates, none of which could be conclusively identified.

Figures 6a and b are TEM's of the gold diffused and P_2O_5 gettered material. These TEM's are of the surface region and were taken through the thin phosphosilicate glass. The dislocation network induced by the shallow phosphorus diffusion which occurs during the gettering is evident. Numerous small dark particles between the dislocation network and larger geometrically shaped particles can be seen in Fig. 6b. An identification of these precipitates could not be made by the transmission electron diffraction technique.

Discussion

By TEM methods not much difference in the Au-diffused wafers was observed in the appearance of the free surface and the oxidized surface. This is understandable, since the gold diffusion times and temperatures were such that the gold should have diffused all the way through the wafers. The free surface, furthermore, was always covered with a thin

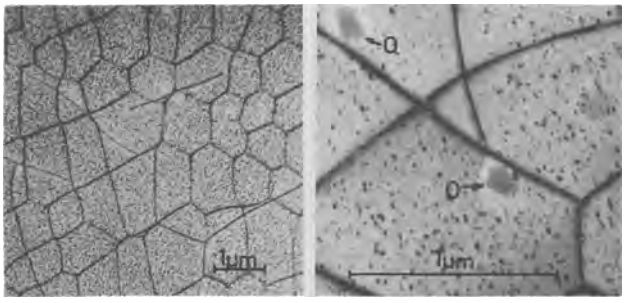

Fig. 6. Transmission electron micrographs of surface region of Si-wafer Au-diffused at 1235°C for 2 hr, fast cooled, and P_2O_5-gettered at 1040°C for 15 min: a (left) dislocation network generated during gettering step; b (right) same area at higher magnification, note fine precipitated particles (small black dots) and massive precipitate (O).

oxide layer (100-1000Å) after the gold diffusion. Thus, there was on both sides of the wafer a Si-SiO_2 interface at which precipitation could occur, and a relatively equal concentration of gold near these surfaces may be expected. This thin oxide layer apparently is formed from traces of H_2O introduced with the $AuCl_3$. Variation in thickness of the oxide, amount of thermal etching, and perhaps the formation of SiC may be due to variations in the residual gas atmosphere.

Most of the investigations were made in the region comprised of the SiO_2 film, the Si-SiO_2 interface, and a Si layer about 0.5 μm thick. The Au_2P_3 precipitates identified in group 2 wafers were found to be present at or near the Si-SiO_2 interface. It is likely that, during the slow cooling from the diffusion temperature, the gold diffused out of the silicon toward the surface, reacted with phosphorus, and precipitated at the interface. The redistribution of appreciable quantities of gold to the surface can be understood in view of the decreased solubility with decreasing temperature, the relatively high diffusion coefficient at temperatures as low as 750°C, and the deactivation of Au by the formation of Au_2P_3. However, an approximate calculation shows that insufficient phosphorus was present in the starting material to account for the amount of the precipitate observed. It is possible that these group 2 wafers were accidentally phosphorus contaminated during the heat-treatment employed to produce dislocations. Phosphorus contamination from certain lots of quartz tubing has been observed in our laboratory.

Precipitates were also observed in all other groups at the Si-SiO_2 interface and at or near the oxide platelets extending into the heavily damaged material. They were also observed at or near dislocations and cracks, predominantly at those intersecting the surface. Some effects of the diffusion treatment could also be observed in the bulk at the loop-type defects. These precipitates could not be identified because there was not enough material to produce an ED pattern. Only SiC near the surface especially in the wafers of groups 3 and 4 could be positively identified. The presence of SiC in these groups may be a result of the reaction of the silicon with residual oil vapors from the seal-off system.

The unidentified precipitates are likely to be gold or gold compounds since they occur only after the gold diffusion. They are more pronounced in the slow-cooled wafers. In the slow-cooled wafers the gold has time to diffuse to defects, interfaces, and to form precipitates.

We have been unable to reproduce the conditions for the formation of the large precipitate in subsequent experiments. Precipitates were formed in other phosphorus doped specimens (Fig. 6a) but these were small, presumably because of a greater number of dislocation sites for precipitation. They could not be identified. Wafers of 0.01 ohm-cm phosphorus doped silicon with all surface damage removed by polish etching were gold diffused at 1235°C for 2 hr and slow cooled. Large precipitates were observed but not nearly as bulky as those seen in Fig. 2c and again they could not be identified from the few diffraction spots obtained. Although we have been unable to reproduce the conditions for formation of the massive, identifiable Au_2P_3 precipitate as formed in the one experiment in several wafers, it may be present in other specimens in smaller quantities and crystal sizes.

Both in the heavily dislocated wafers of groups 3 and 4 and in the gettered wafers of group 5 precipitates were prominent at dislocations which intersected the surface. Since diffusion proceeds faster along dislocations, these dislocations may provide a convenient "exit" for the gold during the slow cooling or gettering and precipitates may form at or near their terminus.

The precipitation of gold is expected to affect the determination of gold solubility and the determination of the electrical effects in silicon devices. Most determinations of the solubility of gold in silicon have been performed by tracer or activation analysis. These techniques determine the total amount of gold in the silicon and do not differentiate between the electrically active and precipitated gold. Thus, when the change in resistivity of gold diffused silicon is calculated from the total amount of gold as Wilcox, LaChapelle, and Forbes (1) have done, agreement between calculated and measured values need not exist. On the other hand, Bemski (7) and Collins *et al.* (9) both found agreement between electrically determined values of gold concentration and concentrations determined by neutron activation analysis and radioactive tracer analysis, respectively.

Our value for concentration of electrically active gold obtained at 1235°C corresponds more closely with that calculated from the change in resistivity data of Wilcox *et al.* (1) than with that of Collins *et al.* (9). However, our diffusions were from a gaseous source with a concentration of 10^{15} cm^{-3} rather than from a solid. The limit of solid solubility of gold in silicon may not have been reached in our experiments and, consequently, only a relatively small fraction of the gold may have been available for precipitation.

Summary and Conclusions

Precipitates occur in silicon wafers which are gold diffused at 1235°C for 2 hr and either fast or slow cooled. These precipitates are more prevalent in slow-cooled than in fast-cooled wafers. The precipitates occur mainly at or near defects, including dislocations and loop-type features, and at the Si-SiO_2 interface. In one group of wafers large regular-shaped precipitates at the Si-SiO_2 interface were identified as Au_2P_3 by a comparison of ED patterns from the precipitates and x-ray diffraction patterns from Au_2P_3 prepared in bulk in the laboratory. The conditions under which large Au_2P_3 precipitates are formed in silicon are not yet fully explored. The electrically active concentration of gold introduced by our diffusions at 1235°C for 2 hr was about 10^{16} cm^{-3}. The $AuCl_3$ diffusion process can be used to obtain gold concentrations less than those obtained by elemental diffusion methods.

The Occurrence and Identification of Precipitates in Zinc-Diffused GaAs

J. F. Black

The Bayside Laboratory, research center of General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Both submicroscopic and microscopically visible precipitates in zinc-diffused GaAs have been studied by means of conventional optical microscopy of etched samples, infrared transmission microscopy of polished samples, and electron probe microanalysis. The microscopically visible precipitates were discrete particles located principally at grain boundaries in polycrystalline samples and at subgrain structures in "single" crystals, and they were identified as zinc rich by the electron probe. The submicroscopic precipitates were concluded to be zinc rich by arguments based on the existence of zones depleted of these precipitates around the larger visible particles. Samples in which part of the diffused zinc was present as submicroscopic precipitates were found to cause attenuation of IR far greater than that caused in samples in which all of the zinc was in solution.

It has recently been established (1, 2) that the diffusion of zinc into GaAs can, under certain conditions, cause the appearance of submicroscopic precipitates. It was, however, not possible from the evidence presented to establish that these precipitates were zinc rich. This is important because the occurrence of zinc-diffusion-induced precipitation in GaAs cannot be completely understood until these precipitates have been identified. There is yet no direct proof of the precipitation of zinc in GaAs, nor for that matter in any other III-V compound, as a result of diffusion with zinc. Although Gershenzon and Mikulyak (3) and others (4) have reported the formation of "zinc" precipitates in III-V compounds, their identifications were based on circumstantial evidence.

The current work was intended to provide direct proof of the major presence of zinc in precipitates induced in GaAs by the indiffusion of zinc. By means of the electron probe microanalyzer, visible precipitate particles formed in GaAs by the indiffusion of zinc were positively identified as zinc-rich. In addition, infrared (IR) transmission microscopy of precipitate structures and the study of etch figures developed by a dislocation etchant provided confirming evidence that the submicroscopic precipitation was also zinc-rich. Finally it was demonstrated that, for equal zinc concentrations, samples containing part of their zinc in the form of submicroscopic precipitates were much more effective in attenuating IR radiation than samples in which the zinc was present only as dissolved ionized acceptors.

Experimental Procedures

Because precipitates formed at grain boundaries are usually larger and therefore easier to observe and identify than those formed within single crystals the bulk of the data presented herein were obtained on polycrystalline GaAs. This polycrystalline material was undoped n-type with n $\sim 5\times10^{17}/cm^3$. The single crystals used in this investigation were Cd-doped with a resistivity of $\sim$ 1 ohm·cm (p $\sim 5\times10^{16}/cm^3$) and a dislocation density of 10,000-50,000/cm^2. P-type crystals were used for simplicity in making Hall effect measurements after zinc diffusion (5), for later comparisons with chemical (zinc) analysis. Cadmium-doped material was selected since the Cd diffusion coefficient was sufficiently small compared with that of zinc to preclude any change in the background p-doping during the indiffusion of zinc. Prior to diffusion, wafers were ground and lapped flat and parallel with No. 600 alumina grit and then carefully polished with 0.3 and 0.05 micron alumina to remove the damage introduced by the diamond wafering saw. Single crystal test samples processed by this technique and annealed at 1000°C for 2 hr showed no significant increase in dislocations as determined by etch pit counting. The final thickness of both single crystal and polycrystal samples was 0.030 $\pm$ 0.002 in. Diffusion was carried out in evacuated sealed quartz capsules of 50 cm^3 volume containing 10-50 mg of pure zinc and 1g of finely powdered GaAs.

Diffusion was conducted at fixed temperatures ranging from 900° to 1100°C. Unless otherwise indicated, all diffusions were terminated by slowly withdrawing the capsule from the furnace over a period of 2 min and then immersing it in a bucket of water. Care was taken during the diffusion cycle to keep the end of the capsule containing the zinc at a temperature at least 10°C below that of the samples and the powdered GaAs.

Samples diffused at the upper extremes of temperature and zinc vapor concentration usually showed clear evidence of surface melting, especially in polycrystalline samples. The surface melting was spotty and in polycrystalline samples showed a strong preference for the grain boundaries. Cross sectioning of samples showed that even in the worst cases (50 mg Zn at 1100°C) surface melting penetrated no more than 5μ at grain boundaries and less than 2μ elsewhere beneath the original surface of the sample.

After diffusion, samples to be viewed in a direction normal to the plane of diffusion were lapped so that the surface of section was approximately in the center plane of the original sample. During final polishing a slowly rotating lap was used with 0.05μ alumina in order to keep as few precipitate particles as possible from being swept away by the lapping action.

IR transmission microscopy was generally performed on polished samples, since etching enhanced surface features such as scratches and produced grooves at grain boundaries which interfered with the study of the subsurface precipitate structures. Samples were examined under transmitted IR illumination by means of an IR image converter adapted to the ocular of an inverted stage metallographic microscope. Observations of IR transmission through polished profile sections were made with the aid of slotted masks positioned and fixed under the IR microscope so that only the diffused region of the sample was exposed to the illumination. Without the use of a mask, IR radiation passing through the relatively transparent undiffused portion of the section made it difficult to assess the true optical character of the diffused layer. Infrared photomicrographs were obtained with Eastman Kodak Type I-M Spectroscopic Plates.

P-n junctions were revealed by swabbing samples with a freshly prepared solution of 1 part HF, 5 parts HNO_3, 3 parts 1% $AgNO_3$ solution for 10 to 30 sec, quickly followed by a rinse in deionized water. In addition to p-n junctions, this etch revealed grain boundaries and p + p junctions. An NaOH-H_2O_2 etchant which was specific to a {111} Ga surface was also used (1 part 30% H_2O_2-5 parts 2% NaOH solution). Previous investigation (1) has shown that in the presence of submicroscopic precipitation in zinc-diffused GaAs the NaOH-H_2O_2 solution develops a {111} Ga etch structure of densely packed (10^7/cm^2 and higher) shallow triangular etch pits (see Fig. 1).

Experimental Results and Discussion

Optical effects of the submicroscopic precipitates.— It was found that for a given zinc content, diffused samples containing submicroscopic precipitates caused IR attenuation far greater than that which could be caused by free-carrier absorption alone. Figure 1a is a photomicrograph of an etch structure typical of a diffused sample in which precipitation has occurred. In Fig. 1b the same region is shown by transmitted infrared (0.9-1.2μ) where the thickness of the section is 75μ. Figure 1c shows a typical zinc concentration profile determined by electron probe microanalysis.[1] Note that the boundary of the layer containing the submicroscopic precipitation (see Fig. 1a) coincides with the boundary of the IR opaque layer (Fig. 1b), and note also that the diffusion profile in Fig. 1c shows that the critical zinc concentration for precipitation is about 1x10^{19} atoms/cm^3. The dashed line at the tail end of the zinc profile in Fig. 1c is the zinc concentration gradient estimated from the probe analysis. However, because the zinc concentration in this region was close to the limit of the probe sensitivity (which was about 5x10^{18} zinc atoms/cm^3), the dashed line is probably not the true zinc profile. Measurements of p+p and p-n junctions in diffused n-type

[1] The penetration profile of Fig. 1 is convex toward the origin rather than concave as is generally the case for zinc in GaAs. Convex profiles, which have been observed before at very high zinc concentrations (1a) suggest that the diffusion coefficient is decreasing with increasing zinc concentration. See ref. (12) for a more complete discussion.

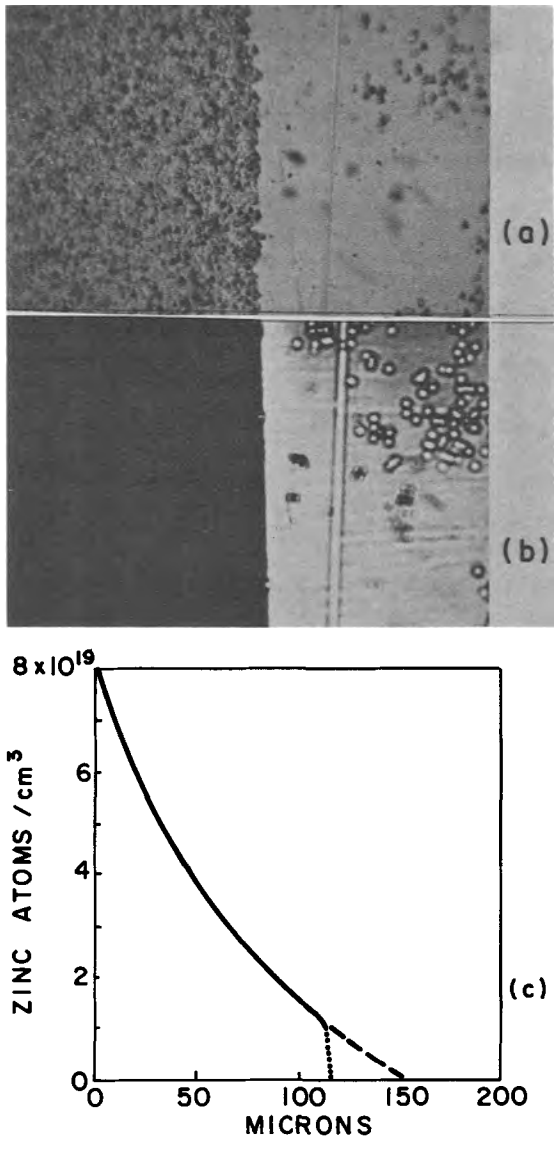

Fig. 1. GaAs single crystal diffused at 900°C for 2 hr from 10 mg zinc (see text for details of diffusion): (a) (111) Ga, plane of cross section viewed by conventional optical microscopy after etching with NaOH-H_2O_2; (b) same area viewed under transmitted IR; (c) zinc penetration profile of the diffused layer determined from point by point Zn$K\alpha_1$ scan. The dashed line and the dotted line are explained in the text.

samples suggest that the dotted line is closer to the actual shape of the zinc profile in this region. The high attenuation of IR shown in Fig. 1b was not caused by scattering of IR from the densely packed etch pits, since the sample was just as opaque to IR in its polished condition. The etched sample is shown instead of the polished sample because the etching provides convenient fiducial marks to correlate the two photographs; for instance the scratch mark and the array of etch pits (the pits appear as small dark halos in Fig. 1b).

For purposes of comparison, a sample of zinc-(melt)-doped GaAs of the same thickness as the slice of Fig. 1b but doped to 3.7x10^{19} zinc atoms/cm^3 (free hole concentration 4.0x10^{19}/cm^3) was examined under the same incident IR intensity using the masking technique described under Experimental Procedures. It was expected that the melt-doped sample would be quite opaque to IR because of its high doping level (high free-carrier absorption) compared to the diffused sample; instead it was moderately transparent.

From the known absorption coefficient of the zinc-melt-doped sample (which was about 500 cm^{-1}

averaged over 0.9-1.2μ), the "absorption" coefficient at the boundary of the diffused region in Fig. 1b was determined to be larger than 500 cm^{-1}. If only free-carrier absorption were acting, a zinc concentration of $1x10^{19}$ atoms/cm^3 (the boundary concentration) would have produced GaAs with $\bar{\alpha}$ of only 100 cm^{-1} or so (6). Thus it appears that the precipitation present at the boundary of the diffused layer is sufficient to cause excess attenuation amounting to 400 cm^{-1}.

It is clear that the IR attenuation of the thin section shown in Fig. 1b does not follow the zinc concentration profile, *i.e.*, the IR attenuation appears just as strong at $1x10^{19}$ atoms/cm^3 (the boundary concentration) as it does at $8x10^{19}$ atoms/cm^3 (the surface concentration). If the submicroscopic precipitates were zinc rich, one would expect that the amount of precipitate present, and hence the degree of IR absorption, would increase at the higher zinc concentrations. Such an increase in IR absorption could, however, only have been observed if the sample were thin enough so that at least part of it, presumably that part near the boundary, transmitted some IR. Even when the profile section was thinned to a few hundredths of a millimeter, the diffused portion was still completely opaque to IR. For the amount of zinc contained near the boundary of the diffused region [$1x10^{19}$ atoms/cm^3 $\equiv$ 0.02 w/o (weight per cent) Zn] such strong attenuation (absorption + scattering) is surprising and implies at least a very fine particle size for the precipitate well dispersed throughout the matrix.

The optical properties of the diffused layer have important consequences relative to the fabrication of injection electroluminescent devices. The presence of a highly attenuating layer such as shown in Fig. 1b can seriously reduce the external quantum efficiency and radiant power output of the electroluminescent diodes. On the other hand such a layer can be useful in absorbing emissions from p-n junctions in optoelectronic devices to keep such emissions from affecting other light-sensitive parts of the device.

Identification of the visible precipitates.—The chemical identification of precipitates in solids is currently most conveniently accomplished by *in situ* analysis with the electron probe microanalyzer (7). To execute the analysis it is necessary to develop precipitate structures with particles large enough to be seen under the microscope and large enough to be seen and analyzed by the electron probe. In practice it was found that particles a few microns in diameter were of sufficient size for these purposes.

Extended diffusion of polycrystalline wafers of GaAs caused them to become saturated with zinc, producing submicroscopic precipitation throughout the sample as well as causing discrete microscopically visible precipitate particles to appear along grain boundaries or twin boundaries. Figure 2 shows a series of photomicrographs of one of a number of areas found in a polycrystalline wafer saturated with diffused zinc. This particular area was selected because it contained a number of discrete precipitate particles at two grain boundaries, and a grain whose surface of section was close enough to a {111} Ga plane to allow the study of defect etch structures developed by the NaOH-H_2O_2 etchant. Figure 2a is a photomicrograph of the as-polished sample, showing particles up to several microns in diameter strung out along two of three intersecting boundaries. All or part of the many particles have been swept away during polishing, and this is the reason for the dark appearance of particles. Figure 2b is an electron probe topograph of the same area, showing the ZnKα_1 characteristic x-ray emissions excited by the focused (about one micron diameter) electron beam. Figure 2c is the same area as Fig. 2a and 2b but a higher magnification, after etching the sample with NaOH-H_2O_2 solution. A comparison of Fig. 2a and 2b shows that without doubt the precipitate particles are zinc rich. Note that one of the

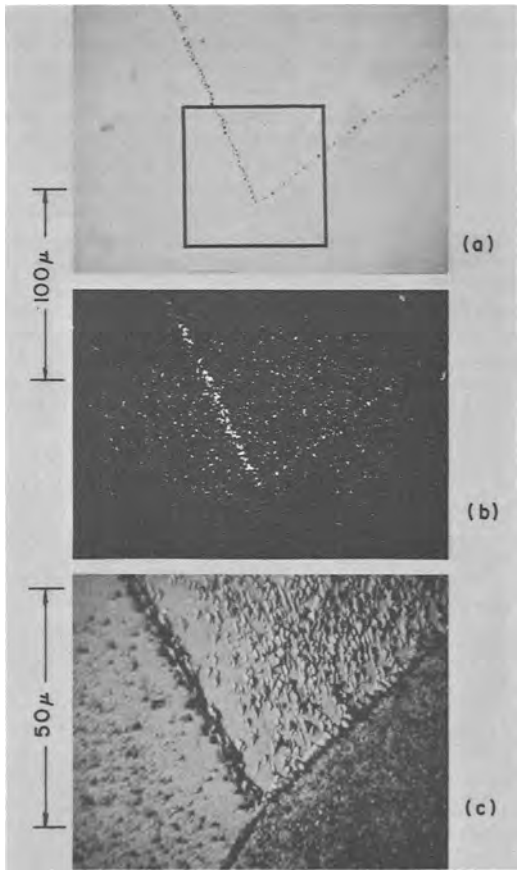

Fig. 2. Cross section of polycrystalline GaAs diffused from 10 mg of zinc at 900°C for 48 hr: (a) as-polished sample; (b) same area shown by CRT display of electron probe scan for ZnKα_1 radiation. The white spots not in the V represent the electronic noise background during this scan; (c) area outlined in (a) after etching with NaOH-H_2O_2.

three grain boundaries is not seen in Fig. 2a or 2b because it is free of visible precipitates and note also that of the other two boundaries the one on the left is definitely more heavily decorated. This marked difference in the amount of precipitation between the three grain boundaries is consistent with the different degrees of mismatch in the contiguous lattices along each of these boundaries (8), indicated by the distinctly different etch figures in each grain.

The etch structure of Fig. 2c is of particular interest. The grain at the top shows a triangular pit etch structure which is typical of submicroscopic precipitation. Because the surface of section is about 10° from the <111> Ga direction, the etch pits in this grain appear as strongly skewed triangles. Notice that there is a corridor along the grain boundary at the upper left that is relatively free of etch pits. The significance of this etch pit free corridor will be discussed in detail later.

Prolonged diffusion with zinc resulted in larger and more readily characterized particles. These particles were best observed in nearly single crystals, *i.e.* crystals with small-angle grain boundaries. Large precipitate particles formed in a region of small angle-grain boundaries in an otherwise single crystal are shown in Fig. 3. Instead of comparing an optical photomicrograph with the ZnKα_1 scan, as in Fig. 2, we compare a backscattered electron topograph (Fig. 3a) with the ZnKα_1 scan (Fig. 3b). The backscattered electron topograph of Fig. 3a reveals structural details of the kind that would be shown by a reflection optical micrograph. In this case we have much stronger patterns to compare than before (notice that the magnification is the same as in Fig. 2a and 2b). Once again the correspondence of zinc-rich regions with

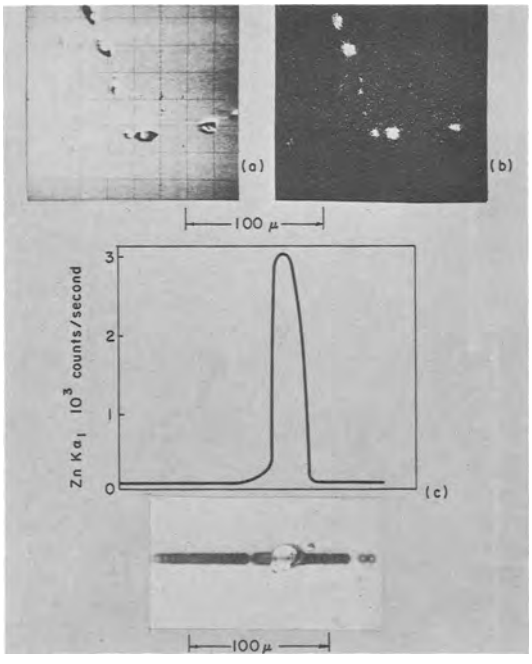

Fig. 3. Precipitates in region of small angle grain boundaries of "single" crystal GaAs diffused for 16 hr at 1100°C from 50 mg of zinc. Sample is sectioned in plan view, i.e., parallel to plane of diffusion, and the surface viewed is approximately coincident with midplane of original sample. (a) Area shown by backscattered electrons; (b) same area shown by CRT display of ZnKα_1 scan; (c) point by point ZnKα_1 scan of large precipitate particle, the dark circular spots, most of which overlap, mark the course of the electron beam.

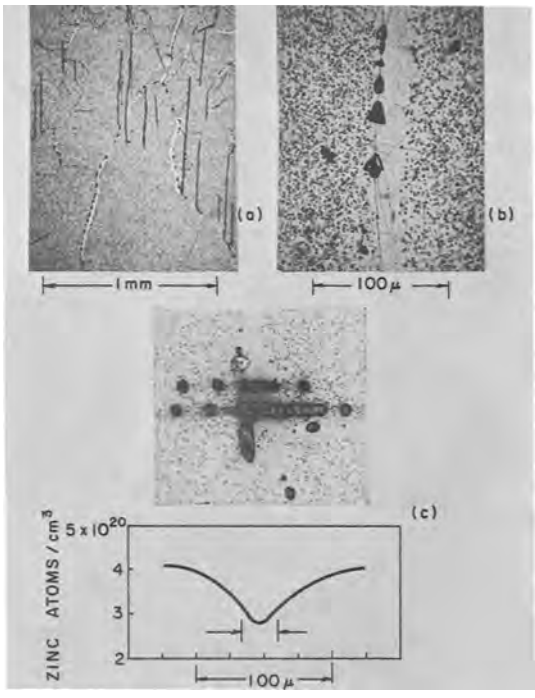

Fig. 4. Precipitates along small angle grain boundaries in a GaAs crystal diffused for 16 hr at 1100°C from 50 mg of zinc; sample has been etched with NaOH-H_2O_2. (a) View at low magnification; (b) high magnification view of one of the boundaries showing details of the structure; (c) zinc concentration profile of boundary determined by point to point ZnKα_1 scan.

visible discrete precipitate particles is unmistakable. A point-by-point ZnKα_1 scan made across an especially large particle is shown in Fig. 3c. Note the sharp and considerable increase in zinc counting rate that was recorded as the particle was scanned by the electron beam. By comparing the counts obtained on a pure zinc standard (5200 counts/sec) with counts obtained on these visible precipitates (3000 counts/sec), it was established that although the precipitates were not pure zinc, they were composed of major proportions of zinc. Electron probe scans for arsenic and for gallium showed these elements to be present, but at relatively low levels compared with the surrounding GaAs matrix.

The photomicrographs of Fig. 4 show small-angle grain boundaries in a zinc-diffused "single" crystal of GaAs. This crystal was oriented in the <111> direction, and the surface observed is a {111} Ga plane parallel to the plane of diffusion. The sample has been etched with NaOH-H_2O_2 solution, producing the triangular pit etch structure indicative of submicroscopic precipitation. Besides the small densely packed etch pits, the etchant has also produced many dark voids along the grain boundaries. These dark voids are the regions formerly occupied by the visible precipitates which etched away faster than the surrounding zinc diffused GaAs. (The size and shape of these voids has been exaggerated by the etchant.) Notice the corridors essentially free of etch pits running along many of the boundaries, especially those which contained appreciable numbers of discrete particles. Note also the similarity of the corridor in Fig. 4b to the one in Fig. 2c.

Figure 4c shows an area of the sample that has been analyzed by the electron probe. This analysis was performed after the sample has been repolished and lightly etched since the relatively heavy etching shown in 4a and 4b would have produced undesirable scattering in the analytical results. A region free of visible precipitates was chosen to avoid the possibility that precipitate voids or residual pockets of zinc rich precipitate would interfere with the analysis. Figure 4c shows that the boundary of the etch-pit-free corridor corresponds to a zinc concentration of about $3x10^{20}$ atoms/cm^3, while in the corridor itself the concentration is only slightly less. The zinc concentration in the surrounding grain is about $4x10^{20}$/cm^3. Thus only a small part of the diffused zinc appears to be tied up as submicroscopic precipitates; a result which is in agreement with other studies of zinc-diffused GaAs(1,9).

Identification of the submicroscopic precipitates.— The following argument is presented, along with substantiating evidence, to show that the existence of etch-pit-free zones immediately adjacent to zinc-rich microscopically visible precipitate particles is strong evidence that the submicroscopic precipitation in diffused single crystals is zinc rich.

In a given polycrystalline solid solution the formation of precipitates proceeds in two stages (8): (*i*) rapid nucleation of precipitates at grain boundaries, initially forming submicroscopic particles but very soon producing relative large particles; (*ii*) slow nucleation and growth of submicroscopic precipitates in the rest of the system. It is well-established that, in a given solid system, at fixed temperature, whenever chemically identical precipitates exist with widely different particle sizes, one of which is very fine (submicroscopic), the larger particles grow at the expense of the smaller particles (10). The driving force is the excess energy of the fine particles due to their high surface-to-volume ratio.

Since the densely packed etch pits in zinc-diffused GaAs are associated with submicroscopic precipitation (1), the disappearance of the etch pits must therefore mean the disappearance or dissolution of the precipitates. The submicroscopic precipitates shed their excess energy by dissolving and, in so doing promote, the growth of the visible grain boundary precipitates. Then, since the visible precipitates are zinc rich, it follows that the submicroscopic precipitation is also zinc rich. The tendency of internal crystal boundaries

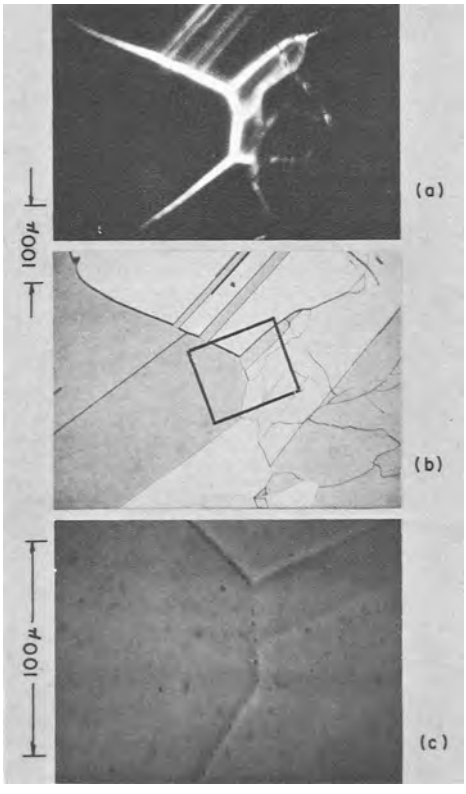

Fig. 5. Polycrystalline GaAs diffused for 7 days at 900°C from 10 mg of zinc; (a) grain boundaries revealed by transmitted IR; (b) same area viewed by conventional optical microscopy after etching with NaOH-H_2O_2; (c) area outlined in (b) after repolishing to show the discrete precipitate particles.

to "absorb" precipitates from the bulk of the crystal is well known in solid-state science (8).

It was noticed that the grain boundaries, along with their precipitates, were sometimes located near the center of the etch pit free corridors, but they were more often located toward one side of the corridor as in Fig. 4b. This type of grain boundary precipitate structure indicates that many of the grain boundaries have moved during the course of precipitation (11). This is very interesting because it implies Ga and As diffusion rates that are several orders of magnitude higher than the accepted values for pure GaAs (12).

If the submicroscopic zinc-rich precipitates are dissolving and promoting the growth of visible grain boundary precipitates, as has been postulated above, then a corridor of IR transparent material, corresponding to the corridor free of etch pits, should appear along the grain boundaries. (Recall the relative IR transparency of precipitate-free zinc doped GaAs discussed earlier, with regard to Fig. 1b.) Such an IR transparent corridor is seen in one of the series of photomicrographs of Fig. 5. These photos show a region of a polycrystalline sample diffused with zinc at 900°C for 7 days. Figure 5a is a view of the polished sample under transmitted IR radiation, and Fig. 5b shows the grain boundary structure of this same region. Figure 5c is a view, at high magnification, of the region enclosed by the square in Fig. 5b, after repolishing to show the precipitate particles. The structure shown in Fig. 5a was recorded after the sample had been thinned to a few hundredths of a millimeter. To make sure that the transmitted light was not due to cracking of the sample at the grain boundaries, a separate exposure was made using photographic plates sensitive to the visible spectrum only (Eastman Kodak Type IF). No transmission structure could be seen in these plates, confirming that the structure of Fig. 5a was due to the selective IR transparency of the grain boundary region. None of the grains in the area shown in Fig. 5 had orientations close enough to a <111> Ga orientation to develop the etch structure associated with submicroscopic precipitation, so it was not possible to correlate etch pit free corridors with IR transparent corridors in this sample. Nevertheless it is clear from the evidence presented so far that the correlation exists.

Gershenzon and Mikulyak (3) have described IR structures similar to Fig. 5a in zinc-diffused GaP which, after diffusion, had been annealed at high temperatures in evacuated capsules. They attributed their structures to preferential out-diffusion of zinc along grain boundaries. In the present case, however, the IR transparent grain boundaries cannot be attributed to the out-diffusion of zinc since a zinc atmosphere was maintained throughout the entire diffusion period.

Concluding Remarks

The results of this investigation lead to the conclusion that the submicroscopic precipitation that has been found to occur in heavily zinc diffused GaAs (1) is zinc rich. If this conclusion is to be accepted, however, some interesting questions are raised. For example, how can the existence of zinc-rich precipitates in GaAs diffused with $1x10^{19}$ zinc atoms/cm^3 be reconciled with prior investigations which appear to show that zinc is soluble, *i.e.*, gives one free-charge carrier for every zinc atom present (5, 13) at zinc concentrations much greater than $1x10^{19}$ atoms/cm^3? Recently, comparisons of the free-carrier concentration and the zinc concentration in diffused samples containing intense submicroscopic precipitation have shown that in many samples the amount of zinc tied up as precipitates may not be more than 10% of the total amount of zinc indiffused (1, 9). In this case precipitation would escape detection by the comparison of chemical analysis and free-carrier concentration (Hall effect) of the usual accuracy and precision. In fact, were it not for the studies of etch structure, IR transmission, and x-ray (anomalous) transmission, such as are reported in this and other recent publications (1-4), the existence of precipitates in zinc-diffused GaAs would still be suspect. If, however the precipitates constitute only a small fraction of the indiffused zinc, it is difficult to understand the very strong IR attenuation they cause.

In addition, it is important to note that these zinc-rich precipitates have not been observed in crystals doped from the melt; they have been found to appear only on the introduction of zinc into GaAs by diffusion. This implies that diffusion induced dislocations might be necessary for precipitation. In spite of some evidence to the contrary (1), it is this mechanism that is most consistent with all of the experimental facts.

Stresses due to the presence of precipitates usually cause an enhancement of diffusion rates. If, in addition, the precipitate contains the diffusant as a major constituent, the effect on diffusion rates becomes even more complicated. None of the accepted theories of zinc diffusion in GaAs are based on experiments in which it was established that the samples were free of diffusion induced precipitates. Thus it would appear that the current theories (12) should be re-examined. On the other hand, the excellent agreement between current theory and extensive quantitative studies of the diffusion of zinc into GaAs constitutes a strong argument against precipitates having a significant effect on the diffusion process. These conflicting viewpoints could be resolved if the diffusion induced precipitates were not present during the diffusion period. If precipitation occurred onto diffusion induced dislocations only during cooling (or quenching) or afterward then the precipitates would have no effect, unless the sample were re-diffused.

Acknowledgments

The author is indebted to W. Sutkowski for the electron probe analyses, to J. Hurley for his assistance

in some of the experimental work and to Dr. L. Bodi and Dr. J. Bilello for helpful suggestions in reviewing this manuscript.

Impurity Redistribution in a Semiconductor during Thermal Oxidation

Wen H. Chen[1]

Hughes Aircraft Company, Culver City, California

and Wen S. Chen

Boeing Scientific Research Laboratory, Seattle, Washington

ABSTRACT

A general review of mathematical treatments on this redistribution phenomena has been made and discussed. A series method is developed and exact solutions describing the redistributed impurity concentration profiles in both the oxide and the semiconductor can be given. Boundary conditions of diffusion equations are discussed according to different physical situations. Special cases are treated for three initial impurity concentration profiles in silicon: Gaussian, complementary error function, and uniform. Experiments were performed on boron-doped silicon by wet oxygen at 1200°C. The initial concentration profile was a Gaussian, and the segregation coefficient was found to be about 1.8.

It is well known that impurities will be redistributed near the oxide-semiconductor interface during the thermal oxidation process. A model of the redistribution process was developed by Atalla and Tannenbaum (1). Their model was based on the case where the diffusion coefficient of impurities in the oxide was negligibly small. A solution of the diffusion equation for uniformly doped silicon thas been given by Cooper, Doucette, and Mehnert (2). Leuenberger (3) has shown that boron is depleted in the silicon near the oxide-silicon interface after the redistribution process and that a p-n junction is formed in boron-phosphorus, compensated, p-type silicon. Grove, Leistiko, and Sah (4) and Ku (5) treated this problem with consideration of diffusion of impurities in both the oxide and silicon. Grove *et al.* assumed that impurity concentration was kept constant at the outer oxide surface during the redistribution process. Their solution agrees with that of case II in Ku's study where the same boundary condition was assigned. Ku, in his case I, assumed that the outer oxide surface was impermeable. The result he obtained using this boundary condition, is the same as the one obtained by Cooper *et al.* (2). Mathematical treatment for a case of nonuniformed doped silicon was first made by Kato and Nishi (6). The impurity profile before redistribution was a complementary error function. An analytic solution to describe the redistributed concentration profile was given approximately in an integral form by means of the method of Green's function. Cave (7) simplified the problem by assuming that the oxide growth is linear instead of parabolic and the initial profile was a simple exponential function of coordinate. Both Cave and Kato utilized Atalla's model in which the diffusion in the oxide was assumed to be negligibly small and therefore the redistribution process in oxide and the boundary condition at the outer oxide surface were completely neglected in their mathematical formulation. In general, the diffusion process in the oxide and the boundary condition at the outer oxide surface are factors which affect the redistribution of impurities in the semiconductor, especially when the diffusion coefficient in the oxide is not negligibly small.

This paper develops a series method to obtain the exact solutions of the diffusion equations with appropriate boundary and initial conditions which describe

[1] Formerly with Boeing Company, where most of this work was done. Present address: United Aircraft Research Laboratories, East Hartford, Conn.

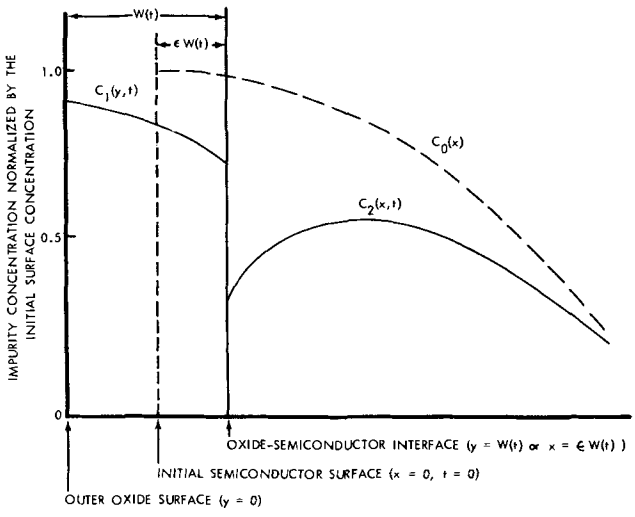

Fig. 1. Diagram of impurity-concentration profiles following the thermal-oxidation process and the oxide layer thickness and location of the oxide-semiconductor interface with respect to the initial silicon surface at time t. $C_0(x)$ is the initial impurity concentration profile in the semiconductor, $C_1(y, t)$ is the impurity concentration profile in the oxide layer at time t, and $C_2(x, t)$ is the impurity concentration profile in the semiconductor at time t.

the redistribution process. Various boundary conditions at the outer oxide surface have been assigned and discussed according to different physical situations. Solutions which describe the redistributed impurity concentration profiles in the oxide and semiconductor will both be given. The initial profile before the redistribution is a constant or a Gaussian or a complementary error function. When boundary conditions consistent with those of Grove *et al.* and Ku and an initial uniform impurity concentration are used, the solution obtained agrees with those of Grove *et al.* and Ku.

Experiments were performed by wet oxidizing at 1200°C boron-doped silicon slices that had Gaussian impurity distributions. The impurity profile obtained after oxidation was found to agree closely with the profile predicted from the theory when a segregation coefficient of 1.8 was used.

Mathematical Formulation

The model for the redistribution of impurities in a semi-infinite semiconductor during thermal oxidation, is shown in Fig. 1. At $t = 0$, the semiconductor surface of one end is at $x = 0$ and the concentration profile is $C_0(x)$. At a time t later the oxide thickness is $W(t)$. The corresponding thickness of semiconductor material used in producing the oxide layer is $\epsilon W(t)$, where ϵ is a constant. In a silicon silicon-dioxide system, ϵ is about 0.41 to 0.44 for an amorphous oxide (1, 5). The concentration profile in the oxide is described by $C_1(y,t)$ and in the semiconductor by $C_2(x,t)$, where $C_1(y,t)$ and $C_2(x,t)$ are solutions of the diffusion equations[2]

$$\frac{\partial C_1}{\partial t} = D_1 \frac{\partial^2 C_1}{\partial y^2} \quad 0 < y < W \qquad [1]$$

and

$$\frac{\partial C_2}{\partial t} = D_2 \frac{\partial^2 C_2}{\partial x^2} \quad \epsilon W < x \qquad [2]$$

where D_1 and D_2 are diffusion coefficients of the impurity in the oxide and the semiconductor, respectively.

During the redistribution process, the outer oxide surface and oxide-semiconductor interface move, and the location of the interface is at $x = \epsilon W(t)$ or $y = W(t)$. The impurities will then be redistributed such that a discontinuity in concentration may exist at the oxide-semiconductor interface. This discontinuity is described by a segregation coefficient η, defined as

$$\frac{C_1(W, t)}{C_2(\epsilon W, t)} = \eta \qquad [3]$$

where η is a constant. A set of values of η for different elements in silicon and germanium have been estimated by Thurmond (8). This equation also defines one of the boundary conditions at the oxide semiconductor interface. Another boundary condition at the interface is that of the conservation-of-impurity during oxidation[3]

$$[C_1(W, t) - \epsilon C_2(\epsilon W, t)] \frac{dW}{dt} = -D_1 \left(\frac{\partial C_1}{\partial y} \right)_{y=W} + D_2 \left(\frac{\partial C_2}{\partial x} \right)_{x=\epsilon W} \qquad [4]$$

Two possibilities for the boundary condition at the outer oxide surface have been considered and are discussed below.

(*A*) The impurity concentration in the ambient gas is such that the oxide surface impurity concentration reaches the equilibrium value C_s instantly and remains constant throughout the growth of the oxide layer. This condition is expressed as

$$C_1(0, t) = C_s \qquad [5]$$

(*B*) If the impurity concentration in the ambient gas is such that an appreciable time is required for the equilibrium impurity concentration, C_s, to be established at the oxide surface, the rate of loss or gain of impurities through the outer oxide surface can be assumed proportional to the difference between the surface impurity concentration, $C_1(0,t)$ at any time t in the oxide, and the equilibrium concentration C_s.

This condition is expressed as

$$-\left(\frac{\partial C_1}{\partial y} \right)_{y=0} = g[C_s - C_1(0, t)] \qquad [6]$$

where g is a constant. Equations [5] and [6] with $g \neq 0$, describe the boundary condition when there is impurity transport either in or out across the outer oxide surface. Equation [6] with $g = 0$ (Ku's case I) means the outer oxide surface is impermeable that there is no impurity transport across this surface. It is interesting to note that the solution of the diffusion equation, with the boundary condition described by Eq. [6] and g large, approaches the same solution as when the boundary condition is described Eq. [5]. The two solutions approach each other at $g \to \infty$ because the boundary conditions themselves approach each other. In other words as $g \to \infty$, $C_1(0,t) \to C_s$ in Eq. [6] since the flux must remain finite.

The oxide thickness is a parabolic function of time (1)

$$W(t) = kt^{1/2} \qquad [7]$$

where k is a constant.

The importance of these boundary conditions is determined largely by the value of D_1 and k. If $(D_1 t)^{1/2}$ is small with respect to $kt^{1/2}$, the influence of the boundary condition at the outer oxide surface on the impurity profile in the silicon will be negligible. The influence will also be small on the impurity distribution in the oxide at distances greater than $(D_1 t)^{1/2}$ from the surface. Thus, if $(D_1 t)^{1/2}$ is small with respect to $kt^{1/2}$, then g in Eq. [6] can be assumed to be zero.

The initial conditions are defined by

$$C_2(x, 0) = C_0(x) \qquad [8]$$

[2] They are described by two independent coordinates x and y. They also can be described in one coordinate system, see ref. (1) and (5).

[3] See Eq. [13] of ref. (4) and Eq. [4] of ref. (1) with $D_1 = 0$ and $D_2 = D$.

where $C_0(x)$ can be a Gaussian, a complementary error function, or a constant.

Equations [1] and [2] with conditions described by [3], [4], [5], [6], [7], and [8] can be solved by letting

$$u_1 = y/2\,(D_1 t)^{1/2} \quad [9]$$

and

$$u_2 = x/2\,(D_2 t)^{1/2} \quad [10]$$

The solutions can then be written as[4]

$$C_1(u_1, t) = \sum_{n=0}^{\infty} (D_1 t)^{n/2} [a_n h_n(u_1) + A_n i^n \operatorname{erfc} u_1] \quad [11]$$

and

$$C_2(u_2, t) = \sum_{n=0}^{\infty} (D_2 t)^{n/2} [b_n h_n(u_2) + B_n i^n \operatorname{erfc} u_2] \quad [12]$$

where a_n, A_n, b_n, and B_n are constants determined from the initial and boundary conditions and the functions $h_n(u)$ and $i^n \operatorname{erfc} u$ are defined below.

$$h_n(u) = j^{3n} H_n(ju)$$

$$= (2u)^n + \frac{n!}{(n-2)!}(2u)^{n-2} + \frac{n!}{(n-4)!2!}(2u)^{n-4} + \cdots + \begin{cases} \dfrac{n!}{3![(n-3)/2]!}(2u)^3 + \dfrac{n!}{[(n-1)/2]!}(2u) & \text{for odd } n, \\ \dfrac{n!}{2![(n-2)/2]!}(2u)^2 + \dfrac{n!}{(n/2)!} & \text{for even } n, \end{cases}$$

$$n = 0, 1, 2, 3 \ldots \quad [13]$$

where $j = \sqrt{-1}$ and $H_n(ju)$ is the n^{th} Hermite polynomial of an imaginary argument. The term $i^n \operatorname{erfc} u$ is an integral of the complementary error function (12, 14), defined as

$$i^n \operatorname{erfc} u = \int_u^{\infty} i^{n-1} \operatorname{erfc} \xi d\xi \quad n = 0, \pm 1, \pm 2, \ldots \quad [14]$$

and

$$i^{-1} \operatorname{erfc} u = \frac{2}{\sqrt{\pi}} e^{-u^2}$$

$$i^0 \operatorname{erfc} u = \operatorname{erfc} u \quad [15]$$

Some properties of these functions are given in Appendix I.

Each term of the series in Eq. [11] and [12] can be an individual solution of the diffusion equation, and they are described in ref. (10). The first part of C_1 and C_2 series with coefficients a_n and b_n has been called the double power series solutions in ref. (10), and they are described in terms of the Hermite polynomials in this paper. At $t = 0$, the series A_n or B_n coefficients will vanish. For a case there is no oxide at $t = 0$, coefficients b_n can be evaluated from the initial condition alone by equating like power of x between $C_2(x,0)$ and $C_0(x)$. Coefficients a_n, A_n and B_n are then determined from the boundary conditions described in Eq. [3], [4] and either [5] or [6]. Derivations of Eq. [16] and [17] are given in Appendix II. Equations [19]-[22] can be obtained by similar derivations.

Equation [12] can be interpreted in a simple way. The first part of C_2, the series with b_n coefficient represents diffusion of the initial profile $C_2(x,0)$ if no oxide were grown because the first part is not related with the oxide growth. The second part of C_2 is a correction due to the oxide growth. An example for a Gaussian profile is presented in Appendix III.

The series in Eq. [11] and [12] may converge very slowly so that numerical analysis is tedious. The complexity of the coefficients and the amount of work required for an accurate solution is materially reduced if g can be taken as zero in the boundary condition (B). In some cases, D_1 is so small that $g = 0$ is a good approximation.

Only solutions for the boundary condition (B), when $g = 0$ and the initial profile is (a) Gaussian, (b) a complementary error function, or (c) a constant, are given below. The first part of C_2, the series with b_n coefficients has been represented in a compact form. The derivations are in Appendices III and IV.

(A) When the initial concentration profile is Gaussian, $C_0(x) = \alpha \exp(-\beta^2 x^2)$

$$C_1 = \sum_{n=0}^{\infty} (-1)^n \frac{\alpha \beta^{2n}}{n!}\left(\frac{D_2}{D_1}\right)^n \times \frac{h_{2n}(S_2)\,\eta\,(H_2^{2n-1} + I_2^{2n-1})}{h_{2n}(S_1)\,(\eta H_1^{2n-1} + I_2^{2n-1})} (D_1 t)^n h_{2n}(u_1) \quad [16]$$

$$C_2 = \frac{\alpha}{(1 + 4\beta^2 D_2 t)^{1/2}} \exp\left(-\frac{\beta^2 x^2}{1 + 4\beta^2 D_2 t}\right) + \sum_{n=0}^{\infty} \left[(-1)^n \frac{\alpha \beta^{2n}}{n!} \frac{h_{2n}(S_2)}{i^{2n} \operatorname{erfc} S_2} \times \frac{(H_2^{2n-1} - \eta H_1^{2n-1})}{(\eta H_1^{2n-1} + I_2^{2n-1})} (D_2 t)^n i^{2n} \operatorname{erfc} u_2\right] \quad [17]$$

where $S_1 = k/2\,D_1^{1/2}$ and $S_2 = \epsilon\, k/2\,D_2^{1/2}$.

$$I_a^m = \frac{1}{2 S_a} \frac{i^m \operatorname{erfc} S_a}{i^{m+1} \operatorname{erfc} S_a} - 1 = \frac{(m+2)(i^{m+2} \operatorname{erfc} S_a)}{S_a (i^{m+1} \operatorname{erfc} S_a)} \quad \text{(see [A8])}$$

and

$$H_a^m = \frac{m+1}{S_a} \frac{h_m(S_a)}{h_{m+1}(S_a)} + 1 = \frac{h_{m+2}(S_a)}{2 S_a h_{m+1}(S_a)} \quad \text{(see [A5])} \quad [18]$$

where $a = 1$ or 2, and $m = -1, 0, 1, 2, \ldots$.

(B) When the initial concentration profile is an error function complement, $C_0(x) = \alpha \operatorname{erfc} \beta x$,

$$C_1 = \frac{\alpha \eta (1 + I_2^{-1})}{\eta + I_2^{-1}} + \sum_{n=0}^{\infty} \left\{(-1)^{n+1} \frac{2 \alpha \beta^{2n+1}}{\sqrt{\pi}(2n+1)n!} \times \frac{(D_2/D_1)^{(2n+1)/2} h_{2n+1}(S_2)\,\eta\,(I_2^{2n} + H_2^{2n})}{2^{2n+1}(2n+1)!\,(I_2^{2n} - \eta I_1^{2n})\, i^{2n+1} \operatorname{erfc} S_1 + h_{2n+1}(S_1)\,(I_2^{2n} + \eta H_1^{2n})} \times [(D_1 t)^{(2n+1)/2} h_{2n+1}(u_1) + 2^{2n+1}(2n+1)!\,(D_1 t)^{(2n+1)/2} i^{2n+1} \operatorname{erfc} u_1]\right\} \quad [19]$$

[4] This series has been introduced by the author in *Proc. IEEE*, 55, 101 (1967). Detail of the individual term can be seen in ref. (10), p. 52, Eq. [10] and [13] and the footnote in the same page, also ref. (11), p. 1566, for relations with the Weber function.

$$C_2 = \alpha \operatorname{erfc}\left(\frac{4\beta^2 D_2 t u_2^2}{1+4\beta^2 D_2 t}\right)^{1/2} + \frac{\alpha(1-\eta)}{(\eta + I_2^{-1})\operatorname{erfc} S_2}\operatorname{erfc} u_2 + \sum_{n=0}^{\infty}\left[(-1)^{n+1}\frac{2\alpha\beta^{2n+1}}{\sqrt{\pi}(2n+1)n!}\frac{h_{2n+1}(S_2)}{i^{2n+1}\operatorname{erfc} S_2}\right.$$
$$\times \frac{2^{2n+1}(2n+1)!\,(H_2^{2n}+\eta I_1^{2n})\,i^{2n+1}\operatorname{erfc} S_1 + h_{2n+1}(S_1)\,(H_2^{2n}-\eta H_1^{2n})}{2^{2n+1}(2n+1)!\,(I_2^{2n}-\eta I_1^{2n})\,i^{2n+1}\operatorname{erfc} S_1 + h_{2n+1}(S_1)\,(I_2^{2n}+\eta H_1^{2n})}$$
$$\left.\times (D_2 t)^{(2n+1)/2}\, i^{2n+1}\operatorname{erfc} u_2\right] \qquad [20]$$

(*C*) Where the initial concentration profile is a constant, $C_0(x) = \alpha$. C_1 and C_2 can be obtained immediately by letting $\beta = 0$ in (*A*) and (*B*) above.

$$C_1 = \frac{\alpha\eta(1+I_2^{-1})}{\eta + I_2^{-1}} \qquad [21]$$

$$C_2 = \alpha + \frac{\alpha(1-\eta)}{(\eta + I_2^{-1})\operatorname{erfc} S_2}\operatorname{erfc} u_2 \qquad [22]$$

Note that C_1 is constant in Eq. [21] and independent of D_1, while C_2 in Eq. [22] is the same as the result of Ku (5) and Cooper *et al.* (2), and is also independent of D_1. Recall that their mathematical models to describe the redistribution process were different. Their results agree with each other because, as shown in Eq. [21] and [22] C_1 and C_2 are not functions of D_1. The theoretical model with $g = 0$ (*i.e.*, the outer oxide surface is impermeable) must satisfy the condition that impurity atoms are conserved in the oxide and the semiconductor, that is

$$\int_0^W C_1(y,t)\,dy + \int_{\epsilon W}^{\infty} C_2(x,t)\,dx = \int_0^{\infty} C_0(x)\,dx$$
(a constant independent of t) [23]

This statement can be proved by direct integration.

Solutions for boundary conditions described in Eq. [5] and [6] can be also obtained by directly applying the series method in the diffusion equations. Coefficients of the series will be evaluated by the initial and boundary conditions. In many cases, a recurrence formula for coefficients will appear. A case with $g \neq 0$ is given in Appendix V.

Experimental Results

Two different rates of growing thermal oxides on silicon slices with Gaussian impurity distributions were used in the studies. Boron was deposited on n-type wafers (background phosphorus concentration 1.3 x 10^{16}/cm^3) in an open tube furnace at 930°C for 15 min. The boron glass, formed on the surface of the wafers during the deposition, was etched off. This procedure formed a shallow diffused layer with an abrupt junction about 0.2μ below the silicon surface. The wafers were then placed back in a furnace at 1200°C for 1 hr, and nitrogen gas (dried by passing through liquid nitrogen) was passed through the tube. The boron distribution after this diffusion procedure was assumed to be Gaussian.[5] The surface concentration was measured and found to be approximately 1.0 to 1.1 x 10^{19} atoms/cc.

The thermal oxidation was carried out in an open tube furnace (temperature 1200°C), with water vapor carried by nitrogen gas bubbled through hot water. Water temperature was 82°C for case (*A*), 92.5°C for case (*B*). A curve was obtained for each of the following two cases.

(*A*) The initial concentration profile was $C_0(x) = 1.0 \times 10^{19} \exp(-5.14 \times 10^7 x^2)$. Oxidation time was 1 hr and a 5600Å-thick oxide was produced.

(*B*) The initial concentration profile was $C_0(x) = 1.1 \times 10^{19} \exp(-5.14 \times 10^7 x^2)$. Oxidation time was 0.5 hr and a 5100Å-thick oxide was produced.

[5] The actual profile, measured in a separate experiment, was close to Gaussian.

The oxide thickness was measured with an interferometer. After the oxide layer was removed, the concentration profile of the redistributed boron was determined by four-point probe measurement and thin layer etch technique (15). The values of $\epsilon = 0.44$ and $D_2 = 1.35 \times 10^{-12}$ cm^2/sec have been used for the calculation. The value of D_2 was obtained from the work of Kurtz and Yee (16), and the value of D_1 was obtained from the work of Yamaguchi and Horiuchi (17) which showed that $(D_2/D_1)^{1/2}$ was approximately equal to 58. The experimental results along with calculated curves, are shown in Fig. 2 and 3.

The calculated curves used to fit the data of Fig. 2 and 3 were obtained from Eq. [7]. The segregation coefficient (η) was used as an adjustable parameter to fit the experimental results. The best fit was obtained using the value $\eta \approx 1.8$.

This value is somewhat smaller than the value of 3.1 obtained by Grove *et al.* (4). However, when the difference in initial conditions is considered, the results are in reasonable agreement. The difference may be due to a concentration dependence of η.

The values of that can be determined accurately by

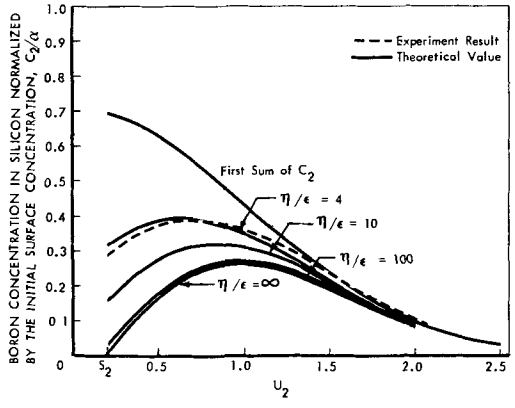

Fig. 2. Concentration profile of boron in silicon after an oxide layer has been grown at the surface under condition A. Theoretical curves for several values of η are also shown.

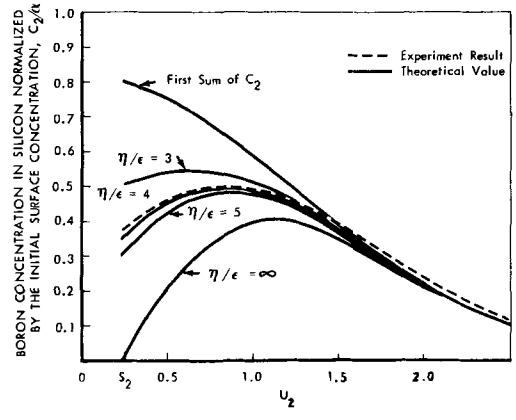

Fig. 3. Concentration profile of boron in silicon after an oxide layer has been grown at the surface under condition B. Theoretical curves for several values of η are also shown.

curve fitting are limited to values between $\approx$ 0.1 and 10. For values larger than $\approx$ 10 and smaller than 0.1, the curves are insensitive to η.

Summary

The analysis presented a mathematical treatment of the impurity redistribution phenomena during thermal oxidation. Exact solutions of diffusion equations can be obtained for many cases when the initial and boundary condition have been well defined as Eq. [3] and [8]. Application of this series can be extended to solve many diffusion and heat conduction problems, *e.g.*, diffusion or heat conduction through different media, or with moving boundaries, double diffusions, *etc.*

Good agreement was found between the theory and the experimental results when $\eta = 1.8$ was used for the segregation coefficient. This agrees reasonably well with the value of 3.1 obtained by Grove *et al.* (4).

Acknowledgments

The authors wish to express their gratitude to G. S. Horsley and D. W. Nichol for their stimulating discussions and encouragement, to L. R. Kolb, P. A. LaClaire, R. A. Jacomb, and H. R. Arrowood for their help in carrying out these experiments, and to L. E. Spanel and R. W. Cunningham for their help in the preparation of this paper.

Manuscript received April 3, 1967; revised manuscript received Aug. 9, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

APPENDIX I

Functions $h_n(u)$ and i^n erfc u, defined in Eq. [13] and [14], have the following properties

(Unless otherwise indicated, n is an integer ≥ 0.)

$$h_{2n}(0) = (2n)!/n! \qquad [A1]$$

$$h_{2n+1}(0) = 0 \qquad [A2]$$

$$\frac{d}{du} h_n(u) = 2n\, h_{n-1}(u) \quad (n \geq 1) \qquad [A3]$$

$$h_{2n+1}(u) = 2(2n+1) \int_0^u h_{2n}(\xi)\, d\xi \qquad [A4]$$

$$h_{n+1}(u) = 2u\, h_n(u) + 2n\, h_{n-1}(u) \quad (n \geq 1) \qquad [A5]$$

$$i^n \text{ erfc } 0 = \frac{1}{2^n \Gamma\left(\frac{n}{2} + 1\right)} \qquad [A6]$$

$$\frac{d}{du} i^n \text{ erfc } u = -\, i^{n-1} \text{ erfc } u \qquad [A7]$$

$$2(n+1)\, i^{n+1} \text{ erfc } u = i^{n-1} \text{ erfc } u - 2u\, i^n \text{ erfc } u \qquad [A8]$$

$$H_n(u) = (-1)^n e^{u^2} \frac{d^n}{du^n} (e^{-u^2}) \qquad [A9]$$

$$i^{-n} \text{ erfc } u = \frac{2}{\sqrt{\pi}} e^{-u^2} H_{n-1}(u) \quad (n \geq 1) \qquad [A10]$$

$$H_{2n}(u) = \frac{(-4)^n n!}{\Gamma(n + 1/2)} L_n^{-1/2}(u^2) \qquad [A11]$$

$$H_{2n+1}(u) = \frac{2(-4)^n n!}{\Gamma(n + 3/2)} u\, L_n^{1/2}(u^2) \qquad [A12]$$

where $L_n^a(u)$ are Laguerre polynomials with the following generating function

$$\frac{1}{(1-t)^{a+1}} \exp \frac{-ut}{1-t} = \sum_{n=0}^{\infty} \frac{t^n}{\Gamma(n + a + 1)} L_n^a(u) \qquad [A13]$$

Additional details are contained in ref. (10) through (14).

APPENDIX II

In this appendix, a process to determine the redistributed impurity profiles C_1 and C_2 (Eq. [16] and [17]) are given. The case discussed in the following is for a semi-infinite semiconductor. At $t = 0$, there is no oxide at one end (at $x = 0$), and the initial impurity profile is a Gaussian, *i.e.*

$$C_0(x) = \alpha \exp(-\beta^2 x^2) = \alpha \sum_{n=0}^{\infty} (-1)^n \frac{(\beta x)^{2n}}{n!} \qquad [A14]$$

The impurity will be redistributed during a thermal oxidation. The boundary conditions for the diffusion equation during this process are described in Eq. [3], [4], and [6] with $g = 0$. After a certain time t, the redistributed impurity profiles in the oxide and the semiconductor are described by C_1 and C_2, respectively.

Coefficients b_n in C_2 can be easily determined by the initial profile. At $t = 0$, C_2 (u_2, 0) is a simple power series in x, *i.e.*

$$C_2(u_2, 0) = \sum_{n=0}^{\infty} b_n x^n \qquad [A15]$$

and all terms with coefficients B_n vanish. By equating like powers of x between Eq. [A14] and [A15], b_n are determined as

$$\left.\begin{aligned} b_{2n} &= (-1)^n \frac{\alpha \beta^{2n}}{n!} \\ b_{2n+1} &= 0 \end{aligned}\right\} \qquad [A16]$$

where n is a nonnegative integer and remains so through this appendix. According to the boundary condition at the outer oxide surface described by Eq. [6] with $g = 0$, we can obtain

$$\sum_{n=0}^{\infty} \left[a_{2n} (D_1 t)^n \frac{(2n+1)!}{n!} - \frac{A_{2n+1}}{2} (D_1 t)^n\, i^{2n} \text{ erfc } 0 - \frac{A_{2n}}{2} (D_1 t)^{(2n-1)/2}\, i^{2n-1} \text{ erfc } 0 \right] = 0 \text{ for all } t > 0 \qquad [A17]$$

where i^{2n} erfc $0 = 1/2^{2n}n!$ (Eq. [A6]). In Eq. [A17], the coefficient of each individual term of the like power t should vanish, therefore,

$$\left.\begin{aligned} A_{2n} &= 0 \\ A_{2n+1} &= 2^{2n+1}\,(2n+1)!\,A_{2n+1} \end{aligned}\right\} \quad [A18]$$

Similarly, the following relations can be obtained from Eq. [3] and [4], the boundary conditions at the oxide-semiconductor interface

$$a_{2n+1}\,h_{2n+1}\,(S_1) + A_{2n+1}\,i^{2n+1}\,\text{erfc}\,S_1 = \eta\left(\frac{D_2}{D_1}\right)^{(2n+1)/2} B_{2n+1}\,i^{2n+1}\,\text{erfc}\,S_2 \quad [A19]$$

$$a_{2n}\,h_{2n}\,(S_1) = \eta\left(\frac{D_2}{D_1}\right)^{n}\left[b_{2n}\,h_{2n}\,(S_2) + B_{2n}\,i^{2n}\,\text{erfc}\,S_2\right] \quad [A20]$$

and

$$a_{2n+1}\,D_1{}^n\left[\frac{k}{2}\,D_1{}^{1/2}\,h_{2n+1}\,(S_1) + (2n+1)\,h_{2n}\,(S_1)\right] + A_{2n+1}\,D_1{}^n\left[\frac{k}{2}\,D_1{}^{1/2}\,i^{2n+1}\,\text{erfc}\,S_1 - \frac{1}{2}\,i^{2n}\,\text{erfc}\,S_1\right] + B_{2n+1}\,D_2{}^{n+1}\left[-\frac{k}{2}\,\epsilon D_2{}^{1/2}\,i^{2n+1}\,\text{erfc}\,S_2 + \frac{1}{2}\,i^{2n}\,\text{erfc}\,S_2\right] = 0 \quad [A21]$$

$$a_{2n}D_1{}^n\left[\frac{k}{2}\,h_{2n}(S_1) + 2nD_1{}^{1/2}\,h_{2n-1}\,(S_1)\right] + b_{2n}D_2{}^n\left[-\frac{k}{2}\,\epsilon h_{2n}\,(S_2) - 2nD_2{}^{1/2}\,h_{2n-1}\,(S_2)\right] + B_{2n}D_2{}^n\left[-\frac{k}{2}\,\epsilon i^{2n}\,\text{erfc}\,S_2 + \frac{1}{2}\,D_2{}^{1/2}\,i^{2n-1}\,\text{erfc}\,S_2\right] = 0 \quad [A22]$$

The values of a_{2n+1}, A_{2n+1}, and B_{2n+1} can be determined immediately by Eq. [A18], [A19], and [A21]

$$a_{2n+1} = A_{2n+1} = B_{2n+1} = 0 \quad [A23]$$

The values of a_{2n} and B_{2n} can be determined by Eq. [A16], [A20], and [A22]

$$a_{2n} = (-1)^n\,\frac{\alpha\beta^{2n}}{n!}\,\frac{D_2{}^n\,h_{2n}(S_2)\,\eta[H_2{}^{2n-1} + I_2{}^{2n-1}]}{D_1{}^n\,h_{2n}(S_1)\,[\eta H_1{}^{2n-1} + I_2{}^{2n-1}]} \quad [A24]$$

$$B_{2n} = (-1)^n\,\frac{\alpha\beta^{2n}}{n!}\,\frac{h_{2n}\,(S_2)\,[H_2{}^{2n-1} - \eta H_1{}^{2n-1}]}{i^{2n}\,\text{erfc}\,S_2\,[\eta H_1{}^{2n-1} + I_1{}^{2n-1}]} \quad [A26]$$

where $H_1{}^{2n-1}$, $H_2{}^{2n-1}$, $I_1{}^{2n-1}$, $I_2{}^{2n-1}$ are defined in Eq. [18], the first part of C_2, the series with b_n coefficient, can be put into a compact form. The derivation is in the Appendix III. Equations [16] and [17] will follow after the substitution of Eq. [11] and [12] with the values of their coefficients.

APPENDIX III

The following example shows the first part of C_2 in Eq. [12] and proves that the series with the b_n coefficient is a solution of the diffusion equation having the same initial conditions but no oxide grown on the surface.

Assume that a slice of silicon has an initial impurity concentration profile of

$$C_0(x) = \frac{Q}{(\pi\,D_2t_0)^{1/2}}\exp\left(-\frac{x^2}{4\,D_2t_0}\right) \quad [A26]$$

where Q is the total quantity of impurity in the slice. The slice is heated so that the impurities are diffused deeper with the diffusion coefficient D_2 and no impurity loss at the surface. No oxide is grown on the slice. After time t the concentration profile will be

$$C(x,t) = \frac{Q}{[\pi\,D_2\,(t+t_0]^{1/2}}\exp\left[-\frac{x^2}{4\,D_2(t_0+t)}\right] \quad [A27]$$

Assume that another slice, with an initial concentration profile described by Eq. [A26], is diffused. The diffusion coefficient remains unchanged, but an oxide layer is grown on the surface. After time t the concentration profile in the semiconductor will be described by $C_2(x,t)$ in Eq. [12]. The b_n coefficient in Eq. [12] is evaluated using the initial condition

$$\left.\begin{aligned} b_{2n} &= (-1)^n\,\frac{\alpha\beta^{2n}}{n!} \\ b_{2n+1} &= 0 \quad n = 0, 1, 2, 3 \ldots \end{aligned}\right\} \quad [A28]$$

where $\alpha = Q/(\pi\,D_2t_0)^{1/2}$ and $\beta^2 = 1/4\,D_2t_0$. Using Eq. [A11] and [A13] and the definition of $h_{2n}\,(u_2)$ in (13), the first sum of $C_2\,(x,t)$ (the series with the b_n coefficient) can be written in this compact form

$$\sum_{n=0}^{\infty}(-1)^n\,\frac{\alpha\beta^{2n}}{n!}\,(D_2t)^n\,h_{2n}\,(u_2) = \sum_{n=0}^{\infty}(-1)^n\,\frac{\alpha\beta^{2n}}{n!}\,(D_2t)^n\,(-1)^n\,H_{2n}\,(ju_2) = \sum_{n=0}^{\infty}(-1)^n\,\frac{\alpha\beta^{2n}}{n!}\,(-D_2t)^n\,\frac{(-4)^n\,n!}{\Gamma(n+1/2)}\,L_n{}^{-1/2}\,(-u_2{}^2) = \alpha\sum_{n=0}^{\infty}\frac{(-4\,\beta^2\,D_2t)^n}{\Gamma(n+1/2)}\,L_n{}^{-1/2}\,(-u_2{}^2) = \frac{\alpha}{(1+4\,\beta^2\,D_2t)^{1/2}}\exp\left(-\frac{4\,\beta^2\,D_2\,tu_2{}^2}{1+4\,\beta^2D_2t}\right) = \frac{\alpha}{(1+4\,\beta^2\,D_2t)^{1/2}}\exp\left(-\frac{\beta^2\,x^2}{1+4\,\beta^2\,D_2t}\right) \quad [A29]$$

Equations [A27] and [A29] are identical when the values for α and β have been inserted.

APPENDIX IV

The following process is used to obtain the first part of C_2 in Eq. [12] and to transform the series into a compact form for the case where the initial distribution is a complementary error function.

From the initial condition

$$C_0(x) = \alpha\,\text{erfc}\,\beta x = \alpha\left[1 - \frac{2}{\sqrt{\pi}}\sum_{n=0}^{\infty}\frac{(-1)^n\,(\beta x)^{2n+1}}{(2n+1)\,n!}\right]$$

the b_n coefficient is determined as

$$b_0 = \alpha$$
$$b_{2n} = 0 \text{ for } n > 0$$
$$b_{2n+1} = (-1)^{n+1}\,\frac{2\alpha}{\sqrt{\pi}}\,\frac{\beta^{2n+1}}{(2n+1)\,n!}, \quad n = 0, 1, 2, \ldots$$

The first part of C_2, $C_2{}^{\text{I}}$, in Eq. [12] can be written as

$$C_2{}^{\text{I}} = \alpha - \sum_{n=0}^{\infty}(-1)^n\,\frac{2\alpha}{\sqrt{\pi}}\,\frac{\beta^{2n+1}}{(2n+1)\,n!}\times(D_2t)^{(2n+1)/2}\,h_{2n+1}\,(u_2)\,.$$

Using Eq. [A4] and [A17], $C_2{}^{\text{I}}$ can be written as

$$C_2{}^{\text{I}} = \alpha\left\{1 - \frac{4\beta\,(D_2t)^{1/2}}{\sqrt{\pi}}\int_0^{u_2}\sum_{n=0}^{\infty}\left[(-1)^n\,\frac{\beta^{2n}}{n!}\,(D_2t)^n\,h_{2n}\,(\xi)\right]d\xi\right\} = \alpha\left[1 - \frac{4\beta\,(D_2t)^{1/2}}{\sqrt{\pi}}\int_0^{u_2}\frac{1}{(1+4\,\beta^2\,D_2t)^{1/2}}\exp\left(-\frac{4\,\beta^2\,D_2t\,\xi^2}{1+4\,\beta^2\,D_2t}\right)d\xi\right] = \alpha\left[1 - \text{erf}\left(\frac{4\,\beta^2\,D_2t\,u_2{}^2}{1+4\,\beta^2\,D_2t}\right)^{1/2}\right] = \alpha\,\text{erfc}\left(\frac{4\,\beta^2\,D_2t\,u_2{}^2}{1+4\,\beta^2\,D_2t}\right)^{1/2} \quad [A30]$$

APPENDIX V

This appendix discusses the case where impurities are redistributed in a semiconductor during thermal oxidation using [6] as the boundary condition at the outer oxide surface and assuming that $C_s = 0$. This corresponds to the physical condition where the environment contains no impurities and the loss due to evaporation at the surface is linearly proportional to the instantaneous concentration at the surface (9). The initial concentration profile is assumed to be Gaussian, *i.e.*, $C_0(x) = \alpha \exp(-\beta^2 x^2)$. The b_n coefficient is determined as Eq. [A16] by employing the initial conditions. After the b_n coefficient has been determined, a set of equations for a_n, A_n, and B_n can be obtained by using the boundary conditions and equating the like powers of t as follows

$$A_0 = 0 \qquad [A31]$$

$$A_{2n+2} + 2g\,A_{2n+1} = 0 \qquad [A32]$$

$$-(2n)!\,g\,a_{2n} + (2n+1)!\,a_{2n+1} - 2^{-2n}\,g\,A_{2n} - 2^{-(2n+1)}\,A_{2n+1} = 0 \qquad [A33]$$

$$h_{2n}(S_1)\,a_{2n} + (i^{2n}\operatorname{erfc} S_1)\,A_{2n} - \eta\left(\frac{D_2}{D_1}\right)^n (i^{2n}\operatorname{erfc} S_2)\,B_{2n} = (-1)^n \frac{\alpha\beta^{2n}}{n!}\left(\frac{D_2}{D_1}\right)^n \eta\,h_{2n}(S_2) \qquad [A34]$$

$$h_{2n+1}(S_1)\,a_{2n+1} + (i^{2n+1}\operatorname{erfc} S_1)\,A_{2n+1} - \eta\left(\frac{D_2}{D_1}\right)^{n+1/2} (i^{2n+1}\operatorname{erfc} S_2)\,B_{2n+1} = 0 \qquad [A35]$$

$$h_{2n+1}(S_1)\,H_1^{2n}\,a_{2n+1} - (i^{2n+1}\operatorname{erfc} S_1)\,I_1^{2n}\,A_{2n+1} + \left(\frac{D_2}{D_1}\right)^{n+1/2} (i^{2n+1}\operatorname{erfc} S_2)\,I_2^{2n}\,B_{2n+1} = 0 \qquad [A36]$$

$$h_{2n}(S_1)\,H_1^{2n-1}\,a_{2n} - (i^{2n}\operatorname{erfc} S_1)\,I_1^{2n-1}\,A_{2n} + \left(\frac{D_2}{D_1}\right)^{n} (i^{2n}\operatorname{erfc} S_2)\,I_2^{2n-1}\,B_{2n} = (-1)^n \frac{\alpha\beta^{2n}}{n!}\left(\frac{D_2}{D_1}\right)^n h_{2n}(S_2)\,H_2^{2n-1} \qquad [A37]$$

where I_1^{2n}, H_1^{2n}, etc., are defined as in Eq. [18]. By eliminating a_{2n}, a_{2n+1}, B_{2n}, and B_{2n+1} in Eq. [A33] through [A37] a recurrence formula for A_n's can be obtained as

$$A_0 = 0,\ A_{2n+2} + 2\,g\,A_{2n+1} = 0,\ \left[\frac{2^{2n+1}(2n+1)!\,(i^{2n+1}\operatorname{erfc} S_1)\,(I_2^{2n} - \eta\,I_1^{2n})}{h_{2n+1}(S_1)\,(I_2^{2n} + \eta\,H_1^{2n})} + 1\right]A_{2n+1} + 2g\left[1 - \frac{2^{2n}(2n)!\,(i^{2n}\operatorname{erfc} S_1)\,(I_2^{2n-1} - \eta\,I_1^{2n-1})}{h_{2n}(S_1)\,(I_2^{2n-1} + \eta\,H_1^{2n-1})}\right]A_{2n} = (-1)^{n+1}\,2\,g\,\frac{\alpha\beta^{2n}}{n!}\left(\frac{D_2}{D_1}\right)^n \frac{2^{2n}(2n)!\,h_{2n}(S_2)\,\eta\,(I_2^{2n-1} + H_2^{2n-1})}{h_{2n}(S_1)\,(I_2^{2n-1} + \eta\,H_1^{2n-1})} \qquad [A38]$$

from which all the A_n's will be obtained. Then a_{2n}, a_{2n+1}, B_{2n}, and B_{2n+1} will be solved in terms of A_{2n} and A_{2n+1} from Eq. [A33] through [A37].

The Preparation and Properties of Large, Solution Grown GaP Crystals

T. S. Plaskett, S. E. Blum, and L. M. Foster

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

A method of growing large crystals of GaP from solution, similiar to that of Broder and Wolff in which a zone of liquid gallium saturated with GaP is passed upward through a GaP ingot, is investigated. With this method, all the advantages of a solution growth process are retained, *i.e.*, low temperature, and therefore low phosphorus pressure, and minimum contamination from container materials. In order to grow large crystals it was found necessary to initiate growth on a twinned seed crystal, with all of the twin planes parallel, and parallel to a <211> growth direction. The effect of repeated zone passes through the same ingot on the purity and electrical properties is presented.

Gallium phosphide has emerged over recent years as a potentially useful electroluminescent material. Its exploitation has been deterred, however, by the lack of suitable procedures for controlled growth of bulk single crystal. Crystals of GaP can be prepared easily by precipitation from gallium or other metal solvents in which it has an appreciable solubility. However, the crystals produced in this way are usually in the form of thin dendritic platelets of various sizes and morphologies(1-5), and it is difficult to form reproducibly large, uniformly doped platelets that are essential for device applications and physical characterization studies. Nevertheless, solution growth processes in general offer distinct advantages for the growth of GaP and similar high melting, unstable compounds because of the low temperatures that can be employed for off-stoichiometric growth [stoichiometric GaP melts at 1467°C under about 35 atm of phosphorus pressure (6)]. Chief among these are the minimal equipment requirements because of the greatly reduced pressure and the lessening of contamination from container materials. With Ga as a solvent, for example, the solubility of GaP at 1220° is about 15% by weight and the P pressure is only 0.02 atm(7, 8). At this temperature there is a choice of several possible container materials, including quartz, boron

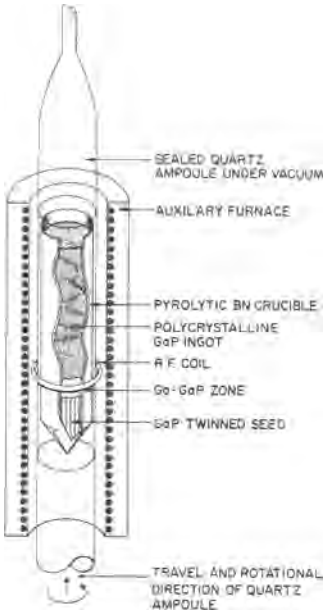

Fig. 1. Cut-away drawing of the solution zoning apparatus

nitride, and graphite. A secondary advantage of solution growth is the purification that can result simply by dilution of impurities in the large volume of solvent.

One method of growing a large bulk crystal of GaP by a solution growth process was described by Broder and Wolff(9). In their method a high-temperature, saturated Ga-GaP zone is passed through a composite of liquid Ga and solid GaP. By dissolution of GaP at the leading edge of the zone and precipitation at the trailing edge, a solid ingot with large grains was produced. In this paper, an extension of their process, in which large monocrystalline sections are produced, is described, together with some electrical and chemical properties of the product.

Experimental Technique

In Fig. 1 is shown a schematic drawing of the essential features of the apparatus. At the start, the layer of Ga, approximately ¼ in. thick, is placed between the seed and polycrystalline ingot of GaP, all of which are contained in a pyrolytic BN crucible.[1] The loaded crucible is then sealed under vacuum in a quartz tube with a minimum of free space. The zone of Ga is heated to about 1160°C by the single turn RF coil. At this temperature the zone dissolves about 10% of its weight of GaP, taking the material initially from both the seed and ingot surfaces. [The Ga temperature is actually estimated by its GaP content, determined after completion of an experiment, and the use of published solubility data(7, 8)].

The auxiliary furnaces, located above and below the coil, control the shape of the solid-liquid interface and provide the required temperature profile along the axis of the system. The rate of zone travel upward through the ingot is about 4 mm/day. The tube is also rotated in the coil at about 8 rpm to smooth out radial temperature nonuniformities. The mechanical motions and the RF heating are obtained by modifying a commercial Lepel, Model FLZ-100 float zone silicon refiner.

For the successful passage of the liquid zone it was found that an essentially nonporous ingot had to be employed as the feed; otherwise a void would accumulate above the gallium and eventually isolate it from the feed. Completely sound, single-phase polycrystalline ingots were synthesized for this purpose from Ga and phosphorus by the vertical Bridgman technique, with the phosphorus source controlled to give approximately 10 atm pressure. The synthesis was

[1] Obtained from the High Temperature Materials Division of the Union Carbide Corporation.

Fig. 2. Typical crystal grown by solution zoning technique. Seeding occurred at the 2 cm position. The button at the 6 cm position is what is left of the unzoned ingot. The Ga-GaP zone has been removed by acid leaching.

carried out in a BN crucible of the same dimensions as the one subsequently used for the travelling solvent regrowth. This synthesis is described by Blum and Chicotka (10).

Results and Discussion

Nature of the regrown crystal.—A typical crystal grown by this technique is shown in Fig. 2. The remaining unzoned feed material is also shown at the position approximating that during growth. Seeding occurred in this instance at about the 2-cm position. The growing interface at the last to freeze is slightly convex. This represents the actual growing interface since the termination of a run occurred by abruptly turning off the rf power and auxiliary furnaces. The GaP precipitating during cooling under this condition is as fine platelets surrounded by Ga, and any adhering to the crystal is easily removed during the acid leach to dissolve away the Ga. A convex interface was required to prevent polycrystalline growth around the periphery of the crystal.

At a growth rate of about 4 mm/day and with the precipitating surface considerably colder than the dissolution surface, the zone travelled through the polycrystalline ingot with no visible entrapment of the Ga solvent. The actual temperature gradient could not be measured but the top auxiliary furnace was run at about 1000°C and the lower furnace at 800°C. The temperature of the zone as mentioned previously was estimated to be about 1160°C.

Initially, an attempt was made to seed onto a large grain ingot, as shown in Fig. 3a, but it was not successful. Instead of the large grains propagating, the small twinned grain shown in the seed began to predominate, as shown in Fig. 3b after about 4 cm of growth. After about 6 cm of growth the whole cross section consisted of this one twinned crystal (Fig. 3c). This length of growth was obtained in three separate experiments, with the last part of one ingot used as the seed for the next one. (To make an additional zone pass it was necessary to open the system, cut the crystal at the seed, and insert a new zone of gal-

lium.) The twin structure was observed to be a consistent pattern; that is, regardless of the size and orientation of the grains in the seed, the structure that soon developed and propagated up the ingot consisted of lamellar twins whose growth direction was parallel to the travel of the zone. Since there were no seeds available initially to directly initiate that type of growth, they had to be generated in the program; the best section of a regrown ingot would be retained as seed for subsequent experiments.

The concentration and nature of impurities in the feed ingot seemed to have an effect on the quality of the regrown crystal, although their role has not been definitely established. Generally, regrowth was better when the seed and feed ingot were n-type, indicating a predominance of nonmetallic impurities. These typically have high distribution coefficients and therefore would be readily incorporated in the crystal rather than accumulate at the interface where they may inhibit further nucleation and growth.

The structure of the twinned regrown crystal, and the structure desired for a seed to initiate such growth, is one in which the twin planes are parallel to each other and parallel to a <211> growth direction. The leading edges of two such adjacent twins intersect at indestructible grooves which present favorable sites for nucleation and growth. The same growth mechanism applies to the growth of dendritic GaP platelets from dilute gallium solutions(4). A model of an idealized seed structure is shown in Fig. 4. In some experiments seeds with large untwinned areas, as shown in Fig. 3c, were used to determine if an untwinned crystal would propagate. Usually, however, the twinned area increased at the expense of the untwinned. The exact reason for the large area free of twins shown in Fig. 3c is not known.

A macrograph of a lapped cross section is shown in Fig. 5a. A longitudinal section taken parallel to the (111) twin planes from the same crystal and through the untwinned portion, as indicated by the above cross section, is shown in Fig. 5b. The twinned structure is apparent in the cross section but in the longitudinal section the structure appears polycrystalline because it lacks the straight line twin boundaries. However, an x-ray examination of the grains showed all to have (111) surfaces but with a 60° rotation to each other

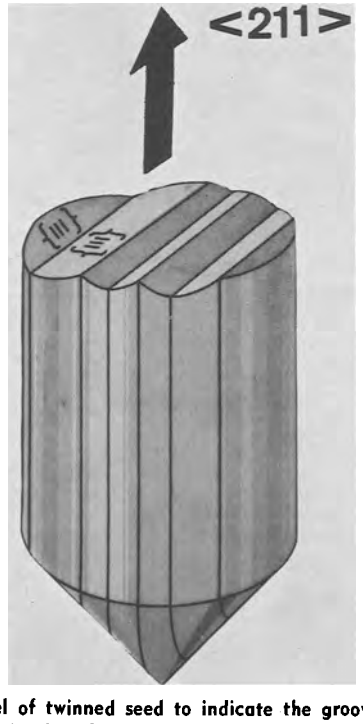

Fig. 4. Model of twinned seed to indicate the grooved nature of solid-liquid growing interface.

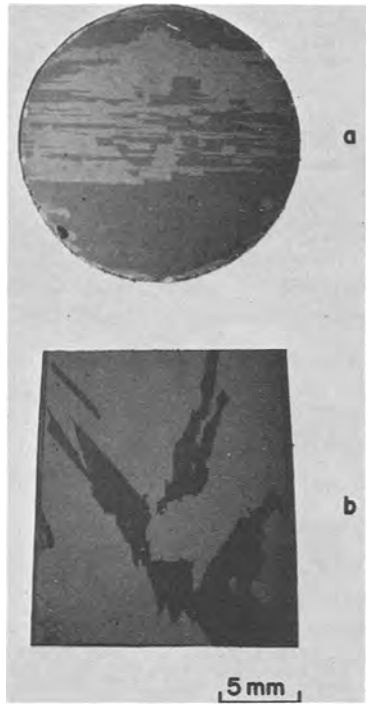

Fig. 5a. Transverse and Fig. 5b longitudinal sections of a solution zoned crystal.

normal to the longitudinal surface. This means that the only twin planes, as suggested by the model shown in Fig. 4, are those parallel to the growth axis. However, since more than one grain is evident in a longitudinal section, this indicates that the twin planes are not flat but may jog in a step-wise manner or else terminate and new parallel twin planes start elsewhere.

Twinning in GaP should not detract from its usefulness in electroluminescence studies. If the twins in the material are confined to those described above (first-order), then the twin boundaries would not perturb the electrical transport across them. Moreover, a common method of forming the p-n junction in GaP for the production of light emitting diodes employs a solution over-growth process onto (111) oriented substrates (11). Such substrates are obtained by cutting longitudinal slabs parallel to the twin planes.

Chemical and electrical properties.—The feed ingots as synthesized were generally p-type as determined by point contact rectification. On occasion they were n-type, however. In these cases analysis generally indicated higher silicon contamination during synthesis. If the feed ingot was p-type, it remained p-type after the passage of the zone. The acceptors have not been clearly identified. Table I shows emission spectroscopic analysis of a p-type starting feed ingot and the same ingot after one and two zone passes. The entries are order of magnitude figures. "Less than" a given concentration means that a line was seen on the plate but adequate calibration had not been carried out to provide narrower sensitivity limits. The analyses

show a reduction in the silicon and iron content with the additional zone passes.

Table II shows Hall data, provided by J. F. Woods of this Laboratory, after two zone passes through a p-type ingot and one zone pass through an n-type ingot. The Hall specimens were ultrasonically cut bars with three pairs of Hall probes which also served as resistance probes. Ohmic contacts were made to n-type material with Au-Sn and to p-type material with Au-In alloys.

Improved purity of the regrown ingots would undoubtedly result from the use of a larger gallium zone in which to further dilute the impurities. This is impractical in the present system. A more effective way of upgrading the purity is to use higher purity feed ingots. This approach is being pursued.

Conclusions

This initial investigation has shown the feasibility of producing large, solution grown GaP crystals by a travelling solvent method. The success of the process is to a large extent dependent on the orientation and twinned structure of the seed. There is no evidence of contamination of an ingot during the regrown process. Rather, appreciable purification results from passage of the molten zone. Material of sufficient purity can be made by the present practice for doping studies to be undertaken in the mid 10^{17} cm^{-3} range, either by adding the dopant to the gallium zone or by predoping the feed ingot during synthesis. Higher purity regrown ingots are expected from the use of purer feed ingots.

Technical Notes

Fluorescence of Rhodium-Activated Aluminum Oxide

G. Blasse and A. Bril

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

In his survey of phosphors Kröger (1) mentions the red fluorescence of Al_2O_3:Rh. It seemed interesting to study this phosphor in more detail.

Samples were prepared by firing intimate mixtures of aluminum- and rhodium hydroxide in oxygen at 1350°C. The rhodium concentration was 0.1-1.0 a/o (atomic per cent). The reaction products had a light-yellow body color and showed an orange-red fluorescence under long-wave uv and cathode-ray excitation. Samples prepared from the same aluminum hydroxide without rhodium did not show fluorescence. The performance of the optical measurements has been described previously (2).

Figure 1 shows the spectral energy distribution of the fluorescence of Al_2O_3:Rh under long-wave uv excitation, the excitation spectrum of the fluorescence and the diffuse reflection spectrum. The fluorescence shows a pronounced temperature dependence: the light output under long-wave uv excitation at room temperature is about 60% of that at liquid nitrogen temperature. At about 450°K the fluorescence is completely quenched. The radiant efficiency for cathode-ray excitation of our samples is 2% at room temperature. In view of the weak uv absorption no measurements of the efficiency for uv excitation were performed. The decay time of the fluorescence of Al_2O_3:Rh under

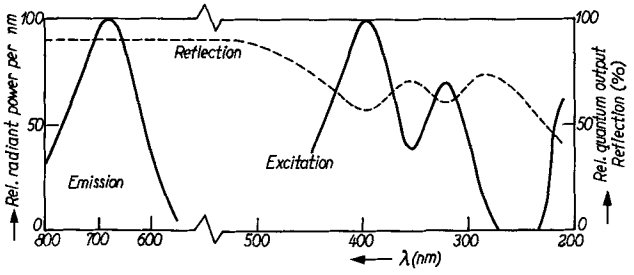

Fig. 1. Left-hand side: spectral energy distribution of Al_2O_3:Rh under cathode-ray excitation. Right-hand side: relative excitation spectrum of the emission of Al_2O_3:Rh. The broken line is the diffuse reflection spectrum of Al_2O_3:Rh. Note the change in the wavelength scale between 500 and 600 nm.

cathode-ray excitation is 0.6 msec at room temperature and 1.6 msec at liquid nitrogen temperature.

The Rh^{3+} ion ($4d^6$) occupies (irregular) octahedral sites in the corundum structure of α-Al_2O_3 and will be in the nonmagnetic low-spin state (t^6_{2g}, $^1A_{1g}$). The lowest excited configuration is $t^5_{2g}e_g$, which is split in the states $^3T_{1g}$, $^3T_{2g}$, $^1T_{1g}$, $^1T_{2g}$. The spin-forbidden transitions $^1A_{1g} \rightarrow {}^3T_{1g}$ and $^3T_{2g}$ were not observed by us, but the two absorption (and excitation) bands located at 25,400 and 31,200 cm^{-1} are undoubtedly due to the transitions $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1T_{2g}$. According to Jørgensen (3) the wave numbers of these transitions are given to a good approximation by

$$\sigma(^1A_{1g} \rightarrow {}^1T_{1g}) = \Delta - 4B + 86B^2/\Delta$$

and

$$\sigma(^1A_{1g} \rightarrow {}^1T_{2g}) = \Delta + 12B + 2B^2/\Delta$$

Here Δ is the cubic crystal field splitting and B the electrostatic interaction parameter. The last term of these formulas accounts for the off-diagonal elements of the electron repulsion matrix. It is assumed that the electrostatic interaction parameter C equals $4B$. From our experimental data we find that $\Delta = 26{,}400$ cm^{-1} and $B = 400$ cm^{-1}. The value of B for the free ion is 720 cm^{-1} (3). The low value of B for the Rh^{3+} ion in Al_2O_3 points to strong delocalization of the d-electrons of Rh^{3+} in Al_2O_3. For comparison we also give the values of Δ and B for $Rh^{3+}(H_2O)_6$ (27,000 and 510 cm^{-1}) and for $Rh^{3+}(Cl^-)_6$ (20,300 and 350 cm^{-1}) (3).

At higher wave numbers the excitation and reflection spectra show another band, which is not present in the case of undoped Al_2O_3. The peak of this band is beyond the limit of our apparatus, but is estimated to be located at approximately 50,000 cm^{-1}. It seems probable that this band corresponds to a charge-transfer transition in the $Rh^{3+}(O^{2-})_6$ complex. For $Rh^{3+}(Cl^-)_6$ such a band is found at 39,200 cm^{-1} (3).

The fluorescence emission of Al_2O_3:Rh consists of one broad band in the far red (680 nm), which is probably due to the spin-forbidden $^3T_{1g} \rightarrow {}^1A_{1g}$ transition, in agreement with the relatively long decay time.

We have also studied some other Rh^{3+}-activated aluminates, viz., $YAl_3B_4O_{12}$, $Li_{0.5}Al_{2.5}O_4$, and $Y_3Al_5O_{12}$. The photoluminescence of these materials is, however, very weak and the radiant efficiency for cathode-ray excitation less than 0.5%.

Manuscript received Aug. 7, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Evaluation of Electronic Grade Silicon and Trichlorosilane by a Frozen Drop Method

F. Hubbard Horn

General Electric Company, Research and Development Center, Schenectady, New York

The evaluation of silicon and its precursors for electronic purposes presents problems to both suppliers and users. In the case of silicon, it is clear that electrical resistivity alone does not uniquely specify the purity since the number of carriers measured is a net number, which in the worst situation may result from a near compensation of a relatively high concentration of both donors and acceptors. In the case of chemicals such as trichlorosilane used to prepare silicon either as massive crystals or for epitaxy, sufficiently sensitive tests for all of the impurities and particularly boron have not been developed.

Evaluation methods have been devised to meet some of these problems. The zone refining of test rods of silicon has been in most common use for both crystalline silicon and for silicon-bearing chemicals after deposition of silicon on a test rod. Electrical resistivity and resistivity profiles are used in conjunction with information on impurity segregation to determine the background concentration of boron and the concentration of some of the other possible impurities. Zone refining for such analytical purposes must be performed with great care and control and requires considerable time.

The same kind of analytical information as is obtainable from zone refining may be obtained by a frozen drop method, which requires less material and may be conducted more rapidly. Use is made of the fact that the surface tension of silicon will support a molten drop of sufficient length for significant electrical resistivity measurement. The progressive freezing of the molten drop from the supported end can give a unique and simple distribution of impurities according to their segregation coefficients. In the case of evaluating a silicon-bearing chemical, silicon is deposited on the bottom of a rod of silicon of known purity, a drop is formed from the deposited silicon, and refrozen for evaluation.

The steps that need to be considered in the application of the frozen drop method for silicon and trichlorosilane are: (*i*) formation of frozen drop and evaluation of silicon or silicon "seed" crystal; (*ii*) deposition of silicon from trichlorosilane on evaluated "seed" silicon; (*iii*) formation of frozen drop from silicon deposit and application of corrections; (*iv*) evaluation of silicon deposit from frozen drop. These steps will be discussed sufficiently to describe a general procedure; there is room for individual preference

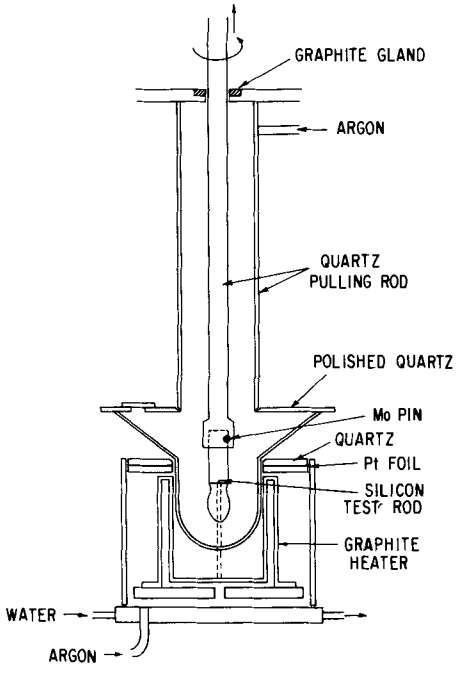

Fig. 1. Schematic drawing of furnace used to form a frozen drop from silicon rod.

in the choice of apparatus or measuring equipment used.

Formation of Frozen Drop from Silicon

A ⅜ in. diameter rod of silicon will support a molten drop about ¾ in. long. This length of refrozen crystal is sufficient for evaluation. A rod of single crystal silicon grown of appropriate known diameter or cut, centerless ground, and etched clean is mounted in a crystal-growing apparatus of the type shown in Fig. 1.[1] All parts are carefully etched clean and dried beforehand, and pure argon is allowed to flow slowly through the apparatus. The furnace is brought to a temperature sufficient to melt silicon. The silicon rod, originally held such that the bottom of the rod is above the crucible, is lowered part way into the crucible. As melting of the rod tip starts and proceeds, the rod is further lowered until the molten drop shows a necked-in region close to the liquid-solid interface. After allowing time for stabilization, *i.e.*, complete melting through the drop, the rod is withdrawn from the furnace or the furnace temperature reduced slightly such that freezing of the drop takes place from the rod downward to the tip. Typical frozen drops of varying length are shown in the photograph of Fig. 2. Freezing should be performed slowly in order that near equilibrium conditions are obtained. It is possible to control the freezing rate to about 1 mm/min. After cooling, the rod and frozen drop are removed. The frozen drop is cut from the rod at least several mm above the point at which recrystallization took place. Bars of uniform cross section 2-2.5 mm are cut longitudinally. These are lapped and the cross section measured for use in computing the electrical resistivity from electrical resistance measurements.

Procedure for Evaluating Silicon Using Frozen Drop

The central bar of approximately square cross section, cut from the frozen drop and some of the original crystal, is lapped and mounted for electrical resistance measurement in equipment such as illustrated by Fig. 3. The traveling probe is made to traverse the bar quickly in a search for p-n junction.[2] These are recognized as steps in the trace of the voltage-drop *vs.*

[1] High frequency (4 mc) may be used to form a frozen drop; however, it is more difficult to control the rate of freezing and to assure that freezing proceeds entirely from the rod-drop boundary. The drop shape also is affected by the method of formation.

[2] A thermoelectric probe is also useful for this purpose.

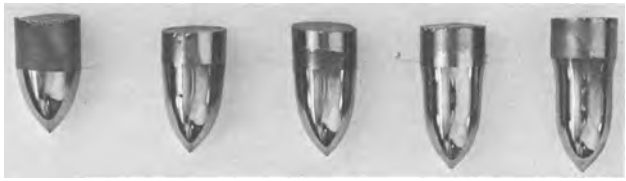

Fig. 2. Photograph of frozen drops of silicon from ⅜-in. diameter silicon rod.

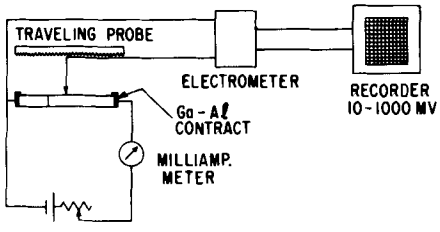

Fig. 3. Schematic electrical circuit for resistivity measurement of sections of frozen drop.

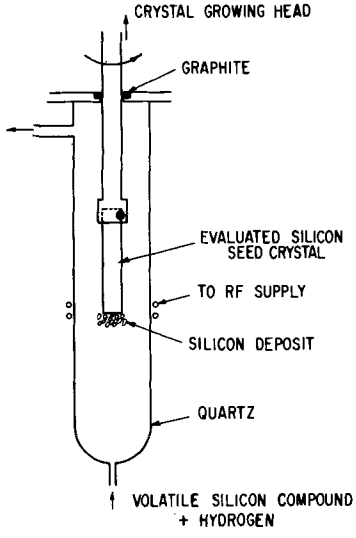

Fig. 4. Schematic drawing of apparatus used to decompose trichlorosilane for silicon evaluation.

position. Note is made of the position on the test bar at which a junction first appears. For electrical resistivity measurements, the electrical contacts should be made such that the current path is through silicon of the same type. The voltage drop through the sample is then measured as a function of position using the slow traverse traveling probe. The rate of movement of the paper in the recorder is fixed for a known rate of movement of the traveling probe. The electrical resistivity of any point in the bar is determined from the slope of the voltage-position curve since the measuring current and cross section of the test bar are known.[3]

Procedure for Evaluating Silicon from Trichlorosilane

A weighed rod of silicon previously evaluated by the frozen drop method to determine purity is mounted in an apparatus, such as shown schematically in Fig. 4, suitable for decomposing trichlorosilane to silicon. The apparatus is purged with pure hydrogen, the bottom tip of the rod brought to a temperature of about 1250°C, and the trichlorosilane to be tested then admitted from a weighed source. The decomposition is allowed to proceed until an appropriate amount of silicon is deposited on the rod. After stopping the flow of TCS, the power to heat the rod is turned off and the apparatus allowed to cool. The rod with silicon deposit is transferred to the furnace previously described

[3] The rate of change of voltage drop may also be obtained directly by the appropriate circuit to differentiate.

(Fig. 3) and a frozen drop formed. After cooling, the rod and frozen drop are weighed to determine the amount of silicon deposited. The length of the frozen drop from the refreeze position to the sprout is measured. These values are necessary to determine the concentrations of boron and phosphorus originally present in the trichlorosilane. Although the yield of silicon from trichlorosilane is low, it is substantially the same as will be encountered in the use of trichlorosilane to produce silicon. One does not thus really arrive at concentrations of impurities in the trichlorosilane; one obtains a measure of the impurities that will be present in silicon derived from trichlorosilane. This is no different from the problem encountered with deposition and zone refining for evaluation in general practice. Comparisons between zone refining and the frozen drop method have shown agreement to within less than 0.1 ppb in 40% of the cases and within 0.1 ppm in the other 60%.

Analysis of Data

The use of the electrical resistivity *vs.* position on the drop for determining the concentrations of boron and phosphorus present initially in the silicon rod or deposit (that is, what they were before making a frozen drop) requires several types of corrections. First, account must be taken of the redistribution of boron (p-type) and phosphorus (n-type) during formation of the frozen drop. Second, there are corrections that depend on the size and shape of the drop. In addition, in the case of evaluating silicon from trichlorosilane, a correction is required for dilution of the deposited silicon by some of the seed rod.

The ability to analyze for impurities in silicon is based on the fact that the two most important ones, boron and phosphorus, have slightly different segregation coefficients, both of which are much larger than the coefficients for all other impurities. Although the segregation coefficient for arsenic is nearly that for phosphorus, arsenic is not generally present in concentrations approaching that for phosphorus. For this reason, the donor impurity will be treated as being phosphorus. Boron ($K_B = 0.8$) and phosphorus ($K_P = 0.35$) and other impurities ($K \lesssim 0.01$) will be distributed in the frozen drop according to the laws of normal freezing. In normal freezing, the initial concentration of an impurity, C_i, before redistribution is given by

$$C_i = \frac{C_g}{K(1-g)^{K-1}} \qquad [1]$$

where C_g is the concentration of the impurity after redistribution, at some point in the crystal expressed as g, the fraction of crystal solidified. Since the conductivity type of boron (p-type) and phosphorus (n-type) is opposite, a crystal containing these two impurities will have an electrical conductivity governed by their algebraic sum. Thus, if the electrical resistivity ρ_o is measured at (near) $g = 0$, the net carrier concentration C_{net} is obtained from

$$\underset{g=0}{C_{net}} = \frac{1}{\rho_o e \mu} \qquad [2]$$

But from [1]

$$\underset{g=0}{C_{net}} = C_B - C_P = K_B C_{Bi} - K_P C_{Pi} \qquad [3]$$

where C_{Bi} and C_{Pi} are the initial concentrations of boron and phosphorus in the silicon before forming a frozen drop.

Similarly, from the electrical resistivity ρ_g measured at a known value for g, the net carrier concentration at position g after redistribution of the impurities can be obtained. Thus, from ρ_g one obtains

$$C_{net_g} = K_B C_{Bi}(1-g)^{K_B-1} - K_P C_{Bi}(1-g)^{K_P-1} \qquad [4]$$

in terms of C_{Bi} and C_{Pi}. Rather than solve for C_{Bi} and C_{Pi} simultaneously from Eq. [3] and [4], it is found more convenient to work through the ratio

$$\frac{C_{Pi}}{C_{Bi}} = R \qquad [5]$$

and to identify three regimes in which the ratio is obtained conveniently. Once the ratio is known, C_{Pi} and C_{Bi} are evaluated using Eq. [3].

The three operational regimes for evaluating R in [5] are: (*i*) that there are electrical junctions for values of g less than 0.85, (*ii*) that a junction appears for g greater than 0.85, and (*iii*) there are no junctions present. The latter case may arise either because there are virtually no n-type impurities present or because the ratio $C_{Pi}:C_{Bi}$ is greater than 2.3 in which case the entire frozen drop is n- rather than p-type. This case can be treated, but it has not been here.

In Fig. 5 are plotted the curves for the distribution of boron and phosphorus in a frozen drop. Position in the drop is in terms of g, the fraction of crystal solidified. It is observed that when the initial concentrations of boron or phosphorus are equal, their concentrations will again be equal after redistribution at $g = 0.85$. Conversely, if in the drop their concentrations are equal at $g = 0.85$, their initial concentrations before forming the drop were equal. Under such conditions $C_{net} = 0$ and an electrical junction is formed since the type changes at such a point. In Fig. 6 is plotted the position of a junction in terms of g as a function of the ratio C_{Pi}/C_{Bi}. This has been obtained from Eq. [4] setting $C_{net} = 0$ and calculating g for arbitrary values of C_{Pi}/C_{Bi}. The position of a junction can be used

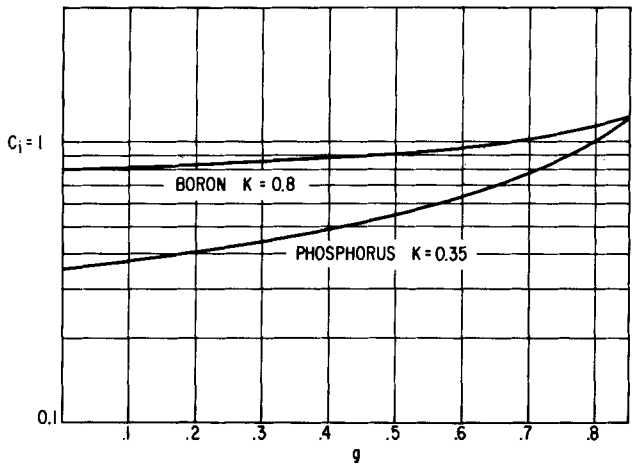

Fig. 5. Ideal distribution of boron and phosphorus in frozen drop

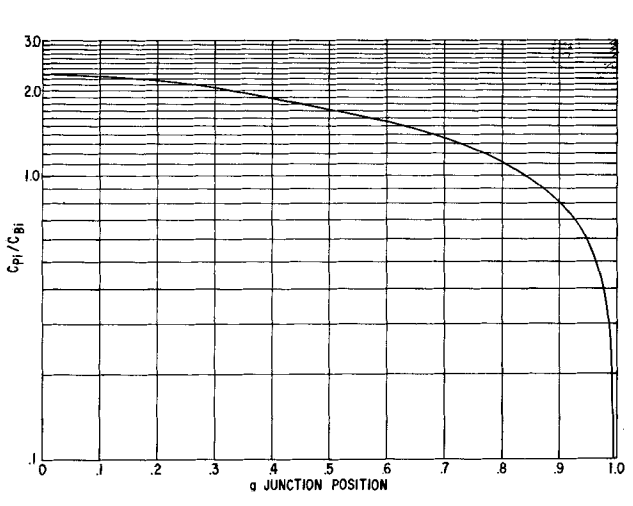

Fig. 6. Ratio of initial phosphorus to boron concentrations as a function of junction position on frozen drop. Position expressed as g, the fraction recrystallized.

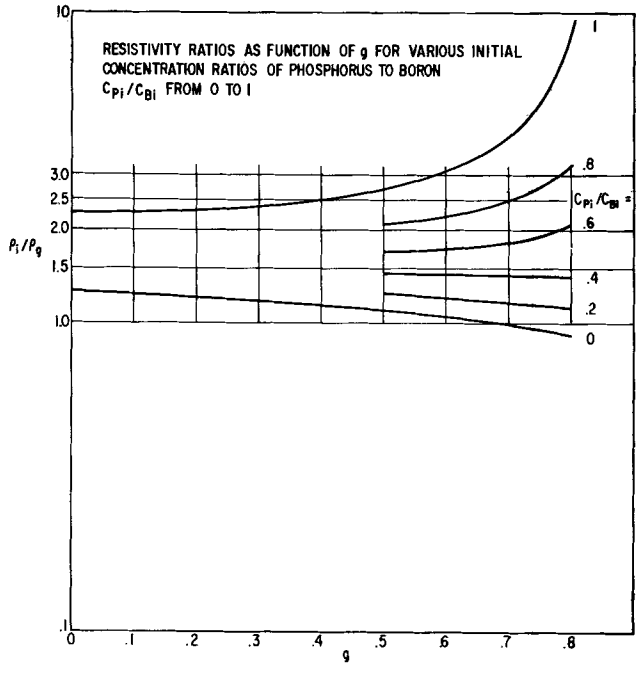

Fig. 7. Ratio ρ_i/ρ_g as a function of g, the fraction of drop crystallized for different initial concentration ratios of phosphorus to boron (C_{Pi}/C_{Bi}).

therefore to obtain the $C_{Pi}:C_{Bi}$ ratio from which C_{Pi} or C_{Bi} can be calculated from Eq. [3]. This step, which requires knowing the relation between the measured length and the fraction crystallized, g, will be discussed later.

If the ratio of C_{Pi}/C_{Bi} is less than unity, the junction is found at a value of g too close to the sprout for accurate measurement, and the ratio of the electrical resistivity at two known points on the crystal rather than the position of junctions should be used. This may be developed numerically each time; however, in order to make possible the use of a simple chart later, it will be presented graphically here. In Fig. 7 are plotted different resistivity ratios ρ_i/ρ_g where ρ_i is the resistivity of the sample before forming a frozen drop and after forming a drop, ρ_g is the resistivity at a point given in terms of g for various initial ratios of phosphorus to boron concentrations from 0 to 1. From these curves, one observes that sensitivity is lost for small values of g, and unjustified high resistivity is generated for large values of g and ratios approaching unity. Values for g of 0.6 or 0.7 offer a compromise. In Fig. 8, therefore, are plotted curves relating ρ_o/ρ_g

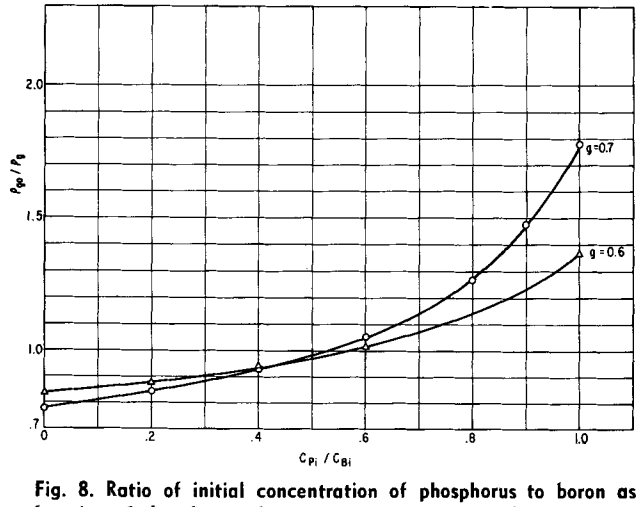

Fig. 8. Ratio of initial concentration of phosphorus to boron as a function of the electrical resistivity ratios at $g = 0$ to $g = 0.6$ and 0.7.

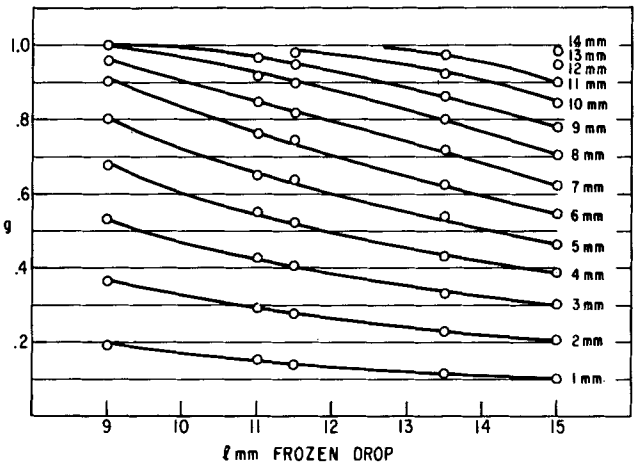

Fig. 9. Equivalent of each millimeter of length on frozen drop to g, fraction solidified, as a function of length of frozen drop.

(where ρ_o is the resistivity measured at $g = 0$ on a frozen drop) to the ratio C_{Pi}/C_{Bi} for values of $g = 0.6$ and 0.7. Thus, from the ratio of the measured resistivities at $g = 0$ to, say $g = 0.6$ one may obtain the C_{Pi}/C_{Bi} ratio necessary to calculate the original concentrations of boron and phosphorus.

The use of the ratio C_{Pi}/C_{Bi} depends on knowing g, the fraction of crystal solidified as a function of position along the test bar. For a crystal of uniform dimensions, g is related linearly to distance along the crystal. Frozen drops are not of uniform dimension, and some means must be found to relate position along the crystal (test bar) to the fraction of crystal solidified. This has been done for frozen drops formed on a 0.375-in. diameter rod by making enlarged shadow images of the drops. From these, assuming circular symmetry, one can measure the diameter at equal small distances along the image and calculate the volume per unit of distance. The change in volume (fraction solidified) as a function of length for drops of different length made on 0.375-in. diameter rod and calculated in the above manner are plotted in Fig. 9. From such a plot, knowing the length of the drop and the electrical resistivity trace as a function of distance from the drop-rod interface, it is possible to obtain the electrical resistivity corresponding to a particular value of g for a junction or for $g = 0.6$ or 0.7 needed for computing the impurity concentrations. The shapes of drops depend on the rod diameter and the process used to form them. The data presented here apply only to drops formed on a ⅜ in. diameter rod in a static system. A relation between g and distance along the crystal should be obtained for the particular system used. Drops formed using high-frequency heating differ also depending on whether the rod is moved or the power reduced during freezing.

When the ratio C_{Pi}/C_{Bi} has been obtained either from the position of junctions or from the resistivity ratios in terms of g, Eq. [3] may be solved and either the boron or phosphorus concentration calculated. This solution is presented graphically for boron in Fig. 10, where concentration is expressed in parts per billion atomic as is done in the industry. The constants used are mass, 22.08: density, 2.33 g/cm^3; μ, 480 cm^2/volt sec (hole mobility). The mobility is assumed to be constant. Thus, from the resistivity ρ_o and the ratio C_{Pi}/C_{Bi} obtained as explained above, the initial concentration of boron may be read directly from the graph of Fig. 10. The initial phosphorus concentration is of course obtained in the same units (ppb) from the product of the known boron concentration and the ratio C_{Pi}/C_{Bi}.

In the case of evaluating a drop formed primarily from silicon deposited from trichlorosilane on a rod, allowance must also be made for dilution by the silicon of the rod. To make this correction, one needs to

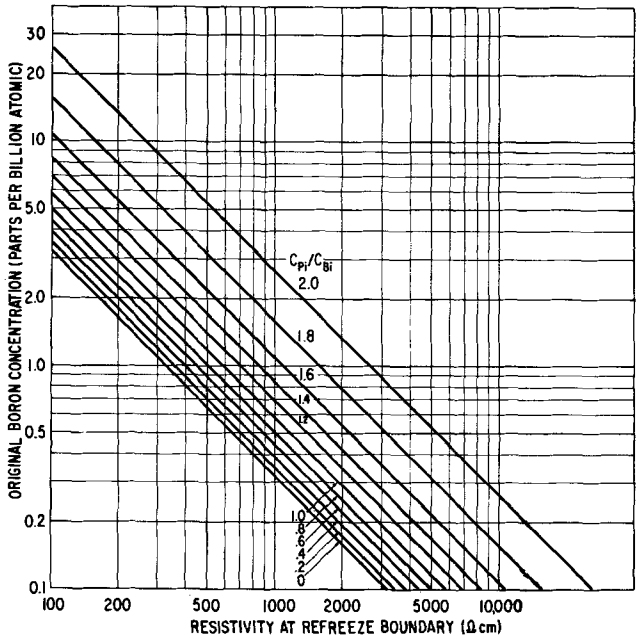

Fig. 10. Original concentration of boron in parts per billion as a function of electrical resistivity at $g = 0$ at refrozen boundary of frozen drop.

know the concentrations of boron and phosphorus initially present in the rod. These are obtained from analysis of a frozen drop made from the rod. If the same rod is weighed prior to and after depositing silicon, the weight of silicon deposited is readily obtained. In order to prevent contamination, the rod and deposit are weighed after the drop has been formed rather than before. It has been observed that for a given rod diameter, the weight of the frozen drop formed is a reproducible function of the length of the drop for a particular method of formation. Use is made of this to obtain the dilution factor. Results for the weight of drop as a function of length for drops made on ⅜-in. diameter rod are given in Fig. 11 from which, knowing the length of the drop, the corresponding weight of the drop is obtained. The weight of rod making up the drop is obtained from the difference between the weight of the drop and the weight of the deposit. Straightforward dilution rules can be applied to determining the original concentration in the deposit since one knows concentrations of impurities in the original rod and the frozen drop and knows the weights of silicon in the deposited silicon, the frozen drop, and rod silicon in the frozen drop. The more nearly comparable the purity of the rod and deposited silicon, the less important becomes the dilution correction.

Other Impurities

The sprout of the frozen drop is useful to determine the presence of certain other impurities, since in the sprout have been highly concentrated those impurities with very small segregation coefficients that may

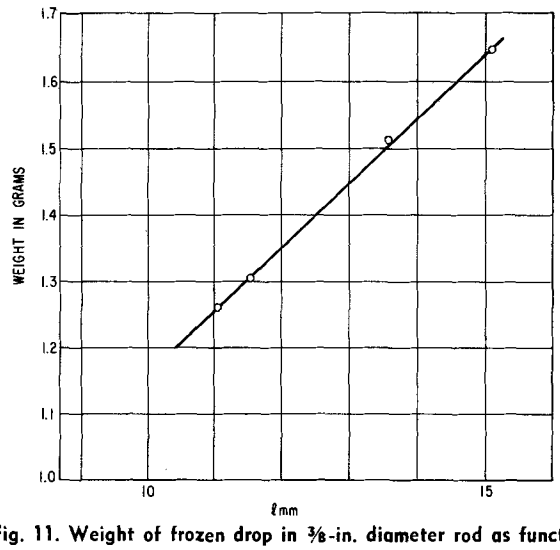

Fig. 11. Weight of frozen drop in ⅜-in. diameter rod as function of length of drop.

have been present in very small initial concentrations in the silicon. Solid source mass spectroscopy or x-ray emission analysis of the sprouts can frequently identify the presence of such impurities as Fe, Ni, Cr known to be deleterious in very low concentrations in electronic applications. This is particularly valuable information in evaluating trichlorosilane for use in epitaxial processes where subsequent melting and regrowth of crystal for eliminating impurities will not be possible.

Summary

A method is described for analyzing crystals for impurities whose segregation coefficients are known, and the method is applied to the determination of impurities of concern in electronic applications in silicon and trichlorosilane. The method depends on forming a molten drop and allowing it to freeze such that a "normal" freezing redistribution of impurities occurs. Analysis for boron and phosphorus is achieved by a proper use of electrical resistivity measurements on bars cut from the frozen drop. Additional information on impurities is obtained by analysis of the sprout by other than electrical means.

Acknowledgments

The author gratefully acknowledges the contributions from many others in helping to apply this frozen drop method. Dr. A. Torkelson of the Silicone Products Department was particularly instrumental in successfully applying the method to evaluating trichlorosilane. Max Tochner, Lloyd Keifer, and Robert Haislip made many valuable contributions in refining the technique to make it useful in routine evaluations. The work has benefited also from discussions with Dr. R. N. Hall.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Twin Configurations in FCC Dendrites

J. W. Faust, Jr.

The Pennsylvania State University, University Park, Pennsylvania

and Fielding Ogburn, Daniel Kahan, and A. W. Ruff, Jr.

National Bureau of Standards, Washington, D.C.

Long ribbons of germanium have been grown from a supercooled melt by Bennett and Longini (1). These ribbons were shown to have two or more closely spaced parallel twin planes (2-4), which afforded indestructible re-entrant edges at which nucleation could more easily occur. Ribbons and webs of other

diamond type materials have also been grown (5-7) from the melt. Faust and John showed that this mechanism (*i.e.*, growth by two or more closely spaced parallel twin planes) could be made operative in growth from molten metal solutions for diamond type and zinc blende materials (8) and for fcc metals (9). They went on to show that parallel twin planes play a role in the dendritic growth of fcc metals by electrodeposition (10, 11), as did Ogburn *et al.* (12, 13).

Several workers (8, 14-20) have reported that under certain growth conditions fcc metals and semiconductors contain five twin planes intersecting at a common line. From the morphology, it is evident that the five intersecting twin planes played a major role during growth. Summing the angles for five twin planes in the fcc and zinc blende structure show that 7°20′ of arc are unaccounted for. There is no agreement on how this mismatch is taken up. Some authors believe it is taken up by strain, while others believe a mismatch boundary is present. A new symmetry group was even suggested that contains no twin planes (21). Faust and John suggested a number of other intersecting twin plane structures that may be found to operate in crystal growth. They went on to show experimental evidence for several of these.

It is the purpose of this paper (*a*) to show that some of the models of Faust and John were incorrect and to give the corrections, (*b*) to give additional models, and (c) to give experimental evidence for one more model.

Discussion of Results

We are dealing with two or more twin (composition) planes intersecting along a line in the body of the dendrite, which is parallel to the [110] growth axis of the dendrite. The orientations of adjacent twin crystals must be mirror images of each other across the twin plane. Since the twin planes in an fcc structure are of the type {111}, the angle of intersection between two of these twin planes must be either 70°32′ or 109°28′.

These restrictions require that wherever two or more twin planes intersect there must be a mismatch boundary. This is seen by inspection of the possible configurations. For example, let us consider the structure (shown in Fig. 1a) in which the solid lines are composition planes and the dashed lines are traces of {111} planes. In Fig. 1, II is a twin of I, and III is a twin of I. Further, II and III must be two different crystals since their {111} traces are not parallel. The two are not in a twin relation and, hence, their common boundary must be a mismatch, as is shown by the dotted line. Our general conclusion is that wherever two or more twin planes intersect, there will be a mismatch boundary or boundary region.

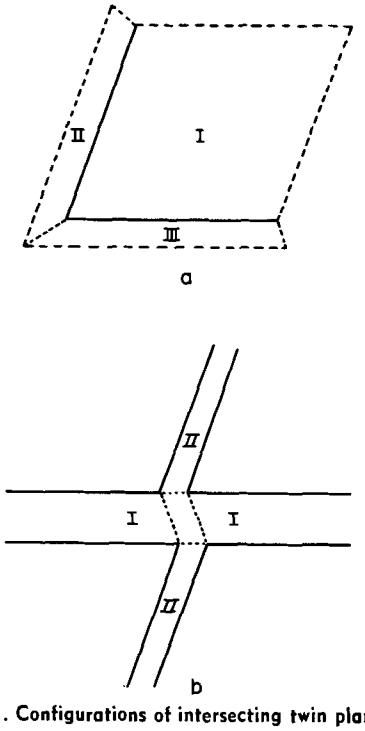

Fig. 1. Configurations of intersecting twin planes

Faust and John (8) in their Fig. 8a and g, and 9a, b, c, d, e, and f (and associated discussion) show configurations with intersecting twin planes, but do not include the required mismatch boundaries. Figure 8e of Faust and John has the mismatch boundary, but a twin plane was inadvertently omitted. With the twin plane the configuration would be essentially that of their Fig. 8b. Other configurations of intersecting twin planes in crystals with a <110> growth direction are theoretically possible using the 109°28′ angle between {111} planes on the {110} surface as the central angles.

In a configuration such as Fig. 9a of Faust and John (shown here as Fig. 1b) there are four pairs of intersecting twin planes. There will be a mismatch boundary ending at each of the four intersections within the intersecting lamallae. Three cases seem possible: (*i*) both of the I and II dotted lines will be mismatch boundaries; (*ii*) either dotted lines I or II (but not both) can be twin boundaries while the other pair must be mismatch boundaries; and (*iii*) either dotted lines I or II do not occur, while the remaining pair must be mismatch boundaries. Experimental evidence for the configuration of case (*ii*) has recently been obtained.

A silver dendrite, electrodeposited from a silver nitrate solution[1], was observed to have two planar arms extending out from the growth axis. A back-reflection Laue x-ray diffraction pattern indicated[1] that the dendrite was a single crystal with a <110> growth axis. The dendrite was mounted and sectioned normal to the growth axis for microscopic examination. The sectioned surface was chemically polished (2 ml 5% HCl; 24g CrO_3; 20 ml H_2O) and etched (2.5g KCN; 2.5g $(NH_4)_2S_2O_8$; 95 ml H_2O) to reveal the microstructure. Figure 2a shows a composite optical micrograph of one such section from the dendrite. In Fig. 2a, both planar arms are seen to contain lamellae extending along their length. The encircled portion in the micrograph is additionally enlarged, making the details somewhat more discernible. The narrowness of the lamellae, the fact that they occupy such a small fraction of the volume of the dendrite, explains the absence of their reflections in the x-ray diffraction pattern. The angle included between arms was about 70°, suggesting that {111} twinning was possibly involved in these features.

In order to verify the nature of the intersecting boundaries and their relationships, an electron-optical examination of the sections was undertaken. Under suitable etching conditions, the lattice relationships across the boundaries should be revealed. Palladium-shadowed plastic replicas were obtained and examined in an electron microscope. Figure 2b is an electron micrograph of the areas under consideration, showing the boundary intersection details. Measurements of the angular rotation of the etched microstructure across the various boundary lines shown here were always consistent with a mirror-plane relation, except for the two shortest boundary lines. Further, the main lamellae intersected each other at an angle of about 70° and the narrow lamellae were mirror-reflected on intersecting the other. We conclude that these lamellae are narrow twins intersecting in this dendrite. All the boundaries except for the two shortest sections (arrows) are twins. These two short mismatch boundaries are required for continuity. In addition, the lamellae can apparently thicken during growth as is shown in this figure at two locations (arrows) of

[1] The dendrite was grown by J. P. Young; the x-ray examination was done by C. J. Bechtoldt.

Fig. 2a (top). the wide lamella. The importance of twin lamellae in influencing the external crystal habit is suggested in Fig. 2a.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 114, No. 3 and 4 (March and April 1967).

Physical Description of the Anisotropic Stress Effect in the Silicon P-N Junction Cantilever Transducer

L. K. Russell and W. H. Legat (pp. 277-285, Vol. 114, No. 3)

J. J. Wortman[1] and **J. R. Hauser**[2]: In the theoretical discussion of the ASE in p-n junctions, the authors treat the electrical current which results from generation-recombination in the space charge region. This current is not only related to junction width and lifetime as the authors consider but is also directly proportional to the intrinsic carrier density, n_i, of the material. The authors fail to consider any stress dependence on n_i. It has been shown that in fact variations in n_i due to stress induced band structure changes can explain the observed changes in generation-recombination current.[3,4]

[3] J. J. Wortman and J. R. Hauser, *J. Appl. Phys.*, 37, 3527 (1966).
[4] H. Kressel and A. Elsea, *Solid State Electronics*, 10, 213 (1967).

The 30% changes induced in lifetimes by stress that are given in ref. (23,24 of the paper under discussion) are doubtful. For example, it is pointed out in the discussion of ref. 23 that the method used to estimate the lifetime may not apply since a negligible lifetime is required in the stressed region. The 10-30% changes cited in ref.(23) are the combined effects of the small stressed area and the much larger unstressed area. In ref. (25), which the authors used but failed to mention in the text, approximately an order of magnitude change in lifetime with stress in germanium is shown to occur. This data is for near intrinsic material in which log $(1/\tau_\sigma)$ is linearly related to stress. Such a dependence on stress naturally leads one to suspect a shift of the recombination energy level with stress rather than a reversible change in the density of the recombination centers. From considerations of changes in energy level with stress one would expect lifetime in intrinsic material to be much more sensitive to stress than that in extrinsic material such as used in p-n junctions.

In conclusion, we feel that the major features of the reversible results reported can be explained in terms of shifts of the energy band edges and the recombination levels with stress. The sensitizing of

the junction probably introduces generation-recombination centers which are electrically active. The induced centers may be annealed out with time and temperature but for short time periods probably appear to be stationary.

A Method of Growing CuCl Single Crystals with Flux

Minoru Soga, Rikizo Imaizumi, Yoshihiro Kondo, and Takahiro Okabe (pp. 388-390, Vol. 114, No. 4)

H. Jaffe[5]: This paper is a most welcome contribution for the description of a method for growth of good CuCl crystals as well as the presentation of new data on the electro-optic Pockels effect. To the writer's knowledge these are the first quantitative data since the original work of West[6] which was of a preliminary nature. For a comparison it is, however, necessary to know the orientation of the CuCl crystal rods used by Soga *et al.* The transverse effect observed by them can be obtained either with electric field in the [111] direction and light propagation normal thereto, or with the field in a [110] direction with light propagation along the [110] direction. In the former orientation the effect is smaller by a factor $2/\sqrt{3}$ than in the latter. If Soga *et al.* used the [111] arrangement their results is in good agreement with West's, taking the difference in wavelength of the two measurements into account. If however Soga used the [110] bar his retardation values are about 20% lower than would have been expected from West.

[5] Clevite Corp., Electronic Research Division, 540 East 105th Street, Cleveland, Ohio 44108.

[6] West, Am. Inst. Phys., Handbook, McGraw-Hill Publishing Co., 1957, pp. 6-97.

Minoru Soga, Rikizo Imaizumi, Yoshihiro Kondo, and Takahiro Okabe: As for the orientation of the particular crystal rods used in our experiment, our laboratory note records of etch pit observation indicate that electric field was in the [111] direction and light was propagating perpendicular to it, as Mr. Jaffe pointed out. Possible misalignments were a few tenth of a degree for the crystal grown with $BaCl_2$ (Δ in Fig. 3) and 3~4 degrees for the crystal grown with $SrCl_2$ (O in Fig. 3).

Apart from the above discussion, we would like to add an information which may be useful: CuCl single crystals grown with $BaCl_2$ and $SrCl_2$ (about 1.5 mole % each) did not show adherence to the quarts crucible.
