SOLID STATE SCIENCE

The Preparation and Properties of Thin Film Silicon-Nitrogen Compounds Produced by a Radio Frequency Glow Discharge Reaction

R. C. G. Swann, R. R. Mehta, and T. P. Cauge

ITT Semiconductor Research Department, Palo Alto, California

ABSTRACT

Silicon nitride was deposited by a radio frequency glow discharge reaction of silane and ammonia. Films were deposited at a fixed substrate temperature of 300°C but the silane/ammonia concentration was varied between 3 and 50%. The effect of changing gas concentrations has been correlated with the change in physical and electrical properties of the deposited material. In particular, measurements of dielectric constant, loss factor, and voltage breakdown strength have been made as well as surface studies by the MOS technique. Material properties have also been qualitatively studied by monitoring IR absorption, chemical etch rate, and film growth rate.

The advent of MOST's and high field devices has revealed some limitations in the use of silicon dioxide as a gate insulator or passivating medium. In particular, attention has been drawn to the inability of the oxide to stop fast diffusing alkali metals, *e.g.*, sodium, potassium, or lithium. The relatively low dielectric constant of SiO_2 also imposes design problems where very high frequency operation is desired. Silicon nitride is one of several materials that has been selected to overcome these problems, and its physicochemical properties were studied to compare it to the oxide.

The silicon nitride was deposited by reacting ammonia and silane in a radio frequency glow discharge which was reported earlier by Sterling and Swann (1). This is now one of several processes under investigation both here and in other laboratories. The merits of the rf glow discharge method with respect to deposition temperature, film purity, stoichiometry, and instrumentation are considered below.

Depositions can be carried out at any desired substrate temperature, even below room temperature with the necessary refrigeration facilities. However, structural modifications of the film have been observed to take place at deposition temperatures higher than room temperature, as exemplified by densification of the film structure resulting in lower etch rates. A similar effect has been reported after the annealing of sputtered oxides (2). This factor coupled with a thermal limitation imposed by the substrate, (*e.g.*, melting point or movement of diffusion front) may in turn determine the deposition temperature. In this report, a substrate temperature of 300°C has been studied, to achieve acceptable etch rates and yet maintain a good film structure without resorting to temperatures used in the pyrolytic process.

The rf discharge process can utilize gaseous sources which in general are available in an extremely pure form and so offers a purer source than, for example, sintered target materials used in some sputtering processes. It should be noted, however, that this process is not restricted to hydrides or even silicon compounds, *e.g.*, boron nitride from boron trichloride and ammonia. Electrode contamination is also eliminated by the use of an external energy source to produce an electrodeless discharge. Films produced in a d-c or low frequency discharge often suffer from electrode impurities as well as changes in chemistry (*e.g.*, polymer formation has been observed in a low frequency glow discharge reaction) (3).

In most sputtering systems, stoichiometry is limited by the target material whereas this process will enable a choice of film stoichiometry by simply controlling the proportions of the reactants. For example, compounds of silicon and oxygen have been produced by varying the ratio of nitrous oxide to silane, and SiO, Si_2O_3, and SiO_2 have been identified by the authors in an earlier study.

The apparatus is very simple (Fig. 1), requiring no internal electrodes, targets, biasing, or water cooling facilities as employed in sputtering systems. The apparatus simplicity is in contrast to the complexity

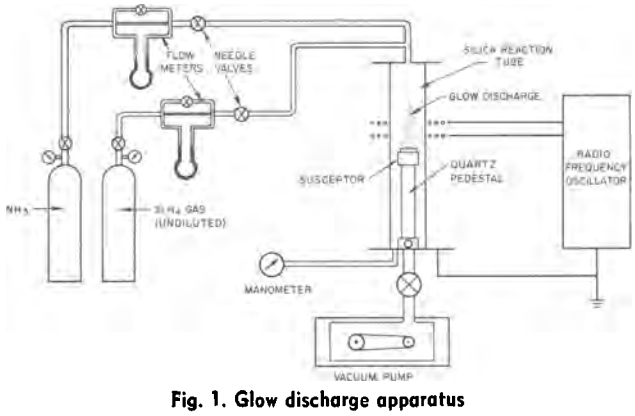

Fig. 1. Glow discharge apparatus

of the chemical reactions which take place in a glow discharge environment.

Glow Discharge Reactions—General

The glow or "cold" discharge referred to in this text occurs between the Townsend and the arc discharge which are only part of the family of electrical breakdown phenomena. Discharges can be further classified into two different types which have been detailed by Babat (4). The capacitive or "E" type discharge is excited by an electric field and the inductive or "H" type discharge is excited by a magnetic field. The latter is probably of greater significance in the system used for this work, as evidenced by incomplete chemical reactions in the case of high frequency capacitive discharges in the absence of internal electrodes.

The physical processes involved in a glow discharge are not simple, since they involve the interaction of positive ions, electrons, and excited molecules as well as the presence of neutral atoms and molecules. From a chemical standpoint, reaction products can be formed by the breaking of existing bonds, or the formation of new bonds, free radicals, and metastable ions. In the latter case, ions can even behave as catalysts by giving up their latent energy to associated molecules at the recombination sites. These sites can be the reaction tube walls or any object placed in the discharge which absorbs energy released by the recombination. All these possible events indicate the complexity of plasma chemistry.

A complete understanding of discharge reactions requires detailed study which has not been attempted in this present work. Here, a semi-empirical approach has been taken to optimize growth conditions. Future studies will include measurements of electron temperature and its relationship to chemical bonding and reaction yield.

Apparatus

Figure 1 shows the general arrangement of the apparatus. The chemical components of the silicon nitride are supplied from gaseous sources of undiluted silane and anhydrous ammonia. (The gases were supplied by Matheson Company, Newark, California, having the following purities—silane 99% + 1% H_2 and anhydrous ammonia 99.99%.) Small flow rates of the gases are monitored through calibrated capillary-type flow meters in conjunction with regulating valves. The gases are mixed and fed into a reaction tube which is continuously evacuated to pressures in the 10^{-1} Torr range. System pressure was monitored by a McLeod vacuum gauge to eliminate any gaseous decomposition.

A 1 MHz, 500w, high impedance radio frequency generator, Model 500M (special) Stanelco, Boreham Wood, England, was used to supply energy to the low pressure gas stream by means of a radio frequency coil which surrounds the fused silica reaction tube. The generator can supply energy for both chemical reaction and substrate heating when desired. The substrate temperature was measured by an infrared pyrometer; Thermodot Model TD 6A (Radiation Electronics Company).

Experimental

It has been reported (5) that the above system will enable changes in film stoichiometry by varying the ratios of the gaseous constituents. A study of the silicon nitride system was therefore made by changing the silane to ammonia concentration from 3 to 50% by volume. The total gas flow rate and substrate temperatures were maintained constant at 11 cc/min and 300°C, respectively.

Films were deposited on mechanically polished n-type silicon wafers, cut in the 111 plane and of resistivity (2-3) ohm-cm. Slices were precleaned in HF and hot HNO_3 m with intermediate washes in deionized water. Samples for electrical evaluation were evaporated with chrome and gold contact areas (1.25 x 10^{-3} cm^2) on the nitride and an ohmic gold film on the reverse side. Capacitance and loss factor measurements were made on a G. R. (1 kc) digital bridge and a Boonton (100 kc) bridge with applied d-c bias of + 10v to the Cr-Au gate electrode to ensure maximum capacitance values. MIS C-V plots were obtained for several devices on each wafer to evaluate surface state charge Q_{ss}. Automatic plotting on an X-Y recorder, at a measurement frequency of 100 kHz, showed less than 10% variation in Q_{ss} over the wafer.

Growth and etch rates.—Figure 2 shows the rate of film deposition *vs.* silane concentration under conditions of constant radio frequency power, gas flow rate, and substrate temperature. Thicknesses were monitored approximately by observation of the interference fringes.

For accurate determination of film thickness, a step was etched with pure HF, over which a thin coating of aluminum was evaporated, and the step height measured using a Hilger Watts multiple beam interferometer. For film thicknesses less than 2000Å the error in measurement is ± 20Å. Above this thickness the probable error is greater (up to 40Å).

The growth rate is substantially linear, having a rate of 180Å/min at 50% silane concentration and 35 Å/min at 10% concentration.

Etch rates were determined for a 1:8 HF/NH_4F solution since this gave a controlled rate. Samples were prepared by selective protection with KPR and then etched to approximately half their total thickness. The KPR was removed and a reflecting surface was evaporated over the step for measurement as described above. Etch rates were of the order of 50 Å/min with a decrease to 20 Å/min at higher silane concentrations. It has been noted that at much higher substrate temperatures the etch rate is significantly decreased.

Infrared spectroscopy.—Figure 3 shows the spectra for identical silicon nitride depositions but with different KBr preparations. The top graph shows the I-R grade KBr powder with its characteristic absorption bands. The heavy graph is the result of a silicon nitride deposition onto a preformed KBr pellet. This shows the broad silicon-nitrogen absorption peak for a silane gas concentration of 25%. The main band ranges from 9-14μ and peaks at approximately 12.1μ.

The dotted absorption peak at ~ 9.4μ is found to occur when the same deposition is made on powdered KBr which is subsequently pressed into pellet form. This Si-O shoulder has also been seen on the Si_3N_4 spectra published in the literature (6). We postulate the presence of free silicon in the nitride which becomes oxidized on exposure to the atmosphere. (A similar effect has been noted by other workers (7, 8) when powdering crystalline silicon.) Samples prepared by the KBr powder technique show a shift in

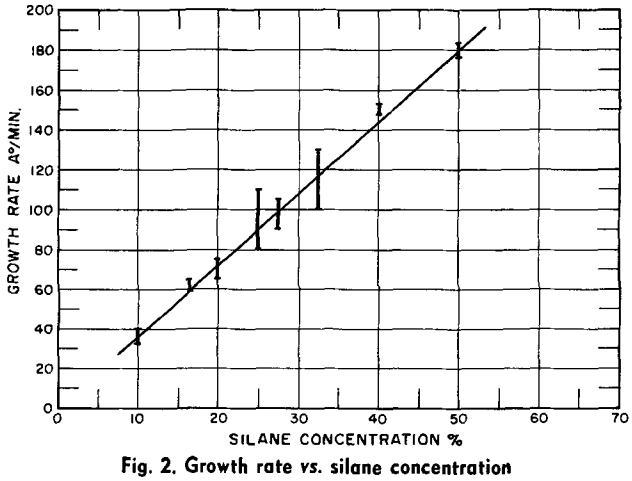

Fig. 2. Growth rate *vs.* silane concentration

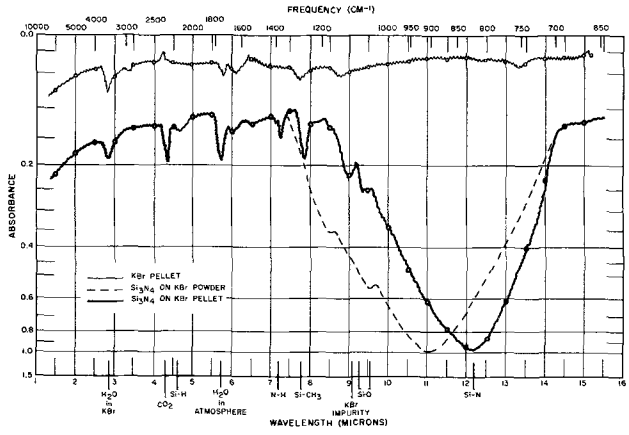

Fig. 3. Infrared spectra

the Si-O peak from 9.85 → 9.55μ for a 6 → 50% change in silane concentration. The Si-N peak is correspondingly influenced by the amount of Si-O bonds present.

We have observed a peak at 4.6-4.7μ as reported in the literature (9). We would rather attribute this to Si-H bonds, which occur at lower energies, than to Si ≡ N triple bonds.

More recent work has been to study the infrared absorption by transmission through silicon nitride which was deposited onto a single crystal silicon wafer (600μ thick, 40 ohm-cm, N-type) mechanically polished on both surfaces. A gradual change in the absorption peak from 11.6 to 12.2μ was observed for a change from 1 to 50% silane, respectively. The shift to a higher wavelength supports our earlier hypothesis that the layers become silicon rich at high silane concentrations. When using the more recent technique, as opposed to the KBr method, there is virtually absence of the Si-O band which suggests that, in the case of high silane concentrations, the free silicon is bound within the film and not available for oxidation.

Dielectric constant and loss factor.—Figure 4 shows the dielectric constant *vs.* silane concentration for film thicknesses of approximately 1000Å. Its value is seen to change from 7 to 11 for a corresponding change in silane concentration from 3 to 50%. The value of dielectric constant for bulk silicon nitride is quoted (10, 11) between 9 and 10. In thin film form many workers (6, 12-16) have reported various values in the range 6-8 and some as high as 12. In this present work the variation is attributed to changes in stoichiometry, especially the amount of silicon, free or chemically bonded, in the deposited layer. Additional evidence to support such a hypothesis is seen at high silane concentrations where the value of dielectric constant approaches that of bulk silicon. Also at these high concentrations the resistivity and breakdown field strength are tending toward the values typical of bulk silicon.

Measurement of loss factor *vs.* silane concentration revealed a trend to become more lossy as amorphous silicon is approached. A typical tan δ value at 1 kc/s is 0.0007 increasing to 0.002 at 50% concentration.

In drawing up the data for dielectric constant *vs.* silane concentration an anomalous effect was noted for film thickness slightly greater or less than 1000Å. In particular values greater than expected were observed for thicknesses less than 1000Å for a given silane concentration. Therefore a detailed study of this effect was undertaken at a given SiH_4/NH_3 (1:3) concentration over the thickness range 800 → 5000Å. Figure 5 shows the change which occurs in the dielectric constant plotted as a function of film thickness. We are tentatively attributing this phenomenon to stress, which is known to exist in films deposited by this technique. A more detailed analysis of this effect will be reported (17).

Resistivity and dielectric breakdown.—Both resistivity and dielectric strength have been measured as a function of silane concentration. Resistivities were obtained from steady-state values of current for a field of 4 x 10^5 v/cm. A change from 8 x 10^{16} ohm-cm to 5 x 10^{12} ohm-cm has been observed for concentrations in the range 9 to 50% silane, respectively.

Breakdown field strength has similarly decreased from approximately 6 x 10^6 v/cm at 9% silane to 1 x 10^6 v/cm at 50%.

Figure 6 shows the change in resistivity when plotted as a function of breakdown strength. Extrapolation of the lower portion of this graph gives the resistivity of glow discharge prepared amorphous silicon (10^{11} ohm-cm) at a breakdown voltage of 3 x 10^5 v/cm, which is a typical avalanche breakdown field for crystalline silicon. Dielectric strengths of 1.5 x 10^7 v/cm have been obtained for thicker films.

C-V measurements.—C-V measurements were made on the samples in order to evaluate their interfacial properties (18). Figure 7 shows a typical plot where the broken line represents the theoretical curve in the absence of surface charges, N_{SS}, and metal semiconductor work function difference, ΔW. The voltage offset ΔV, at flat band condition, is a direct measurement of N_{SS} for the static curve 1.

Figure 8 shows the change in surface charge density with silane concentration. At concentrations >20% there is a general tendency to lower the surface charge density from 5 x 10^{12} charges/cm^2 to 10^{11}/cm^2. At concentrations lower than 10% the density is around 8 x 10^{12}/cm^2.

Sample preheat conditions, *i.e.*, gaseous ambient and the presence of the rf glow discharge, have an effect on the surface state densities. Elimination of the discharge during the heating cycle results in lower

surface charges. The hysteresis, *i.e.*, the difference in N_{SS} values as calculated from curves 1 and 2 in Fig. 7, depends on the amplitude of the scanning bias and can be as large as $\sim 10^{12}$ charges/cm^2. All factors controlling surface charge density and hysteresis have not been determined, and work is continuing.

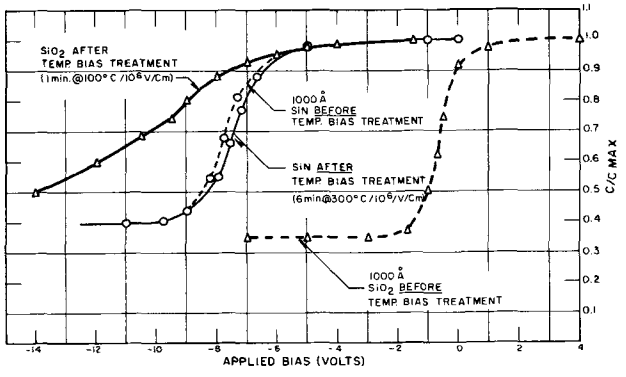

Fig. 9. C-V plots for comparison of SiO_2 and SiN after sodium contamination followed by a bake-bias treatment.

Barrier to sodium migration.—These low temperature nitrides form a barrier against the migration of sodium ions. This was tested in the following experiment with two silicon wafers. One wafer was deposited with nitride (1000Å, 30% silane concentration) and the other contained a thermally grown oxide (1000Å). Both were rinsed in NaOH solution (0.1% normal) and then evaporated with Cr-Au contacts. Their instability due to sodium drift was measured by plotting C-V curves before and after temperature-bias treatment. Figure 9 shows that for SiO_2 the drift in the C-V curves was about 9v for a temperature of 100°C and field of 10^6 v/cm applied for 1 min. For silicon nitride, no perceptible drift (<0.3v) was observed at the same applied field for 6 min at an elevated temperature of 300°C.

Silicon device passivation characteristics.—MIS transistors were fabricated from a 1000Å layer of silicon nitride (deposited using 3:1 NH_3/SiH_4, onto 2 ohm-cm N-type silicon). The threshold voltage for the subsequent P channel devices was −4.5v, G_m (at 1 ma I_D) = 500 μmhos and mobility $\overline{\mu}_p$ = 110 cm^2/v sec. The V-I characteristics of the source and drain junctions indicated diodes comparable in performance to those passivated with thermal SiO_2. The results, coupled with the absence of sodium migration, indicate that the low temperature nitride is suitable for passivating silicon planar devices.

Further measurements on surface studies and device passivation will be reported in the future.

Conclusions

Both growth and etch rates have demonstrated the compatibility of this material with existing semiconductor technology. Infrared and electrical data have shown the ability of this process to provide reproducible layers as well as controlled behavior.

The low substrate temperature offers an attractive feature for passivating P-N junctions where movement of the diffusion front is not desired.

The Preparation and Properties of Amorphous Silicon Nitride Films

T. L. Chu, C. H. Lee, and G. A. Gruber

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Amorphous silicon nitride films have been deposited in a gas flow system by the ammonolysis of silicon tetrachloride and the nitridation of silane with ammonia on heated substrate surfaces. The dependence of the deposition rate on the substrate temperature and the reactant composition and flow rate are discussed. The deposited films have been shown by the chemical analysis and electron beam induced crystallization to have the composition Si_3N_4. The density, refractive index, infrared absorption, and dissolution rate of deposited silicon nitride films have been determined. The substrate temperature during the deposition process appears to have the most significant influence on these properties, particularly density and dissolution rate. Silicon nitride films can be used as masks against the diffusion of aluminum, boron, and phosphorus into silicon. However, these dopants have been found to react with silicon nitride in varying degrees at high temperatures, and these reactions must be considered in determining the thickness of silicon nitride film required for masking purposes.

Silicon nitride has been known as a refractory for over a century. Crystalline silicon nitride ceramics, obtained by the reaction-sintering or hot-pressing technique, are noted for their chemical inertness, high temperature strength, high electrical resistivity, good thermal shock resistance, and extreme hardness (1). They have been used for many high temperature applications, such as container for molten metals and glasses, radiation heat shields, rocket-nozzle inserts, stator blades for gas turbines, etc. Very recently, silicon nitride has been used as a dielectric in electronic devices, utilizing its imperviousness to supplement the more commonly used silicon dioxide (2). The disadvantages of silicon dioxide, such as the high permeability toward moisture and other impurities, associated with its inherent structural porosity are well known. To be useful in devices, however, silicon nitride must be prepared in the form of amorphous and adherent films on semiconductor surfaces; the amorphous films possess more uniform properties than polycrystalline films.

In this work, the thermochemistry of the formation of silicon nitride from silicon and silicon compounds has been considered. The ammonolysis of silicon tetrachloride and the nitridation of silane with ammonia in a flow system were used to deposit silicon nitride films on silicon substrates. The properties of these films, such as structure, composition, density, refractive index, infrared absorption, dissolution rate, and masking ability, were studied. The experimental approaches and results are discussed in this paper. Wherever appropriate, comparisons with results of other workers are also made.

Preparation of Silicon Nitride Films

Thermochemistry of formation of silicon nitride.— Silicon dioxide has been produced by a number of chemical reactions, such as the oxidation of silicon or silane, and the hydrolysis of silicon halides. Analogous reactions can be used for the formation of silicon nitride (1). The standard free energy changes of (*a*) the nitridation of silicon and silane with nitrogen or ammonia and (*b*) the reaction of silicon tetrachloride with ammonia or nitrogen-hydrogen mixtures in the temperature range 1000° to 1500°K, calculated from the JANAF thermochemical data (3), are shown in Fig. 1. All these reactions are thermochemically feasible. It should be noted that the reactions using ammonia are more favorable than similar reactions using nitrogen because of the higher free energy of formation of ammonia. The use of ammonia is also advantageous kinetically; nitrogen is chemically inert due to the large bond energy in the molecule.

Not all reactions shown in Fig. 1 are suitable for the deposition of amorphous silicon nitride films. The nitridation of silicon is a slow process at 1300°C and above because of the diffusion-controlled mechanism (4). Furthermore, the heating of single crystal silicon

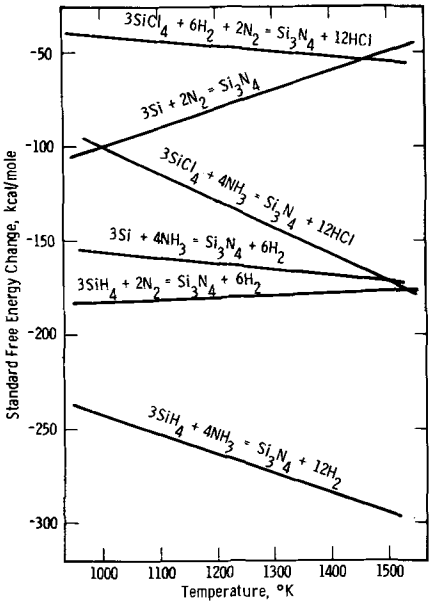

Fig. 1. Free energy changes of the formation of silicon nitride from silicon, silicon tetrachloride, and silane.

wafers of {111} orientation in nitrogen or an argon-nitrogen mixture has been found to produce discontinuous films of crystalline α-silicon nitride (5). Similar results have been obtained when single crystal silicon wafers were heated in ammonia at one atmosphere pressure (6). These films are not suitable for many device purposes because of grain boundaries.

The ammonolysis of silicon tetrachloride is a complicated reaction. When ammonia is present in excess, silicon diimide is the principal product at room temperature (7). $SiCl_4 + 6\ NH_3 \rightarrow Si(NH)_2 + 4NH_4Cl$. The silicon diimide formed polymerizes readily, and its pyrolysis yields α-silicon nitride according to the following equation (8)

$$6[Si(NH)_2]_x \xrightarrow[-2\ NH_3]{400°C} 2[Si_3(NH)_3N_2]_x \xrightarrow[-NH_3]{650°C}$$

$$3[Si_2(NH)N_2]_x \xrightarrow[-NH_3]{1250°C} 2\alpha\text{—}Si_3N_4$$

The deposition of silicon nitride films on silicon substrates by the reaction between silicon tetrachloride and ammonia in the temperature range 550°-1250°C has been reported recently (9). Earlier attempts to prepare silicon nitride films by the reaction of silicon tetrabromide, nitrogen, and hydrogen at 960°C were not successful (10).

The reaction between silane and ammonia is less complex, involving presumably the formation of silicon-hydrogen radicals or silicon and its subsequent reaction with ammonia. The deposition of amorphous silicon nitride films has been accomplished by this reaction using an rf discharge technique (11) or high temperatures (6, 12, 13).

Experimental.—The deposition of silicon nitride was carried out in a flow system using the ammonolysis of silicon tetrachloride and the nitridation of silane with ammonia on heated substrate surfaces. In the ammonolysis process, hydrogen was used to carry silicon tetrachloride into the reaction tube. No diluent was used in the nitridation process to eliminate any nitrogen deficiency in the deposit, in contrast with the large excess of hydrogen used in other reported work (12, 13). Ammonia used in this work was of better than 99.995% purity.

The deposition process was carried out in a horizontal fused silica tube of 55 mm I.D. In the ammonolysis technique, ammonia and silicon tetrachloride were introduced separately into the reaction tube since they react instantaneously at room temperature. Furthermore, the reaction tube was maintained at 375°C to eliminate the condensation of ammonium chloride, a by-product of the reaction. In the nitridation process, on the other hand, the reaction tube was water-cooled to minimize homogeneous nucleation in the gas phase. Single crystal silicon wafers of {111} orientation, chemically polished with a nitric acid-hydrofluoric acid mixture, were used as substrates in all experiments. They were supported on a silicon-coated susceptor in the reaction tube, and the susceptor heated externally by an rf generator.

The thickness of silicon nitride films was determined in the following manner. For films of a few microns thickness, direct measurement of the fractured cross section of the specimen with an optical microscope was used. The thickness of thin films was determined by using sodium light interference fringes in an etched wedge. The wedge was produced by dissolving a portion of the film in 49% hydrofluoric acid while the remainder was masked with Apiezon W wax. The refractive index of silicon nitride is taken as 2.0 in these determinations, and one interference fringe of sodium light corresponds to a thickness of 1470Å.

Results and discussion.—The most important criterion of obtaining adherent films by the chemical deposition technique is that the reaction should take place predominately on the substrate surface. In the ammonolysis technique, the wall of the reaction tube was maintained at 375°C, and the reactant mixture produced no deposit on the wall before reaching the substrates. Furthermore, by using a low partial pressure of silicon tetrachloride in the reactant mixture and a high gas velocity over the substrate surface, the deposited films were transparent and adherent to the substrate. Thus, no solid intermediates of the ammonolysis of silicon tetrachloride were produced in the volume of the reaction tube. The polymerization of silicon diimide and other intermediates is presumably a slow process.

Silicon nitride films were deposited on silicon substrates at 1000°-1200°C using ammonia at flow rates of 6-16 l/min and silicon tetrachloride at flow rates of 3×10^{-4} to 3×10^{-3} moles/min. Under these conditions, adherent and transparent films were obtained, and the deposition rate was found to be essentially independent of temperature in the temperature range studied. Some examples showing the dependence of the deposition rate on the composition and flow rate of the reactant mixture are summarized in Table I.

The deposition of silicon nitride films by the nitridation of silane with ammonia was studied in more detail; this technique is simpler and more flexible in operation than the ammonolysis of silicon tetrachloride. A large excess of ammonia was also used to minimize any nitrogen deficiency in deposited films. The effect of substrate temperature on the deposition rate was studied in the temperature range 800°-1200°C. The flow rate of silane was 2 ml/min, and that of ammonia was 20 or 40 l/min, corresponding to SiH_4/NH_3 molar ratios of 10^{-4} or 5×10^{-5}. The results are shown in Fig. 2. The deposition process is comprised of several consecutive steps: diffusion of reactants to the substrate surface, their absorption and subsequent reaction on the surface, the desorption of by-products, and their diffusion away from the surface. At substrate temperatures below about 1000°C,

Table I. Deposition rate of silicon nitride as a function of reactant composition and flow rate

Flow rate of NH_3, l/min	$SiCl_4/NH_3$ molar ratio	Average deposition rate, μ/min
16	6×10^{-3}	0.8
12	6×10^{-3}	0.95
6	6×10^{-3}	1
6	3×10^{-3}	0.65
6	1.2×10^{-3}	0.5

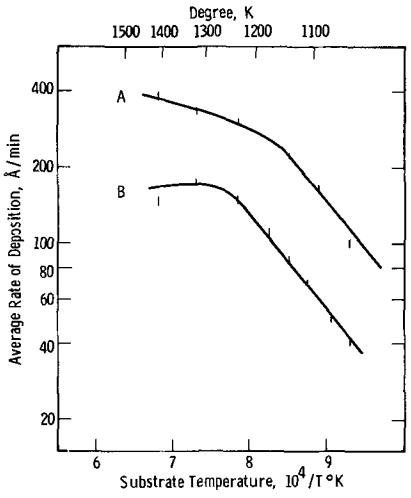

Fig. 2. Temperature dependence of deposition of silicon nitride films. A: Flow rate of NH_3 = 20 l/min, flow rate of SiH_4 = 2 ml/min. B: Flow rate of NH_3 = 40 l/min, flow rate of SiH_4 = 2 ml/min.

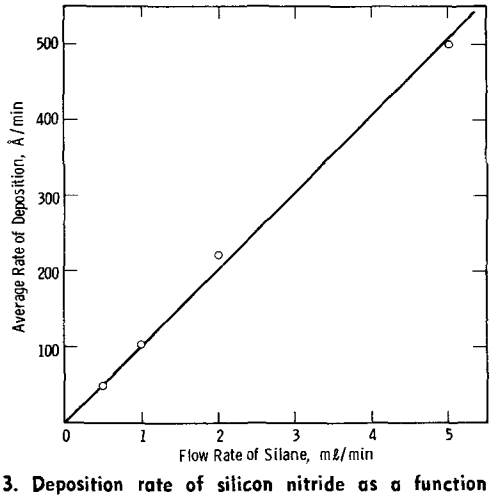

Fig. 3. Deposition rate of silicon nitride as a function of the silane flow rate. Flow rate of NH_3 = 20 l/min, substrate temperature = 900°C.

the deposition rate varied exponentially with temperature, with an apparent activation energy of 17 kcal/mole, indicating that chemical processes on the substrate surface are presumably the rate-determining step. At higher temperatures, the deposition rate leveled off with increasing temperature, indicating that the diffusion processes become more important.

The effects of reactant composition on the deposition rate of silicon nitride films were studied using ammonia flow rate of 20 l/min at a substrate temperature of 900°C. The flow rate of silane was varied from 0.5 to 5 ml/min; the results are shown in Fig. 3. In this concentration range, the deposition rate appeared to be a linear function of the silane concentration.

Properties of Silicon Nitride Films

Structure and composition.—Silicon nitride films deposited on silicon substrates by the ammonolysis of silicon tetrachloride or the nitridation of silane with ammonia were uniform, transparent, and highly adherent to the substrate. [The cracking of the film and the warping of the substrate at large film thickness were observed, as reported by others (12).] They exhibited no structural features when examined with an optical microscope. Several films were examined by both reflection and transmission electron microscopy; in the latter case, the substrate was removed by jet etching using a hydrofluoric-nitric acid mixture. Very diffused ring patterns were observed in all cases

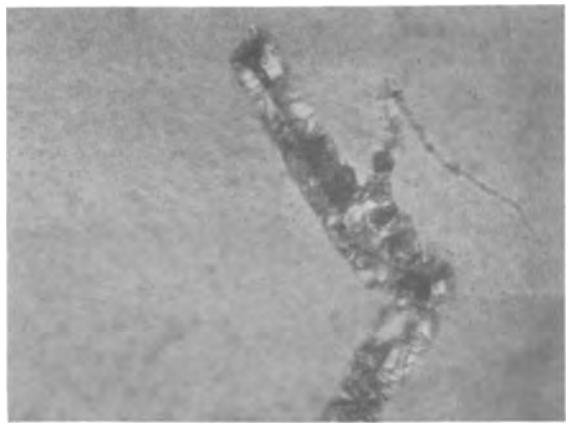

Fig. 4. Alpha-silicon nitride crystallite in an amorphous silicon nitride film deposited at 1200°C. Magnification 30,000X.

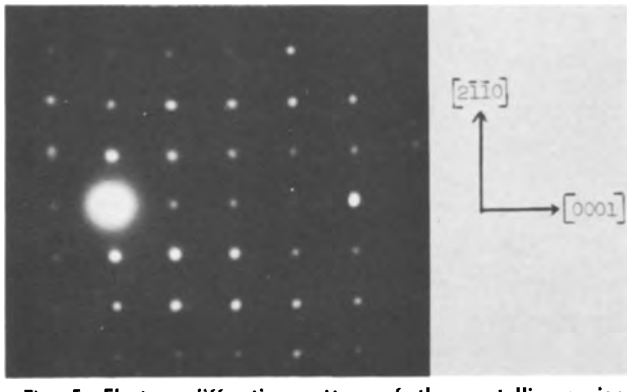

Fig. 5. Electron diffraction pattern of the crystalline region shown in Fig. 4.

indicating the amorphous nature of the film. In films deposited at 1200°C, however, localized regions of single crystalline α-silicon nitride have been observed. An example is shown in Fig. 4; this crystallinity was presumably induced by foreign impurities or defects on the substrate surface before deposition. Figure 5 shows the electron diffraction pattern of the crystalline region shown in Fig. 4, the surface of the nitride crystal being of $\{11\bar{2}0\}$ orientation, perpendicular to the basal plane. These results are different from those obtained when a large excess of hydrogen is used in the nitridation process. In the latter case, small crystallites appeared on the substrate surface at 900°-1000°C, and their concentration increased with increasing temperature of deposition (13).

Silicon nitride films deposited at 800°-1000°C were annealed at 1200°C in a nitrogen atmosphere for 4 hr or longer. The resulting films remained amorphous as indicated by the diffuse electron diffraction patterns.

Amorphous silicon nitride films were found to crystallize after being subjected to an intense electron beam in the electron microscope. Figure 6 shows the crystallized region of an amorphous film; the diffraction pattern of this region, shown in Fig. 7, was identified as that of single crystalline α-silicon nitride with its surface parallel to the basal plane. Thus, the composition of the amorphous film is Si_3N_4. Bombardment of silicon nitride films with a very intense electron beam resulted in the decomposition of the film to yield diffraction patterns characteristic of polycrystalline silicon.

The composition of amorphous silicon nitride films deposited by the nitridation of silane was also determined by chemical analysis. Silicon nitride layers were separated from the substrates by dissolving the substrate in a 10 : 1 HNO_3-HF mixture. The nitrogen content of the specimens was determined by an al-

kali fusion technique. A weighed amount of the specimen, about 0.1g, was mixed with 5g of sodium hydroxide in a platinum crucible, and the mixture was heated in a tube furnace to about 700°C for about 2 hr. The liberated ammonia, from the reaction between silicon nitride and sodium hydroxide, was carried by a nitrogen flow, absorbed in a saturated solution of boric acid, and titrated with 0.1*N* hydrochloric acid. The silicon analysis was also carried out by alkali fusion; a similar quantity of specimen was heated with a mixture of $NaNO_3$ and Na_2CO_3 in a platinum crucible. The resulting mass was treated with perchloric acid, and the precipitated silica was washed, and ignited at 1000°C for 1 hr. The weight of silica is used to determine the silicon content of the specimen. The results of the chemical analysis of deposited films and silicon nitride powder supplied by the Union Carbide Metals Company are shown in Table II; the composition of the deposited films is seen to correspond to Si_3N_4.

Density, refractive index, and infrared absorption.—The density of silicon nitride films, deposited by the ammonolysis and nitridation techniques, was determined by the floating equilibrium technique using a mixture of methylene iodide and bromoform. The results are summarized in Table III; the nitride films deposited at higher temperatures possess higher density as expected. It is also noted that the density of amorphous silicon nitride approaches that of the crystalline modification as the deposition temperature increases, while the density of amorphous silica (2.2g cm^{-3}) is considerably lower than that of quartz (2.65g cm^{-3}).

α-Si_3N_4, theoretical (1)		3.18

The refractive index of silicon nitride film was determined by an optical interference technique. The nitride film was removed from a portion of the specimen by masking and etching techniques to produce a smooth wedge. A portion of the specimen surface was metallized across the wedge with an aluminum film of about 500Å thickness. The displacement of thallium light (λ = 5350Å) interference fringes on crossing the wedge in the metallized and nonmetallized portions was measured using a Zeiss double beam interferometer. The fringe displacement on the metallized portion, p, is related to the absolute thickness of the film, and that on the nonmetallized portion, q, is related to the optical thickness of the film. The refractive index of the silicon nitride film, 1 + q/p, was determined to be 2.00 ± 0.04, irrespective of the chemical reaction used for the deposition process and the substrate temperature. However, ellipsometric measurements indicate that the refractive index of silicon nitride films, deposited by the nitridation process, at 5460Å increases slightly with increasing temperature of deposition. Typical values are 1.975 ± 0.005, 1.980 ± 0.005, and 2.020 ± 0.005 for films deposited at 800°, 950°, and 1200°C, respectively.

The infrared absorption spectra of silicon nitride films deposited by ammonolysis and nitridation techniques were taken on a Model 531 Perkin-Elmer Spectrophotometer. They all showed a broad absorption band with maxima at 830-860 cm^{-1} depending on the deposition temperature; this absorption is associated with one of the Si-N bond stretching frequencies. A typical example is shown in Fig. 8. In this case, a nitride film of 0.85μ thickness was deposited on an n-type 40 ohm-cm silicon substrate at 950°C, and the absorption peak is at about 850 cm^{-1}. Qualitatively, the absorption peak is shifted toward higher frequencies at higher deposition temperatures. For example, films deposited at 1000° and 1100°C showed absorption peak at 860 cm^{-1}.

Dissolution rate in hydrofluoric acid.—In contrast to crystalline silicon nitride, amorphous silicon nitride is soluble in concentrated hydrofluoric acid. The dissolution rate of amorphous silicon nitride is affected by porosity, impurities, etc., in the film, and provides a

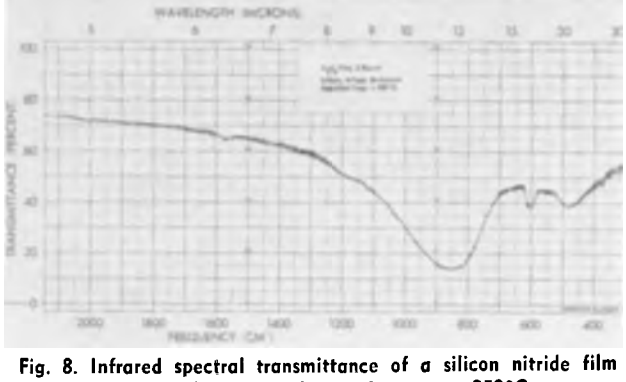

Fig. 8. Infrared spectral transmittance of a silicon nitride film deposited on n-type 40 ohm-cm silicon substrates at 950°C.

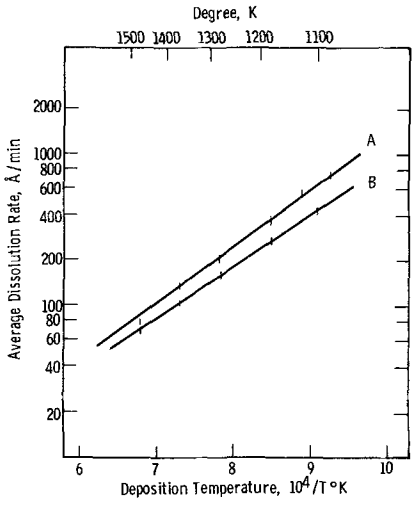

Fig. 9. Dissolution rate of silicon nitride in 49% HF at 24°C as a function of deposition temperature. A: Flow rate of ammonia = 20 l/min, flow rate of SiH_4 = 2 ml/min. B: Flow rate of ammonia = 40 l/min, flow rate of SiH_4 = 2 ml/min.

qualitative comparison of nitride films prepared under different conditions. Whenever localized areas of crystalline silicon nitride are present, these areas are essentially unaffected by hydrofluoric acid.

The dissolution rate of silicon nitride films deposited by the nitridation technique under conditions shown in Fig. 2 was determined at 24°C, using 49% hydrofluoric acid as the etchant. The temperature of deposition appears to have the most pronounced influence on the dissolution rate of silicon nitride films, as shown in Fig. 9. The linear relations shown here probably have no theoretical significance. The dissolution rate increases rapidly with decreasing deposition temperature. This is due presumably to the higher density of the films deposited at higher temperatures. Figure 9 also indicates that at a given substrate temperature, the dissolution rate also increases with increasing rate of deposition. Silicon nitride films deposited by the ammonolysis technique showed similar dependence of dissolution rate on the deposition temperature and deposition rate. Furthermore, the dissolution rate of silicon nitride films deposited at low temperatures was found to decrease after annealing at higher temperatures due to densification.

Masking ability.—Amorphous silicon nitride, because of its higher density, is expected to be more impervious than amorphous silica. The activation energy of dopant diffusion in silicon nitride should also be very high due to its refractory nature. Silicon nitride films have been shown to be more effective than silica films for masking against the diffusion of dopants into silicon (14). The capabilities and limitations of silicon nitride films as masks against the diffusion of aluminum, boron, and phosphorus into silicon were studied in this work.

Silicon nitride films deposited on silicon substrates at 800° to 1100°C by the ammonolysis or nitridation technique were used in the diffusion experiments. The silicon substrates were n-type, 20-50 ohm-cm resistivity for the diffusion of aluminum and boron, and were p-type, 10-20 ohm-cm resistivity for the diffusion of phosphorus. The silicon nitride film was removed completely from selected areas of the specimen by masking and etching techniques. The aluminum diffusion was carried out at 1150°C in a sealed fused silica tube using aluminum-silicon eutectic as the source material. A silicon nitride film of 0.18μ thickness deposited by the ammonolysis technique was found to show negligible deterioration after 44 hr of diffusion. The resistivity of silicon under the nitride film remained the same, while in unmasked regions, the surface concentration of aluminum in silicon and junction depth were estimated to be 10^{16} cm^{-3} and

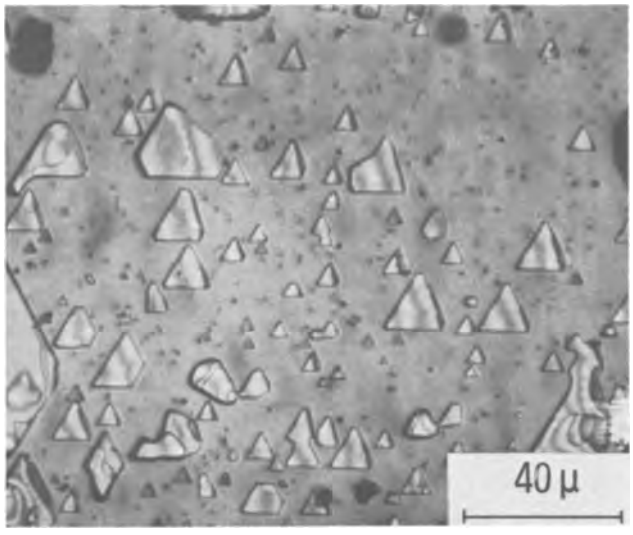

Fig. 10. Surface of a silicon nitride film after subjected to aluminum diffusion in a closed tube at 1150°C for 98 hr.

23μ, respectively. As the duration of diffusion increased, however, the silicon nitride film gradually deteriorated. Figure 10 shows the surface of a silicon nitride film after having been subjected to aluminum diffusion in a closed tube at 1150°C for 98 hr.

The boron diffusion was carried out using a two-step process. In the first step, boron oxide glass was deposited on the specimen surface at 1100°C for an hour using boron tribromide as the source. A diffused layer of about 3μ deep with a surface concentration of 10^{20} cm^{-3} was formed in the unmasked regions of the specimen. The boron oxide glass was then removed by using aqueous hydrofluoric acid before the second step of diffusion, or "drive-in." The masking ability of silicon nitride is independent of the "drive-in" step if the boron oxide glass is completely removed. A silicon nitride film of 500Å thickness deposited by the nitridation technique was found to be successful for masking the diffusion of boron under the conditions used here. Figure 11 shows the angle-lapped and stained surface of a specimen, where a nitride film of 500Å was used in the masked region and the "drive-in" step was carried out at 1200°C for 16 hr. The junction depth in the unmasked region was about 20μ, and silicon under the nitride film was found to remain n-type with essentially no change in resistivity.

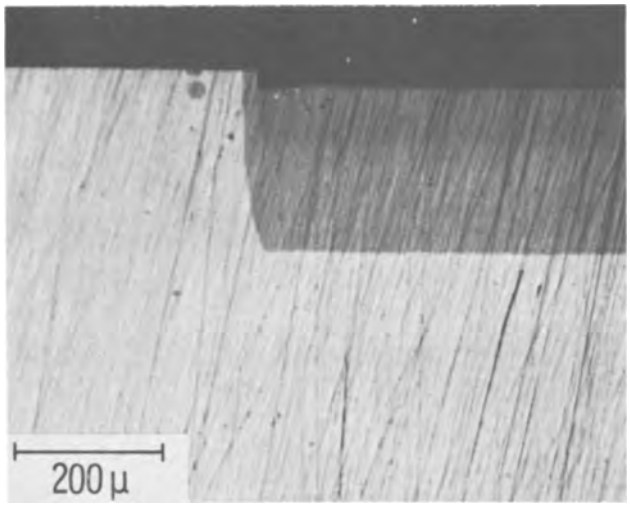

Fig. 11. Angle-lapped and HF stained surface of a specimen showing the effectiveness of a 500Å thick silicon nitride film as a mask against the diffusion of boron into silicon. Boron oxide glass was deposited at 1100°C for 1 hr followed by heating at 1200°C for 16 hr.

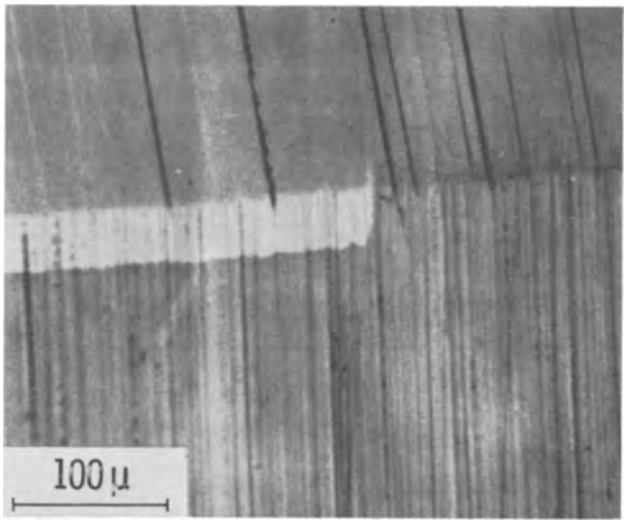

Fig. 12. Angle-lapped and HF stained surface of a specimen showing the effectiveness of a 1300Å thick silicon nitride film as a mask against the diffusion of phosphorus into silicon. Phosphorus oxide glass was deposited at 1100°C to yield a junction depth of 3μ and a surface concentration of 10^{21} cm^{-3}.

It should be pointed out, however, that silicon nitride reacts slowly with boron oxide at high temperatures. Thicker films used by others (14) are perhaps more desirable.

In the phosphorus diffusion process, phosphorus oxide glass was deposited on the specimen surface at 1100°C for 1 hr using phosphorus oxytrichloride as the source. A diffused layer of 3μ thickness with a surface concentration of about 10^{21} cm^{-3} was formed in unmasked regions. Phosphorus pentoxide was found to be more reactive toward silicon nitride than boron oxide. A silicon nitride film of 1000Å thickness deposited by the nitridation technique was found to be completely reacted under the conditions used here. In contrast to silicon nitride, the reaction product between silicon nitride and phosphorus pentoxide dissolves readily in diluted hydrofluoric acid. A nitride film of 1300Å was sufficient to mask the diffusion of phosphorus as shown in Fig. 12; however, thicker films are necessary for many device purposes.

Summary and Conclusions

Amorphous silicon nitride films have been deposited on silicon substrates in a gas flow system by the ammonolysis of silicon tetrachloride or the nitridation of silane with ammonia on heated substrate surfaces. The ammonolysis reaction is complicated by the formation of ammonium chloride and polymeric intermediate products. The nitridation reaction is more flexible for the deposition of silicon nitride films. In this deposition process, the chemical processes on the substrate surface are the rate-determining step at temperatures below 1000°C, and the diffusion processes become more important at higher temperatures.

All silicon nitride films, including those annealed at 1200°C for several hours, have been shown to be amorphous by electron diffraction examinations. However, foreign impurities or defects on the substrate surface could catalyze the formation of crystalline silicon nitride, particularly at high substrate temperatures. Amorphous silicon nitride films can be crystallized into α-silicon nitride by using electron bombardment in an electron microscope. This crystallization phenomenon and the use of chemical analysis have shown that the composition of silicon nitride films deposited in this work is Si_3N_4.

The density, refractive index, infrared absorption, and dissolution rate of deposited silicon nitride films are dependent on the substrate temperature during the deposition process. Films deposited at high temperatures are characterized by higher density and lower dissolution rate than those deposited at lower temperatures.

Amorphous silicon nitride is more dense and more impervious than amorphous silica. Silicon nitride films are, therefore, expected to be more effective than silica films for masking against the diffusion of dopants into semiconductors. However, silicon nitride has been found to react in varying degrees with the commonly used dopants for silicon at high temperatures, particularly phosphorus pentoxide. These reactions must be considered when deep junctions are required.

The Heat-Treatment of Anodic Oxide Films on Tantalum

VI. The Effect of Chemical Thinning

Donald M. Smyth

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The dielectric properties of anodized tantalum, which has been heat-treated in air, have been studied as a function of subsequent chemical reduction of the oxide thickness. The results are in quantitative agreement with an exponential distribution of dielectric losses decreasing monotonically from the Ta-Ta_2O_5 interface.

It has been found that the dielectric properties of anodic oxide films on tantalum, which have been heated to 300°-500° in air or oxygen, are explainable on the basis of an exponential conductivity gradient across the oxide (1). This conductivity was assumed to be related to oxygen deficiency in the Ta_2O_5 which results from extraction of oxygen from the oxide by the underlying tantalum metal. Thus the equilibration of the oxide between the reducing character of the metal and the oxidizing ability of the ambient air leads to a gradient of stoichiometry, and hence of conductivity, across the oxide. This explanation would require that the conductivity in the oxide decrease monotonically from the Ta-Ta_2O_5 interface (unless there is an oxygen-excess, p-type conducting region at the other interface). Qualitative evidence has been presented which shows that the major portion of the conductivity lies near the metal (2). The purpose of this report is to show that the spatial distribution of losses in the heat-treated oxide is in quantitative agreement with the proposed model.

A-C bridge measurements give no information about the spatial distribution of dielectric losses in a given piece of dielectric. In effect, such measurements yield a collection of incremental thicknesses, each with a known equivalent parallel conductivity, but cannot distinguish between the possible sequential arrangements of these increments. The only technique now available for obtaining the spatial distribution of losses is to make consecutive measurements as the dielectric is chemically thinned. This technique can lead to serious misinterpretation if the dissolution is so nonuniform as to open paths through the oxide to the underlying metal, but, with suitable precautions, meaningful results can be obtained (3-6).

The conductivity across the heat-treated film is expressed as

$$\sigma = \sigma_1 e^{ax} \qquad [1]$$

where x is the distance from the Ta_2O_5-electrolyte (or electrode) interface, and σ_1 is the conductivity at $x = 0$, the point of lowest conductivity. (σ_1 has no physical reality; it is merely the value obtained by extrapolation of the conductivity gradient measured near the Ta-Ta_2O_5 interface as shown in Fig. 1). It has previously been shown that the equivalent series capacitance, C_s, can be expressed as

$$\frac{1}{C_s} = \frac{1}{aA\epsilon\epsilon_0} \ln \frac{\omega\epsilon\epsilon_0}{\sigma_1} \qquad [2]$$

where ϵ is the dielectric constant of the oxide, ϵ_0 is the permittivity of free space, ω is the angular frequency of the bridge signal, and A is the sample area [1]. $\omega\epsilon\epsilon_0$ is frequently abbreviated as

$$\sigma_0 = \omega\epsilon\epsilon_0 \qquad [3]$$

[2] and [3] are approximations which are valid in the region

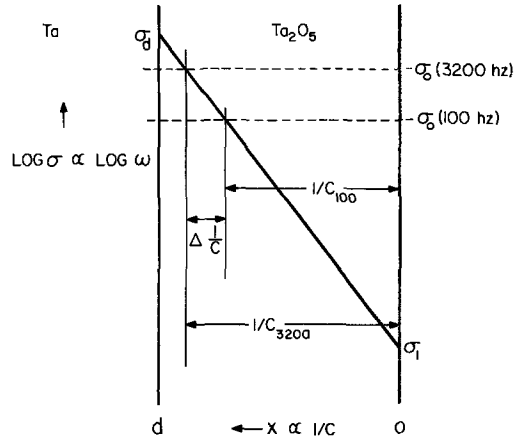

Fig. 1. Schematic representation of the relationship between the frequency dependence of capacitance and the distribution of conductivity.

$$\left(\frac{\omega\epsilon\epsilon_0}{\sigma_1}\right)^2 >> 1 >> \left(\frac{\omega\epsilon\epsilon_0}{\sigma_d}\right)^2 \qquad [4]$$

where σ_d is the conductivity at the Ta-Ta_2O_5 interface. σ_0 is further defined as the conductivity level such that the thickness between $x = 0$ and its intersection with the conductivity profile gives C_s when substituted into the parallel plate formula. In other words the intersection of σ_0 and $\sigma(x)$ defines an effective dielectric thickness, x, as in Fig. 1. From [1] and [2] it can be seen that the frequency dependence of capacitance is related to the position dependence of conductivity

$$\left[A\epsilon\epsilon_0 \frac{d\frac{1}{C_s}}{d\ln\omega}\right]^{-1} = a = \frac{d\ln\sigma}{dx} \qquad [5]$$

Since the slope, a, which can be measured only near the Ta-Ta_2O_5 interface, is independent of oxide thickness once the gradient has been established by heat-treatment, $d\frac{1}{C_s}/d\ln\omega$ should similarly be independent of subsequent thinning. This is the basis of the experimental test.

An 18.4 cm^2 sample of 0.010 in. tantalum sheet was anodically oxidized to 150v and then heated in air at 400° for 30 min. After cooling, the frequency dependence of capacitance was measured in an electrolyte of 40% H_2SO_4 and the measurement repeated after successive thinnings in 48% HF. The sample preparation and other experimental details have been described previously (1, 2, 7). It is sufficient to compare the change in $1/C$ between the same two frequencies in each case; the values at 100 and 3200 Hz were used. (See the schematic representation in Fig. 1.) The

equivalent anodization voltage thickness was determined by visual comparison with the interference colors of a set of standards made by anodic oxidation at 5v intervals. The initial color corresponded to a 160v film on the standard which was not prepared under identical conditions.

The results are presented in Table I in the form of two complete, experimental cycles separated by step 6, reanodization of the sample to 150v. The validity of the proposed model is indicated by a comparison of Δ 1/C for steps 1, 2, and 3; 7, 8, and 9; 4 and 5; and 10 and 11. The constancy of Δ 1/C is quite good for the first two sets. For the latter two, the thinning was becoming noticeably nonuniform as indicated by some variation in the interference colors, but the agreement is still reasonable.

These results actually confirm only that no significant dielectric losses were present in the portion of oxide removed by thinning, and thus indicate only that the property-determining losses are located closer to the Ta-Ta_2O_5 interface. In order to confirm the exponential distribution by this type of analysis it would be necessary to remove 80-90% of the oxide to determine how the properties change as the lossy oxide is removed. It is very unlikely that thinning of Ta_2O_5 to this extent by dissolution in HF could be accomplished without opening physical flaws in the oxide.

From the data obtained during this experiment it is possible to make a detailed check of the applicability of the exponential gradient theory. Calculated and observed values are shown in Table II where the data refer to measurements made at 34° and 100 Hz. The step numbers refer to the sequence listed in Table I. The calculations were based on $\sigma_d = 9 \times 10^{-7}$ ohm^{-1} cm^{-1} [estimated from Fig. 4 of ref. (1)], and $\sigma_0 = \omega\epsilon\epsilon_0 = 1.6 \times 10^{-9}$ [ϵ was taken as 1.05 x 27.6 where the factor of 1.05 is a correction for the irreversible increase in ϵ caused by heat-treatment (2, 7)]. The analysis can be better understood by reference to Fig. 2 which depicts the conductivity gradient across the heat-treated oxide (the solid diagonal from σ_d to σ_1). The capacitance after heat-treatment measures x_1, the effective dielectric thickness. The value of σ_1 can be calculated from the relation

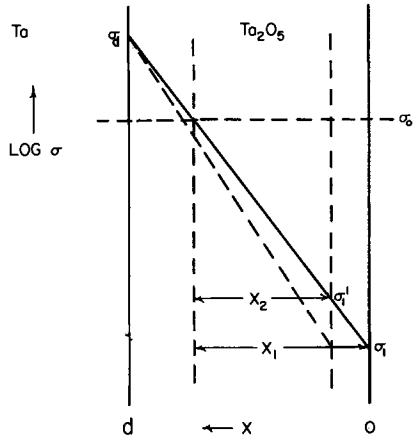

Fig. 2. Schematic representation of the analysis of dielectric losses of heat-treated, anodized tantalum after thinning.

$$\tan \delta = \frac{\pi}{2 \ln (\sigma_0/\sigma_1)} \qquad [6]$$

which was derived in ref. (1) and is accurate within the limitations of [4]. After thinning the oxide to the right-hand, vertical, dashed line, the new capacitance measures x_2, and σ'_1 can be obtained by the principle of similar triangles

$$\frac{\ln \frac{\sigma_0}{\sigma_1}}{x_1} = \frac{\ln \frac{\sigma_0}{\sigma'_1}}{x_2} \qquad [7]$$

Then a new tan δ can be calculated from σ'_1 and [6] and compared with the experimental value. [All experimental values of tan δ were corrected for the electrolyte resistance by subtraction of the extrapolated value of R_s at $1/f = 0$ (8)]. The agreement with observed values is particularly good for steps 2, 3, 8, and 9.

Another important point comes out of these data. When the sample was initially heated the capacitance and tan δ increased as usual, reflecting the effect of the losses due to increased conductivity. When the sample was reheated after thinning, however, the capacitance and losses both decreased. This behavior is anticipated by the proposed model. During the initial heating, the equilibrium conductivity gradient is established between σ_d and σ_1, which are determined solely by the equilibrium conditions at the two interfaces. As a result of the thinning process σ_1 is increased above this equilibrium, heat-treatment value (see Fig. 2). On reheating, a new gradient is set up across the reduced thickness between the original, equilibrium values of σ_d and σ_1 (the diagonal, dashed line in Fig. 2). This results in a steeper gradient which is observed as a decrease in both capacitance and tan δ. This new gradient is the same as that which would have been obtained by heat-treatment of a sample originally anodized to this thickness. (The steeper gradient means that less thickness is effectively shorted out and that there is a sharper boundary between conducting and insulating oxide.) This is perhaps the most direct evidence that physical damage to the oxide during heat-treatment does not play a significant role in the determination of the dielectric properties. Further heating could only result in further damage which would cause another increase in capacitance and losses.

The calculated conductivity gradients for the heat-treated samples (steps 1, 4, 7, and 10) are slightly steeper than previously reported. It should be particularly noted that the gradients for the reheated films after thinning are steeper than those of the original heated films (4 and 10 *vs.* 1 and 7). This is in line with a second-order effect which has been noted consistently throughout this work. The equilibrium value

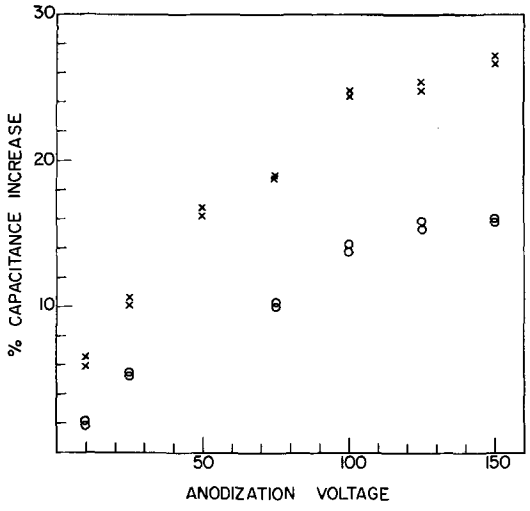

Fig. 3. Equilibrium capacitance increase due to heat-treatment at 400° in air as a function of oxide thickness (50 Hz data): x relative to unheated capacitance; o relative to reanodized capacitance after heat-treatment.

of log σ_d/σ_1 is larger the thinner the film. It has previously been stated that the percentage capacitance change due to heat-treatment is independent of film thickness for anodization voltages above 50v, but that the change is less for thinner films. This behavior is shown in detail in Fig. 3 which shows the equilibrium percentage capacitance change after heating at 400° in air relative to both the unheated capacitance and also to the capacitance after 4 hr of reanodization at the formation voltage subsequent to heat-treatment. The former thus includes the effects of both the conductivity gradient and the permanent increase in dielectric constant, whereas the latter includes only the effect of the conductivity gradient. The reanodization time is approximately that necessary to remove the effects of the conductivity gradient; no attempt was made to test each sample for the precisely appropriate time. The capacitance increase is a smooth function of film thickness, with a tendency to flatten out toward the greater thicknesses. As a first order approximation it appears that a certain portion of the thickness does not participate in the establishment of the equilibrium gradient, and that this inert portion assumes a relatively greater importance with decreasing film thickness. The reason for this behavior is obscure at present.

In summary, the results of these experiments are in good agreement with the theory of an exponential conductivity gradient. The constancy of $d(1/C)/\ln \omega$ with thinning indicates that there are no significant dielectric losses in the outer third of the heat-treated oxide. The agreement between the calculated and observed values of tan δ for the thinned oxide depends entirely on the validity of [6] which was derived specifically from the proposed model. When thinned, heat-treated samples are reheated, the reproducible decrease in series capacitance and tan δ is a necessary consequence of the theory and indicates that the heat-treatment results in no significant physical damage to the oxide. These factors, together with those discussed in the earlier papers in this series, represent practically irrefutable evidence that there is a monotonic, exponential distribution of dielectric losses in the heat-treated oxide. Previously discussed results lead to the conclusion that these losses are most likely due to electronic conduction related to the stoichiometry of the oxide.

Acknowledgment

The technique of following the dielectric properties as a function of oxide thinning was suggested by Dr. Charles A. Steidel of the Bell Telephone Laboratories.

ABSTRACT

Electroluminescent thin films of ZnS:Cu,Pb,Cl are prepared by means of vacuum evaporation followed by post-firing. Lead incorporation is found to have a great effect on luminosity and emission spectrum. Brightness wave form is usually asymmetric with respect to each half cycle of applied a-c voltage, and as negative d-c bias is superposed on it, a new emission peak appears. It might be concluded from several experimental results that the asymmetry is due to inhomogeneities in copper distribution and quenching centers, and the new peak is caused by a d-c mechanism, perhaps by tunneling. An activation energy for copper diffusion in the films is obtained as 0.61 ev using a luminescence method.

Up to now, several papers (1-5) have been presented on the electroluminescence (EL) of thin films, where mechanisms of EL are discussed. Vlasenko and others (1) concluded that the excitation of EL in ZnS:Mn film is due to an impact mechanism. Thornton (3) proposed a mechanism of excitation by the injection of minority carriers in p-n junctions, which are randomly distributed in the volume of phosphors. According to Goldberg and Nickerson (4), heterojunctions are considered to be responsible for excitation mechanisms. However, the experimental data from which they reached their conclusions might

cover only part of the truth. Since experimental data depend on the preparation of luminescent films, inconsistencies in the above-mentioned works may be due to the different samples investigated. Most of them were Mn-activated phosphors, presumably because they are easier to prepare than phosphors containing no manganese. Since, even in powder cases, Mn-activated phosphors behave differently in electroluminescence and photoelectroluminescence from phosphors otherwise activated, it is doubtful that mechanisms in Mn-activated phosphor apply to the general phenomena of EL in fluorescent thin films of the ZnS:Cu,Cl series. To probe these ambiguous points, the author first tried to improve the luminescence properties and preparative reproducibilities of luminescent films of the ZnS:Cu, Cl series and found that lead incorporation in the films had remarkable effects on brightness, emission color, and reproducibility of the films.

This paper deals with experimental results and discussions on the preparation and EL properties of the ZnS:Cu,Pb,Cl films mentioned above.

Preparation

Thin luminescent films of ZnS:Cu,Pb,Cl were made by a two-step process of evaporation and postfiring similar to that described previously (6, 7). In evaporation, for the first 10 min a substrate was kept at 200°C by a nichrome heater attached near the rear surface of the substrate; after turning off the current of the heater, the substrate was heated slightly by radiation from the evaporation source-heater. The equilibrium temperature of the substrate was about 80°C. This method of heating substrates was most adequate to obtain tightly adherent and transparent films of good performance in this work. The evaporation was done in 60 min at an average of about 300 Å/min. The postfiring was done at a fixed temperature between 500° and 700°C for 10 to 20 min in an argon atmosphere. Cells with about 1 cm^2 area were used in the following investigation. Specimens were composed of tin-oxide coated Pyrex or quartz, a luminescent film about 2μ thick, and an aluminum film evaporated directly on the film. The original phosphor powders used as starting material were prepared in the usual way so that necessary contents of copper, lead, and chlorine were included in the host crystals of ZnS. X-ray and electron diffraction patterns with these films revealed that they have cubic structure with some traces of hexagonality, and the degree of crystallization is increased with postfiring.

Results

Luminescent properties.—In Fig. 1 effects of lead incorporation are shown on films postfired at 600°C for 20 min. Figure 1(a) is a comparison of emission spectra between ZnS:Cu,Cl and ZnS:Cu,Pb,Cl films made from powder phosphors initially activated with 2 x 10^{-3} g/g ZnS of Cu and with the same amount of Pb, and Fig. 1(b) shows the effect of Pb contents added to the phosphor on brightness and on the ratio of the blue to yellow component of luminescence of the film, where excitation is with an a-c field of 5 kc, 30v. The color components were measured through the "blue" and "visual brightness" filters of a Spectra brightness spot meter. It is obvious that in the ZnS:Cu,Pb,Cl films the blue component is more remarkable than that of the ZnS:Cu, Cl film, and both the brightness and the blue component increase with increasing Pb concentration of the original powder phosphors. The luminous intensity of the film with the concentration of 10^{-3} g/g ZnS of lead is approximately four times as high as when no lead was added. The following investigations were made with the films prepared in the same way as those used in Fig. 1 except where otherwise noted.

From the thermoluminescence shown, together with the temperature dependence of EL in Fig. 2, the film

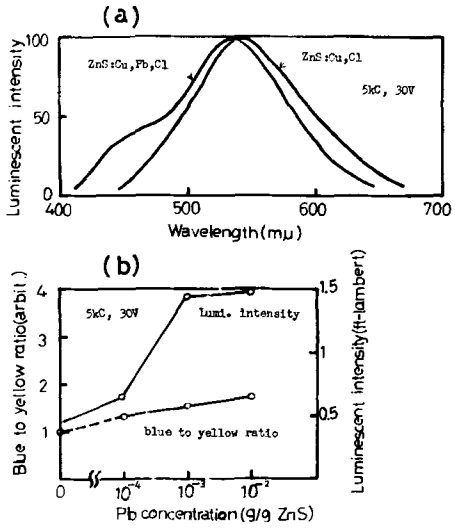

Fig. 1. Effects of lead-incorporation (a) on emission spectrum, and (b) on brightness and on the ratio of blue to yellow components of EL.

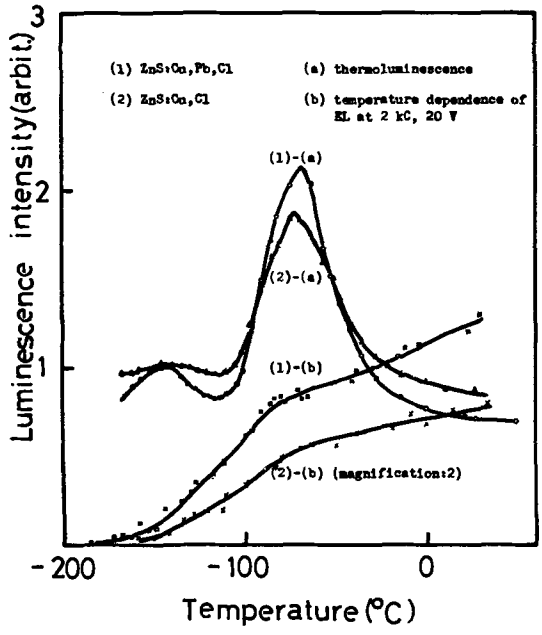

Fig. 2. Thermoluminescence and temperature-dependence of EL in a ZnS:Cu,Pb,Cl film compared with those of a ZnS:Cu,Cl film.

is found to have two peaks corresponding to 0.28 and 0.43 ev, respectively, if a frequency factor is assumed as 10^{10} sec, which is similar to those of the original powder phosphor. Although no signs showing the existence of deeper traps are perceptible from the thermoluminescence, the film shows luminescence with rather longer persistence under uv excitation, compared with the powder; this becomes more appreciable with lower lead content. In the absence of lead, the glow curve is not changed substantially except that in most cases the peak corresponding to the shallower trap becomes lower. The voltage-dependence of the luminescence of the film fits the well-known relationship (8) $B = Bo \exp(-C\sqrt{V})$ which is very familiar with conventional EL, within three orders of magnitude or more of the variation of luminescence intensity. The film has only weak d-c response, except when d.c. is superposed on an a-c field as seen later.

D-C current-voltage characteristics.—Evaporated films without any posttreatment have peculiar d-c

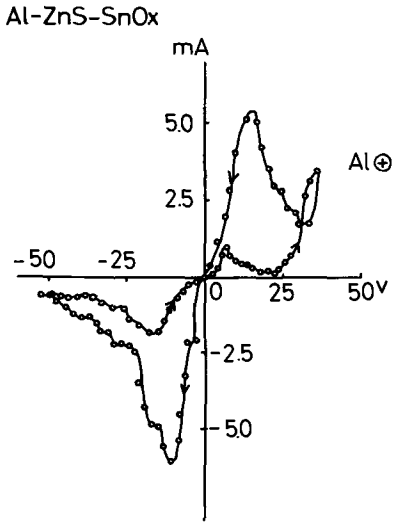

Fig. 3. Current-voltage characteristics of an evaporated film

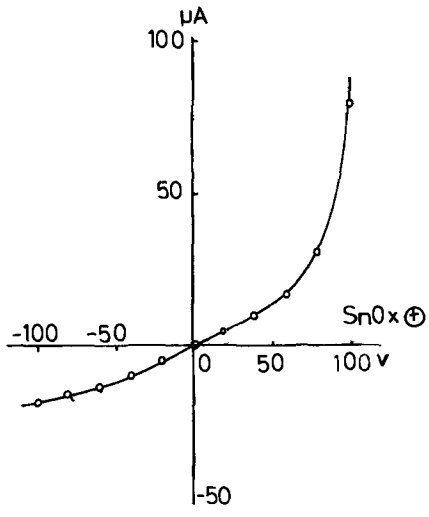

Fig. 4. Typical current-voltage relationship of a postfired luminescent film.

current-voltage characteristics. Figure 3 shows such a relationship. As voltage applied across a film which has a fairly high resistivity at first is gradually increased, at a critical voltage of some tens of volts a rapid increase occurs in current through the film. In the film thus made conductive, a negative resistance region appears on tracing the curve of current-voltage characteristics, both for increasing and decreasing voltage. This is rather noisy and varies in extent from film to film or in repeated measurement on the same sample, but is a pronounced and reproducible phenomenon, independent of the polarities of the applied voltage. However, the negative resistance characteristics should not be considered as related directly to luminescence phenomena of the film nor to any specific activator, since the phenomenon was observed regardless of the kind of activators and it disappears after postfiring. There are some cases where, at the initial application of voltage, heat-treated films show rather low resistivity of the order of hundreds of ohms between the metal and tin oxide electrodes; after such structural defects as pin holes and cracks, which cause leakage current, have been burnt out by short-circuit current through them, they become luminescent and highly resistive (several megohms). This does not mean such an essential "forming" as reported by Goldberg (4). Evidence for this view is given by the fact that, as an insulating layer made up of various materials, *e.g.*, SiO, pure ZnS, or organic materials, are put in between the film and the aluminum electrode, luminescence sets in at the first application of voltage without any forming procedures in all cases. The postfired luminescent films show more or less rectifying properties in their current-voltage relationship as seen from Fig. 4 where the direction of greater current or the forward direction is usually such that the glass side is positive. The extent of the current rectification and the behavior of the over-all current flow vary appreciably in different specimens because of slight variations by unknown factors during preparation.

Brightness wave form.—Figure 5(a) depicts a typical waveform of luminescence when a specimen is excited with a sinusoidal a-c field. It can easily be seen that at the positive polarity of voltage on the aluminum electrode, emission occurs strongly, having two peaks, P_1 and P_1', and at the reverse polarity it becomes negligible. In some other cases the emission at the negative polarity is also detectable but rather weak. Asymmetric brightness waveforms were observed also by Thornton (9) in a ZnS:Cu,Cl film, which, together with clipping or d-c bias of the applied voltage, was used to confirm separability of ex-

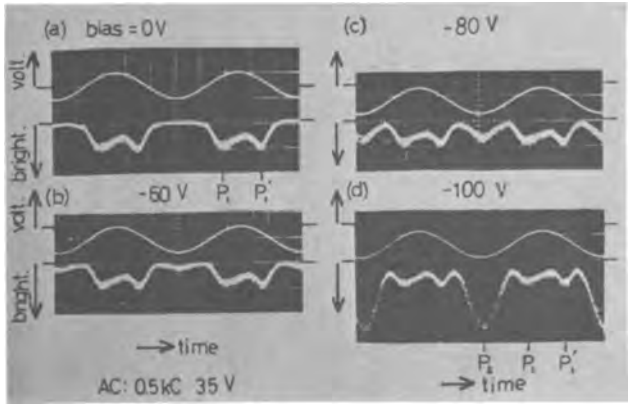

Fig. 5. Typical brightness wave forms under excitation with sinusoidal a-c field with and without a d-c bias on it. Positive voltage on the aluminum electrode is to the top of the pictures and zero levels of the voltage and brightness are marked by short-lines drawn beside them.

citation and recombination steps in EL. In this work, a small pulse superposed on the sinusoidal voltage was used to confirm this separation, which technique is familiar to workers in this field (10). The experiment leads to a conclusion similar to Thornton's, that excitation and recombination take place separately, the former occurring as the metal electrode is negative prior to the latter, that is, such a delayed emission occurs as proposed by Waymouth and Bitter (11) and others (12).

A negative d-c bias on the Al electrode superposed on sinusoidal voltage makes no change in the brightness waveform in the region of rather low bias, but, as seen from Fig. 5(b) to (d), at higher bias voltage, a new peak P_2 becomes pronounced, whereas the other peaks P_1 and P_1' remain almost unchanged. Figure 6 features the bias-voltage dependencies of P_1, P_2, and d-c current I_{dc} through the film at 0.5 kc a-c field. This behavior does not change in essence with other frequencies and voltages in the a-c field. It can be seen that both the peak P_2 and the d-c current I_{dc} vary nearly exponentially with the bias voltage. The dependencies of P_2 and I_{dc} on temperature are rather small as shown in Fig. 7, in great contrast to those of P_1 and P_1'. On the other hand, a positive d-c bias also causes a new peak in phase with the a-c voltage although it is so small that it is hardly distinguished from peaks P_1 and P_1' even at a much higher bias-voltage than in the case of the negative bias. Neither positive nor negative bias gives any

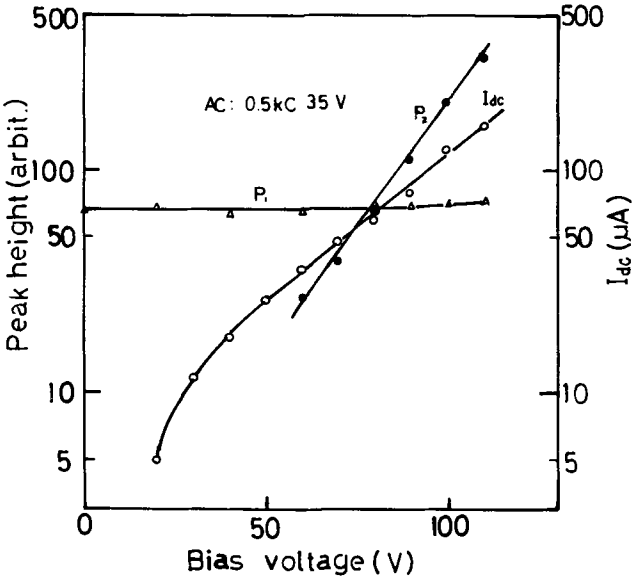

Fig. 6. Bias-voltage dependence of P_1, P_2, and I_{dc}

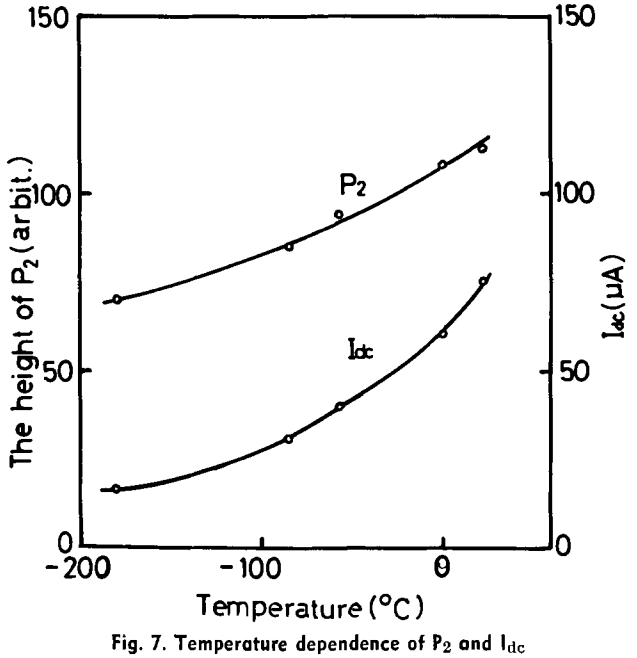

Fig. 7. Temperature dependence of P_2 and I_{dc}

drastic influence on the height and on the phase of P_1 and P_1', contrary to the result in the above reference (9). A small pulse superposed on a-c voltage also gives a pronounced influence on the peak P_2. The behavior, however, is quite opposite to those of P_1 and P_1', that is, there cannot be observed any sign to show the separability of excitation and recombination. In the build up of EL there is also present a contrast between P_1 and P_2. Peak P_2 does start without any build up, whereas peak P_1 needs several cycles to get its steady-state magnitude, as is well known in usual intrinsic EL (13).

Cathodoelectroluminescence or electrocathodoluminescence.—Some measurements were carried out to examine the effects of electric field on cathodoluminescence. Figure 8 illustrates the brightness waveforms of cathodoluminescence modified by a sinusoidal field. The field quenching of cathodoluminescence with positive polarity on the glass side is quite marked, so that the total effect of the modification results in quenching of cathodoluminescence. On varying the intensity of the electron beam, the brightness waveform changes from the modified form to that of

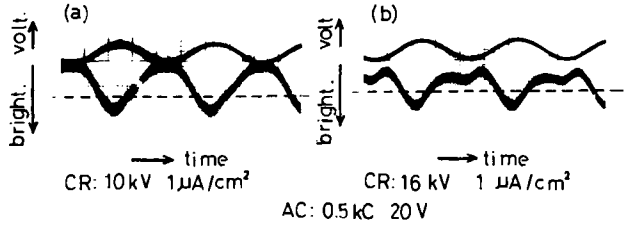

Fig. 8. Brightness waveforms of cathodoluminescence modified by a-c field. Dashed lines display the zero field cathodoluminescence level.

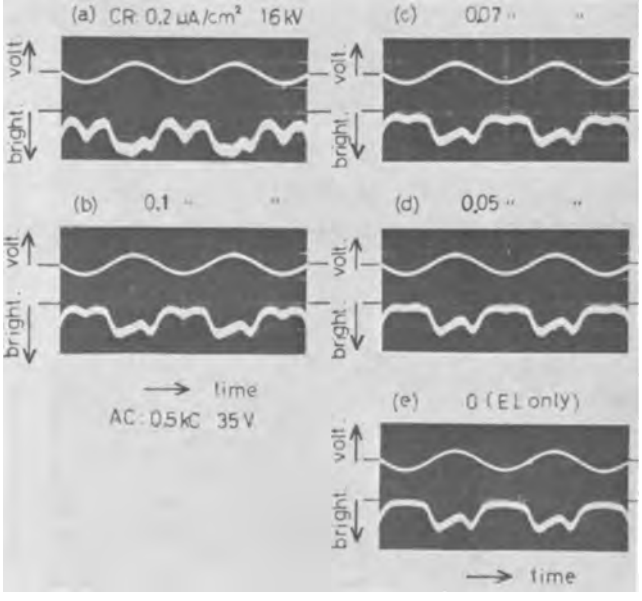

Fig. 9. Brightness waveform of cathodoluminescence superposed with EL, as both luminescences have comparable intensities. Positive voltage on the aluminum electrode is to the top of the pictures and zero levels of the voltage and brightness are marked by short lines drawn beside them.

electroluminescence. In Fig. 9 there are shown from (a) to (e) brightness waveforms with different beam intensities. As EL is competitive to cathodoluminescence, both field modified and EL waveforms can be observed to exist together, and with increasing cathodoluminescence, the modified pattern comes to dominate the over-all wave form. It is obvious that no sign of cathodoelectroluminescence appears, that is, EL is not stimulated to any degree by the electron beam, since the height of the EL peak does not vary to a noticeable degree, as seen from Fig. 9.

Copper distribution.—As is described in the Discussion, the copper added as an activator is expected to be distributed unhomogeneously throughout the films and to cause some asymmetric behavior in luminescence. The expectation gives the author a motivation to investigate the problem of copper diffusion into the film. Experiments were performed by means of a simplified technique as stated below.

Assuming that the number of luminescence centers, N, is proportional to copper-concentration $C(x)$, which is expressed as a function of the distance x from the top surface of the film, the total luminescence output B is approximately given as

$$B = \int_0^l A\eta\, C(x) \frac{dE}{dx} dx = A\eta \int_0^l C(x) \frac{dE}{dx} dx \simeq A\eta Em \int_0^l C(x)\, dx \quad [1]$$

where l is the film thickness, η is the efficiency of the center, dE/dx is the absorbed energy per unit length,

Em is the mean value of dE/dx in the film, and A is a constant. On the other hand, Fick's second law concerning diffusion yields the following equation by the assumption of the boundary conditions that $C = 0$ at $t = 0$, $C = C_1$ at $x = 0$, and $\partial c/\partial x = 0$ at $x = l$,

$$1 - \frac{\overline{C}}{C_1} = \frac{8}{\pi^2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} e^{-D\left(\frac{2m+1}{2l}\pi\right)^2 t} \quad [2]$$

where $\overline{C}$ is the mean value of the copper concentration at time t, which is equal to $\frac{1}{l}\int_0^l C(x,t)\,dx$, and C_1 is the saturated copper concentration in the equilibrium state. Using Eq. [1], $\overline{C}/C_1$ can be substituted by $B(t)/B(\infty)$ which is determinable experimentally.

In order to eliminate the effects of promoted crystallization by heat-treatment for diffusion, which results in increasing η, specimens prepared as follows were used. First, films 2μ thick were made up on quartz substrates by evaporation of a manganese-activated powder phosphor, followed by post-heating; then metallic copper was evaporated on the films to be diffused into them by different heat-treatment. For these specimens, $B_{Cu}(t)/B_{Mn}(t)/B_{Cu}(\infty)/B_{Mn}(\infty)$ can be decided instead of $B(t)/B(\infty)$, where the subscripts of Cu and Mn mean luminescence intensities due to copper and manganese, respectively. As an excitation source, cathode rays of 30 kev were used, where the variation in dE/dx is calculated as 20% in the films according to a previous work (14); this may be ignored as compared with other gross assumptions. The brightnesses of the specimens heated for 30 min and 2 hr were taken as $B(t)$ and $B(\infty)$, respectively. For the Cu-emission an interference filter with a transmission peak at 480 mμ was used, while the Mn emission was measured at 584 mμ through another interference filter. The result is shown in Fig. 10, in which the straight line expresses the relation

$$D = 2.5^{-7} \exp\left(-\frac{0.61}{kT}\right) \quad [\mathrm{cm^2/sec}] \quad [3]$$

where the activation energy for copper diffusion is obtained as 0.61 ev, that is, 14 kcal/mole. From this result, by heat-treatment for 30 min at 700°C, copper concentration at the rear, is calculated to reach 68% of that of the front. Since the films examined for luminescence properties were made from finished

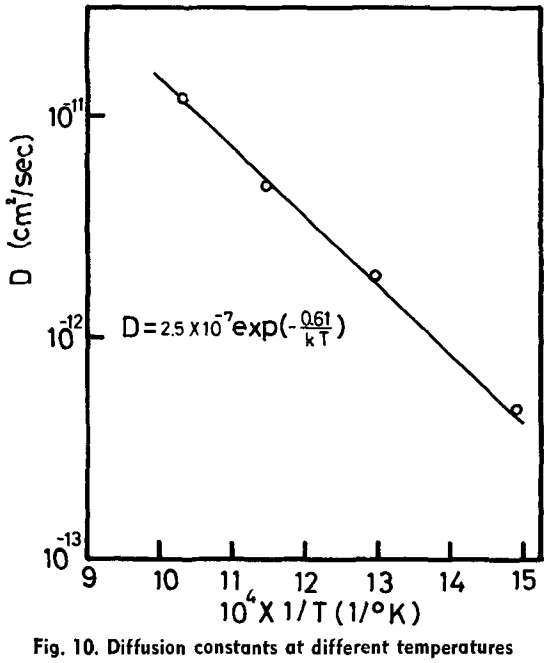

Fig. 10. Diffusion constants at different temperatures

Table I. Variations of copper concentration in a film during evaporation

Sampling	Copper concentration, g/g ZnS	
	ZnS:Cu,Pb,Cl	ZnS:Cu,Cl
In the film evaporated		
From the beginning to 10 min	1.17×10^{-4} (17%)	2.10×10^{-4} (27%)
Between 10 and 20 min	1.70×10^{-4} (25)	—
Between 20 and 30 min	3.00×10^{-4} (44)	2.92×10^{-4} (37)
In the residual in the source		
After evaporation for 30 min	9.75×10^{-4} (143)	—
Found in the original powder phosphor	6.82×10^{-4} (100)	7.80×10^{-4} (100)
Added in the original powder phosphor	20×10^{-4}	20×10^{-4}

powder phosphors, copper is supposed to be more homogeneously distributed than expected from the above result, so far as the luminescence center is concerned. Barriers due to copper, however, still seem to have some distributions.

Discussion

The evaporated films in this experiment are somewhat colored, which coloring becomes more pronounced as the lead content increases and gradually diminishes by postfiring. The coloring is attributed either to metallic copper, lead, or zinc, produced during evaporation by decomposition of the components of the powder phosphor. Table I shows how copper concentration in a film varies during evaporation. It is of note that the content of evaporated copper in a ZnS:Cu,Pb,Cl film varies markedly during evaporation and a decrease occurs in the copper concentration from the top to the rear surface of the film. Together with this, in view of the fact that an absorption appears in the vicinity of 450 mμ (15), which is characteristic of copper and becomes stronger with lead incorporation in the phosphor, the layer might be considered to be composed largely of metallic copper. It is also seen that the variation in the copper concentration also occurs in the absence of lead, but it is appreciably moderated The increase in the brightness of EL in the film containing lead would be considered to have some connection with the existence of this copper-rich layer, which might favor the formation of a potential barrier necessary for the excitation of EL. The behavior of lead which promotes the blue component of luminescence was reported also by Homer *et al.* (16) with powder phosphors doped highly with copper. Since any sample does not show remarkable emission by excitation either with electric field or with ultraviolet if only lead is incorporated, lead may act only as an auxiliary element to promote the blue emission of copper at the expense of the green, instead of contributing as its characteristic emission center. The blue center of copper was proposed by Blicks *et al.* (17) to be related to the association of the interstitial and substitutional copper. A situation like this might arise in this case by the displacement of the substitutional copper atoms which are forced out of their normal positions by the lead incorporation.

The experimental results on voltage-dependence, pulse-superposition, and build-up lead to the following conclusion. The same mechanisms as in the conventional a-c EL are available to interpret the behaviors of peaks P_1 and P_1'. The impact mechanism by accelerated electrons in potential barriers, commonly believed for excitation, seems to be most relevant. Since any cases without rather high copper concentration failed to yield good EL films, it does not seem unreasonable that a Cu_2S-phosphor contact is responsible for the potential barrier for excitation (18). The asymmetric brightness waveform might be considered to be caused by the following situations. In the region near the tin oxide electrode, the barrier is hardly formed owing to rather low copper concen-

tration as described before; moreover, as revealed in the results of electrocathodoluminescence, this region is rich in quenching centers, which might be produced due to some contaminations of the film by a reaction with the tin oxide or with other contaminants during evaporation and postfiring. The asymmetry was not remarkable in a film well made by alternately repeating evaporation and postfiring several times to get a desirable total thickness. This supports the above consideration because in such a film the barriers and the luminescence centers seem to be more uniformly distributed. On the other hand, from the facts that peak P_2 is not a delayed emission, that its temperature dependence is so little compared with those of the peaks P_1 and P_1', and its occurrence does not give any significant effects on the other peaks, the emission of the P_2 is thought to be due to a different excitation mechanism from those of the others. Tunneling of electrons with high energy through a barrier from the metal could be a part of a possible mechanism. The polarity dependence of peak P_2 may be thought to be related to the rectifying properties in the I-V curve, which is caused by asymmetric contacts between the film and the electrodes. As for the contacts, some dead layer is supposed to be built up in the vicinity of the tin oxide since the resistivity of the conductive glass was usually raised by some orders of magnitude by forming the luminescent film on it, while, on the aluminum side, the deposited copper and some oxide layer are expected to exist. It is, however, still obscure how these factors act on the rectifying properties in the I-V relationship. The experiments on electrocathodoluminescence indicate that the EL is not enhanced to any degree by cathode rays. This behavior is similar to that of powder phosphors except for Mn-activation (19). Although clear elucidation of the mechanisms responsible for the negative resistance is difficult unless further experiments are explored, it has now been found that adsorbed moisture gives a remarkable effect on the negative resistance.

A New Masking Technique for Semiconductor Processing

D. M. Brown, W. E. Engeler, M. Garfinkel, and F. K. Heumann

General Physics Laboratory, General Electric Research and Development Center, Schenectady, New York

ABSTRACT

A new masking method utilizing an intermediate integral Mo film is described. The Mo mask is a practical method for etching very high resolution patterns in passivating dielectric films including films of silicon nitride which heretofore have been unmanageable. The Mo film has much better masking properties than the photoresists now used.

For a number of years the semiconductor industry has been dominated by a single material, Si, and by its oxide, SiO_2. The diffusion masking and passivating properties of thermally grown SiO_2 and the ability to produce an etched design pattern in this oxide by photoengraving using photoresist (KPR) techniques has been central to the semiconductor process technology. Recently, however, a new material, silicon nitride (Si_3N_4), has been introduced which promises to perform not only many of the functions previously reserved exclusively for the oxide, but which may also be useful for other tasks as well (1). It is, for example, a more effective diffusion mask since it is less permeable than SiO_2 to standard semiconductor dopants (2). In addition, it is more impervious to alkali metals than SiO_2 (3). Because alkali ion drift in SiO_2 is one of the main causes of semiconductor device instability, silicon nitride passivation should, therefore, improve device stability. Since Si_3N_4 has a higher degree of chemical stability than SiO_2 and is not as easily penetrated by water (4) and other atmospheric gases, it should generally have better passivation properties.

A problem exists, however; Si_3N_4 has a very, very low reactivity to known solvents, being only very slowly dissolved by concentrated (48%) HF. Several

minutes are required to remove a few hundred angstroms. Chemical etching of this type lifts the photoresist masking films in current use from the nitride before the unmasked nitride regions can be removed by the etch. Nitride patterns are thus difficult to form.[1]

This adherence problem was also originally observed in SiO_2 processing. It was solved for SiO_2 by using a less reactive etch. This etch commonly referred to as "buffered HF"[2] increases the durability of the photoresist sufficiently to enable the etch to dissolve the SiO_2 before the resolution of the mask pattern is destroyed. For thick layers of SiO_2, however, a single layer of KPR in buffered HF is marginal. These solutions are practicable for SiO_2 because of its rapid dissolution rate in HF. These solutions are not practical for Si_3N_4. The problems of dissolution rate and photoresist life are brought into sharper focus by the data given in Table I which compares dissolution rates of SiO_2 and nitride coatings in HF and buffered HF and photoresist lifetimes on SiO_2 and Si_3N_4 when in these acid solutions. For example, the time required to etch 1000Å of Si_3N_4 is clearly beyond the endurance of a KPR mask. Figure 1 shows how concentrated HF destroys a KPR film on a nitrided wafer. The KPR pattern is severely cracked after only 5 sec in concentrated HF which destroys its masking ability. Because of these problems, an improved masking technique would be desirable. This report discusses results achieved by a new technique for masking, which utilizes an integral layer of Mo. This intermediate layer of Mo, which is not soluble in concentrated HF adheres to the nitride film, serves as a mask during the nitride etching, and provides an excellent base for the adhesion of the photoresist film.

Experimental Techniques and Results

A silicon wafer was prepared and a layer of pyrolytic Si_3N_4 deposited on its surface at 1000°C. A layer of Mo was then evaporated onto the wafer by electron beam heating, in a high vacuum oil-free vacuum system. A layer of KPR was then applied, and a pattern developed in this material. The photoresist was baked at 200°C for 2 hr in dry nitrogen. The wafer was etched using a Ferricyanide etch (3). This etch quickly removed the molybdenum that remained unprotected by the photoresist. The KPR pattern was thus transferred to the Mo layer. The wafer was then etched in concentrated HF until the Si_3N_4 not covered by the photoresist and Mo was removed. Seven minutes of etching were required. The Mo and photoresist were removed by etching in hot cleaning solution.

Figures 2 and 3 show some of the results achieved by this technique. Figure 2 shows an over-all view of a pattern formed in a 1000Å (blue) Si_3N_4 film. The pattern dimensions are 0.028 x 0.008 in. The smallest hole in the pattern is 0.00029 in. A comparison be-

[1] Silicon nitride etching by hot phosphoric acid using silicon dioxide as a mask has recently been shown to be a useful technique (5).

1000Å Si_3N_4	66	7 min	—	<½

* Si_3N_4 films referred to here have been grown by the pyrolytic decomposition of silane (SiH_4) and ammonia (NH_3) gases at 1000°C. The etching properties of silicon nitride depend on the conditions for its formation and on subsequent heat-treatments.

** The silicon-oxy-nitride compound is prepared in the same manner as the silicon nitride except in this instance small amounts of O_2 are added to the ammonia and silane gas mixture (6).

† Photoresist life in the etching solution is defined as the approximate time it takes to lift the edges of the photoresist mask or crack the photoresist mask or for the etch to permeate the photoresist to an extent that destroys the resolution of the pattern.

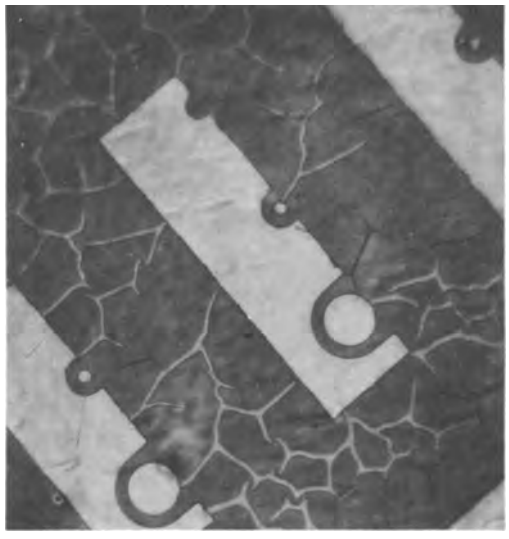

Fig. 1. Cracked KPR pattern on a silicon nitride film resulting from 5-sec immersion is concentrated HF. Dark regions are KPR and light regions are nitride.

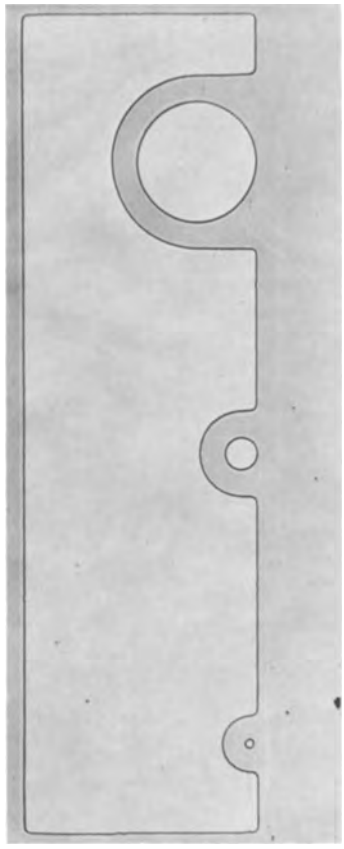

Fig. 2. Over-all pattern. Light regions are bare silicon. Dark region is nitrided silicon. The over-all pattern dimensions are 28 mils long by 8 mils wide; the holes are, respectively, 4 mils, 1.1 mils, and 0.29 mil in diameter.

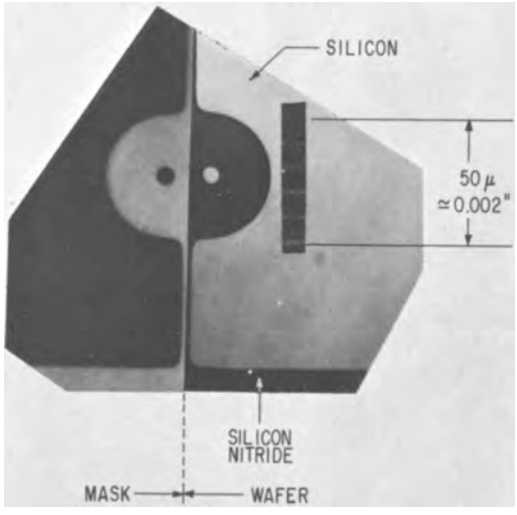

Fig. 3. Composite photograph showing a detailed view of the ¼ mil hole in Fig. 2; the mask is shown at the left and the resulting nitride pattern on the right. The scale divisions are 10μ (≃0.0004 in.) each.

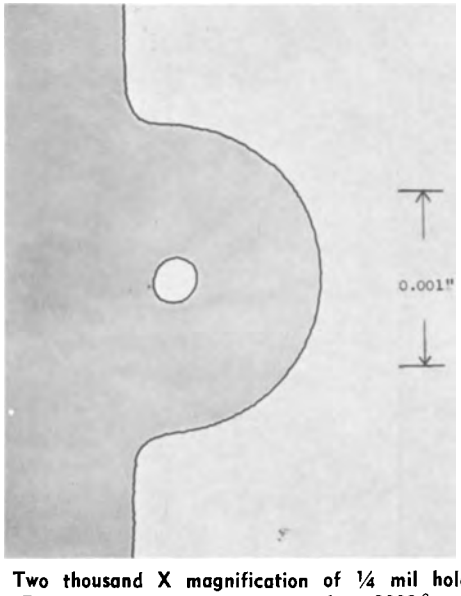

Fig. 4. Two thousand X magnification of ¼ mil hole shown in Fig. 3. Estimated resolution is better than 3000Å as determined by measuring the amount of "wiggle" in the straight line portions of the pattern.

tween the original mask and the smallest hole produced in the nitride is shown in Fig. 3. The mask is shown to the left of the nitride pattern. The resolution was estimated using Fig. 4 which is a a picture of the region shown in Fig. 3 using 2000X magnification. The edge of the pattern is straight to better than 3000Å. The size of the large half circle is faithfully reproduced. However, the small hole is elliptical in shape, being correct in length, but half a micron narrower than the mask. This is most probably due to incomplete etching of the Mo at the bottom of the photoresist hole during the Mo etching step.

In the above tests, the Mo layer was evaporated onto a hot substrate in high vacuum. Other tests were carried out using sputtered Mo films. The thickness of the Mo films ranged from 700 to 8000Å. The thicker films resulted in poorer edge definition due to the required increase in Mo etching time, but resolution comparable to the thickness of the films was achieved. For good definition, the thinner film is sufficient and results in the excellent resolution described above. None of the problems encountered during any of the process steps could be attributed to the Mo mask.

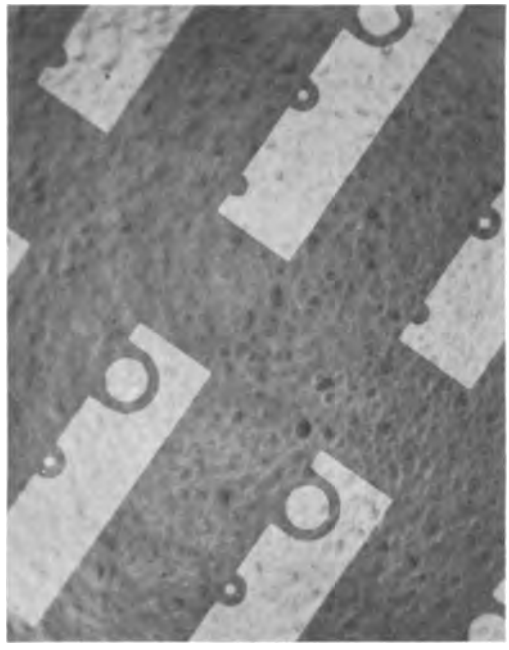

Fig. 5. Pattern etched in silicon nitride using Mo mask and 28 min of immersion in concentrated HF. There are no holes visible in silicon nitride regions which have been protected by the Mo mask. Silicon nitride is 3000Å thick (dark regions). Light regions are bare silicon.

Standard KPR problems associated with linked monomer residue, exposure control, and humidity were the most troublesome.

During our investigations it became apparent that, although KPR is not soluble in HF, the KPR film can be permeated and penetrated by this strong acid. This permeation may be the cause of many of the difficulties connected with KPR masking of SiO_2. If HF penetrates the mask, it will etch a pinhole in the oxide. Figure 5 shows the pattern formed in 3000Å of Si_3N_4 by using a Mo mask and etching in concentrated HF for 28 min. What is noteworthy here is the absence of pinholes in the Si_3N_4 even after the long immersion in concentrated HF. This indicates that the Mo film is continuous, pinhole-free, and insoluble in HF.

Conclusion

This investigation has shown that Mo masking techniques can reproduce high resolution patterns in Si_3N_4 films ranging in thickness from 500 to 3000Å. Furthermore, the nitride regions covered by the Mo film appear to be free of holes even after long immersions in concentrated HF.

It is important to emphasize that KPR sticks extremely well to Mo, and the Mo etching step, which only takes a few seconds, does not damage the KPR mask. This means that there is a very high probability that the pattern and resolution of the original photo-

Table II. Mo mask process steps

1.	Silicon nitride coating	Any thickness without cracks and pinholes is workable.
2.	Mo deposit	Evaporated or sputtered* Mo films. About 1000Å or thicker is suitable, depending on the desired resolution.
3.	Photoresist	Standard KPR techniques.
4.	Mo etching	A few seconds in ferricyanide etch, depending on thickness. The etch rate of the Mo film in this etch is about 150Å/sec.
5.	Silicon nitride etching	Concentrated (48%) HF.

mask is transferred to the Mo film which is insoluble and not permeable to HF. These combined properties of KPR on Mo and the durability of the Mo mask in HF eliminate the need for prolonging the lifetime of the photoresist in HF.

In summary, the molybdenum masking technique as outlined in Table II has been shown to be highly successful for etching patterns in pyrolytically formed silicon nitrides. The technique should be applicable for etching silicon dioxide patterns whenever the standard KPR or KMER techniques are marginal and particularly when prolonged etching can produce pinholes which are caused by the permeation of the photoresist by HF.

Acknowledgments

The authors wish to thank Gerry Gidley for coating many of the silicon wafers with Si_3N_4, Lloyd Keifer for building the triode sputtering apparatus, and George Charney for operating the sputtering and evaporation systems.

ABSTRACT

The effects of process variables on the growth rate and properties of insulating films grown from a hydrogen-silane-ammonia mixture have been studied. Growth rate *vs.* $1/T$ is observed to have a break at 900°C, coincident with an observed amorphous-polycrystalline transition. Hardness, growth rate, and refractive index are found to move toward values appropriate for silicon as the per cent ammonia is reduced. The thermal expansion coefficient can be varied from approximately that of silicon to appreciably more by increasing the per cent ammonia. A variety of other properties, such as breaking strength and Youngs' modulus were also measured and are discussed.

Several methods for the synthesis of silicon nitride have been reported (1-8). While most of these are particularly applicable to large ceramic objects, some of them, for example the silane-ammonia-hydrogen reaction described here have proven satisfactory for thin film deposition.

The flow system employed for this work was quite conventional and the reactor was a resistance heated horizontal cold wall unit. The substrates used for film deposition were single crystal silicon of various orientations. Vapor phase etching (9-11) (for example, HCl in H_2 at 1200°C) was used for substrate clean-up prior to these depositions. Omission of this step usually gave films with many visible defects, but it has been reported that, if the film is to be used as the insulator in an MIS transistor, etching is deleterious (12).

Morphology and Film Composition

Films deposited at temperatures below 900°C[1] appear amorphous and show no x-ray diffraction lines. Between 900° and 1000°C some small crystallites grow over the surface, and above 1100°C they are almost continuous. Figure 1 shows representative areas from each of these temperature ranges. Others (1) have not reported the high crystallite concentrations at temperatures as low as 1100°. Emissivity correction of the temperature combined with higher deposition and flow rates used here could explain the difference. An enlarged view of the crystallites deposited at approxi-

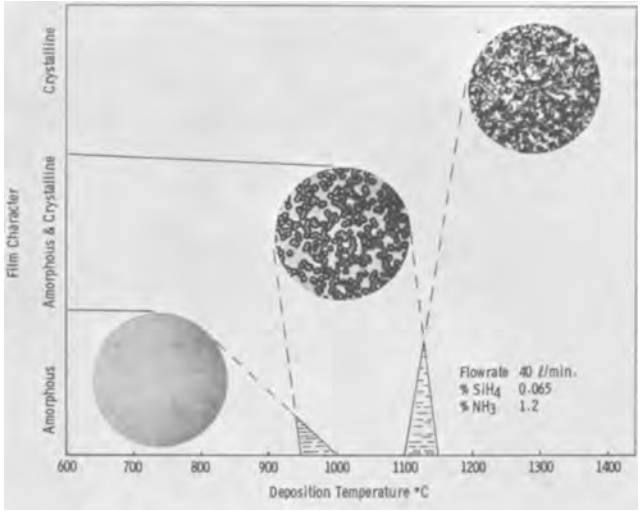

Fig. 1. Film character *vs.* deposition temperature

Fig. 2. High temperature crystallites. Magnification 105X

mately 1200°C for an extended period of time is shown in Fig. 2. X-ray diffraction data indicate that these crystallites are α Si_3N_4.

The composition of the amorphous films has not yet been determined. There are some data based on neutron activation analysis which indicate a possible formula of $Si(NH_2)_4$ (13) (See, for example, ref. 4, p. 88). Direct chemical analysis of films prepared in a similar fashion indicated a composition of Si_3N_4 (14). Because of the varying physical properties that are observed as deposition conditions are changed, it seems probable that the actual amorphous film composition can be varied over rather wide limits from silicon rich to nitrogen rich. Additionally, those films deposited at lower temperatures may contain hydrogen as well as silicon and nitrogen.

Deposition Behavior

The effect of temperature on deposition rate is shown in Fig. 3. Log rate *vs.* 1/*T* plots are given for silane concentrations of 0.095 and 0.065% (all percentages are volume %) with a fixed concentration of 1.2% ammonia. The film growth rate increases rapidly with temperature up to about 900°C. Above this temperature the growth rate becomes less temperature dependent. The apparent activation energy below 900°C is approximately 52 kcal/mole, and above 900°C 6 kcal/mole.

There are three possible explanations for the apparent change in deposition rate.

1. The decomposition of the silane before it reaches the substrate as postulated by Doo *et al.* (1).
2. The difficulty of measuring film thickness by ellipsometer when crystallites start to cover the surface. The energy striking the surface is scattered, and

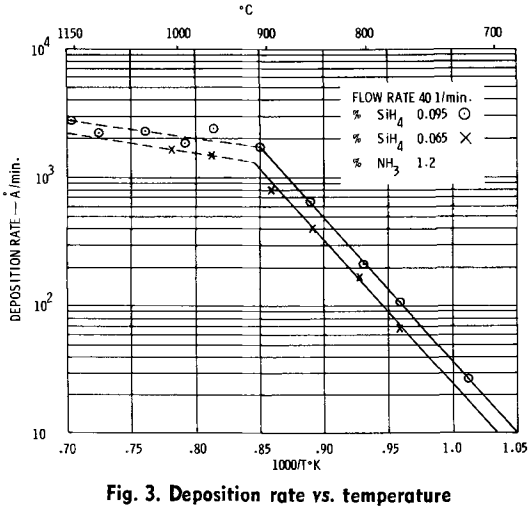

Fig. 3. Deposition rate vs. temperature

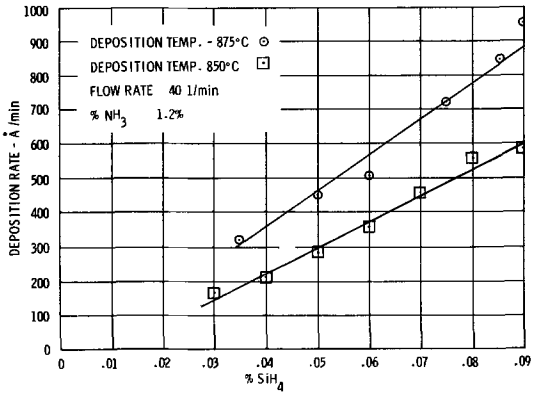

Fig. 4. Deposition rate vs. per cent SiH_4

only a portion is returned to the ellipsometer detector.

3. The decrease may mark the entrance into a diffusion controlled reaction which would be expected to be nearly temperature insensitive.

A plot of deposition rate as a function of per cent silane at deposition temperatures of 850° and 875°C is shown in Fig. 4. These data indicate a linear relationship of deposition rate with respect to silane concentration. Extrapolation of the curves indicate a deposition rate approaching zero at 0% silane as would be expected.

A plot of deposition rate as a function of ammonia concentration of 0.03, 0.065, and 0.095% silane is shown in Fig. 5. Note the 0.065% silane curve. Below an ammonia concentration of about 0.3% there is an increase in deposition rate due apparently to a change in the stoichiometry of the film. It is postulated that films deposited with an ammonia concentration below 0.3% and with a 0.065% silane concentration are silicon rich (see Index of Refraction discussion under optical properties). This corresponds to a silane-ammonia ratio of approximately 1:5. For the other two silane percentages shown, the increase in deposition rate occurs at nearly the same silane-ammonia ratio. It is also interesting to note that the deposition rate at very low ammonia concentration approaches the silicon deposition rate from pure silane in this reactor.

Films approximately 5000Å thick were deposited on silicon substrates for a study of the effect of thermal cycling. Film thicknesses were measured on the ellipsometer (15), the slices were subjected to 2- and 10-min hydrogen cycles at 1000° and 1200°C, and the films were remeasured. These results are collected in Table I. The top two slices were heated for 2 min at 1200°C. The next two slices were heated 2 min at 1000°C followed by a 10-min treatment at 1200°C. Note that the loss in thickness for the two different treatments was roughly the same (~150Å). Six slices were cycled for 2 min at 1000°C with a negligible loss

in thickness. These experiments indicate that the films are quite stable at 1200°C in H_2. As further evidence of stability there was no change observed in the index of refraction after thermal cycling.

Etch Studies

A series of etch rate studies was made using Bell No. 2[2] etch contained in a constant temperature bath which was controlled to within ±0.1°C of the desired temperature. Slices with a known silicon nitride film thickness were etched for a specified length of time with constant stirring and then remeasured on the ellipsometer to determine the change in film thickness.

The effect of etch temperature on etch rate is shown in Fig. 6. The films were deposited at the usual deposition conditions. Calculation of apparent activation energy from these data gave a value of 15 kcal/mole.

A plot of etch rate *vs.* changing ammonia concentration at an etch temperature of 25°C is shown in Fig. 7. Above approximately 0.4% ammonia the etch rate is uniform (~6.25 Å/min), but below this concentration the etch rate decreases rapidly and approaches zero. This is taken as additional evidence that the films become silicon rich in this region and with Bell No. 2 as an etchant one would expect this decrease in etch rate. The effects of varying the percentage silane on the etch rate can be seen in Fig. 8. Again, as the films become silicon rich the etch rate decreases.

The etch resistance of 2000Å silicon nitride and 2000Å silicon dioxide films to a mixture of 5% HCl in hydrogen at 1200°C for 2 min was compared. The silicon dioxide film was grown thermally. The results are shown in Fig. 9. The silicon nitride film is almost impervious to HCl and H_2. The triangular pit

probably resulted from HCl attacking the silicon through a pinhole in the silicon nitride film. The silicon dioxide film has been completely removed, and etching of the silicon surface has occurred.

Optical Properties

Optical transmittance data were obtained over the range from 0.2 to 24μ. Between 0.2 and 0.4μ, films deposited on fused silica blanks were used. Figure 10 gives a typical curve and indicates an absorption edge at about 0.28μ (4.4 ev). Between 0.4 and 8μ there appears to be no absorption bands. Above 8μ the most prominent absorption is that due to the Si-N

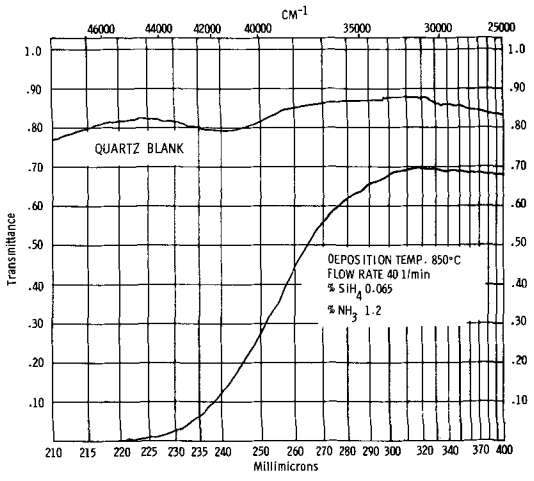

Fig. 10. Optical transmission (0.2-0.4μ) of silicon nitride

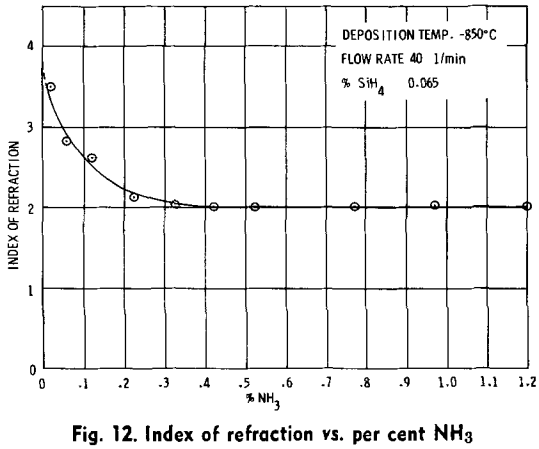

Fig. 12. Index of refraction vs. per cent NH_3

bond which occurs in the 10-12μ range as shown in Fig. 11.

The index of refraction of several films was determined from ellipsometer measurements at 5461Å. In Fig. 12 the refractive index *vs.* ammonia percentage is shown for 0.065% silane. Over most of the compositional range studied, it varied from 2.0 to 2.05, but as the gas stream percentage of ammonia decreased below 0.3% an increase in the index of refraction was noted. It is presumed that the index increases uniformly to that of silicon (about 4.02) as the ammonia concentration is decreased to zero. This is taken as confirming evidence of the silicon rich nature of such films.

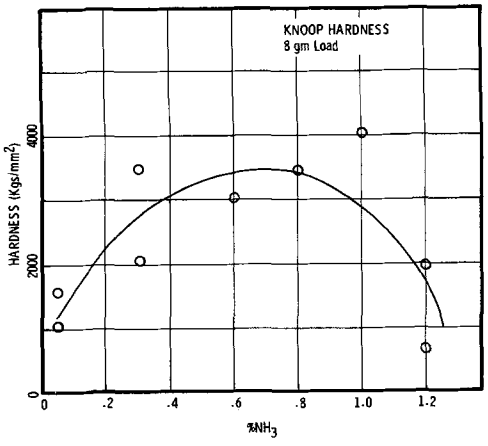

Fig. 13. Knoop hardness vs. per cent NH_3

Mechanical Properties

Microhardness measurements were made on a series of 10,000Å thick films deposited on a silicon substrate. The silane concentration was held constant at 0.065% with NH_3 percentage from 0.05 to 1.2. The results are shown in Fig. 13 and indicate appreciably softer films at each end of the composition range. The variation at the low ammonia end coincides with the observed change of index of refraction (Fig. 12), but the decrease at the other end was unexpected and is not yet explained. A Knoop indentor was used to minimize penetration, and a very light load (~8g) was required to prevent film cracking. Indentations were made using a weight sliding in a modified Reichert microscope objective housing. Measurements were then made using a Reichert microscope with Namorski contrast. Because of the light load used and the correspondingly small indentations, reproducibility was poor even for hardness measurements. The points indicated in the graph are actually averages of several readings which sometimes differed by as much as 100%. Despite the scatter, however, the films are definitely softer at each end of the composition range.

Moh's hardness measurements were made on a series of films deposited at various temperatures from 800° to 1200°C. These data are shown in Fig. 14 and indicate a change in behavior at about 900°C, which is in agreement with the deposition rate *vs.* $1/T$ and the morphology data.

Young's modulus and breaking strength were determined from one film 0.34 mil thick deposited from a gas composition of 0.1% NH_3, 0.065% SiH_4, and 99.84% hydrogen. Holes were etched through the silicon substrate in diameters of 55, 75, and 180 mils. Young's modulus was then computed from deflection *vs.* pressure as measured on the 180 mil diameter film (Fig. 15). This value, coupled with maximum pressure required for failure, was used to compute breaking stress. This stress increased as the size of the

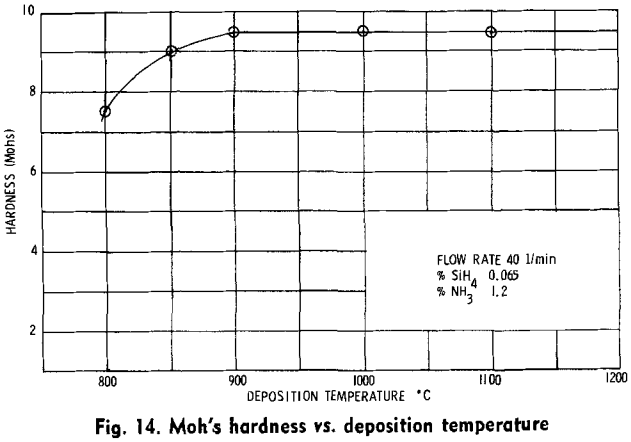

Fig. 14. Moh's hardness vs. deposition temperature

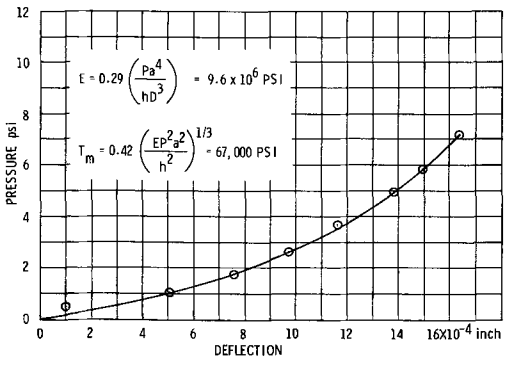

Fig. 15. Pressure vs. deflection for silicon nitride film

hole decreased and would be expected since the edges become progressively smoother as the hole became smaller. Values ranged from 67,000 psi for the largest diameter to 135,000 psi for the 55 mil diameter. It should be noted that these data are from a silicon rich film. The equations used for computation are

$$E = 0.29 \left(\frac{Pa^4}{hD^3} \right)$$

and

$$T_m = 0.42 \left(\frac{E P^2 a^2}{h^2} \right)^{1/3}$$

where E is Young's modulus in psi, T_m the maximum breaking stress in psi, P is pressure differential applied to the film, in psi, a the diameter of the hole, in inches, h film thickness, in inches, and D deflection of film at center of hole, in inches. These are approximations cited in Timoshenko and Woinowsky- Krieger (16) and are appropriate for deflections greater than film thickness.

The thermal expansion coefficient was not measured directly, but it is reasonably close to and somewhat greater than that of silicon (4.2×10^{-6}, 0°-1000°C) and can be changed by compositional variation of the reactant stream. Figure 16 shows this change by a plot of slice curvature (1 in. diameter) *vs.* per cent ammonia. Note that this value is appreciably larger than that reported for sintered samples, which is 2.5×10^{-6}/°C (5).

Conclusions

The physical, optical, and mechanical properties of the films can be varied by changing the deposition conditions. When compared to silicon dioxide films, the silicon nitride films are more stable in H_2 and H_2-HCl mixtures at the temperatures studied. The latitude of parameters observed and their increased stability over normally used insulators should add to the usefulness of such films.

Impurity Distribution in Single Crystals

III. Impurity Heterogeneities in Single Crystals Rotated during Pulling from the Melt

K. Morizane, A. Witt, and H. C. Gatos

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The characteristics of crystal growth from the melt by a Czochralski-type technique under rotation were investigated with experimental arrangements in which the thermal and rotational axes did not coincide. A pronounced type of impurity heterogeneity was studied in particular. It was attributed to a periodic remelt process associated with rotation and was shown to be a limiting case of the normally observed rotational striations. A theoretical analysis is presented which accounts for the observed experimental results. According to this analysis the microscopic growth rate of the "core" region in crystals pulled in the <111> direction is constant, whereas the microscopic growth rate of the "off core" region undergoes pronounced periodic fluctuations as a result of the thermal asymmetry of the experimental arrangement.

Previous studies concerning the distribution of impurities in single crystals pulled from the melt have shown that periodic impurity heterogeneities in the form of striations are quite common (1-3). Depending on their origin these heterogeneities are usually referred to as rotational and nonrotational striations. Nonrotational striations are characterized by a random appearance, widely varying intensity, and are continuous throughout the crystal. Rotational striations, on the other hand, exhibit a high degree of periodicity and increased intensity in going from the crystal interior to the periphery.

The formation of both types of striations is commonly attributed to a dependence of the distribution coefficient on the growth rate (4). Accordingly, nonrotational striations reflect irregular temperature fluctuations of the melt which may originate in thermal convective currents and power input variations. Rotational striations are believed to be caused by a lack of thermal symmetry in the melt, *i.e.*, by a spatial separation of the thermal and rotational axes (5). In studies concerned with a formation of impurity striations it is usually assumed that the temperature fluctuations which lead to growth rate variations are small and generally exclude the possible occurrence of remelt phenomena (1, 6). Remelting has been imposed on pulled crystals by deliberate power input changes (7). This procedure has served to develop a rate growth technique for the production of rectifying junctions (8). We believe that such remelt phenomena are quite common in most crystals pulled from the melt.

Experimental Procedure

Single crystals of InSb containing Te as intentionally added impurity (2-50 mg Te in 50g melt) were grown in the <111> direction using a Czochralski-type puller and proportional temperature control. The crystals were subsequently cut along a (211) plane parallel to the growth axis and mechanically polished. The impurity distribution was revealed by a recently developed permanganate etchant (1HF, 1CH_3COOH, and 1$KMnO_4$ 0.05M) (9). In a typical etching operation the etchant was applied with a cotton applicator to the semiconductor surface immediately after polishing and rinsing. Etching proceeded steadily without a noticeable incubation period and was interrupted by rinsing after about 3 min. Etching times in excess of 5 min resulted in a slight reduction of resolution and were therefore avoided. Pitting, which usually accompanies etching with CP4 was never observed with the present etchant.

A Reichert microscope (Zetopan-F) equipped with a Nomarski interference contrast attachment was employed in this study. Individual striations could thus be resolved with a spacing of less than 0.2μ. This spacing corresponds to the limit of resolution of the optical system. It is quite likely that the resolution of the etching process exceeds this limit. Details of the surface preparation were previously reported (3).

Experimental Results

Single crystals grown without rotation revealed periodic heterogeneities in impurity distribution (Fig. 1) which vary in sharpness and intensity. Of particular interest for the present investigation are the intense striations which appear as deep depressions on the etched surface.

Crystals pulled in the same system but with rotation exhibited the so-called rotational striations (Fig. 2) of increased intensity and high periodicity. In all rotated crystals examined, the intensity of these striations decreased in going from the crystal periphery to the axis of rotation (Fig. 2).

In view of the reported dependence of the formation of rotational striations on a lack of thermal symmetry (5) we investigated the lateral temperature distribution in the melt. These measurements were performed with rotating thermocouples which were attached to the seed holder. They showed that along a circumference 6 mm in radius (from the center of rotation) there was a temperature variation of 2.4°C during a full rotation. By adjusting the location of the furnace thermal asymmetry could be reduced but not eliminated. The decreased thermal asymmetry resulted in rotational striations of decreased intensity in the pulled crystals.

Figure 3 depicts a crystal in which nonrotational striations as well as rotational striations of high intensity are simultaneously present. The interaction of the two types of striations leads to the abrupt termination and partial disappearance of some nonrotational striations. It is believed that this disappearance is due to the occurrence of local remelting. It is seen that the resulting remelt lines have a significantly different appearance when compared with the usual nonremelt striations (see also Fig. 2). Their primary characteristics is an increased intensity and sharpness which reflects abrupt and extensive impurity concentration changes. Such remelt striations

Fig. 1. Nonrotational impurity striations in the off core region of an InSb single crystal grown in the <111> direction. In addition to the ordinary striations there are three lines indicated by the arrows of high intensity and sharpness. They are attributed to a remelting process. (For plane shown and etchant in all figures see text). Magnification 325X.

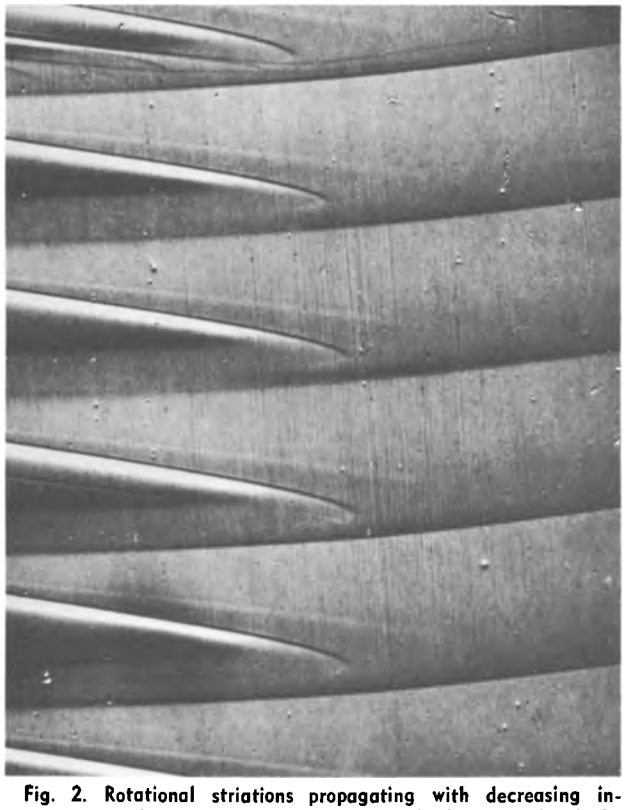

Fig. 2. Rotational striations propagating with decreasing intensity from the periphery to the center (right to left) of the crystal. Note the protruding part of the "core" region. (Compare with schematic representation of Fig. 8). Magnification 325X.

may appear also in the form of nonrotational striations (Fig. 1).

Remelt striations frequently interfere with the normal formation of the (111) impurity "core" which is a result of an (111) facet formation at the growth interface (Fig. 4). The observed abrupt changes of the core boundary are due to regrowth, following remelting, at a curved crystal melt interface at which the supercooling required for nucleation on the (111) facet is no longer necessary. Thus, rotational striations of the remelt type essentially control the lateral expansion of the impurity core which always increases with increasing spacing of consecutive remelt striations and recedes as their spacing decreases. This phenomenon is seen in Fig. 5 where closely spaced striations (resulting from reduction in the pulling rate) led to the actual disappearance of the impurity core. The core reappears after the spacing of the

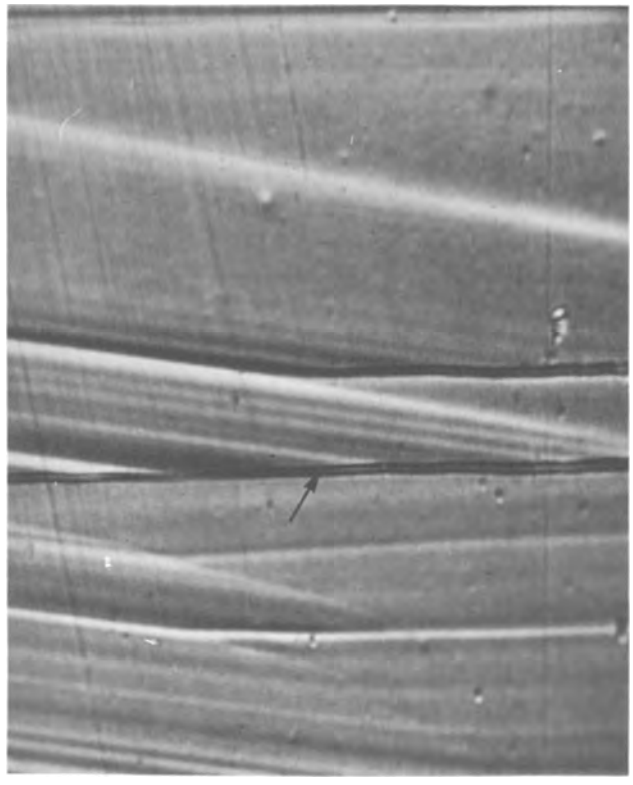

Fig. 3. Interaction of rotational remelt striations with regular nonrotational striations. The abrupt termination of nonrotational striations is caused by partial remelting associated with the formation of rotational striations. Magnification 315X.

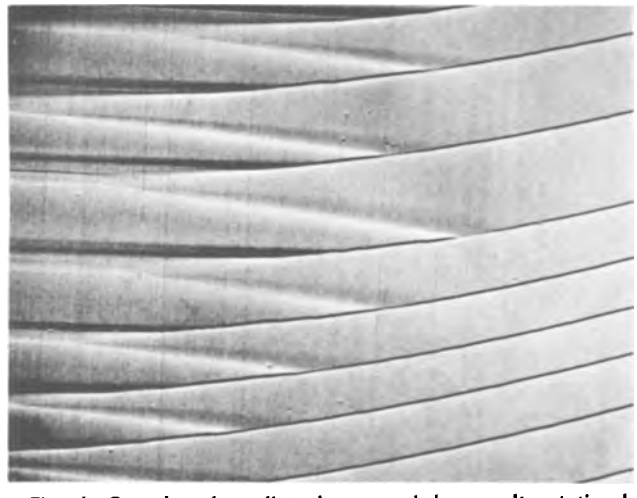

Fig. 4. Core boundary distortion caused by remelt rotational striations. The interaction of rotational striations with the impurity core has resulted in the partial elimination of the core region. (Compare with Fig. 2 and 8). Magnification 210X.

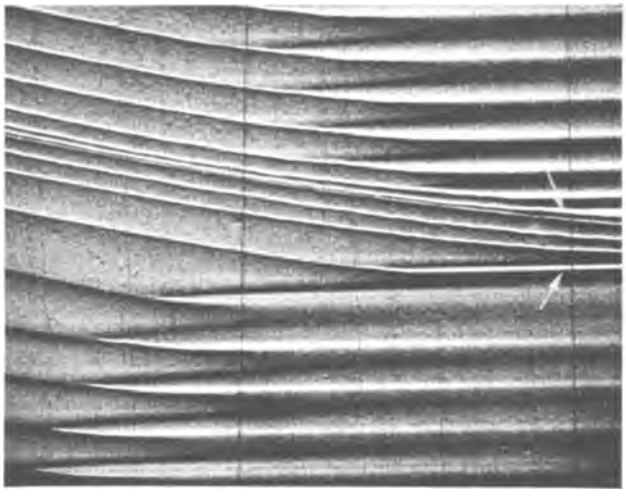

Fig. 5. Elimination of the impurity core in part of the crystal (between arrows) as a result of close spaced rotational striations of the remelt type. Magnification 165X.

Fig. 6. Irregular remelt striations in the off core region. Magnification 150X.

striations was brought to its original value. It is apparent that the interaction of the remelt striations with the impurity "core" becomes more pronounced as the curvature of the crystal-melt interface increases.

Rotational striations appear always as rather smooth curved lines of somewhat varying intensity provided that they are not associated with remelting. Remelt striations, on the other hand, frequently exhibit certain irregularities. In several crystals remelt striations were observed with rather irregular shapes, indicating the presence of significant disturbances at the growth interface (Fig. 6). These disturbances are very likely associated with localized "faceting" in the remelt area. A similar phenomenon can also be observed in Fig. 7 which depicts a crystal in which a small twin was formed. Highly irregular remelting can be observed on the left side of the twin while the right side exhibits remelt striations which are very smooth. The origin of this phenomenon is not understood at present.

Analysis of the Effect of Thermal Asymmetry on Rotational Crystal Growth

Rotational striations due to localized remelting are similar in appearance to remelt striations caused by intentional power input variations. The mechanisms of formation, however, are basically different. Remelting caused by crystal rotation occurs only on a small section of the crystal-melt interface, while remelting due to power input variations takes place

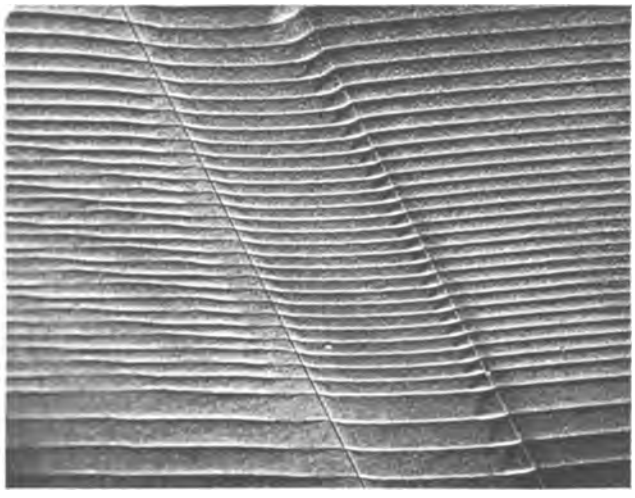

Fig. 7. Remelt striations in a crystal which was twinned. The striations are smooth and regular on the right side of the twin and highly irregular on the left side. Magnification 70X.

more or less instantaneously across the whole interface.

The formation of rotational striations will be considered in a crsytal pulled in the <111> direction (Fig. 8) with a pulling rate V_o and a rotational rate R. The distance of separation of the parallel rotational and thermal axes is d. The crystal grows with the rotational axis as its center and assumes a convex growth interface with a circular (111) facet of radius r ($r > d$) centered about the thermal axis. A fixed temperature distribution in the melt is assumed unperturbed by convection or rotation. This assumption appears valid whenever V_o and R are small. In the crystals investigated V_o was varied between ½ and 2 in./hr and R from 2 to 10 rpm. Since the temperature distribution in the melt determines the location as well as the shape of the crystal-melt interface the position of the growth facet during rotation will be stationary about the fixed thermal axis. Thus, the impurity core (which is the result of an increased impurity incorporation on the (111) growth facet) assumes the form of a "screw" during rotational pulling. Consequently, any cut along a plane which contains the axis of rotation will exhibit a sinusoidally fluctuating core boundary with an amplitude d and a "wave length" V_o/R (Fig. 8).

Under the above conditions the growth facet rotates on its own plane and growth proceeds in the <111> direction with a constant rate V_o. The curved "off core" interface, however, cannot advance at a constant

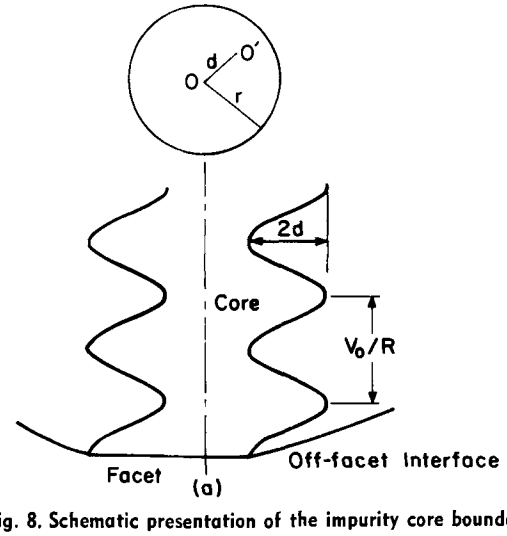

Fig. 8. Schematic presentation of the impurity core boundary

rate since its shape and location is determined by the fixed temperature distribution in the melt and the location of the thermal axis which does not coincide with the rotational axis. The resulting asymmetry of the interface with regard to the axis of rotation leads to a condition whereby each point on the "off core" interface is subjected to a different but constant growth rate during rotation. It can be shown (see Appendix) that for a temperature variation of ΔT for a full rotation the instantaneous growth rate at any point is given by

$$V = V_o - \frac{2\pi\Delta TR}{G}\cos 2\pi Rt = V_o(1 - \alpha\cos 2\pi Rt);$$

$$\alpha = \frac{2\pi\Delta TR}{V_oG} \quad [1]$$

where G is the temperature gradient in the melt adjacent to the growth interface. The minimum growth rate during each rotation is accordingly

$$V_{min} = V_o(1 - \alpha) \quad [2]$$

From Eq. [2] it is apparent that when $\alpha > 1$ then $V_{min} < 0$, *i.e.*, local remelting takes place. The extent of remelting increases with increasing rotational rates R and decreasing pulling rates V_o. At the same time any decrease in the temperature gradient in the melt will result in a decrease of V_{min} and, thus, will increase the probability of remelting.

Discussion

Whenever the solid-melt interface of a growing crystal is subject to temperature fluctuations the instantaneous (microscopic) growth rate is bound to vary. In the presence of a sinusoidal temperature change the time interval during which increased growth rate takes place is the same as the time interval during which a decreased growth rate occurs. Thus, the portion of the crystal grown under increased rate is larger than the corresponding portion grown under a decreased rate within a given cycle. A greater impurity concentration (for a distribution coefficient smaller than one) is expected in the portion grown under an increased rate than in the portion grown under a decreased rate (4). In the presence of thermal asymmetry the off core region of a crystal is subjected to such sinusoidal temperature fluctuations during rotation. Accordingly a crystal grown under rotation should exhibit impurity heterogeneities consisting of alternating helical broad and narrow bands of an increased and decreased impurity concentration, respectively. The narrow bands (whose width may amount to a line depending on the extent of thermal asymmetry) constitute the so-called rotational impurity striations.

The extent of the growth rate variation during rotation increases with increasing thermal asymmetry (Eq. [1]). Since the rotational temperature variation is zero at the center of rotation and increases toward the crystal periphery, it is expected that the rotational striations will reflect a radially decreasing growth rate (V). The observed intensity change of the rotational striations in the outward direction (Fig. 2) is consistent with this model. It is further apparent from the model that, even in the regions between the rotational striations, the growth rate and thus the impurity concentration, is not constant but varies continuously. Obviously, the experimentally determined impurity distribution coefficients are subject to error whenever thermal asymmetry is present, as manifested by rotational striations. In such a case reliable values of effective distribution coefficients can be obtained only in the "core" region of crystals grown exactly in the <111> directions.

The sharpness of the rotational striations reflects the magnitude of V_{min} during each rotation. Thus, remelt striations ($V_{min} < 0$) are a limiting case of regular impurity striations which result from excessive temperature variations. Thus a local remelt process is responsible for the observed partial disappearance of nonrotational striations (Fig. 3) and the pronounced changes of the crystal core boundaries (Fig. 4).

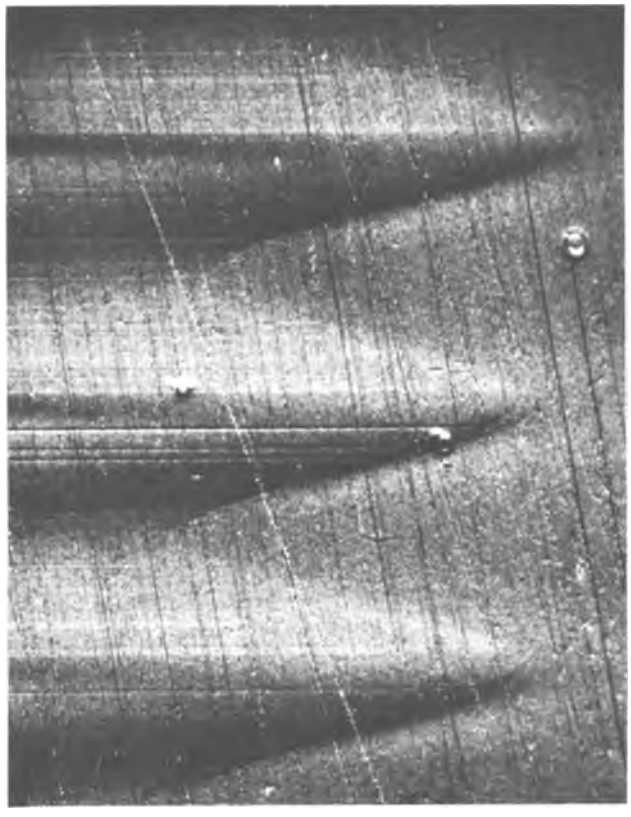

Fig. 9. Sinusoidally shaped core boundary along a single crystal on a (211) plane which contains the rotational axis. Magnification 385X.

Impurity core boundaries of sinusoidal shape as indicated by the present model are very infrequently observed in single crystals (Fig. 9) since their appearance depends on rather ideal growth conditions (no localized remelt phenomena) and a very precise (211) cut. Thus, deviations of the growth axis from the <111> direction lead to a vertically inclined growth facet and result in rather complex core boundaries (Fig. 10). A rather common deviation of the core boundary from that predicted is due to the effect of local remelting discussed earlier.

The present model is qualitatively consistent with the experimental results. A quantitative confirma-

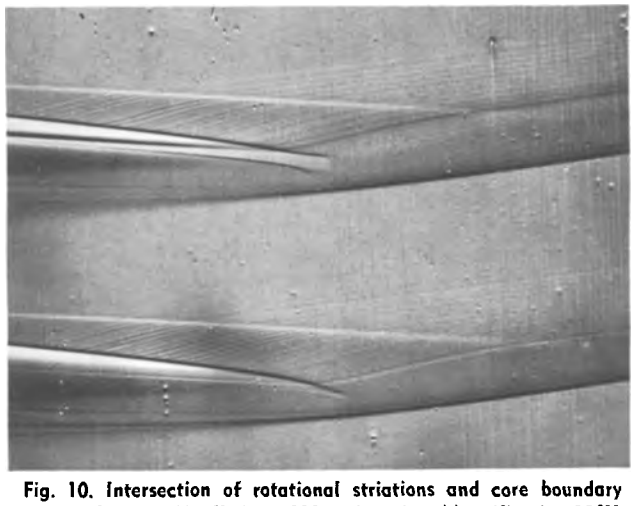

Fig. 10. Intersection of rotational striations and core boundary in a crystal grown 6° off the <111> direction. Magnification 310X.

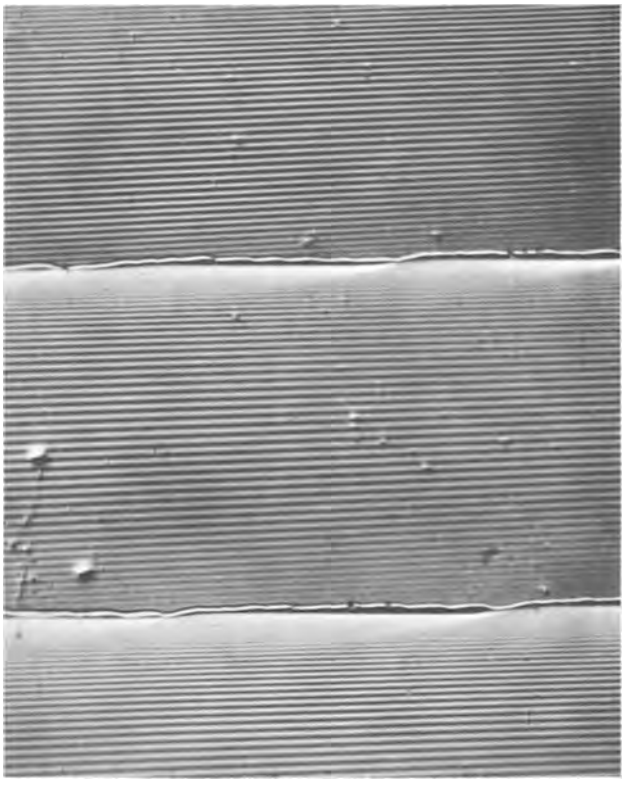

Fig. 11. Vibrational striations (18 per sec) superimposed on remelt type rotational striations in the "off core" region (see text). Magnification 430X.

tion would require knowledge of the instantaneous local growth rates or alternately the determination of concentration profiles across individual impurity striations. Because of the limited resolution of autoradiography and microresistivity measurements, microvariations in impurity distribution associated with rotational striations can only be deduced from etching experiments.

While this paper was being prepared we succeeded in introducing into single crystals high-frequency striations which are superimposed on the regular striations. Such high-frequency striations were introduced by subjecting the melt to controlled vibrations. Since these vibrations do not affect the normal growth process it becomes possible from their known frequency and their local separation to determine quantitatively the instantaneous microscopic growth rates in the various parts of the grown crystal (Fig. 11). The asymmetry in spacing of vibrational strictions above and below the "remelt" line shows directly the occurrence of remelting. Detailed results obtained with this technique will be discussed in a future report.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

APPENDIX

Equation [1] in the text can readily be arrived at with the aid of Fig. 12. A is an arbitrary point on the

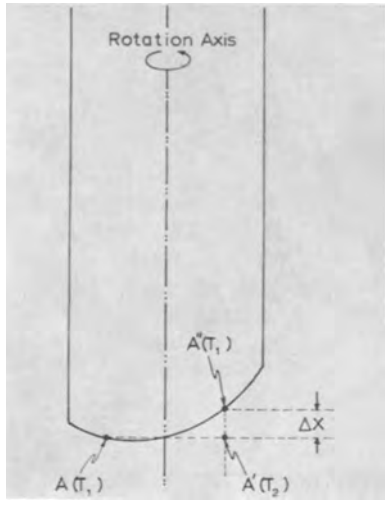

Fig. 12. Schematic presentation of rotational crystal growth in the presence of thermal asymmetry.

crystal-melt interface at a temperature T_1. During a complete revolution about the axis of rotation (without pulling) a maximum temperature T_2 is encountered at A'. Taking $T_2 - T_1 = \Delta T$, the temperature gradient, G, in the melt between A' and A'' on the solidification isotherm is then given by

$$G = \frac{\Delta T}{\Delta x} \qquad [1A]$$

Assuming steady-state conditions and that the solidification isotherm is stationary during rotational pulling at V_o (does not change position during crystal growth) then the vertical translation x of any point on the solidification isotherm is sinusoidally fluctuating with time as follows

$$x = V_o t - \Delta x \sin 2\pi R t \qquad [2A]$$

by combining [1A] and [2A] one obtains

$$x = V_o t - \frac{\Delta T}{G} \sin 2\pi R t$$

and the instantaneous rate of growth is given by

$$V = \frac{dx}{dt} = V_o - \frac{2\pi \Delta T R}{G} \cos 2\pi R t \qquad [3A]$$

taking $\alpha = 2\pi \Delta T R / G V_o$ one obtains

$$V = V_o(1 - \alpha \cos 2\pi R t) \qquad [4A]$$

Control of the Surface Potential of Germanium by Means of a Variable *p*H Electrolyte Containing Hydrogen Peroxide and Potassium Chloride

G. Brouwer

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

A new form of surface stabilization of germanium is discussed. When the germanium is in contact with an electrolyte containing hydrogen peroxide and potassium chloride the surface potential is a linear function of the pH. To within a constant difference its value is equal to the voltage measured between the germanium and a calomel electrode. No current flows through the interface. A new stationary state is obtained in a few minutes after the *p*H has been changed. The range of surface potentials covered is 360 mv.

Many transistor properties depend on the state of charge of the semiconductor surface, characterized by the surface potential, Ψ_s. When it is desired to vary Ψ_s, the electrons, or holes, must be induced to leave the semiconductor bulk to occupy states which have been made accessible in the exterior, by chemistry, for example. An illustrative case is found in the junction between intrinsic and doped germanium, which explains the principles of the new method.

Figure 1a shows an electron energy level diagram of both parts of the junction before contact is made. No excess charge is present, and the hatched conduction band and the cross-hatched valance band are completely straight. There is a difference of Fermi potentials $\phi_i - \phi_n$ between the intrinsic and n-type material (1) given by

$$\phi_i - \phi_n = \beta \log (n/n_i) \qquad [1]$$

$$\beta = 2.30\, kT/q \qquad [2]$$

in which $\beta = 60$ mv at room temperature, k is the Boltzmann constant, T the absolute temperature, and q the absolute electronic charge. The common logarithm is employed throughout this paper. The value n, which is given by the doping level, is the free electron concentration in the conduction band and n_i is the specific value for pure germanium: $n_i \approx 10^{13}$/cm^3. When the dopant concentration, n_D, equals 10^{17}/cm^3 the difference of Fermi potential amounts to 240 mv. After contact is made the electrons of the n-type material will cross the boundary into the region with the lower Fermi level.[1] As the electrons carry a charge, a double layer is built up at the interface which discourages further crossings. Equilibrium is established when the driving force of the electrons and holes, $F(e^-) = -q \operatorname{grad} \phi$, becomes zero. The width of the space charge is greater in the material with the lower concentration of mobile charge-carriers, that is in the intrinsic germanium. Accordingly, most of the drop in the electrostatic potential, Ψ, is found on this side of the junction, as is shown in Fig. 1b. To a good approximation the interface potential Ψ_s equals the original difference of Fermi potentials

$$\Psi_s = \beta \log (n/n_i) \qquad [3]$$

When the doping is varied from 10^{17}/cm^3 of shallow acceptors to the same density of shallow donors, Ψ_s can be varied from -240 to $+240$ mv.[2]

This principle is applicable not only to homojunctions but also to heterojunctions. From the point of view of a research tool it is interesting to have a junction between a solid and a liquid, because the latter can be doped at room temperature. In this case a continuous variation of Ψ_s can be achieved, provided the Fermi level of the liquid can be controlled. In this paper the germanium/water junction is studied, and the position of the Fermi level in the latter is discussed next.

It is interesting to study water from the point of view of compound semiconductors (2) with a possible deviation from stoichiometry and allowing for mobile centers. At room temperature no free electrons and holes are present in water. It is a wide-gap semiconductor in which the bands can be disregarded. As is the case in all wide-gap compounds, the position of the Fermi level must be stabilized by partially filled electron states. Pure, stoichiometric water already contains charged defects, hydroxyl ions, OH^-, and hydrogen ions, H^+ or OH_3^+. These defect pairs are created by proton exchange between two neighboring

[1] When a tenfold increase of the concentration of the electrons in the conduction band is introduced the Fermi level is raised by 60 mev and the Fermi potential is lowered by 60 mv according to the definition given in Fig. 1.

[2] Two different definitions of the surface or interface potential are commonly employed. First, Ψ_s is defined as the difference of the electrostatic potential at the surface or interface and the neutral bulk. Second, Ψ_s can be defined as the distance between the mid-gap position Ψ_i and the Fermi potential, as shown in Fig. 1. In the case of intrinsic germanium both definitions are identical.

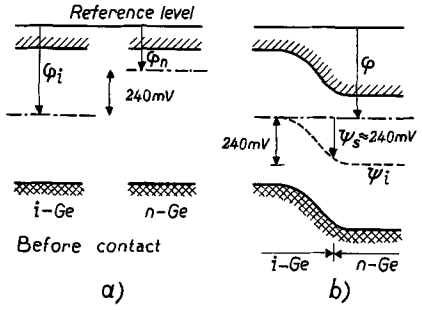

Fig. 1. Energy band diagram of the junction between intrinsic and n-type germanium, illustrating the principle of the surface stabilization method.

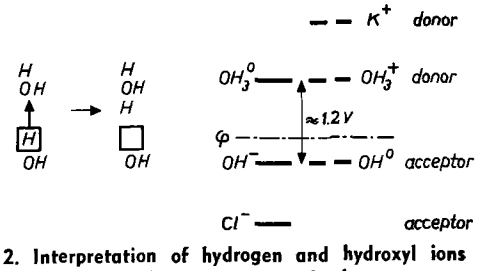

Fig. 2. Interpretation of hydrogen and hydroxyl ions in water in terms of defect electron-donor and electron-acceptor levels.

water molecules. In Fig. 2, a somewhat artificial approach is given. Suppose that this time more energy is spent and a neutral hydrogen atom is transferred from one water molecule to an adjacent one (3). Two free radicals are formed, OH and OH_3, of which the former defect shows a hydrogen deficiency with associated electron-acceptor character, whereas the latter has an excess of hydrogen with a resulting electron-donor character. As the donor level is situated above the acceptor level, both defects become charged by a simple electron transfer.

If the Fermi level is to be stabilized in the vicinity of the OH^- level, both OH and OH^- groups must be present. The free radicals can be introduced in associated form as hydrogen peroxide. When the preference for association is marked, few free radicals will exist even when the peroxide concentration is considerable. Yet the OH concentration is quite stable as a result of buffering by the peroxide. Suppose two electrons from the germanium were transferred to two OH groups, giving two OH^- groups, then dissociation of the peroxide will replenish the lost free radicals. When ϕ_{OH^-} is the particular potential at which the Fermi level coincides with the OH^- level, the Fermi potential is given by

$$\phi_{OH^-} - \phi = \beta \log [OH^-]/[OH] \qquad [4]$$

At a constant $[H_2O_2]$ or [OH], the Fermi potential can be varied by means of the pH.

Assuming, for the moment, that no chemical reaction occurs between the germanium and the electrolyte, the situation at the interface is given in Fig. 3. On the left-hand side of Fig. 3a the semiconductor is represented by the conduction and valence band, which are the allowed states for free electrons and holes. The bands are curved as a result of a space charge. In the solution the electron levels have been limited to the defect donors and acceptors. Some space charge is also present on this side of the junction, but it is assumed that the variation of Ψ in the solution can be neglected. Thus all OH^- states are at the same level. The Fermi potentials are equal on both sides, as only electron exchange was supposed to occur. The value of Ψ_s is completely determined by $[H_2O_2]$ and pH. What happens when the pH is increased by one unit is shown in Fig. 3b. According to [4] the Fermi level in the electrolyte is raised by 60 mev, or the Fermi potential lowered by 60 mv. Then Ψ_s is bound to increase by 60 mv as well. Thus the surface potential will vary by 60 mv per pH unit.

In Fig. 3 it is assumed that a calomel electrode with a saturated salt bridge is also present in the solution. This electrode exchanges Cl^- ions with the electrolyte and as $[Cl^-]$ is kept constant by the salt bridge, the position of the Fermi potential in the metallic lead, denoted by ϕ (cal), is invariant to the pH. The cell voltage is equal to the difference of the Fermi potential of the germanium and of the lead to the calomel electrode. Therefore it varies by 60 mv per pH unit, whatever the type of the germanium. Provided the variations of Ψ are restricted to the germanium, the surface potential and the cell voltage obey the same Nernst law theoretically and the measured

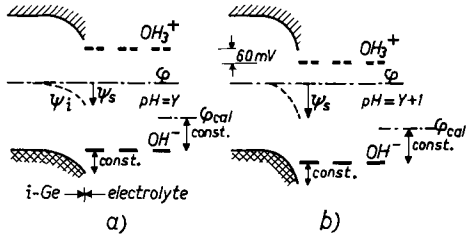

Fig. 3. Energy level diagram of the junction between germanium and water; (a) and (b) are distinguished by a difference in pH values of one unit.

voltage should be a direct measure of Ψ_s. The limitations of this relation will be discussed later. The variation of Ψ_s with the pH is the result of an exchange of electrons

$$e^-\ (Ge) + OH \rightleftharpoons OH^-, \text{ or } 2e^-\ (Ge) + H_2O_2 \rightleftharpoons 2\ OH^- \qquad [5]$$

The introduction of the peroxide leads to a deviation from stoichiometry in the water, resulting in an excess of acceptors over donors. The pH can be varied by addition of acids, such as HCl, and bases, such as KOH. In the presentation, given in this paper, HCl can be considered to be an associate of a very energetic electron-acceptor, Cl^-, and a defect donor, OH_3^+, which have exchanged an electron. In a similar way KOH is an associate of an energetic donor, K^+ and a defect acceptor, OH^-. Neither HCl nor KOH is able to disturb the balance of donors and acceptors.

Experimental

In order to check the theory given so far, the relation between the surface potential Ψ_s and the germanium/calomel voltage has to be investigated as a function of the pH. A convenient way to determine Ψ_s is to measure the conductivity of the germanium parallel to the interface with the electrolyte. This conductivity can be varied when charge is transferred from the semiconductor to the solution. This can be done by varying the pH of the solution, containing H_2O_2 and KCl or by the field effect (20), in which an external voltage is applied between the germanium and an electrolyte, serving as a polarized field electrode. In order to evaluate Ψ_s, a germanium electrode, which also serves as a conductivity cell[3], is put into a solution together with a saturated calomel electrode with salt bridge and a glass-membrane electrode. The voltage between the last-mentioned electrodes is a direct measure of the pH. The germanium conductivity cell is adapted to the van der Pauw measuring technique (5). It consists of a slice 0.4 mm in thickness with (100) planes cut ultrasonically into the shape of a Swiss cross with a central area of 1 mm^2. After polishing and etching, four tin contacts are alloyed to the bars on one side. The nonalloyed side and a Plexiglas mould are cemented to a Teflon plate. Plastic insulated wires are pulled through holes in the mould and soldered to the contact. Then the mould is filled with a mixture of Araldite and a hardener. Overnight the cell is ready for removal from the greasy Teflon plate. The now exposed side of the slice is slightly ground, polished, and subsequently etched for 20 min in slow etch consisting of two equal volumes of 0.5M KOH and 10M H_2O_2. The liquid is gently stirred and in the end about 0.05 mm of germanium is removed. After rinsing in deionized water the cell is ready to enter the electrolyte. As the conductivity of intrinsic germanium is very sensitive to temperature, the latter is kept constant to within 0.02°C. A two-stage thermostat is employed in which the temperature is measured with intrinsic germanium thermometers. The actual measuring vessel consists of polythene and the solution is stirred by a magnetically driven centrifugal pump made of Teflon.

The circuit in Fig. 4 is used for measuring the conductivity of the van der Pauw cell. The latter has four contacts: I_1 and I_2 are used as current contacts and V_1 and V_2 as voltage probes. Via the galvanometer G of a Kipp micrograph this voltage is compared with a constant voltage of 10 mv. A control system regulates the current through the sample in such a way that the galvanometer carries no current. Any deviation from zero is amplified opto-electrically and the resulting signal is used to drive a servo motor which is coupled to two potentiometers, one of which is normally employed for internal feedback. This circuit is disconnected, but the spare potentiometer P is connected to a battery. As the sliding contact moves from posi-

[3] This conductivity cell exclusively serves the purpose of measuring the conductivity of the germanium.

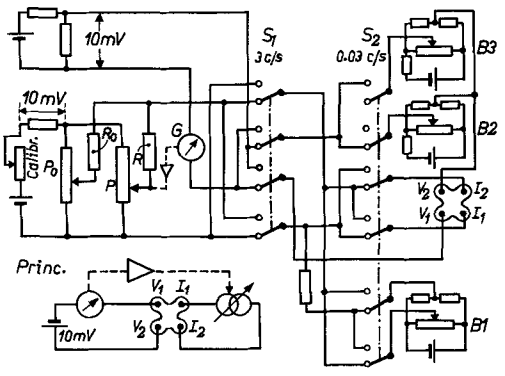

Fig. 4. Circuit employed for the measurement of the surface conductivity of germanium. The insert explains the principle.

tion 0 to 100 the voltage over one part of the potentiometer increases linearly and from it a linear current source is derived by means of a large resistance R. The source feeds the current contacts of the conductivity cell. Full-scale deflection of the recorder corresponds to 100 μohm^{-1}, including the van der Pauw geometry factor 0.221 for samples with fourfold symmetry. A calibrated auxiliary circuit P_o, R_o extends the range of the instrument in discrete steps of 100 μohm^{-1}. To avoid the customary d-c errors, a multiple vibrating-reed switch S_1 serves as a commutator operating at a frequency of 3 c/sec. The van der Pauw technique requires two independent measurements and a relay S_2 interchanges I_1 and V_2 every 30 sec. Three manually operated auxiliary circuits are employed: B_1 compensates the small difference of two consecutive readings which should be zero if the symmetry of the sample is complete; B_2 eliminates the influence of parasitic emf during the first 30-sec period, B_3 during the second one to prevent a 3 c/sec nuisance-signal. The conductivity as a function of time appears as a trace of dots on the recorder. The pH and the germanium-calomel voltage are recorded simultaneously.

It is important to keep the measuring voltage as small as 10 mv, because this is much smaller than kT/q, so that there are no rectification difficulties. In order to reduce a possible by-pass current through the electrolyte, the contact area must be limited (6).

Results

The experimental relation between the germanium/calomel voltage and the glass/calomel voltage which measures the pH, is given in Fig. 5. The electrolyte contains 0.01M H_2O_2 and 0.1M KCl and, in order to facilitate the pH control, 0.002M acetic, phosphoric, and boric acid as buffers (4). The germanium is intrinsic 50 ohm-cm material. In the range of pH values between 2 and 10 a straight line at an angle of 45° is found and the germanium/calomel cell can be employed as a pH meter (7). Within experimental error, 2 ohm-cm n-type and p-type germanium give the same voltage against calomel. When the pH is cycled, in the absence of H_2O_2, a scattering of up to 200 mv is found in the germanium/calomel voltage. Addition of H_2O_2 then invariably makes the germanium electrode more negative. When the concentration of H_2O_2 exceeds 0.001M no further increase of the cell voltage is observed. Without a high concentration of KCl the germanium electrode becomes slow. A few minutes after the pH has been varied a new stationary voltage is measured, provided both H_2O_2 and KCl are present in sufficient amounts. Stirring the liquid has no appreciable effect on the measurements. At pH > 10 the germanium/calomel voltage becomes unstable.

Simultaneously with the emf measurements, the conductivity of the 50 ohm-cm germanium cell has been determined and the result is plotted in Fig. 6. The temperature has been kept at 25° ± 0.02°C. Four series of measurements were made in a single day, alternately in the direction of increasing and of diminishing pH values. In order to check the influence of parallel conductivity through the electrolyte, two conductivity cells of the type described in the Experimental section were employed, one current and one voltage probe of each being connected to the measuring equipment, so that the current had to pass through the electrolyte. The by-pass conductivity was found to be negligible in the acid and neutral ranges, but not entirely so in the alkaline region. Uncertainty of geometrical factors did not allow for a correction of the conductivities presented in Fig. 6. Generally it is found that reproducibility is best in the acid and neutral regions. The liquid was always stirred during all experiments.

Finally the following experiment was performed: in addition to the germanium and the calomel electrode, a gold and a platinum electrode, both sandblasted, were inserted into the same solution, and the voltage against calomel as a function of the pH is also given in Fig. 5. The measuring points of both noncorroding electrodes almost coincide, but a nearly constant difference of some 800 mv is observed with respect to germanium. The same insensitivity to the peroxide concentration is present both in the germanium/calomel and gold/calomel cell (8).

A very slow etching of the germanium occurs when it is in contact with the solution employed, which is greatest at alkaline pH values. The etching rate can

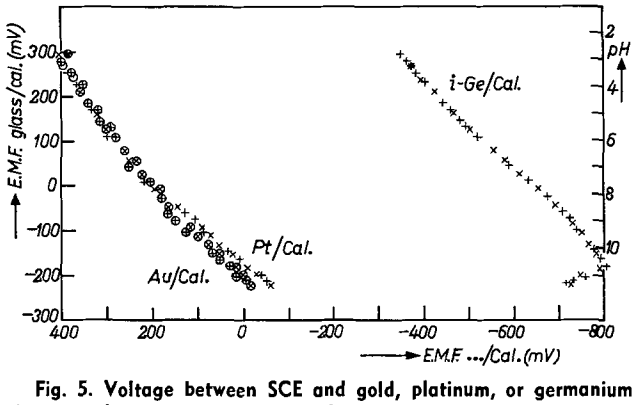

Fig. 5. Voltage between SCE and gold, platinum, or germanium (horizontal axis) as a function of pH vs. a glass/calomel system (vertical axis). The electrolyte contains 0.01M H_2O_2 and 0.1M KCl.

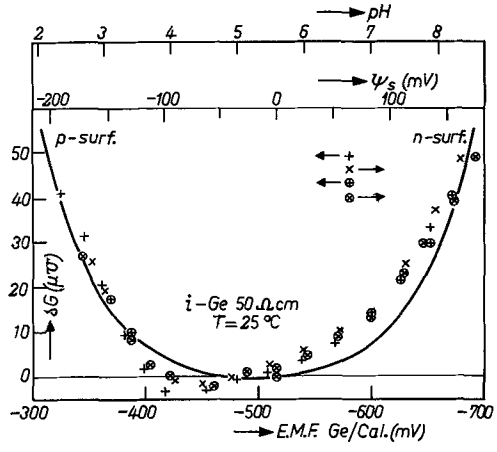

Fig. 6. Experimental relation between the germanium/calomel voltage (horizontal axis) and the surface conductivity of the germanium (vertical axis). Theoretically, the horizontal axis is also a direct measure of the surface potential, Ψ_s, and of the pH. The theoretical relation between surface conductance and surface potential is shown by the solid curve.

be judged from the variation of the conductivity of the cell with time. In the range of pH values between 2 and 8 no conductivity variations can be detected in an 8-hr period when intrinsic germanium is employed, but the sensitivity is increased by a factor 25, when 2 ohm-cm n- or p-type material is used.

Discussion

The simple theory of a passive germanium/electrolyte junction seems to explain the main experimental results. When both H_2O_2 and KCl are present, the germanium/calomel voltage varies by 60 mv per pH unit as predicted. When H_2O_2 is not present, the system is so poorly defined that no reproducible voltages can be measured unless extreme precautions have been taken (9). Even then the situation at the electrode is confused.

According to the model presented in this paper, the surface potential Ψ_s should show the same variations with pH as the cell voltage. The theoretical conductivity contribution along the interface from the surface layer of the germanium, δG, is determined by the bulk doping and the surface potential Ψ_s. This relation between δG and Ψ_s is plotted in Fig. 6, assuming that the bulk mobilities, $\mu_n = 3740$ cm^2/vsec and $\mu_p = 1870$ cm^2/vsec, are still valid at the surface (10). The fit of theoretical and experimental δG *vs.* cell voltage curves is quite satisfactory.

The assumption of a passive germanium/electrolyte junction is in contradiction, however, with other observations. When the germanium is in contact with oxygen-free water, no reaction occurs but, as soon as oxygen gas is admitted, the etch rate is finite (11). Such a slow etching rate is also found when H_2O_2 is present in the solution. When H_2O_2 is added to a H_2O_2-free solution, theory predicts a lowering of the Fermi level in the electrolyte and a decrease of the germanium/calomel voltage. In the experiment the germanium becomes more negative. If germanium behaved as a passive electrode with respect to the H_2O_2/2 OH^- redox-couple, it should be possible to replace the germanium by the noncorrosive gold or platinum electrodes without change in the cell voltage. Experimentally the germanium is roughly 800 mv negative with respect to either gold or platinum. Ellipsometric measurements performed by Bootsma and Meyer (12) provide evidence of the existence of a transparent layer of a width of 30Å at most, when the composition of the electrolyte is the same as in the previous experiments.

Theory and experiment can be reconciled completely when it is assumed that the germanium and the water, containing H_2O_2, react to give some form of oxide, say GeO_2, in which the oxygen transport is carried effectively by singly charged defects. In that case it can be shown that the resulting emf across the intermediate layer is independent of the pH. Thus the Fermi potentials on the germanium side and in the electrolyte are maintained at different levels. Provided some limiting conditions are satisfied, the intermediate layer does not interfere with the dependence of the germanium/calomel voltage and Ψ_s on the pH. The new situation at the interface is illustrated in Fig. 7a. The width of the oxide layer is exaggerated with respect to the width of the space charge region in the germanium. Theoretical treatment of the oxide is discussed in the next section.

So far, no mention has been made of interface states. From the work of Mead and Spitzer (13) it is known that at the germanium/metal interface the position of the Fermi level is completely determined by such states. If these states were also present at the germanium/solution junction, it would be impossible to change Ψ_s. Oxidation of the germanium generally reduces the number of surface states (14). An interface state density of 10^{12}/cm^2, when charged, gives a drop of about 30 mv across a layer 30Å in width. Thus the surface stabilization is insensitive to interface states, provided their concentration is low enough.

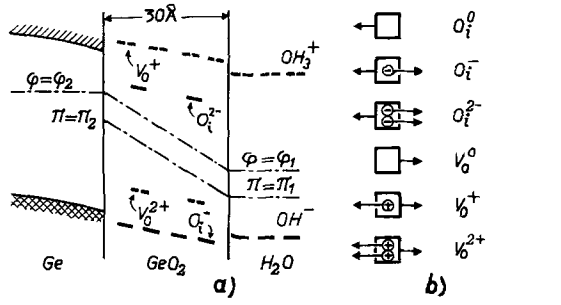

Fig. 7(a). Germanium/oxide/water: as a result of reaction between H_2O_2 and germanium, a difference in Fermi potentials is maintained across the oxide. Fig. 7(b). Force acting on various possible defects; all force vectors are equal.

Often Cu^{2+} ions in the solution are troublesome, but when H_2O_2 is present and pH < 8, the Fermi level is very low and the copper ions remain in the doubly charged state (15).

When H^+ or OH^- groups can be desorbed a pH dependent variation of Ψ is to be expected in the electrolyte, contrary to what was assumed. The experiments give no evidence of such a desorbtion in the range 3 < pH < 8.

Intermediate Layer

In the previous section, arguments were put forward for the existence of an intermediate layer. Little is known about its composition, but first the composition GeO_2 will be assumed, though the conclusions to be drawn are not restricted to this compound.

Wagner, Schottky, and Hauffe have given a theory of oxidation (16), which can also be applied to the germanium/oxide/electrolyte system and can explain the emf across the oxide. A very simplified version of the reaction

$$Ge + 2H_2O_2 \rightleftharpoons GeO_2 + 2H_2O \qquad [6]$$

is given in Fig. 8. In this diagram the following phases are represented from left to right: Ge, GeO_2, and H_2O, containing H_2O_2 as an additive. The difference between the upper and middle row of the diagram is a simultaneous displacement to the left of all oxygen atoms in the oxide plus two borrowed from the peroxide. Thus an additional layer of oxide is created. At the same time chemical energy is consumed. As such a simultaneously motion of atoms is unrealistic, defects that will do the job more efficiently must be found such as, for instance, interstitial oxygens O_i and oxygen vacancies V_O. When two O_i particles traverse the oxide completely an additional layer is formed. A continuous creation of O_i particles occurs according to the reaction

$$2H_2O_2 \rightleftharpoons 4\,OH \rightleftharpoons 2H_2O + 2\,O_i \qquad [7]$$

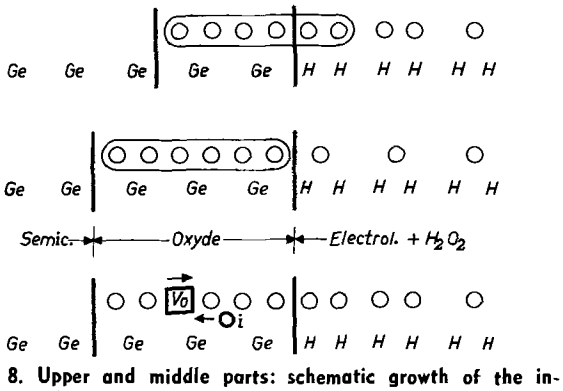

Fig. 8. Upper and middle parts: schematic growth of the intermediate layer; simultaneous motion of oxygen is involved; lower part: growth of the oxide is the result of defect transport.

and annihilation in accordance with

$$2\,O_i + Ge \rightleftharpoons GeO_2 \qquad [8]$$

Although no equilibrium exists between both extremes of the oxide, a local equilibrium can be expected if the diffusion of defects through the layer is the rate-limiting process. Then the concentration of interstitials is constant at the germanium/oxide interface (2) and proportional to the peroxide concentration at the oxide/electrolyte interface (1). Because the density of interstitials is greater at side (1) than at the opposite side, a diffusion of these particles toward the germanium occurs. The driving force is given by

$$F(O_i) = -q \text{ grad } \beta \log [O_i]/N_O \equiv -q \text{ grad } \pi \qquad [9]$$

in which N_O is a temperature-dependent constant, and the identity gives a definition of π. The loss of chemical energy resulting from the motion of the O_i particles in the force field $F(O_i)$ could be eliminated if an O_i were forced to take up an electron at (1), which could be yielded at a higher Fermi potential at interface (2). The electron, temporarily trapped at the interstitial, has to be conveyed against the gradient of the Fermi potential. This means that a complete balance of forces can be obtained, as is illustrated in Fig. 7b. The mean force, acting upon O_i^-, is given by

$$F(O_i^-) = -q \text{ grad } (\pi - \phi) = 0 \qquad [10]$$

because the majority of the mobile charge-carriers is of the type O_i^- and no current is allowed to flow in the stationary state. Integration of [10] yields

$$\phi(1) - \phi(2) = \pi(1) - \pi(2) \qquad [11]$$

As the values of $\pi(1)$ and $\pi(2)$ are given by the local equilibria [7] and [8], the emf across the oxide depends on the hydrogen-peroxide concentration only, and not on the pH. As required, the emf is the result of a finite force, acting over a finite distance. A stable voltage across the oxide can only be expected when one kind of charged defect is present, such as O_i^- and its associated particle V_O^+. The latter need not be treated separately as it gives the same result as O_i^- and also obeys the same electrochemical potential as O_i^-.

So far, special assumptions have been made as to the composition of the intermediate layer and the dominating type of charged defect, but the conclusions can be generalized. As long as the Fermi level in the electrolyte is stabilized by the H_2O_2 and the pH, the emf across the layer will be constant and the germanium/calomel voltage will always vary by 60 mv per pH unit. In the most general case the layer consists of GeO_mH_n and the dominating defects are given by $(O_pH_q)^{r-}$ and $(GeO_{m-p}H_{n-q})^{r+}$. At the interface with the germanium the negative defects are discharged and they should form a new layer according to

$$2p/m\,Ge + 2\,(O_pH_q)^{r-} \rightleftharpoons 2p/m\,GeO_mH_n + 2r\,e^-(Ge) \qquad [12]$$

provided $p/q = m/n$. The generation of negative defects proceeds by the reaction

$$2r\,OH^- 2 + (2p\text{-}q\text{-}r)\,H_2O_2 \rightleftharpoons 2\,(O_pH_q)^{r-} + 2(p\text{-}q)\,H_2O \qquad [13]$$

and the total reaction of the germanium/calomel cell reads

$$2r\,e^-(Ge) + 2p/m\,GeO_mH_{mq/p} + 2r\,Cl^- + 2r\,Hg + 2(p\text{-}q)\,H_2O \rightleftharpoons 2r\,e^-(Hg) + r\,Hg_2Cl_2 + 2p/m\,Ge + 2r\,OH^- + (2p\text{-}q\text{-}r)\,H_2O_2 \qquad [14]$$

Because the coefficient of the electron terms and of the OH^- is the same, the cell voltage varies by 60 mv per pH unit, as long as only one type of charged defect dominates the layer. More complicated relations are found when several consecutive regions are present in the layer, each of which is dominated by a different type of charged defect.

Another interesting point is the coefficient in front of the H_2O_2, which can be positive, negative, or zero, according to whether H_2O_2 is consumed, produced, or not necessary at all.

When the concentration of electrons in the germanium conduction band is kept constant at the surface by artificial means and Ψ can vary in the intermediate layer only, the variation of this drop of Ψ across it will always be 60 mv per pH unit. This is the case when the germanium bands are kept flat by means of a voltage applied between the germanium and the calomel electrode.

The insensitivity to the high-level concentrations of hydrogen-peroxide can be explained in two ways. It is possible that the oxide/solution interface is covered completely by OH groups. Then, according to [7] and [11] the emf is independent of $[H_2O_2]$, as [4] is required at the solution interface only. In the solution, K^+ and Cl^- keep Ψ constant, and ϕ is no longer of any interest. An alternative is excess of the deviation from the stoichiometry ultimately possible in water, which would lead to the formation of a second phase, oxygen gas.

Relation to Other Work

No surface stabilization work on germanium similar to that described in this paper has so far come to the notice of the author. A letter has been published on silicon, however (18). Three objections can be raised to the work referred to in this letter. (*a*) The electrolyte was doped by Ce^{4+} at pH = 0, but a well-defined Fermi level requires both Ce^{4+} and Ce^{3+} in fixed concentrations. The Ce^{4+} state, however, is essentially unstable and decays into Ce^{3+} such that a sufficient constant $[Ce^{3+}]$ will no doubt have been obtained to suggest greater stability than the results turned out to have. (*b*) Then the silicon/calomel voltage and Ψ_s must be expected to vary by 60 mv for every tenfold increase of $[Ce^{4+}]$. This is certainly not in accord with the experimental results presented in the letter. (*c*) Finally, the measured emf was given as depending on the doping of the silicon, in contradiction to theory in general (19).

A number of studies have been made of the germanium/electrolyte interface (20) in which an external voltage is applied between the germanium and the calomel electrodes. The position of the Fermi level in the electrolyte is never stabilized in these experiments, although anodic polarization prior to the measurements might lead to short-lived stability at the interface. The surface potential is either derived from capacity measurements or from conductivity experiments. It is possible to determine the applied germanium/calomel voltage at which the bands are flat. When this voltage is plotted as a function of the pH of the solution, a variation of 60 mv per pH unit is found. As the semiconductor is kept space-charge free, some sort of double layer must be present at the germanium/solution interface, and the drop of Ψ across it is pH-dependent. As the total variation of the applied voltage necessary for flat bands is 480 mv, a drop in Ψ of at least 240 mv has to be explained. None the less, electrokinetic measurements reveal but small fields in the electrolyte (21). It is known that anodic oxidation forms quite substantial layers, exceeding 100Å in a strongly alkaline solution (22). This can be understood, for the compensation current can flow through the external circuit and the charged defects can be transported without opposing fields. The experimental results can be explained by an intermediate layer as the carrier of the double layer. As the efficiency of the oxide growth at higher voltages is only a few per cent, the greater part of the conduction through the oxide must be of electronic nature. Then the discharge of OH^- groups could result in the local formation of H_2O_2 temporarily. Im-

mediately after cessation of the anodic polarization the reaction

$$H_2O_2 + 2\,OH^- \rightleftharpoons 2\,O_i^- + 2\,H_2O \qquad [15]$$

results in $[O_i^-] \sim [OH^-]$. It is clear that such a proportionality will also be obtained after a mild cathodic treatment but the ratio $[O_i^-]/[OH^-]$ will be much smaller. At the germanium/oxide interface a local equilibrium is established by the reaction

$$Ge + 2\,O_i^- \rightleftharpoons GeO_2 + 2\,e^-\ (Ge) \qquad [16]$$

and when the bands are kept flat or the value $[e^-(Ge)]$ is constant $[O_i^-]$ is also constant. Both diffusion and an electric field act on O_i^- and the mean force $F(O_i^-)$ equals[4]

$$F(O_i^-) = -q\ \text{grad}\ (\beta \log [O_i^-]/N_i - \Psi) \qquad [17]$$

where N_i is a temperature-dependent constant. When the current flow in the flat-band condition can be neglected $F(O_i^-) = 0$ and the drop of Ψ across the oxide varies by 60 mv per *p*H unit according to [17]. This voltage also depends on the type of pretreatment, cathodic or anodic. Again the case can be generalized to an arbitrary type of layer and defect. It is not sufficient that [17] is obeyed for, if the drop of Ψ is 240 mv, a certain space-charge carrying capacity is required. Excluding interface states, for the moment, it is possible to calculate the density of singly charged defects necessary at the interface with the electrolyte as a function of the width of the layer. In the case of accumulation of O_i^- the Poisson-Boltzmann equation gives the following approximate result (23)

$$[O_i^-(o)]/[O_i(x)] = (L+x)^2/L^2 \qquad [18]$$

where x is the distance from the electrolyte/oxide interface and L is the Debije-Hückel screening distance for a flat geometry. This L is inversely proportional to the square root of $[O_i^-(o)]$ and when the latter is $10^{19}/cm^3$, $L \approx 10$Å. The product of these quantities gives the number of electronic charges per square centimeter present in the space charge layer, $10^{12}/cm^2$ in this case. At a distance $x = 100\ L = 1000$Å, $[O_i^-(x)]$ has decreased by a factor 10^4 and a drop of about 240 mv is present across the oxide.

The 240 mv drop can also be explained by a density of surface states of $10^{12}/cm^2$ at the germanium/oxide interface but such states, if fast enough, would cause anomalous capacitance *vs.* Ψ_s curves and generally these anomalies are absent in the experiments.

If no intermediate layer were present, interface-state densities of $10^{13}/cm^2$ would be needed and very high fields would be the result. There seems to be a general rule in nature that intermediate compounds are formed whenever the field strength at a junction becomes too high, because the mismatch of both Fermi levels is excessive. A number of examples can be found. When two metals with a large difference of work functions are brought together an intermediate intermetallic compound is formed which initiates alloying. A p-n junction in germanium, in which Li is employed as a donor, tends to build up an intermediate phase of intrinsic germanium (24). The intermediate layer of the germanium/electrolyte system is another example.

When a comparison is made between the work described in ref. (20) and this paper, the conclusion must be drawn that only in the presence of H_2O_2 and KCl, the charge exchange between the germanium and the solution is intense enough to give a well-determined electrode potential and only in this case a chemical stabilization of Ψ_s can be obtained.

Conclusions

A chemical control of the surface potential of germanium can be obtained with a germanium/water junction, when the latter contains sufficient H_2O_2 and KCl and the *p*H is stabilized. When the *p*H is varied both the surface potential and the voltage of the cell germanium/calomel change by 60 mv per *p*H unit. No current flows through the interface. The range of surface potentials covered is 360 mv. The germanium/calomel voltage is a direct measure of the surface potential. Extreme cleaning procedures are eliminated by buffering all essential concentrations.

[4] Equation [17] is compatible with [10].

Epitaxial Growth of Germanium on Single Crystal Spinel

D. J. Dumin

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Films of germanium have been grown on single crystal spinel, $MgAl_2O_4$ grown with excess Al_2O_3, *via* the pyrolysis of germane, GeH_4. The films were single crystal when the growth temperature exceeded 500°C, but contained a high degree of twinning, strain, and grain boundaries. Film thicknesses have ranged from 0.2 to 49 μm. The electrical properties of films grown on (100) and (111) spinel have been measured as a function of growth temperature. The Hall mobility increased with increasing growth temperature, up to growth temperatures of about 750°C, where island growth began. Mobilities of the order of 300 cm^2/vsec have been obtained in 7μ thick films. The acceptor concentration increased as the growth temperature decreased, and this increase in acceptor concentration has been attributed to increased defect density, the defects acting as acceptors. The growth rate of the films was found to increase with increasing growth temperature with an activation energy of 47.5 kcal/mole. The films and substrate were deformed after growth due to the different coefficients of thermal expansion between germanium and spinel and this deformation has been used to estimate that the films were under a compressive stress of about 10^9 dynes/cm^2. The deformation of Ge on spinel is not as great as Si on spinel or sapphire reflecting both the closer match in coefficients of thermal expansion and the decreased temperature change from growth temperature to room temperature.

Prompted by the usefulness of epitaxial silicon-on-sapphire films in the fabrication of MOS transistors (1), the deposition of germanium films on sapphire substrates by chemical vapor transport has been studied (2). Germanium has been epitaxially grown on germanium substrates via the pyrolysis of germane, GeH_4 (3). The growth of germanium from germane has the advantage of being compatible with the use of gaseous hydrides such as arsine, phosphine or diborane as controlled doping agents. In this paper the growth of single crystal layers of germanium on spinel, $MgAl_2O_4$ + excess Al_2O_3, is reported using the pyrolysis of germane. Electrical and mechanical properties of the germanium layers were measured and are reported. The germanium-on-spinel system was chosen to take advantage of the closer match of coefficients of thermal expansion as compared with the match between silicon and sapphire or spinel. Furthermore, because the growth temperature is lower, the strain produced on cooling from growth temperatures to room temperatures should be less. Instead of sapphire, spinel was chosen as the substrate since it is a cubic material and less lattice mismatch can be expected than for sapphire. The use of spinel as a substrate for the epitaxial growth of silicon has been reported (4), and the high quality of these silicon films prompted the use of spinel as a substrate for the germanium growth.

Experimental Techniques

The germanium films were grown in a vertical reaction chamber similar to the horizontal chamber previously described (3). The substrate, on a susceptor of silicon-carbide coated graphite, was heated by R-F induction. The walls of the growth chamber were kept cool to prevent deposition of germanium on the walls. The germane was diluted with hydrogen from a palladium diffuser to about 0.03% by volume of germane in hydrogen. The flow of the hydrogen was sufficient to assure turbulence in the reaction chamber. Provisions were made to supply diborane, arsine, and phosphine to the gas stream for doping of the germanium.

The spinel was flame fusion magnesium aluminate grown with excess Al_2O_3 to produce boules with $MgO:Al_2O_3$ ratios between 1:2 1/2 and 1:3 1/2. The boules were oriented, cut, and mechanically polished to a scratch-free surface. Both (111) and (100) orientations have been used. Prior to growth the spinel wafer was prefired in hydrogen for 10 min at 1100°C. This treatment removed a major portion of the work damage resulting from the mechanical polishing operation without leading to exsolution of the excess Al_2O_3 in the spinel (5). Growth rates were varied from 0.1 to 3 μm/min by either varying the ratio of GeH_4 to H_2 or by varying the growth temperature. The electrical properties of the films appeared to be relatively insensitive to growth rate for growth rates between 0.3 and 1 μm/min.

The films were grown at temperatures between 400° and 900°C. The temperature was measured by either optical or infrared pyrometer focused on the substrate and suitably corrected for emissivity and absorption (6, 7). The films grown at temperatures below 500°C were polycrystalline as determined by the presence of rings in Laue back reflection patterns. Above 500°C the ring pattern gave way to a spot pattern with the presence of stress, twinning, and grain boundaries becoming evident. Subgrain boundaries in the substrates were replicated in the germanium films and were visible optically as regions differing slightly in reflectivity. Above 750°C the formation of unconnected islands of germanium was observed and, while those islands observed microscopically appeared to be good single crystals, the films were often electrically discontinuous. The surface tension of the films apparently increased with increasing growth temperature and increasing film thickness resulting in the observed island formation. (111) germanium was grown on (111) spinel and (100) germanium was grown on (100) spinel. A photograph of a 20 μm thick film grown on (100) spinel is shown in Fig. 1a along with the etch pattern of this film after polishing and chemical etching as shown in Fig. 1b. The Laue back reflection photograph taken on this film is shown in Fig. 1c, where strain and misorientation are evident. Diffractometer measurements have confirmed the single crystal nature of the germanium films.

After growth, the deformation of the film and the substrate was measured using a light section microscope (8). A Hall sample was delineated in the film by masking and etching. The resistivity, Hall mobility, and film thickness were then measured. The film thickness was also measured *in situ* by infrared interference techniques. The carrier concentration was derived from the Hall data using $N = 1/\rho e \mu$ where N is the number of free carriers, ρ is the resistivity, e is

the electron charge, and μ is the Hall mobility. The sign of the Hall voltage was used to determine the film conductivity type.

Experimental Results

The growth rate *vs.* growth temperature was measured using a constant ratio of germane to hydrogen of 0.03% by volume. The films were grown at a constant flow rate of GeH_4-H_2 for a fixed time, and the thickness of the films was measured after growth. The growth rate was found to increase from 0.1 μm/min at 575°C to 0.375 μm/min at 750°C as shown in Fig. 2. The activation energy associated with the growth has been calculated from the data of Fig. 2 as 47.5 kcal/mole, which lies between the zero order and first order reaction activation energies for the thermal decomposition of GeH_4 (9).

The electrical properties of p-type films grown on

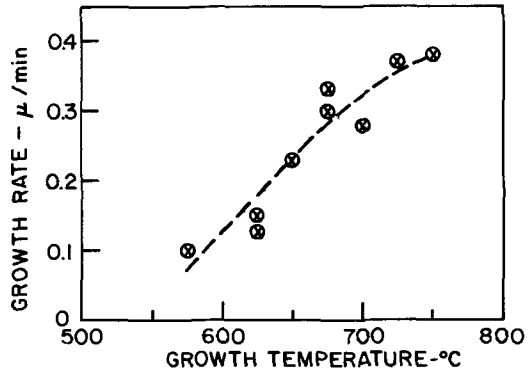

Fig. 2. Growth rate *vs.* growth temperature using 0.03% GeH_4 in H_2 mixture.

(100) and (111) spinel are shown in Fig. 3. The measured values of resistivity and mobility are shown in Fig. 3a and Fig. 3b, respectively, and values of acceptor concentration calculated from these data are shown in Fig. 3c. The Hall mobility increased as the growth temperature increased, indicative of improving crystal structure with higher growth temperatures. This was confirmed by chemically etching films grown at 500° and 700°C and noting that the edge dislocation density decreased for films grown at the higher temperature. Island growth was observed at growth temperatures above 750°C, and while the islands were relatively free of dislocations the films were often discontinuous electrically and very thick layers had to be grown to connect the individual islands.

The resistivities of the films were nearly independent of growth temperature at about 0.1 ohm-cm p-type as deposited from the GeH_4-H_2 mixture. The carrier concentration as derived from the Hall data

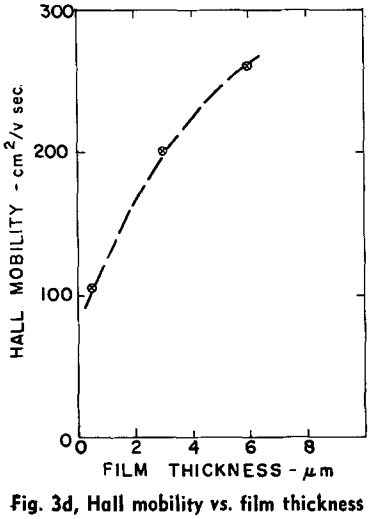

Fig. 3d, Hall mobility vs. film thickness

decreased as the growth temperature increased, but was always greater than the concentration of acceptors obtained in germanium films grown epitaxially on bulk germanium under similar conditions to those used for growth of Ge on spinel. When the source of germane used to grow these films was used to grow germanium films epitaxially on bulk germanium, the measured carrier concentration varied between $3 \cdot 10^{16}$/cc and $6 \cdot 10^{16}$/cc presumably due to small quantities of diborane in the GeH_4. This concentration is shown in Fig. 3c as the background acceptor concentration. The acceptor concentrations found in the films grown on spinel, however, were much larger, of the order of 10^{17}/cc to 10^{18}/cc. This increase in acceptor concentration is attributed to crystalline defects in the germanium films acting as acceptors. That crystalline defects can act as acceptors in bulk germanium has already been shown (10). Similar conclusions concerning the action of defects in germanium films vacuum deposited on CaF_2 (11) and silicon films grown on sapphire (12) have been reported. The increase in acceptor concentration observed in the films grown at about 500°C correlated with the increase in defect density observed by dislocation etching of these films. No autodoping of the germanium by aluminum from the spinel substrates has been observed in these films as has been the case in silicon films grown epitaxially on sapphire (13). This lack of aluminum autodoping results from the lower growth temperature used here.

As the films became thicker, the Hall mobility increased as shown in Fig. 3d for films grown on (111) spinel. The increase in mobility was attributed to improvement in the crystal structure and to a lessening of the effects of surface scattering in the thicker films. The films grown on (111) spinel had a somewhat higher hole mobility than the films grown on (100) spinel as shown in Fig. 3b.

The deformation of the germanium-on-spinel films was found to be less than for films of silicon grown on spinel, indicative of the closer match in coefficients of thermal expansion of the germanium and spinel and the lower growth temperature used in the germanium growth. The deformation of the germanium on spinel films as shown in Fig. 4a was also found to be isotropic, something not observed in silicon-on-spinel films. The displacement of the center of 0.95 cm disks of spinel after deposition is plotted in Fig. 4b as a function of germanium film thickness. Two thicknesses of substrate were used, 0.25 and 0.38 cm. Since the deformation should vary as the reciprocal of the substrate thickness squared (8), the deformation on the 0.26 cm substrate should be about twice that on the 0.38 cm substrate. This is approximately the ratio of the deformations described in Fig. 4b. No differences in deformations on the (100) or (111) spinel were observed.

The stresses in the germanium films have been estimated from the deformation using the following constants: Young's modulus for spinel = $3.3 \cdot 10^{12}$ dyne/cm², Poisson's ratio for spinel = 0.25 (14-16). Stresses of the order of 10^9 dynes/cm² have been calculated. This is approximately the stress that would be calculated using $\sigma = E\Delta\alpha\Delta T$ where σ is the stress, E is Young's modulus of the spinel, $\Delta\alpha$ is the difference in expansion coefficients and ΔT is the difference between growth temperature and room temperature. The films were under compressive stress as expected. The expansion coefficient of the spinel is reported to be greater than that of the germanium, and we ob-

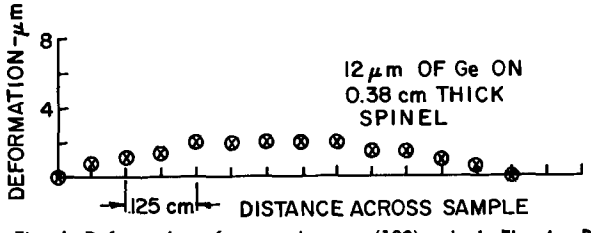

Fig. 4. Deformation of germanium on (100) spinel: Fig. 4a, Deformation across a 0.95 cm disk of spinel.

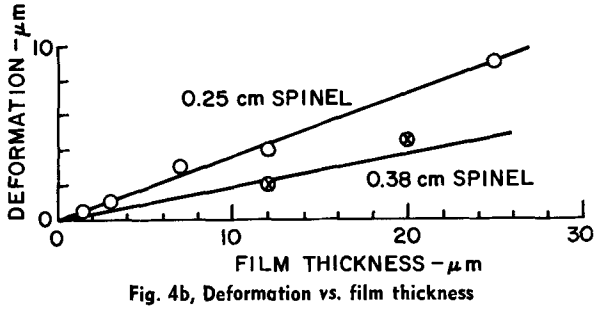

Fig. 4b, Deformation vs. film thickness

served that the films were deformed with the germanium surface convex.

Conclusions

Germanium thin films have been grown epitaxially on single crystal spinel substrates of (111) and (100) orientation. The Hall mobility increases with increasing growth temperature until island growth sets in at growth temperatures above 750°C. The incidence of island growth at temperatures above 750°C is probably indicative of a high surface mobility of the nucleating atoms. For a constant GeH_4-H_2 ratio the growth rate increased with growth temperature with an activation energy of 47.5 kcal/mole. The films were under compressive stresses of the order of 10^9 dynes/cm^2 as determined from the deformation of the films.

Acknowledgments

The author wishes to thank C. W. Mueller, P. H. Robinson, and J. A. Amick for their many useful technical comments during the course of this work and during preparation of the manuscript and R. F. Adams and R. O. Wance for assistance in the electrical measurements. The Laue back reflecting measurements and the diffractometry work were performed by R. T. Smith and E. Krieger.

Manuscript received Feb. 8, 1967; revised manuscript received March 25, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Mixed Conduction in $Zr_{0.85}Ca_{0.15}O_{1.85}$ and $Th_{0.85}Y_{0.15}O_{1.925}$ Solid Electrolytes

John W. Patterson,[1] E. C. Bogren, and Robert A. Rapp

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio

ABSTRACT

The d-c polarization technique according to Wagner was applied for the first time at elevated temperatures for the determination of $\sigma_\ominus$ and $\sigma_\oplus$ in the $Zr_{0.85}Ca_{0.15}O_{1.85}$ and $Th_{0.85}Y_{0.15}O_{1.925}$ electrolytes over a range of oxygen activity and temperature. The applicability of the technique and an improved method for data analysis are demonstrated. Experimental difficulties and limitations are discussed. The total conductivity of $Zr_{0.85}Ca_{0.15}O_{1.85}$ was determined over a range of oxygen activity and temperature.

Stabilized zirconia with the $Zr_{0.85}Ca_{0.15}O_{1.85}$ composition exhibits a high ionic conductivity because of its CaF_2-type structure with a high ionic defect concentration. Since the introduction of the $Zr_{0.85}Ca_{0.15}O_{1.85}$ electrolyte by Kiukkola and Wagner (1), it has been used in about fifty high-temperature galvanic cell, fuel cell, and oxygen pressure gauge investigations. Lattice parameter, density (2-4), and x-ray diffraction peak intensity (4, 5) measurements indicate that Ca^{+2} ions substitute directly on Zr^{+4} sites and give rise to a significant fraction (7.5%) of vacant oxygen ion sites. The P_{O_2}-independence of the total conductivity (1, 6), the corresponding value for the oxygen self-diffusion coefficient (6, 7) and the numerous excellent correlations of galvanic cell voltages to known free energy data have served as evidence that electrical conduction in $Zr_{0.85}Ca_{0.15}O_{1.85}$ at elevated temperatures is primarily due to the migration of doubly charged anion vacancies. The P_{O_2} range of predominant ionic conductivity ($t_{ion} > 0.99$) extends at least from 1 atm oxygen pressure down to a moderately low P_{O_2} which has been estimated from several indirect measurements (5, 8-10).

[1] Present address: Department of Metallurgy, Iowa State University, Ames, Iowa.

Doping the CaF_2-type structure of pure ThO_2 with Y_2O_3 results in an analogous cation substitution with the creation of oxygen vacancies (11-13). For the $Th_{0.85}Y_{0.15}O_{1.925}$ composition at 1000°C, predominant ionic conductivity with a P_{O_2} independent total conductivity covers a wide P_{O_2} range between $P_{O_2} \approx 10^{-6}$ atm and a very low P_{O_2} which has not yet been established (9, 14, 15). The predictions from the dilute solution theory of Lasker and Rapp (14) indicate that a relatively highly doped electrolyte composition like $Th_{0.85}Y_{0.15}O_{1.925}$ should exhibit a wider P_{O_2} range of predominant ionic conduction than a composition containing less Y_2O_3 dopant.

The total conductivity σ_T (ohm^{-1}-cm^{-1}) of a material containing s independently migrating carrier species is given by

$$\sigma_T = \sum_{i=1}^{s} q_i^2 c_i B_i = \sum_{i=1}^{s} \sigma_i \qquad [1]$$

where q_i is the charge (coulombs/particle), c_i the concentration (particles/cm^3), B_i the absolute mobility (particles-cm^2/sec-volt-coulomb) and σ_i the partial conductivity of the i species. The important carrier candidates for the doped oxides $Zr_{0.85}Ca_{0.15}O_{1.85}$

and $Th_{0.85}Y_{0.15}O_{1.925}$ are presumed to be $V_{\ddot{O}}$, $\oplus$, and $\ominus$, where $V_{\ddot{O}}$ is a vacant oxygen ion site and where $\oplus$ and $\ominus$ denote positive holes and excess electrons, respectively. Conductance due to the migration of cation defects is negligible (16-18). Thus, addition of 15 mole % CaO to ZrO_2 and of 15 mole % $YO_{1.5}$ to ThO_2 greatly increases the partial anion vacancy conductivity, *i.e.*, $\sigma_{V_{\ddot{O}}} = q^2 v_{\ddot{O}}\, c_{V_{\ddot{O}}}\, B_{V_O}$. For sufficiently high dopant levels, $c_{V_{\ddot{O}}}$ is so large relative to electronic defect concentrations that the $\sigma_{V_{\ddot{O}}}$ term dominates σ_T of Eq. [1] over wide ranges of P_{O_2} at elevated temperatures.

Presumably the P_{O_2} dependences of the partial excess electron conductivity $\sigma_\ominus$ and the partial positive hole conductivity $\sigma_\oplus$ are dictated by the local equilibria

$$\tfrac{1}{2}\, O_2(g) + V_{\ddot{O}} + 2\ominus = O_O^x \qquad [2]$$

and

$$\tfrac{1}{2}\, O_2(g) + V_{\ddot{O}} = 2\oplus + O_O^x \qquad [3]$$

where O_O^x is an oxygen ion on its lattice site. If the abundant dopant cations and the compensating oppositely charged anion vacancies are sufficiently dissociated, these species should dominate the neutrality condition, $\sum_{i=1}^{s} c_i q_i = 0$, with

$$[V_{\ddot{O}}] = [Ca_{Zr}^{11}] \text{ for } Zr_{0.85}Ca_{0.15}O_{1.85} \qquad [4]$$

and

$$[V_{\ddot{O}}] = \tfrac{1}{2}[Y_{Th}^{1}] \text{ for } Th_{0.85}Y_{0.15}O_{1.925} \qquad [5]$$

where $[V_{\ddot{O}}]$, $[Ca_{Zr}^{11}]$, and $[Y_{Th}^{1}]$ represent the concentrations of the fully ionized, dissociated species. At a given temperature, $[V_{\ddot{O}}]$ should be established by the dopant content and therefore change only slightly with P_{O_2}, so that the equilibrium constants for Eq. [2] and [3] give $c_\ominus \propto P_{O_2}^{-1/4}$ and $c_\oplus \propto P_{O_2}^{+1/4}$ if a dilute solution of electronic defects is assumed. These same dependences extend immediately to $\sigma_\ominus$ and $\sigma_\oplus$, respectively, if, as is frequently presumed (1, 14, 19), the quantities $B_\ominus$ and $B_\oplus$ are independent of $c_\ominus$ and $c_\oplus$.

On the other hand, excessive association of the dopant cations and anion vacancy defects to form neutral aggregates should cause departure from the $P_{O_2}^{-1/4}$ and $P_{O_2}^{1/4}$ dependences of $\sigma_\ominus$ and $\sigma_\oplus$ if the concentrations of dissociated and charged vacancy defects and dopant cations were insufficient to dominate the neutrality condition. Such a proposal has been advanced by Kröger (20) for $Zr_{0.85}Ca_{0.15}O_{1.85}$ to explain the effect of small aliovalent-cation additions on the electronic conduction in $Zr_{0.85}Ca_{0.15}O_{1.85}$. However, the agreement between the dilute solution theory (dissociated defects) and the experimentally determined values for $\sigma_\oplus$ in $ThO_2 - Y_2O_3$ solutions (14, 15) indicates the validity of Eq. [5] even if a significant fraction of these species were associated in neutral aggregates. Further experimental determinations of the variation of $\sigma_\ominus$ and $\sigma_\oplus$ with P_{O_2} at elevated temperatures would assist in establishing the degree of dopant-vacancy association.

The primary objectives of the present work were to measure directly $\sigma_\ominus$ and $\sigma_\oplus$ in $Zr_{0.85}Ca_{0.15}O_{1.85}$ and $Th_{0.85}Y_{0.15}O_{1.925}$ and σ_T in $Zr_{0.85}Ca_{0.15}O_{1.85}$ over a wide range of P_{O_2} in the temperature range 800°-1000°C. The corresponding measurements of σ_T for $Th_{0.85}Y_{0.15}O_{1.925}$ have been reported by Lasker and Rapp (14). The present study represents the first attempt to measure electronic conductivities in oxide electrolytes at high temperatures using the polarization technique as described by Hebb (21) and Wagner (19, 22). The high-temperature polarization studies of oxides by Danforth and Bodine (23) and by Vest and Tallan (24) have not involved the use of a reversible electrode.

Partial Electronic Conductivities from Polarization Measurements

The d-c polarization techniques employed in this investigation have been described elsewhere (19, 22, 25) and have been used previously to study electronic conduction in the halides of Ag (26, 27), Cu (28), and Tl (29). Application of the technique to the oxide specimens of this investigation follows the same principles. Briefly, the cell (I)

Reversible Electrode | Oxide Specimen | Nonreversible Electrode (I)
$x = 0$ $x = L$

is subjected to a d-c emf below the decomposition voltage of the specimen. The electrode at the right ($x = L$) is made negative so that anions within the specimen are repelled from the nonreversible (Au, Pt) electrode at $x = L$ and hence migrate initially to the reversible electrode where they are consumed. The reversible electrode must therefore function simultaneously as an electronic lead and an oxygen sink and at the same time maintain a known oxygen chemical potential μ_{O_2} at $x = 0$. To perform these functions, the chosen reversible electrodes consisted of a metal-metal oxide or metal oxide (1)-metal oxide (2) equilibrium two-phase mixtures. Because the noble metal nonreversible electrode cannot provide oxygen, the local oxygen activity at $x = L$ is reduced during the transient through oxygen ion depletion. Finally, steady-state is reached in which the oxygen concentration gradient at each position in the oxide represents a force on the anions which is equal and opposite to the electrostatic force, so that net charge transport by ionic species vanishes. Because the transport of anion species and the consideration of nonmetal chemical potentials are involved in this study, it is worthwhile to review Wagner's theoretical treatment (19, 22) in terms of mobile anionic defects as follows.

Local equilibrium at any location within the oxide specimen of cell (I) is presumably dictated by the reactions [2] and [3]. In the presence of an electrostatic field, the equilibria [2] and [3] are described by the equilibrium relationships

$$\tfrac{1}{2}\mu_{O_2} + \eta_{V_{\ddot{O}}} + 2\eta_\ominus = \mu_{O_O^x} \qquad [6]$$

and

$$\tfrac{1}{2}\mu_{O_2} + \eta_{V_{\ddot{O}}} = 2\eta_\oplus + \mu_{O_O^x} \qquad [7]$$

where η_i is the electrochemical potential of the appropriate species, and is defined as

$$\eta_i = \mu_i + z_i \mathbf{F} \phi \qquad [8]$$

where $\mathbf{F}$ is the Faraday constant, ϕ the electrostatic potential, and μ_i and z_i the chemical potential and valence, respectively, of the species i. Subtracting Eq. [7] from Eq. [6]

$$\eta_\ominus + \eta_\oplus = \mu_\ominus + \mu_\oplus = 0 \qquad [9]$$

Because the dopant content virtually fixes the concentration of oxygen ions and oxygen vacancies in a homogeneously doped oxide electrolyte with immobile cations, this material behaves like a virtually stoichiometric compound and hence exhibits only a very small fractional change in oxygen content for large changes in μ_{O_2}. This condition insures that

$$\mu_{O_O^x} = \text{constant} \qquad [10]$$

and

$$\mu_{V_{\ddot{O}}} = \text{constant} \qquad [11]$$

within the oxide specimen in cell (I), regardless of the local oxygen activity or the state of polarization. Using Eq. [8], [10], and [11] in Eq. [6] and [7]

$$\tfrac{1}{4}\mu_{O_2} + \mu_{\ominus} = \text{constant} \quad [12]$$

and

$$\tfrac{1}{4}\mu_{O_2} - \mu_{\oplus} = \text{constant} \quad [13]$$

The low concentrations of excess electrons and positive holes which obtain at any location within a doped oxide electrolyte may be described by the laws of dilute solutions, *viz.*,

$$c_{\ominus} = c^{o}_{\ominus} \exp\left[(\mu_{\ominus} - \mu^{o}_{\ominus})/RT\right] \quad [14]$$

and

$$c_{\oplus} = c^{o}_{\oplus} \exp\left[(\mu_{\oplus} - \mu^{o}_{\oplus})/RT\right] \quad [15]$$

For such low concentrations, the excess electron and positive hole mobilities may be regarded as concentration independent. Thus, combining Eq. [1] and [12] through [15],

$$\sigma_{\ominus} = \sigma^{o}_{\ominus} \exp\left[-(\mu_{O_2} - \mu^{o}_{O_2})/4RT\right] \quad [16]$$

and

$$\sigma_{\oplus} = \sigma^{o}_{\oplus} \exp\left[(\mu_{O_2} - \mu^{o}_{O_2})/4RT\right] \quad [17]$$

where the reference state for each polarization experiment is chosen as the electrolyte at the oxygen activity of the reference electrode at $x = 0$. It should be noted that all of the above relations result from the chemical nature of the electrolyte, and not from any consequences of the polarization experiment.

The partial current density I_i for species i within the oxide specimen of cell (I) is given by (22)

$$I_i = -(\sigma_i/z_i\mathbf{F})(\partial\eta_i/\partial x) \quad [18]$$

At steady state in the polarization experiment $I_{ion} = 0$ so that

$$(\partial\eta_{V_O^{\cdot\cdot}}/\partial x) = 0 \quad [19]$$

Then the steady-state current density I_∞ is due only to the migration of excess electrons and positive holes so that

$$I_\infty = I_{\ominus} + I_{\oplus} = (1/\mathbf{F})\left[\sigma_{\ominus}(\partial\eta_{\ominus}/\partial x) - \sigma_{\oplus}(\partial\eta_{\oplus}/\partial x)\right] \quad [20]$$

where $I_{\ominus}$ and $I_{\oplus}$ are the partial excess electron and partial positive hole current densities. From Eq. [6], [7], [10], and [19], it follows that

$$-(\partial\eta_{\ominus}/\partial x) = (\partial\eta_{\oplus}/\partial x) = \tfrac{1}{4}(\partial\mu_{O_2}/\partial x) \quad [21]$$

Substituting Eq. [16], [17], and [21] into [20] gives

$$I_\infty = -(\tfrac{1}{4}\mathbf{F})\{\sigma^{o}_{\ominus}\exp\left[-(\mu_{O_2} - \mu^{o}_{O_2})/4RT\right] + \sigma^{o}_{\oplus}\exp\left[(\mu_{O_2} - \mu^{o}_{O_2})/4RT\right]\}(\partial\mu_{O_2}/\partial x) \quad [22]$$

for the steady-state current density at any location within the oxide specimen. However for a specimen of uniform cross sectional area, I_∞ is independent of location x so that Eq. [22] may be integrated over the specimen length L to give

$$I_\infty L = -\frac{RT}{\mathbf{F}}\left[\sigma^{o}_{\ominus}(1 - \exp\left[-(\mu^{L}_{O_2} - \mu^{o}_{O_2})/4RT\right]) + \sigma^{o}_{\oplus}(\exp\left[(\mu^{L}_{O_2} - \mu^{o}_{O_2})/4RT\right] - 1)\right] \quad [23]$$

where $\mu^{L}_{O_2}$ is the effective oxygen chemical potential at the nonreversible electrode ($x = L$) in cell (I).

In view of Eq. [6], [10], and [19]

$$\eta^{L}_{\ominus} - \eta^{o}_{\ominus} = -\tfrac{1}{4}(\mu^{L}_{O_2} - \mu^{o}_{O_2}) \quad [24]$$

where $\eta^{L}_{\ominus}$ is the electrochemical potential of excess electrons at $x = L$ in the oxide specimen. Assuming that $\eta_{\ominus}$ is essentially constant across the current lead/electrode and specimen/electrode interfaces, Eq. [24] reduces to

$$E = -(\tfrac{1}{4}\mathbf{F})(\mu^{L}_{O_2} - \mu^{o}_{O_2}) \quad [25]$$

Substituting Eq. [25] into [23] gives

$$I_\infty = RT/\mathbf{F}L\{\sigma^{o}_{\oplus}[1 - \exp(-u)] + \sigma^{o}_{\ominus}[\exp(u) - 1]\} \quad [26]$$

where $\sigma^{o}_{\oplus}$ and $\sigma^{o}_{\ominus}$ are the partial positive hole and partial excess electron conductivities (ohm^{-1}-cm^{-1}), respectively, for the oxide electrolyte at the μ_{O_2} of the reversible electrode, and the dimensionless quantity u is given by

$$u = E\,\mathbf{F}/RT \quad [27]$$

The current I_∞ in Eq. [26] is positive if positive holes migrate from left to right in cell (I), and the emf E is positive if the left-hand (reversible) electrode in cell (I) is positive. As seen, the derivation of Eq. [26] assumes independent migration of all species, local equilibrium throughout the specimen, independence of $B_{\oplus}$ and $B_{\ominus}$ on concentrations and concentration gradients of ionic and electronic defects, zero ionic current at steady state, and negligible specimen decomposition.

All previous investigations (22, 25, 26-28) involving this d-c polarization technique have been restricted to experimental conditions in which either $\sigma^{o}_{\oplus}$ or $\sigma^{o}_{\ominus}$ dominated in an expression analogous to Eq. [26]. In these cases, evaluation of the predominant term was obtained from either a current plateau of an I_∞ *vs.* E plot or from the intercept of a log I_∞ *vs.* E plot. Consideration of these limiting cases for interpreting quantitatively I_{oo} *vs.* E d-c polarization data is unsuccessful, however, under experimental conditions in which $\sigma^{o}_{\oplus}$ and $\sigma^{o}_{\ominus}$ are of comparable magnitudes. The method used in the present investigation is valid in the limiting cases mentioned above as well as in cases where $\sigma^{o}_{\oplus}$ and $\sigma^{o}_{\ominus}$ are comparable. Dividing both sides of Eq. [26] by $[1 - \exp(-u)]$ gives

$$I_\infty/[1 - \exp(-u)] = \frac{RT}{\mathbf{F}L}[\sigma^{o}_{\oplus} + \sigma^{o}_{\ominus}\exp(u)] \quad [28]$$

A "converted" plot of $I_\infty/[1 - \exp(-u)]$ *vs.* $\exp(u)$ according to Eq. [28] should give a straight line of slope $(RT/\mathbf{F}L)\sigma^{o}_{\ominus}$ and intercept $(RT/\mathbf{F}L)\sigma^{o}_{\oplus}$.

All previous investigations have been restricted to cation-conducting electrolytes and negative emfs. For this case, the present method then consists of plotting $I_\infty/[\exp(u) - 1]$ *vs.* $\exp(-u)$ which gives a straight line of slope $= (RT/\mathbf{F}L)\,\sigma^{o}_{\oplus}$ and intercept $= (RT/\mathbf{F}L)\sigma^{o}_{\ominus}$. Application of this method to the polarization curve of Ilschner (26) for AgBr in equilibrium with Ag at 372° and 353°C is shown in Fig. 1. This converted data plot demonstrates the linearity predicted and has been used to evaluate $\sigma^{o}_{\oplus}$ as well as $\sigma^{o}_{\ominus}$ under conditions where AgBr decomposition is

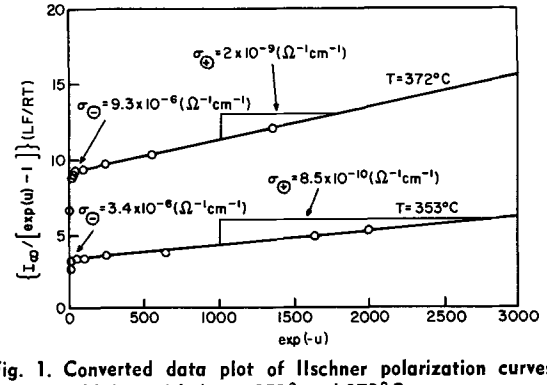

Fig. 1. Converted data plot of Ilschner polarization curves for AgBr in equilibrium with Ag at 353° and 372°C.

negligible. Proper extrapolation of these $\sigma_{\oplus}^{\circ}$ values over more than five orders of magnitude to $P_{Br_2} = 1$ atm gives order of magnitude agreement with data from Raleigh (27). This method for the simultaneous determination of $\sigma_{\oplus}^{\circ}$ and $\sigma_{\ominus}^{\circ}$ has been used to interpret the polarization data of the present investigation.

Experimental Materials and Apparatus

The $Zr_{0.85}Ca_{0.15}O_{1.85}$ polarization specimens were prepared from a mechanical mixture of —325 mesh 99.9% pure Wah Chang ZrO_2 and 99.86% pure Baker Reagent $CaCO_3$. The cold-pressed ½ in. diameter by 1/10 in. thick specimens were calcined in air at 1100°C for 4 hr and further sintered in air at 1600° and 1800°C for 4 and 2 hr, respectively. The $Th_{0.85}Y_{0.15}O_{1.925}$ polarization specimens consisted of ThO_2 powder prepared by converting 99.9% pure $Th(NO_3)_4$ and 99.9% pure Y_2O_3 powder; the specimens were sintered at 2300°C for 2 hr in vacuum ($P < 10^{-4}$ Torr). After firing, all the specimen surfaces were abraded and dusted carefully. Each specimen was then coated on one side with an electrically continuous layer of Au applied by vapor deposition in vacuum.

The reversible electrodes used for cell (I) were prepared from reagent quality materials to yield two-phase equilibrium mixtures of Cu_2O-CuO, Cu-Cu_2O, Co-CoO, Fe-FeO, Cr-Cr_2O_3, Nb-NbO, and V-VO. With the exceptions of the Cu_2O-CuO and V-VO electrodes, the reversible electrode mixtures contained about a 20:1 weight ratio of metal to metal oxide. The Cu_2O-CuO and V-VO electrodes were prepared to ensure the existence of both phases in the temperature range 800°-1000°C. In Table I are listed the equilibrium oxygen activities for the various reversible electrodes, as calculated from reliable thermodynamic data. The nonreversible electrode consisted of a Pt cylinder ½ in. in diameter and about 1/10 in. thick pressed against the vapor deposited Au layer on the oxide specimen.

In the polarization experiments, the emf was provided from a d-c constant voltage supply. Current was measured with a Kiethley 153 microvolt-ammeter. The current was recorded on a chart recorder to facilitate the prompt detection of steady-state conditions. An L&N K-2 potentiometer was used to measure the applied voltage. Voltages up to about 600 mv were applied, while the steady-state currents ranged from about 0.1 to 100 μa depending on the temperature and the electrolyte material.

The a-c conductivity study was performed on similarly prepared CaO-doped ZrO_2 "H" cells (30) of 12, 15, 18, and 21 mole % CaO. The prototype cell

Reversible electrode	CaO-doped ZrO_2 specimen	Reversible electrode

(II)

(where both electrodes for a given experiment are of identical composition) was used for all the a-c measurements. The a-c experiments involved the use of Cu-Cu_2O, Ni-NiO, Cr-Cr_2O_3, Nb-NbO, V-VO, and Ti-TiO electrodes, and measurements were made at 50°C intervals in the temperature range 800°- 1000°C with the use of a 1592 Hz Wayne-Kerr Universal Bridge.

For both d-c and a-c measurements, the cells were held suspended horizontally in a spring-loaded cell holder similar to that previously described (30, 31). Temperatures were indicated by a calibrated Pt/Pt-Rh thermocouple contacting an electrode. The cell temperature was held constant to ± 0.5°C during measurements by the manual supply of the current to the tube furnace surrounding the cell. To minimize interactions with the surrounding gas, purified He of ambient pressure was set at a P_{O_2} approximating that of the cell by passing the gas over a combustion boat filled with the two-phase electrode mixture of the cell placed immediately upstream from the cell.

Table I. Equilibrium oxygen activities for reversible electrodes

Electrode	$-\log P_{O_2}$ (1000°C)	$-\log P_{O_2}$ (900°C)	$-\log P_{O_2}$ (800°C)
Cu_2O, CuO	0.89	1.82	2.89
Cu, Cu_2O	6.29	7.43	8.83
Ni, NiO	10.35	11.99	13.94
Co, CoO	11.98	13.52	15.10
Fe, FeO	14.89	16.71	18.90
Cr, Cr_2O_3	21.79	24.39	27.48
Nb, NbO	25.10	28.03	31.52
V, VO	26.40	29.36	32.87
Ti, TiO	34.76	38.44	42.81

Results and Discussion

Polarization study.—An extensive series of preliminary experiments was required to discover and minimize the experimental difficulties introduced in this initial application of the Wagner polarization technique to oxides at high temperatures. In particular, the Ni-NiO mixture was found to be unsuitable for use as a reversible electrode in these experiments. Apparently, the diffusion of nickel ions in NiO is too slow to enable the electrode to function simultaneously as an oxygen sink and yet maintain Ni-NiO equilibrium at the mixed conductor/electrode interface. Further, relatively large open-circuit emf's (30-300 mv) persisted for long periods of time for cells involving the Ni-NiO electrode.

The "instability" of the steady-state current was studied under changing experimental conditions. In these preliminary experiments, the steady-state current was established for a given emf and temperature while the He flow rate, total gas pressure, Pyrex wall temperature, and cold trap levels were varied. Because all of these changes affected the steady-state current, the system was redesigned so that all greased joints were positioned on the upstream side of the liquid nitrogen cold trap. Further, all Pyrex and mullite tubing between the cold trap and the furnace chamber was thereafter maintained at 200°-300°C. With these precautions and with evacuations between subsequent runs, polarization currents showed very little instability over long periods of time. Evacuation of the furnace chamber during steady state seemed to increase the conductance of extraneous leakage paths in parallel with the polarized specimen. High-purity He was found to provide less instability than technical-grade He. From these experiments, the use of an extremely pure inert gas atmosphere of ambient pressure was found to be essential for d-c polarization experiments at high temperatures.

For each type of reversible electrode, *I vs. E* polarization traverses were conducted at 1000°, 900°, and 800°C using specimens of $Zr_{0.85}Ca_{0.15}O_{1.85}$ in one series of experiments and $Th_{0.85}Y_{0.15}O_{1.925}$ in a second series. The resulting data were converted to $I_\infty/[1 - \exp(-u)]$ and $\exp(u)$ values and plotted to determine the values of both $\sigma_{\oplus}^{\circ}$ and $\sigma_{\ominus}^{\circ}$ corresponding to equilibration of the specimen with the μ_{O_2} fixed by the reversible electrode. Despite experimental precautions, *I vs. E* transverses for the three electrodes of lowest μ_{O_2} did not correspond to Eq. [28], but exhibited ohmic behavior; these data were not considered significant. Apart from apparent linearity of the $I_\infty/[1 - \exp(-u)]$ *vs.* $\exp(u)$ (converted data) plots for most runs, an independent check on the validity of Eq. [26] is available for any traverse in which $\sigma_{\oplus}^{\circ}$ is much smaller than $\sigma_{\ominus}^{\circ}$ (*i.e.*, the converted data plot extrapolates through the origin). The log I_∞ *vs. E* plot for sufficiently large *E* from such a traverse should show a straight line with the predicted slope

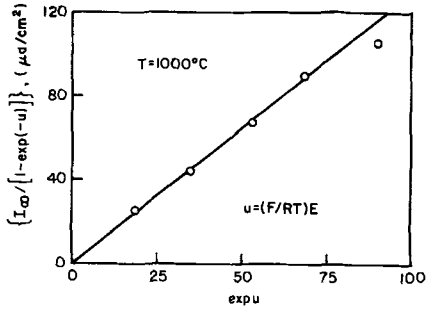

Fig. 2. Converted data plot for d-c polarization measurements with the cell Fe, FeO/$Zr_{0.85}Ca_{0.15}O_{1.85}$/Au,Pt at 1000°C.

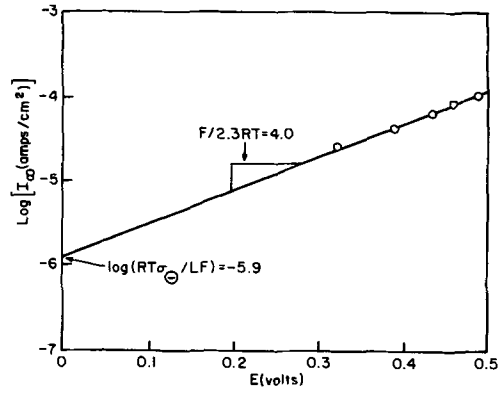

Fig. 3. Plot of log I_∞ vs. E for the cell Fe-FeO/$Zr_{0.85}Ca_{0.15}O_{1.85}$/Au,Pt at 1000°C.

$\mathbf{F}/2.30\,RT$ and with an intercept log $(RT/FL)\,\sigma_\ominus^\circ$. Such a traverse was provided by the 1000°C traverse of the cell

$$\text{Fe, FeO} \mid Zr_{0.85}Ca_{0.15}O_{1.85} \mid \text{Au, Pt} \qquad \text{(III)}$$

The data from this traverse are plotted as $I_\infty/[1-\exp(-u)]$ *vs.* exp (u) in Fig. 2 and as log I_∞ *vs.* E in Fig. 3. The line in Fig. 3 has a slope of 4.0 v^{-1}, which is the value of $\mathbf{F}/2.303\,RT$ at $T = 1273$°K. This agreement between theory and experiment serves to confirm the validity of applying Eq. [26] to describe data derived from polarization traverses for an ionically conducting oxide at elevated temperatures. The values of $\sigma_\ominus^\circ$ deduced from the slope of Fig. 2 and the intercept of Fig. 3 are identical. It may be noted also that since the derivation of Eq. [26] presumes $P_{O_2}^{-1/4}$ and $P_{O_2}^{1/4}$ dependences of $\sigma_\ominus$ and $\sigma_\oplus$, the check provided by cell (III) at 1000°C affords additional strength to the presumption of significant dissociation between dopant cations Ca_{Zr}'' and vacancies $V_O^{\cdot\cdot}$.

The values of log $\sigma_\ominus$ and log $\sigma_\oplus$ derived from data conforming to Eq. [28] were plotted *vs.* the value of log P_{O_2} corresponding to equilibrium coexistence of the reversible electrode constituents. These results for $Zr_{0.85}Ca_{0.15}O_{1.85}$ are shown in Fig. 4, and those for $Th_{0.85}Y_{0.15}O_{1.925}$ are given in Fig. 5. The values of log $\sigma_\oplus$ shown on these plots are those derived from high P_{O_2} conditions where minor side effects are expected to have little effect on the intercept values used to calculate log $\sigma_\oplus$. On the other hand, values of log $\sigma_\ominus$ under these high P_{O_2} conditions have not proved to be significant due to background currents. The data for the very low P_{O_2} reversible electrodes exhibited ohmic behavior as well as other inconsistencies and were therefore deleted for the most part. Accordingly, only 1000°C data appear on the low P_{O_2} region of Fig. 4, and these data are not thought to be significant. These observations of ohmic behavior for the low P_{O_2} electrodes in conjunction with $Zr_{0.85}Ca_{0.15}O_{1.85}$ have led to the exclusive use of cell (III) and the following cell (IV) for determining

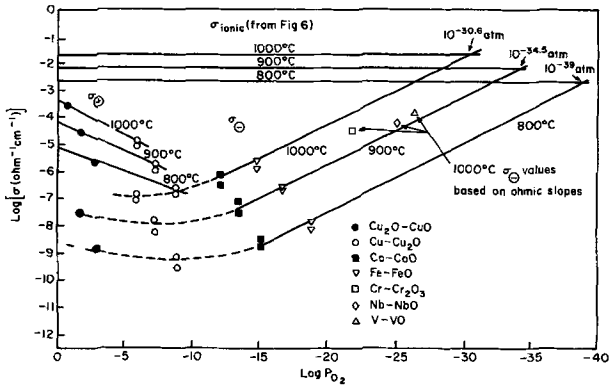

Fig. 4. Plot of log $\sigma_\ominus$, log $\sigma_\oplus$ and log σ_{ionic} vs. log P_{O_2} for polarization study of $Zr_{0.85}Ca_{0.15}O_{1.85}$ at 1000°, 900°, 800°C.

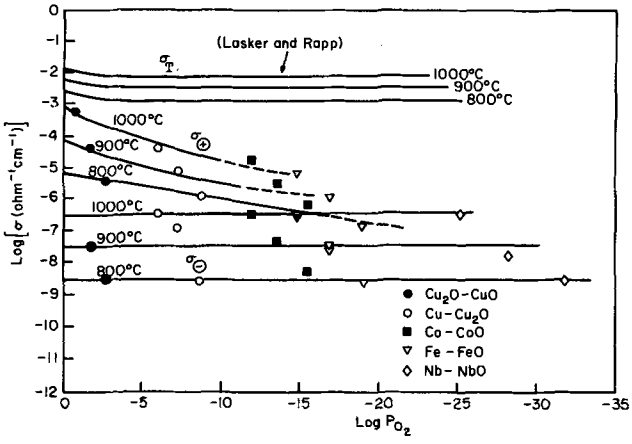

Fig. 5. Plot of log $\sigma_\ominus$, log $\sigma_\oplus$, log σ_T vs. log P_{O_2} for polarization study of $Th_{0.85}Y_{0.15}O_{1.925}$ at 1000°, 900°, 800°C.

$\sigma_\ominus$ in $Zr_{0.85}Ca_{0.15}O_{1.85}$

$$\text{Co} - \text{CoO} \mid Zr_{0.85}Ca_{0.15}O_{1.85} \mid \text{Au, Pt} \qquad \text{(IV)}$$

The lines for $\sigma_\ominus$ for $Zr_{0.85}Ca_{0.15}O_{1.85}$ of Fig. 4 have been drawn with the assumption of a $P_{O_2}^{-1/4}$ dependence. Comparing these polarization values of $\sigma_\ominus$ for $Zr_{0.85}Ca_{0.15}O_{1.85}$ with ionic conductivities determined from the results of the a-c measurements given below, Schmalzried's (5, 8) $P_\ominus$, for which $\sigma_{ion} = \sigma_\ominus$, was calculated. For the temperatures 800°, 900°, and 1000°C, these values are about 4 orders of magnitude below those deduced solely from the a-c conductivity results described below. From open-circuit emf measurements with $Zr_{0.85}Ca_{0.15}O_{1.85}$ at 1000°C, Schmalzried (5) estimated $P_\ominus$ at 10^{-24} atm whereas Steele and Alcock (9) reported $P_\ominus$ equal to 10^{-23} atm. The work of Lasker and Rapp (14), however, indicated a poor correlation between t_{ion} and $E_{meas.}/E_{thermod.}$ for cells involving metal/metal-oxide electrodes in a region of mixed conduction. The more recent work of Tretjakov and Schmalzried (10) indicates that $P_\ominus$ for $Zr_{0.85}Ca_{0.15}O_{1.85}$ at 1000°C is lower than 10^{-26} atm.

A comparison of the present polarization measurements with those of Vest and Tallan (24) on $Zr_{0.85}Ca_{0.15}O_{1.85}$ would not be meaningful. In addition to the fact that Vest and Tallan did not employ a well-defined reversible electrode in their polarization cell, they did not report any polarization results for $Zr_{0.85}Ca_{0.15}O_{1.85}$ above about 750°C nor did they report the effect of oxygen potential on the steady-state current for this material.

The values of log $\sigma_\oplus$ for $Th_{0.85}Y_{0.15}O_{1.925}$ shown in Fig. 5 were derived from the appropriate converted

data plots for high P_{O_2} cells. Interestingly, these values are not sufficiently large to rationalize the rise in total conductivity (14) observed in $Th_{0.85}Y_{0.15}O_{1.925}$ near $P_{O_2} = 1$ atm at 800°-1000°C. The values of log $\sigma_\ominus$ derived from the converted data plots are also shown in Fig. 5 and appear to exhibit P_{O_2} independence, which indicates that the actual values of $\sigma_\ominus$ in $Th_{0.85}Y_{0.15}O_{1.925}$ are below the limits of resolution for the apparatus used in this investigation. In other words, leakage conductances around the specimen exceeded the electronic conduction through the bulk of the specimen under these conditions. Preliminary experiments in which a void space (He gas) replaced the specimen yielded the same magnitude for this leakage conductance. Because the leakage conductance showed a positive temperature dependence and increased on evacuation of the system, electron transport via the gas phase is suspected as the principal leakage. Despite the precautions which were taken, another possible source of leakage current at steady state is a small ionic contribution maintained by the reduction of O_2 molecules of the gas phase at the nonreversible electrode, passage of oxygen ions through the electrolyte, and oxidation of metal at the reversible electrode. This attempt to resolve $\sigma_\ominus$ in $Th_{0.85}Y_{0.15}O_{1.925}$ indicates that $\sigma_\ominus$ is at least between 3 to 4.5 orders of magnitude less than σ_{ionic} in $Th_{0.85}Y_{0.15}O_{1.925}$ down to P_{O_2} values corresponding to Nb-NbO equilibrium between 800° and 1000°C. These upper limits on $\sigma_\ominus$ together with total a-c measurements by Lasker and Rapp (14) allow an estimation of the maximum low P_{O_2} such that $t_{ion} > 0.99$. These values are $P_{O_2} = 10^{-34.3}$ atm at 1000°C, $10^{-39.5}$ atm at 900°C, and $10^{-44.7}$ atm at 800°C.

Although the improved method of data analysis should in principle yield values for both $\sigma_\oplus$ and $\sigma_\ominus$ for all experimental conditions, it was found for these polarization measurements at high temperatures that leakage conductances which shunt the cell generally precluded a meaningful determination of the conductivity for the minority carrier. Likewise, experimental distinction between ±1/4 and ±1/6 slopes of log σ *vs.* log P_{O_2} plots of polarization data was not possible due to cell-to-cell experimental variations introduced by the assembly procedure in combination with a high level of ohmic leakage conductances. Consequently, correlation of log $\sigma_\oplus$ and log $\sigma_\ominus$ results obtained from different electrodes cannot be used to infer defect structure models. However, the values of $\sigma_\oplus$ in $Th_{0.85}Y_{0.15}O_{1.925}$, and values of $\sigma_\oplus$ and $\sigma_\ominus$ in $Zr_{0.85}Ca_{0.15}O_{1.85}$ obtained by the d-c polarization technique in this investigation are thought to be significant, despite the difficulties encountered in the determination of the conductivity of the minority carrier in a given run.

The determination of a significant shunting electronic conductance in the polarization study of $Th_{0.85}Y_{0.15}O_{1.925}$ suggests an improvement in the experimental setup not only for future polarization studies but also for galvanic cell investigations. Presuming that the principal electronic leakage is a result of thermionic emission, this leakage should be considerably reduced for polarization studies by the placement around the cell of a metallic cylinder which would be maintained at some considerable positive potential relative to the cell. Such an electron collector might also prove important to galvanic cell studies. It is well recognized that electronic conduction through the electrolyte will result in a transport of mass through the electrolyte under open-circuit conditions. Especially when metal-metal oxide electrodes are involved, polarization of the electrodes could result in electrode potentials below the reversible potentials, so that again low cell voltages would result. Thus, minimization of open-circuit electronic leakages through the use of a surrounding electron collector may also prove important in galvanic cell studies. Guard-ring techniques have been used previously by Mitoff (32) and Vest *et al.* (33).

Total conductivity studies of CaO-*doped* ZrO_2.—The results of the total conductivity studies of CaO-doped ZrO_2 are shown in Fig. 6, 7, and 8. Figure 6 shows the variation of σ_T for $Zr_{0.85}Ca_{0.15}O_{1.85}$ as a function of log P_{O_2} at the temperatures 800°, 850°, 900°, 950°, and 1000°C. The plateaus indicate predominate ionic conductivity while the branches at the right may be

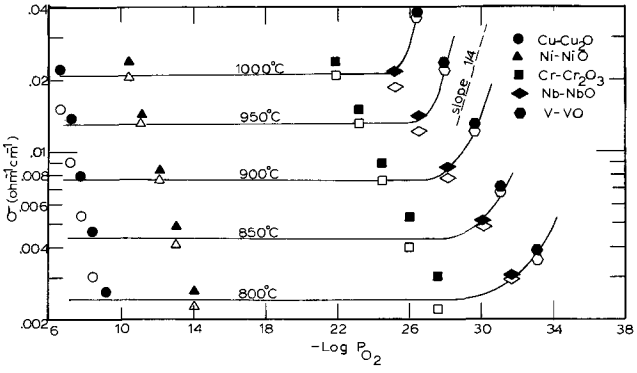

Fig. 6. Oxygen pressure dependence of total conductivity for $Zr_{0.85}Ca_{0.15}O_{1.85}$ at 800°-1000°C; ● and O denote separate experiments.

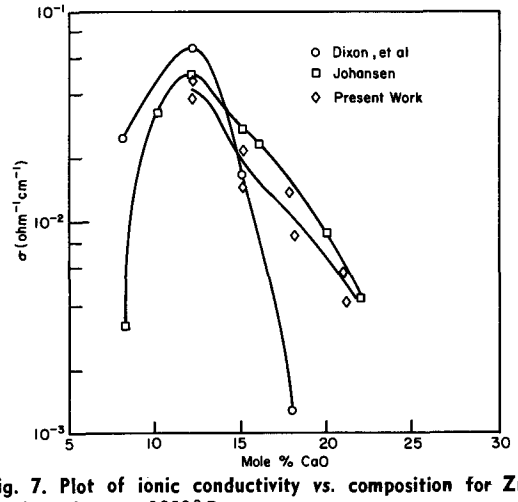

Fig. 7. Plot of ionic conductivity *vs.* composition for ZrO_2 + CaO electrolytes at 1000°C.

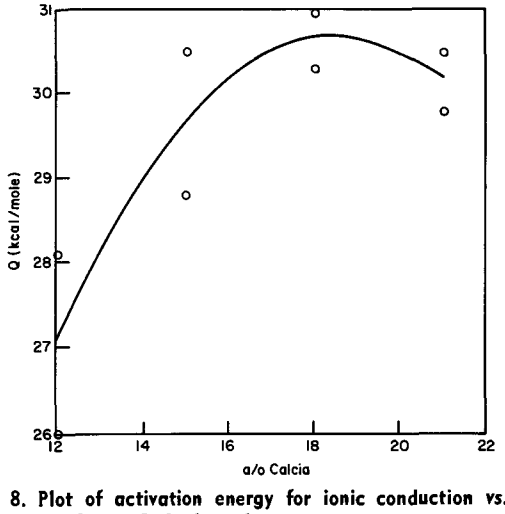

Fig. 8. Plot of activation energy for ionic conduction *vs.* composition for ZrO_2 + CaO electrolytes.

attributed to the onset of electronic conduction. These branches are expected to approach a ¼ slope in accordance with the $P_{O_2}^{-1/4}$ dependence anticipated for $\sigma_\ominus$. The anticipated ¼ slope was not verified from the a-c measurements of this study because the Ti-TiO electrodes (at very low P_{O_2}) failed to yield reliable or reproducible results despite extended experimental attempts. Although the $Zr_{0.85}Ca_{0.15}O_{1.85}$ specimens used for this a-c study were prepared independently of those used in the polarization study, the results of both studies were combined in order to compare the relative magnitudes of ionic and electronic conduction in $Zr_{0.85}Ca_{0.15}O_{1.85}$. Attributing the rise in log σ_T for the V — VO electrodes to the onset of $\sigma_\ominus$ leads to $P_\ominus$ values of $10^{-34.7}$ atm at 800°C, $10^{-30.2}$ atm at 900°C, $10^{-26.5}$ atm at 1000°C.

Other values of $P_\ominus$ from the literature and from the polarization measurements have been discussed. The difference in $P_\ominus$ between the a-c and d-c methods may be attributed either to differences in trace impurity contents in the specimens, or else to contamination of $Zr_{0.85}Ca_{0.15}O_{1.85}$ by the V — VO electrode in the a-c study. In the latter case, $P_\ominus$ should be lower than that obtained from the a-c measurements.

The effect of CaO dopant concentration on σ_{ion} for doped-ZrO_2 at 1000°C is given in Fig. 7. In Fig. 8 is given the empirical activation energy Q for ionic conduction in CaO-doped ZrO_2. The decrease in σ_{ion} and increase in Q with dopant content above 12 mole % CaO is in agreement with other investigations (24, 34-38).

Conclusions

From this initial use of the Wagner d-c polarization technique for the investigation of electronic conductivity in oxide electrolytes at elevated temperatures, the following results were forthcoming:

1. An improved method for plotting polarization data was demonstrated which allows the simultaneous determination of both $\sigma_\oplus$ and $\sigma_\ominus$ from a single experimental run;
2. Values for $\sigma_\oplus$ and $\sigma_\ominus$ in $Zr_{0.85}Ca_{0.15}O_{1.85}$ and $\sigma_\oplus$ in $Th_{0.85}Y_{0.15}O_{1.925}$ were determined for several oxygen chemical potentials at temperatures of 1000°, 900°, and 800°C;
3. Experimental difficulties were encountered in the application of the polarization technique at very low oxygen activities and in the determination of the conductivity of the minority electronic carrier;
4. The P_{O_2} ranges for predominant ionic conductivity were estimated for the oxide electrolytes.

The total conductivity for a series of ZrO_2 + CaO electrolyte compositions was determined over a range of P_{O_2} and temperature.

Acknowledgment

Helpful discussions by C. Wagner and the cooperation of the Aerospace Research Laboratory at Wright-Patterson Air Force Base are appreciated. This research was supported under Contract No. AT (11-1)-1440 by the United States Atomic Energy Commission. This paper is based on portions of the theses by E. C. Bogren in partial fulfillment of the requirements for the degree Master of Science and by J. W. Patterson for the degree Ph.D. in Metallurgical Engineering, The Ohio State University.

Technical Notes

Phase Diagram of the Pseudo-Binary System Ag_2Te-In_2Te_3 and Semiconducting Properties of $AgIn_9Te_{14}$

Ping-Wang Chiang,[1] D. F. O'Kane,[2] and Donald R. Mason[3]

Department of Chemical and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan

Hahn *et al.* (1) have made x-ray analyses at six compositions within the Ag_2Te-In_2Te_3 pseudo-binary system and reported that all the materials crystallized in chalcopyrite structures. Austin *et al.* (2) and Zhuze *et al.* (3) studied the optical and electrical properties of $AgInTe_2$ and reported that its energy gap is 0.9 ev. O'Kane (4) investigated the electrical properties of $AgIn_3Te_5$. No work has been done on the compound $AgIn_9Te_{14}$ which is at the composition 10 mole % Ag_2Te in In_2Te_3.

Experimental Results

DTA measurements have been made on samples within the Ag_2Te-In_2Te_3 pseudo-binary system using either the equipment described by Barnes *et al.* (5) or an Aminco Thermoanalyzer, or both. The transition temperatures obtained in either apparatus on samples of the same composition agreed within 2°C. The study of the phase diagram indicates that $AgIn_9Te_{14}$ exists as a peritectic compound. Electrical conductivity and Hall effect measurements using the circuit described by LaBotz *et al.* (6) have been made on the single-phase portion of a zone-refined ingot of this material.

Phase diagram of the Ag_2Te-In_2Te_3 *pseudo-binary system.*—DTA measurements have been made on quenched samples at 0, 2.5, 5, 8, 10 (two samples), 12.5, 20, 35, 40, 55, 60, 80, and 90 mole % Ag_2Te; on annealed samples (450°-600°C for 4 to 23 days) at 17 and 50 mole % Ag_2Te; on both quenched and annealed samples at 25, 43, 52, 55, 58, 65, 70, 82, 85, and 95 mole % Ag_2Te; and on zone-refined samples at 10 and 30 mole % Ag_2Te. The thermograms of the annealed samples did not differ from those of the quenched samples. The composition distribution of a zone-refined sample should be different from that of an as-cast one and is not interpreted here. However, it was observed that the thermogram of the single-phase portion of the 10 mole % Ag_2Te alloy was identical to the thermogram of the quenched sample, thus indicating the existence of the compound $AgIn_9Te_{14}$.

Based on these DTA measurements, the tentative phase diagram shown in Fig. 1 has been constructed. In the low Ag_2Te region, the solid solution of Ag_2Te in In_2Te_3 (which melts peritectically at 674°C in this system) may extend to 3 mole % Ag_2Te. However, this tentative conclusion reguires confirmation by x-ray diffraction studies. In addition, two more peritectic compounds exist. One at 7.5 mole % Ag_2Te melts at 686°C, and the other at 10 mole % Ag_2Te melts at 694°C. The congruent compound at 25 mole % Ag_2Te which melts at 699° ± 1°C has a very wide homogeneity range. The compound at 50 mole % Ag_2Te

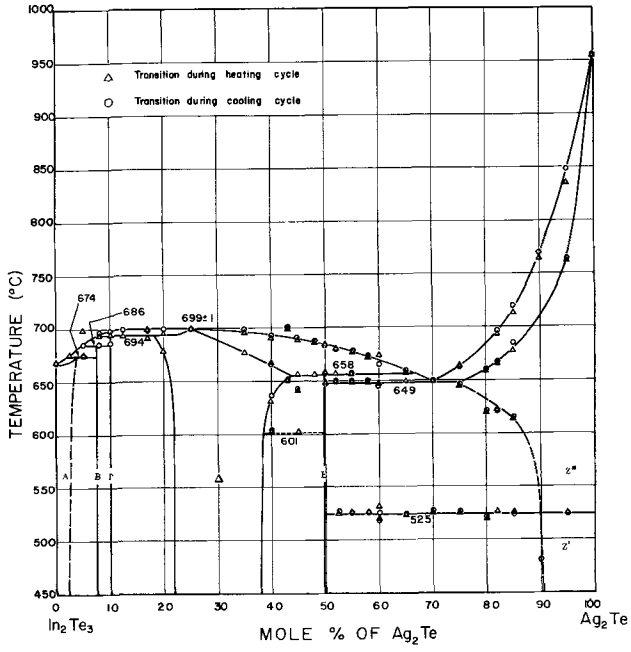

Fig. 1. Tentative phase diagram for the Ag_2Te-In_2Te_3 pseudo-binary system.

($AgInTe_2$) melts peritectically at 658° ± 5°C. The phase diagram of the high Ag_2Te region is relatively simple. At 70 mole % Ag_2Te, there is a eutectic point at 649° ± 2°C. It appears that the solubility of In_2Te_3 in Ag_2Te may be high. However, this should be confirmed by x-ray diffraction. In addition to the solid-solid transition at 525° ± 2°C, the Ag_2Te phase has a solid-solid transition at 150° ± 3°C which is not shown in the figure.

Electrical properties of $AgIn_9Te_{14}$.—Electrical conductivity and Hall coefficient measurements have been made on specimen No. 186(2), a single phase polycrystalline portion of an ingot with the nominal composition $(Ag_2Te)(In_2Te_3)_9$, which had ten zone-refining passes. Figure 2 shows a plot of the logarithm of the electrical conductivity *vs.* the reciprocal absolute temperature, and Fig. 3 shows a plot of the logarithm of $|R_H T^{3/2}|$ *vs.* the reciprocal absolute temperature. The material was n-type. The composition was verified by a DTA measurement which showed a transition temperature of 694°C. At room temperature, the material has an electrical conductivity of 2.5 x 10^{-6} mho/cm, which increases as the temperature increases. The intrinsic energy gap of $AgIn_9Te_{14}$ estimated from the slopes of the plots above 330°C is 1.50 ev from the electrical conductivity data and 1.5 ev from the Hall coefficient data. A donor energy level

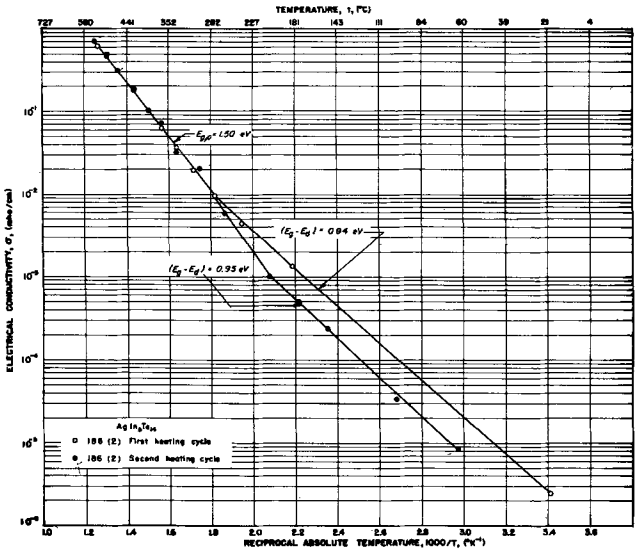

Fig. 2. Logarithm of electrical conductivity vs. reciprocal absolute temperature for $AgIn_9Te_{14}$.

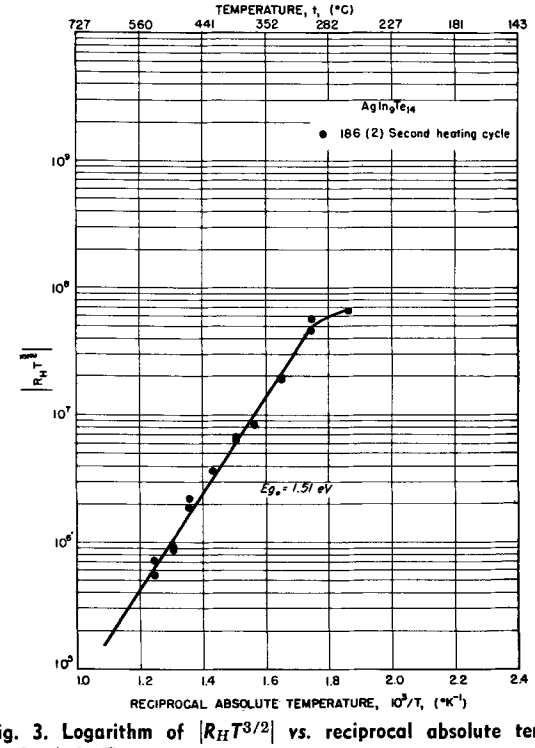

Fig. 3. Logarithm of $|R_H T^{3/2}|$ vs. reciprocal absolute temperature for $AgIn_9Te_{14}$.

0.95 ev below the bottom of the conduction band is observed at temperatures below 200°C. Log $|R_H\sigma|$ is plotted against log T as shown in Fig. 4. The data were scattered. A slope of —1.0 is obtained by a least square correlation for temperatures above 600°K, indicating that lattice scattering is probably the dominant scattering mechanism. The Hall mobility of $AgIn_9Te_{14}$ is 40 cm²/v-sec at 600°K.

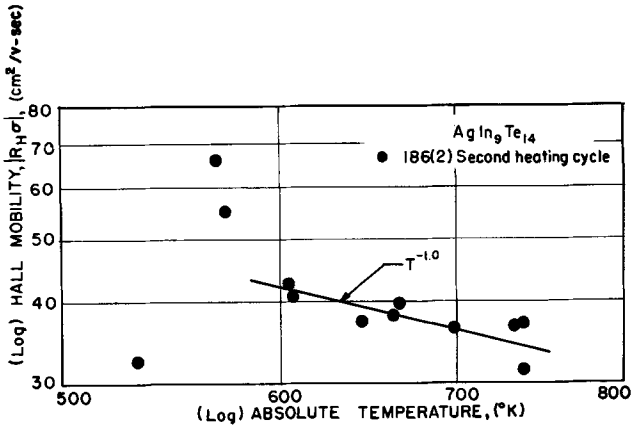

Fig. 4. Logarithm of $|R_H\sigma|$ vs. logarithm of absolute temperature for $AgIn_9Te_{14}$.

Discussion

No x-ray, density, or Seebeck measurements were made on the compound $AgIn_9Te_4$. Hahn (1) reported lattice parameters at 9 mole % and 20 mole % Ag_2Te as a = 6.19 kX, c = 12.38 kX, and c/a ratio of 2.0. According to our phase diagram, these values should be characteristic of $AgIn_9Te_{14}$.

The decrease in conductivity and the decrease in the temperature at which the activation energy changes from 0.95 to 1.50 ev on the second heating cycle are probably due to the loss of the most volatile component, Te.

The 1.50 ev energy gap of this material is greater than that of 1.1 ± 0.1 for $AgIn_3Te_5$ reported by O'Kane (4) and that of 1.20 ± 0.05 observed for In_2Te_3 (7).

Manuscript received Nov. 22, 1966; revised manuscript received March 17, 1967. Contribution No. 30 from the Semiconductor Materials Research Laboratory, The College of Engineering, The University of Michigan, Ann Arbor, Michigan. This work has been supported by Texas Instruments Incorporated, Dallas, Texas and the National Science Foundation. Some of DTA analyses were carried out at Tecumseh Products Research Laboratory, Ann Arbor, Michigan.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Vapor Grown SiAs Crystals

S. W. Ing, Jr., Y. S. Chiang, and W. Haas

Research Laboratories, Xerox Corporation, Webster, New York

Single crystals of SiAs in the form of tiny needles have been grown by Wadsten (1) from the melt, and the crystal structure has been determined. However, other properties of the material have not been reported in the literature. We have grown SiAs crystals of sufficient size, using a vapor transport technique, to enable us to study some of the SiAs crystal physical properties.

The crystal growth was carried out in an evacuated quartz tube. Elementary Si (99.9999% purity) and As (99.999% purity) were placed at opposite ends of the tube. I_2 or AsI_3 was used as the transport agent and was introduced into the tube along with the As in an I_2-to-As ratio of 0.5 to 1%. The tube was then placed in a two-zone furnace with the Si located at the hot zone between 1000° and 1100°C and the As at the cooler zone around 450°C. The temperature gradient between the zones was approximately linear. In 24 hr, a mass of SiAs crystals appeared in a region where the temperature was measured to be around 900°C. The crystals grew in a flat ribbon fashion with the larger ones measuring over 1 cm long as shown in Fig. 1. Frequently, an individual ribbon would be made up of two or three crystals with grain boundaries running along the length of the ribbon.

X-ray measurements were made on the vapor-grown single crystals. The results showed that these crystals are monoclinic and have the symmetry of the space group C2/m which is in agreement with the findings of Wadsten (1). The growth direction of the ribbons was found to parallel the c-axis. The crystals were analyzed chemically,[1] and the results showed a one-to-one ratio of Si-to-As with an accuracy of determination of 1 a/o (atomic per cent).

In some batches, Te was added to the As source in the reaction tube; the atomic ratio of Te-to-As was 1:2. The resulting crystals has the same appearance as without the addition of Te. Chemical analyses showed that these crystals contained about 5 a/o of Te. X-ray measurements showed no alteration in the crystal structure when Te was incorporated.

The SiAs crystals have metallic, highly reflecting surfaces and are completely transparent in the yellow-red region of the spectrum but not in the blue region. Observation in polarized light shows that the crystals are strongly pleochroic. Between crossed nicols, the crystals exhibit straight extinction and in convergent light a biaxial interference figure. Figure 2 shows two faces of a single-crystal SiAs between crossed nicols in the 45° position. A and B are different faces of the crystal, and a growth line can be seen running across the crystal.

[1] Chemical analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.

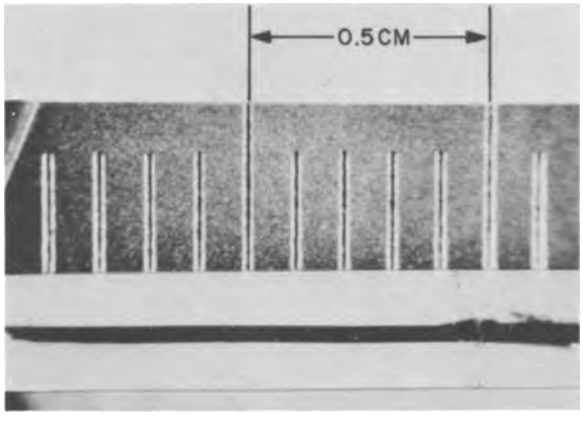

Fig. 1. Vapor grown SiAs crystal

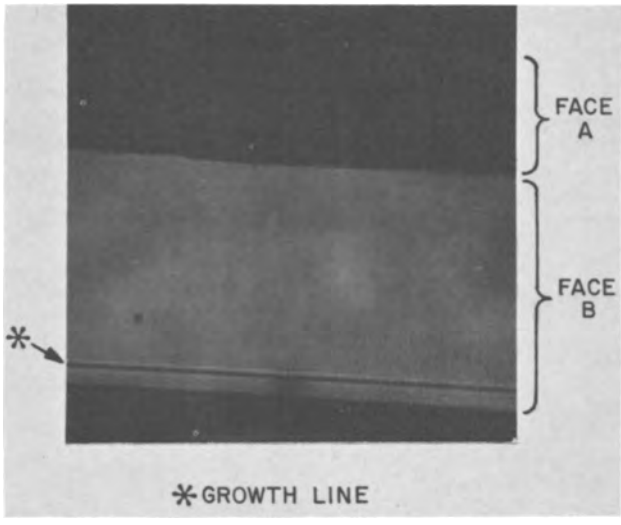

Fig. 2. Light transmission of a SiAs crystal between cross nicols; magnification 100X.

Optical transmission measurements of the Te-doped SiAs crystals have also been made using polarized light. The measurements were made with a Perking Elmer Model 16U monochromator which has resolutions of 25 and 79Å at light wavelengths of 4200 and 7400Å, respectively. The relative optical density spectra with the light polarized perpendicular and parallel to the c-axis of the crystal are presented in Fig. 3. No reflection measurements were made. The optical density spectra indicate that the material has an optical bandgap of around 2.2 ev. This value certainly represents a lower limit of the optical bandgap energy. The spectra also reveal a few small peaks in the long wavelength region. A significant amount of shift in the absorption spectrum was observed between the light polarized perpendicular and the light

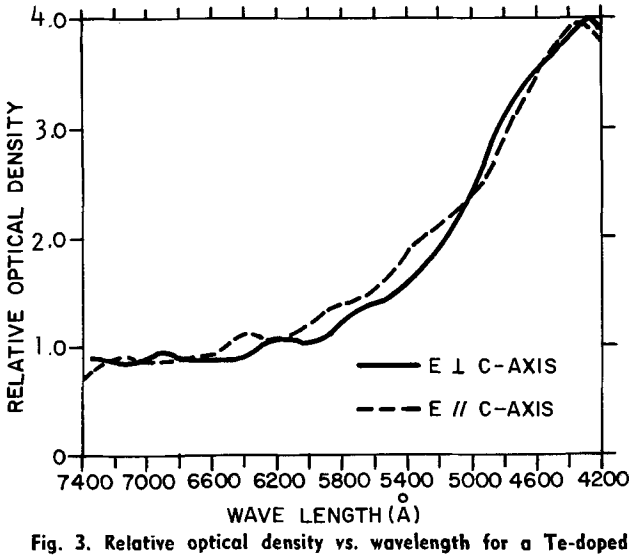

Fig. 3. Relative optical density vs. wavelength for a Te-doped SiAs crystal.

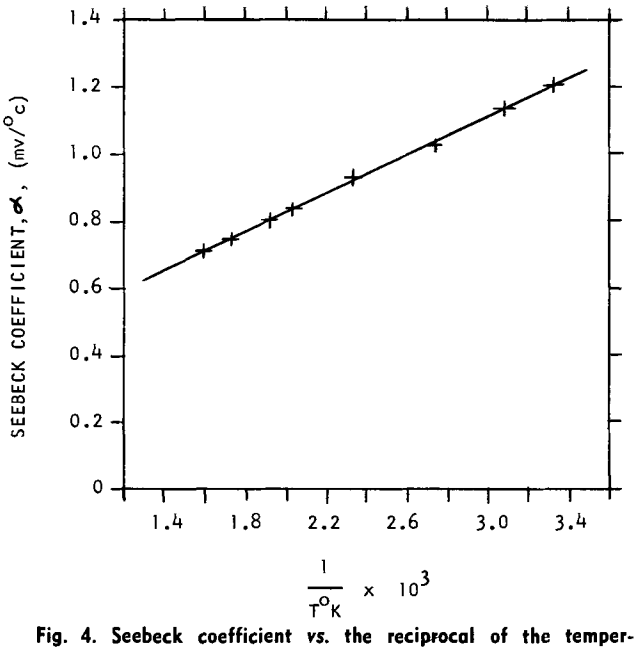

Fig. 4. Seebeck coefficient *vs.* the reciprocal of the temperature of a SiAs crystal doped with 5 a/o Te.

polarized parallel to the crystal c-axis. Several crossings of the spectra were observed in the short wavelength region: we cannot, at present, advance an explanation for these crossings.

Thermoelectric measurement indicated that the SiAs crystals were n-type. A Seebeck coefficient of 1.9 mv/°C was obtained near room temperature. The bulk resistivities of the undoped crystals at 22°C were 10^7 ohm-cm as measured by using the familiar 4-contact technique. The resistivity increased exponentially with increasing reciprocal temperature in the temperature range measured (295°-500°K). An activation energy of 0.43 ev was obtained. The Te-doped crystals were also n-type, but exhibited lower resistivities of around 1.4 x 10^3 ohm-cm. A lower activation energy, about 0.28 ev, was observed in the doped material. The Seebeck coefficient of the doped crystal has been measured as a function of temperature in the range 300°-620°K. The results are plotted *vs.* the reciprocal of the temperature in Fig. 4. A linear relationship is observed. By using the simplified expression (2), $\alpha = -(k/e)(\delta - E_f/kT)$, where α is the Seebeck coefficient, k the Boltzmann constant, e the electronic charge, δ a constant depending on the carrier scattering mechanism, E_f the Fermi energy, and T the absolute temperature, the δ and the E_f have been calculated based on the data obtained, to be 3.0 and 0.29 ev, respectively. The value of 3.0 for δ indicates that lattice scattering is the controlling mechanism for electron transport. The calculated Fermi energy agrees closely with the activation energy (0.28 ev). The Fermi level appears fixed either by a set of deep lying donor states or by the negatively charged centers located approximately 0.28 ev below the conduction band if the material is highly compensated. A Ga-In eutectic was used as the contacts in making the electrical measurements. These contacts are ohmic as indicated by the linear current-voltage relationship obtained with applied fields increasing up to 100 v/cm.

The electrical and the optical properties of SiAs clearly characterize the material as a semiconductor. Since it is a group IV-V compound, the atomic bonding within the crystal must satisfy the valence saturation rule (3), *i.e.*, $m(\mu-1) = xX$, where m is the number of cations and x the number of anions in the chemical formula, μ the valence of the cation, and X the valence of the anion. The term $(\mu-1)$ indicates the formation of a cation-cation bond for each cation present. These requirements are indeed satisfied based on the crystal structure of SiAs as proposed by Wadsten (1).

Acknowledgment

The authors wish to thank Mrs. P. S. Unger for the x-ray measurement, Dr. R. H. Zallen for the optical transmission measurement, and Dr. C. Wood for helpful discussions.

Manuscript received Feb. 20, 1967; revised manuscript received March 8, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

The Kinetics of Propane Adsorption on Platinum in Hydrofluoric Acid

Elton J. Cairns[1] and Adrian M. Breitenstein[2]

General Electric Company, Research & Development Center, Schenectady, New York

ABSTRACT

As a first stage in the investigation of the electrochemical oxidation of saturated hydrocarbons on platinum in acid electrolytes, the rate of adsorption of propane on a smooth platinum electrode was studied at 90°C in 37 mole % HF. Using an all-PTFE apparatus and single linear voltage sweep techniques, the surface coverage by hydrocarbon species was measured as a function of adsorption time and potential. The steady-state coverage resulting from propane adsorption shows a sharp maximum at 0.2v (*vs.* rhe). The amount of the most electrochemically active species is highest at 0.3v. The adsorption rate follows Langmuir kinetics with a third-order dependence on free surface. The rate constant has been measured for 0.2 and 0.3v at 90°C.

During the last few years there has been an active interest in the direct anodic oxidation of saturated hydrocarbons in fuel cells (1-10). Exploratory fuel cell investigations pointed out the usefulness of strong acid electrolytes in this connection. The acidic electrolytes which have received the most attention in hydrocarbon fuel cells are sulfuric acid (1), phosphoric acid (2-4), hydrofluoric acid (5-8), and cesium fluoride-hydrofluoric acid mixtures (5, 6, 9, 10). In order to understand better the kinetics and mechanisms involved in the over-all process of anodic oxidation of hydrocarbons, it is desirable to study the various individual steps in the process, starting with the adsorption of the hydrocarbon on a suitable electrode material in the presence of electrolyte.

Some work on the adsorption of methane (11) and ethane (12, 13) on platinum in perchloric acid has been done at temperatures below those where significant reactivity is shown in fuel cells. The results of Gilman (12) on ethane adsorption on platinum in perchloric acid were interpreted in terms of the kinetics of the adsorption process, the adsorption being second order in free surface and first order in ethane concentration. Propane adsorption on platinum in phosphoric acid has been studied (14, 15), but since the adsorption process was diffusion-controlled, no rate expressions could be derived from those results. Butane adsorption on platinum in sulfuric acid has been measured at steady state by tracer methods (16), and under unsteady-state conditions by the use of flow-through porous electrodes (17); neither investigation yielded quantitative kinetic information.

In order to study the kinetics of the adsorption process, it is necessary to perform the adsorption experiments under conditions where diffusion is not controlling. This requires that the product of the concentration of dissolved hydrocarbon and its diffusion coefficient be large enough (and therefore, diffusion fast enough) that the adsorption step is the slower process. It is known that hydrofluoric acid enhances the solubility of saturated hydrocarbons in water (18), and it is expected that the fluoride anion is not adsorbed on platinum electrodes (19, 20). For these reasons and because of the fact that fuel cells using hydrofluoric acid electrolyte oxidize saturated hydrocarbons at high current densities, it was decided that a study would be made of the adsorption of a saturated hydrocarbon on platinum in hydrofluoric acid. Propane was selected as the simplest typical saturated hydrocarbon because it is the smallest molecule containing both CH_2 and CH_3 groups, and it exhibits good reactivity on platinum in hydrofluoric acid (5, 6).

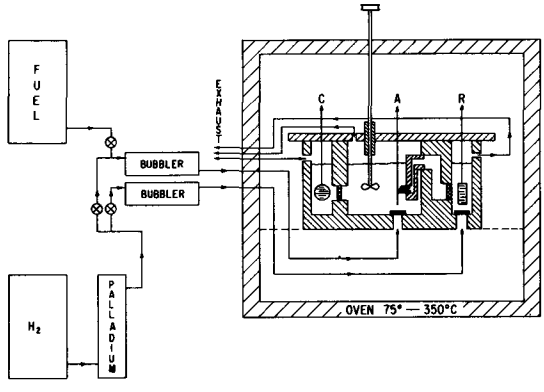

Fig. 1. Schematic diagram of PTFE cell, air thermostat and gas supplies.

Experimental

A schematic diagram of the PTFE three-compartment electrochemical cell, the air thermostat, and gas supplies is shown in Fig. 1. The working electrode compartment (~ 100 cm^3) had provision for bubbling argon or propane over the platinum wire working electrode, and provision for stirring by means of a two-bladed paddle stirrer which could be operated at any speed over the range 0-5000 rpm. A platinum thermocouple well allowed accurate temperature measurement of the electrolyte. Porous PTFE separators were used between the compartments. A PTFE Luggin capillary connected the working electrode compartment to the reference electrode compartment. The reference electrode compartment contained two platinized platinum flags (2 cm^2) which served as reversible hydrogen reference electrodes. Their potentials were observed to remain within 0.2 mv of each other at all times. The counter electrode was a platinized platinum flag of 2 cm^2 area. A forced-convection air thermostat controlled the air stream temperature to within ±0.1°C; control of the electrolyte temperature was better.

The working electrode consisted of a smooth platinum wire 0.146 cm in diameter with an exposed portion 1.034 cm long having a hemispherical end. The surface of the electrode was polished as follows: The Pt wire was mounted in a chuck on the shaft of a high-speed (20,000 rpm) motor with speed controller, and its end was made hemispherical by the application of fine emery paper as the electrode was rotated (~ 2000 rpm). Next, No. 600A emery paper was used to remove the pitted and mechanically damaged (from

[1] Present address: Argonne National Laboratory, Argonne, Illinois 60439.

the wire-drawing process) surface. When no more pits were visible at 50X, the electrode was washed in hot chromic acid, rinsed in distilled water, and annealed carefully in a hydrogen-air flame. The electrode was given a final series of polishing steps using spherical-grained Al_2O_3 powder in wet velvet. This wet-polishing proceeded in 3 stages using 20, 1, and 0.05μ particle sizes in succession, with microscopic examination at 50 and 100X between stages. When the surface appeared smooth at 100X after polishing with 0.05μ powder, the electrode was rinsed in distilled water, annealed, and cleaned by application of alternate anodic and cathodic currents ($\sim$ 10 ma/cm^2) in purified 37 m/o HF. The "true" surface area of the polished electrode was determined by cathodic hydrogen deposition using a linear voltage sweep. The true area was found to be 0.5467 cm^2, assuming 220 μcoul/true cm^2 for hydrogen deposition. This area corresponds to a roughness factor of 1.15.

The electrolyte solution was prepared from quartz redistilled water and Mallinckrodt analytical reagent grade hydrofluoric acid (48 w/o HF) containing a maximum of 5 ppm of heavy metals impurities and a maximum of 100 ppm H_2SiF_6. The HF and water were mixed to produce the 37 m/o HF azeotrope (boiling point, 112°C) which was then purified by distillation in an all-PTFE apparatus. The first and last portions of the distillate were discarded. The center-cut (about 60% of the starting material) was further purified in an all-PTFE cell by an electrochemical treatment consisting of alternate potentiostatic adsorption of impurities on a large ($\sim$ 50 cm^2, r.f. $\simeq$ 1000) platinum electrode and subsequent electrochemical oxidation at intervals of 15-20 min for 24 hr at 90°C. The electrolyte was then transferred to the all-PTFE cell of Fig. 1 where final electrochemical purification took place at 90°C for 48 hr, using a 4 cm^2 platinized platinum electrode (r.f. $\simeq$ 100). All electrochemical purification procedures were carried out under an argon atmosphere using Matheson 99.998% minimum purity argon with oxygen removed (Cu turnings at 800°C).

All gases fed to the electrochemical cell were first saturated with electrolyte solution vapor at the cell temperature using Pt and PTFE bubblers. All tubing and fittings downstream from the bubblers were made of PTFE. The propane used was of two grades: Phillips Research Grade, 99.99+ % pure, and Matheson Instrument Grade, 99.5% minimum purity. Both yielded identical results. The hydrogen was prepurified grade, 99.95% minimum, further purified by diffusion through a silver-palladium tube.

The electrochemical measurements were carried out with the aid of the instruments shown schematically in Fig. 2. The potentiostat was a Wenking fast-rise, model 6301RS, the function generator was a Hewlett-Packard Model 202A, modified for single pulse operation, the potentiometer was an L&N Model K-3, and the oscilloscope was a Tektronix type 555 dual-beam, X-Y, with type D preamplifiers. A make-before-break wafer switch allowed convenient switching from one signal source to another. It was necessary to adopt very careful shielding, guarding, and grounding practices in order to obtain the very low noise levels desired ($\pm$ 5 μa for 1 cm^2 electrodes).

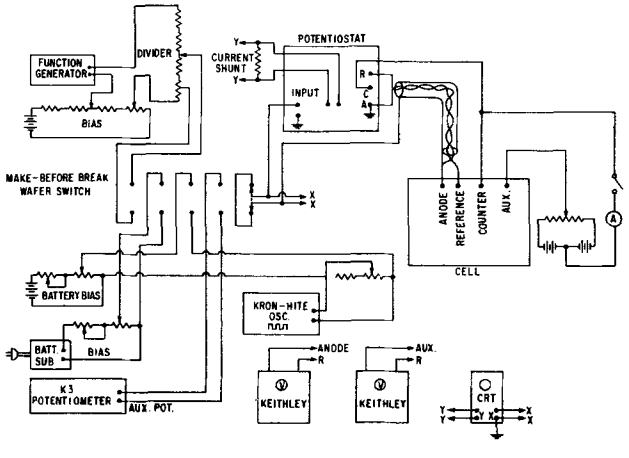

Fig. 2. Block diagram of electronics used for measurement of propane adsorption.

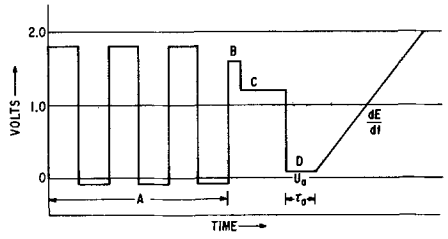

Fig. 3. Voltage sequence for propane adsorption measurement

The electrochemical studies centered around the determination of the amount of electrical charge required either for the anodic oxidation of adsorbed species on the electrode, or for the cathodic deposition of hydrogen on the electrode, usually in the presence of adsorbed hydrocarbon species. In these studies, it was necessary to prepare a reproducibly clean electrode surface. This was done by use of the well-known method of alternately passing anodic and cathodic currents. In this case, the alternate anodic-cathodic treatment was applied potentiostatically using a Kron-Hite square wave generator (Fig. 2) as a signal source for the potentiostat. This cleanup cycle is portion A of the voltage sequence shown in Fig. 3. Each anodic and cathodic potentiostatic pulse was 15 sec in duration, and the voltages were set at values such that equal anodic and cathodic charges were passed. Usually, 10 pulses were more than sufficient to prepare a clean, reproducible electrode surface. This cleanup was performed immediately prior to every experiment, and served to remove all species from the electrode surface which could be oxidized, reduced, and repelled from the surface by high and low potentials (about 1.8 and —0.04v *vs.* rhe). The rate of transition between 1.8 and — 0.04v was made slow enough that surface roughening of the electrode could not take place (21). After the cleanup was completed, the electrode and surrounding electrolyte were prepared for the adsorption step: a protective oxide layer was rapidly formed by stepping the potential up to 1.6v for 6 sec (step B, Fig. 3), and the potential was then dropped to 1.2v (step C) to maintain the oxide layer without passing any additional current. During step C, the propane (or argon) was bubbled (10 cc/min) and stirring was continued at 400 rpm for 60 sec, after which bubbling was stopped and stirring continued for an additional 60 sec to sweep any gas bubbles away from the electrode; the desired mass transport situation was established: usually, quiescent, propane-saturated electrolyte (120 sec of no bubbling or stirring). The working electrode was then stepped to a potential U_a at which reduction of the protective oxide layer took place (within a couple of milliseconds) and propane was allowed to adsorb on the electrode surface for a time τ_a, after which an anodic (or cathodic) linear voltage sweep of speed dE/dt v/sec was applied. The current-voltage trace during application of the voltage sweep was photographed from the screen of the oscilloscope, giving a permanent record of the oxidation of the species on the electrode surface (or a record of hydrogen deposition in the presence of the adsorbed species). Experiments performed as just described, but in the presence of argon rather than propane, gave results characteristic of the behavior of the electrode-electrolyte system alone, which were used as "blanks" in data reduction. The use of this type of voltage sequence in connection with adsorption studies has been reported by Gilman (22).

The details of the various voltage sequences used and their application will be clear from the discussions below. The areas under the current-voltage traces were measured with a compensating polar planimeter and were used for determining the amount of adsorbed material on the electrode surface, as described below.

Results

The objective of this work, as indicated above, was to determine the kinetics of the adsorption process for propane on platinum in hydrofluoric acid. In order to obtain results of sufficient accuracy for a kinetic analysis, it is necessary that the current-voltage trace in the presence of adsorbed propane be reproducible and significantly different from the "blank" trace in the presence of argon and that this difference be a measure of the amount of material adsorbed on the electrode surface. A sample trace, together with its corresponding blank is shown in Fig. 4 for 180 sec of propane adsorption at 0.3v (*vs.* rhe) and 90°C, the anodic sweep speed being 10 v/sec. The area between the two traces (Q) has the units of charge (coulombs), and this charge may be made up of several contributions:

$$Q = Q_{HC} + \Delta Q_{dl} + \Delta Q_O + Q_{diff} \qquad [1]$$

The term Q_{HC} is the charge required to oxidize the hydrocarbon species which were adsorbed on the electrode at the end of time τ_a (the start of the sweep), the numerical value of which is desired. The term ΔQ_{dl} is the change in the charge stored by the double layer as the voltage sweep is applied. This is a very small term (about 1-2%, usually), and can be corrected for (approximately) by noting the difference in current between the argon blank trace and the propane trace (see Fig. 4) in the potential range 0.4-0.6v. The term most difficult to correct for quantitatively is ΔQ_O, which is the change in the charge requiring to oxidize the platinum surface to the potential where the two traces merge (about 1.7v). This change exists because a very small amount of hydrocarbon species stays on the electrode surface until higher potentials (say, 2v) are reached (see below), since the rate of oxidation of this small amount of residue was not high enough to keep up with the voltage sweep. The value of ΔQ_O was always very small compared to Q_{HC} (less than 4%), and was readily determined with sufficient accuracy for use in Eq. [1]. Any additional propane which diffuses to the electrode surface and is adsorbed and oxidized during the anodic sweep is accounted for as Q_{diff} and causes an increase in the charge Q. This effect can easily be avoided by proper choice of sweep speed (see below). Since all of the terms on the right-hand side of Eq. [1] are small compared to Q_{HC} under appropriate experimental conditions, it is possible to obtain Q_{HC} to a high degree of accuracy, using small correction terms of only moderate (percentage) accuracy.

Two peaks are present in the propane trace of Fig. 4: a sharp one near 0.8v and a broad one near 1.2v. It is of interest to follow the behavior of these peaks separately, because it is likely that they represent different classes of materials on the electrode surface. The peak at 0.8v will be called type I, and represents material which is rapidly oxidized (high currents) at relatively low potentials. The broad peak at 1.2v will be called type II and represents material which is oxidized more slowly (lower currents) and over a broader potential range. The separation of the total area Q ($\approx Q_{HC}$) into the two component areas is indicated by the shading in Fig. 4. The exact shape of the shaded area in the overlap region does not have much influence on the results, but was drawn corresponding to the boundary expected from two overlapping probability distribution curves having the shapes of the type I and type II peaks. It was observed that the presence of adsorbed hydrocarbon tended to modify the shape of the rising portion of the trace representing the oxidation of the platinum surface, but this effect was small. It is possible, however, that this slight change in shape of the current-voltage curve for oxidation of the platinum surface could cause an error in the Q_I values, amounting to a few per cent of the values quoted. This effect probably does not influence the Q_{HC} values.

Steady-state surface coverage as a function of potential.—Since it was expected that the rate and extent of propane adsorption would vary with adsorption potential (U_a), a set of survey experiments was performed to determine the adsorption potentials to be used in the detailed kinetics studies. A fixed adsorption time (τ_a) of 300 sec was chosen, since this was sufficient for reaching essentially steady-state surface coverages (see later). The value of ${}^{1.7}_{0.5}Q_{HC}$, the charge required for oxidation of adsorbed hydrocarbon species in the potential range 0.5-1.7v, was determined as a function of potential, as shown in Fig. 5. Note that the results are expressed on the basis of "true" surface area of the electrode. The charge under the type I peak, with suitable corrections for double layer effects, is also presented in Fig. 5. Note that the largest total amount of material (in terms of charge) was present at 0.2v, where only a very little type I was present, while the largest amount of type I was found at 0.3v.

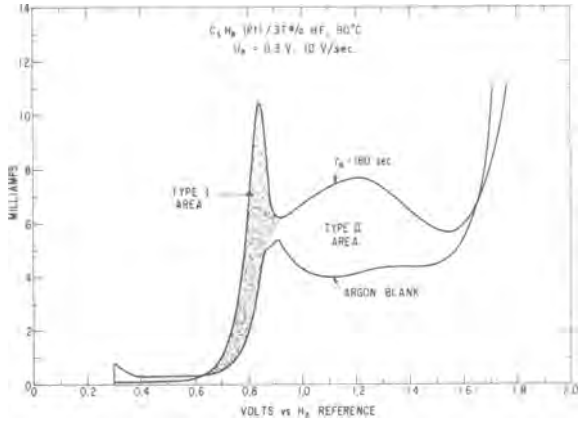

Fig. 4. Sample current-voltage traces for 180 sec of propane adsorption on Pt in 37 m/o HF at 90°C and for argon under the same conditions. Shaded portion indicates area of type I peak.

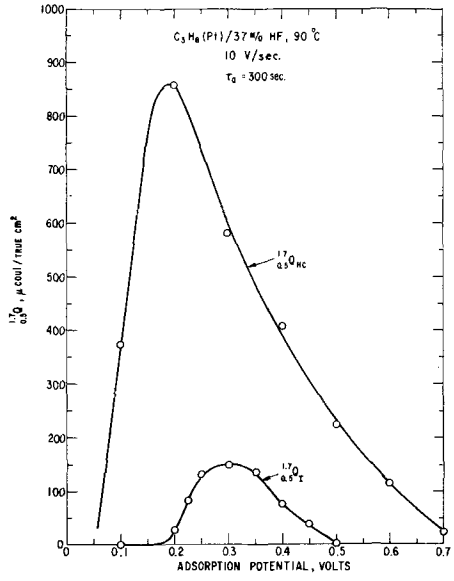

Fig. 5. Charge required for the oxidation of surface species resulting from the adsorption of propane for 300 sec, as a function of adsorption potential.

There are several major processes responsible for the establishment of the maximum in the $^{1.7}{}_{0.5}Q_{HC}$ curve of Fig. 5, the shape of which is in good agreement with the results of Brummer *et al.* in H_3PO_4 (14). At low potentials, the steady-state coverage decreases rapidly with decreasing potential because of hydrogenation-desorption of the hydrocarbon species (12) [largely as propane (23, 24)] and because of a competition between propane and (electrochemically produced) hydrogen for surface sites, the hydrogen tending to prevent propane adsorption. The result is a low coverage with "propane" at low potentials. At the higher potentials, the steady-state value of $^{1.7}{}_{0.5}Q_{HC}$ decreases with increasing potential because of the fact that the adsorbed hydrocarbon species are being electrochemically oxidized and are leaving as CO_2 and H_2O (24). In addition, the stoichiometry of the material on the surface is that of partially oxidized and dehydrogenated species, requiring less charge for oxidation to CO_2 and H_2O than the material which was present at 0.2v (see below).

The potentials 0.2 and 0.3v were selected for the more detailed adsorption rate studies because a comparison could be made between the results obtained with a maximum amount of type I present, and those with the maximum total adsorption (in terms of charge), but only a small amount of type I.

For the adsorption rate studies, the value of Q_{HC} was determined as a function of adsorption time τ_a for several sweep speeds between 1 and 100 v/sec. By plotting the value of Q_{HC} as a function of sweep speed for each τ_a, a plateau value of Q_{HC} could be found, assuring the elimination of any ΔQ or Q_{diff} contribution, since these contributions are dependent on sweep speed. The plots of $^{1.7}{}_{0.5}Q_{HC}$ *vs.* sweep speed for U_a = 0.3v are shown in Fig. 6, where $^{1.7}{}_{0.5}Q_{HC}$ is the charge measured for the 0.5467 cm² true area electrode. Note that the values of Q_{HC} were constant over the sweep-speed range of 2.5-25 v/sec. The plateau values of Q_{HC} for both U_a = 0.2 and 0.3v found in this way were used in all subsequent analyses of results.

Propane adsorption at 0.3v.—Because of the experiences of other investigators in finding that the adsorption of hydrocarbons was diffusion-limited, it was in order to establish the conditions under which the diffusion limitation could be avoided in this work to permit the determination of the adsorption rate law in the absence of diffusion limitations. The fact that a significant amount of material was adsorbed in only 50 msec at 0.3v (cf. Fig. 6) indicated that these results should be tested for diffusion control. If the adsorption process was diffusion controlled, and if $^{1.7}{}_{0.5}Q_{HC}$ is proportional to the number of moles of propane diffusing to the electrode surface, then $^{1.7}{}_{0.5}Q_{HC}$ as a function of time should follow the semi-infinite cylindrical diffusion equation, in the absence of convection.

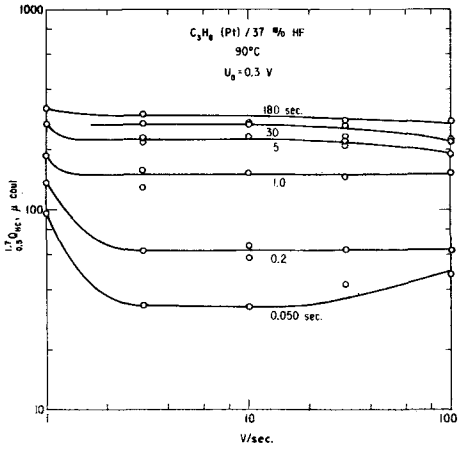

Fig. 6. Charge required for the oxidation of adsorbed species between 0.5 and 1.7v, as a function of anodic sweep speed, for several adsorption times. Propane was adsorbed at 0.3v and 90°C.

The differential equation for semi-infinite cylindrical diffusion to an electrode of constant potential in the absence of convection has been solved by Rius, Polo, and Llopis (25). The solution is

$$i = \frac{4\,n\mathbf{F}D_{AB}C_\infty}{\pi^2 r_o}\int_0^\infty \frac{\exp\left(-\frac{D_{AB}t}{r_o^2}Z\right)}{J_o^2(Z) + Y_o^2(Z)}\frac{dZ}{Z} \qquad [2]$$

Tables of the integral have been published by Jaeger and Clarke (26). An approximate solution for short times, integrated with respect to time to yield coulombs of material transferred to the surface after time t, is given by

$$Q = \frac{n\mathbf{F}D_{AB}C_\infty}{r_o}\left[\frac{t^{1/2}r_o}{\pi^{1/2}D_{AB}{}^{1/2}} + \frac{t}{2} - \frac{D_{AB}{}^{1/2}t^{3/2}}{4\,\pi^{1/2}r_o} + \frac{D_{AB}t^2}{8\,r_o^2} - \ldots\right] \qquad [3]$$

or,

$$Q = \frac{n\mathbf{F}D_{AB}C_\infty}{r_o}f(t) \qquad [4]$$

where Q = coul/cm² sec of propane diffusing to the electrode; D_{AB} = diffusion coefficient of propane in 37 m/o HF at 90°C, cm²/sec; n = number of equivalents per propane molecule; C_∞ = solubility of propane in 37 m/o HF at 90°C, moles/cm³; r_o = radius of electrode, cm; and t = time, sec.

In order to use Eq. [3] to test for diffusion-limited adsorption, it is necessary to know the value of the diffusion coefficient of propane in 37 m/o HF at 90°C. Since the physicochemical properties of 37 m/o HF are very similar to those of water, the value for the diffusion coefficient of propane in water was used as a starting point. The value of the group $(T/D_{AB}\mu)$ used by Wilke and Chang (27) in their correlation of liquid-phase diffusion coefficients was calculated, using the properties of the propane-water system. The measured value of the diffusion coefficient of propane in water at 29.9°C is 1.28 x 10^{-5} cm²/sec ± 2%, as reported by Saraf and Witherspoon (28). This value, and the viscosity of water were used to calculate the value of the group $(T/D_{AB}\mu)$, giving 3.05 x 10^7 °K — sec/cp — cm², in excellent agreement with an estimate of this group using Wilke and Chang's correlation. Since this group is not a function of temperature (27), it is only necessary to have the value of the viscosity of 37 m/o HF at 90°C in order to calculate the diffusion coefficient of propane in this electrolyte at 90°C. The viscosity of the electrolyte was measured at 24° and 96°C, using an all-PTFE Ostwald-type viscometer calibrated with water at each temperature. The values obtained, and that calculated for 37 m/o HF at 90°C are given in Table I, along with the calculated diffusion coefficients, using the value of $(T/D_{AB}\mu)$ given above. The value of the diffusion coefficient for C_3H_8 in 37 m/o HF, 3.516 x 10^{-5} cm²/sec at 90°C was then used in Eq. [3] to calculate the values of the bracketed expression, designated $f(t)$ in Eq. [4].

Using the calculated values of $f(t)$ for each adsorption time τ_a up to 1 sec, the plateau values of $^{1.7}{}_{0.5}Q_{HC}$ from Fig. 6 and some additional data for 10 v/sec

Table I. Properties of 37 m/o HF

Property	Temperature		
	24°C	90°C	96°C
Viscosity, centipoise	0.9492	—	0.3175
Density, g/cm³	1.148	—	1.076
$D_{C_3H_8\text{-}HF}$, cm²/sec	1.026 x 10^{-5}	3.516 x 10^{-5}	—

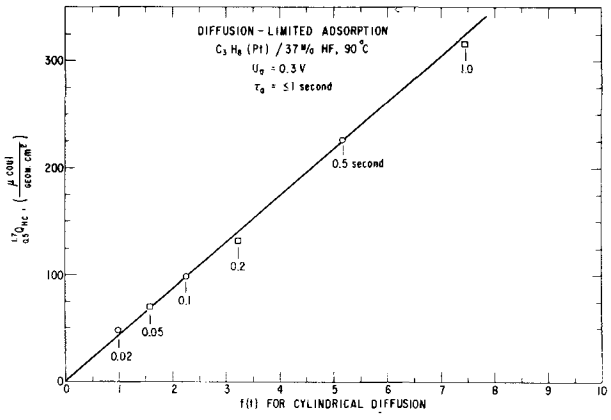

Fig. 7. Plot of $^{1.7}{}_{0.5}Q_{HC}$ vs. $f(t)$ for cylindrical diffusion, indicating that the adsorption of propane at 0.3v from 37 m/o HF at 90°C is diffusion controlled for about the first second of the adsorption period.

were plotted against $f(t)$ as shown in Fig. 7. The linearity of this plot indicates that the adsorption process is diffusion-limited for times shorter than 1 sec, and that $^{1.7}{}_{0.5}Q_{HC}$ must be proportional to the total amount of propane adsorbed on the electrode. For values of τ_a greater than 1 sec, $^{1.7}{}_{0.5}Q_{HC}$ falls below the expected curve, indicating that some other process is limiting for $\tau_a > 1$ sec. The proportionality between $^{1.7}{}_{0.5}Q_{HC}$ and $f(t)$ for small τ_a gives support to the use of Q_{HC} as a direct measure of surface coverage, even under conditions where diffusion does not happen to be rate limiting. The value of the slope of the line in Fig. 7 is directly related to the solubility of propane in the electrolyte as indicated by Eq. [3]. The calculation of the solubility from the slope requires a knowledge of the ratio of $^{1.7}{}_{0.5}Q_{HC}$ to the total amount of charge required to oxidize all of the propane which arrives at the electrode surface. This ratio was found to be 0.685 (see later), and was used together with the value 17 for n (see later) to give a solubility of 8.13 x 10^{-8} moles C_3H_8/cm^3. This solubility corresponds to 0.145 m-mol/l-atm as the Henry's law constant, and is in the same range as the values experimentally determined for C_3H_8 in water and aqueous H_3PO_4 at 90°C (30).

The plateau values of $^{1.7}{}_{0.5}Q_{HC}$ for all adsorption times at $U_a = 0.3$v are shown in Fig. 8, together with the component values $^{1.7}{}_{0.5}Q_I$ and $^{1.7}{}_{0.5}Q_{II}$. The rate of adsorption at 0.3v was diffusion-limited for less than 1 sec, the rate decreasing to a kinetically determined one as adsorption proceeded. In less than 100 sec, the electrode adsorbed about 90% of the amount that it adsorbed in 10^4 sec, which value it seemed to approach asymptotically. The values of $^{1.7}{}_{0.5}Q_I$ and $^{1.7}{}_{0.5}Q_{II}$ were obtained by integrating the type I and type II peaks separately, as indicated in Fig. 4, and the plateau values were determined from plots of Q_I and Q_{II} against sweep speed. These plateau values are the ones plotted in Fig. 8. It was found that the type I species was formed (and oxidized) rapidly, hence the higher sweep speeds (20-100 v/sec) were required to establish its plateau values. Note that the type I material starts appearing only after the surface is largely covered with type II.

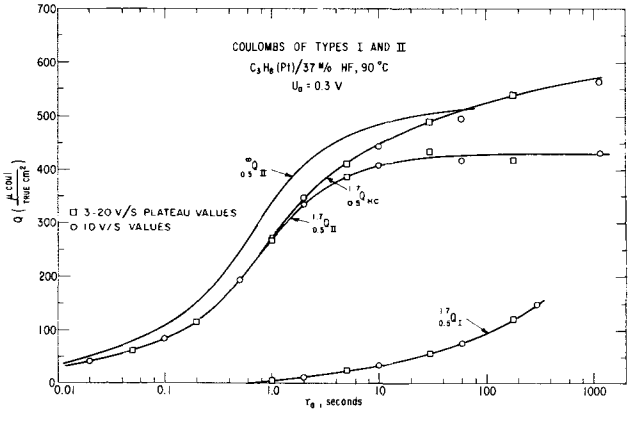

Fig. 8. Plateau values of $^{\infty}{}_{0.5}Q_{HC}$, $^{1.7}{}_{0.5}Q_{HC}$, $^{1.7}{}_{0.5}Q_I$, and $^{\infty}{}_{0.5}Q_{II}$ as a function of adsorption time for propane on Pt in 37 m/o HF at 0.3v, 90°C.

In order to learn more about the species on the electrode surface, it is necessary to have not only a measure of the number of coulombs required to oxidize the material on the surface, but also a measure of the fractional coverage, or its equivalent. This information would then allow the calculation of the number of electrons per monolayer, or per surface site, required to oxidize the carbonaceous species; hence, some information about stoichiometry and oxidation state of the surface species would be obtained.

The fractional surface coverage by carbonaceous species was measured by the blockage of the surface for hydrogen deposition and for oxygen evolution. In the case of hydrogen deposition, a linear cathodic sweep was used to measure the amount of hydrogen which could be deposited on that portion of the surface not blocked by adsorbed hydrocarbon species. The usual pretreatment and adsorption steps A through D of Fig. 3 were used, followed by a linear cathodic sweep. The number of coulombs required to saturate the remaining free surface with hydrogen was measured by integration of the area under the cathodic curves in the range 0.3-0.0v, except at the highest sweep speeds where integration to somewhat lower potentials was required in order to include all of the hydrogen deposited before rapid hydrogen evolution set in (29).

The relationship for the fraction of the surface covered by hydrocarbon species (and therefore not available to hydrogen) is expressed by

$$^{0.0}{}_{0.3}\theta_{HC} = \frac{^{0.0}{}_{0.3}Q_{SH} - ^{0.0}{}_{0.3}Q_H}{^{0.0}{}_{0.3}Q_{SH}} \qquad [5]$$

where $^{0.0}{}_{0.3}Q_{SH}$ is the number of coulombs required for cathodic hydrogen deposition starting at 0.3 *vs.* rhe, in the presence of argon (or for $\tau_a = 0$), corrected for double layer charging. $^{0.0}{}_{0.3}Q_H$ is the number of coulombs required for cathodic hydrogen deposition starting at 0.3v in the presence of adsorbed hydrocarbon, corrected for double layer charging.

As with the Q_{HC} experiments, complete sets of $^{0.0}{}_{0.3}\theta_{HC}$ values were determined for the full range of sweep speeds for each value of τ_a. The values of $^{0.0}{}_{0.3}\theta_{HC}$ were plotted against sweep speed, and the results showed two plateaus for each value of τ_a. At low sweep speeds ($\leq$ 3 v/sec) the plateau value of $^{0.0}{}_{0.3}\theta_{HC}$ indicated the coverage by material which was not readily hydrogenation-desorbed. This material can be identified as type I from the propane adsorption work of Grubb and Lazarus (24) and from the ethane work of Gilman and co-workers (12, 13), in which it was found that type I material is very difficult to hydrogenate-desorb, while type II does so very readily, even at only 60°C. In addition, the time of appearance and rate of increase of $^{0.0}{}_{0.3}\theta_{HC}$ at low sweep speeds ($\leq$ 0.3 v/sec) corresponded very well to $^{1.7}{}_{0.5}Q_I$ in Fig. 8. For these reasons, the plateau values of $^{0.0}{}_{0.3}\theta_{HC}$ at low sweep speeds were assigned to the type I species.

The plateaus of $^{0.0}{}_{0.3}\theta_{HC}$ at high sweep speeds ($>$ 30 v/sec) were taken to correspond to the total amount of adsorbed material, because the cathodic sweep depositing hydrogen was so fast that no detectable hydrogenation-desorption took place. The plateau values of $^{0.0}{}_{0.3}\theta_I$ (low sweep speeds) and $^{0.0}{}_{0.3}\theta_{HC}$ (high sweep speeds) are plotted in Fig. 9. The data points for $^{0.0}{}_{0.3}\theta_{HC}$ for times less than 5 sec were not mea-

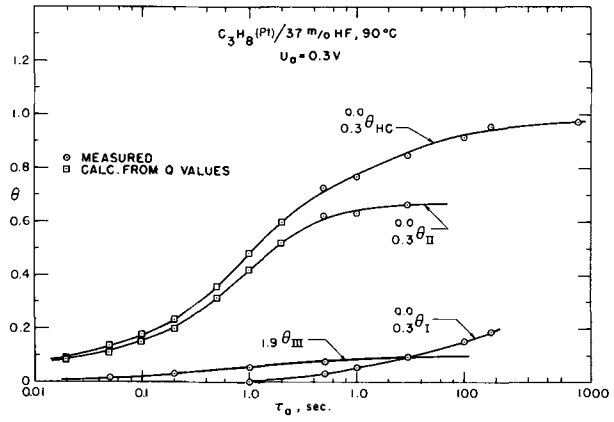

Fig. 9. Fractional surface coverage of all species as a function of adsorption time for an adsorption potential of 0.3v.

sured directly by means of the cathodic sweeps because the plateau values of θ for short adsorption times had not been reached at the fastest sweep speeds used in this study (100 v/sec). The curve of $^{0.0}_{0.3}\theta_{HC}$ for short times was calculated from the corresponding Q_{HC} values, using the number of electrons per surface site determined below.

The fractional surface coverage of the small amount of carbonaceous residue present at 1.9v during the anodic sweep was measured by its blockage of oxygen evolution in a manner similar to the blockage of hydrogen deposition during a cathodic sweep. This diminution of oxygen evolution current by adsorbed species was taken as a direct measure of the fractional surface coverage

$$_{1.9}\theta_{HC} = \frac{_{1.9}i_{Ar} - _{1.9}i_{HC}}{_{1.9}i_{Ar}} \qquad [6]$$

where $_{1.9}i_{Ar}$ is the current at 1.9v with argon present instead of propane (this is the same as $_{1.9}i_{HC}$ at $\tau_a = 0$) and $_{1.9}i_{HC}$ is, the current at 1.9v in the presence of adsorbed propane, as read from the voltage-sweep oscillogram. The value 1.9v was chosen because it was located in the linear region of the Tafel plots for oxygen evolution. The diminution of oxygen evolution was accepted as a quantitative measure of the fractional surface coverage by hydrocarbon species because plots of the plateau values of $_{1.9}\theta_{HC}$ *vs.* $f(t)$ from Eq. [3] gave good straight lines for adsorption times of up to 1 sec. This, coupled with the information of Fig. 7, is evidence for the validity of Eq. [6].

The values of $_{1.9}\theta_{HC}$ for various adsorption times, calculated using Eq. [6], plotted against sweep speed show two plateaus for each τ_a. At the low sweep speeds, essentially all of the type II material was oxidized before the potential reached 1.9v, and only a small amount of a very refractory residue, called type III, remained. This type III material was much more difficult to oxidize than either type I or type II, but it was completely removed by the cleanup procedure employed between experiments. At the high sweep speeds, a small amount of type II material was left on the surface, in addition to the type III. The small amounts of type II material left on the surface at high sweep speeds correspond to the slight decreases of $^{1.7}_{0.5}Q_{HC}$ which were found at the high sweep speeds. The maximum accumulation of type III, which was found at long times, was less than 0.1 monolayer, as shown in Fig. 9.

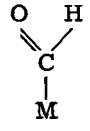
The values of $^{0.0}_{0.3}\theta_{II}$ in Fig. 9 were obtained from the expression

$$^{0.0}_{0.3}\theta_{II} = {}^{0.0}_{0.3}\theta_{HC} - {}^{0.0}_{0.3}\theta_{I} - {}_{1.9}\theta_{III} \qquad [7]$$

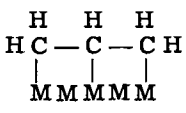
Now that values of Q and θ as a function of time for types I and II are known, it is possible to calculate the number of electrons per H site obscured required for the oxidation of these species. This will give some information about the state of oxidation of these materials. The stoichiometry of type I can be established from a plot of $^{1.7}_{0.5}Q_I$ *vs.* $^{0.0}_{0.3}\theta_I$, the slope of which is the number of electrons required for the oxidation of type I to CO_2 and H_2O, per H site obscured

$$n_I = \frac{^{1.7}_{0.5}Q_I}{^{0.0}_{0.3}\theta_I Q_{SH}} \qquad [8]$$

Figure 10 shows the plot, which indicates that the stoichiometry is constant with surface coverage over the full range of time and coverage. The slope corresponds to 2.95 electrons per H site, indicating a partially oxidized species. This is consistent with other kinds of studies which also led to the conclusion that type I was partially oxidized (13, 24). Such a species, consistent with $3e^-$/H site, could be



A plot similar to Figure 10 was prepared for the type II species, with the result that $n_{II} = 3.47$, which could correspond to a partially dehydrogenated propane molecule, which obscures 5 H sites after dehydrogenation. If 3 hydrogen atoms are lost by the dehydrogenation, then there are 17 e^-/adsorbed "propane," yielding $n_{II} = 3.40$ in good agreement with the experimental result. Such an arrangement could be



The value $n_{II} = 3.47$ is also in good agreement with a value of 3.71 found by Grubb and Lazarus (24) at a lower temperature and a lower potential; the difference is in the expected direction. Now that n_{II} is known, it is possible to make a small correction for the type II material not completely oxidized at the intermediate sweep speeds used to obtain $^{1.7}_{0.5}Q_{II}$. This correction was calculated from

$$_{1.9}Q_{II} = {}_{1.9}\theta_{II} n_{II} Q_{SH} \qquad [9]$$

and was added to $^{1.7}_{0.5}Q_{II}$ to give $^{\infty}_{0.5}Q_{II}$, as shown in Fig. 8. The ratio of $\left(\frac{^{\infty}_{0.5}Q_{HC}}{^{1.7}_{0.5}Q_{HC}}\right)$ used earlier for the calculation of the propane solubility was obtained from the $^{\infty}_{0.5}Q_{II}$ values, with an additive correction for the type III species on the surface, using the estimated value of 3.9 for n_{III}.

In addition to the calculation of the oxidation stoichiometry of the surface species, Fig. 9 can be used

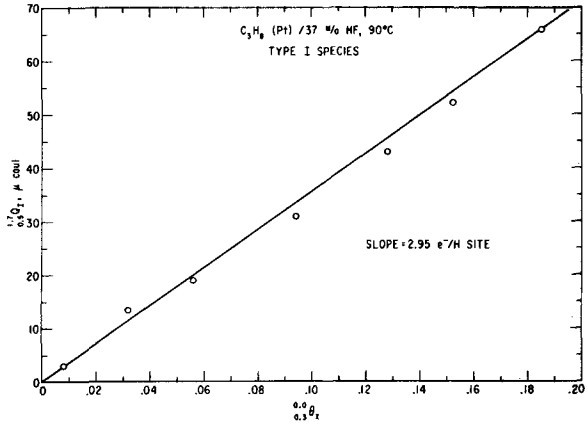


Fig. 10. Determination of the charge required for oxidation of type I material, per hydrogen site obscured.

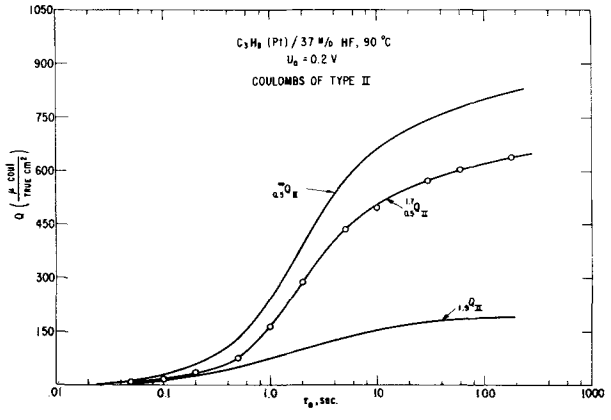

Fig. 11. Charge required for the oxidation of type II species resulting from propane adsorption at 90°C and 0.2v.

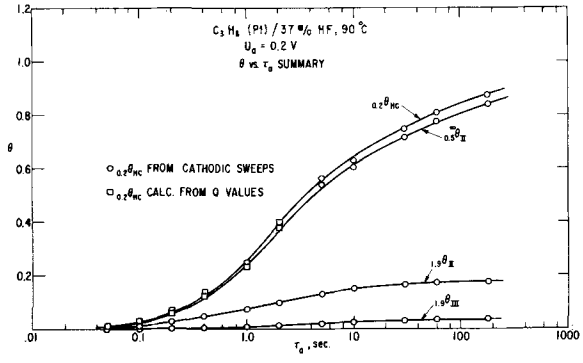

Fig. 12. Fractional surface coverages of the species resulting from propane adsorption at 90°C and 0.2v.

for the determination of the kinetic law followed by the adsorption of propane. This will be done later, after the results for U_a = 0.2v have been presented.

Propane adsorption at 0.2v.—Propane adsorption was studied at 0.2v, because very little type I material was formed at this potential, and because the largest total amount of propane was adsorbed (in terms of coulombs for its oxidation) at this potential. The experimental procedures were the same as those used for U_a = 0.3v, with the exception that the potential was held at 0.2v *vs.* rhe during the adsorption time τ_a. The sweep speed was varied from 1 to 100 v/sec, and the adsorption time covered the range 0.01 to 180 sec.

As above, all ${}^{1.7}{}_{0.5}Q_{HC}$ results were plotted against sweep speed, and the plateau values were used for the preparation of Fig. 11. Note that in the earlier stages of adsorption, ${}^{1.7}{}_{0.5}Q_{HC}$ is smaller for U_a = 0.2v than for U_a = 0.3v, indicating that adsorption is slower at 0.2v, and probably not diffusion limited, even at the shortest time studied; thus all of the data for U_a = 0.2v can be used in the kinetic analysis to be performed below.

Cathodic sweep experiments yielded information about ${}^{0.0}{}_{0.2}\theta_{HC}$ in the same manner as described above, but with a slight modification. Because some hydrogen is present on the electrode surface at 0.2v, it is necessary to include this in the calculations corresponding to Eq. [5]. The modified equation is

$$ {}^{0.0}{}_{0.2}\theta_{HC} = \frac{\Sigma Q_{H,\,\tau=0} - \Sigma Q_H}{\Sigma Q_{H,\,\tau=0}} \qquad [10] $$

where $\Sigma Q_H = {}^{0.0}{}_{0.2}Q_H + {}^{0.5}{}_{0.2}Q_H$. It is necessary to sum all of the charge required for saturating the free surface with hydrogen, not just that which is deposited below 0.2v, in order to obtain the fractional total surface available to hydrogen deposition. The value of $\Sigma Q_{H,\,\tau=0}$ is the same (within a few per cent) as ${}^{0.0}{}_{0.4}Q_{SH}$, measured for purposes of surface area determination.

The results for ${}^{0.0}{}_{0.2}\theta_{HC}$ were plotted against sweep speed for each τ_a, and the high sweep-speed plateau values (absence of hydrogenation-desorption) were then used to prepare the curve for ${}^{0.0}{}_{0.2}\theta_{HC}$ shown in Fig. 12. Note that a complete monolayer is not formed for times approaching 10^3 sec, even though ${}^{0.0}{}_{0.2}\theta_{HC}$ = 0.5 is achieved in less than 4 sec. Clearly, the rate of adsorption depends strongly on surface coverage.

The surface coverage of type III material was determined in the same manner as described above for U_a = 0.3v, using the low sweep-speed plateau values from the ${}_{1.9}\theta_{HC}$ *vs.* sweep speed plots. The ${}_{1.9}\theta_{III}$ curve thus obtained is shown in Fig. 12. As for U_a = 0.3v, ${}_{1.9}\theta_{III}$ stays very low, even at long adsorption times. The value of ${}_{1.9}\theta_{II}$ reaches somewhat higher values at U_a = 0.2v than it did for U_a = 0.3v, as might be expected from the fact that the total number of coulombs of material on the surface is greater at 0.2v, and essentially all of this material is type II, which oxidizes less readily than the type I present at 0.3v.

A correction for the type II material left on the surface above 1.7v was made according to Eq. [9], using the n_{II} value obtained from a plot of ${}^{1.7}{}_{0.5}Q_{II}$ *vs.* ${}^{1.7}{}_{0.5}\theta_{II}$ as was done for U_a = 0.3v. This corrected curve ${}^{\infty}{}_{0.5}Q_I$, is shown in Fig. 11. The value of n_{II} was 4.50 e^-/H site, higher than that for 0.3v, as would be expected for a surface species less oxidized and less dehydrogenated, because of the lower value of U_a.

The curve for ${}^{0.0}{}_{0.2}\theta_{HC}$ for short times was completed using the relationship

$$ {}_{0.2}\theta_{HC} = \frac{{}^{1.7}{}_{0.5}Q_{II}}{n_{II}Q_{SH}} + {}_{1.9}\theta_{II} + {}_{1.9}\theta_{III} \qquad [11] $$

as was done for 0.3v. Now, with the curves of θ_{HC} available for both 0.2 and 0.3v, over the full range of adsorption times, it is possible to perform an analysis of the kinetics of adsorption.

Adsorption kinetics at 0.2v and 0.3v.—Because the θ_{HC} curves of Fig. 9 and 12 are smooth, well-behaved functions of time, it seemed likely that the data were amenable to a straightforward kinetic analysis. The general character of the θ_{HC} *vs.* log τ_a curves is suggestive of Langmuir kinetics, because of the very distinct decrease in adsorption rate as the fraction of free surface ($\theta_F = 1 - \theta_{HC}$) decreases. The Langmuir rate law may be written as

$$ \frac{d\theta_{HC}}{dt} = k_{ads}C_{HC}(1 - \theta_{HC})^m \qquad [12] $$

where m is the order of reaction with respect to free surface, and represents the number of surface sites involved in the rate-determining step of the adsorption process. The problem is to determine if Eq. [12] fits the observed rates, and if so, to evaluate m and k_{ads}. Taking the log of both sides of Eq. [12] yields

$$ \log\left(\frac{d\theta_{HC}}{dt}\right) = \log k_{ads}\,C_{HC} + m \log(1 - \theta_{HC}) \qquad [13] $$

By plotting log $(d\theta_{HC}/dt)$ against log $(1-\theta_{HC})$, the value of m can be found from the slope, and the value of k_{ads} C_{HC} can be determined from the intercept on the log $(d\theta_{HC}/dt)$ axis. These plots were made, using graphically determined values of $d\theta_{HC}/dt$ from the data of Fig. 9 and 12. Both sets of data gave straight lines with m = 3.0. The values of $k_{ads}C_{HC}$ were 1.3 for U_a = 0.3v and 0.35 for U_a = 0.2v.

Knowing the value of m, Eq. [12] was integrated, yielding

$$ \left(\frac{1}{\theta_F{}^2} - \frac{1}{\theta_{F,\,t_o}{}^2}\right) = 2k_{ads}C_{HC}(t - t_o) \qquad [14] $$

where $\theta_{F,\,t_o}$ is the free surface at some reference time t_o. Equation [14] was used for a final consistency

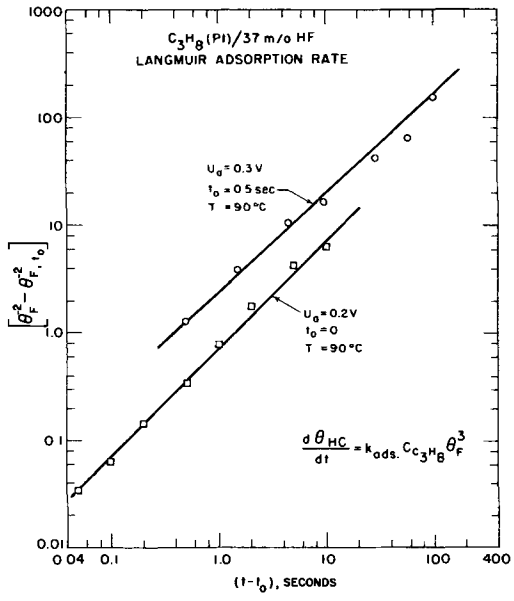

Fig. 13. Langmuir adsorption kinetic plot for the adsorption of propane on Pt in HF at 90°C. The adsorption potentials were 0.2v and 0.3v vs. rhe.

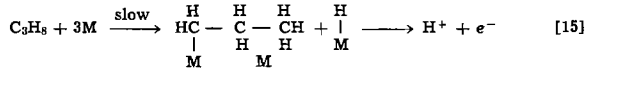
check on the fit of the data to the third-order rate law. A plot of log $(1/\theta_F^2 - 1/\theta_{F,t_o}^2)$ *vs.* log $(t - t_o)$ should yield a straight line of unit slope, the intercept of which is $2k_{ads}C_{HC}$. This plot is shown in Fig. 13, from which it can be seen that a very good fit was obtained for both sets of data, over the full ranges of time and surface coverage. The value of t_o for $U_a = 0.3$v was set at 0.5 sec because for shorter times, the absorption process was diffusion-controlled, as indicated by the results of Fig. 7.

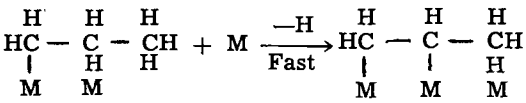
Discussion

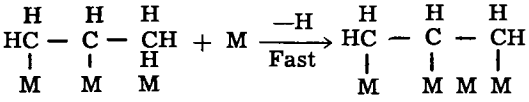
The rate of adsorption for propane on platinum in 37 m/o HF for $U_a = 0.2$ and 0.3v *vs.* rhe at 90°C has been found to be proportional to the third power of the fraction of free surface available for adsorption. This suggests that three platinum surface sites are involved in the rate-determining step of the adsorption of propane. It is possible that not all of these three sites are involved in a direct bonding to the adsorbate; one or two may be sterically obscured from involvement in the adsorption of other propane molecules. Since the Langmuir expression for adsorption kinetics is followed over a wide range of surface coverages, it is likely that the heat of adsorption changes little with surface coverage. An example of the type of adsorption which may take place initially is given by

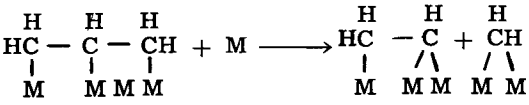


The adsorption process has an activation energy in the range of 15-20 kcal/mole (31) indicating a dissociative chemisorption, producing hydrogen atoms, which are quickly oxidized at $U_a = 0.2$ and 0.3v. The M which is not bonded to the propane in Eq. [15] indicates the possibility of steric hindrance. The rate of adsorption is affected by potential, being a factor of 3.7 higher at 0.3v than at 0.2v, which effect is expected on the basis that more rapid removal of the product H_{ads} increases the rate of adsorption. The values of k_{ads} are 1.6 x 10^7 cm^3/mole-sec for $U_a = 0.3$v and 4.3 x 10^6 cm^3/mole-sec for $U_a = 0.2$v at 90°C, using a value of 8.13 x 10^{-8} moles/cm^3 for the concentration of propane in the electrolyte.

After the initial rate-determining adsorption step (*e.g.*, Eq. [15]), the adsorbate is probably easily (and rapidly) dehydrogenated further, resulting in the bonding of the propane to more platinum sites, yielding hydrogen, which is consumed. The additional bonding causes straining of the carbon-carbon bonds, leading to fracture of the molecule. This may be indicated schematically, as follows



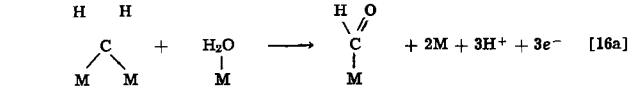


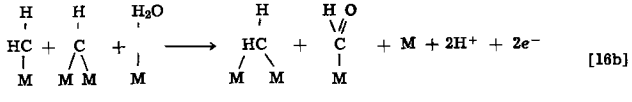


All of the products of the progressive dehydrogenation indicated above should yield saturated hydrocarbons on hydrogenation-desorption. All of the above fragments are considered to comprise the type II material on the electrode surface, which is oxidized over a broad range of potentials centered around 1.2v.

The product of reaction [15b] obscures 4 surface sites and yields 17 electrons on oxidation to CO_2 and H_2O, or about 4.25 e^-/H site, in reasonable agreement with the experimental result of 4.5 e^-/H site for $U_a = 0.2$v. The products of reaction [15c] yield 3.40 e^-/H site, compared to the value of 3.47 observed for type II at $U_a = 0.3$v. These comparisons are not intended as an identification of species, but merely serve to show that the suggested reactions are not incompatible with the experimental results.

In addition to dehydrogenation and carbon-carbon bond cleavage, partial oxidation takes place at potentials above about 0.15v (24, 13), yielding a product which is not hydrogenation-desorbed, and requires less than 4 e^-/CO_2 for its oxidation to CO_2 and H_2O (24). The oxidation of the type I species was found to require 2.95 e^-/H site, suggesting the following reactions





where the HCO species requires $3e^-$/H site for its oxidation, in agreement with the value found for the type I species. The type I species is the most easily oxidized, yielding high current densities at relatively low potentials. It is probably the type I species which is responsible for the high current densities obtainable at low overvoltages from hydrocarbon fuel cells.

In parallel with reactions [16a] and [16b], a further dehydrogenation of the products of reactions [15a], [b], and [c] can take place, yielding a carbon-rich residue which is not rapidly oxidized, and remains on the surface at potentials as high as 1.9v under anodic voltage sweep conditions. This material is expected to behave like what has been called type III above.

Conclusions

Propane adsorbs on platinum from a 37 m/o HF solution at 90°C at a rate which is third-order in free surface, at potentials of 0.2 and 0.3v *vs.* rhe. The kinetic expression is

$$\frac{d\theta_{HC}}{dt} = k_{ads}C_{HC}(1 - \theta_{HC})^3$$

The adsorption rate constant is a function of potential, having the values 4.3 x 10^6 cm^3/mole-sec at 0.2v and 1.6 x 10^7 cm^3/mole-sec at 0.3v *vs.* rhe, both at 90°C. This adsorbed propane, called type II requires 3.5 — 4.5 e^-/H site for its oxidation, depending on adsorption potential.

The adsorbed propane yields a partially oxidized surface species (type I) which is much more electrochemically active (oxidized more rapidly at lower potentials) than the initially adsorbed propane and requires 3 e^-/H site for its oxidation to CO_2 and H_2O. In a process concurrent with (and presumably parallel to) the formation of type I, a relatively unreactive residue (probably carbon-rich material) is formed, which is oxidizable at reasonable rates only at potentials significantly above 1.7v *vs.* rhe. This material, called type III, is present in only small amounts (< 0.1 monolayer accumulates in hundreds of seconds) at 90°C.

Acknowledgments

The authors are grateful to Dr. S. Gilman for the loan of a design for the all-PTFE electrochemical cell, and for helpful discussions. Dr. F. G. Will kindly provided the circuit for modifications in the function generator. Dr. A. D. Tevebaugh collaborated in the design, construction and testing of the apparatus.

This work is a part of the program under contracts DA 44-009-AMC-479(T) and DA 44-009-ENG-4909, ARPA Order No. 247 with the U. S. Army Engineer Research and Development Laboratories, Fort Belvoir, Virginia, to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plans for operation on ambient air and hydrocarbon fuels.

Correction

In the paper "Permeation of Isolated Anodic Zirconium Oxide Films by Potasium Nitrate" by A. H. Mitchell and R. E. Salomon which appeared on pages 599 to 602 of the June 1967 issue of the *Journal*, the apparent activation energy for 27v films listed in Table IV, page 601 should be 9 kcal $mole^{-1}$ instead of 1 kcal $mole^{-1}$.

Catalysis of the Electrochemical Oxidation of Formaldehyde and Methanol by Perrhenate

Joseph A. Shropshire

Government Research Laboratory, Esso Research and Engineering Company, Linden, New Jersey

ABSTRACT

The electrooxidation of formaldehyde and methanol on platinum in sulfuric acid solution is catalyzed by rhenium heptoxide. The process requires that the rhenium species remain adsorbed at the platinum surface throughout the cycle. Studies have been carried out to define the mechanism and comparisons made with the previous results with molybdates.

As a result of recent widespread interest in the development of hydrocarbon fuel cells, a substantial effort has been devoted to studies of the mechanisms of adsorption and electrooxidation of low molecular weight fuels such as methanol, formaldehyde, and formic acid (1-6). These studies, many of which have been directed at platinum surfaces in strong acid media, have contributed substantially to a general understanding of the electrooxidation of carbonaceous fuels and the concommitant improvement of practical fuel cell systems. In a previous paper (7) the usefulness of soluble molybdates in improving the electrochemical oxidation of methanol and formaldehyde on platinum has been reported. In that study it was shown that the observed improvements were a result of catalytic enhancement through chemical reduction of adsorbed molybdate by the fuel and subsequent electrochemical reoxidation. This "surface redox" (as it was termed in the previous paper) substantially improved the electrical efficiency of methanol and formaldehyde oxidation provided that overpolarization and loss of adsorbed molybdate were avoided.

In the present study, it has been observed that small quantities of heptavalent rhenium display similar effects on the electrooxidation of formaldehyde and methanol on platinum in H_2SO_4. A series of investigations has been carried out to define the advantages and limitations of this system and to determine if in fact a catalytic mechanism similar to that observed with molybdate is operative.

Experimental Techniques and Equipment

Electrodes used in this study were of two types. For performance studies (polarization-log current) of CH_3OH and HCHO in rhenium-containing electrolytes, the electrodes were prepared by pressing powdered platinum black into platinum screens. The platinum, prepared by the reduction of H_2PtCl_6 by $NaBH_4$ in aqueous solution, was found to have high surface area and to provide high activity for this purpose. In the chronopotentiometric studies on this system, small platinized platinum electrodes of about 0.25 cm^2 apparent area were used. All electrochemical measurements in these systems were carried out in conventional glass "H" cells with anode and cathode compartments separated by glass frits. Voltage measurements were made against commercial saturated calomel reference electrodes through Luggin capillaries containing H_2SO_4 of concentration equal to that in the cell proper.

Due to the practical necessity of high conductivity for fuel cell electrolytes, studies were carried out in 3.7M H_2SO_4, a solution exhibiting near-optimum conductivity. High-purity rhenium heptoxide was obtained from the University of Tennessee (8) and used without further purification. Other pertinent experimental details will be found in the previous publication (7). All polarizations in this study are referred to the saturated calomel electrode (SCE), measured difference in this reference *vs.* NHE being 0.194v at 25°C in the systems involved.

Oxidation of Formaldehyde and Methanol in the Presence of Perrhenate

The electrochemical oxidation of formaldehyde and methanol in acid media is a highly irreversible process. Despite a computed difference of about 0.14v in theoretical potential, both fuels react on platinum electrodes at about the same potential level. This similarity has led to the belief that oxidation of both fuels involves a common slow step, possibly the "reduced CO_2" intermediate described by Giner (9). The product of the electrooxidation of either fuel in acid is essentially 100% CO_2 at steady state (4-6). Tafel slopes of about 0.06 v/decade are commonly observed on platinum catalysts (Fig. 1).

As in the case of molybdate, the addition of low concentrations of rhenium heptoxide to the acid electrolyte prior to fuel addition was found to result in substantial changes in the electrochemical performance curves (Fig. 1). In the range of 1-100 ma/cm^2 polarization for HCHO oxidation decreased by nearly 0.3v. Methanol showed substantial differences from HCHO with polarization decreases of 0.15-0.20v. Tafel slopes were generally somewhat curved, with b values of the order of 0.10-0.14 v/decade. In contrast to the observations previously made with molybdate, the polarization curves were continuous and unbroken to current levels beyond several hundred ma/cm^2. As in the case of direct electrooxidation on platinum, the observed product was carbon dioxide (evolved). The polarization curves showed no hysteresis during repeated cycling up to the highest current levels. Occasionally, after severe overpolarization, transient responses typifying oscillation between two stable states would be observed on slowly decreasing the current load. While addition of perrhenate to the electrolyte prior to fuel addition gave guaranteed improvements

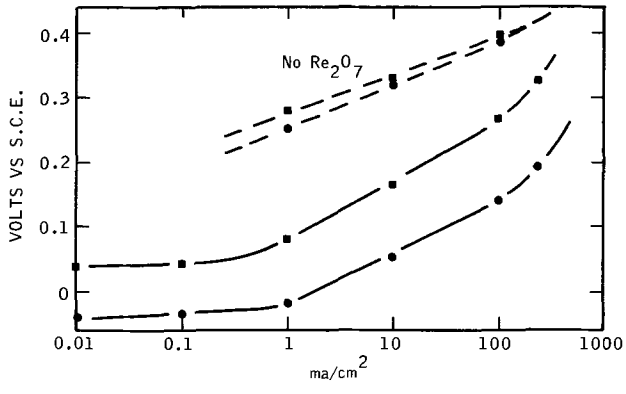

Fig. 1. Best observed performance on $NaBH_4$-reduced platinum in 0.002M Re_2O_7 — 3.7M H_2SO_4, 82°C; ● HCHO; ■ CH_3OH.

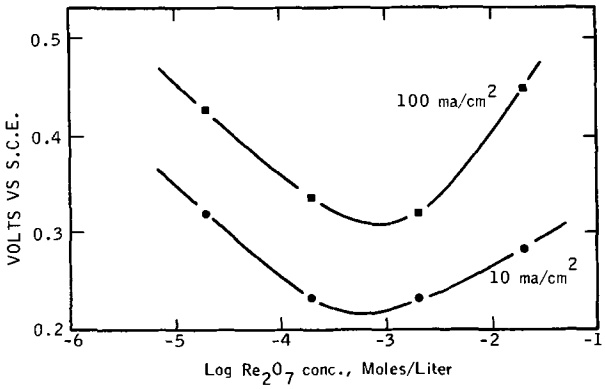

Fig. 2. Effect of Re_2O_7 concentration on CH_3OH performance on $NaBH_4$-reduced platinum, 3.7M H_2SO_4, 82°C.

it was generally observed, in contrast to molybdate, that the system would attain the low polarization level of performance under load cycling regardless of the order of addition of fuel and perrhenate.

A series of experiments designed to test the concentration dependence on perrhenate indicated optimum performance for CH_3OH at a perrhenate concentration of about 10^{-3}M. This concentration dependence was somewhat less critical at low current densities as shown in Fig. 2. There is reason to believe that this perrhenate concentration corresponds roughly to the value necessary to produce maximum coverage of the platinum surface (Appendix I). It is not known, however, to what extent, *i.e.*, in terms of monolayer coverage, the adsorption exists.

The effect of temperature on the electrochemical reaction of CH_3OH in the presence of perrhenate was investigated in the range 25°-90°C on an electrode potentiostatted at 0.4v polarization (from $E°_{25}$ CH_3OH). The Arhennius plot showed a straight line relationship over the range with a slope indicative of an activation energy of about 10.2 kcal/mole. This value is substantially less than that normally found for the direct electrooxidation of CH_3OH on platinum black (15-18 kcal/mole) while at the same time much too high to indicate any diffusion effects involving a reduced rhenium species.

Nature of the Perrhenate Reduction

With these indications of catalytic currents, steps were taken to determine the nature and extent of perrhenate reduction in the 3.7M H_2SO_4 system. It was observed that no visible reaction took place between CH_3OH or HCHO and perrhenate in H_2SO_4 solution in the absence of platinum. If a platinum black electrode was immersed in 0.002M Re_2O_7 — 3.7M H_2SO_4 and fuel added, a small quantity of gas evolution from the electrode was observed. This was taken to represent that quantity of fuel oxidized to CO_2 in reducing the perrhenate adsorbed on the platinum surface. Since this CO_2 evolution was simply a transient phenomenon it is assumed that the reduced rhenium species remains adsorbed and undergoes no further interactions under open-circuit conditions in the presence of fuel.

Using the platinum black microelectrode, a system was assembled to study the reactions of perrhenate in the voltage range of interest for fuel oxidation. Chronopotentiograms obtained on the platinum black microelectrode in 0.002M Re_2O_7 — 3.7M H_2SO_4 (25°C) showed the presence of a well-defined anodic wave after polarization to 0.0v SCE (Fig. 3). This oxidation wave showed a half wave potential of about +0.4v (S.C.E.) under the high current conditions used, and the reduction potentials ($E_{1/2} \simeq +$ 0.2v SCE) necessary to produce the species oxidized during this wave are still substantially positive to the computed theoretical potentials for HCHO and CH_3OH. Thus, on thermodynamic considerations alone, both these fuels

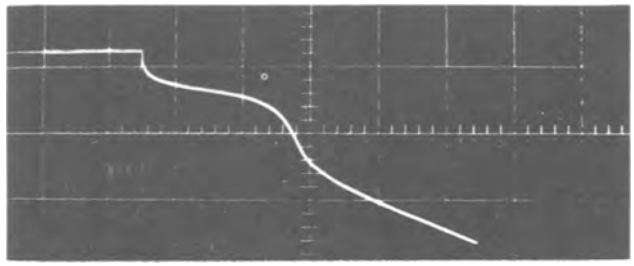

Fig. 3. Anodic chronopotentiogram on platinized platinum microelectrode in 0.002M Re_2O_7 — 3.7M H_2SO_4, following cathodization to 0.0v SCE. Top 0.0v SCE, 300 mv/div (positive downward), 1 sec/div left to right, 40 ma/cm², 25°C.

would be expected to chemically reduce the adsorbed perrhenate, producing an Re(VI)/Re(VII) ratio in accord with the standard free energy change for the respective reactions.

While for the purposes of the fuel cell study presented here, the exact valence change in the initial perrhenate reduction need not be known, a series of coulometric and chronopotentiometric studies was carried out to determine this parameter. These investigations have been reported elsewhere (10, 11). The results indicate that the initial reduction involves a univalent change to the Re(VI) state. Under long-term coulometric analysis on platinum, however, it was found that this state was capable of disproportionating to Re(IV) and Re(VII) states. The reader is referred to the original publications for details of these studies.

Chronopotentiometry on Platinized Platinum

Since it was apparent that the over-all reaction of fuel and perrhenate did not involve the rhenium species in solution, a study of the factors involved in perrhenate adsorption and interaction with fuel was made using the anodic stripping technique of Pavela (12). In this method, the preconditioned electrode was placed in the solution of adsorbate for a desired interval, removed rapidly to a rinse solution to remove excess bulk solution, then placed in a cell containing 3.7M H_2SO_4 and the anodic stripping transient recorded. While this technique suffers the drawback of permitting the determination of strongly adsorbed material only, it nevertheless allows the separation of the independent factors in perrhenate and fuel adsorption.

The 0.25 cm² platinized electrode used for this study was preconditioned by evolving H_2 and O_2 successively a few times in H_2SO_4 solution with final equilibration (potentiostatted) at 0.0v (SCE) before removal to the adsorbate solutions. Anodic transients, with the exception of Fig. 8, were recorded in pure 3.7M H_2SO_4. While the general behavior of HCHO and CH_3OH is equivalent, the stronger adsorption of HCHO makes the effects with that fuel somewhat more pronounced, and transients obtained with HCHO have been used to illustrate the behavior.

It was found that a few seconds immersion of the platinum electrode in 3.7M H_2SO_4 — 0.025M Re_2O_7 was sufficient to produce a tenaciously held layer of perrhenate which oxidized (after potentiostatting at 0.0v SCE) at about the same potential levels observed previously in perrhenate solution (Fig. 4). The blank transient, shown in Fig. 4a, clearly shows the initial regions of pseudocapacitance from oxidation of chemisorbed hydrogen atoms, the steep so-called double layer region, followed by platinum oxide formation at more positive voltages. By comparison, the electrode with adsorbed perrhenate shows loss of about one-half the hydrogen pseudocapacitance, indicating that the rhenium species is blocking hydrogen chemisorption sites. The tenacity of the perrhenate adsorption is indicated in Fig. 5, which shows the transient obtained after four cycles from 0.0-1.2v SCE on the adsorbed layer of Fig. 4b. The approx-

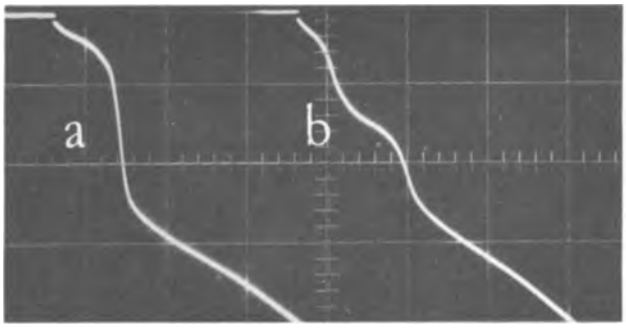

Fig. 4. Chronopotentiograms on platinized platinum in 3.7M H_2SO_4: (a) blank, (b) following 2-min dip in 0.025M Re_2O_7 — 3.7M H_2SO_4 and rinse. Conditions as in Fig. 3 except 160 ma/cm^2.

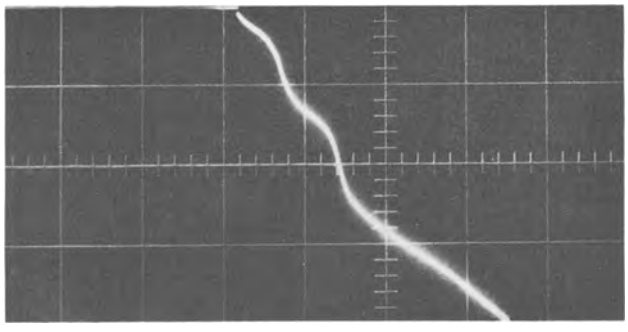

Fg. 5. Transient obtained after four cycles from 0.0 to 1.2v SCE on electrode of Fig. 4b; conditions as in Fig. 4.

imate equivalence of these transients indicates that the rhenium species remains strongly adsorbed in both valence states over a wide potential range. It was found that this single chemisorbed layer of perrhenate was capable of producing markedly improved steady-state electrooxidation of HCHO in a subsequent test in 1M HCHO — 3.7M H_2SO_4 up to current levels of several hundred ma/cm^2.

Immersion of the platinized electrode in 3.7M H_2SO_4 — 1M HCHO with no perrhenate resulted in the rapid formation of a tightly bound layer of HCHO with an oxidation transient as shown in Fig. 6. The absence of pseudocapacitance in the range 0.0-0.25v SCE is indicative that formaldehyde occupies the majority of the surface, including these sites normally held by adsorbed hydrogen atoms. Oxidation of this strongly held HCHO appears to occur only at or near voltages at which platinum oxidation occurs.

If the electrode is immersed in perrhenate solution, rinsed, then immersed in HCHO solution, both species occupy parts of the surface simultaneously as shown by the presence of both characteristic waves in the transient of Fig. 7a. The quantity of perrhenate appears comparable to that observed in the absence of formaldehyde, and absence of hydrogen pseudocapacitance suggests that the HCHO is present on these hydrogen-type sites not occupied by the perrhenate. As was reported earlier for molybdate, it was again recognized that the strongly adsorbed HCHO apparently does not interact with the adsorbed perrhenate. Thus, no significant catalytic enhancement of the rhenium oxidation wave by strongly held HCHO is observed, as evidenced by the fact that HCHO remains on the surface until electrooxidized (Fig. 7a). As indicated in Fig. 7b, however, the direct electrooxidation of HCHO near platinum oxide levels does have a substantial effect on the adsorption of the rhenium species. The single transient (of Fig. 7a) serves to remove a substantial part of the adsorbed perrhenate. This effect is less severe in the case of coadsorbed methanol with a major fraction of the perrhenate surviving after methanol is oxidized from the surface.

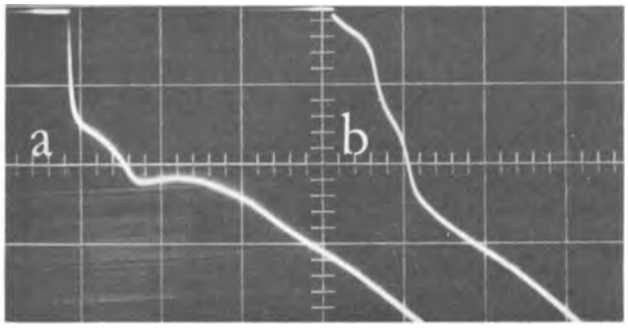

Fig. 7. Chronopotentiograms on platinized platinum in 3.7M H_2SO_4: (a) after 2-min dip in acid-perrhenate solution, rinse, 2-min dip in acid—formaldehyde solution and rinse; (b) first subsequent transient on same electrode; conditions same as in Fig. 4.

In accord with the suspected catalytic mechanism, anodic stripping of a preadsorbed layer of perrhenate in a solution containing 1M HCHO — 3.7M H_2SO_4, showed a sustained interaction. As shown in Fig. 8, the catalytic enhancement of the rhenium oxidation wave by HCHO solution is to all appearances sustained indefinitely at the normal rhenium oxidation potential. Noting that these transients were obtained at 160 ma/cm^2, the high current capability of the catalytic interaction is confirmed.

Discussion

Based on the foregoing observations, the Pt-perrhenate-fuel interaction appears to closely resemble that observed previously for molybdate in H_2SO_4 solutions. Thus, in brief

Adsorption

$$\text{Re (VII) (soln)} \rightleftarrows \text{Re (VII) (Strongly Adsorbed)}$$

Chemical Reaction

$$n[\text{Re (VII)}_{ads}] + \begin{pmatrix} \text{HCHO} \\ \text{CH}_3\text{OH} \end{pmatrix} \rightarrow n\,[\text{Re (VI)}_{ads}] + \text{CO}_2 + (n-1)\,\text{H}_2\text{O (fast)}$$

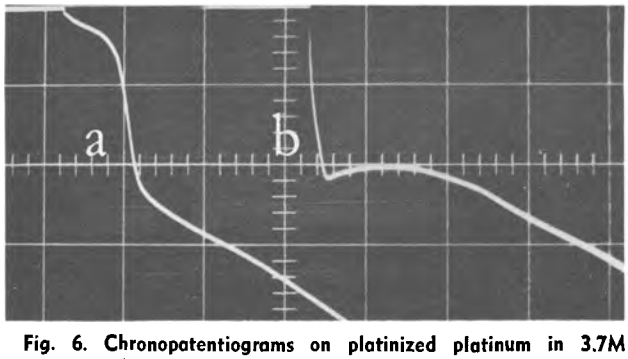

Fig. 6. Chronopatentiograms on platinized platinum in 3.7M H_2SO_4: (a) blank, (b) after 2-min dip in 1M HCHO — 3.7M H_2SO_4 and rinse; conditions as in Fig. 4.

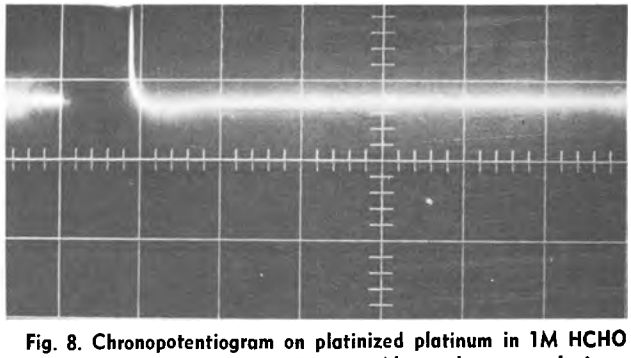

Fig. 8. Chronopotentiogram on platinized platinum in 1M HCHO — 3.7M H_2SO_4 after 2-min dip in acid—perrhenate and rinse; conditions as in Fig. 4 except 2 sec/div.

Electrochemical Reaction

$Re\ (VI)_{ads} \rightarrow Re\ (VII)_{ads} + e^-$ (potential determining)

Since the complete chemical and electrochemical reactions occur only for the strongly adsorbed rhenium species it would appear that the term "surface redox" is applicable to this case as well as molybdate.

Based on the observations to date, the slow step in this mechanism differs from that observed for molybdate. It would appear, based on the high current capability of HCHO and CH_3OH on high area platinum electrodes in perrhenate solution (Fig. 1), that the chemical reaction rates of both fuels with perrhenate adsorbed in platinum are substantially high. At the same time, however, the difference in reducing power of the two fuels is evident in the observed polarization differences during operation. In addition, the Tafel slopes of 0.10-0.14 v/decade tend to indicate that we are actually observing the one-electron charge-transfer limited reoxidation of Re(VI). The observed temperature dependence does little to clarify the issue since it lies in a range possibly applicable to either a chemical or electrochemical limitation. Since the observed polarization differences in HCHO and CH_3OH operation correspond reasonably well with the computed theoretical potential difference it is perhaps best to accept the view that the charge-transfer limitation is observed, with the surface Re(VI) concentration fixed by the relative reducing power of the fuel. This condition simply requires that the perrhenate reaction with HCHO exhibit the expected free energy advantage over CH_3OH reaction, but that the rate of approach to chemical equilibrium be rapid for both fuels. This differs from the molybdate case in that a slow chemical reaction step is observed relatively clearly in that instance.

In this scheme no pretense of knowledge is made as to the exact nature of the adsorbed rhenium species. It seems clear, however, based on the residual hydrogen pseudocapacitance and transients with coadsorbed fuel that strongly adsorbed perrhenate occupies no more than half the surface. As in the molybdate case, it seems highly significant that catalytic enhancement of the Re(VI) oxidation does not occur with strongly adsorbed fuel. Thus, catalytic interaction is observed only when the perrhenate-containing electrode is anodized in the presence of dissolved fuel. It is not meant to imply, however, that interaction with a weaker, perhaps physically adsorbed, fuel state is precluded. In a recent paper (13), the suggestion has been advanced that efficient direct electrooxidation of fuels such as HCHO and CH_3OH is precluded near the expected potentials due to an excessively strong adsorption and blockage of low polarization water-discharge processes. The failure of strongly adsorbed HCHO and CH_3OH to react catalytically with adsorbed molybdate and rhenate species, while less strongly adsorbed fuel does react, would seem to provide some implications along those same lines.

Summary

The use of perrhenate as a cocatalyst in the complete oxidation of HCHO and CH_3OH on platinum in acid electrolyte results in a substantially higher efficiency for the reaction. The improvement results from the catalytic chemical reaction of the fuel with an adsorbed perrhenate species with subsequent electrooxidation of its reduced form. This surface redox reaction is quite similar in many respects to that previously reported for molybdate, but differs in that the adsorption of perrhenate is apparently much stronger and rates of HCHO and (particularly) CH_3OH chemical reaction with perrhenate are substantially higher. Since loss of perrhenate from the electrode under normal operating conditions appears to be minimal, this redox system shows a substantial advantage over platinum alone for the operation of practical methanol-air cells.

Acknowledgments

The work reported in this paper was made possible by the support of the Advanced Research Projects Agency under Order No. 247 through the U.S. Army Electronics Laboratories (Contract No. DA 36-039 SC-89156). Permission to publish is gratefully acknowledged. The author wishes to thank H. E. Frew for carrying out much of the experimental work.

Manuscript received March 8, 1967; revised manuscript received April 27, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

APPENDIX

It is stated above that the apparent optimum in Re_2O_7 concentration corresponds closely to that which produces maximum surface coverage. This conclusion was derived from a study of the effect of Re_2O_7 on the capacitance of a platinum black electrode. Studies were carried out in which the initial (linear) voltage-time response to a square wave current pulse was recorded from a platinized platinum electrode potentiostatted at voltage levels in the range 0.0-1.2v SCE. The square wave current was derived from mercury relay switching between parallel potentiostatic and constant current circuits. The switch was actuated by a Tektronix pulse generator at 40 Hz. Voltage deviations from the potentiostatted level were not allowed to exceed 20 mv. Under those conditions the potentiostat was easily able to return the potential to its prearranged value prior to the next current pulse. Transients were recorded and photographed from the oscilloscope display.

It was found that the addition of Re_2O_7 to the acid solution had a substantial effect (decrease) on the capacitance of the platinum electrode in the range 0.2-0.6v SCE. This capacitance decrease at 0.5v was treated in terms of the familiar parallel plate capacitor model (14) to derive a surface coverage parameter. Thus,

$$C_{meas} = \gamma C^o_{Pt-Re} + (1 - \gamma)\ C^o_{Pt}$$

where C^o_{Pt-Re} is taken as that capacitance level which is not changed by further additions of Re_2O_7.

The isotherm (25°C) derived from this treatment is shown in Fig. 9. It is clear that the adsorbed Re_2O_7 layer is substantially complete in the concentration range 1-3 x 10^{-3}M Re_2O_7. This level corresponds very well with that observed to produce optimum performance. As pointed out previously, however, it should be kept in mind that this is an approach to maximum "functional" coverage, and gives no quantitative measurement of the extent of coverage in terms of the true surface area. The apparent decrease in performance at higher Re_2O_7 concentration may reflect the further blocking by Re_2O_7 of surface sites normally occupied by fuel in the optimum case.

Galvanic Corrosion Characteristics of Aluminum Alloyed with Group IV Metals

D. S. Keir, M. J. Pryor, and P. R. Sperry

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

The electrochemical behavior of aluminum alloyed with selected Group IV elements has been investigated in 0.1*N* sodium chloride solution. Of the group IV elements studied only tin had a major effect on aluminum; Al-Sn alloys carried surface oxide films of very low ionic resistance, exhibited potentials more active than —1.0v on the hydrogen scale and gave very large galvanic currents when coupled to mild steel cathodes. The conditions permitting entry of a group IV alloying addition from the metal into the surface oxide film have been partly clarified.

Considerable effort has been directed by the writers' laboratory to clarifying the manner in which various aqueous electrolytes modify the electron and ion conductivities of the thin film of γ-Al_2O_3 that is always present on essentially pure aluminum in nearly neutral solutions. The frequency dispersion of the loss tangent of the film has been one of the main experimental values measured. Electrolytes that have been studied include the corrosive sodium halides (1-5) and sodium sulfate (5) together with passivating sodium chromate solutions (6). Halide ions from solution appear to be able to enter the structure of the surface γ-Al_2O_3 film and to create additional cation vacancies in the film without necessarily changing its thickness, crystallographic structure, or topography. The additional cation vacancies, so produced, lower the ionic resistance of the γ-Al_2O_3 film but do not change its electronic resistance. The relative effectiveness of the halide ions in entering the alumina lattice and lowering ionic resistance is in the order $F' > Cl' > Br' > I'$ (1). Simple immersion of oxide-covered aluminum in aqueous sodium sulfate solutions does not appear to result in any defect structural modification of the film, and so the ion and electron resistances remain unchanged (5). The defect structural aspects of passive films formed in chromate solutions are more complicated and include an increase in electronic resistance (compared with thermal γ-Al_2O_3) combined with a decrease in ionic resistance (6). The former has been ascribed to the inclusion of a small concentration of protons in the film replacing aluminum ions and the latter to the presence of low ionic resistance crystalline γ-Al_2O_3 located in the outer portion of the passive film.

With the exception of some limited study of aluminum purity at levels above 99.997% (1) none of the foregoing studies were concerned with modification of surface film defect structure resulting from alloying the base aluminum. The work described in this paper is accordingly concerned with this latter variable. Group IV elements appeared to be of particular interest when alloyed with aluminum. If they were able to enter the cation lattice of the natural oxide film in the quadrivalent condition and replace trivalent aluminum ions, they should result in the creation of additional cation vacancies and lowered ionic resistance much in the fashion of halide ions previously studied. Such alloys could well have interesting electrochemical properties.

Accordingly, in the present work, the electrochemical properties of aluminum alloyed with silicon, germanium, titanium, zirconium, and tin were studied. Because a significantly lowered ionic resistance of the surface film will result in a displacement of corrosion potential in the active direction, these alloys are potentially interesting in the field of sacrificial protection. Accordingly, the electrochemical method used to study these alloys primarily involved investigation of their galvanic behavior when coupled to mild steel in sodium chloride solution. The electrochemical studies were augmented by impedance studies of the surface oxide films in sodium chloride solution only when significant improvement in current output was observed in the galvanic experiments. Of the above alloys of aluminum with group IV elements, only the Al-Sn system, in certain structural conditions, deviated markedly from the galvanic behavior of pure aluminum. The investigation has thrown new light on the metallurgical and associated defect structural requirements in the surface oxide film that must be met before significant changes can be made to the electrochemical behavior of an aluminum alloy carrying a stable surface oxide film.

Experimental and Results

Materials.—All alloys were prepared with high-purity (99.992%) aluminum as a base. The high-purity aluminum was induction melted, in air, in alumina crucibles. All binary and ternary alloying additions were added to the melt at a temperature of 730°C and thoroughly stirred to ensure homogeneity. The melts were degassed with gaseous chlorine for 10 min, the melt temperature lowered to 670°C, and the alloys poured into massive copper chill molds having internal dimensions of 2.5 x 2.5 x 15.0 cm. Group IV alloying additions were evaluated at a level of around 0.1 to 0.2% by weight (Table I). Aluminum-tin alloys of a wider compositional range from 0.02-0.3% by weight were prepared for more extensive investigation of this system. All aluminum-tin alloys had

0.004% iron and 0.003% silicon as the major impurities.

The mild steel cathodes were cut from commercial mild steel sheet 0.11 cm thick having the chemical composition shown in Table II. All solutions were made up from A.R. reagent grade chemicals and distilled deionized water.

Material preparation.—Mild steel cathodes were cut as specimens 1 cm wide having 5 cm in length (10 cm^2) exposed to the sodium chloride electrolyte. Prior to the galvanic experiments the cathodes were degreased in benzene, etched in 50% by volume hydrochloric acid, washed, dried in acetone, exposed to dry air over phosphorus pentoxide for 24 hr, and weighed.

Aluminum alloy specimens were machined from the castings in the form of square rods having dimension of 0.5 x 0.5 x 8.0 cm. In the galvanic experiments only 5 cm of the rod (10 cm^2) were immersed in the electrolyte. The machined specimens were degreased in benzene, etched in 1.0*N* NaOH for 5 min, washed, dried in acetone, exposed to dry air over phosphorus pentoxide for 24 hr, and weighed.

Selected Al-Sn alloy castings were given a thermal treatment. This treatment involved heating in air at 620° ± 3°C for 16 hr and immediately quenching in still water. Thereafter samples were machined and prepared for the galvanic experiments in the standard manner described above. Alloys treated in this fashion will be referred to as "homogenized" alloys in the text.

Certain of the homogenized Al-Sn alloys were given a subsequent thermal treatment designed to ensure precipitation of tin from solid solution. This thermal treatment comprised reheating for 24 hr at 400°C and quenching in still water. Aluminum-tin alloys receiving this precipitation treatment will be described as "heterogenized" alloys in the subsequent text.

Experimental methods.—Galvanic experiments.—Galvanic couples of 10 cm^2 of the appropriate aluminum alloy coupled to 10 cm^2 of mild steel were investigated using the cell and the experimental method described earlier by two of the authors (7). Experiments were conducted at least in duplicate and usually in triplicate. Briefly the cell is a glass unit with an electrolyte capacity of 100 ml. In the present work 0.1*N* NaCl solution was used throughout at a temperature of 25° ± 0.05°C. The cell, which is closed, provides electrical connections for the dissimilar electrodes, mounted rigidly 2.0 cm apart, together with one for a saturated calomel reference electrode. The two metals were connected together through a 1-ohm external resistor across which the potential drop and accordingly the galvanic current could be measured continuously. Connection of the reference electrode with the anode through a high impedance recorder permitted the closed circuit cell potential[1] to be monitored.

The galvanic currents and cell potentials were recorded continuously for 48 hr, the standard duration of all galvanic experiments in this paper. After any experiment had been terminated the aluminum anode was freed from corrosion product by treatment in 2% chromic-5% phosphoric acid at 85°C, rinsed, dried, and reweighed. The steel cathode was similarly cleared in 1:1 HCl inhibited with Rhodine 41, rinsed, dried, and reweighed. From the above measurements the following important electrochemical information could be obtained: (*i*) whether the aluminum alloy completely protected the steel cathode; (*ii*) the number of coulombs flowing; (*iii*) the weight loss of the anode and; (*iv*) from a combination of 2 and 3 the anodic efficiency of galvanic corrosion of the aluminum alloy anode. Correlation of these variables with alloy composition and structure could then be carried out.

Capacitance-dielectric loss studies.—The specific resistance of the surface oxide film was measured by a minor modification of the a-c technique described earlier by two of the authors (3). Measurements were confined to a frequency of 1 kc only because ionic resistivity was of primary importance in this study (4, 5). Unlike previous studies the measurements were made in 0.1*N* NaCl instead of in a chromate solution because the interaction of defects produced by tin in the alloy and chloride in the environment was of primary interest. Specimens having an exposed area of 0.8 cm^2 with tin contents from 0.02-0.08%, were immersed in 0.1*N* NaCl at 25°C for 30 min. At this time series capacitance and dielectric loss were measured directly by a General Radio 716-C capacitance bridge by application of a 50 mv p-p signal across the oxide covered specimen and a large concentric platinum grid counter electrode. Parallel resistivity was calculated from the two measurements using an analog for the film of a capacitor with a simple parallel resistance as had been utilized in previous studies (2-6). Measurements were conducted in the homogenized and heterogenized conditions.

Results.—The number of coulombs flowing in 48 hr in galvanic couples of steel coupled to aluminum alloyed with the five group IV elements are shown in Table I. Also included are results for unalloyed high-purity aluminum coupled to mild steel. Table I shows that only tin produces any major effect in increasing the current flow in these couples. However, the difference between the Al-Sn alloy and the other alloys, including pure aluminum, is very large. The steel was completely protected by pure aluminum and Al-Sn alloys but not by the other alloys.

Accordingly, attention was focused mainly on the Al-Sn system. A series of binary alloys containing from 0.02-0.3% Sn was subjected to the same electrochemical investigation in the "as-cast" condition. The effect of Sn content on anodic weight loss, number of coulombs flowing, anodic efficiency, and closed circuit cell potential is shown for triplicate specimens in Fig. 1, 2, 3, and 4. It may be seen from these figures that, in the as-cast condition, tin raises the number of coulombs flowing significantly as well as the anodic weight loss. The effect of tin becomes readily apparent at a concentration of around 0.1% by weight and above. Furthermore, tin reduces anodic efficiency and lowers the closed circuit cell potential from around —0.5v to around —1.0v on the hydrogen scale at tin levels of 0.1% or more.

However, the results for as-cast specimens are highly erratic, and no clear trend exists, at least in anodic weight loss and number of coulombs flowing, at tin contents between 0.1-0.3%. This behavior is related to the constitution of the Al-Sn binary system (13). The solid solubility of tin in aluminum at the

[1] All potentials in this paper are expressed on the standard hydrogen scale.

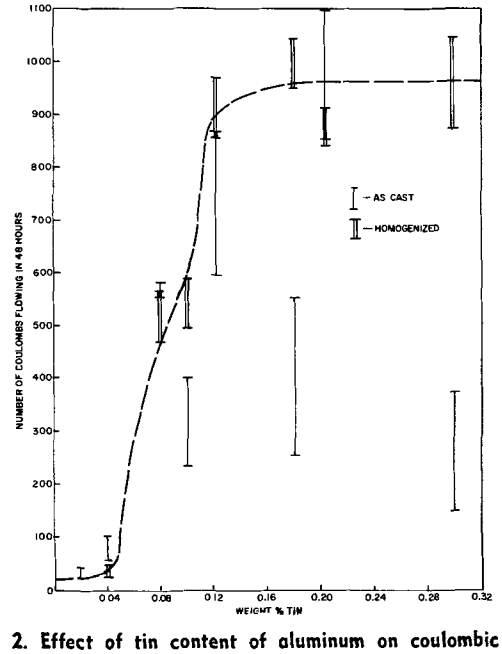

Fig. 2. Effect of tin content of aluminum on coulombic output when coupled to steel in 0.1*N* NaCl for 48 hr.

eutectic temperature (228.3°C) is very low being only around 0.02%. However, a small solubility loop exists around 620°C where the tin solubility is greater. The maximum solubility of tin in aluminum at this temperature is still somewhat doubtful. Hardy *et al.* (8) has found a value of 0.10% by weight, but Samuels (9), using some identical samples, reported a higher value of 0.11%. Irrespective of the actual maximum value of solid solubility at this temperature, it is clear that nonequilibrium solidification in this type of phase diagram will tend to leave somewhat variable amounts of tin in solid solution in the as-cast condition. This contention is supported by the photomicrograph of an as-cast Al-0.08% Sn alloy in Fig. 5(a). Here it is evident that the microstructure is very heterogeneous. The small discrete black spherical particles are metallic tin whereas the deeply etched bands

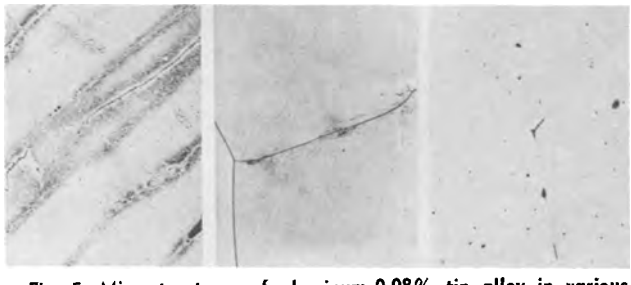

Fig. 5. Microstructures of aluminum-0.08% tin alloy in various metallurgical conditions. Magnification approximately 340X. (a) (left) As-cast, showing cored solid solution (tin-rich areas are darkened) and tin particles in grain boundaries; (b) (center) homogenized (620°C for 16 hr) and quenched, showing uniform solid solution; (c) (right) heterogenized (400°C for 24 hr following homogenization), showing precipitated tin particles.

may either represent concentrations of tin in solution or very fine tin particles. The difficulty of distinguishing between these conditions accounts for much of the disagreement in locating the phase boundary in the aluminum-rich end of the Al-Sn equilibrium diagram.

With the obvious heterogeneity of the Al-0.08% Sn alloy in the as-cast condition, and with the observa-

tion from ref. (13) that this amount of tin could be taken into solid solution at 620°C, a series of Al-Sn alloys was homogenized at 620°C as described earlier. The homogenized castings were quenched to retain the tin in solid solution. The microstructure of the Al-0.08% Sn alloy after homogenizing is shown in Fig. 5(b), which is a typical solid solution microstructure showing none of the gross heterogeneity found in the as-cast condition. The galvanic experiments conducted earlier in the as-cast condition were repeated in the homogenized condition. Results are also shown in Fig. 1-4. Reproducibility of results, in triplicate specimens, was markedly improved, and well-defined trends in electrochemical behavior became apparent. Anodic weight loss and coulombic output now rose sharply at about 0.05% Sn and reached a plateau at around 0.1% Sn or slightly above (Fig. 1 and 2). Anodic efficiency was lessened in the homogenized condition (Fig. 3) and closed circuit cell potential was around 0.1v more active above 0.1% Sn than in the as-cast condition (Fig. 4).

The results of impedance studies of the oxide film stable on Al-Sn alloys in 0.1*N* NaCl are shown in Fig. 6. γ-Al_2O_3 films on pure aluminum have an a-c resistivity of around 10^{10} ohm cm at 1 kc (3). Tin dissolved in solid solution markedly lowers this value to around 7×10^7 ohm cm at 0.08% Sn. This experiment represents the combined effects of tin and chloride ions in reducing resistivity at a frequency of 1 kc. Previous work (3) has shown that chloride ions alone reduce 1 kc resistivity to around 2×10^9 ohm cm only. It is clear, therefore, that the majority of the much larger decrease in resistivity seen in Fig. 6 is due to tin in the alloy although the possibility of a synergistic interaction between the tin and chloride ions cannot be ruled out. Aluminum-tin alloys containing from 0.02-0.08% tin were also heterogenized at 400°C as described earlier to precipitate most of the tin from solid solution. A typical photomicrograph of a heterogenized Al-Sn alloy is shown in Fig. 5(c) and it is evident that the precipitation treatment was quite effective. Despite the numerous leakage paths that must exist in the surface oxide film from this amount of elemental second phase carrying, at best, a very poorly protective and low resistance film, Fig. 6 shows that average film resistivity in the heterogenized condition is significantly higher than in the homogenized single phase condition. Furthermore, precipitation of tin from solid solution destroys completely the beneficial effect that tin in solid solution will exhibit in greatly raising the level of current output in a galvanic couple with iron in sodium chloride solution (Fig. 7).

Discussion

The effect of tin on the galvanic behavior of Al-Sn alloys coupled to mild steel in sodium chloride solution is quite remarkable as shown in Fig. 1-4. Tin in aluminum can debase the closed couple circuit potential by as much as 0.6v and can increase galvanic output by over 30 times that of pure aluminum in the same couple. The results in Fig. 6 show that 1 kc a-c resistivity of the surface oxide film is lowered by over two orders of magnitude compared with that figure obtained previously for γ-Al_2O_3 films on pure aluminum (3). Here it does appear that Sn^{4+} ions have been able to enter the surface oxide film on aluminum, replacing aluminum ions and thus creating additional cation vacancies. Were tin to be present in the oxide film as Sn^{++}, the marked drop in resistivity at 1 kc (Fig. 6) would not be observed; neither would the marked changes in electrochemical behavior be expected. It is possible that some very small concentrations of Sn^{++} may exist in the oxide film immediately adjacent to the metal interface, because of thermodynamic considerations. However, from Fig. 6 their importance, if present, is quite minor and the bulk of the tin surface oxide film is clearly doped with Sn^{4+} ions and controls the behavior of the aluminum alloy as an anode.

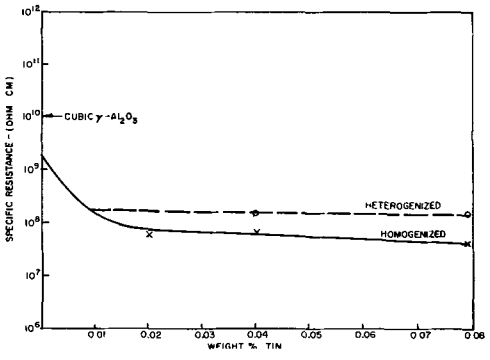

Fig. 6. Specific a-c resistance of surface oxide film formed on Al-Sn alloys in 0.1*N* NaCl, calculated from capacitance and loss at 1 kc.

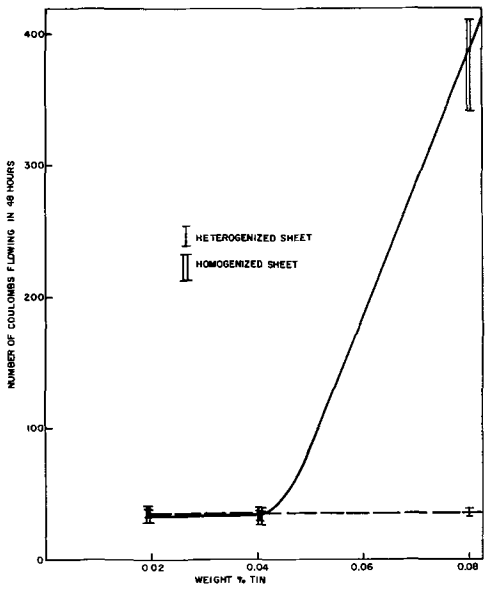

Fig. 7. Effect of tin remaining in solid solution in aluminum on coulombic output when coupled to steel in 0.1*N* NaCl for 48 hr.

The form in which tin is present in the metal is quite critical in enabling the alloying addition to enter the surface oxide. Figure 7 shows clearly that tin, as a series of elemental particles, will produce virtually no enhancement of galvanic current output. Likewise, despite the obvious presence of many low resistance leakage paths in the surface oxide film on heterogenized Al-Sn alloys [Fig. 5(c)] the average film resistivity is higher on heterogenized Al-Sn alloys than on similar single phase homogenized alloys. Evidently tin will only reduce the resistivity of the aluminum oxide film if it is dispersed relatively uniformly in the aluminum solid solution substrate. Despite the fact, that only around 0.1% tin can only be retained in a metastable solid solution, at room temperature it still appears to be distributed sufficiently uniformly so as to permit relatively reproducible doping of the surface oxide film with the attendant decrease in ionic resistivity.

The form of the weight loss and coulomb flow curves in Fig. 1 and 2 as a function of tin content further emphasizes the importance of the amount of tin retained in metastable solid solution at room temperature. Quantities of tin up to around 0.04% have little effect on the electrochemical properties of Al-Sn alloys despite the fact that they lower the oxide film resistivity (Fig. 6). The effect of these small quantities of tin is not sufficient from Fig. 4 to debase the potential of the couple (or the aluminum alloy) suffi-

ciently to permit evolution of hydrogen from a steel cathode. Accordingly, galvanic corrosion of these alloys with thin surface films only moderately doped with Sn^{4+}, is cathodically controlled by dissolved oxygen reduction at the steel cathode in the same fashion as with pure aluminum as an anode (10). Quite similar current outputs must be anticipated with a similar cathode, electrolyte, and cell geometry, under these conditions. As the tin content is further increased, the anode potentials and the cell potentials are debased into the potential region where hydrogen may be freely evolved from the steel cathodes (11). Brisk hydrogen evolution from the steel cathode (and from the Al-Sn anodes) characterizes all galvanic experiments conducted on homogenized alloys containing 0.08% Sn and more. The current output is no longer limited by diffusion of dissolved oxygen and now increases sharply with increasing tin content as long as tin can be added and retained in metastable solid solution. Galvanic corrosion is still however, likely under cathodic control. From Fig. 1, 2, and 4 it appears that the maximum solid solubility of tin in aluminum is between 0.10 and 0.12% with the form of the curves suggesting that the maximum solubility is slightly in excess of 0.1% at 620°C as had been found by Samuels (9). Indeed, in the Al-Sn system galvanic experiments or potential measurements are probably a more effective method of locating the phase boundary than conventional optical metallography. Further increases in tin content above 0.12% result only in the presence of more elemental tin out of solid solution. It follows from the above that this extra elemental tin produces no increase in galvanic current output (Fig. 2), but does result in some further decrease in anodic efficiency (Fig. 3) presumably due to the provision of low resistance local cathodes.

As-cast Al-Sn alloys exhibit variable galvanic behavior intermediate between that of homogenized and heterogenized Al-Sn alloys. Because the tin retained in solid solution is highly dependent on uncontrolled variables during solidification, maximum solid solubility is seldom obtained and the tin distribution is nonuniform [Fig. 5(a)]. Variable galvanic results are therefore not surprising.

The curves of anodic efficiency *vs.* tin content in the homogenized condition (Fig. 3) do not match completely the weight loss, current flow, and cell potential curves. The latter all become relatively insensitive to tin content above 0.10-0.12% Sn whereas the former does not show a plateau till around 0.2% Sn. Pure aluminum generally shows a very high efficiency of anodic dissolution of around 85% or more in sodium chloride solution (7, 10). This is due to its single valency and due to the fact that, in chloride solutions at a potential of around —0.5v, aluminum itself is a poor cathode due to the high electronic resistance of its natural oxide film (11). In the above potential range only 1-5% of an oxide covered aluminum cathode is active at any given time at current densities below 10 $\mu a/cm^2$. In galvanic corrosion under similar conditions an aluminum anode should also be reluctant to act as an effective local cathode, this fact resulting in high anodic efficiencies. When sufficiently small amounts of tin in solid solution have been added (up to 0.04%) so that galvanic corrosion is still controlled by oxygen diffusion to the steel cathode, no change in anodic efficiency is seen. This argues that these small amounts of tin do not reduce the electronic resistance of the oxide film despite the fact that they lower ionic resistivity (Fig. 6). This is in accord with the previously expressed views on the form in which tin is present in the oxide. Such is clearly not the case in the as-cast condition (Fig. 3) where the elemental tin that is present out of solution [Fig. 5(a)] reduces average electronic resistance of the film by providing low resistance local cathodes. In this case even small quantities of tin reduce anodic efficiency. As more tin is added in solid solution and the potential of the couple moves into the range where hydrogen can be evolved both from the cathode and the anode, anodic efficiency decreases. Presumably the additional driving force for the local cell reaction overcomes to some degree the effect of the high electronic resistance oxide film permitting it to function as a more effective local cathode. As the solid solution becomes saturated with tin and now contains second phase particles of elemental tin, anodic efficiency continues to drop presumably due to the second phase tin particles acting as low resistance local cathodes. The lower values of anodic efficiency in the homogenized condition are attributed to the fact that the tin particles are smaller than in the as-cast condition and so exhibit a greater ratio of spherical surface area to volume as the corrosion advances into the metal.

The fashion in which the Al-Sn anodes corrode is of some interest. As-cast alloys with their heterogeneous distribution of tin corrode nonuniformly and often intergranularly. Typically corrosion follows the dark etching bands shown in Fig. 5(a). Homogenized Al-Sn alloys containing 0.1% Sn or less also corrode somewhat nonuniformly and by shallow pitting. Presumably completely uniform distribution of tin was not achieved despite the homogenizing treatment. Since tin is known to be strongly clustered in aluminum-tin solid solutions (12) this result is in accord with the anticipated metallurgical structure of the metastable solid solution. Homogenized Al-Sn alloys containing 0.12% Sn or more corroded quite uniformly when coupled to steel. Presumably the numerous small local cathodes are beneficial in ensuring uniformity of anodic corrosion despite the fact that their presence results in the loss of some anodic efficiency.

There is finally the question remaining as to why tin is so effective in reducing the ionic resistance of oxide films on Al-Sn alloys while other group IV elements are virtually without effect. Ti, Zr, Si, and Ge have solid solubilities at least as high as that of tin and in most cases higher. Yet they do not significantly increase current output. It is believed that these dissimilar effects can be rationalized by more detailed considerations of the γ-Al_2O_3 crystal lattice. γ-Al_2O_3 is a pseudospinel and has a close packed fcc oxygen lattice. The structure of the cation lattice is poorly understood, but it doubtless contains a number of cation vacancies at stoichiometry. Accordingly, a foreign cation can likely assume one of two types of positions in the γ-Al_2O_3 cation lattice: (*A*) it may replace an aluminum ion in a filled cation position in the lattice or (*B*) it may enter an already vacant position in the cation lattice.[2]

Alternative (*A*) will tend to create additional cation vacancies and (*B*) will tend to annihilate preexisting cation vacancies (and increase electronic conductivity). It is evident from the present work that tin enters the aluminum lattice in the quadrivalent condition in replacement for aluminum ions, *i.e.*, Sn^{4+} ions substitute by alternative (*A*). However, the oxides of Si, Ti, Zr, and Ge all have very strong tendencies to form highly stable, high melting point compounds with alumina. A natural precursor to the formation of such components would be for the foreign cations to enter vacant sites in the γ-Al_2O_3 cation lattice. In this case ionic resistivity would not be lowered neither would high galvanic outputs be observed. Accordingly, it is considered that with defect spinels such as γ-Al_2O_3 classic substitution and doping effects will only be obtained when the oxide of the doping element is free from strong chemical interaction with the defect spinel itself.

Calculation of Currents of Local Galvanic Cells

John A. Simmons, Sam R. Coriell, and Fielding Ogburn

Institute for Materials Research, National Bureau of Standards, Washington, D. C.

ABSTRACT

The current flow for a local electrolytic cell with rectangular anode and cathode is calculated as a function of a polarization parameter, electrolyte thickness and conductivity, anode and cathode size, and zero current potential difference. The total current is obtained from the numerical computation (with error analysis) of a series solution of Laplace's equation assuming a linear polarization relation at the electrode-electrolyte interface. For high values of the polarization parameter and sufficiently thick electrolytes an asymptotic formula obtains for the current approximately proportional to the anodic fraction, as was found by Waber *et al.* However, in general the cell geometry greatly influences the amount of current flow, especially for anode shapes near to linear rather than near to square. This effect can be greater than an order of magnitude. The calculated results are compared with experimental data obtained by Ogburn and Schlissel and are shown to be in good agreement. Corrosion currents in randomly pitted surfaces may be estimated from the above results.

Local electrolytic cells occur frequently in corrosion—wherever pitting occurs. Whether they are due to local breakdowns of passivity, imbedded impurities, or imperfections of metal coatings they lead to pits and corrosion damage and have been the subject of many investigations. By making appropriate approximations, a theoretical analysis of such local cells can be carried out.

Using a model of an alternating array of infinitely long coplanar electrodes, Waber *et al.* (5) calculated the galvanic cell current in terms of the thickness of the electrolyte layer, the sizes of the electrodes, the conductivity of the electrolyte, σ, and the polarization parameter, $k (k = \sigma|de/dj|$, where de/dj is the slope of the potential-current density curve). In this paper we carry out a similar calculation for the current due to a rectangular lattice of cells assuming that the cathodes and smaller anodes are rectangular and lie in one plane. This model comprises a generalization of the one dimensional geometry employed by Waber *et al.* (1-7). Although in some cases the total corrosion current is independent of cell geometry, being a function only of the anodic fraction (the ratio of anodic area to total area), it is shown that in general the cell geometry may influence the corrosion current by more than one order of magnitude. This effect is especially pronounced for thin electrolytes and low polarization. In addition to permitting calculation of the current due to a lattice of cells, the rectangular model may also be used to determine the current in an isolated rectangular corrosion cell. Currents calculated for such cells are shown to be in good agreement with the experimental results of Ogburn and Schlissel (8).

There are certain assumptions which are implicit in this treatment. The cell geometry, electrolyte composition, surface conditions of the electrodes, and so forth, are assumed to be unvarying and uniform. (For example, we do not consider the effects of local cells within the cathodic or anodic areas.) Furthermore we assume, as did Waber *et al.*, that the polarization parameter, k, is the same for both electrodes of a cell and is independent of current density. For many cells, this requirement of a single polarization parameter is not too severe. For instance, in the case of pitting corrosion where the current densities of the small anode are generally much higher than those of the cathode, the polarization behavior of the cathode is of little consequence and only that of the anode is of significance. Further, although a logarithmic polarization law or more accurate empirically determined law is certainly better, a judiciously chosen approximating linear law still can be expected to represent many of the salient features of corrosion behavior.

The ensuing derivation and discussion will be in terms of an anode embedded in a cathode. The mathematics is equally applicable to the reverse situation, a cathode embedded in an anode, if one recognizes that the direction of the current will change, but not its magnitude.

The corrosion current due to a random array of pits is of considerable practical interest. Our results apply directly to a regular rectangular array of pits, but such an array can be used to approximate a random array.

Derivation of Corrosion Current

In this section we derive an equation for the total electric current I for the corrosion cell whose geometry is illustrated in Fig. 1. The cell is a rectangular parallelepiped with sides of length 2a, 2b, and c. We choose our coordinate system so that the x, y, and z axes are parallel to those cell edges of length 2a, 2b, and c, respectively. The origin of the coordinate system is taken so that the eight corners of the cell

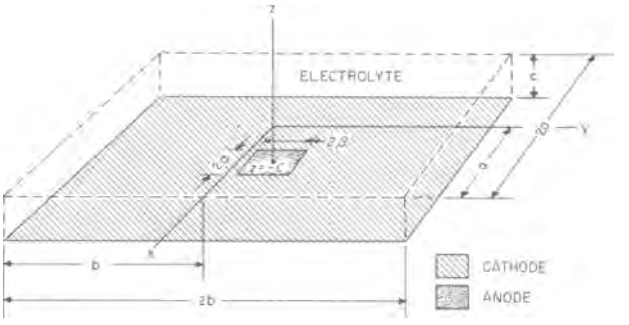

Fig. 1. Cell geometry with coplanar electrodes on the plane $z = -c$ and origin located on the top surface of the electrolyte.

are located at (±a, ±b, 0) and (±a, ±b, —c) as indicated in Fig. 1. For mathematical convenience, the surface containing both the anodic and cathodic areas is placed in the plane $z = -c$. The corrosion pit which acts as the anode is assumed to be a rectangle centered at $x = 0$, $y = 0$, with sides of length 2α and 2β parallel to the x and y axes, respectively. The cathode surrounds the anode and constitutes the rest of the cell surface lying in the plane $z = -c$. The remaining 5 sides of the corrosion cell are taken to be perfect insulators.

To find the total current which governs the rate of corrosion we shall solve first for that potential distribution, $P(x, y, z)$, in the whole cell induced by the emf difference of the two electrodes as modified by a linear polarization at the metal-electrolyte interface. The local current flow at the interface is obtained from the potential distribution by Ohm's law

$$I(x, y, -c) = -\sigma \left.\frac{\partial P}{\partial z}\right|_{(x,y,-c)} \qquad [1]$$

where σ is the conductivity. Since all cell faces are insulators except the anode and cathode surfaces, the total current flowing in the system can be obtained by integrating the local current distribution over either of the electrodes. Thus we shall obtain the total current in the corrosion cell by integrating over the anode surface the local current distribution deduced from the cell potential distribution.

The potential distribution P in the cell is given by the solution of Laplace's equation

$$\nabla^2 P = 0 \qquad [2]$$

subject to the boundary conditions (9)

$$\left.\frac{\partial P}{\partial x}\right|_{x=\pm a} = \left.\frac{\partial P}{\partial y}\right|_{y=\pm b} = \left.\frac{\partial P}{\partial z}\right|_{z=0} = 0 \qquad [3a]$$

$$P(x, y, -c) = E + k \left.\frac{\partial P}{\partial z}\right|_{z=-c}$$

for $|x| < \alpha$ and $|y| < \beta$ [3b]

and

$$P(x, y, -c) = k \left.\frac{\partial P}{\partial z}\right|_{z=-c} \quad \text{for } |x| > \alpha \text{ or } |y| > \beta \qquad [3c]$$

Equation [3a] describes the fact that there are insulating walls at $x = \pm a$, $y = \pm b$, and $z = 0$. In Eq. [3b], E is the potential for zero current flow, and k is the linear polarization constant arising from the assumed linear polarization law at the metal-electrolyte interface.[1] We have also taken both electrodes to have the same linear polarization constant, k, as previously discussed.

We solve Laplace's equation by using the method of separation of variables, *i.e.*, we let $Q(x, y, z)$ be a particular solution of Laplace's equation of the form

$$Q(x, y, z) \equiv X(x)\, Y(y)\, Z(z) \qquad [4]$$

From Eq. [2], X, Y, and Z, satisfy the following equations

$$\frac{d^2X}{dx^2} + \lambda^2 X = 0 \qquad [5a]$$

$$\frac{d^2Y}{dy^2} + \mu^2 Y = 0 \qquad [5b]$$

and

$$\frac{d^2Z}{dz^2} - \kappa^2 Z = 0 \qquad [5c]$$

where λ, μ, and κ are in general complex numbers and $\kappa^2 = \lambda^2 + \mu^2$. The solutions to Eq. [5] are

$$X = c_1 \sin(\lambda x) + c_2 \cos(\lambda x) \qquad [6a]$$

$$Y = c_3 \sin(\mu y) + c_4 \cos(\mu y) \qquad [6b]$$

and

$$Z = c_5 \exp(\kappa z) + c_6 \exp(-\kappa z) \qquad [6c]$$

where $c_1 \ldots, c_6$ are constants. We may assume without loss of generality that each of the functions, X, Y, Z satisfies the boundary conditions given in Eq. [3a] and that $X(x)$ and $Y(y)$ are symmetric about $x = 0$ and $y = 0$, respectively, so that

$$Q(x,y,z) = C_{lm} \cos(\pi lx/a) \cos(\pi my/b) \cosh(rz/a) \qquad [7]$$

and try an expansion for

$$P(x,y,z) = \sum_{l=0}^{\infty} \sum_{m=0}^{\infty} C_{lm} \cos(\pi lx/a) \cos(\pi my/b) \cosh(rz/a) \qquad [8]$$

where $l \equiv a\lambda/\pi$ and $m \equiv b\mu/\pi$ are positive integers or zero, $r^2 = a^2\pi^2[\lambda^2/a^2 + m^2/b^2]$ and C_{lm} are the expansion coefficients to be determined from Eq. [3b] and [3c].

It is convenient to define a step function $S_{\alpha\beta}$ such that

$$S_{\alpha\beta} = \begin{cases} 1 & |x| < \alpha \text{ and } |y| < \beta \\ 0 & |x| > \alpha \text{ or } |y| > \beta \end{cases} \qquad [9]$$

The boundary conditions given in Eq. [3b] and [3c] may then be written as

$$P(x,y,-c) = ES_{\alpha\beta} + k \left.\frac{\partial P}{\partial z}\right|_{z=-c} \qquad [10]$$

Combining Eq. [8] and [10] we obtain

$$\sum_{l=0}^{\infty} \sum_{m=0}^{\infty} C_{lm} \cos(\pi lx/a) \cos(\pi my/b) [\cosh(rc/a) + (kr/a) \sinh(rc/a)] = ES_{\alpha\beta} \qquad [11]$$

Multiplying both sides of Eq. [11] by $\cos(\pi l'x/a)$ $\cos(\pi m'y/b)$ and integrating over x and y from $-a$ to a and $-b$ to b, respectively, we find that

$$C_{lm} = 4Eg_{\alpha l}g_{\beta m} \{(1 + \delta_{ol})(1 + \delta_{om}) [\cosh(rc/a) + (kr/a) \sinh(rc/a)]\}^{-1} \qquad [12a]$$

where

$$g_{\alpha l} = (1 - \delta_{ol})(\pi l)^{-1} \sin(\pi l\alpha/a) + \delta_{ol}(\alpha/a)$$

$$g_{\beta m} = (1 - \delta_{om})(\pi m)^{-1} \sin(\pi m\beta/b) + \delta_{om}(\beta/b) \qquad [12b]$$

and

$$\delta_{ij} = \begin{cases} 1 ; i = j \\ 0 ; i \neq j \end{cases}$$

[1] As indicated, for example, by Wagner (9) or Waber (7) few electrolytic cells are truly linearly polarized. In general the graph of current density, j, *vs.* surface potential, e is curved rather than straight and intersects the $j = 0$ axis at E_c, the open circuit single electrode potential. However when a linear approximation of slope M is used for the polarization curve of an electrode, the value of e corresponding to $j = 0$ is not E_c but some other constant E_c'. It is the value of σ.M that is used as the constant k for both electrodes, where M is the slope at the operating current densities of the polarization curve for the controlling electrode (or the best approximation thereto), and the value of [E_c' (anode) $-E_c'$ (cathode) that is used as the constant E].

In order to demonstrate that the series expansion given in Eq. [8] for $P(x, y, z)$ is sufficiently general to satisfy the mixed boundary condition given by Eq. [10], it suffices to show that the series for $P(x, y, z)$ converges and that the series for $\partial P/\partial z$ obtained by differentiation of Eq. [8] converges uniformly in the region $|x| \leq a$, $|y| \leq b$, $-c \leq z \geqq 0$ (10). The series given for P may easily be seen to converge uniformly and absolutely throughout this region. Using a simple generalization of Dirichlet's convergence criterion (10) it is possible to show that $\partial P/\partial z$ converges uniformly on all closed sets of the region which do not intersect the line $z = -c$ and $|x| = \alpha$ or $z = -c$ and $|y| = \beta$. On these anomalous lines the series for $\partial P/\partial z$ converges, but, due to the nature of the step function occurring in Eq. [10] nonuniform convergence appears at the anode boundaries. Furthermore, due to the separation of variables technique the region of nonuniform convergence is projected along the lines bounding the anode but extending beyond the anode in the x and y directions. However, since $\partial P/\partial z$ converges everywhere, it is evident that changing the polarization behavior on a system of lines produces no effect in the current flow density and hence the series given by Eq. [8] and [12] correctly represents the solution to Eq. [2] and [3].

The local current distribution at the metal electrolyte interface, $I\ (x, y, -c)$, may now be obtained from Eq. [1] by

$$I\ (x, y, -c) = \sigma \sum_{l=0}^{\infty} \sum_{m=0}^{\infty} (r/a)\ C_{lm} \cos\ (\pi l x/a) \cos\ (\pi m y/b) \sinh\ (rc/a) \quad [13]$$

where C_{lm} are given in Eq. [12]. The total current flowing in the corrosion cell is obtained by integrating $I\ (x, y, -c)$ over the anode surface, so that

$$I = \int_{-\alpha}^{\alpha} \int_{-\beta}^{\beta} I\ (x, y, -c)\ dx dy \quad [14]$$

Substituting Eq. [13] into Eq. [14], interchanging the order of summation and integration,[2] and carrying out the explicit integration gives

$$I = (16\ \sigma E a b) \sum_{\substack{l=0 \\ l^2+m^2>0}}^{\infty} \sum_{m=0}^{\infty} [g_{\alpha l}^2\ g_{\beta m}^2/\ (1 + \delta_{ol})\ (1 + \delta_{om})]\ [k + (a/r) \coth\ (rc/a)]^{-1} \quad [15]$$

To evaluate I explicitly we first make use of an upper bound for I which is, in fact, an asymptotic approximation for I when

$$\begin{aligned} k/a &>> 1 \\ k/b &>> 1 \\ c/a &\gtrsim 1 \\ c/b &\gtrsim 1 \end{aligned} \quad [16]$$

such as the case of a thick electrolyte layer and very high values of k. In this case the hyperbolic terms in the denominator may be ignored and we have

$$I \simeq I_A \equiv (16\ \sigma E a b/k) \sum_{\substack{l=0 \\ l^2+m^2>0}}^{\infty} \sum_{m=0}^{\infty} [g_{\alpha l}^2\ g_{\beta m}^2/ (1 + \delta_{ol})\ (1 + \delta_{om})] \quad [17]$$

In general, even when the conditions [16] are not satisfied one sees that

$$I \leq I_A \quad [18]$$

The expression for I_A may be evaluated explicitly using the identity

$$\sum_{j=1}^{\infty} \{[\sin^2\ (j\theta)]/j^2\} = \tfrac{1}{2}\ \theta\ (\pi - \theta) \quad [19]$$

to yield

$$I_A = (4\sigma E \alpha\beta/k)\ [1 - \alpha\beta/ab] \quad [20]$$

It does not seem possible to obtain an analytic expression for the general current I, but I may be computed numerically as discussed below.

Numerical Evaluation

To facilitate the calculation of I numerically, we make use of the asymptotic expression I_A as given by Eq. [17] and write

$$\begin{aligned} I &= I_A - (I_A - I) = I_A - (16\ \sigma E a b/k) S \\ &= (4\ \sigma E \alpha\beta/k)\ [1 - (\alpha\beta/ab) - 4(ab/\alpha\beta) S] \end{aligned} \quad [21]$$

where the sum

$$S \equiv \sum_{\substack{l=0 \\ l^2+m^2>0}}^{\infty} \sum_{m=0}^{\infty} g_{\alpha l}^2 g_{\beta m}^2\ [(1 + \delta_{ol})\ (1 + \delta_{om})\ \{1 + (kr/a) \tanh\ (cr/a)\}]^{-1} \quad [22]$$

on the right hand side of Eq. [21] becomes vanishingly small for conditions approaching those given in Eq. [16]. Since I_A is given in closed form by Eq. [20] we need only evaluate the sum, S. This has been done numerically on a 7094 computer by summing over a finite region in the l, m plane. To further simplify the calculations and economize on computer time we have restricted the physical constants a, b, α, β in such a way that the parameters

$$\begin{aligned} A^{-1} &\equiv (a/\alpha) \\ B^{-1} &\equiv (b/\beta) \\ s^{-1} &\equiv (b/a) \end{aligned} \quad [23]$$

are integers. This restriction imposes some limitation on the problem geometry, but may be removed if desired. On insertion of Eq. [23] into Eq. [21], we have

$$I = (4\sigma E \alpha\beta/k)\ [1 - AB - (4S/AB)] \quad [24]$$

where, since $r = \pi(l^2 + s^2 m^2)^{1/2}$ and since both $g_{\alpha l}$ and $g_{\beta m}$ depend only on A and B, respectively, the computed sum, S, and the normalized current

$$I^* \equiv (kI/4\sigma E \alpha\beta) \quad [25]$$

depend only on the parameters A, B, c/a, k/a, s.

In order to make the numerical results meaningful, we must derive an error bound for the remaining terms which are not included in the numerical sum. Such a bound is derived in the Appendix.

Results and Discussion

In this section we give the results for numerical calculation of the corrosion current emphasizing the case when $a = b$ and $\alpha = \beta$ and present a comparison of the theory with experimental results of Ogburn and Schlissel.

Case 1: $\alpha = \beta$ and $a = b$.—In Tables I-IV, the corrosion currents are summarized for a series of values α/a between 10^{-5} and 0.5 and k/a between 10^{-4} and

Table I. Computation of I^* for various values of α/a, and k/a (when $\alpha = \beta$ and $a = b$); $c/a = 1.0$

I^* k/a \ α/a	0.5	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}
10^2	0.75	0.99	1.00	1.00	1.00	1.00
10^1	0.73	0.98	1.00	1.00	1.00	1.00
10^0	0.61	0.92	1.00	1.00	1.00	1.00
10^{-1}	0.26	0.60	0.92	1.00	1.00	1.00
10^{-2}	0.054	0.18	0.61	0.92	1.00	1.00
10^{-3}	0.0084	0.033	0.18	0.61	0.92	1.00
10^{-4}			0.033	0.18	0.61	0.92

[2] Interchange of summation and integration may easily be seen to be valid when the limits of integration lie inside the anode. Continuity of the sum of the integrals as the limits tend to α, β on the anode surface guarantee a consistent definition for the total current over the entire anode.

Table II. Computation of I^* for various values of α/a, and k/a (when $\alpha = \beta$ and $a = b$); $c/a = 10^{-1}$

I^* k/a \ α/a	0.5	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}
10^2	0.74	0.99	1.00	1.00	1.00	1.00
10^1	0.70	0.98	0.99	1.00	1.00	1.00

10^{-2}	0.018	0.088	0.56	0.92	1.00	1.00
10^{-3}	0.0041	0.020	0.17	0.61	0.92	1.00
10^{-4}			0.031	0.18	0.61	0.92

Table IV. Computation of I^* for various values of α/a, and k/a (when $\alpha = \beta$ and $a = b$); $c/a = 10^{-3}$

I^* k/a \ α/a	0.5	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}
10^2	0.48	0.91	0.99	0.99	1.00	1.00
10^1	0.19	0.65	0.99	0.99	1.00	1.00
10^0	0.062	0.28	0.91	0.99	1.00	1.00
10^{-1}	0.020	0.097	0.65	0.98	0.99	1.00
10^{-2}	0.0062	0.031	0.28	0.89	0.98	1.00
10^{-3}	0.0018	0.0092	0.088	0.56	0.92	1.00
10^{-4}			0.020	0.17	0.61	0.92

10^2 for four orders of magnitude of c/a. Most of the results are accurate to within 2% although a few may have inaccuracies of as much as 5%.

The results of Tables I and IV are illustrated in Fig. 3 and 4. Additional extrapolated points have been added to fill out the calculated surface. As may be seen for $\alpha/a << c/a$ and $\alpha/a << k/a$, $I^* \cong I_A^*$, where $I_A^* = 1 - (\alpha/a)^2$ is the normalized asymptotic current, and $I_A^* \cong 1$ except when $\alpha/a > 0.1$; in fact the graph of I_A^* is the same as the front contour curve of the I^* surface in Fig. 3 on which $k/a = 100$ and $c/a = 1$. Thus the extrapolation for small values of α/a in these figures is clearly justified. The two points for which $k/a = 10^{-4}$ and $\alpha/a = 0.1$ or 0.5 on each of the two surfaces require excessive machine time to calculate and have been interpolated graphically using the additional fact that $I^* = I^*_A \equiv 0$ when $\alpha/a = 1$. Calculations using $c/a > 1$ appear to be unnecessary, at least when $\alpha/a \leq 0.5$, since the use of larger c's gives negligible effect on I^*.

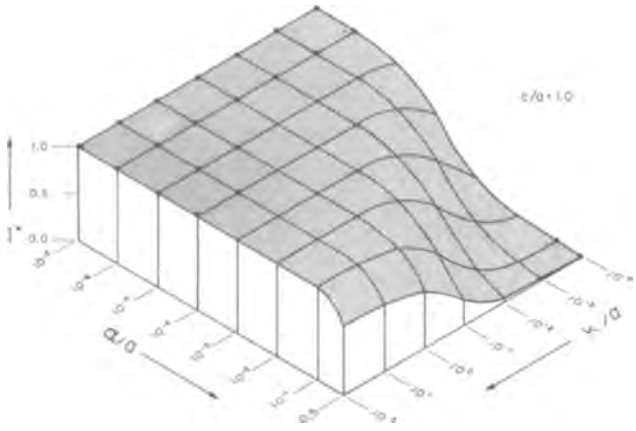

Fig. 3. Normalized current as a function of polarization parameter and cathode size with $c/a = 1$. Extrapolated points are indicated by large dots.

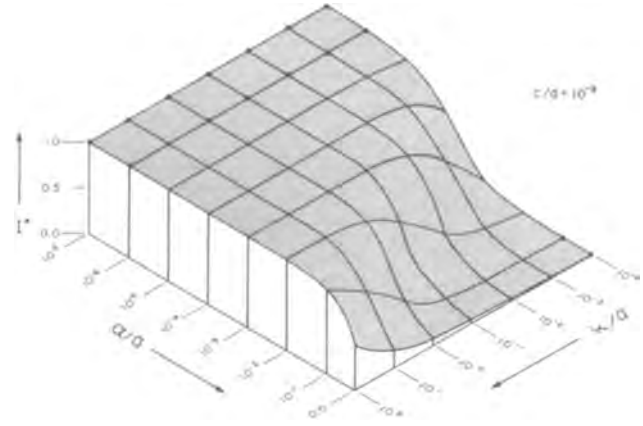

Fig. 4. Normalized current as a function of polarization parameter and cathode size with $c/a = 10^{-3}$. Extrapolated points are indicated by large dots.

As seen from Eq. [25], I^* depends only on the ratios α/a, c/a, and k/a; Tables I-IV have been made up accordingly. To render these tables more useful, the separate dependence of I^* on a, when α, c, k are held fixed, is given in Table V for a series of values of c and k where α has been fixed at 10^{-2} cm. Due to the dependence of I^* on the ratios α/a, c/a, k/a, fixing α imposes no real limitation on the range of applicability of the results. It is clear from Table V that α/a has the greatest effect on I^* when c/a and k/a are large, *i.e.*, when $I^* \simeq I^*_A$. Thus we may conclude that when $\alpha/a \leq 0.1$ the error introduced by assuming $a = \infty$ is less than 1%. This fact has been used to simplify the calculations of Table I-IV; *e.g.*, I^* for $c = 10^{-2}$ cm, $\alpha = 10^{-2}$ cm, $a = 1.0$ cm, $k = 10^{-2}$ cm is the same as I^* for $c = 10^{-1}$ cm, $\alpha = 10^{-1}$ cm, $a = 1.0$ cm, $k =$

Table V. Dependence of I (in amperes) on cathode size for various values of c and k. In all cases $\alpha = 10^{-2}$ cm, $E = 0.31$v and $\sigma = 0.25 \times 10^{-4}$ ohm^{-1} cm^{-1}. Values are accurate to 0.1% except where indicated, and when $k = 10^2$ all computed values of I coincide with those of I_A to within 0.1%

c \ k		10^{-4} cm	10^{-1} cm	10^{2} cm
10^{-4} cm	$a/\alpha =$ 2	0.28×10^{-6}	0.879×10^{-8}	0.232×10^{-10}
	3	0.28×10^{-6} 4% Error	0.881×10^{-8}	0.274×10^{-10}
	6	0.28×10^{-6}	0.881×10^{-8}	0.299×10^{-10}
	10	0.28×10^{-6}	0.881×10^{-8}	0.303×10^{-10}
	100		0.881×10^{-8}	0.305×10^{-10}
10^{-1} cm	$a/\alpha =$ 2	0.977×10^{-6}	0.222×10^{-7}	0.232×10^{-10}
	3	0.100×10^{-5}	0.260×10^{-7}	0.276×10^{-10}
	6	0.101×10^{-5} (0.5% Error)	0.281×10^{-7}	0.301×10^{-10}
	10	0.101×10^{-5} (1.5% Error)	0.284×10^{-7}	0.307×10^{-10}
	100		0.286×10^{-7}	0.310×10^{-10}

	3	0.100×10^{-5}	0.260×10^{-7}	0.276×10^{-10}
	6	0.101×10^{-5} (1% Error)	0.281×10^{-7}	0.301×10^{-10}
	10	0.102×10^{-5} (2% Error)	0.284×10^{-7}	0.307×10^{-10}
	100		0.286×10^{-7}	0.310×10^{-10}

10^{-1} cm since replacement of $a = 10$ cm by $a = 1$ cm in the second case produces no effect.

As pointed out by various authors (2, 9, 11, 12) the size of the polarization constant k affects the nature of the current distribution as well as the magnitude of the corrosion current. As indicated in Fig. 3 and 4 and as expressed in Eq. [24], for large k/a and small α/a the effect of k is essentially that of a resistance when σ is held constant. However, when $k/\alpha \gtrsim 1$ the influence of k becomes less pronounced until (for example, when $c/a = 1$ and $\alpha/a = 0.5$) change of k/a by a factor of 10 from 10^{-2} to 10^{-3} produces an increase in I of only about 1.5. This latter effect is a consequence of the behavior of the series representation given by Eq. [15] for I. Here it may be seen that as $k \to 0$, the qualitative behavior of the series is of the type $I \simeq O(\ln k)$ as $1/k \to \infty$. Thus $I^* \simeq O(k \ln k)$ which tends to zero as k tends to zero.

Case 2: $\alpha \neq \beta$ and/or $a \neq b$.—Currents produced by configurations where $\alpha \neq \beta$ or $a \neq b$ involve too many parameters to permit a general compilation of results. However, certain trends are relatively clear. Thus, as observed above when $\alpha = \beta$, $a = b$, the dependence of I^* on a and b for α/a, β/a, α/b, and β/b all <0.1 may be expected to be negligible; this has been verified in a number of special cases. The effect of changing the ratio a/α while maintaining the anode area, $\alpha\beta$, constant produces significant effects on the corrosion current as indicated in Fig. 5 where I^* *vs.* β/α is graphed for the six possible combinations of $c/a = 10^{-3}$ or 1.0 and $k/a = 10^{-3}$, 10^{-2}, or 100. Here $a = b$ and the anodic fraction $\alpha \cdot \beta / a \cdot b = 1/1296$. It should be noted that when one of the anode dimensions, say β, is taken equal to the correspondent cathode dimension, *i.e.*, b, the model employed here reduces to that employed by Waber *et al.* and Eq. [21] becomes equivalent to their expression for the corrosion current. For ratios of β/α between 1 and 2 the amount of corrosion current is seen to vary by less than about 10%. This result is relatively independent of the anodic fraction for anodic fractions $\lesssim 0.5\%$ and holds for all configurations where α/a, α/b, β/a, and β/b, are all less than 0.1. Thus, in treating problems involving random corrosion pits where the pits are approximately circular in shape, *i.e.*, the ratio of the maximum diameter to minimum diameter is less than 2, errors of $\leq 10\%$ may be expected. Further, the more oblong pits, which produce the greatest corrosion current and thus the greatest rate of corrosion, should have the fastest growth rate among various anode shapes.

In Fig. 5 when $\beta/\alpha = 1296$, *i.e.*, when $\beta = b = 1$, the geometry is that of the one dimensional strip model. As may be seen for small values of k and small electrolyte thickness, variation in the anode shape from a square to a one-dimensional strip produces as much as a factor of 13.5 in the corrosion current while for large values of k and thick electrolytes the anode geometry produces no significant effect. The effects due to anode geometry shown in Fig. 5 are expected to be magnified for smaller anodic fractions, (provided that $k/\alpha \lesssim 1$) and thinner electrolytes. On the other hand, when k and c are sufficient large $I \cong I_A$ (the asymptotic corrosion current value) which is independent of anode geometry.

Experimental comparison.—Using the computer program developed for determining the corrosion current, calculations have been made for comparison with experimental data of Ogburn and Schlissel (8). Figures 6 and 7 taken from ref. (8) show the experimental and calculated results for the case of Ni-Fe electrolytic cells with synthetic rain water electrolyte in which the (*i*) anode diameter and (*ii*) electrolyte thickness, respectively, have been varied. In both experiments $a = 2.5$ cm, $b = 0.5$ cm, and the open circuit potential of 0.3v was used as an estimate of E. For Fig. 6, $c = 100$ cm, $\sigma = 53 \times 10^{-6}$ ohm^{-1}, and k was estimated to be 95.4×10^{-4} cm. The anodes, which were circular in shape, have been approximated by squares of equal area: $\alpha = \beta = 0.00225$, 0.00675, and 0.01 cm. For Fig. 7, $\sigma = 105 \times 10^{-6}$ ohm^{-1} cm^{-1}, k was estimated to be 189×10^{-4} cm, and $\alpha = \beta = 0.01$ cm for a square of area equal to that of the circular anode. The electrolyte thickness ranged from 0.004 to 0.015 cm. Although these data show extensive scatter due

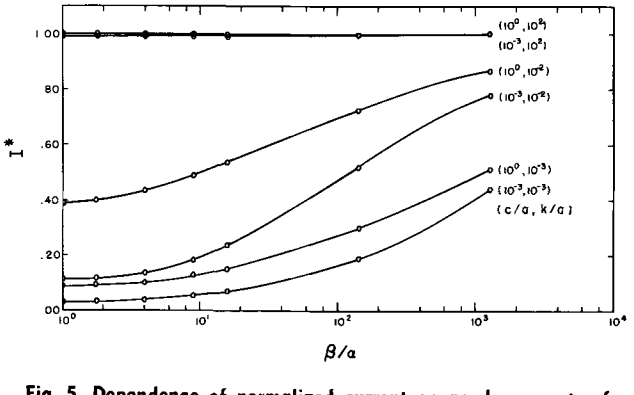

Fig. 5. Dependence of normalized current on anode geometry for various values of c/a and k/a. In all cases $a = b$ and the anodic fraction $\frac{\alpha \cdot \beta}{a \cdot b} = 1/1296$.

to experimental difficulties (8) and comprise a very limited check on the theory presented in this paper, they are in reasonable agreement with the theoretical calculations.

APPENDIX

Analysis of Numerical Error Bound

We consider a rectangular region in the l, m plane, $0 \leq l \leq l^*$, $0 \leq m \leq m^*$, where $l^*/m^* = s$ as illustrated in Fig. 2. The magnitude of l^* is ultimately dependent on either available computer time or the degree of accuracy desired. The expression for the error, which consists of the sum over those mesh points lying outside the summing rectangle, may be calculated by breaking up the error sum into two regions, $l \leq ms$, $l \geq ms$ separated by the diagonal line $l = ms$. The methods for computing the error bound for these two regions are the same, so we shall discuss only the region $ms \leq l$.

We shall further subdivide the region $ms \leq l$ by defining the blocks

$$S_n : \begin{cases} n \leq mB < n+1\ , \quad n = 0, 1, 2 \ldots \\ l^* \leq l \end{cases} \qquad [26]$$

We shall bound the error in each of the blocks S_n.

The set of points included in the union of the blocks S_n includes the entire region $sm \leq l$ lying outside the summing rectangle and a considerable portion of the region $l \leq ms$ as seen in Fig. 2. However, the contribution of the overlap portion to the error has been shown to be unimportant and is only included for simplicity of the final error expressions.

In each of the blocks S_n, we use the following approximations

$$\sin(\pi y) \leq 4y(1-y) \qquad 0 \leq y \leq 1$$
$$g_{\alpha x} \leq 1/\pi x$$
$$(\pi b/a)\tanh(cr/a) \geq v \equiv (\pi k/a)\tanh(\pi cl^*/a)$$
$$1 + (rv/\pi) \geq 1 + lv \qquad [27]$$

The bound for S_o, which contributes the major error, may be separately calculated by showing

$$\sum_{l>l^*}^{\infty} \sum_{m \leq B^{-1}} g^2_{\alpha l}\, g^2_{\beta m} \{(1+\delta_{ol})(1+\delta_{om})\,[1 + (kr/a)\tanh(cr/a)]\}^{-1} \leq \int_0^{B^{-1}} (4By)^2 (1-By)^2 (\pi y)^{-2}\, dy \int_{l^*}^{\infty} (\pi x)^{-2} (1+xv)^{-1}\, dx \qquad [28]$$

so that

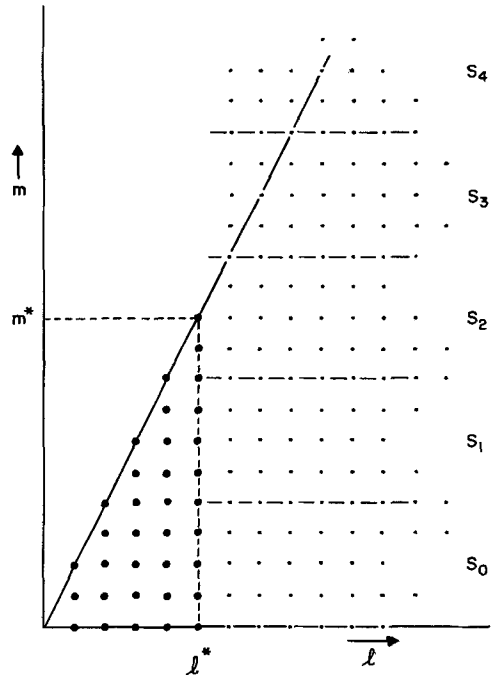

Fig. 2. Schematic representation of summing regions for error analysis.

$$\text{Err } S_o \leq (16B/3\pi^4)\,[(l^*)^{-1} - v \ln\{1 + (vl^*)^{-1}\}] \qquad [29]$$

To bound the error sum for the remaining blocks, we observe

$$\text{Err } S_n \leq (16/\pi^4)\left[\sum_{l=l^*+1}^{\infty} l^{-2}(1+vl)^{-1}\right] \times \left[(B^2/n^2)\sum_{m=(n/B)}^{[(n+1)/B]-1} (Bm-n)^2\,[1-(Bm-n)]^2\right]$$
$$\leq (16B^2/\pi^4 n^2)\{[(1/30B) + (1/16)] \times [(l^*)^{-1} - v\ln\{1 + (vl^*)^{-1}\}]\} \qquad [30]$$

so that

$$\sum_{n=1}^{\infty} \text{Err } S_n \leq (16B^2\, s_2/\pi^4)\,\{[(1/30B) + (1/16)] \times [(l^*)^{-1} - v\ln\{1 + (vl^*)^{-1}\}]\} \qquad [31]$$

where

$$s_2 \equiv \sum_{n=1}^{\infty} n^{-2} \simeq 1.645$$

Thus the error for $ms \leq l$ is bounded by

$$(16B/\pi^4)\{(l^*)^{-1} - v\ln[1 + (vl^*)^{-1}]\} \times \{(1/3) + (s_2/30) + (Bs_2/16)\} \qquad [32]$$

and the total error in the approximation to S is bounded by the inequality

$$\text{Error } (l^*) \leq (16/\pi^4)\left\{\left(\frac{1}{3} + \frac{s_2}{30}\right)(As+B) + \frac{s_2}{16}(A^2 s + B^2)\right\} \times \{(l^*)^{-1} - v\ln[1 + (vl^*)^{-1}]\} \qquad [33]$$

The values of m^* utilized ranged from 5 to 1400 and Error (l^*) was generally taken at 2%.

The High-Temperature Oxidation of Fe-Cr Alloys in the Composition Range of 25-95% Cr

C. S. Tedmon, Jr.

Research and Development Center, General Electric Company, Schenectady, New York

ABSTRACT

The oxidation behavior of Fe-Cr alloys containing 25-95% Cr has been studied over the temperature range of 1000°-1300°C. Near-parabolic kinetics were observed, but detailed structural analysis indicated that the scaling kinetics cannot be interpreted solely in terms of diffusion transport mechanisms. Structural characteristics of the scale and the scale-alloy interface must be considered. The tendency to spall increased with increasing Cr content; spalling behavior is analyzed in terms of the mechanical properties of both the oxide and the alloy. The Wagner analysis relating interdiffusion in the alloy to oxidation rates was applied to the Fe-Cr system, and qualitative agreement with experimental results was found. The observation that parabolic rate constants decreased with decreasing Cr content is discussed.

The extensive literature concerning the oxidation behavior of iron-chromium binary alloys is primarily oriented toward alloys containing up to about 26% Cr. (All compositions are reported in weight per cent.) Very little work has been directed to compositions richer in Cr.

The oxidation behavior of alloys containing less than 13% Cr is very complicated; scales form consisting of spinels and various other Fe and Cr oxides. Seybolt has shown, however, that when the Cr concentration at the metal-oxide interface exceeds 13% Cr_2O_3 is the stable oxide (1). Many of the Fe-Cr binary alloys which form Cr_2O_3 scales have oxidation kinetics controlled principally by cation diffusion through the oxide, although other factors such as surface preparation, scale adherence and blistering (2, 3), and oxide volatilization (4-6) may cause the kinetics to exhibit departure from parabolic behavior. Differences in the thermal expansion coefficients of metal and its oxide may also give rise to spalling tendencies. Tylecote has reviewed and summarized some of the factors which influence the adherence of oxides on metals (7, 8).

Another factor which must be considered when analyzing the oxidation behavior of Fe-Cr alloys is the gradual depletion in the Cr content of the alloy which occurs during oxidation. The interdependence of diffusion processes in the metallic and the oxide phase has been treated theoretically by Wagner (9). Wood and Whittle have experimentally demonstrated that, in the range of Cr contents of 28-68%, replenishment of Cr to the alloy oxide interface increases with decreasing bulk Cr content (10). This effect was attributed to the observation that the self-diffusion coefficients for Cr in Fe-Cr alpha-phase alloys increase with decreasing Cr content (11, 12).

There is a widespread technological need for new high-temperature, oxidation-resistant alloys. For certain applications at elevated temperatures where sigma-phase embrittlement is not a problem, binary Fe-Cr alloys rich in Cr are of interest. It was the purpose of this investigation to survey the high-temperature oxidation behavior of Fe-Cr binary alloys in the composition range of 25-95% Cr, and to attempt to elucidate the effects of such parameters as bulk alloy composition, temperature of oxidation, thermal expansion of alloys and oxides, and diffusive processes in the alloy and the oxide.

Experimental

Sample preparation.—Alloys in the range of 25-70% Cr were made from Ferrovac iron (vacuum-melted electrolytic iron). Fifty and 100g buttons were arc-melted under purified argon; the buttons were remelted 5 times to insure homogeneity. They were then hot-rolled at about 600°C to a final thickness of about 0.08 cm. For compositions containing more than 70% Cr, the procedure was the same except that samples were cut from the as-cast buttons.

Oxidation experiments.—Rectangular samples were obtained having a surface area of about 5 cm^2. All samples were surface ground and polished through No. 400-grit SiC paper and degreased and cleaned in toluene and acetone immediately before insertion into the spring balance furnace. With the exception of one set of experiments, all weight-gain data reported were obtained from samples having abraded surfaces. Since surface preparation has been demonstrated to have an effect on the scaling rates of certain Fe-Cr alloys (13, 14), a set of experiments was carried out on the Fe-45% Cr alloy in which various polishing and etching procedures were used to prepare the sample surface.

Isothermal weight-gain data were obtained using a helical quartz spring; the sample was hung on a sapphire rod that was suspended from the spring. The system was evacuated and the furnace brought to temperature. The desired atmosphere (dry O_2 at 100 Torr) was introduced into the furnace and the run was commenced. Sample temperature was measured with a Pt/Pt-10Rh thermocouple located in an Alundum tube, with its junction about ¼ in. from the center of the sample. Temperature control was about ± 5°C. Sample weight-change was determined by following a fiducial mark on the sapphire rod with a cathetometer. The sensitivity was about ± 30 $\mu g/cm^2$. When a run was completed, the furnace was turned off and the system was evacuated.

Thermal expansion measurements.—The coefficients of thermal expansion for alloys in the composition range of 13-100% Cr were measured using a Chevenard mechanical dilatometer. Differential measurements were made against a fused SiO_2 standard. Both heating and cooling cycles were recorded. All tests were carried out in an argon atmosphere.

Electron microbeam probe measurements.—Samples of Fe-45% Cr and Fe-80% Cr alloys were oxidized for 51 hr at 1100°C in pure O_2. The oxidized samples were then mounted in an electrically conducting base of copper-filled diallyl phthalate for examination in the microprobe. Scans for both elements were carried out in a Cambridge Mark II unit, which had been modified (15) so that the sample could be translated under a static beam in 4μ increments. The data at each point were collected on a scalar for a 10-sec counting period. The operating conditions were 30 kv with a specimen current of 0.1 μa, which resulted in 2000-9000 counts being recorded in the 10-sec interval, depending on the alloy and the component being scanned. Standard

data were taken at the beginning and the end of the run to correct for instrumental drift. Corrections were also made for background radiation and counter-tube dead time. The corrected relative intensities were converted to compositions using the Poole and Thomas atomic number correction (16), Philibert's absorption correction (17), and Castaing's fluorescence correction as modified by Green to correct for overvoltage (18). Using these procedures, the accuracy of the data is believed to be ± 5% of the total amount present.

Auxiliary measurements.—Metallographic and x-ray data were obtained using standard procedures. Debye-Scherrer patterns of oxide scale were made for various alloy compositions and oxidation temperatures; lattice parameters were also calculated. On several samples, the extent of metal recession and the thickness of the oxide scale were determined metallographically as a check on the weight-gain data.

Results

Kinetic measurements.—Gravimetric runs on samples of various compositions were run over the temperature range of 1000°-1300°C. Typical weight-gain *vs.* time data, plotted on logarithmic coordinates, are presented in Fig. 1a through 1e. A slope of ½ would indicate parabolic kinetics. It is apparent that most of the alloys exhibited rates which were approximately parabolic, although the 1100°C data for the lower Cr compositions are less consistent. Some of the runs were repeated to check the reproducibility of the data; generally fair agreement was found. For example, the 1100°C data plotted in Fig. 1e show about the best reproducibility obtained in these experiments at that temperature. Consequently, there resulted considerable scatter in rate constant data, which will be discussed later.

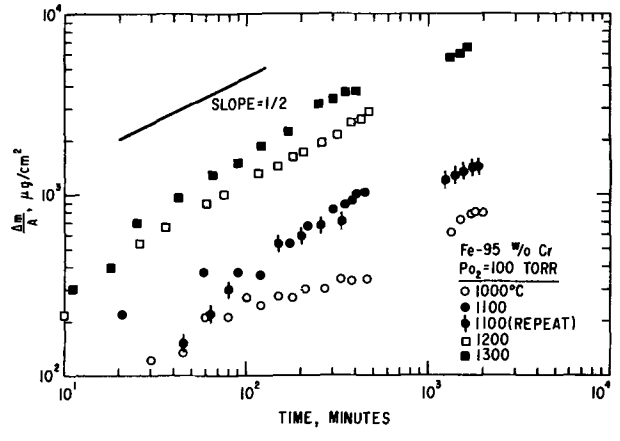

Fig. 1e. Typical gravimetric data for Fe-95% Cr alloys for the temperatures indicated.

It has been established that oxide volatilization, probably occurring by the reaction

$$Cr_2O_3(s) + \frac{3}{2}O_2(g) \rightarrow 2CrO_3(g) \qquad [1]$$

can influence the oxidation kinetics of Cr and Fe-Cr alloys (4-6). However, volatilization losses are usually negligible for short-time oxidation runs such as reported here (6), and indeed the amount of metal-recession measured on several samples was found to be consistent with the corresponding gravimetric data.

For data that fit the relation

$$\frac{\Delta m}{A} = (k_p t)^{1/2} \qquad [2]$$

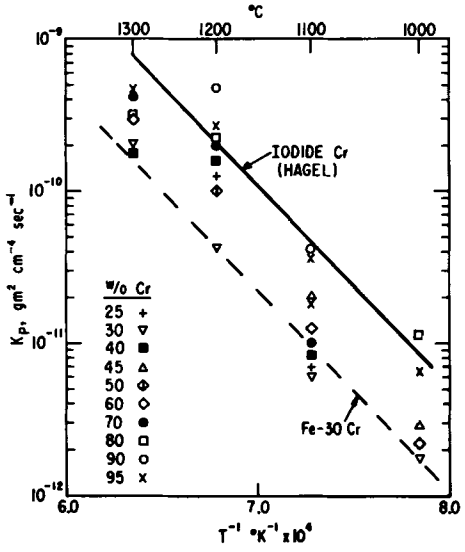

Fig. 2. Temperature dependence of the parabolic rate constant for the oxidation of various Fe-Cr binary alloys.

the parabolic rate constant, k_p, was determined. In Eq. [2], $\Delta m/A$ is the weight-gain per unit area, g-cm^{-2}, and t is the oxidation time in seconds. The temperature dependence of these data is shown in Fig. 2. The solid line indicates the temperature dependence of high-purity (iodide-grade) Cr, as given by the expression (4)

$$k_p \text{ (g}^2\text{ cm}^{-4}\text{ sec}^{-1}) = 0.111 \exp(-59{,}000 \pm 1800/RT) \quad [3]$$

It is obvious that there is considerable scatter in the variation of the rate constant data for a given composition at various temperatures, which obviates the possibility of determining the dependence of an activation energy for oxidation on alloy composition. A possible exception to this is the Fe-30% Cr alloy data, which plot on a straight line approximately parallel to the line for the iodide Cr. It is evident, however, and important to note, that most of the rate constant data for almost all alloys lie below the curve for pure Cr.

The compositional dependence of k_p is shown in Fig. 3. There is a clear trend of decreasing parabolic rate constant with decreasing Cr content of the alloy. The 1100°C data show the most scatter, which is not unexpected in view of the corresponding gravimetric data shown in Fig. 1 for this temperature. The values for pure Cr were obtained from ref. (4).

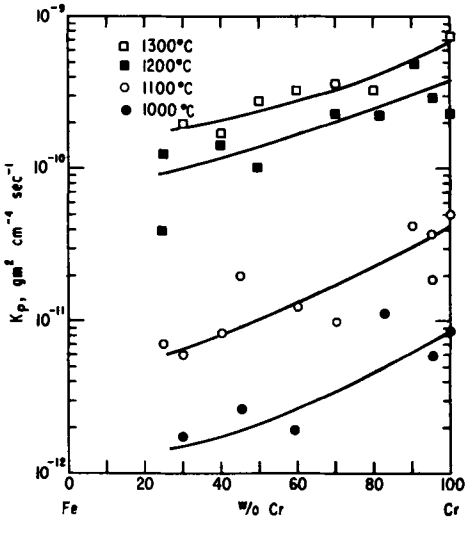

Fig. 3. Composition dependence of the parabolic rate constant of Fe-Cr binary alloys.

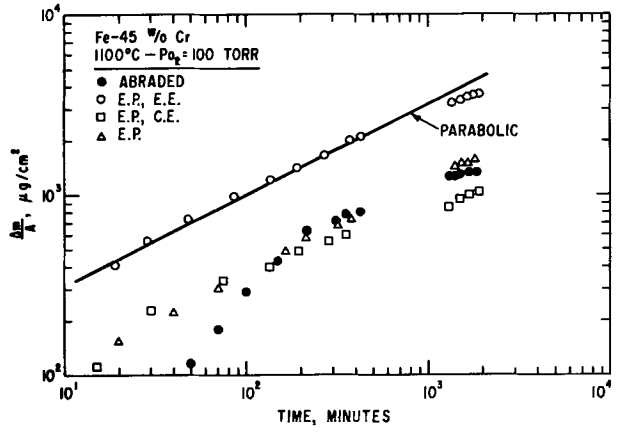

Fig. 4. Effect of surface preparation on the oxidation rate of Fe-45 w/o Cr alloy at 1100°C. Symbols: E.P., Electropolished in a 1:20 solution of 70% perchloric acid in ethyl alcohol for 60 sec. at 40v; E.E., electrolytically etched in a 1:20 solution of 48% HF in water for 50 sec at 3.2v; C.E., chemically etched in a 1:20 solution of 48% HF in water for 15 sec.

Figure 4 presents gravimetric data for samples of Fe-45% Cr that had various different surface preparations prior to oxidation. All the data exhibited essentially parabolic kinetics, and there was a negligible difference in the kinetics for samples that had been abraded, electropolished followed by chemical etching, or just electropolished. The sample which had been electropolished and then electro-etched oxidized considerably faster, however. Possible reasons for this effect will be discussed later.

Thermal expansion coefficients.—The compositional dependence of the coefficient of thermal expansion, at 1100°C, for the range of 13-100% Cr is shown in Fig. 5. The data for Fe-26% Cr include values obtained for several lots of commercial Type 446 stainless steel (Fe + 25-27 Cr). There is a fairly well-defined maximum in the curve in the vicinity of 23% Cr. At 1100°C, the thermal expansion coefficient for Cr_2O_3, obtained by extrapolation of data presented by Tylecote (7), is about 7.5 x 10^{-6}/°C. The mismatch in thermal expansion between the oxide and metal, which may be as much as a factor of 2, will certainly give rise to stresses in the oxide and local shear stresses in the metal adjacent to the metal-oxide interface when the sample temperature is changed, for instance, during cooling to room temperature after a run.

Metallographic observations.—Two general kinds of metallographic observations were made. First, the external surfaces of "as-oxidized" samples were examined at both low and high magnification. Thus topological features of the oxide scale could be observed, along with other structural characteristics such as oxide grain size and texture. Transverse cross-sections were then made, in order to examine other

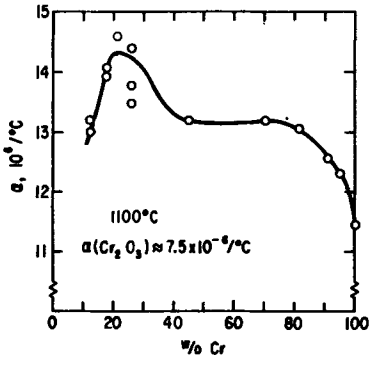

Fig. 5. Thermal expansion coefficient vs composition for the Fe-Cr system at 1100°C.

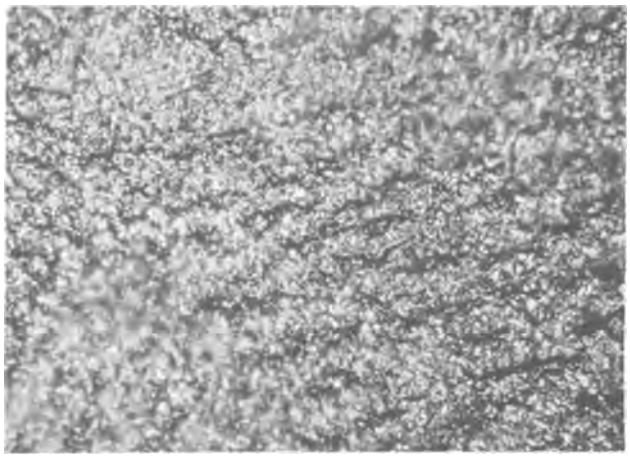

Fig. 6. Micrograph of the external surface of an Fe-30 Cr alloy sample oxidized at 1000°C for 53 hr. Magnification approximately 500X.

properties such as scale density, adherence to the metal, and the nature of the metal/oxide interface.

As is often the case with thermally grown oxides, the grain size was quite small, with the largest grains being about 50μ in diameter. There was no apparent dependence of oxide grain size on either oxidation temperature or bulk composition of the alloy.

The surface topology of the oxidized samples was quite interesting, in that the scales were usually quite wrinkled and irregular. Figure 6, for example, is a photomicrograph of the surface of a sample of Fe-30% Cr alloy oxidized for 53 hr at 1000°C. The oxide scales formed on alloys of this composition were usually quite adherent. At this rather high magnification (approximately 500X) it is readily apparent that the scale is quite wrinkled. The surface appearance of the oxide scales did not depend on oxidation temperature, but was sensitive to bulk alloy composition. An example of this is presented in Fig. 7, which is a low magnification (14X) photomicrograph of a sample of the Fe-70% Cr alloy. Blistering, ridges, and other surface irregularities are obvious and spalled regions are also present. In fact, alloys of this composition or richer in Cr spalled very badly; this particular sample was mostly spalled, and the region shown is one of the few places where the scale was at least partially intact and adherent. Note the difference in magnification betwen Fig. 6 and 7; at 14X, the surface of the sample shown in Fig. 6 would appear smooth and uniform.

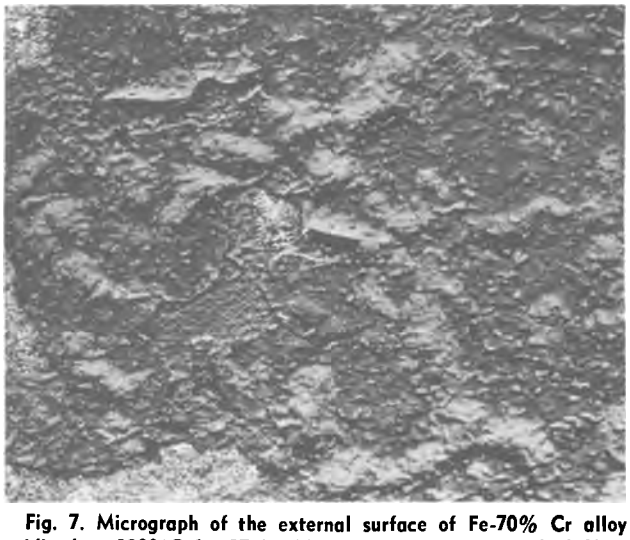

Fig. 7. Micrograph of the external surface of Fe-70% Cr alloy oxidized at 1300°C for 27 hr. Magnification approximately 14X.

In addition to the nonuniformity of the scales, there was oxidation attack at grain boundaries. This was most evident when examining the surface topology of spalled samples, as is shown for an Fe-70% Cr sample in Fig. 8. This sample was oxidized for 50 hr at 1000°C. An additional example of this grain boundary attack is shown in Fig. 9, which is a transverse cross section of a sample of Fe-30% Cr alloy oxidized for 30 hr at 1300°C. Note that where each grain boundary in the metal terminates at the oxide, there is excessive attack. There is also an area of accelerated attack where there is no metal grain boundary termination. Possibly the grain boundary responsible for this effect does not intersect the plane of the photomicrograph.

No obvious correlation could be found between grain boundary attack and spalling or between composition and grain boundary attack. The presence of voids in the scale near metal grain boundary junctures was common.

A general observation was that spalling during cooling became more severe as the Cr content of the alloy increased. As a first approximation, alloys containing less than 50-60% Cr showed considerably more spalling resistance than those alloys richer in Cr. This is opposite of what would have been anticipated from the consideration of the thermal expansion mismatches of the oxide and the alloys. From Fig. 5, it might be expected that spalling would be most severe in the range of 25-40% Cr, where the thermal expansion coefficients of the alloys are nearly a factor of two greater than that of the scale. Since spalling was most severe for alloy compositions where thermal expan-

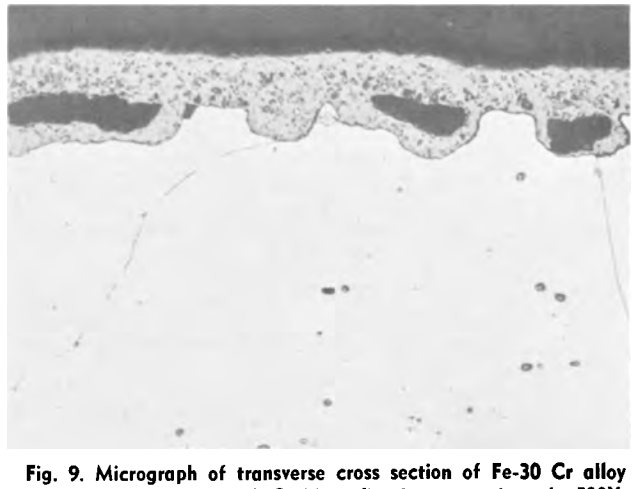

Fig. 9. Micrograph of transverse cross section of Fe-30 Cr alloy oxidized for 30 hr at 1300°C. Magnification approximately 500X.

sion mismatch was the least, it is apparent that some other explanation for the spalling tendencies is necessary. This point will be discussed later.

X-ray investigations.—Debye-Scherrer patterns were taken from the scales found on all alloy compositions. Room temperature lattice parameters were calculated, and values of $a_o = 4.960 \pm 0.001$Å and $c_o = 13.590 \pm 0.003$Å were obtained, regardless of the bulk composition of the alloy on which the scale formed, which implies that the amount of Fe dissolved in the Cr_2O_3 was very small. DiCerbo and Seybolt have reported lattice parameter data for the Fe_2O_3-Cr_2O_3 system (19). At the Cr_2O_3-rich end, the compositional dependence of the a_o parameter may be approximated by the relation

$$a_o \text{ (Å)} = 4.959 + 0.001 \text{ (\% } Fe_2O_3\text{)} \quad [4]$$

This relation is valid to Fe_2O_3 concentrations of about 30%. The lattice parameter data attained in this study therefore indicate that the Fe_2O_3 content in the Cr_2O_3 scales is less than 1%. This is in agreement with Seybolt's results (1).

Chromium-depletion at the metal oxide interface.—As was shown by the above results and by the work of Seybolt (1), the oxidation product of Fe-Cr binary alloys containing more than about 13% Cr is Cr_2O_3 which contains little or no Fe. Therefore, as the alloy oxidizes, the metal matrix becomes depleted in Cr. If depletion reaches the point that the Cr composition at the metal/oxide interface becomes less than 13%, then formation of a nonprotective oxide will ensue (1). Consequently, it is of considerable practical interest to have knowledge of the rate and extent to which Cr-depletion occurs in an alloy as oxidation proceeds and, in particular, to know the alloy composition at the metal/oxide interface.

A theoretical analysis of the problem has been presented by Wagner (9). He considered the case of a binary alloy of components A and B, in which only A oxidizes, and derived expressions which gave the composition of A as a function of distance from the metal/oxide interface and time. Of particular interest is his expression for the alloy composition at the interface. Using Wagner's notation, the mole fraction of A at the metal/oxide interface is given by

$$N_{A(i)} = \frac{F(u) - N_{A(b)}}{F(u) - 1} \quad [5]$$

where $N_{A(b)}$ is the mole fraction of A in the bulk, *i.e.*, the initial concentration of *A*. The term $F(u)$ is given by

$$F(u) = \pi^{1/2} u[1 - \text{erf}(u)] \exp(u^2) \quad [6]$$

where the general argument u is defined by the equation

$$u = \left(\frac{k_c}{2D}\right)^{1/2} \quad [7]$$

In Eq. [7], k_c is the Wagner "corrosion rate constant" ($cm^2\ sec^{-1}$), defined by the relation

$$\Delta x_{\text{metal}} = (2k_c t)^{1/2} \quad [8]$$

where Δx_{metal} is the amount of metal consumed during oxidation. The term D in Eq. [7] is the interdiffusion coefficient of the alloy (assumed by Wagner to be composition independent). Note that as defined by Eq. [5]-[8]

$$N_{A(i)} = f(k_c, D, N_{A(b)}) \quad [9]$$

Thus, in order to calculate the interface composition, only the oxidation rate constant, the interdiffusion coefficient, and the bulk, or initial composition of the alloy are required. Unfortunately, the interdiffusion coefficient D for the Fe-Cr system is composition-dependent (12, 20), so there is ambiguity as to which value of D should be used in the calculation of the interface composition. A conservative estimate of the

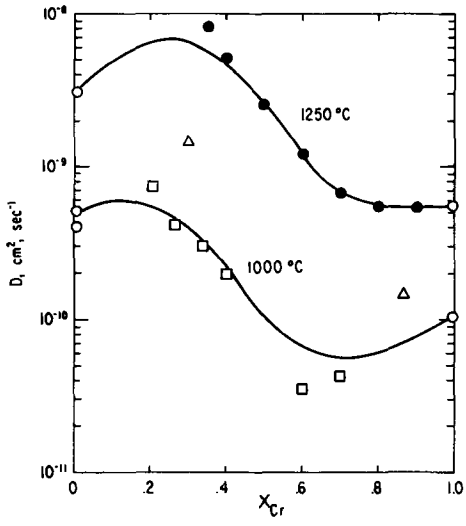

Fig. 10. Interdiffusion data for Fe-Cr system at temperatures indicated. • Ref. (12); □ ref. (16); △ Gorbunov *et al.* [taken from ref. (16)]; O calculated from ref. (17) and (18).

interface composition may be made in the following manner. By substituting Eq. [6] and [7] into Eq. [5], it can be seen that the minimum value of $N_{A(i)}$ possible for a given bulk concentration $N_{A(b)}$ will be determined by the minimum value of D for the composition range of interest. This is intuitively reasonable, since as it becomes more difficult for Cr atoms to move to the interface from the interior of the alloy, it would be expected that $N_{A(i)}$ would decrease. The substitution of Eq. [6] into [5] can be greatly simplified by the approximation

$$F(u) \cong \pi^{1/2} u, u << 1 \quad [10]$$

As an example of how the calculation of a minimum value of $N_{A(i)}$ is carried out, consider an Fe-30% Cr alloy. The minimum value of $N_{A(i)}$ possible for this alloy will be determined by the minimum value of D that exists in the composition range of 0-30% Cr. Obviously, values of D for Cr contents greater than 30% are of no interest in this case. Therefore, by choosing the minimum value of D that exists in the composition range of interest, *i.e*, the range 0% Cr to $N_{A(b)}$, it is possible to calculate the minimum value of $N_{A(i)}$ for the alloy that could occur at a given temperature.

Figure 10 presents all of the interdiffusion data for the Fe-Cr system that the author was able to find. It is surprising that for a system of such practical interest as Fe-Cr there are so few data.

Values of k_p for 1250°C were estimated by interpolation from the data shown in Fig. 1. The relationship between the "corrosion rate constant," k_c, and the "parabolic rate constant," k_p, as used in this study is given by

$$k_c = \frac{1}{2}\left[\frac{M_{Cr_2O_3}{}^{Cr}}{M_{Cr_2O_3}{}^{O}} \cdot \bar{V}_{Cr}\right]^2 \cdot k_p \quad [11]$$

where $M_{Cr_2O_3}{}^{Cr}$ and $M_{Cr_2O_3}{}^{O}$ are the grams of Cr and O per mole of Cr_2O_3, respectively, and $\bar{V}_{Cr}$ is the specific volume of Cr.

Using data as outlined above, the minimum value of $N_{A(i)}$ as a function of $N_{A(b)}$ was calculated for 1000° and 1250°C oxidation. The values used in the computations are given in Table I.

It should be remembered that the values of D presented in Table I are the minimum values that occur in the composition range of 0% Cr to $N_{A(b)}$. The results of the calculation are shown in Fig. 11.

Because of the uncertainties in the values used in the calculation, especially in D, the curves shown in Fig. 11 can be interpreted in semiquantitative terms only. They do, however, bring out several salient fea-

Table I. Values used in calculation of $N_{A(i)}$

tures. The calculations predict that the amount of Cr depletion at the metal-oxide interface will be quite small, on the order of a few per cent. This means that the replenishment of Cr to the metal-oxide interface should take place at rates that are fast compared to the rate of Cr loss in oxidation. Because the amount of depletion is expected to be small, Cr_2O_3 should always be the stable oxide in these alloys, regardless of the extent of oxidation, as long as the Cr content in the center of the sample is maintained at $N_{A(b)}$.

It is of interest to compare the predicted values of Cr depletion with experimental observations. The results of the probe scans are presented in Fig. 12. Traces for both elements are presented. Within experimental error, the compositions sum to 100%. No gradient could be observed in the Fe-45% Cr alloy, although scans were made at several points along the specimen, and consequently the composition near the interface is essentially the same as the bulk composition. A depleted zone was observed in the Fe-80% Cr alloy, with the interface composition being about 68%. Since the accuracy of the probe data is believed to be about ± 5% of the total amount present, the error in determining the Cr content at the interface would be about ± 3.5%.

It should be mentioned that considerable difficulty was experienced in measuring alloy compositions accurately and reproducibly at distances within about 10μ from the metal/oxide interface. The most probable reason for this is that the difference in hardness between the oxide scale and the alloy inevitably leads to some rounding-off of the metal near the interface, even when using the best metallographic procedures, such as vibratory polishing. This rounding-off of the metal can lead to an attenuation of the emitted x-rays. Furthermore, with the best focussing conditions, the incident electron-beam intersects a sample area of about 1μ^2. The amount of excited material in the alloy will therefore be several cubic microns, representing a volume that can be a few microns in diameter. Hence,

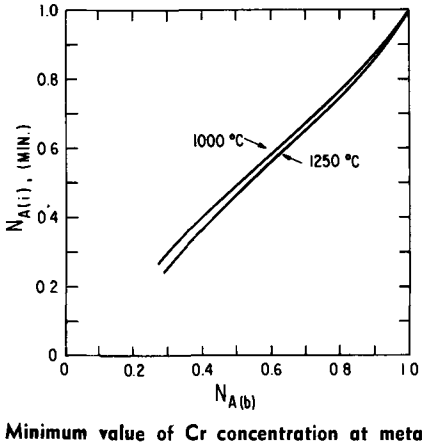

Fig. 11. Minimum value of Cr concentration at metal/oxide interface ($N_{A(i)}$) vs. bulk Cr concentration ($N_{A(b)}$), at temperatures indicated.

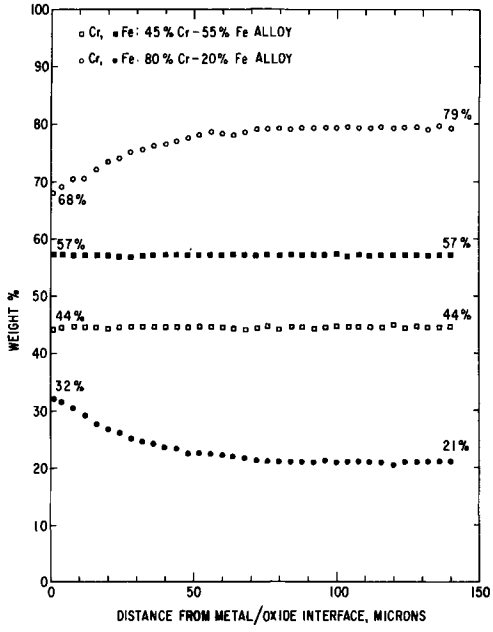

Fig. 12. Alloy compositions as a function of distance from the metal/oxide interface, for alloys oxidized 51 hr at 1100°C.

as the metal/oxide interface is approached to within 2 or 3μ, the excited volume emitting x-rays could include part of the scale, which in general has a different composition than the alloy. Using very great care, reliable composition data might be obtained as close as 5μ from the interface; a more reasonable distance would be about 10μ. Of course, if the metal/oxide interface is irregular, the situation becomes all the more complicated.

Discussion

Although parabolic kinetics were generally observed for all compositions and temperatures, it is apparent from the structural features of the scales and the variations in rate constant data that other factors besides diffusive transport mechanisms must be considered in attempting to understand the oxidation of Fe-Cr alloys. The fact that the gravimetric data plot in a smooth, continuous manner, with essentially parabolic kinetics, suggests that, at the temperature of oxidation, the scales which form are structurally integral and grow primarily by ionic diffusion. It is reasonably well established that in Cr_2O_3, cation diffusion (with appropriate concurrent electronic diffusion) proceeds much faster than anion diffusion (1, 4, 10, 23) and, therefore, will be rate-controlling. It is not known at this point whether the blistering and other structural irregularities in the scales formed during isothermal oxidation, during cooling, or both. The smooth appearance of the data suggests that scale deformation occurred during cooling. Scale porosity of the type shown in Fig. 9, however, could have formed at temperature. If the porosity in the scale of this alloy (Fe-30% Cr) did form under conditions of isothermal oxidation, then the true area for oxidation would be less than the apparent geometric area of the sample (assuming mass transport across the voids is negligible), and seemingly slower kinetics would result. However, if blister volume is small and the blisters form at random times, then parabolic kinetics would still obtain. The cause of the accelerated attack at grain boundaries is not known, although it could be induced by impurities which segregated there.

It is reasonably certain that spalling occurred during cooling. In support of this is the observation that spalled surfaces were fairly bright and untarnished. Since the samples cool slowly in the furnace, this implies that spalling probably occurs below 600°C. Presumably there is some minimum stress required to

cause spalling. The value of this stress will depend on many factors, such as the amount of porosity in the scale, the nature of the metal/oxide interface, relative strengths of the scale and the alloy, and the thickness of the scale. Specimen geometry will also be important. In any case, however, the stress required for spalling will be equal to the sum of the stresses generated during isothermal oxidation (σ_I) plus stresses arising during athermal conditions (σ_A), *i.e.*,

$$\sigma_s = \Sigma\sigma_I + \Sigma\sigma_A \qquad [12]$$

Cohen and his co-workers have observed the formation of highly irregular scales on both pure Cr and Fe-Cr alloys (2, 14, 24, 25), and concluded that the defects in the scales formed during the isothermal oxidation. The origin of the defects was believed to be associated with compressive stresses generated in the scale during growth (14). If that were the case, then the isothermal contribution to σ_s in Eq. [12] would be small, since stress relief is occurring at temperature. Other evidence that the isothermal stress contributions will be small are the observations by Westbrook (26), who has shown that the hardness of most common oxides decreases rapidly at temperatures above about one-half the absolute melting point. For Cr_2O_3, 0.5 T_m = 860°C, so it is reasonable on that basis to expect Cr_2O_3 to be capable of plastic deformation at temperatures of 1000°C or higher.

The strong dependence of spalling behavior on composition in these alloys cannot be accounted for by the mechanical properties of the oxide, however. Since Cr_2O_3 scales have essentially stoichiometric compositions, independent of the bulk composition of the alloy, it would be expected that the mechanical properties of the oxide ought to be independent of the bulk alloy composition. Of course, it is possible that the defect concentration of the scale could vary with alloy composition, in which case the mechanical properties would vary in a related manner. However, there is no evidence to support this.

Some insight into this problem may be gained by considering the compositional dependence of the high-temperature strength of Fe-Cr binary alloys, which is presented in Fig. 13 (27). The high-temperature strength of the alloys increases rapidly with increasing Cr content; for example, at 1000°C, the hardness increases by more than a factor of 4 as the Cr content is increased from 50 to 100%. It is suggested, therefore, that the Fe-rich alloys have more resistance to spalling because their relative lack of high-temperature strength permits them to accommodate by plastic flow the stresses arising during cooling from mismatch in thermal expansion coefficients. These data provide support for the hypothesis that stress relief by plastic deformation of the metal adjacent to the scale is an important factor in preventing or reducing spalling. In summary, then, the principal contribution to the spalling stress arises during athermal conditions. Stresses generated under isothermal conditions, during scale growth, are relieved by plastic deformation of both the scale and the metal. During cooling, however, the yield stress of the oxide increases and the scale is no longer capable of relieving stress by flow. Consequently, stress relief will depend on the capability of the metal adjacent to the scale to flow. Alloys rich in Cr have higher strengths at a given temperature than alloys rich in Fe; consequently they cannot deform as easily and therefore spall more readily.

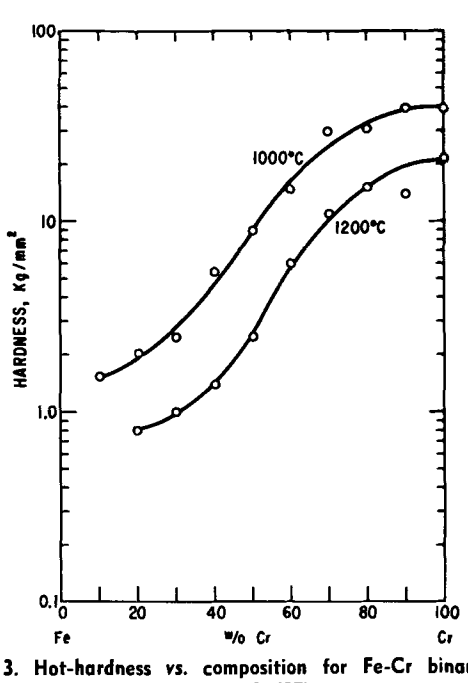

Fig. 13. Hot-hardness *vs.* composition for Fe-Cr binary alloys at temperatures indicated, after ref. (27).

The results from the interface-depletion experiments and calculations may be considered to be in fairly good agreement. The results of the microprobe scans are in excellent agreement with the data of Wood and Whipple (10). It is evident, at least from the data obtained from the Fe-80% Cr alloy, that somewhat greater Cr depletion occurs in the alloy during oxidation than was predicted from the calculation. The Cr concentration near the interface was observed to be 68 ± 3.5%, indicating a depletion of about 12%, whereas the predicted depletion would be about 4% (obtained by interpolation of the data in Table I). A more refined method of calculating interface compositions from Wagner's equation may be possible, but is probably not warranted at this time because of the lack of good data, particularly interdiffusion coefficients.

The decrease in rate constant, k_p, with decreasing Cr content (Fig. 3) is of interest. If Fe^{+2} ions were present in solid solution in the scale, a decrease in Cr^{+3} diffusion would be expected, according to the model of Hauffe (28). However, only amounts on the order of the Cr_2O_3 cation-vacancy concentration are required, so it is not obvious why an extended dependence on Fe concentration is observed. An alternative explanation is that, as the over-all Cr content of the alloy is decreased, the Cr content at the metal/oxide interface is decreased. In the temperature range of 1200°C, the Fe-Cr system is nearly thermodynamically ideal (29, 30), hence the Cr activity at the interface is essentially numerically equivalent to the mole fraction of Cr at the interface. As the Cr content of the alloy is decreased, the Cr content and therefore the Cr activity at the metal/oxide interface decreases. For oxidizing conditions where the partial pressure at the gas/oxide interface remains invariant, a decrease in Cr activity at the metal/oxide interface will decrease the chromium activity gradient across the oxide, resulting in slower oxidation kinetics. This argument is very similar to that used by Phalnikar *et al.* (31) to explain their results for the Co-Cr system.

Finally, it is of interest to speculate on the sensitivity of oxidation kinetics to surface preparation. Caplan *et al.* (13) have demonstrated a pronounced dependence of surface preparation on the oxidation of pure Cr and Fe-Cr alloys in the range of 0-26% Cr. In particular, they found that Fe-Cr alloys with electropolished surfaces had a markedly higher initial reaction rate during high-temperature oxidation than samples with other surface preparations. It has been suggested by Wood (3) that such an effect could be caused by the presence of a thin film which contained Cr^{+6} ions. The presence of these ions in the scale during the initial stages of oxidation would lead to an increased cation vacancy concentration and hence increased oxidation rates. In this study, the sample prepared by electropolishing did not exhibit kinetic behavior markedly different from the sample that had an abraded surface or an electropolished-chemically

etched surface. It is possible that the sample which had been given an electro-etch prior to oxidation did have on it a thin film containing Cr^{+6} ions, in which case Wood's argument would apply.

Conclusions

The oxidation behavior of Fe-Cr alloys in the composition range of 25-95% in dry O_2 has been studied and found to be composition-dependent. Essentially parabolic kinetics were observed over the entire range of Cr concentrations; parabolic rate constants decreased with decreasing Cr content. Alloys containing less than about 50-60% Cr had superior resistance to spalling than did alloys richer in Cr. Although severe mismatch exists in the coefficients of thermal expansion of the alloys and Cr_2O_3, it is suggested that stress relief by plastic flow of the metal near the scale/alloy interface plays a dominant role in reducing spalling tendency. The Wagner analysis relating metal interdiffusion in alloys to oxidation rates of the alloys was applied to the Fe-Cr system. It was concluded that Cr depletion at the metal/oxide interface will not be a significant problem.

Acknowledgments

Appreciation is extended to D. E. Broecker, who made the kinetic measurements, and to R. E. Carter, P. J. Jorgensen, A. U. Seybolt, and D. W. White, who critically reviewed the manuscript.

Thermal Regeneration of Oxide Covered Iron {100} and {110} Surfaces

H. Thomas Yolken and Jerome Kruger

Institute for Materials Research, National Bureau of Standards, Washington, D. C.

ABSTRACT

The effects of ultrahigh vacuum annealing on thin oxide films grown to a limiting thickness at room temperature on {100} and {110} iron surfaces were studied using an ellipsometer. After vacuum annealing at 400°C or above these films, which showed essentially no change in optical properties, grew when reexposed to 1 x 10^{-5} Torr of oxygen at 25°C. This process could be repeated several times, with the film each time exhibiting a greater limiting thickness until a thickness was reached which could not be appreciably increased by further annealing. The thermal regeneration of oxide covered iron can be explained by a phase change of the oxide film from Fe_3O_4 to FeO on annealing at about 400°C or above. Cooling to room temperature causes the reappearance of Fe_3O_4. Thin areas in the oxide film and some enrichment of iron in the film are the results of the phase changes. Concurrently, the adsorbed monolayer of oxygen anions is incorporated in the oxide during annealing.

When some metal surfaces are exposed to oxygen at room temperature, an oxide film grows until a limiting thickness is reached. If this oxide covered metal surface is then annealed in vacuum, the oxide film which had previously ceased growing will start to grow again when reexposed to oxygen at room temperature. This effect was called "thermal regeneration" by Dell (1) who studied the oxidation of cobalt, nickel, and copper. Thermal regeneration, or a process resembling it, has also been studied by Zettlemoyer and co-workers (2) (copper, nickel, and cobalt); Dell and Stone (3) (nickel); Anderson and Klemperer (4) (nickel); and Burshtein and co-workers (5) (iron).

Several possible mechanisms have been proposed by these authors to explain thermal regeneration: (*i*) the incorporation of the monolayer of oxygen anions into the oxide during heating in vacuum, and then the subsequent adsorption of a new monolayer of oxygen anions on readmission of oxygen at room temperature (1, 2, 4); (*ii*) the dissolution of the oxide into the bulk of the metal in some systems [*i.e.*, Cu] (1); (*iii*) the recrystallization of the oxide film into thicker crystallites which cover part of the surface leaving bare metal exposed in between (1, 4); and (*iv*) the diffusion of metal to the oxide-gas interface (5).

This study is a continuation of previous work done in our laboratory on the early stages of oxidation of polycrystalline iron (6). In the present study, the oxidation of {100} and {110} iron surfaces is investigated, and the effects of thermal regeneration on oxide films formed on these surfaces are studied.

The present work differs from that of previous workers in several respects. The changes produced by annealing were followed by observing variations in film thickness and properties with an ellipsometer capable of detecting changes as small as 0.5Å in film thickness (7). Annealing temperatures from 25° to 700°C were investigated. This was an extension of the temperature range studied by Burstein and co-workers (5) for iron (25°-300°C) and its importance will be discussed later. The emphasis in this study was on direct surface measurements of well-defined single crystal surfaces prepared in ultrahigh vacuum. This was not the case for previous work in the literature except for the photoelectric measurements on evaporated, polycrystalline nickel films by Anderson and Klemperer (4). Our work also included the use of a mass spectrometer to detect possible evaporation or desorption of oxygen from the oxide film during annealing.

Experimental Procedure

Vacuum system.—The ultrahigh vacuum system was an ion pumped, bakeable, stainless steel system. Pure hydrogen or oxygen could be introduced by diffusion through nickel or silver thimbles (8), respectively. Precise control (± 5%) of the oxygen pressure was obtained by allowing the oxygen from the silver diffusion leak to build up behind a precision mechanical leak valve before admission to the system. The ambient pressure after a 325°C bake for 8 hr was 5 x 10^{-10} Torr[1] as measured by a triggered cold cathode discharge gauge. The gauge produced no detectable contamination. Gases in the system were analyzed by a bakeable 90° magnetic deflection mass spectrometer capable of detecting partial pressures of 10^{-13} Torr. The specimen chamber contained strain-free quartz windows positioned perpendicular to the ellipsometer light beam, which was at a 66° angle of incidence with the iron surface.

Specimen preparation.—Smooth, flat, strain-free (as determined by x-ray diffraction), and clean (monolayer or less of adsorbed gas) {100} and {110} surfaces (about 1 cm^2 surface area) were prepared from floating-zone refined iron[2] obtained from the Battelle Memorial Institute. The preparation of these oxide free specimens is described elsewhere (9).

The temperature of the specimen was determined by an infrared pyrometer which had been calibrated previously using a thermocouple attached to a dummy specimen. The infrared pyrometer removed the possibility of contamination to the specimen by a thermocouple.

Oxidation and thermal regeneration.—All oxidation was done at an oxygen pressure of 1 x 10^{-5} Torr and 25°C. The kinetics of oxidation of clean iron {100} and {110} surfaces were studied by admitting oxygen to the system after the specimen had been cleaned by using the procedure mentioned earlier. Ellipsometric measurements were made during the film growth to determine film thickness. The method used to evaluate these results is described elsewhere (10).

After a limiting oxide thickness[3] was reached, the oxygen was pumped out of the system and a pressure of 5 x 10^{-10} Torr was obtained. The specimen was

[1] 1 Torr = 133.32 newton/$meter^2$.

[2] As received—gaseous impurities (ppm by weight): O_2 (vacuum fusion), 2.1; S (colorimetric), 4 ± 3; C (combustion-conductometric), 3 ± 3; N_2 (vacuum fusion), 0.5; H_2 (vacuum fusion), 0.3. Major metallic impurities (ppm): Al, 15; Cr, 5; Co, 5; Cu, 7; Ni, 20; P, 9; Si, 10.

[3] Growth rate less than 10^{-12} cm/s.

thermally regenerated by heating to a given temperature using R.F. induction heating and then cooling to room temperature. During annealing the mass spectrometer was used to analyze the gases being evolved. Thermal regeneration was studied using annealing temperatures from room temperature to 700°C and various annealing times. Ellipsometric measurements were repeated to detect any changes in the film that resulted from heating in vacuum. Oxygen was readmitted to the system at a pressure of 1×10^{-5} Torr, and ellipsometric readings were taken during oxidation of the thermally regenerated surface at 25°C.

After a new limiting thickness was reached the system was evacuated to 5×10^{-10} Torr. The specimen was thermally regenerated a second time by annealing at a given temperature and then cooling to room temperature. Oxygen was readmitted, and the regenerated surface oxide grew again. This cycle was repeated several times.

Results

Initial oxidation of {100} and {110} iron surfaces.—Figure 1 shows the growth kinetics of the early stages of oxidation of the unregenerated {100} and {110} surfaces of iron. The data for the later stage of the oxidation of the {100} and {110} surfaces of iron follows either a direct logarithmic growth rate (Fig. 2) or an inverse logarithmic growth rate. These results are given here to show that growth kinetics of the film that is to be thermally regenerated. They are in agreement with our earlier work (9) where a detailed discussion of the results for polycrystalline iron is given. There have been several proposed mechanisms for oxidation such as this at room temperature in the thin film region (<100Å) (12-16).

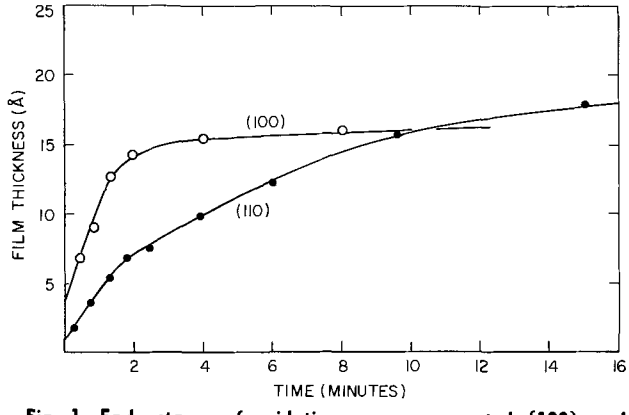

Fig. 1. Early stages of oxidation on unregenerated {100} and {110} surfaces of iron at 25°C and 1×15^{-5} Torr of oxygen.

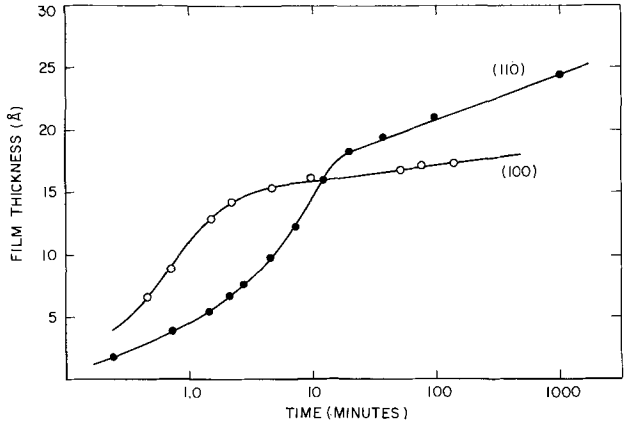

Fig. 2. Direct logarithmic plot of the oxidation of unregenerated {100} and {110} iron surfaces at 25°C and 1×10^{-5} Torr of oxygen.

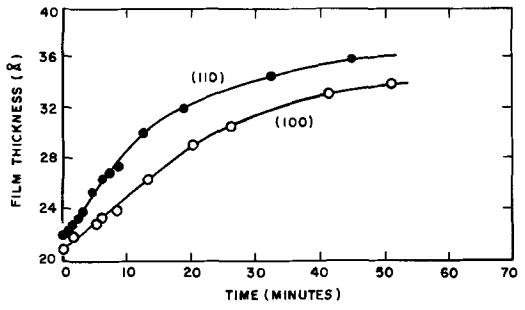

Fig. 3. Early stages of the oxidation of an iron surface once regenerated at 500°C; the {100} and {110} regenerated surfaces were oxidized at 25°C and 1×10^{-5} Torr of oxygen.

Thermal regeneration of oxide covered {100} and {110} iron surfaces.—After the initial oxidation, the film was annealed at various temperatures in a vacuum. This annealing, which altered the film so that further film growth could occur on the readmitting of oxygen at room temperature, caused very little change in the ellipsometer readings, no more than 0.1° in the polarizer or analyzer values. In Fig. 3 the kinetics of the early stages of oxidation of an oxide film so regenerated one time at 500°C for 1 min on both {100} and {110} iron surfaces are shown. The rates are less than those for the oxidation of the unregenerated surfaces. Also, the initial (nonlogarithmic) portion of the curves involves less film growth for the regenerated case. The data for the regenerated surfaces also followed a logarithmic growth in the latter stages of oxidation as can be seen from Fig. 4.

The increases in oxide thickness on each thermal regeneration and oxidation (ΔX) decreases with successive thermal regenerations until ΔX reaches a constant low value of about 2-3Å at an over-all oxide thickness of approximately 100Å. Figure 5 shows ΔX for successive regenerations at 600°C.

Figure 6 shows the effect of annealing temperature (all anneals shown are 30 sec at temperature); ΔX does not decrease as shown in Fig. 5, but tends to increase, when the temperature is raised in the 400°-700°C range. This is in spite of the fact that the ΔX values shown here for successive temperature changes are smaller than they would be if each regeneration at higher temperature were made on a new unregenerated film. Thus, the increase is damped due to the decreasing effect of successive regeneration.

Annealing in the 200°-400°C range produced ΔX's of only 2-3Å, while ΔX's greater than this could only be produced by annealing at temperatures greater than roughly 400°C. It should also be noted in Fig. 6 that ΔX decreases as expected from Fig. 5 when the temperature is held at 485°C for two successive regenerations. Room temperature annealing for periods as

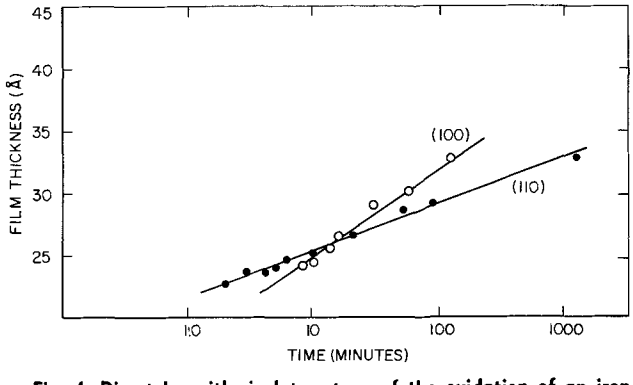

Fig. 4. Direct logarithmic later stage of the oxidation of an iron surface twice regenerated at 500°C. The {100} and {110} regenerated surfaces were oxidized at 25°C and 1×10^{-5} Torr of oxygen.

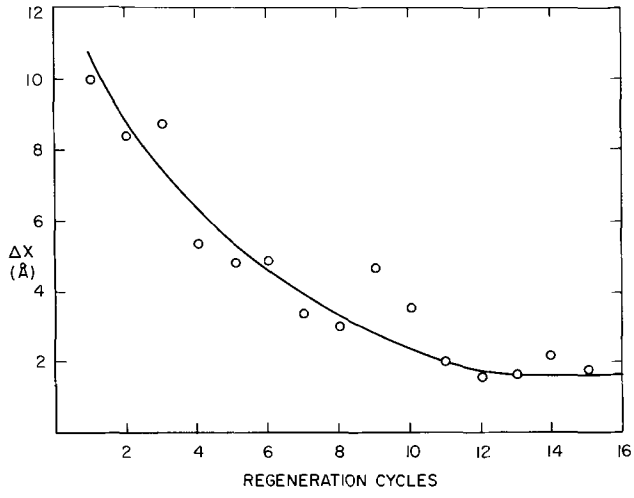

Fig. 5. Variation of the increase in oxide thickness on each thermal regeneration and oxidation (ΔX) with successive thermal regenerations at 600°C and oxidation cycles at 25°C and 1 × 10^{-5} Torr of oxygen.

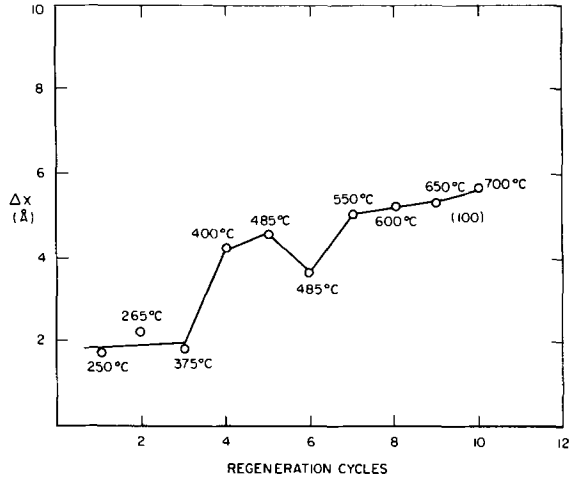

Fig. 6. Effect of annealing temperature in the 250°-700°C range on ΔX for a {100} surface.

long as two weeks in ultrahigh vacuum produced no detectable regeneration. ΔX also appeared to be independent of annealing time for times greater than about 30 sec (shortest time studied) to the longest time studied (15 min at 375°C).

Figure 7 shows electron micrographs of the {100} surface with about 25Å of oxide before thermal regeneration and with about 100Å of oxide after 12 cycles of oxidation and thermal regeneration. The regenerated surface is noticeably roughened compared to the unregenerated surface.

During annealing from room temperature to 700°C no detectable amounts of oxygen were evolved. However, annealing specimens contaminated with carbon did produce CO, along with a noticeable reduction in the film thickness as determined ellipsometrically. This problem did not occur for specimens with low carbon content (10 ppm). After annealing "carbon free" specimens the film thickness appeared to remain constant or to decrease very slightly (< 3Å); an increase in film thickness never occurred during annealing.

Discussion

These data can be used to construct a plausible explanation of thermal regeneration which depends on the phase transformation that occurs in Fe_3O_4 on heating above about 400°C. The importance of this phase transformation on the thermal regeneration of iron was not detected by Burstein and co-workers (5) in their iron powder studies, because they worked below 300°C. The transformation temperature usually quoted is 570°C, but this is in equilibrium with 1 atm of air. Transformation of Fe_3O_4 to FeO in vacuum below 570°C was reported by Haase (18). Also, recent (low angle-high energy electron diffraction) work on iron in the same type of system by Mitchell and Sewell (19) shows this transformation to occur at about 450°C in ultrahigh vacuum. They state that this transformation appears to be time, temperature, and oxide thickness dependent. Finally, low energy electron diffraction studies of a {100} iron surface by Pignocco and Pellissier (20) have also shown that for coverages of oxygen in the monolayer or less range, an FeO type structure is stable in ultrahigh vacuum at 25°C.

These transformations will produce two changes in the film: (*i*) an increase in its iron content and (*ii*) thin areas. The first change occurs because iron from the bulk will diffuse into the oxide to supply the iron needed for the following reaction:

$$Fe_3O_4 + Fe\ (\text{bulk}) \xrightarrow{\text{heat in vacuum}} 4Fe_{x<1}O \quad (\text{cation deficient})$$

On cooling, the FeO will transfer back to Fe_3O_4 resulting in an iron rich film

$$4FeO \xrightarrow{\text{cooling in vacuum}} Fe_3O_4 + Fe\ (\text{precipitated})$$

As Fig. 7 shows, the second change due to recrystallization initiated by the transformation produces a film that is much less uniform in thickness (thin areas and roughening). Since large values of ΔX occur only above about 400°C (the average of several experiments), the phase change which occurs at about the same temperature is indicated as being responsible for the roughening.

Since the ellipsometer readings were almost constant both before and after annealing, this roughening can be attributed to a rearrangement of oxide and not a removal of oxide from the surface. On readmission of oxygen at room temperature these thin areas should grow back to a limiting thickness first following linear and then logarithmic kinetics.

Besides the possible production of thin areas by the phase transformation as described above, iron enrichment in the Fe_3O_4 lattice by diffusion, or the presence of precipitated iron produced after the transformations may be the main reasons for the ability of the film to grow after cooling. The fact that the optical measurements after annealing change very little indicates, however, that drastic changes in the film composition have probably not taken place.

The decrease in ΔX with successive regeneration cycles is consistent with the explanation described because as the film roughens and thickens with each cycle, ΔX decreases. This occurs because the possibility for producing areas by recrystallization thin enough to be below the limiting thickness decreases as the over-all film thickness increases. Thus, ΔX should finally become zero when the thin areas in the film are

no longer regenerated to less than the limiting thickness. The fact that ΔX is never reduced to zero, but always remains about 2-3Å is probably due to two causes: readsorption of a monolayer or less of oxygen on the surface, and a slight film growth due to the Fe_3O_4 being richer in iron after the transformation from FeO.

The small amount of growth observed when oxygen is admitted at room temperature after annealing at temperatures below 400°C can be attributed to the above-mentioned readsorption of a monolayer or less of oxygen and its subsequent incorporation upon annealing. This is probably the first step in every instance of growth after annealing and cooling.

The effect of increasing temperature, which increases ΔX in the 400°-700°C range, is consistent with the explanation given for thermal regeneration in one or both of the following ways: (*i*) FeO (wüstite) has a variable composition with the oxide becoming richer in iron as the temperature is increased. This will result in an iron rich Fe_3O_4 whose composition is dependent on the annealing temperature of the FeO; (*ii*) higher temperatures could produce rougher surfaces due to enhanced grain growth of FeO during annealing.

In summary, these data thus suggest that the following two steps, either together or separately, are involved in the thermal regeneration of iron: (*a*) incorporation of the adsorbed monolayer of oxygen into the oxide from 250°C to the highest temperature studied, 700°C; (*b*) a phase change from Fe_3O_4 to FeO on annealing from 400° to 700°C and a phase change back to Fe_3O_4 on cooling. Thin areas in the oxide films and enrichment of iron in the oxide are a result of these phase changes.

Acknowledgment

The authors wish to thank Mrs. Mary Ann Giles for providing them with the electron micrograph.

Thermodynamic Interaction between Zinc and the Dilute Solutes Antimony, Bismuth, and Cadmium in Solution In Liquid Lead

R. D. Pehlke, K. Okajima,[1] and T. L. Moore[2]

Department of Chemical and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan

ABSTRACT

The activity of zinc has been measured in dilute liquid lead alloys containing small additions of a third element. The study which was conducted in the temperature range 450°-650°C employed a galvanic cell with a liquid chloride electrolyte. The concentration cell was

Zn (Pure Liquid)	Zn^{++} (In Fused KCl + LiCl Electrolyte)	Zn + Third Element in Pb (liquid alloy)

The activity of zinc in the dilute lead-zinc binary shows Henry's law behavior at concentrations up to 0.0375 mole fraction zinc. The activity of zinc in lead exhibits a strong positive deviation from Raoult's law, the activity coefficient at infinite dilution being 11.4 at 550°C. Measurements have been made of the influence of antimony, bismuth, and cadmium on the activity coefficient of zinc in liquid lead. Antimony markedly decreases the activity coefficient, while cadmium and bismuth slightly decrease the activity coefficient of zinc in liquid lead. These results have been summarized in terms of first-order interaction parameters which can be expressed as a function of temperature by the relations

$$\epsilon_{Zn}^{Sb} = -\frac{8840}{T°K} + 2.84$$

$$\epsilon_{Zn}^{Bi} = -\frac{2950}{T°K} + 2.81$$

$$\epsilon_{Zn}^{Cd} = -\frac{1000}{T°K} + 0.68$$

The thermodynamic interaction between elements dissolved in liquid metallic solutions is of both scientific and engineering interest. An adequate representation of the equilibria encountered in systems involving liquid metallic solutions is only possible if the effects of one solute on the activity coefficients of other solutes are taken into account. The determination of these mutual thermodynamic influences, or interaction parameters, has been attempted on both theoretical and experimental grounds.

The theoretical, or more often empirical, considerations employed in an effort to determine a general approach to predicting interaction parameters have been the subject of several contributions to the scientific literature. Several approaches have been attempted including correlation with the electron to atom ratio (1), or relative electronegativity (2-4). A systematic variation of interaction parameters on the basis of periodicity with atomic number has been noted by several investigators including Ohtani and Gokcen (5). Alcock and Richardson (6) have used a chemical approach in considering solvent-solute and intersolute binding energies to derive a semiquantitative expression for predicting interaction parameters. Similar concepts have been employed in other investigations (7, 8).

The primary goal of these investigations has been to develop a method for predicting intersolute effects based on information relating to the physical structure and general thermodynamic properties of liquid metallic solutions. The theoretical progress has been limited, largely because of the lack of experimental results on which theoretical models could be based. Although a number of investigations have treated interactions between solutes, much of the research has been limited to interstitial elements in liquid iron (9), and to certain nonferrous alloys in more concentrated solutions (10). Some recent work (4, 11-15) has been directed toward a systematic investigation of intersolute effects in dilute metallic solutions.

An estimation of the activity coefficient of a solute in a liquid metallic solution can be made based on the activity coefficient in a dilute binary, if additional terms are added which relate to interactions with any additional dilute solute elements. Wagner (16) has suggested an expression for calculating the activity coefficient of a dilute solute based on the Taylor series expression for the logarithm of the activity coefficient

$$\ln\gamma_i = \ln\gamma_i^{o} + \left[x_i \left(\frac{\partial \ln\gamma_i}{\partial x_i}\right)_{x_i=x_j=0} + x_j \left(\frac{\partial \ln\gamma_i}{\partial x_j}\right)_{x_i=x_j=0} + \dots \right] + \left[\frac{1}{2} x_i^2 \left(\frac{\partial^2 \ln\gamma_i}{\partial x_i^2}\right)_{x_i=x_j=0} + x_i x_j \left(\frac{\partial^2 \ln\gamma_i}{\partial x_i \partial x_j}\right)_{x_i=x_j=0} + \frac{1}{2} x_j^2 \left(\frac{\partial^2 \ln\gamma_i}{\partial x_j^2}\right)_{x_i=x_j=0} + \dots \right] + \dots \quad [1]$$

where i = primary solute, j = added solute(s), k = solvent, and x_i, etc = concentration in mole fraction. The higher order terms of the expansion take into account the effects of the interaction of every dilute solute and their combined effect on the activity coefficient of the primary solute. The small contribution of these terms in dilute solutions can be accounted for by extrapolation to zero concentration. The partial derivatives in the resulting first-order expression are of the form

[1] Present address: Department of Metallurgy, Nagoya University, Nagoya, Japan.
[2] Present address: Inland Steel Company, East Chicago, Indiana.

$$\epsilon_i^i = \left(\frac{\partial \ln \gamma_i}{\partial x_i}\right)_{x_i=0}, \text{ self-interaction parameter} \quad [2]$$

$$\epsilon_i^j = \left(\frac{\partial \ln \gamma_i}{\partial x_j}\right)_{x_i=x_j=0}, \text{ ternary interaction parameter} \quad [3]$$

and are customarily given the shorthand notations ϵ_i^i, the self-interaction for solute i, and ϵ_i^j, the individual interaction parameter relating the influence of various solutes, j, on the logarithm of the activity coefficient of solute i. Since these expressions form a convenient means for handling data on solute interactions, the available literature was surveyed (17, 18) for the purpose of presenting experimental data in this form. This survey of the literature revealed limitations of the available data. The purpose of the present investigation was, therefore, to evaluate experimentally the interaction between several alloying elements and zinc dissolved in liquid lead. It is hoped that this investigation will extend present data and expand the possibilities for additional theoretical work in this area.

The interactions studied in this investigation were those between antimony and zinc, bismuth and zinc, and cadmium and zinc in dilute solution in liquid lead. Other related studies (19, 20) have been discussed elsewhere.

Experimental Technique

The galvanic cells employed in this investigation can be represented by

Pure Zn (reference standard)	KCl + LiCl + $ZnCl_2$ (electrolyte)	Zn + Third Element in Pb (liquid alloy)

The reversible cell potential was determined over the range 450°-650°C, and the activity coefficient of zinc in the alloy was calculated relative to the standard of pure zinc by employing the relationship

$$\gamma_{Zn} = \frac{1}{x_{Zn}} e^{-n\tilde{F}E/RT} \quad [4]$$

where $\tilde{F}$ = Faraday's constant, E = measured emf, n = valence of zinc, taken as 2. The interaction parameters were then determined from the limiting slopes of plots of $\ln\gamma_{Zn}$ *vs.* concentration of the solutes.

The experimental apparatus and procedures have been described previously in detail (4, 11, 12). Recrystallized alumina crucibles, 1 in. high by ⅝ in. in diameter, were used as containers for the zinc reference electrode or lead-base alloy electrodes. Either four or five electrode crucibles were held in a larger recrystallized alumina crucible which contained the fused chloride electrolyte. In the runs with the cadmium and bismuth additions one of the five alloys in each cell was a binary zinc-lead alloy, while the remaining four electrodes were ternary alloys containing the same mole fraction zinc plus various amounts of a given third element. In these experiments the electrode potentials could be measured relative to the pure zinc standard, or relative to the binary alloy of the same zinc content. In the course of this and related studies (19, 20), data were accumulated on a large number of binary electrodes, thus permitting an accurate determination of the activity of zinc in dilute binary solution with lead.

The galvanic cell assembly was enclosed in a gastight Vycor tube which was provided with a Pyrex head through which the electrode leads and thermocouple were passed. The electrode leads were 18 gauge tantalum wire. An L&N Type K-3 potentiometer was used to measure the emf of the galvanic cells and of a chromel-alumel thermocouple.

The electrolyte was the eutectic mixture of potassium chloride and lithium chloride plus approximately 5 w/o zinc chloride. These electrolyte salts were J. T. Baker reagent grade chemicals. The eutectic potassium lithium chloride salt was vacuum refined in the liquid state, and the zinc chloride was dried at 200°C prior to use. The metals were supplied by The American Smelting and Refining Company and were of 99.999% minimum purity.

After assembly the cell was held at 500°C for 36 hr to permit homogenization of the liquid phase. After 24 hr, 4 or 5 readings were taken at 15-min intervals to insure that the system had reached steady state. For the ternary alloys, the emf measurements were made over the temperature range 450°-650°C at roughly 50° intervals. After each change in temperature, approximately 3 hr were allowed for thermal equilibrium to be established in the cell before readings were taken again. All runs lasted a minimum of 72 hr.

A temperature variation of less than ±1°C was maintained during the period lasting from 45 to 60 min, in which 4 or 5 separate cell potential measurements were made. Data were compiled for each case by taking averages of these separate measurements.

Experimental Results

Binary lead-zinc system.—The activity coefficient of zinc in liquid lead has been measured in the temperature range 450°-800°C and at zinc concentrations ranging up to 0.05 mole fraction zinc (20). The activity coefficient shows a strong positive deviation from Raoult's law, having a value of 11.4 at 550°C. The results of 28 independent experiments involving 140 individual measurements of the zinc activity in this composition and temperature range were analyzed statistically. The results of this analysis showed that ϵ_i^i is of such magnitude that substantial deviations from Henry's law are apparent at zinc concentrations around 0.05 mole fraction, but deviations from Henry's law are small enough to be neglected at concentrations up to and including 0.0375 mole fraction zinc. In the Henry's law region, the activity coefficient of zinc in dilute solution in liquid lead is given by the expression

$$\log \gamma^\circ_{Zn} = \frac{1215}{T_{°K}} - 0.418 \quad [5]$$

This correlation is in good agreement with the results of Kleppa (21) and Kozuka *et al.* (22).

Lead-zinc-antimony system.—Sixteen dilute ternary alloys in the lead-rich corner of the system were studied. These alloys represented a 4 by 4 matrix of 4 levels of zinc and antimony: 0.015, 0.0250, 0.0375, and 0.050 mole fraction. In addition, previous measurements (20) on the lead-zinc binary system were used in evaluating the interaction parameters.

The emf-temperature relationships were linear and nearly parallel for all compositions studied in the temperature range 450°-650°C. The experimental results are summarized in Table I.

The thermodynamic interaction parameter defined as (16)

$$\epsilon_i^j = \left(\frac{\partial \ln \gamma_i}{\partial x_j}\right)_{x_i=x_j=0} \quad [6]$$

was determined by plotting the natural logarithm of the zinc activity coefficient *vs.* the mole fraction of antimony at each constant composition of zinc. The limiting slope of each plot gave the value

$$\left(\frac{\partial \ln \gamma_{Zn}}{\partial x_{Sb}}\right)_{x_{Sb}=0;\ x_{Zn}=\text{ const.}}$$

This graphical technique is illustrated in Fig. 1 at a zinc mole fraction of 0.015. Plotting these slopes against the zinc concentration and extrapolating to $x_{Zn} = 0$ yielded the ternary interaction parameter

$$\left(\frac{\partial \ln \gamma_{Zn}}{\partial x_{Sb}}\right)_{x_{Sb}=x_{Zn}=0}$$

as shown in Fig. 2.

An alternate method also can be used to determine the interaction parameter. This consists of plotting $\ln\gamma_{Zn}$ *vs.* x_{Zn} for constant mole fractions of antimony and then plotting the intercept $(\ln\gamma_{Zn})_{x_{Zn}=0}$ *vs.* x_{Sb}. The interaction parameter $(\epsilon_{Zn}^{Sb})_{x_{Sb}=0}$ obtained by the first method is mathematically equivalent with the interaction parameter $(\epsilon_{Zn}^{Sb})_{x_{Zn}=0}$ determined by

$$x_{Zn}=0 \qquad x_{Sb}=0$$

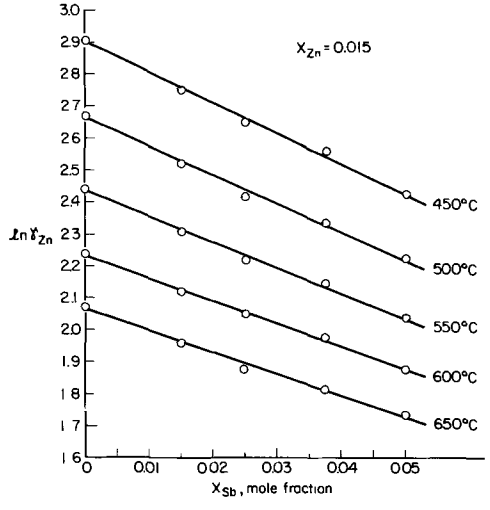

Fig. 1. Logarithm of zinc activity coefficient vs. mole fraction antimony at 0.015 mole fraction zinc.

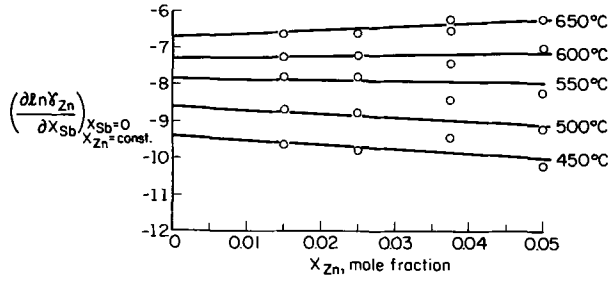

Fig. 2. Slope of zinc activity coefficient-antimony relation at infinite antimony dilution vs. mole fraction zinc.

the second method.

The interaction parameter can be shown over reasonably small temperature ranges to vary linearly with reciprocal temperature in the form (17)

$$\frac{\partial \epsilon_i^j}{\partial(1/T)} = \frac{1}{R}\left(\frac{\partial^2 H}{\partial x_i \partial x_j}\right)_{x_i=x_j=0} \qquad [7]$$

This relationship was applied to the present results and the interaction parameters were plotted against the reciprocal absolute temperatures as shown in Fig. 7. A strict linearity was observed, implying a constant value of the second derivation of molar enthalpy. The equation representing this relationship is

$$\epsilon_{Zn}^{Sb} = -\frac{8840}{T_{°K}} + 2.84 \qquad [8]$$

Lead-zinc-bismuth system.—In this system, measurements were carried out on single-phase liquid solutions in a temperature range from 450°-650°C. The emf was measured both with increasing temperature and with decreasing temperature. A 4 by 4 composition matrix at bismuth and zinc solute concentrations of 0.015, 0.025, 0.0375, and 0.05 mole fraction was studied. In addition, replicate experiments were carried out at bismuth and zinc mole fractions of 0.015, 0.025, and 0.05 mole fraction. Furthermore, in evaluating the interaction parameters, data on the lead-zinc binary system were used to define the intercepts at 0% bismuth.

The emf-temperature relationships were linear and nearly parallel for all compositions studied. Experimental results are summarized in Table II. Employing the same method outlined above for the lead-zinc-antimony system, $\ln\gamma_{Zn}$ *vs.* x_{Bi} relations were plotted as shown for example in Fig. 3 at a zinc mole fraction of 0.025. The limiting slopes of plots of the type shown in Fig. 3, taken at $x_{Bi} = 0$, were plotted against x_{Zn}. The values at $x_{Zn} = 0$ define the interaction parameters, ϵ_{Zn}^{Bi}, as shown in Fig. 4. The interaction parameters, ϵ_{Zn}^{Bi}, thus obtained are plotted against reciprocal absolute temperature in Fig. 7. A strict linearity was found which may be represented by the relationship

$$\epsilon_{Zn}^{Bi} = -\frac{2950}{T_{°K}} + 2.81 \qquad [9]$$

The zinc-bismuth interaction parameter is slightly negative and shows a moderate dependence on temperature over the range studied in this investigation.

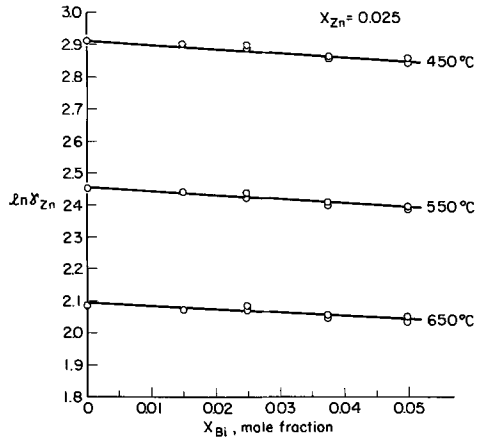

Fig. 3. Logarithm of zinc activity coefficient vs. mole fraction bismuth at 0.025 mole fraction zinc.

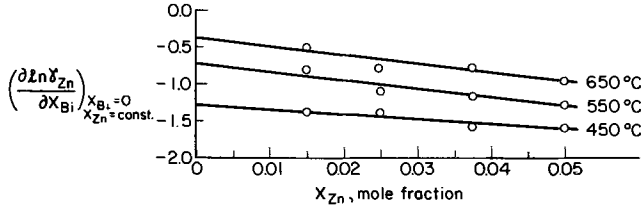

Fig. 4. Slope of zinc activity coefficient-bismuth relation at infinite bismuth dilution vs. mole fraction zinc.

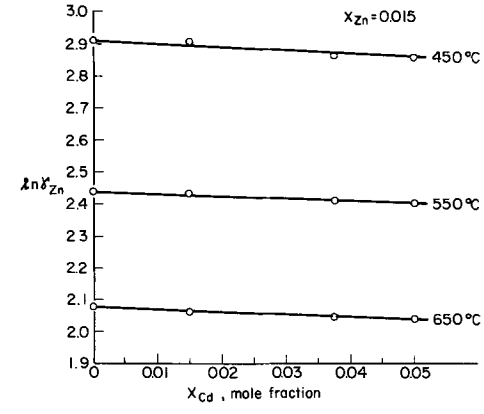

Fig. 5. Logarithm of zinc activity coefficient vs. mole fraction cadmium at 0.015 mole fraction zinc.

Lead-zinc-cadmium system.—The alloy compositions studied and the experimental results are summarized in Table III. The emf-temperature relationships for these alloys were linear. Using the same procedure outlined above for lead-zinc-antimony and lead-zinc-bismuth systems, the interaction parameter, ϵ_{Zn}^{Cd}, was evaluated over the temperature range 450°-650°C. The variation of the natural logarithm of the activity coefficient of zinc with cadmium concentration is shown in Fig. 5 at a zinc mole fraction of 0.015. The limiting slopes of plots of this type, taken at $x_{Cd} = 0$, were plotted against mole fraction zinc. The values at

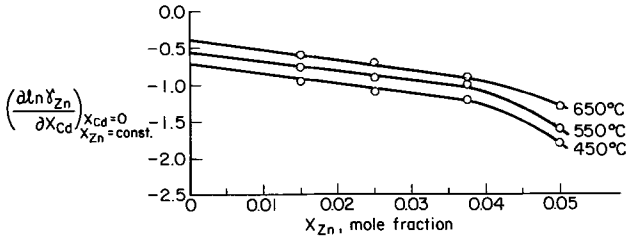

Fig. 6. Slope of zinc activity coefficient-cadmium relation at infinite cadmium dilution vs. mole fraction zinc.

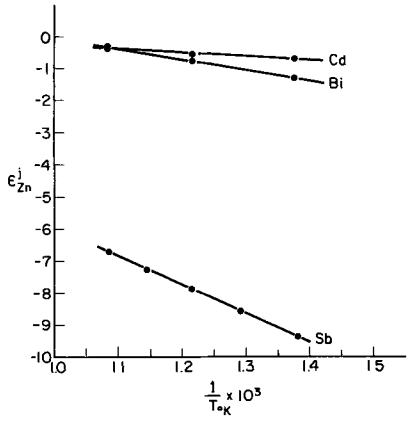

Fig. 7. Interaction parameters vs. reciprocal temperature

$x_{Zn} = 0$ define the interaction parameters, ϵ_{Zn}^{Cd}, as shown in Fig. 6.

The interaction parameters, ϵ_{Zn}^{Cd}, thus obtained are plotted against reciprocal absolute temperature in Fig. 7. The variation of the interaction parameter with reciprocal temperature is given by the relationship

$$\epsilon_{Zn}^{Cd} = -\frac{1000}{T_{°K}} + 0.68 \qquad [10]$$

A comparison between the interaction parameters of the lead-zinc-antimony, lead-zinc-bismuth, and lead-zinc-cadmium systems is shown in Fig. 7. The zinc-antimony interaction parameter is negative and shows a strong temperature dependence over the range of temperatures studied for this investigation. The zinc-bismuth and zinc-cadmium interaction parameters are much less negative and not as dependent on temperature.

Discussion

In the study of dilute solutions by the galvanic cell technique, the cell should be reversible, conduction in the electrolyte should be purely ionic, the valence of the active element in the electrolyte must be known, and there should be no significant displacement reactions taking place.

The reversibility of these cells was inferred by the consistent behavior of the cell emf which was stable during the experimental observations and drifted very little over prolonged periods of operation. The emf-temperature relations were linear, and the binary data were consistent with the galvanic cell results of other investigators at higher concentrations of zinc

(21, 22). Consideration was given to the possible error caused by displacement reactions. Emf measurements in the lead-zinc system are possible at low zinc concentrations because of the relatively large difference in the standard free energy of formation of the respective metal-chlorides. A consideration of displacement reactions was made based on the analysis of Wagner and Werner (23, 24) and an estimation made of the extent of error to be expected in the experimental systems examined in this investigation. The order of magnitude of such displacement errors on the measured cell potential at 500°C was estimated for the lead-zinc system to be well below 1% for a zinc concentration of 0.01 mole fraction. The errors caused by displacement reactions involving the added third elements, antimony, bismuth, and cadmium, in the dilute ternary alloys were shown to be of the same order of magnitude.

Summary

The galvanic cell method has been used to determine the interaction parameter of zinc in ternary lead-zinc-j alloys containing the added third elements antimony, bismuth, or cadmium. The interaction parameters were shown to vary linearly with reciprocal absolute temperature, the effect of antimony being to markedly decrease, whereas bismuth and cadmium slightly decrease, the activity coefficient of zinc. The variations of these interaction parameters with temperature are given by the following relations

$$\epsilon_{Zn}^{Sb} = -\frac{8840}{T_{°K}} + 2.84$$

$$\epsilon_{Zn}^{Bi} = -\frac{2950}{T_{°K}} + 2.81$$

$$\epsilon_{Zn}^{Cd} = -\frac{1000}{T_{°K}} + 0.68$$

Acknowledgment

The authors gratefully acknowledge the contribution of Dr. J. V. Gluck in discussions and in critical assessment of the experimental data. This work was supported in part by the Atomic Energy Commission under Contract Number AT(11-1)-1352. This work is based in part on a research program carried out by one of the authors (T.L.M.) in partial fulfillment of the requirements for the M.Sc. degree in Engineering (metallurgical) at the University of Michigan.

Pressure Effects on the Electrical Properties of Polycrystalline Boron

Terrell N. Andersen, Onnig H. Bezirjian, and Henry Eyring

Institute for the Study of Rate Processes, University of Utah, Salt Lake City, Utah

ABSTRACT

The electrical resistances of β-rhombohedral and tetragonal polycrystalline boron were measured at temperatures from 25° to 300°C and pressures from 1 atm to 60 kb (kilobars); the thermoelectric power was measured to 13 kb. Pressures were applied with an anvil press. With increasing temperature the resistance, R, continually decreased and the thermoelectric power, Q, at first increased and then levelled off. The shapes of the log R *vs.* $1/T$ and Q *vs.* T curves are explained by intrinsic conduction at high temperatures going to extrinsic conduction at the lowest temperatures studied. In the intrinsic region an increase in pressure causes a reduction in the resistance, energy gap, and thermoelectric power of boron. For the low-temperature extrinsic region pressure lowers the resistance and hardly affects the thermoelectric power. These effects are discussed.

The effects of pressure on the band gap have been studied for several elements such as the group IV semimetals, phosphorus, selenium, and iodine (1-3). Although quite a number of electrical measurements have been made on boron at atmospheric pressure, work at elevated pressures is sparse. Hamann (4) has reported the electrical resistance of a boron sample at room temperature and pressures up to 40 kb, and Vereshchagin *et al.* (5) have measured the resistance of boron at room temperature from 25 to 250 kb. The crystal form of the boron in both of the above studies was unspecified, but both studies revealed a decrease in resistance with increasing pressure, as well as an absence of any phase transitions. Studies of boron are made difficult by the fact that it has several crystal modifications, the structures of which are all quite complex (6), and only one of which appears to be commercially available. Furthermore, the melting point of boron is very high (2300°C) which makes purification of it difficult (especially since the forms other than β-rhombohedral crystallize to β-rhombohedral upon being melted and recrystallized) (6).

In the present work the effects of pressure and temperature on the electrical resistance and thermoelectric power of three polycrystalline boron samples have been studied. The three materials studied were β-rhombohedral and a tetragonal modification of boron, both prepared in this laboratory, and a commercially available β-rhombohedral boron. Since the two types of crystals prepared here appeared to have similar impurity content, which was at least an order of magnitude lower than that of the commercial β-rhombohedral boron, the study was intended to serve also as a comparison of the importance of structural *vs.* purity differences on electrical properties of boron.

Preparation and Identification of Boron

Being unable to purchase tetragonal boron, we prepared it, as well as some β-rhombohedral boron, using the hot filament technique (7) in which BBr_3 was reduced by H_2 on a glowing Ta filament. The conditions of preparation (8) were identical for the two modifications except for the filament temperature which measured 1250°C in the case of the tetragonal boron and 1575°C for the β-rhombohedral. The actual filament temperatures may have been a little higher than those measured since the temperatures were measured with an optical pyrometer of the disappearing filament type without correction for the cell not being a black body. The flow rate of H_2 was 200 cm^3 min^{-1}, the total pressure was 1 atm, and the temperature of the BBr_3 (through which H_2 was bubbled) was −20°C. Reaction times were up to 30 hr during the early stages of which β-tantalum diboride was formed on the filament surface with boron growth later (after a few hours) continuing on the tantalum diboride. The only control of purity was through selection of the starting materials. The Ta wire (0.05 mm diameter) was 99.9+% pure, the BBr_3 was 99+% pure, and 99.99% H_2 was passed through activated alumina for further purification. Emission spectrographic qualitative analysis of the deposited boron (with carbon electrodes) showed only traces (up to a few hundredths per cent total) of Si, Cu, Mg, Ag, and Ta. The commercial β-rhombohedral sample was obtained from U. S. Borax Research and was of 99.+% purity.

Identification of the deposited boron was made by means of x-ray diffraction using a Guinier focusing camera (9). Details of our identification and x-ray results (as well as the details of the preparation of our tetragonal boron) are listed here because (*i*) several tetragonal modifications of boron have been prepared, all from somewhat similar experimental conditions (6), (*ii*) the tetragonal boron we prepared was deposited on tantalum, which is a different substrate than this modification has previously been deposited on, and (*iii*) the use of the focusing camera gives better line positions than would seem to have been obtained using previous methods. The crystalline samples showed crystal faces, but these were too small and imperfect to use in making microscopic identifications (8). Diffraction d-values and visually estimated intensities for the tetragonal boron are shown in Table I along with the determined cell constants and hkl values. The x-ray patterns were indexed using a computer program (8) which utilizes a modified version of Ito's method (10). The powder pattern of our tetragonal samples matched closely to the tetragonal pattern of Talley *et al.* (11), ASTM Card No. 11-617. Their sample was prepared by the reduction of BBr_3 with H_2 using W and Re filaments at 1267°C. Their d-spacings were computed from patterns recorded with a diffractometer using filtered Co and Cu radiations.

The x-ray powder pattern of our β-rhombohedral sample (the d-spacings of which were also obtained with the Guinier focusing camera) was in close agreement with that of Hughes *et al.* (12), ASTM Card No. 11-618.

The densities of the prepared tetragonal and β-rhombohedral samples, as determined by the flotation method, were 2.345 ± 0.020 and 2.356 g/cm^3, respectively.

Experimental Procedure

The boron to be studied was finely powdered and formed into cylindrical pellets. Each pellet was then pressed into an annular pyrophyllite retaining ring of approximately the same thickness as the pellet and approximately 1/32 in. in wall thickness. The sample-containing pellet was pressed between two opposed

$a_o = 10.12$Å; $c_o = 14.14$Å

anvils which derived their thrust from a hydraulic ram. The retaining ring acted to prevent the extrusion of the boron from the pressurized region. The over-all pellet diameter was ¼ or ½ in. with a final thickness of about 1/25th the pellet diameter.

During the resistance measurements the sample was heated by means of a split furnace, and a thermocouple against the sample served to measure the temperature. For thermoelectric power masurements, heating tapes were used to control the temperature of each anvil individually, such that the desired temperature differences between the two boron-copper contacts could be obtained. Thermocouples, which were in contact with each junction, served to detect the required temperatures which differed by about 25°C. The mean of the two temperatures was taken as that of the sample. Sufficient insulation was placed around the anvils and sample that gradients did not exist between the thermocouples and sample, and the heating rate of about 1 deg/min was adequate to assure temperature equilibrium as shown by the agreement of resistance readings during heating and cooling cycles. Since boron oxidizes in air at several hundred degrees, some runs were made in an N_2 atmosphere, by encasing the entire press in an N_2-inflated polyethylene sack. Since the results in N_2 were in agreement with those in air, it appeared that the pyrophyllite rings, alone, prevented oxidation.

Direct-current resistance measurements were made by passing current through the anvil faces and measuring the potential drop across them with a Keithley electrometer (the resistance of the pyrophyllite was several orders of magnitude greater than that of the boron and could hence be neglected). The Seebeck voltages were measured with a Keithley electrometer or with a potentiometer coupled with a very sensitive galvanometer. These voltages were due only to the boron as shown by the lack of potentials of the observed order of magnitude for pyrophyllite alone. Resistance measurements were made both at constant pressure with varying temperature and at constant temperature with increasing pressures. The recorded pressures were computed directly from the gauge pressure and the anvil area. Although pressure gradients exist across flat anvil faces, the expected errors from these would not affect the present discussion. Samples were first subjected to the maximum experimental pressure, and then the pressure was slowly released. Pressure was increased again slowly to the desired pressure and held constant while measurements were made. This compaction of the sample minimized extrusion during the experiments. Also, the resistance at the low pressure end of the first pressure cycle was higher and that at the high pressure end usually slightly lower than for subsequent cycles.

Experimental Results

Evidences that the measured resistance changes were due to the boron, itself, and not to boron-metal contacts, boron-boron contacts, or space charge are (*i*) the measured resistance was ohmic for potentials across the sample of from 1 to 90v, (*ii*) electrical resistance readings rapidly came to equilibrium upon application of current, (*iii*) various metal contacts (Cu, Pt, etc.) gave identical resistance readings, and (*iv*) powdered samples of various particle size (—100 to —300 mesh) gave the same results. Furthermore the resistances, energy gaps, and thermoelectric power values from this work at low pressures (as well as from other work on polycrystalline boron) are in agreement with the values found in single crystal work for material of comparable purity.

Figure 1 shows that the resistance for all the samples continually decreases with increased pressure, which supports the earlier findings (4, 5). The curves for boron at higher temperatures (up to 300°C) are similar in shape to those of Fig. 1 and are shifted successively to lower R values (they are not necessarily parallel). Equation [1] was used to obtain the experimental activation energy, E_{act}, for conduction.

$$\rho = \frac{1}{\sigma} = A' \exp(E_{act}/kT) \qquad [1]$$

Here ρ is the resistivity, σ is the conductivity, A' is a term which varies much more slowly with T than does the exponential, and k and T are Boltmann's constant and the temperature. Details of the terms in [1] will be given later. Since $R = \rho L/A$ where L and A are the length and area of the sample, then

$$E_{act} = k\ \partial\ \ln R/\ (1/T) \qquad [1]$$

Plots of log R *vs.* $1/T$ are shown in Fig. 2 from which it is seen that the slope (*i.e.*, the activation energy) increases with increasing temperature, and appears to reach a limiting value.

The thermoelectric power is defined as

$$Q = -\Delta V/\Delta T \qquad [3]$$

where ΔV is the potential difference (Seebeck voltage) and ΔT the temperature difference between the two boron-metal junctions. The thermoelectric power, for the various boron samples studied, is shown in Fig. 3

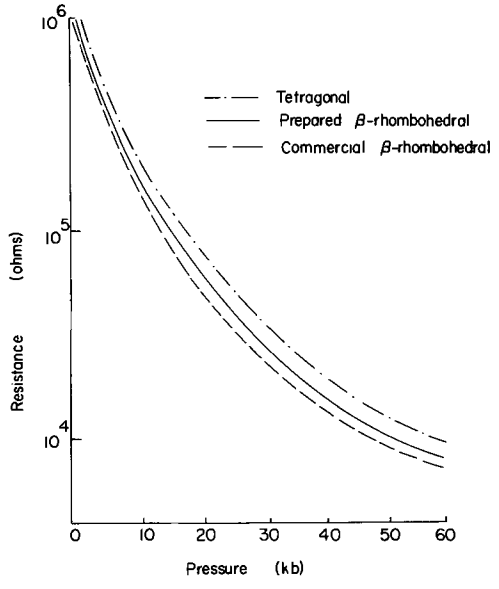

Fig. 1. Resistance *vs.* pressure at 25°C for polycrystalline boron

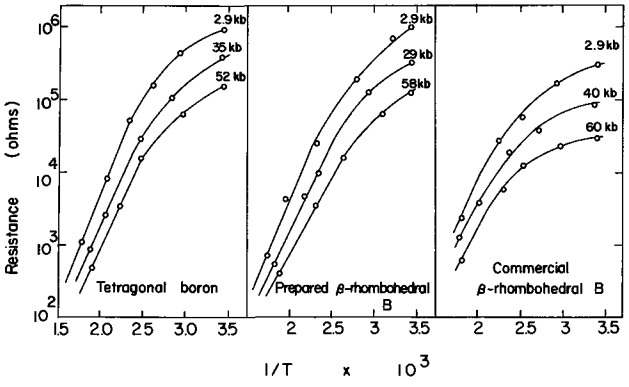

Fig. 2. Resistance (log scale) *vs.* $1/T$ at various pressures for boron samples.

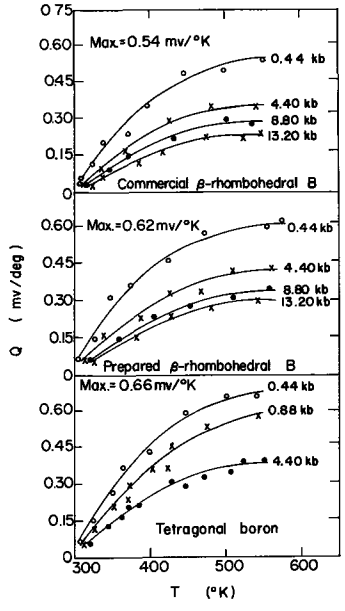

Fig. 3. Thermoelectric power, Q, *vs.* T at various pressures for boron samples.

as a function of the average sample temperature and at various pressures. The pressures employed were lower than in the case of the resistance studies, since larger sample thicknesses and hence anvil diameters (½ in. instead of ¼ in.) were required in order to separate the junctions sufficiently for accurate temperature measurements. Since the thermoelectric power, as well as the relative potential of the cold junction, has the same sign as the majority carrier (for extrinsic semiconductors) or the carrier of highest mobility (for intrinsic semiconductors), it is seen that the samples studied are all p-type.

Discussion

The shapes of the resistance and Seebeck curves as functions of temperature are consistent with the idea that the boron conducts extrinsically in the low-temperature region going smoothly to intrinsic conduction at the highest temperatures attained (300°C). Purely extrinsic conduction was seemingly not attained at our lowest temperatures as shown by the rapidly changing curvature of the log R *vs.* $1/T$ curves. Higher impurity contents or lower temperatures would have been required for this limit. On the other hand these curves are linear (or nearly linear in the case of the less pure commercial β-rhombohedral boron) in the experimental high-temperature limit, and the samples thus appear to behave intrinsically. Other resistance studies of polycrystalline boron, made only at atmospheric pressure but with wider temperature variation or impurity variation, have shown the intrinsic region to be reached near 200°C for samples with purity comparable to that in the present study (13, 14). Likewise, the thermoelectric power curves show leveling at the highest temperatures which indicates the onset of intrinsic properties with the accompanying decrease in thermoelectric power (cf. Eq. [6]). Thermoelectric power measurements on single crystal boron (of purity comparable to ours) at 1 atm have shown Q to rise, then level out and finally decrease with increasing temperature (15-17). In the above studies the temperature at which Q reached a plateau was 125°-300°C, and the maximum Q values were 550-750 μv deg^{-1}, in satisfactory agreement with the present work. The polycrystalline boron in the work of Uno (21) did not yield a maximum in the Q *vs.* T curve. This is perhaps due to the presence of impurities as evidenced by lower resistivities obtained compared to other workers. In ref. (15) the thermoelectric power *vs.* T curves for n- and p-type boron join at $T \simeq 500$°C, but the n- boron was very impure. The "typical" p-type boron gave a maximum thermoelectric power value at approximately 250°C.

Intrinsic Region

We assume in this discussion that at the highest temperatures studied the boron is intrinsic and that its properties may be formulated accordingly. The energy gap is large enough that Fermi-Dirac statistics may be replaced by Boltzmann statistics (assuming the Fermi level to lie half way between the conduction and valence bands). In this region the density of holes in the valence band, n_h, is equal to the density of electrons in the conduction band, n_e. We then have for the conductivity, σ, (19)

$$\sigma = |e|(n_e\mu_e + n_h\mu_h)$$
$$= |e|(\mu_h + \mu_e)2\left(\frac{2\pi kT}{h_2}\right)^{3/2}$$
$$(m^*_e m^*_h)^{3/4} \exp(-E_g/2kT) \quad [4]$$

Here e is the electronic charge, μ_h and μ_e are the mobilities of holes and electrons, m^*_h and m^*_e are the effective masses of the holes near the top of the valence band and the electrons near the bottom of the conduction band; E_g is the energy gap between the bottom of the conduction band, E_c, and the top of the valence band, E_v; k, T, and h have their usual significance. Since $E_g = 2E_{act}$ from Eq. [1] and [4], E_g is readily obtained from Fig. 2 (assuming the mobility, μ, varies more slowly with T than does $\exp(-E_g/2kT)$), and is shown in Fig. 4 for the highest temperatures studied, 300°C. If $\mu \propto T^{-7/4}$ as was found by Hagenlocher (20) for polycrystalline β-rhombohedral boron, then $|d(-E_g/2kT)/d(1/T)|$ is more than ten times larger then $|d \ln \mu/d(1/T)|$.

From Fig. 2 it is noted that the log R *vs.* $1/T$ curves for the commercial β-rhombohedral boron (especially for 2.9 kb) have not reached a limiting slope as evi-

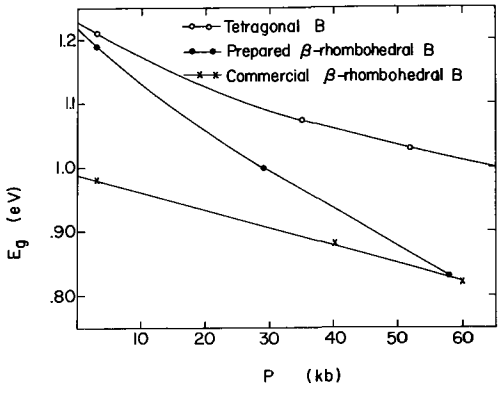

Fig. 4. Energy gap, E_g, *vs.* P for boron samples at 300°C

denced by the fact that the three highest temperature points do not lie on a straight line. This is due to the high concentration of impurities giving appreciable extrinsic conduction, even at the highest temperature. Thus it may be assumed that the energy gap *vs.* pressure curve for intrinsic β-rhombohedral boron more closely follows that for the prepared material than that for the commercial boron. The E_g values extrapolated to 1 atm in Figure 4 (*i.e.* 1.2-1.3 eV), are in fair agreement with other workers in the field for tetragonal (14, 16, 18, 21, 22) and β-rhombohedral boron (13, 17, 20, 23-30). The energy gap values of the above workers range from 1.1 to 1.6 eV, which is a considerable spread of values for the energy gap of one material. Although the present work cannot solve the problem of this variation, it is noted from the above literature that no obvious energy gap differences exist between β-rhombohedral and tetragonal boron, or between single crystal and polycrystalline material. The present results show that E_g for β-rhombohedral and tetragonal boron are about the same at low pressures while E_g for the latter is greater at high pressures. The explanation of this result must await x-ray data for boron at elevated pressures. Impurities, which in the present study are seen to lower the activation energy for conduction at $T \leq 300°C$, are probably responsible for a sizeable portion of the variation of E_g observed in the literature. Since intrinsic and extrinsic conduction are parallel mechanisms, the production of proportionately many intrinsic carriers is required in order to observe bulk intrinsic properties. This is usually accomplished by elevating the temperature. Figure 4 shows that the same result apparently can also be obtained by increasing the pressure as shown by the convergence of E_g for the β-rhombohedral boron samples of different purity. It is seen that dE_g/dP for tetragonal boron decreases from -6×10^{-3} ev/kb at 3 kb to -2.5×10^{-3} ev/kb at 60 kb; the corresponding values for β-rhombohedral boron are -9×10^{-3} ev/kb at 3 kb and -6×10^{-3} kb at 60 kb. This order of band gap deformation with pressure is often found for semiconducting elements and compounds which have been studied (1), though dE_g/dP has been found to be either positive or negative depending on the material.

The thermoelectric power, Q is obtained from integrating the Thomson relation

$$\sigma_T = T\, dQ/dT \qquad [5]$$

where σ_T, the Thomson coefficient, is obtained from the thermal and electrical current density expressions (31). A direct expression for the thermoelectric power of an intrinsic semiconductor has been derived by Johnson and Lark-Horowitz (32) under the assumptions that (*a*) Fermi statistics may be replaced by classical statistics, (*b*) the conduction electron and hole densities are equal, and (c) the only important scattering of carriers is due to the covalent lattice. Assumptions (*a*) and (*b*) were already used in writing expression [4] and appear justified from the size of E_g and the evidence that the intrinsic region had been reached. Q is given by (32)

$$Q = -\frac{k(c-1)}{|e|(c+1)}\left(\frac{E_g}{2kT} + 2\right) \qquad [6]$$

where

$$c = \mu_e/\mu_h \qquad [7]$$

From energy gap values interpolated from Fig. 4 and the maximum Q values of Fig. 3, c was calculated from Eq. [6], the results of which are shown in Fig. 5. From the results it can be seen that the hole mobility is greater than the electron mobility, and that the difference decreases with an increase in pressure. The decreases in the resistance and thermoelectric power with increasing pressure may both be explained by the energy bands broadening with a decrease in lattice parameter, such that the upper edge of the valence band and lower edge of the conduction band approach each other. If carrier scattering were due to some

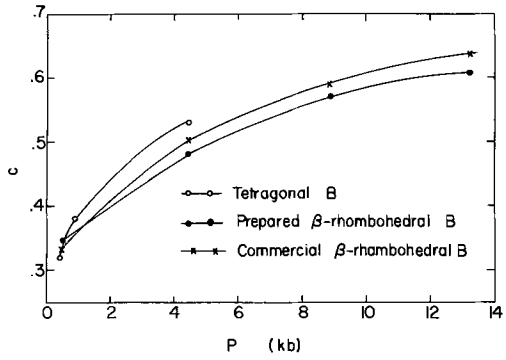

Fig. 5. Ratio of electron mobility to hole mobility, c, as a function of pressure for boron samples at 275°C.

cause other than the covalent lattice (*e.g.*, an ionic impurity), the 2 in Eq. [6] would be replaced by some other small integer. However such an effect would hardly affect c since $E_g/2kT \geqq 10$.

From Fig. 5 one observes that the mobility ratio and its variance with pressure are the same for all the boron samples independent of crystal structure or purity. From Fig. 4 we see that impurities significantly affected the energy gap. This would indicate that the mobility (the scattering mechanism) is due to the lattice vibrations and not to the impurities which produce extrinsic carriers. Differences in E_g with structure increased with pressure, being comparatively small at 13 kb, the highest pressure at which thermoelectric power measurements were made.

Extrinsic Region

In the low-temperature region (25°C) of the present study the intrinsic conductivities extrapolate to resistance values more than twenty times larger than the measured resistance (except for prepared β-rhombohedral boron at 58 kb, for which $R_{\text{intrin}} > 6R_{\text{meas}}$); the activation energies are also only a small fraction of those for the intrinsic region. Thus the room temperature electrical properties would seem to be dominated by extrinsic carriers from one or several sources, the latter being likely as evidenced by the changing slopes of the log R *vs.* $1/T$ plots. Because these slopes are changing with T it is not possible to isolate activation energies for a given process. However the following observations can be made for the extrinsic region: (*a*) the resistance decreases with increasing temperature, (*b*) as the temperature is decreased the thermoelectric power becomes less positive, extrapolating to negative values at temperatures a little below room temperature, (c) the resistance decreases with increasing pressure, and (*d*) increasing pressure decreases the thermoelectric power when the latter is positive, the effect of pressure diminishing as Q and T decrease.

The low-temperature thermoelectric power results indicate that donor and acceptor levels are both operative below and near room temperature with the p-type conduction predominating as T increases. Such an effect has been observed previously at atmospheric pressure (16, 17). The thermoelectric power under these conditions is given by

$$Q = \frac{Q_h n_h \mu_h + Q_e n_e \mu_e}{n_h \mu_h + n_e \mu_e} \qquad [8]$$

and accordingly $Q \lesseqgtr 0$ for $Q_h n_h \mu_h \lesseqgtr Q_e n_e \mu_e$. As the temperature is increased from some value less than 275°K, excitation of electrons from the valence band to an acceptor level causes an increase n_h, and this increase is the dominating factor in causing σ and Q to increase.

The continued increase in Q with T up to 500°K

may be explained as the result of a further increase in n_h with respect to n_e, with Q_h being greater than the maximum Q value recorded in Fig. 3. In this case holes and electrons both insignificantly contribute to Q at all temperatures studied, Q again decreasing at $T > 600°K$ because of n_e (cf. Eq. [8]) catching up with n_h as intrinsic conduction occurs. Any decrease in ionization energy for carrier production, caused by increasing pressure, would result in large increases in the numbers of carriers. Thus P would affect both Q and σ through n_+ and n_-.

An alternative interpretation for the data can be given which involves the production of so many positive carriers, with increasing temperature, that above about 350°K $Q_h\mu_h n_h >> Q_e\mu_e n_e$. Based on this model Eq. [8] reduces to

$$eQT \simeq eQ_hT = E_F - E_v + AkT \qquad [9]$$

Here E_F is the Fermi energy and A is a constant which depends on the transfer of kinetic energy by the carriers from the hot to the cold junction. For reasonable values of A (4 or less), $d(eQT)/dT$ as obtained from the present data is an order of magnitude larger than $d(AkT)/dT$, so the Fermi level increases with respect to the valence band as T increases. This model, with the present data, leads to the conclusion that n_h varies slowly with temperature while μ_h increases by about the same factor as σ. It then follows from Eq. [9] and Fig. 3 that pressure causes a decrease in $E_F - E_v$, and hence increases the number of carriers, n_h, and also the conductivity. The latter is given by

$$\sigma = |e|n_h\mu_h = |e|\mu_h 2\left(\frac{2\pi m^* kT}{h^2}\right)^{3/2} \exp(-(E_F - E_v)/kT)$$
$$= |e|\mu_h N \exp(-(E_a - E_v)/kT) \qquad [10]$$

Here E_F is the Fermi energy, E_a is the energy of the acceptor level, and N is a function of the effective mass of the carriers and the impurity density-of-states. The major effect of pressure on σ, from the above model, is to decrease the ionization energy, $E_a - E_v$. The effect of pressure in decreasing the ionization energy for carrier production has previously been observed for silicon (33) and thallous halides (34).

If the second model is correct, boron may then be thought of as a hopping semiconductor similar to NiO doped with lithium (35). In the latter case the increase of conductivity with temperature is due to an increase in mobility. Uno *et al.* (13) have interpreted their thermoelectric power data on various impure boron samples in terms of a single trapping level, and deduced that μ increased exponentially with temperature while n was about constant. On the other hand, Hagenlocher (20) found μ to be proportional to $T^{-7/4}$, which is more nearly classical semiconductor behavior; μ decreases with temperature due to lattice scattering. Such discrepancies are difficult to reconcile since impurities and their effects on the electrical properties are very difficult to control in boron, and hence problems such as opposite, compensating carriers are not under control. Thus the energy level scheme for the present extrinsic samples could be much more complicated than the discussion depicts, with an interplay of several donors and acceptors (and perhaps more than one charge-carrying band) yielding the observed results.

Overpotential-Time Variation for Galvanostatic Charging with Potential Dependent Capacitance

Leonard Nanis

and Philippe Javet
Institute for Direct Energy Conversion, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The nonlinear differential equation for the time variation of overpotential during galvanostatic charging is solved by introducing a close approximation for the second term of the rate equation. The results obtained are in close agreement with known solutions, covering all values of transfer coefficient, and are simple in form. Further, potential dependent capacitance is readily treated and is shown to have a considerable effect on the overpotential transient.

A simple and useful relation describing the time variation of overpotential, η, following the switching on of a constant current density, J_T, has been determined. In the absence of mass transport effects (activation overpotential only), two separate reactions take place simultaneously at the electrode-electrolyte interface:

1. the normal Faradaic relation, involving current density J_F;

2. charging of the double layer capacity, C, using current density J_C.

It is well-known that (for a cathodic reaction)

$$\frac{J_F}{J_o} = \exp\left(-\frac{\alpha ZF\eta}{RT}\right) - \exp\left(+\frac{(1-\alpha)ZF\eta}{RT}\right) \quad [1]$$

$$J_C = C\frac{d\eta}{dt} \quad [2]$$

$$J_T = J_F + J_C \quad [3]$$

The differential equation obtained from the above relations is nonlinear, because of the terms arising in Eq. [1], and cannot be integrated. In the most general case, C is a function of η, and the relation between t and η is thus further complicated. Two types of simplification can be made for the solution of Eq. [1], [2], [3].

1. The capacitance may be considered to be independent of potential. This has been done by some authors (1-3) who can ultimately obtain the relation between time and overpotential, but only for particular values of the transfer coefficient, α, *i.e.*, $\alpha = 0$; 0.5; 1.

2. The Faradaic component of the current, J_F, may be approximated, *i.e.*, Eq. [1] is modified by (*a*) linearization of the exponentials by series expansion, which gives the well-known result

$$\frac{\eta}{\eta_\infty} = 1 - \exp\left(\frac{-ZFJ_o}{RTC}t\right) \quad [4]$$

limited, however, to small values of η_∞. (*b*) Tafel approximation obtained at high overpotentials when the second exponential term of Eq. [1] is negligible in comparison with the first term. The Tafel approximation has been used for the decay transient by Frumkin (4), but the application of the Tafel relation for the charging transient has never been used, owing to the fact that this approximation does not pass through the origin of $\eta - J$ coordinates, which leads to very important errors at small times.

Modification of Rate Equation

The present approach consists of modifying the rate expression (Eq. [1]) to a form which is reasonable as an approximation of the $\eta - J$ relation and which is simple enough to be integrated. The procedure consists of setting the second exponential term of Eq. [1] equal to unity. The effect of this step is best seen in Fig. 1 as a vertical shift of the Tafel approximation so as to begin at the $\eta - J$ origin as does the full rate equation (Eq. [1]). In a graphical sense, the new approximation appears to be only a fair representation of Eq. [1]; however, fitting at the origin of $\eta - J$ proves to be advantageous for transient $\eta - t$ computation. Using the modified Eq. [1] together with Eq. [2] and [3], there is obtained

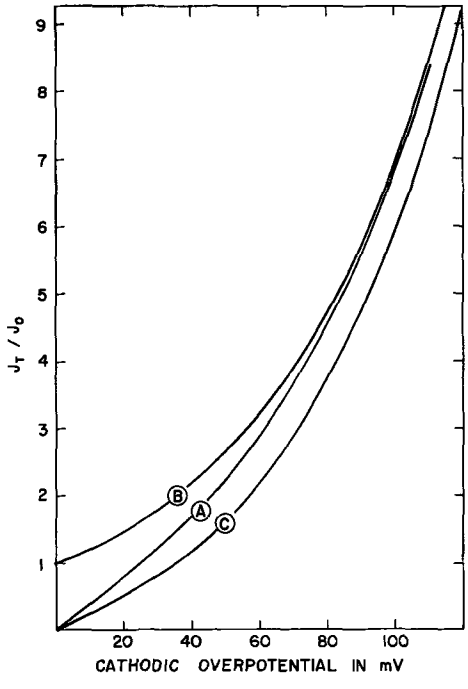

Fig. 1. Comparison of exact and approximate $\eta - J$ relations

A **Full rate equation:**

$$J_T/J_o = \exp\left[-\frac{\alpha ZF}{RT}\eta\right] - \exp\left[+\frac{(1-\alpha)ZF}{RT}\eta\right]$$

B **Tafel approximation:** $J_T/J_o = \exp\left[-\frac{\alpha ZF}{RT}\eta\right]$

C **Tafel modified to go through the origin ($\eta = 0$, $J = 0$):**

$$J_T/J_o = \exp\left[-\frac{\alpha ZF}{RT}\eta\right] - 1$$

For all curves: $\alpha = 0.5$; $Z = 1$; $T = 300°K$.

$$J_T = J_o \left\{ \exp\left(\frac{-\alpha Z\mathbf{F}\eta}{RT}\right) - 1 \right\} + C\frac{d\eta}{dt} \quad [5]$$

Equation [5] may readily be integrated to yield a relation between time and overpotential (for constant C) as

$$t = -\frac{C}{J_o + J_T}\eta - \frac{RTC}{\alpha Z\mathbf{F}(J_o + J_T)} \ln\left[1 + \frac{J_o}{J_T}\left(1 - \exp\left(\frac{-\alpha Z\mathbf{F}\eta}{RT}\right)\right)\right] \quad [6]$$

The form of Eq. [6] for small time, *i.e.*, η small, is such that the logarithmic term becomes negligible; the remaining first term is identical with the small time result for Eq. [4] if $J_T >> J_o$. It is to be expected that Eq. [6] will be an increasingly accurate description of the $\eta - t$ transient as the approximated region of low overpotential is more rapidly traversed, *i.e.*, when the total current density is very much greater than the exchange current density, $J_T >> J_o$.

It is useful to compare previously obtained analytic results with the present solution given in Eq. [6]. For the special case of $\alpha = 1.0$, Karasyk (3) obtained the expression

$$\eta = \frac{RT}{Z\mathbf{F}} \ln\left[\frac{\exp\left[\frac{-Z\mathbf{F}(J_o + J_T)t}{RTC}\right] + \frac{J_o}{J_T}}{1 + J_o/J_T}\right] \quad [7]$$

In the present study, the form of the approximation used in Eq. [5] may also be considered as a special case of $\alpha = 1$. It may be shown by rearrangement of Eq. [6] that the exact form of the special result of Karasyk (3) (Eq. [7]) for $\alpha = 1$ is obtained.

A graphical check of Eq. [6] has been made in Fig. 2 using an analytic solution due to Rojter *et al.* (1) and also Karasyk (3) for the special case of $\alpha = 0.5$. This special result is valid if $J_o/J_T \leq 0.15$ and is

$$\eta = \frac{RT}{\alpha Z\mathbf{F}} \ln\left[\frac{J_o}{J_T} + \left(1 - \frac{J_o}{J_T}\right) \exp\left[\frac{-\alpha Z\mathbf{F}J_T t}{RTC}\right]\right] \quad [8]$$

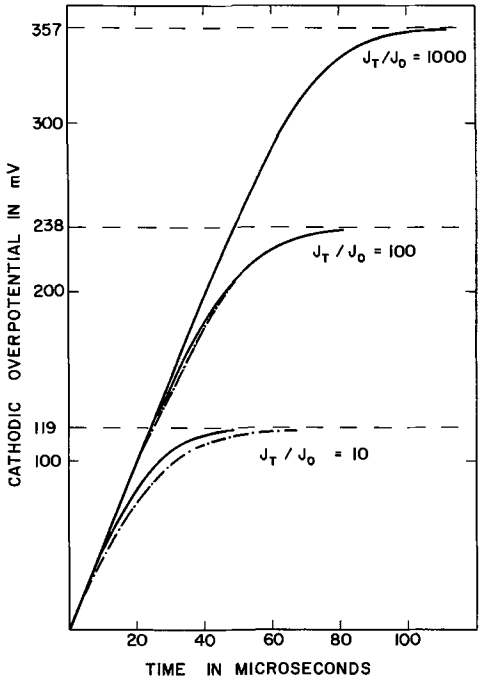

Fig. 2. Comparison of present integrated solution (Eq. [6], full line) with the analytic result of Karasyk (Eq. [8], dotted line). For both curves: $\alpha = 0.5$; $Z = 1$; $C = 20\ \mu\text{F cm}^{-2}$; $T = 300°\text{K}$; $J_T = 10^{-1}$ amp cm^{-2}.

As shown in Fig. 2, Eq. [8] is closely matched by Eq. [6] with improving accuracy as the steady state overpotential increases. As pointed out above, exact agreement between Eq. [6] and completely correct analytic results exists at $\alpha = 1.0$ and graphical correlations indicate excellent agreement for $\alpha = 0.5$, even though Eq. [6] is based on an assumption equivalent to setting $\alpha = 1$. Mattsen (2), using analog computer solutions to Eq. [1], [2], [3] has concluded that the $\eta - t$ transient does not depend strongly on the value of α. Thus, Eq. [6] and the well-known Eq. [4] can be used to bracket all practical cases of activation overpotential transient since, although the accuracy of Eq. [6] as α approaches zero may become poor, most real cases of electrode reactions are associated with a transfer coefficient close to 0.5.

Potential Dependent Capacity

The interesting feature of Eq. [5] is that it can be integrated even in the most general case of an interfacial capacitance which is itself a function of potential. For practicality, a polynomial series representation of $C = f(\eta)$ is suitable. For a simple linear dependence of capacitance with overpotential given as

$$C(\eta) = C_o + 2C_1\eta \quad [9]$$

equation [5] may be integrated using a series summation based on the binomial expansion for the denominator of the overpotential integral. The result is

$$t = \frac{1}{(J_T + J_o)}\left[-C_o\eta + C_1\eta^2 + \sum_{m=1}^{\infty}(-1)^m C_o \frac{I^m}{mb}\exp(-mb\eta) + \sum_{m=1}^{\infty}(-1)^m \frac{2C_1 I^m}{m^2b^2}(-mb\eta - 1)\exp(-mb\eta) - \sum_{m=1}^{\infty}(-1)^m I^m\left(\frac{C_o}{mb} - \frac{2C_1}{m^2b^2}\right)\right] \quad [10]$$

where $I = \dfrac{J_o}{J_o + J_T}$ and $b = \dfrac{\alpha Z\mathbf{F}}{RT}$

and the boundary condition $\eta = 0$, $t = 0$ has been used. The form of Eq. [10] is apparently complicated, but the series terms are rapidly convergent because of the alternating sign. The first two terms in the brackets of Eq. [10] are already the $m = 0$ terms of the summation. Thus, for polynomial representation of $C = f(\eta)$ involving higher order terms than shown in Eq. [9], it should be expected that the corresponding zero order summation terms which will arise, analogous with Eq. [10], will consist of the polynomial coefficients of the equivalent of Eq. [9] in association with the next higher order of overpotential.

Application

Two hypothetical cases of capacitance variation with potential have been treated:

Case 1: Capacitance increasing with cathodic overpotential $C(\eta) = 4.0 - 53.4\eta$, $\mu\text{F cm}^{-2}$
Case 2: Capacitance decreasing with cathodic overpotential $C(\eta) = 20.0 + 53.4\eta$, $\mu\text{F cm}^{-2}$
Case 3: $C = 12\ \mu\text{F cm}^{-2}$

For the numerical coefficients chosen for Case 1 and 2, a typical set of conditions has been chosen in which the steady-state overpotential is attained within the physically meaningful domain indicated by the capacitance-overpotential functions. In particular, substitution of the appropriate $C = f(\eta)$ coefficients in Eq. [10] for $J_o = 10^{-3}$ amp cm^{-2}, $J_T = 0.1$ amp cm^{-2}, $\alpha = 0.5$, $Z = 1$, $T = 300°\text{K}$, leads to a steady-state overpotential of 238 mv in all cases, but the

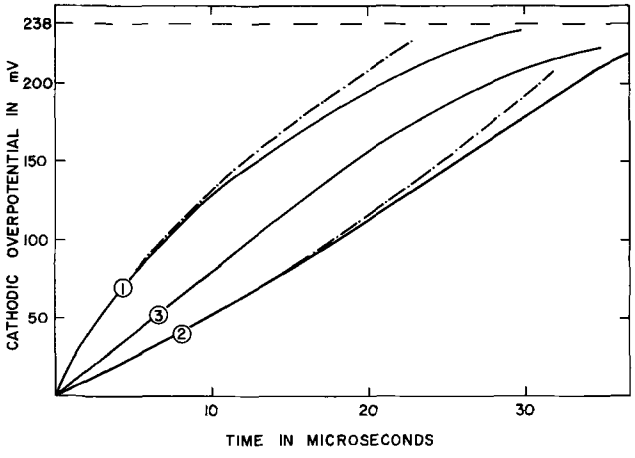

Fig. 3. Galvanostatic transient as described by Eq. [10] for three different capacitance-overpotential relations:

1. $C(\eta) = 4.0 - 53.4\ \eta$, $\mu F\ cm^{-2}$
2. $C(\eta) = 20.0 + 53.4\ \eta$, $\mu F\ cm^{-2}$
3. $C = \text{const.} = 12\ \mu F\ cm^{-2}$

In cases 1 and 2, the dotted lines represent the contribution of the zero order terms only from Eq. [10].
For all curves: $\alpha = 0.5$; $Z = 1$; $T = 300°K$.

$$J_T = 0.1\ \text{amp cm}^{-2};\ J_o = 10^{-3}\ \text{amp cm}^{-2}.$$

transients are considerably different. The results for the three cases are shown in Fig. 3 both for the application of Eq. [10] in its entirety and also for the zero-order terms of Eq. [10]. It may be seen that zero-order terms alone are a good approximation allowing a rapid estimation of the transient. Practically, in the case chosen, the time error made by using only the zero-order terms amounts to 10% only for potentials greater than 75% of the steady-state potential in Case 1 and greater than 93% of the steady-state potential in Case 2. Thus, in most cases, the summation terms in Eq. [10] may be omitted since they are associated with the final convergence to a steady value and the initial behavior of the $t - \eta$ transient may be readily estimated from $C - \eta$ curves of the type shown in the present examples. Furthermore, it is evident in Fig. 3 that the curves for Cases 1 and 2 have a nonnegligible curvature in the vicinity of $t = 0$ (due to the occurrence of quadratic overpotential in the zero-order summation terms). It is clear that caution should be exercised in the procedure of extrapolating $\eta - t$ transient curves to obtain the capacitance from the slope at zero time. In particular, good resolution of potential and time is needed near to the beginning of the transient. In principle, it should be possible to analyze overpotential transients to determine the nature of the capacitance-potential variation. The present results may readily be shown to conform, at least at small times, with the general criterion for nonconstant capacitive systems devised by Budewski and Stoinoff (5).

Impurity Effects in High Current Density Cl_2 Electrodes

D. A. J. Swinkels

Electrochemical Laboratory, General Motors Corporation, Indianapolis, Indiana

ABSTRACT

The development of high current density porous electrodes (>1 amp/cm^2) places increasing demands on the purity of the gas fed to the electrode. The concentration polarization associated with inert impurities in the electroactive gas is treated for the Cl_2 electrode in fused LiCl. The Cl_2 electrode consists of porous carbon or graphite which is not wetted by fused LiCl.

The presence of electro-inactive impurities in the gas feed to a porous gas electrode can result in the rapid build-up of considerable polarization due to the accumulation of these inactive impurities in the pores (1). This is particularly true for high current density systems such as the Cl_2 electrode in fused alkali halides. Commercial grades of Cl_2 typically contain 0.5% of inert impurities such as N_2 and CO_2. When the rate at which Cl_2 is supplied to the electrode is exactly sufficient to maintain the electrode reaction (*i.e.*, the electrode is dead ended) these inert impurities rapidly accumulate at the electrode-electrolyte interface. The impurities can leave the interface by dissolution in the electrolyte and diffusion into the bulk or by back diffusion against the flowing Cl_2 stream.

The first of these is negligible because of the low solubility and low diffusion coefficients involved. If we assume that the impurity has the same solubility and diffusion coefficient as Cl_2 (2) then the maximum rate of diffusion through the electrolyte at 1 atm (j) is typically

$$j = -D\frac{\Delta C}{\Delta x} \quad [1]$$

$$= -4 \times 10^{-5} \times \frac{0-10^{-6}}{1} N_i = 4 \times 10^{-11} N_i \quad [2]$$

where N_i = mole fraction of impurities at the interface.

This assumes that the impurity concentration is zero at a distance of 1 cm from the Cl_2 electrode (due to reaction with Li for example) and has a solubility of 10^{-6} moles/cm^3 at 1 atm.

At current density of 3 amp/cm^2 the flux of Cl_2 is $i/2\mathbf{F} \approx 1.5 \times 10^{-5}$ moles/sec. Hence, the maximum concentration of impurities in the Cl_2 feed which can be removed by this process is $4 \times 10^{-11} N_i/1.5 \times 10^{-5} = 2.67 \times 10^{-6} N_i$. Since N_i must be less than unity the impurity level must be less than 2.67 ppm.

However, as current is drawn from a Li-Cl_2 cell more electrolyte is generated at the electrodes which can dissolve $10^{-6} N_i P_T$ moles of impurity per cubic centimeter of electrolyte, where P_T is the total pressure. Since the transport number of Li^+ in LiCl is 0.75 (3) then 0.75 of the new electrolyte is generated at the Cl_2 electrode. One mole of Cl_2 will then produce 1.5 moles of LiCl at the Cl_2 electrode which can dissolve $43 \times 10^{-6} N_i P_T$ moles of impurity. For typical values of $P_T = 5$ atm and $N_i = 0.05$ an impurity level of ≈ 11 ppm can be tolerated.

Much larger quantities of impurities can be removed from the electrode by flowing excess Cl_2 either through the porous electrode or behind the porous electrode. A study of the latter type of electrode (a "flow-by" electrode) is reported here.

Theory

Back diffusion of impurities in the pores against the flowing Cl_2 gas can be treated as a linear diffusion problem and is described by Eq. [3].

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \frac{\partial (Cv)}{\partial x} \quad [3]$$

where C = concentration of impurity gas, v = velocity of gas flow, and x = linear dimension in the direction of net flow.

The transient problem described by Eq. [3] has recently been treated (4). Since under most conditions steady state is reached in a few seconds all experiments were done under steady-state conditions, *i.e.*,

$$\frac{\partial C}{\partial t} = 0$$

Equation [3] after integrating once with respect to x becomes

$$D\frac{dC}{dx} - Cv = j \quad [4]$$

where j is the net flux of impurity through the pore under steady-state conditions.

We now assume that the impurity does not react or dissolve at the gas-liquid interface in which case $j = 0$.

Hence

$$D\frac{dC}{dx} - Cv = 0 \quad [5]$$

The solution of Eq. [5] is

$$\ln C(x) = \frac{vx}{D} + \text{constant} \quad [6]$$

If at $x = 0$ the impurity content is kept at a constant value C_o by flowing gas past the electrode Eq. [6] becomes

$$C(x) = C_o \exp\frac{vx}{D} \quad [7]$$

Since fused LiCl does not wet porous graphite, the total length (L) of the diffusion path is equal to the thickness (t) of the porous electrode times the tortuosity (τ) of the pores within the porous material.

The concentration of impurity at the gas-liquid interface is then

$$C_s = C_o \exp\frac{vL}{D} \quad [8]$$

The velocity of gas flow within the pores in the x direction is given by

$$v = \frac{iRT}{n\mathbf{F}P_T\phi} \quad [9]$$

where i = current density per geometrical cm^2, ϕ = porosity, and P_T = total pressure.

Hence

$$C_s(i) = C_o \exp\left(\frac{iRT\tau t}{n\mathbf{F}P_T\phi D}\right) \quad [10]$$

or in terms of the impurity pressure

$$P_s(i) = P_o \exp\left(\frac{iRT\tau t}{n\mathbf{F}P_T\phi D}\right) \quad [11]$$

where P_o = impurity pressure in the incoming gas, and $P_s(i)$ = impurity pressure in the gas at the gas-liquid interface at current density i amp/cm^2. The concentration polarization of such an electrode during discharge compared to the potential of the same electrode at open circuit consists of two parts: the polarization in the gas-phase (η_g) and the polarization in the electrolyte (η_e)

$$\eta_g(i) = \frac{RT}{n\mathbf{F}} \ln \frac{P_{Cl_2}(\text{Bulk})}{P_{Cl_2}(\text{Electrolyte interface})} = \frac{RT}{n\mathbf{F}} \ln \frac{P_T - P_o}{P_T - P_s(i)} \quad [12]$$

$$\eta_e(i) = \frac{RT}{n\mathbf{F}} \ln \frac{P_{Cl_2}(\text{Electrolyte interface})}{P_{Cl_2}(\text{Electrode surface})} = \frac{RT}{n\mathbf{F}} \ln \frac{i_L}{i_L - i} \quad [13]$$

where i_L = limiting current density for the given Cl_2 pressure at the gas-liquid interface

$$i_L = K[P_T - P_s(i)] \quad [14]$$

The maximum current which can be drawn for a given value of P_T and P_o is given by

$$i_L = K[P_T - P_s(i_L)] \quad [15]$$

In Eq. [14] and [15] K is a constant for a given porous graphite equal to the limiting current density which could be obtained from the given material with absolutely pure Cl_2 at 1 atm.

It is assumed here that the pressure drop across the electrode is negligible under the test conditions. The total concentration polarization at a given current density is then the sum of $\eta_g(i) + \eta_e(i) = \eta_t(i)$. It should be noted that this polarization is the difference between the electrode at a current density i compared to that same electrode at open circuit not compared to that same electrode in pure Cl_2. To refer the electrode potential back to a pure Cl_2 electrode Eq. [12] should be

$$\eta_g(i) = \frac{RT}{n\mathbf{F}} \ln \frac{P_T}{P_T - P_s(i)} \quad [12A]$$

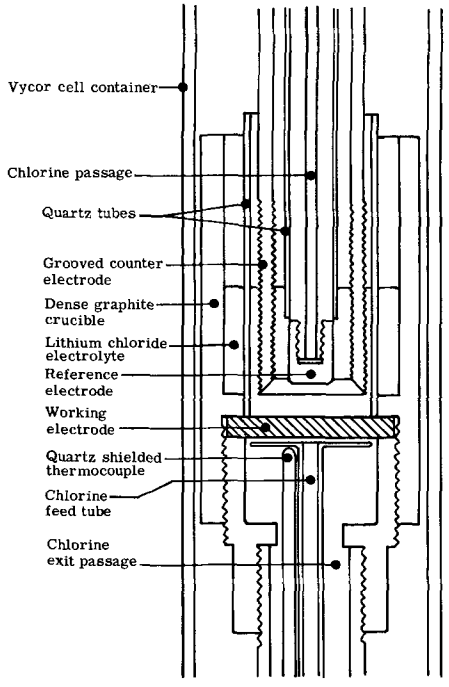

Fig. 1. Cell used in impurity effect studies

All polarizations used in this paper are referred to the OCV with impure Cl_2 gas.

Experimental

The cell and accessories.—A schematic diagram of the cell used in these studies is shown in Fig. 1. Lithium chloride electrolyte is contained in a graphite crucible, the bottom of which consists of a piece of porous graphite (Pure Carbon Company Grade FC-11). This porous graphite was the working electrode to which Cl_2 or mixtures of Cl_2 and Ar could be fed. The quartz feed tube below the electrode was flanged in order to insure uniform chlorine flow past the entire inner electrode surface. A thermocouple placed in the gas stream was used to control the temperature of the system. A quartz insert inside the graphite crucible exactly defined the useful area of the working electrode.

The reference and counter electrodes were mounted concentrically. The reference electrode electrically isolated by a quartz tube was slipped inside a hollow counter electrode which was grooved to give maximum surface area.

To prevent the development of a pressure difference between the inside and the outside of the counter electrode vertical slots were cut to above the electrolyte level. The entire assembly was placed inside a Vycor tube and was heated by means of clamshell heaters outside the Vycor container. The reference electrode was fed with commercial chlorine which was passed through a sulfuric acid drying bubbler. The chlorine and argon which were fed to the test electrode were also obtained from commercial cylinders. They were passed through concentrated sulfuric acid drying bubblers and introduced into a mixing chamber which consisted of a 500 ml flask filled with ceramic beads. The gases effectively mixed in this manner then flowed into the cell.

Gas analysis.—After flowing past the electrode, the gas mixture passed through an exit tube which was adapted for taking syringe samples for analysis by means of gas chromatography. A Barber-Coleman, Series 5000 gas chromatography was used to determine the amount of argon in the sample. A soda-lime absorption column was used to remove the Cl_2 from the sample so that only the impurity entered the detector. The impurity level of the gas sample was determined by comparing the amount of argon detected in a sample of known volume to an equal volume of pure argon.

Procedure.—Cells were assembled in air and heated in an argon or helium atmosphere to 650°C overnight to make sure the graphite parts were clean and dry. LiCl was previously purified by melting under vacuum and bubbling HCl through the melt which was contained in a graphite crucible. The melt was then allowed to solidify and was stored in a He drybox until needed. LiCl was crushed in the drybox and introduced into the cell by momentarily removing the reference electrode and pouring the salt down the counter electrode tube.

After the salt melted the reference electrode was introduced and connected to its Cl_2 supply. A mixture of Ar and Cl_2 was then supplied to the working electrode, and samples of the exit gas were analyzed until a constant composition was reached.

A current sweep was then applied to the working and counter electrodes. Voltage *vs.* current plots were recorded on a Varian F-80 x-y recorder. The current sweep rate was such that the current density changed by about 0.1 amp/cm^2/min. The sweep rate was determined by sweeping in both directions (increasing and decreasing currents) at various rates until the hysteresis in the I-V plot was less than 5%. Several plots at varying degrees of recorder sensitivity were obtained for each impurity level.

Electrode thickness varied from 1/16 to 3/4 in., but all electrodes were cut from a single block of FC-11 to give maximum uniformity of electrodes.

Results and Discussion

Each set of plots, obtained in the manner described above, was used in conjunction with IR measurements obtained from pulse transients to determine the polarization of the electrode under study. A set of curves was obtained for each thickness and impurity level at different recorder sensitivities. Thus, an average value of the polarization at each current density was obtained. Reproducibility of the polarization for a given set of conditions was better than ±10% except at very low polarizations (< 10 mv).

These average polarizations plotted *vs.* current density for various thicknesses and impurity concentrations are shown in Fig. 2 to 6 (solid lines).

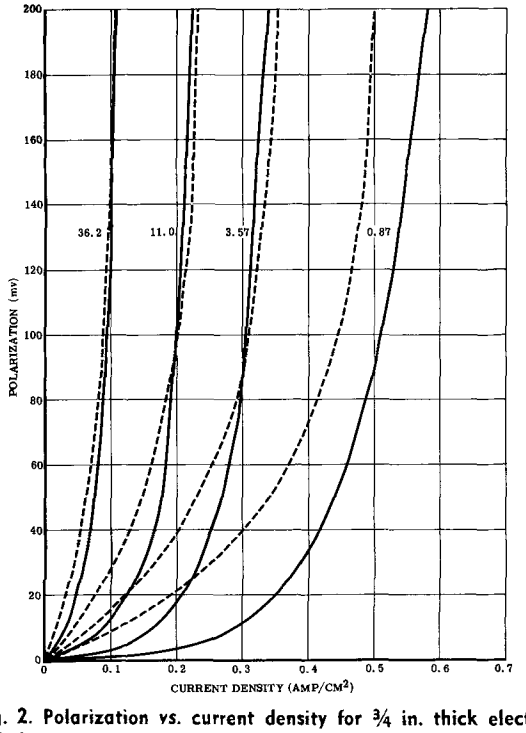

Fig. 2. Polarization *vs.* current density for ¾ in. thick electrode. (Solid line, experimental; dashed line, theoretical; % impurity indicated on curves.)

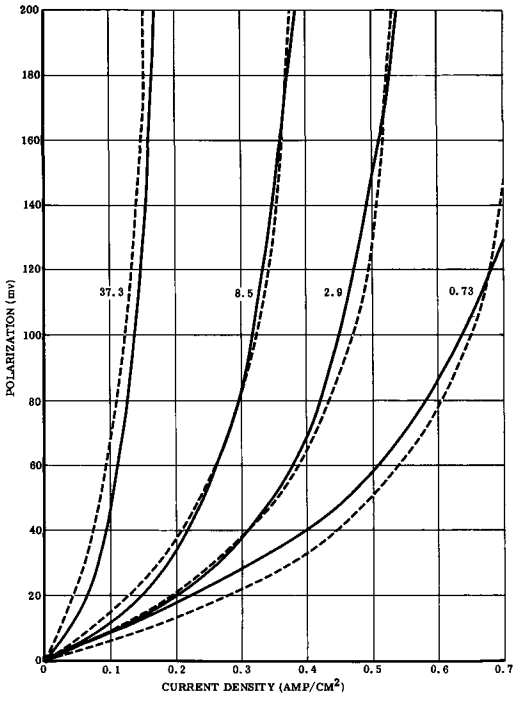

Fig. 3. Polarization *vs.* current density for ½ in. thick electrode. (Solid line, experimental; dashed line, theoretical; % impurity indicated on curves.)

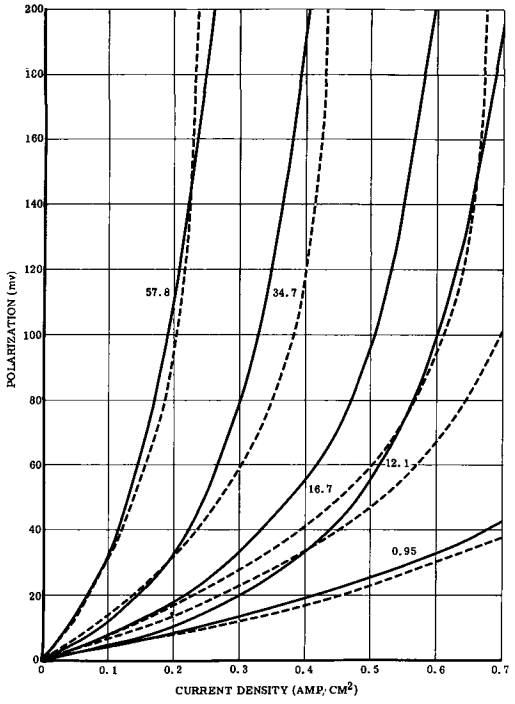

Fig. 5. Polarization *vs.* current density for ⅛ in. thick electrode. (Solid line, experimental; dashed line, theoretical; % impurity indicated on curves.)

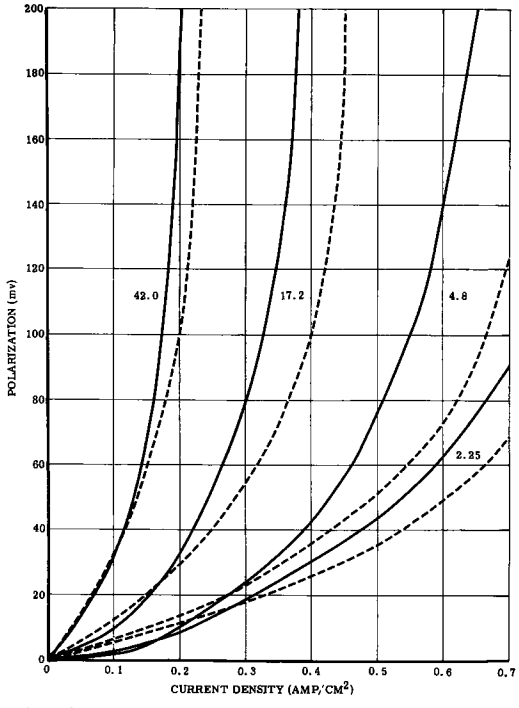

Fig. 4. Polarization *vs.* current density for ¼ in. thick electrode. (Solid line experimental; dashed line, theoretical; % impurity indicated on curves.)

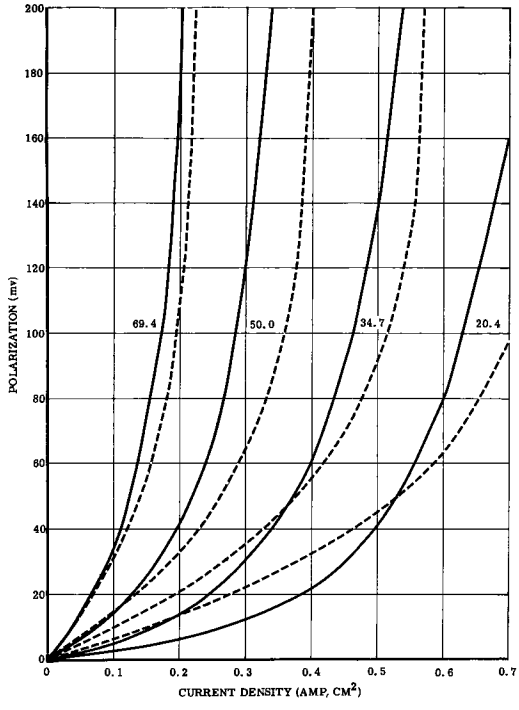

Fig. 6. Polarization *vs.* current density for 1/16 in. thick electrode. (Solid line, experimental; dashed line, theoretical; % impurity indicated on curves.)

Using Eq. [12] and [13] theoretical polarization *vs.* current density curves were calculated for the experimental conditions used. These are shown as dashed lines on Fig. 2 to 6. In these calculations the following constants were used: K = limiting current density which could be obtained on FC-11 with pure Cl_2 at 1 atm; K = 1.2 amp/cm². This value is within the range of values previously reported for FC-11 (1), but is significantly higher than the average value previously obtained. This is due to variations in the FC-11 material as well as the fact that the previous data were for impure Cl_2. The value of K = 1.2 amp/cm² has not been observed experimentally since sufficiently pure Cl_2 was not available. It is rather the present best estimate of what could be obtained.

The diffusion coefficient D for a binary gas mixture may be calculated (5) from

$$D = \frac{0.00185\, T^{3/2} \left[\dfrac{M_1 + M_2}{M_1 M_2} \right]^{1/2}}{P\sigma^2_{12}\Omega_D}$$

where T = temperature (°K); M_1,M_2 = molecular

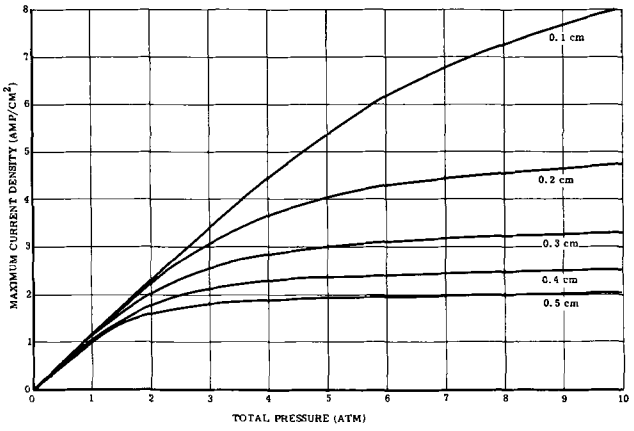

Fig. 7. Maximum current density (i_L) calculated for FC-11 porous graphite as a function of electrode thickness and total pressure at a 1% impurity level.

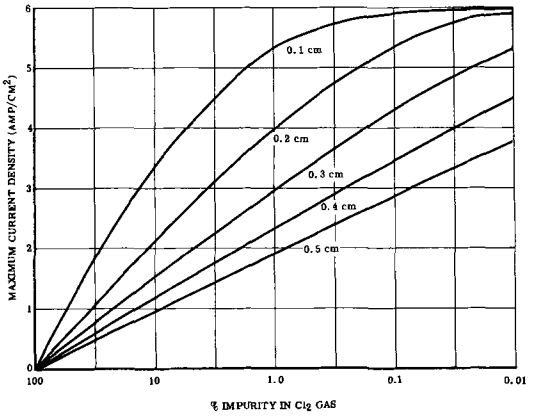

Fig. 8. Maximum current density (i_L) at a total pressure of 5 atm as a function of electrode thickness and impurity level.

weights of the two gases; $\sigma_{12} = \frac{1}{2}(\sigma_1 + \sigma_2)$; $\sigma_1, \sigma_2 =$ collision diameters; and $\Omega_D =$ collision integral available from tables (5).

For argon and chlorine we have: $M_1 = 39.95$, $M_2 = 70.91$, $\sigma_1 = 3.418$Å, $\sigma_2 = 4.115$Å, $\Omega_D = 0.8652$ and hence, $D = 0.842/P$ cm^2 sec^{-1} where P is total pressure in atmospheres.

Another constant used is the porosity $\phi = 0.22$. This value of the porosity only takes into account the larger pores in FC-11, *i.e.*, the pores between particles. It does not include the much smaller pores within the particles since these pores do not contribute appreciably to the flow of gases through the porous body.

The tortuosity τ is calculated as before (1) from

$$\tau = 0.765\ \phi^{-0.65} \qquad [14]$$

It is clear from Fig. 2 to 6 that the agreement between theory and experiment is excellent at the low polarizations shown. One shortcoming of the present treatment is that the theoretical treatment predicts very little increase in current density beyond $\eta = 0.2$v, whereas experimentally a 10-20% increase is observed in going from $\eta = 0.2$v to $\eta = 1.0$v. This will be treated in more detail in a future publication. Figure 7 shows what is predicted for various pressures and electrode thicknesses at a fixed impurity level of 1%. Increasing the total pressure has beneficial effects only for thin electrodes.

Figure 8 shows the maximum current density which can be obtained at 5 atm as a function of impurity level for various thicknesses. For a 0.5 cm thick electrode an impurity level of less than 1000 ppm is necessary to reach a current density of 3 amp/cm^2. The same current density can be reached with a 0.1 cm thick electrode with over 10% impurities in the Cl_2. Thus, electrode thickness has a large effect on the performance of this type of electrode.

Finally it is clear from Eq. [14] that the performance at a given impurity level is related to the porosity and pore size distribution of the graphite since these determine the value of K.

Conclusion

The effect of inert impurities in Cl_2 on the performance of flow-by electrodes has been demonstrated experimentally at 1 atm. The data have been compared with a theoretical treatment of the diffusion processes involved and good agreement was obtained.

The results indicate that at high current densities inert impurities can quickly poison porous electrodes unless some means of removing the inert gas is provided.

Technical Notes

The Double Layer Capacitance in Aqueous Solution

1. Polycrystalline Silver

N. A. Hampson, D. Larkin, and J. R. Morley

Chemistry Department, Loughborough University of Technology, Leicestershire, England

A number of studies of the double layer capacitance of polycrystalline silver in aqueous solution have been reported (1-9). Agreement among observed values is poor, and the values of the parameters which are required by the Stern theory (10) to adjust for changes in electrolyte type and concentration are improbable. There has been considerable disagreement regarding the position of the point of zero change (pzc), values have ranged from 0.51v (NHE) to the more probable value, —0.7v.

There is however general agreement that during the early stages of electrode/electrolyte contact, pronounced capacity changes occur. Wagner (4) observed a rapid reduction of double layer capacity on a freshly formed silver surface in contact with KCl solution. Gerischer and Fischer (11) found that the double layer capacity on silver fell to one half of its initial value in about 5 min at room temperature. Although certain results might be explained by the adsorption of impurities from solution on to the electrode in general impurity levels have been satisfactorily controlled. Moreover initial changes in electrode activity have been reported for other metals, *e.g.*, zinc (12), lead (13), and copper (14), and it is likely that pronounced changes in double layer structure occur on all metals during the early stages of electrode/electrolyte contact.

The purpose of this note is to present recent experimental findings of the double layer capacity of silver in sodium perchlorate solution.

Experimental

The Schering bridge, electrolytic cell, and purification procedure have been described elsewhere (12). For the present experiments the bridge was polarized using a potentiometer symmetrically applied across the bridge in series with a 40 henry choke. Potentials were measured with an electrometer (Wayne-Kerr precision-type M141) against an HgO/Hg reference electrode. The silver electrode was prepared from silver wire (2.553×10^{-2} cm^2 superficial area; 99.9999% supplied by Johnson-Matthey and Company) sheathed with polyethylene (this material was shown to be suitable for electrode construction by adding it to electrolyte in which the capacity of a sitting mercury drop electrode conformed to established data-addition produced no capacity change). Water was twice distilled from deionized stock, all chemicals were of A. R. quality.

The flat X-section of the silver wire formed the working electrode. Electrodes were polished mechanically on roughened glass lubricated with water. Etching (10% HNO_3 or 10% $HClO_4$) was carried out either chemically (30 sec) or electrochemically (10 ma/cm^{-2}). Electrodes were thoroughly washed with water before introduction (wet) into the cell.

Results

Electrometric measurements indicated that the electrode was readily polarizable in the region 0.5v to —1.1v (NHE). Outside this region faradaic current flowed particularly at the more positive potentials.

Some initial change in double layer capacity measurement were observed, but provided that the polarizable region was swept from potentials more negative than 0.4v (NHE) capacity readings quickly stabilized and differential capacity curves reproducible over many hours were taken as indicative of a clean silver surface. For example a mechanically polished and chemically etched electrode in 1M $NaClO_4$ at 23°C held at —0.1v NHE gave a double layer capacity (212 c/sec) after 1 min of 108 μF/cm^{-2} and a stable value of 84 μF/cm^{-2} after 30 min. Changes of double layer capacity were generally more pronounced with electrodes which had only been mechanically polished.

Figure 1 shows differential capacity curves typical

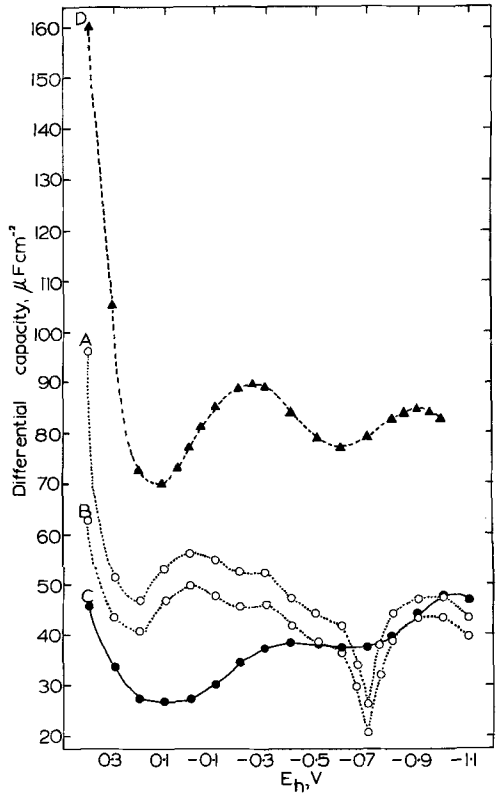

Fig. 1. Differential capacity curves for polycrystalline silver in $NaClO_4$ solutions at 23°C; pH, 6.5-7. Curve A, 0.01M $NaClO_4$; held at —0.3v (NHE) for 1 hr; swept from negative potentials; 212 c/sec. Curve B, 0.01M $NaClO_4$; held at —0.3v (NHE) for 1 hr; swept from negative potentials; 1000 c/sec. Curve C, 0.01M $NaClO_4$; held at —0.4v (NHE) for 1 hr; swept from 0.4v (NHE); 212 c/sec. Curve D, 1M $NaClO_4$; held at —0.3v (NHE) for 1 hr, swept from negative potentials; 212 c/sec.

of a clean surface determined at 212 and 1000 Hz. Generally capacity values were within ± 20% of the values shown. Figure 1 also shows a capacity curve swept from potentials more positive than 0.4v. The sharp minimum at —0.7v, indicating the position of the pzc, is absent (in all cases), and curves were not reproducible; attempts to reestablish differential capacity curves typical of a clean silver surface by cathodic polarization were not successful. Capacity curves in which the minimum at —0.7v was absent were often obtained with electrolytically etched electrodes.

For comparison a typical differential capacity curve obtained with a clean silver surface in relatively concentrated (IM) electrolyte is also included in Fig. 1.

Discussion

The position of the capacitance minimum in the differential capacity curves obtained with dilute solutions, —0.7v (NHE), indicates the pzc, and confirms Russian work (5, 9). A capacitance minimum is not a satisfactory criterion for the position of the pzc if potential dependent adsorption, *e.g.*, of H or O on Pt or Pd. In the case of Ag (also Sn, Cd, Pb) in the polarizable region the adsorption of these species is not a complication (relatively small frequency dispersion-pseudocapacitance, high hydrogen overpotential similar to Hg, absence of hysteresis effects in the range 0.38 to —1.1v [NHE]).

The ease with which electrodes became irreversibly affected at potentials positive to 0.4v (NHE) suggests that this might be the reason for conflicting double layer capacitance data particularly with electrolytically etched surfaces where the potential is much more positive than 0.4v. The disappearance of the capacity minimum under these conditions indicates the influence of adsorbed reaction products.

The form of the differential capacity curve in molar electrolyte is very similar to that of mercury confirming the work of Ramaley and Enke (8). Since impurity levels were satisfactorily controlled the relatively high value of the differential capacity in the more concentrated electrolyte indicates that the surface of the silver electrode is relatively rough. Time dependence is very pronounced and appears to be a simple equilibration process. That a simple mechanical polished (surface layers structurally disturbed) should show more initial capacity change than a chemically etched (partially equilibrated) surface is in agreement with this suggestion.

A small dispersion of frequency is shown clearly in Fig. 1. Since the possibility of crevices between the electrode and sheath was absent in this work, dispersion must be ascribed to surface roughness as discussed by De Levie (15).

Summary

Differential capacity curves for clean silver surfaces in dilute and 1M sodium perchlorate solution are recorded. The differential capacitance is dependent on electrode/electrolyte contact time.

A Specimen Holder for Precise Electrochemical Polarization Measurements on Metal Sheets and Foils

W. D. France, Jr.

Chemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

Experimental difficulties often arise when sheet-metal electrodes are exposed for precise electrochemical polarization measurements. Both solution contamination and crevice effects, which cause marked data distortion (1), must be avoided, and a solderless electrical contact that is insulated from the electrolyte must be provided. Our laboratory evaluations of sheet specimens that were masked by tape, paint, or resin encapsulation have caused us to lose confidence in these procedures. Therefore, we have designed the rapidly assembled sheet specimen holder illustrated in Fig. 1 for use in conventional polarization cells. The polycarbonate and Teflon combination provides the strength, compressibility, and solution resistance necessary for this application (2, 3). Circular specimens, cut with a die and punch, are positioned on the replaceable Teflon gasket within the holder, followed by a copper disk contact whose electrical lead wire passes through a Teflon insulator. The threaded Teflon bolt is tightened with sufficient torque to compress the sheet against the gasket. The exposed specimen pictured in Fig. 2 exhibits a typical, distinct demarcation between the corroded and the protected areas that demonstrates the effectiveness of the seal. Accumulation of corrosion products and evolved gas at the specimen face is avoided by an oblique entrance angle.

Figure 3 shows two potentiodynamic anodic polarization curves for an annealed stainless steel (Fe-18Cr-12Ni-0.08C) in hydrogen-saturated, 1.0*N* H_2SO_4 at 25 °C. Following a standard procedure, we polished specimens on 600-grit SiC, degreased them in boiling benzene, rinsed them in distilled water, and immersed them in the test solution 1 hr before automatically plotting the experimental semilogarithmic curves at

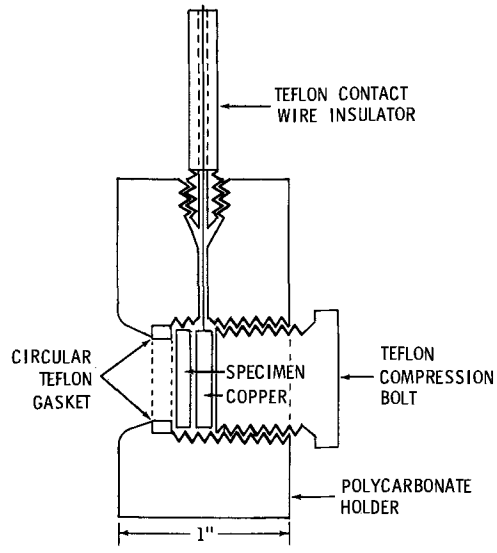

Fig. 1. Specimen holder for metal sheets and foils (side view)

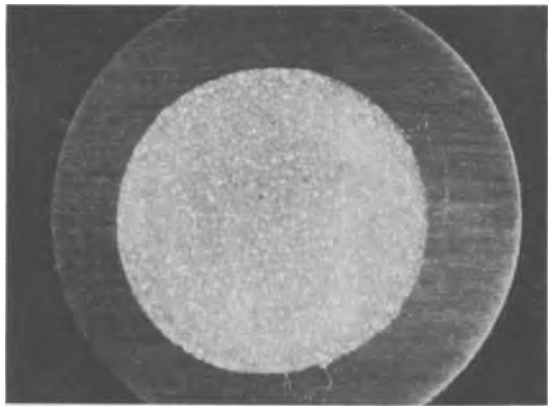

Fig. 2. Photomicrograph of exposed sheet-metal specimen. Magnification 3.5X.

1.2 v/hr, using apparatus similar to that described earlier (4, 5).

Curve A represents the results for a sheet specimen exposed in the described holder, and curve B represents the results for a bulk specimen of the same alloy mounted on a Stern-Makrides assembly (6). The sheet specimen curve effectively duplicates the standard curve, showing no evidence of crevice effects or shielding of the specimen electrode.

This sheet specimen holder is easily fabricated and has the advantage of rapid and effective assembly. Besides providing a known and reproducible exposed

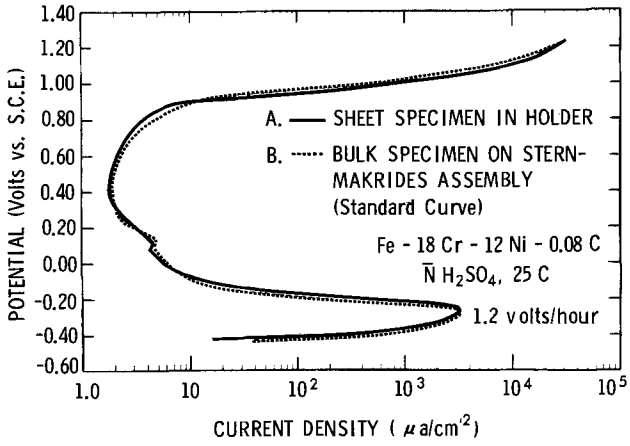

Fig. 3. Potentiodynamic anodic polarization curves for Fe-18Cr-12Ni-0.08C Alloy in *N* H_2SO_4 at 25°C. Curve A, sheet specimen mounted in holder; curve B, bulk specimen mounted on Stern-Makrides assembly.

area for each experiment,[1] edge effects are completely avoided, and a geometrically equivalent surface is exposed, as recommended elsewhere (7). Laboratory experiments have demonstrated that this mounting technique provides an efficient means for exposing any sheet specimen, including polished, coated, or plated surfaces as well as thin foils.

[1] A 0.445 in. (1.13 cm) diameter orifice provides a 1.0 cm^2 exposed specimen area, which is highly desirable for recording potentiodynamic polarization curves, since recorded current (μa) is then current density ($\mu a/cm^2$).

Brief Communications

Comments on the Paper "Transport Processes in the Thermal Oxidation of Silicon"

P. J. Jorgensen

General Electric Company Research and Development Center, Schenectady, New York

The paper "Transport Processes in the Thermal Oxidation of Silicon" by Raleigh (1) is actually a discussion of the paper "Effects of an Electric Field on Silicon Oxidation" (2). Raleigh concludes that at the present time it is not possible to determine whether an ionic transport process or a molecular transport process predominates. He begins by asserting "that the external application of an electric field *per se* cannot provide a steady-state driving force for a diffusion-controlled process such as the thermal oxidation of silicon" and further that the voltage at which oxidation ceases is "unrelated to the free energy of formation of SiO_2."

The first assertion has been adequately treated by Collins and Nakayama (3) in their recent paper on "Transport Processes in the Thermal Growth of Metal and Semiconductor Oxide Films." These authors point out that the application of an electric field using insulating electrodes, which do not provide an external path for electron flow, does not cause an increase in the flux, in accordance with Raleigh's assertion. However the use of electrodes which are in ohmic contact with the oxide film provides an external path for electrons and an increase in the ionic flux is to be expected. In the silica oxidation experiments discussed by Raleigh, electrodes in ohmic contact were used, and therefore an increase in ionic flux is to be expected.

The second assertion in Raleigh's paper concerning the so-called halt voltage being unrelated to the free energy of formation has recently been discussed by Kröger (4). Wagner (5) has also written an excellent treatise on the effect of an external electric field applied to a growing oxide layer. In this unpublished memo Wagner treats the situation in which corrosion is stopped by a potential difference across the growing film.

The argument briefly stated is as follows: The flux of a given species J_i, in mol/cm^2 sec, may be expressed as

$$J_i = -\frac{\sigma_i}{Z_i^2\mathbf{F}^2}\left(\frac{\partial \mu_i}{\partial X} + Z_i\mathbf{F}\frac{\partial \Phi}{\partial X}\right) \qquad [1]$$

where σ_i is the conductivity due to the ith species, Z_i is the valence, $\mathbf{F}$ is Faraday's constant, μ_i is the chemical potential, and Φ is the local electrical potential. From the principles of electrochemistry the difference in potential ($\Delta\psi$) across an oxide film is

$$\Delta\psi = -\frac{\eta_e'' - \eta_e'}{\mathbf{F}} \qquad [2]$$

where η_e'' and η_e' are the electrochemical potentials of the electrons at the oxide-gas and metal-oxide interfaces, respectively.

Since $\eta_e = \mu_e - \mathbf{F}\Phi$. Then

$$\Delta\psi = \frac{(\mu_e'' - \mu_e')}{\mathbf{F}} + \Phi'' - \Phi' \qquad [3]$$

from [1], if $J_i = 0$, then

$$\frac{\partial \Phi}{\partial X} = -\frac{1}{Z_i\mathbf{F}}\frac{\partial \mu_i}{\partial X} \qquad [4]$$

The term $(\Phi'' - \Phi')$ in Eq. [3] is equal to the integral of Eq. [4]. Now considering the case where only the anions are mobile, and using the definition for the chemical potential of oxygen atoms $\mu_0 = \mu_1 + Z_1\mu_e$ where the subscript 1 refers to anions and $Z_i = -2$, then the chemical potential of the molecular oxygen is $\mu_{0_2} = 2\mu_0 = 2\mu_1 - 4\mu_e$ and one obtains

$$\Delta\psi\ (J_1 = 0) = \frac{\mu_0' - \mu_0''}{Z_1\mathbf{F}} = \frac{\mu_{0_2}'' - \mu_{0_2}'}{4\mathbf{F}} \qquad [5]$$

which illustrates the relationship between the change in free energy, and the voltage at which a reaction can be stopped. Hence the stopping voltage is related to the change in free energy.

The conclusion that available data do not allow one to decide whether an ionic or a molecular type process predominates during the oxidation of silicon merits discussion.

The voltage necessary to stop an oxidation reaction will be E_o regardless of the magnitude of the electronic transport number, where

$$\Delta G = -n\mathbf{F}E_o \qquad [6]$$

and ΔG is the change in free energy, n is the number of equivalents involved in the reaction, $\mathbf{F}$ is Faraday's constant, and E_o is the theoretical cell voltage. If a molecular transport process occurs simultaneously, the value of E_o might be lowered in value somewhat as discussed by Schmalzried (6). However, this reduction in the value of E_o is not expected in the case of the oxidation of silicon since the transport of oxygen through the silica layer is rate determining, and equilibrium can most probably be established at the oxide interfaces.

The application of a voltage equal and opposite in sign to E_o across the growing oxide layer would stop any ionic transport, but a further increase in voltage would be necessary in order to establish a decomposition rate of the oxide which would be equal to the formation rate of oxide by a simultaneous molecular and ionic transport process.

Experiments (7) on approaching the stopping voltage from voltages greater than E_o, *i.e.*, reducing the oxide with an electric field have shown a correlation with E_o of ± 5-10 mv, indicating, within experimental error, a negligible amount of oxygen transport by a molecular process.

Some of the effects of an applied electric field on the rate of permeation of oxygen through fused silica have also been investigated (8). A schematic represen-

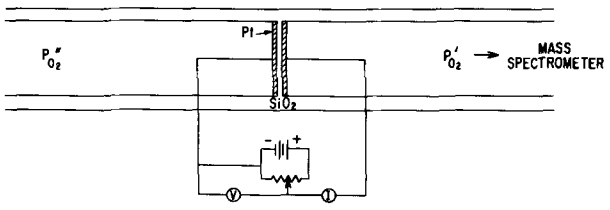

Fig. 1. Schematic drawing of the permeation cell.

tation of the permeation cell which was used is shown in Fig. 1.

Corning 7940 fused silica having a negligible alkali ion content was used for the membrane and GE 204a fused silica tubing was used for the outside walls of the cell. The system was baked at 1000°C under a vacuum for several weeks to remove the hydroxyl content in the Corning 7940 silica. Other details of the experimental apparatus have been previously described (8). The application of a pressure of 10^{-7} mm of oxygen on the mass spectrometer side of the cell and 323 mm of oxygen on the opposite side at 1000°C under open-circuit conditions yielded a permeation rate of 1.68×10^{-12} cm^3 gas (STP) per sec for a 1 mm thick membrane, per cm^2 area per cm Hg gas pressure difference. Interpolating Norton's (9) oxygen permeation data through fused SiO_2 to obtain a rate of permeation at 1000°C yielded a value of 1.85×10^{-12} with the above quoted units. These values are in excellent agreement and indicate the placing of sputtered platinum electrodes on the SiO_2 does not measurably interfere with the permeation process.

Open circuit potentials were developed when an oxygen pressure difference was applied across the silica. The calculated ionic transport numbers ranged between 0.40 and 0.53 varying with the magnitude of the pressure difference. These voltages again indicate an ionic transport.

The application of 6 Torr of oxygen to one side of the permeation cell and 10^{-7} Torr to the other side, *i.e.*, the mass spectrometer side (see Fig. 1), yielded an ionic transport number of 0.40. Using this value and Faraday's laws, the amount of oxygen due to ionic transport was calculated at zero volts. The amount calculated per second was 8.2×10^{-13} g equiv, and the amount measured using the mass spectrometer was 7.2×10^{-13} g equiv. The difference between these values is within experimental error. Again indicating a negligible molecular transport compared to the ionic transport.

Finally there are many small points in Raleigh's paper which are incorrect, but are beyond the scope of this communication. However, two of these minor points should be commented on:

1. The statement that "oxygen ions were involved in the oxidation of zinc" (10) is misleading in that it infers that diffusion of oxygen ions through ZnO is the rate-determining step in the oxidation of zinc. The effects of an electric field on the oxidation of zinc place no restrictions on which ion is rate limiting and the oxide may form either at the zinc-zinc oxide interface or the oxide-platinum electrode interface.
2. An impure SiO_2 exhibits pure ionic conductivity, as the purity increases, the fraction of the ionic conductivity decreases. The high-purity SiO_2 used in the permeation experiments and the SiO_2 formed on the silicon had ionic transport numbers near 0.40. This fact causes Raleigh's model for the stopping voltage to predict a value greater than 3v, which is unrealistic. Hence his model to account for the stopping voltage is suspect.

In conclusion, the application of an electric field across growing oxide layers can affect the rate of oxidation. The voltage at which a reaction can be stopped is directly related to the free energy of formation, and available experimental evidence indicates that an ionic process could be the predominant transport mechanism for oxygen through SiO_2. However, the linear pressure dependence on the permeation and oxidation rates argues strongly for the diffusion of oxygen molecules, and this fact must be properly accounted for in terms of ionic and electronic transport, before the conclusion can be made that the prevailing mechanism of oxidation of silicon involves only ionic and electronic transport processes.

Acknowledgments

The author wishes to express his gratitude to Dr. D. A. Vermilyea and S. P. Mitoff for many stimulating discussions, and to Professor Carl Wagner for his comments and permission to refer to his unpublished memo.

The Anodic Dissolution of Electrodeposited Nickel

P. A. Brook, D. B. Jenkins, and M. Saleem

Department of Metallurgy, The University of Nottingham, University Park, Nottingham, England

The anodic dissolution of electrodeposited metals should reveal details of their structure; this note reports some such observations. All initial deposits were made on polycrystalline copper strip from a standard Watts nickel bath as described previously (1) except that a current density of 20 amp/ft^2 for 2 hr was used. After preparation the deposits were anodically dissolved for various times at 20 amp/ft^2 in an electrolyte of 100 g/l $NiSO_47H_2O$ or 100 g/l $NiCl_26H_2O$ or N/11.9 HCl. After dissolution the surface was examined by electron microscopy of carbon replicas.

The as-plated surface showed the typical pyramidal structure previously reported (1, 2). For the sulfate electrolyte, the attack appears as a generalized pitting for times of up to 1 min (Fig. 1), but with increasing time the pits coalesce to form steps which run parallel to the basal edges of the pyramids (Fig. 2). Another feature of the dissolution is the coalescence of the pits

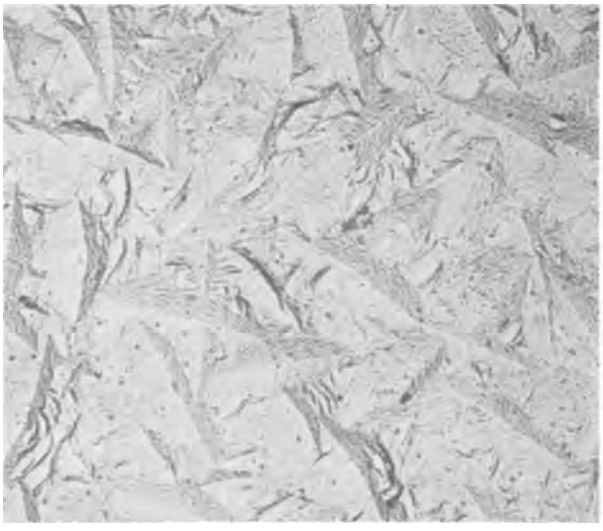

Fig. 1. Nickel surface after 1 min dissolution. Magnification 8000X.

Fig. 2. Nickel surface after 2 min dissolution. Magnification 8000X.

across one pair of opposite pyramidal edges causing the original pyramid to become more ridgelike. After 10 min the step spacing has increased to form ledges, and the breakdown of the pyramids has reached an advanced stage although in many cases ridges are still clearly visible (Fig. 3).

Dissolution in the chloride electrolytes produces similar effects, but ledge formation is less well defined.

It appears that dissolution does not take place from the emergent screw dislocation and the initial attack is, apparently, random. However, at about 2 min the process has assumed a crystallographic characteristic since the steps are parallel to the pyramid basal edges. Hulett and Young (3) have discussed step formation

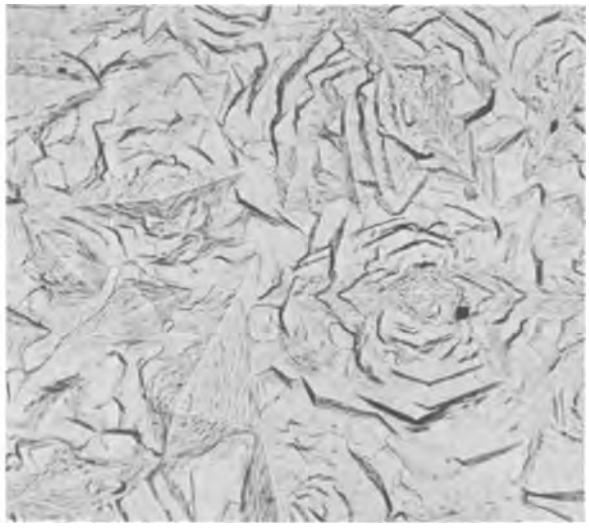

Fig. 3. Nickel surface after 10 min dissolution. Magnification 8000X.

during the dissolution of (111) copper faces, and they suggest that there is a threshold step spacing of about 500-700Å beyond which there is no interaction between steps. The earliest discernible steps on the dissolving nickel faces occur after about 2 min and their spacing is about 600Å. This takes no account of the inclination of the pyramidal faces, but for normal values the step spacing will be changed only to a small extent. Once formed the steps interact to form the ledges shown in Fig. 2.

The side faces of the pyramids are not smooth, and in some cases striations are visible as if the pyramids are formed by piling up of macrolayers.

This seems to be confirmed by the present results. The dissolution takes place from the edges of the macrolayers initially in an apparently random manner, but later there is an ordered process forming visible steps which move across the surface interacting to form ledges.

At the moment it is not possible to explain the persistence of the ridges long after the main pyramidal structure has gone.

Acknowledgment

The authors would like to thank the Scientific Research Council for a grant for the purchase of an electron microscope.

Electrochemical Studies on the Effect of Water in Nonaqueous Electrolytes

A. N. Dey

Laboratory for Physical Science, P. R. Mallory & Company, Inc., Burlington, Massachusetts

The role of water in nonaqueous electrochemistry is not very well understood. Although problems related to the cathodic deposition of lithium from nonaqueous media containing water have been reported (1), the questions as to whether water behaves like a solvent or a cathode active material, as to whether water interacts with the electrolyte or the solvent, etc., are still quite open. We report here some experimental results which provide answers to some of the above questions.

The effect of water on the cathodic discharge reactions in a nonaqueous medium was studied by deliberately adding known amounts of water to the electrolyte and carrying out galvanostatic and potential sweep experiments. The galvanostatic experiments consisted of imposing a constant cathodic current on the working electrode (placed in an H-type cell) and recording the potential of the electrode against a reference Ag wire electrode (placed within 0.5 cm of the electrode) as a function of time. The potential sweep experiments consisted of imposing a linearly varying potential (with respect to Ag wire reference) on the electrode at various sweep rates, and recording the current as a function of potential with an X-Y recorder.

Propylene carbonate (PC) was used as a solvent and anhydrous $LiClO_4$ and $Mg(ClO_4)_2$ as electrolyte salts. The initial concentration of water in the distilled PC was between 10^{-3} to 10^{-2} M/liter, as determined by gas chromatographic analysis.

The cathodic galvanostatic transient on a copper electrode in $LiClO_4$-PC gave rise to three distinct plateaus (in the potential-time curves) in the potential ranges of —1.0 to —1.5, —1.5 to —2.5, and —2.5 to —3.0v *vs.* the Ag wire reference before the lithium deposition potential was reached. The above transient was found to be reproducible when the electrodes were chemically etched with dilute HNO_3 before every transient. On the deliberate addition of water, it was found that the length of only the second plateau (corresponding to the potential range —1.5 to —2.5v) increased, whereas the other two remained constant. The presence of OH^- was also detected on the electrode when the transient was discontinued in the middle of the second plateau by using the following simple test. The electrode was removed from the electrolyte and immediately placed in water containing phenolphthalein. The appearance of blue color on the electrode as well as in aqueous medium showed that there was enough LiOH (sparingly soluble in the electrolyte) present on the electrode to change the *p*H of aqueous solution of phenolphthalein. The above evidence led to the conclusion that water discharged on the copper electrode from the $LiClO_4$-PC system at a potential corresponding to the second plateau in the galvanostatic transient. The reasons for the first and the third plateau were not very clear at this stage. However, the lengths of the first and the third plateaus were negligible compared to the length of the second plateau at higher concentrations of water (*e.g.*, 1.0 M/liter). It was found that $i\tau^{1/2}$ (i is the cathodic current density, and τ is the transition time corresponding to the second plateau only) was independent of i over a range of half a decade of current density. The dependence of $i\tau^{1/2}$ on the concentration of added water showed a very interesting property. Figure 1(A) shows a plot of $i\tau^{1/2}$ *vs.* the concentration of added water in 1M $LiClO_4$ in PC. There was a sharp break

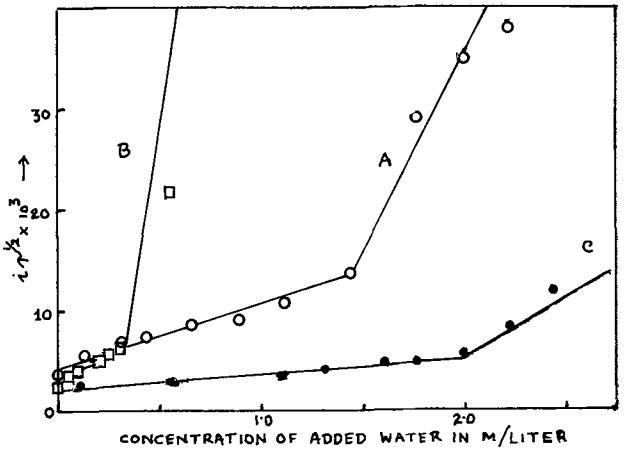

Fig. 1. Dependence of $i\tau^{1/2}$ on the concentration of added water in (A) 1.0M $LiClO_4$ in PC, (B) 0.1M $LiClO_4$ in PC, and (C) 0.5M $Mg(ClO_4)_2$ in PC.

in the curve giving rise to two linear regions having two distinctly different slopes. The slope at the lower concentrations of water was much lower than expected on the basis of linear diffusion (Sand's equation) (2). The diffusion coefficient calculated from the lower slope was of the order of 10^{-8} cm²/sec whereas it was of the order of 10^{-6} cm²/sec at the higher slope. The transition point (*i.e.*, the concentration at which the two lines intersect) was reproducible within ± 10%. The point of break appeared to depend on the concentration of $LiClO_4$. It occurred at a lower concentration of added water (0.33 M/liter) at lower concentrations (*e.g.*, 0.1M) of $LiClO_4$ [Fig. 1(B)]. The transition point also depended on the nature of the cation. In 0.5M $Mg(ClO_4)_2$, the transition point occurred at 2.0 M/liter [Fig. 1(C)].

The results of the potential sweep experiments were identical with the above results. A distinct current peak corresponding to water discharge in the potential range of —1.5 to —2.5v was observed. The peak current i_p was found to be dependent on the sweep rate, v, and $i_p/v^{1/2}$ was found to be independent of the sweep rate at constant concentration within the range examined (200 to 50 mv/sec) in conformity with the equation (2)

$$i_p = AD^{1/2}Cv^{1/2}$$

where A is a constant for the particular system, D is the diffusion coefficient, and C is the concentration of the discharging species. The plot of i_p *vs.* C, the concentration of added water, showed the transition point to occur [Fig. 2(A)] at exactly the same concentration of added water (1.45 M/liter) as was found in the galvanostatic experiment. The dependence of the transition point on the concentration of the salt and the cation was also found to be similar to that found in the galvanostatic expriments.

The effect of the substrate on the transition point was studied by using the potential sweep method. Figure 2 shows a plot of the peak currents as a function of the concentration of added water on three substrates: Cu, Ni, and Pt. As is evident from the figure, there is no substrate effect.

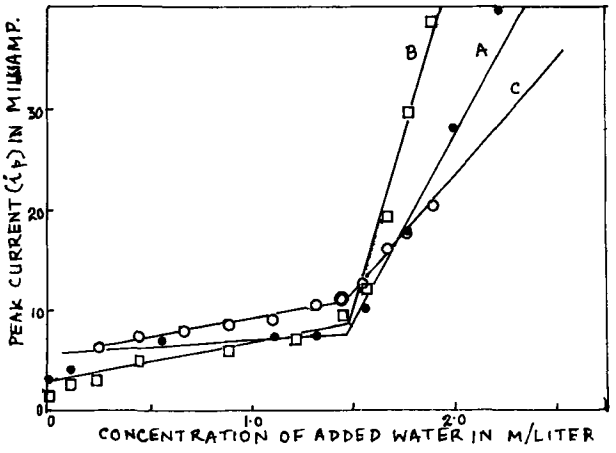

Fig. 2. Dependence of peak current (i_p) at a sweep rate of 200 mv/sec on the concentration of added water in 1M $LiClO_4$ on (A) copper, (B) nickel, and (C) platinum substrates.

An interpretation of the above experimental results in terms of a change of diffusion coefficient of the discharging species with concentration appears to be rather improbable. Considering the fact that water was the discharging species corresponding to the peaks and plateaus of the potential sweep and galvanostatic experiments, respectively, a simple interpretation of the above results can be given as follows. The affinity of water for cations is well known in aqueous solutions (3). It can be similarly postulated that water interacts with the dissolved salts in the nonaqueous medium to such an extent that it may not discharge, depending on the salt/water ratio. When sufficient water is added to satisfy the hydration requirements of the salts, the excess water can discharge normally, giving rise to a sharp break in the $i\tau^{1/2}$ *vs.* C or i_p *vs.* C curves. The bound water would behave differently from the free water both electrochemically and physically.[1] The dependence of the transition point on the concentration of the added salt can be explained by this hypothesis. The divalent Mg^{++} ion is known to be hydrated more strongly than the monovalent Li^+ ion. Therefore, a stronger interaction would be expected in 0.5M $Mg(ClO_4)_2$ than in 1M $LiClO_4$, if cations are involved in the interaction. Although the concentration of ClO_4^- was identical in both 1M $LiClO_4$ and 0.5M $Mg(ClO_4)_2$, the transition point increased from 1.45 to 2.0 M/liter in going from $LiClO_4$ to $Mg(ClO_4)_2$. This indicates that the cations rather than the anions participate in the interactions between the water and the dissolved salts in PC. However, interactions with the anions cannot be ruled out.

The above interactions constitute a bulk phenomenon, and no substrate effects would be expected, as was found to be the case. More detailed results concerning this phenomenon will be reported in a subsequent paper.

[1] The decrease in the diffusion coefficient of water due to its interaction with the cation does not appear to be very likely as the diffusion coefficients (4) of a number of salts in aqueous medium are of the order of 10^{-5} cm^2/sec.

Acknowledgment

The author is indebted to Dr. Per Bro, Dr. M. L. B. Rao, and Dr. R. G. Selim for encouragement and stimulating discussions.

Manuscript received May 19, 1967. This paper will be presented at the Chicago Meeting, Oct. 15-20, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Silicon Nitride Films by Reactive Sputtering

S. M. Hu and L. V. Gregor

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Silicon nitride films (from 500 to 7500Å in thickness) have been deposited on silicon and silicon dioxide by reactive sputtering of a silicon cathode in a N_2 glow discharge. Both d-c and rf sputtering have been investigated. Physical and chemical properties of silicon nitride films prepared by sputtering were examined in reference to the process variables. The rate of deposition was approximately proportional to the square root of rf power density. Film density increased with power density, and decreased with gas pressure. Optimum gas pressure was in the range 3-10 x 10^{-3} Torr. Higher pressures resulted in less dense and electronically leaky films. Dielectric constant and etch rate in HF solution appeared to correlate well with film density. Residual pressure higher than 1-2 x 10^{-6} Torr was found to have a most detrimental effect. Argon and nitrogen gas mixtures resulted in excess silicon incorporation in the deposited nitride films.

Silicon dioxide has for the past several years been the most important material to serve the multiple function of insulation, passivation, and diffusion masking. Because of its chemical nature and its structural characteristics, there are a number of shortcomings inherent in silicon dioxide. The most serious of these is its low resistance to diffusion of certain impurities and to field migration of ions, which causes instability and deterioration of surface characteristics of electronic devices, and, in particular, field effect devices. From the properties of crystalline silicon nitride one may extrapolate to the generally superior properties of amorphous silicon nitride compared to silicon dioxide, except for higher electronic conductivity.

Precisely because of its desirable high resistance to the diffusion of atomic, molecular, or ionic species, silicon nitride cannot be grown on a silicon substrate by thermal nitridation, either in nitrogen or in anhydrous ammonia, in contrast to the thermal oxidation of silicon in oxygen and in steam. Experiments with thermal nitridation (1) and plasma anodization (2) failed to produce coherent silicon nitride films on silicon substrates. In addition, thermal nitridation or oxidation has a limitation on the scope of its use to silicon only. A deposition method thus seems to be a more logical approach.

Sterling and Swann (3) and Doo *et al.* (4) have succeeded in the deposition of continuous amorphous silicon nitride films by means of vapor phase reaction of silane and anhydrous ammonia. At the same time the authors and Pennebaker (5) also succeeded in obtaining continuous silicon nitride films, properly identified as silicon nitride (dielectric constant 6.0-7.0; IR absorption band at 11.5-12μ) by means of d-c and rf reactive sputtering, respectively. Recently, others have described various processes for depositing silicon nitride (6).

Sputtering deposition of insulating-passivating films over semiconductors is a process which involves more difficulties than the sputtering of metal films. Some of these are: (*i*) most insulating films are chemical compounds rather than elements, and thus there is the problem of the control of the stoichiometry of the films; (*ii*) although impurities affect the resistivity of metal films considerably, this is a relatively small effect except for superconductive films; the conductivity changes in insulators, however, caused by the presence of impurities, is generally several orders of magnitude; (*iii*) there is also a surface charge problem arising from one or a combination of the following: substrate surface damage, trapped impurities, interface mismatch, and interfacial stress. In addition, there is another fact that sets silicon nitride apart from silicate glasses: The high melting point, high hardness, and essentially covalent nature, make thermal annealing almost impossible. To understand these many complex problems and to relate them to parameters of the sputtering process, various properties of the films, such as carrier injection, electric conduction, ion migration and impurity diffusion, surface charge and trapping centers, etc., should be studied.

Reactive sputtering has been used to prepare oxide glasses (7, 8). It is a logical extension that silicon nitride may also be prepared by reactive sputtering in a nitrogen plasma. However, there is an additional factor: the possible contamination of the system by oxygen, because oxygen is much more reactive than nitrogen. This is much more critical to d-c sputtering than rf sputtering, as was found out in the course of this work. In the case of reactively sputtered silica, although Sinclair and Peters (7) found that the infrared absorption spectrum and the refractive index as well as the density of the film to be the same as ordinary fused silica, they found the dielectric strength to be less than 10^6 v-cm^{-1}, which is only 20% of the dielectric strength of the thermally grown silicon dioxide film. These they believed were caused by microscopic flaws in the thin films.

High-frequency fields were first used by Anderson *et al.* (9) and Davidse and Maissel (10) for sputtering of dielectric targets, to enable the neutralization of the ion-bombarded dielectric surface via displacement currents. In addition to its originally intended use for dielectric sputtering, tthe rf sputtering process involves a number of interesting characteristics which make it advantageous for physical and reactive sputtering of metals and semiconductors as well. These features were found from a comparison of the results of dc and rf sputtering of silicon nitride.

Experimental

Three different experimental systems were used in this investigation. The first, which was employed for dc reactive sputtering, was constructed of glass. The second system consisted of a stainless steel bell jar, and both d-c and rf sputtering were studied. The third system was constructed solely for rf sputtering, and consisted of a cylindrical glass bell jar with aluminum top and base plates. Most of the results discussed were obtained with the latter system. The system is generally similar to that described previously (10), except that the dielectric target has been replaced by a polycrystalline silicon disk, 4 in. in diameter, and ¼ in. in thickness, soldered to the cathode (see Fig. 1). The cathode was water-cooled to reduce gas evolution. Although the rf field applied to the "cathode" was with respect to ground, the cathode potential was actually formed because of the very low mobility of positive ions. The dark space is a function of pressure

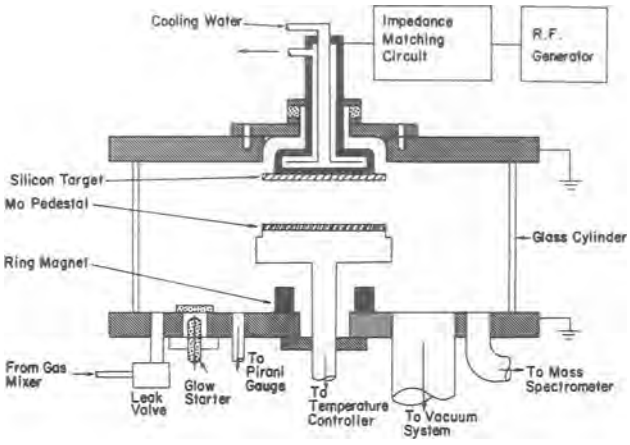

Fig. 1. Schematic diagram of rf sputtering apparatus.

and applied voltage. It was always visible in d-c sputtering, but it was not visible in rf sputtering with zero magnetic field. In a field of ~12 gauss caused by a permanent ring magnet below the cathode, however, the dark space was again very clearly visible. With or without a magnetic field, a glow discharge could be sustained at pressures as low as 2×10^{-3} Torr, although it was necessary to start the discharge by auxiliary means (usually a high frequency Tesla coil applied to a window of the sputtering chamber). In both d-c and rf operation, the chamber and the substrate pedestal were all grounded.

Nitrogen was used in all cases except where other gases are specifically mentioned. To study the effect of mixing with other gases, each of the gases used was first passed through a flowmeter, and then mixed together and branched to the exhaust and the system respectively through two needle valves. Nitrogen used contained less than 1 ppm of water and oxygen. To minimize gas contamination during sputtering, advantage was taken of purging with high throughput to maintain system pressure, *i.e.*, the pumping system was not throttled during sputtering.

Films were usually deposited on polished silicon substrates except for samples prepared for uv absorption spectroscopy, in which case the films were deposited on fused quartz plates, and some samples were deposited on various special substrates for other purposes. Typical examples of such substrates are oxidized silicon, gallium arsenide, germanium, various glasses, and metallic substrates including aluminum, copper, gold, and molybdenum. Satisfactory adherence was obtained for these substrates, although adhesive force and interfacial stress had not been measured. The silicon substrates used were of 5-10 and 0.012 ohm-cm resistivity respectively (both p- and n-type), the former being for preparation of films for surface studies and infrared spectroscopy; the latter being for investigation of electric and dielectric properties. The HCl vapor-polished surface of these substrates was cleaned by means of collodion stripping, which was found to be an excellent method for minimizing surface contamination. The cleaning of the substrates was found to be absolutely essential in producing good quality films.

The frequency of the rf field was 13.6 MHz. The rf wave was fed to the cathode through an impedance matching circuit (10). Since sputtering power density, expressed in watts per cm^2 of cathode, and peak-to-peak voltage are interrelated and dependent on gas pressure, system geometry, and rf frequency, the power density was chosen as the controlled factor while the peak-to-peak voltage was measured. The choice was only a matter of convenience. However, the choice of peak-to-peak voltage as an independent variable to be controlled may be more compatible with the d-c sputtering process and more suitable for theoretical analysis, especially following the established practice in d-c sputtering. The floating d-c voltage at the cathode during rf sputtering could not be controlled independently and is determined primarily by the rate of generation and drift velocities of the positive ions in the plasma. This d-c voltage could not be measured accurately. However, measurement with a high voltage probe showed it to be more than 90% of the half-peak voltage above ground. In the cases studied, the maximum floating potential at the substrate surface was ~ —40v.

Results and Discussion

D-c vs. rf reactive sputtering.—Although it is not certain that what is true for the reactive sputtering of silicon nitride may be applicable to the reactive sputtering of other insulator films, it is quite clear that rf reactive sputtering gives superior results to d-c reactive sputtering for the deposition of silicon nitride films. With d-c reactive sputtering, oxygen contamination was found to be a problem difficult to eliminate. The oxygen did not come from the nitrogen gas used, since analysis showed the nitrogen gas to contain <1 ppm each of oxygen and water. Further purification of the nitrogen gas by passing it through a silica tube filled with copper turnings heated to 700°C for removing oxygen followed by passing it through a cold trap for removing moisture did not show any improvement. Furthermore, the glass sputtering system seemed to show lesser tendency toward oxygen contamination, while in the all-metal sputtering system, the oxygen contamination was predominant. In rf sputtering with the all-metal system, oxygen contamination did not occur under normal conditions. Intentional incorporation of 1% of oxygen into the nitrogen stream did not give any appreciable amount of silicon-oxygen bonds detectable by infrared spectroscopy, although its effects on such properties as electronic conduction, carrier trapping and etching rate in HF solution have not yet been established.

From these observations, it appeared that the contaminating oxygen or oxygen bearer (H_2O, CO, etc.) might have come from the wall of the sputtering chamber. The evolution of these gases might have been caused by negative ion bombardment. A glass chamber wall would accumulate negative charges as a result of negative ion bombardment and become self-biased with respect to the ground, until it reached a static potential high enough that further ion bombardment became negligible. In the case of rf sputtering, the peak-to-peak voltage was usually in the range of 2 kv, and the net dc voltage across the dark space was below 1 kv. On the other hand, because of much lower sputtering rate, it was necessary to use higher voltages in the d-c sputtering, usually in the range of 2-4 kv. No quantitative data are available concerning the relative negative ion concentrations in the d-c and rf glow discharge, nor about the excited species of nitrogen in the two cases.

The difference in the net d-c voltage across the anode and the cathode between the d-c and the rf sputtering also appeared to cause a film damage problem, to the disadvantage of the d-c sputtering. The film damage was most probably caused either by negative ion bombardment, or electron bombardment, or both. This damage exhibited itself in various forms, such as high film leakage current, surface charge, and more obviously, in some extreme cases, as a grain-textured film surface observable by electron microscopy. Unfortunately, a higher d-c voltage was needed because of the low deposition rate in d-c sputtering, due to the extremely low efficiency in the d-c glow discharge. Figures 2 and 3 show the surface texture of deposited silicon nitride films by d-c and rf reactive sputtering, respectively.

Another phenomenon usually observed in high voltage d-c sputtering was the appearance of an absorption band at 4.7μ in the IR spectra. It is not clear whether this was caused by negatively charged particle bombardment. The possible chemical constituents

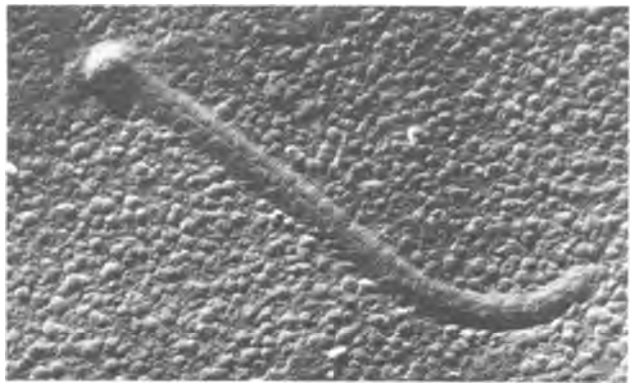

Fig. 2. Surface texture of silicon nitride film by dc sputtering

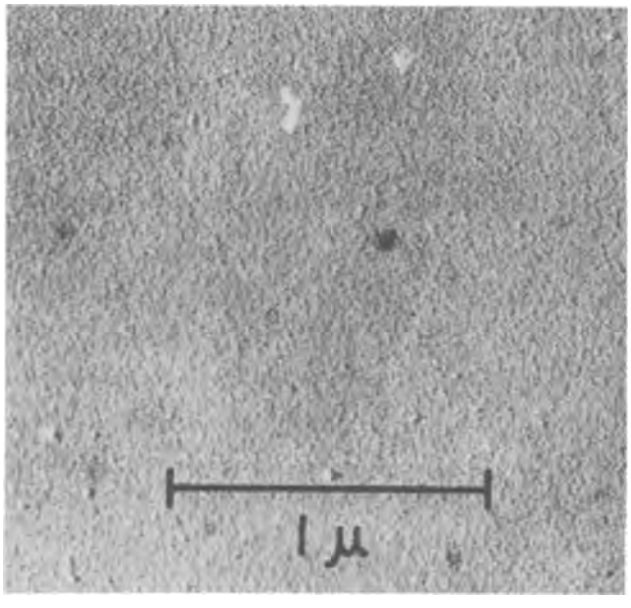

Fig. 3. Surface texture of silicon nitride film by rf sputtering

that might give rise to this absorption band include Si ≡ N, Si—H, N=Si=O, N=C=O, C=N, N=N=N, etc. One cannot rule out the presence of oxygen and oxygen bearers such as water, as well as carbon constituents mainly due to the presence of contamination hydrocarbons and their ions. The much higher rate of deposition, the absence of oxide contamination and film damage, and the improved chemical and physical properties of silicon nitride films prepared by rf reactive sputtering led to the choice of the rf process as the method to be studied in detail. The rest of the data to be presented pertain to rf reactive sputtering.

Effect of power density.—In rf reactive sputtering the power density had multiple and interrelated effects on such properties as film density, film etch rate in hydrofluoric acid solutions, film conductivity, dielectric constant, surface charge at the silicon-silicon nitride interface, C-V hysteresis of MIS devices, as well as rate of deposition.

At a fixed N_2 pressure, the rate of deposition was approximately proportional to the square root of the power density. There was also indication of a threshold power density for film deposition. At 4 x 10^{-3} Torr, the rate of deposition is shown in Fig. 4. It should be noted that the rate of deposition will depend strongly on the geometry of the sputtering system, and in particular on the diameter of the target and the spacing between the target and the substrate. Hence, the results shown in Fig. 3 can only be regarded as a typical example. In this case, the target had a diameter of 10 cm, and the spacing was 4 cm. Scaling to another system cannot be readily calculated, but in

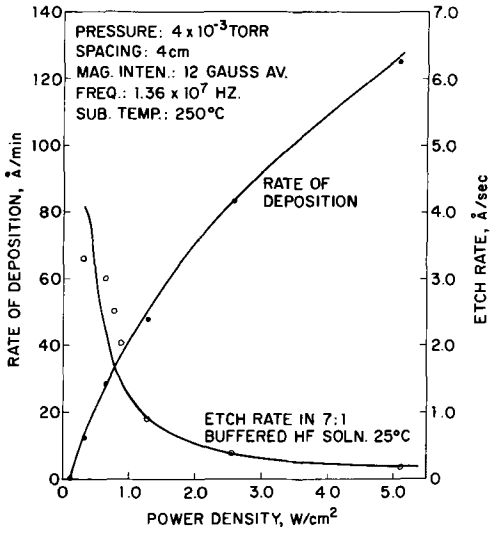

Fig. 4. Effect of power density on deposition and film etch rates in HF.

general, the efficiency of both sputtering and deposition will increase with target diameter, until it reaches a limiting value for electrodes of infinite diameter.

Etch rate is a very sensitive indicator of both chemical and structural properties of an amorphous solid. For example, the etch rate in dilute HF solution has been found to be directly related to the phosphorus concentration in a phosphosilicate glass film (2). The etch rate of an amorphous film, such as silicon nitride, in dilute HF solution varies over a very wide range. It goes up drastically when the film becomes structurally looser. It is apparently related to the film density. One sees from Fig. 3 that the etch rate at 25°C of sputtered films in 7:1 buffered HF solution (7 parts 40% NH_4F aqueous solution and 1 part 49% HF aqueous solution) goes up sharply when the power density is below 1.0 w/cm². When the etch rate is below 1 Å/sec, as is the case with typical silicon nitride films, practical problems arise in photolithography when the film is applied to device manufacturing. On the other hand, the low etch rate is an indicator of the good quality of a nitride film. It has been observed that films with etch rate (in 7:1 HF solutions at 25°C) of 10 Å/sec or higher failed to mask diffusion of steam, oxygen, and certain dopants. Such films were also electrically conductive.

The primary effect of the power density was its relationship with the kinetic energy of the depositing particles as well as negative ion bombardment. The floating d-c potential at the "cathode" with respect to the ground can be given by an empirical formula $w = kV^2$, where w is the power density and V is the space charge potential. The factor k is a complicated function of other parameters such as system geometry, gases used, pressure, etc. The increase in power density results in the deposition of denser films. This is shown in Fig. 5. The film density of reactively sputtered silicon nitride was thus approximately 2.8 g/cm³ when deposited at power density below 1.0 w/cm², and increased to about 3.0 g/cm³ at power density higher than 2.5 w/cm². The density was determined by differential weighing technique using a Cahn microbalance. The substrate was vapor polished silicon. The films were deposited to thicknesses of 3500-5000Å. The differential weighing technique gave an error of <0.5% of the net film weight. However, the over-all error was estimated to be approximately ±2%, arising mainly from thickness measurement using Tolansky interferometry. The crystallographic density of both α- and β-silicon nitride is 3.18 g/cm³ (11, 12). Thus, the deposited amorphous films of silicon nitride were somewhat structurally looser. This seems to confirm

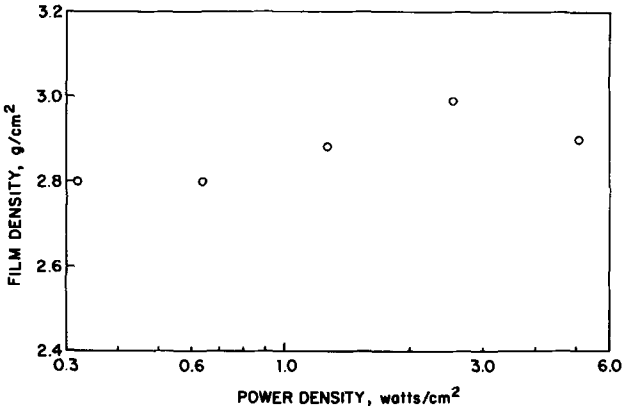

Fig. 5. Film density as a function of sputtering power density

the previous hypothesis (13) that shifting of the infrared absorption band from 10.7μ for crystalline β-silicon nitride to ~12.0μ for amorphous films of silicon nitride was the result of the structural looseness of the amorphous films. Indeed, the structural looseness of the deposited films affected not only the etch rate of the films in HF solutions and the position of the infrared absorption band, but also the barrier to impurity diffusion, injection and trapping of charge carriers, as well as dielectric constant of the films, which will be discussed in a later section.

However, there is a major detrimental effect in the use of high power density, which is the deterioration of silicon surface properties. The total surface charge, as measured from the C-V characteristics of MIS devices made of the sputtered silicon nitride films, was observed to increase with sputtering power density. When the power density was below 0.64 w/cm^2, the surface charge was about 0.5-1.0 x 10^{12} e/cm^2, which is defined as the n-shift of the silicon surface. At a power density of ~1.2 w/cm^2, the surface charge in silicon (with respect to the flat band condition) was ~3 x 10^{12} e/cm^2. When the power density was increased to 2.5 w/cm^2 and above, the surface charge was 10^{13} e/cm^2 or larger. Quite frequently, at this higher power level, a transition in the C-V curve could not be obtained due to the dielectric breakdown of the nitride films, indicating a surface charge density of greater than 3.5 x 10^{13} e/cm^2. This surface charge generally could not be significantly reduced by annealing processes. In fact, there were a few samples in which the n-shift was seen to increase somewhat after annealing. This is in certain respects similar to what has been observed in thermal silicon dioxide-silicon interfaces, where the n-shift increases after 450°-500°C heat-treatment and is generally thought to be due to the thermal decomposition of certain oxygen-bearing complexes into electrically active centers (14).

There appeared to be at least one bit of evidence in support of the hypothesis of particle bombardment-induced surface charge. A sample prepared at ¾ in. distance showed a surface charge density of $>1.5 - 2 \times 10^{13}$ cm^{-2} by means of MIS C-V measurement. The silicon nitride film was then stripped off, and the surface conductivity was measured by means of a three-point probe. An increase was found in carrier density at the surface to ~10^{18} cm^{-3}, assuming a 100Å accumulation layer. This value is an order of magnitude lower than the charge found from the MIS C-V measurement before the silicon nitride film was stripped off. Although small, the increase in conductivity was definite.

An electron photomicrograph was taken of the silicon surface after the silicon nitride film was carefully removed to just expose the bare silicon. No structural damage was observed in the micrograph.

Effect of residual pressure.—The residual background pressure of the vacuum system was found to be one of the most detrimental factors affecting various properties of the silicon nitride films. It is believed that the detrimental elements associated with high residual pressure are hydrocarbons or other molecules from the pump fluids. A residual pressure of 10^{-6} Torr was sufficiently high to be harmful. At a residual pressure of 3-5 x 10^{-6} Torr, the damaging effect on the silicon nitride films became mechanically observable. In the worst case, poor adhesion of the sputtered film to the silicon substrate resulted. The films could be scratched with stainless steel points, and occasionally even disintegrated during the HF etching process. Gradual decomposition and deposition of organic materials on the sputtering chamber walls and the back streaming of pump fluids made it imperative that the sputtering system be periodically and frequently cleaned.

At a lower degree of contamination due to the same cause mentioned above, poor adhesion might not be detectable by mechanical testing. However, when the samples were subject to heat treatment at 1050°C for a period of 30 min, "blisters" *i.e.*, film separations, developed and some blisters appeared to have exploded and left microscopic openings behind (see Fig. 6.) At a still lower background pressure, neither poor adhesion nor blisters were observed. However, more subtle effects on properties such as electric conductivity, carrier trapping and dielectric hysteresis could not be ruled out. In addition, the resistance to impurity diffusion was also affected. Samples prepared under the conditions of a contaminated sputtering system failed to mask diffusion of zinc, gallium, steam, and even phosphorus. As might be expected, the uncontrolled contamination also greatly increased the dissolution rate of the film in HF solutions. In conclusion, to obtain good films, the residual pressure should be below 10^{-6} Torr and no organic materials or vacuum grease, etc., should be present in the sputtering chamber.

Mass spectrometric analyses of the gases before and during the sputtering showed most gaseous impurities to be CH_4, CO H_2O, C and CO_2. Little, if any O_2 was observed.

Oxygen contamination.—Formerly, it was thought that very small amounts of oxygen or water in the nitrogen would be deleterious to the entire sputtering deposition process, because it was believed that oxygen and water are much more reactive than nitrogen in the glow discharge. Hence, in earlier experiments

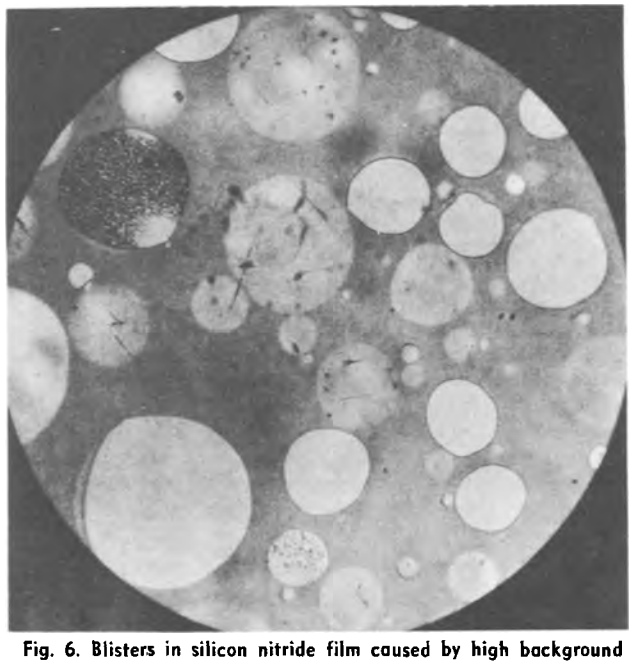

Fig. 6. Blisters in silicon nitride film caused by high background pressure.

with d-c sputtering, care was taken to purify the nitrogen gas by first passing it through copper turnings in a quartz tube at 700°C followed by freezing out residual moisture and condensable materials in a liquid nitrogen trap. Analyses of the line nitrogen before purification, however, showed oxygen and water to be present at less than 1 ppm. Hence, it was supposed that the contaminating oxygen and water must have come from the walls of the sputtering chamber (c.f. the discussion in the section of d-c *vs.* rf sputtering). To test how much more reactive oxygen is than nitrogen in an attempt to understand the reactive sputtering mechanism, oxygen was incorporated into the nitrogen stream at volume concentrations from 1 to 5%. At 1.0% oxygen concentration (total pressure 18 x 10^{-3} Torr, spacing 1½ in., power density 4 w/cm²), a film was obtained which showed the regular IR band due to Si-N bond stretching (12μ), and very little, if any, Si-O constituent. The band at 4.6-4.7μ again showed up, similar to the case of high voltage d-c reactive sputtering (2-5 kv). A mixture of Si-N and Si-O was observed with 2% O_2 in N_2 sputtering gas. When the oxygen content was increased to 5.0%, the film formed showed an IR band characteristic of Si-O stretching (9.4μ) and little, if any, Si-N band.

Effect of gas pressure.—It was found that the gas pressure was very critical to the quality of the films deposited. No good quality films have been obtained with pressure greater than 40 x 10^{-3} Torr in rf reactive sputtering. In d-c sputtering, unfortunately, the gas pressure used had to be of this magnitude or higher because of the very inefficient collision of electrons with gas molecules in a d-c field, which is essential to the sustention of the ionization process. At high gas pressure, especially in rf reactively sputtering where the floating d-c voltage is low (1.0-1.5 kv), the films deposited were generally very leaky electrically, and the etch rate was of the order of 10 Å/sec in 7:1 buffered HF solution at 25°C. The films failed to block diffusion of certain impurities, including steam and oxygen at high temperatures. The surface charge was seemingly low with the increase of gas pressure. However, larger C-V hysteresis in MIS devices was observed. From Fig. 7, it is seen that the etch rate of the deposited films increased drastically with the increase of gas pressure beyond 20 x 10^{-3} Torr. This could not be attributed to the lowering of the film density alone. There is reason to believe that more impurities were trapped in the films during the deposition. The density of the deposited films generally decreased with the increase of gas pressure, as is seen in Fig. 8. As the gas pressure decreased below 2.5 x 10^{-3} Torr, the efficiency of ionization became greatly reduced, and one started to observe the spreading of the

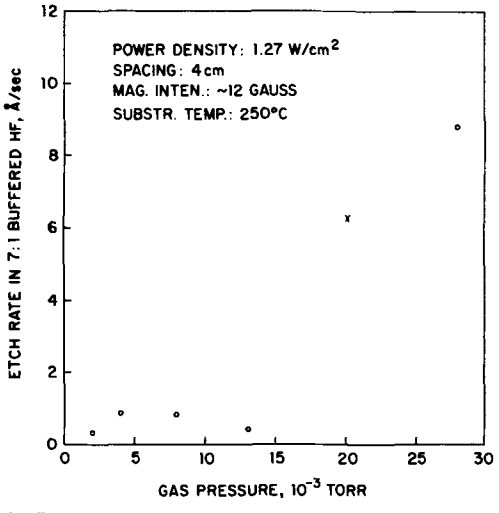

Fig. 7. Effect of gas pressure on film etch rate in a buffered HF solution.

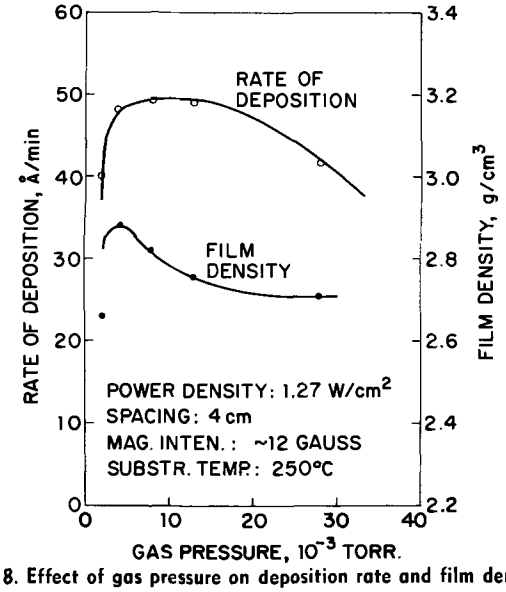

Fig. 8. Effect of gas pressure on deposition rate and film density

plasma over the entire sputtering system. The average magnetic field in this case was 12 gauss. Reasonably stable glow discharge could be maintained down to 2.0 x 10^{-3} Torr with this magnetic field intensity. However, at this low ionization efficiency, the rate of deposition decreased sharply. The density of the deposited film also decreased abruptly. It should be noted that with 1.27 w/cm² power density, the cathode d-c floating potential did not change significantly with gas pressure. The variation was from ~1.4 kv at 28 x 10^{-3} Torr to 1.6 kv at 2 x 10^{-3} Torr. From this observation, it can be argued that negative ion bombardment played an important role in densifying deposited films during sputtering at high power density, for one would expect the sputtered particles to be more energetic in the 2 x 10^{-3} Torr case, while the concentration of the negative ions might be much lower. Thus, less negative ion bombardment caused the film to be somewhat less dense at extremely low pressure,

The rate of deposition was relatively constant in the pressure range 4 to 20 x 10^{-3} Torr under described conditions, and dropped off rapidly at the low pressure end, while it dropped off more slowly with increasing pressure.

With increased magnetic field of, for example, 100 gauss, the ionization efficiency and stability of glow discharge at low pressure probably could be improved.

Reactive sputtering in argon and nitrogen mixture.—Experiments were made with reactive sputtering of a silicon cathode in mixtures of argon and nitrogen with various percentages of nitrogen concentration. It was found that two distinctive phases were obtained by reactive sputtering in a A + N_2 mixture of below 5% N_2 and above 10% N_2. Above 10% N_2, the films obtained were transparent and insulating. The infrared absorption band remained practically unchanged at 12.0μ. Below 5% N_2, the films obtained had a metallic lustre and were semiconducting. The infrared absorption band was shifted to ~13-14μ, and considerably broadened (Fig. 9). This deposit of silicon nitride is believed to be the dispersed phase of Si-N in an amorphous matrix of silicon. An MIS structure of such a phase deposited on a p-type silicon substrate showed a p-i diode characteristic, *i.e.*, $i \propto \exp q\mathbf{V}/2kt$, in the forward bias sense.

The i-V characteristics of films deposited in these gas mixtures is shown in Fig. 10. One sees that the films became progressively more conductive with the decrease of nitrogen concentration. This seemed to imply the non-stoichiometry of the films sputtered in mixtures of N_2 + A. Measurement of the dielectric constant of the deposited films also showed a trend

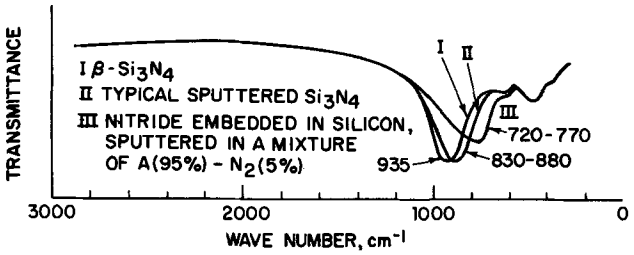

Fig. 9. Infrared spectrum of normal sputtered silicon nitride

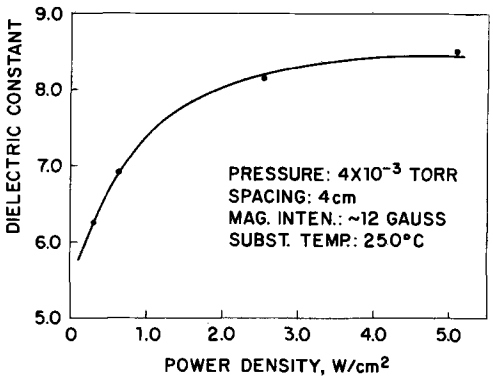

Fig. 11. Effect of power density on the dielectric constant of sputtered films.

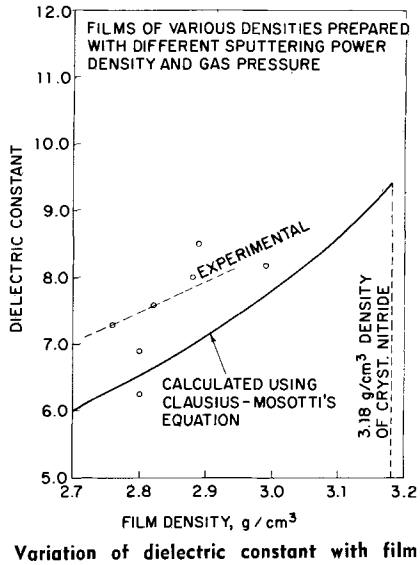

Fig. 12. Variation of dielectric constant with film density of sputtered silicon-nitride.

of increase with decreasing nitrogen concentration, indicating excess silicon incorporation at lower end of the nitrogen concentration in the N_2 + A mixture.

Dielectric constant of sputtered silicon nitride films.—The dielectric constant of silicon nitride films was given as 6.5 in an earlier work (13). Apparently, the films on which the measurement of the dielectric constant was based earlier were somewhat less dense, and there was evidence of trace contamination of silicon dioxide. More extensive evaluation of the dielectric constant of films deposited under various conditions indicated that no unique value existed for the amorphous silicon nitride films. It varied widely with conditions under which the films were formed, and may range from 6.2 to 8.5. If an average range should be given, it would probably be 7.5-8.0. For example, films deposited with various power densities, and otherwise similar conditions appeared to have their dielectric constant increased, initially rapidly, to a limiting value of 8.2-8.5 (Fig. 11). The reason is apparently the difference in the density of the various films formed. A plot of the dielectric constant of various films, prepared under conditions of various power densities and gas pressures, against the film density is shown in Fig. 12. Assuming the constancy of all types of polarizability in the nitride films involving no physical interaction nor variation of chemical constituents, a curve of dielectric constant *vs.* film density based on the Clausius-Mosotti equation is also shown in Fig. 12 for comparison. The curve was calculated using the crystallographic density of 3.18 g/cm^3 (11, 12), and a dielectric constant of 9.4 (15) for the crystalline material. It is seen from this plot that the dielectric constant seems to be consistently higher than would be predicted from a simple Clausius-Mosotti relationship. Three possible causes may be reasonable for this high dielectric constant: (*i*) the increase of molecular and dipole polarizabilities due to looser structure; (*ii*) the presence of shallow impurity levels in the amorphous films causing higher electronic polarization; and (*iii*) the possible inclusion of silicon. The first and the second causes are believed to be more likely for films deposited in pure nitrogen.

Ion and impurity migration in silicon nitride films and silicon nitride-silicon dioxide composite films.—Although little data were available in the literature concerning the migration of ions and atomic impurities in crystalline silicon nitride, it was speculated that the migration rate must be negligible compared with silicon dioxide because of its tight network and largely convalent nature (based on sp^2 planar bonding between N and Si atoms). With due allowance for the slightly less dense amorphous network yet with the absence of grain boundaries, the amorphous silicon nitride film can be expected to possess the same virtue. This speculation has been supported by experimental data obtained in this laboratory.

Ionic migration.—This work has not attempted to study mobilities of various ions in silicon nitride films quantitatively, because of the unavailability of a relatively simple method to determine minute quantities of different impurities in the nitride film. Two techniques have been used to study ionic migration in silicon nitride in this work, and have furnished some qualitative data. One method which was developed by Yamin in the study of polarization in SiO_2, is based on the observation of polarization and depolarization current by applying a slow triangular voltage across a thin film (16).

An example is shown in Fig. 13-a. From this figure, one sees that ionic polarization is essentially negligible

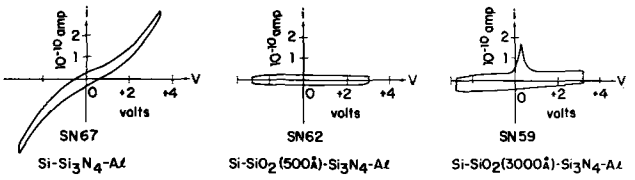

Fig. 13. Yamin-loop study of ionic polarization Si_3N_4 and SiO_2 —Si_3N_4 at 400°C.

in silicon nitride up to 400°C. However, one did see measurable electronic conductivity. In Fig. 13-b, it is shown that a thin layer (~500Å) of SiO_2 between silicon nitride and silicon is capable of blocking electronic conduction in the MIS structure. With the SiO_2 layer increased to 3000Å, ionic polarization becomes observable, presumably occurring in the SiO_2 layer, although the electronic conductivity is still blocked (Fig. 13-c).

The second method is based on the detection of the ions which under a positve d-c bias at elevated temperatures had migrated and piled up at the Si-silicon nitride interface by measuring the corresponding change in carrier density in the space charge layer at the silicon surface. The determination of the excess in the space charge layer is made by determining plate charge at flat-band situation, the so-called MOS C-V measurement. Experiments with controlled Na^+ contamination as well as contamination with isopropanol, indicated that Na^+ and H^+ did not migrate appreciably through a 600Å layer of nitride. It is interesting to note that, even though the etch rate could be increased greatly, and even more so the conductivity increased with change of sputtering conditions such as increased pressure and unidentified background contamination, the ability of the nitride film to block ion migration was still remarkable. Sample 992a is an example, which consisted of 5100Å of thermal SiO_2 and 600Å of sputtered silicon nitride (25 x 10^{-3} Torr N_2 pressure). The conductivity of the composite film was low because of the SiO_2 layer. After controlled contamination by evaporating NaOH onto the surface, the sample was subject to annealing at 300°C for 30 min and then subject to each of the following steps of temperature-bias treatment (bias at +30v; each step 30 min). The results are shown in Table I.

It is also noted that the hysteresis phenomenon usually observed in silicon nitride, which has been suggested to be caused by injection of holes from silicon into silicon nitride film and the subsequent trapping (17, 18), was not observed with the M-nitride —SiO_2 —Si structure. At a much higher field of 3-4 x 10^6 v-cm^{-1}, the normal type of hysteresis could be observed, in contrast to simple M-nitride —Si structure (18).

Diffusion of other impurities.—Experiments showed that when high quality sputtered silicon nitride films were obtained, substances such as water, oxygen, phosphorus, and gallium did not diffuse through the films at temperatures of 1050°-1200°C.

The ability of silicon nitride films to block gallium is quite remarkable. Experimental results were obtained with two different film specimens. The first was prepared by depositing silicon nitride onto silicon at a power density and pedestal temperature which would produce an etching rate of 2.5 Å/sec. From Fig. 4, this is seen to be 0.7 w/cm^2. This film was then coated with KTFR, exposed, and etched to produce the diffusion windows. The second film was deposited on a

Table I. Results

silicon wafer which had a previously etched pattern of aluminum 0.5μ thick to conform to the diffusion window pattern. The film deposition was done at 2.5 w/cm^2, *i.e.*, the silicon nitride etch rate was exceedingly low. Hence, the aluminum pattern was then dissolved out, carrying away the silicon nitride and opening the diffusion windows. Both specimens were then exposed to gallium vapor at 1000°C for 60 min. The results were similar; both films were effective masks. Figure 14 shows typical stained angle-lapped cross sections of the junctions. The definition of the edge of the window is somewhat better for the etched film.

Conclusions

Good quality silicon nitride films can be prepared by reactive sputtering of a silicon cathode in nitrogen under proper conditions. The rate of deposition is in the practical range of ~ 100 Å/min. For good results, the residual pressure in the chamber should be well below 10^{-6} Torr. The gas pressure is preferably in the lower end of the range from 4-10 x 10^{-3} Torr. The density of the films is somewhat lower than that of the crystalline material, with an average of about 2.9 g/cm^3, and the dielectric constant is higher than would be predicted from the film density.

In general, high power sputtering is preferred. In this case, surface damage and total surface charge may become a problem. However, the flexibility of the combination of various sputtering factors and the use of low temperature process make it possible to produce films with varying properties for various applications.

Acknowledgments

The authors wish to thank Dr. L. Maissel for his many helpful suggestions and encouragement, and Drs. P. Davidse and D. R. Kerr for stimulating discussions. Dr. Kerr also helped with the Na^+ contamination experiment. They are also indebted to Messrs. R. Baker, Jr., R. F. Marvel, and J. A. Petrak for assistance in the experiment.

APPENDIX I. A Summary of Some Physical Properties of Crystalline Silicon Nitride

For comparison with amorphous films by reactive sputtering, and for convenience of quick reference, a table of physical properties has been compiled, and provided below.

Phase	α and β — Si_3N_4	*(a)*
Transition temp.	$\alpha \rightarrow \beta$, 1400°C, sluggish	*(a)*
Crystal system	Hexagonal	*(a)*
Space group	α, P31c; β, Pb 3/m	*(a)*
Lattice parameters	α(a = 7.738Å, c = 5.617Å)	*(a)*
	β(a = 7.608Å, c = 2.991Å)	*(a)*
Crystallographic density	α, 3.184 g cm^{-3}	*(a)*
	β, 3.187 g-cm^{-3}	*(a)*
Si-N	1.72Å	*(a)*
Experimental density	3.448 g-cm^{-3}	*(b)*
Index of refraction	2.1	*(c)*
Dielectric constant	9.4	*(d)*
Energy gap	3.9-4.0 e.v.	*(e)*
Infrared absorption band	10.6μ (Si-N)	*(f)*
Electric resistivity	10^{13}-10^{14} ohm-cm	*(e, g)*
Melting point	1900°C (under pressure)	*(f)*
Heat capacity	0.1746 cal. g^{-1} $°C^{-1}$ (0-995°C)	*(h)*
	0.2145 cal. g^{-1} $°C^{-1}$ (0-585°C)	*(h)*
Thermal expansion coefficient	α 3.0 x 10^{-6} $°C^{-1}$; β 3.5 x 10^{-6} $°C^{-1}$	*(i)*
Thermal conductivity	0.067 cal cm^{-1} $°C^{-1}$ sec^{-1}	*(j)*
Solubility in silicon	$<10^{12}$ atoms cm^{-3} (room temp)	*(f)*
	$\sim 10^{19}$ atoms cm^{-3} (in melt at m.p.)	
Hardness	>9 Moh's scale	*(j)*
Heat of formation	$\Delta H_{298.1} = -179.250$ kcal mol^{-1}	*(k, l)*
Entropy	$S_{298.1} = 22.8$ cal mol^{-1} $°K^{-1}$	*(k, l)*
Free energy of formation	$\Delta G°_{298.1} = 154.740$ kcal mol^{-1}	*(k, l)*
At 1700°K	$\Delta H_{1700} = 176.300$ kcal mol^{-1}	*(m)*
	$\Delta G_{1700} = 176.300 + 0.07835$ T kcal mol^{-1}	*(m)*

Polycrystalline Zinc Oxide Dielectrics

R. A. Delaney and H. D. Kaiser

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

This paper describes a dielectric material with certain properties unique to prior art and offers a practical method of resolving some of the circuit problems encountered in low-impedance circuits with extremely fast switching times. The basic material is semiconducting polycrystalline zinc oxide. Modifications of this base material are obtained by thermal diffusion doping via grain boundaries. The end result is a polycationic complex material with controlled valency characteristics. Specific attention is focused on those properties which make these materials uniquely suited for microminiature high-frequency, low-impedance decoupling or filter-type capacitor devices. Utilizing screen printing technology, devices with apparent low-frequency dielectric constants on the order of 3000 and high-frequency dielectric constants of 1700 have been achieved. These devices attenuate high-frequency signals with either a damped oscillatory or critically damped response. This system of device dielectrics belongs, respectively, to either the semiconducting or semi-insulating classes of solids.

Zinc oxide is a well-known n-type semiconductor, the properties of which have been investigated by many workers (1-8). Excellent reviews of much of this work have been made recently by Thomas and by Heiland, Mollwo, and Stockmann (9, 10). Although the properties of bismuth oxide are less well characterized, some work has been done (11-13), and it is well established that under most circumstances it is a p-type semiconductor (13). Some of the dielectric, resistive, and electroluminescent properties of zinc oxide with additions of bismuth oxide have been reported recently by Kosman and Gesse (14), Kosman and Pettsold (15), and Delaney and Kaiser (16).

The present investigation supplements and extends the previous ones in a specific area, namely, that of utilizing the material in the form of a silk-screened

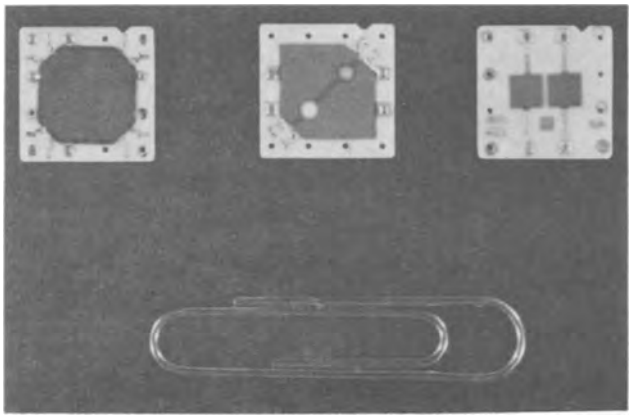

Fig. 1. Typical completed capacitor units utilizing the new nonlinear dielectric system.

parallel plate capacitor suitable for incorporation in high speed microelectronic switching circuits. Typical examples of such units appear in Fig. 1.

Zinc Oxide

Zinc oxide crystallizes in the hexagonal wurtzite lattice in which the oxygen ions are arranged in the hexagonal close packing and the zinc ions occupy half the tetrahedral interstitial positions. It is an n-type semiconductor with an excess of interstitial zinc atoms which are responsible for the conductance electrons in the crystal.

Its semiconducting properties can generally be said to be due primarily to interstitial zinc atoms. It thus can be considered as an electronic semiconductor with a large energy gap of 3.2 ev, classified somewhere between the heteropolar alkali halides and the homopolar semiconductors of the group IV elements. It is known to be a nonstoichiometric substance with an unstable oxygen content and changing semiconducting properties.

Zinc Oxide with an Admixture of Bismuth Oxide

The electric properties of zinc oxide, an n-type semiconductor, are changed considerably by the admixture of bismuth oxide, a p-type semiconductor. The most interesting property of such a mixture is the high dielectric constant. Initial experiments performed by Kosman and Gesse (14) give effective dielectric constants as high as 1500. This is very spectacular when one considers that the dielectric constant of polycrystalline zinc oxide is on the order of 30 or 40 and that of bismuth oxide on the order of 10 or 20. They found that dielectric constant is strongly dependent on the sintering temperature, the increase with increasing sintering temperature being more pronounced with a low bismuth oxide content.

This system has properties of nonlinear symmetrical and asymmetrical resistivity depending on fabrication methods. By changing the specimen fabrication, one can obtain electrical conductivities from 10^{-6} to 10^{-11} mho/cm. Recent investigations on this system with constant, alternating, and impulse voltages by Kosman and Pettsold (15) show that the conductivity is increased considerably if the excitation is accomplished by the impulse method. The I-V characteristics for both constant as well as alternating excitations within a wide voltage interval approximates

$$I \alpha V^{\eta} \qquad [1]$$

where the coefficient of nonlinearity (η) is dependent on the conductivity.

Sample preparation.—All capacitors were prepared by silk-screening techniques as shown in Fig. 2. The capacitors were fabricated on 96% alumina substrates in a simple parallel plate configuration. In most cases the area of the plates was 0.01 in.^{2}. The bottom plate and associated lead were silk-screened using a suitable conductive paste. In most cases a gold-platinum paste was used. Quenching was accomplished by removing the units from the furnace at temperature and immediately placing them on a large aluminum block. Electrical connectors were made with copper pins placed through the holes in the substrate, which were subsequently soldered to the conductive leads from the capacitor (Fig. 2).

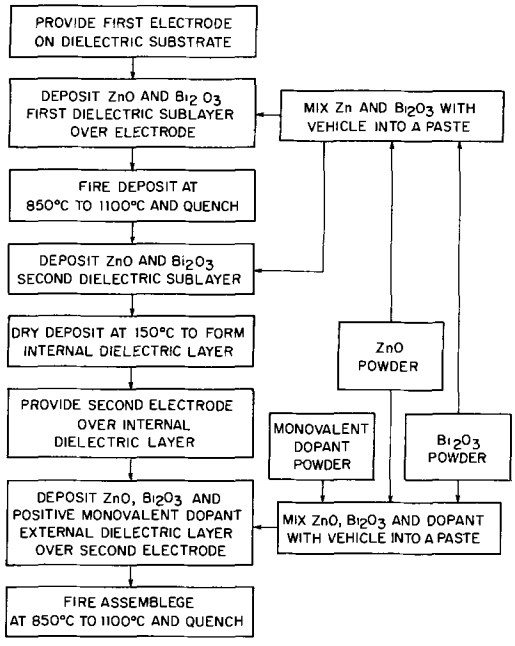

Fig. 2. Flow chart for fabrication of ZnO dielectric systems

Electrode.—The effects of various materials when used as part of the electrode system were also studied. It was found that gold, platinum, and combinations thereof give comparable results, while silver, even in combination with up to 35% platinum or 20% palladium, is extremely detrimental to the system. Apparent doping of the system by silver lowers the dielectric constant to roughly that of pure zinc oxide fired with platinum electrodes under comparable conditions. The use of various lead glasses as electrode fluxes had no adverse effects, while the incorporation of Bi_2O_3 as a flux strongly doped the ZnO and gave a capacitor whose properties were insensitive to the amount of Bi_2O_3 in the body. However, when up to 10% Bi_2O_3 was added to a silver-bearing electrode, it did not overcome the effects of the silver, indicating extremely strong diffusion of silver into the capacitor body.

Thermal effects.—An extended study was made of the variation of capacitance, conductance, and d-c resistance with temperature using capacitors made from the 5% Bi_2O_3 material. The results are summarized in Fig. 3 and 4. The change in capacitance in the region −50° to +150°C can be expressed quite accurately by the relation

$$C = C_o e^{\alpha T^3} \qquad [2]$$

where α is determined by both the temperature and soak time of firing. The d-c resistivity may be approximated by

$$R = R_o e^{-\beta T}$$

where β is also governed by the firing conditions.

It can also be seen that both the capacitance and resistance at a given temperature and the slope of the curve vary considerably with the firing conditions. Capacitance measurements at liquid nitrogen temperatures (−196°C) show that the dielectric constant of the zinc oxide −3% bismuth oxide system has dropped from ~ 1500 to ~ 40, that of the polycrystalline zinc oxide.

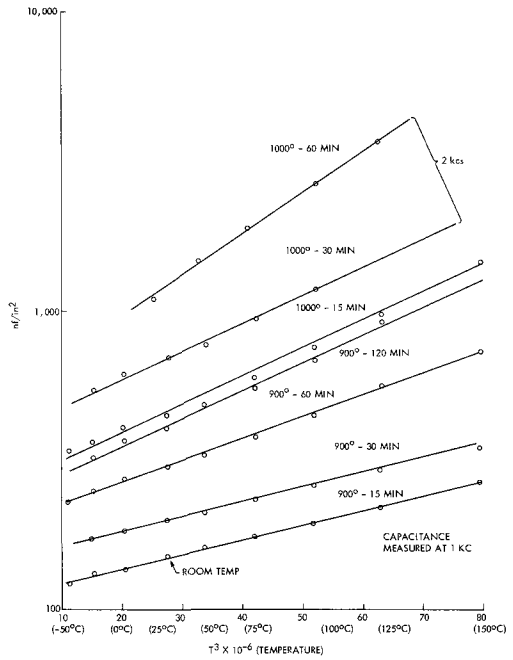

Fig. 3. Capacitance *vs.* temperature for various firing times

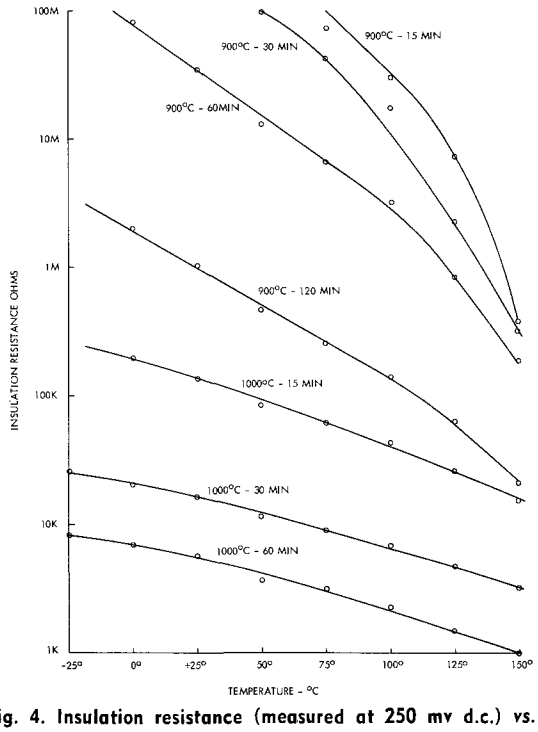

Fig. 4. Insulation resistance (measured at 250 mv d.c.) *vs.* temperature for various firing times.

Frequency response.—The frequency response was measured over the range 1 kcps to 50 Mcps (Fig. 5 and 6). The higher firing temperatures and longer times have a deleterious effect on the variation of capacitance and conductance with frequency, the capacitance falling off more rapidly and the conductance more slowly with higher temperature and longer firing times. The capacitance varies almost linearly and reasonably slowly with frequency, and the conductance varies directly as frequency, that is

$$G \alpha \omega \qquad [4]$$

thus indicating that the quality factor (Q) should be approximately invariant with frequency. The quality factor as used here is defined as the average energy stored to energy dissipated within the capacitor.

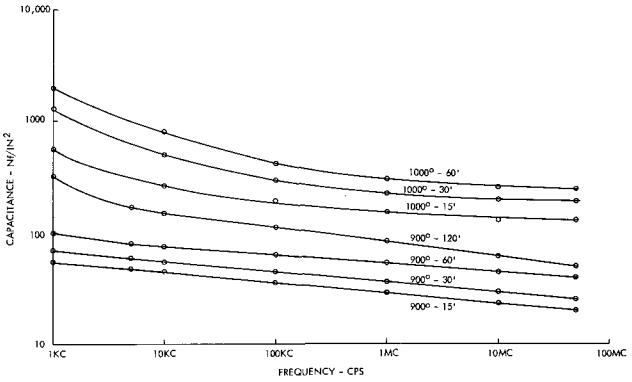

Fig. 5. Capacitance *vs.* frequency

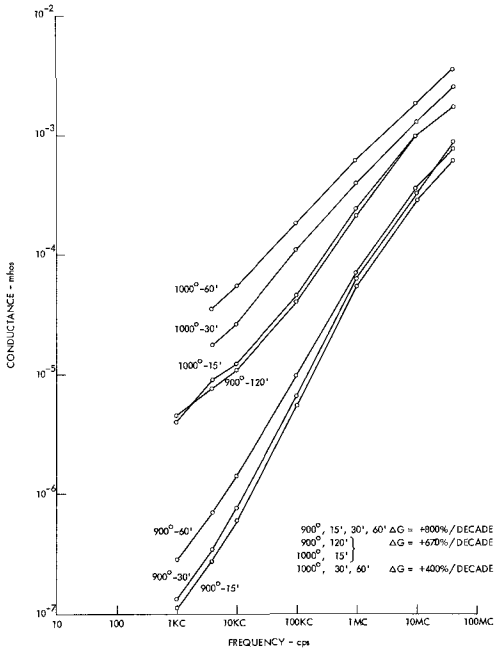

Fig. 6. Conductance *vs.* frequency for various firing parameters

Quenching.—As may be suspected from the nature of zinc oxide, the rapidity of the quench after firing has a strong influence on the final parameters. This is illustrated in Fig. 7 which shows the quench rates achieved by suspending the samples in still air, or placing them on a large alumina or aluminum block.

Drastic quenching has been achieved by deflecting the cold gas from expanding liquid CO_2 onto the device surface. The temperature was lowered from 1000° to 0°C in 60 sec. A capacitance of 100 μf/in.^{2} resulted; however, the resultant d-c resistivity was only 10 ohm-cm.

QUENCHING METHOD	t (u)	DAMP (%)	C_pA (NF IN^2)	KE (eff)	R_p (Ω) DC-1/4 V	10MC

ALUMINUM	19	82	480	1600	50	10

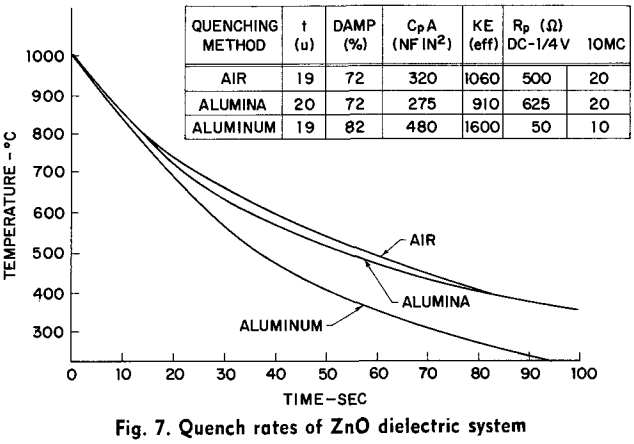

Fig. 7. Quench rates of ZnO dielectric system

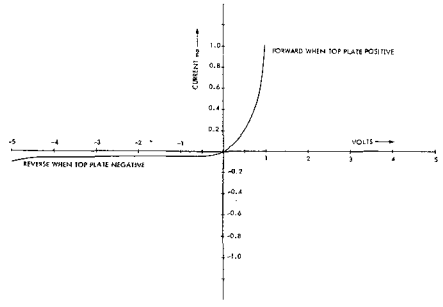

Fig. 8. D-C current-voltage relationship showing rectifying properties of the ZnO system.

Voltage response.—The investigation of the influence of a d-c bias on the electrical parameters revealed some unusual features. There is also a slight directional or rectification effect in both capacitance and conduction as "forward" and "reverse" bias curves do not superimpose at higher biases.

This directional effect becomes much more obvious when the top plate of the capacitor is solder coated and biased positive. This may be partially due to the change in work function of the top plate.

This asymmetry is also noticeable in the V-I curves of Fig. 8, especially for the soldered samples. The junction is asymmetric in nature and polarity dependent for similar electrodes.

When dissimilar electrodes are separated by a sufficiently thin insulating film, current can flow between them in an asymmetric mode by various current transfer mechanisms. If the electrodes are of the same metal, the junctions are symmetric and polarity independent. This leads to the conclusion that there may be some potential here for a rugged, low-cost power diode (17).

Since this rectification is undesirable in a capacitor, the condition can be corrected by the use of a solder stop-off, *i.e.*, an inert coating over the top plate to prevent the adhesion of solder during tinning. It was found that a layer of the dielectric material screened over the top plate and fired in the final step was most effective.

Topology.—Since there was some speculation as to whether or not the capacitance was due to a bulk effect or to a high capacitance at the electrode-dielectric interface, a determination of capacitance and d-c resistance *vs.* thickness was made. If the capacitance were due to a bulk effect, it should follow the usual relation for a parallel plate capacitor.

$$C \approx K\epsilon \frac{A}{d} \qquad [5]$$

If the capacitance were in any large degree due to an interface effect, it should be nonlinear with regard to reciprocal thickness or follow a linear law with a large additive constant.

Results are given in Fig. 9. The dielectric constant is approximately invariant with thickness, and the capacitance follows the normal law for parallel plate capacitors. This rules out the electrode-dielectric interface as being a major source of the capacitance. However, it does not rule out the possibility of the capacitance being due to some type of three-dimensional barrier layer or interface effect involving the individual grains of zinc oxide. Since this effect would be distributed throughout the whole layer, it could very easily exhibit the usual type of thickness dependence.

The resistance follows a nonohmic relationship, that is (Fig. 10).

$$R = t^m + R' \qquad [6]$$

Since differences in slopes and intercepts were obtained for different electrode-dielectric combinations,

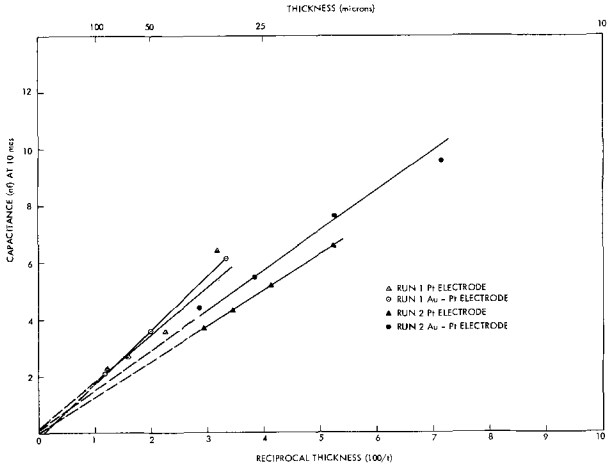

Fig. 9. Capacitance vs. thickness for ZnO + 3% Bi_2O_3

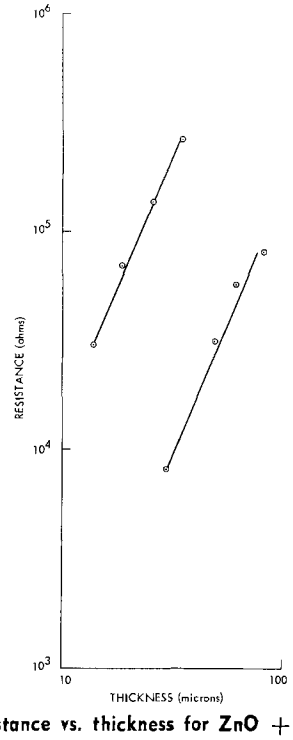

Fig. 10. Resistance vs. thickness for ZnO + 3% Bi_2O_3 and Au-Pt electrodes.

it is possible that the resistance is at least partially governed by interface effects.

Further Materials Development

General.—Zinc oxide is n-type, and bismuth oxide is basically p-type. X-ray diffraction studies show that with up to 15% bismuth oxide content the mixture retains the zinc oxide lattice. Subsequent diffraction studies show that the lattice structure remains unchanged regardless of sintering temperature, cooling conditions, or subsequent heat-treatments. Based on this evidence, it is theorized that a depletion layer of relatively high resistance is formed around the zinc oxide granules by shallow diffusion of the bismuth oxide. That this layer is not at the electrode-dielectric interface is shown by the thickness dependency experiment. The zinc oxide bismuth oxide interface interpretation leads to a situation similar to that discussed by Koops (18) for semiconducting nickel-zinc ferrites and summarized by Volger (19). In these models, a physical picture of conducting grains separated by layers of poorly conducting material is successfully equated to an electrical analog of parallel

RC network connected in series. By using this model, Koops was able to calculate curves which fit the experimental data fairly closely.

As a material for a capacitive device, zinc oxide with 3% bismuth oxide meets or exceeds most requirements when fabricated into a simple parallel plate configuration and fired at 1000°C for 60 min followed by rapid quenching as can be seen in Table I.

Factors which give rise to high effective capacitance values also produce high-conductance values. One would rather like to maximize the effective capacitance effect but at the same time minimize the conductance. In fact, one would like to convert this zinc-bismuth oxide mixture from a semiconducting dielectric to a semi-insulating dielectric while retaining the depletion layer mechanism for high effective capacitive values.

One logical approach would be to diffuse a monovalent dopant into the defect zinc oxide lattice to fill vacant cation sites. This would give a polycationic arrangement with a high population of electron deficient cation sites acting as electron "traps."

Success has been achieved with this approach. As a specific example, this study first considers a zinc-bismuth oxide semiconductor doped with copper. Doping was accomplished through volume diffusion by the direct addition of copper titanate. The resistivity of the dielectric increased from 10^4 to 10^8 ohm-cm. This, however, cannot be accomplished without a 50% decrease in effective dielectric constant due to a dilution effect. As expected, the dielectric dissipation also dropped. An additional effect was observed, *viz.*, a change in frequency characteristic from a damped oscillatory to a critically damped response.

The latter effect is unusual since one might expect the opposite to occur. As the dielectric approaches the insulator state, the effective shunt resistance increases and thus is capable of storing charge for longer periods of time, *viz.*, the relaxation time diminishes. Thus, the damping coefficient should approach zero, and the dielectric should respond as a pure oscillating network. However, due to the monovalent substitution doping at the cationic site, a small effective series resistance on the order of an ohm is introduced into the printed dielectric network. It is this effective series resistance that causes critical damping. The effect of the series resistance becomes apparent at high frequencies when the reactance drops below this value and the complex impedance becomes constant in value.

To eliminate the dilution effect brought about by direct addition of the doping material, it was decided to utilize a unique characteristic of screen printing technology. The dopant material was screened over the porous top electrode and then fired so that the monovalent cationic species thermally diffuses through the zinc-bismuth oxide grain boundaries.

The top electrode acts as a selective barrier to the dopant material prohibiting the undesired dilution of the internal dielectric by large amounts of the anionic species. This technique attains the same high resistivity as did volume diffusion through the crystal interior, but unlike the latter exhibits only a 20% decrease in effective dielectric constant instead of the 50% due to dilution.

Volume diffusion doping.—In the first series, the dopant was incorporated directly into the zinc-bismuth oxide dielectric. Utilizing the above method, several test samples were fabricated to evaluate the effect of various monovalent substitutions into the semiconducting zinc-bismuth oxide dielectric.

In each of the samples, the dielectric composition was composed of 97% by weight of zinc oxide, 3% by weight bismuth trioxide, and either silver, lithium, or copper dopant in concentrations as shown in Table II.

These capacitors were given a series of standard tests which included measurement of the dielectric resistance at 1v d-c., and damping and capacitance at 10 megacycles. The effective constant was calculated.

The results of these examples indicated that dielectrics having the desired characteristics of high d-c resistance and near critical damping can be made using silver, lithium, or copper dopant. The copper dopant was shown to be the superior to silver and lithium in raising the d-c resistivity.

Having established that monovalent copper substitution produced the more favorable results, it now became important to determine the optimum fabrication technique needed. This technique became quite evident during the course of subsequent investigation.

The procedure for the preparation of the dielectric composition and for the fabrication of the capacitor devices for this group of examples was identical to those above. It can be seen from Table II that the dielectric exhibiting the most pronounced affect utilized 1 mole % copper titanate as the source of copper. A dielectric constant on the order of 900-1000 was achieved, critical damping was obtained, and the d-c resistance was quite high. Other copper salts showed poorer dielectric constant characteristics. Examples 13, 14, and 15 using varying amounts of titanium dioxide or barium titanate were used to determine whether the doping was caused by the monovalent copper or the titanium dioxide. It can be seen from the results that examples 14 and 15 produced di-

electrics with small damping coefficients and Q values which were much too high. Only in example 13 which contained the copper nitrate dopant in addition to the titanium dioxide was the substitution valency effect obtained. It is therefore concluded that the titanate or titanium dioxide is not responsible for the effects noted.

Grain boundary diffusion doping.—Although the conductivity of the semiconductor zinc-bismuth oxide is lowered by monovalent copper substitution and the damping coefficient increased, it was noted that the first system (volume diffusion) shows a marked decrease in apparent dielectric constant due to the presence of the inert material. While adequate for some applications, this system would not be suitable for applications requiring a higher effective dielectric constant. The above examples infer that perhaps by grain boundary diffusion doping of the monovalent ion, one could still minimize the conductivity and yet maximize the dielectric constant due to elimination of the dopant anion from the semiconductor dielectric.

Work done with experimentally determined grain boundary self-diffusion of silver (20), the diffusion of gold into copper bicrystal grain boundaries (21), etc., shows that a theoretical diffusion-penetration relationship for grain boundary diffusion can be developed. One might picture grain boundary diffusion (and similarly for surface diffusion) as diffusion along a thin layer of high diffusivity material sandwiched between large volumes of low diffusivity material after the Fisher model (21, 22) (Fig. 11).

Assuming this diffusion model and the above boundary conditions and further assuming that the lateral diffusion concentration penetration in the vicinity of the grain boundary is greater than the uniform lattice diffusion penetration in regions well removed from the grain boundary, one can obtain a simple analytical expression for the concentration of laterally diffused material in the vicinity of the grain boundary.

Control of the cationic substitution into the lattice can be controlled through grain boundary diffusion. During the fabrication process as shown in Fig. 12, the monovalent dopant in the external dielectric layer 38 is diffused through the pores of the second electrode 34 into the grain boundaries of the dielectric body 36. Preferably, this is done by firing or sintering the assembly at a temperature of 1000°C for a period of approximately 1 hr to diffuse the monovalent dopant from dielectric layer 38 through the pores of the second electrode 34 and into the grain boundaries of the dielectric body. The capacitor is then removed from the furnace and again quenched. The result of the above technique transforms the semiconducting zinc-bismuth oxide dielectric via cationic monovalent substitution diffusion doping into a semi-insulating dielectric.

Two types of initial semiconductor dielectric materials were prepared for this series of examples. The first included 97% by weight zinc oxide, 3% by weight bismuth trioxide, and a 1 mole % of copper titanate. The second dielectric material included 97% by weight zinc oxide and 3% by weight bismuth trioxide.

The examples are distinguished by the presence or absence of a dopant in the internal or external dielectric layer as given in Table III. Examples 20 and 21 differ in that the external layer in example 20 fully covers the second electrode and touches large areas of the internal dielectric layer as illustrated in Fig. 9 while example 21 has its external dielectric layer restricted to a small dot-shaped area which contacts only the second electrode and does not touch the internal dielectric material.

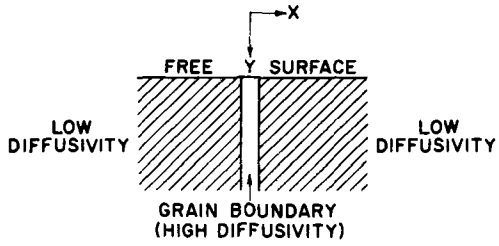

Fig. 11. Fisher model for grain boundary diffusion

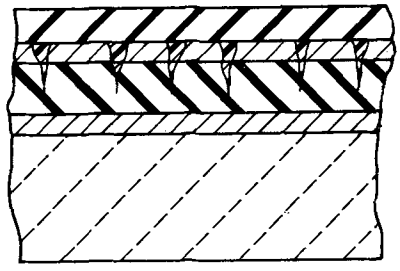

Fig. 12. Schematic model showing grain boundary diffusion of the monovalent dopant.

Example 18 shows that with no dopant in either dielectric layer the d-c resistance is low, Q is low, damping is only 80%, and the apparent dielectric constant is high. Example 19 shows the effect of having dopants in the first and second dielectric layer and has excellent properties except for its unduly low dielectric constant and higher impedance. The surprising 50% increase in dielectric constant, as compared to the example 19 capacitor, is shown in examples 20 and 21 wherein a dopant is present only in the external dielectric layer and not in the internal dielectric layer. No difference in properties was noted between examples 20 and 21, so the touching of the first and second dielectric layers is of minor importance, thus establishing the grain boundary diffusion phenomena through the top electrode. Further evidence is given by the time at formation temperature *vs.* electrical characteristics which closely follows what would be predicted by the diffusion equation.

Device Technology

Utilizing this dielectric system, printed ceramic capacitors as described earlier were manufactured and evaluated.

Frequency response.—Since the specifications of the physical dimensions and electrical parameters are dependent on actual device application, it was decided to devise a capacitor test pattern which would solely yield the dielectric response independent of its geometry. This method is feasible since it has been experimentally demonstrated that these printed dielectrics can be scaled with their respective parametric experimental values being quite accurately predictable from calculations based on actual geometrical dimensions.

Table III. Effects of Cu dopant in the zinc dielectric

Example	Dopant present in: Internal dielectric layer	Dopant present in: External dielectric layer	RC resistance, ohm-cm	Damping, %	Dielectric constant, 5 Mc	Q-value, 52 Mc	Impedance, ohms, 100 → 700 Mc
18	No	No	10^4	80	2000	0.1-0.3	1
19	Yes	Yes	10^8	98	1000	1-2	2-3
20	No	Yes	10^8	98	1500	1-2	1-2
21	No	Yes	10^8	98	1500	1-2	1-2

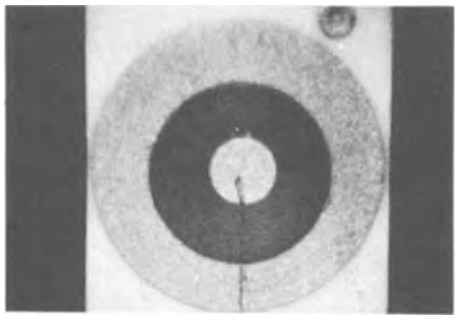

Fig. 13. Picture of concentric bullseye capacitor pattern used for all frequency evaluation testing. Innermost disk is top electrode, middle disk is dielectric body, and outer disk is lower electrode. Effective capacitor plate area is the same as the area of the top electrode.

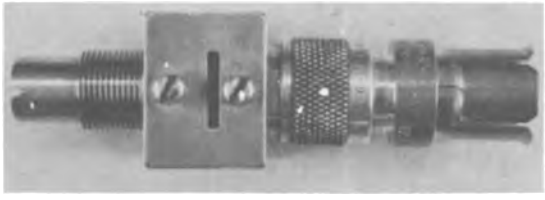

Fig. 14. Jig assembly used to measure samples shown in Fig. 13. A spring loaded copper ball connected to the inner line of the coaxial fixture makes contact to the inner electrode while the outer lip of the fixture contacts the outer electrode. The screw presses the sample onto both contacts.

The choice of a suitable pattern should be such that it does not exhibit any effective series land or plate resistance or inductance, the pattern used is shown in Fig. 13. Likewise, it is equally important to use a jig assembly which also does not exhibit either series resistance or inductance, the jig used is shown in Fig. 14. Figures 15 and 16 show the dielectric constant, dissipation, impedance, reactance, and both equivalent parallel and series resistance characteristics of this dielectric system as a function of frequency. Note the dispersion occurring at 2 x 10^8 Hz in both the dissipation and parallel reactance curves indicating a resonant frequency point. A calculation of the relaxation time, τ_o, by extrapolation of the impedance in the limit to d-c conditions at 25°C gives

$$\tau_o \equiv K_\epsilon \rho_o = (RC)\ \text{static} = 5.3 \times 10^{-9}\ \text{sec}$$
$$\nu_o \equiv \tau_o^{-1} \cong (5.3 \times 10^{-9}\ \text{sec})^{-1} \cong 1.9 \times 10^8\ \text{sec}^{-1} \quad [7]$$

which is in remarkably close agreement with the experimental dispersion point of 2 x 10^8 sec^{-1} noted in Fig. 15. This observed dispersion would correspond to a bulk resistivity of about 200 ohm-cm; a value that is in accord with reported values for single crystals such as noted in the Maxwell-Wagner dispersion as discussed by Hahn (22). Note the splitting of the equivalent parallel and series reactances from the impedance curves at 1 MHz, both asymptotically approach a constant value with the parallel combination roughly equaling the numerical value of the impedance. The dispersion of the equivalent parallel reactance at 200 MHz is identical to the frequency noted for the dissipation dispersion. Finally, note that the impedance asymptotically approaches a constant value. This latter response is modified somewhat when the dielectric is used in a parallel plate capacitor device pattern. The printed lead series inductance and resistance causes a sharper bend in the knee of the impedance curve and shifts it to the left as seen in Fig. 17. Although not shown in the figure, the impedance curve remains flat out to the low gigacycle range, with the limiting value of the impedance between 1 and 2 ohms.

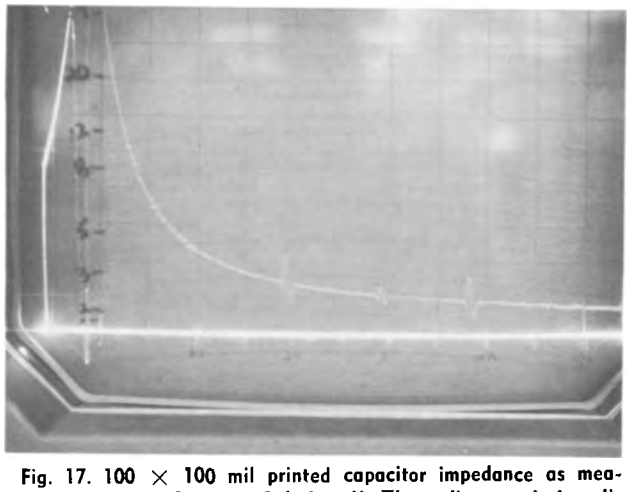

Fig. 17. 100 × 100 mil printed capacitor impedance as measured on a Rhode-Schwartz Polyskop II. The ordinate axis is calibrated in ohms. The abscissa in megacycles, the frequency marker blips are located at every 10 MHz. The curve is a visual display of complex impedance vs. frequency.

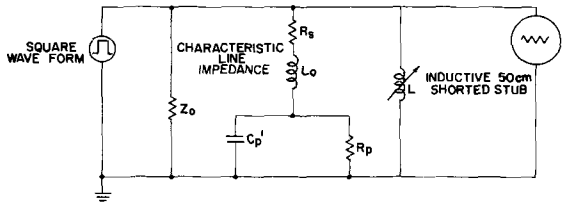

Fig. 18. Equivalent pulse-resonance complex impedance circuit

This is in close agreement to the plotted curve in Fig. 16 which asymptotically approaches 1.4 ohms.

Since computers use pulse signals for internal communication, it was decided to test this capacitor system in a pulsed network. These capacitors were incorporated into a tunnel diode circuit array and functioned very successfully. Evaluation of this system was done by subjecting it to a fast repetitive signal: it was allowed to resonate with a known inductance. A sampling oscilloscope was used to detect the response of the resonant network and display it as a resonant exponentially damped wave form. Such a measurement yielded the amount of damping, time of cycle, and resonant inductance value. With these parametric values, the capacitance and conductance of the decoupling capacitor device was calculated.

The measuring circuit described earlier is essentially an RLC circuit, as shown in Fig. 18, which is pulsed with a square wave. This circuit has a transient response. If one were to study the manner in which this circuit behaves when, following some initial stimulus, it is left to its own devices; that is to say, when it is permitted to execute its own unique natural behavior, one would find that it takes the form of a decaying oscillation as shown schematically in Fig. 19.

This solution of the characteristic response in the limit as the impedance goes to infinity has the general form of the cubic equation

$$s^3 + as^2 + bs + c = 0 \qquad [8]$$

which can be solved by Cardan's method if transferrable to a reduced form or by the trigonometric method if "irreducible." However, in the range of interest it can be shown that the s^3 term may be neglected and Eq. [8] reduces to the familiar quadric form with general solution

$$s = -\frac{b}{2a} \pm \sqrt{\left(\frac{b}{2a}\right)^2 - \frac{c}{a}} \equiv -\alpha \pm \sqrt{\alpha^2 - \omega_o^2} \qquad [9]$$

where α is referred to as the damping coefficient and the radian frequency, and ω_o is referred to as the natural frequency of the physical system described by the RLC circuit.

Four distinct possibilities can now occur, depending on the relative values of α and ω_o: (*a*) the aperiodic or overdamped case wherein $\alpha > \omega_o$; (*b*) the critically damped case where $\alpha = \omega_o$; (c) the damped oscillatory

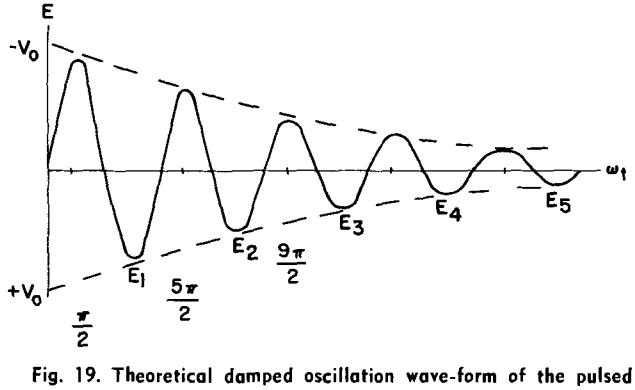

Fig. 19. Theoretical damped oscillation wave-form of the pulsed L-C resonant measuring circuit.

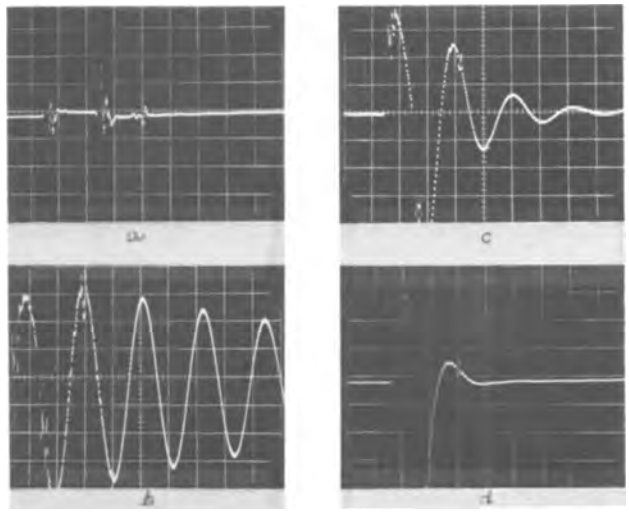

Fig. 20. Sampling scope display of (a) shorted stub impedance trace; (b) standard high impedance capacitor which resonates with the inductance of the shorted stub (oscillatory case; $\alpha = 0$); (c) low impedance decoupling capacitor which damps out 80% of the inductance of the shorted stub (damped oscillatory case; $\alpha < \omega_o$); (d) low impedance decoupling capacitor which critically damps out the inductance of the shorted stub (critically damped case; $\alpha = \omega_o$).

case wherein $\alpha < \omega_o$; and (*d*) the oscillatory case wherein $\alpha = 0$.

Each of these cases is shown pictorially (pictures of scope trace) in Fig. 20. The response of Fig. 20c is that of the zinc-bismuth oxide semiconducting dielectric as discussed previously. Figure 20d is characteristic of the present monovalent copper doped semi-insulating dielectric.

The critically damped nature is brought about by an inherent low series resistance introduced by the cationic monovalent dopant. To determine the damping coefficient, consider Fig. 19. The damped wave form may be represented by the product of a sinusoidal function and a decaying exponential,

$$E = V_o\, e^{-\alpha t} \sin \omega_o t \qquad [10]$$

One may accurately determine the amount of damping by taking the voltage ratio (vertical axis of the sampling scope) of the two wave crests in the first cycle. The damping envelope itself (represented by the dashed curve of Fig. 19) is characteristic of the damping coefficient. Thus we have

$$\frac{E_1}{E_2} = e^{\alpha(t_2 - t_1)} \frac{\sin \omega_o t_1}{\sin \omega_o t_2} = e^{\alpha(t_2 - t_1)} \qquad [11]$$

$$\alpha = \nu_o \ln \frac{E_1}{E_2} \qquad [12]$$

Using this concept and solving for Eq. [9] one obtains as a solution for the capacitance and conductance

$$C = \left[\nu_o^2 \left(4\pi^2 + \ln^2 \left(\frac{E_1}{E_2}\right)\right) (L + L_o) \right]^{-1} \qquad [13]$$

$$G = \left[2\nu_o C \ln \left(\frac{E_1}{E_2}\right) - \frac{Z_o R_s C + L}{Z_o(L + L_o) + LR_s} \right] \qquad [14]$$

Thermal response.—Thermal shock test.—Both systems were tested for mechanical reliability by testing their ability to withstand thermal shocks of 100°C differential. The samples were placed in a programmed delta chamber and cycled between 0° and 100°C with a 1-min rise time, 2-min soak time, 2-min fall time, and 2-min lapse time. The results show no apparent drifting of dielectric constant, dissipation, or resistivity values and no dielectric failures.

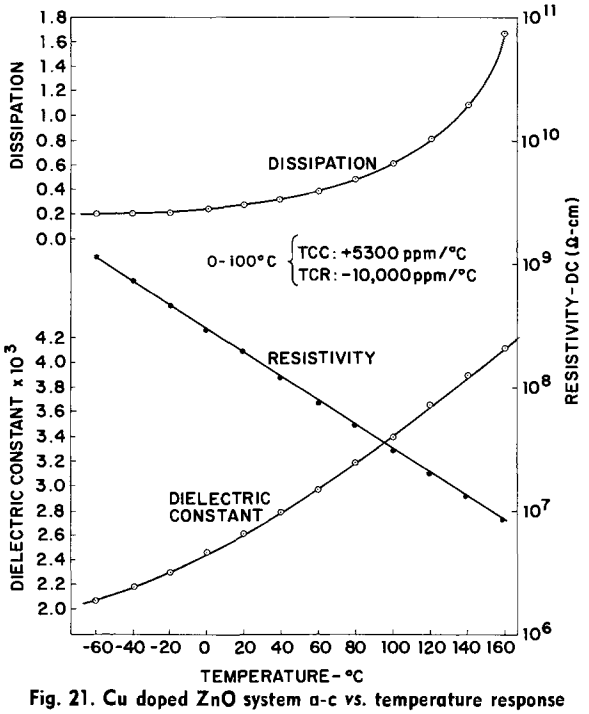

Fig. 21. Cu doped ZnO system d-c vs. temperature response

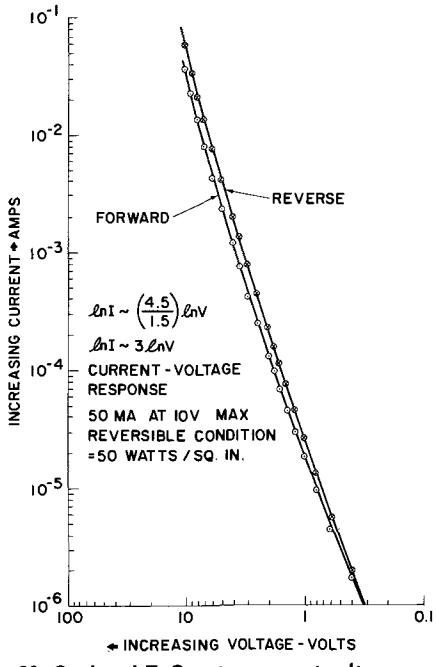

Fig. 22. Cu doped ZnO system current-voltage response

Temperature characteristics.—The dielectric constant, dissipation, and d-c resistivity were evaluated as a function of temperatures from —25° to 160°C in incremental steps of 25°C (see Fig. 21). The frequency characteristics were evaluated at 1 kHz and voltage characteristics at 1 vdc. Note that the frequency characteristics are an increasing function of temperature while the voltage is decreasing.

Room storage and thermal aging.—As a final consideration of thermal properties, this system was also tested for its room storage stability and thermal aging rate if any.

All samples, fabricated as explained earlier, were resubjected to a final processing step, *viz.*, soaking at 250°C for 5 min. They were withdrawn at temperature and allowed to cool to room temperature rapidly in a dessicator. Measurement began exactly 1 hr after withdrawal and terminated after several readouts at 1152 hr. Except for readouts, these units were continuously stored in a dessicator supplied with fresh dissicant at frequent intervals. The results of this test indicate that this system shows no apparent drift during room storage and exhibits no apparent thermal aging.

Electrical response.—A current-voltage evaluation was conducted on this system on 0.01 in.² parallel plate capacitors at 25°, 50°, and 75°C. This system exhibits a nonlinear assymetric d-c resistivity, *viz.*, it is a polar semi-insulator.

There is about a 2 to 1 ratio between reverse and forward resistivities at a given voltage and temperature. There is also a 2 to 1 ratio in resistivities between temperatures at a given voltage and polarity, the higher $\rho_{d\text{-}c}$ values are in the lower temperature-voltage ranges.

An expanded plot of the 25°C test is shown in Fig. 22. The relation between current and voltage appears in Eq. [15].

$$\ln I \sim 3 \ln V \text{ or } I \sim V^3 \qquad [15]$$

This dielectric is capable of an overload of 50 w/in.² before dielectric breakdown occurs. In fact, these samples will emit a dull glow prior to "burn out." The burn out phenomena occurs as a spark avalanche over the entire plate area.

Environmental response.—Low voltage tests.—Accelerated temperature humidity life testing was conducted on typical capacitor units fabricated from this dielectric system under the following matrix:

Dry: Voltage stresses of 0.1, 0.25, 0.50 and 1.0v d.c. each at temperatures of 100°, 125°, and 150°C for a 12 test cell matrix.

Wet: Saturated relative humidity conditions (samples placed over water in closed chamber) at 95°C and 0.25v d.c. voltage stress. All samples were evaluated at 25°C and ambient environment.

Although corrosion of electrode plates produced open-circuit failures, not one failure was attributed to dielectric short circuit degradation. Units that were not open circuits operated normally with less than ±15% deviation in capacitance from initial conditions. This is remarkable in view of the stressed condition brought to bear by the corroded electrodes.

Moisture seems to affect capacitance by shifting the high-and low-frequency drift patterns. Under ambient RH conditions capacitance drift for low frequency was generally negative and less than —15%, while high-frequency capacitance drift was generally positive (never greater than —5%) and less than + 10%. Saturated RH testing brought about a reversal of this drift pattern. In general, topography does not seem to affect the dielectric drift patterns.

Higher voltage tests.—Several units were further tested under dry conditions at 0, 2.5 and 5.0v d.c. (accelerated stress) each at 60°, 90°, 120°, and 150°C. There were no dielectric failures in any test cell except the following:

5v d.c. — 120°C

5v d.c. — 150°C

Capacitance drifting generally occurred in the high voltage-temperature cells but was confined to less than +10%. Dielectric dissipation drift was found to increase positively with an increase of temperature and voltage with a maximum drifting of about +300%. Resistance drift was found to decrease with an increase of temperature and voltage with a maximum drifting of about —300%. This tends to indicate that the drift in dielectric dissipation is caused almost entirely by the drift in resistance. Again, all sample units were evaluated at 25°C and ambient humidity.

Device types.—Figures 23a and b, Fig. 24a and b, and Fig. 25a and b show various forms of multiple

capacitors that may be made utilizing this semi-insulating dielectric material. Figure 23 shows an independently operable pair of juxtaposed parallel capacitors with a common ground plane and the equivalent circuit. Figure 24 shows an independently operable pair of parallel stacked capacitors with a common interposed ground plane and the equivalent circuit. Figure 25 shows a stacked parallel capacitor network with interleaved electrodes and equivalent circuit illustrated.

Discussion

In the foregoing experimental study it was pointed out that a semiconducting dielectric can be converted into a semi-insulating dielectric by monovalent substitution doping at the cationic lattice site.

The zinc-bismuth oxide semiconductor is characterized as a damped oscillatory network with about 80% effective damping due to the existence of a very low effective dielectric shunt resistance at high frequency. After monovalent substitution doping, the resulting semi-insulating dielectric becomes a critically damped network with effective damping reaching values greater than 98%. This effect is due to a small effective series resistance on the order of an ohm being introduced into the dielectric network.

This semi-insulating dielectric system is unique to dielectrics and can be used with screen printing technology to produce useful capacitor devices for applications requiring high K_e — low Q decoupling or filter capacitors capable of critical damping. The chemical-physical nature of this system of dielectrics offers a wide area of further research into yet unknown and new phenomena.

The Anodic Oxidation of Aluminum in the Presence of a Hydrated Oxide

Robert S. Alwitt

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The effect of a hydrated oxide on the kinetics of anodic oxidation of aluminum has been studied and the properties of the resulting composite oxides compared with those of purely anodic oxides. The presence of a hydrate layer reduced the amount of anodic oxide needed to support a given voltage and increased the current efficiency to as much as 100%. Water was lost from the oxide during anodization, probably as the result of transformation of boehmite to γ-Al_2O_3, which was incorporated into the barrier layer. The dielectric strength was greater for a composite oxide than for an oxide produced in the absence of a hydrate, though the dielectric constants were probably not very different. The impedance characteristics of a composite oxide indicated fewer microfissures than in a purely anodic oxide.

The formation of an oxide film on aluminum by the sequential processes of reaction in hot water followed by anodic oxidation produces a composite oxide with some unique properties. This process has been of technological importance for some time in the manufacture of electrolytic capacitors (1, 2), but has received scant attention in the scientific literature. Altenpohl (3) briefly mentioned that the anodic oxide grows underneath the hydrate and that the latter is partially consumed by the growing film. He suggested that water is eliminated from the consumed portion of the hydrate whenever this portion crystallizes into γ-Al_2O_3 under the influence of a high electric field. Unfortunately, no experimental evidence accompanied this discussion. Burger and Cheseldine (4, 5) also advanced the idea that the barrier portion of the composite oxide consists of both anodic oxide and converted hydrate, but their data were insufficient to confirm this.

The lack of information on the composite oxide prompted us to perform the investigation reported here of the effect of a hydrated oxide on the kinetics of anodic oxidation, and the properties of the resultant composite oxide. Our data support the hypothesis that some hydrate is dehydrated during anodization and becomes converted to barrier oxide. Moreover, details of this process are presented that have not been available previously.

Experimental Procedures

Commercially etched 99.97% pure aluminum foil was used throughout. The increased surface area improved the sensitivity of weight measurements and the "corrugations" increased the rigidity and strength of the isolated oxide, greatly simplifying handling procedures. Any change in surface area over the range of oxide thickness studied was sufficiently small to have no effect on the interpretation of results. Sample size was 6.4 x 7.6 cm for weight and charge measurements and smaller samples, 2.6 x 3.6 cm, were used for impedance measurements. The foil was not treated in any way prior to hydration in boiling water at atmospheric pressure.[1] Anodic oxidation was at 2 ma/cm^2 in 100 g/l boric acid at 90°C. The boric acid was electronic grade, and distilled deionized water with a resistivity *ca.* 500,000 ohm-cm was used throughout. Foils were rinsed in acetone and dried at 85°C for about 10 min prior to weighing. Weights were accurate to ± 0.1 mg.

The oxide film was isolated from base metal by slowly dissolving the metal in a warm solution of 10% bromine in methanol, followed by thorough rinsing with several changes of hot methanol. Bernard and Randall (6) found that this technique could be used to quantitatively recover hydrated oxide. To check its efficacy with anodic oxide, a sample anodized at room temperature in a solution of 30% ammonium pentaborate in glycol was immersed in bromine-methanol. The oxide recovered was equal to 98% of the amount calculated for the expected current efficiency of 100% (7).

The water content of the oxide was taken to be the weight loss that resulted on heating the isolated oxide for 2 hr at 900°C.

In some instances the oxide was dissolved from base metal by immersing samples in an aqueous solution of 2% CrO_3 + 5% H_3PO_4 at 85°C. For samples covered solely with hydrated oxide a sufficient immersion time was calculated from the data of Bernard and Randall (6). To insure complete dissolution of anodic oxide, samples were alternately immersed and weighed until the rate of weight loss dropped to that of the base metal.

Aluminum dissolved in the electrolyte was determined using a method of Sandell [procedure A in ref. (8)] based on the extraction of aluminum hydroxyquinolate by chloroform and photometry of the resultant yellow extract. In some electrolytes a white precipitate formed during anodization. This was collected and considered to be Al_2O_3 after heating for 2 hr at 600°C. The total weight of dissolved aluminum was the sum of that found in solution and in the precipitate.

Impedance measurements were made with a conventional a-c bridge that measured the equivalent series capacitance and RC product. Two measuring solutions with different resistivities were used. The first, 50 g/l H_3BO_3 adjusted to neutral *p*H with NH_4OH, had a resistivity of about 400 ohm-cm. The second solution had a resistivity of about 10 ohm-cm and was used previously by Burger and Cheseldine (4). It had a composition of 2.5% ammonium pentaborate, 12.5% ammonium formate, 10% glycol, and 75% water. The measuring cell was designed to hold a foil sample equidistant between two platinized plates spaced 1 cm apart.

Results

Properties of the hydrated oxide.—Bernard and Randall (6) found that the oxide produced in boiling water was a water enriched boehmite, with approximately two moles of water per mole of Al_2O_3. This oxide is not a good dielectric. Some of their experiments were repeated using etched foil and excellent agreement was obtained.

The growth of hydrated oxide in boiling water followed a logarithmic rate law over the interval 1-30 min (data in columns 1 and 2 of Table I). The deviation at the shorter time may have been due either to

[1] A mild alkaline cleaning resulted in a slightly greater rate of hydration, but had no affect on hydrate composition.

Table I. Effect of hydrate on anodic oxidation 200v barrier film

Boil Time, min	ΔW, mg/dm²	Wt. Al_2O_3, mg/dm² Total	Anodic	Charge, Q, meq.	Current eff, %	$W_{Al}/_{0Q} \times 100$

30	39.8	85.2	38.1*	2.24		

* Weight of anodic Al_2O_3 calculated from charge, assuming 100% current efficiency. Total oxide is the sum of calculated weights of anodic and hydrated oxides.

uneven hydration of the surface or the production of an oxide of lower water content. The hydrate thickness was calculated to be about 100 Å/mg of weight gain, based on the density of isolated hydrate films measured in toluene (6). Since these films are porous, the true thickness would be greater than this.

Samples of two different etched foils and an unetched foil was boiled for 1, 3, and 5 min, and then the oxide was dissolved in CrO_3-H_3PO_4 solution. The weight of hydrated oxide and the water content were calculated from the weight changes. The water content ranged from 24 to 30% with an average value of 27%. There were no significant differences among the different types of foil or the different reaction times. Burger and Cheseldine (9) found the composition of the hydrate produced in boiling water to be constant at 27% H_2O for immersion times from 5 to 60 min. In all subsequent calculations it was assumed that the hydrated oxide contained 27% water.

Effect of the hydrate on the anodization process.— Foils were anodized to 200v after immersion in boiling water for times up to 30 min. The oxide films were then isolated and heated at 900°C for 2 hr. The effect of the hydrate on weight of oxide, charge, and current efficiency is summarized in Table I. Each entry is the average for two samples.

The total weight of Al_2O_3 was that found after heating at 900°C. The calculated weight of Al_2O_3 grown during the boil (based on average hydrate composition) was subtracted from the total to obtain the weight of anodic oxide. The current efficiency is the ratio of equivalents of anodic oxide to equivalents of charge passed during anodization, expressed as a per cent. The last column in Table I gives the weight of dissolved aluminum as a per cent of the charge passed. The data in the last column were obtained in a separate set of experiments.

When the weight of hydrate is a large part of the total oxide weight, deviation from the average hydrate composition can introduce significant error in the calculated weight of anodic oxide. It was estimated for a 5-min boil that uncertainties in the hydrate composition could introduce an error of ± 6% in the weight of anodic oxide.

An alternate method can be used to calculate the weight of anodic oxide. The observed weight gain during anodic oxidation (ΔW_{an}) represents the difference between the weight of oxygen gained and the weight loss from reduction of water content (ΔW_{H_2O}) and dissolution of aluminum (W_{Al}). The weight of anodic oxide is then,

$$W_{anodic} = (102/48)\ (\Delta W_{an} + \Delta W_{H_2O} + W_{Al}) \quad [1]$$

A precipitate forms during anodization if W_{Al} is large, and the experimental error in determining W_{Al} is then probably as great as the uncertainty in hydrate composition. When W_{Al} is small, the major source of error is in the quantity ΔW_{H_2O}, the difference between the calculated weight of water in the hydrate and the weight loss at 900°C.

In the last column in Table I it is seen that W_{Al} is very small for a 5-min boil, and may be neglected in Eq. [1] without introducing serious error. For this case it was estimated that the uncertainty in ΔW_{H_2O} could result in a ± 3% error in the weight of anodic oxide calculated from Eq. [1]. This method was used to arrive at the figures in parentheses in Table I. These are believed to be more accurate than the corresponding figures arrived at by the first method.

The presence of a hydrated oxide sharply reduced the amount of anodic oxide required to produce a 200v barrier film. The total weight of oxide changed little for boil times of 5 min or less. The small decrease in total oxide weight with a 1-min boil could be due to experimental error, but under some conditions the total weight of composite oxide may be less than that of a purely anodic oxide because of a greater dielectric strength. This is discussed in a later section.

The current efficiency with no hydrate was usually about 70-75%, but sometimes dropped as low as 50%. The presence of a hydrated oxide greatly improved the current efficiency, so that after a 5-min boil the efficiency was close to 100%. (Spectrographic analysis of two composite oxides made with 5-min boils showed the presence of 0.17% and 0.37% boron. If present as B_2O_3, this would contribute 0.5-1.0% to the apparent weight of oxide.) The combination of improved current efficiency and reduced anodic oxide resulted in charge consumption with a 5-min boil less than 40% of that required in the absence of a hydrate. Such reduced charge was one of the earliest benefits attributed to the presence of a hydrate layer (1). The increase in charge for the 30-min boil is very likely a real effect, since a similar observation has been made by Randall (10).

Copious gas evolution was sometimes observed at the anode when a hydrate film was absent. This was presumably oxygen, but no attempt was made to verify this. This gas evolution would account for the fraction of the charge not consumed in oxide formation and aluminum dissolution. There was negligible gas evolution during formation of films to 200v after a boil of 1 min or longer. Both gas evolution and aluminum dissolution increased when thicker films were formed. For example, for films formed to 400v after a 5-min boil the current efficiency was only 92.6% and dissolved aluminum accounted for 2.6% of the charge.

When a foil sample was anodized in a solution of 30% ammonium pentaborate in ethylene glycol at room temperature and constant current, current efficiency was 100%, and dV/dt was constant up to at least 200v. When a sample was boiled in water for 5 min and then anodized in 100 g/l H_3BO_3 at 90°C, current efficiency was again 100%, but dV/dt was not constant. A typical recorder trace is shown in Fig. 1. The values of dV/dt initially and at 200v are indicated. There was some variation among samples, but the general pattern was that for the initial 15-25v the voltage rise was constant at a value between 7 and 9

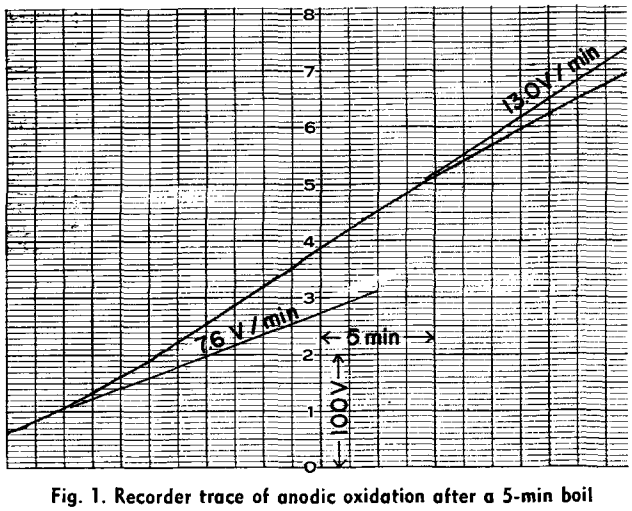

Fig. 1. Recorder trace of anodic oxidation after a 5-min boil

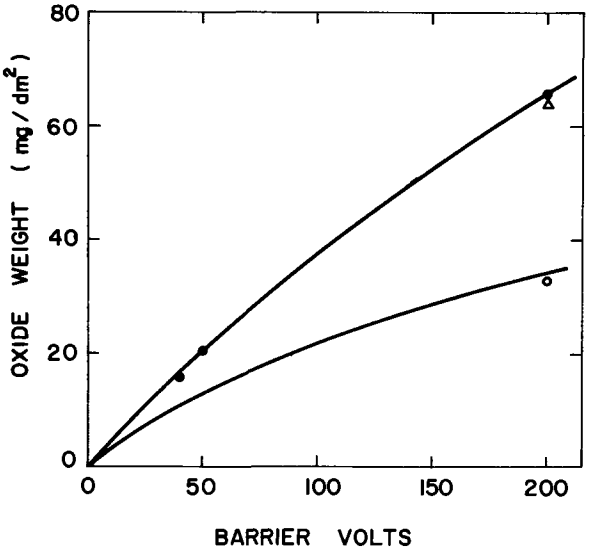

Fig. 2. Effect of hydrate (5-min boil) on oxide weight: ● = total oxide weight with no hydrate; △ = total oxide weight with hydrate; ○ = anodic oxide weight with hydrate.

v/min. The voltage then increased more rapidly into the range 50-100v until dV/dt was between 12 and 14 v/min. The rate of voltage rise was then constant to above 200v where increased aluminum dissolution and gas evolution accompanied a decrease in dV/dt. The same behavior was obtained with plain foil as with etched foil.

The change in oxide weight with increasing anodization voltage is shown in Fig. 2. The total oxide weight was measured after heating at 900°C. The open circle and triangle are data from Table I, while the lower curve represents average anodic oxide weights calculated from several recorder traces of voltage *vs.* time, assuming 100% current efficiency. The weight of total oxide in the absence of initial hydrate is shown by the top curve. It is possible that some hydrate was produced during anodization since the isolated 40 and 200v oxides formed in the absence of initial hydrate lost 0.2 and 0.8 mg/dm², respectively, at 900°C.

Composition and structure of the composite oxide.—Water content.—The oxide films contained less water after anodization than was present in the initial hydrate. In Table II the weight loss at 900°C of a 200v composite oxide is compared with the water content of the hydrate film. The difference between these two quantities represents the water depleted during anodization and is given in the last column of the table. This quantity varied little over a threefold range in hydrate weight, which implies that the reaction responsible for the loss of water did not occur uniformly throughout the hydrate.

The decrease in water content with increasing thickness of barrier oxide for foils that initially received a 5-min boil is shown in Fig. 3. The points represented by dark circles were determined from the 900°C weight loss while the open circles were calculated in the same way as the last entry in Table II. The com-

Table II. Water content of 200v composite oxides

5	10.9	6.9	4.0
30	17.6	—	4.5*

* Calculated from ΔW_{an} and charge, using Eq. [1] and an assumed current efficiency of 100%.

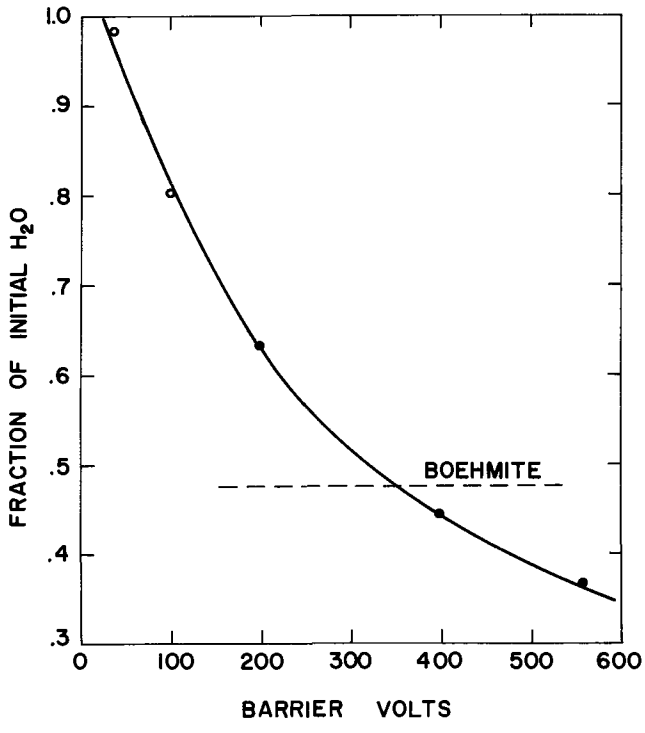

Fig. 3. Water content of composite oxide made with 5-min boil: ○ = calculated; ● = experimental.

position corresponding to boehmite for the hydrate is indicated by the horizontal dashed line. It would seem that during the formation of the first 25v of barrier film little or no water was lost. This corresponds in magnitude with the initial period of constant dV/dt.

The loss of water could occur in three ways: (*a*) expulsion of water from the oxide to the solution; (*b*) reaction of aluminum ions with water from the hydrate instead of with species from solution to form oxide (4), *viz.*, $2Al^{+3} + 3H_2O \rightarrow Al_2O_3 + 6H^+$; and (*c*) reaction of water from the hydrate with base metal to form oxide, *viz.*, $2Al^{o} + 3H_2O \rightarrow Al_2O_3 + 3H_2$.

If (*c*) is the prevailing mechanism, then the total weight of metal reacted should exceed that consumed by the initial hydration and charge passed during anodization. To examine this, two foil samples were given a 5-min boil, anodized to about 200v, and then the oxide was dissolved in CrO_3-H_3PO_4 solution. It was calculated that the average weight of aluminum consumed by hydration and anodization was 34.4 mg, compared with an observed metal weight loss of 33.0 mg. If water reacted with base metal, it was estimated that an additional weight loss of 5 mg should have been observed. Clearly, mechanism (*c*) is not consistent with the experimental results.

Mechanisms (*a*) and (*b*) cannot be distinguished on the bases of weight changes and charge passed. Indeed, we have devised no way to determine which of these mechanisms prevail.

Water distribution.—Two isolated 200v composite oxides made with a 5-min boil were heated at several temperatures between 600° and 900°C. The average weight loss at each step is given in Table III. Sixty eight per cent of the water was removed at 600°C, but not until 900°C did it appear that all the water was removed. This contrasts with the results of Bernard and Randall (6) who found that at 600°C, 97% of the water was removed from the film produced by the reaction of aluminum and boiling water. Thus, some of the water remaining in the composite oxide is bound much more strongly than is the water in the initial hydrate. This water, as hydroxyl groups, may be a part of the γ-Al_2O_3 structure in the barrier oxide (11, 12).

Table III. Removal of water from composite oxide (5-min boil, 200v)

Temp, °C	Time, hr	Wt. loss, mg/dm²
600	2	4.7
700	2	1.1
800	2	0.8
800	Overnight	0.15
850	2	0.1
900	4	0.05
		6.9

X-ray analyses.—Diffraction patterns of several oxides were made using a Debye-Scherrer powder camera. Only qualitative results were obtained. A significant amount of γ-Al_2O_3 was found in a 200v oxide formed in 100 g/l H_3BO_3 at 90°C with no hydrated oxide present. The pattern for a 200v composite oxide formed in the same way, but after a 5-min boil showed about the same amount of γ-oxide present, and also a lesser amount of boehmite. No evidence of a crystalline phase was found for a 200v oxide formed in a solution of 30% ammonium pentaborate in glycol at room temperature.

Impedance measurements.—Capacitance vs. film thickness.—For the discussion of Fig. 4 it is convenient to introduce the dielectric strength, D, defined as the ratio of barrier volts to barrier thickness. Then $1/C = (k/\epsilon D)V$, where ϵ is the dielectric constant and k is a constant. The product ϵD was constant for oxide formed in the absence of initial hydrate. Up to about 50v ϵD was the same, with or without an initial hydrate produced by reaction with boiling water for 5 min. The oxide grown in the interval 50-200v had about a 50% higher ϵD product when the hydrate was present. (Assuming no change in the initial 50v oxide, which may not be the case.)

Frequency and electrolyte dependence.—Impedance measurements were made on oxide films formed in three different ways:

Oxide H, Five minutes in boiling water, then anodized to 200v at 90°C in aqueous 100 g/l H_3BO_3.
Oxide NH, No hydration, anodized as for oxide H.
Oxide NHG, No hydration, anodized to 245v at 25°C in 30% ammonium pentaborate in ethylene glycol.

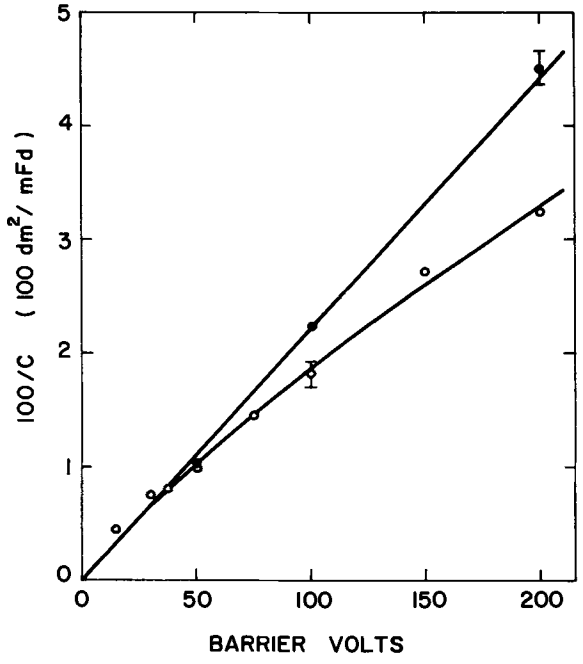

Fig. 4. Effect of hydrate (5-min boil) on capacitance at 120 Hz: ● = no hydrate; ○ = hydrate. Each point is average for at least two samples; vertical lines show range of six samples (I) and five samples (I).

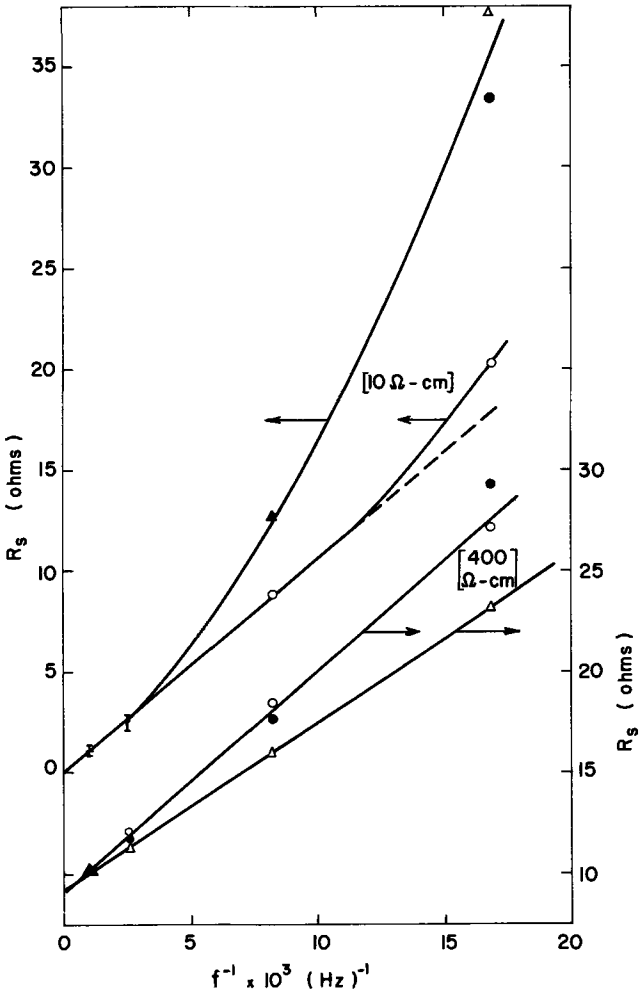

Fig. 5. Frequency dependence of series resistance in two measuring solutions: ○ = oxide H, ● = oxide NH, △ = oxide NHG.

Impedance measurements were made over the frequency range 60-1000 Hz in two solutions with resistivities of about 10 and 400 ohm-cm. The results are shown in Fig. 5 and 6.

The results in the 400 ohm-cm solution with oxides H and NHG were close to those predicted by theory (13, 14). Plots of $1/C$ *vs.* log f and R_s *vs.* $1/f$ were linear, and the ratio of the slopes of these lines was 9.7 (H) and 8.8 (NHG), which compares with a predicted ratio of 9.2. The value of R_s for oxide NH deviated slightly from linearity at the lowest measuring frequency (Fig. 5) and the ratio of the slopes for this oxide was only 6.9.

When viewed on unetched foil, oxide NH had a hazy appearance and contained random, irregularly shaped black spots with a characteristic dimension 0.03-0.1 mm. After heating isolated oxide at 900°C these spots disappeared. Electron probe microanalysis detected no impurity elements within the particles. Their exact nature is unknown, but they may be a secondary oxide phase or a localized dispersion of fine metallic aluminum particles (15). Oxide NHG and all composite oxides were always clear and free of blemishes.

In the 10 ohm-cm solution none of the oxides gave linear impedance plots. Oxides NH and NHG exhibited exceedingly high R_s at low frequencies, while the deviation for oxide H was only slight. The plots of $1/C$ *vs.* log f were slightly curved for all oxides due to high series capacitance at low frequencies. Additional anodic polarization (healing) did not remove these effects, indicating the absence of large fissures.

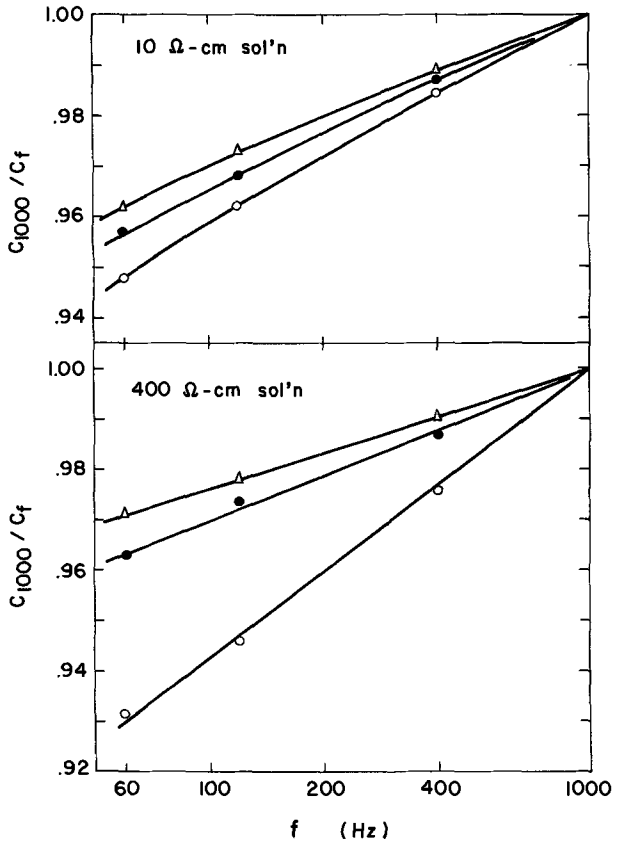

Fig. 6. Frequency dependence of series capacitance in two measuring solutions: ○ = oxide H, ● = oxide NH, △ = oxide NHG.

Young (16) has attributed this type of dependence on measuring solution conductivity to the presence of microfissures in the oxide film. From the relative values of R_s in the 10 ohm-cm solution it seems that the presence of a hydrate results in either the formation of an oxide with less microfissures, or reduces the effect of any existing microfissures. None of the known properties of these oxides can explain the improved low-frequency behavior of the composite oxide. One possibility that can be suggested is that forces could be distributed across the barrier/hydrate interface, relieving stresses within the barrier layer and thus reducing microfissures.

Surface area.—The hydrated oxide is very porous, so the only way it could become part of a barrier layer is if the anodic oxide grew into the interstices. This would result in a reduction of surface area. No change in surface area would be expected if the anodic oxide grew only under the hydrate. Thus, surface area measurements are important evidence in determining the role of the hydrate.

The surface areas of specimens that received a 5-min boil and were then anodized were determined using a dynamic BET method employing nitrogen adsorption. The following results were obtained, expressed as surface area/projected area. Each figure represents a different sample:

Barrier volts	Area ratio, m^2/dm^2
0	4.51, 5.33
200	2.11, 2.56
400	1.74

The surface area prior to hydration was too small to be determined by this method, but from capacitance measurements on samples anodized to low voltages this area was estimated to be about 0.1 m^2/dm^2.

The significant decrease in surface area during anodization supports the idea that hydrate is incorporated into the barrier layer. The larger decrease in area during the first 200v compared with the next 200v increment is qualitatively similar to the decrease in water content with film thickness (Fig. 3).

Discussion

The most satisfactory explanation of the anodization results is that some hydrate was converted to barrier oxide by dehydration during anodic oxidation, so that the total barrier oxide was the sum of anodic oxide plus converted hydrate. Boehmite is usually dehydrated to form γ-Al_2O_3 at about 450°C, but the transformation can occur as low as 350°C (17). Under the influence of an electric field, the hydrate lattice may be sufficiently distorted to permit the transformation at still lower temperatures. Precedents for field-assisted crystallization are the production of γ-Al_2O_3 during anodic oxidation at 90°C (as seen in this experiment) and the formation of anodic α-Al_2O_3 at less than 300°C (18). The high field in the barrier layer during anodization will not exist in the bulk of the hydrate layer. However, it probably does extend some small distance across the barrier/hydrate interface, and in this surface region field-assisted dehydration would occur. This would account for the observation that the weight of water lost was independent of the amount of bulk hydrate present (Table II). Since there is evidence that hydroxyl groups exist within the anodic portion of the composite oxide, complete dehydration would not be required for conversion to barrier film.

It appears that there is an inhibition period for the dehydration of hydrate, during which the ϵD product is unaffected by the presence of hydrate. However, the barrier oxide formed during this time is not identical with that produced in the absence of a hydrate as evidenced by the difference in anodic oxide weights that exists from the very start of anodization.

Although no direct determination could be made of the amount of hydrate converted to barrier oxide, it is possible to compare several estimates of this quantity. The fraction of hydrate converted was assumed to be equal to each of expressions (a)-(c), where W_{H_2O} is the weight of water in the initial hydrate and

$$1 - \Delta W_{H_2O}\ (900°C)/W_{H_2O} \quad (a)$$
$$1 - \Delta W_{H_2O}\ (600°C)/W_{H_2O} \quad (b)$$
$$1 - (\text{surface area composite oxide/surface area initial hydrate}) \quad (c)$$

ΔW_{H_2O} is the weight loss of the composite oxide at the indicated temperature. Expression (b) is an attempt to account for water that may be in the barrier oxide. The fraction converted was calculated in these ways for 200v and 400v composite oxides made with a 5-min boil. The results are shown below:

	(a)	(b)	(c)
200v	0.37	0.57	0.43-0.60
400v	0.56	—	0.65

Considering the assumptions inherent in each of these estimates, the agreement is reasonably good.

Making the further assumption that the true fraction converted lies within the range of the above estimates enables us to examine the dielectric properties of the composite oxide. The weight of barrier oxide in the 200v composite oxide was calculated using the limits of 37 and 60% hydrate conversion. The ratio of the dielectric strength of the composite oxide to that of a film with no hydrate (assuming equal density barrier oxides) and the ratio of dielectric constants could then be determined, with the following results:

	37%	60%
$D_{comp.}/D_o$	1.43	1.24
$\epsilon_{comp.}/\epsilon_o$	1.05	0.91

Thus, the major effect of the hydrate is to produce a barrier film with significantly greater dielectric strength, with little or no change in dielectric constant. A similar calculation for 400v films led to the same conclusion. This argument also holds when considering the composite oxide *vs.* amorphous films formed in glycol-borate electrolyte, since for the same weight of oxide these latter films had the same capacitance (120 Hz) as films formed in aqueous boric acid with no hydrate.

The improved current efficiency for oxide formation in the presence of a hydrate could be due to two factors. First, the reduced barrier oxide/electrolyte contact area would decrease any general oxide dissolution, although this could not account for the complete absence of dissolution. Second, no black spots were observed in the composite oxide, and these were probably sites for secondary reactions such as oxygen evolution. The more fundamental question as to the cause and elimination of these defects remains unanswered.

Conclusions

1. The presence of a hydrate layer during anodic oxidation of aluminum not only reduces the amount of anodic oxide needed to support a given voltage, but also increases the current efficiency to as much as 100%.

2. The loss of water during anodic oxidation is associated with transformation of hydrate into barrier oxide. The high temperatures needed to remove water from the isolated composite oxide suggest that some water, as hydroxyl groups, is present in the anodic oxide.

3. The dielectric strength of a composite oxide is greater than that of an oxide produced in the absence of a hydrate. The impedance characteristics of a composite oxide indicate it contains fewer microfissures than a purely anodic oxide.

Luminescence Efficiency of Silicon Carbide Doped with Boron and Nitrogen

R. M. Potter

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio

and D. A. Cusano

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Luminescence quantum efficiencies of the order of 10% have been measured at 300°K for α-SiC doped with boron and nitrogen. The values obtained using cathode-ray and 3650Å excitation agree within the uncertainty of the measurements.

This paper reports some new results on the quantum efficiency[1] of luminescence in both single crystal and powdered SiC doped with boron and nitrogen. The measurements were made using cathode-ray and 3650Å uv excitation, at 77°K and at room temperature. Until recently, (1, 2) the quantum efficiency of SiC at room temperature had been reported as extremely poor. The present work has shown that room temperature quantum efficiencies of the order of 10% are possible for suitably prepared SiC:B,N powders and crystals.

[1] In this paper, quantum efficiency is defined as the ratio of luminescence photons generated to electron-hole pairs produced by excitation.

Experimental Procedures and Results

SiC:B,N powder phosphors used in the investigation were kindly supplied by Addamiano, who has described their preparation in detail (3, 4). Briefly, they were prepared by firing at around 2500°C a mixture of "semiconductor grade" silicon and "spectroscopically pure" graphite along with 10^{-4} to 5×10^{-4}

mole fraction boron in Ar gas containing a small percentage of N_2. As shown in Table I, the impurity levels in the product (aside from boron) were generally too low to be detected by emission spectroscopy. Samples prepared without adding boron exhibited no room temperature photoluminescence. As noted in ref. (4), these powders consist of a mixture of several α-SiC polytypes. The luminescence peaks near 6000Å (Fig. 1a).

Single crystals were prepared by a modified Lely technique (1). The charge was Carborundum "high-purity" SiC grain, acid-washed to remove surface impurities. Controlled amounts of BCl_3 and N_2 were mixed with the furnace atmosphere (flowing Ar) throughout the run in concentrations which yielded a light green (n-type) product. Bright room temperature photoluminescence was found in a minority of the crystals; the bulk appeared considerably dimmer. It should be noted however that, when BCl_3 was omitted from the atmosphere, the photoluminescence was much dimmer and no bright individuals were found.

Because of the scarcity of bright samples, it was only possible to analyze a batch of crystals of generally low brightness (see Table I). This analysis is useful in establishing the background level of impurities from the furnace and from the SiC charge. The analysis shows that the common SiC impurities, except Al and B, are below the detection limits of emission spectroscopy.

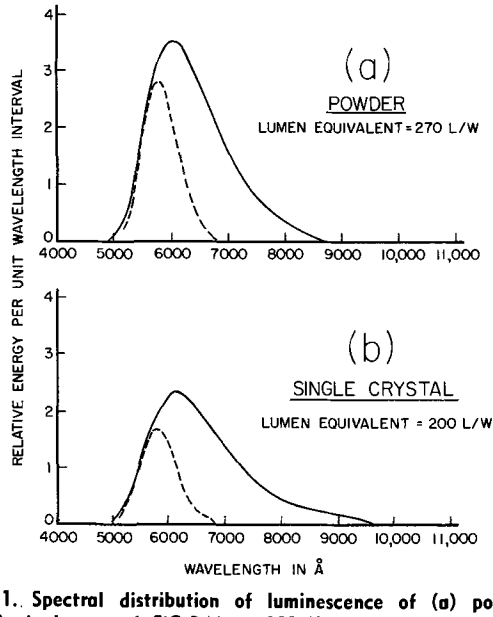

Fig. 1. Spectral distribution of luminescence of (a) powdered and (b) single crystal SiC:B,N at 300°K; excited by a 15 kv, 1 μa/cm^2 electron beam. Dashed curves are the product of the normalized photopic eye response and the spectral distribution.

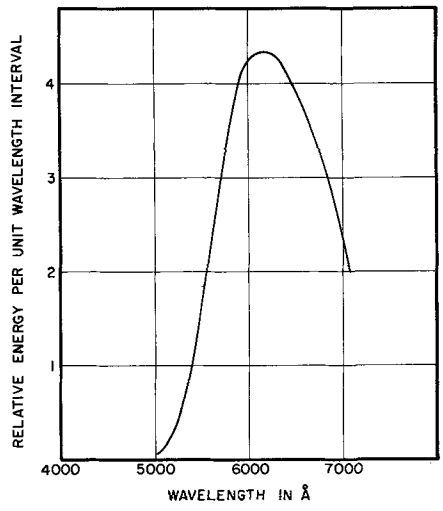

Fig. 2. Spectral distribution of luminescence of the single crystal of SiC:B,N at 300°K, excited by uv.

The structure of the crystal selected for the measurements was not determined, but the luminescence spectrum peak is close to that ascribed to the 21R polytype (3), *i.e.*, 6200Å (see Fig. 1B and Fig. 2).

Powder sample, 3650Å excitation.—The quantum efficiency of the powder under 3650Å excitation was determined by comparing the fluorescent output with that of a powdered sodium salicylate standard whose quantum efficiency is reported to be 0.45 (5). A filtered G.E. AH-6 mercury lamp was used to excite the samples with about 10^{-2} w/cm^2 of uv light peaking near 3650Å with some energy from 3300 to 3850Å. The photoluminescence measurements were carried out using a grating spectrophotometer with an external optical system which accepted a fixed small solid angle of the emitted fluorescence (see Fig. 3a). The detector was a RCA 1P22 photomultiplier. The total optical system plus detector was calibrated in terms of relative energy per unit wavelength interval. The curves in Fig. 1 and 2 were plotted in these units.

For the quantum efficiency estimates, the spectral distribution data were obtained for the SiC sample and the sodium salicylate standard under identical 3650Å intensity. These data were converted to relative photons per unit energy interval plots (not

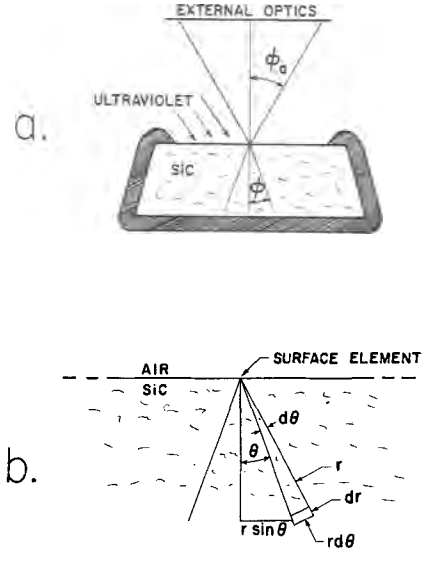

Fig. 3. (a) Experimental arrangement used for single crystal SiC:B,N, and (b) diagram illustrating the geometric approach used to establish the optical factor.

shown); the ratio of the areas under the curves in these plots are equal to the ratio of photon outputs.

The correction factor by which this ratio must be multiplied to give the quantum efficiency is

$$K_p = \frac{(1-R_{uv})_s}{(1-R_{uv})_p} \cdot \frac{2}{(1+R_e)_p} = \frac{0.53}{0.92} \cdot \frac{2}{1.50} = 0.77$$

where R is diffuse reflectance, the subscripts s and p denote the sodium salicylate standard and the powdered SiC, respectively, and R_e is the diffuse reflectance of the SiC for its own emission. (It was assumed that the fluorescence and the reflected uv were perfectly diffuse for both sample and standard.) Using 45% for the quantum efficiency of sodium salicylate, the quantum efficiency under uv excitation of a typical SiC:B,N powder was found to be about 6.4%.

Single crystal, 3650Å excitation.—The quantum efficiency of single crystal SiC:B,N was also obtained by comparison with sodium salicylate. In this case, the crystal surfaces except the central region of a smooth natural face were painted black with kerosene "dag." This procedure virtually eliminated multiple internal reflections and also simplified the corrections to be made below in deriving internal quantum efficiency.

These corrections can be understood by reference to Fig. 3b. The fluorescent light incident on an infinitesimal surface element of the crystal which originates within the solid angle corresponding to $d\theta$ is

$$dL = A(2\pi e^2 \sin\theta dr)\left(\frac{\cos\theta}{r^2}\right) e^{-kr\cos\theta}$$

where A is a constant, r is the distance of a light-producing volume element from the infinitesimal surface element, and k is the absorption constant for 3650Å light. The first term in parentheses is the volume element, the second term arises from the assumption of isotropic emission within the volume element, and the third represents the variation of relative emission intensity with vertical distance from the surface of the crystal. This expression integrates to $(2\pi A/k)(1-\cos\phi)$ for an angle ϕ in the crystal accepted in the external optical system. The fraction of the light generated in the whole hemispherical solid angle which is accepted in the solid angle corresponding to ϕ is then $(1-\cos\phi)$. The relation of the internal acceptance angle ϕ to the external (in air) acceptance angle, ϕ_a, is given by Snell's law: $\phi_a = n\sin\phi$, where n = refractive index of SiC at 6200Å.

This gives a fraction accepted (for small values of ϕ_a)

$$f_x \cong \frac{\sin^2\phi_a}{2n^2}$$

For the sodium salicylate powder, fluorescence is diffuse, and the fraction accepted is

$$f_p = \sin^2\phi_a$$

The optical correction factor when comparing crystal and standard is then

$$K_x = \frac{(1-R_{uv})_s}{(1-R_{uv})_x} \cdot \frac{1}{(1-R_e)_x} \cdot 2 \cdot \frac{f_p}{f_x} = \frac{(1-R_{uv})_s}{(1-R_{uv})_x} \cdot \frac{4n^2}{(1-R_e)_x}$$

where the $(1-R_e)_x$ term corrects for emitted light lost by specular reflection at the crystal-air interface and redirected toward the absorbing dag base, and the factor 2 accounts for the loss of the half of the light emitted initially toward the dag base. After substitution of the refractive index at 6200Å (2.63) and the reflectance values, one obtains

$$K_x = \frac{0.53}{0.775} \cdot \frac{4(2.63)^2}{0.80} = 23.7$$

The 3650Å diffuse reflectance of the sodium salicylate was measured by comparison to MgO powder (reflectance assumed 100%); the SiC specular reflectances were calculated for normal incidence from the refractive indices (6) (2.81 at 3650Å). Using this value of K_x, a quantum efficiency of 18% was deduced for the crystal selected.

Cathode-ray excitation.—The cathode-ray efficiency measurements were made at 15 kv and 22.5 kv, at current densities of 0.01 to 0.1 μa/cm^2, for 77° and 300°K. Both powders and single crystals were bombarded and viewed at 45° to the sample surface. The cathodoluminescent brightness in foot lamberts was measured with a Salford Electrical Instruments, Ltd. photometer. The external power efficiencies (watts out/watts incident) were determined directly from the photometric measurements using the lumen equivalents of the radiation (see Fig. 1) and the power in the incident beam. The best of these efficiencies for powdered and single crystal SiC were found to be 2.7 and 0.08%, respectively.

It was then assumed (conservatively) that ~6 ev of cathode-ray energy were needed to create an electron-hole pair which then resulted in an emitted photon of ~2 ev, giving a correction factor of 3. The remaining correction for powder and crystal is analogous to that for ultraviolet excitation above, since a brightness measurement also implies a diffuse source. The complete correction factor becomes

$$K_p = 3\frac{2}{(1+R_e)_p} = 4.0 \quad \text{for the powders and}$$

$$K_x = 3 \cdot \frac{4n^2}{(1-R_e)_x} = 105 \quad \text{for the crystals}$$

The quantum efficiencies of SiC:B,N deduced by correcting the above external power efficiencies are then ~ 12% for the powder and ~ 8% for the crystals.

In summary, the four determinations of quantum efficiency at 300°K are compared in Table II. At 77°K, the quantum efficiencies for both types of excitation are about two times greater than the 300°K values.

Discussion

The lower value of efficiency found under uv excitation for the SiC:B,N powder may be accounted for by (*i*) the samples used for the two measurements were from different preparations, (*ii*) the uv excitation intensity was much higher than the cathode-ray excitation intensity. (We have found that efficiency varies as the —0.1 to —0.3 power of excitation intensity), and (*iii*) the assumption of diffuse reflectance of uv may be a poor one. The higher value of efficiency found under uv excitation for the single crystal may be due to the difference in penetration of the electrons and the uv (~ 3μ compared to ~ 10μ), and suggests that the single crystal may not be uniform in properties near the surface. (The same crystal was used for the uv and cathode-ray measurements). We feel that our results indicate a quantum efficiency of between 5 and 20% for SiC:B,N at 300°K.

SiC is an indirect material and, as such, might be expected to have a low efficiency for luminescence resulting from band to band recombination or recombination by way of shallow levels. There is, however, no theoretical barrier to high efficiency radiative re-

Table II. Quantum efficiencies of SiC:B,N

	SiC:B,N powder	SiC:B,N single crystals
Ultraviolet	6%	18%
Cathode ray	11%	8%

combination involving deep levels, which is undoubtedly the case for SiC:B,N. The same is true for the 7000Å emission of GaP, for which fairly high injection electroluminescence efficiencies have been reported recently (8-10).[2]

Acknowledgments

The authors are indebted to Dr. A. Addamiano for supplying samples of powdered SiC:B,N and to Dr. R. P. Taylor for the analytical work.

Closed System Vapor Growth of Bulk CdS Crystals from the Elemental Constituents

Naim Hemmat and Martin Weinstein

Tyco Laboratories, Inc., Bear Hill, Waltham, Massachusetts

ABSTRACT

The growth of large, high-purity CdS monocrystals has been accomplished by a closed system technique. Crystals weighing up to 150g, 9 cm in length by 25 mm in diameter have been grown in a closed quartz ampoule directly from the high-purity elemental constituents. The technique lends itself to the preparation of high-purity CdS, since the possibility of extraneous impurity pick-up is minimized. Homogeneous doping during vapor growth has also been accomplished. In addition, techniques are described whereby bulk crystals containing 10^3 dislocation/cm^2 have been prepared. The mechanisms of dislocation production, propagation, and removal are discussed in the specific context of constrained growth from the vapor phase.

A number of methods have been proposed for the growth of large, high-purity, single crystals of CdS (1-3). Many procedures have also been described for the synthesis of CdS. In general, the two basic methods are precipitation from aqueous solution of Cd with H_2S (4) and precipitation from vapor phase reaction (5).

In the latter approach, commonly known as the Frerich's method (6), the metal is vaporized in one section of the furnace and carried over to the reaction zone by a carrier gas (H_2) where it reacts with H_2S to form the metal sulfide vapor. The sulfide subsequently is deposited in a cooler zone of the furnace. The Frerich's technique and all its modifications can therefore be described as a chemical vapor transport process. This type of vapor phase technique requires a composite assembly in which a relatively large surface area of the system is in contact with the constituent elements and the compound. This paper describes in detail a new closed-system synthesis and growth technique by which large, high-purity, and uniformly doped single crystals of CdS are grown from starting charges of Cd and S.

Synthesis of CdS

In order to minimize contamination and improve crystal homogeneity, an attempt was made to synthesize CdS in a closed reaction tube.

The experiments that led to the successful synthesis of CdS in a closed vessel can be summarized as follows: stoichiometric quantities of high-purity (99.9999+%) Cd in the form of shot (United Mineral and Chemical Corporation, New York) and S (99.999%) type A-58, fragmented pieces (American Smelting and Refining Company, South Plainfield, New Jersey) were sealed in a 25 mm ID, 20 cm long, clear quartz tube under vacuum (10^{-6} Torr). The sealed reaction tube was positioned in the uniform temperature zone of a horizontal resistance furnace. A number of experiments following various time-temperature cycles were conducted. The time-temperature cycle for which complete synthesis was successful consisted of holding the charge at 600°C for 12 hr, followed by 24 hr at 900°C and then gradually increasing the temperature to 1200°C. The charge was maintained at 1200°C for 8 hr or more and then cooled to room temperature. Figure 1 is a macrograph of the CdS crystallites obtained in a run following this specific time-temperature cycle. The resulting crystals have a transparent yellowish-brown color and are randomly sized single crystals in the form of hexagonal rods and platelets, some with extremely well-defined crystallographic faces. The size of the crystals ranges up to 3 x 4 x 8 mm.

In general, it was experienced that in order to avoid an explosive reaction the system had to be held at 600° and 900° for a minimum of 20 hr. On examination it was concluded that the explosive reaction was intimately associated with the initial formation of a CdS film that surrounded the liquid Cd and retarded the Cd + S → CdS reaction. Such observations have previously been noted by Reisman and Berkenblit (7). The CdS film forms in some cases below the melting point of Cd. At 600° the film became thicker and much less porous. The thick film grown at 600° was capable of sustaining the internal pressure equal to the Cd vapor pressure at this temperature. If this thick, tenacious film was not given sufficient time to grow, the

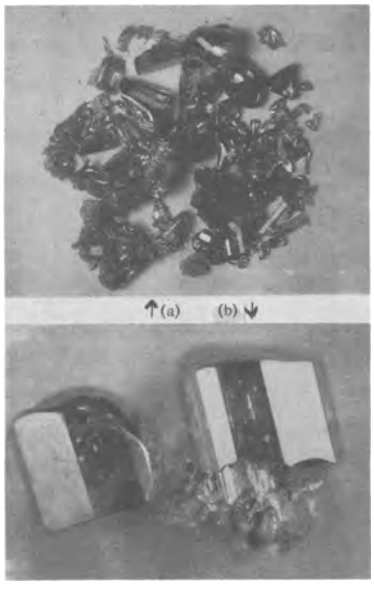

Fig. 1. CdS crystallites produced by closed tube synthesis approach, (a) 1X, (b) 8X.

film fractured at a temperature above 700° and the exothermic reaction Cd + S → CdS took place in a violent manner. At 900° Cd (or S) diffusion through the CdS film was sufficiently fast so that, after 20 hr at temperature, the reaction goes to completion. If the synthesis reaction is not carried to completion, above approximately 925°, the vapor pressure of S becomes sufficiently high ($P_S \sim 35$ atm) to cause failure of the 1.5 mm thick quartz capsule.

Based on an analysis of the results obtained from these experiments, it was concluded that the synthesis of CdS directly from the elements in a closed system is feasible; in order for the synthesis to be carried to completion successfully, the constituent elements should be separated initially by means of a proper temperature gradient in order to avoid the formation of a CdS film at low temperatures on the Cd melt. Also in order to avoid excessive pressure build-up, the S reservoir must be kept below 500° while the exothermic reaction is in progress.

The synthesis procedure finally arrived at utilized a batch-type technique. Stoichiometric quantities of S and Cd were initially placed into the growth ampoule and sealed under vacuum (10^{-6} Torr). The tube was then placed into a movable furnace which allowed observation of the ampoule during reaction. The furnace was first passed over the Cd reservoir in order to cause vaporization of Cd with subsequent deposition of a Cd film in the central portion of the tube. Next, the furnace was manually moved to the S reservoir where vaporization of the S occurred with subsequent deposition of a portion of the S charge again in the central portion of the tube. The furnace was then moved to the center of the tube where reaction of the constituent films took place. For a 100g elemental charge approximately 5-7g of CdS was formed per pass at the central portion of the reaction tube. This process was repeated until all reactants were consumed.

The CdS prepared by this technique is a yellowish powder containing fine needlelike crystallites. The above described closed system technique was also found to be applicable to the synthesis of high-purity CdSe, ZnSe, and ZnS, provided that the optimum temperature-time cycle was used for each compound.

It has been reported that deviations from stoichiometry in CdS crystals significantly affect their electrical properties (8). It is also known that an excess of one of the constituent elements can radically change the crystal growth parameters (9). For these reasons it was found advisable in certain cases to extract the excess free elements from the synthesized CdS charge prior to single crystal growth. The extraction of excess constituent elements was readily accomplished using the following procedure. The initial reaction tube was made a few inches longer than the intended growth ampoule. Following the synthesis the sealed reaction tube was positioned in a two-zone furnace (with temperature flats of approximately 1050° and 800°) for 2 to 4 hr, with a portion of the tube exposed to ambient temperature. This procedure resulted in the sublimation of the entire charge at the hotter zone and crystallization at the 800° region; during this recrystallization process the excess Cd or S condensed at the coolest region of the tube. The tube was then brought to room temperature and the ampoule resealed, isolating the region containing the volatile element from the remainder of the tube containing the recrystallized CdS charge. (This process, of course, can only be utilized in the case of undoped charge.)

Crystal Growth

After the synthesis step, the growth ampoule was positioned inside a mullite tube in a travelling horizontal furnace. Since the vapor pressure of CdS at 1200° is ~ 0.25 atm the mullite tube was maintained under dynamic vacuum so as to reduce the stress on the quartz tube, thus reducing the rate of devitrification and preventing collapse of the ampoule during the run. In practice, the pointed end of the growth ampoule is positioned relative to the temperature gradient of the furnace as shown in Fig. 2. Figure 3 is a schematic representation of the crystal growth apparatus. The optimum speed of the furnace travel is dependent on the temperature profile of the furnace; 0.25°/hr (corresponding to approximately 0.3 mm/hr) was found to be the most practical rate for growth. It should be noted that the amount of charge relative to the length of capsule and temperature gradient determines the exact temperature corresponding to the start of nucleation. The temperature of the furnace was controlled to ± 0.25° by a Honeywell precision set point system Model No. 687081. When the crystal growing run was terminated, the temperature of the furnace was decreased gradually (25°/hr to room

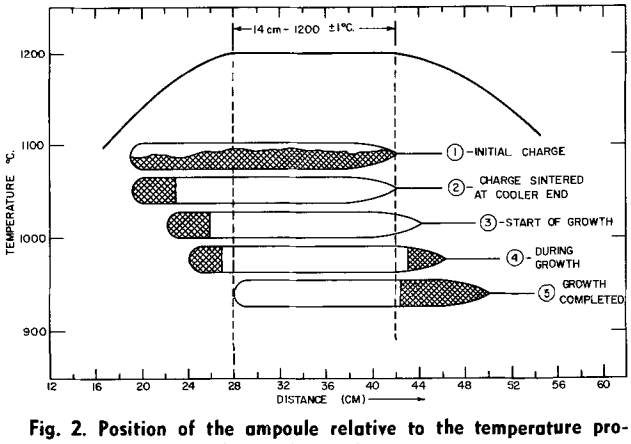

Fig. 2. Position of the ampoule relative to the temperature profile at various stages of crystal growth.

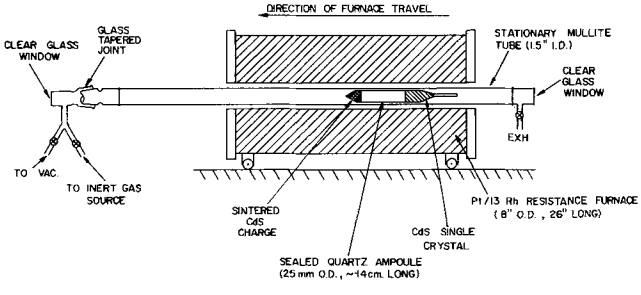

Fig. 3. Schematic drawing of crystal growth apparatus

temperature) by automatic programming, to avoid thermal strain. A thorough analysis of the growth rate as a function of distance was made to improve process reliability and yield.

CdS single crystals weighing up to 150g and 25 mm in diameter have been grown by the method described. Figure 4 is a photograph of some typical crystals grown by this approach. It was also feasible to grow single crystals of CdS with nearly the same dimensions in a vertical apparatus.

It was experienced that a Cd excess of approximately 400 ppm did not affect single crystal growth. We have found, however, that excess S inhibits the growth process by severely decreasing the dynamic vapor pressure of CdS. The excess S suppresses the sublimation rate more than Cd since it has a higher vapor pressure than Cd. Therefore, in order to maintain the relationship $K = P_{Cd} \times P_{S_2}$, P_{Cd} decreases to a point where sublimation is seriously retarded. Utilizing the previously described technique we have observed that the growth of single crystals from high-purity Cd and S necessitates more careful control of process variables (temperature, ampoule position, rate of growth, etc.) than the growth from a doped charge or from commercially available presynthesized compound.

Doping of CdS

The pure crystals grown by the closed system synthesis and growth technique exhibit a resistivity in the range 0.01-0.1 ohm-cm. This low resistivity may well be the consequence of a tendency for CdS to grow slightly off stoichiometry. The Hall mobility of these crystals varied on average from 300 cm^2/v-sec to 350 cm^2/v-sec at room temperature (25°).

The closed system technique also lends itself to the doping of crystals. For example, when 10^{18} atoms/cc of Cu (~55 ppm) were added in the form of CuS to the initial elemental charge prior to synthesis, the crystals exhibited a resistivity of approximately 10^3 ohm-cm with a variation of less than ±15% along their entire length. The Cu doped crystals exhibit a uniform transparent-reddish color. Also it was experienced that the resistivity of the pure crystals could be increased by approximately an order of magnitude by adding excess S (corresponding to a P_S of approximately 200 mm Hg at 1200°) to the initial elemental charge, prior to synthesis.

The impurity concentration of the bulk grown CdS crystal was analyzed by mass spectrometry. The overall analysis is given in Table I. Total impurities, other than carbon and sodium, were found to be approximately 2 ppm atomic. The carbon concentration was not homogeneous, varying from 0.1 to 1 ppm. Sodium varied between 0.4 and 3.8 ppm. Impurities not listed were not detected and have concentrations less than 0.3 ppm atomic, except O, Mn, Fe, and Zn which are interfered with by the background lines of S and Cd combinations.

Crystal Perfection

In order to facilitate the structural analysis of the grown crystals, an etchant composed of 35% phosphoric acid saturated with CrO_3 with 65% HCl (denoted "HPC") was developed which produced distinct and reproducible etch pits on the (0001) face of CdS. Prior to etching, the (0001) faces were mechanically polished and chemically repolished by heating in phosphoric acid at 100° for 30 min. The chemical polish removed the surface damage introduced by mechanical polishing. Etching of the chemically polished specimens was carried out for 10 to 20 sec at room temperature without agitation. For specimens with higher etch pit densities, shorter etching times were employed to prevent overlapping of pits. Also, a number of adjacent wafers (with planes perpendicular to the c-axis) were etched in a similar manner and examined microscopically. It could be demonstrated that the etch pit denoted the emergence of a line defect at the crystal surface thereby indicating a 1:1 correspondence between etch pits and emergent dislocations.

In most cases, a chemical etch should produce soluble or gaseous products. Insoluble products generally contaminate the surface inhibiting further action of the etch or mask its effect. Reaction of the (HPC) etch on CdS most probably proceeds as follows

$$3CdS + 2H_3PO_4 \rightarrow Cd_3(PO_4)_2 + 3H_2S \quad [1]$$

$$H_3PO_4 + CrO_3 + 3HCl \rightarrow CrPO_4 + 3H_2O + 1.5Cl_2 \quad [2]$$

$$H_2S + 4H_2O + 4Cl_2 \rightarrow H_2SO_4 + 8H^+ + 8Cl^- \quad [3a]$$

$$CdS + 4H_2O + 4Cl_2 \rightarrow CdSO_4 + 8HCl \quad [3b]$$

It is to be noted that the products $CdSO_4$, $Cd_3(PO_4)_2$, $CrPO_4$, and Cl_2 are either soluble in water or are gaseous. It is also to be noted that with time, depletion of Cl_2 gas will weaken the effect of the etch; for this reason a freshly made etch is necessary for best results.

Figure 5 is a photomicrograph of the (0001) plane (the "Cd-face") (10) of CdS. The effect shown was produced by heating a polished oriented sample in phosphoric acid for approximately 15 min. It is to be noted that a series of layers form a uniform background for a few highly symmetrical hexagonal terraces. In order to determine the origin of the "terracing effect," a section of the (0001) plane was bevelled 5 degrees and again was polished chemically. The direction of terracing changed, indicating that the lamellar effect produced by chemical polishing merely reveals the deviation of surface orientation from the basal plane.

Typical pits produced by the (HPC) etch are shown in Fig. 6 The hexagonal pits are produced on the (0001) face in which the uppermost layer is com-

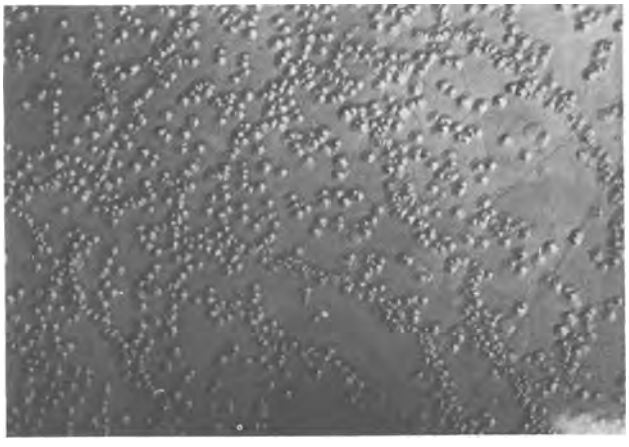

Fig. 6. Typical etch-pits produced by "HPC" etch on a (0001) plane, 30X.

posed of Cd atoms but not on the opposite $(000\bar{1})$ face which terminates with sulfur atoms. This effect arises because of the noncentrosymmetric structure of CdS. Reproducibility of these pits was confirmed by successively lapping and etching crystals with low etch-pit densities and retracing individual pits.

The distribution of dislocations in bulk single crystal CdS was studied by cutting wafers along the length of a large crystal the "c"-axis of which was perpendicular to growth direction. Figure 8 shows a composite photomicrograph of the (0001) plane of the entire surface of a slice (5X) taken from the midsection of this large single crystal. The crsytal weighed approximately 100g and was 4.2 cm long. The sawtooth pattern shown in Fig. 7 is actually an etch-pit pattern produced by the (HPC) etch.

Prior to etching, the surface was chemically polished. It is noted that the first region of the crsytal to grow contains an extremely high dislocation content. The observed dislocation aggregates act as a source for numerous low angle boundaries dispersed throughout the bulk of the crystal. Another source of dislocations appears to be present at the periphery of the crystal where the crystal is in contact with the quartz ampoule. The midsection of the crystal constitutes a third highly dense region; that is where the low-angle boundaries originating from the two mentioned sources intersect. The lowest etch-pit density is found in the last portion of the crystal to grow.

Figure 8 is a plot of the etch pit density as a function of distance along the length of a pure crystal. The c-axis was approximately 15 degrees from the growth direction in this crystal. Etch pit densities were determined on eight wafers cut perpendicular to the "c"-axis, the slices being 6 mm thick. It is noted that in the first grown section of the crystal, the dislocation density is high at the edge and center of the crystal. The density at the edge and center remains nearly constant through the midsection of the crystal but sharply decreases as it approaches the last grown region.

In the course of the imperfection study, two unique types of etch-pit patterns were distinguished. Figure 9 is a photomicrograph of the pattern of the first type in which the etch-pits originate from a mechani-

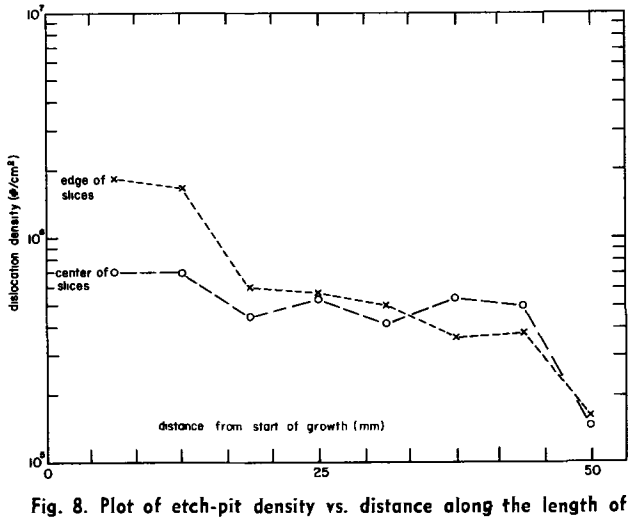

Fig. 8. Plot of etch-pit density vs. distance along the length of a pure crystal.

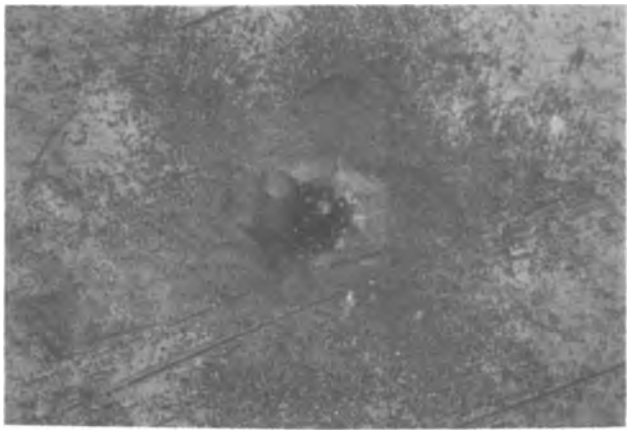

Fig. 9. Etch-pit pattern originating from a mechanically damaged point source (pure crystal) 275X.

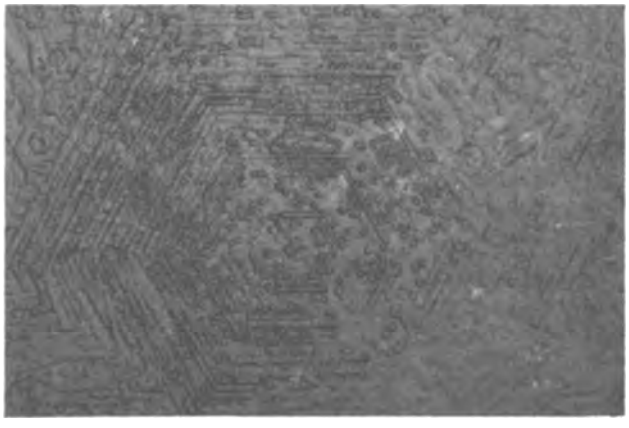

Fig. 10. Etch-pit pattern aligned in $<11\bar{2}0>$ directions associated with stress originating at the periphery of the region (pure crystal) 275X.

cally damaged point source. In this type of pattern the etch-pits disperse along the $<11\bar{2}0>$ direction, gradually disappearing some distance from the source. Figure 10 shows a pattern of a second type in which the etch pits are also aligned in $<11\bar{2}0>$ directions but collectively form an aggregate of unicentered hexagonals. In this latter type of disorder, it is suspected that slip is caused by stress originating at the periphery of the region.

The direction of etch pit alignment was established from the geometry of the hexagonal pits. By a careful study of Laue back reflection photographs and light figure patterns of etched single crystals of CdS having Wurtzite type (B_4) structure, it was confirmed that the arms of the hexagonal etch pits on (0001) surface extend in the $<11\bar{2}0>$ directions. The Burger's vector directions were established from the observation of slip traces and the movement of dislocations during crystal bending.

For the most part the pit-arays on the (0001) plane were found to align in $<10\bar{1}0>$ directions, with $\{1\bar{2}10\}$ planes as the glide system. These arrays constitute a group of edge dislocations with Burger's vector $b = a_o\sqrt{3}$ in $<10\bar{1}0>$ directions where a_o is the lattice constant. This type of edge dislocation in CdS has also been identified by Nishimura (11). In addition to the dislocations formed in $<10\bar{1}0>$ directions, we also observed a formation of dislocations in $<11\bar{2}0>$ directions, most likely having a Burger's vector of $b = a_o$ (see Fig. 11a). This type of dislocation has also been observed by Woods (12). Figure 11b shows a particular region on the (0001) plane where both types of dislocations intersect.

An attempt was also made to determine the structure of imperfections terminating at the $(000\bar{1})$ "S-face." Figure 12 shows the effect of heating a crystal in H_3PO_4 for approximately 1 hr. It is to be noted that the $(000\bar{1})$ plane in this case consists of an interlaced spiral growth pattern, indicating the influence of screw dislocations on the growth mechanism. Upon close examination, the sixfold symmetry characteristic of the basal plane is noted within the growth spirals. The region on the lower left hand side of Fig. 12 shows a different grain, which has not been affected by etching due to misorientation relative to "c"-axis.

Based on observations of the dislocation pattern, it was concluded that the dislocation density could be minimized by starting growth from a low dislocation density properly oriented seed crystal and/or by using a semiflexible container to reduce the thermal stress (and subsequent dislocation generation) produced during cooling.

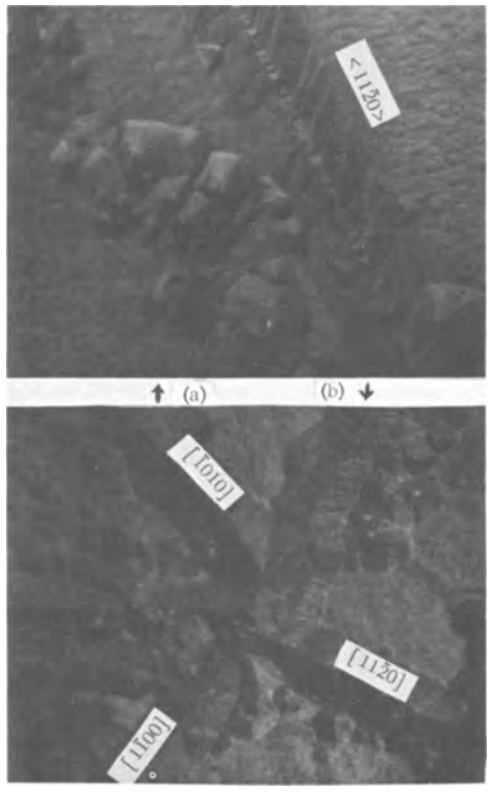

Fig. 11. Photomicrograph of (a) dislocations formed in $<11\bar{2}0>$ directions, (b) a region showing intersection of dislocations, formed in $<11\bar{2}0>$ and $<10\bar{1}0>$ directions.

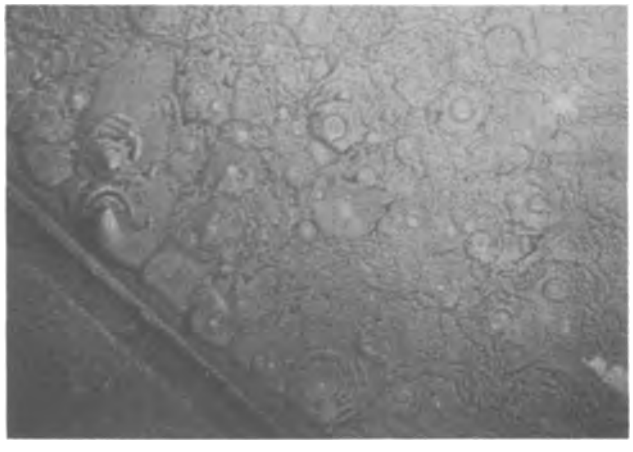

Fig. 12. Photomicrograph of (0001) "S-face" heated in H_3PO_4 at 100°C, 1 hr.

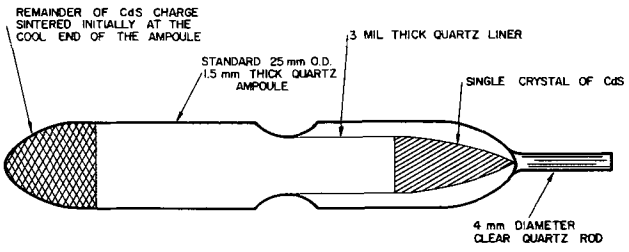

Fig. 13. Schematic drawing of ampoule assembly utilizing thin quartz liner.

Since the system was readily adaptable to the latter approach, a few experiments were carried out to determine the validity of the initial hypothesis. Figure 13 shows schematically the assembly with the 3 mil semiflexible quartz liner. The charge was positioned inside the thin ampoule. The main ampoule and the liner were sealed under high vacuum at the same time. Also a sufficient quantity of CdS powder was placed between the two ampoules to equalize the pressure inside and outside the liner. This prevented inflation of the thin liner at the growth temperature due to the vapor pressure of CdS. The single crystals obtained using this technique exhibited a dislocation density of 3 x 10^3/cm^2, two orders of magnitude lower than the crystals grown in the standard ampoule.

Conclusions

Synthesis and growth of large single crystals of CdS have been successfully accomplished by a closed system technique. This technique lends itself to growth of high purity, uniformly doped bulk crystals. In this technique contamination due to the carrier gas and/or intermediate handling of the compound is eliminated. Also the reaction (or growth) chamber surface area in contact with the elements and compound is considerably minimized. (Only 1.5 cm^3 is needed per gram of compound.) From the standpoint of the system assembly, the closed system technique is extremely economical; *i.e.*, the source-to-product conversion efficiency approach 100%, and the length of the crystal is not limited by the temperature profile of the furnace. This technique also makes possible the growth of CdS crystals under a predetermined vapor pressure of one of the constituent elements.

Electrical and Transport Properties of Cu in InAs

C. S. Fuller and K. B. Wolfstirn

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The solubility and diffusion of Cu in InAs has been investigated by means of electrical and radiochemical methods. The solubility determined by equilibration with an external Cu phase follows the relation $N_{Cu} = 4.0 \times 10^{22} \exp(-1.0 \text{ ev}/kT)$. The Cu solubilities determined from diffusion measurements in air were significantly lower presumably because of a different surface composition. The diffusion follows the relation $D = 0.0036 \exp(-0.52 \text{ ev}/kT)$. Cu is present almost exclusively as a single-charged interstitial donor in InAs. Defect acceptors, $\sim 3 \times 10^{15}$ cm^{-3}, are introduced into InAs by quenching from 875°C. These react with Cu giving about double the acceptor concentration. The maximum number of acceptors (substitutional Cu) introduced is essentially equal to the original donor concentration $\sim 10^{16}$ cm^{-3}. The possibility of drifting Cu to produce space-charge layers in InAs similar to Li in Ge is discussed.

Materials problems still restrict the utility of many of the III-V semiconductors. This is true, for example, of InAs where intensive efforts at purification (1, 2) have only succeeded in reducing the residual donors present to $\sim 10^{16}$ cm^{-3}. It has been suggested (1) that these may be native defects (antistructure) rather than residual impurities, although this remains to be proven. In addition to the residual donors, the question as to whether InAs crystals contain significant concentrations of vacancy clusters, is of interest in many applications. Such clusters are believed present in Ge (3), InSb (4), and in large concentration in GaAs (5).

The purpose of the present work is to obtain information on both of the problems mentioned above, through the use of ^{64}Cu as a probe. For example, interactions between substitutional Cu, or between vacancies produced by Cu, and donor antistructure disorder, As_{In}, might be expected. Also, since Cu interacts with vacancies present in clusters or present in

associates with impurity atoms in Ge (3), Si (6) and many compound semiconductors, it is of interest to examine InAs for similar reactions.

Before the above problems can be undertaken, it is necessary to know considerably more than is known at present about the electrical and diffusion behavior of Cu. The electrical effects of Cu in InAs have already been investigated. Edmond and Hilsum (7, 8) showed that Cu is responsible for heat treatment effects (9) in InAs and that Cu diffuses rapidly producing donors. They also found that it becomes electrically inactive (precipitates) when crystals diffused with Cu are allowed to stand at room temperature. On the other hand very little quantitative information on either the detailed electrical behavior or the diffusion of Cu is available in the literature. Another object of the present work therefore is to help fill this gap in our knowledge.

Materials and Methods

The undoped single crystal InAs employed in this work was prepared by the Czochralski technique (Monsanto Chemical Company) and had the following properties: electron concentration was 1.6-2.0 $\times$ 10^{16} cm^{-3} (298°K) and 1.4-1.8 $\times$ 10^{16} cm^{-3} (77°K); electron mobility was 27,000 (298°K) and 58,000 (77°K) cm^2/v-sec; etch pit density was 100 cm^{-2}. Mass spectrographic analyses on the crystal showed the following: all metallic impurities and S, Se, and Te <0.5 atomic part per million; carbon, oxygen, and nitrogen <1.0 part per million. Specimens (~50 mils thick) were prepared by cutting perpendicular to the growth axis [111] and lapping on No. 303 grade Aloxite abrasive in water to remove the cutting damage. Etching was done by means of bromine in methyl alcohol (10).

Copper, either ordinary Cu or Cu containing the radioactive isotope ^{64}Cu, was introduced into the InAs crystals by diffusion. This was done by electroplating Cu on one or more surfaces of the specimen (one face for the diffusion determinations). In some experiments known amounts of Cu, less than enough to saturate at the temperatures in question, were applied by "chem-plating" from 0.1*N* solutions.

The ternary phase diagram, Cu:In:As, has not as yet been investigated in any detail. We determined that Cu forms a eutectic melt with InAs at 340° ± 5°C. Consequently, for temperatures above this we assume that equilibrium alloys corresponding to the pseudo-binary liquidus form on the surface at each temperature. Below the eutectic temperature it is often difficult to achieve surface equilibrium. Consequently, the practice was adopted of prealloying all specimens at ~400°C for 2-5 sec prior to diffusion. No prealloying was employed for the solubility determinations. The error introduced in the diffusion runs by the prealloy treatment was estimated by examining the penetration of Cu radiochemically. This was found to affect only the first 15μ and, since most of the diffusions penetrated 0.5 mm or more, the correction is small and has been neglected.

Diffusions were carried out by heating the specimens in air on a stainless steel block controlled to within 1°C. All saturations were done in silica ampoules (0.001 Torr) placed in furnaces controlled to within 1°C. The accuracy of the temperatures was to ±1°C and was checked by melting pure Pb (327.4°C) and Sn (231.9°C) and by boiling water. Quenching required less than 1 sec on a metal block (22°C) or, for the encapsulated specimens, about 3 sec, in water at room temperature.

Electrical measurements were made by means of point contacts in a van der Pauw (11) arrangement at 300° and 77°K. These measurements are precise to ±2%. In calculating the electron concentrations, the relation $n = 1/R_H e$ was assumed in which R_H is the Hall coefficient and e is the electronic charge. Because of the high electron-to-hole mobility ratio (~100) in InAs the simple expression above holds for n-type specimens. However, for p-type specimens the two-carrier Hall expression must be used. We found that R_H determined in this way on Cu diffused Zn-doped InAs (p-type) was very inaccurate as a measure of the hole concentrations. Consequently, almost all of the electrical measurements reported here were made on extrinsic n-type specimens. A few measurements are reported for specimens which are intrinsic at 300°K. Because of the high mobility ratio, however, the simple expression is correct to within our experimental error even for these.

Penetration curves were determined by lapping the surfaces of the diffused specimens (after removal of the edge activity) parallel to the diffusion plane and counting the gamma activities of the grindings. Diffusion was approximately on the (111) plane, but no effect of the crystallographic direction is expected. Depth measurements were made by means of a Zeiss optimeter to ±2μ. The Cu concentration, plotted at the midpoint of each layer, was calculated from the corrected activity of Cu in each layer, the layer thickness, the specimen area, and the density of InAs (5.66). The surface concentration corresponding to each diffusion may be determined by extrapolation of the penetration curve to the origin taken as the surface of the specimen. Better values, however, are obtained from extrapolation of the best theoretical curves fitting the data (see below). This method was employed here.

The diffusion coefficient, D, was calculated from the "constant surface concentration" boundary condition (12)

$$C_x = C_o \operatorname{erfc} (x/2\sqrt{Dt}) \quad [1]$$

where C_x is the concentration at distance x from the specimen surface, C_o is the concentration at $x = 0$, erfc is the so-called complementary error function (1—error integral), and t is the time of diffusion at constant temperature.

A graphical procedure described previously (13) was employed to determine D. This consists of matching the log-log plot of the penetration curve to that of the complementary error function plotted against $x/2\sqrt{Dt}$ on the same scale. This procedure has an advantage when, as here, the data points are necessarily rather far apart (the short half life of ^{64}Cu precludes as detailed an analysis as might be desired), and the determinations near the origin are likely to be uncertain. The diffusion coefficients are calculated by reading the experimental distances corresponding to unity on the complementary error function plot. This provides values of $2\sqrt{Dt}$ and, since t is known, values for D.

Although solubilities can be determined from the C_o values as described above, this procedure usually does not yield as reliable results as the direct method which involves saturation with active Cu at each temperature. The latter method, however, fails when the diffusion coefficient becomes too small (below ~200°C) since the times then become too long. Both methods have been employed here. As shown below, however, the results do not agree. This is attributed to the fact that the surface phases differed in the two procedures.

Results

Diffusion and solubility of Cu.—The diffusion results are given in Fig. 1. These show the best fits to the complementary error function curves for the five temperatures: 248°, 342°, 393°, 449°, and 506°C. Figure 2 shows a semilog plot of D, calculated from Fig. 1, *vs.* reciprocal absolute temperature. The point at 506°C is low probably because of the appreciable heat-up time. An activation energy for diffusion of 0.52 ev (12.0 kcal) is obtained. Figure 3 is a semilog plot of the solubility against reciprocal absolute temperature including results from both the diffusion measurements and the direct determinations employing ^{64}Cu. The results from the two methods are not the same. Reasons for this are discussed below. A plot of the in-

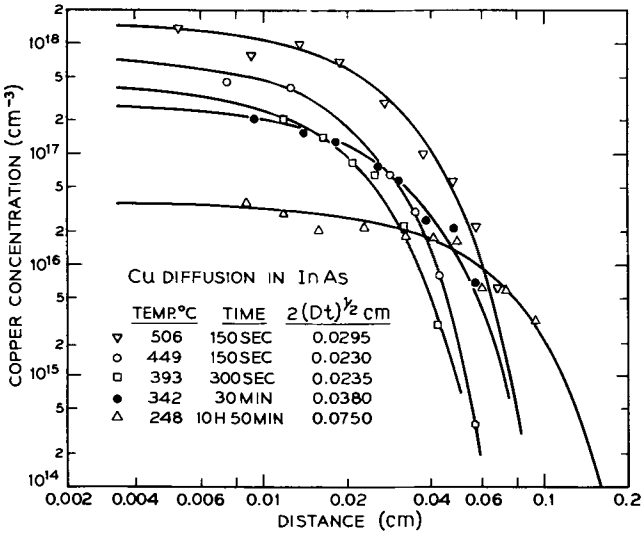

Fig. 1. Points show experimental determinations of Cu concentration as a function of distance from the surface for as-grown InAs specimens diffused at 248°, 342°, 393°, 449°, and 506°C. Solid lines show best fits of complementary error function (erfc U) curve plotted against $U = x/2\sqrt{Dt}$ to the same scale as the experimental data. Values of $x = 2\sqrt{Dt}$ which correspond to unity for the function U are given in the legend.

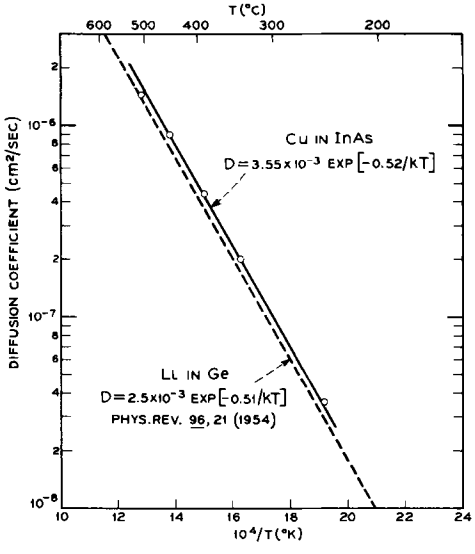

Fig. 2. Plot of diffusion coefficients derived from Fig. 1 vs. reciprocal absolute temperature. Data for Li in Ge are plotted (dashed line) for comparison.

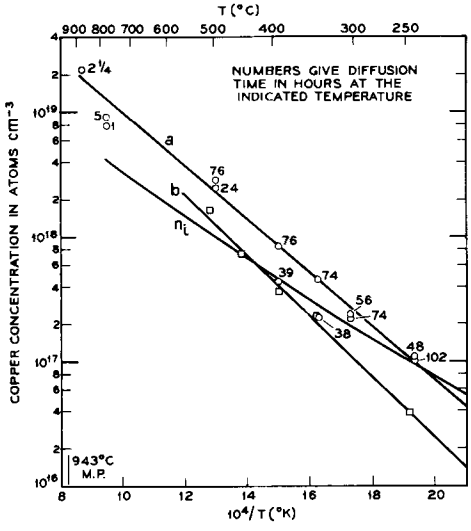

Fig. 3. Solubility of Cu in InAs. Open circles, determined radiochemically by saturation from an external Cu phase; open squares, determined from the solid curves of Fig. 1 by extrapolation, prealloyed at 440°C. A calculated curve of the intrinsic carrier concentration, n_i, for InAs is included.

trinsic carrier concentration, calculated using $m_e^* = 0.02\ m_o$, $m_h^* = 0.41\ m_o$, and $E_G = 0.47$ ev, is included in Fig. 3.

Electron-to-Cu ratio.—Table I shows a comparison of the electron and Cu concentrations for various InAs specimens. It is evident that the [e]/[Cu] ratios, except for specimen 14 are less than unity by appreciable amounts. This is because of rapid precipitation of Cu during and after cooling from the diffusion temperatures. Specimen 14 was prepared using a limited amount of Cu so that the specimen after diffusion was uniformly undersaturated. Table I shows that for this case the [e]/[Cu] ratio is essentially unity indicating that all of the Cu is interstitial, Cu_i. The ratio observed (1.08) deviates from unity by somewhat more than is expected from our estimated error. This may be caused by Cu leaving substitutional positions. Evidence for such Cu is discussed below.

Table I also shows the strong effect of the degree of supersaturation on the extent of precipitation during quenching. Thus only about 4% of the Cu remains electrically active when specimens saturated at 875°C are quenched to room temperature in about 3 sec. This is a result of the high diffusion coefficient of Cu_i (10^{-5}-10^{-7} cm²/sec) in the cooling range.

Substitutional Cu.—The result above, namely, that Cu in InAs is essentially all present as an interstitial donor is interesting, because in every case so far in-

[b] Fast quench to 78°K.
[c] Control specimen, 3 sec quench to 300°K, no Cu present.

vestigated up to now Cu exists in solution in a large part as substitutional (acceptor) Cu, designated Cu_S. In order to investigate the possibility that some Cu is substitutional in InAs the following additional experiments were carried out:

(*i*) Small amounts of labeled Cu were introduced into InAs at high temperatures (800°-900°C) in order to favor substitution. The specimens were rapidly quenched and measured both for Cu and electron content.

Table II gives these results together with those on a control specimen (D4) of InAs not containing Cu but given the same heat treatments. It is clear from the control specimen that $\sim 3 \times 10^{15}$ cm^{-3} acceptors (vacancy defects) are quenched into InAs during rapid cooling from high temperatures. This is quite analogous to Ge (3). From the specimens diffused with Cu in Table II it is evident that about twice as many acceptors are introduced as are introduced in the control specimen. This suggests that Cu in these occupies the vacancies (presumably In vacancies) and thus becomes a doubly charged acceptor.

(*ii*) Several specimens of undoped InAs were saturated at 658°C with labeled Cu and then extracted at 658°C with In or Ga to remove the Cu. The extraction with In was much slower (at the same temperature) than the Ga. With Ga it was possible to remove essentially all the Cu at 658°C in about 10 hr. The electrical results on these specimens (allowing for the original donor) indicate that $< 3 \times 10^{14}$ cm^{-3} substitutional Cu remains under these conditions. Hence, if substitutional Cu forms at 658°C, it is lost on extraction. Vacancy acceptors left by the Cu are also apparently lost under these conditions.

(*iii*) Labeled Cu was introduced into InAs specimens at 342°, 495°, 778°, and 875°C. The specimens were quenched to room temperature and measured electrically. They were then annealed at 115° ± 5°C and the changes in electron concentration (25°C) measured at intervals as a function of time. The results are shown in Fig. 4. The initial electron concentration (after the Cu diffusion but before the 115°C anneal), n_o, reflects the loss of Cu because of precipitation. The concentrations of Cu introduced were the saturated amounts except for the specimen prepared at 875°C which was purposely undersaturated. It is evident from Fig. 4 that in all cases the electron concentration, n_f, finally reached on annealing at 115°C is less than the electron concentration in the original crystal (indicated by an arrow on Fig. 4). The amounts of the compensation vary among the different specimens reaching a maximum of 1.6×10^{16} cm^{-3} for the specimen prepared at 495°C. The significance of these data is discussed below.

(*iv*) About 10^8 cm^{-2} dislocations were introduced into a specimen of InAs by bending to a radius of 1.2 cm at ~825°C. Originally n was 1.94×10^{16}, the mobility was 27,400 cm^2/v-sec at 24°C. After bending n was 1.84×10^{16} cm^{-3}, and the mobility was 26,250. After saturation at 500°C for 17 hr with Cu, n was 3.75×10^{17} cm^{-3} and the mobility was 21,600. These results are entirely comparable to those observed on unbent InAs specimens and show that Cu does not substitute to any great extent in InAs. The final mobility value (21,600 cm^2/v-sec) agrees with the value expected for 3.75×10^{17} cm^{-3} scattering centers (Fig. 5). This indicates that $\lesssim 2 \times 10^{16}$ cm^{-3} substitutional Cu is present since the additional scattering, even assuming singly charged ions, would be easily detectable.

Hall mobility.—Figure 5 shows a plot of the electron mobility as determined from Hall measurements

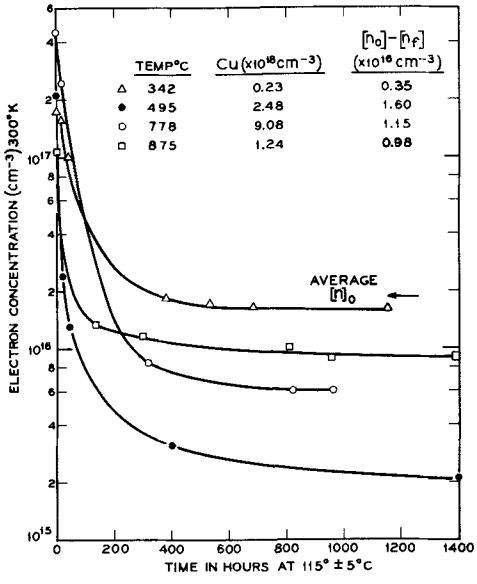

Fig. 4. Decrease in electron concentration n as a function of time at 115° ± 5°C after Cu-diffusions at 342°, 495°, 778°, and 875°C. Cu concentrations and differences between initial and final n's are given on figure. Arrow shows average n in specimens before Cu diffusion.

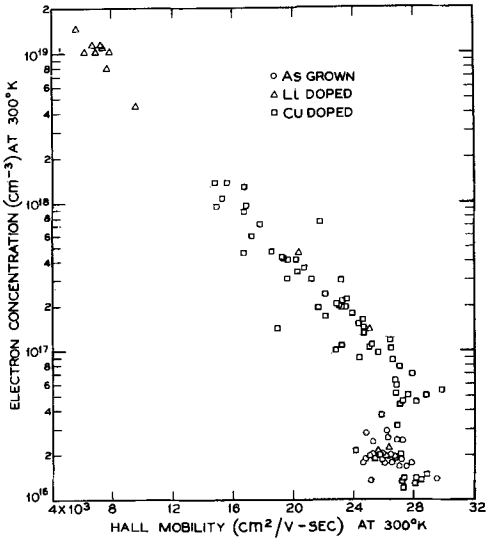

Fig. 5. Electron mobility (24°C) as a function of electron concentration for as-grown InAs and InAs diffused with Cu and Li.

at 22°-24°C as a function of n for Cu-doped InAs. Some data on Li-diffused InAs are included. The scatter in the results may be due in part to the presence of precipitates. Also shown on Fig. 5 are values for the mobilities measured on the original specimens before Cu diffusion. The scatter here is about the same. However, the mobilities for the same values of n are lower (14). We attribute this to a more nonuniform distribution of the original donors as compared to the mobile Cu_i^+ donors.

Discussion

Diffusion and solubility of Cu.—A comparison of the diffusion of Cu in InAs to that of Cu and other fast-diffusing elements in other semiconductors is interesting. The entropy and enthalpy terms for diffusion as indicated by the equation (Fig. 2)

$$D = 0.0036 \exp(-0.52/kT) \quad [2]$$

show that, in analogy with H, He, and Li in Ge and Si (15) and with Cu in Si (16), Cu in InAs is essentially a pure interstitial. The diffusion apparently proceeds with little or no participation of vacancies. In fact, as Fig. 2 shows, the diffusion of Cu in InAs is almost identical in all respects to that of Li in Ge. This is in contrast to Cu in Ge (16), GaSb (17), InSb (4) and GaAs (18) and to Li in GaSb (19) and GaAs (20) where marked substitution occurs. Substitution in GaSb, however, occurs readily only after plastic deformation (bending). Bending InAs, in contrast, does not markedly increase Cu substitution as was shown above. The fact that the diffusion of Cu in InAs follows ideal diffusion also supports the simple interstitial as opposed to a dissociative (21) mechanism.

As for the other interstitial diffusions, D_0 for Cu in InAs (corresponding to the pre-exponential in Eq. [2]) can be calculated (22) from

$$D_0 = (a_0^2\nu/8) \exp[(-\Delta H/R)\partial(\mu/\mu_0)/\partial T] \quad [3]$$

where a_0 is the lattice constant (6.06Å), ν is the lattice vibration frequency (23) ($5.15 \times 10^{13}/2\pi$), ΔH the enthalpy (12.0 kcal), R, the gas constant, (1.98 cal/deg), and μ the appropriate elastic modulus (C_{12}) with μ_0 the value at 0°K. Since these moduli for InAs are known only for room temperature (23), an estimate (1.5×10^{-4} dynes/cm^2 deg) for the quantity $\partial(\mu/\mu_0)/\partial T$ was made by interpolation between values for InSb and GaAs (24). D_0 calculated in his way is 0.0015 compared to 0.0036 found by experiment. This is about the same order of agreement found for interstitial diffusions in Ge and Si.

Although only preliminary results of the authors are available for the diffusion of Li in InAs, these indicate that Li is slower diffusing than Cu. This is in qualitative agreement with the relative interstitial diffusivities of Li and Cu in Ge and Si and with theoretical predictions (25).

So far no adequate theory of interstitial or of the closely related dissociative mechanism of diffusion exists. The Wert-Zener theory (21) provides a thermodynamic basis for treating diffusion based on lattice distortion. It does not treat the local potentials which differ for each diffusant and host crystal. An attempt to consider these has recently been made (25) in which the repulsive potentials due to overlap of nonbonding electrons and the polarization of the crystal by the ionic charge on the diffusant are taken into account. The fact (Fig. 2) that Li and Cu show almost identical behavior in spite of their large difference in ionic radii (~40%) shows the need for a theory which takes into account these additional factors. From simple distortion considerations Ge and InAs are expected to behave quite differently toward Li and Cu.

The interesting point about the solubility of Cu in InAs is that it is the highest interstitial solubility so far found for Cu in any of the elementary and III-V semiconductors. It is comparable to that of Li in Ge and Si. Cu precipitation at room temperature is slower than Cu in Si because the diffusion coefficient of Cu in InAs is markedly lower (16).

It was noted previously (Fig. 3) that the solubilities determined directly by saturation do not agree with those determined from the diffusion measurements, although the external phase was Cu alloy in both instances. The diffusion results give solubilities which are about a factor of 2 lower, although the enthalpy of solution (slope) is about the same in the two cases. The reason for the difference is not clear. However, the diffusions were done in air at atmospheric pressure whereas the solubilities were determined essentially in the absence of air. Therefore, a difference in the compositions of the surface phases could account for the different solubility results. In fact, a specimen equilibrated to the lower curve in Fig. 3 added additional Cu almost equivalent to the upper curve when heated in the same manner as the solubility specimens.

Nature of the compensation introduced by Cu.—The acceptors introduced into InAs by quenching from 850°-900°C are very similar to those found for Ge (3) and Si (6). In all cases 3-4 x 10^{15} cm^{-3} acceptor defects are introduced after quenching from temperatures near the melting points. Evidence that more acceptors are introduced in InAs when heat-quenched in the presence of 1-5 x 10^{17} cm^{-3} Cu is given in Fig. 4. This figure shows that the loss of electrons, due to Cu donor precipitation at 115° ± 5°C, leaves acceptors. At 495°C nearly all of the original donors are compensated or paired.

Measurements of electron mobility (25°C) show only small changes for the different final specimens in Fig. 4, but the specimen treated at 495°C does show a somewhat higher value (27,200 cm^2/v-sec) than the higher temperature ones (26,000 ± 200 cm^2/v-sec). This may indicate that pair formation occurs between the residual donor in InAs and substitutional Cu or vacancy defects produced by the Cu.

The fact that more acceptors, rather than less as might be expected, are formed at 495°C compared to 778° or 875°C, suggests that the trapping of both vacancies by the original donors and of Cu by the trapped vacancies may be critically dependent on diffusion temperature and quench rate. For example, it is possible that vacancies are trapped more effectively at 495°C than at 778° or 875°C because of the slower quench-rate at 495°C and that this results in the formation of more acceptors.

The specimen diffused at 342°C (Fig. 4) shows only a small concentration (~3 x 10^{15} cm^{-3}) of residual acceptors after annealing at 115°C. This suggests that fewer vacancies are dissociated from the clusters at the lower diffusion temperature.

Some observations suggest that Cu is removed from vacancies and so becomes interstitial at temperatures as low as ~200°C. For example the specimen diffused at 495°C (Fig. 4) after the final anneal at 115°C (n = 2.1 x 10^{15} cm^{-3}) was heated to 193°C for 5 min. The value of n rose to 5.3 x 10^{16} cm^{-3} which is 1.7 x 10^{16} cm^{-3} above the Cu solubility at this temperature (3.6 x 10^{16} cm^{-3}).

This increase in n can be understood if the original donors are assumed to have a shallow and a deep donor level. Formation of a Cu_{In}=D^{++} pair at 115°C could account for a 1:1 compensation by Cu_s if all the donors were paired. According to this hypothesis p-type material would not be obtained after the 115°C anneal since only those vacancies (assumed single-charged) which were trapped by the original donors are available for reaction with Cu. The observed increase in n at 193°C results from the dissociation of the Cu-donor pair into Cu_i^+ donors and a vacancy-donor pair both of which are assumed to be completely ionized at room temperature. The following reactions may be postulated:

$$V_x \rightleftarrows xV \quad [4]$$

$$e^- + V^- + D^{++} \rightleftarrows V^-D^{++} + e^- \quad [5]$$

$$V^-D^{++} + 2e^- + Cu_i^+ \rightleftarrows Cu_s{=}D^{++} \quad [6]$$

The varying degrees of compensation (Fig. 4) on this picture depend on the extents to which the reactions [5] and [6] proceed to the right. These in turn are dependent on the diffusion temperature, the quench rate, and the final temperature. The diffusion temperature determines the extent of cluster dissociation, Eq. [4]. The quench-rate and final temperature determine the fraction of vacancies and Cu trapped, Eq. [5] and [6].

The above observations indicate that Cu is capable of reacting substitutionally in InAs, presumably with In vacancies already present in the crystal. Cu does not appear to react with vacancies generated at dislocations and other loci as it does in Ge. Furthermore, as we have seen, bending InAs does not initiate Cu substitution as it does in GaSb (17).

The limit to which Cu can be present substitutionally seems to be determined by the number of vacancies present in clusters or by the concentration of donors originally present in the crystal. We assume here that the latter may be identifiable with InAs antistructure donors. This view limits the concentration of substitutional Cu to that of the donors, namely $\sim 10^{16}$ cm^{-3}.

Possibility of drifted pn junctions using Cu.—The diffusion coefficient of Cu in InAs is almost identical with that of Li in Ge. This raises the question as to whether Cu might be used to broaden the pn junction space-charge region as is now done by means of Li drift (26). Cu is expected to have some advantages over Li since it is much less reactive and hence will not be lost as readily at surfaces. Also, because of its higher average atomic number, InAs offers an advantage over Ge for particle counters. However, there are serious problems with InAs.

One of these is the presence of the residual donors, a subject which has been discussed above. Unless these can be removed almost completely so that hole conduction is predominant at a very low level, compensation cannot be achieved with donor Cu. Removal of the original donor centers has so far not been accomplished.

Another problem is presented by the fact that the intrinsic carrier concentration, n_i, for InAs is large ($\sim 10^{15}$ cm^{-3}) at temperatures where the diffusion coefficient is of the correct magnitude to allow drift ($\sim 10^{-12}$ cm^2/sec).

The question of whether InAs is worthwhile for particle detector applications, therefore, cannot be readily answered. If the residual donors can be removed it may be profitable to investigate Cu drifting in InAs below room temperature. It is doubtful, however, that a performance superior Li-drifted Ge will be easily achieved.

Studies of Sodium in SiO_2 Films by Neutron Activation and Radiotracer Techniques

T. M. Buck, F. G. Allen,[1] J. V. Dalton, and J. D. Struthers

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Electrical instabilities in SiO_2 films under high fields at elevated temperatures have been widely attributed to mobile ionic impurities, with sodium suspected as the most important ion. Phosphate glass treatments on SiO_2 are known to have a stabilizing effect. This paper reports neutron activation experiments to determine sodium contamination on and in steam-grown SiO_2 films and also diffusion and drift experiments with tracer sodium. Phosphate glass-treated SiO_2 films were included in the samples. SiO_2 films grown and handled under various conditions had sodium densities of 7×10^{11} to 3×10^{14} atoms/cm^2, which could be easily removed or exchanged by washing and light etching. Densities remaining inside the 6000Å films after washing and light etching were $\gtrsim 4 \times 10^{11}$-4×10^{12}/cm^2.

Tracer diffusions into SiO_2 at 600°C produced profiles which were high near the surface and lower through the interior of the film, similar to those observed by neutron activation for unintentional sodium contamination. Phosphate glass layers on SiO_2 absorbed and stopped the sodium under similar conditions. With an applied field at elevated temperature (+4v, 1 min, 400°C) tracer sodium drifted through an SiO_2 film under gold dot electrodes, piled up at the Si-SiO_2 interface, and carried a substantial part of the charge transported. There was no detectable diffusion in uncharged areas. A layer of phosphate glass applied over an SiO_2 film absorbed sodium and prevented it from drifting into the SiO_2 film under the gold dots.

Intensive study has been made in a number of laboratories (1-8) in recent years of the electrical behavior of metal-silicon dioxide-silicon (MOS) structures because of their importance as devices and because new designs for junction devices employ structures in which high fields are applied across passivating oxide films. Certain types of electrical instability observed in MOS structures (2, 6-8), and also in junction devices (9), have been attributed to drift of oxygen vacancies (2) or, more commonly, to ionic impurities in the oxide. Sodium in particular has been suspected (7, 9) as an important impurity because of its known high mobility in quartz and vitreous silica (10, 11) and its common occurrence as a contaminant. It was found (12) that a layer of phosphate glass over an SiO_2 film could eliminate or drastically reduce the drift behavior. In some cases the electrical instabilities have been reproduced and studied by deliberate addition of sodium (nonradioactive) (7, 9, 13, 14) to the SiO_2 film.

The aims of the work reported in this paper were: (*i*) to determine sodium contamination levels on and in as-grown SiO_2 films and in silicon substrates by neutron activation analysis; (*ii*) to follow deliberately added tracer sodium in diffusion and drift experiments. Phosphate glass-treated SiO_2 films were included in the samples for both neutron activation and tracer experiments. Where the results can be compared they are in general agreement with those recently reported by Yon, Ko, and Kuper (15), and also by Carlson, Fuller, and Osborne (16). However, there are differences in experimental approach and information obtained.

Neutron Activation Experiments

Materials and experimental procedure.—Six neutron activation experiments were carried out, five at the Brookhaven National Laboratory and one at the Union Carbide reactor at Tuxedo, New York. Samples included silicon slices with steam-grown SiO_2 films, slices with phosphate glass layers over SiO_2 films, and etched slices which had never been oxidized. A weighed sample of sodium carbonate was included in each run for calibration. In the activations at Brookhaven samples were contained in polyethylene or quartz capsules which were placed in a water-cooled reaction chamber where they were exposed to a thermal neutron flux of 1 x 10^{13}/cm^2 sec for 2-3 days. Fast neutron flux was estimated to be a few per cent of this. At the Union Carbide reactor aluminum capsules were used and the chamber was not water-cooled; sample temperatures may have risen as high as 500°C. After samples were returned from irradiation they were washed and etched progressively in dilute buffered HF and the Na^{24} activity remaining on the sample after each step was counted. Oxide thickness was determined by comparing colors with oxide films of known thickness. Counting was done on either the 1.37 Mev or 2.76 Mev gamma peaks of Na^{24} ($T_{1/2}$ = 15 hr). When the 1.37 Mev peak was used, etching was delayed for about 24 hr after irradiation to permit sufficient decay of Si^{31} activity at 1.27 Mev ($T_{1/2}$ = 2.6 hr). No such delay was required for the 2.76 Mev peak, but the gain in higher activity was offset by reduced counting efficiency for the higher energy γ's. Counting was done on a single-channel RIDL pulse height analyzer with a well-type 2 × 2 in. sodium iodide scintillation crystal, or on a 100-channel TMC analyzer (Gammascope) with a flat-faced 3 × 3 in. crystal. The entire gamma spectrum up to 3 Mev was scanned frequently to verify that sodium was present, and decay times were determined when feasible.

Results of neutron activation experiments.—Figure 1 shows results of one neutron activation run which was reasonably representative of the others. Sodium concentration per square centimeter remaining on the sample is plotted against thickness of oxide remaining, as the sample was washed and then etched in toward the Si-SiO_2 interface. In this experiment there were ten slices of each type of sample. Each slice had 2 cm^2 of oxide surface area. The ten slices were etched individually to the same oxide thickness in each step. Activity was then measured on all ten together as one sample. In some other runs only one slice of each type was used; the curves were similar to those of Fig. 1, but counting rates and sensitivities (Na atoms/cm^2/count/minute) were correspondingly lower. The sensitivity in this run, using the 2.76 Mev peak, was in the range 2.4-4.4 × 10^{11} Na atoms/count/minute or 1.2-2.2 × 10^{10} Na atoms/cm^2/count/minute. The stand-

[1] Present address: Bellcom Inc., Washington, D. C.

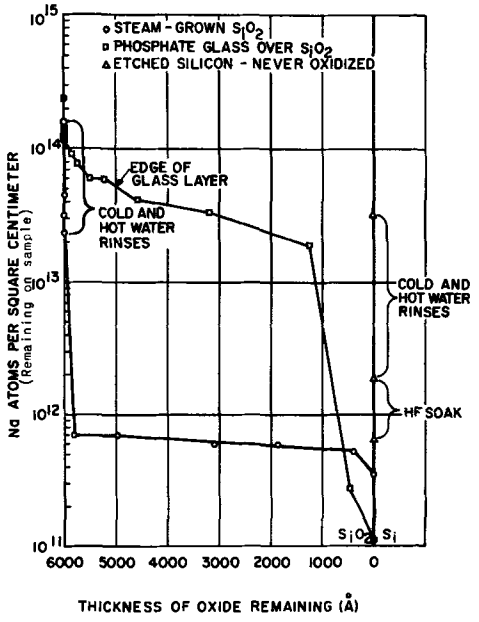

Fig. 1. Removal of sodium by washing and etching after neutron activation.

ard deviation of the points varies from 0.5% for the high initial points to about 5% for the low points. Standard deviations are indicated directly on all other distribution plots. The silicon substrate material used in the experiment was 100 ohm-cm n-type, phosphorus doped. In all other experiments to be discussed the silicon was 100 ohm-cm p-type, boron doped.

The plot for steam-grown SiO_2 in Fig. 1 shows an initial sodium density of $>10^{14}/cm^2$, most of which washed off, or perhaps exchanged for nonradioactive sodium, during washing. A light etch ($\sim$ 150Å) removed most of the remaining sodium. The curve shows a slight downward slope through the middle region and a drop at the interface, corresponding to a pile-up in this region. The total counting rate decreased from 12,000/min to 35/min in this series of etches. Background count was 9/min. Since sodium per square centimeter remaining on the specimen is plotted in Fig. 1, the downward slope is a measure of local concentration (cm^{-3}).

The concentration is high near the outer surface ($\sim 10^{19}/cm^3$), low in the middle ($3 \times 10^{15}/cm^3 \pm 1 \times 10^{15}/cm^3$) with a turn-up at the Si-SiO_2 interface ($\leq 10^{16}/cm^3$). The results are similar to those of ref. (15) and (16) although the interior concentration indicated in the present work is somewhat lower.

The etched silicon sample was treated and handled in the same manner as the oxidized sample except that it was never oxidized. Like the oxidized silicon it had considerable sodium which could be washed off. This may have come from the etching and cleaning, or subsequent handling, or both. An HF soak removed some Na which remained after hot and cold water rinses, presumably adhering tightly to the very thin oxide layer present on any etched Si surface. Neutron activation analysis of phosphate glass-treated samples has given rather unexpected results, one of which is shown by the plot in Fig. 1. In this case and in several other experiments a relatively high sodium concentration was found in the SiO_2 film beyond the edge of the phosphate glass layer which could be determined by an abrupt change in etching rate. This was surprising since phosphate glass layers are known to eliminate drift behavior believed to result from ionic impurities, and one might have expected all the sodium to be found in the 1000Å glass layer. (The phosphate glass was deposited on a steam-grown SiO_2 film by exposure to P_2O_5 vapor for 10 min at 1050°C.) As will be shown later, tracer experiments with Na^{22} do show a blocking and gettering action by phosphate glass for sodium which has been deliberately deposited on the surface. Therefore, in the neutron activation results it seems likely that the sodium deep in the SiO_2 is associated with phosphorus.

Some sodium may have been carried by phosphate glass through pinholes or other flaws in the SiO_2 layer, although in this case one might expect it to etch out of the holes readily and appear to be in the outer glass layer. Phosphorus may have penetrated into the SiO_2 layer as a result of neutron bombardment. Schmidt (17) has recently reported phosphorus penetration deep into SiO_2 and into the silicon substrate under fast neutron bombardment of $3 \times 10^{17}/cm^2$ total flux at 300°C. He has also studied a sample from one of our sodium experiments in which samples were maintained close to room temperature and found a phosphorus diffusion tail extending beyond the glass layer into the SiO_2 and Si. (During irradiation the phosphate glass-treated samples and untreated SiO_2 samples were in separate containers, so the transfer of phosphorus, and possibly sodium to the untreated samples observed by Schmidt (17) could not have occurred in our samples.) Carlson, Fuller and Osborne (16) using higher temperatures and longer times for their diffusions saw considerable phosphorus penetration beyond the oxide-glass interface. They showed some results in which the sodium was more effectively segregated in the glass layer than in our case, but also they showed one sample in which sodium at a concentration of $\sim 1 \times 10^{18}/cm^3$ had penetrated to the silicon interface. In the experiment at the Union Carbide reactor very high sodium contamination ($1\text{-}5 \times 10^{14}/cm^2$ inside the film) was detected. In this case it was evident that sodium produced by transmutation of Al (Al^{27} n, α Na^{24}) had evaporated from the capsule onto the samples and diffused into the oxide at the elevated temperature ($\sim$ 500°C) of this experiment. The phosphate glass treated sample showed considerable sodium beyond the glass layer.

Data for SiO_2 films from curves like those of Fig. 1 are summarized in Table I which gives ranges of values for sodium contamination at the surface, inside SiO_2 films, and in silicon substrates. (Results from the Union Carbide reactor are not included.) A variety of oxidation and handling conditions are represented in Table I; the work has been of an exploratory nature rather than an exhaustive study in which each process factor has been studied independently. However, certain observations can be enumerated:

(*i*) Unintentional sodium contamination on the films varied over almost three orders of magnitude, that inside the film over one order, and these levels are easily sufficient to account for the type of electrical instability which has been attributed to some mobile ion in SiO_2 films.

(*ii*) Improvements in furnace cleanliness and in handling techniques, *e.g.*, the use of a dust-free, laminar-flow hood, yielded reductions in sodium activity.

(*iii*) The lowest total sodium contamination was observed on a sample supplied by Schmidt (18) which had been oxidized by O_2 in a special furnace (quartz tube inside another quartz tube inside a high purity

Table I. Summary of data for SiO_2 films

	SiO_2 films	Etched Si (never oxidized)
Na removed by Wash and light etch (100-300A)	7×10^{11}-$3 \times 10^{11}/cm^2$	2×10^{13}-$2 \times 10^{11}/cm^2$
Na inside SiO_2 film	4×10^{11}-$4 \times 10^{12}/cm^2$ (7×10^{15}-$7 \times 10^{19}/cm^3$)	
Na in Si (Average in 5-16 mil slice)	6×10^{13}-$1.2 \times 10^{15}/cm^3$	8×10^{12}-$1.7 \times 10^{11}/cm^3$

alumina tube). The sample was encapsulated in quartz for activation.

(*iv*) The lowest value listed (7×10^{15}/cm^3) for sodium inside the SiO_2 film was obtained on a film which was steam-grown in a standard quartz tube furnace. This, however, was not necessarily the cleanest oxide tested. Other oxide samples, *e.g.*, those supplied by Schmidt or by Goetzberger (field-grown) (19) may have had less sodium inside but the sensitivity for detection was not good enough in those experiments to prove it.

(*v*) The silicon itself did not appear to be an important source of sodium since the levels in silicon samples which had never been oxidized were always somewhat lower than in oxidized samples from the same crystal.

(*vi*) The outstanding feature of the neutron activation experiments was that a large fraction of the total sodium could be removed by washing and light etching. Although the possibility of exchange for nonradioactive sodium in the water or acid cannot be ruled out, the results show that large reductions in sodium contamination could be achieved if very pure water and acid were used. These results are consistent with those of Schmidt (18) who eliminated electrical drift effects by light etching.

Other contaminants were found in the samples cleaned and oxidized by standard techniques. In several cases the gamma spectra showed the presence of copper in the silicon substrate, and phosphate glass samples prepared by the PBr_3-O_2 reaction showed bromine in the glass layer and in the oxide under the glass.

Tracer Experiments

Diffusion into SiO_2 *films.*—Tracer diffusion experiments were performed with Na^{22} ($T_{1/2} = 2\frac{1}{2}$ yr). The carrier-free isotope was received as an acid solution of NaCl of specified concentration which permitted calibration of counting rate in terms of sodium atoms. Radioactive sodium was applied to oxidized silicon slices (1 cm^2) by evaporation from a hot platinum boat on which a few drops of diluted solution had been dried in a manner similar to that reported by Logan and Kerr for nonradioactive sodium (14). This procedure yielded deposits of density 3×10^{13}-1×10^{14}/cm^2. Post-diffusion autoradiographs showed that these deposits on SiO_2 were sometimes free of spots but on other occasions had a few spots which may have been associated with flaws in the SiO_2 film. In contrast, deposition by drying a dilute solution directly on an oxidized slice always resulted in a very spotty distribution. Progressive etching showed that the nonuniformity of the dried-solution samples persisted through the film to within a few hundred Angstroms of the silicon interface. Evaporation from a hot source was therefore used in all the tracer experiments to be discussed. Deposits on phosphate glass were entirely free of spots. Sodium distribution profiles in the films were determined by progressive etching and counting of the 0.51 Mev gamma activity remaining on the slice. Sensitivity was typically 2.5×10^{10} Na atoms/count/minute.

Figure 2 shows the sodium profile (Na atoms/cm^3 *vs.* depth in the film) in a steam-grown SiO_2 film which was diffused for 22 hr at 600°C in a forming gas atmosphere (85% N_2, 15% H_2). Forming gas was suggested by A. A. Bergh who had observed enhancement of sodium effects on transistors, presumably because of a hydrogen interaction which accelerates sodium migration. The profile shows sodium concentration high near the surface and lower through the middle region with a dip and a turn-up near the Si-SiO_2 interface. The curve of Fig. 2 is similar to some reported by Yon, Ko, and Kuper (15).

The behavior of a phosphate glass-treated SiO_2 film is shown in Fig. 3. Sodium was deposited and diffused into the glass-treated film under the same conditions

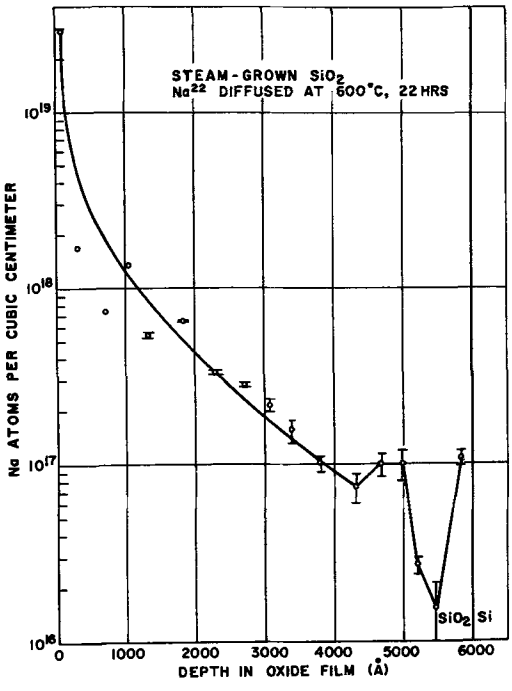

Fig. 2. Na profile in SiO_2 film after diffusion, 22 hr at 600°C. Standard deviations are indicated on all distribution profiles.

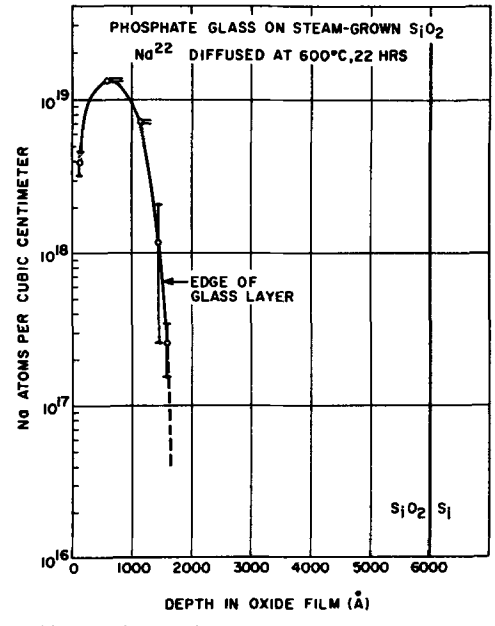

Fig. 3. Na profile in phosphate glass-treated SiO_2 film after diffusion, 22 hr at 600°C.

used for the plain SiO_2 film of Fig. 2. However, in Fig. 3 it may be seen that the sodium was stopped in or very close to the phosphate glass layer as defined by etching rate. Additional experiments under the same conditions have shown some variation in the shape of the sodium profile in the glass layer, but always a reduction of sodium activity to background level beyond the glass layer. Typically, the counting rate on a sample was reduced from an initial value of 2700 counts/min down to background (26 counts/min) just beyond the glass layer. In contrast, the counting rate on an untreated SiO_2 film (Fig. 2) was reduced from 2826 to 284 counts/min (above the background of 26) by etching to the same depth.

Another significant difference between the two types of films was that very little sodium activity could be washed off the phosphate glass after diffusion, whereas with untreated SiO_2 more than half of the

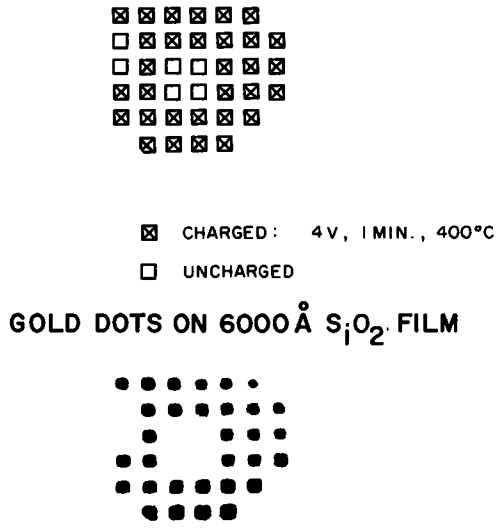

Fig. 4a (top) Diagram of gold dots on SiO_2 film for sodium drift experiment. Na^{22} was deposited on sample before gold dots were put down. Fig. 4b (bottom) Autoradiograph of Na^{22} in SiO_2 film after drifting (4v, 1 min, 400°C). Sample was washed and gold dots removed before exposure.

total activity was easily removed by washing. The greater uniformity of sodium, or freedom from spots, in the phosphate glass layer has already been mentioned. The sodium had evidently been absorbed into the glass and stopped there.

Drift experiments with tracer sodium.—The influence of an electric field on tracer sodium in SiO_2 was studied at 400°C. Figure 4a is a diagram of a specimen designed for these experiments by M. Yamin, who also performed the drifting and charge measurements by a method described previously (6). $Na^{22}Cl$ was evaporated onto an oxidized silicon slice. Square gold dots were then deposited through a mask. The dots marked X were then charged, one at a time, by applying 4v (+) for 1 min. The charge was measured by integrating the transient charging current. The silicon slice was held at 400°C for more than an hour during this operation.

After charging of the gold dots was completed, the sample was cooled and washed and the gold dots removed by aqua regia. An autoradiograph taken at this point is shown in Fig. 4b. By comparison with Fig. 4a it may be seen that sodium activity (indicated by darkening) remained only in areas which had been covered by charged gold dots. There was no detectable diffusion in uncharged areas, under gold dots or elsewhere. This was consistent with some earlier diffusion experiments (1 hr, 400°C in air) in which no sodium diffusion could be detected by counting. (Sodium activity was present before washing; the sodium was not lost by exchange during heating.)

Figure 5 shows the sodium profile in the film under the gold dots, as determined by etching and counting. Computations of sodium concentration values (cm^{-3}) were made using only the area under charged gold dots. Ninety per cent of the radioactive sodium was found to be piled up within 800Å of the SiO_2-Si interface. This result is in agreement with the charge distribution inferred by Snow *et al.* (7) from capacitance-voltage measurements on (nonradioactive) sodium-drifted SiO_2 films. All of the sodium detected in the film accounts for about 20% of the total charge introduced. The density of tracer sodium under the dots was $3 \times 10^{13}/cm^2$ and, since neutron activation results have shown that sodium contamination levels may be higher than this, it is likely that the remaining 80% of the charge was carried by sodium present as unintentional contamination.

The images of the gold dots in Fig. 4b are fairly distinct, *e.g.*, the image of the lower left-hand dot clearly

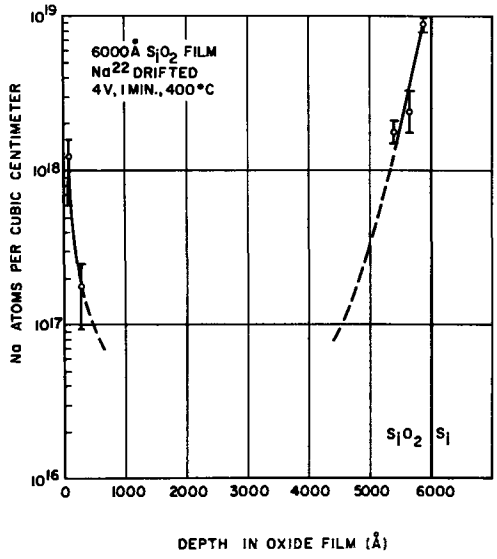

Fig. 5. Na profile in SiO_2 film under gold dots after drifting.

shows that a corner had been removed. Thus there was no appreciable thermal diffusion either directly into the film or laterally in the film or along the Si-SiO_2 interface. The sodium followed electric field lines (13).

A similar tracer drift experiment was performed on a phosphate glass-treated sample at 400°C. However, in this case, as expected (6), no charging current flowed when the 4v bias was applied to the gold dots. Figure 6a shows the gold dot pattern and Fig. 6b shows an autoradiograph taken after thorough washing and removal of the gold dots. It shows a uniform darkening over the entire area of the slice. With stepwise etching the image grew weaker but remained uniform; there was never any image of the dots which

Fig. 6a (top) Diagram of gold dots on phosphate glass-treated SiO_2 film for sodium drift experiment. Fig. 6b (bottom) Autoradiograph of Na^{22} in phosphate glass-treated sample after attempt to drift.

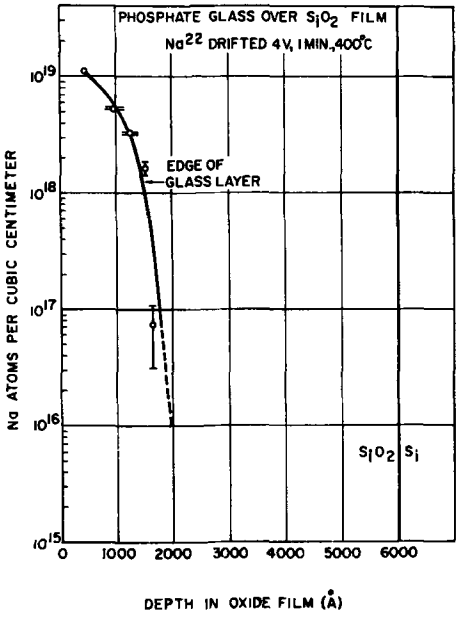

Fig. 7. Na profile in phosphate glass-treated sample after attempt to drift.

had been charged. The sodium had evidently been quickly and uniformly absorbed by the phosphate glass at 400°C, and the applied bias caused no redistribution. Figure 7 shows the sodium profile in this film, all of the sodium confined in or close to the phosphate glass layer. No sodium activity was detected in the silicon substrate after any of the drift experiments at 400°C.

Discussion and Summary

The neutron activation results on SiO_2 showed relatively high sodium concentrations on or near the surface which could be removed or exchanged by washing and light etching. Sodium concentrations at the surface could be reduced by improvements in processing. Average sodium concentration inside the films was as low as $7 \times 10^{15}/cm^3$, or $4 \times 10^{11}/cm^2$ in a 6000Å film, and improved sensitivity might have shown lower values in some films.

Tracer diffusion experiments in SiO_2 at 600°C produced profiles high at the outer surface, low through the middle region and with a dip and turn-up at the Si-SiO_2 interface. This characteristic profile suggests some barrier at the outer surface of the oxide. The difficulty of diffusing large negative ions such as Cl^- required for charge neutrality may account for it (15).

At 400°C diffusion from NaCl into SiO_2 (in air) was very slight but drift under gold dots with +4v applied was very rapid. The ease with which the sodium ions move under an applied field suggests that small potential differences in the oxide, *e.g.*, electrochemical potentials and work function differences, may influence the sodium distribution which is frozen in a film at room temperature.

Phosphate glass layers clearly showed a blocking action for tracer sodium in diffusion and drift experiments. Sodium on the surface penetrated readily into the glass layer but was held there against further diffusion into the SiO_2 region. More extreme conditions would presumably show a limit to the blocking action as found by Kerr (20) in electrical measurements. In neutron activation experiments significant sodium concentrations were found beyond the phosphate glass layer as defined by etching rate. It seems likely that this sodium is associated with phosphorus deep in the SiO_2 layer which may have gotten there during deposition of the glass layer, or by some effect of neutron bombardment.

The tracer drift results clearly illustrate the fact that even though an SiO_2 film grown by a very clean process might be free of internal sodium contamination it would still be vulnerable to subsequent contamination by sodium which could drift in to the silicon interface very readily under bias at elevated temperatures.

Acknowledgments

The authors are indebted to M. Yamin for designing the specimen for drift experiments and performing the charging operation, to P. F. Schmidt for obtaining a phosphorus profile, and to R. Kraetsch for supplying oxide film samples. The authors have had helpful discussions with several associates, in particular, C. S. Fuller, Miss K. B. Wolfstirn, W. M. Gibson, and D. W. Maurer.

Measurement of the Retention of Fluoride by Silicon and Silicon Dioxide Surfaces

G. B. Larrabee, K. G. Heinen, and S. A. Harrell

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Techniques are described for the production of fluorine-18 labeled HF etches and their use in the study of the retention of fluoride on silicon and silicon dioxide surfaces. Results are presented that show fluoride is retained by a chemical adsorption mechanism.

In the fabrication of planar silicon semiconductor devices it is necessary to etch the silicon dioxide films on the surface of the device. Hydrofluoric acid is used in all of these SiO_2 etches with various additives to modify the etch rate. The subsequent washing and removal of residual fluoride is important to ensure good device characteristics and long term device stability.

The chemical analysis for trace quantities of residual fluoride ion is extremely difficult, particularly if the fluoride is entrapped and/or chemically adsorbed on the silicon dioxide film. Dissolution of the film to free the fluoride for subsequent analysis is not possible because these films are only soluble in fluoride containing etches. Neutron activation analysis via $^{19}F(n, \gamma)^{20}F$ cannot be used in a silicon matrix because of the large yield of 2.3 minute aluminum-28 from the $^{28}Si(n, p)^{28}Al$ reaction. The preponderance of 1.78 Mev gamma from the aluminum-28 precludes the detection of the 1.62 Mev gamma from fluorine-20. The 10.7 second half-life of fluorine-20 prohibits waiting for other activities to decay away.

The use of radiotracer 118 minute fluorine-18 was only attractive if fluorine-18 tagged hydrofluoric acid could be produced and the etch solution formulated using this $H^{18}F$. Fluorine-18 has been produced by several workers (1, 2) by the $^{6}Li(n, t)^{4}He$; $^{16}O(t, n)^{18}F$ reaction but the final product is either in NaOH or HCl solution. However the problem in this work was to produce $H^{18}F$ in sufficient yield and with a high enough specific activity to tag an etch solution containing up to 10% fluoride ion.

Experimental

The fluorine-18 was produced by irradiating 7-9g of $^{6}Li_2CO_3$,[1] containing 10 mg/g LiF as carrier, at a flux of 2×10^{12} n/sec/cm^2 for 2 hr at the Texas A&M University reactor. The high neutron capture cross section (945 barns) of lithium-6 made it necessary to use a special irradiation container such that a thickness of not greater than 2 mm of $^{6}Li_2CO_3$ would be presented to the neutron flux.

A cylindrical quartz irradiation container was constructed with inner wall separations of 2 mm as shown in Fig. 1. The $^{6}Li_2CO_3$ was introduced through the upper tube to fill the cylinder wall cavity. The container was then sealed off at the bottom of the fill tube and a loose fitting polyethylene plug placed in the bottom to help scatter neutrons into the inner part and thus increase the yield.

At the end of the irradiation the container was inverted, allowing the powder to move down out of the inner wall cavity. It was placed in an all Teflon distillation apparatus, Fig. 2, the top was screwed on tightly, and the quartz container broken. Through a small port on the top, 40 ml of 9M H_2SO_4 was added and the Teflon distillation flask was sealed. The flask was heated with a heating mantle to distill 5 ml of solution containing the fluorine-18 into a polyethylene receiver.

[1] Lithium carbonate was purchased from Oak Ridge National Laboratory and was 95.44% lithium-6 and 4.56% lithium-4.

The etch solution to be studied was tagged with this $H^{18}F$ and a suitable aliquot was reserved for analysis for fluoride ion and fluorine-18 content. Gamma spectra were run immediately after distillation and again the next day (10 half-lives elapsed) and no extraneous activities were observed.

Fig. 1. Quartz irradiation container used in the production of fluorine-18.

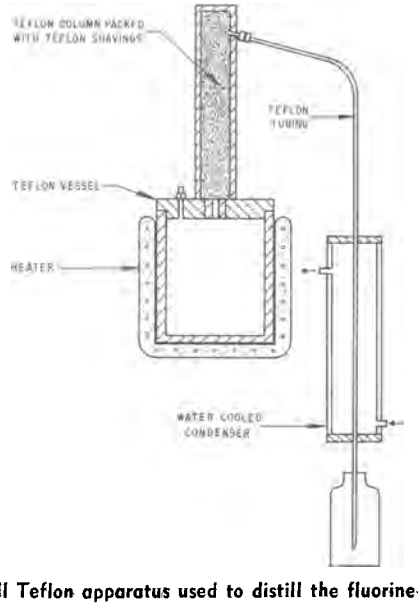

Fig. 2. All Teflon apparatus used to distill the fluorine-18 labeled HF.

The decay of fluorine-18 proceeds via 0.65 Mev positron emission. Since positrons annihilate to form two back to back 0.511 Mev gammas, it is possible to use gamma-gamma coincidence counting. The background for this counting technique, with the particular instrument settings used in this work, was one count per minute. The detection limit on the samples used in this study, was calculated to be 1.4×10^{13} atoms/cm^2 of silicon surface area with a counting error corrected for background of less than 17% with a confidence level of 90%.

The silicon slices were etched in a plexiglass etching vessel containing 3-5 ml of tagged etch solution. In each etch experiment two slices (20.3 cm^2 surface) were processed and counted.

Results

Buffered fluoride etch.—The retention of fluoride on silicon and silicon dioxide films was determined by preparing a fluorine-18 labeled etch solution (400g NH_4HF_2, 500 ml H_2O, 90 ml HF). The silicon slices were etched and washed as described in Table I. Fresh water washes were used for each slice. It can be seen that the bare or unoxidized slices retained more fluoride than the slices with 5000Å SiO_2 films.

1:10 Hydrofluoric acid.—A 1:10 hydrofluoric acid etch was labeled with fluorine-18 and the silicon slices were etched and washed as shown in Table II. In this experiment the silicon slices were washed by two different techniques. In one case only hot water washes were used while on duplicate slices a hot nitric acid wash was given as soon as the slices were removed from the etch. This was then followed by three hot water washes.

Unoxidized slices washed with hot nitric acid retained significantly more fluoride than the corresponding slices washed with hot water. The amounts of fluoride retained by hot water washed slices agree well with the values obtained for the buffered HF etch (Table I). On the other hand, the slices with 5000Å SiO_2 films retained fluoride at concentrations comparable to those observed on duplicate slices etched in buffered fluoride etch (Table I).

There are several salient points that must be considered in postulating a mechanism for the retention of fluoride ion by silicon and silicon dioxide films. Both silicon and silicon dioxide retain fluoride ion after repeated washings. Silicon surfaces retain more fluoride than SiO_2 surfaces and hot nitric acid washing causes more fluoride to be retained on silicon surfaces than hot water washing. Silicon dioxide films retain the same amount of fluoride with either hot nitric acid or water washing.

Table I. Retention of fluoride from buffered fluoride etch

Silicon sample	Etch time, min		Rinse, min			Fluoride concentration, atoms/cm^2
A. Unoxidized slices						
Chemically polished	2	25°C	2	25°C	H_2O	2.1×10^{14}
Chemically polished	2	25°C	2	95°C	H_2O	2.4×10^{14}
Chemically polished	0.4	60°C*	2	25°C	H_2O	1.9×10^{14}
B. Oxidized slices						
5000Å oxide film	2	25°C	2	25°C	H_2O	9.3×10^{13}
5000Å oxide film	2	25°C	2	95°C	H_2O	5.5×10^{13}
5000Å oxide film	0.4	60°C*	2	25°C	H_2O	4.0×10^{13}
5000Å oxide film	0.4	60°C*	2	95°C	H_2O	4.1×10^{13}

* Etch time adjusted for 60°C etch so that an amount of oxide would be removed equal to the 25°C etch.

Table II. Retention of fluoride from 1:10 HF etch

Silicon sample	Etch time, min, 25°C	Rinse	Fluoride concentration, atoms/cm^2
A. Unoxidized slices			
Chemically polished	5	3 × 95°C H_2O	1.1×10^{14}
Lapped	5	3 × 95°C H_2O	1.9×10^{14}
Chemically polished	5	1 × 105°C HNO_3, 3 × 95°C H_2O	7.5×10^{14}
Lapped	5	1 × 105°C HNO_3, 3 × 95°C H_2O	4.9×10^{15}
B. Oxidized slices			
5000Å oxide film	0.5	3 × 95°C H_2O	1.2×10^{14}
5000Å oxide film	0.5	1 × 105°C HNO_3, 3 × 95°C H_2O	5.1×10^{13}

Discussion

The tenacious behavior of the fluoride ion must be ascribed to the strength of the silicon-fluoride bond (136 kcal/mole compared to 106 kcal/mole for Si-O) on the silicon or SiO_2 surface. Iler (3) and Atalla *et al.* (4) report that HF treated silicon surfaces are strongly hydrophobic and Iler (3) suggests that this is due to the nonpolar character of the SiF surface. This would also suggest that the Si-F bond is not easily broken by hydrolysis. Attala *et al.* (4) observed that boiling in water, organic solvents or water containing detergents did not produce a hydrophillic surface. They also observed that boiling in nitric acid produced a hydrophillic surface.

The hot nitric acid treatment of etched silicon surfaces in our fluoride tracer studies indicates that the surface fluoride is not removed with this nitric acid treatment but is probably entrapped in a freshly grown SiO_2 film which itself is hydrophillic.

Kimberlin (5) feels that a fluoride surface explains the fact that silica gel treated with HF is hydrophobic. This would indicate a similar tenacious retention of fluoride by silica surfaces.

The chemical bonding of fluoride to silicon and silicon dioxide surfaces would suggest a chemical adsorption mechanism. If chemical adsorption is operative, there should be only a given number of sites available for adsorption. On <111> oriented single crystal surfaces there are 4.8×10^{14} sites/cm^2, assuming a surface roughness factor of one for a polished and chemically etched surface. In this work, for both etches, the amount of fluoride retained on these surfaces averaged 1.9×10^{14} atoms/cm^2.

The enhanced retention of fluoride ion by silicon surfaces on rinsing in hot concentrated nitric acid is probably due to a rapid growth of surface SiO_2 which physically traps the fluoride ion. Once this physical entrapment occurs, repeated washings will not remove the fluoride ion. The fact that hot nitric acid washing of a freshly etched SiO_2 film does not increase the fluoride retained, tends to support this theory. No further growth of oxide would occur to entrap fluoride ion on oxide films.

On silicon dioxide films it is more difficult to estimate the total number of available Si-OH sites available for the fluoride to replace and form stable Si-F bonds. Iler (4) has shown that a fully hydrated surface has 8×10^{14} silanol (Si-OH) groups per cm^2 of surface. Lowen and Broge (6) in a study of the effects of dehydration and chemisorbed materials on the surface properties of amorphous silica showed that the number of available silanol groups was related to the absolute dehydration temperature according to Eq. [1]

$$\text{Si} - \text{OH groups/cm}^2 = 5200 \times (1/T_A - 1/1600) \times 10^{14} \quad [1]$$

For a silica film grown on silicon at 1100°C there would be only 5.4×10^{13} Si-OH groups available. However this figure is complicated by the fact that partial rehydration can occur on prolonged exposures to high relative humidity (> 50%). The samples used in this work had been exposed to less than 50% humidity for only a few days. For these reasons one would expect less than 10^{14} atoms/cm^2 of fluoride chemisorbed assuming a surface roughness of one and this is what was observed.

Attala *et al.* (4) have pointed out that as little as 1/10,000 of a monolayer of an ionic impurity is sufficient to invert the surface of one ohm-cm silicon.

While it might be argued that chemically adsorbed fluorine is not an ionic impurity, the Si-F bond has 70% ionic character (7) and would be strongly polarized. Cunningham *et al.* (8) reported that a specimen of p-type silicon soaked in HF, rinsed and stored in a dry nitrogen ambient exhibited a strong n-type inversion layer. These data along with the demonstrated strong adsorption of fluoride point out the potential problems in device fabrication.

While the results presented here are adequately explained by chemisorption, subsequent work has shown that higher amounts of fluoride can be retained by different types of silica films. This is particularly true of heavily boron doped films where enhanced adsorption has been observed. Further work will be required to completely understand the variation in fluoride retention by the different types of oxides. The use of fluorine-18 labeled etches as described in this work appears to offer the best method of studying this phenomenon.

Acknowledgment

The authors are indebted to Donald Meyer for his comments and suggestions on part of this work. The staff of the Texas A&M Nuclear Science Center, particularly John Randall and Dave Mueller, were most cooperative in providing assistance during the irradiation and processing of the fluorine-18 activity.

Manuscript received April 7, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

The Etching of Silicon Nitride in Phosphoric Acid with Silicon Dioxide as a Mask

W. van Gelder and V. E. Hauser

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

ABSTRACT

The water content of phosphoric acid in etching silicon nitride and silicon dioxide plays an important role. An increase in water content increases the etch rate of silicon nitride and decreases the etch rate of silicon dioxide. The highest possible temperature for a fixed water content at atmospheric pressure in the system H_2O-P_2O_5 is realized by boiling the liquid and refluxing the vapor phase. Refluxed boiling phosphoric acid at 180°C was found to be a useful etchant for silicon nitride films. The etch rate is 100 Å/min. Under the same conditions deposited silicon dioxide had an etch rate of 0-25 Å/min depending on the method of preparation, and elemental silicon 3 Å/min. Etch rates of silicon nitride, silicon dioxide, and silicon in refluxed boiling phosphoric acid were measured as a function of temperature (and concentration) in the range of 140°-200°C. All etch rates increased with temperature. The "apparent" activation energies are 12.7, 27.6, and 26.4 kcal/mole, respectively. The etch rate of silicon nitride in phosphoric acid of constant concentration (94.5% H_3PO_4) was measured as a function of temperature only. In this case the "real" activation energy was 22.8 kcal/mole. The difference in etch rate between silicon nitride, deposited silicon dioxide, and silicon offers a technique for etching contact holes in silicon nitride using deposited silicon dioxide as a mask. Such a technique was used successfully in making transistors with silicon nitride over SiO_2 as a junction seal.

A good deal of attention has recently been focussed on silicon nitride (Si_3N_4) as a semiconductor junction seal, partly or fully replacing silicon dioxide. The reason for this is that Si_3N_4 is a better mask than SiO_2 against diffusants of all kinds including water, oxygen, and sodium. The better masking properties of Si_3N_4 go hand in hand with lower etch rates in HF or buffered HF. Silicon nitride films prepared by various deposition processes ($SiCl_4$ + NH_3, SiH_4 + NH_3 and d-c plasma) were reported to exhibit "very slight" diffusion of sodium (1). These films all had low etch rates in buffered HF[1] (~10Å/min). This meant that new ways of etching contact holes had to be developed because photoresist material, now used for etching SiO_2, does not mask sufficiently against buffered HF at the excessively long etching times necessary (2 hr for a film 1200Å thick). Silicon nitride films have a reasonably fast etch rate (200-300 Å/min) in concentrated HF (48%), but it was found that the ordinary photoresist materials, as used for SiO_2, do not mask sufficiently against the concentrated HF. Even if a good etching mask for concentrated HF were available, the etching of a contact hole in Si_3N_4 which is deposited on an SiO_2 film will present the problem of undercutting because the underlying SiO_2 is etched much faster than Si_3N_4 in concentrated HF.

This paper reports etching experiments with Si_3N_4, SiO_2, and Si in phosphoric acid. It was found that Si_3N_4 has a high etch rate in refluxed boiling phosphoric acid, compared to SiO_2 and elemental Si. Accordingly, phosphoric acid can be applied as an etchant for Si_3N_4 using deposited SiO_2 as a mask.

[1] Composition: 40g NH_4F + 60 ml H_2O + 15 ml 48% HF.

Etching Conditions

The silicon nitride films for the etching experiments with phosphoric acid were deposited by use of a pyrolytic process with SiH_4 and NH_3 at 880°C. [Silicon nitrides prepared by a d-c plasma process (2) and by

a process using $SiCl_4 + NH_3$ at 1000°C had approximately the same etch rate in phosphoric acid as the silicon nitride prepared from $SiH_4 + NH_3$.]

SiO_2 films were deposited in three different ways as follows:

1. $SiCl_4 + H_2 + O_2$ at 880°C
2. $SiH_4 + N_2 + O_2$ at 350°C
3. Same as No. 2 but densified for 20 min in O_2 at 800°C.

Film thickness was measured interferometrically with a Perkin-Elmer 202 spectrophotometer in the ultraviolet and visible wavelength range. A detailed description of the technique is given by Reizman and van Gelder (3). Reference (3) also gives the refractive index of the Si_3N_4 films as a function of wavelength. At $\lambda = 5460$Å the refractive index was 1.97.

A few tests were made to determine the etch rate of silicon in phosphoric acid. Silicon slices for this purpose were 58 ohm-cm p-type and were mechanically polished on both sides. The etch rate was determined by weighing on a microbalance before and after etching. In one case (at 180°C) a silicon slice half covered with SiO_2 was etched for 2 hr. The SiO_2 was then removed, aluminum was evaporated, and the step height in the silicon was measured with a multiple beam interferometer. The two methods agreed to within ±10%.

At first the phosphoric acid was kept in an open beaker at 200°C. The acid was initially 85% H_3PO_4 by weight and was slowly heated from room temperature to 200°C. The etching process was started after the acid had reached a constant temperature of 200°C for 1 hr. At that point most of the water in the acid had evaporated (partly by boiling), but the acid was not necessarily in equilibrium with atmospheric moisture. It was, in fact, observed that the Si_3N_4 etch rate was slowly decreasing with time which was explained by assuming that the acid was still losing water. According to Brown and Whitt(4) the vapor phase in equilibrium with phosphoric acid up to 250°C is virtually pure water (0.03% P_2O_5 at 250°C). Figure 1 gives the vapor pressure of phosphoric acid solutions *vs.* temperature for various concentrations. This figure shows, for instance, that phosphoric acid containing 75.3% P_2O_5 has a vapor pressure of 37 mm Hg at 200°C. This means that even a highly concentrated phosphoric acid of 75.3% P_2O_5 will still lose water when kept in an open beaker at 200°C because the water vapor partial pressure in a normal atmospheric ambient of 25°C and 50% relative humidity is 12 mm Hg.

To overcome the problem of keeping the acid concentration at a constant and known value later etching experiments were done with boiling phosphoric acid at atmospheric pressure and at constant temperatures ranging from 140° to 200°C with emerging water vapor constantly being condensed and returned to the boiling acid. Under these refluxing conditions the acid remains at a constant temperature and concentration. The slices were held in a quartz basket. The "boiler" was a quartz 1-liter round-bottom flask provided with a thermometer well, a reflux water-cooled condenser, and a wide, ground-glass tapered connector to admit the basket with slices.

Figure 1 is basically a part of the pressure-temperature diagram of the two component system H_2O-P_2O_5. The concentration of phosphoric acid can best be expressed in terms of weight per cent P_2O_5. However, for commercially available phosphoric acid the concentration is given as weight per cent H_3PO_4. The concentrations in Fig. 1 are therefore expressed both in per cent P_2O_5 and in per cent H_3PO_4. Applying Gibbs' phase rule to the system H_2O-P_2O_5 for the two phases liquid and gas in equilibrium, we find that there are two degrees of freedom. This means that of the three variables pressure (p), temperature (T), and concentration (x) we can choose only two while the third variable is fixed when the choice is made. For instance, the highest concentration of commercially available phosphoric acid is 85% H_3PO_4. This liquid boils at 154°C (see Fig. 2) or, in other words, at 154°C its vapor pressure is 760 mm Hg (see Fig. 1). If the boiling liquid is totally refluxed we have chosen the vapor pressure to be constant at 760 mm Hg (or whatever the local barometric pressure is) and the concentration at 85% H_3PO_4. Consequently, the temperature as, the third variable, is fixed at 154°C and cannot change unless p or x is changed. The higher boiling phosphoric acids in this work were obtained by letting some water vapor escape and the lower boiling acids were obtained by adding water.

In addition to measuring the etch rates as a function of the boiling temperature (and therefore necessarily also as a function of the concentration) the etch rate of silicon nitride was measured as a function of temperature only, at a constant concentration of 94.5% H_3PO_4. Refluxed boiling phosphoric acid at 200°C has a concentration of 94.5% H_3PO_4. This acid was cooled down and held at 158° and 140°C to measure the etch rate. Care was taken to let no water vapor escape. It should be noted that in the case of refluxed boiling acid the temperature is controlled by the amount of water in the system and not by the amount of heat put into the system.

Results

Table I shows results of etching experiments with Si_3N_4 and SiO_2, comparing "open beaker" phosphoric

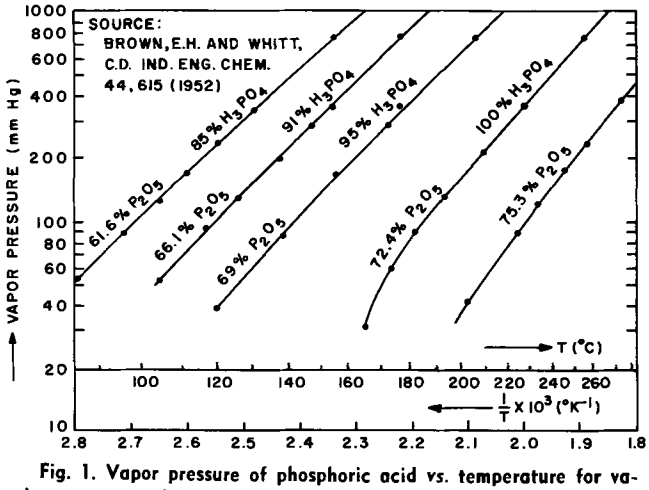

Fig. 1. Vapor pressure of phosphoric acid *vs.* temperature for various concentrations.

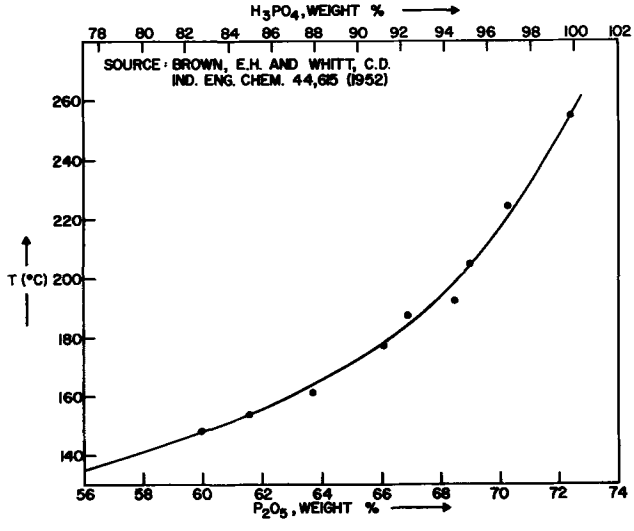

Fig. 2. Boiling point of phosphoric acid at 760 mm Hg *vs.* concentration.

Table I. Etch rates of Si_3N_4 and SiO_2 in H_3PO_4 (Å/min)

Type of film	Si_3N_4	SiO_2	SiO_2	SiO_2	
Method of film preparation	$SiH_4 + NH_3$ 880°C	$SiCl_4 + O_2 + H_2$ 880°C	$SiH_4 + O_2$ 350°C Not densified	$SiH_4 + O_2$ 350°C Densified at 800°C	Acid concentration at P_2O_5
Open beaker H_3PO_4 200°C	30	70	250	Not measured	>75.3% (>100% H_3PO_4)
Refluxed boiling H_3PO_4 200°C	178	32	Not measured	Not measured	68.5% (94.5% H_3PO_4)
Refluxed boiling H_3PO_4 180°C	105	10	25	0	66.4% (91.5% H_3PO_4)

acid at 200°C with refluxed, boiling phosphoric acid at 200° and 180°C. It is shown that the etch rate of Si_3N_4 was increased by a factor of 6 in going from open beaker acid to refluxed acid at 200°C. A factor of 2.2 was observed in the opposite direction for SiO_2 (deposited from $SiCl_4$, O_2, and H_2 at 880°C). In other words at a constant temperature of 200°C an increase in water content caused an increase in the etch rate of silicon nitride and a decrease in the etch rate of silicon dioxide.

The etch rates of Si_3N_4, SiO_2, and Si in refluxed boiling phosphoric acid were measured as a function of boiling temperature and are represented in Fig. 3 by the solid lines. Note that the acid concentration necessarily varies with the boiling temperature. An increase in boiling temperature goes together with an increase in acid concentration and *vice versa* as indicated by the abscissas of Fig. 3. The slope of the Si_3N_4 line in Fig. 3 is smaller than the slope of the SiO_2 line because the water content affects the etch rate of Si_3N_4 and SiO_2 in an opposite direction. The "apparent" activation energies derived from the straight solid lines in Fig. 3 are 12.7, 27.6, and 26.4 kcal/mole for Si_3N_4, SiO_2, and Si, respectively.

Figure 3 also shows a dashed line drawn through three points. This represents the etch rate of silicon nitride as a function of temperature only, at a constant concentration of 94.5% H_3PO_4. The "real" activation energy is 22.8 kcal/mole. The much steeper slope of the dashed line confirms that at one particular temperature a higher water content causes a higher etch rate for silicon nitride.

It is apparent that SiO_2 is quite suitable as a masking layer for Si_3N_4 films against attack by the boiling phosphoric acid. Since standard photoresist masking

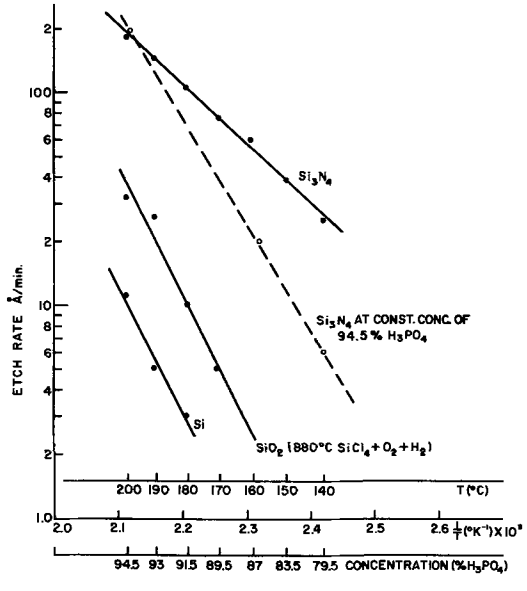

Fig. 3. Solid lines: etch rate of Si_3N_4, SiO_2, and Si in refluxed boiling phosphoric acid at atmospheric pressure as a function of boiling temperature and acid concentration. Dashed line: etch rate of Si_3N_4 at a constant concentration of 94.5% H_3PO_4 as a function of temperature only.

techniques can be used to open windows in an oxide film that has been deposited on top of a Si_3N_4 film, it is possible therefore, in turn, to dissolve out Si_3N_4 which lies exposed in the opened window areas by use of refluxed boiling phosphoric acid. If the Si_3N_4 is deposited on SiO_2, the SiO_2 can in turn be dissolved with buffered HF using the Si_3N_4 as a mask. It appeared that steam grown SiO_2 has about the same low etch rate as Si in refluxed boiling phosphoric acid. Undercutting of SiO_2 below the Si_3N_4 did occur to a certain extent, but it did not present a problem in making contacts to transistors if the SiO_2 layer is not too thick (<6000Å). As can be seen from Fig. 3 a temperature of 180°C appears to be a good choice since it combines reasonably fast dissolution of Si_3N_4 with very little attack on the masking SiO_2 layer.

Mechanism

Water has been found to play a vital role in various etching processes. For instance Finne and Klein (5) found that water is an active component in their amine-catechol etchant for silicon, generating hydroxyl ions in the amine solvent system. The hydroxyl ions supposedly ". . . oxidize the silicon to a hydrated silica (which) . . . is then brought into solution by coordination with pyrocathechol which serves as a chelating agent for the silica in the presence of the amine solvent." Hu and Kerr (7), as another example, found that dilute HF etches silicon faster than concentrated (48%) HF.

An exact mechanism for the etching process of Si_3N_4 in phosphoric acid and for the role of water is not given here. It is suggested however that the water is essential in hydrolyzing the Si_3N_4 to some form of hydrous silica and ammonia, the ammonia remaining in solution as ammonium phosphate. The low etch rate of SiO_2 in boiling H_3PO_4 at 180°C could be explained by the fact that the Si-O-Si bond is stronger than and not as easily hydrolyzed as the Si-N bond. With regard to the "open beaker" method it should be noted that concentrated phosphoric acids obtained by boiling off water from orthophosphoric acid (or by adding P_2O_5 to it) are members of a continuous series of amorphous condensed phopshoric acid mixtures, extending from orthophosphoric acid (H_3PO_4) via pyrophosphoric acid ($H_4P_2O_7$) and metaphosphoric acid (HPO_3) to pure P_2O_5 (6). Accordingly it is suggested that the high temperature, low water content acid attacked SiO_2 faster than Si_3N_4 because a soluble phosphorus-silica complex was formed between the "poly" phosphoric acid and the SiO_2 in which the Si-O bonds are largely preserved.

Remarks, Conclusions, and Recommendations

Refluxed boiling phosphoric acid at 180°C was found to be a convenient etchant for Si_3N_4 films. The etch rate is of the order of 100Å/min. Deposited SiO_2 can be used as a mask. Its etch rate under the same conditions is approximately 10 Å/min, depending on the deposition temperature. Many silicon planar transistors were made using this technique to etch contact holes in Si_3N_4 films. Delineation of contact holes is good. Holes with a width of 5μ are easily produced.

For Si_3N_4 and SiO_2 it was found that the water content of the phosphoric acid plays an important role. At constant temperature addition of water increased

the etch rate of Si_3N_4 and decreased the etch rate of SiO_2. The maximum possible temperature at atmospheric pressure for a fixed water content was realized by boiling the acid and "refluxing" the vapor phase.

For safe operation of the etching bath boiling aids such as Teflon-coated stirring bars should always be used.

Macroscopic Defects in Epitaxial Silicon

E. R. Shaw[1] and K. M. Busen

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

A macroscopic defect in epitaxial silicon layers, known as hillock, has been studied. In addition to other causes described by several authors, the origin of the defect was found to be a microalloy which is liquid at deposition temperatures and which is positioned on the substrate surface prior to epitaxial growth. The microalloy arises from an interaction between contaminants and the substrate. A model is proposed which explains phenomena observed in conjunction with the growth of a hillock.

Among the commonly observed defects in epitaxial silicon layers are dislocations and stacking faults. Another type of defect often occurring in epitaxial layers has been the subject of many recent publications (1-3). This defect which is shown in Fig. 1 has been described by a variety of terms such as tetrahedral growth, macroscopic pip, tripyramid, or hillock. In the following discussion the defect will be referred to as a hillock. The general consensus of the literature cited above is that hillocks are caused by an impurity (as α-SiC or SiO_2) on the surface of the substrate. A similar origin has been postulated for stacking faults. This would mean that the origin of a hillock must be at the substrate surface, and apparent evidence for this is presented in the literature (4, 5). It is shown in this paper, however, that for the hillocks studied in conjunction with this work, the origin penetrates the substrate surface. In addition, evidence has been found which supports a liquid drop model for the growth of hillocks.

Experimental and Results

Epitaxial silicon layers were prepared by the hydrogen reduction of silicon tetrachloride at 1250°-1400°C. The substrate material came from Czochralski grown crystals with a dislocation density of about 500-1000 cm^{-2}. The thickness of the epitaxial layers was between 0.1 and 1 mil. Several system designs based on those reported by Li (6) and Theuerer (7) as well as a commercial "Ecco" multiple slice unit were employed. Substrate material used included both n- and p-types in the limits of 0.001 to 50 ohm-cm. The hillocks were investigated by the following methods:

(*A*) Optical microscopy. This portion of the study was carried out using a Leitz Metallographic Microscope model MM5 with magnifications up to 1200X.

(*B*) Electron microscopy. Negative replication techniques were employed, the samples being shadowed at approximately 15°.

(*C*) Microprobe analysis. Probe spectral scans were conducted using an EdDT crystal and 20 kv at 0.1 μa.

(*D*) Cross-sectioning perpendicular to the surface and decorating with either chromium (Sirtl etch) or copper.

(*E*) Polishing parallel to the surface and decorating at various depths the growth layer with either chromium or copper.

The following observations were made via the above mentioned experimental techniques:

1. Under standardized conditions of cleanliness hillocks occur only when specific crystals are employed as a substrate material. This observation was confirmed by preparing slices from different crystals

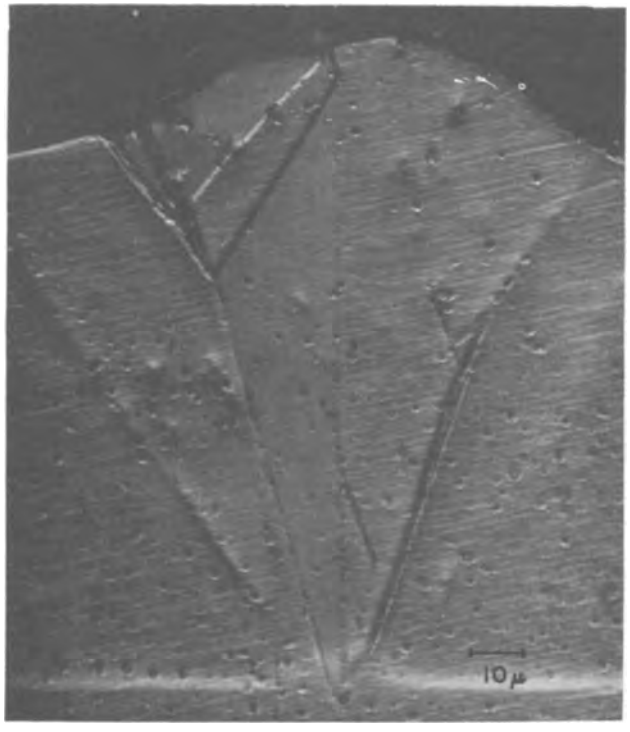

Fig. 2. Photomicrograph showing the origin of a hillock to be below the substrate surface.

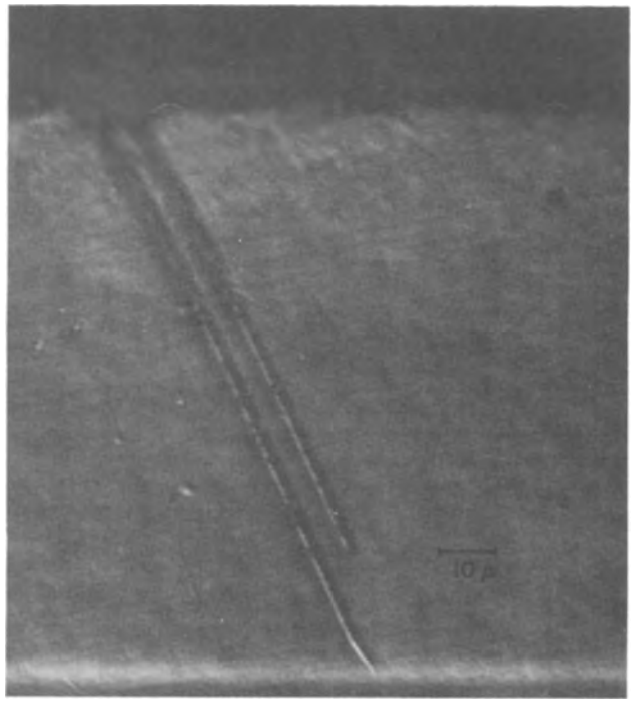

Fig. 3. Photomicrograph showing a stacking fault terminating at the interface.

in experimentally identical manners and depositing epitaxial layers on them simultaneously. Only wafers from crystals, which had previously yielded hillocks, produced hillocks in this experiment.

2. Hillocks generally do not form if the substrate is heated to 1300°-1400°C in hydrogen for 45-90 min prior to deposition.

3. Hillocks which were examined do not terminate at the substrate surface, but rather penetrate below it as shown in Fig. 2. In this figure a cross section through a hillock is shown. The white line at the bottom end of the hillock is a delineated junction between the substrate and the epitaxial layer.

4. Stacking faults, delineated by the same etch, do not penetrate the substrate surface as shown in Fig. 3, where the white line at the bottom is again a delineated junction between substrate and epitaxial layer. This observation is consistent with similar observations already reported in the literature (8).

5. Both copper and chromium (Sirtl etch) decorations of the surface show the hillocks embedded in a circular region (Fig. 4 and 5), which also contains high concentrations of what appear to be dislocations.

6. A hillock is of polycrystalline structure as shown by electron microscopy.

7. Hillocks are observed on (100) oriented substrates (Fig. 6) as well as on (111) oriented ones.

8. In an extra experiment it was observed that substrate material from a crystal, which was known to yield hillocks during epitaxy, when heated in hydrogen for approximately 1 min to temperatures equal to or greater than growth temperatures yielded small ($\sim 10\mu$ diameter) defects as shown in Fig. 7. (These defects will be referred to as "pockets.")

9. Microprobe analysis reveals high concentrations (600-10,000 ppm) of impurities to be present in the hillocks and "pockets" studied. Impurities which have been identified are aluminum, chlorine, phosphorus, sulfur, titanium, and gold.

Discussion and Conclusions

The hillocks reported in the literature have been observed to originate at the substrate surface. However, the hillocks examined in this study were found to originate below the interface (see observation 3).

During the investigations it was realized that some

Fig. 4. Photomicrograph of defects in the "ring" around the hillock.

substrate material rather consistently gave epitaxial layers with hillocks, whereas other material did not. This observation has also been made by others (3). In particular, only certain n-type and certain p-type crystals with impurity concentrations of 10^{20} cm^{-3} and 10^{20}-10^{14} cm^{-3}, respectively, gave rise to hillocks in epitaxial layers. (It is important to emphasize that not all substrates in these resistivity ranges gave hillocks.)

A closer examination of substrates from those crystals which do give hillocks revealed that, on heating to temperatures of 1250°C or greater, small pockets formed on the surface (observation 8). Similar pockets have been observed by Pearson *et al.* (9) and Goodman (10) and have been shown to be sites of local

melting due to impurity particles on the surface which depress the melting point of silicon at that particular point. Detailed examination of the effect of these pockets on epitaxial growth revealed that hillocks nucleate only at these pockets as shown in Fig. 8. Therefore, a direct link is established between a microalloyed pocket on the bare substrate surface (compare observation 8) and the occurrence of a hillock in the epitaxial layer subsequently grown on such a surface. Because pockets were observed on highly doped n-type crystals the conclusion was drawn that there is a relation between a high doping level and the appearance of pockets. The fact that p-type crystals of higher resistivities yielded pockets too may be explained by assuming that these crystals (which were purchased) had a high p-type concentration but were compensated by a suitable amount of n-type. Such unwanted material has been observed to be on the market from time to time. The link between highly doped crystals and pockets may be a precipitate of doping impurities at preferred sites as dislocations. Such a precipitate could cause a local source for an alloy pit. By the same token it can be inferred that contaminates from the ambient as well as from handling processes are potential local sources for pockets too.

Once a hillock has nucleated it must be propagated within the epitaxial layer. The mechanism of propagation is not understood, but there are observations which may give some hints for the nature of the hillock growth. One observes for example that the applied Sirtl etch (or copper etch) delineates a circular region around the star-shaped hillock (see Fig. 4 and 5). The region is of a different shade than the surrounding silicon and may indicate a different resistivity. This observation together with the formation of the pockets can be utilized to advance the following model: If one assumes that the initial pocket is an alloy between an impurity and the substrate and that this alloy migrates upward as a thin liquid layer on

top of the growing hillock,[1] then one is able to rationalize both the observed circular region and the apparent difference in resistivity: The circular region is a consequence of surface tension between liquid layer and epitaxial surface and the resistivity change arises from continuous dissolution and recrystallization of silicon within the migrating liquid layer. Also considerable internal structure is observed within the hillock pointing to some complications during the growth process. One also observes (see Fig. 1a-d) that the majority of the hillocks are associated with stacking faults. Stacking faults have been considered as a mechanism of relieving strain in growing layers (12) and very probably serve a similar function in the case of hillocks.

Polycrystalline formation very probably takes place during crystallization as evidenced by the electron microscope data. They do not give a simple silicon structure but rather a structure, which has not been resolved, and is quite complex. Since microprobe analysis has shown a high content of impurities at the hillocks and since it is known that grain boundaries act as a gettering center for impurities during crystal growth support is given to the model above.

[1] A similar model has been employed by Wagner (11) who observed that silicon whiskers grow under a gold drop, which moves up during growth.

Technical Notes

On the Eu^{3+} Fluorescence of Mixed Metal Oxides

VI. Temperature Dependence of the Fluorescence

G. Blasse and J. de Vries

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

In earlier parts of this series of papers the spectral energy distribution and the photoluminescent efficiency of well-defined Eu^{3+}-activated mixed metal oxides have been studied (1-5). It was found, among other things, that a relation exists between the position of the broad uv absorption band (charge-transfer band) of the Eu^{3+} ion and the maximum quantum efficiency for excitation in this band (4). We have now studied the temperature dependence of a number of Eu^{3+}-activated phosphors in which the Eu^{3+} center is directly excited by short-wave uv excitation. Phosphors that are excited in the host lattice were not studied because the temperature dependence of the energy transfer from host lattice to activator, as found, *e.g.*, by Botden (6), may complicate the final results in this case.

The preparation and analysis of the phosphors were described in the preceding papers. The temperature dependence of the fluorescence of the phosphors was determined by irradiating the phosphor with the radiation from a high-pressure mercury discharge lamp with a Schott UG 5 filter (2 mm) and a $NiSO_4$ filter (600 g/l, 2 cm) placed in front of it. For phosphors that have the excitation band in the 300 mm region the $NiSO_4$ filter was omitted. The phosphor was spread on a copper plate which could be either heated or cooled by liquid nitrogen. A photomultiplyer fitted with a Schott OG 5 filter (2 mm) was used for detecting the Eu^{3+} fluorescence. Figure 1 presents some of the curves obtained.

For all phosphors investigated, except $LaAlO_3$:Eu, the light output below room temperature is practically independent of temperature.

For none of the phosphors, except $LaAlO_3$:Eu, is the emission completely quenched below 700°K. We

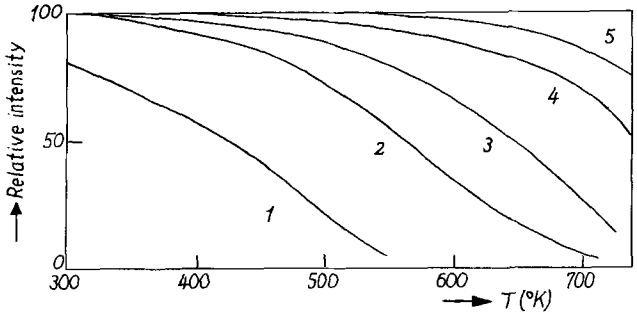

Fig. 1. Temperature dependence (above room temperature) of the fluorescent emission of $LaAlO_3$:Eu (2%) (curve 1), $LaYO_3$:Eu (curve 2), Gd_2O_3:Eu (monoclinic, curve 3), Gd_2O_3:Eu (cubic) and $LaBO_3$:Eu (both curve 4), and $YAl_3B_4O_{12}$:Eu (curve 5).

Table I. Properties of some Eu^{3+}-activated phosphors

Phosphor	Eu^{3+} concentration, a/o	Position charge-transfer band (λ_{max}, nm)	Quantum efficiency for excitation with λ_{max} (%)[e]	Quenching temperature, $T_{0.5}$, °K
$GdBO_3$	3	235[a]	80-100[a,b]	>>800[a]
Gd_2O_3 (cubic)	3	243[a]	70[a]	750[a]
Y_2GeO_5	2	247[c]	35[c]	630[d]
$YAl_3B_4O_{12}$	3	249[c]	35[c]	>750[d]
Gd_2O_3 (monoclinic)	3	255, 220[c]	30[c]	650[d]
$GdAlO_3$	2	263[c]	25[c]	600[d]
$LaBO_3$	3	270[a]	20[a]	~750[d]
$LaYO_3$	2	291, 236[c]	15[b,c]	560[d]
$LaAlO_3$	2	310[c]	10[b,c]	420[d]

[a] See ref. (17).
[b] Inaccurate data, λ_{max} being far from 250-270 nm, where q was actually measured.
[c] See ref. (4).
[d] This work.
[e] At room temperature.

therefore consider the temperature at which the emission output is half of the low temperature value as the quenching temperature ($T_{0.5}$).

Table I gives the position of the charge transfer band (λ_{max}), the quantum efficiency for excitation in this band ($q\lambda_{max}$) at room temperature and the quenching temperature ($T_{0.5}$). It must be kept in mind that the quenching temperature may depend on the preparation circumstances, as does the quantum efficiency (7), so that the values of $T_{0.5}$ in Table I cannot be considered as very accurate data. For the host lattices $LaAlO_3$ and $YAl_3B_4O_{12}$ we also studied the variation of the temperature dependence with Eu^{3+} concentration. In the case of $YAl_3B_4O_{12}$ there is no concentration dependence, not even up to 100% Eu, but in $LaAlO_3$ there is a rapid decrease of $T_{0.5}$ with increasing Eu^{3+} concentration. At 2% Eu the value of $T_{0.5}$ is 420°K, but at 5% Eu it is 300°K.

Discussion

From Table I it follows that the quenching temperature decreases if the quantum efficiency at low temperatures (practically equal to that at room temperature) is lower and if the charge-transfer band moves to lower energies. The borate host lattices, especially $YAl_3B_4O_{12}$ and $LaBO_3$, are an exception, because the quenching temperature of the Eu^{3+} fluorescence in these host lattices is much higher than expected from the correlation mentioned above. This correlation, however, is a little suspicious for the following reason. Usually charge-transfer absorption bands move to longer wavelengths with increasing temperatures. Phosphors that have this band at very short wavelengths show, therefore, an increasing absorption in this band with increasing temperatures (and a too high value of $T_{0.5}$), phosphors that have this band at wavelengths considerably longer than 254 nm show a decreasing absorption with increasing temperatures (and a too low value of $T_{0.5}$). We therefore restrict ourselves to a discussion of the relatively high values of $T_{0.5}$ of the borate phosphors (and a too low value of $T_{0.5}$). Nevertheless, the correlation probably exists, because the charge-transfer excitation bands are usually very broad (for example, the half-width value of this band in the case of $YAl_3B_4O_{12}$:Eu is about 13000 cm^{-1}), so that corrections due to the temperature dependence of the excitation band will only make the correlation less marked, but will not remove it. We restrict ourselves to a discussion of the most striking result, *viz.*, the relatively high values of $T_{0.5}$ of the borate phosphors.

The phosphors under investigation are excited in the charge-transfer band of the Eu^{3+} center. Between the corresponding energy level and that of the fluorescing $^5D_0$ level a large number of energy levels exist, from which radiationless processes can occur as shown by Bril, Blasse, and Bertens (8). Such a large number of radiationless processes complicates the problem drastically. Moreover, the decay mechanism of the radiationless processes is unknown. Within a 4f configuration multiphonon processes are a probable possibility for radiationless decay. These have been considered by Kiel (9). The rate of a multiphonon process involving n phonons with energy $h\nu$ is proportional to

$$\{(\exp h\nu/kT - 1)^{-1} + 1\}^n \qquad [2]$$

so that this rate has a constant value at low temperatures ($h\nu >> kT$) and varies with T^n in the limit $kT >> h\nu$. For host lattices that have high-energy phonons available the number of phonons in the multiphonon process, n, is relatively small and the temperature dependence of these processes relatively weak (compare Eq. [2]). This is the case for compounds containing a lighter element such as the borates. The BO_3 group in $YAl_3B_4O_{12}$ and $LaBO_3$ has a vibration frequency of 1250 cm^{-1}, the BO_4 group in YBO_3 (10) has 1000 cm^{-1} (11). This might be the reason for the relatively high quenching temperature found in borate host lattices.

It is interesting to note that the fluorescent emission of the Eu^{3+} ion in borates does not show transitions down from the $^5D_1$ levels, not even at concentrations lower than 1 a/o, whereas these transitions are usually observed in our phosphors at low Eu^{3+} concentrations (12). The $^5D_1$-$^5D_0$ transition involves an energy separation of only about 1750 cm^{-1}, so that usually three phonons must be created. In borates, however, two phonons suffice. Analogous results were reported by Bhaumik and Nugent for Eu^{3+} chelates (13), where the C = O and C = C stretching vibrations make important contributions to the relaxation process. For certain applications of Eu^{3+}-phosphors the use of host lattices that have high-energy phonons available may be profitable in view of the weak temperature dependence of the luminescence and the absence of green lines in the emission.

The temperature dependence of the Tb^{3+} fluorescence in borate host lattices is extremely weak (14). This might also be ascribed to the high-energy phonons available in these lattices.

At high Eu^{3+} concentrations the number of radiationless transitions can be increased by the concentration quenching of the Eu^{3+} fluorescence. Therefore we studied the concentration dependence of the temperature dependence of the Eu^{3+} fluorescence in $YAl_3B_4O_{12}$, for which host lattice no concentration quenching is observed, not even up to 100% Eu (15), and in $LaAlO_3$, for which lattice concentration quenching has already been found at some 4% Eu (16). The temperature dependence of the fluorescence of $EuAl_3B_4O_{12}$ is almost equal to that of $YAl_3B_4O_{12}$:Eu with low Eu^{3+} concentration, whereas the quenching temperature of the fluorescence of $LaAlO_3$:Eu decreases from 420° to 300°K, if the Eu^{3+} concentration increases from 2 to 5 a/o. These results agree with the earlier work on concentration quenching in $YAl_3B_4O_{12}$:Eu and $LaAlO_3$:Eu.

We conclude that, whatever the exact nature of the nonradiative decay mechanism may be, the energy of the phonons available plays a role in this mechanism.

For Eu^{3+} fluorescence in solutions the same conclusion holds in view of the work of deuterated compounds (18).

Wettability Measurements on Rough, High-Energy Surfaces

Robert O. Lussow, Louis H. Wirtz, and Harold A. Levine

Components Division, International Business Machines Corporation, East Fishkill Facility, Hopewell Junction, New York

Liquid drop size measurement for determining surface characteristics of solids has been used for many years. Typical methods use the contact angle between the liquid droplet and the solid surface (1) or the measurement of the height of the sessile drop (2). These measurements are readily applied to very smooth surfaces and in particular to low-energy surfaces. However, when one wishes to examine high-energy surfaces that exhibit some degree of roughness, the interpretation of the data is complex and accurate analysis is difficult (3, 4). This note describes a method for determining the relative wettability of high-energy surfaces that exhibit some degree of surface roughness.

The method presented is based on the contact area between a droplet of liquid and a solid surface when both are in equilibrium with the vapor of the liquid. A drop of liquid will spread over a solid surface until the forces attracting the liquid to the surface balance the cohesive forces within the liquid. If the droplet and solid are in equilibrium with the vapor of the liquid, the droplet dimensions will remain constant after the foregoing condition is reached. Since the cohesive forces of the liquid do not change, the area covered by a droplet of a given volume will be determined by the forces exerted on the liquid by the solid surface. One can compare the areas covered by droplets of equal volume to obtain a relative measure of the forces exerted by different surfaces.

A simple technique for determining the area covered by such droplets is to photograph the droplets at their equilibrium spread size from an overhead position. The droplet size is obtained by measuring the image size from the photograph and correcting this value for photographic magnification. On rough, high-energy surfaces, the droplet cross sections may vary from circular to ameboform shapes. The contact areas may be estimated as accurately as desired by the application of the usual methods for irregular areas (5). However, if the droplets have smooth peripheries and approach circularity in cross section, one can measure the maximum and minimum axis to find an average representative diameter. When this method is used, one can calculate a representative circular area or use the average diameters themselves to compare wettability.

Experimental

Procedure.—To determine the wettability of a solid, the sample is placed in the environmental chamber, a rectangular glass calibration chip is placed on its surface, and the chamber is closed. The ambient atmosphere of the chamber is air saturated with vapors of the liquid from which the droplets are formed. After the solid has equilibrated with the vapor, the chamber is opened and the liquid drops are placed on the sample surface. The droplets are formed at the tip of a microsyringe needle and placed on the solid, without the syringe needle touching the solid surface. The environmental chamber is closed, and the droplet is allowed to attain its equilibrium contact size with the solid. The droplet and the chip are photographed through an optically flat, transparent cover without disturbing the equilibrated system. The apparatus used is shown in Fig. 1.

The contact area between the solid and liquid was estimated by use of the average diameter technique. The wettability of each sample was determined by the average value of the contact diameters of four water droplets, one placed in each quadrant of the surface. The correction for photographic magnification was calculated by comparing the true dimensions of the calibration chip with its dimensions in the photograph. With 95% confidence the wettability results obtained in this manner were reproducible within $\pm 2.5\%$.

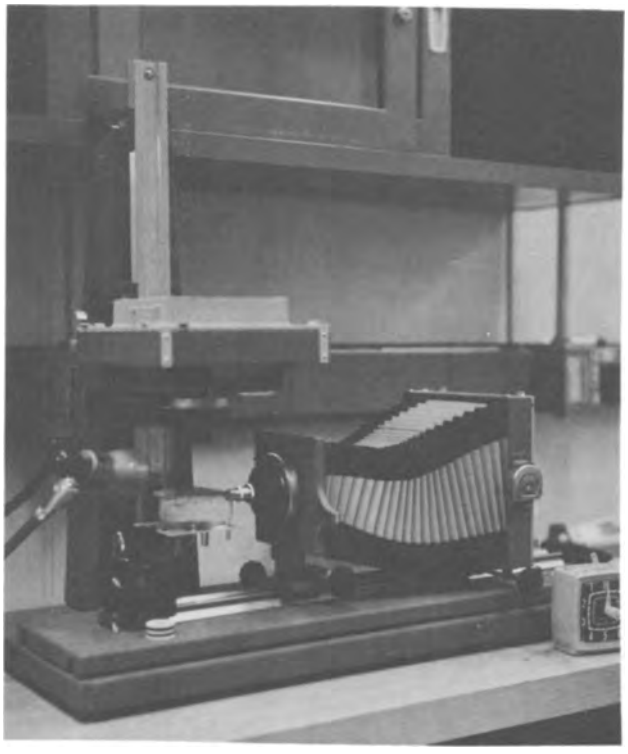

Fig. 1. Wettability apparatus

Materials.—The surfaces used for these experiments were thin layers of SiO_2 prepared by oxidation of n-type epitaxial silicon. The oxide layer was grown by thermal oxidation at 970°C in an alternating ambient atmosphere of steam and dry oxygen. The resulting oxide layers were about 6000Å thick.

The liquid used to create the atmosphere in the environmental chamber and to form the liquid droplets was boiled, 5 x 10^4 mhos, deionized water. Droplet size in all measurements was 4.0 x 10^{-6} liters. Figure 2 shows a typical set of water droplets and calibration chip on a thermal SiO_2 surface. The photographic magnification was of the order of 4X.

Results.—Table I shows the water wettability of thermal SiO_2 surfaces at three different stages: (*i*) after initial outgassing, (*ii*) after chemical treatment described in Table I, and (*iii*) after final outgassing. Both outgassing operations were at 50°C for 30 min at about 100 millitorr pressure. Wettability in all cases increased after the chemical surface treatment. The final vacuum outgassing of wafers treated with H_2O, HNO_3, and H_2SO_4 caused wettability to decrease to values close to those obtained after the initial outgassing. For surfaces treated with the HF-NH_4F mixture, final outgassing reduced wettability, but the ultimate values were greater than those obtained after initial outgassing.

Table I. Effect of chemical treatment on the water wettability of thermal SiO_2

Sample treatment	Wettability, D_T, in.		
	After initial outgassing	After treatment[a]	After final outgassing
D.I. H_2O	0.130	0.180	0.127
Boil 30 min	0.133	0.168	0.128

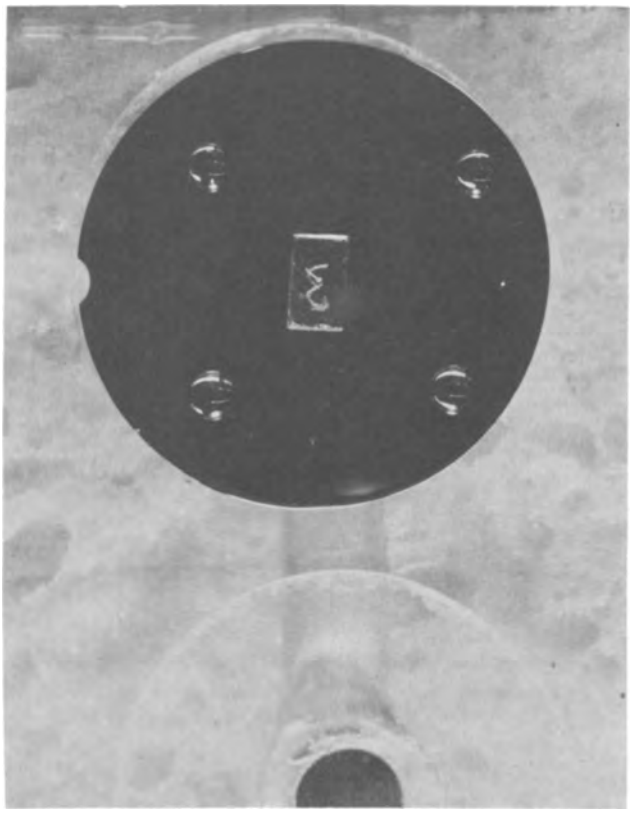

Fig. 2. Contact areas between water droplets and thermal SiO_2 surfaces.

Table II shows the water wettability changes on thermal SiO_2 brought about by exposure to various ambient conditions at elevated temperatures. Wettability measurements were made as for Table I. Exposure to steam at 350° and 500°C caused an increase in surface wettability. The 500°C samples showed the largest increase. Subsequent vacuum outgassing reduced the wettability of all samples, but not to the values after initial outgassing. Two of the final outgassed samples from the 500°C steam exposure were heated at 750°C in dry N_2. Their wettability was reduced to values below their original, initial outgassing wettability. Subsequent vacuum outgassing of the 750°C samples produced no change in their surface wettability.

These data illustrate the use of the proposed method for following water wettability changes on thermal SiO_2 surfaces. The water wettability of these surfaces has been shown to be important in the production of microelectronic devices (1); the significance of these values will be the subject of a forthcoming publication (6).

Table II. Effect of heat-treatment in various ambient atmospheres on the water wettability of thermal SiO_2

Sample treatment	Wettability, D_T, in.		
	After initial outgassing	After treatment	After final outgassing
350°C steam/N_2	0.125	0.146	0.132

Brief Communication

Propagation of Growth Striae in GaAs Epitaxial Films

P. Wang, F. Pink, and J. Sciola

Semiconductor Division, Sylvania Electric Products Inc., Woburn, Massachusetts

We have carried out epitaxial deposition of GaAs films on (100) GaAs substrates cut from Te-doped <111> single crystals of doping impurity concentration greater than 10^{18} atoms cm^{-3} grown by the Czochralski technique. The deposition was carried out in a three-zone furnace using Ga and AsH_3 sources in a hydrogen ambient, and HCl as the carrier for Ga, similar to the one reported by Tietjen and Amick (1). A peculiar topography on the (100) epitaxial film surface was observed which was not seen on films grown on (111) substrates cut from the same material. This surface feature becomes more pronounced after etching in a chromic acid etch developed for revealing crystallographic defects on low index planes in GaAs (2). Figure 1 illustrates one such specimen before and after a 3-min etch.

A number of GaAs (100) substrates went through a heat treatment cycle with no deposition and did not show this surface topography, *i.e.*, there was no thermal etching.

The regularly spaced, uniform band structure reminds one of the growth striations observed in single crystal GaAs (3, 4). The spacing is within the range of 10-50μ, corresponding to those previously reported for GaAs single crystals pulled by Czochralski-type techniques (3). In order to establish any relationship between the surface band structure and growth striae, a number of thick GaAs epitaxial films were grown with no intentional doping on these substrates at temperatures lower than 700°C and then cleaved from the film surface. The nn^+ interface was delineated by a 10-sec dip in a $AgNO_3$-HNO_3-HF-water solution. The cleaved surface was etched in the chromic acid etch from 2 to 10 min. Typical specimens are shown in Fig. 2.

It is clearly seen that the single crystal <111>

growth striae propagate in perfect alignment into the (100) epitaxial film, with equal spacing and revealed with almost identical contrast. The single crystal growth striae are generally attributed to periodical heterogeneous distribution of impurities along the growth axis (5). However, from our observations, we may speculate that the propagation of growth striae in the epitaxial film is at least partly associated with a defect structure. These striae reached through the entire epitaxial film thickness of 10-20μ. At the deposition temperature of less than 700°C, it is inconceivable that a tellurium diffusion front will move that far in less than 100 min. In addition, we detected only very faint contrast of striation in the film after the delineation etch; this striae propagation became well-defined only after the dislocation etch, indicating its probable association with a defect structure. Of course, this observation does not rule out that there was a preferred tellurium diffusion along dislocations. The exact nature of this defect structure is yet to be determined. The peculiar behavior of this unidirectional generation of defects or propagation of growth striation is not explained. We plan to pursue this point in the future.

Acknowledgments

The authors wish to express their appreciation to R. Yee, W. Russell, and A. Hathaway in growing the GaAs epitaxial films.

Deformation of Passive Films

S. F. Bubar and D. A. Vermilyea

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

An estimate of the ductility of a passive film can be made by straining the metal covered by the film and observing the current required to keep the film at its normal thickness. For the metals tested, the relative ductilities of passive films as measured by this technique decrease in the order tantalum; 16 Cr, 14 Ni, bal. Fe; type 304 stainless steel; iron; aluminum; 60 Ni, 16 Cr, bal. Fe; zirconium; and 80 Ni, 20 Cr.

In a previous publication (1) we reported that anodic oxide films on tantalum were surprisingly ductile, while those on zirconium and aluminum were much more brittle. In this paper we describe experiments which show that the thin passive films formed on many metals also have appreciable ductility.

Experimental

The electrical circuit used is basically the same as that described previously (1) with a few changes. A small constant speed electric motor provided a strain rate of 28.7%/min; an Anotrol model 4100 potentiostat maintained specimen potential, and a Varian G-14A-1 recorder measured the voltage drop in a precision resistor, produced by the anodizing current. A saturated calomel electrode, connected to the cell by a salt bridge (to prevent chloride contamination) and to the potentiostat, was used as a reference electrode. All experiments were conducted at room temperature.

Consider the following. If a specimen is held at a constant anodic potential, a rapidly decreasing anodizing current is observed. This current quickly becomes negligible when the passive film thickness reaches a value characteristic of the potential. If the specimen is strained the passive film must either elongate and thin, or crack. If during straining the potential at which the film was grown is maintained, an anodizing current would be observed as either the thinning film grows to maintain thickness, or the cracked film repairs itself. It may be shown that both cases yield approximately the same current. Consider now the case of a specimen on which the passive film was grown at a higher potential than that maintained during elongation. The film thickness is greater than that which would be produced at the elongation potential. If the film is brittle, it cracks on elongation and generates an anodizing current of the same magnitude as for the specimen strained at the anodizing potential. If the film is ductile, however, it will thin and elongate, and no anodizing current will flow until the film thickness is decreased to a value characteristic of the potential being maintained during elongation.

If curves are obtained for specimens anodized at the elongation potential and at a higher potential, the difference between these curves is a measure of the ductility of the film.

All specimens were prestrained slightly to eliminate slack in the system and to insure axial stressing of the specimen and film. There is a finite time required at start-up for the motor to reach its normal operating speed, corresponding to a strain of approximately 0.5%, and therefore we do not regard these experiments as providing good evidence for any elastic deformation of the passive films. We assume the deformations noted to be plastic.

The aluminum wire used was drawn from ingots of 99.9999% purity. The zirconium was swaged and drawn from zone refined single crystals. Tantalum wire of 99.96% purity was obtained from National Research Corporation, and tantalum wire was swaged and drawn from zone refined single crystals. Some of this latter material was recrystallized at 1050°C in order to obtain greater wire elongation. The surface preparation of these materials involved chemical or electrochemical polishing (1).

Type 304 stainless steel was obtained from Techalloy Company, Inc., and Nichrome (approximately 60Ni, 16Cr, balance Fe) from Driver-Harris Company. A 16Cr, 14Ni, balance Fe, and an 80Ni, 20Cr alloy were arc melted and drawn in this laboratory. Zone refined iron was further purified to reduce oxygen content to <5 ppm and carbon content to <5 ppb (2). These materials were all electropolished in a mixture of acetic and perchloric acids and water following procedures given by Tegart (3). The unstable character of certain acetic-perchloric solutions and the hazards involved in their use are described by Tegart (3) and Bartlett and Turner (4). After electropolishing, the specimens were dipped several seconds in concentrated (48%) HF in order to remove the electropolishing residues. The HF treatment did not give results significantly different from specimens tested either without such treatment, or, when possible, from specimens held at cathodic potentials to reduce films initially present.

Results and Discussion

Current-elongation curves are shown in Fig. 1 through 9. When a specimen fractured there was either a large increase of current if fracture occurred within the cell or a rapid current decrease if the break occurred outside; such current excursions have not been included in the figures. The film thicknesses given in parentheses in the figures were calculated from the difference between the potential at which the film was formed and the standard potential for the reaction between metal and water to form metal oxide, using for Ta_2O_5-17 Å/v, for ZrO_2-20, for Al_2O_3-14, for chromium containing alloys-16 (assuming the film was Cr_2O_3), and for iron oxide-17, using data given by

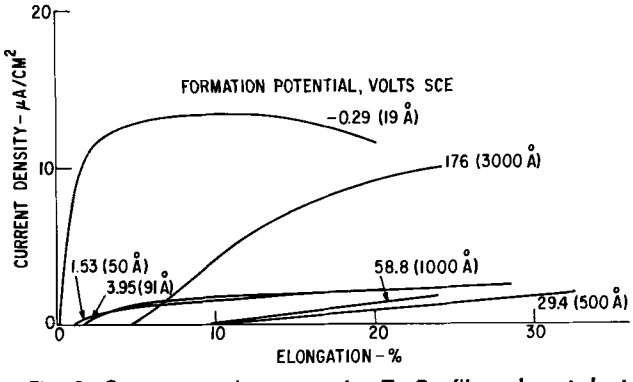

Fig. 1. Current-extension curves for Ta_2O_5 films elongated at —0.29v SCE in 1% ammonium borate.

Nagayama and Cohen (5). The approximate character of these thickness values should be obvious.

Some discussion of errors and difficulties of interpretation is in order. First, a capacitive current flow accompanies stretching because the exposed area decreases as the wire diameter decreases. Calculations and simple experiments have shown this current to be less than 10^{-8} amp/cm^2, and hence negligible compared to the observed currents. Second, the observed current at any time is the sum of currents from all increments of area on which the film is thin enough to produce current flow. Suppose the film cracks, exposing bare metal. The current on that area is initially high and decreases rapidly with time (about as t^{-1}), but is never zero and always contributes to the total current. Quantitative interpretation of current elongation curves is therefore very difficult. Third, nonuniform deformation of the metal, for instance at local slip bands or near inclusions, may cause early deformation or fracture of portions of the film and hence abnormally large currents. Inhomogeneities in the film itself, for instance at inclusions, may also cause local fracture. For these reasons these tests underestimate the true ductility of the reaction films. Finally, if a crack having a width less than the film thickness occurs and if oxygen ions move the current flow will be larger than expected for just the crack area since a hemicylinder of new film will be formed under the crack. This latter error, while probably negligible for most cracks, is also in a direction to result in an underestimation of the film ductility.

A further difficulty becomes evident from a comparison of the results shown in Fig. 1, for Ta_2O_5, with the results reported previously using the technique of measuring tunnel currents through very thin films formed in the cracks of a thicker insulating film. The previous work (1), which also underestimated the film ductility for reasons similar to those given above, indicated that there was essentially no cracking (limit of detection $\sim 10^{-3}$%) of Ta_2O_5 films less than 100Å thick upon 10% elongation. If 10^{-2}% bare surface was exposed the film reformation current would be about 10^{-9} amp/cm^2, while Fig. 1 shows that 50 and 100Å Ta_2O_5 films gave currents of the order of 10^{-6} amp/cm^2 on straining a few per cent. Since the previous method is better suited to the detection of small bare areas in insulating films, it is apparent that the current measured in the present method may be much larger than that corresponding to the bare area produced. This very serious complication severely hampers interpretation. The large currents may arise because of ion drift in the film during straining. The electric field applied during straining is smaller than the forming field of about 10^6 to 10^7 v/cm but is still large. If deformation of the film occurs, as with Ta_2O_5, so that ions are being moved parallel to the surface by mechanical forces, the electric field may be expected to cause some drift perpendicular to the surface. This phenomena is related to the reports by Bradhurst and Leach (6) and by Leach and Neufeld (7) that film deformation can be enhanced by ionic current flow.

It seems that the interpretation of the data reported here must be confined to qualitative statements of the following kind. First, the observation of smaller currents for a film strained at a potential less positive than its forming potential is evidence for film deformation rather than film fracture. Second, the method may very seriously underestimate the true film ductility. Third, it is not likely that the combination of mechanical deformation and a smaller electric field would yield a current as great as that produced by the full forming field, and hence the coincidence of current-elongation curves for thick and thin films is evidence for film fracture.

With the above considerations in mind, we now discuss the data. It is evident from Fig. 1 that the main features of ductility of Ta_2O_5 films reported previously are confirmed by the present technique. Thus

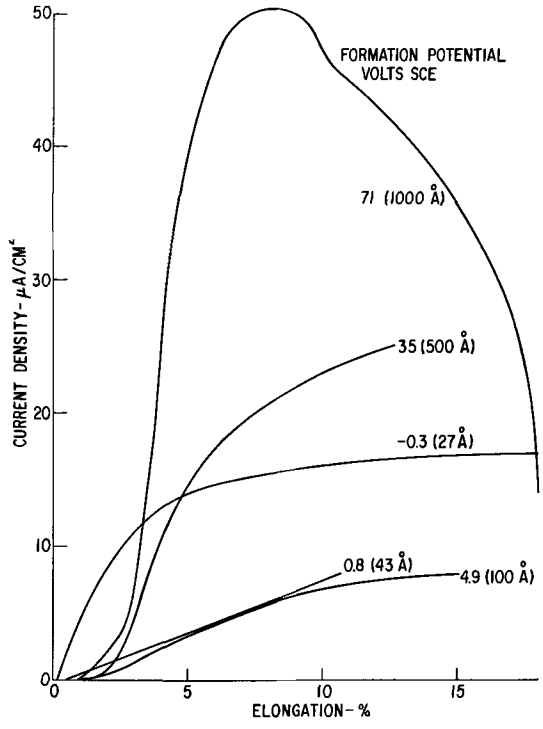

Fig. 2. Current-extension curves for Al_2O_3 films elongated at —0.3v SCE in 1% ammonium borate.

films less than 1000Å thick are very ductile, while thicker films are more brittle. We did not notice any effect of metal purity in these tests while the earlier method indicated that flaws present in films on less pure material nucleated fracture. Apparently the previously mentioned ion drift in the present method masks any effect of flaws. Films formed and tested in ammonium borate, sodium sulfate, and sodium phosphate solutions all gave very similar results.

Figure 2 shows that thin Al_2O_3 films have some ductility, while thicker films appear to be entirely brittle. Poor adhesion probably accounts for the very large currents observed for the thicker aluminum oxide films. Edeleanu and Law (8) reported evidence that the thin natural corrosion film was brittle. They reported cracking only on some grains, and lack of reproducibility. Their results are not inconsistent with our finding of limited ductility. No significant differences were observed in mechanical properties between films formed in ammonium borate and in sodium sulfate.

For ZrO_2, Fig. 3, the curves indicate that all films crack immediately on straining. Thicker films continue

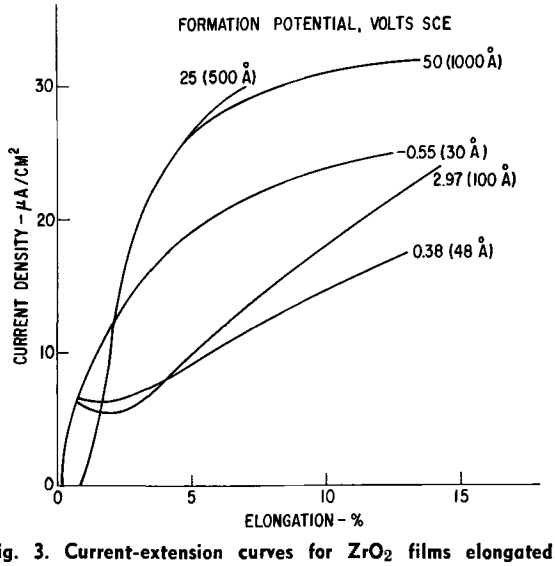

Fig. 3. Current-extension curves for ZrO_2 films elongated at —0.55v SCE in M Na_2SO_4.

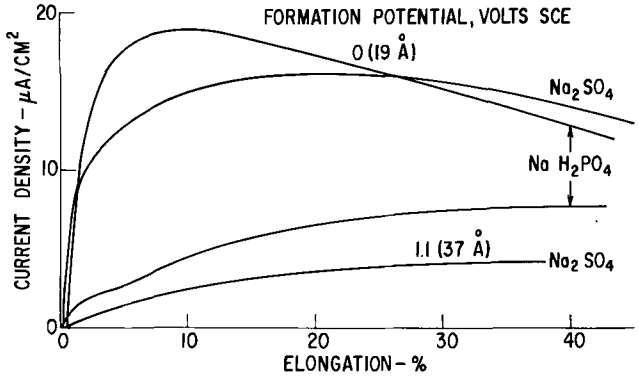

Fig. 4. Current-extension curves for type 304 stainless steel elongated at 0v SCE in M Na_2SO_4 and in M NaH_2PO_4.

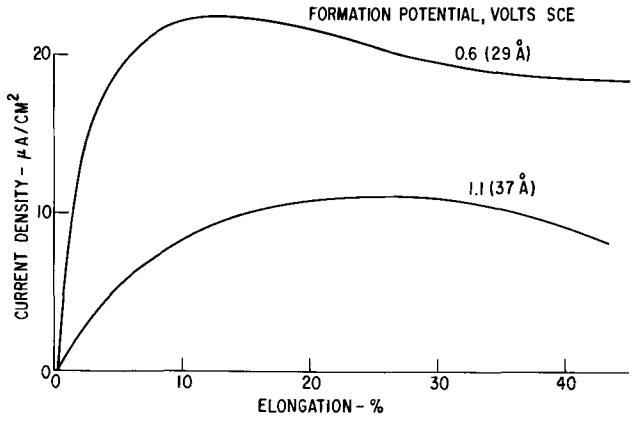

Fig. 5. Current-extension curves for type 304 stainless steel elongated at 0.6v SCE in M Na_2SO_4.

to crack, probably with loss of adhesion. The thinner films are evidently capable of some limited deformation as shown by the results at higher strains. The initial cracking may be associated with high local deformation of the metal.

Figures 4 and 5 give data for type 304 stainless steel. Results in phosphate and sulfate solutions both indicate appreciable ductility, although the current-elongation curves are somewhat different. Figure 5 shows that the current at a given elongation is greater when the difference between forming potential and straining potential is less, as might be expected from the ion drift hypothesis. We attempted to determine whether chloride ions would influence the results by anodizing in sodium sulfate solutions and testing in a solution containing M Na_2SO_4 and M NaCl. The results were essentially the same as with Na_2SO_4 alone. However, Swann and Embury (9) have given evidence for rupture of films formed on 18Cr, 8Ni stainless steel in

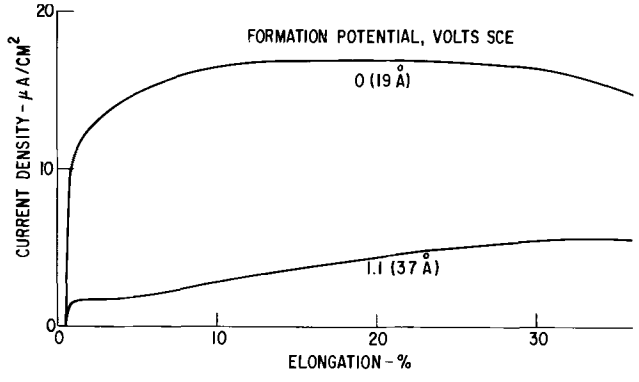

Fig. 6. Current-extension curves for 16 Cr, 14 Ni balance iron alloy elongated at 0v SCE in M Na_2SO_4.

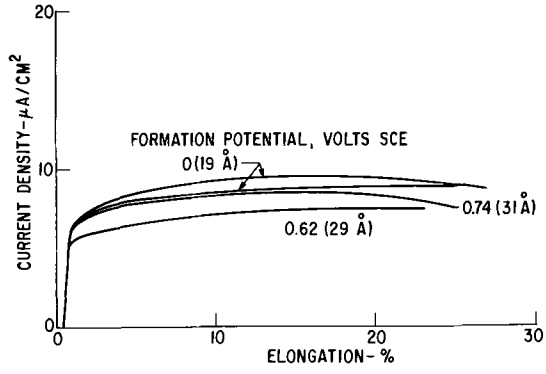

Fig. 8. Current-extension curves for 80 Ni, 20 Cr alloy elongated at 0v SCE in M Na_2SO_4.

boiling 42% $MgCl_2$. A comparison is difficult because of the very different techniques.

The laboratory produced 16Cr, 14Ni, balance iron alloy gave results similar to those for type 304 stainless steel, as shown in Fig. 6. The intent was to compare the film on a "dirty" commercial alloy (304) with the film on a high-purity alloy of similar composition and structure. This objective was frustrated by the finding that the laboratory alloy was not entirely homogeneous. Presumably it contains fewer interstitials, and the inhomogeneities arose from incomplete mixing during melting. In any case the results for the two materials are very similar.

The commercial nichrome alloy, Fig. 7, could not be anodized above about 0.5v SCE without the passage of large currents. The curve for 1.0v in Fig. 7 is almost identical to that obtained with an anodizing potential of 0.6v, and it is likely that the film thicknesses produced by the two potentials are no different. Appreciable ductility is indicated for this film.

Figure 8 gives data for the laboratory prepared 80Ni, 20Cr alloy. Anodizing voltages were limited for this

Table I

Metal	%C Wire elongation 5%	%C Wire elongation 10%
Ta (50Å)	91.5	89
16Cr, 14Ni, bal. Fe	87	84
304 Stainless	86	77
Fe	81	56
Al (average of 3)	75	50
60Ni, 16Cr, bal. Fe	56	54
Zr	52	38
80Ni, 20Cr	16	18

alloy also. The films appear to be substantially less ductile than those on the Cr, Ni, Fe alloys. This alloy also proved to be inhomogeneous.

For pure iron, Fig. 9, the data again suggest appreciable ductility for the oxide film.

In order to make a semiquantitative comparison of materials we have listed in Table I the value of %C, which is defined by the equation

$$\%C = \frac{i_e - i}{i_e} \times 100 \qquad [1]$$

in which i_e and i are the currents (at the same elongation) for specimens anodized at the straining potential and at a higher potential, respectively. The value of %C gives a rough measure of the fraction of the newly generated specimen area which is covered by the original oxide film; for a completely ductile film %C should be 100, while for a brittle film it should be 0.

Conclusions

The ductility of some of these passive films may be as great as that of Ta_2O_5, which evidently can be stretched as much as 50%. Because of the difficulties of interpretation it is perhaps premature to speculate about the mechanisms of deformation and implications. Perhaps the easy deformation results from ion motion under the applied electric field, as suggested by Bradhurst and Leach (6) and by Leach and Neufeld (7). The presence of water, which is known to enhance deformation of some nonmetallic materials (10, 11), may also be important. Finally, the difference in ease of deformation of bulk oxides and passive films may be associated with differences in the structures of these two types of materials. One implication of the results may be that the explanation for the better resistance of high nickel alloys to stress corrosion cracking does not lie in the reaction film ductility.

Acknowledgment

Anodic Dissolution of Zinc in Potassium Nitrate

M. E. Straumanis, J. L. Reed, and W. J. James

Departments of Metallurgical Engineering, Chemical Engineering, and Chemistry, University of Missouri at Rolla, Missouri

ABSTRACT

The apparent valence of pure zinc dissolving anodically in 3% KNO_3 was determined as a function of current density, temperature, and ultrasonic agitation. The apparent valence of zinc dissolving anodically at 24°C diminishes from 2.01 ± 0.01 at low current densities to 1.86 at about 50 ma and remains fairly constant up to about 80 ma cm^{-2}. This valence is affected to some extent by the preparation, *e.g.*, polishing of the electrode, but is independent of its structure (mono- or polycrystal). Ultrasonic vibrations do not influence the apparent valence at high current densities. In all cases a black film (corrosion product) spalls off the anode but to a larger extent with ultrasonics. The apparent valence decreases with increasing temperature (measurements between 25° and 68°C) and again with increasing current density, and appears to vary as a function of metal history. Fine metallic Zn particles are found in the dark corrosion product. The average size of the particles increases with increasing temperature. On the basis of the above, it is concluded that the normal valency of zinc ions, +2, does not change during anodic dissolution in nitrate solutions, but the apparent valence of less than 2 arises as a consequence of increased local corrosion and of surface disintegration of the anode. Both occur outside the electrical circuit thus accounting for the lower coulombic equivalent. A mechanism for the disintegration phenomenon is presented.

When either Zn or Cd (having a normal valence of +2) is dissolved anodically in aqueous neutral salt solutions, containing nitrate, chlorate, or bromate ions, the number of coulombs required to dissolve one gram equivalent of metal is less than the faradaic weight equivalent, especially at high current densities. Other active metals, such as Be, Mg, Al, In, Ga, Tl, Fe, Sn, and Pb also exhibit this phenomenon.

One mechanism which has received wide acceptance is the concept of the "uncommon valence ion" as pro-

posed by Epelboin (1) for zinc undergoing anodic dissolution in perchlorate solution. Later work on Zn, Cd and other metals by Davidson and co-workers (2-6) has supported this mechanism, the results having been attributed to the expulsion of univalent ions.

The purpose of this study was to obtain experimental data for the anodic dissolution of zinc in 3% aqueous KNO_3 as a function of: (*i*) current density, (*ii*) temperature, and (*iii*) ultrasonic vibrations, and to establish a mechanism consistent with the results.

Experimental

Effect of Current Density

Apparatus.—The apparatus consisted of a 400 ml cell, a zinc electrode made of either a polycrystalline bar (99.99% purity) or of a single crystal (exposed surface nearly parallel to the basal plane, 99.95% purity), an external d-c source, a sensitive milliammeter, a decade type resistance box, a knife switch, and a platinum cathode, all connected in series. A microburet of 10 ml capacity with 0.02 ml graduations was used to titrate the zinc content of the electrolyte following electrolysis.

Procedure.—The zinc electrodes were polished shortly before each run. Two hundred ml of a 3% KNO_3 solution were transferred to the thermostatted cell (24.0° ± 0.5°C). Air was not excluded because experiments in a N_2 atmosphere gave the same results within the limits of error. The Zn anode and the Pt cathode were then inserted and connected in series with the external circuit and the circuit closed. A timer and milliammeter were used to measure the number of coulombs passed (checked by a copper coulometer). After a sufficient time interval the circuit was broken and the electrodes removed from the beaker. Any loosely adhering film on the anode was removed by scrubbing with a rubber policeman in the electrolyte. Two drops of 6M HCl added dissolved the sediment. The clear solution was then diluted to 500 ml with distilled water. Aliquots of 100 ml volume were withdrawn from this solution, heated to about 90°C, buffered to pH of 10, and titrated with disodium EDTA standardized against 99.99% pure Zn, using Erichrome Black T as indicator. Thus, the weight loss w of the Zn electrode was calculated.

Results

Influence of current density.—The valence V was determined from Eq. [1]

$$V = ItA/\mathbf{F}w \qquad [1]$$

where It is the quantity of electricity in coulombs, A the atomic mass of Zn, $\mathbf{F}$ is Faraday's constant, and w the weight loss of the anode (calculated from titration data). The measurements were performed over a current density range of 0.5 to 85 ma·cm^{-2} with a possible error range of ±1%. Since the behavior of a polycrystalline and of the single crystal anode (0001 plane exposed) was the same (see Table I), the resulting

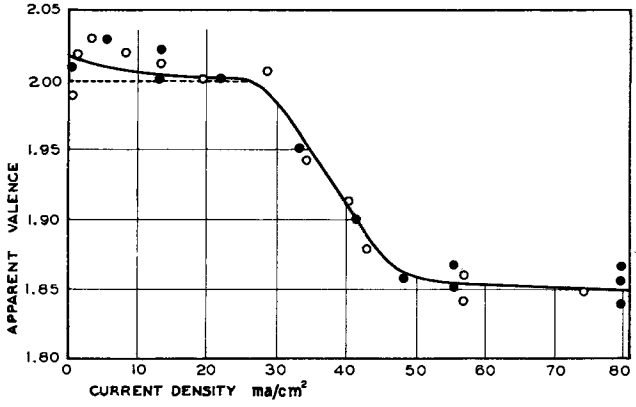

Fig. 1. Calculated valence as a function of current density for Zn dissolving anodically in 3% KNO_3. Dots, monocrystal; circles, polycrystal.

data were combined and are presented graphically in Fig. 1.

At low current densities (< 30 ma·cm^{-2}) a very thin, usually spotty, black film was observed on the face of the anode. On removal from the electrolyte the film turned grayish white after about 5 min exposure. Tests at higher current densities (> 30 ma·cm^{-2}) resulted in a thicker and continuous black film. Also a white precipitate was observed directly below the vertical electrode. An x-ray analysis of the deposit revealed it to be ZnO.

Since there was no difference between a mono- and polycrystalline anode, no attempt was made to use various crystalline planes for dissolution. Table I and Fig. 1 show that the calculated valence of Zn-ions approaches, with increasing current density, a fairly constant value of 1.86 ± 0.01, which is in agreement with the results of previous investigators (2). However, the constant value of about 2 at small current densities (up to 30 ma·cm^{-2}) is not always observed. Depending on experimental conditions, the drop can start at a much lower current (7). The calculated valence drops lower, even down to 1.65 if the consecutive tests are performed without repolishing the electrode, merely transferring it (after rinsing with distilled water) to a fresh solution to start another run.

A black film was always observed forming on the Zn anode. At low current densities the film was thin and its thickness increased with the current. On removal of the anode from the solution, the black film turned grayish white in a few minutes, as observed for Mg (8). X-ray analysis showed the grayish film to consist of ZnO and/or $Zn(OH)_2$. If the Zn anode was etched slightly with dilute H_2SO_4 before the run, the black film formed at electrolysis spalled from the anode upon application of ultrasonic agitation. A sample of the gray black sediment was collected, quickly rinsed by decantation with water, and then washed with dry acetone. Even then part of the sample turned white after filtering. The darkest flakes were examined under the microscope, using oil immersion objectives, at magnifications of 1430. In the reflected light parts of the sample revealed a multitude of shiny metallic particles embedded in the corrosion product ZnO or $Zn(OH)_2$. The diameter of the smallest particles was of the order of 10^{-5} mm. Larger chunks, as found during electrolysis of Zn in $NaBrO_3$ solutions (9), were also observed floating around in the oil. All the metallic particles were completely opaque to transmitted light. They consisted of Zn, as proved by x-ray diffraction.

It is, therefore, clear that the deviation from Faraday's law or the calculated lower valence of Zn ions (Fig. 1, Table I) is, in part, the result of surface disintegration of the Zn anode during dissolution which occurs outside the faradaic current and, hence, contributes to the calculation of ions of lower valence.

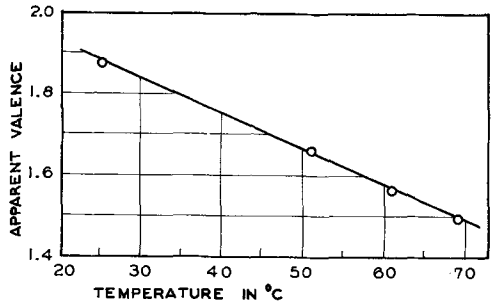

Fig. 2. Apparent valence as a function of temperature for Zn dissolving anodically in 3% KNO_3 solution. 50 to 80 ma.cm^{-2} (see Fig. 1.).

Thus, this valence is only apparent, particularly as the existence of Zn^+ has not been confirmed analytically (2). Furthermore, no lower valence was calculated when the disintegration of the anode was prevented, *e.g.*, by amalgamation (10). Amalgams as anodes produce only normal valence ions, as found for Al(11), Ga(12), In(13), Tl(14), and Sn(15). Unfortunately it is difficult to collect the particles and quantitatively determine the amount of Zn particles present due to the high activity of the fine particles. However, the presence of metallic particles in large amounts, and the absence of Zn^+, together with the absence of disintegration (in case of an amalgamated anode) and the calculated normal charge of the Zn-ions are sufficient evidence for anodic surface disintegration.

Effect of temperature on apparent valence.—The apparatus and procedure were similar to previous studies. The cell was open to the atmosphere and any evaporation which occurred during electrolysis was corrected by addition of water at the same temperature to the electrolyte. The apparent valence as a function of temperature is shown in Fig. 2.

Some current density experiments were also performed at a temperature of 87°C. At this temperature the apparent valence dropped to 1.13 and to 1.10 for a poly- and monocrystal at current densities of 57 and 79 ma·cm^{-2}, respectively. Under such conditions the apparent valence seemed to be a function of time, current density, and perhaps of crystal structure. A large amount of gray corrosion product was observed on the bottom of the reaction beaker. On treatment with HCl, the material evolved hydrogen, indicating that chunks of Zn were still present in the hydroxide, while the fine metallic particles had rapidly reacted with H_2O (hydrolysis) at the elevated temperature. The larger chunks were also detected microscopically. The electrolyte contained nitrite ions, the amount of which was proportional to the decrease in apparent valence.

The activation energy.—It was speculated that this temperature dependence could be related to the activation energy by assuming that the over-all rate constant k was proportional to the normal valence less the apparent valence. Accordingly, an Arrhenius plot of log(2 minus apparent valence) *vs.* reciprocal temperature was made as illustrated in Fig. 3. An activation energy of ~4.2 kcal was found from the slope of the straight line.

Application of ultrasonic vibrations.—The beaker used in the previous experiments was replaced by an ultrasonic cell of equivalent diameter and connected to an ultrasonic generator. Vibrations of a frequency of 32,500 cycles sec^{-1} and of maximum possible amplitude were passed through the reaction cell during the electrolysis. The results were both of quantitative as well as of qualitative nature. The average value for the apparent valence of a poly- and monocrystalline anode at current densities between 50 and 80 ma·cm^{-2} was about 1.84 ± 0.01, while without ultrasonics a valence of 1.86 ± 0.01 was obtained. Thus, the

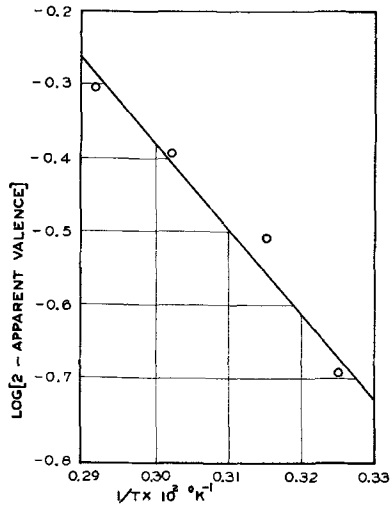

Fig. 3. The variation of log (2 minus apparent valence) with reciprocal absolute temperature.

difference was very small and within the limits of error. With ultrasonic stirring the solution turned gray black in a few minutes and the electrodes became barely visible. When the circuit was opened and ultrasonic stirring stopped, the dark flakes settled to the bottom. As previously mentioned, the sediment contained metallic Zn in the form of very fine particles or larger chunks. A few drops of concentrated HCl were added to the electrolyte to determine quantitatively the Zn which spalled from the anode. The sediment dissolved easily. Etched Zn electrodes gave the same apparent valence as nonetched ones. The gelatinous $Zn(OH)_2$ film generally formed during electrolysis was not present to any appreciable degree.

Discussion and Conclusions

At current densities of 50 to 80 ma·cm^{-2}, the apparent valence of zinc was found to be 1.86 ± 0.01. This value is in agreement with the results of previous works cited (2, 10). However, when the current density dropped below 50 ma·cm^{-2} the valence started increasing, and below 30 ma·cm^{-2} values close to the normal oxidation state of two were obtained.

These results are more in accord with the concept of anodic disintegration rather than with that of formation of lower valence ions, since the rate of mass loss due to breakout of particles from the anode must be a function of the instantaneous current density (16). On this basis one would expect a decrease in the apparent valence with increasing current density possibly to some limiting value (Fig. 1). This expectation was clearly verified for Mg and Cd anodes (17). It is noteworthy that at low current densities, <10 ma·cm^{-2}, the metal surface was in most cases completely free of the black surface film, suggesting that no disintegration of the anodic surface occurred.

Furthermore, it is difficult, on the basis of lower valence ion formation, to explain the appearance of the very small and larger metallic particles, usually embedded in the surface oxide layer, which impart the dark color to the latter. According to the older theory Zn particles should appear as a consequence of a reduction-oxidation reaction

$$2Zn^+ \rightarrow Zn^{++} + Zn \qquad [2]$$

However, the improbability of such reactions, especially as regards very active metals, has been discussed previously (8, 11, 18).

All these results can be satisfactorily explained by assuming that the only faradaic process is

$$Zn \rightarrow Zn^{++} + 2e \qquad [2a]$$

In addition to [2a] there is surface disintegration, oxidation (reactions [3] and [4]) and self dissolution,

thus resulting in more Zn dissolved than expected according to [2a].

The exact mechanism of surface disintegration is presently not known in detail, but the observations made with Zn anodes suggest a mechanism as follows: The Zn anode adsorbs onto its surface NO_3^-, similarly as is proposed for BrO_3^- (9)

$$Zn + NO_3^- \rightarrow ZnO + NO_2^- \quad [3]$$

This action increases with increasing nitrate concentration resulting in a decreased apparent valence (7). Simultaneously, hydrolysis may also occur

$$ZnO \text{ (on the Zn surface)} + H_2O \rightarrow Zn(OH)_2 \quad [4]$$

These generally thin oxide layers will vary in adherence and thickness, depending on the surface structure of the Zn anode. There will be places where the oxide layer adheres very well and where it will be thicker, causing partial passivation of the anode. On application of an anodic current the weakest spots will be attacked first and there the Zn^{++} will go into solution, partially undermining the passive spots, but no noticeable separation of these weakened metallic places from the anode will occur. With an increase of the current density, the flow of the electrons from the anode will be increased. Since the positive ions in the solid will be in excess, ions (Zn^{++}) will be driven into solution by a repulsion force corresponding to the Nernst solution tension P. It is, possibly, not always realized how large this force is. It can be calculated from Nernst's original equation

$$P = p \cdot \exp(-\epsilon n\mathbf{F}/RT) \quad [5]$$

where p is the osmotic pressure of the Zn^{++} in the electrolyte, ϵ the potential of Zn (=—0.76v, hydrogen scale), n the valence of Zn-ions, **F** Faraday's constant, R the gas constant, and T the absolute temperature. For a standard Zn electrode a value of P of about 10^{26} atm is obtained which represents the free energy expressed in pressure units. If only a part of this pressure (due to the limited current) is in action, even then the pressure which drives the ions into solution is enormous. Therefore, the moving ions may hit the oxide layer on the electrode surface with such force that this layer breaks away from the surface. However, if the layer adheres well to the metal, it can carry small particles of the electrode metal with it (19). And this is what is observed: metallic particles in an oxide network. The oxide may react further with H_2O, Eq. [4], and then the particles will appear embedded in a white oxide or hydroxide layer (11). The particles break away at places where their contact with the bulk of the electrode is somehow weakened, e.g., by undermining. The clean metallic surface is now able to react again with the electrolyte or with the NO_3^- according to Eq. [3] and after some time the process of disintegration can start again at the same site. However, at high current densities there will be less time for the oxidation reaction [3]. Hence, the degree of disintegration and the apparent valence will approach a constant value with increasing current (Fig. 1). Under such conditions the apparent valence may even increase because there will be less opportunity for the ions, going into solution, to take with them parts of the oxide layer containing fragments of the anodic metal (14).

Thus, the degree of disintegration and, hence, the apparent valence will depend on the quality of the oxide layer on the Zn anode, the formation of which depends on the nature of the electrolyte: there may be electrolytes producing porous or weakly adhering layers, or both, and as a result the apparent valence will be close to normal.

This concept explains why the apparent valence is the same for both poly- and monocrystalline anodic surfaces. Evidently oxide layers of the same quality are produced on Zn of various surface structures (in the same solutions). The grain boundaries are of little influence since disintegration occurs within these borders (the grains themselves are not falling out). However, if the anode surface is not repolished between the runs, the surface becomes rough and there will be an increased possibility for breakout of larger metallic particles together with the oxide layer: a lower apparent valence is observed (down to 1.65). Forces introduced by ultrasonic vibration are small as compared with those represented by Eq. [5]. Therefore, these vibrations will not markedly influence the degree of disintegration and the apparent valence. However, ultrasonic agitation is sufficient to disperse the oxide flakes loosely adhering to the Zn electrode, especially the white gelatinous hydroxide which is formed on the Zn particles (Eq. [4]). All this is consistent with the experimental results, and the white hydroxide is not found on the Zn anode if ultrasonic waves are applied.

It is more difficult to understand the influence of temperature on the degree of disintegration. Although the temperature coefficient of potential change $\partial\epsilon/\partial T$ for Zn is known (20), there are still some difficulties in the application of the original Nernst equation, as the osmotic pressure p (Eq. [5]) changes (increases) with temperature. However, considering the derivation of the equation, the solution pressure P will increase with temperature and, hence, the degree of disintegration. The apparent valence will decrease (Fig. 2). The increased P may not be the only reason for the increased disintegration rate, because compressional stresses between the anodic film and the bulk of the anode may increase with temperature and force the film to crumple or dilate. In addition hydrogen developed due to the very slow reaction

$$Zn + 2H_2O \rightarrow Zn(OH)_2 + 2H \quad [6]$$

may increase the spalling of the oxide layer containing larger metallic particles. The activation energy of about 4.2 kcal (Fig. 3) suggests other possible rate determining steps such as adsorption or some other physical process.

The Zn particles which spall from the electrode are very small and completely clean toward the side of the anode. They, therefore, will be vary active and react with water according to [6] and still faster with an oxidizer, if such is present in the electrolyte. In nitrate solution reaction [3] occurs. Indeed, NO_2^- ions can be proved to be in solution and their amount is proportional to the amount of departure from the apparent valency (2-6). If disintegration of the Zn anode is prevented, NO_2^- ions are not present in the electrolyte (10, 17).

In conclusion, the assumption of formation of lower valence ions, the presence of which cannot be proved, is not necessary and does not account for the experimental data. It is very improbable that the number of lower valence Zn ions formed will depend on current density, the nature of the electrolyte, the temperature, and the surface treatment of the anode. Surface disintegration of the dissolving anode can account for the observed facts, including the reducing ability of the anolyte.

Adherence and Porosity in Ion Plated Gold

C. F. Schroeder and J. E. McDonald

Sandia Corporation, Albuquerque, New Mexico

ABSTRACT

The accelerated ion deposition process is shown to provide gold films and coatings which are strongly adherent even when deposited on oxidized beryllium-copper substrates. The porosity of these coatings when deposited under conditions which provide high substrate surface temperature is undetectable at thicknesses of approximately 2μ and is the result of the formation of a gold-copper solid solution.

The ion plating process developed by Mattox (1) has been demonstrated to provide excellent adherence across a film-substrate boundary, and the observed adherence is apparently less dependent on meticulous precleaning treatment than in conventional deposition processes. Further, qualitative observation of the films deposited by the process has indicated that nonporous deposits could be obtained in thicknesses in the micron range and that the porosity resulting from substrate surface contamination can be eliminated or controlled. It is the purpose of this paper to discuss the adherence and porosity of ion plated gold films and to project a mechanism for the formation of the adherent, nonporous deposits formed.

Experimental Procedure

The apparatus used to deposit the ion plated gold is shown in Fig. 1 and is essentially that described by Mattox (1). Specimens were prepared in the configuration shown in Fig. 2a, in order that subsequent adherence tests could be performed.

The specimens used for adherence determination were firmly clamped to the substrate holder to maximize heat transfer and are indicated as the low-temperature group. In contrast, the specimens on which porosity and alloying observations were made were supported along approximately 0.8 cm^2 at the sample ends to minimize heat transfer to the substrate holder and are called the high-temperature group. Porosity data for the low-temperature group are also reported.

Sample Preparation

High-temperature group.—Specimens were 0.8 cm thick annealed beryllium copper alloy, not heat-treated. Surfaces were lightly abraded with steel wool and rinsed in acetone prior to plating.

All ion bombardment and ion plating was at 5 kv, 0.5 ma/cm^2. Specimens in the low-temperature group were ion plated for 2 min. Specimens in the high temperature were argon ion bombarded for 10 min and ion plated for times as shown in Table I.

Low-Temperature group.—Specimens were 0.15 cm thick annealed beryllium-copper alloy (B-194) which were heat-treated to condition AT[1] by the following processes: Oxide-free substrates were produced by heat-treating at 300°C for 180 min in argon followed by acid cleaning in nitric, acetic phosphoric acid mixture (3*N*, 4*N*, 8*N*, respectively).

Approximately 0.2μ of oxide coating was produced by heating at 300°C for 175 min in argon and 5 min in air. Approximately 2μ of oxide coating was produced at 300°C for 180 min in air.

All heat-treated specimens were vapor degreased in trichloroethylene and rinsed in alcohol prior to plating.

Test Procedures

The relative adherence of the coatings was measured by means of a tensile test in which the film is deposited onto one side of a specimen (Fig. 2a). The measurement involves the observation of the strain required to produce adhesive failure between the film and substrate as in Fig. 2b. Since the maximum elongation which can be observed is associated with the rupture of the substrate, and the ductility of the beryllium-copper increases as a result of increased thermal input from the discharge, the strain to adhesive failure reported is normalized to cohesive substrate failure. Substrate failure without film failure occurs as in Fig. 2c.

Coincidentally, the effects of bombardment on the condition of the beryllium-copper substrate were also observed. These are reported as Knoop hardness of the beryllium-copper as a function of bombardment time. The values obtained are shown in Fig. 3 and are the average of five indention hardness measurements taken on transverse sections of the coated specimens.

From these hardness data, an estimate of the bulk substrate temperature obtained during plating can be made. The extent of overaging shown, *i.e.*, δ phase precipitate growth, indicates a temperature of approximately 150°-200°C (over the range of bombardment times indicated).

Film thicknesses were measured using beta backscatter techniques except where alloy coatings invalidated such measurements. In those cases, optical metallography supplemented the measurement.

For porosity estimates, films were exposed to moist hydrogen sulfide and the number of spots of copper sulfide visible in 1 cm^2 (under 75X magnification) was reported as a relative porosity measure.

[1] Solution treated, quenched, and precipitation hardened (2).

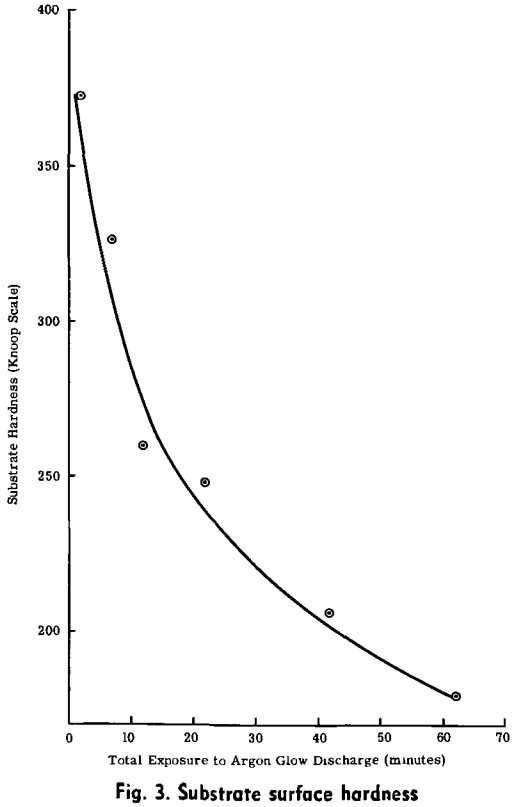

Fig. 3. Substrate surface hardness

Results

The results of the adherence investigations for ion plated samples are shown in Fig. 4 and presented as normalized strain *vs.* the energy dissipated in the glow discharge. It can be seen from Fig. 4 that only on the heavily oxidized surfaces is there any dependence of adherence on bombardment time or energy input within the ranges explored. One might expect a correlation to exist between the energy input required to produce the maximum measurable adherence and the amount of oxide present on the surface in terms of the dissociation and sputtering of copper oxide. It is true that the energy expended during a 20-min ion bombardment is the correct order of magnitude to sputter the quantity of oxide present; however, subsequent metallography on transverse sections indicates that the oxide is still present but broken up into islands in the interfacial region. The areas between these copper oxide islands are characterized by a sharp gold-copper interface.

In the low-temperature group (adhesion experiment), no alloying or diffusion was detectable across the gold copper interface even though the bulk temperature reached approximately 150°-200°C. Analysis of the gold films stripped from the substrate indicated substantially <1% Cu content. Porosity experiments were carried out on both the low- and high-temperature groups and are presented in Table I and II. The data for the ion plated samples in the low temperature group may be represented by the expression

$$PT^n = K \qquad [1]$$

where P is the pore count per unit area and T is the film thickness. The determined values of n and K are 1.3 and 1.2 x 10^{-3}, respectively, and agree well with

the earlier work of Frant (3) for electroplated gold deposition. It should be noted, however, that the electroplated and evaporated films show increased porosity with oxide film thickness, *i.e.*, while K is 6.3×10^{-4} for oxide-free specimens, K increases to 1.9×10^{-3} for 0.2μ oxide and 4.4×10^{-3} for 2μ oxide.

The striking absence of detectable porosity in the high-temperature group is attributed to the lack of a heat sink, and, therefore, temperature increases occur during ion bombardment which are significantly greater than reported for the low temperature group. Included also in Table II is the analysis of the stripped coating as obtained by x-ray absorption and gravimetric techniques. Such analysis are obviously averages over the bulk of the film and were supplemented by surface composition measurements using the electron microprobe. It is striking that these surface compositions are ~54 a/o (atomic per cent) gold. These results are consistent with the bulk analysis (~45 a/o, ~70 w/o gold) reported above and with the distribution of gold and copper in a typical specimen as shown in Fig. 5. This distribution curve was also obtained by the electron microprobe. In addition, x-ray diffraction analysis indicate that the films are a continuous series of solid solutions of gold-copper.

A set of independent experiments were conducted on these specimens (high-temperature group) to determine the effective bulk substrate temperature the beryllium-copper alloy had experienced. Beginning with the substrate in the AT condition and investigating the decrease in hardness indicated a bulk temperature of approximately 400°C. Comparable temperatures were indicated by the rate of hardness increase of annealed beryllium-copper with ion bombardment time.

Discussion

The absence of porosity can be directly attributed to the formation of the gold-copper solid solution which has been demonstrated to be unreactive to a corrosive atmosphere (4); however, the more interesting phenomena which will require interpretation is the mechanism of formation of the alloy coatings. Two principal experimental results require explanation: (*i*) the existence of a constant surface composition in the alloy film, and (*ii*) an apparent diffusion constant for copper and beryllium into the film which is orders of magnitude above the rate calculable from the indicated bulk temperature of the substrate.

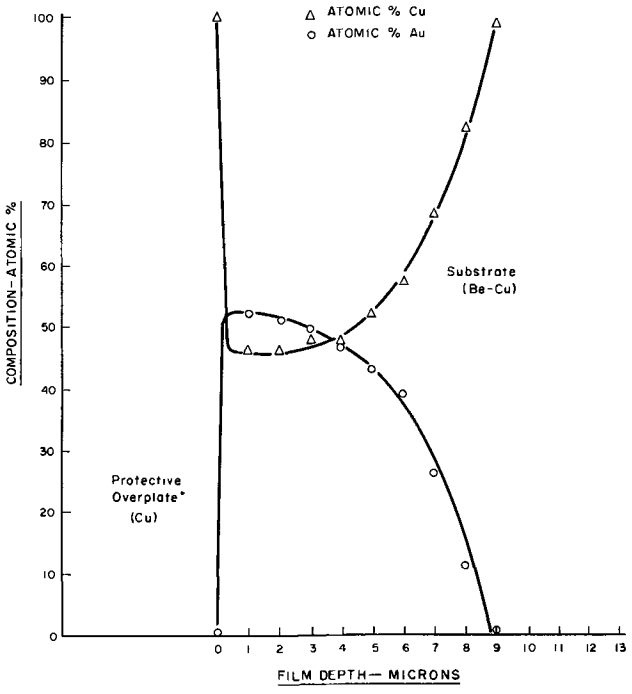

Fig. 5. Copper-gold interfacial distribution

The existence of a constant surface composition alloy film is the result of the fact that the sputtering yield of this gold-copper solid solution is 0.4 that of pure gold and the continued ion bombardment during the deposition would sputter the pure copper and gold phases at rates considerably greater than the solid solution formed by diffusion. The reduced sputtering yield of the minimum melting temperature

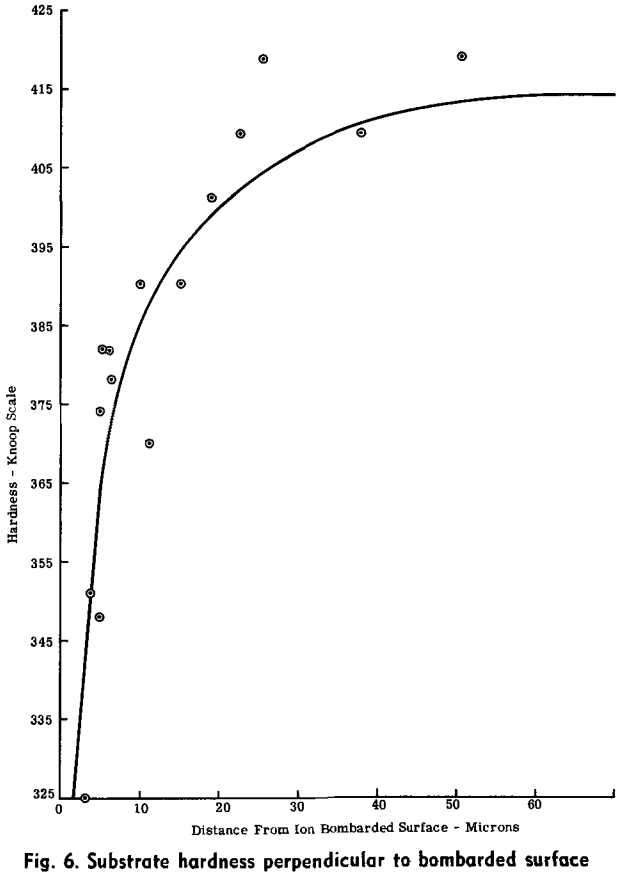

Fig. 6. Substrate hardness perpendicular to bombarded surface

solid solution is consistent with the work tabulated by Wise (5).

The formation of the minimum melting temperature solid solution requires the diffusion of copper into the gold film at rates comparable to the deposition rate of the gold onto the substrate surface. This observation allows an estimate of the diffusion rate of copper into the gold of about 2×10^{-8} cm^2/sec. This value is comparable to the equilibrium diffusion rate at temperatures of 750°C and is obviously in disagreement with a maximum bulk temperature of 400°C.

The picture is further complicated by the lesser diffusion of gold into the substrate as shown by Fig. 5 as well as etched metallographic specimens which indicate a sharp interfacial boundary between the solid solution and the substrate.

These contradictory observations can be rationalized by the existence of an extremely sharp temperature gradient near the surface undergoing bombardment. Such a gradient has been indirectly observed in the overaging of the surface layers of AT condition beryllium-copper and is illustrated in Fig. 6 as the microhardness variation with depth. Electron microscopy of these same specimens also verifies the fact that the thermal history of the surface regions ($<0.5\mu$ depth) differs drastically from that of the bulk material. The model thus generated provides that gold is deposited on a sufficiently hot surface to permit copper diffusion outward at a rate which allows the formation of a solid solution consistent with the deposition rate. The counter diffusion of gold into the substrate material also occurs, but encounters a rapidly decreasing temperature gradient and produces a sharp interface (sharp in terms of the electron microprobe resolution of 1μ). Excess gold or copper in the region of the free surface would be removed by the increased sputtering yields of these elements.

Implicit in this model is the conclusion that as the thickness of the alloy coating is increased the temperature of the interface will decrease until the copper diffusion rate can no longer support a constant film composition at the free surfaces. In these experiments this limit has not been reached at coating thicknesses of 10μ. This is apparently the result of the relatively low thermal conductivity of the beryllium-copper (0.25). Comparable experiments with a pure copper substrate (thermal conductivity 0.91) produce copper concentration gradients in the film at a thickness of $>5\mu$.

Conclusions

The adherence of gold deposited by ion plating onto beryllium-copper is relatively independent of surface contamination. Only in the case where gross oxidation exists, is adherence dependent on removal of the surface contamination layer.

Low porosity gold alloy films at coating thicknesses of less than 2μ result when the deposition parameters permit a sufficiently high interfacial temperature to allow copper to diffuse into the coating.

A model is presented to explain a constant composition alloy formed in terms of its sputtering yield and a sharp thermal gradient near the substrate surface.

Investigations of Electrocrystallization at Silver Electrodes

W. Michael Krebs[1] and David K. Roe

Department of Chemistry and Laboratory for Nuclear Science,

Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Electrochemical studies have been carried out on silver single crystals using a probe technique which permitted areas from 1 to 30 x 10^{-4} cm^2 to be investigated. Electrolytes were composed of acidified silver perchlorate at constant ionic strength. Cyclic current-voltage curves, involving quantities of silver corresponding to 0.3-15 atom layers, clearly revealed the greater reactivity of freshly deposited silver compared to the substrate. Deposition did not proceed in a layer-like fashion, but rather gave rise to hemispherically shaped deposits. The phenomena associated with the anodic and cathodic processes under linear voltage scan and potentiostatic conditions were analyzed successfully in terms of changes in the total deposit (active) area.

Current measurements are sufficiently sensitive to permit detecting the deposition or dissolution of the equivalent of considerably less than a monolayer of metal. When the electrode on which deposition and dissolution occurs is more noble than the deposit, a problem arises concerning the properties of the electrode system: trace metal/metal ion. Hertzfeld (1) first considered the possibility of variations in the thermodynamic activity of a metal which only partially covers an inert electrode. He proposed that the applicability of the Nernst equation could be extended to partial monolayers by equating the activity term to the degree of coverage.

In some contrast with this model are the findings of Haissinsky (2) who employed radiographic analysis to elucidate the nature of deposition onto an inert (*e.g.*, platinum) electrode. The nonuniform distribution of metal found immediately suggested that the electrode surface was heterogeneous and a controlling factor.

Byrne and Rogers (3) have considered some of the thermodynamic aspects of fractional monolayer and trace deposition. Four ideal cases were described which considered both the distribution and population of

[1] Present address: Tyco Laboratories, Inc., Waltham, Massachusetts.

energetically favorable sites on the electrode and the relative energy differences for deposition onto the inert substrate and deposition onto existing deposits.

In three of these cases, a varying number of sites on the inert electrode is energetically more favorable for deposition than on the metal of interest. As a result, monolayer coverage can occur depending on the density of such sites. The phenomenon of "undervoltage" is associated with these three cases.

In the fourth case, however, deposition onto the metal itself is sufficiently more favorable to require nucleation as a prerequisite for deposition. Large overvoltages will be a characteristic of this process.

It must be added that situations similar to the above could exist even when the electrode and deposit are of the same metal. The number and type of growth sites would be important in determining the deposition characteristics, but at lower overvoltages than for inert electrodes. Furthermore large "undervoltages" are precluded.

Berzins and Delahay (4), in their theoretical treatment of the reversible deposition of an insoluble substance, recognized the possibility of activity changes during the early stages of deposition preceding complete coverage, but neglected this complication. Nicholson (5), using the same assumptions and approach, derived the corresponding anodic stripping equation. The sudden drop to zero predicted for the anodic current by the equation was contrary to the more gradual decrease and tailing found experimentally. In an attempt to treat the anodic stripping of monolayer quantities of deposit, Nicholson assumed monolayer deposition, with the activity proportional to the fractional coverage. Good agreement for silver on platinum was followed by much poorer agreement in the case of copper and lead.

Alternate conditions which would be in accord with the general characteristics of anodic stripping curves include (*i*) alloying of the deposited metal with the substrate, and (*ii*) changes in the total active (deposit) area.

The first condition is of limited applicability in the cases of interest for solid state diffusion is not suggested by experiment, although it could result in tailing of the type observed.

The second alternative is based, in part, on the observations of Haissinsky (2) and Vahramian (6) and is consistent with the observations of Kaischew *et al.* on the nucleation of silver (7) and mercury (8) on platinum cathodes. Vahramian explained the startling lack of agreement among the polarization curves which had been obtained for silver by noting that current densities were meaningful only if expressed in terms of the active electrode area. This latter quantity was not equal to the electrode area, and moreover increased during deposition.

Thus, in cases where deposition commences at active sites, which subsequently grow, profound changes in active area will occur even when the quantities involved lie in the monolayer range.

In the work to be described, the unusual nature of the current-potential and current time curves associated with the deposition and stripping of mono- and polylayer equivalents of silver on a silver substrate was analyzed and found to be attributable to the changes occurring in the deposit area. The greater reactivity of the freshly deposited silver permitted the separation of the deposit and substrate contribution during stripping. Previous observations (10,11) have shown that freshly deposited metals often are more "active" than the substrate and that activity changes with time (12). This topic and many others have been reviewed and discussed recently (13).

Experimental

Single crystal rods of silver 2 x 20 mm were grown from 99.99 + % pure silver wire by a modified Bridgeman method. The single crystal spheres were prepared from these rods using a modification of the fusion technique described by Roe and Gerischer (9). This involved melting one end of the mounted rod in a purified hydrogen atmosphere to form a clinging, molten droplet which, when allowed to freeze slowly, resulted in a single crystal sphere. The (111) facets which formed on the surface of the sphere were quite insensitive to induced vibration during the freezing process even when the perturbation was severe enough to cause rippling in the surrounding surface.

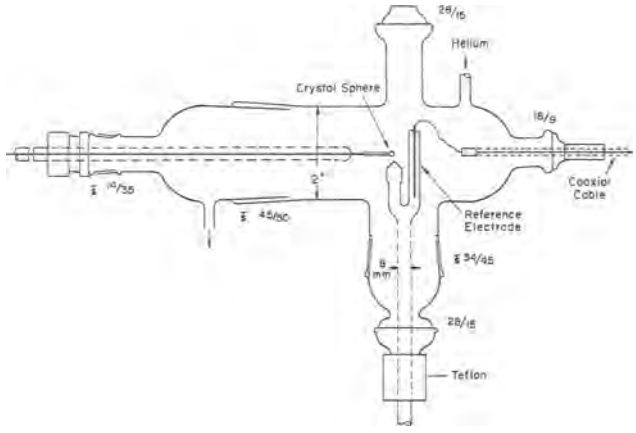

Fig. 1. Electrochemical cell

After cooling, the crystal was withdrawn into the ground glass joint and transferred to the electrochemical cell which is seen in Fig. 1. This operation was carried out with a rapid flow of gas through the joint assembly to prevent the electrode from contacting the air.

The atmosphere in the cell was helium which had been purified, deoxygenated, and humidified by passage through Anhydrone, activated charcoal, 13X Linde molecular sieves at −200°C, and finally, 0.1*N* silver perchlorate.

The probe assembly seen at the bottom of the cell contained the electrolyte and counter reference electrode. The probe tip had a small orifice to permit the formation and maintenance of a narrow column of electrolyte between the bulk electrolyte contained within the probe and the selected area on the crystal sphere. The diameter of the column was determined by that of the tip orifice. Both Teflon and silver cones were employed as tips, the latter serving also as the counter reference electrode. When utilizing Teflon cones, a length of pure polycrystalline silver wire having a geometric area of at least 1 cm^2 was used.

There are several distinct advantages to using a probe technique rather than attempting to mask off areas. Not only is the danger of contamination from the masking agent eliminated, but also the electrode area/electrolyte volume ratio is several orders of magnitude more favorable, resulting in a corresponding decrease in the danger of contamination. For the arrangement used, this ratio was at least a 2500 times that for a 1 cm^2 electrode in 50 ml of electrolyte.

The electrolyte column was formed by positioning the tip to within 0.3 mm of the crystal area and tapping the base of the probe. This operation was facilitated by the use of a binocular microscope. Electrolyte contact areas on the crystal were calculated from the diameter of the electrolyte column which was measured via a calibrated micrometer eyepiece. These areas usually ranged between 1×10^{-4} to 3×10^{-3} cm^2. An a-c bridge was used to measure the cell resistance.

The electrolyte was silver perchlorate and perchloric acid. The former was prepared from reagent grade silver nitrate, sodium hydroxide, and perchloric acid by the repeated precipitation and dissolution of silver hydroxide. The first 5-10% of the precipitate was discarded each time. After standardization of the final

solution of silver perchlorate, solutions 0.005, 0.099, and 0.05M in silver ion were made up, sufficient perchloric acid being added to bring the ionic strength to 0.1.

All water was doubly distilled from quartz. The final step in cleaning the glassware and cell parts was simmering in perchloric-nitric acids for several hours.

A system utilizing three G. A. Philbrick UPA-2 chopper stabilized operational amplifiers provided the linear voltage scans and current amplification. A Keithley Model 610A electrometer was employed to monitor the cell voltage and activate one axis of a Houston Model 100 X-Y plotter. Current-time variations were followed on a Varian Model G-11 strip chart recorder.

Following the completion of a series of measurements on an electrode, it was etched in hot dilute nitric acid, rinsed well, then remelted to form a new crystal sphere.

Results

The (111) facets which formed on the spherical crystals were roughly triangular in shape, and *ca.* 150 x 100μ. Surrounding each facet were a series of descending concentric steps as can be seen in Fig. 2a and 2b. The height and width of the steps varied over a wide range, averaging 2μ and 10μ, respectively. No microsteps or irregularities were visible on the surface of the steps at a magnification of 1000X.

The measurements to be described were all performed on these step regions. The electrochemical behavior of the (111) facets alone will be reported in a future communication.

Following cathodic and anodic polarizations, representative electrodes were examined microscopically in order to determine the mode of deposition and dissolution. Micrographs, such as in Fig. 3a, showed that deposition had commenced mainly at the edges of the steps. More extensive deposition led to the mound or hemispherically shaped deposits seen in Fig. 3b. In this case, the steps have been all but obliterated by the deposits. In a similar manner anodic attack also commenced at the step edges.

Cyclic current voltage curves were obtained on the steps utilizing scan rates between 0.05 and 1.0 mv/sec.

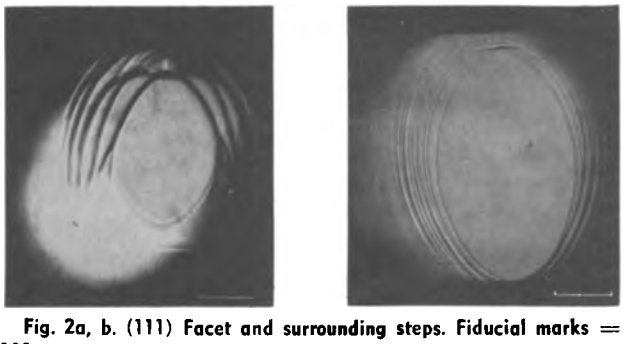

Fig. 2a, b. (111) Facet and surrounding steps. Fiducial marks = 100μ.

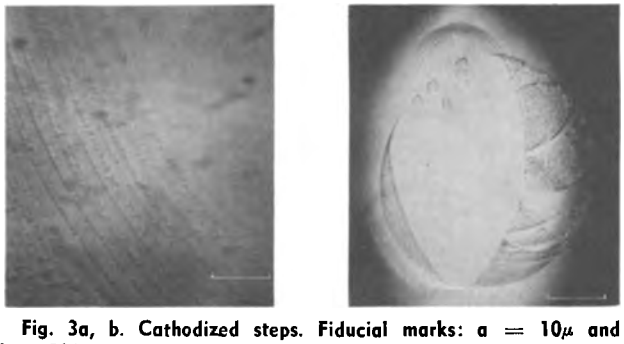

Fig. 3a, b. Cathodized steps. Fiducial marks: a = 10μ and b = 100μ.

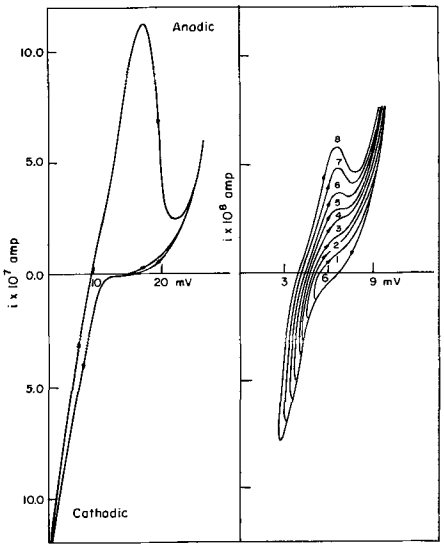

Fig. 4. Cyclic current-potential curves. [Ag^+]:0.05 m/l. Scan rate: 0.57 mv/sec (L); 0.15 mv/sec (R). Electrolyte contact area: 2.3 x 10^{-3} cm^2 (L); 2.5 x 10^{-3} cm^2 (R).

In all cases, the scans were started from the rest potential, the first usually being in the anodic direction. In order to avoid significant IR drops, and to keep the quantity of deposit to between 0.3 and 15 atom layers, the scans were usually restricted to ± 30 mv of the rest potential.

Most of the cyclic current-potential curves obtained showed some degree of hysteresis which, in extreme cases, appeared as a distinct anodic peak similar to that in Fig. 4a.

Throughout this section, the following terms will be used and are defined as follows.

The initial anodic scan is the anodic current-potential curve obtained on deposit-free steps.

The return anodic scan is the anodic current-potential curve obtained immediately following deposition.

The junction point is that point where the return anodic scan joined and followed the initial anodic scan.

The consistent lack of hysteresis in cyclic scans restricted to the anodic region clearly demonstrated that the deposited silver was responsible for the hysteresis in return anodic scans. The proportionality existing between the quantity deposited and degree of resulting hysteresis was established by running a series of cyclic scans involving progressively greater amounts of deposit. Such a series is to be seen in Fig. 4b.

The quantitative nature of this dependence was established on integrating both the cathodic scans and subsequent anodic peaks. In an attempt to correct for the simultaneous removal of substrate silver, the initial anodic scan was subtracted from the anodic peak in each case. The agreement between the two quantities, of 95%, represents the average of twenty determinations involving a variety of scan rates, silver ion concentrations, and electrodes.

It was not unexpected that the return anodic scans were strongly time dependent in the region up to the junction point. Holding the potential in this region resulted in an exponential-type decay in the current to a value close to that of the initial anodic scan at that potential. Beyond the junction point, both the initial and return anodic scans exhibited only a slight time dependence, which appeared as a very slow increase in the current when the scan was halted. An additional characteristic of the junction point was that the entire current potential curve could usually be reproduced after, but not before, it had been passed.

The anodic behavior of the cathodized steps was investigated potentiostatically by depositing a determinable quantity of silver via a linear voltage scan,

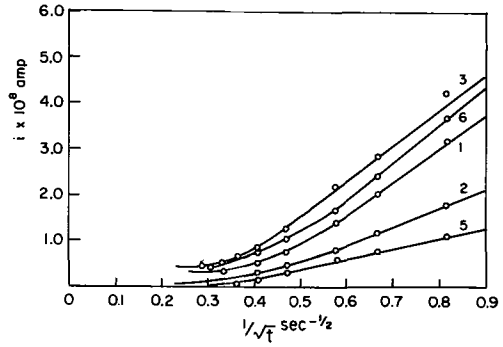

Fig. 5. Potentiostatic stripping of deposit. $[Ag^+] = 0.05$ m/l. Electrolyte contact area: 1.5×10^{-4} cm².

Curve	Anodic overvoltage, mv	Amount of deposit, μ coulomb	Quantity removed, μ coulomb
1	4.5	0.143	0.142
2	3.3	0.155	0.084
3	7.5	0.128	0.207
5	4.0	0.145	0.041
6	7.5	0.135	0.196

adjusting the applied voltage to an anodic value with the cell out of circuit, then recording the current-time variations after switching the cell into circuit. A preliminary current-potential curve was run on all electrodes as a check for satisfactory stripping behavior and to determine the initial anodic scan for purposes of correcting for the substrate contribution. The anodic overvoltage is defined as the difference between the open circuit potential immediately following deposition and the stripping potential.

In anticipation of diffusion control, the current-time data were replotted in the form i *vs.* $1/\sqrt{t}$. A typical series of plots obtained on one electrode can be seen in Fig. 5. The curves showed initial linearity which when extrapolated intersected the $1/\sqrt{t}$ axis, as is expected for the complete removal of a labile deposit. Depending on the stripping potential with respect to the preliminary initial anodic scan, the plots either intersected the time axis or levelled off to a steady state. The latter situation occurred when the stripping potential lay within the initial anodic scan, signifying the simultaneous removal of substrate silver.

The effect of decreasing the silver ion concentration was to increase the over-all linearity of the plots. All the other features remained the same. It is interesting to note that the degree of removal of the deposited silver was not normally quantitative under potentiostatic conditions, but was strongly dependent on the anodic overvoltage.

The deposition process was also investigated under potentiostatic conditions. Preliminary current-voltage curves were obtained on all electrodes in order to insure that the silver deposited during a series of cathodizations could be stripped off after each, thus minimizing history effects which would have otherwise resulted due to the accumulation of deposit.

Again, in anticipation of diffusion control, the data were plotted in the form i *vs.* $1\sqrt{t}$. Although similar to the anodic stripping plots, these differed in that the extrapolated initial linear portions intersected the current axis, and, in several instances, the current increased after having leveled off. In Fig. 6 is shown a typical series of plots obtained on one electrode.

Discussion

The near quantitative agreement between the amount of silver deposited and the amount represented by the subsequent anodic peak, in conjunction with the cathodic position of this peak relative to the initial anodic scan, was interpreted to mean that the deposited silver was more reactive than the substrate.

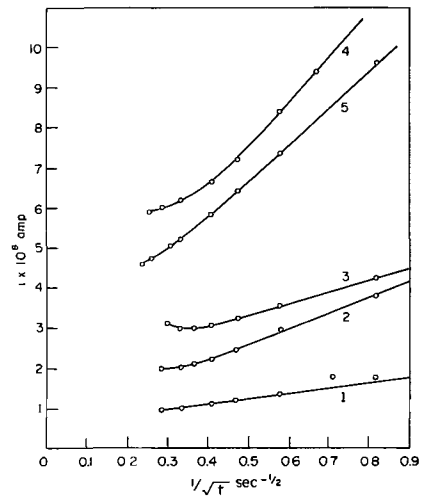

Fig. 6. Potentiostatic deposition on one electrode. $[Ag^+] = 0.05$ m/l. Electrolyte contact area $= 1.9 \times 10^{-4}$ cm².

No.	Quantity deposited, μ coulomb	Cathodic overvoltage, mv
1	0.15	2.1
2	0.40	3.9
3	0.36	5.1
4	1.65	6.6
5	1.37	5.1

It is interesting to note, in this connection, that a similar observation concerning the greater reactivity of freshly deposited silver at silver cathodes has been reported by Mamantov (10).

In spite of the over-all variability found in the current potential curves obtained on different electrodes, and even on different portions of the same electrode, the fact that the behavior of specific areas could be reproduced on returning to them strongly suggests that the source of the variability existed in the electrode surface itself, *i.e.*, type and density of growth sites, and was not due to some external factors.

Despite the fact that the system was not the optimum for stripping analysis studies, it did have the advantage that deposition occurred in a fairly regular pattern yielding deposits whose shape could be closely approximated by hemispheres.

Insofar as the quantities of silver involved ranged below a monolayer, and the substrate could be considered inert, the situation was analogous to that treated by Nicholson (5). However, since there was no question that the deposit area changed greatly during the course of deposition and stripping, it appeared more than likely that the electrochemical phenomena accompanying the above processes reflected these area changes. The model chosen was that of a polyelectrode of changing area.

In the derivations of the equations for the reversible stripping under potentiostatic and linear scan conditions which are presented in Appendix 1, it was necessary to make several assumptions either because of a lack of the necessary information or to maintain the simplicity of approach.

(*i*) All deposits were assumed hemispherical and of equal size.

(*ii*) The activity of the deposits was constant. The observed dependance of the stripping efficiency on the anodic overvoltage under potentiostatic conditions does, however, imply variations in the reactivity of the deposits. Since the source of such a variation is not know, no provision for it has been made in the derivation.

(*iii*) The electrolyte is considered to be completely homogeneous at the start of the stripping. This is not strictly true since stripping immediately followed

deposition. However, the reproducibility of multiple cyclic scans and the small quantities of silver involved relative to the amount present in the electrolyte column alone, indicated that any compositional inhomogeneities at the electrode surface were of minor importance.

(*iv*) Conditions for semi-infinite linear diffusion existed. A calculation of the integral thickness of the Nernst diffusion layer for the worst case yielded a value considerably less than the average length of the electrolyte column.

Diffusion to a single hemisphere is, of course, hemispherical rather than linear. In a situation such as the present, involving many hemispheres, the linear approximation will improve as the degree of overlap of the individual diffusion layers increases. From the quantity of deposit and number of deposits used in the calculations, the distance between deposits was calculated, assuming uniform size and distribution. This distance was of the order of one deposit radius. Thus for low scan rates, the linear approximation probably was not too bad. In any event, the complexity of the nonlinear diffusion equations associated with hemispherical diffusion also prompted the approximate treatment.

(*v*) It was assumed that true potential control exists. Although the IR drop was considerable in some cases due to the high cell resistance, only those data have been analyzed in which the maximum IR drop was under 0.5 mv.

It should be added that no provision has been made for simultaneous substrate removal during stripping. Any contribution was subtracted from the experimental curves before comparing them with those calculated.

The derived equation for the linear scan stripping of silver is

$$i = -3\mathbf{F}\gamma C^{\circ} N^{1/3} (\beta D)^{1/2} G\{\beta t\}$$

$$X \left\{ Qc^{1/3} - \frac{\mathbf{F}\gamma C^{\circ} N^{1/3} D^{1/2}}{\beta^{1/2}} \left[G\{\beta t\} - \frac{2(\beta t)^{1/2}}{\pi^{1/2}} \right] \right\}^2 \quad [1]$$

where

$$G\{\beta t\} = \exp(\beta t)\ \mathrm{erf}\ [(\beta t)^{1/2}]$$

$$\gamma = 2\pi \left(\frac{3M}{2\pi} \right)^{2/3}$$

$$M = \frac{\text{at. wt}}{\mathbf{F}\delta}$$

Qc = quantity of deposit at $t = 0$

N, the number of hemispheres, is the only adjustable parameter in the equation. The resemblance between this equation and the anodic form of Berzins and Delahay's Eq. [5] becomes apparent if one notes that the squared quantity within the major parenthesis is proportional to the total deposit or active electrode area. At low scan rates (*ca.* 1 mv/sec) the calculated plots tend to rise fast and decay more slowly whereas the reverse is true at faster scan rates (*ca.* 30 mv/sec). At the scan rates employed experimentally, increasing N for a given Qc tended to sharpen the peaks. In making the experimental-calculated comparisons, the value of N chosen was that required for the best fit. Four typical comparisons can be seen in Fig. 7.

The derivation for the potentiostatic case was similar (Appendix 1) yielding the following equation

$$i = -\frac{3\mathbf{F}D^{1/2}\gamma N^{1/3} C^{\circ}[\exp(\phi\eta) - 1]}{(\pi t)^{1/2}} \quad [2]$$

$$X \left\{ Qc^{1/3} - \frac{2\mathbf{F}D^{1/2}\gamma N^{1/3} C^{\circ}[\exp(\phi\eta) - 1] t^{1/2}}{\pi^{1/2}} \right\}^2$$

where γ and Qc are defined as before.

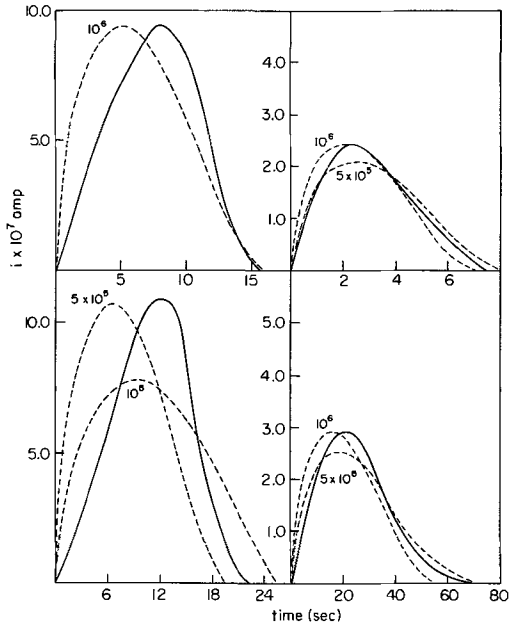

Fig. 7. Comparisons of experimental and calculated curves for the linear scan stripping of deposit. Calculated curves:— Value of N used indicated.

Plot	Amount of deposit, μ coulomb	Scan rate, mv/sec	Electrolyte contact area, cm^2	[Ag$^+$], m/l
Top L	9.0	0.57	3.0×10^{-3}	0.05
Top R	1.01	1.0	3.0×10^{-3}	0.05
Bottom L	12.9	0.57	2.2×10^{-3}	0.05
Bottom R	9.23	0.10	3.0×10^{-3}	0.05

N was again the only adjustable parameter and the squared quantity within the major parenthesis was proportional to the total deposit area. The calculated i *vs.* $1/\sqrt{t}$ plots were strikingly similar to the experimental curves showing initial linearity which gave way to curvature at longer times, followed by intersection of the time axis.

Decreasing the concentration of the electro-active species served to increase the over-all linearity of the plots, as had been observed experimentally. Before comparing the experimental and calculated curves, the substrate contribution was accounted for, when necessary, by subtracting the steady state current value from the curves. The amount of silver remaining was used for Qc. N was chosen on the basis of best fit. Three typical comparisons can be seen in Fig. 8.

The mathematical treatment of the corresponding cathodic case for either linear scan or potentiostatic conditions proved to be far more complex than for the anodic stripping case. Consequently, a finite difference method had to be adopted. The Cottrell equation and the Berzins and Delahay equation (4) were employed after first substituting for the constant area term a time dependent expression. The two modified equations are

$$i(t + \Delta t) = \frac{\mathbf{F}A(t)D^{1/2} C^{\circ}}{(\pi t)^{1/2}} [1 - \exp(-\phi\eta)] \quad [3]$$

for the potentiostatic case, and

$$i(t + \Delta t) = \frac{2}{\pi^{1/2}} \left(\frac{n\mathbf{F}}{RT} \right)^{1/2} n\mathbf{F}C^{\circ} D^{1/2} \gamma^{1/2} A(t) Y[(\beta t)^{1/2}] \quad [4]$$

for linear scan deposition.

Where

$$A(t) = 2\pi \left[\frac{3MQ(t)}{2\pi\mathbf{F}\delta} \right]^{2/3}$$

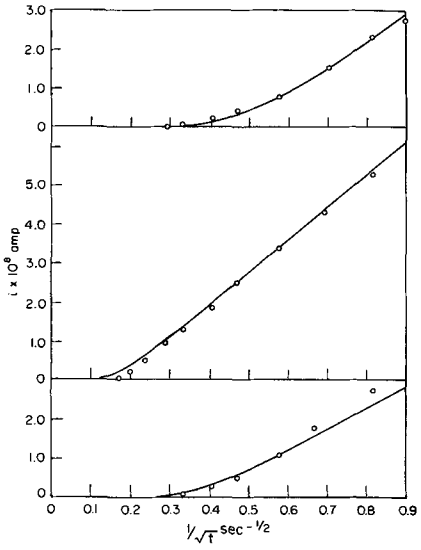

Fig. 8. Comparisons of experimental and calculated curves for the potentiostatic stripping of deposit. Experimental points: ○.

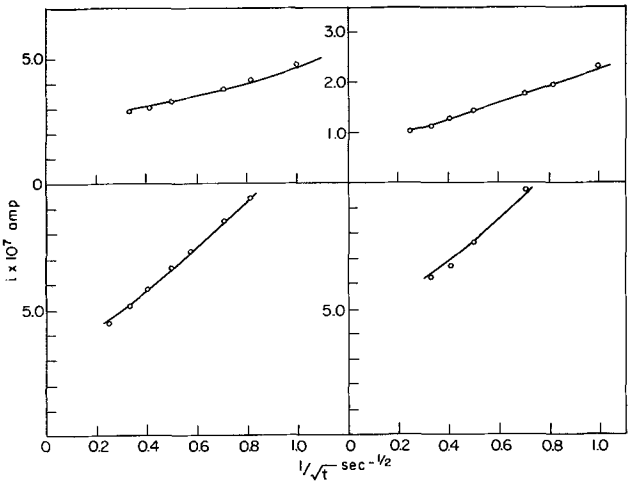

Fig. 9. Comparisons of experimental and calculated curves for a series of potentiostatic depositions. Experimental points: ○ Electrolyte contact area = 1.2 x 10^{-3} cm^2.

Plot	Amount of deposit, μ coulomb	Anodic overvoltage, mv	N	[Ag^+], m/l
Top	0.159	5.0	10^5	0.05
Middle	0.544	10.0	10^6	0.005
Bottom	0.157	5.0	5 x 10^4	0.05

$$Q(t) = Qi + \Delta t \sum_{n=0}^{n} i(0.005 + n\,\Delta t)$$

and

$$Y[(\beta t)^{1/2}] = \exp(-\beta t) \int_0^{(\beta t)^{1/2}} \frac{\exp(z)\,dz}{z^{1/2}}$$

$$t = 0.005 + n\,\Delta t \text{ sec}$$

The treatment contains all the assumptions present in the derivation of the original equation, *i.e.* semi-infinite linear diffusion, constant deposit activity, plus a hemispherical shape for the deposits. The equations were set up for a single deposit.

Because this type of calculation has to be started at some time greater than $t = 0$, this was chosen to be 0.005 sec at which time the deposit contains Qi coulomb of silver. Consequently, several values of Qi were used in each series of calculations. The time interval chosen was 0.01 sec. As can be seen from the equations, the area used in calculating the current at time t + 0.01 sec is that based on the amount of silver deposited up to time t.

Due to the lengthy, repetitive nature of the computations the procedure was programmed for an IBM 7044 computer.

In comparing the experimental curves with those calculated, the value of Qi chosen for the latter was based on the best curve shape. The value of N used was chosen to give the correct current range. Qi and N were not completely independent parameters.

In general, a larger value of Qi was required in the potentiostatic case than for linear scan deposition. This was expected since at the low sweep rates used, more silver had been deposited during the first 0.005 sec under potentiostatic conditions. Through the equation relating the area at any time with the quantity of silver, the active electrode area can be calculated and compared with the total area contacted by electrolyte. For a typical case involving an electrolyte contact area of 10^{-3} cm^2, one microcoulomb of deposit, and

Plot	Cathodic overvoltage, mv	Q_i coulomb	N
Top L	5.1	10^{-13}	9 x 10^5
Top R	3.0	10^{-13}	8 x 10^5
Bottom L	5.1	10^{-12}	5.5 x 10^5
Bottom R	7.0	10^{-12}	4.2 x 10^5

10^6 sites the deposit area would be *ca.* 8 x 10^{-5} cm^2 which is 8% of the total area.

The shape of the calculated i *vs.* $1/\sqrt{t}$ plots agreed very well with the experimental curves. Under proper conditions, the calculated current increased after having decreased as had been noted experimentally. It is interesting to note that in comparing a series of potentiostatic depositions carried out on the same electrode, the value of Qi required for best fit tended to increase, indicating that some deposited silver remained after the anodic stripping which followed each cathodization. A typical set of comparisons is presented in Fig. 9.

Similar agreement was found for the linear scan deposition of silver. A series of comparisons can be seen in Fig. 10.

It is of interest to speculate on the possible reason for the greater lability of the freshly deposited silver. In this regard it should be noted that the deposits on the steps were not well defined, as were those formed on the facets, but rather were mound-like. The degree of removal of the deposited silver, via linear voltage scan, could be reduced by 10-20% by holding the cell at open circuit for 5-10 min before stripping. Furthermore, the epitaxial deposits formed on the (111) facet (see Fig. 3b) were not preferentially removed under conditions of anodic polarization, nor did they yield the characteristic stripping behavior of the stepped regions. These observations suggest that the greater lability of the deposits on the steps is crystallographic in origin but there is no direct information as to why there is a difference. Possible reasons are differences in growth sites (dislocations) or differences in the (apparently) major deposition mechanism. The decreased stripping efficiency with time is readily interpreted as due to a recrystallization process. This process arises through the exchange current with silver ions as well as by surface migration of atoms; the former path is considered to be more probable in this case because of the high value of the exchange current, although strong evidence (12) has been collected for surface diffusion in the case of copper electrodes.

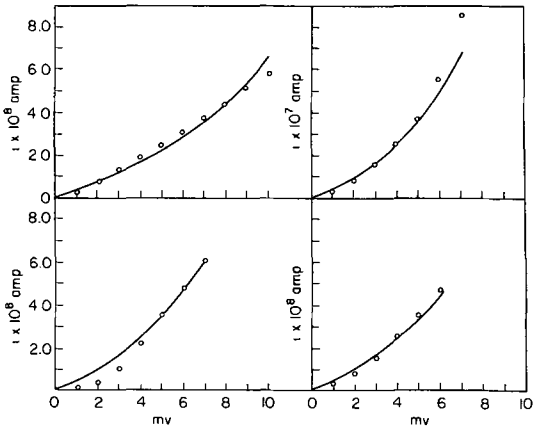

Fig. 10. Comparisons of experimental and calculated curves for linear scan deposition. Experimental points: ○ $[Ag^+] = 0.05$ m/l.

Plot	Scan rate, mv/sec	Electrolyte contact area, cm^2	Q_i coulomb	N
Top L	0.572	3×10^{-4}	10^{-13}	3.5×10^5
Top R	0.572	• 3.7×10^{-3}	10^{-14}	1.3×10^7
Bottom L	1.0	1.0×10^{-4}	10^{-14}	1.3×10^6
Bottom R	1.0	1.0×10^{-4}	10^{-14}	1.2×10^6

Conclusions

Confirmation of Mamantov's (10) observation regarding the greater reactivity of freshly deposited silver has been obtained. Of far greater importance is the fact that the phenomena associated with the deposition and stripping of the equivalent of sub- and polyatomic layers of silver on silver can be attributed to changes in the deposit area alone. The system used is particularly well suited to such a study because of the regular nature of the deposits formed. It would be of great interest to apply the model to the case of silver deposition and stripping at platinum electrodes.

APPENDIX 1

A. Derivation of Equations for Linear Scan Stripping

Solving Fick's Law for linear diffusion

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} \qquad [A\text{-}1]$$

using the following initial and boundary conditions

$$C(o,t) = C^\circ \exp(\beta t),\ C(x,o) = C^\circ,$$
$$\text{and } C(x,t) = C^\circ \quad x \to \infty$$

where

$$\beta = \frac{nFv}{RT}$$

results in

$$C(x,t) = \frac{C^\circ}{2}\exp(\beta t)\left\{\exp[x(\beta/D)^{1/2}]\left[\operatorname{erfc}\left[\frac{x}{2(Dt)^{1/2}} + (\beta t)^{1/2}\right]\right] + \exp[-x(\beta/D)^{1/2}]\left[\operatorname{erfc}\left[\frac{x}{2(Dt)^{1/2}} - (\beta t)^{1/2}\right]\right]\right\} + C^\circ \operatorname{erf}\left(\frac{x}{2(Dt)^{1/2}}\right) \qquad [A\text{-}2]$$

Differentiating [A-2] and setting $x = 0$ yields

$$\left(\frac{dC(x,t)}{dx}\right)_{x=0} = -\frac{C^\circ \beta^{1/2}}{D^{1/2}}\exp(\beta t)\operatorname{erf}[(\beta t)^{1/2}] \qquad [A\text{-}3]$$

The relationship between the flux at the electrode surface

$$\left(\frac{dC(x,t)}{dx}\right)_{x=0}$$

and the change in deposit area with quantity of silver as a function of time is derived as follows. All primed quantities refer to a single deposit.

For the Hemisphere Model

$$V'(t) = MQ'(t) = \frac{2\pi r'^3}{3}$$

where

$$M = \frac{\text{Atomic weight}}{F\rho}$$

$$A'(t) = 2\pi r'^2$$

Substituting and rearranging yields

$$A'(t) = 2\pi\left(\frac{3M}{2\pi}\right)^{2/3} Q'(t)^{2/3} \qquad [A\text{-}4]$$

For N deposits, [A-4] becomes

$$A(t) = NA'(t) = \gamma N^{1/3} Q(t)^{2/3} \qquad [A\text{-}5]$$

where

$$\gamma = 2\pi\left(\frac{3M}{2\pi}\right)^{2/3}$$

Since

$$D\left(\frac{dC(x,t)}{dx}\right)_{x=0} = \frac{d}{dt}\left(\frac{Q(t)}{FA(t)}\right) \qquad [A\text{-}6]$$

By substituting [A-5] into [A-6] and differentiating, one obtains

$$\left(\frac{dC(x,t)}{dx}\right)_{x=0} = \frac{Q(t)^{-2/3}}{3FD\gamma N^{1/3}}\frac{dQ}{dt} \qquad [A\text{-}7]$$

To obtain the current-voltage relationship for the hemisphere model, Eq. [A-3] is equated to [A-7] yielding

$$Q(t)^{-2/3}\,dQ = -3F D^{1/2}\gamma N^{1/3}\beta^{1/2}C^\circ \exp(\beta t)\operatorname{erf}[(\beta t)^{1/2}]dt \qquad [A\text{-}8]$$

Upon integrating both sides, from Qc at $t = 0$ to $Q(t)$ at $t = t$, the following equation is obtained

$$Q(t) = \left[Qc^{1/3} - FD^{1/2}\gamma N^{1/3} C^\circ \beta^{-1/2}\left\{\exp(\beta t)\operatorname{erf}[(\beta t)^{1/2}] - \frac{2(\beta t)^{1/2}}{\pi^{1/2}}\right\}\right]^3 \qquad [A\text{-}9]$$

where

Qc = the initial quantity of deposit present.

Noting that $i(t) = dQ(t)/dt$, Eq. [A-9] is differentiated with respect to time to give

$$i = -3\mathbf{F}\gamma C^\circ N^{1/3} (\beta D)^{1/2} \exp(\beta t) \operatorname{erf}[(\beta t)^{1/2}] \left\{ Qc^{1/3} - \mathbf{F}\gamma C^\circ N^{1/3} D^{1/2} \beta^{-1/2} \left[\exp(\beta t) \operatorname{erf}[(\beta t)^{1/2}] - \frac{2(\beta t)^{1/2}}{\pi^{1/2}} \right] \right\}^2 \quad [A\text{-}10]$$

B. Derivation of Equations for Potentiostatic Stripping

Solving Fick's law for linear diffusion [A-1] for the following boundary and initial conditions

$$C(o,t) = C^\circ \exp(\phi\eta), C(x,o) = C^\circ, \text{ and } C(x,t) = C^\circ \quad (x \to \infty)$$

one obtains

$$C(x,t) = C^\circ [\exp(\phi\eta) - 1] \operatorname{erfc}\left[\frac{x}{2(Dt)^{1/2}}\right] + C^\circ \quad [A\text{-}11]$$

Differentiating [A-11] with respect to x and setting $x = 0$

$$\left(\frac{dC(x,t)}{dx}\right)_{x=0} = \frac{C^\circ[1 - \exp(\phi\eta)]}{(\pi D t)^{1/2}} \quad [A\text{-}12]$$

The current-time relationship for the hemisphere model is obtained by equating [A-12] and [A-7] thus yielding

$$Q(t)^{-2/3}\, dQ = \frac{3\mathbf{F}\gamma D^{1/2} N^{1/3} C^\circ}{(\pi t)^{1/2}} [1 - \exp(\phi\eta)]\, dt \quad [A\text{-}13]$$

Integrating both sides of [A-13] from Qc at $t = 0$ to $Q(t)$ at $t = t$

$$Q(t) = \left[Qc^{1/3} - \frac{2\mathbf{F}D^{1/2}\gamma N^{1/3} C^\circ}{\pi^{1/2}} [\exp(\phi\eta) - 1]\, t^{1/2} \right]^3 \quad [A\text{-}14]$$

Differentiating [A-14] with respect to t yields the current

$$i = -\frac{3\mathbf{F}D^{1/2}\gamma N^{1/3} C^\circ}{(\pi t)^{1/2}} [\exp(\phi\eta) - 1] \left\{ Qc^{1/3} - \frac{2\mathbf{F}D^{1/2}\gamma N^{1/3} C^\circ}{\pi^{1/2}} [\exp(\phi\eta) - 1]\, t^{1/2} \right\}^2 \quad [A\text{-}15]$$

Appendix 2

List of Symbols Used

A	Area cm^2
C°	Bulk silver ion concentration moles/cm^3
D	Diffusion coefficient for silver ion taken as 1.6 x 10^{-5} cm^2/sec
$\mathbf{F}$	Faraday constant
M	Atomic weight of silver/$\mathbf{F}\rho = 10^{-4}$ cm^3/coulomb
N	Number of hemispheres
Qc	Quantity of silver deposit removed, coulomb
Qi	Quantity of silver in a single hemisphere at t = 0.005 sec
t	Time, sec
v	Scan rate volt/sec
β	$n\mathbf{F}v/RT$
γ	$2\pi(3M/2\pi)^{2/3}$
η	Overvoltage
ρ	Density g/cm^3
ϕ	$n\mathbf{F}/RT$

Hydrodimerization of Acrylonitrile

Y. Arad, M. Levy, I. R. Miller, and D. Vofsi

Plastics Research Laboratory, The Weizmann Institute of Science, Rehovoth, Israel

ABSTRACT

The reduction of acrylonitrile by electrolysis and by reaction with alkali metal amalgams was studied in acid and in neutral media. It was shown that the adiponitrile yield increases with the concentration of the acid. This was explained by assuming protonation of acrylonitrile by the acid, followed by interaction with the alkali metal and dimerization of the free radicals formed. In neutral media it was shown that tetraalkyl ammonium salts have a specific solvating effect on the reactants. Contrary to previous views it was proved that high adiponitrile yields can be obtained not only by electrolysis in the absence of alkali metal ions but also by reduction with alkali metal amalgams.

The hydrodimerization of acrylonitrile (AN) by direct electrolysis or by alkali metal amalgams has been the subject of many investigations, due to the importance of the hydrodimer, adiponitrile (ADN), as an intermediate in the manufacture of Nylon 66. The primary reactions of electron transfer and interaction of the anions or radical ions formed are of fundamental interest and are not yet well understood. Numerous patents have dealt with the reduction by alkali metal amalgams. Knunyants *et al.* (1) and Katchalsky *et al.* (2) have carried out the reaction in strongly acid media. They claim relatively high yields of ADN together with minor quantities of propionitrile (PN). The disadvantage of the method is that a large portion of the alkali metal is wasted on reaction with the acid to give off hydrogen, instead of reacting with the AN. More recently, Baizer (3a) developed a direct electrolytic method which has attracted a lot of attention and has achieved commercial realization. The method is based on the finding that quaternary ammonium salts can dissolve high concentrations of AN and yield on electrolysis mainly ADN without any losses on side products such as PN or hydrogen. In a series of articles published by Baizer (3) he discusses the various problems involved in the electrolytic hydrodimerization of both acrylonitrile and other vinyl derivatives. In comparing the electrolytic and amalgam reductions, he arrived at a conclusion that electrolysis in the presence of alkali metal ions is merely *in situ* amalgam reduction. On electrolysis in neutral solution in the presence of alkali metal ions he obtained a low yield of ADN and a high yield of PN while in the presence of quaternary ammonium salts his product consisted mainly of ADN. He therefore concluded that it is necessary to avoid any use of amalgams or alkali metal ions and restricted his work to electrolysis in the presence of quaternary ammonium salts.

In the course of our studies of both the amalgam and the electrolytic reactions we have shown that although Baizer's conclusions were logical when based on his experimental data, additional data prove that the presence of alkali metals is not the cause for PN

formation. High yields of ADN can be obtained even with amalgam reductions, in neutral solutions, provided a suitable reaction medium is chosen.

After this work was completed, Matsuda (11) published a note proving that AN can be dimerized by alkali amalgams provided a proper solvent is used. His findings are in full agreement with our data and in contradiction with Baizer's interpretation.

In this work we have carried out a polarographic study of AN reduction to clarify some of the problems involved in the hydrodimerization. We then studied the reduction of AN in HCl solution by alkali metal amalgam, following the work of Knunyants and others, and compared the reduction reaction by direct electrolysis and by amalgam in neutral media. From these results in conjunction with Baizer's experiments we arrived at our conclusions.

Experimental and Results

Polarography in neutral solution.—All the polarographic measurements were carried out on a Metrohm Polarecord E261R polarograph. The supporting electrolyte was tetramethylammonium bromide (TMABr).

The reduction of AN was studied in aqueous solution in the concentration range of 10^{-3}M to 1M. The experiments carried out at high concentrations did not give well-defined polarograms and were very irreproducible. We therefore limited our studies to concentrations of AN up to 2 x 10^{-1}M. The half wave potential $E_{1/2}$ is between —1.95 and —2.02v. The number of electrons involved in the reduction was calculated and found to be $n=1.84$. The value reported by Platonova (4) is 1.6, while Sevastyanova and Tomilov (5) found $n=2.32$. Lazarov *et al.* (6) calculated from polarographic and galvanometric measurements, $n=2$. It seems therefore, justified to conclude that the reduction involves a two electron transfer process.

Polarography in acid solution.—Most polarographic studies in acid pH's are carried out in buffer systems or in the presence of phenol, benzoic acid, and such proton donors which do not give hydrogen discharge waves in the range of the reduction wave of the investigated compound. As we had special interest in hydrodimerization in the presence of HCl we decided to carry out our polarographic measurements also in the presence of HCl. The acid itself gives a wave for hydrogen discharge at $E_{1/2}$ = 1.6v. When a solution of both HCl and AN is analyzed it is possible to obtain two waves provided the acid concentration is low. The first coincides exactly with the hydrogen wave and the diffusion current equals the diffusion of HCl itself and the second is the AN reduction wave. The total diffusion current is equal to the current of AN. However, when one works at a constant AN concentration and increases gradually the acid content the hydrogen wave increases until it reaches the height of the AN diffusion current and then only one wave is observed. This is demonstrated in Fig. 1. The measured drop time was $t=3$ sec, and the rate of mercury flow was $m=2.55$ mg/sec. The height of the mercury reservoir was 55 cm. In order to determine the ratio of HCl/AN where a single wave appears, we carried out a series of experiments where, for every AN concentration, the HCl concentration was gradually increased. By interpolation we found in every case the acid concentration where a single wave appears and plotted this HCl concentration against the corresponding AN concentration (Fig. 2). The slope of the line gives (HCl)/(AN) = 0.65, the average experimental value for the appearance of a single wave. The presence of KCl does not interfere with the single wave of AN/HCl and the K wave appears at more negative values of —2.2v.

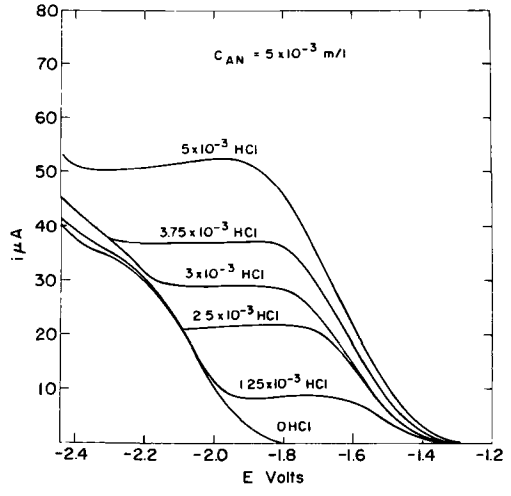

Fig. 1. Polarographic waves of AN with increasing concentrations of HCl.

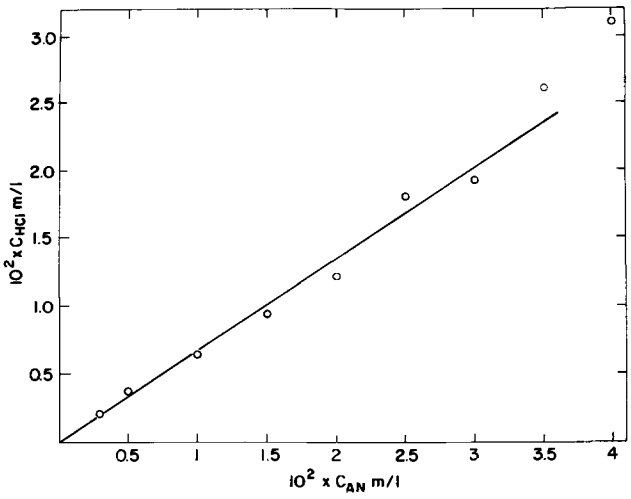

Fig. 2. Interpolated values for HCl concentration yielding a single wave with AN *vs.* the corresponding AN concentrations.

In the presence of acid the over-all cathode reaction may be written as

$$AN + nH^+ + ne \rightarrow ANH_n$$

Taking the values for diffusion constants of AN, D_{AN} = 8.2 x 10^{-6} cm²/sec (4) and of H^+, D_{H^+} = 9.3 x 10^{-5} cm²/sec, one can calculate the number of electrons involved in the reduction step. When the ratio of concentration HCl/AN=0.65 the diffusion currents for AN and HCl may be considered equal and therefore

$$n_{AN}C_{AN}D_{AN}^{1/2} = n_H + C_H + D_{H^+}{}^{1/2}$$

hence

$$n_{AN} = 2.2$$

This number depends of course, on the values of the diffusion constants used and could therefore vary slightly. It shows, however, that the reduction under these conditions involves two electrons and two protons and should lead to PN exclusively. This point will be further elaborated in the Discussion.

Amalgam reduction in acid solutions.—Knunyants *et al.* (1) and Katchalsky *et al.* (2) have carried out K-amalgam reductions of AN dissolved in 10-20% HCl. They claimed ADN yields of 60-80% and PN yields of about 10%, based on the amount of AN consumed in the reaction. We have repeated their experiments in order to get a quantitative correlation between the HCl and AN concentrations in the reacting mixture on the one hand and the yields of ADN, PN, and H_2 on the other.

The experiments were carried out in the following way: The reaction flask, described in Fig. 3, consisted of a glass tube, 20 cm long, provided with a cooling jacket, a supply of amalgam through a capil-

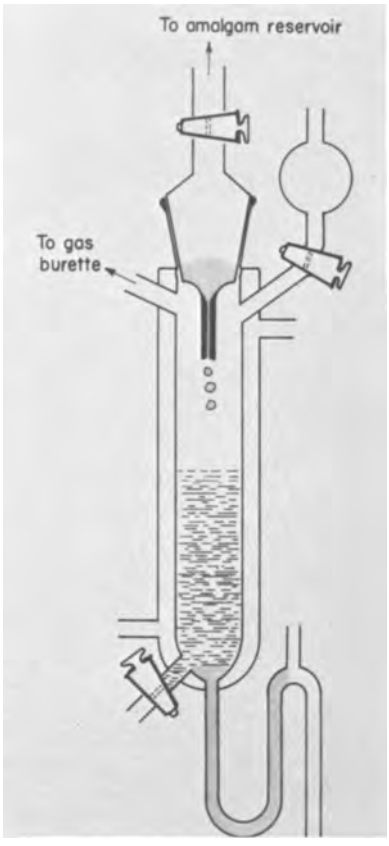

Fig. 3. Reaction flask for amalgam reduction in acid media

lary at the top of the tube, a narrow syphon at the bottom for the outflow of the depleted amalgam, two stopcocks for introduction of the solution and recovery of the products, and a gas buret for measuring the hydrogen evolved. In every experiment 15 cc of a 5% AN solution were used (experiments with 2 and 10% AN were also carried out). The amalgam was freshly prepared by electrolysis of KOH, and was kept under a layer of toluene until used. The concentration of the alkali metal was 4-9 m moles/100 g amalgam. The hydrogen evolved ensured proper mixing of the reaction mixture. The temperature was kept at 5°C. At the end of the reaction the K concentration in the depleted amalgam was determined by titration. The reaction mixture was diluted with water, made strongly alkaline with KOH, a weighed amount of butyronitrile was added as internal marker, and the organic components were extracted with methylene chloride. The products were analyzed by gas chromatography on a polyester resin as stationary phase. In every experiment the per cent conversion was kept low (under 30%) in order to avoid the interference of large quantities of alkali chloride precipitating during the reaction. The calculated yields refer to cyano group equivalents and are based on the potassium metal consumed. The results of experiments for 5% AN in HCl solution of concentrations ranging from 1 to 20%, are presented in Fig. 4. As could be expected the amount of hydrogen evolved increases with the HCl concentration while the PN decreases. The interesting fact is that ADN increases with the increase in HCl concentration, and considering the decrease in PN, it amounts to an increase in the ADN/PN ratio roughly proportional to the square of the HCl concentration. This accounts for the fact that prior to Baizer's work the hydrodimerization was carried out preferentially at high HCl concentration in spite of the large losses in alkali metal reacting with the acid. The effect of the nature of the alkali metal was studied by reacting K, Na, and Li amalgams with a 5% AN solution in 20% HCl. The results are presented in Fig. 5. The

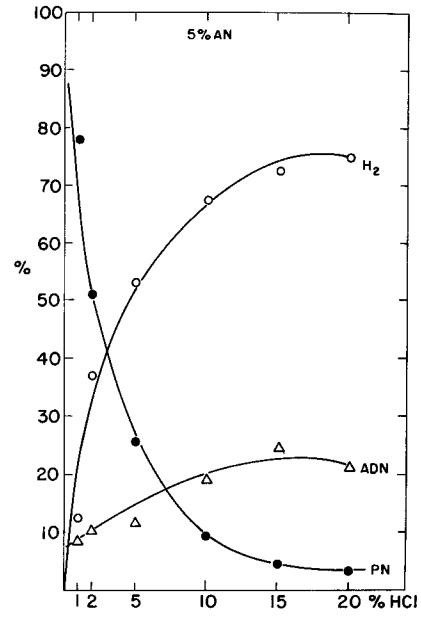

Fig. 4. Per cent yields of H_2, PN, and ADN calculated on the basis of reacted potassium metal.

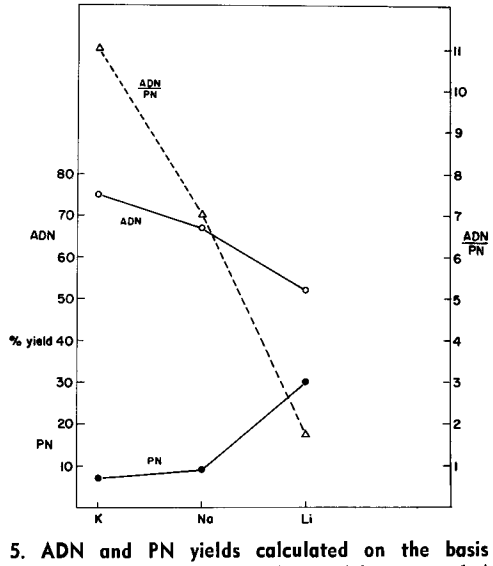

Fig. 5. ADN and PN yields calculated on the basis of reacted AN, for K, Na, and Li amalgams. The ratio of ADN/PN for the same metals.

yields of ADN and PN are calculated, in this case, in respect to the amount of reacted AN and also refer to cyano group equivalents. It can be seen that the ADN yield decreases, while the PN yield increases, thus making the ADN/PN ratio decrease sharply in the order K, Na, Li.

Amalgam and electrolytic reduction in neutral solutions.—Numerous experiments carried out in HCl solutions, or even in buffered solutions at pH 5 have shown that no ADN can be obtained by direct electrolysis. In order to compare electrolytic and amalgam reductions we had to restrict ourselves to neutral or slightly alkaline media. We have used solutions buffered with 1M phosphates (see Table I), to maintain a pH between 6.5-8. We have also designed the electrolytic and amalgam cells in such a way as to obtain comparable conditions at the mercury interface for both sets of experiments. The electrolysis cell was comprised of a cathode compartment and an anode compartment separated by a sintered glass diaphragm. The mercury cathode (3 cm^2 area), and the catholyte were stirred mechanically. The cathode voltage was

Table I. Comparison of electrolysis and amalgam reactions in neutral media

Type of experiment	Buffer	pH	QmF	Kmeq	2PN/H_2	2ADN/PN
Electrolysis	NaK phosphate	6.3-7.4	7.2	—	20	0.05
Electrolysis	NaK phosphate	6.3-7.4	7.2	—	13	0.09
Electrolysis	$(CH_3)_4N$ phosphate	7.0-7.8	7.6	—	6.4	0.04
Electrolysis	$(CH_3)_4N$ phosphate	6.5-7.4	7.2	—	4.2	0.09
K amalgam	Na, K phosphate	6.2-7.7	—	5.3	22	0.09
K amalgam	Na, K phosphate	6.2-7.7	—	5.4	26	0.05
K amalgam	Na, K phosphate	6.2-8.6	—	4.9	25	0.08

maintained at —2.0v *vs.* a calomel electrode. The currents used were approximately 100 ma, and the experiments were carried out for 1-3 hr each. The amalgam reactor was made from a 20 mm diameter glass tube (same as the cathode compartment in the electrolysis cell). The amalgam was introduced through a side capillary tube into the bottom of the reactor where a small pool of amalgam formed. The surface area of this amalgam pool was the same as the mercury cathode in the electrolysis experiments. The reacted amalgam then overflowed through a syphon system into a measuring cylinder. Here also both the amalgam and the reaction solutions were stirred mechanically. The rate of flow of the amalgam was adjusted to be equivalent to the electric current, thus approaching, as much as possible, the conditions in the electrolytic runs. The results are presented in Table I. The AN concentration was 5%, and the phosphate buffer was 1M. The *p*H was measured before and after the reaction, and the values are given in the third column. Column 4 gives the number of mili Farads used in every electrolysis run, and column 5, the number of milliequivalents of K metal reacted. 2PN/H_2 and 2ADN/PN represent molar ratios.

From Table I one can see that identical results are obtained from electrolytic or from amalgam reductions in neutral media. It is also evident that replacing the Na^+ and K^+ by $(CH_3)_4N^+$ does not affect any change on the ADN/PN ratio. This is contrary to Baizer's observations. The discrepency is due to the difference in experimental conditions and will be dealt with in the Discussion. In order to check our experimental technique, we also repeated some experiments, under the same conditions as prescribed by Baizer, namely, a high concentration of AN in concentrated aqueous solution of tetraethylammonium p-toluene sulfonate; we obtained results identical with those reported by that author.

Discussion

Acid media.—Electrolysis experiments in the presence of M^+ or $(CH_3)_4N^+$ in acid media yielded only hydrogen and PN without any trace of ADN. The polarographic runs under similar conditions also show that the AN wave disappears and only the hydrogen discharge wave remains. Thus electrolytic reduction of AN in the presence of acid is apparently carried out by the hydrogen atoms discharged at the cathode. It was shown that the single wave appears when two hydrogen atoms are discharged for every AN molecule diffusing to the cathode. This means, that the reduction should result in PN formation, in accordance with the findings of the electrolysis experiments. It was also shown that potassium ions in solution do not affect the products of the reaction. This is in accord with the polarographic analysis that shows that the potassium wave does not interfere with the HCl-AN wave.

The amalgam experiments, on the other hand, yield hydrogen, PN, and also ADN. The interpretation of this difference between the electrolytic and amalgam reactions may be due to the fact that while the bulk of the solution in both cases is acid, the reaction site, *i.e.* the mercury interface, is more alkaline in the amalgam reaction. In the latter case the metal cations are in very high concentration in the double layer and will therefore affect the outcome of the reaction. The short life intermediate formed will interact with acid to give PN. In the case of lithium amalgam, this product has a higher reduction potential and will therefore give higher yields of PN (see Fig. 5).

The mechanism of formation of ADN must take into consideration the rather interesting fact that the ADN yield increases as a function of HCl concentration. This suggests that a bonding between HCl and AN may be formed. It is well known that strong acids induce N-protonation of nitriles and form crystalline nitrilium salts, *e.g.*, acetonitrile yields with anhydrous HCl, a crystalline compound having a formula of $CH_3-\underset{\underset{Cl}{|}}{C}=N=H$ (7, 8). Interaction with the acid would probably also account for the fact that the solubility of AN increases from 5% in water to 10% in a 20% solution of hydrochloric acid. If protonation of the nitrile in aqueous acid can be assumed, an equilibrium would be established

$$CH_2=CH-C\equiv N + H^+ \rightleftarrows CH_2=CH-C\equiv \overset{+}{N}H$$

This would be followed by interaction with an alkali metal atom (Me) from the amalgam to produce an intermediate radical, which will isomerize to give

$$CH_2=CH-C\equiv \overset{+}{N}H + Me \rightarrow (CH_2=CH-\dot{C}=NH) + Me^+ \rightleftarrows \dot{C}H_2-CH_2-C\equiv N + Me^+$$

The free radicals thus obtained will yield ADN on dimerization. One should realize that when dealing with a reaction taking place on the mercury interface the concentration of free radicals at the reaction site is very high and therefore the probability of dimerization is much higher than for polymerization. The later reaction does, in fact, take place to some extent and can be diminished somewhat by free radical inhibitors. The above mechanism is in complete accord with the one recently suggested by Misono *et al.* (9) for the hydrodimerization of acrolein in p-toluenesulfonic acid solution.

Neutral media.—From our polarographic data we concluded that in neutral media a two electron transfer takes place to yield the dinegative ion $AN^=$. In the case of amalgams the double adduct MeANMe is probably formed. From the results presented in Table I it seems that in neutral media the amalgam and electrolytic reduction give the same results, and in the latter case the presence or absence of alkali cations does not affect the results. We can therefore treat the two cases similarly and consider the active species as $AN^=$. As no acid is present the $AN^=$ formed will have a longer life, and it can interact either with water or with another molecule of AN in a mechanism similar to that suggested by Baizer (3a).[1]

$$(CH_2-\underset{\underset{CN}{|}}{CH})^= + H_2O \xrightarrow{k_1} CH_3-\underset{\underset{CN}{|}}{CH}^- \xrightarrow{+H_2O} CH_3-\underset{\underset{CN}{|}}{CH_2} \qquad [1]$$

$$(CH_2-\underset{\underset{CN}{|}}{CH})^= + CH_2=\underset{\underset{CN}{|}}{CH} \xrightarrow{k_2}$$

[1] Beck (12) suggests that the intermediate anion is $-CH_2-CH_2-CN$. On energetic grounds this does not seem plausible to us.

$$\begin{array}{l} {}^{-}CH-CH_2-CH_2-\bar{C}H \\ \quad\;\; | \qquad\qquad\quad | \\ \quad CN \qquad\qquad CN \end{array}$$

$$\xrightarrow{+2H_2O} \begin{array}{l} CH_2-CH_2-CH_2-CH_2 \\ \quad | \qquad\qquad\quad | \\ \quad CN \qquad\qquad CN \end{array} \qquad [2]$$

The rate of reaction [1] will be determined by the interaction with the first molecule of water because the anion $CH_3-\bar{C}H$ formed can either give PN on
|
CN
interaction with another molecule of water or initiate the polymerization of AN. Since very little polymer is formed we can neglect this polymerization reaction and consider that every such anion formed will have to lead eventually to PN. The rate of reaction [2] will be determined by the interaction with AN to give the dimeric dianion $^{-}CH-CH_2-CH_2-CH^{-}$. Here
| |
CN CN
again we neglect the polymerization reaction, and therefore this anion will have to lead to ADN formation on protonation. We can thus consider that the ADN/PN ratio will be given by the equation

$$\frac{ADN}{PN} = \frac{k_2(AN)}{k_1(H_2O)}$$

In order to be able to estimate the rate constant from our data we have to know the concentrations of AN and H_2O in the reaction site which is the mercury interface. This will depend on the relative polarities of the two species and also on interaction factors with the solvent medium. Since we do not know, at this stage, the various factors involved we will only assume that the ratio of the concentrations AN/H_2O at the mercury interface is proportional to the ratio in the bulk of the solution. The AN concentration in our experiments was 1M, the water concentration about 50M, and the average experimental value for ADN/PN = 0.08. We therefore estimate $k_2/k_1 = 4$, leading to the rather unexpected results that AN is more reactive than water towards the di-anion species. This can be rationalized on the grounds that both reactions will need little or no activation energy and it is only the entropy factors that will determine the rate constants. In this case of interaction of two similar molecules such as $AN^{=}$ and AN the steric factors are much more favorable and therefore it is conceivable that it will be faster. Increasing the AN concentration will increase the ADN yield as is also evident from Baizer's results. The same effect can also be achieved by decreasing the water concentration, *e.g.*, by working at high salt content. This was done by Baizer when carrying out electrolysis in a solution of 13% AN in a 40% solution of Na or K p-toluene sulfonate to yield a ratio of ADN/PN = 0.65. From our data we could predict a value ADN/PN = 4 x 3/30 = 0.4, in fairly good agreement with the value obtained by Baizer. This is not the case, however, with a concentration of 40% AN in 50% tetraethylammonium p-toluene sulfonate solution. There, we would expect a value of ADN/PN = 4 x 8/20 = 1.6, and the experimental value from both our data and Baizer's is higher than 100. We conclude, therefore, that it is the presence of tetraethylammonium tosylate that is responsible for the higher yields of ADN, rather than the presence of alkali metals being responsible for the higher yields of PN, according to Baizer's claims. This point could be settled by interacting alkali amalgam with an AN solution of tetraethylammonium tosylate. If our argument is correct we should be able to obtain high ADN yields in spite of the presence of alkali metals. This was really shown to be the case for K, Na and even Li amalgams. They all yielded ADN/PN ratios higher than 100 when reacting with a 40% AN solution in 60% (Et_4N)pTS. Similar results were also reported by Matsuda (11) and in ICI patents (13).

Other quaternary ammonium ions such as trimethylbenzylammonium were also very effective while tetramethylammonium was much less effective. A full study of the effect of the cationic and the anionic parts of the salt as well as the effect of the salt concentration and the AN concentration is in progress. At this stage we can only state the well-established fact that salts like tetraethylammonium p-toluene sulfonate have a pronounced effect on the yield of ADN in both electrolytic and amalgam reactions.

Feoktistov *et al.* (14) have studied the effect of water on the electrochemical reduction of AN in dimethyl formamide in the presence of tetrabutylammonium iodide. They claim that the accumulation of large organic cations in the electric double layer leads to a decrease in the volume occupied by the water molecules, thus leading to a lower protonation to propionitrile and to a higher probability of the $AN^{=}$ reacting with a neutral AN. This may be an over simplification of the problem. In a more general way we may say that the effectiveness of these salts may be due to their large ionic size and to the peculiar characteristic of their aqueous solutions as discussed for example by Wen and Saito (10). These characteristics and their ability to solvate both water and AN enables them to change the path of the reaction of alkali metal amalgams from the normal reduction to PN to hydrodimerization into ADN.

Adsorption and Oxidation of Methanol on a Platinum Electrode

T. Biegler and D. F. A. Koch

Division of Mineral Chemistry, CSIRO, P.O. Box 124 Port Melbourne, Victoria, Australia

ABSTRACT

Kinetics of adsorption of methanol from 1M H_2SO_4 onto a Pt electrode is examined. The electrode potential is stepped from 1.55v to a value in the range 0.2-0.7v, and an anodic current flows due to chemisorption of methanol. The resulting current-time curves are analyzed according to Elovich kinetics, a procedure which allows evaluation of the initial current for a clean surface. A rate equation for adsorption is obtained on the basis of the potential and concentration dependence of initial current. Steady-state equations for coverage and current are derived with the assumption of irreversibility for the adsorption and further oxidation reactions. The nature of the adsorbed intermediate is discussed by comparing the charges used in forming and oxidizing a monolayer, and the evidence suggests it has the same oxidation state as CO.

The mechanisms of oxidation of organic fuels at catalytically active electrodes, in particular platinum, have been studied intensively over the past few years (1). The electrochemical behavior of these systems is complex. Current-voltage curves can show several maxima and are strongly dependent on time and the prehistory of the electrode; a steady state is an elusive condition although conventional polarization curves have found a limited application; reaction orders are generally fractional and sometimes negative; the reactions involve adsorbed species which remain attached to the electrode during washing or exposure to air and can subsequently be detected electrochemically.

In their interpretation of current-voltage curves Bagotskii and co-workers (2-5) have concluded that (*a*) adsorption of reactants follows a logarithmic isotherm, (*b*) only adsorbed species are oxidized, and (c) the catalytic activity of the electrode is modified by the formation of various kinds of surface oxides. On this basis they have explained the presence of current minima in similar potential regions for a number of compounds and have developed kinetic equations which account for the shapes of the curves and their dependence on reactant concentration.

The present work is concerned with adsorption and oxidation of methanol in the low potential region. It is clear from recent work (5-8) that adsorption of methanol involves dehydrogenation of the molecule. If the process occurs at open circuit, the potential of the electrode falls (7), the surface becoming covered with H atoms and a chemisorbed methanol residue. At constant potential, however, ionization of the H atoms occurs and the chemisorption of methanol is accompanied by an anodic current (5, 9). We have used this fact to characterize the adsorption process by means of a simple potential-step technique.[1] In general, our results confirm the conclusions of the Russian workers concerning the kinetics of adsorption and its role in the over-all reaction, but we differ considerably in matters of detailed interpretation.

Experimental

An all-glass cell of conventional design contained the working electrode of 30 gauge Pt wire sealed into soft glass to expose 4.5 mm (geometric area 0.0454 cm^2). Determination of maximum H adsorption for this electrode from potential sweep measurements (10, 11) gave a value of 350 $\mu coul/cm^2$, indicating a roughness factor of about 1.7. A few runs using a larger Pt foil electrode (1.69 cm^2) gave comparable results. Currents are quoted on the basis of geometric electrode area.

The counter electrode (Pt) was in a compartment separated from the main body of the cell by a glass sinter, and the reference electrode (saturated calomel) was well isolated from the cell by a bridge (1M H_2SO_4) closed at one end by a fine sinter and terminating in a Luggin capillary in the cell. All potentials are quoted with respect to the standard hydrogen electrode (—0.245v *vs.* SCE).

The supporting electrolyte, 1M H_2SO_4, was prepared from AnalaR reagent and water redistilled from alkaline permanganate. Reagent grade methanol was used, and neither distillation of the methanol nor preelectrolysis of the supporting electrolyte affected results significantly. Nitrogen was purified by passage over heated copper turnings and through a cold trap, followed by scrubbing in a presaturator containing the solution under investigation.

A simple bias unit of potential dividers and switches was used to program the electrode potential which was controlled by a Wenking fast rise potentiostat; the final potential step operated through a mercury-wetted relay. By discharging a capacitor through the relay coil, rectangular pulses of duration 10-500 msec (depending on the capacitor value) could be obtained.

Current was measured as the voltage drop across a decade resistance box. Transients were observed on a Tektronix type 533 oscilloscope with type B plug-in amplifier and photographed with a type C12 camera. All measurements were made at 25°C.

Results and Discussion

Qualitative features of current-time transients.—The adsorption reaction at low potentials was studied by holding the electrode for a period t_{ox} at a fairly positive potential ϕ_{ox}, around +1.5v, where coverage by species other than oxide was negligible, and then stepping the potential to the desired value ϕ. For 0.7v $> \phi >$ 0.2v, the sequence of events is as follows (Fig. 1). The oxide layer is rapidly reduced and a large cathodic current flows. This region is not resolved with the current and time scales of Fig. 1. As the surface is reduced, sites become vacant for the adsorption of methanol, and the current soon becomes anodic. The time at which the current changes sign depends on the extent of initial oxidation of the surface and the kinetics of surface reduction and methanol adsorption; it is usually in the range 30-50 msec. The anodic current then rises steeply to a maximum and decays at a relatively slow rate. A similar decrease in anodic current with time has been observed (5, 9) in experiments where methanol is rapidly added to a supporting electrolyte in which a Pt electrode is held at a low potential. However, the pulse technique used here allows the current to be followed at shorter times

[1] After completion of this manuscript, a paper by S. S. Beskorovainaya, Yu. B. Vasil'ev, and V. S. Bagotskii [*Electrokhimiya*, 2, 167 (1966)], in which a similar potential step technique was used, came to our attention.

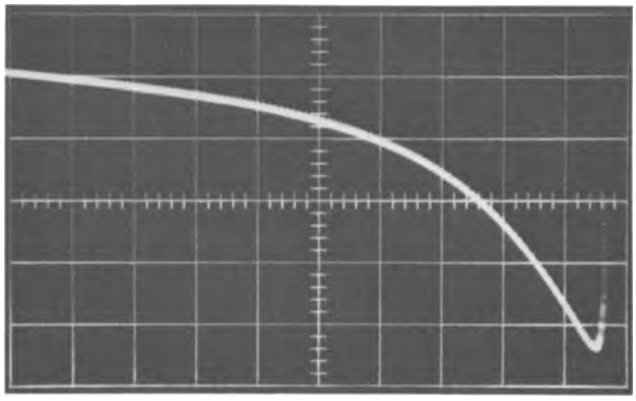

Fig. 1. Current/time curve for methanol adsorption. 0.5M methanol, ϕ_{ox} = 1.55v, t_{ox} = 20 msec, ϕ = 0.37v. Horizontal scale 200 msec/cm vertical 3.33μa/cm. Cathodic potential step occurs at 0.2 cm from left-hand edge.

(the anodic maximum is reached in as little as 50 msec), and the importance of this will become clear below.

The shape of the early portion of such a current-time curve depends largely on the kinetics of reduction of the Pt surface and hence on ϕ_{ox} and t_{ox}, as well as on ϕ. At constant ϕ, the other factors can be varied between wide limits without altering significantly the latter part of the curve. If ϕ_{ox} is less than about 1.1v, insufficient oxide is formed and, on reduction, the surface does not reach full activity. At too high potentials (>1.75v) oxygen is evolved, and its reduction after the cathodic step influences the measured current. The value of t_{ox} determines the amount of oxide formed and hence the kinetics of its reduction. With longer t_{ox} surface reduction is slower and the anodic peak is slightly lowered and shifted to longer times. However, this shift in the maximum does not influence later portions of the current-time curves.

As our aim was to observe as much of the transient as possible, the procedure finally adopted was to anodize at 1.55v for short periods (~15 msec, a time appropriate to the small electrode but too short for the larger one) and repeat with manual switching of the relay until the surface reached a maximum activity. In other words, a series of rectangular pulses of short duration separated by intervals of a few seconds was applied between the potential of interest, ϕ, and 1.55v. After a few such pulses the desired condition of maximum anodic current after the cathodic potential step was attained. This activation procedure resulted in very reproducible current-time curves. A surface cleaning program similar to that of Gilman (11), which gave a more complete and less easily reduced Pt surface oxide, was not suitable for the present purposes.

Analysis of current-time curves.—Curves of the same general shape as Fig. 1 are found in the potential range 0.2-0.7v. The current decreases with potential (see below) and 0.2v represents about the lower limit at which the transient can be measured with the present equipment. It is important to note that below about 0.55v there is no appreciable steady-state current, the curve eventually decaying to zero.

These curves can be interpreted if the oxidation of methanol is considered to occur in two stages, the first being a chemisorption process involving dehydrogenation of the molecule and the second the further oxidation of the adsorbed species to CO_2; at low potentials the first process is much the faster. Similar views have also been put forward by Petrii *et al.* (8, 9) and Bagotskii and Vasil'ev (2, 5). The first step is written as

$$CH_3OH \rightarrow A_{ads} + n_1H^+ + n_1e \qquad [1]$$

and its rate is expected to decrease as the product, chemisorbed methanol (A_{ads}), accumulates on the surface. Thus, the form of the current decay curves reflects the way in which adsorption kinetics varies with surface coverage, provided that further oxidation of A_{ads} is slow.

The Elovich equation [see *e.g.* (12)] is frequently used to describe the kinetics of adsorption onto heterogeneous surfaces and has in fact recently been applied to the methanol system (4, 5). In a form appropriate to the present case the Elovich equation for the rate of reaction [1] is

$$I_1 = I_i \exp(-m_1\theta) \qquad [2]$$

which indicates that the current I_1 decreases exponentially with θ, the fractional coverage by A_{ads}, from an initial value I_i. The constant m_1 has the significance that, in the model where the free energy of activation $\Delta G_\theta^{o\neq}$ for adsorption on a heterogeneous surface increases linearly with coverage

$$m_1 = \frac{1}{RT}\frac{d\,\Delta G_\theta^{o\neq}}{d\theta} \qquad [3]$$

At potentials less than 0.55v, the approach to zero steady-state current indicates that the rate of further oxidation of A_{ads} is negligible compared with its rate of formation, at least over most of the curve. Under these circumstances

$$\theta = Q_t/Q_{sat} \qquad [4]$$

where Q_t is the charge passed to time t *via* reaction [1] and Q_{sat} is the charge needed to give θ = 1. Also

$$I_1 = \frac{dQ_t}{dt} = Q_{sat}\frac{d\theta}{dt} \qquad [5]$$

From [2] and [5]

$$\frac{d\theta}{dt} = \frac{I_i}{Q_{sat}}\exp(-m_1\theta) \qquad [6]$$

Integrating with boundary condition t = 0, θ = 0 gives

$$\exp(m_1\theta) = \frac{I_i m_1 t}{Q_{sat}} + 1 \qquad [7]$$

Using [7] and [2] and rearranging gives

$$\frac{1}{I_1} = \frac{1}{I_i} + \frac{m_1 t}{Q_{sat}} \qquad [8]$$

A current-time relationship of this form has previously been applied to the kinetics of Pt surface re-

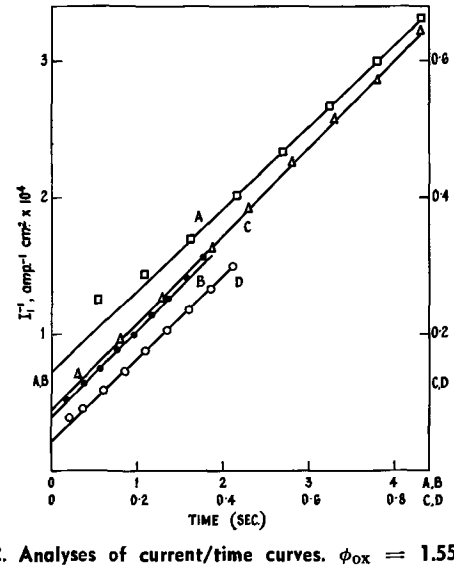

Fig. 2. Analyses of current/time curves. ϕ_{ox} = 1.55v, t_{ox} = 20 msec. A, 0.05M methanol, ϕ = 0.42v; B, 0.5M methanol, ϕ = 0.32v; C, 1.0M methanol, ϕ = 0.37v; D, 2.0M methanol, ϕ = 0.37v.

duction (13). Analyses of current-time curves for methanol adsorption according to Eq. [8] are shown in Fig. 2. Deviations occur at the very beginning of the curve, as a result of the influence of oxide reduction discussed above, and also after a time interval which corresponds to some 50% of the charge passed until the steady state is reached. The latter departures from Eq. [8] have at least two reasons: (*A*) Evaluation of the integrated current from Eq. [4] and [7] gives

$$\int_o^t I_i dt = Q_t = \frac{Q_{sat}}{m_1} \ln\left(1 + \frac{m_1 I_i t}{Q_{sat}}\right) \qquad [9]$$

which shows that the above equations cannot hold for long times since they predict an indefinite increase in Q_t. (*B*) As the current decays, any contribution from a further (slow) oxidation of A_{ads} or impurities becomes more significant.

It is found that for $\phi > 0.45$v significant deviations from Eq. [8] occur, the slopes of I_1^{-1} *vs.* t plots becoming dependent on potential. However, within the range 0.2-0.45v and over the concentration range examined, 0.05-5M methanol, the slopes of these plots are found to be constant, within experimental error, at 6.1 ± 0.6 x 10^3 cm^2 coulomb^{-1} based on the geometric area. We consider that so long as a slope of this value is obtained, extrapolation of these plots can reasonably be expected to yield the correct value of I_i^{-1} and hence give a measure of the rate of reaction [1] on a bare Pt surface. This assumption forms the basis of the study of the kinetics of this reaction.

Potential dependence of adsorption rate.—The potential dependence of I_i for 0.2M methanol is shown in Fig. 3. A Tafel slope of 125 mv is found at low potentials, but then the current passes through a flat maximum at about 0.55v. It is interesting to note that Beskorovainaya *et al.* (4) report a similar result, using an entirely different technique, for adsorption rates at constant, but not zero, coverage. The maximum in Fig. 3 occurs well before the main current peak, observed at 0.8-0.9v under sweep or steady-state conditions, which is supposed to be due to inhibition by Pt surface oxidation (14-16).

Three explanations for the departure from a Tafel relation can be suggested.

(*A*) A real decrease in the velocity of the rate-determining step of reaction [1] occurs, due to factors connected with the potential dependence of double layer structure, *e.g.*, hydrogen and oxygen adsorption.

(*B*) At higher potentials, the method of analyzing current-time curves is invalid and gives erroneously low I_i values. In support of this is the fact that the decrease in slopes of I_1^{-1} *vs.* t plots coincides with the departure from linearity in Fig. 3.

(*C*) At sufficiently high currents a different step of reaction [1], possibly involving a potential-independent surface reaction, becomes rate-determining. In this regard, there is some evidence from concentration dependence studies (see below) to suggest that rate limitation of reaction [1] is closely connected with the attainment of a certain current density.

Bagotskii and Vasil'ev (5) favor the first explanation and claim that the adsorption rate is highest when the combined coverage by hydrogen and oxygen is least. The Tafel behavior is then explained on the basis of an exponential increase in rate with decrease in H coverage which varies linearly with potential. However, the linear region in Fig. 3 extends to 0.47v, well beyond the H region [see *e.g.*, (1)], so that the above explanation for Tafel behavior seems unlikely. Furthermore, the decrease in rate observed at 0.55v occurs well below the minimum potential (~0.8v) for oxygen adsorption (10) and in view of these objections, an alternative explanation for Tafel behavior is desirable. Thus, if chemisorption is considered to be a charge transfer process as in reaction [1] an exponential dependence of rate on potential is to be expected. At present it is difficult to assess the relative importance of (*B*) and (*C*) above in explaining the observed departures from Tafel behavior.

Concentration dependence of adsorption rate.—Bagotskii and Vasil'ev (5) have shown that adsorption of methanol at constant coverage and potential follows first order kinetics. Figure 4 shows the variation of I_i with methanol concentration at three potentials. A linear dependence, in agreement with (5), is found at the lowest potential while curvature starts at 2M methanol for 0.37v and 1M for 0.42v. We feel it is significant that these deviations from linearity, together with the departure from a Tafel region mentioned above, occur when the current exceeds about 2 ma/cm^2 and the comments made in (C) above also hold here.

Rate equations for oxidation of methanol.—With the above mentioned limitations on potential and methanol concentration, the experimentally determined initial rates of reaction [1] can be described by

$$I_i = n_1 F k_1 C_m \exp\left(\frac{\beta_1 F \phi}{RT}\right) \qquad [10]$$

where the symmetry factor $\beta_1 \approx 0.5$, C_m is the methanol concentration and k_1 a rate constant. The product $n_1 k_1$ has the value 1.4 x 10^{-8} cm sec^{-1} at $\phi = 0$v, based on geometric electrode area.

Combination of Eq. [2] and [10] gives the full rate expression for reaction [1]

$$I_1 = n_1 F k_1 C_m \exp\left(\frac{\beta_1 F \phi}{RT}\right) \exp(-m_1 \theta) \qquad [11]$$

The further oxidation of chemisorbed methanol can be formulated

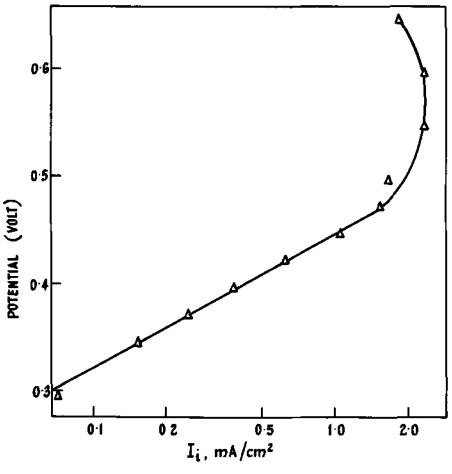

Fig. 3. Tafel plot for initial adsorption current (I_i). Methanol concentration 0.2M.

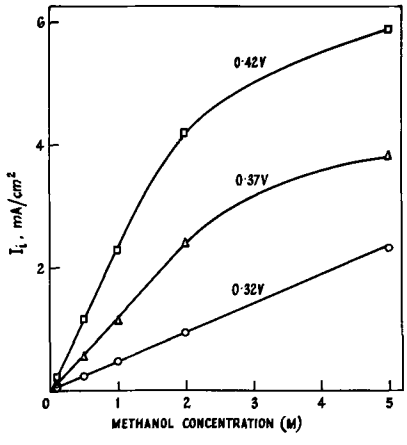

Fig. 4. Concentration dependence of initial adsorption current (I_i) at potentials indicated.

$$A_{ads} + H_2O \rightarrow CO_2 + n_2H^+ + n_2e \quad [12]$$

and, in view of the kinetics observed for reaction [1], a reasonable rate equation for this second step is

$$I_2 = n_2Fk_2 \exp\left(\frac{bF\phi}{RT}\right) \exp(m_2\theta) \quad [13]$$

where the constant b is determined by the Tafel characteristics of reaction [12].

This view of the mechanism of methanol oxidation is similar to those expressed in recent Russian work (2, 8) and Eq. [13] has the same form as Eq. [5] of ref. (2). Although combination of this type of relation with a logarithmic isotherm for adsorption of the intermediate has successfully been used to explain the observed fractional order of the over-all oxidation with respect to bulk methanol (2), we suggest an alternative interpretation of this result, as shown below.

Steady-state conditions.—There are strong grounds for considering both reactions [1] and [12] to be irreversible. The reversible methanol potential is close to $\phi = 0$v so all measurements are done at overpotentials of at least 0.2v. Experimentally it is found that desorption does not occur when an electrode bearing chemisorbed methanol is washed or transferred to a pure supporting electrolyte solution (9, 17). Furthermore, the hydrogen deposition method used to determine methanol coverages (3-5, 18) relies entirely on the irreversibility of the system.

With the assumption of irreversibility, the steady-state condition for constant θ (denoted by θ_{ss}) is that

$$\frac{I_1}{n_1} = \frac{I_2}{n_2} \quad [14]$$

From Eq. [11], [13], and [14] we obtain

$$\theta_{ss}(m_1 + m_2) = \ln\frac{k_1}{k_2}C_m + \frac{F\phi}{RT}(\beta_1 - b) \quad [15]$$

whence

$$\left(\frac{\partial\theta_{ss}}{\partial \ln C_m}\right)_\phi = \frac{1}{m_1 + m_2} \quad [16]$$

and

$$\left(\frac{\partial\theta_{ss}}{\partial\phi}\right)_{C_m} = \frac{F}{RT}\left(\frac{\beta_1 - b}{m_1 + m_2}\right) \quad [17]$$

The total current is the sum of I_1 and I_2 so that, using condition [14], the steady-state current is given by

$$I_{ss} = I_1\left(1 + \frac{n_2}{n_1}\right) \quad [18]$$

Introduction of equations for I_1 ([11]) and θ_{ss} ([15]) yields, after rearrangement,

$$\ln I_{ss} = \ln(nFk_1C_m) + \frac{\beta_1F\phi}{RT} - \frac{m_1}{m_1 + m_2}\left\{\ln\frac{k_1}{k_2}C_m + \frac{F\phi}{RT}(\beta_1 - b)\right\} \quad [19]$$

where $n = n_1 + n_2$.

Hence

$$\left(\frac{\partial \ln I_{ss}}{\partial \ln C_m}\right)_\phi = \frac{m_2}{m_1 + m_2} \quad [20]$$

and

$$\left(\frac{\partial\phi}{\partial \ln I_{ss}}\right)_{C_m} = \frac{RT}{F}\left(\frac{m_1 + m_2}{bm_1 + \beta_1m_2}\right) \quad [21]$$

The important result is that this treatment predicts variations of coverage and current with methanol concentration (Eq. [16] and [20]) which are very similar to those obtained (2, 5) when adsorption is presumed to be at equilibrium and to follow a logarithmic isotherm. Bagotskii and Vasil'ev (5) contend that the attainment of a definite concentration-dependent coverage is proof of a reversible equilibrium isotherm for the adsorption of methanol. The above evidence for irreversibility and the successful explanation of the concentration dependence of steady-state coverage and current on the basis of a strictly irreversible mechanism make this contention seem highly unlikely. We feel that similar considerations could have far-reaching implications in the interpretation of other electrocatalytic oxidations and support Brummer's recent remarks (19) concerning the relevance of adsorption "isotherms" in such studies.

It is not surprising that [16] has the characteristics of a logarithmic Temkin isotherm since the rate equation for the reverse of reaction [1] would contain an $\exp(m\theta)$ term as does [13]. In general, the rates of change of free energy and free energy of activation for adsorption with coverage are related through a symmetry factor [see *e.g.*, ref (20)], *i.e.*

$$m = \alpha f \quad [22]$$

where f appears in the Temkin isotherm

$$\theta = \frac{1}{f}\ln C_m + \text{const} \quad [23]$$

If it is assumed that $m_1 = m_2$ and that $\alpha = 0.5$ in [22], then the coefficient in [16] is the same as in the corresponding reversible isotherm. The two mechanisms are therefore experimentally indistinguishable on this point.

Experimental verification of [20] has been given (2) with values for $(\partial \ln I_{ss}/\partial \ln C_m)_\phi$ of 0.55-0.6 for methanol and similar values for other organic compounds. These results could be criticized on the grounds that they do not refer to steady-state measurements but were obtained with a sweep technique. However, we have carried out steady-state measurements, reached within several minutes, on the methanol system and find values of 0.53 increasing to 0.75 for concentrations up to 1M over the potential range 0.55-0.8v (Fig. 5). The maxima which occur at high concentrations and low potentials (Fig. 5) are probably due to the retardation of reaction [12] through a "high coverage" effect as suggested in ref. (2). It should be stressed that the above equations are only applicable within the validity of both the basic rate expressions, and

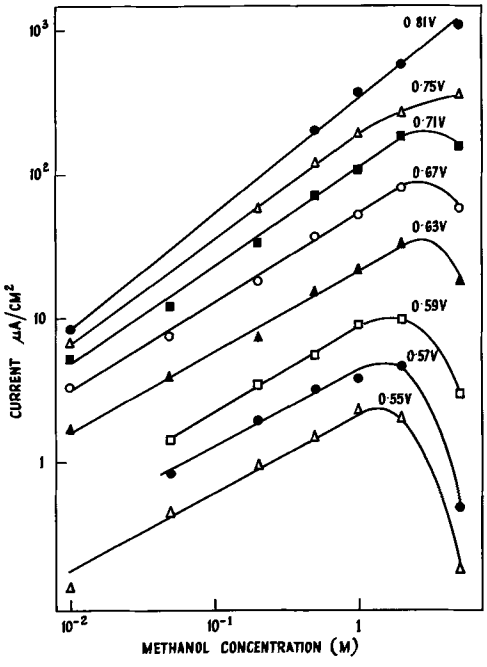

Fig. 5. Concentration dependence of steady-state current at potentials indicated.

Table I. Charges obtained by integration of current/time curves

Methanol concentration, M	Potential, v	Charge μcoul·cm^2
1	0.25	570
1	0.30	585
1	0.35	740
2	0.25	635
2	0.30	720

0.55v is probably the upper limit for this condition. The correct value of $m_2/(m_1 + m_2)$ is therefore close to 0.5 so that $m_1 \approx m_2$.

Evidence for the validity of the other coefficients, Eq. [17] and [21], is not overwhelming. With the assumption that $\beta_1 = b = \frac{1}{2}$, [17] shows that θ_{ss} should be independent of potential. Published results are somewhat encouraging on this point since Breiter and Gilman (18) and Lal *et al.* (9) find coverage independent of potential up to 0.6v while Khazova *et al.* (3) dispute this and give a bell-shaped curve with a maximum at 0.4-0.5v. There are reasons for believing that none of these experiments may have been able to produce correct results. Khazova *et al.* (3) have already pointed out that the procedures used in (9) and (18) both involve passage of the electrode through a potential region of high and, more importantly, fast adsorption prior to the coverage measurement. The irreversibility of the adsorption process then ensures that high coverages are also measured in the lower potential range. A possible objection to the measurements in ref. (3)-(5) (there are appreciable differences in the low potential data given in these references) is that insufficient time was allowed for the steady state to be reached at low potentials and concentrations. Thus, according to [7]

$$I_i t = \frac{Q_{sat}}{m_1} \{\exp(m_1\theta) - 1\} \qquad [24]$$

so that the time needed to reach a given value of θ is inversely proportional to I_i. For example, the data in ref. (5) indicate that for 0.5M methanol at 0.5v, a coverage of 0.8 is reached in about 10 sec. Assuming a Tafel slope of 120 mv for I_i the same coverage would be reached in 3000 sec at 0.2v and, if the steady-state coverage ($\sim$0.9) were indeed independent of ϕ, it would only be reached in a somewhat longer period. These experiments were apparently extended to 1200 sec, but longer term runs are needed to establish conclusively the potential dependence of θ_{ss}. For these reasons we prefer to consider the question still open.

With regard to [21], Bagotskii and Vasil'ev (2) found Tafel slopes of $\sim$120 mv for methanol oxidation in the low potential region; their measurements do not refer strictly to the steady state. Lal *et al.* (9) found a short linear region (0.45-0.6v) in steady-state Tafel plots with a slope of 60 mv. We have also obtained linear plots, over the same potential range, with slopes of around 90 mv. Taking $m_1 = m_2$ and $b = \beta_1 = 0.5$, Eq. [21] predicts a slope of 118 mv. The experimental discrepancies need to be resolved before any conclusions can be drawn.

Nature of adsorbed intermediate.—This is perhaps the central problem in elucidating the reaction mechanism. Giner (21) confirmed the existence of such an intermediate and suggested it had the composition CO or HCOOH. Podlovchenko and Gorgonova (6) used charging curves to determine the relative amounts of hydrogen and methanol adsorbed at open circuit. Finding that the two charges were about equal they concluded that three H atoms were lost upon chemisorption and therefore the intermediate was CHO. Bagotskii and Vasil'ev (5) compared the charge passed during adsorption at constant potential after adding methanol to the cell with the charge needed to oxidize the chemisorbed layer so produced. Although they gave no data, they claimed that these charges were equal and agreed with the assignment of a formula CHO to the intermediate. This conclusion would indicate that $n_1 = n_2$ in reactions [1] and [12].

The potential-step technique developed here can be used to provide information on this question. Current-time curves for reaction [1] are integrated from $t = 0$ by using the extrapolated portion of I_1^{-1} *vs.* t plots to give data for short times. The integration is extended until a steady state is reached (50-70 sec for the high methanol concentrations used). We assume that at sufficiently low potentials all of the charge is used to produce A_{ads} which remains on the surface. Double layer charging is of course complete at the times for which measurements are made. A rather arbitrary correction has to be made for the small steady-state current which, as a first approximation, is assumed to stay constant during the experiment. Results are shown in Table I. The problems involved in integrating the long and slowly decaying "tail" of the curves suggest that these values represent lower limits in each case.

Comparison with the results of ref. (5) indicates that the higher values of Table I correspond to coverages of about 0.9. We can therefore conclude that the deposition of a monolayer of A_{ads} involves at least 740 μcoul/geometric cm^2 (440 μcoul/real cm^2) and possibly some 10% more than this value. It is now possible to calculate m_1 from the experimental slopes of I_1^{-1} *vs.* t plots (Eq. [8]) and the above value for Q_{sat}. The value so found is 4.5 which is slightly less than half the f values (Eq. [22] and [23]) determined by Bagotskii *et al.* (2-5). Since a higher Q_{sat} would have given a larger m_1, this suggests that the value used here is indeed a lower limit for Q_{sat}.

From the point of view of comparison of Q_{sat} with Q_{ox}, the charge needed to oxidize a monolayer of intermediate to CO_2, it is unfortunate that much of the work on stripping of chemisorbed methanol has employed platinized electrodes of unknown or very approximately known areas (17, 21). However, Breiter and Gilman (18) report a value for Q_{ox} of 300 μcoul/geometric cm^2 which, using their value for saturation hydrogen coverage, corresponds to 185 μcoul/real cm^2. In agreement with this we obtain a value of 200 μcoul/real cm^2 by integrating the current peak given in (9) for the oxidation of adsorbed methanol on platinized platinum. Taking the mean of these two results for Q_{ox} and our value for Q_{sat} gives $Q_{sat}/Q_{ox} = 2.3$ and by reference to reactions [1] and [12] this is also equal to n_1/n_2. If these reactions represent the mechanism correctly then $n_1 + n_2 = 6$ and the ratio n_1/n_2 can only be 1, 2, or 5 (or their reciprocals). The data indicate that the experimental ratio is closest to 2, giving $n_1 = 4$, $n_2 = 2$. The oxidation state of the adsorbed intermediate would then correspond to CO.

It is possible that the different value for Q_{sat}/Q_{ox} found in (5) could be due to the difficulty in integrating the charge passed in the initial seconds of an experiment in which methanol is added to the cell with the electrode held at constant potential. We note that in Fig. 2 of ref. (5), showing the adsorption of 0.1M methanol at 0.4v, the maximum current was 45 μa/cm^2 compared with I_i of about 200 μa/cm^2 under similar conditions in the present experiments. This discrepancy supports the suggestion that values of Q_{sat} used in (5) were in error.

Manuscript received May 15, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL

Effect of Hydrogen Absorbed by Electrode and Electrolyte on Hydrogen Coverage

David J. BenDaniel and Fritz G. Will

General Electric Research & Development Center, Schenectady, New York

ABSTRACT

An analysis is made of the effect of atomic hydrogen absorbed by the electrode and of molecular hydrogen absorbed by the electrolyte on the hydrogen coverage of the electrode as determined by nonsteady-state methods. The cases of anodic and cathodic voltage pulses and sweeps and the significant case of anodic charging curves are treated. A numerical evaluation of the results is made for the particular case of platinum electrodes in aqueous electrolytes for which reliable data on diffusion coefficients and solubilities could be obtained. The errors that are introduced in surface coverage determinations are found to be significantly larger than assumed previously. Theoretical results are compared to some experimental data obtained by other authors and agreement within 20% is found.

The coverage of an electrode surface with atomic hydrogen can be determined with nonsteady-state methods, like the methods of applying current steps (charging curves) (1) or voltage sweeps (2). Both methods have been used frequently for this purpose in the past. However, the equivalent amount of surface charge measured with these methods contains contributions from atomic hydrogen dissolved in the interior of the electrode and from molecular hydrogen dissolved in the electrolyte. Both effects have qualitatively been recognized quite early (1). However, no quantitative description of either effect on the measured amounts of charge has been given.

In fact, considerable misunderstanding exists with regard to the size of the two effects and their possible estimations. For example, some authors (3) believe that the maximum amount of hydrogen that can diffuse from the electrolyte to the surface in the hydrogen adsorption region is given by $i_o t_1$, where t_1 is the transition time for this region and i_o the limiting diffusion current. Others (4) believe that the amount of hydrogen diffusing from the interior of the electrode to the surface can be determined from measurements in helium-saturated solutions and that this amount is applicable to solutions containing various concentrations of molecular hydrogen.

This paper analyzes in a general fashion the relevant nonsteady-state diffusion problem under the assumption of diffusion control, *i.e.*, the rates of the phase boundary reactions, like discharge and recombination, are assumed to be fast compared to the rate of diffusion. The paper establishes the errors introduced in measurements of hydrogen coverage by dissolution of hydrogen in the electrode and in the electrolyte. The particular case of clean active platinum electrodes in aqueous electrolytes is considered for which the assumption of diffusion-control is known (5, 6) to apply. The calculations show that previous rough estimates can be off by as much as two orders of magnitude. The results may be applied to any metal-electrolyte system exhibiting diffusion control and true solution behavior for hydrogen. Metals showing true solution behavior absorb hydrogen endothermically and proportionally to the square root of hydrogen pressure (7, 8).

Analysis

We consider the semi-infinite slab geometry shown in Fig. 1, in which the electrode surface is at $x = 0$, the electrode interior at $0 < x < +\infty$ and the electrolyte at $-\infty < x < 0$. The errors of the mathematical

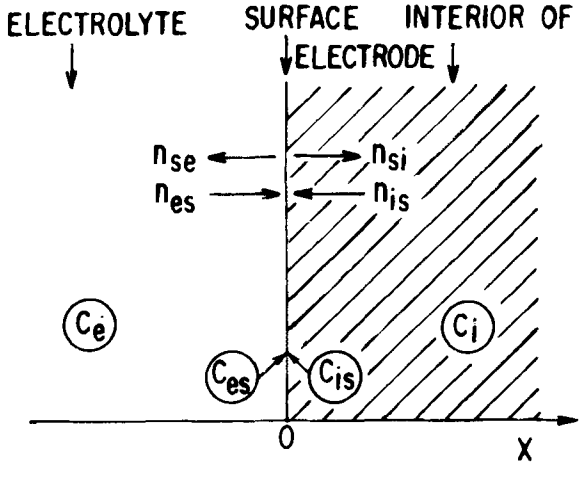

Fig. 1. Schematic diagram showing the interior of the electrode and the bulk of the electrolyte with the gas concentrations c_i and c_e, the concentrations near the surface, c_{is} and c_{es}, and the moles of gas n diffusing to and from the surface.

solutions for the semi-infinite problem due to the finite thickness of the electrode and electrolyte layer in actual practice are negligible for the experimental times of interest here.

In Fig. 1, the subscript e stands for electrolyte, s for surface, and i for interior of the electrode. Thus, c_i and c_{is} are the concentrations of atomic hydrogen in the electrode in its interior and near its surface, respectively; c_e and c_{es} are the corresponding concentrations of molecular hydrogen in the electrolyte. Also, n_{si} is the number of moles diffusing from the surface to the interior of the electrode and n_{is} is the number of moles diffusing in the opposite direction. Similarly, n_{se} and n_{es} are the number of moles diffusing from the surface into the electrolyte and in the opposite direction, respectively (see Fig. 1).

The diffusion of hydrogen both in the electrode and in the electrolyte is described by the familiar diffusion equation

$$D\partial^2 c/\partial x^2 = \partial c/\partial t \qquad [1]$$

where c is the concentration and D the diffusion coefficient of hydrogen in the electrode or in the electrolyte, respectively. The boundary conditions are determined as follows:

The concentration $c(x,t)$ vanishes for all finite times t as $x \to \infty$ in the electrode and as $x \to -\infty$ in the electrolyte. Thus, the first set of boundary conditions is

$$c_i(\infty,t) = 0 \qquad [2a]$$

$$c_e(-\infty,t) = 0 \qquad [2b]$$

In all cases of simple dissociative solution, the solubility of gases in metals is proportional to the square root of the gas pressure (8). This has been particularly shown for the absorption of hydrogen by platinum (7). Hence, for all times under equilibrium conditions

$$c_i(o,t) = c_{is}(t) = {}_oc_i\sqrt{p(t)/{}_op} \qquad [3a]$$

where ${}_oc_i$ is the standard solubility of atomic hydrogen for standard pressure ${}_op = 1$ atm.

According to Bunsen-Henry's law, the solubility of molecular hydrogen in the electrolyte is

$$c_e(o,t) = c_{es}(t) = {}_oc_e p(t)/{}_op \qquad [3b]$$

For equilibrium between molecular hydrogen and hydrogen ions, we can apply Nernst's equation for the electrode potential E

$$E(t) = -(RT/2\mathbf{F}) \ln (p(t)/{}_op) \qquad [4]$$

With [4] and the abbreviation

$$\Phi \equiv \mathbf{F}/RT \qquad [5]$$

we can obtain from [3a] and [4a] a second set of boundary conditions

$$c_{is}(t) = {}_oc_i \exp(-\Phi E(t)) \qquad [6a]$$

$$c_{es}(t) = {}_oc_e \exp(-2\Phi E(t)) \qquad [6b]$$

We consider two different initial time conditions.

1. The electrode and the electrolyte are essentially free of dissolved hydrogen, *i.e.*, a voltage $E_o >> 1/\Phi$ has been maintained for some time (several minutes) previous to $t = 0$ and is then changed in a cathodic direction.

Hence,

$$c_i(x,o) = 0 \qquad [7a]$$

$$c_e(x,o) = 0 \qquad [7b]$$

2. The electrode and the electrolyte hold equilibrium concentrations of hydrogen over finite distances $\pm x$ from the electrode surface, *i.e.*, a voltage $E_o \lesssim 1/\Phi$ has been maintained for some time and is changed in an anodic direction at time $t = 0$.

Hence,

$$c_i(x,o) = c_{is}(o) \qquad [8a]$$

$$c_e(x,o) = c_{es}(o) \qquad [8b]$$

The cases of voltage pulses and voltage sweeps will be treated below. The case of current steps (charging curves) reduces with good approximation to the case of voltage sweeps since, in the range of interest, the voltage changes to the first approximation linearly with time (1, 3, 4).

Electrode and electrolyte free of hydrogen, i.e. $E_o >> 1/\Phi$.—Cathodic voltage pulses.—At time $t = 0$, the voltage changes from its original value $E_o >> 1/\Phi$ to a value E_1 where it is maintained until at time t_1 it changes back to E_o, as shown in Fig. 2a. The analysis involves the application of standard mathematical techniques, *i.e.*, Laplace transforms.

The amount of atomic hydrogen dissolved in the electrode in moles H/cm² of electrode surface as a function of time is

$$n_{i\downarrow}(t) = 2{}_oc_i\sqrt{D_i t/\pi}\exp(-\Phi E_1)\,[1 - \sqrt{1 - t_1/t}\,u(t - t_1)] \qquad [9a]$$

The corresponding expression for the amount of molecular hydrogen dissolved in the electrolyte in moles H_2/cm² is

$$n_{e\downarrow}(t) = 2{}_oc_e\sqrt{D_e t/\pi}\exp(-2\Phi E_1)\,[1 - \sqrt{1 - t_1/t}\,u(t - t_1)] \qquad [9b]$$

The expression $\exp[-\Phi(E_o - E_1)]$ has to be added within the brackets of [9a] in cases when $E_o \approx 1/\Phi$. For [9b] the correction factor is $\exp[-2\Phi(E_o - E_1)]$. In [9a] and [9b] we define

$$u(t - t_1)\begin{cases} \equiv 0 \text{ for } t < t_1 \\ \equiv 1 \text{ for } t > t_1 \end{cases} \qquad [10]$$

If we let $t = t_1$ in [9a], we obtain the amount of hydrogen diffusing from the surface into the interior of the electrode during time t_1

$$n_{si\downarrow}(t_1) = 2{}_oc_i\sqrt{D_i t_1/\pi}\exp(-\Phi E_1) \qquad [11a]$$

For diffusion into the electrolyte we obtain from [9b]

$$n_{se\downarrow}(t_1) = 2{}_oc_e\sqrt{D_e t_1/\pi}\exp(-2\Phi E_1) \qquad [11b]$$

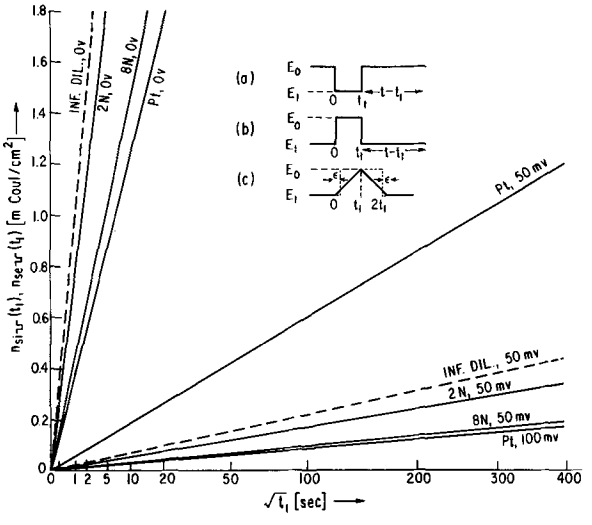

Fig. 2. Amounts of hydrogen, diffusing into Pt, *i.e.*, $n_{si}(t_1)$, and into electrolyte (8*N*, 2*N* H_2SO_4, infinite dilution), *i.e.*, $n_{se}(t_1)$, both in mcoul/cm² against $\sqrt{t_1}$. Numbers on abscissa give t_1 in sec. Voltage E_1 is parameter. Figure applies to cathodic voltage pulses (a), anodic voltage pulses (b), and anodic sweeps (c).

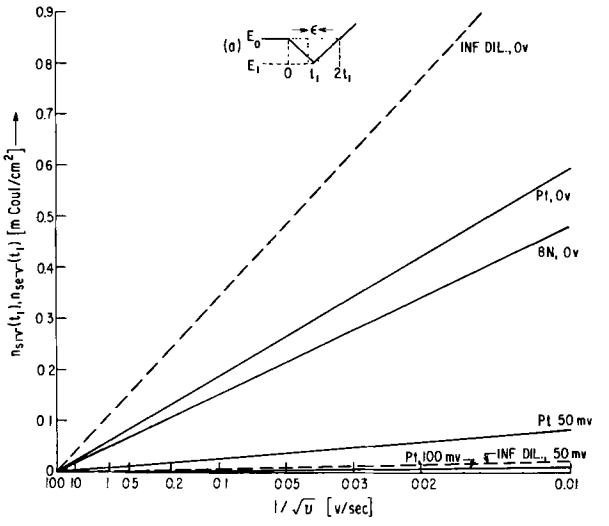

Fig. 3. Amounts of hydrogen diffusing into Pt and electrolyte during time t_1 of a cathodic voltage sweep as a function of $1/\sqrt{v}$. Electrolyte concentration and E_1 are parameters.

The fraction of hydrogen diffusing back from the interior of the electrode to its surface for times $t > t_1$ is readily obtained from [9a] and [11a] by forming

$$\nu_{iss\downarrow}(t) = [n_{i\downarrow}(t) - n_{si\downarrow}(t_1)]/\, n_{si\downarrow}(t_1) = n_{is\downarrow}(t)/n_{si\downarrow}(t_1) \quad [12a]$$

For the electrolyte $\nu_{ess\downarrow}$ is defined correspondingly. We find identical expressions for electrode and electrolyte

$$\nu_{is\downarrow}(t) = \nu_{es\downarrow}(t) = 1 + \sqrt{t/t_1 - 1} - \sqrt{t/t_1}, \quad \text{for } t \geqq t_1 \quad [12b]$$

Cathodic voltage sweeps.—At time $t = o$, the voltage starts decreasing linearly with time from its original value $E_o >> 1/\Phi$ where it had been maintained for some time prior to $t = o$, (see Fig. 3a). At time $t = t_1$, the voltage reaches its lowest value E_1 and then starts increasing linearly with time. The exact solution for this case is far more complex than for the case of voltage pulses and is given in the appendix as equation (A-2). For the times of main interest, $t = t_1$, and $t = 2t_1$, and for the usually occurring case $E_o - E_1 \geqq 0.1$v, the solutions simplify considerably.

The amount of atomic hydrogen diffusing from the surface into the interior of the electrode during time t_1 is

$$n_{sit\,v}(t_1) \approx {}_oc_i \sqrt{D_i/\Phi v}\, \exp(-\Phi E_1) \quad [13a]$$

which may also be written as

$$n_{sis\,v}(t_1) \approx \sqrt{\pi/4\Phi(E_o - E_1)}\; n_{sis\,v}(t_1) \quad [13b]$$

where

$$v = (E_o - E_1)/t_1 \quad [13c]$$

is the voltage sweep rate in v/sec. For $E_o - E_1 > 0.1$v, the error of [13a] compared to (A-2) is $< 1\%$.

The expression for the amount of molecular hydrogen diffusing from the surface into the electrolyte is simply obtained from [13a] by substituting 2Φ for Φ and ${}_oc_e$ and D_e for ${}_oc_i$ and D_i. In this case, the error for $E_o - E_1 > 0.1$v is $< 0.01\%$.

The fractions of hydrogen diffusing back to the surface from the interior and the electrolyte from t_1 to $2t_1$ are

$$\nu_{ist\,v}(2t_1) \approx 1 - [1 - 1/2\Phi(E_o - E_1)]/\sqrt{\pi\Phi(E_o - E_1)} \quad [14a]$$

$$\nu_{es\,v}(2t_1) \approx 1 - [2 - 1/4\Phi(E_o - E_1)]/\sqrt{2\pi\Phi(E_o - E_1)} \quad [14b]$$

The errors involved in these approximations for $E_o - E_1 > 0.1$v are $< 0.1\%$.

Electrode and electrolyte saturated with hydrogen, i.e. $E_1 \lesssim 1/\Phi$.—Anodic voltage pulses.—If voltages $E_1 \lesssim 1/\Phi$ have been maintained for some time prior to applying an anodic voltage pulse (see Fig. 2b), then electrode and electrolyte hold equilibrium amounts of hydrogen. At time $t = 0$, when an anodic step $E_o > E_1$ is applied, hydrogen starts diffusing from the bulk of electrode and electrolyte to the electrode surface. At the time of step reversal, t_1, hydrogen starts diffusing from surface to bulk until the original equilibrium condition is obtained again. The treatment of this case is identical to the case of cathodic voltage pulses. This is apparent if we consider that the diffusion of hydrogen from the bulk to the surface is equivalent to the diffusion of holes in the opposite direction and that the concentration of holes in the bulk as a function of time is identical to the amount of hydrogen that has diffused from the bulk to the surface. Hence, Eq. [9], [11], and [12] can be applied without changes, and we can write

$$n_{is\uparrow} = n_{si\downarrow},\; n_{es\uparrow} = n_{se\downarrow},\; \nu_{is\uparrow} = \nu_{si\downarrow},\; \nu_{es\uparrow} = \nu_{se\downarrow} \quad [15]$$

Anodic voltage sweeps.—The voltage-time function is shown in Fig. 2c. The amount of hydrogen diffusing to the surface as a function of time is a complicated function which is given in the appendix as Eq. [A-3]. For time t_1 the approximate solution for $E_o - E_1 >> 1/\Phi$

$$n_{ist\uparrow}(t_1) \approx 2\,{}_oc_i \sqrt{D_i t_1/\pi}\, \exp(-\Phi E_1)[1 - 1/2\Phi(E_o - E_1)] \quad [16]$$

is obtained from [A-3] which is in error by $<3\%$ for $E_o - E_1 > 0.4$v.

The fraction of hydrogen diffusing from time t_1 to $2t_1$ is

$$\nu_{ist\uparrow}(2t_1) \approx 1 - \sqrt{2}\,[1 - \sqrt{\pi/8\Phi(E_o - E_1)} - 1/4\Phi(E_o - E_1)]/[1 - 1/2\Phi(E_o - E_1)] \quad [17]$$

It will be shown that $\nu_{is\,A} < 0$, *i.e.*, there is a net diffusion of hydrogen from the interior to the surface from t_1 to $2t_1$.

As in the case of voltage pulses, the expressions for diffusion of molecular hydrogen from the electrolyte to the surface can simply be obtained from [16] and [17] by substituting 2Φ for Φ and ${}_oc_e$ and D_e for ${}_oc_i$ and D_i.

Numerical Evaluation and Discussion

For a numerical evaluation of the preceding analysis, we are in want of values of the solubility ${}_oc_i$ and the diffusion coefficient D_i of hydrogen in platinum near room temperature. While a number of studies has dealt with this subject from a qualitative viewpoint (9-13), there appears to be only one study (14)[1] from which ${}_oc_i$ and D_i could be determined. The values ${}_oc_i = 2.2 \cdot 10^{-5}$ mole H/cm^3 and $D_i = 3.0 \cdot 10^{-8}$ cm^2/sec were calculated for 25°C.[2]

The solubility of hydrogen in water, sulfuric acid, and potassium hydroxide near room temperature is well established (17-19). The values of three different authors agree within 5%.

For the diffusion coefficient of molecular hydrogen in water and sulfuric acid the data of different authors

[1] The loan of the relevant thesis by Professor K. J. Vetter is gratefully acknowledged.

[2] Note added during revision of manuscript: In a recent study E. Gileadi, M. A. Fullenwider, and J. O'M. Bockris [*This Journal*, 113, 926 (1966)] obtained permeation rates at 70°C which are by a factor of 8 smaller than those observed by Vetter and Knaack. These low values were obtained on platinum that had been intentionally poisoned with arsenic and will not be considered in this study. The permeation rate is generally known to decrease strongly when the surface is poisoned or inactive (15, 16).

(20-24) agree at best within ±20%. The data of Ruetschi (24), obtained at 30°C, were extrapolated to 25°C and used in this study. The following values for the solubility $_oc_e$ and the diffusivity D_e were used in the evaluation: In water $_oc_e = 7.7 \cdot 10^{-7}$ mole H_2/cm^3 and $D_e = 4.1 \cdot 10^{-5}$ cm^2/sec, in $2N$ H_2SO_4 $6.5 \cdot 10^{-7}$ mole H_2/cm^3 and $3.5 \cdot 10^{-5}$ cm^2/sec and in $8N$ H_2SO_4 $4.2 \cdot 10^{-7}$ mole H_2/cm^3 and $2.7 \cdot 10^{-5}$ cm^2/sec. All values are for 25°C. The amounts of hydrogen, n_i and n_e, will in the following be expressed in their charge equivalents (mcoul/cm^2). These are obtained by multiplying n_i with F and n_e with $2F$.

Cathodic voltage pulses.—The amounts of hydrogen diffusing into electrode and electrolyte according to Eq. [11a] and [11b] are plotted in Fig. 2 as a function of $\sqrt{t_1}$. The charges were calculated for different values of E_1 for diffusion into platinum electrodes, $8N$ H_2SO_4, $2N$ H_2SO_4, and infinitely diluted electrolytes. The formation of a monolayer of hydrogen atoms on the surface requires only 0.24 mcoul/cm^2, assuming close-packed crystal planes. Hence, the equivalent of several monolayers diffuses into electrode and electrolyte during a few seconds if E_1 is close to 0v. As E_1 increases, the hydrogen fluxes decrease exponentially. The decrease occurs far more rapidly for the electrolyte than for the electrode on account of the factor 2 in the exponential of Eq. [11b]. Thus, for $E_1 = 100$ mv the equivalent of one monolayer diffuses into the platinum during 400 sec while the amount diffusing into the electrolyte is <0.01 mcoul/cm^2.

Because of the larger values of $_oc_e$ and D_e in dilute electrolytes as compared to $8N$ H_2SO_4, 2.3 times more hydrogen diffuses into the former. The dotted lines in Fig. 2 represent an upper limit of the amount of hydrogen diffusing into any aqueous electrolyte.

The fraction of hydrogen diffusing back to the surface after step reversal at time t_1 according to Eq. [12b] is plotted in Fig. 4 as a function of $\sqrt{(t-t_1)/t_1}$. For t only slightly larger than t_1, *i.e.*, $t - t_1 \approx 0$, the fractions ν_i or ν_e approach zero. As t_1 increases, larger fractions of hydrogen diffuse from the interior to the surface. For $t = 2t_1$ the fraction $2 - \sqrt{2} \approx 0.6$ diffuses to the surface. Even if the time after step reversal is 10 times larger than the step duration t_1, only the fraction 0.84 of the hydrogen in electrode and electrolyte diffuses back to the surface. This result is explained by the fact that some hydrogen continues to diffuse into the bulk of electrode and electrolyte after step reversal.

It is interesting to note that no material constants enter into Eq. [12b]. This means that Eq. [12b] and Fig. 4 may be applied to any electrode material and electrolyte and any gas exhibiting true gas solution.

Cathodic voltage sweeps.—According to Eq. [13a] the amounts of hydrogen diffusing into electrode and electrolyte during time t_1 of a cathodic voltage sweep are inversely proportional to the square root of the sweep rate. In Fig. 3 the amounts of hydrogen are

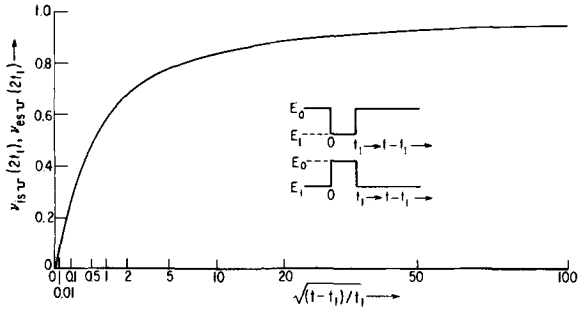

Fig. 4. Fractions of hydrogen back-diffusing to surface when applying anodic or cathodic pulses as function of $\sqrt{(t-t_1)/t_1}$. Note: numbers on abscissa give $(t-t_1)/t_1$.

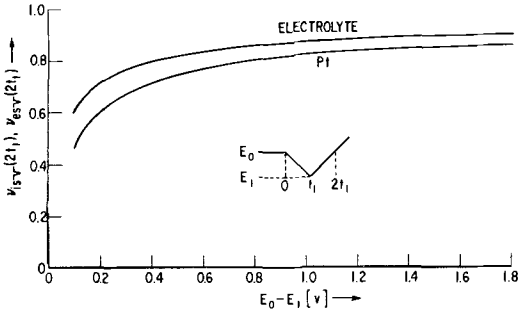

Fig. 5. Fractions of hydrogen back-diffusing to surface from t_1 to $2t_1$ as function of sweep range $E_0 - E_1$ of a cathodic sweep.

plotted against $1/\sqrt{v}$ for different values of E_1 and for diffusion into platinum, $8N$ H_2SO_4, and infinitely diluted electrolytes. We note from [13a] that the starting voltage E_o of the sweep (see Fig. 3a) does not affect the amount of hydrogen for $E_o >> 1/\Phi$. In contrast the amount decreases exponentially with increasing (more anodic) sweep reversal voltage E_1. This is understood if we consider that the concentration of hydrogen near the surface, c_{is} and c_{es} (Fig. 1), is vanishingly small for voltages $>> 1/\Phi$. It is only for voltages approaching $E_1 \lesssim 1/\Phi$ or times approaching t_1 that the diffusion of hydrogen becomes significant. In essence we can replace the cathodic sweep with a cathodic step of duration $\epsilon << t_1$ (see Fig. 3a). This assertion finds its quantitative expression in Eq. [13b] which compares the amount of hydrogen diffusing into electrode and electrolyte in the case of a cathodic sweep with that of a cathodic step applied for equal time t_1. Since [13b] was derived for $E_o - E_1 \geqq 0.1$v and since $\Phi = 38.9$ 1/v, we verify that the former is always smaller. In fact, for $E_o - E_1 = 0.4$v only about 1/4 of the amount diffuses into the electrode and 1/6 into the electrolyte.

According to [14a] and [14b] the fractions of hydrogen diffusing back to the surface between time t_1 and $2t_1$ are independent of the sweep rate and any material constants, but do depend on the sweep range $E_o - E_1$. A larger sweep range, using the analogy with a voltage step (see Fig. 3a) again, simply means more time $t - t_1$ available for the back-diffusion of hydrogen. The back-diffusing fractions are plotted in Fig. 5 as a function of sweep range. Assuming $E_1 \lesssim 1/\Phi$, we note that in the range of hydrogen coverage 0-0.4v, the fractions are approximately 0.7 for the electrode and 0.8 for the electrolyte. Considerably smaller fractions back-diffuse in the double-layer (0.4-0.8v) and oxygen adsorption regions (0.8-1.6v).

To facilitate assessing the errors involved in determining hydrogen coverages from voltage sweep experiments. Table I shows the charges due to hydrogen diffusion for some typical sweep rates and reversal voltages based on platinum in $8N$ H_2SO_4 at 25°C. The column $n_{\text{cath v}}$ gives the errors for the cathodic branch of the sweep, $n_{\text{anod v}}$ those for the anodic branch. The errors add up to the charge n_{ad} due to hydrogen coverage: $n_{meas} = n_{ad} + n_{\text{cath v}}$ (or $n_{\text{anod v}}$). Recalling that 240 μcoul/cm^2 corespond to a monolayer coverage of the electrode with atomic hydrogen, the errors are large indeed, especially if a reversal voltage of 0v is used.

The hydrogen diffusing to the electrode surface during the anodic branch of the sweep in the double layer region from 0.4 to 0.8v shows up as an equivalent capacity. The values range from 145 μF/cm^2 for 0.03 v/sec and $E_1 = 0$v to 3 μF/cm^2 for 1 v/sec and $E_1 = 0.05$v. These values have to be considered when determining double layer capacities from voltage sweep curves.

Anodic voltage pulses.—It has been mentioned before that the equations derived for the case of ca-

thodic voltage pulses are identical to those for anodic voltage pulses. Hence, Fig 2 shows the amounts of hydrogen that diffuse to the electrode surface from the bulk of electrode and electrolyte during time t_1 of applying an anodic voltage pulse. By analogy, Fig. 4 shows the fractions of hydrogen diffusing back into electrode and electrolyte after step reversal at time t_1.

Anodic voltage sweeps.—Using Eq. [11a] for cathodic pulses and noting Eq. [15], then Eq. [16] for anodic sweeps may be written as

$$n_{is\,\Lambda}(t_1) = n_{is\,\Lambda}(t_1)[1-1/2\Phi(E_o - E_1)] \qquad [18]$$

Noting that $E_o - E_1 >> 1/\Phi$ was assumed, $1/2\Phi\,(E_o - E_1)$ becomes a minor correction term. For $E_o - E_1 = 0.4$v the correction amounts to 3%. This means that the amount of hydrogen that diffuses from the interior of the electrode to the surface during time t_1 of applying an anodic voltage sweep is only slightly smaller than for the case of applying a voltage step. This is, because potentials, at which c_{is} (see Fig. 1) becomes vanishingly small, are reached for times $\epsilon << t_1$, if $E_o - E_1 >> 1/\Phi$. The effect is the same as if we would replace the sweep in Fig. 2c with a step of slightly shorter duration $t_1 - \epsilon$. The step is indicated in Fig. 2c by dashed lines. Figure 2 may be used to determine the amounts of hydrogen diffusing into the bulk of electrode and electrolyte. Equation [18] specifies the correction to be applied to the amounts thus determined.

Equation [17] represents the fraction of hydrogen diffusing from time t_1 to $2t_1$. The evaluation of [17] for $E_o - E_1 \geqq 0.1$v shows that the fraction $\nu_{i\,\Lambda}$ is always negative. This means that there is a net diffusion of hydrogen from the interior to the surface from t_1 to $2t_1$. This is in contrast to the cases discussed hitherto. Figure 6 shows how the fraction $\nu_{i\,\Lambda}$ increases with the sweep range $E_o - E_1$. From [17] we see that for very large values $E_o - E_1$ the fraction $\nu_{i\,\Lambda}$ approaches a limiting value $1 - \sqrt{2}$ which is indicated in Fig. 6 as a dashed line.

Qualitatively the net diffusion from the interior to the surface can be understood as follows. After the sweep reverses at time t_1 (see Fig. 2c), hydrogen continues to diffuse to the surface, since the concentration of hydrogen near the surface, c_{is}, is vanishingly small. For $E_o - E_1 >> 1/\Phi$ it is only at times approaching $2t_1$, that c_{is} becomes large enough to cause a diffusion of hydrogen from the surface into the interior. The amount of hydrogen that diffuses to the surface from time t_1 to $2t_1 - \epsilon$ exceeds the amount that diffuses in the opposite direction during time ϵ. Thus, we are left with a net diffusion to the surface.

For $E_o - E_1 \lesssim 1/\Phi$, ϵ is no longer small compared to t_1, and the amount of hydrogen diffusing to the surface from t_1 to $2t_1 - \epsilon$ no longer exceeds the amount diffusing in the opposite direction during time ϵ. In fact, for $E_o - E_1 << 1/\Phi$, the fraction diffusing to the surface approaches zero, while the fraction diffusing into the interior approaches the limiting value $2 - \sqrt{2}$ which one would calculate from Eq. [12b] for the application of a voltage pulse.

Equivalent arguments as above can be applied to the diffusion of hydrogen in the electrolyte. The fraction of hydrogen diffusing from the electrolyte to the surface from time t_1 to $2t_1$ is somewhat larger than for the electrode. The fraction was calculated from [17] and plotted in Fig. 6 observing that 2Φ is to be substituted for Φ.

Table II lists the amounts of hydrogen in μcoul/cm² diffusing to the surface during the anodic branch $n_{anod\,\Lambda}$ and the cathodic branch $n_{cath\,\Lambda}$ of an anodic sweep. Note that $n_{cath\,\Lambda}$ is negative, *i.e.*, the error due to diffusion makes the surface charge appear smaller: $n_{meas} = n_{ad} - |n_{cath\,\Lambda}|$. The values in Table II are calculated for Pt and $8N$ H_2SO_4 at 25°C with $E_o = 0.4$v. We note that the errors can become one order of magnitude larger than the surface charge to be determined.

Anodic charging curves.—When an anodic current step is applied to a platinum electrode, the voltage rises with time following a characteristic curve, called charging curve. In sulfuric acid and most other aqueous electrolytes, the voltage rises approximately linearly with time in certain voltage ranges (1, 3, 4). In sulfuric acid these ranges are the hydrogen adsorption region, 0-0.4v, the double layer region, 0.4-0.8v, and the oxygen adsorption region, 0.8-1.6v. Such a charging curve is schematically shown in Fig. 7.

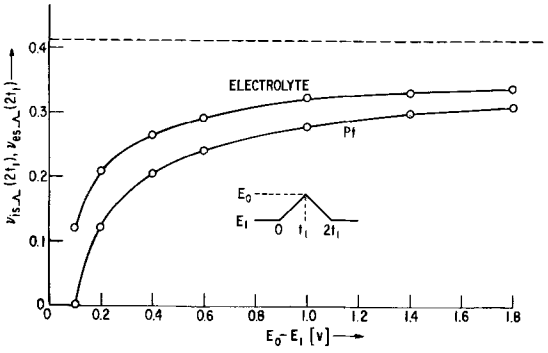

Fig. 6. Fractions of hydrogen continuing to diffuse to surface from t_1 to $2t_1$ as function of sweep range $E_o - E_1$ of an anodic sweep.

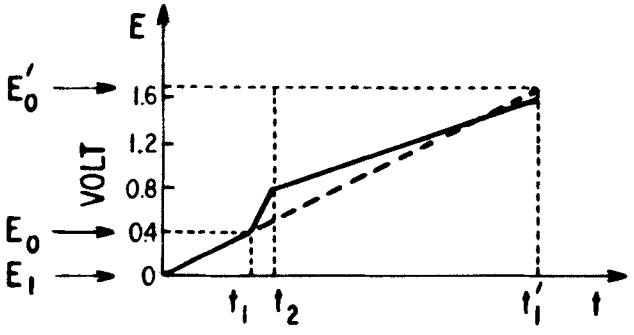

Fig. 7. Schematic diagram of anodic charging curve with hydrogen adsorption region 0 to 0.4v, double layer region 0.4 to 0.8v, and oxygen adsorption region 0.8 to 1.6v.

Table II. Amounts of hydrogen diffusing to the surface

v, v/sec	E_1, v	t_1, sec	$n_{is}\,\Lambda'$ μc/cm²	$n_{es}\,\Lambda'$ μc/cm²	$n_{anod}\,\Lambda'$ μc/cm²	$n_{si}\,\Lambda'$ μc/cm²	$n_{se}\,\Lambda'$ μc/cm²	$n_{cath}\,\Lambda'$ μc/cm²
0.03	0	13.3	1711	1720	3431	−353	−456	−809
0.1	0	4.0	799	389	1187	−164	−251	−415
1.0	0	0.4	253	297	551	−52	−79	−131
0.03	0.05	11.7	209	33	242	−40	−9	−49
0.1	0.05	3.5	114	18	132	−22	−4	−26
1.0	0.05	0.35	36	6	42	−7	−1	−8
0.03	0.10	10.0	28	<1	28	−5	<−1	−5
0.1	0.10	3.0	15	<1	15	−4	<−1	−4
1.0	0.10	0.3	5	<1	5	−1	<−1	−1

Table III. Errors $(n_{is} + n_{es})/n_{ad}$ involved in hydrogen coverage determinations

i, ma/cm²	t_1, sec	n_{is}, μc/cm²	n_{es}, μc/cm²	$n_{is} + n_{es}$, μc/cm²	$(n_{is} + n_{es})/n_{ad}$, %	$i_o t_1/n_{ad}$, %
1	2.4	650	1290	1940	810	1000
10	$6.0\cdot10^{-2}$	100	210	310	130	25
100	$3.6\cdot10^{-3}$	25	50	75	31	1.5
1000	$3.0\cdot10^{-4}$	7	15	22	9.2	0.1

It is immediately evident from a comparison of Fig. 2c and 7 that Eq. [16], derived for an anodic voltage sweep, can be used to approximately determine the amounts of hydrogen diffusing to the surface in the hydrogen adsorption region $E_o - E_1$ of an anodic charging curve. Furthermore, for all practical purposes, the concentration of hydrogen near the surface, c_{is} and c_{es}, can be considered zero for voltages >0.4v. Hence, the effect of replacing the three straight-line sections in Fig. 7 by the dotted straight line on the amounts of hydrogen calculated from Eq. [16] is negligible (<1% for $E_1 < 0.2$v). This means that Eq. [16] may be used to calculate the amounts of hydrogen diffusing to the surface during the whole time t_1' of an anodic charging curve, and Fig. 2 shows these amounts for a variety of conditions. Table III gives the errors $(n_{is} + n_{es})/n_{ad}$ involved in hydrogen coverage determinations for charging curves in $2N$ H_2SO_4 starting from $E_1 = 0$v for different charging currents i. Also given are the errors $i_o t_1/n_{ad}$ that result if one considers only steady-state diffusion (3). $i_o \approx 1$ ma/cm² is the limiting diffusion current, $n_{ad} = 0.24$ mc/cm² the surface charge due to hydrogen adsorption. It can be seen that the errors are sizeable, even at high charging currents and that the errors can be two orders of magnitude larger than those determined under the assumption of steady-state diffusion.

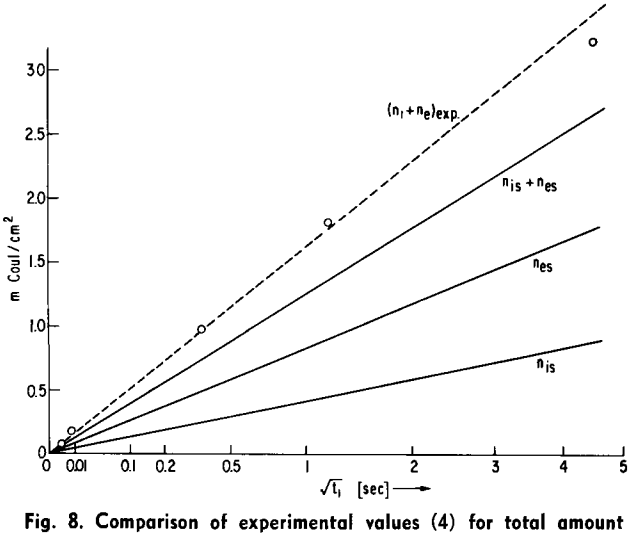

Fig. 8. Comparison of experimental values (4) for total amount of hydrogen diffusing from electrode and electrolyte (points and dotted line) with calculated curve in case of anodic charging curves.

Comparison with Experiments

Experimental results obtained by Schuldiner and Warner (4) can be used to verify the theoretical results obtained here. Conversely the present analysis enables us to interpret their relevant experiments on a quantitative basis.

Figure 8 shows experimental values for $(n_{is} + n_{es})_{exp}$ obtained by Schuldiner and Warner on a platinum bead[3] electrode in $2N$ H_2SO_4 at 23°C for 1 atm hydrogen pressure. Over the whole range af charging current densities from 0.78 to 203 ma/cm², the data points fall on a straight line when plotted against the square root of time, as required by Eq. [16]. Also shown in Fig. 8 are the calculated amounts n_{is} and n_{es} due to diffusion of hydrogen from the interior of the platinum and from the electrolyte. The first part is about half as large as the second. Their sum $(n_{is} + n_{es})$ is roughly 20% smaller than the experimental values. This is as good agreement as expected, considering that the values of D and c are not known more accurately.

The fact that the experimental data are well described by slow diffusion of hydrogen atoms from the metal interior and of hydrogen molecules from the electrolyte shows that up to current densities of at least 200 ma/cm² the assumption of fast phase boundary reactions is well justified. In particular, this means that the rates of the dissociation of hydrogen molecules and of the ionization of hydrogen atoms are fast compared to the rate of diffusion up to at least 200 ma/cm². This is in agreement with generally accepted views about the hydrogen reaction on clean active platinum electrodes (5, 6, 25).

The calculation allows a quantitative separation of the measured charge $(n_{is} + n_{es})_{exp}$ into two parts n_{is} and n_{es} which is not afforded by the experiments alone. Schuldiner and Warner believe that an experimental separation is possible by making measurements in helium saturated solutions and assuming that the value of n_{is}, thus determined holds for the whole range of hydrogen partial pressures and that only n_{es} changes. However, this is not the case. It is evident from the preceding treatment (compare Eq. [3], [6], and [16]) that both n_{is} and n_{es} increase with increasing hydrogen partial pressure. Thus, for 1 atm, n_{is} is by a factor of 4 larger than estimated by the cited authors.

Conclusions

On clean, active platinum electrodes, hydrogen absorbed by the metal and by the electrolyte contributes significantly to the total amount of charge determined with nonsteady-state methods like the current step (charging curves) and voltage sweep methods. These contributions have to be considered when deter-

[3] The diffusion distances are much smaller than the bead diameter; hence, the linear treatment can be applied.

mining surface coverages with hydrogen atoms. The magnitude of the errors increases exponentially when the starting voltage E_1 of an anodic charging curve or an anodic voltage sweep (or the reversal voltage of a cathodic sweep) is made more cathodic. With less cathodic E_1, the error due to diffusion from the electrode interior becomes proportionally much more important than diffusion from the electrolyte. Both statements are equivalent to saying that the error due to the electrolyte is proportional to the partial pressure of hydrogen while the error due to the electrode is proportional to the square root of pressure. Furthermore, the errors increase inversely proportional to the square root of the transition time of the charging curve and of the sweep rate of the voltage sweep, respectively. Typically, the total errors amount to 30% for a current density of 100 ma/cm² and 10% for 1 amp/cm² for an anodic charging curve started from 0v. For a cathodic sweep wih 1 v/sec the total errors are 45% for $E_1 = 0$v and 4% for $E_1 = 50$ mv.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

APPENDIX

In the following expressions, n, D, and ${}_oc$ are left without subscript and apply to both the interior of the electrode and the electrolyte. For the electrode interior $z = 1$; for the electrolyte $z = 2$. The symbol

$$a = \sqrt{(z\Phi|E_o - E_1|)/2t_1} \qquad \text{[A-1]}$$

is used for convenience.

Cathodic voltage sweeps.—The exact expression from which the approximate formulas [13a] through [14b] were derived is, for all times $t < 2t_1$,

$$n_v(t) = ({}_oc\sqrt{D/a})\Big\{\exp(-z\Phi E_o/2 + a^2t)\,\operatorname{erf}(a\sqrt{t}) - u(t-t_1)\exp[-z\Phi E_1/2 + a^2(t-t_1)]\,\operatorname{erf}(a\sqrt{t-t_1}) + u(t-t_1)\,2\pi^{-1/2}\exp[-z\Phi E_1/2 - a^2(t-t_1)]\int_o^{a\sqrt{t-t_1}}\exp(\lambda^2)\,d\lambda\Big\} \qquad \text{[A-2]}$$

Anodic voltage sweeps.—The exact expression from which the approximate formulas [16] and [17] were derived is, for all times t

$$n_v(t) = ({}_oc\sqrt{D/a})\Big\{2a\sqrt{t/\pi}\exp[-z\Phi E_1/2] - 2\pi^{-1/2}\exp[-z\Phi E_1/2 - a^2t]\int_o^{a\sqrt{t}}\exp(\lambda^2)\,d\lambda + u(t-t_1)\,2\pi^{-1/2}\exp[-z\Phi E_o/2 - a^2(t-t_1)]\int_o^{a\sqrt{t-t_1}}\exp(\lambda^2)\,d\lambda - u(t-t_1)\exp[-z\Phi E_o/2 + a^2(t-t_1)]\,\operatorname{erf}(a\sqrt{t-t_1}) + u(t-2t_1)\exp[-z\Phi E_1/2 + a^2(t-2t_1)]\,\operatorname{erf}(a\sqrt{t-2t_1}) - u(t-2t_1)\,2a\pi^{-1/2}\exp[-z\Phi E_1/2]\sqrt{t-2t_1}\Big\} \qquad \text{[A-3]}$$

These expressions were reduced to approximate forms by the use of well-known asymptotic expansions (20).

Discussion

Comments on

"Effect of Hydrogen Absorbed by Electrode and Electrolyte on Hydrogen Coverage" by David BenDaniel and Fritz G. Will

(Vol. 114, 909 (1967))

by Sigmund Schuldiner, Naval Research Laboratory, Washington, D. C.

BenDaniel and Will claim to give a general analysis of the nonsteady-state diffusion problem as applied to diffusion of H in metals and H_2 in solution to the electrode surface. Their analysis of H diffusion in the metal is based on the assumption that only diffusion of soluble H, in equilibrium with H_2 in solution, from the metal interior to the surface is the controlling factor. However, it has been known for some time that slow phase-boundary processes cannot be ignored for studies of the permeation rates of hydrogen through metals.[1] It also is known that part of the hydrogen associated with a platinum surface is strongly bonded and is not in equilibrium with H_2.[2]

Several workers[3] have shown that measurable amounts of H do not diffuse through a Pt membrane electrode when the polarization side is clean. BenDaniel and Will, however, evidently conclude that this work was not on clean surfaces and that the only acceptable work on a clean surface was that reported by Vetter and Knaack.[4] Vetter's book states that the Tafel slope found on the polarization side of their Pt membrane was 0.12. This value of Tafel slope clearly shows that the diffusion of molecular hydrogen is not rate controlling (this would give a 0.03 slope) and that the fast phase boundary (metal/solution) reactions claimed by BenDaniel and Will (which are necessary for their derivation) are not realized. The 0.12 slope found by Vetter and Knaack indeed shows that the hydrogen reaction took place on an electrode which was inactive, *i.e.*, dirty. In short, Vetter and Knaack's overvoltage and diffusion data are for a poisoned Pt electrode.

Further evidence which supports the conclusion that the Vetter and Knaack electrodes were not clean can be shown by comparing their results with those of Hoare and Schuldiner.[3] Vetter and Knaack's work at a current density of -11.5 ma/cm^2 gave an overvoltage of -340 mv, whereas Hoare and Schuldiner found at a current density of -5.3 ma/cm^2 an overvoltage of -48 mv. This, in addition to the fact that the 0.03 Tafel slope is well established for clean Pt surfaces[5] clearly shows that the diffusion of hydrogen through Pt membranes reported by Vetter and Knaack was on a Pt foil with a poisoned polarization side. This meant that a retarded phase boundary reduction to hydrogen occurred and that the atomic hydrogen formed was not in equilibrium with H_2 in solution.

BenDaniel and Will confuse the issue of electrode cleanliness and activity for hydrogen permeation. For Pt electrodes with high activity for the hydrogen formation reaction, the permeation of hydrogen through a membrane is negligible. For poisoned Pt electrodes with a low activity for the hydrogen formation reaction, the permeation of hydrogen through a membrane is appreciable. Hoare and Schuldiner[3] further showed that poisoned palladium could either lower or raise the H permeation rate. Barrer[6] did not, as claimed, show any experimental relationship between Pd electrode cleanliness and activity for hydrogen permeation. Instead, Barrer, on a purely random basis found that some Pd electrodes transmitted hydrogen faster than others. He defined the electrodes with the fastest permeation rates as the most active electrodes and postulated that they were the least poisoned. It is obvious from the work on hydrogen permeation through Pd and Pt that a little of some species which poison the hydrogen generation reaction on the polarization side of the membrane electrode can greatly increase the rate of H permeation while a substantial amount of practically any adsorbent (and perhaps even a little of some species) may retard H permeation. It is incorrect to conclude that, if hydrogen permeation is faster on one Pt electrode than another, the first is cleaner and more active for the hydrogen generation reaction than the second.

BenDaniel and Will's assumption that migration inside the metal is a function of the square root of hydrogen partial pressure is based on data obtained from the exposure of metals to hydrogen gas in either the gas or solution phase. When a potential is applied to a metal the effective hydrogen partial pressure and/or atomic hydrogen activity on the polarization side of the electrode surface is now the primary factor controlling the rate of solution and migration of H through the metal, and this will depend on the applied potential and current density up to a limiting value.[7] The partial pressure of hydrogen above the solution only would have a negligible effect. The much higher overvoltage and the associated much higher effective atomic hydrogen concentration on the polarization side of a poisoned Pt electrode explains the migration of H through such an electrode whereas on a clean electrode (low overvoltage) H migration through the metal is insignificant.

The numerical evaluation of the solubility and diffusion coefficients for hydrogen in Pt by BenDaniel and Will are much larger than would be reasonably expected. The solubility is given as 4.4×10^{-5} mole H/cm^3 and the diffusion coefficient is given as 1.5×10^{-8} cm^2/sec, both at 25°C. The solubility of H in Pt given in the literature is at least an order of magnitude lower. For example, Smith's[8] data gives 1.3×10^{-6}

mole H/cm³ at 400°C. Since, Pt is an endothermic occluder of hydrogen this means that the solubility of hydrogen at room temperature will be much less.

Gileadi *et al.*[3] obtained a solubility of H in poisoned Pt at 70°C of 2.7 x 10^{-5} g atoms H/cm³. Of this it was shown that only 5-15% of the H (2 x 10^{-6} g atoms H/cm³) is free to move through the lattice. The rest of the H was relatively stable and diffused out of the metal at much slower rates than diffusion into the Pt. The solubility data at 25° would, of course, be substantially lower. The diffusion coefficient found by Gileadi *et al.* was 3.4 x 10^{-9} cm²/sec at 70° and they estimated that it would be an order of magnitude less at 25°C.

BenDaniel and Will claim that equilibrium was not obtained in the helium-saturated experiments of Schuldiner and Warner.[2] If this were so then the $P_{H_2} = O$ results of Schuldiner and Warner should be dependent on the square root of time (according to the BenDaniel and Will derivation), both owing to H in the metal interior and H_2 diffusing into the solution. In fact, Schuldiner and Warner showed that from current densities of 3.53 to 0.78 ma/cm² (0.085-0.38 sec) there was virtually no change in the amount of hydrogen oxidized. The time dependence shown in the oxygen region for this same range of current densities shows that an experimental artifact cannot explain the invariance with time in the H region.

In conclusion, BenDaniel and Will cannot assume that slow phase boundary reactions did not affect the H permeation rate found by Vetter and Knaack, or that the Vetter and Knaack Pt electrode was clean. Indeed the overvoltage data given by Vetter and Knaack definitely show that their electrode was poisoned. (It should be pointed out that even though the Vetter and Knaack data did show a 0.02-0.04 Tafel slope on the diffusion side of the electrode, the 0.12 Tafel slope on the polarization side clearly shows a poisoned Pt surface.) Work by others[3] have shown that on a clean Pt surface hydrogen diffusion through Pt is immeasurable. The assumption used by BenDaniel and Will that the rate of diffusion of hydrogen through a Pt electrode is dependent on the square root of the hydrogen partial pressure in the gas phase above the solution is not applicable to a polarized electrode.

A Lumped Parameter Electrical Model for Predicting Concentration Transients in a Reversible Transference Cell

P. G. Griffith

Solid-State Electronics Laboratory, Department of Electrical Engineering, Texas Technological College, Lubbock, Texas

and J. R. Peebles

Texas Instruments, Incorporated, Dallas, Texas

ABSTRACT

The basic phenomenological equations governing electrical conduction of ions in an electrolyte are reviewed. As an approximation, these equations are redefined in the form of differential-difference equations for an incremental region in the electrolyte. A lumped parameter model, which is analogous to an electrical network, is developed for an incremental region in the form of an iterative network. Because the model exhibits a linear relationship between concentration and current, it can be analyzed using standard circuit-theory techniques. Specific examples are considered to demonstrate the use of the model. The agreement between the transient responses, calculated from the lumped parameter models and the theoretical solution, is, in general, sufficiently close to justify the use of these models in lieu of the more complicated theoretical solution.

Recent interferometric studies (1, 2) on $Zn/ZnSO_4/Zn$ and $Cu/CuSO_4/Cu$ systems have been devoted to the investigation of only the initial portion of the concentration transient response for a constant current excitation. The purpose of this approach has been to take advantage of the first term of a series solution. Even limited to this term (a form of the complementary error function), the analysis is rather complicated.

Because of these limitations, it is desirable to develop an approximate model for such a system which is applicable to a more general current excitation and to larger values of time. The term "model" is used in the sense of a discrete approximation to the exact system under consideration. The model itself is envisioned as a lumped parameter network, similar to an electrical network, with resistors, capacitors, etc. Such a model will be developed for the electrolyte.

A lumped parameter model for the electrolyte of a reversible transference cell will be developed for some rather idealized conditions, to illustrate the modeling procedure and to demonstrate how the model can be modified for improved accuracy. As an illustration of how the lumped parameter models are employed, concentration transients will be determined for a constant current excitation. The more general transient response for different current excitations is determined by standard circuit-theory techniques.

The use of lumped parameter models to approximate distributed systems with positive and negative ions is not new (3, 4). Such models have been used with excellent results on, for example, transistors and pn junction diodes. Since these have proved to be effective tools in analyses involving many semiconductor problems, similar results can be anticipated for electrochemical systems.

Basic assumptions.—The system under consideration is assumed to be a reversible transference cell in which the electrodes are the same metal and the electrolyte is a salt of the metallic element, *e.g.*, a $Zn/ZnSO_4/Zn$ transference cell. The anode and cathode reactions are defined by the equations

$$M \rightleftarrows M^{z+} + ze \quad [1]$$

$$M^{z+} + ze \rightleftarrows M \quad [2]$$

where M = metal of which the electrode is composed, z = valence of the ion formed, e = charge on the electron. The electrolyte MA is assumed to be in equilib-

rium with its ions M^{z+} and A^{z+} according to the equation

$$MA \rightleftarrows M^{z+} + A^{z-} \quad [3]$$

We shall assume that the electrolyte consists of ions with the same valence[1] and that the electrolyte is completely dissociated; consequently, the equilibrium condition represented by Eq. [3] is tipped entirely to the right.

We shall also make the following idealized assumptions:

1. Ions are transported in the x-dimension of a planar geometry.
2. Convection currents do not exist.
3. The diffusion coefficients (D_+, D_-) for the ions are constants and related to the drift mobility coefficients (μ_+, μ_-) by the Einstein relationship $D_+/\mu_+ = D_-/\mu_- = kT/zq$, where k is Boltzmann's constant, T is the absolute temperature in degrees Kelvin, and q is the magnitude of the charge on an electron. All of these parameters are assumed to be positive constants.
4. The electrolyte is assumed to be neutral with a pH of 7 at room temperature, *i.e.*, the electrolyte represents a two-ion system.

Theory.—The basic equations[2] for the cations and anions of the electrolyte may be summarized as follows:

$$I_+ = Azq\mu_+ EC_+ - AzqD_+(\partial C_+/\partial x) \quad [4]$$

$$I_- = Azq\mu_- EC_- + AzqD_-(\partial C_-/\partial x) \quad [5]$$

$$\partial C_+/\partial t = -(1/Azq)(\partial I_+/\partial x) \quad [6]$$

$$\partial C_-/\partial t = (1/Azq)(\partial I_-/\partial x) \quad [7]$$

$$\partial E/\partial x = (zq/\epsilon)(C_+ - C_-) \quad [8]$$

where I_+, I_- = cation and anion currents, respectively, in amperes, C_+, C_- = cation and anion concentrations, respectively, in No./cm^3, A = cross-sectional area in cm^2, E = electric field intensity in volts/cm, ϵ = dielectric constant in farads/cm.

Reviewing briefly, the first two equations represent the cation and anion currents; each of these can be subdivided further into drift (*i.e.*, electromigration) and diffusion components. Equations [6] and [7] are the displacement currents, based on the conditions for continuity. Equation [8] is a form of Poisson's equation which gives the relationship between the electric field intensity and charge density, divided by the dielectric constant. All of the constants in these equations are assumed to be positive.

In order to calculate the transient response of a transference cell for a given excitation, it is necessary to solve these equations simultaneously for the appropriate boundary conditions. This is not an easy task, unfortunately, even when several approximations are made. If these equations have to be resolved for each new set of boundary conditions, it follows that little is gained from previous experience. To circumvent this problem the model concept is employed.

To illustrate the modeling procedure, consider the incremental volume of the electrolyte shown in Fig. 1.

[1] The assumption of equal valences is not necessary for the theory but is imposed only as a means for simplifying the notation for the equations to be developed.

[2] The rationalized MKS system of units will be employed in this discussion, with the exception that all units containing length will be given in centimeters rather than meters.

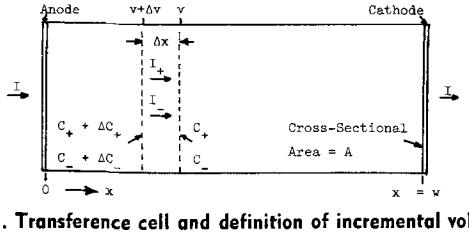

Fig. 1. Transference cell and definition of incremental volume

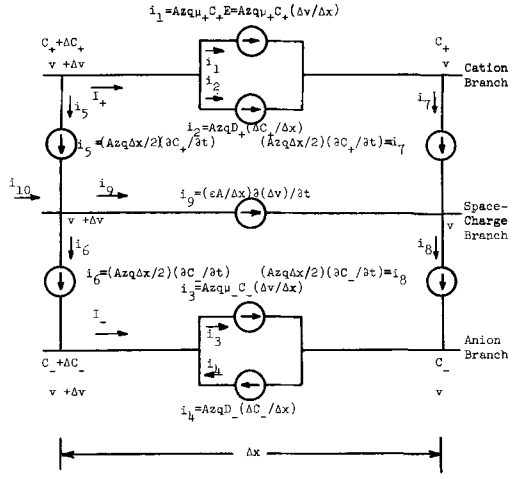

Fig. 2a. Incremental model for Eq. [4]-[8]

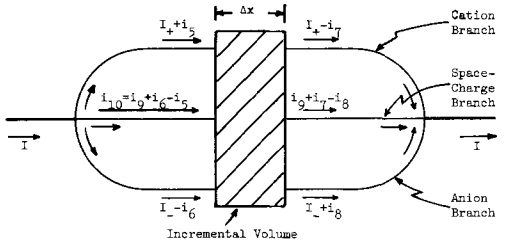

Fig. 2b. Division of the total current into its respective branch components.

As an artifice, we shall separate the cations and anions and their respective currents into two distinct regions of the electrolyte. If Eq. [4]-[8] are now synthesized for the spacial increment Δx, the incremental model shown in Fig. 2(a) results. Figure 2(b) illustrates, in a qualitative manner, the division of the total current into its respective branch components. It remains to be shown that a one-to-one correspondence exists in the limit as $\Delta x \rightarrow 0$ between the above equations and the incremental model. Referring to Fig. 2(a), the currents i_1 and i_2 are seen to be the drift and diffusion components of the cation current since $\Delta v/\Delta x \rightarrow E$ and $\Delta C_+/\Delta x \rightarrow -\partial C_+/\partial x$ in the limit as $\Delta x \rightarrow 0$. The sign conventions for the incremental parameters in Fig. 2(a) account for the mixed signs when the limits are evaluated. The anion current components i_3 and i_4 follow in exactly the same manner, except that the current i_4 is reversed in accordance with the definition of the direction for conventional current. Currents $i_5 - i_7$ and $i_6 + i_8$ are displacement currents for the cations and anions which correspond to Eq. [6] and [7] in the limit as $\Delta x \rightarrow 0$. Here we note that these currents are divided equally in the incremental region. The current i_9 is also a displacement current which tends to maintain charge neutrality in the electrolyte. (It is interesting to note that a displacement current can still flow even when charge neutrality, *i.e.*, $i_9 = 0$, applies.) The current i_9 is equal to $i_5 - i_6$, plus the summation of all displacement currents (i_{10}) from $x = 0$ to the reference point at which the incremental volume is chosen according to the equation

$$i_9 = \sum_{i=1}^{N} (\Delta I_+ - \Delta I_-)_i = Azq \frac{\partial}{\partial t}\left[\sum_{i=1}^{N} (C_+ - C_-)_i \Delta x\right] \quad [9]$$

If Eq. [9] is set equal to the defined current i_9, integrated with respect to t, and differentiated with re-

spect to x, we obtain in the limit as $\Delta x \to 0$ the following equation

$$\partial^2 v/\partial x^2 = (zq/\epsilon)(C_+ - C_-) \qquad [10]$$

It follows, thus, that Eq. [10] reduces to Eq. [8] since, $\partial^2 v/\partial x^2 = \partial E/\partial x$. Of interest is the fact that the current i_9 is equal to an electrical capacitor $C = \epsilon A/\Delta x$, multiplied by the time rate of change of voltage across the incremental volume of the electrolyte.

The next step in the modeling process is that of demonstrating that the transient associated with the displacement current i_9 decreases to zero at the relaxation time of the electrolyte. To illustrate why this is true, we shall assume that a step of current is applied to the transference cell at $t = 0$, *i.e.*, a step of positive ion current ($t_+ = 1$) at the electrode-electrolyte interfaces. If another current is already flowing in the cell when the step of current is applied, it will be assumed that this other current is changing slowly with time. The meaning of "slowly" will become clear as the argument is developed. The concentration of the electrolyte cannot change instantaneously on the onset of the step of current, ignoring regions immediately adjacent to the electrodes; thus, diffusion currents of types i_2 and i_4 throughout the electrolyte cannot change initially at the onset of the step of current but will change rather "slowly" beginning at the electrodes where the concentration initially begins to change. Currents of types i_5, i_6, i_7, and i_8 can and do change at a rate dictated by the following mechanism. Drift currents of types i_1 and i_3 change as the voltage changes across the electrolyte. It follows that the initial step of current all flows through a capacitor of $\epsilon A/w$ where w is the separation of the electrodes. This capacitor is actually shunted and distributed by incremental resistive components which carry the drift currents. The instantaneous electrical model of the electrolyte at the onset of the step of current is given by the distributed resistance-capacitance network shown in Fig. 3. The initial transient recovers at the relaxation time of the distributed R-C network according to the equation

$$\tau = \frac{\Delta C \Delta R_a \Delta R_c}{\Delta R_a + \Delta R_c} = \frac{\epsilon}{zq\mu_+ C_+ + zq\mu_- C_-} = \frac{\epsilon}{\sigma_+ + \sigma_-} \qquad [11]$$

where σ_+ and σ_- are the conductivities of the positive and negative ions of the electrolyte. Since the conductivity of the electrolyte varies with x due to current flowing prior to the application of the step input, the relaxation time is x-dependent and has a maximum value in that region of the electrolyte where the concentration is a minimum. For typical values of dielectric constants and conductivities, this relaxation time can be shown to be quite small, indeed, in comparison with the transient times that will be computed for the redistribution of ions, assuming that space-charge neutrality is present.

It should be pointed out that space-charge neutrality cannot exist unless dE/dx is zero. Since dE/dx will not be zero in the models to be developed, charge neutrality will not be met exactly. In general, this situation is not serious and can easily be tested by perturbation methods for determination of the degree of charge unbalance. It is not the intention to imply, however, that the equations can be indiscriminately manipulated.

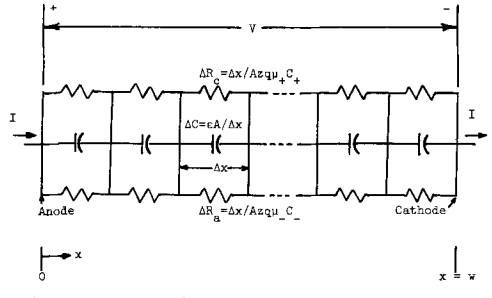

Fig. 3. Instantaneous electrical model of the electrolyte for the relaxation transient response.

Assuming the displacement current of type i_9 is zero, we shall demonstrate that the incremental model of Fig. 2 can be simplified by taking advantage of the fact that $C_+ \simeq C_-$. Solving for the electric field intensity E in Eq. [5] and substituting into Eq. [4], we obtain the equation

$$I_+ = I_-(\mu_+/\mu_-) - 2AzqD_+(\partial C_+/\partial x) \qquad [12]$$

Differentiating Eq. [12] with respect to x and substituting Eq. [6] and [7], we obtain the diffusion equation

$$\partial C_+/\partial t = \frac{2D_+\mu_-}{\mu_+ + \mu_-}(\partial^2 C_+/\partial x^2) = D_e(\partial^2 C_+/\partial x^2) \qquad [13]$$

in which the effective diffusion process is governed by the ambipolar diffusivity D_e. Referring to Fig. 2, it follows that the anion current I_- can be determined by integrating the displacement current from $x = 0$ to the reference point of the incremental model. The anion current, thus, is given by the equation

$$I_- = Azq\frac{\partial}{\partial t}\int_0^x C_+ dx \qquad [14]$$

and Eq. [12] becomes

$$I_+ = Azq(\mu_+/\mu_-)\frac{\partial}{\partial t}\int_0^x C_+ dx - 2AzqD_+(\partial C_+/\partial x) \qquad [15]$$

From these results, a modified incremental model can be synthesized as shown in Fig. 4(a). The model in its new form corresponds to Eq. [6] and [12] in the limit as $\Delta x \to 0$, for the assumed current directions in Fig. 2. The model still does not seem to be very tractable, unfortunately, in realizing the goals set forth at the outset. The basic problem stems from the fact that the anion current appears in the cation branch as a dependent current source $I_-(\mu_+/\mu_-)$. Kirchhoff's current law in conjunction with Eq. [14], will take care of this difficulty, however. Remembering that the current at the electrode-electrolyte interface is entirely positive ion, let us move the incremental volume to $x = 0$. Since the initial displacement current can be determined, it follows from Kirchhoff's current law that all currents entering the second incremental model are known. From a knowledge of the displacement current flowing in the second incremental model, all of the remaining currents can again be determined by this law. Proceeding thus from $x = 0$ to $x = w$, it is clear that a complete solution

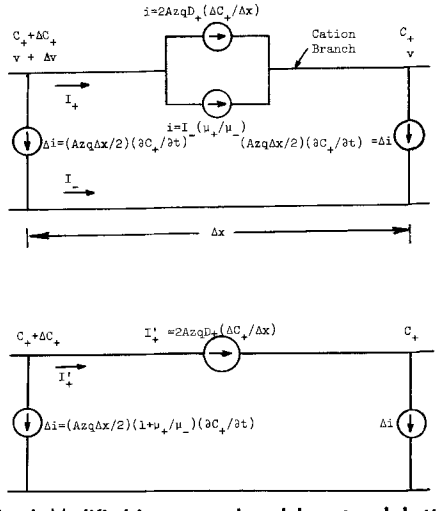

Fig. 4. Modified incremental models, a top, b bottom

can be effected, although somewhat difficult to perform in an exact analysis, assuming $i_9 = 0$.

An equivalent, but more abstract, model can be derived which avoids the dependent current source in Fig. 4(a) if we redefine the cation current in Eq. [15]. By incorporating the first term in Eq. [15] with Eq. [6], we obtain the following incremental equations

$$I_+' = -2AzqD_+(\Delta C_+/\Delta x) \quad [16]$$

$$\Delta I_+' = -(Azq\Delta x)(1 + \mu_+/\mu_-)(\partial C_+/\partial t) \quad [17]$$

where I_+' is the cation current, neglecting the contribution of the displacement component[3] (the first term in Eq. [15]). An alternative interpretation for the current I_+' is that it is the steady-state cation current that flows, after the displacement current becomes zero. The factor of two in Eq. [16] thus implies that the steady-state cation current is equally divided between drift and diffusion components. Employing this new definition for current, we can synthesize Eq. [16] and [17] as shown in Fig. 4(b), where the current in Eq. [17] is again symmetrically divided for the incremental volume.

The lumped model.—Thus far, the incremental model has been a useful tool for visualization purposes. The point of departure from a more exact analysis is to use one or more sections of the incremental model for approximation. In effect, thus, simultaneous partial differential equations are converted into simultaneous-differential-difference equations, differential in time and difference in space.

The lumped parameter model for the differential-difference approximation is obtained by letting Δx be a finite quantity in Fig. 4(b). For Δx finite and constant, the model is analogous to a lumped parameter electrical network, if we define the following analogies; concentration for voltage, current for current, $2AzqD_+/\Delta x$ for electrical conductance, $(Azq\Delta x/2)(1 + \mu_+/\mu_-)$ for electrical capacitance. Thus, the current sources in Fig. 4(b), can be replaced by lumped components analogous to electrical resistors and capacitors. In order to differentiate between the two analogies, we will follow Linvill's (3, 4) nomenclature and refer to the analog of conductance as "diffusance" and the analog of capacitance as "storance." The lumped-parameter model for an incremental region is shown

[3] Actually, the cation current in Eq. [15] consists only of drift and diffusion components. Since the first term is proportional to the displacement current as defined by Eq. [6], it is referred to, in this sense, as a displacement current.

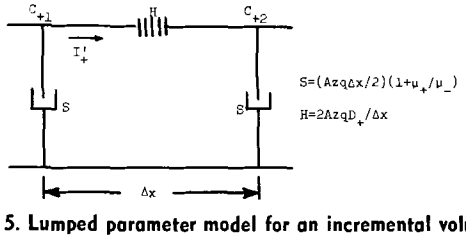

Fig. 5. Lumped parameter model for an incremental volume

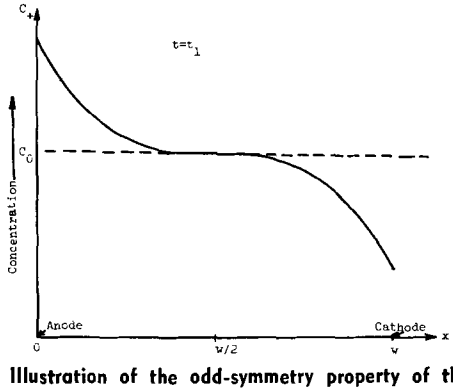

Fig. 6. Illustration of the odd-symmetry property of the excess concentration.

in Fig. 5 where the symbol H denotes diffusance and the symbol S denotes storance.

The final step in the modeling procedure is to ascertain the number of incremental regions which should be used to represent the electrolyte. This question can be answered partially by considering the odd-symmetry property of the excess concentration of the electrolyte. Let us consider the concentration profile in Fig. 6 at some instant during a transient response. For a reversible transference cell, the concentration profile will possess odd-symmetry about its equilibrium value, *i.e.*, the concentration for no excitation. Since the concentration at the center of the cell is clamped at its equilibrium value, it is seen that a model for the half-cell is sufficient to calculate the transient response. Thus, it follows that a knowledge of the excess concentration from $x = 0$ to $w/2$ can be used to determine the concentration from $x = w/2$ to w. This relationship is given by the equation

$$C_+(x,t) - C_0 = C_0 - C_+(w - x,t) = C_e(x,t) \quad [18]$$

where C_0 = equilibrium concentration and $C_e(x,t)$ = excess concentration.

It should be noted that Eq. [18] gives rise to two interesting implications. The first point to be observed is that the maximum concentration $C_+(0,t)$ at the anode cannot exceed twice the equilibrium concentration. This follows because the concentration at $x = w$, the cathode, cannot become negative. The second point to be noted is that the currents flowing in the lumped parameter model always depend on the excess concentration $C_+(x,t) - C_0$. Thus it follows that it is only necessary to consider the excess concentration in the computation of the concentration transient response. We shall take advantage of this property in the lumped parameter models.

Even though we can reduce the size of the over-all model by a factor of two by considering only a half-cell, we still have not resolved the problem of specifying the number of incremental regions to be used to approximate the region from $x = 0$ to $x = w/2$. This consideration will be deferred until the next section.

Application of the lumped parameter models.—In this section, we will use the half-cell lumped parameter models to calculate concentration transient responses for the special case of a constant current excitation. As previously indicated, the number of incremental regions necessary to approximate the region from $x = 0$ to $x = w/2$ has not been specified. Rather than take a large number of increments at the outset, we shall begin with only one incremental region ($\Delta x = w/2$), followed by two incremental regions ($\Delta x = w/4$), and, finally, three incremental regions ($\Delta x = w/6$).

Concentration transient responses will be considered for these three cases. In particular, one example will be given for the concentration response at the anode for these cases, and one example will be given, using the two-increment model, which demonstrates the spacial variation of the concentration for different normalized time increments. In order to demonstrate the accuracy of the calculations using the lumped parameter models, the theoretical response for each example will also be given in graphical form. It will be shown, that for as few as two or three increments to approximate a half-cell, that convergence to the theoretical solution is quite rapid. The theoretical solution will be given after these examples have been presented.

The first transient to be considered is that of the excess concentration at $x = 0$, the anode. The incremental models shown in Fig. 7 will be used to predict the concentration response which will be compared to the theoretical response. The models shown in Fig. 7(b) and Fig. 7(c) are obtained by letting $\Delta x = w/4$ and $\Delta x = w/6$, respectively, in Fig. 5 and cascading two or three of these sections, as required, to complete the

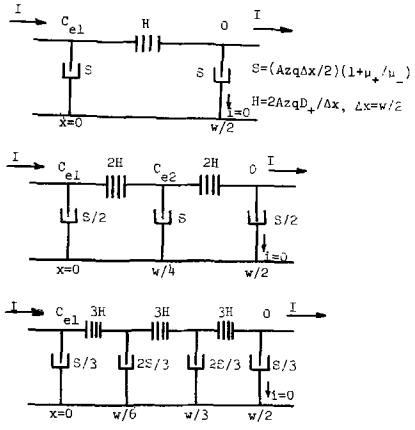

Fig. 7. Half-cell lumped parameter models for calculating excess-concentration transients: a (top) one-increment model; b (center) two-increment model; c (bottom) three-increment model.

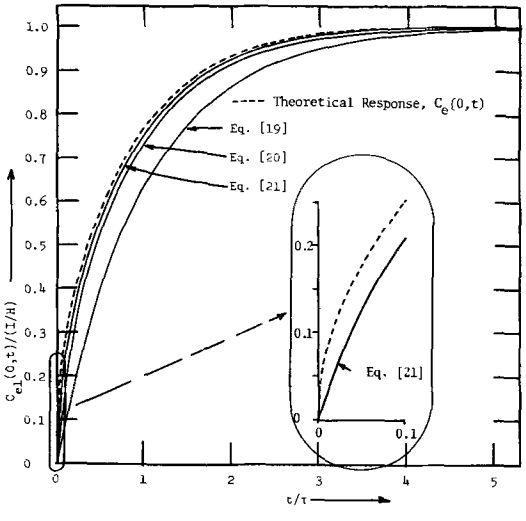

Fig. 8. Excess concentration transient responses at the anode based on the lumped parameter models and the theoretical solution.

models. For a constant current excitation I, the following equations for the excess concentration $C_{e1}(0,t)$ can be obtained by standard circuit-theory techniques (5)

$$C_{e1}(0,t) = (I/H)[1 - \exp(-t/\tau)] \quad [19]$$

$$C_{e1}(0,t) = (I/H)[1 - 0.8536\exp(-1.172t/\tau) - 0.1464\exp(-6.828t/\tau)] \quad [20]$$

$$C_{e1}(0,t) = (I/H)[1 - 0.8293\exp(-1.206t/\tau) - 0.1111\exp(-9t/\tau) - 0.0596\exp(-16.794t/\tau)] \quad [21]$$

where $\tau = S/H = w^2(1 + \mu_+/\mu_-)/16D_+$. Equations [19], [20], and [21] and the theoretical solution (Eq. [23] for $x = 0$) are plotted in Fig. 8 to illustrate the nature of the transient response and to demonstrate the rapid convergence to the theoretical response as the number of volume increments is increased. Referring to Fig. 8, it is seen that the convergence is quite good for the three-increment model, except for the initial portion of the transient response. Further, it should be noted that the principal error is represented by an almost constant time delay. If greater accuracy is desired for smaller values of time, the model is easily modified by adding more increments and readjusting parameters, as previously indicated. Although this may seem impractical, it is a relatively simple task to program digital computer to add more increments to the model since it has an iterative structure.

As a final example, an indication of the over-all concentration profile in a cell will be determined. Because of the incremental properties of the lumped parameter model, the concentration will vary linearly across each increment. In other words, if several increments are used to approximate a given cell, the concentration will vary in a piecewise-linear manner, consisting of a straight-line segment across each increment. To illustrate these ideas, let us consider the model shown in Fig. 7(b). Remembering the excess concentration at $x = w/2$ is zero and taking advantage of the odd-symmetry property of Eq. [18], the concentration profile is obtained by plotting Eq. [20] and the equation for $C_{e2}(w/4,t)$, as defined in Fig. 7(b)

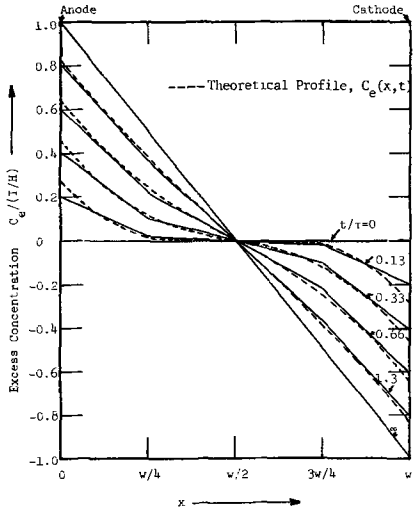

Fig. 9. Piecewise-linear excess concentration profile for the two-increment model and the theoretical profile for the cell.

$$C_{e2}(w/4,t) = (I/2H)[1 - 1.2071\exp(-1.172t/\tau) + 0.2071\exp(-6.828t/\tau)] \quad [22]$$

for different values of time. An indication of the approximate and theoretical excess concentration profiles for the entire cell is shown in Fig. 9. From Fig. 9, it follows that the concentration change initially increases more rapidly at the anode, followed by concentration build-up at $x = w/4$, until the steady-state concentration becomes truly linear on completion of the transient. Of course, the actual concentration profile exhibits curvature throughout the cell, and the piecewise-linear representation is only an approximation to the theoretical profile. Even so, the two-increment model gives a fairly accurate indication of the nature of the transient response. The three-increment model would have been even more accurate, especially at smaller values of t/τ. By considering more increments, the piecewise-linear representation can be made as accurate as desired.

The theoretical solution of the excess concentration, for the approximation set forth earlier, for the constant current excitation can be obtained by solving Eq. [13], subject to the condition at $x = 0$ that $I = -2AzqD_+(\partial C_+/\partial x)$ which is just Eq. [12] at $x = 0$ since I_- is zero and I_+ is the applied current and the condition that the excess concentration is zero at $x = w/2$. The theoretical solution is given by the equation[4] (6).

$$C_e(x,t) = (I/H)\left\{(1 - 2x/w) - (8/\pi^2)\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp[-(2n+1)^2\pi^2 t/8\tau]\cdot\cos[(2n+1)\pi x/w]\right\} \quad [23]$$

[4] This equation is identical to Eq. [5], p. 113, of Carslaw and Jaeger, except for minor transformations.

This equation is plotted for $x = 0$ in Fig. 8 and is plotted as a function of x for different values of t/τ in Fig. 9.

The above examples were intended to illustrate the general procedure for employing the lumped parameter models in the computation of concentration transient responses. Even though we have restricted these examples to a constant current excitation, other types of current excitations can readily be considered in a similar manner. In particular, for other excitations the lumped parameter approach becomes even more attractive. This follows because the solution of the diffusion equation, Eq. [13], is practically intractable except for very few excitations, such as the constant current excitation.

Conclusions

The incremental model has been shown to be a convenient vehicle with which to study electrical conduction phenomena in the electrolyte of a reversible transference cell. The linear relationship between concentration and current, for the approximations set forth, suggests a tangible means for describing a distributed system with a circuit analog. This follows because the same system can be analyzed for different excitations without recourse to the exact partial differential equations which are, in general, more difficult to solve than differential-difference equations. Even though the lumped parameter model has its principal limitation in predicting rapid transients, such as the initial portion of the concentration transient for a constant current excitation, its iterative structure provides a convenient means for adding more increments to the model to improve the accuracy. For many applications, where the over-all transient is to be investigated, a two-increment model for the half-cell should be adequate.

The possibility of extending and applying the lumped parameter model to other electrolytic systems should pose some challenging and interesting problems.

Primary and Solvent Isotope Effects in the Anodic Evolution of Oxygen

Mark Salomon[1]

School of Chemistry, Rutgers—The State University, New Brunswick, New Jersey

ABSTRACT

The use of hydrogen isotopes in studying the oxygen evolution reaction (o.e.r.) is discussed. It is shown that along with other experimental data such as pH studies, Tafel behavior, etc., the H/D-isotope effects can be used as additional criteria for the elucidation of reaction mechanisms. Normal isotope effects, *i.e.*, those corresponding to the o.e.r. being faster in H_2O than in D_2O, arise normally from considerations of the primary isotope effect. Depending on the magnitude of the solvent isotope effect, several cases involving an inverse isotope effect arise, *i.e.*, the rate of the o.e.r., is now faster in D_2O than it is in H_2O. A treatment of these isotope effects is given in this paper and experimental data for the o.e.r. at Ni anodes is discussed.

The oxygen evolution reaction (o.e.r.) has been of interest to electrochemists for many years (1-12). To mention only a few papers, the reactions occurring at the oxygen electrode have been studied by methods such as the pH effect (2,10) current-potential behavior (3-12), emf decay (6), and by oxide film formation (12). Conway and Bourgault (6, 12, 13), in their studies of the nickel-oxygen system, found that under certain conditions the rate of oxygen evolution was faster in heavy water than in light water, *i.e.*, an inverse isotope effect was experimentally observed. In 1965, Conway *et al.* (14) presented calculations and discussed the origin of this inverse isotope effect. In the present paper, a formal and more detailed analysis is presented, and the calculations briefly introduced in the original work (14) are extended to new cases as well as being developed in more detail. In general this paper deals with calculations of primary and solvent isotope effects in the o.e.r. The inverse isotope effect is attributed mainly to the solvent effect, *i.e.*, the reason why this effect appears can be traced to the evidence that the deuteroxide ion (OD^-) in D_2O is a stronger base than the OH^- ion in H_2O. Correspondingly, D_3O^+ in D_2O is a stronger acid than is H_3O^+ in H_2O (15).

[1] Present address: NASA, ERL, Cambridge, Massachusetts.

Kinetics of the O.E.R.

General considerations.—In alkaline solution, the possible kinetic sequences considered here are [cf. Bockris, ref. (2)]

$$M + OH^- \rightarrow MOH + e \quad [1]$$

$$MOH + OH^- \rightarrow MO + H_2O + e \quad [2a]$$

$$2MOH \rightarrow M + MO + H_2O \quad [2b]$$

$$2MO \rightarrow 2M + O_2 \quad [3]$$

Reactions [2a] and [2b] are considered to be alternative mechanisms therefore giving rise to two possible reaction sequences. In acid solutions, the schemes considered involve the following reactions [cf. Conway, ref. (7)]

$$M + H_2O \rightarrow MOH + H^+ + e \quad [4]$$

$$MOH + H_2O \rightarrow MO + H_3O^+ + e \quad [5a]$$

$$2MOH \rightarrow M + MO + H_2O \quad [5b]$$

$$2MO \rightarrow 2M + O_2 \quad [6]$$

where reactions [5a] and [5b] are considered to be alternative. One can of course write reactions analogous to [1]-[6] substituting deuterium for hydrogen, and these can thus serve as the basis for comparison of the H/D-isotope effect in the o.e.r.

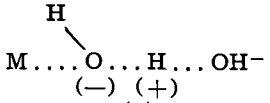
According to MacDonald and Conway (7), the initial discharge step always occurs from a water molecule so that reactions [1] and [4], respectively, should be written as

$$M + H_2O^* + OH^- \rightarrow MO^*H + H_2O + e \quad [1a]$$

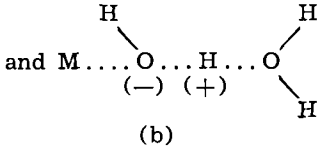
and

$$M + 2H_2O \rightarrow MOH + H_3O^+ + e \quad [4a]$$

The asterisk in Eq. [1a] indicates the original source of OH for the surface species. Hence, as in an earlier publication (16), the activated complexes corresponding to reactions [1a] and [4a], respectively, are



(a)



(b) [7]

and the rate-determining discharge step then involves the transfer of OH^- to the electrode surface and a proton transfer to an adjacent hydroxyl ion or water molecule in the double layer. Electron transfer to the metal then can occur when the activated complex relaxes to the final state configuration (32, 37).

To derive a rate equation for reaction [1a], the statistical method can be employed (17) as reported previously for the h.e.r. (18). The condition for equilibrium between initial and activated states for reaction [1a] is

$$\mu_M + \mu_{H_2O} + \bar{\mu}_{OH^-} = \bar{\mu}^{\ddagger} \quad [8]$$

where $\bar{\mu}$ is the electrochemical potential of the indicated species and μ is the chemical potential (19). For species i, $\bar{\mu}_i$ is defined as (19)

$$\bar{\mu}_i = \mu_i + z_i\phi_i\mathbf{F} \quad [9]$$

where ϕ_i is the inner potential of species i in the phase under consideration and z_i is the valence, including the sign, of the charged species. From statistical mechanics we have (17)

$$\mu_i = -kT \ln f_i \quad [10]$$

where f_i is the molecular partition function (p.f.) per molecule, *i.e.*

$$f_i = q_i/n_i \quad [11]$$

Hence it is clear that $\mu_i = \mu_i^\circ$ for the standard state when $n_i = 1$, and the standard state can, of course, be chosen in terms of molecules or moles. Using the latter convention, Eq. [9] and [10] can be combined to give

$$\bar{\mu}_i = -RT \ln f_i + z_i\phi_i\mathbf{F} \quad [12]$$

Taking $z = -1$ for both the OH^- and the activated complex, Eq. [8] and [12] can be combined and rearranged to give

$$f_M f_{H_2O} f_{OH^-} = f^{\ddagger} \cdot \exp[(\phi^{\ddagger} - \psi_1)\mathbf{F}/RT] \quad [13]$$

where ψ_1 is the potential at the outer Helmholz plane and $\phi^{\ddagger}$ is the inner potential of the system corresponding to the activated complex configuration. This follows from the model of the activated complex used here (Eq. [7]) and elsewhere (14, 16, 18). Since the electrode is at some potential ϕ_M and the reactants in the initial state (*i.e.*, in the outer Helmholz plane) are at some potential ψ_1, it follows that the potential $\phi^{\ddagger} - \psi_1$ is intermediate between $\phi_M - \psi_1$, *i.e.*, it corresponds to some fraction β of $\phi_M - \psi_1$. Expressed mathematically

$$\phi^{\ddagger} - \psi_1 = \beta(\phi_M - \psi_1) \quad [14]$$

From Eq. [11], [13], and [14]

$$n^{\ddagger} = n_M n_{H_2O} n_{OH^-} \frac{q^*}{q_M q_{H_2O} q_{OH^-}} \exp[\beta(\phi_M - \psi_1)\mathbf{F}/RT]$$

Removing the imaginary frequency from q^* and replacing it by $q^{\ddagger}$ (this is the frequency corresponding to the motion along the reaction coordinate), one now takes $q_M = 1$ (16, 18), multiplies by $\mathbf{F}$ and divides through by the area A (to obtain concentrations in units of moles cm^{-2}) and the above equation takes on the familiar form

$$i = \mathbf{F}\frac{kT}{h}[M][H_2O][OH^-]\frac{Q^{\ddagger}}{Q_{H_2O}Q_{OH^-}} \exp[\beta(\phi_M - \psi_1)\mathbf{F}/RT]$$

where $Q = q/A$. The terms in concentration should be replaced by ones in activities, but since we will be dealing in ratios (H_2O to D_2O), it is a good approximation to take the ratios of activity coefficients in H_2O to that in D_2O as equal to unity. Further simplification of this equation can be made by referring to the model of the activated complex in Eq. [7a]. The assumption is made (see calculations below) that the unreacting OH^- bond does not suffer any change in frequency in going from the initial to the activated state [cf. ref. (20)] so that the p.f. Q_{OH^-} cancels since it appears in both states. Taking the activity of water = 1, and considering the rate of reaction at the reversible potential, *i.e.*, ϕ_M (alk.) = $\phi r,b$ and $i = i_o$, the above equation becomes

$$i_o = \mathbf{F}\frac{kT}{h}[M][OH^-]\frac{q^{\ddagger}}{q_{H_2O}} \exp[\beta(\phi_{r,b} - \psi_1)\mathbf{F}/RT] \quad [15]$$

By an analogous procedure, the exchange current density for discharge in acid solutions is

$$i_o = \mathbf{F}\frac{kT}{h}[M]\frac{q^{\ddagger}}{q_{H_2O}} \exp[\beta(\phi_{r,a} - \psi_1)\mathbf{F}/RT] \quad [16]$$

Since similar relations can be written for the D-analogues of Eq. [15] and [16], a ratio of exchange current densities, R, can be defined as

$$R_1 = \frac{i_{o(H)}}{i_{o(D)}} = \frac{q_{D_2O}}{q_{H_2O}} \cdot \frac{q_{H^{\ddagger}}}{q_{D^{\ddagger}}} \exp[\beta\Delta\phi_b^\circ\,\mathbf{F}/RT] \quad [17]$$

and similarly

$$R_4 = \frac{q_{D_2O}}{q_{H_2O}} \cdot \frac{q^{\ddagger}{}_H}{q^{\ddagger}{}_D} \exp\beta[\Delta\phi_a^\circ\mathbf{F}/RT] \quad [18]$$

Equations [17] and [18] were obtained by assuming ψ_1 and [M] to be isotopically independent and by allowing $[OH^-] = [OD^-]$ and $[H_3O^+] = [D_3O^+]$. This latter condition permits one to write the potential difference term $\phi_{r,H^-}\ \phi_{r,D}$ in terms of the standard values, $\Delta\phi^\circ = \phi^\circ{}_H - \phi^\circ{}_D$. The remaining relations for R for reactions [2], [3], [5], and [6] shall be presented in a brief manner since they all follow from treatments similar to that described above.

Reaction scheme [1], [2a], [3].—For the case of a rate-determining step [2a], the values of R for limiting Langmuir coverages of $\theta_{MOH} \to 0$ and 1, respectively, are

$$R_{2a} = \left(\frac{q_{OD^-}}{q_{OH^-}}\right)^2 \cdot \frac{q^+_H}{q^+_D} \exp\left[(1+\beta)\Delta\phi^\circ \mathbf{F}/RT\right] \quad [19]$$

and

$$R_{2a} = \left(\frac{q_{OD^-}}{q_{OH^-}}\right)^2 \cdot \frac{q^+_H}{q^+_D} \exp\left[\beta\Delta\phi^\circ \mathbf{F}/RT\right] \quad [20]$$

If a Temkin isotherm is applicable, the rate of reaction [2] is (21, 22),

$$i_{O,2} = Z\mathbf{F}\frac{kT}{h}[MOH][OH^-]\frac{q^+}{q_{MOH}\, q_{OH^-}} \exp\left[f(\theta) + \beta\phi^\circ \mathbf{F}\right]/RT$$

where the function $f(\theta)$ has been previously defined (21, 22) as

$$f(\theta) = \phi^\circ \mathbf{F} + \text{constants}$$

By considering reaction [1] to be in quasi-equilibrium, it follows that the explicit form of the above equation is

$$f(\theta) = RT \ln [OH^-] + RT \ln\left[(1-\theta_t)/\theta_{MOH}\right] + RT \ln(q_{MOH}/q_{OH^-}) + \phi^\circ \mathbf{F} \quad [21]$$

where θ_t is the total surface coverage. Making the appropriate substitutions it is found that the theoretical expression for R_2 is identical to Eq. [19].

For a rate-determining step [3], use of the Langmuir isotherm for $\theta_{MO} \to 0$ and 1, respectively, gives

$$R_3 = \left(\frac{q_{OD^-}}{q_{HO^-}}\right)^4\left(\frac{q_{H_2O}}{q_{D_2O}}\right)^2 \frac{q^+_H}{q^+_D} \exp\left[4\Delta\phi^\circ \mathbf{F}/RT\right] \quad [22]$$

and

$$R_3 = \frac{q_{MO(D_2O)}}{q_{MO(H_2O)}} \cdot \frac{q^+_H}{q^+_D} \quad [23]$$

For the cases where the Temkin isotherm might be applicable, several cases arise for activated and nonactivated adsorption. Using Eq. [21] and employing simple equilibrium relations [cf. ref. (22)] the following R_3 values are easily obtained: (*i*) For activated adsorption we have

$$R_3 = \left(\frac{q_{OD^-}}{q_{HO^-}}\right)^4\left(\frac{q_{H_2O}}{q_{D_2O}}\right)^2 \frac{q^+_H}{q^+_D} \exp\left[\Delta\phi^\circ \mathbf{F}/RT\right] \quad [24]$$

for $\theta_{MO} \approx \theta_{MOH}$ and

$$R_3 = \left(\frac{q_{OD^-}}{q_{HO^-}}\right)^4\left(\frac{q_{H_2O}}{q_{D_2O}}\right)^2 \frac{q^+_H}{q^+_D} \exp\left[3\Delta\phi^\circ \mathbf{F}/RT\right] \quad [25]$$

for $\theta_{MO} << \theta_{MOH}$ and potential dependent.

(*ii*) For nonactivated adsorption

$$R_3 = \left(\frac{q_{OD^-}}{q_{HO^-}}\right)^4\left(\frac{q_{H_2O}}{q_{D_2O}}\right)^2 \frac{q^+_H}{q^+_D} \cdot \exp\left[2\Delta\phi^\circ \mathbf{F}/RT\right] \quad [26]$$

for $\theta_{MO} \approx \theta_{MOH}$. For the case where $\theta_{MO} << \theta_{MOH}$ (and is therefore potential dependent) R_3 is given by Eq. [22].

Reaction scheme [1], [2b], [3].—For this sequence of reactions, R_1 and R_3 values are the same as those given above. For the limiting Langmuir conditions of $\theta_{MOH} \to 0$ and 1, respectively, it can easily be shown that

$$R_{2b} = \left(\frac{q_{OD^-}}{q_{OH^-}}\right)^2 \frac{q^+_H}{q^+_D} \exp\left[2\Delta\phi^\circ \mathbf{F}/RT\right] \quad [27]$$

and

$$R_{2b} = \left(\frac{q_{OD^-}}{q_{OH^-}}\right)^2 \frac{q^+_H}{q^+_D} \quad [28]$$

For the intermediate Temkin type behavior

$$R_{2b} = \left(\frac{q_{OD^-}}{q_{OH^-}}\right)^2 \frac{q^+_H}{q^+_D} \exp\left[\Delta\phi^\circ \mathbf{F}/RT\right] \quad [29]$$

Reaction scheme [4], [5a], *and* [6].—R values for this scheme are obtained by methods very similar to that discussed above and involve mainly algebraic substitutions. Hence only the final results need be given with the exception that the $f(\theta)$ required for the Temkin cases in acid solution is defined by

$$f(\theta) = -RT \ln [H_3O^+] + RT \ln (1-\theta_t/\theta_{MOH}) + RT \ln\left[(q_{H_3O^+})(q_{MOH})/q^2_{H_2O}\right] + \phi^\circ \mathbf{F} \quad [30]$$

The relation for R_4 is given by Eq. [18]. For a rate-determining reaction [5a]

$$R_{5a} = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^3 \frac{q_{H_3O^+}}{q_{D_3O^+}} \cdot \frac{q^+_H}{q^+_D} \exp\left[(1+\beta)\Delta\phi^\circ \mathbf{F}/RT\right] \quad [31]$$

and

$$R_{5a} = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^3 \frac{q_{H_3O^+}}{q_{D_3O^+}} \frac{q^+_H}{q^+_D} \exp\left[\beta\Delta\phi^\circ \mathbf{F}/RT\right] \quad [32]$$

for the Langmuir conditions of $\theta_{MOH} \to 0$ and 1, respectively. For the Temkin case of $\theta_{MOH} \approx 0.5$, R_{5a} is given by Eq. [31].

For a rate-determining step [6], the quasi-equilibrium treatment gives

$$R_6 = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^6\left(\frac{q_{H_3O^+}}{q_{D_3O^+}}\right)^4 \frac{q^+_H}{q^+_D} \exp[4\Delta\phi^\circ \mathbf{F}/RT] \quad [33]$$

and

$$R_6 = \frac{q_{MO(D_2O)}}{R_{MO(H_2O)}} \cdot \frac{q^+_H}{q^+_D} \quad [34]$$

respectively, for $\theta_{MO} \to 0$ and $\theta_{MO} = 1$ (Langmuir conditions).

If the Temkin isotherm is applicable we again have: (*i*) Activated adsorption gives two cases, respectively, for

$$\theta_{MO} \approx \theta_{MOH} \text{ and } \theta_{MO} << \theta_{MOH}$$

$$R_6 = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^6\left(\frac{q_{H_3O^+}}{q_{D_3O^+}}\right)^4 \frac{q^+_H}{q^+_D} \exp[\Delta\phi^\circ \mathbf{F}/RT] \quad [35]$$

and

$$R_6 = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^6\left(\frac{q_{H_3O^+}}{q_{D_3O^+}}\right)^4 \frac{q^+_H}{q^+_D} \exp[3\Delta\phi^\circ \mathbf{F}/RT] \quad [36]$$

(*ii*) For nonactivated adsorption

$$R_6 = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^6\left(\frac{q_{H_3O^+}}{q_{D_3O^+}}\right)^4 \frac{q^+_H}{q^+_D} \exp[2\Delta\phi^\circ \mathbf{F}/RT] \quad [37]$$

for $\theta_{MO} \approx \theta_{MOH}$. For $\theta_{MO} << \theta_{MOH}$, R_6 is given by Eq. [33].

Reaction scheme [4], [5b], *and* [6].—The values of R_4 and R_6 will again remain unchanged. Under Langmuir adsorption conditions, it follows that

$$R_{5b} = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^3 \cdot \frac{q_{H_3O^+}}{q_{D_3O^+}} \cdot \frac{q^+_H}{q^+_D} \exp[2\Delta\phi^\circ \mathbf{F}/RT] \quad [38]$$

and

$$R_{5b} = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^3 \cdot \frac{q_{H_3O^+}}{q_{D_3O^+}} \cdot \frac{q^+_H}{q^+_D} \quad [39]$$

for $\theta_{MOH} \to 0$ and 1, respectively. For the intermediate Temkin type behavior

$$R_{5b} = \left(\frac{q_{D_2O}}{q_{H_2O}}\right)^3 \cdot \frac{q_{H_3O^+}}{q_{D_3O^+}} \cdot \frac{q^+_H}{q^+_D} \exp[\Delta\phi^\circ \mathbf{F}/RT] \quad [40]$$

Calculations

Initial state quantities.—The p.f. ratios for the various H and D species were obtained from previous calculations using spectroscopic (15, 38) and equilibrium (39, 40) data found in the literature (15). For 25°C, the appropriate p.f. ratio values are (cf. 18, 23)

$$\frac{q_{D_2O}}{q_{H_2O}} = 1437; \frac{q_{D_3O^+}}{q_{H_3O^+}} = 19{,}023; \frac{q_{OD^-}}{q_{OH^-}} = 21.15$$

The potential difference, $\Delta\phi^\circ$.—In alkaline solution, ϕ°_r for the reversible oxygen electrode can be calculated from the free energy change of the equilibrium

$$2\,OH^- \rightleftarrows \tfrac{1}{2}O_2 + H_2O + 2e_M$$

The condition for equilibrium is

$$2\bar{\mu}_{OH^-} = \tfrac{1}{2}\mu_{O_2} + \mu_{H_2O} + 2\bar{\mu}_e$$

Using Eq. [9]-[12] and taking all activities equal to unity (*i.e.*, standard states are being employed), the above equation becomes

$$(\phi^\circ_r - \phi_s)_{H_2O} = \frac{RT}{2F} \ln [Q_{OH^-}{}^2/Q_{O_2}{}^{1/2}Q_{H_2O}Q_{e(M)}]$$

Since an analogous expression exits for the reversible oxygen electrode in D_2O, it follows that

$$\phi^\circ_{r(H_2O)} - \phi^\circ_{r(D_2O)} = \Delta\phi^\circ_{alk} = \frac{RT}{2F} \ln \left\{ \left(\frac{q_{OH^-}}{q_{OD^-}} \right)^2 \frac{q_{D_2O}}{q_{H_2O}} \right\}$$

where the potential in the bulk, ϕ_s, is taken to be zero. Using the values of partition function ratios above, it is found that $\Delta\phi^\circ_{alk} = 0.0150$v at 25°C.

In acid solutions, the reversible reaction is

$$3H_2O \rightleftarrows 2H_3O^+ + \tfrac{1}{2}O_2 + 2e_{(M)}$$

and using the procedure just described,

$$\phi^\circ_{r(H_2O)} - \phi^\circ_{r(D_2O)} = \Delta\phi^\circ_{acid} = \frac{RT}{2F} \ln \left\{ \left(\frac{q_{H_2O}}{q_{D_2O}} \right)^3 \left(\frac{q_{D_3O^+}}{q_{H_3O^+}} \right)^2 \right\}$$

At 25°C, $\Delta\phi^\circ_{acid} = -0.0270$ volt.

Activated complexes.—Whereas the p.f. ratios for the initial state species were calculated from spectroscopic and equilibrium data, those for the activated complex must be estimated either from a potential energy surface, or empirically by comparison to similar stable species where force constants and vibrational frequencies are known, or can be reasonably inferred. In this paper, the latter method is used not only because of its simplicity, but because the assumptions required for analysis of the activated complex are quite similar in both cases as discussed below.

If a potential energy surface were to be constructed, the following assumptions would have to be made:

(*i*) All bonds not directly involved in the reaction do not undergo changes in vibrational frequency.

(*ii*) The activated complex can be treated as a pseudo-three or four atom system.

(*iii*) Assumption (*ii*) leads to the conclusion that a Morse function can now be used to describe the energies of the various "diatomic" species involved; *e.g.*, the O-H bond in H_2O can be treated in terms of the Morse equation.

(*iv*) Some method must be used to obtain the coulombic and exchange energies so that the London equation may be solved. Eyring's method (24) assumes the overlap integral to be zero and further assumes a constant coulombic/exchange energy ratio. A second method (25) assumes a constant value for this overlap integral (chosen to fit the experimental activation energy), and the coulombic and exchange energies can then be calculated from bonding and antibonding Morse equations. Despite some serious objections to either method (26-28), there is no doubt as to their general usefulness. In order to construct the potential energy surface for an electrochemical reaction, one would have to know the "real" activation energy so that the adjustable parameters in the theory could be properly utilized (23, 29-31).

In view of all these assumptions and difficulties, it seems perhaps more valid to use some strictly empirical method for characterization of the activated complex. In such a treatment, one has to make the following assumptions (cf. 29, 32):

(*i*) Same as (*i*) above

(*ii*) Secondary isotope effects are neglected since they are small to begin with (33) and also since the limits of reproducibility are such that it is very doubtful if such effects could be experimentally demonstrated for the o.e.r. This assumption permits us to immediately simplify the p.f. ratios involving only oxide surface species. In reactions [3] and [6], we can therefore take the p.f. ratios $q_{MO(D_2O)}/q_{MO(H_2O)}$ and $q^{\pm}_H/q^{\pm}_D$ as being equal to unity. Also differences in the ψ_1-potentials (which are very small) can be neglected on this basis (18, 29, 32), and $1 - \theta_t$ terms are assumed to be independent of isotope.

(*iii*) The symmetric stretching frequency for activated complexes of the type O . . . . . H . . . . . O are independent of isotopic substitution.

(*iv*) Assuming the activated complex in (*iii*) is linear (24), only the doubly degenerate bend need be considered. For the O-H-O bend, an average frequency of 1200 cm^{-1} will be used here as this value seems to be the most reasonable one as discussed elsewhere (18, 29, 34, 35). Hence the vibrational contribution to the activated complex p.f. ratio for this degenerate vibration is

$$\left(\frac{\sinh u^{\pm}_D}{\sinh u^{\pm}_H} \right)^2 = 0.179$$

where $u = hc\nu/2kT$ (ν being in cm^{-1}).

Using these four assumptions, the mechanics of solving $q^{\pm}_H/q^{\pm}_D$ for the above R values, reduce to simple algebraic substitution. Results of the calculations are given in Table I.

Discussion

Whereas the primary isotope effect refers to the effect by isotopic substitution on an atom undergoing transfer, the solvent isotope effect refers to the medium effect on equilibria resulting from isotopic substitution (41). In all cases where a proton or deuteron is directly involved in the activated complex, normal isotope effects arise, *i.e.*, R_1, R_2, R_4, and R_5 are greater than unity. However, for the recombination of MO species to produce molecular oxygen, an inverse isotope effect arises depending upon the solvent. This solvent isotope effect arises from the assumption of equilibria between bulk H_2O, or D_2O, and the surface species MO. Any uncertainty due to empirical assignment of frequencies to the activated complex is absent in this calculation because, as discussed above, the p.f. ratio for the activated complex is unity.

Some uncertainty undoubtedly exists in the empirical assignment of bending frequencies for activated complexes of the type O . . . . H . . . . O. A value of 1200 cm^{-1} for $\nu^{\pm}_{H,b}$ was chosen empirically because it seems to be quite reasonable by comparison to observed frequencies for stable molecules (29, 32, 35, 42).

According to Bader (35), values of $\nu^{\pm}_{H,b}$ may be expected to vary from 800 to 2000 cm^{-1} depending on asymmetry and charge distribution. Since an inverse isotope effect can also arise in the primary isotope

Table I. Kinetic parameters for O_2 evolution from H_2O and D_2O

R	Langmuir conditions $\theta \to 0$	Langmuir conditions $\theta \to 1$	Temkin conditions activ. ads.	Temkin conditions nonactiv. ads.

R_3	1.50	1.00	0.19 (Eq. [24])	1.50 (Eq. [22])
			0.76 (Eq. [25])	0.38 (Eq. [26])
R_4	4.00	6.78	—	
R_{5a}	4.00	11.4	4.00	
R_{5b}	2.35	19.3	6.74	
R_6	1.00	1.00	23.2 (Eq. [35])	1.00 (Eq. [33])
			2.82 (Eq. [36])	8.12 (Eq. [37])

Table II *R*-values for various values of $\nu^{+}_{H,b}(\nu^{+}_{D,b} = \nu^{+}_{H,b}/\sqrt{2})$

$\nu^{+}_{H,b}$, cm^{-1}	R as calculated from Eq. [17]	[19]	[20]	[27]	[28]	[29]
2000	3.0	3.0	1.7	4.0	1.3	2.3
1200	9.0	9.1	5.1	12.1	3.8	6.8
800	15.0	15.0	8.3	20.0	6.2	11.2
0	25.3	25.3	14.2	34.0	10.6	19.0

effect if the zero point energy of the activated complex is greater than that for the initial state (33, 43), it is instructive to see what the minimum R values are using a value of 2000 cm^{-1} for $\nu^{+}_{H,b}$. This is shown in Table II. The isotope effects, although smaller than those in Table I, are still considerably larger than unity and within those limits, any of the primary isotope effects considered here are all "normal" ones.

Conclusion

The results of the theoretical calculations presented in this paper demonstrates that the use of hydrogen isotopes in electrochemical reactions, other than the h.e.r., can be added to the existing techniques used for the confirmation of reaction mechanisms. Although work is under progress in this laboratory extending these studies in oxygen evolution to various metals in acid and alkaline solution, other reactions such as Zn and Mg deposition and dissolution might also benefit by this treatment. In the o.e.r., the only reaction giving rise to an inverse isotope effect is the recombination step in alkaline solution. Conway and Bourgault (6, 12, 13) found a value of ~0.5 for R_3 in the o.e.r. at nickel wire anodes. The observed Tafel slopes were 60 mv for the o.e.r. in both $D_2O(OD^-)$ and $H_2O(OH^-)$ solutions, and these results are in satisfactory agreement with those predicted here for the activated adsorption scheme (see Table I). The results of these calculations show that there are some cases in which a clear cut assignment of reaction mechanism is not possible and that other criteria must be sought. However, the important thing that results from these studies is that the isotope effect, when combined with other criteria, is a useful method for evaluating these complex reactions. Recently McIntyre and Salomon (36) have found very small isotope effects in the electrochemical reduction of O_2 to peroxide and again, as in the above case, this small isotope effect can be predicted for a unique step in the overall scheme of consecutive steps.

Acknowledgments

The author would like to thank the Chemistry Department and the Research Council of Rutgers, The State University, for financial support. He would also like to thank Professor B. E. Conway in whose laboratory some of these ideas crystallized and were discussed (cf. ref. 14), and finally Dr. J. D. E. McIntyre for many critical discussions and suggestions.

Manuscript received Nov. 28, 1966; revised manuscript received March 23, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

An Experimental Study of the Mode of Operation of Porous Gas-Diffusion Electrodes with Hydrogen Fuel

L. G. Austin[1] and Satish Almaula

Department of Fuel Science, Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Current-polarization curves from zero current to limiting current have been obtained for anodic ionization of H_2 at Teflon-bonded, platinum-black, gas-diffusion electrodes in 1*N* H_2SO_4. Limiting currents were almost linearly proportional to hydrogen pressure and varied with pressure and temperature in approximately the same way as *DC*, the product of solubility and diffusivity of dissolved H_2. Effects of mass transfer of dissolved gas appear to predominate over ohmic or kinetic effects. Based on a comparison of double-layer capacities in gas diffusion and fully flooded conditions, it is concluded that between 2 and 5% of the electrode internal area is wetted by electrolyte in the gas-diffusion condition, and the mean electrolyte penetrations are 4-7μ. It is unlikely that extended thin films of electrolyte exist on the internal surface of the electrode. It is suggested that only a thin layer near the plane electrode-electrolyte surface is wetted and takes part in reaction, and that limiting currents and polarization are due to mass transfer of dissolved hydrogen to submerged platinum-black particles. For an electrode containing 55 mg Pt-black/cm^2, the limiting current was 2.9 amp/cm^2 at 1 atm H_2 and 25°C; polarization at 1 amp/cm^2 was 30 mv.

The precise manner in which porous, gas diffusion electrodes for fuel cells operate is not known, although three distinct models have been proposed (1-3). Most treatments (4-7) have considered electrodes where the electrolyte covers a considerable fraction of the internal surface of the electrode. As discussed by Austin *et al.* (1), it is unlikely that a "thin film" of electrolyte covers the internal surface of electrodes which are strongly wet-proof, such as Teflon-bonded, platinum-black electrodes (8, 9). This type of electrode shows great promise for use in fuel cells since it is easy to make, light-weight, thin and capable of high power output without flooding.

The experiments reported here were performed in an attempt to obtain a better model for the mode of operation of wet-proofed, gas-diffusion electrodes, to form the basis for quantitative treatment of electrode design.

Experimental Techniques

Disk-shaped electrodes were placed in the Teflon electrode holder shown in Fig. 1 and the electrode surface placed horizontally in contact with 1*N* H_2SO_4, as shown in Fig. 2. The Teflon pieces of the holder were machined to give a tight press fit, and the tubes mounted in the Lucite lid in Fig. 2 were fitted with O rings to allow ready raising and lowering. The counter electrode was a clean platinum sheet, and the saturated calomel reference electrode was connected to a Luggin capillary with a KCl bridge, via a closed stopcock between the KCl and H_2SO_4 solutions. Hydrogen and nitrogen were prepurified (10) and saturated with water vapor in equilibrium with 1*N* H_2SO_4 before use; Fisher Reagent Grade sulfuric acid was fumed (11) and diluted to 1*N* strength with high-purity water (12). After assembly, it was convenient to deaerate the electrolyte with bubbled nitrogen overnight, before lowering the test electrode into the electrolyte. Any gas bubble trapped below the electrode face was readily removed by gentle flushing with the J arrangement shown in Fig. 2.

Steady-state current *vs.* voltage results were obtained with a flow of hydrogen (or hydrogen-nitrogen mixture) at 1 atm through the electrode holder, with a flow rate of at least 30 times the maximum rate of hydrogen ionization. The potential between test and reference electrode was measured with a high-impedance recorder, and current was measured by potential drop across standard resistors in series with the cell. Ohmic resistance in the electrolyte between the test electrode and the tip of the Luggin capillary was determined from the immediate change in test

to reference potential on passing a constant current through the test-counter electrode system. This jump was measured with an oscilloscope at fast sweep rates, using the rapid switching circuit described by Lerner (13). Results were corrected for this resistance, which was between 0.6 and 0.8 ohms. It was occasionally found that voltage cycling occurred as the limiting current was approached. A Wenking potentiostat (model 61/R) was then used to set the test electrode at 0.5v (plus the ohmic voltage loss) *vs.* standard hydrogen electrode, and the steady limiting current obtained at this potential. At the highest limiting currents obtained (3 amp/cm²), the ohmic correction was approximately 0.6v.

Double-layer capacities and surface coverage by adsorbed hydrogen were determined from galvanostatic voltage-time curves. To avoid faradaic current from gaseous or dissolved hydrogen the electrode holder was supplied with nitrogen only, and a small cathodic current passed until the electrode reached zero volts *vs.* standard hydrogen. A constant anodic current was then switched on and the voltage recorded as a function of time until it reached 1.0-1.3v; the current was reversed and voltage recorded until the potential was brought back to zero volts. This procedure was satisfactory for an immersed, flooded electrode, but a gas-diffusion electrode could not be brought to zero volts with a small cathodic current (see later) and starting potential was about 50-70 mv *vs.* standard hydrogen electrode. Since oxygen was evolved at the counter electrode during passage of cathodic current, the counter electrode was contained in a separate compartment for these tests, as shown in Fig. 2.

Mean hydraulic pore diameters were estimated from permeability measurements, using nitrogen flowing through the electrode clamped in a lucite holder with rubber seal rings.

Electrodes.—It was originally planned to test a number of electrodes covering a wide range of pore sizes, but it was found that several of the electrodes performed poorly, mainly due to flooding of the pore system. These included platinum-catalyzed electrodes of baked carbon supplied by the Pure Carbon Company (FC1, 23, 31, 36, approximately 250μ thick) and electrodes of microporous plastic material, Millipore (made by Millipore Company, Bedford, Massachusetts, types VM, RA, GS, and VF), spattered with a porous layer of platinum. Millipore type-H plated with a porous layer of platinum by the J. Bishop Company was nonwetting, but it had a high ohmic resistance and the platinum layer was so fragile that it broke when a current collector of platinum screen was pressed against it. All of these electrodes gave limiting currents of less than 100 ma/cm², performance decreased with time, and the electrodes were seen to be wet on the gas entry face. The limiting current of FC36 was approximately 20 ma/cm², and a more stable limiting current of approximately 100 ma/cm² was obtained by covering the electrolyte face with Millipore type H (nominal pore diameter of 1.5μ). The Millipore appeared to reduce flooding of the electrode. No further experiments were performed on this group of electrodes.

A second group of electrodes performed well and stable current-voltage curves were obtained. This group consisted of American Cyanamid Company CAA1, Pure Carbon Company FC100, and two electrodes, SM1, SM2, prepared in our laboratory. SM1 was made from a mix of platinum black (Fisher) with Teflon dispersion (Dupont 30, containing 59-61% solids, sp gr 0.6-0.9g Teflon/cc) diluted 10 times with distilled water, in approximate proportions of 10/1.5 of platinum-black to Teflon by weight, spread uniformly on a 45 mesh platinum screen. The mix was made to give a homogeneous paste, and the amount of Teflon stated above is not exact (see later). This was pressed at 18000 psi for 2 min, dried at 120°F for 1 hr, taken to 350°C over 5 min and sintered for 2 min at 350°C. After cooling, the electrode was rinsed with pure water and redried. SM2 was prepared in a similar manner using a mix of platinum black, SP1 graphite (National Carbon Company, New York) and Teflon in approximate proportions of 5/5/1.5 of platinum black to SP1 graphite to Teflon by weight. Later, the material contents of the electrodes were determined directly by weighing before and after burning off the Teflon (10), and these are reported in Table I.

This group of electrodes appeared from visual observation to be highly resistant to flooding at room temperature. After use as gas-diffusion electrodes, the electrodes were removed, wiped free of surface liquid with filter paper, and reweighed. FC1, 31, 36 electrodes increased in weight by approximately 10% due to penetration by electrolyte, but the second group

of electrodes had weight gains of less than 0.6%. These figures do not give accurately the weight gain of electrolyte during use, since the wiping process probably removed some water from the interior, but on a comparative basis they demonstrate the resistance to electrolyte penetration of the Teflon-bonded electrodes.

Results

Some typical results of steady current-voltage measurements are shown in Fig. 3. The curves could be retraced on reducing current density, and were reproducible on a given electrode at different times. Different samples cut from a patch of electrode material gave somewhat variable results in the case of the CAA1, and very variable results for the FC100 material. The limiting currents (defined at 0.5v polarization) were almost linearly proportional to the partial pressure of hydrogen, as shown in Fig. 4. The same limiting current and current-polarization curve was obtained if several thicknesses of electrode were pressed together and used as an electrode. Limiting currents increased with temperature as shown in Fig. 5, giving an increase of 30-40% from 25° to 60°C. It should be noted that these results cannot be compared directly with results obtained using an electrolyte matrix such as porous asbestos (9), since it is probable that a matrix-electrode interface has a significant temperature rise at these high current densities.

Double layer capacities were determined from the linear slopes of the galvanostatic voltage-time traces between 0.4 and 0.6v *vs.* standard hydrogen, in the absence of hydrogen. In this region of potential there is negligible faradaic current due to ionization of adsorbed hydrogen ($[H] \rightleftarrows H^+ + e^-$) or oxygen adsorption ($H_2O \rightarrow 2H^+ + [O] + 2e^-$). The capacities were measured on electrodes in the gas-diffusion condition, and on fully immersed, flooded electrodes which had been vacuum impregnated with electrolyte. In the gas-diffusion condition the double-layer capacities

were unchanged when several thicknesses of electrode were used. Table II gives the results. The coverage by adsorbed [H] at zero volts was determined from the voltage-time trace between 0 and 0.4v using

$$q_f = it - C\Delta V \qquad [1]$$

where q_f is the charge derived from surface coverage at time t and constant current i, C is the double-layer capacity and ΔV is the potential change in time t. At approximately 0.4v the current is supported entirely by double-layer charge-discharge, and q_f is the starting surface coverage in coulombs. It was not possible to measure this value for electrodes in the gas-diffusion condition because large cathodic currents were necessary to bring the electrode towards zero volts, the system was consequently contaminated with gaseous hydrogen, and a gas bubble was trapped below the electrode. Apparently the gas-diffusion condition is sufficiently reversible in the kinetic and mass transfer sense for the reaction $2H^+ + 2e^- \rightarrow 2[H] \rightarrow H_2$ diffusing out into N_2 stream to proceed at relatively high current densities, even at 50 to 70 mv positive potential. (In the flooded condition, the mass transfer of dissolved hydrogen away from the electrode has limiting currents of roughly 1 ma/cm², therefore a current density of a few ma/cm² is sufficient to bring the electrode to zero volts.)

Fig. 6 shows the permeability results, from which equivalent hydraulic pore diameters were calculated using (14)

$$J = B_o(\bar{p}/\eta)(\Delta N/L) \qquad [2]$$

where J is in moles/cm² sec, B_o is the permeability coefficient in darcies, $\bar{p}$ is the arithmetic mean pressure in atmospheres over the length, L, of the sample, η is the gas viscosity in centipoises, and ΔN is the concentration drop across the sample in moles/cm³. B_o is related to viscous area and flow path in a porous solid and is

$$B_o \simeq (\epsilon/q^2)(M^2/2)(10^8) \text{ darcies} \qquad [3]$$

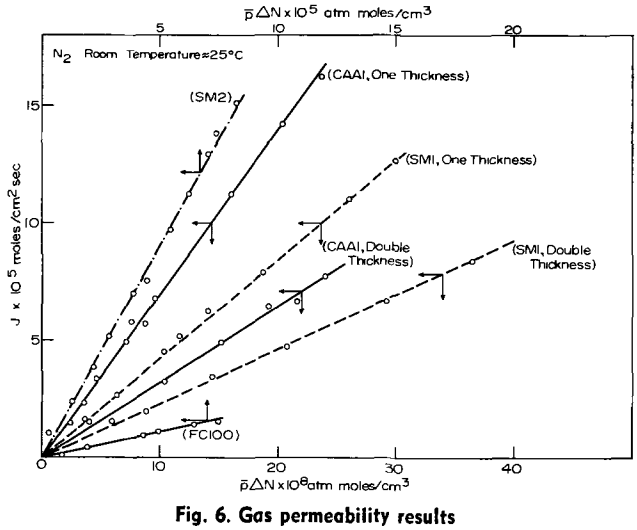

Fig. 6. Gas permeability results

ϵ is the porosity, q the tortuosity factor, and M the mean hydraulic radius of the porous solid. A plot of J *vs.* $\bar{p}\Delta N$ yields a straight line with a slope of $B_o/\eta L$, and B_o can be calculated. Knowing B_o, q, and ϵ, M can be calculated and an equivalent diameter found from $D = 4M$. Slip flow terms were found to be negligible. Table I gives the equivalent pore diameters for the four electrodes.

Discussion of Results

Figure 4 shows that limiting currents are almost linearly proportional to the partial pressure of hydrogen. This is not due to limitations of gas transfer through the nonflooded pores of the electrodes, because doubling or tripling electrode thickness had no effect on the limiting current. In addition, the maximum rate of normal hydrogen diffusion through these thin, open electrodes was calculated to be about 500 amp/cm². The magnitude of the equivalent hydraulic diameters precludes low diffusion coefficients due to Knudsen diffusion. Table III and Fig. 5 show the variation of limiting current density with temperature, compared to variation of DC with temperature, D being diffusion coefficient and C concentration of dissolved hydrogen in 1N H_2SO_4, estimated by interpolation from data quoted by Breiter (15). Making allowance for the errors in interpolation, the limiting currents increase is in close ratio to the increase in DC, indicating that simple mass transfer of dissolved gas is the rate-limiting factor. It is probable that any mechanism involving surface diffusion of hydrogen adsorbed on platinum would have a larger temperature coefficient than that found experimentally.

Figure 7 shows the values of i/i_L *vs.* polarization, η, for the different partial pressures of hydrogen. For a

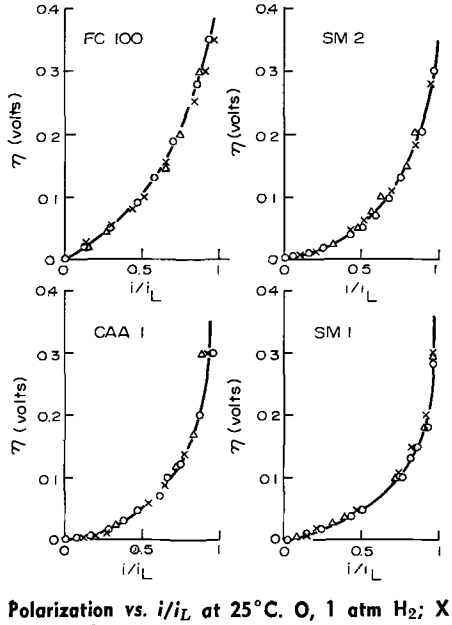

Fig. 7. Polarization *vs.* i/i_L at 25°C. O, 1 atm H_2; X 1/2 atm H_2; △, 1/10 atm H_2.

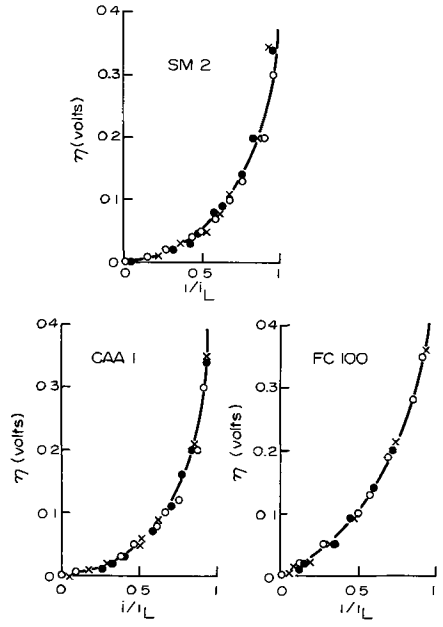

Fig. 8. Polarization vs. i/i_L at 1 atm H_2. O, 25°C; X, 48°C; •, 60°C.

given electrode, η is the same function of i/i_L for all pressures, even though i_L varies by almost a factor of 10. Similarly, Fig. 8 shows that η is a function of i/i_L for all temperatures, within experimental error. These results are strong indication that the current-polarization curves are solely dependent on mass transfer effects and have negligible contributions from kinetic or ohmic effects.

The results in Table II show that double-layer capacities and hydrogen coverage do not vary with the current densities used in the determination; therefore, there is no distributed capacity effect due to the porosity of the electrodes. The absence of distributed effects is due to the thinness of the electrodes, and the low current densities used in the determination (16). Except for FC100, the double-layer capacities in the gas-diffusion condition compared to the fully flooded condition show that only 2-5% of the internal area of the electrode is wetted by electrolyte in the gas-diffusion condition. It is highly unlikely, therefore, that any extended thin film of electrolyte covers the internal surface of the electrodes when in use as fuel cell electrodes. Mean electrolyte penetration into the electrodes was estimated as between 4 and 7μ, that is, of the same magnitude as the macropore diameter found from the permeability measurements.

Table IV gives the double-layer capacity and surface coverage by hydrogen, per cm² of platinum black area of the electrodes; a value of 30 m²/g was assumed for platinum black (17). The results are reasonably consistent and agree with those reported by the General Electric Company, although values of 70 to 100 μfd/cm² for double-layer capacity are significantly greater than the value of 56 μfd/cm² found by us for bright platinum, using the same techniques. Values of FC100 are anomalous, either due to a much lower BET area per gram of platinum catalyst, or due to incomplete flooding of the electrode even after vacuum impregnation with electrolyte.

Table V. Comparison of ratios of wetted platinum, platinum packing, and limiting currents

Electrodes	Ratio of double-layer capacities/cm² (nonflooded)	Ratio of platinum contents/cm³†	Ratio of limiting current densities
SM1 / CAA1	1.4	3.0	2.7
SM1 / SM2	3.3	3.6	4.0
CAA1 / SM2	2.4	1.2	1.4

† From weight measurements.

The comparison of the capacities per cm² of two nonflooded electrodes gives a relative measure of the total amount of wetted platinum black in the two electrodes, under actual gas-diffusion working conditions, *e.g.*

$$\frac{\text{double-layer capacity/cm}^2 \text{ of SM1}}{\text{double-layer capacity/cm}^2 \text{ of CAA1}} = \text{area of SM1 to CAA1.}$$

On the other hand, the weight of platinum black per cm³ gives the packing density of the platinum in the electrode. Comparison of the above mentioned ratio and the packing-density ratio to the ratio of limiting current densities for the two electrodes will indicate if the limiting currents are influenced (*a*) by the density of platinum-black packing or (*b*) by the total amount of wetted platinum in the diffusion condition (wetted platinum-black/cm²). Table V compares the above ratios for CAA1, SM1, and SM2 electrodes. The SM1 to CAA1 comparison indicates that the ratios for the platinum-black weights per unit volume and the limiting currents are within a reasonably close range (2.7-3.0). This is also true for the CAA1/SM2 ratios (1.2-1.4). The ratio of limiting currents does not agree with the ratio of double-layer capacities in the nonflooded condition. (In the case of SM1/SM2, all the ratios are rather close, the electrodes have nearly the

† General Electric electrodes for comparison (17).

same electrolyte penetration, and it is not possible to distinguish whether the limiting current ratio is closer to that of the packing density ratio or the wetted area ratio.) The evidence suggests that the limiting currents of the electrodes are influenced by the platinum-black packing density in the electrodes and not by the total platinum-black content.

For the platinum black-Teflon type electrodes, it is reasonable to expect that the platinum black is in small, loosely packed aggregates lying between Teflon particles and Teflon fibrils (9). The Teflon binds the platinum-black aggregates and prevents the electrolyte from penetrating the electrode material to any great degree. The flakes of graphite present in SM2 probably distributes platinum-black aggregates around the carbon flakes, while the Teflon again provides binding and hydrophobicity. The carbon tends, of course, to give less over-all porosity of the electrode material.

An approximate value of the limiting current predicted by the simple-pore model (1) can be estimated from

$$i_L = 12n\mathbf{F}D\theta C/r \qquad [4]$$

where i_L is the limiting current density per cm^2 of plane electrode area, $n = 2$ for hydrogen, $\mathbf{F}$ is Faraday's constant, θ is the area of pore mouths at the gas-electrolyte interface per cm^2 of plane electrode area, and r is the mean radius of the micropores filled with electrolyte. As before, D is the diffusion coefficient of dissolved hydrogen, C is the amount of dissolved hydrogen in equilibrium with 1 atm of hydrogen gas pressure. It is reasonable to assume that although an electrode as a whole is highly porous, the closely packed platinum-black particles will have a small porosity, say 10% of the total volume. The area of pore mouths will be proportional to this porosity, but may be several times higher if the gas-electrolyte interface within the electrode has a greater area than the plane area (see Fig. 9, for example). Further, assuming a loose packing of platinum particles in aggregates, a rough value for the pore size may be taken as 100Å, since the size of the particles is 100-200Å. At room temperature (25°C), taking $n = 2$, $\mathbf{F} = 96500$ coul/equiv, $D = (3.4)(10^{-5})$ cm^2/sec, $C = (7)(10^{-7})$ g-moles/cm^3, $\theta = 0.1$ and $r = 100$Å, the value of i_L is approximately 5 amp/cm^2. This value of i_L is, of course, strongly dependent on the values chosen for r and θ. The calculation shows only that values of 1 to 10 amp/cm^2 for i_L are feasible; this is of the same magnitude as the experimental limiting currents. Agreement has been reported (18) between the limiting current predictions of the simple-pore model and experimental results from nonwetted porous electrodes using Cl_2, in molten LiCl electrolyte.

Conclusions

Based on the experimental evidence and the discussion above, a possible physical configuration of the gas/electrode/electrolyte boundary established at the platinum-black-Teflon electrodes may be visualized as in Fig. 9. This shows electrolyte stabilized at a short distance within a platinum black-Teflon electrode. The gas side of the electrode has dry platinum aggregates and Teflon particles, while the platinum black on the electrolyte side will be wetted. The approximate size of the platinum-black particles is 100 to 200Å (8), that of Teflon particles is 0.2 to 0.5μ (8), while that of SP1 graphite flakes is roughly 0.3μ high and 20μ in diameter. There must be sufficient contact between the platinum-black particles to provide electronic conduction to the electrode screen and the current collector, but the Teflon particles appear to prevent penetration of electrolyte beyond a thin surface layer.

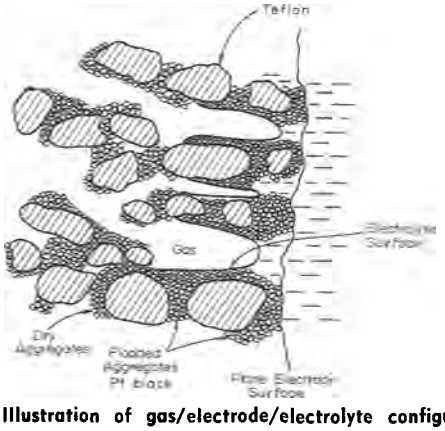

Fig. 9. Illustration of gas/electrode/electrolyte configuration

Electrodes SM1, SM2, and CAA1 are packed differently (see Table V). Compared with CAA1, SM1 has a larger part of the cross section packed with platinum-black aggregates, and since each aggregate produces current, a larger limiting current is observed for SM1. SM2 is more closely packed with material, but the platinum-black packing density is lower than SM1 or CAA1. In addition, the presence of graphite flakes tends to distribute platinum-black aggregates around the carbons, and the diffusional distance of dissolved gas to the active platinum-black may be increased, leading to lower limiting currents. Limiting currents can only be high when the mean diffusion path of dissolved gas is short, which means that small micropore diameters are necessary.

Although there is no evidence to suggest extended thin films of electrolyte within the electrode pores, there is a short, definite electrolyte penetration into the electrode. The electrolyte will tend to fill the micropores (spaces between platinum-black particles) within this penetration while some of the macropores will be free of electrolyte. Regions of flooded micropores along the walls of a macropore may lead to thin, finger-like electrolyte penetration into the electrode, as shown in Fig. 9. Thus the electrode will consist of nonflooded macropores which serve as gas feeders, plus flooded micropores, as shown. If the electrolyte penetration is considerable, long fingers of electrolyte may extend into the electrode, but in this study, since the mean electrolyte penetration is approximately 7μ or less and since the approximate macropore diameter is of the same magnitude, it is reasonable to expect that short, thumb-like penetration exists.

It is concluded that although a precise quantitative model cannot be proposed from this study, a reasonable picture of a physical model existing in nonflooded, platinum black-Teflon electrodes (operating in the gas-diffusion condition) has been obtained, and the mode of operation of such a model is reasonably close to that predicted by the simple-pore model. In these electrodes the electrolyte penetration is small, and a thin, well-packed, catalyst layer on the electrolyte side should be sufficient for efficient performance, providing other factors such as electronic conductivity are also satisfactory. A quantitative theory of current-polarization relations based on this model is under development, and recent treatments (19, 20) of models similar to that proposed here will be discussed in a future publication.

Acknowledgments

Financial support from the Harry Diamond Laboratories, Army Materiel Command, Washington, D. C., is gratefully acknowledged. Millipore material spattered with platinum was supplied by the Tyco Company; the J. Bishop Company laid platinum on millipore and carbon materials at our request, and electrode material CAA1 was supplied by the American Cyanamid Company. These organizations are sincerely thanked for supplying materials and services without charge.

Manuscript received Nov. 7, 1966; revised manuscript received April 21, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Technical Notes

The Double Layer Capacitance in Aqueous Solution

II. Polycrystalline Cadmium

N. A. Hampson and D. Larkin

Chemistry Department, Loughborough University of Technology, Leicestershire, England

Exchange reactions involving cadmium are of considerable industrial and theoretical interest. The value of the rate constant at amalgam electrodes is found to be very dependent on experimental conditions; moreover it is time dependent (1, 2). Explanation of these effects has been given (1, 2) in terms of the adsorption of impurities in view of the reduction potential of Cd(II) being close to the point of zero charge (pzc). It has also been suggested (2) that all reported observations can be explained in terms of migration within the diffuse double layer.

Experiments with exchange reactions at solid cadmium electrodes have indicated interesting time dependencies (3). Discussion of these results has necessitated a knowledge of the double layer capacity-potential curves for cadmium and the position of the pzc. Although Russian workers (4, 5) had reported the results of differential capacity measurements on solid cadmium in KCl solution it was decided to redetermine the curves and to extend the results to Na ClO_4 electrolytes. In this note the results of differential capacity measurements on flat polycrystalline cadmium in aqueous KCl and $NaClO_4$ electrolytes are reported.

Experimental

Details of the electrolytic cell, electrode construction, and electrical circuit have been described previously (6,7). Electrodes (3.46×10^{-2} cm^2 superficial area) were prepared from 99.999% cadmium supplied by Société de la Vielle Montagne. Water was twice distilled from deionized stock; all chemicals were of A. R. quality.

Electrodes were polished mechanically on roughened glass, lubricated with water. Etching (10% H_2SO_4 or 10% $HClO_4$) was chemical (1 min) or electrolytic (10 ma cm^{-2}). Polished and/or etched electrodes were washed thoroughly with water and introduced directly into the cell without drying.

Results

Figure 1 shows differential capacity curves for electrolytically etched electrodes in aqueous 0.01M KCl electrolyte; chemically etched electrodes gave very similar results. Time dependence in highly purified systems was not pronounced; equilibrium was established within 30 min with both etched and mechanically polished electrodes. A feature of this work with cadmium, however, was the very high degree of electrolyte purity required to obtain time-independent values of C_L after attainment of electrode/electrolyte equilibrium. Stable values of C_L have been obtained at silver and mercury electrodes after 3-4 days (6) of electrolyte purification whereas for cadmium comparable stabilities required much longer electrolyte purification. Figure 1 shows results for an "unstable" electrode; after 24 hr the capacity curve was shifted to more positive potentials, and C_L was somewhat reduced.

Figure 2 shows the relatively small effect of frequency in sodium perchlorate electrolytes on the dif-

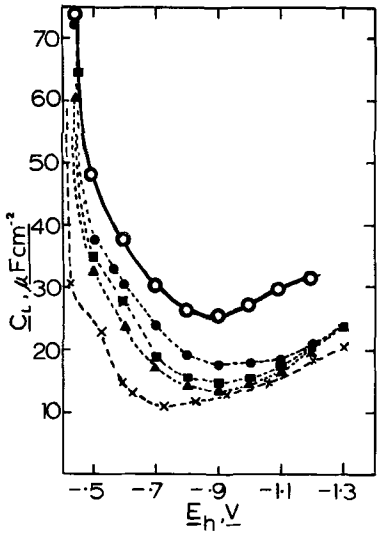

Fig. 1. Differential capacity curves for mechanically polished and for electrolytically etched electrodes, in aqueous 0.01M KCl. 25°C 2 k Hz. ferential capacity curves. Similar results were obtained in potassium chloride electrolytes. Mechanically polished electrodes showed a greater frequency dispersion than chemically or electrochemically etched electrodes and also gave large electrode-to-electrode variations. Because of this, the majority of our experiments were made with etched electrodes.

The polarizable region is —0.5 to —1.3v (NHE); considerable faradaic current flows outside this. For all electrolytes investigated, the capacity magnitude was lowered in dilute electrolytes without any variation of the minimum potential (Fig. 3).

Figure 2 illustrates differential capacity curves in sodium perchlorate electrolytes. The minimum (—0.9 ±0.035v) is less precisely determinable than with chloride electrolytes.[1]

Discussion

Values of the pzc [—0.91 ± 0.025v (NHE)] indicated by this work compare favorably with the value re-

* It is intended to discuss the broadness of the capacity minima obtained with Cd in a later paper.

ported by Borisova and Ershler (4) —0.9v (NHE). Differential capacity curves in perchlorate, however, were not so well defined in as much as the capacity minimum was broader. Generally, however, the shape was similar and the electrode behavior identical. The method used by these workers was essentially the same as used by us, but the Russians consider that a spherical drop of metal is the only satisfactory electrode and although a cut surface gave identical values of pzc to the spherical surface, the value of C_L and to some extent the shape of the differential capacity curve were both affected. Values of C_L reported by us for etched surfaces are reasonably close to the values of Borisova *et al.* (4).

It is of interest that the magnitude of the differential capacity of cadmium is comparable to that of a mercury electrode and indicates that the true area of cadmium is close to the superficial area.

Dispersion of capacity and time dependence due to initial surface rearrangement (8) observed with cadmium are of the same order as that observed with silver (6). The similarity between the results with chemically and with electrochemically etched surfaces may be explained in a similar manner in terms of surface atom diffusion removing relatively small differences in surface structure. However, a metal surface produced by mechanically polishing is likely to be less homogeneous (*i.e.*, shows a greater surface roughness due to fine scratches) than an etched surface. This increase in actual surface area compared to the superficial area will result in larger apparent double layer capacities on mechanically polished electrodes in relation to those at etched electrodes, as is observed. Mechanically cut (deformed surfaces) would presumably not be "normalized" with etched surfaces by this mechanism; the microscopic roughness may also explain the greater dispersion observed with mechanically polished (abraded) surfaces (9).

The need for ultrapurity in order to obtain reproducible C_L values emphasizes the role of impurities in electrode reactions involving cadmium (1). The shift of the pzc, to potentials positive with respect to its value on a clean cadmium surface, as a result of the insufficient removal of impurities from solution indicates changes in the surface charge density. Such a change would undoubtedly alter the value of the kinetic constants of any electrochemical reaction taking place at the electrode in the manner discussed by Breyer and Bauer (1).

Point of Zero Charge and Work Function

The interdependence of pzc and work function has been the subject of some considerable discussion (10).

It is interesting to note that by resiting the pzc of Cd at —0.9v and that of Ag(6) at —0.7v (NHE) the evidence for a linear relationship cited by Delahay (10) between pzc and the work function is considerably improved.

Activities of Molten Tin Alloys from EMF Measurements

Guy R. B. Elliott and Joe Fred Lemons[1]

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

If the pure solvent is used as the standard state, all solvent activities must approach a value of one as the solution becomes very dilute. By definition, then, the Raoult's law value for the activity-mole fraction relationship ($a_1 = N_1 = 1$) is approached by any solution. Whether all very dilute solutions approach the unit slope also required by Raoult's law is a question which requires an experimental answer. A discussion of experiments bearing on this question has been given elsewhere [(1), and more detailed (2)].

Apparently the most clear cases of asymptotic approaches to the slope of Raoult's law are found in the work of Yanko *et al.* (3), where tin concentration cells were used with silver, gold, and antimony solutes. However, certain questions existed regarding the measurements when compared with other somewhat similar measurements (4, 5). Also certain aspects of their technique could be improved, *e.g.*, stirring, solute addition, exclusion of air, temperature uniformity, chemical purity. Finally, their temperature coefficient of emf was not consistent with Raoult's law.

If Raoult's law is obeyed (*i.e.*, the solvent activity coefficient is unity) then all cells give the same emf and temperature coefficient. This striking conclusion is independent of the materials used for solvent, solute, and electrolyte except as n depends on the ion charge. For $n = 2$ and using pure solvent at the reference electrode

$$\Delta F = -nF\epsilon = RT \ln a = RT \ln N$$

$$\epsilon/T = 9.91856 \times 10^{-5} \log N$$

Obedience to Raoult's law implies that, for the process of mixing the pure components to create the solution, $\Delta\overline{H}_{\text{solvent}}$ is zero and $\Delta\overline{S}_{\text{solvent}}$ is ideal.

Experimental

Material purification.—Commercial hydrated stannous chloride was purified in vacuum by fusion, boiling with pure tin, and triple distillation, the material being introduced into the electrochemical cell as a result of the third distillation. Molten reagent grade tin under vacuum was scrubbed by vigorously boiling $SnCl_2$, cast, remelted to bring any trapped electrolyte to the surface and finally washed with water. Silver and gold were of 99.98% purity by manufacturer's specifications. Copper was sheeting of electrolytic purity. The tungsten electrodes were cleaned electrolytically.

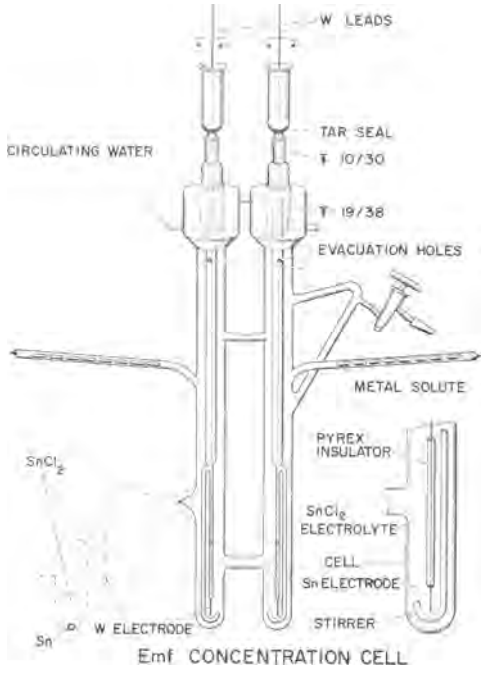

Fig. 1. H-cell design (tubes pictured slightly oversize. Evacuation through stopcock; evacuation holes are into stirrer tubes.)

The Pyrex H-cell is pictured in Fig. 1. This cell was evacuated, flamed, and loaded with argon. Weighed tin was loaded beside the stirrers and weighed solute pieces were added to one or both arms. After evacuation the tin was melted into position, the $SnCl_2$ was vaporized onto it, and the $SnCl_2$ container was melted off and removed. The closed cell was placed in the furnace and reconnected to the vacuum line to be occasionally stirred and repumped. After many hours, as the electrolyte became saturated[2] with tin (and

[1] Deceased.

[2] With considerable discrepancy the solubility of tin in $SnCl_2$ at 773°K is reported to be 3.2×10^{-5} mole fraction (6) or 2.6×10^{-2} mole fraction (7). At 573°K the value is reported to be 8.3×10^{-3} mole fraction (7).

possibly as traces of hydroxide were converted to oxide dissolved in the electrolyte), the cell potential for tin *vs.* tin dropped to near zero emf and became stable.

The system was now isolated at the stopcock which was not opened again during a run. By tilting the cell support slightly and tapping the cell side arm, single pieces of solute could be added while the cell remained hot. The cell then returned easily to its original position and could be stirred until the emf results were stable. Then another solute addition could be made.

The emf was measured by a Leeds and Northrup K-2 potentiometer. The furnace was isolated by partial Faraday cages attached to a ground independent of that used for working electrical equipment. A grounded stainless tube around the temperature control thermocouple (except for the exposed tip) helped prevent stray emf effects from the heater. The cell temperature was measured by a Pt/Pt 10% Rh thermocouple glass-taped to the cell just outside one metal-salt interface.

The heater was outside four large nesting nickel plated copper cylinders with air gaps between to provide a steady, uniform temperature. [The cylinders were similar to those used with the isopiestic balance (8).]

When a cell was broken open and the salt and alloy dissolved away, there was no indication of attack on either the Pyrex or the tungsten.

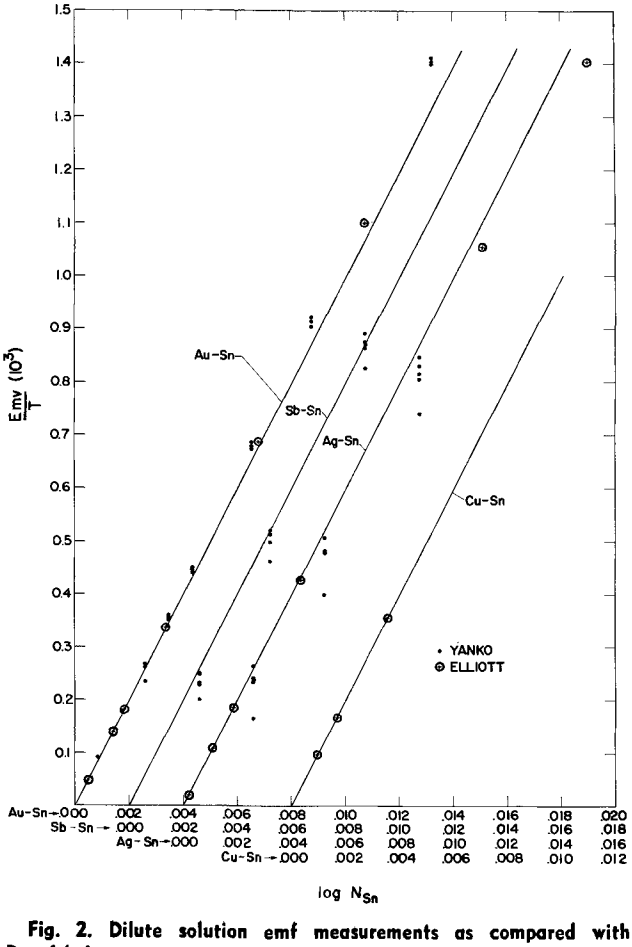

Fig. 2. Dilute solution emf measurements as compared with Raoult's law.

Results

The results are shown in Table I. Once a cell had been adequately stirred, any measurement was stable (without rapid shifts of emf) in the ± 0.1 μv range. However, there was some tendency for the cell voltage to shift over hours or days; this variation is the uncertainty given in Table I.

Figure 2 shows the data for the more dilute solutions plotted with the Raoult's law value for all temperatures shown as the solid line. The solid dots show the results of Yanko *et al.* for comparison. (Note the offset of the abscissa for the different solutes.)

Figures 3 and 4 show all the silver and gold data on Dundee type plots which examine the change of sol-

vent activity with solute mole fraction. The bars show the experimental uncertainty.

For the corrections we have used the emf for the measurements of "pure" tin *vs.* "pure" tin except for the copper where a piece fell in too early.[3] In this case we have corrected the first emf to the Raoult's law value.

Conclusions

As can be seen in the figures, within the accuracy of the measurements, Raoult's law is approached for all three of these systems.

For the Cu-Sn system the solvent behavior is ideal over the whole range of composition measured.

For the Ag-Sn system a correction term is required which follows N_{Ag}^2. Such terms are sometimes ascribed to important solute-solute interactions.

For the AuSn system, in addition to the presence of an N_{Au}^2 term, there is an indication of a change of behavior at $N_{Au} = 0.01$. Similar abrupt changes have been observed by the authors and co-workers in continuing vapor pressure studies of cadmium alloys with gold (9), lead (10), and copper.

Since the dilute solution behavior in these systems proved to be so ideal in satisfying Raoult's law with its corollary temperature dependence, there seemed little reason to test the temperature dependence further. Instead we chose to make extensive studies of Sn-Hg and Au-Cd solutions as will be reported later.

[3] Several factors could contribute to this required correction such as small differences in impurities in the purified tin as added, trace impurities in the electrolyte scavenged more by one tin bath than by the other, or temperature differences of 0.01°K or less between the legs.

Solvent Properties of Molten $NaNO_2$ Using a Freezing Point Technique

Theodore R. Kozlowski and Roger F. Bartholomew

Technical Staffs Division, Corning Glass Works, Corning, New York

The physical and chemical properties of molten alkali metal nitrates have been studied extensively because of their low melting points and ease of handling. In comparison there has been very little work reported on the properties of molten nitrites. Protsenko and co-workers (1-5) have published binary and ternary phase diagrams involving alkali and alkaline earth metal nitrites, and the electrochemical reduction of sodium nitrite has been discussed in recent papers (6-7). However, the experimental difficulties in working with molten nitrites, such as the ease of oxidation to nitrate, and the problems of drying the materials have resulted in the absence of data on these compounds. This work was undertaken as a preliminary investigation on the solvent properties of molten sodium nitrite using a freezing point technique.

Experimental conditions were constrained to permit use of the following equation for temperature change as a function of concentration

$$\Delta T = \nu K_f m \qquad [1]$$

Here ΔT is the temperature depression $T_f - T$, T_f being the melting point (°K) of the pure solvent, and T that of the solution; ν represents the number of entities dissolved in the melt that are distinguishable from the solvent; m is the molality of the solute, defined as moles of solute per 1000g solvent; and K_f is the molal cryoscopic constant in deg/mole. In deriving Eq. [1], K_f was defined as

$$K_f = \frac{RT_f^2}{\Delta H_f n_1} \qquad [2]$$

where ΔH_f is the heat of fusion of the solvent at T_f and n_1 the moles of solvent in 1000g.

Experimental

Freezing points for the melts were obtained using the cooling curve technique. The essential details of the design and operation of the cryoscopic assembly were similar to systems previously described in the literature (8, 9). One minor modification involved the

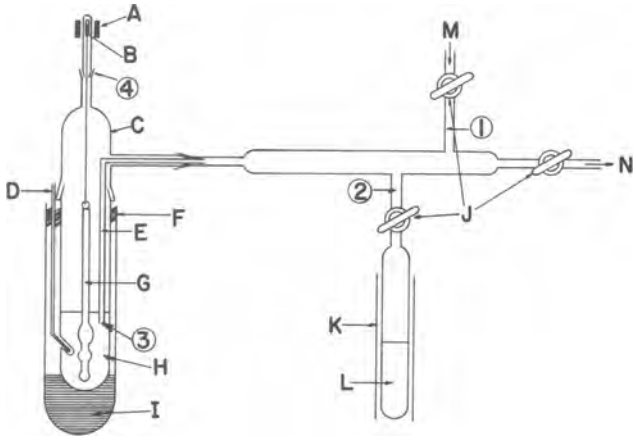

Fig. 1. Apparatus for water solubility measurements: A, solenoid; B, glass enclosed iron cylinder; C, cryoscope head; D, chromel-alumel thermocouple; E, nitrogen-water vapor delivery tube; F, small nichrome wound furnace; G, stirrer; H, melt; I, sand for support; J, vacuum stopcocks; K, water heating coils; L, water reservoir; M, nitrogen inlet; N, to vacuum pump; 1-4, numbers refer to the operation of the apparatus.

use of a motor-driven propellor-type stirrer, rather than a reciprocating magnetic stirrer, to achieve the necessary agitation for solid-liquid equilibrium at the melting point. A small gap between the cryoscope head and the stirrer shaft provided an exit port for the dry nitrogen continuously swept over the melt. A small window cut into the furnace insulation allowed continuous visual inspection and monitoring of the molten sodium nitrite. Approximately 100g of salt were used in each trial.

Diagrammed in Fig. 1 is a closed apparatus, having a capacity of 30g of molten sodium nitrite, which was constructed for water solubility measurements. With reference to Fig. 1, the initial operation consisted of evacuation, followed by immediate filling of the assembly with nitrogen at 1 atm pressure, 1. A water reservoir at known temperature, 2, was opened to the system, and the nitrogen-water vapor mixture was bubbled through the melt, 3, passing out through an opening, 4. A control run utilizing a Hygrodynamics Inc. Line operated Electric Hygrometer Indicator, No. 15-3000, established the vapor pressure of water prior to entering the melt. The simple expedient of elevating the water reservoir temperature increased the amount of water passing through the molten sodium nitrite. Cooling curves were obtained after at least an hour of bubbling nitrogen-water vapor through the melt.

Chromel-alumel thermocouples, referenced to a distilled water-ice cold junction, served as temperature sensors for all measurements. A Sargent Model MR recorder performed the function of bucking all but 2 mv of thermocouple output, amplifying and presenting the remainder as a cooling curve (8, 9) on a 10-in. time-voltage chart. Three cooling curves for given concentrations of solute were generally sufficient to attain a precision of ±0.02°C in the melting point. The melt temperature was kept below 320°C and the cooling rate was maintained at 3 deg/min. Super cooling was especially small, never exceeding 0.25°C.

The following Baker's "Analyzed" reagent grade chemicals were used: $NaNO_2$, Na_2SO_4, NaCl, $NaC_2H_3O_2$, NaSCN, Na_2CO_3, $Ba(ClO_3)_2$, and $BaSO_4$. $NaNO_2$, $Ba(ClO_3)_2$, and NaSCN were dried to constant weight in a National Appliance Company, Model 5830-4, vacuum oven at 110°C for 7 to 10 days. Similar treatment extending 1-2 days sufficed for the remaining chemicals. Concentration changes for the melt were effected by dropping pieces weighing approximately 0.1g into the melt. After each concentration change, a cooling curve was obtained only after the added solute was observed to totally dissolve.

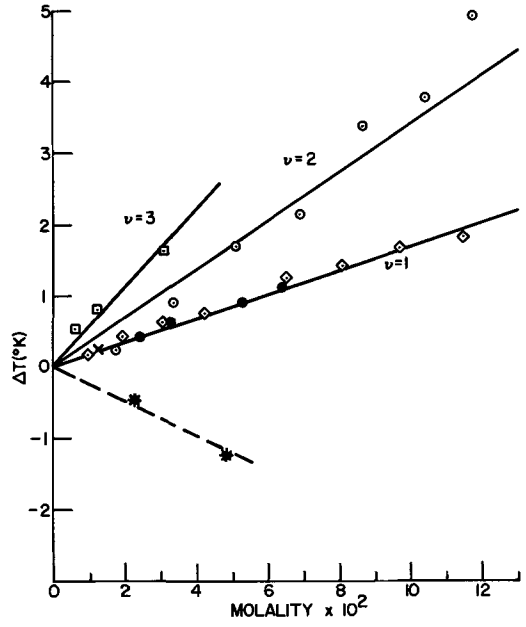

Fig. 2. Change in $NaNO_2$ freezing points (T_f—T) with added solutes: ⊙, $NaC_2H_3O_2$; ◇, Na_2SO_4; ⊡, $Ba(ClO_3)_2$; •, NaSCN; X, Na_2CO_3; *, NaCl.

Results

The average melting point for sodium nitrite was found to be 281.5°C, which is in good agreement with the value of 281°C reported by Frame *et al.* (10). Because there was no available value in the literature for the heat of fusion of sodium nitrite, it was not possible to construct the ideal freezing point curves for the solutes added. Figure 2 presents the experimental points given in Table I. The solid lines shown for $\nu = 1$, 2, and 3 were drawn using the heat of fusion obtained by least-mean-squares analyses on the data obtained for the solutes Na_2SO_4, NaSCN, and Na_2CO_3. The reasons for this are discussed later. The slope of the ΔT *vs.* m plot (*i.e.*, K_f) for the three solutes taken together gave a value of 17.0 deg/mole with a standard deviation of ±0.5 deg/mole. The heat of fusion calculated from Eq. [2], was found to be 2.48 ± 0.07 kcal/mole. The entropy of fusion, ΔS_f, was calculated as 4.47 ± 0.13 eu.

The solubility of water in molten sodium nitrite was determined by varying the vapor pressure of water above the melt and obtaining the freezing-point depression at a known vapor pressure. By assuming that water behaves in the same manner in sodium nitrite as has been found in sodium nitrate (11), *i.e.*, that water dissolves as a monomer, the following concentrations of water in the melt were obtained; 0.63 x $10^{-2}M$ at 7 mm Hg, 2.86 x $10^{-2}M$ at 19.5 mm Hg, and

$4.54 \times 10^{-2}M$ at 37.9 mm Hg. This last value was obtained by extrapolation from the first two because, for two pressures above 37.9 mm Hg, the depression of the freezing point became independent of the vapor pressure of water. This represents the maximum solubility of water in the melt at its freezing point, which corresponds to a concentration of 31.4×10^{-4} moles water/mole sodium nitrite. An approximate value of 8×10^{-5} moles water/mole sodium nitrite-mm Hg was obtained for K, the Henry's law constant.

Discussion

Fusion of the dried material resulted in a clear yellow liquid which displayed no bubbling at atmospheric pressure under nitrogen. This condition could be maintained for weeks if the temperature of the melt was not allowed to exceed 325°C. Above this temperature, an increasing amount of fine sodium oxide precipitate (12) appeared in the melt. With continued overheating, no gas evolution was noted in or on the melt, although the flowing purge gas would have prevented the buildup of nitrogen dioxide and nitrous oxide reported to accompany the decomposition (12-14). Cooling curves obtained on pure sodium nitrite before and after decomposition displayed no change in the melting point, indicating that solubility of the Na_2O was less than $1 \times 10^{-3}M$.

The choice of solutes for freezing point measurements in sodium nitrite is limited because of double decomposition reactions which form unstable metal nitrites (15). Attempts to use cadmium and lead salts were unsuccessful because of this reason. This limits the choice of solutes to alkali or alkaline earth metal salts. Within this range of compounds, further limitations are imposed by the formation of solid solutions between sodium nitrite and salts containing potassium (16), nitrite (16), and chloride ions. In the case of $BaSO_4$ very low solubility was found, since no depression of the freezing point could be detected in a saturated solution.

The best-behaved solute was sodium sulfate, since clear solutions with no bubbling were obtained up to the highest concentration studied, $11.4 \times 10^{-2}M$. Only one point was obtained for Na_2CO_3, because attempts to go to higher concentrations resulted in bubbling and the formation of a flocculent precipitate, presumably sodium oxide. Additions of sodium thiocyanate gave well-behaved melts up to concentrations of 6.4×10^{-2} M. Above these concentrations slight evolution of gas was observed; therefore, only results in well-behaved melts are reported. These three solutes should all introduce one foreign particle in the melt, and, as can be seen in Fig. 2, they all fall on the same line. Because of this good agreement with expected behavior, these data were used to calculate ΔH_f for sodium nitrite which was then used to describe the other solute systems. The value of 2.48 ± 0.07 kcal/mole obtained is not directly comparable with published data. Estimates were made from the heat-capacity data of Voskresenskaya *et al.* (17) and from the phase diagrams reported by Protsenko and his coworkers (2, 4). In the former case the heat of fusion was estimated to be in the range 2.1 to 2.9 kcal/mole at 282°C. From the phase diagrams (Li^+, Na^+), (NO_2^-) and (Sr^{2+}, Na^+), (NO_2^-) values of 4.3 and 9.5 kcal/mole at 284°C were calculated. Our value falls toward the middle of the value obtained from the heat-capacity data, which lends good support to its accuracy. A value of 6 ± 1 kcal/mole was reported by Rapoport (18) in his work on the effect of pressure on the melting point of sodium nitrite. However, it was pointed out (19) that this method of obtaining thermodynamic data does involve considerable extrapolation, which can greatly affect the final value.

Solutions with sodium acetate gave unexpected results. Freezing-point depressions characteristic of $\nu = 2$ rather than the expected $\nu = 1$ were found. As can be seen from Fig. 2, there is considerable scatter in the points; the lowest concentration fell on the $\nu = 1$ line, but at higher concentrations the data tended to fall on the $\nu = 2$ line. Recent work by Hazlewood *et al.* (20) on the properties of molten alkali metal acetates indicated that sodium acetate was thermally stable just above its melting point of 329°C. This is 4°C higher than the highest temperature used in our work. They also pointed out that the thermal stability of molten acetates is enhanced by the absence of oxygen above the melt. Therefore, the freezing point results found for sodium acetate cannot be explained on the basis of thermal instability. The concentration of acetate was kept below $11.7 \times 10^{-2}M$ in this work, and, despite the care used in controlling the temperature, slight bubbling did occur. The behavior of alkali acetates in molten alkali metal nitrates has been examined in this laboratory using freezing point measurements, infrared, polarography, and mass spectra (21). Reactions do occur, the products being alkali nitrites, carbonates, oxides, and gases. On the basis of the results for the nitrate systems, it is suggested that the value of $\nu = 2$, found for sodium acetate in sodium nitrite, occurs because of a chemical reaction between the solute and solvent. Further study is required in order to elucidate the reaction mechanisms and products in molten nitrites. The small amount of nitrite which may be removed from the solvent because of the reaction would not significantly alter the concentration term defined in Eq. [1]. Only three concentrations are shown on Fig. 2 for the addition of $Ba(ClO_4)_2$ because, at concentrations in excess of $3.1 \times 10^{-2}M$, slight evolution of gas was noted. However, the data obtained fell on the calculated $\nu = 3$ line within experimental error. This indicates that at the lower concentrations any reaction taking place is negligible, since the expected three-particle depression was found. The addition of NaCl gave an increase in the freezing point of $NaNO_2$, indicative of solid-solution formation.

The maximum water solubility of 31.4×10^{-4} moles water/mole sodium nitrite can be compared with 14.1×10^{-4} and 3.9×10^{-4} moles water/mole melt at 20 mm Hg of water for sodium nitrate and potassium nitrate, respectively, reported by Frame *et al.* (11). All of these values are for the melts at their freezing points. A Henry's law constant of 7×10^{-5} for sodium nitrate, calculated from their data, is very near the value found for sodium nitrite. The presence of a reaction or some unusual dissolution mechanism, *e.g.*, the passage of water into the melt as $(H_2O)_2$, would have resulted in different values of K. It is suggested that the placement of water molecules in the sodium nitrite melt near its melting point proceeds with the same mechanism postulated for the nitrate, *viz.*, "interstitial dissolution." In retrospect, this conclusion could have been implied from the structural similarity of nitrite and nitrate melts, as well as the low solubilities of water found in the course of the investigation.

From the preceding discussion it is evident that sodium nitrite is not as good a solvent for cryoscopic work as sodium nitrate (22, 23). The greater chemical reactivity of the melt to added solutes and the ease with which solid solutions are formed restrict its use.

Nitrosyl Fluoride Electrolytes

Madeline S. Toy and William A. Cannon

Astropower Laboratory, Missile and Space Systems Division, Douglas Aircraft Company, Inc., Newport Beach, California

There is a growing interest in the field of low-temperature electrolytes which may be utilized in electrochemical energy conversion devices for operation at well below —60°C. As part of a study of low-temperature electrolytes, we have measured the electrical conductivities of solutions of Lewis acid fluorides in nitrosyl fluoride. The electrical conductivity of pure nitrosyl fluoride has been reported by Christe and Guertin as 5.4 x 10^{-5} ohm^{-1} cm^{-1} at —79°C (1). This value indicates a relatively high degree of self-ionization which probably occurs in the following manner

$$NOF \rightleftharpoons NO^+ + F^-$$

Toy and Cannon (2, 3) have reported the large increase of electrical conductivity of a self-ionizing solvent (bromine trifluoride) on addition of a Lewis acid fluoride (boron trifluoride). This paper describes the self-ionizing properties of nitrosyl fluoride (bp —59.9° and mp —137.5°) in the presence of fluoride ion acceptors (boron trifluoride, phosphorus pentafluoride, and arsenic pentafluoride) leading to formation of moderately conductive low-temperature electrolytic solutions below —60°C. An electrochemical energy conversion system using halogen fluoride electrolytes has been reported to be applicable at room temperature to as low as —40°C (4). This paper suggests that an electrochemical energy conversion system using nitrosyl fluoride electrolytes is capable of reaching even lower temperatures.

Experimental

Materials.—Nitrosyl fluoride and arsenic pentafluoride were obtained from Ozark-Mahoning Company. Boron trifluoride and phosphorus pentafluoride were obtained from Matheson Company. All materials were purified by low-temperature distillations. The purity of the samples was checked by infrared analysis of the vapor. The specific conductivities of boron trifluoride, phosphorous pentafluoride and arsenic pentafluoride in the liquid phase were less than 10^{-9} ohm^{-1} cm^{-1}. The specific conductivity of liquid nitrosyl fluoride reported by Christe and Guertin as 5.4 x 10^{-5} ohm^{-1} cm^{-1} at —79°C (1) falls on the specific conductivity *vs.* temperature curve of pure nitrosyl fluoride given in Fig. 1. All electrodes were high-purity commercial materials of 99.9% purity or better.

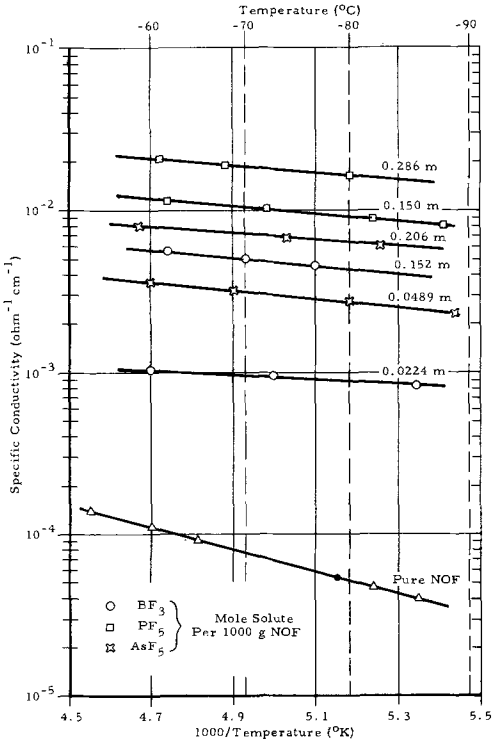

Fig. 1. Specific conductivity of NOF and NOF solutions as a function of temperature.

Apparatus.—The conductivity cell (Fig. 2) was made of stainless steel with a Teflon liner and equipped with two smooth platinum electrodes. The leads passed through Teflon plugs and were compressed between metal fittings to effect a vacuum and pressure tight seal. Temperatures were measured by a thermocouple inserted into a hole drilled in the wall of the conductivity cell. Cell constants ranging from 0.2 to 0.5 cm^{-1} were used. Cell constants were determined by measuring the resistance of standard potassium chloride solutions in the cell. In a conductivity cell of this design, the cell constant varies slightly with the volume of solution due to the variable im-

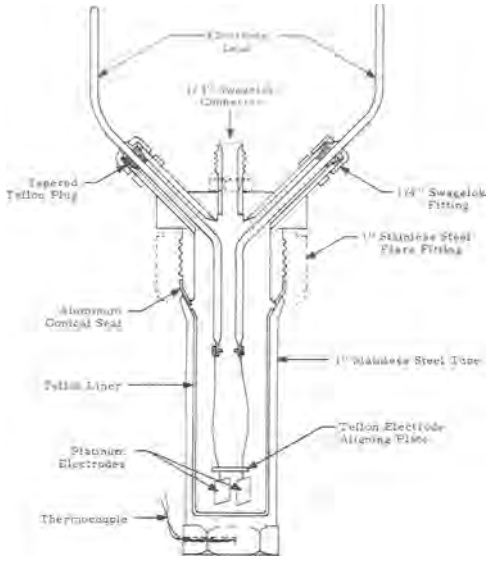

Fig. 2. Conductivity cell

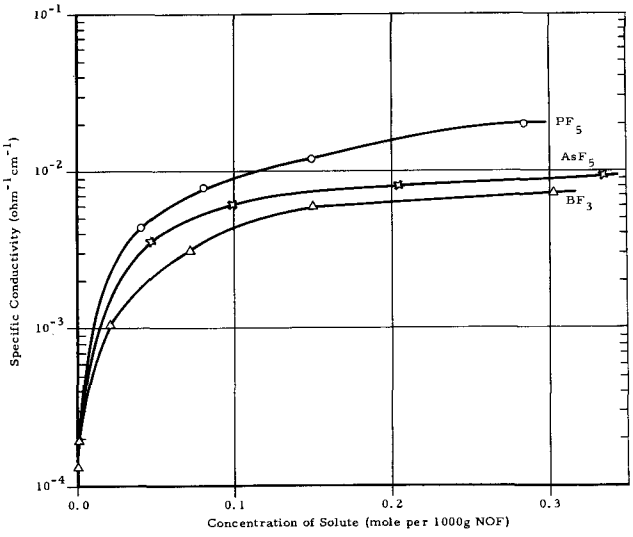

Fig. 3. Specific conductivities as a function of concentrations of BF_3, PF_5, and AsF_5 in NOF solutions at —60°C.

mersion of the platinum lead wires; therefore, calibration and measurements were made with a constant volume of solution.

Cell resistance measurements were made with a General Radio Type 1650-A impedance bridge. It was equipped with an internal, 1000-cycle signal source and tuned null detector. Measurements were also made with an external signal source ranging from 200 to 10,000 cycles to permit correction for polarization. For more sensitive balance, a Hewlett Packard 400 L vacuum tube voltmeter was used as an external null detector.

Glass systems cannot be used for handling nitrosyl fluoride; therefore, a vacuum line constructed of 304 stainless steel tubing, 316 stainless steel valves with Teflon packing, and calibrated stainless steel vapor receivers was employed for distillation and transfer of nitrosyl fluoride, boron trifluoride, and the volatile pentafluorides. Mercury manometers cannot be used. Pressure was measured with a stainless steel Bourdon gauge (30-in. vacuum to 60 psi). Careful exclusion of moisture is essential in handling these compounds as the presence of any water vapor will cause noticeable attack on stainless steel and will likewise affect conductivity measurements. The vacuum system was first degreased with trichloroethylene, rinsed with Freon, then vacuum dried. After assembly, the vacuum system was passivated by filling with gaseous fluorine to 1 atm for 1 hr. Finally the system was evacuated. Under these conditions, it is found that nitrosyl fluoride and its solutions do not attack the stainless steel appreciably during the time required to carry out the experiments, *viz*, 1-2 hr.

Open-circuit voltages of bielectrode cells were measured in a cell similar to that shown in Fig. 2 with the electrodes uniformly spaced 1 cm apart. Cell voltages were measured across the two electrodes with a vacuum tube voltmeter.

Results and Discussion

The specific conductivity of nitrosyl fluoride increases markedly on addition of boron trifluoride, phosphorous pentafluoride, and arsenic pentafluoride, and at the same time there is a decrease of the temperature coefficient of conductivity as shown in Fig. 1. The increase of specific conductivity of NOF solutions as a function of concentration of these Lewis acid fluorides is shown in Fig. 3. On evaporation of the solvent at room temperature, each solution yielded a solid residue. The infrared spectrum of each nitrosyl salt showed a strong absorption peak at about 2,350 cm^{-1} indicating $(NO)^+$ ion (5). These salts are readily soluble in liquid NOF as well as sulfur dioxide to yield moderately conductive low-temperature electrolytic solutions below 60°C (6).

The Lewis acid fluorides (BF_3, PF_5, and AsF_5) are potential electrolytes which function as acids by fluoride ion acceptance giving the cation NO^+ and the corresponding anions (BF_4^-, PF_6^-, AsF_6^-). The higher conductivity of the pentafluoride solutions compared to the boron trifluoride solution may be due to boron trifluoride being a weaker fluoride ion acceptor.

The open-circuit potentials were measured in nitrosyl fluoride solution containing 0.3*M* phosphorus pentafluoride at —70°C. Except for the tin-platinum bielectrode cell, the calculated potentials lack correlation with observed potentials. The postulated cell reactions are as follows

Anode	$M + 2F^- \rightarrow MF_2 + 2e$
Cathode	$2NOF + 2e \rightarrow 2NO + 2F^-$
Over-all cell reaction	$M + 2NOF \rightarrow 2NO + MF_2$ [1]

Standard free energy change at 25°C for lead (7-9) = —39.86 kcal; $E°$ = 0.864v (1.55v observed at —70°C).

Standard free energy change at 25°C for tin (7-10) = —38.76 kcal; $E°$ = 0.840v (1.10v observed at —70°C).

Standard free energy change at 25°C for cadmium (7-9) = —46.56 kcal; $E°$ = 1.01v (0.27v observed at —70°C).

The temperature difference may account for some of the discrepancies of calculated and observed potentials. Due to the limited data on free energy of formation of reactant NOF at —70°C, the potential of postulated cell reaction (Eq. [1]) was thus calculated at 25°C.

Brief Communication

Polarographic Reductions of Benzyl Halides. A Correction

L. B. Rogers

Department of Chemistry, Purdue University, Lafayette, Indiana

and A. J. Diefenderfer

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania

An earlier report from our laboratory (1) postulated formation of the benzyl radical in electrochemical reductions of the benzyl halides primarily because mass-spectral lines derived from bibenzyl were the major ones in mass spectra of the product from controlled-potential electrolyses on the limiting-current plateau of the first reduction step. Although lines attributable to mercury in the product were also reported (1), mercury was dismissed as an impurity when products from blank electrolyses also gave mass spectra that showed mercury to be present. However, our most recent work has shown that bibenzylmercury (also benzylmercuric bromide) decomposes while its mass spectrum is being obtained and produces bibenzyl as the chief product. Mercury is also clearly present.

As a result of that finding, we have re-examined the entire process for the electrochemical reductions of the benzyl halides. The new evidence reported below supports the general mechanism suggested for allyl bromide (2).

First, a chronopotentiometric study clearly indicated that a prior (chemical) step preceded the electron transfer, in accord with the criteria of Reinmuth (3). Second, after approximately 90 min, contact with an open-circuit dropping mercury electrode (and its accumulated mercury pool), the concentration of benzyl chloride (or bromide) in a stirred 1.0*M* solution of lithium chloride in 1:1 methanol-water had decreased to half of its value. The concentration was measured by connecting the dropping electrode to a polarograph only long enough to measure the limiting current for the benzyl halide. When uv spectra of the product obtained by shaking mercury with a 5.0 mM solution of benzyl bromide in 1*M* $LiClO_4$ in 1:1 methanol-water were compared with spectra obtained using authentic samples, they indicated the formation of benzylmercuric bromide. Benzyl chloride reacted more slowly, but in a similar fashion.

When a solution of benzyl bromide was electrolyzed at −0.50v *vs.* SCE, a potential on the plateau of the first reduction step, the resulting solution had a uv spectrum with the same characteristics as those for bibenzylmercury. In addition, the isolated product did not depress the melting point of bibenzylmercury.

Finally, with regard to reduction at a potential on the second limiting-current plateau for benzyl chloride, Wawzonek *et al.* (4) have shown that, in the presence of carbon dioxide, toluene is the main product and phenylacetic acid, a minor one. That result has been interpreted as confirmation of a two-electron reduction that forms a benzyl carbanion. Although their results were obtained using solutions of the benzyl halides in dimethylformamide, a change in solvent to 1:1 methanol-water would not be expected to alter the findings.

Preparation and Characterization of Manganese Oxide Thin Films

R. M. Valletta and W. A. Pliskin

IBM Components Division, East Fishkill, New York

ABSTRACT

Reactive sputtering has been found to be a desirable method for the preparation of conductive manganese dioxide films. The major parameter determining conductivity and the oxide of manganese formed by reactive sputtering is substrate temperature. At substrate temperatures in excess of approximately 350°C, low-conductivity lower oxides of manganese are formed. The infrared spectrum of films is sensitive to variations in the stoichiometry of the oxides and is a valuable tool for the characterization of manganese oxide thin films.

Manganese dioxide is a material which has aroused considerable interest because of its importance in the electrical components industry. It has been established that the physical and chemical properties of the oxides of manganese are extremely complex. The oxides MnO, Mn_3O_4, Mn_2O_3, MnO_2, and Mn_2O_7 exist (1-4). With the exception of Mn_2O_7, which has not had extensive study, these oxides exhibit at least two crystal structures and nonstoichiometry (1). In general, the lower oxides of manganese are not as good conductors as MnO_2.

Recently, interest has been generated in thin films of manganese dioxide since the introduction of these films to tantalum thin film capacitors improves both the reliability (5, 6), thermal stability (7), and yield of capacitors (6). It is believed that this results from the ability of MnO_2 to act as an oxidizing agent healing weak points in the anodic oxide by oxidizing exposed tantalum. The effect of the manganese dioxide film is especially noted in the ability of thin tantalum oxide capacitors ($\sim$ 250Å Ta_2O_5) with a film of manganese dioxide to withstand heating at temperatures in excess of 300°C without shorting (7). However, before heating, capacitors with sprayed MnO_2 layers were found to have a large dependence of capacitance on frequency. This was explained as resulting from the low conductivity of the spray deposited manganese dioxide films (7). It could be semiquantitatively explained by treating the capacitor with MnO_2 as a Maxwell-Wagner two-layer capacitor (8).

During the course of the above-mentioned investigation (7), the manganese oxide films formed by pyrolysis of a manganous nitrate solution were found to vary in composition depending on the conditions employed during the deposition. It was possible to identify the various phases prepared by the spray deposition method from the transmission infrared spectra of the oxides. Also, it was possible by use of the infrared spectrum to gain some information about the incorporation of water and NO_3^- as impurities in the films. Substrate temperature was found to be one of the most important parameters determining the phase obtained by spray deposition. However, concentration of the manganous nitrate solution and spray rate were also found to be important.

Since the resistivity of the manganese oxide is determined by composition, and the resistance of the manganese oxide layer will to a large extent determine the effect of frequency on the capacitor (7), a study was performed of the effect of various preparative parameters on the physical and chemical properties of manganese oxide thin films formed by reactive sputtering. The methods employed to prepare and characterize the films in this study were similar to those reported for reactively sputtered (9, 10) SiO_2 and SiO_2 films deposited by other techniques (10).

Cash and Clark (6) reported on the application of reactive sputtering for the preparation of manganese dioxide films. They reported that conductive MnO_2 can be prepared by reactive sputtering. They found that the percentage oxygen in the sputtering gas determined the composition of the manganese oxide. At a lower oxygen percentage, Mn_3O_4 and MnO were formed.

Experimental

The sputtering apparatus employed for deposition of the manganese oxides is shown in Fig. 1. Rods A are ½ in. diameter stainless steel support rods. B is the 8 x 8 x ⅛ in. sample support plate on which the sample wafers are fastened with clips. C is a circular grounded shield plate, the outer thin plate is 6 in. in diameter and is screwed into plate G; the inner section of C is 4¼ in. in diameter with a 2 in. diameter hole in the center. D is the 3½ in. diameter cathode on which a manganese plate is fastened by screws. E is the electrical lead which screws into the cathode and is a metal-to-glass seal with the metal part shielded by the grounded metal of the cathode support. The unshielded area of the cathode is approximately 20 cm^2. F is a ⅛ in. thick quartz plate on which the cathode rests. G an 8 in. square plate with a ½ in. diameter hole (for the electrical connection of E to the cathode) is a support for the cathode and the cathode shielding. The rods (A) are fastened to the grounded base plate so that all of the sputtering apparatus is at ground potential with the exception of the cathode (D) which is connected to the negative electrode of a high voltage d-c power supply through the connector (E). All of the metal parts of the ap-

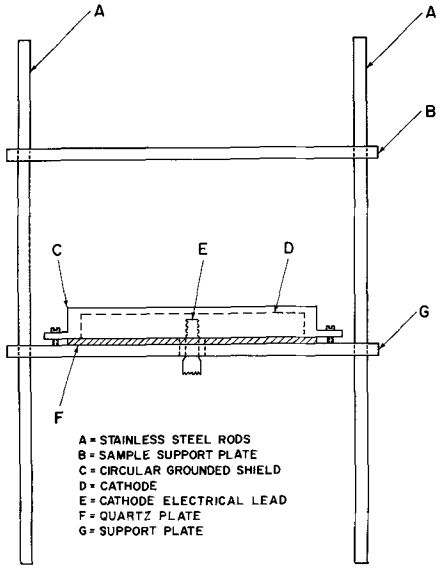

Fig. 1. Sputtering apparatus

paratus are fabricated from stainless steel. Plates B and G are supported by adjustable clamps (not shown in Fig. 1 for clarity) to allow the relative position of plates B and G to be adjusted. A horse-shoe magnet was at times placed on plate B. A nonmagnetic metallic spacer placed between plate B and the magnet adjusted the relative position of the magnet. Plates B and G had copper coils (not shown) brazed to them to allow water cooling of the plates. The sputtering apparatus was placed in a vacuum system with an 18 in. diameter bell jar.

The system was pumped to 2 x 10^{-5} mm Hg or lower prior to the deposition and a 30-min cleanup of the cathode with the wafer shielded was performed with the same gas mixture (usually pure O_2), pressure (usually 50μ) and voltage (1-4 kv) as were to be used during the deposition. The cathode-sample spacing usually was 1⅝ in. with the magnet placed 2⅝ in. from the cathode. The exact conditions described above were arrived at arbitrarily. There was no extensive investigation to determine if these conditions optimized the properties of the manganese oxide films.

The wafer temperature as a function of power was established by a thermocouple soldered to the back of a sample wafer or by temperature indicating salts deposited on the back of the wafer. The agreement between these two methods was excellent. An estimate of the difference in temperature between the front and back surface of the wafers was made. Under the assumption that all of the power used was flowing through the wafer, the maximum temperature difference between the front and the back of the silicon wafer was only 15°C. For this reason, the substrate temperatures quoted in this paper are uncorrected and are the temperatures measured at the back surface.

For infrared spectral evaluation (4000-400 cm^{-1}), the samples were deposited on thick (~ 28 mils) silicon wafers with a resistivity of 2 ohm-cm or greater. The resistivity of the films was measured by a four probe method on films deposited on ~ 5000Å of thermal SiO_2 on 7 mil thick silicon wafers. Film thicknesses were measured by using a Talysurf or Tolansky interferometric technique.

Results

In agreement with the results reported for the spray deposited films (7), the most important determinant of the phases obtained by reactive sputtering was the temperature of the substrate. The temperature of the substrate during sputtering as a function of the power input to the sample is illustrated in Fig. 2. The wafer usually attained this maximum temperature after 15-30 min of sputtering. All measurements were made at 50μ of pure O_2 with varying voltages.

The effect of varying substrate temperature on the composition of the oxides is shown in Fig. 3. All films are ~ 3000Å thick with a deposition rate of 5-10

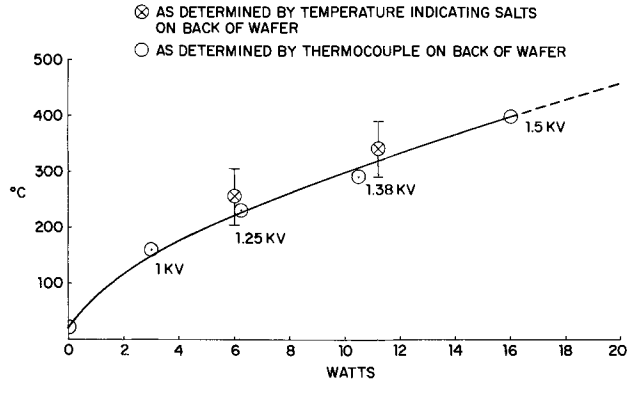

Fig. 2. Variation of temperature with power input—no magnetic field.

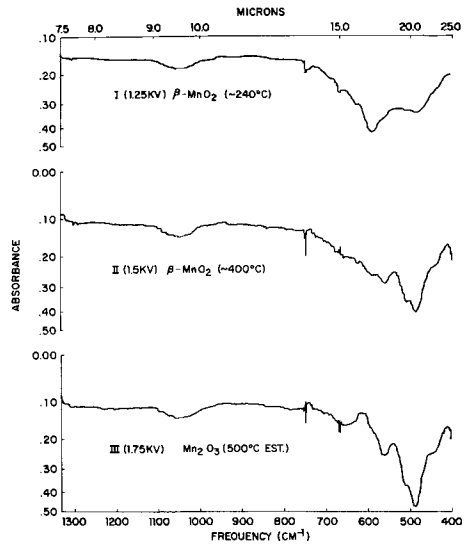

Fig. 3. Infrared spectra of films prepared with different sputtering voltages, 900-400 cm^{-1}.

Å/min. What appears to be an inverse absorption band at 610-620 cm^{-1} in some of the spectra is due to incomplete compensation of the silicon lattice absorption bands due to the use in the reference beam of a silicon wafer which is somewhat too thick. The reference silicon wafer should be somewhat thinner than the sample wafer depending on the refractive index of the sample film (11). The crystal structures of the phases were determined by electron diffraction. However, the infrared spectra has also been found to be a good method of determining the composition of the phases (7). Note in Fig. 3 that there is more similarity between spectra II and III which have different crystalline structures than I and II which are both β-MnO_2. Spectrum III is very similar to that of the spray deposited MnO_2 (7). The resistivities of these films are: I (~ 5 ohm-cm), II (~ 10^3 ohm-cm), and III (~ 10^4 ohm-cm). The spray deposited films had resistivities of ~ 10^4-10^5 ohm-cm. Thus, it can be concluded that the infrared spectra are more sensitive to the stoichiometry of the phase than the crystal structure. Since the lower oxides are poorer conductors than MnO_2, the results indicate that the sample with spectrum II was closer to Mn_2O_3 in composition than it was to MnO_2. Comparison of the results presented in Fig. 2 and 3 establish 300°-350°C as the limiting substrate temperature for the deposition of conductive MnO_2 thin films.

To increase the deposition rate, a magnetic field was introduced into the region of the glow similar to the method used for the preparation of reactively sputtered SiO_2 films (9). In addition to making it possible to increase the deposition rates to as much as 20-80 Å/min, the magnetic field performed another important function. The horseshoe magnet was placed directly above the sample. This resulted in a field primarily parallel to the wafer surface directly above the sample. The field was localized in the vicinity of the wafer with a magnitude of ~ 300-400 gauss while at the cathode the field was 50-60 gauss. It was found that not only did the magnetic field increase the plasma density, but it also made it possible to increase the power (and, therefore, deposition rate) without obtaining extreme substrate temperatures. The magnetic field parallel to the substrate surface would deflect negative ions such as O^- and also the electrons away from the sample.

The variation of substrate temperature as a function of power with the magnet 1⅝ in. from the cathode is depicted in Fig. 4.

It can be seen by comparison with Fig. 2 that with the magnetic field a power of 70w results in a sub-

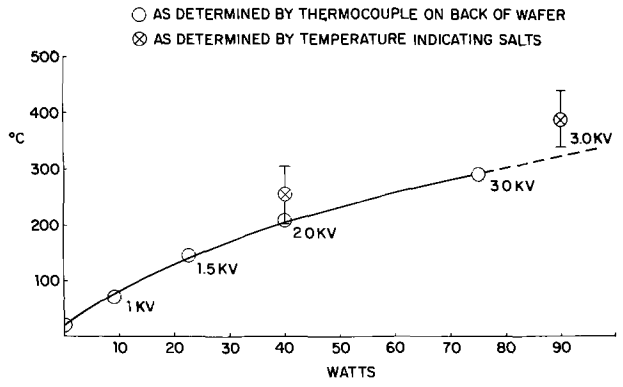

Fig. 4. Variation of temperature with power input with a magnetic field.

strate temperature of less than 350°C. However, without the magnetic field, 16w results in a substrate temperature in excess of 350°C. Clearly, the introduction of the magnetic field makes it possible to increase the power without extreme heating of the sample. It is possible to increase the power density by a factor of 4-5 and still maintain the same substrate temperatures by introduction of the magnetic field.

The uniformity of the films was not greatly affected by the inhomogeneous magnetic field. The thickness did not vary more than 5-7% over a 1¼ in. diameter wafer. Since the pressure was 50μ, the sputtered atoms suffered several collisions before deposition. This tends to decrease any nonuniformity resulting from the inhomogeneous magnetic field.

Since the temperature of the substrates was much lower with the magnetic field, it was possible to prepare conductive MnO_2 at voltages from 1-4 kv. The spectra of several samples of β-MnO_2 prepared at different voltages are presented along with the spectrum of a sample of a β-MnO_2 film prepared by sedimentation (12) in Fig. 5.

The film prepared by sedimentation was formed by centrifuging a suspension of fine particles of β-MnO_2 in a mixture of 25% isopropyl alcohol, 50% methanol, and 25% ethyl acetate. It is apparent that all of the spectra are similar except the band is shifted toward a higher wave number at higher substrate temperatures (higher voltage). There is also a band present beyond 400 cm^{-1}. This is below the limit of the Perkin-Elmer Model 337 Infracord, but it has been seen in the spectrum measured with a Perkin-Elmer Model 521 Spectrophotometer. Note also that as the substrate temperature increases (for example, spectrum II), the spectrum approaches that of the nonmagnetically prepared β-MnO_2. The band is centered close to 600 cm^{-1} with a shoulder at ~ 520 cm^{-1}. The resistivity of all of the β-MnO_2 films was between 1 and 15 ohm-cm. The variation in resistivity appeared to be random and not significantly affected by the deposition parameters. The shift in the band position is attributed to an increase in the density of the film as the substrate temperature is increased, similar to the results obtained with various deposited SiO_2 films (9, 10). The change in the shape of the spectrum at higher substrate temperatures may be reflecting some change in stoichiometry. However, it is believed that, if there is a change in stoichiometry, it is small since there is no significant change in the conductivity of the film. The resistivity of the films is in the range observed for bulk MnO_2 (13, 14).

Films were prepared at 3 kv, 50μ in the magnetic field with varying percentages of oxygen in the sputtering gas. The oxygen percentages were 100, 50, 10, and 1% O_2 in Ar. There were no significant differences in samples. All were found to be β-MnO_2 by electron diffraction with similar spectra as shown in Fig. 6. The conductivity of all the films varied between 1-15 ohm-cm. The variation again appeared to be random and was not a smooth function of oxygen percentage. It is felt that the stoichiometry of the samples is little affected by varying the oxygen percentage in the range of 100-1% O_2 in Ar. The deposition rate of the MnO_2 was 35 Å/min with 100% O_2, 60 Å/min with 50% O_2, 65 Å/min with 10% O_2 and 50 Å/min with 1% O_2. The dependence of sputtering rate on O_2 percentage did not show the large rate increase when the oxygen was reduced to 1% O_2 in Ar that had been observed for reactively sputtered SiO_2 (9).

It was established from the infrared spectra of the sputtered films that they were relatively free of water incorporation in the films. The deposition rates observed for MnO_2, however, were in the lower range of rates employed in the formation of reactively sput-

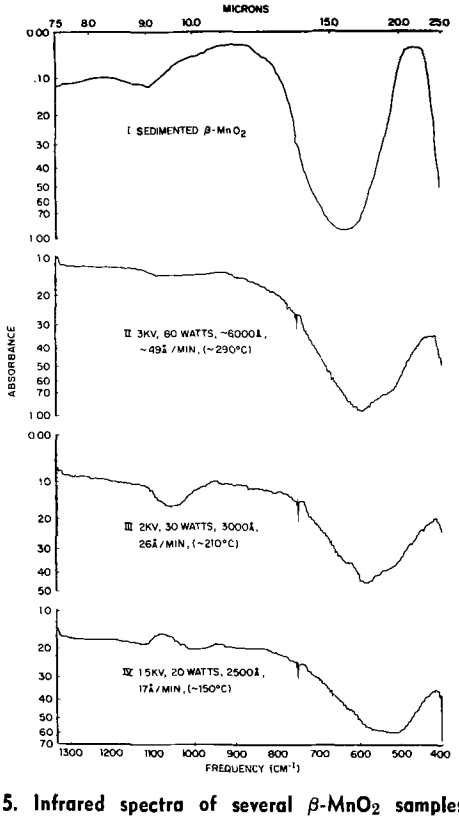

Fig. 5. Infrared spectra of several β-MnO_2 samples, 900-400 cm^{-1}.

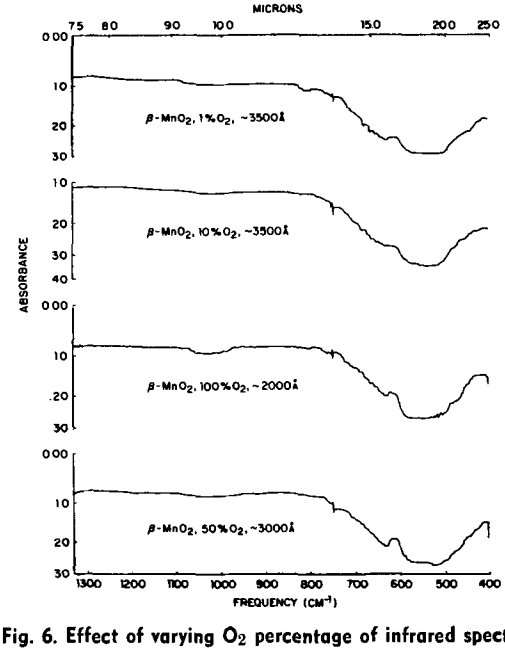

Fig. 6. Effect of varying O_2 percentage of infrared spectra

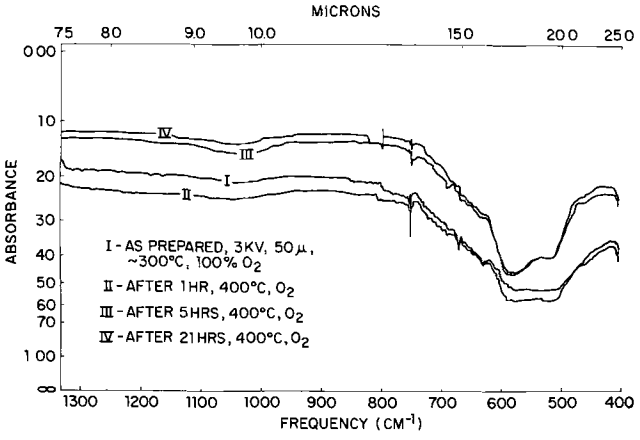

Fig. 7. Infrared spectra of a β-MnO_2 film heated in O_2 at 400°C

tered SiO_2, and at these deposition rates there was no experimentally observed incorporation of water into the SiO_2 films (9).

The reactively sputtered β-MnO_2 films were found to be susceptible to heating in various ambients. For example, a film heated for 15 min at 300°C in N_2 became much more resistive. The infrared spectrum had only one broad band centered at ~490 cm^{-1} and appeared to be intermediate to the spray deposited (7) and reactively sputtered MnO_2.

Sputtered MnO_2 films were easily reduced to Mn_3O_4 after 15 min at 300°C in forming gas. They could be reduced further by forming gas, and the behavior in reducing atmospheres was completely analogous to that observed for the spray deposited films (7). In fact, the infrared spectra can be described as almost identical.

There was some change in the spectrum of a β-MnO_2 film prepared in pure O_2 as a sputtering ambient after heating in O_2 at 400°C. The spectra are shown in Fig. 7. Note that, although there is little initial change after 1 hr at 400°C, the spectra finally look similar to those of films prepared without the magnetic field, *i.e.*, at higher substrate temperatures. The resistivity of the films is changed slightly by this treatment. It remains somewhere between 1 and 15 ohm-cm.

Once a sample has been reduced, it is not possible to reoxidize it to conductive β-MnO_2 by heating in O_2 at 400°C. The phase formed after as much as a week of oxidation (there is little change after 16 hr) is γ-Mn_2O_3. The infrared spectra is identical to that of a sprayed film after long oxidation. This phase is only formed if the film has been reduced. This suggests that a long heating of β-MnO_2 at 400°C even in oxygen would result in loss of some of the oxygen and the formation of Mn_2O_3 after long heating. This is not unreasonable when the susceptibility of bulk MnO_2 to thermal decompositon is noted. Thus, it appears that the β-MnO_2 prepared at the highest possible temperatures (Fig. 3 spectrum I) is somewhat oxygen deficient even though a good conductor.

Discussion

This study established that reactive sputtering is a desirable technique for preparing conductive MnO_2 films. Under favorable conditions, low sputtering rates ~80 Å/min and low substrate temperatures ≤~350°C, films of β-MnO_2 with a resistivity of 1-15 ohm-cm are formed. The films are relatively impurity free when prepared by this method.

In light of the complex chemistry and well-known thermal instability of the higher oxides of manganese, it is not surprising that the films show sensitivity to oxidizing and reducing ambients. This susceptibility to heating must be carefully considered in any capacitor employing these films to enhance the stability of the capacitor since it is known that the formation of a resistive manganese oxide film results in the formation of a frequency dependent capacitor (7).

It has been found that transmission infrared spectroscopy is a very sensitive technique for determining the type of manganese oxide film formed. In addition to being sensitive to stoichiometry and density changes in the same crystalline phase, it also makes it possible to determine the presence of impurities such as water.

It was not possible to make any direct correlation between the infrared spectra previously reported in the literature for manganese oxides and the thin films described herein. However, there is some similarity of the spectrum of reactively sputtered β-MnO_2 and that of finely ground MnO_2 reported by McDevitt and Baun (15). It is believed, however, that the use of infrared techniques will facilitate an understanding of the preparation and properties of manganese oxide thin films.

The study has definitely indicated that, if a conductive film of MnO_2 is required (for example, in thin film capacitors), reactive sputtering is a more desirable means of preparation than the spray deposition method.

Acknowledgment

The authors would like to express their appreciation to Mr. H. S. Lehman for helpful discussions, Dr. E. E. Gardner for making most of the four-probe resistance measurements, and Mr. R. A. Leonard for many of the experimental measurements.

Manuscript received Jan. 25, 1967; revised manuscript received May 17, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Deposition and Properties of Aluminum Oxide Obtained by Pyrolytic Decomposition of an Aluminum Alkoxide

J. A. Aboaf

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

Amorphous aluminum oxide films were deposited at 420°C by thermal decomposition of an aluminum alkoxide. The reducing or oxidizing atmosphere used during deposition affects the chemical and electrical properties of the oxide films. These films have shown superior characteristics when compared to SiO_2 films deposited by a similar process under the same conditions. The dielectric properties of these Al_2O_3 films compare favorably with anodized Al_2O_3 films. The resistance of these films to moisture makes them attractive as coatings for passivation of electron devices. The electrical properties of silicon and germanium surfaces covered with these Al_2O_3 films vary according to the deposition atmosphere.

In the present technology of transistor fabrication, the characteristics required of thin amorphous oxide films are numerous. These glassy films should be dense, pin-hole free, homogeneous, uniform in thickness, chemically inert but still easily etchable, of high dielectric strength, of high thermal conductivity, resistant to thermal shock, should have a coefficient of thermal expansion very near to that of the substrate on which they are deposited so that better adherence is obtained and finally should have surface passivating properties.

Vapor deposition techniques for oxide films consisting in the decomposition of metallo-organic compounds in the vapor phase, with or without oxygen, have been used extensively. The oxide mostly used is SiO_2 obtained from the pyrolysis of tetraethylorthosilicate at high temperature (650°-800°C) (1). The oxide can also be obtained at low temperature (300°-500°C), but the reaction requires the use of oxygen (2). The SiO_2 films deposited at low temperature have some shortcomings; they are not as dense as the high-temperature SiO_2; cracking occurs when films over 2000Å are heat-treated at 800°C; resistance to moisture leaves something to be desired.

Quite an extensive literature (3) exists on polycrystalline and single crystal Al_2O_3, on anodized aluminum and on films obtained by oxidation of aluminum in oxygen and water vapor. Only recently, interest was focused on Al_2O_3 obtained by vapor deposition: thermal evaporation of Al_2O_3 by electron beam bombardment (4), evaporation of aluminum and oxidation in a vacuum system in which a partial pressure of oxygen is maintained (5), and finally sputtering (6). The Al_2O_3 films obtained are considered amorphous since they do not reveal any structure to electron diffraction analysis. Al_2O_3 obtained by thermal decomposition of aluminum triethoxide in vacuo at 550°C was described by Tvorogov (7). In the present study, Al_2O_3 films were obtained by a similar process, but the aluminum alkoxide was transported to the hot zone in a carrier gas. Thick coatings of Al_2O_3 on metals and temperature resistant materials, produced by this method, were described (8) but no study of thin films for electron device applications is known to the author.

Experimental

In the process used, vapors of an aluminum alkoxide compound are transported in nitrogen, mixed with another gas (forming gas, nitrogen, or oxygen) and pyrolyzed in the hot zone of a resistance furnace.

Aluminum Tri-isopropoxide.—Various aluminum alkoxides could be used for the deposition of Al_2O_3; the results given below were obtained using aluminum triisopropoxide $Al(OC_3H_7)_3$. The latter, a crystalline, white powder was obtained from Eastman Kodak and was used without purification. Melting point of the compound is 118°C; its vapor pressure is 5 mm at 134°C (9). An emission spectroscopy analysis of the powder shows that the impurity with the highest content was silicon (100 ppm).

During vapor deposition, the aluminum alkoxide bubbler was maintained at 125°C in a constant temperature oil bath. It was noticed that, on melting the alkoxide in a nitrogen or in an oxygen atmosphere, a solid phase appeared. On cooling of the mass, the compound did not solidify, and a whitish, viscous liquid resulted. An incomplete separation of the solid phase from the liquid was made, and both portions were chemically analyzed for aluminum and isopropyl alcohol. While the composition of the viscous phase is equivalent to aluminum tri-isopropoxide, that of the solid phase could be explained only by a mixture of compounds such as $Al(OH)_3$, $Al(OR)_2OH$, $Al(OR)(OH)_2$. It appears then that the aluminum tri-isopropoxide powder used contained various products of hydrolysis.

Molecular weight determination of aluminum tri-isopropoxide (10) indicates a fourfold polymerization of this compound; this polymerization is present also in the vapor phase.

Deposition apparatus.—A schematic of the apparatus for the deposition of Al_2O_3 films on germanium, silicon, or gold substrates is shown in Fig. 1. Dry nitrogen gas is bubbled through the aluminum source at constant temperature, and vapors of the organic compound mixed with another gas (nitrogen and oxygen or forming gas) are transported to the hot zone of a resistance furnace where they pyrolyze to form Al_2O_3. The resistance furnace is 32.5 cm long and the quartz furnace tube 55 mm in diameter.

The top part of the quartz substrate holder was 20 x 2.5 cm and had a curved bottom which permitted

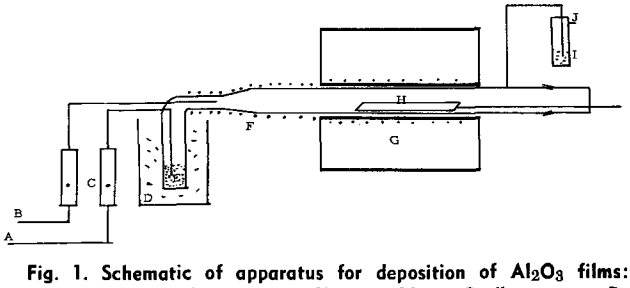

Fig. 1. Schematic of apparatus for deposition of Al_2O_3 films: A, dry N_2; B, dry N_2, O_2, or $90N_2 + 10H_2$; C, flowmeters; D, constant temperature bath; E, aluminum tri-isopropoxide; F, heating mantle; G, tube furnace; H, substrate holder; I, oil bubbler; J, exhaust.

its positioning on the bottom part of the furnace tube. All gases flowed only on the top part of the substrate holder. The temperature of the uniform hot zone on top of the substrate holder (the deposition temperature of Al_2O_3 films) was measured with a chromel-alumel thermocouple, the junction of which rested on it; this temperature was calibrated against the temperature obtained with a thermocouple situated inside the substrate holder. During deposition of Al_2O_3 films, only the temperature inside the substrate holder was recorded.

Formation of Al_2O_3 films.—The parameters involved in the deposition of Al_2O_3 films are the vapor pressure of aluminum tri-isopropoxide, deposition temperature, total flow rate of gases, and geometry of the sample holder and tube where the reaction takes place.

The aluminum tri-isopropoxide temperature was kept at 125°C. The amount of organic vapors transported by the gases was changed by varying the gas flow bubbling through the liquid. Aluminum tri-isopropoxide starts to crack at around 270°C in nitrogen, and at about 250°C in oxygen. At higher temperatures, deposition of the oxide occurs ahead of the zone of interest. The deposition at higher temperatures was made possible by using a high gas velocity so that cracking and/or deposition occur in the zone of interest. The total flow rate does have an effect on the rate of deposition of the oxide. Deposition rates of 100 Å/min could be obtained at 420°C when the total gas flow was 10 l/min. This had to be increased to 30 l/min for deposition at 600°C. The deposition rate is dependent also on the geometry of the reaction tube and substrate as these affect the flow pattern of the gases. Everything being equal, depending on the vertical positioning of the substrate holder in the furnace tube, different deposition rates were obtained. The highest deposition rate was obtained when the substrate holder was sitting on the bottom part of the furnace tube so that all gases flowed on top of it.

Film etch rates.—The etch rate of Al_2O_3 films deposited on germanium or silicon was measured by observing visually the change in interference colors on the basis of the color chart used for SiO_2 (11) adjusted for the refractive index of the Al_2O_3 film in question. The reproducibility obtained indicates that the method gives satisfactory relative values of etch rate. Two etchants were used: H_3PO_4 (85%) at 55°C and buffered HF (113g NH_4F, 22.7 cc HF 48%, and 166 cc of H_2O).

Index of refraction.—The index of refraction of Al_2O_3 films was determined by comparison with liquids of known index of refraction using the method described by Lewis (12).

Dielectric measurements.—Al_2O_3 films, 2000Å thick, were deposited on p-type germanium substrates of 0.0013-0.0015 ohm-cm resistivity. Aluminum dots, 30 mils in diameter and 5000Å thick, were evaporated through a mask over the oxide, and a film of aluminum of the same thickness was deposited on the back side of the sample. The specimen was held down by a vacuum chuck on a stage that served as one terminal of the measuring circuit (Fig. 2). The other terminal was a metal probe brought into contact with any dot by means of a manipulator. The stage was provided with a heater and an insulating cap so that the dielectric properties could be measured as a function of temperature; the temperature was measured near the aluminum dot studied by means of a chromel alumel thermocouple.

The equipment used for measurement of dielectric properties was a General Radio, Model 716-C, Schering-type bridge, generator, and detector instruments. The substitution method was used to obtain a bridge balance. The dissipation factor and capacitance of the specimen were obtained in a straightforward manner from the bridge balance conditions. The instrument allows an accuracy for the calculated capacitance of

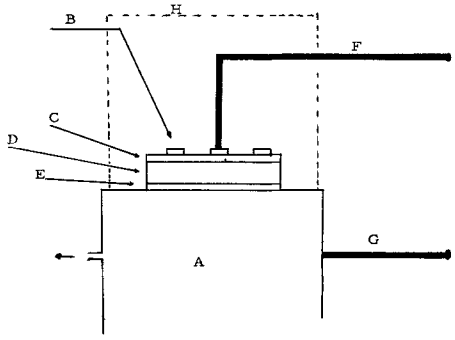

Fig. 2. Experimental set-up for measurement of dielectric properties (not to scale): A, aluminum hot stage connected to vacuum; B, aluminum dots 0.026 in. diameter 5000Å thick; C, Al_2O_3 film, approx. 2000Å thick; D, p-Ge 0.0013 ohm/cm; E, aluminum film; F, G, leads connected to measuring circuit (General Radio Bridge or to V-I circuit); H, insulating cap.

2 $\mu\mu$f or 0.2% whichever is greater and for the calculated dissipation factor 5 x 10^{-5} or 2% error whichever is larger. From the known area of the aluminum dot, and the thickness of the oxide near it as measured by double beam interferometry after etching a step, it was possible to calculate the relative dielectric constant [$k' = 3.6\ \pi t(C/A)$, t = thickness in cm, C capacitance in $\mu\mu$F, A area in cm^2], the loss factor and the a-c conductivity. Dielectric values reported are the average of at least three readings on a film and for at least three wafers.

V-I characteristics.—The same specimen geometry used for the dielectric measurements was used to obtain V-I characteristics of the oxide. A type 531 Tektronix oscilloscope with a type-0 operational amplifier plug-in unit equipped with a leakage current adapter was used. A sawtooth voltage drove the adapter, and a V-I curve was obtained on the scope.

Results and Discussion

Effect of gas ambient, temperature, and deposition rate on films.—Starting with a clean furnace tube, reproducible deposition rates of Al_2O_3 films at 420°C were obtained only after several hours of deposition. This decrease in rate of deposition in the 420° zone might be due to an increase in the decomposition rate of the incoming organic vapors because of the high surface area and/or the catalytic effect of oxide powders already deposited ahead of the hot zone. This effect was found to be more pronounced in the deposition of aluminosilicate films, obtained from the simultaneous decomposition of aluminum tri-isopropoxide and tetraethylorthosilicate, where the rate decreased to zero (13).

The rate of deposition of Al_2O_3, at equilibrium, on germanium or silicon substrates as a function of gas flow through aluminum tri-isopropoxide and for a total gas flow of 10 l/min, at 420°C is shown in Fig. 3. This rate increases with the increase of the concentration of oxygen of the gases and with the amount of aluminum tri-isopropoxide transported. The aluminum alkoxide can absorb sufficient thermal energy to cause bond rupture and formation of (Al-O) species in a nitrogen atmosphere. The oxygen content in the molecule is sufficient to form Al_2O_3. The oxygen apparently assists the process of decomposition of the organic molecule and influences the rate of deposition. While the deposition rate in nitrogen seems to become flow independent at about 2 l/min, that of oxygen is still linear at this flow.

The gaseous products evolved during the decomposition in nitrogen of aluminum tri-isopropoxide are most probably similar to those obtained for the decomposition of tetraethylorthosilicate (14). In oxygen, water vapor would also be formed. Infrared analysis of the Al_2O_3 films (Perkin Elmer Model 21 double beam spectrometer) do not show any water absorption

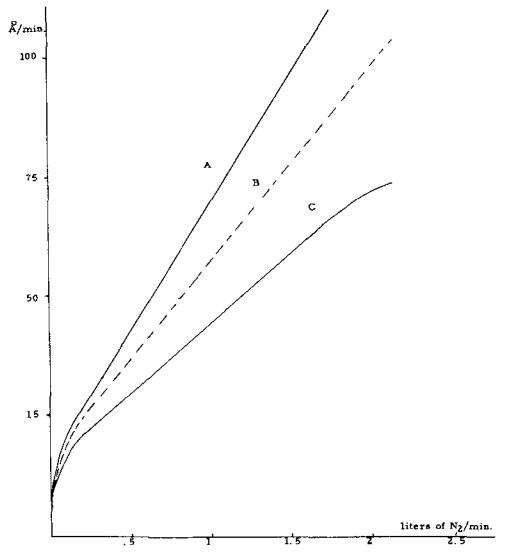

Fig. 3. Deposition rate of Al_2O_3 as a function of gas flow through $Al(OR)_3$. Temperature 420°C; total flow of gases 10 l/min: A = 83% O_2; B = 3% O_2; C = N_2 or 90N_2 + 10H_2.

band; thus, if water is formed during reaction, it is not incorporated in the oxide deposited.

Films deposited at 270°C are mechanically soft and can be easily scratched with a steel point. Their etch rate is one order of magnitude higher than those deposited at 420°C. Their dielectric properties are poor. The oxides studied below were deposited at 420°C in various ambients at a rate of 67 Å/min. It is possible to obtain deposition rates of over 100 Å/min, but the quality of the oxide deteriorates. Hazy looking oxides are deposited and a microscopic examination shows a very porous structure. These oxides have a faster rate of etching, *i.e.*, for O_2-deposited Al_2O_3, the etch rate in phosphoric acid at 55°C is 200 and 325 Å/min for deposition rates of 33 and 330 Å/min, respectively. The oxide deposition rate is linear with time and is not influenced by the amount of oxide already on the substrate.

Structure of films.—(*a*) *As-deposited.*—Oxide films deposited at 420°C, on ¾ in. diameter germanium or silicon wafers were clear, transparent, and hard. Thickness variation from one edge of the wafer to the other was less than 10%. The maximum thickness obtained without cracking of the film on a germanium substrate was approximately 1μ. A 7500Å thick film could be thermally cycled between 25° and 800°C without developing line cracks.

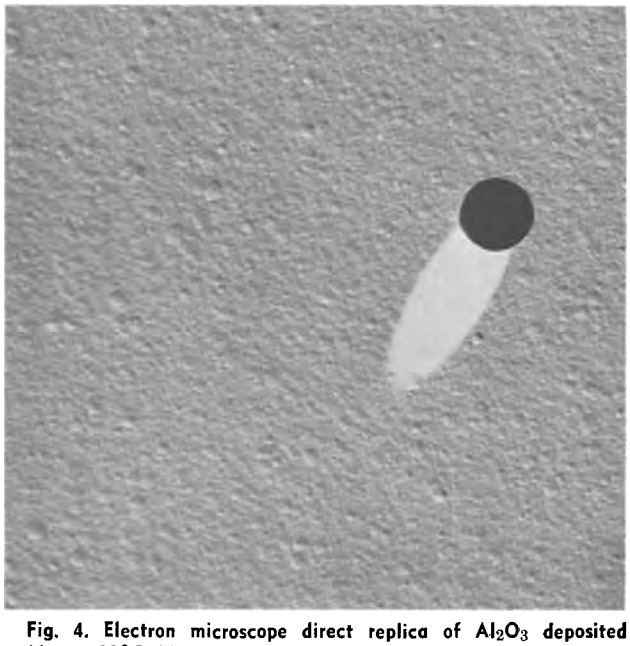

Fig. 4. Electron microscope direct replica of Al_2O_3 deposited in N_2 at 420°C. Magnification *ca.* 20,000X.

Table I. Properties of oxide films

Films deposited at 420°C, rate: 67 Å/min	Etch rate Å/min H_3PO_4 55°C	Etch rate Å/min buff. HF r. t.	Index of refraction	Dielectric constant
90 N_2-10 H_2	160	635	1.610 ± 0.006	7.7
N_2	180	820	1.600 ± 0.004	7.7
O_2	210	1000	1.594 ± 0.006	7.7
SiO_2 (low-temperature oxygen process)		1700	1.454	4.9

No structure could be detected with the optical microscope. Electron micrographs of 2000Å thick Al_2O_3 films show a uniform texture of spots, the bigger being about 1000Å in diameter (Fig. 4). These raised spots (about a few tens of Angstroms high) are seen over the entire wafer, for the N_2-deposited oxide as well as for the O_2-deposited oxide. These spots are very thin platelets and not spheres; 1000Å in diameter spots are seen when 500Å thin films are deposited. It is interesting to note that the surface of Al_2O_3 films deposited at 270°C, as seen at the electron microscope, is very smooth. It is suggested that at 420°C deposition of very fine particles occurs on top of the wafer, particles formed on cracking of the aluminum triisopropoxide prior to reaching the substrate zone in the furnace. However, the structure obtained is not porous as will be shown later.

Electron diffraction of the films deposited at 420°C shows a pattern of diffuse rings.

(*b*) *After heat-treatment.*—On heating these oxides in argon, structural and physical property changes occur. For a heat-treatment at 600°C for 1 hr, diffuse electron diffraction patterns are still obtained. After 1 hr at 800°C three phases are detected, amorphous, γ'-Al_2O_3 and γ-Al_2O_3 (respectively, fcc and spinel structure with lattice constant 3.95 and 7.9). After a 3-hr heat-treatment, only the γ and γ' phases are detected. Anodized Al_2O_3 at room temperature on heat-treatment is transformed to the γ-phase. The γ'-phase is obtained on anodization at 100°C (15).

Etching.—The Al_2O_3 films deposited at 420°C are insoluble in water, but are soluble in bases and acids. Etch rates in angstroms per minute, in phosphoric acid at 55°C, and in buffered HF at room temperature are shown in Table I. Oxides deposited on germanium etch uniformly down to the substrate as could be seen by successive electron micrographs of the resulting surface. The etch rate, in buffered HF, of the oxide deposited in forming gas is lower than that deposited in oxygen (635 and 1000 Å/min). For comparison purposes, etch rates of SiO_2 films deposited at the same rate and at the same temperature *via* thermal decomposition of tetraethylorthosilicate in oxygen are shown.

Table II. Properties of heat-treated Al_2O_3 deposited in N_2 atmosphere

	Etch rate Å/min H_3PO_4 55°C	Etch rate Å/min buff. HF r. t.	Index of refraction	Structure
As deposited at 420°C in N_2	180	820	1.600	Amorphous
Heat-treated at 600°C in argon, ½ hr	125	570	1.620	Amorphous
Heat-treated at 800°C in argon, ½ hr	85	265	1.640	Partially crystalline
in argon, 3 hr		insoluble	—	Crystalline
Heat-treated at 1000°C in argon, ½ hr		insoluble	>1.7	Crystalline

Films deposited in nitrogen at 420°C were heat-treated at various temperatures and for different lengths of time. The etch rate, in buffered HF and in H_3PO_4 at 55°C, decreases with increase temperature of heat treatment as shown in Table II. This is in agreement with the observed change in structure. After a 3-hr heat-treatment at 800°C the oxide is insoluble in both etchants. Only hot phosphoric (200°C) dissolves it.

Index of refraction.—The index of refraction, shown in Table I, is definitely higher (1.610) for films deposited in forming gas than in oxygen (1.594) and increases as a function of the temperature of heat-treatment until it reaches the index of polycrystalline Al_2O_3. The index of refraction of the as-deposited film is comparable to that of Al_2O_3 prepared by thermal evaporation using electron bombardment of polycrystalline alumina ($n = 1.60 \pm 0.01$) (4). The index of refraction reported in the literature for anodized Al_2O_3 is higher (15, 16). Dorsey (17) shows the anodized layer to be a hydrated Al_2O_3.

Masking properties.—Aluminum oxide thin films on germanium can be used for masking of n-type dopants such as antimony and arsenic at 700°C. At 800°C, a 2200Å thick film of Al_2O_3 on germanium mask gallium and indium (surface concentration of gallium 5 x 10^{19} atoms/cc; of indium 4 x 10^{18} atoms/cc) for 1 hr only. Aluminosilicate films provide somewhat better masking (13). Films with an alumina content, ranging between 70 and 90 w/o (weight per cent) act as mask against gallium for 3 hr; this range is extended to 97 w/o for indium.

Surface electrical properties.—It is known that the presence of SiO_2 on silicon tends to make the surface of silicon more n-type independent of the bulk conductivity type (18). Differences between forming gas, N_2-deposited and O_2-deposited Al_2O_3 and SiO_2 (low-temperature oxygen type, high-temperature nitrogen type) are noted when studying the surface properties of silicon and germanium covered with Al_2O_3. Metal-oxide-semiconductor measurements show that a more p-type surface occurs under forming gas or N_2-deposited Al_2O_3, while a neutral or more n-type occurs under O_2-deposited oxide (19). Enhancement mode npn field effect devices on 8 ohm-cm silicon were made using N_2-deposited Al_2O_3 while npn depletion mode devices were obtained with O_2-deposited Al_2O_3. After a heat-treatment in nitrogen, at 350°C for 2-hr, the threshold voltage was about +5v in the first case and −1v in the second (20).

Dielectric properties.—*(a) Films as-deposited and after heat-treatment.*—The dissipation factor (Fig. 5) increases as a function of the oxygen in the gas flow and is not particularly sensitive to the frequency range measured (100 cycles to 100 kc) for the oxide deposited in a neutral or reducing ambient. Some results are given in Table III. The dissipation factor for O_2-deposited Al_2O_3 is much higher (~0.75%) than that for Al_2O_3 deposited in lightly oxidizing or reducing atmospheres (*i.e.*, 0.3%). The dissipation factor of SiO_2 films deposited in oxygen at 420°C in the same conditions is shown for comparison. The dissipation factor decreases very slightly from 0.26 to 0.20% for Al_2O_3 films deposited in nitrogen when these are heat-treated to 420°C. A large decrease (from 0.75 to 0.22%) down to the dissipation factor of N_2-deposited films is observed for the same treatment for the O_2-deposited oxide. The capacitance change for the O_2-deposited oxide (3%) is higher than that for the N_2-deposited oxide (1%) (Fig. 6). After heat-treatment to 420°C, the resulting capacitance change is the same, about 1%, for all oxides. On heat-treatment of the O_2-deposited SiO_2 oxides, the dissipation factor drops from 0.16 to 0.09%. The dissipation factor of these Al_2O_3 films compares favorably with anodized aluminum capacitors (21, 22).

The dissipation factor and capacitance change as a function of temperature at 1 kc are shown in Fig. 7.

Table III. Dielectric properties of Al_2O_3 and SiO_2 films at 1 kc. Thickness: approximately 2000Å*

	N_2-Al_2O_3	O_2-Al_2O_3	O_2-SiO_2
Dissipation factor of film as deposited	0.26	0.76	0.16
Dissipation factor after heat-treatment to 420°C, ½ hr	0.22	0.25	0.09
Capacitance change of film as deposited (from 0.1 to 1 kc)	0.5	1.2	
As above + heat-treatment to 420°C, ½ hr	0.5	0.5	
Dissipation factor change from room temperature to 85°C	0.35		
Capacitance change from room temperature to 85°C	1.2		

* All figures in %.

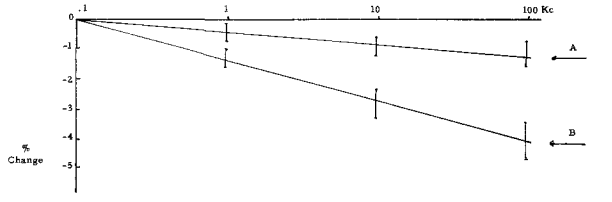

Fig. 6. Capacitance change as a function of frequency for Al_2O_3 films: A = N_2 or 90N_2-10H_2; B = 83% O_2.

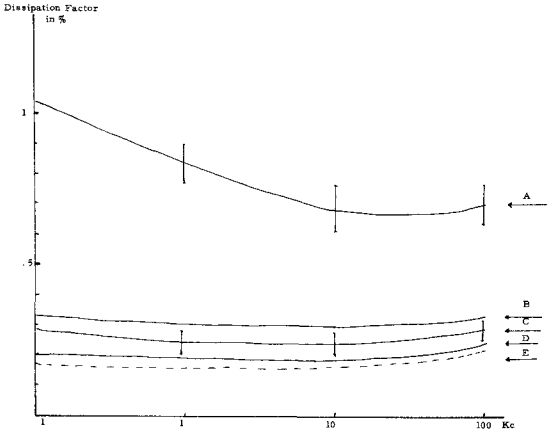

Fig. 5. Dissipation factor as a function of frequency for Al_2O_3 films (A,B,C,D) and for low-temperature SiO_2 films (E): A = 83% O_2; B = 3% O_2; C = N_2; D = 90N_2-10H_2; E = SiO_2.

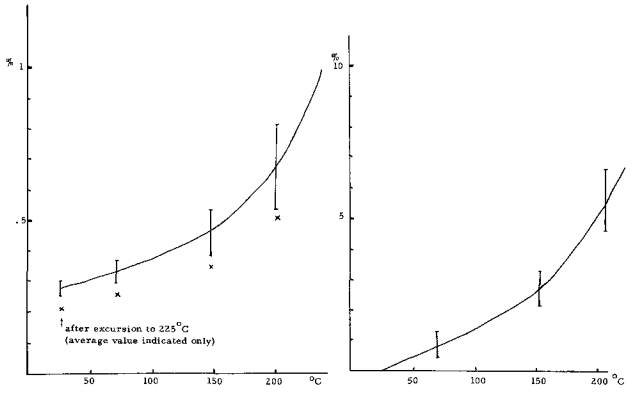

Fig. 7. *(left).* Dissipation factor (%) at 1 kc of N_2-Al_2O_3 films as a function of temperature. *(Right).* Capacitance change (%) at 1 kc of N_2-Al_2O_3 films as a function of temperature.

The retrace of the dissipation factor as a function of temperature after excursion to 220°C is also shown. The capacitance change is the same, before and after excursion to 220°C.

The dielectric constant of the as-deposited films is 7.7 ± 0.3. It was not possible to differentiate between the O_2-deposited Al_2O_3 and the N_2-deposited oxide. After heat-treating at 800°C for 1 hr, the measured dielectric constant was 8.5 very near to the value for crystalline Al_2O_3 (23).

From the dielectric constant and the dissipation factor, at 350°C, the a-c conductivity of Al_2O_3 oxide was calculated. At 350°C, the value calculated, 2×10^{-10} ohm^{-1} cm^{-1}, is in the range of values obtained by various workers for polycrystalline Al_2O_3 (24).

The dielectric breakdown of the Al_2O_3 films is better than 3×10^6 v/cm. Typical V-I characteristics gives 1 mμa at 55v for a 2000Å thick film. It was noted that sharper breakdown occurred for Al_2O_3 deposited in a reducing ambient than in an oxidizing atmosphere. A higher breakdown (6×10^6 v/cm) for N_2-deposited Al_2O_3 films is obtained after a heat-treatment at 800°C.

(b) *Effect of humidity.*—The dielectric properties of Al_2O_3 films were studied after a treatment of 22 days in a 100% relative humidity ambient at room temperature. The dielectric properties are similar to the non-treated specimen. On the contrary, O_2-deposited SiO_2 for the same treatment degrades and gave very poor dielectric characteristics.[1] Al_2O_3 films have thus the advantage of being resistant to moisture; they are superior to SiO_2 films deposited at low temperature and could be used as passivating films.

The high dissipation factor and the relatively large change in capacitance of the oxygen-deposited oxides might be due to water vapor formed during the cracking process. The reduction in the dissipation factor as well as the capacitance change on heating the specimen to high temperatures would support such a conclusion. However, infrared measurements did not show any OH absorption band after deposition. No OH band was detected after treating Al_2O_3 specimens for 22 days, at 25°C, in a 100% relative humidity ambient.

It might be possible to explain the difference in terms of an oxygen sorption mechanism. During deposition of Al_2O_3 in oxygen, incorporation of oxygen in the oxide takes place. The resulting film would be more "porous" in respect to Al_2O_3 deposited in nitrogen. This would explain the higher etching rate and the lower index of refraction of the oxide. The higher dissipation factor of the O_2-oxide and its increase with the oxygen pressure would be accounted for by the polarization of the oxygen. On heating the oxide in air, desorption of oxygen takes place with consequent reduction of the dissipation factor. A mass spectrometric study of the gas evolved on heating the oxide in high vacuum would probably shed some light on this problem.

[1] Actually cracking of SiO_2 on Ge occurred after the treatment in moist ambient. No cracking occurs when SiO_2 films are deposited on Si; the dissipation factor increases, however (25). Aluminosilicate films, of high SiO_2 content (13), also show some cracking and increase dissipation factor after the treatment in moist ambient.

Conclusion

Aluminum oxide thin films obtained by cracking of aluminum tri-isopropoxide at low temperature have shown some superior characteristics when compared to SiO_2 films obtained by a similar process in the same conditions. These films compare favorably with anodized Al_2O_3. The resistance of Al_2O_3 to moisture, its dielectric properties, and the different surface electrical properties it confers on germanium and silicon according to the deposition atmosphere make it quite attractive.

Acknowledgment

Thanks are due to Dr. T. O. Sedgwick for his many conversations, for reviewing the manuscript and for the MOS measurements, to C. F. Aliotta for the electron micrographs, to Mrs. S. Herd for the electron diffraction experiments, to P. Gansauge and H. N. Yu for the diffusion experiments. The technical assistance of W. J. Mesimer is particularly appreciated.

Manuscript received Feb. 27, 1967; revised manuscript received June 2, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Energy Transfer and Fluorescence Processes In Bi^{3+} and Eu^{3+} Activated YVO_4

S. Z. Toma, F. F. Mikus, and J. E. Mathers

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

Fluorescence and excitation spectra of YVO_4:Bi and YVO_4:Eu,Bi are reported and discussed. Energy transfer from Bi^{3+} center to Eu^{3+} was observed. The absorption of Bi^{3+} in YVO_4, deduced from excitation spectra, is compared with other bismuth activated matrices.

Yttrium orthovanadate crystallizes in the tetragonal system of zircon ($ZrSiO_4$) with Y^{3+} and V^{5+} replacing Zr^{4+} and Si^{4+}, respectively. The uv properties of YVO_4:Eu phosphor have been studied extensively (1, 2), and its utility as a red emitting cathode-ray (cr) phosphor is now well known (3). In the present work we studied the luminescent properties of YVO_4 with and without various activators. In particular, we wish to report on the excitation and fluorescence spectra of YVO_4,YVO_4:Bi and YVO_4:Eu,Bi under both cr and uv excitations.

Experimental

Phosphors, as polycrystalline materials, were prepared by solid state reactions (3). UV emission and excitation spectra were measured with a Perkin-Elmer spectrofluorimeter (4). For cathodoluminescent measurements, the phosphors were settled on glass slides and irradiated with 12 kv electrons at 6 μa current. The fluorescence was recorded with a GE spectroradiometer using a 1P22 photomultiplier.

Results and Discussion

The fluorescence of various activators in YVO_4, their temperature dependence, and concentration quenching cannot be interpreted adequately without first attempting to understand the nature of the bonding among the three ions in YVO_4 itself. The broad excitation and emission spectra (Fig. 1) can be due to more than one electronic transition. Such transitions may be of the charge transfer type or among the molecular states of the VO_4^{3-} anions.

McClure (5, 6) discussed the series of isoelectronic tetrahedral ions MnO_4^{1-}, CrO_4^{2-}, VO_4^{3-}, TiO_4^{4-}, and reviewed the semiempirical calculations of the molecular orbital energies for MnO_4^{1-} and CrO_4^{2-} by Wolfsberg (7). The lowest allowed electronic transition was interpreted to be a charge transfer from a predominantly oxygen orbital to a 3d orbital. The long wavelength absorption in YVO_4 was attributed to such transitions from an experimental study of the $YV_{1-x}P_xO_4$ system (8). McGlynn and Kasha (9) studied the lowest electronic transitions of simple molecules of the type XO_y^{z-}, where O is an oxygen atom; X is a nonmetallic or a transition metal atom; y = 1, 2, 3, 4; z = 0, 1, 2, 3. The VO_4^{3-} spectrum was interpreted as $n \rightarrow \pi^*$ transition, where n is a nonbonding oxygen orbital and π^* is the antibonding molecular orbital of the whole anion.

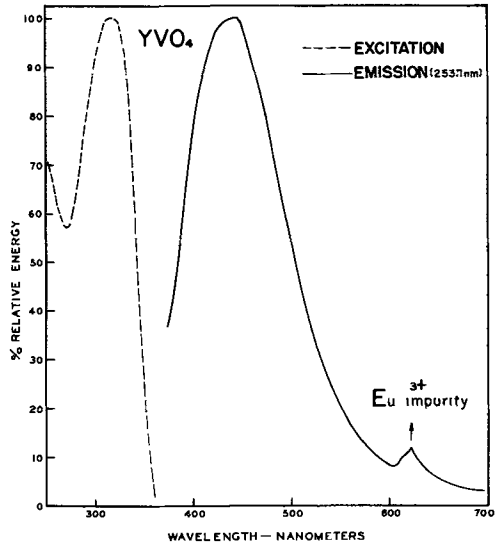

Fig. 1. Excitation and emission (253.7 nm) spectra of YVO_4

A process that can be of significance in YVO_4 is that of a charge transfer from an atomic or molecular orbital of the anion to Y^{3+}. The importance of such transitions depends on the nature and strength of the bonds in the VO_4^{3-} ion. If the latter is not a tight molecular entity, then YVO_4 woull not be appropriately considered a lattice of molecular ions but rather should be relatively more ionic in nature (6). This may enhance charge transfer processes to Y^{3+} and contribute to the formation of exciton and band processes.

A comparison of electronic spectra of MnO_4^{1-}, CrO_4^{2-}, and VO_4^{3-} suggests that the VO_4^{3-} ion is a much less tightly bound molecular unit (5, 6). IR spectra of these ions support this conclusion. The stretching force constants f_r of the M-O bond (M: transition metal) for these ions were calculated using the simple harmonic oscillator approximation (10). The results are shown in Table I which also includes the PO_4^{3-} ion. An average of the two observed stretching frequencies belonging to the A_1 and F_2 species was used. The value of f_r obtained in this manner for the PO_4^{3-} ion is in fair agreement with that calculated for YPO_4 by Wilson's GF matrix method (13). Table I indicates clearly that the V-O bond is the weakest, supporting the conclusion derived from the electronic spectra of these transition metal ions.

From a study of the molecular vibrations of tetrahedral XO_4 ions at a site symmetry D_{2d} and a consideration of the zircon structure, it was shown (13, 14) that, in YVO_4, π-bonding orbitals of a specific VO_4^{3-} ion may overlap two different Y^{3+} along the S_4 axis and, therefore, along this axis there should be a continuous overlap of π-bonding orbitals of the VO_4^{3-} group and the orbitals of Y^{3+}. This geometric and electronic coupling should contribute to a band

Table I. Fundamental frequencies (cm^{-1}) and stretching force constants (10^{-5} x dynes/cm)

Ion	$\nu_1(A_1)$	$\nu_3(F_2)$	f_r(M-O)
VO_4^{3-} (11)	824	790	4.7
CrO_4^{2-} (11)	847	884	5.4
MnO_4^{-1} (11)	845	910	5.6
PO_4^{3-} (12)	980	1082	6.6

process in YVO_4. It also may allow one to consider the S_4 axis as one large molecule and interpret some aspects of the absorption and transfer of energy as intramolecular process.

The applicability of the term "charge transfer" must decrease as the initial and final orbitals of the various ions become less localized. This delocalization can be dominant in YVO_4; hence, molecular orbitals and band processes should be more appropriate in attempting to understand the various effects in this phosphor. Addition of 0.025 m/o (mole per cent) Eu^{3+} reduces its emission peak height by about 60% under cr excitation and with 0.008% Bi^{3+}, 35% quenching was observed. Comparable effects were obtained with Tm^{3+} and Dy^{3+} additions. These results do suggest that the excited states in YVO_4 are quite mobile, and an efficient energy transfer and migration through an extended region of the crystals exists. Exciton motion, exchange effects, and nonradiative (dd) and (dq) resonance energy transfer (15) can occur and account for this efficient transport of energy. The relative importance of the various modes of transfer is difficult to ascertain from the present work.

The absorption of YVO_4 in the 360 nm region was postulated as a charge transfer transition in the V-O bond (8). This conclusion was based on the absorption spectra of the system $YV_{1-x}P_xO_4$:Eu, where the substitution of PO_4^{3-} for VO_4^{3-} ions reduced the absorption in the 3600Å region. This decrease in absorption can also be understood as a dilution effect (16). The broadness of the VO_4^{3-} (or YVO_4) band may be decreased by dilution with PO_4^{3-} (or YPO_4) ions. Similar effects were observed in $KMnO_4$, *i.e.*, band broadening in the MnO_4^- spectrum when the ion is in pure $KMnO_4$ compared to the spectrum in dilute solid solution with, for example, $KClO_4$. This effect should be even more enhanced in YVO_4 if we consider the nature of the bonding in VO_4^{3-}, as discussed earlier.

The characteristic oxidation state of bismuth is very often Bi^{3+}. The ion has $6s^2$ outer electrons, and its radius is comparable to trivalent yttrium. The effect of its utility as an activator in YVO_4 is shown in Fig. 2. This broad emission is relatively intense, and its brightness is comparable to the presently used low-pressure mercury lamp phosphors of approximate color. Its brightness decreases at elevated temperatures.

As to how Bi^{3+} addition modifies the energy levels of YVO_4, one must start with its substitution as a matrix cation for Y^{3+} and, therefore, any transitions involving Y^{3+} should also be considered for Bi^{3+}. Since the latter also possesses outer $6s^2$ electrons, we must also consider $s^2 \rightarrow sp$ transitions. The extensive theoretical and experimental work on such transitions of isoelectronic Tl^{1+} in alkali halides is well known (15, 17). The exposed nature of these outer electrons induces interactions with the neighboring anions in solids. The energies of the localized states of Tl^+ are, thus, usually treated as a function of the anion coordinates which interact differently with the ground and excited states of Tl^+. The center is, then, treated as a polyatomic molecule and configuration coordinate diagrams are used to compute the energies of the various electronic transitions. The absorption and emission of the Bi^{3+} center in YVO_4 is attributed to similar transitions, *i.e.*, $6s^2 \rightarrow 6sp$ and the interaction of the anions of the matrix with the singlet S ground and triplet, singlet P excited states of Bi^{3+}.

The excitation and fluorescence spectra of YVO_4:Eu were discussed by several investigators, as noted earlier. We studied the effects of bismuth addition to this phosphor. Since both Bi^{3+} and Eu^{3+} are primary activators, the excitation and emission spectra of YVO_4:Eu,Bi depend on the relative concentrations of the two additives. Examination of the excitation spectra of YVO_4:Eu and YVO_4:Eu,Bi for the $^5D_0 \rightarrow {}^7F_2$ transition of Eu^{3+} at 619 nm (Fig. 3) shows that the two curves cross at about 340 nm. Thus, Bi^{3+} addition to YVO_4:Eu enhances the 619 nm emission under 340 or longer wavelength excitations. This enhancement is interpreted as evidence of energy transfer from the Bi^{3+} center to Eu^{3+}. Note that at 320 nm, the excitation peak of pure YVO_4, Eu emission decreases.

Bismuth addition must increase the absorption coefficient of the phosphor with 340 nm and higher wave length excitation. Figure 4 clearly indicates this, where the peak at about 340 nm is attributed to Bi center absorption. The absorption of the latter in SrO:Bi was observed at 367.2 nm and higher energies (18). In the molten LiCl-KCl eutectic containing $BiCl_3$, Bi absorption is at 330.6 nm with a molar extinction coefficient of 7000 l/mole·cm (19). This absorption is not very different from that observed in YVO_4 and suggests that $s^2 \rightarrow sp$ transitions play a dominant role in the electronic transitions of the Bi^{3+} center in YVO_4.

The increase in the fluorescence intensity of Eu^{3+} with Bi^{3+} coactivation is due to energy transfer from the Bi^{3+} center to Eu^{3+} as mentioned earlier. Such transfer, in the absence of movement of charge carriers, can occur by radiative cascade and nonradiative resonance transfer as well as the short-range exchange mechanism. The conditions and characteristic properties of these various modes of transfer are discussed elsewhere (15, 20, 21). The broad emission of YVO_4:Bi

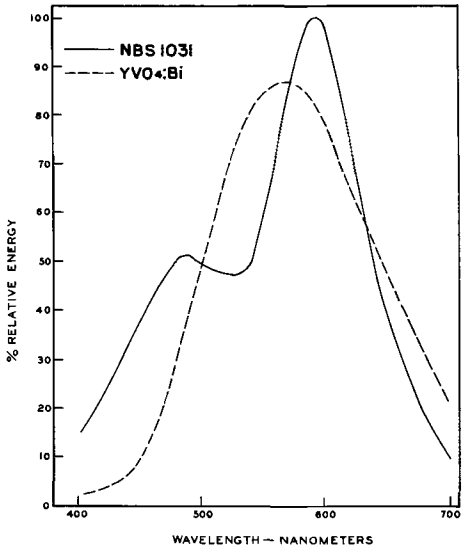

Fig. 2. Emission spectra of YVO_4:Bi (4 m/o) and calcium halophosphate NBS standard 1031 with 253.7 nm excitation.

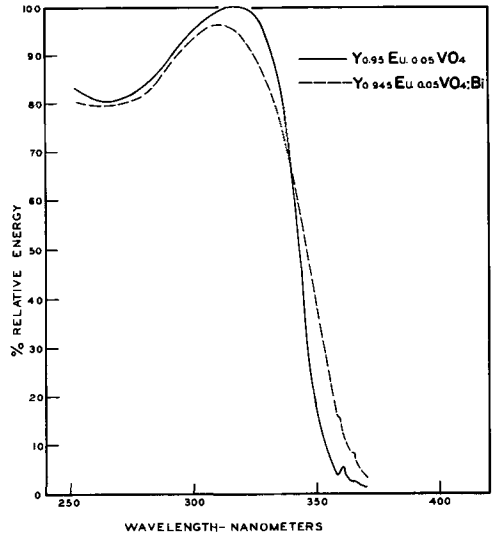

Fig. 3. Relative excitation spectra for the 619 nm Eu^{3+} emission of $Y_{0.95}Eu_{0.05}VO_4$ and $Y_{0.945}Eu_{0.05}VO_4$:Bi (0.5 m/o).

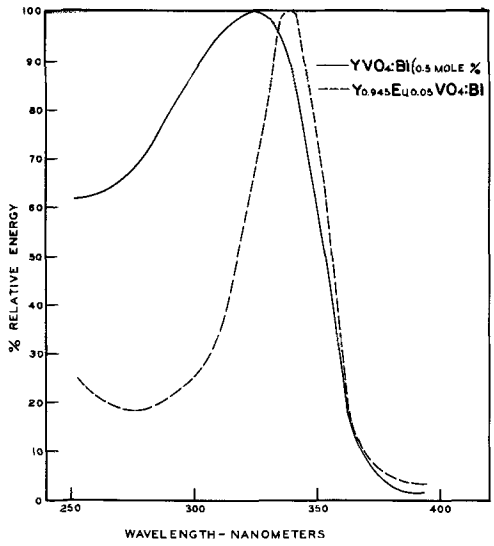

Fig. 4. Excitation spectra for the 550 nm Bi^{3+} center emission YVO_4:Bi (0.5 m/o) and $Y_{0.945}Eu_{0.05}VO_4$:Bi (0.5 m/o).

does not show any sharp depressions (missing lines corresponding to Eu^{3+} absorption) with Eu^{3+} coactivation and, since the latter absorbs weakly in this spectral range, energy transfer by the cascade process cannot be significant here and nonradiative resonance transfer should dominate.

To study the partition of excitation energy between Bi^{3+} and Eu^{3+}, the intensity of Bi^{3+} emission (peak height) with increasing content of Eu^{3+} was measured under 255, 300, and 337 nm excitations. Table II summarizes the results. On addition of Eu^{3+} to YVO_4:Bi the intensity of Bi^{3+} emission decreases under all three uv excitations. However, with 255 and 300 nm the decrease is more pronounced than under 337 nm. Hence, the ratio of the Bi^{3+} peak height with 337 nm over that for 300 or 255 nm increases with increasing concentration of Eu^{3+}. These results can be understood if we consider that 255 and 300 nm energy initially excites the matrix YVO_4 followed by competition for this energy by Eu^{3+} and Bi^{3+} centers. Under 337 nm excitation some of the energy is directly absorbed by the Bi^{3+} center (Fig. 4) and, thus, does not undergo competition with Eu^{3+}. These results should be useful in studying the nature and relative efficiencies of energy transfer from excited YVO_4 to Eu^{3+} *vs.* that for Bi^{3+} center.

The increase in Eu^{3+} emission on addition of Bi (Fig. 3) was used to indicate energy transfer between the two activators. However, even in the absence of such increase this transfer can still occur as long as one observes the characteristic Bi emission. Under cr excitation YVO_4:Eu,Bi is brighter than YVO_4:Eu (5 m/o Eu^{3+}). At very low concentrations of Bi (~500 ppm) the increase in brightness is due to a relatively slight enhancement of Eu emission as well as the appearance of the yellowish white fluorescence of Bi^{3+}, the extent of each effect being very dependent on the relative concentrations of the two activators. At high concentrations of Bi^{3+} (0.5 m/o) the Eu emission decreases with an increase in Bi emission. As in the case of uv excitation, energy transfer can occur from the Bi^{3+} center to Eu^{3+}.

Table II. Relative peak heights of YVO_4:Bi (0.5 m/o) emission under 255, 300, and 337 nm excitations with increasing Eu^{3+} concentration

Eu^{3+}, m/o	Relative peak heights	
	337/300	337/255
0	1.05	1.42
0.05	1.13	1.47
0.10	1.24	1.62
0.20	1.49	1.97
0.50	1.96	2.50

Addition of 0.5 m/o Bi^{3+} to $Y_{0.95}Eu_{0.05}VO_4$ decreases the 619 nm Eu^{3+} emission under both 320 nm and cr excitations. These effects may be related if we consider the nature of energy loss of fast electrons in matter (22). The retardation of incident electrons (primaries) occurs by detachment of electrons (secondaries) from the lattice ions. The secondary electrons, in turn, excite the matrix. The activator (Eu^{3+}) absorbs this excitation energy directly from these secondary electrons and indirectly from the excited matrix by some mode of energy transport. If we assume that with 320 nm excitation, the peak of the excitation spectrum of YVO_4 matrix, the energy is substantially absorbed by the matrix and eventually is transferred to the activator (Eu^{3+}), then, this process is similar to that discussed for cr excitation.

Bismuth addition may decrease the efficiency of energy transport from matrix to Eu, perhaps by distorting the former. Such distortion can be understood from comparing the chemical and electronic nature of Bi^{3+} and Y^{3+} ions and the fact that $BiVO_4$ does not have the zircon structure. The above decrease in Eu^{3+} emission with Bi^{3+} addition can also be due, at least partially, to simple competition for the matrix excitation energy between the two activators. Such competition is not sufficient to interpret these effects, since with smaller amounts of Bi^{3+} coactivation a slight increase in Eu^{3+} emission was observed under cr excitation, as discussed earlier.

Manuscript received June 6, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Stoichiometry of Luminescent Apatites

J. G. Rabatin, G. R. Gillooly, and J. W. Hunter

Lamp Metals and Component Department, CPP, General Electric Company, Cleveland, Ohio

ABSTRACT

Total chemical analysis of luminescent apatite together with quantitative x-ray diffraction analysis for secondary phases have made it possible to delineate the maximum permissible nonstoichiometry. Based on the accuracy of the various methods and expressed as a deficiency of calcium, the extent of nonstoichiometry is less than the absence of one calcium in every 380 calcium sites. Quantitative experimental evidence is also presented to support the hypothesis for charge compensation of antimony by a corresponding oxygen substitution at halogen sites.

Stoichiometry of Luminescent Apatites

In a previous publication (1), the authors reported studies on the phase relationships of calcium halophosphate phosphor systems. Of major interest were pertinent compatibility triangles and tetrahedra. The question of the extent of nonstoichiometry of luminescent apatites was not explored. Previous publications which touch on this point have implied that the chemically measurable deficiencies or excesses of the various components of luminescent apatites were associated with gross defect structures. Ouweltjes and Wanmaker (2) suggested that halophosphates may be examples of phosphors requiring an excess of one of the components within the crystal lattice for highest efficiency. Strange (3) in considering the importance of imperfections to luminescence noted that halophosphates are improved by an excess of the acid radicals. Froelich (4) has observed from general experience that phosphor compositions are preferably nonstoichiometric. Ross (5) reported that improved halophosphates were obtained with halogen deficiencies of from 0.16 to 0.18 moles halogen per mole of apatite.

These publications would lead one to believe that fluorescence in calcium halophosphate phosphors was indeed associated with a gross defect structure, apparently one that was deficient in calcium or halogen ions. Some of the compositions mentioned by Ouweltjes and Wanmaker (2) should have one calcium empty out of every 10 calcium sites. The work of Posner and Perloff (6) would indicate that, in chemically precipitated hydroxyapatites, nonstoichiometry could exist even with calcium to phosphate ratios of 9 to 6. However, their studies do not prove conclusively the absence of secondary phases especially since they state that precipitated apatites are usually finely divided materials yielding x-ray diffraction patterns with broadened maxima. Under these conditions, the presence of a few per cent of secondary phases would be almost impossible to detect by either the optical or x-ray diffraction methods which they used.

Although calcium metaantimonate has been detected as a secondary phase (7) in most halophosphate phosphors, little attention was given to the possibility that other phases may also be present and thus contribute to the so-called "nonstoichiometry" of these phosphors. The present authors (8) have reported that under certain conditions calcium orthophosphate may be present. With the publication of phase studies (1) in this system, it becomes important to reexamine the extent of nonstoichiometry in halophosphate phosphors.

This paper deals with this general question. Experimental evidence is also presented to support the concept first proposed by Ouweltjes (9) that for trivalent antimony substitution in the apatite structure electrical neutrality is maintained by oxygen substitution for a halogen atom.

Methods

Total calcium as Ca (10, 11).—Calcium is determined volumetrically by back titration of an excess of EDTA with magnesium solution using a mixed Erichrome Black T-methyl red indicator. Manganese, which is also chelated, is determined colorimetrically, and the equivalent amount of EDTA used in complexing the Mn is subtracted from the total volume used. Results are accurate to within ±0.05 w/o (weight per cent) Ca.

Total phosphate as PO_4 (12).—After hydrolysis of any nonortho phosphate to the ortho form the phosphate is determined as the yellow molybdivanadophosphate complex by differential spectrophotometry. Results are accurate to within ±0.2 w/o PO_4.

Soluble antimony as Sb^{+3} (13, 14).—Antimony in the trivalent form is determined volumetrically by titration with potassium bromate using methyl orange indicator. The titration is based on the oxidation of trivalent antimony to the pentavalent form. Results are accurate to within ±0.01 w/o Sb.

Manganese as Mn (15).—Manganese is oxidized to permanganate using potassium periodate and determined colorimetrically with a spectrophotometer. Results are accurate to within ±0.02 w/o Mn.

Fluoride as F (16-19).—Fluorine is separated from interfering ions by steam distillation from perchloric acid solution as hydrofluo-silicic acid. The fluoride is then determined by titration with thorium nitrate using sodium alizarin sulfonate as indicator. Results are accurate to within ±0.05 w/o F.

Chloride as Cl (20-22).—Chloride is determined by a modification of the classical Volhard method. An excess of silver nitrate is added to form silver chloride and the excess back titrated with ammonium thiocyanate using ferric alum indicator. Results are accurate to within ±0.003 w/o Cl.

Calcium metantimonate as $Ca(SbO_3)_2$ (23).—Calcium antimonate or "acid insoluble" is separated by filtration from a hydrochloric acid solution and determined gravimetrically after ignition of the insoluble residue. Results are accurate to within ±0.02 w/o $Ca(SbO_3)_2$.

Calcium pyrophosphate as $Ca_2P_2O_7$ (12).—Calcium pyrophosphate as a secondary phase is determined by a modified differential spectrophotometric method as the molybdivanadophosphate complex. The phosphor is solubilized by agitating in a slurry of cation exchange resin and water. The resultant solution of halide and phosphate acids is separated from the resin by filtration. An aliquot of the filtrate is acidified and heated to hydrolyze the pyrophosphate to the ortho form. Equal size aliquots of the hydrolyzed and nonhydrolyzed solutions are treated with a mixed molybdate-vanadate solution to form the yellow molybdivanadophosphate complex. The hydrolyzed portion is compared spectrophotometrically against the nonhydrolyzed portion. Since the complex is formed with phosphate in the ortho form only, the hydrolyzed aliquot will possess a greater intensity of color that is directly proportional to the amount of Ca pyrophos-

phate that has been hydrolyzed. Results are accurate to within ±0.2 w/o $Ca_2P_2O_7$ as a secondary phase.

Calcium orthophosphate, $Ca_3(PO_4)_2$.—The method utilizes the Ge XRD-5 x-ray diffraction apparatus. Counts are made for 400 sec at 31.05° 2θ for the principal line of β $Ca_3(PO_4)_2$ and at 36.6° 2θ for background correction. The ratios of the counts are plotted against weight per cent β $Ca_3(PO_4)_2$ in mixtures containing fluorapatite and β $Ca_3(PO_4)_2$. The per cent β $Ca_3(PO_4)_2$ for the test sample is determined from this graph. Accuracy of ±0.3% β $Ca_3(PO_4)_2$ as a secondary phase can be obtained.

Results and Discussions

Total chemical analyses have been made on many commercial halophosphate phosphors. Analyses are shown in Table I for three typical phosphors. Phosphor A is a blue halophosphate, phosphor B is a white halophosphate, and phosphor C is a cool white halophosphate. It is immediately evident that, in this form, the analytical results have very limited value. The variations in PO_4 from 55.91 to 56.90% together with metal and halogen variations are real differences based on the precision of the chemical analyses as shown in the methods section. The calcium and phosphate contents as measured agree very closely with the amounts present in the formulation which were known to four significant figures. The total other cation impurities such as Sr, Ba, Na, etc., are present to less than 500 ppm. As such these are not used in the following calculations.

Before a meaningful interpretation can be made of the results shown in Table I, it is essential to determine the extent of secondary phases present in these phosphor compositions. When subjected to precision x-ray diffraction analysis for β $Ca_3(PO_4)_2$ and to chemical analysis for $Ca_2P_2O_7$, secondary phases were found in these samples. Results are presented in Table II. Phosphor A has over 9.0 w/o of secondary phases. On the other hand, phosphor C has less than 0.3 w/o of secondary phases. It is obvious that these secondary phases determine in part the differences in the constituents shown in Table I, especially in the halogen content.

With the results of Tables I and II available it is now possible to examine the stoichiometry of luminescent apatites. In considering this question, certain crystallographic principles must be observed since x-ray diffraction analyses show no unaccountable changes in unit cell parameters. The chlorofluoroapatites have the Naray-Szabo-hexagonal structure with space group $P6_3/m$. (24, 25)

The unit cell is composed of 42 sites and can be

expressed as

$$M_{10}(PO_4)_6X_2 \qquad [1]$$

where M are the metal ions and X are the halogen ions. Since interstitial substitution of cations is extremely unlikely in the relatively close packed hexagonal structure of apatites only vacancies are considered (no real excess of any component exists on a unit cell basis). Finally electrical neutrality must be obeyed in any scheme of reconciling total chemical analysis with structural considerations.

Based on these factors, the total chemical analyses listed in Table I can be readily converted to moles of the cations and halogen ions per 6 moles of PO_4^{-3} ions such that the results can be compared to the theoretical stoichiometric expression, $M_{10}(PO_4)_6X_2$, previously mentioned. Further, appropriate calculations have been made to properly account for the secondary phases present in each phosphor (Table II). Calculated results are listed in Table III. These results show that, when the total chemical analyses are used to calculate the formula, the apparent nonstoichiometry of phosphors A and B are large. Phosphor A, for example, would be deficient in both Ca^{+2} and F^- ions. However, when the impurity phases are accounted for in the calculations the formulas are now much closer to stoichiometry. Deficiencies still exist in the halogen sites.

Measuring the amounts of the secondary phases present in the phosphors and using these values in calculating the formulas are major steps in determining the extent of nonstoichiometry in luminescent apatites. However, one more factor must be considered, namely the charge compensating mechanism for the substitution of Sb^{+3} for Ca^{+2} cation sites. Three possible mechanisms have been suggested. To maintain charge balance, Ouweltjes (9) proposed a simple O^{-2} substitution for X^- as Sb^{+3} substitutes for Ca^{+2}. No vacancies are necessary. The size of O^{-2} at 1.40Å is compatible with the F^- size of 1.36Å. Another mechanism proposes the creation of appropriate cation vacancies as Sb^{+3} is substituted into the apatite structure such that the vacancy concentration is expressed as equal to one-half the antimony concentration. The third mechanism as proposed by Butler and Jerome (26) involves a straightforward substitution of Sb^{+3} for Ca^{+2} ions with interstitial O^{-2} ions accounting for charge compensation. Appropriate calculations were made for each of these mechanisms and are listed in Table IV for phosphor A. The

Table IV. Calculations of phosphor A formula and charge balances for the three mechanisms of charge compensation

Calculated formula	Total cation charges	Total anion charges	Charge diff.
I *Ouweltjes mechanism* $(Ca + Sb)_{10.00}(PO_4)_{6.00}(F + O)_{2.00}$	50.11	50.11	0
II Vacancy mechanism $(Ca + Sb + vac)_{10.00}(PO_4 + vac)_{6.00}(F + vac)_{2.00}$	49.84	49.62	+0.22
III Butler and Jerome mechanism $(Ca + Sb)_{10.00}(PO_4)_{6.00}F_{(1.79+vac)}Int.\ O_{0.055}$	50.11	50.00	+0.11

Ouweltjes mechanism simply involves the addition of 0.11 moles of O^{-2} ions to the halogen sites since the Sb^{+3} concentration was 0.11 moles. The vacancy mechanism is somewhat more involved because as 0.055 vacancies are added to the cation sites to obtain electrical neutrality ([Vacancy] = ½ [Sb^{+3}] where [Sb^{+3}] = 0.11 moles), the total cation concentration becomes 10.055 relative to 6.00 PO_4. By dividing through by 1.0055 the formula is changed back to one with no excess cation sites. (This maintains a unit cell with a total of 42 sites.) The Butler and Jerome mechanism does not change the calculations since it invokes interstitial O^{-2} for charge compensation. However only 0.055 moles of interstitial O^{-2} are required for the 0.11 moles of Sb^{+3}. The results in Table IV clearly indicate the Ouweltjes mechanism most nearly fits the criteria of balanced charges and all sites being occupied by appropriate ions. The vacancy mechanism not only does not satisfy charge balance but invokes vacancies of different concentrations at all sites (Ca^{+2}, P^{+5}, O^{-2}, and X^{-}). These vacancies are relatively large for ionic crystals. The Butler and Jerome mechanism, in addition to having a slight excess of positive charges, requires a cell distortion for interstitial O^{-2} together with fluorine ion vacancies. It is unlikely that these two conditions can exist simultaneously. O^{-2} ions would tend to move from the interstitial sites into fluorine vacancies in order to relieve the stress on the unit cell. Similar calculations were made on many other luminescent apatites, and the results invariably show that the Ouweltjes mechanism fits the experimental results most closely. In every case, a significant halogen deficiency was present and, when the oxygen charge compensation mechanism as proposed by Ouweltjes was employed, the resulting formulas were much closer to stoichiometry. The deviations from stoichiometry and in charge imbalance are small and may be attributed primarily to the analytical accuracy. For instance, phosphor C showed a 0.02 excess of X^{-} ions and a 0.02 excess of negative charge.

A somewhat independent approach to the determination of stoichiometry in halophosphate phosphors involved the preferential solubility of various phosphates in ethylenediaminetetraacetic acid (EDTA) solutions. Table V lists the solubility of several phosphates in 5% EDTA at pH 10. $Ca_3(PO_4)_2$ is most rapidly soluble in EDTA. Halophosphate phosphors are incompletely soluble even after 16 hr at pH 10. The difference in solubility of apatite compared to the high rate of solubility of the impurity phases was used as a means of dissolving out the impurity phases. The results are presented in Table VI for three typical phosphors. Analyses for the $Ca_3(PO_4)_2$ and $Ca_2P_2O_7$ were made according to the procedures outlined in the methods section. Note that in all cases, the secondary phases were essentially absent after treatment with EDTA.

When phosphor A was further subjected to total chemical analysis after EDTA treatment [$Ca_3(PO_4)_2$ and $Ca_2P_2O_7$ removed] the changes in amounts of the components were significant compared to the chemical analyses before EDTA treatment. When the new data were converted to the formula based on 6(PO_4) groups the results were

$$(Ca + Sb)_{10.00}(PO_4)_6F_{1.89}$$

in agreement with those shown in Table III. When the Ouweltjes charge compensation mechanism was applied, the formula became essentially stoichiometric as shown in Table IV.

The previous results can be interpreted to mean that luminescent apatites are very close to stoichiometry. Any nonstoichiometry due to vacancies is not detectable by chemical means. Based on the accuracy of the chemical analyses, this nonstoichiometry does not exceed one phosphorous ion vacancy out of every 140 phosphorous sites. In all likelihood, the total vacancy concentrations (nonstoichiometry) are considerably less than one vacancy in 1000 sites. Schottky defects are probably present in very low concentrations. If analogy to alkali halides can be made (27), about one in every 10^5 to 10^6 anions and cations may be missing from the structure.

Radial Solute Segregation in Czochralski Growth

J. R. Carruthers[1]

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The radial variation of solute concentration in Czochralski-grown silicon crystals is shown to be greatly influenced by the effects of secondary liquid flows not associated with crystal rotation. These flows are caused by crucible rotation and thermal convection, and show the greatest effects in the outer regions of the growth interface.

The radial macrosegregation of solute in Czochralski-grown crystals has been quantitatively studied in germanium crystals by Dikhoff (1) and in silicon crystals by Benson (2). Dikhoff attributed his results to differences in the effective distribution coefficient on and off the (111)-type interface facet. However, as Benson points out (2), variations in the diffusion boundary layer thickness at the freezing interface will also contribute to radial macrosegregation.

In this paper, the types of liquid flow and the observed flow patterns in a simulated model are described, and the qualitative influence of these flows on the diffusion boundary layer is discussed. The data of Benson (2) on radial solute segregation in silicon crystals may be qualitatively interpreted by considering both the solute diffusion problem in the liquid at the growth interface and the flow patterns.

Fluid Flow During Czochralski Growth

Before describing the flow configurations which arise in Czochralski growth, the contributions to convection are discussed separately.

Forms of convection.—Forced convection at a rotating crystal.—The velocity boundary layer thickness has been shown (3) to be uniform across the surface of a disk rotating in an infinite isothermal medium, and is roughly equal to $(\mu/\omega)^{1/2}$ where μ is the kinematic liquid viscosity and ω the crystal rotation rate. A rigorous analysis has been performed by Cochran (3), and this has been extended for diffusion boundary layers in crystal growth by Burton, Prim, and Slichter (4). According to the model, the liquid forced outward by centrifugal acceleration is replaced by a central flow up to the disk surface. Observations confirming this mode of flow were made by Goss and Adlington (5) in a simulated transparent liquid model. Thus, if crystal rotation is the only source of convection, then no radial solute segregation would result from fluid flow effects.

Thermal convection.—It has been known for many years that thermal convection flow will be generated as steady circulation in any liquid where the temperature gradient is not aligned with the direction of gravity and no other external forces are present (6). In many geometric configurations, this flow is the steady streamline circulation generated between vertical boundaries by horizontal temperature gradients and occurs in Czochralski growth as hot liquid rising at the stationary crucible walls and falling in the center. However, when heat transfer also occurs at the horizontal surfaces, the classical Rayleigh instability may develop close to these surfaces where hot liquid is located vertically below colder liquid in an otherwise relatively stationary region of liquid (7). A detailed understanding of the cross effects of these two types of flow is now lacking, but both should result in large variations in diffusion boundary layer thickness in the absence of other forms of convection.

Forced convection in a rotating crucible.—During crucible or melt rotation around a vertical axis, the boundary layer at the upper liquid surface cannot remain uniform for the following simple reason. The rotation of an isothermal liquid in a cylindrical container results in a parabolic depression at the upper free surface, due to the velocity and pressure changes (8). Consequently, the boundary layer produced when a stationary disk is placed on the top surface should show a maximum thickness at the rotation axis where the radial velocity has its lowest value.

Combined liquid rotation and thermal convection.—When a liquid which is under thermal convection is spun about a vertical axis, a stabilizing force is provided which discourages thermal convection (9). This additional force is the Coriolis force which acts on particles having a horizontal velocity component. From an analysis by Nakagawa and Frenzen (9), it is possible to show that, in rotating liquid silicon with a free upper surface, unstable thermal convection should commence at an adverse vertical temperature gradient of 3.5°C/cm in a liquid 4 cm high which is rotating at 25 rpm. At 100 rpm, an adverse vertical gradient of 24°C/cm is required. This analysis assumes that only the vertical temperature gradient is present and that the liquid is of infinite lateral extent. Neither of these assumptions is valid for Czochralski growth, but the analysis should serve as a good basis for future work. From a similar analysis by Chandrasekhar and Elbert (10), it is possible to correlate the theoretical period of overstable oscillations, a form of instability arising from the interaction of liquid spin and thermal convection, with the observed period of growth fluctuations on the outer surface of nonrotated silicon crystals (11). Thus, the relaxation of the previous assumptions in Czochralski growth should not modify the theoretical arguments drastically.

[1] Present address: Crystal Chemistry Research Department, Bell Telephone Laboratories, Inc., Murray Hill, New Jersey.

Simulated fluid flow models.—Previous work.—Goss and Adlington (5) used a simulated transparent liquid model with dyes to observe the effects of crystal rotation on flow in an otherwise stationary liquid. They confirmed the simple picture that liquid in the immediate neighborhood of the disk is carried by friction and then forced outward by centrifugal acceleration. This fluid is replaced by an axial flow up to the center of the disk.

Turovskii and Mil'vidskii (12) attempted to view the flow occurring in a rotating, heated, transparent liquid model. Their apparatus made observations difficult, but they found that a flow was formed as an inward spiral around the upper surface which descended axially. When a disk was introduced at the upper surface, this flow was very much intensified. When the crystal was rotated, a region of localized intensive mixing was formed under the crystal because the crystal and crucible flows moved in opposite directions in this region.

Present work.—Experiments were designed to simulate fluid flow existing during Czochralski growth. A water-glycerine mixture of 42.5 w/o glycerine was selected to produce a transparent liquid with viscosity equivalent to that of most liquid metals (1-4 centipoise).

The apparatus is shown in Fig. 1 and consists of a collimated light beam imaging the quartz crucible on a ground-glass screen. A large square Lucite box was placed around the crucible and filled with glycerine to eliminate the converging effect of the cylindrical quartz crucible on the transmitted light beam. The quartz crucible was rotated independently of the Lucite box and, since interest was centered only on the flow in the crucible, baffle plates were used in the Lucite box to minimize any flow patterns in the surrounding glycerine due to crucible rotation.

The temperature gradient was established in the crucible by cooling the crystal below room temperature rather than by heating the liquid above room temperature. This procedure eliminated the necessity of heating coils around the crucible which would have obstructed the view. The crystal consisted of a copper cylinder of 1-in. diameter with a peripheral cone-shaped container around it for containing mixtures of dry ice and acetone. Both the copper cylinder and quartz crucible could be rotated independently in either direction at rates up to 98 rpm.

During operation of the model, drops of ink were injected into the bottom of the crucible by means of a capillary tube. The flow could be followed on the ground-glass screen. During all runs, an actual crystal of water-glycerine grew on the copper cylinder, and the crystal-melt interface temperature was −17.0°C. The temperature of the quartz crucible itself was held close to room temperature by the thermal inertia of the large amount of surrounding glycerine. Consequently, the maximum temperature difference which existed in the liquid was about 42°C.

Experimental results.—The flow patterns observed are shown schematically in Fig. 2 for the various situations indicated. Treating the crystal and crucible rotation rates separately, the following observations were made:

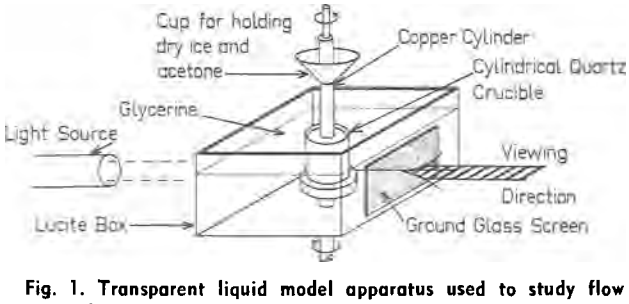

Fig. 1. Transparent liquid model apparatus used to study flow patterns during Czochralski growth.

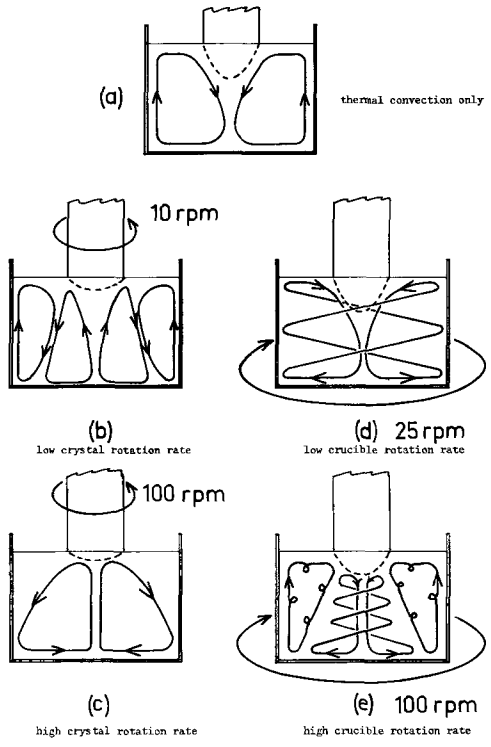

Fig. 2. Schematic flow patterns in transparent liquid model. (a) thermal convection only; (b) low crystal rotation rate; (c) high crystal rotation rate; (d) low crucible rotation rate; (e) high crucible rotation rate.

(*i*) Crystal rotation.—the liquid flow configuration for thermal convection alone, *i.e.*, no crystal rotation, is shown in Fig. 2(a). The hot liquid rose at the outer crucible wall and descended gradually near the center. At low crystal rotation rates, thermal convection flow was diminished close to the interface because the fluid flow from the rotating crystal was countercurrent to that caused by thermal convection. The deflection of streamlines is schematically illustrated in Fig. 2(b). At higher crystal rotation rates, the crystal acted like a fan, drawing liquid up at the center and spinning it out at the sides. Thermal convection is relatively unimportant in this case [Fig. 2(c)] and the assumptions made in the boundary layer analysis for the rotating disk will apply.

(*ii*) Liquid rotation.—At low crucible rotation rates, the liquid flow close to the crucible wall moved in a long closed streamline path, and the extent of thermal convection was diminished. The boundary layer at the upper surface tended to become more nonuniform, as shown in Fig. 2(d). For faster crucible rotation rates, flow separation occurred at the periphery of the crystal, and eddies developed in the outer regions of the liquid. The region close to the crystal-melt interface still possessed the same basic nonuniform flow, as shown in Fig. 2(e).

(*iii*) Combined crystal and crucible rotation.—Combinations of crystal and crucible rotation in the same directions produced only a modification of the simple crucible rotation flow. The crystal rotation did not exert its previous influence on the bulk fluid flow, except at low crucible rotation rates. For counter rotations, the central convection cell shown in Fig. 2(e) became quite stable, and ink did not move readily out of the central region. This effect is shown in Fig. 3, where the crystal and crucible were counterrotated at 60 rpm and the ink introduced into the central region continues to circulate there after several minutes.

Fig. 3. Liquid flow pattern in water-glycerine model; crucible and crystal counterrotating at 60 rpm each.

Radial Solute Segregation

The importance of fluid flow in any crystal growth technique is to influence the redistribution of solute at the growing interface. However, the relevance of convection to such transport also depends very much on other parameters, such as the equilibrium distribution coefficient, k_o, the liquid diffusion coefficient, D, and the growth rate, R. The contribution of these parameters may be determined by differentiating the Burton, Prim, Slichter expression (4) for the effective distribution coefficient, k_e, with respect to δ, the diffusion boundary layer thickness. This gives

$$\frac{\partial k_e}{\partial \delta} = \frac{\gamma(R/D)\exp(-R\delta/D)}{[1+\gamma\exp(-R\delta/D)]^2}$$

where $\gamma = (1-ko)/ko$. This relationship is valid for steady-state changes in δ and negligible lateral solute diffusion. The various solutes in silicon give the curves shown in Fig. 4 where $\partial k_e/\partial\delta$ is plotted against δ for $R/D = 100$ cm^{-1}. For a rotating crystal, the diffusion boundary layer should be about 0.01 cm for normal Czochralski growth conditions. It can be seen that in this range, only phosphorus and arsenic exhibit any large variations in solute concentration with differences in the diffusion boundary layer thickness. At faster growth rates, the other solutes (except B) will show larger radial solute variations for the same δ.

It is necessary at this point to explain why data on radial solute segregation should not be used directly to calculate the amount of preferential solute adsorption due to the facet effect, as described in previous work (1).

For the range of δ interest (0.01-0.03 cm), it is obvious from Fig. 4 that N-type solutes show an enhanced variation of concentration with boundary layer thickness. The most reliable method of separating the two effects is to grow a <100> crystal where the facet effects should be minimized. Benson (2) reports such

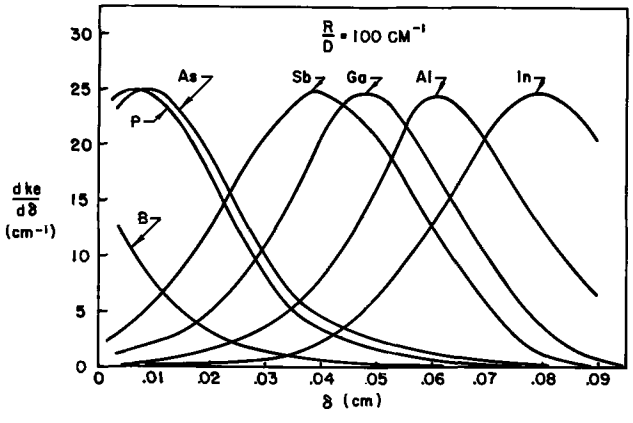

Fig. 4. Variation of solute concentration with steady-state changes in the diffusion boundary layer thickness for different solutes in silicon.

results for antimony-doped silicon crystals where a 7% radial variation was observed. From Fig. 4, using an average $\delta \approx 0.015$ cm, and assuming $R/D = 100$ cm^{-1}, it is seen that $\partial k_e/\partial\delta = 8.75$ for antimony. Thus, writing

$$\frac{\partial k_e}{\partial \delta} \approx \frac{\Delta k_e}{\Delta \delta} \approx \frac{0.07}{\Delta \delta} \rightarrow = 8.75$$

then $\Delta\delta = 0.008$ cm or $\Delta\delta/\delta = 0.53$ for the maximum variation in diffusion boundary layer shape under these growth conditions. This change in boundary layer thickness must be considered when determining the amount of solute adsorption on a facet for growth in more close packed directions.

Benson (2) has published a comprehensive study of radial solute segregation in Czochralski-grown silicon crystals, and the remainder of this paper will interpret his data using the information on fluid flow that has been presented earlier. The results of interest were obtained for phosphorus-doped crystals which, according to Fig. 4, should be quite sensitive to changes in δ for the growth rate range used by Benson. It was found that maximum variations in the radial solute distribution occurred at a crystal rotation of 10 rpm and a crucible rotation of 25 rpm, and that these effects were independent of each other. Furthermore, larger growth rates also gave larger variations, but did not displace the position of the maximum variations associated with rotation of either crystal or crucible. Lastly, larger diameters were found to give a markedly smaller degree of radial solute segregation.

The variation of radial solute distribution with crystal rotation rate will now be discussed. It is important to realize that the Cochran analysis of liquid flow around an infinite plane disk (3) must be modified in the presence of thermal convection in an otherwise stationary liquid. The linear flow velocity normal to the interface at a crystal rotation of 10 rpm is in the range, 10^{-3} to 10^{-2} cm/sec (4), whereas the thermal convection velocity is in the range 1-10 cm/sec. Furthermore, whereas the flow normal to the interface due to rotation is uniform over the radius, that flow due to thermal convection will follow more gradually curved streamlines and possess a definite stagnation point near the center of the interface. Thus, at low crystal rotation rates, the boundary layer thickness near the stagnation point remains unchanged while, at the outer regions of the interface, the thickness is reduced by the additive effects of the tangential velocity component and the thermal convection velocity. This effect will then cause an increase in the radial gradient of solute concentration as the crystal rotation increases in the low range.

The effect of crucible rotation is to inhibit thermal convection, but again not to change the position of the stagnation point, since the streamline flow at the crystal interface is quite similar to that of thermal convection, as shown in Fig. 2. Thus, the tangential flow component should again be enhanced at the outer portion of the interface and the degree of radial solute segregation increased.

Crystal rotation rates above 10 rpm were observed to be much more effective in reducing radial solute segregation than high crucible rotation rates. This effect was observed to be associated with a more rapid decrease in solute concentration and, hence, in δ near the interface center than at the outside, so that effects of secondary flow at the outer periphery are minimized.

The variation of radial solute segregation with crystal diameter will now be discussed. It is well known that an increase in diameter will decrease δ/D (13) and consequently δ alone. This decrease in δ will act in a similar way as a decrease in R to reduce radial solute segregation since, from the curve for phosphorus in Fig. 4, both effects will probably occur to left of the maximum and, hence, decrease $\partial k_e/\partial\delta$. An explanation for the decrease in δ with an increase in

crystal diameter is that for smaller crystal diameters the edge effects are of increasing importance, *i.e.*, the rotating disk analysis ceases to be valid and the boundary layer thickness becomes a function of the radius.

Summary

The radial solute segregation in Czochralski-grown silicon crystals has been shown to be greatly influenced by the effects of secondary liquid flow in the outer regions of the solid-liquid interface. The existence of interface facets will also cause large radial segregation because of the orientation dependence of the equilibrium distribution coefficient. However, the effects of liquid flow must be studied independently if unambiguous information is required on the facet effect alone. Maximum radial solute uniformity is possible only when the diffusion boundary layer at the growing interface is primarily controlled by crystal rotation, when the factor $\partial k_e/\partial\delta$ for the solute is insensitive to changes in δ at any particular growth rate and when the crystal orientation does not permit the development of an extensive close-packed interface facet on an otherwise curved interface.

Deposition of Silicon Nitride Films by the Silane-Hydrazine Process

Satoshi Yoshioka and Shigetoshi Takayanagi

Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka, Japan

ABSTRACT

A new pyrolytic process for depositing silicon nitride films using silane-hydrazine-hydrogen gaseous mixture is described. This system is useful at a temperature between 550° and 1150°C. The hydrazine process gives more rapid deposition rate than the ammonia process, so that the use of this process can reduce the lower limit of deposition temperature. Rate curves are presented for various temperatures and concentrations. In the lower part of the temperature range a linear dependence of log rate *vs.* $1/T$ is obtained. The rate reaches a saturation value above 750°C. The films produced are transparent, smooth, and tightly adherent. The films from this process have relatively larger etch rates in hydrofluoric acid than those from the ammonia process. Some film properties such as structure, Si-N atomic distance, Si-N IR absorption band, refractive index, density, dielectric constant, dielectric strength, and surface charge are presented.

Silicon nitride films show a high electrical resistivity, high dielectric strength, and extremely high resistance against chemicals, which properties are important for applications to microelectronic devices. Formation of silicon nitride films has been reported by reaction of silane and ammonia under a r.f. discharge (1), by pyrolytic reactions of either the silane-ammonia system (2) or the silicontetrachloride-ammonia system (3), and by reactive sputtering of silicon in nitrogen (4). This paper describes a new pyrolytic reaction between silane and hydrazine for depositing silicon nitride films and gives some properties of the films obtained by this process.

It is known that in the silane-ammonia process, for the decomposition of ammonia, the temperature of the reagent must be above 750°C to get a deposition of pure silicon nitride films (2). The use of hydrazine in place of ammonia will reduce the lower limit of the deposition temperature since the hydrazine decomposes at lower temperatures than ammonia. Indeed experimental results show that with the silane-hydrazine process adherent silicon nitride films are formed at relatively high growth rates at temperatures slightly above the decomposition temperature of silane (500°C).

Experimental

A schematic diagram of the apparatus for the film deposition is shown in Fig. 1. A mirror polished Si wafer was placed in a quartz tube of 60 mm diameter. The substrate temperature could be varied between 550° and 1150°C using r.f. heating of a graphite susceptor. The hydrazine was introduced into the reaction chamber by bubbling H_2 through liquid hydrazine kept at a constant temperature. Before entering the quartz tube this gas was mixed with a mixture

of H_2 and SiH_4. The total gas flow rate applied was 0.6 l/min, the SiH_4 concentration was 0.03-0.4% and the SiH_4 to N_2H_4 ratio was 1 to 0.5-50. The hydrazine was purified by repeated distillation on sodium hydroxide until it showed a refractive index of 1.470 at 22°C. The sodium concentration in the purified hydrazine was about 6 ppm by flame analysis. The index of refraction of the deposited films was determined by the optical method described by Booker *et al.* (5). The density was calculated by measuring the film thickness and the weight change before and after removal of the film from the substrate. The electrical properties were measured on the MIS capacitors.

Results

Growth rates obtained are plotted as a function of the reciprocal substrate temperatures for different concentrations of the reagents for the hydrazine process and for one set of concentrations for the ammonia process in Fig. 2. In the temperature range between 550° and 650°C a straight line was obtained for the hydrazine process from which an activation energy could be calculated of about 54 kcal/mole. Above 650°C the growth rate reached a saturation value at about 750°C and then decreased slightly with a further increase of temperature. An abrupt decrease of growth rate occurred at a temperature above 1000°C, when the SiH_4 to N_2H_4 ratio was relatively small. The SiH_4-NH_3 process gave a straight line relation in the temperature range between 750° and 1000°C and showed an abrupt decrease in growth rate above 1000°C in agreement with the results obtained by Doo *et al.* (2). The growth rate of the hydrazine process changed linearly with the SiH_4 concentration in the temperature range between 550° and 1000°C (Fig. 3B). The dependence on the N_2H_4 concentration was

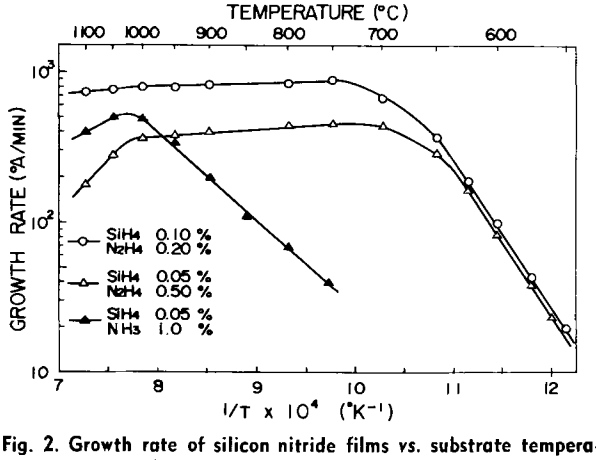

Fig. 2. Growth rate of silicon nitride films vs. substrate temperature for the SiH_4-N_2H_4 process and for the SiH_4-NH_3 process.

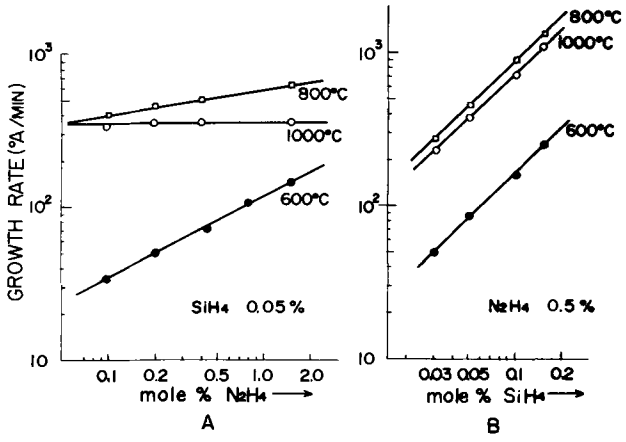

Fig. 3. Dependence of film growth rate. A, mole concentration of N_2H_4 (SiH_4 mole. conc. 0.05%); B, mole concentration of SiH_4 (N_2H_4 mole. conc. 0.5%).

more complicated; at high temperatures the growth rate became gradually independent of the N_2H_4 concentration (Fig. 3A).

Etching of films in a 20% HF solution at a room temperature showed that the etch rate of silicon nitride films prepared by the SiH_4-N_2H_4 process was strikingly dependent on the deposition temperature (Fig. 4) and higher than those grown at the same temperature by the SiH_4-NH_3 process. High etch rates of films are important in a photoengraving process for fabrications of electronic devices. A heat-treatment at a temperature higher than that of the deposition considerably reduces the etch rate as has been illustrated in Fig. 4. After such a heat-treatment some films developed cracks which probably initiated at the substrate film interface. The crack density of the films increased with the film thickness and with the growth rate. A decrease in etch rate indicates that the heat treatment resulted in a densification of the films.

Some film properties are given in Table I. The films prepared at 550°-1150°C are amorphous with extremely short range order by transmission electron diffraction (Fig. 5). From the diameter of the outer ring the spacing between neighboring atoms, probably silicon and nitrogen, was calculated as 1.3 ± 0.05Å. Electron microscopy shows no difference of surface texture between the films deposited by the SiH_4-

Table I. Properties of silicon nitride films
Deposition temperature: 600°-1000°C, $SiH_4N_2H_4$ mole ratio: 0.1

Structure	Amorphous with extremely short range order
Si—N atomic distance	1.3 ± 0.05Å
Si—N IR band	11.3-11.1μ
Index of refraction	2.0-2.1
Density	3.0-3.1 g cm^{-3}
Dielectric constant	6.1 (Deposition temperature: 800°C)
Dielectric strength	6-10 × 10^6 v cm^{-1}
Surface charge (N_{FB})	1-3 × 10^{12} cm^{-2}
ΔN_{FB} after B. T. treatments	$\leq$ + 1 × 10^{10} cm^{-2} (− 3 × 10^6 v cm^{-1}, 150°C, 1 hr)
	$\simeq$ + 7 × 10^{10} cm^{-2} (+ 3 × 10^6 v cm^{-1}, 150°C, 1 hr

N_2H_4 and SiH_4-NH_3 process and between those deposited at 550° and 1150°C by the former process. A 1800Å film was essentially free of pinholes when heated at 800°C for 10 min in a flow of argon containing 30% chlorine.

Infrared transmission spectra of films grown by the SiH_4-N_2H_4 process showed a broad absorption band as shown in Fig. 6 due to Si-N stretching vibration. The absorption peak shifted slightly to shorter wave lengths with increasing deposition temperature. Films deposited at 600°, 800°, and 1000°C give absorption peaks at 11.3, 11.2 and 11.1μ, respectively. No shift of absorption peak was detected after heat-treatment of the films at temperatures below 1200°C for 1 hr. The absorption peak for films grown by the SiH_4-NH_3 process, however, occurred at 11.5-11.6μ.

Discussion

The large difference between the temperatures for a certain film growth rate of the SiH_4-N_2H_4 process and the SiH_4-NH_3 process must be attributed to the fact that decomposition of N_2H_4 occurs at a lower temperature than that of NH_3. It is known that N_2H_4 is decomposed into N_2, H_2, and NH_3 by a steady-state chain mechanism (6). The initiation reaction [7] is

$$N_2H_4 \rightarrow 2NH_2 \qquad H = 60 \text{ kcal} \qquad [7]$$

In a gaseous mixture with a low concentration of N_2H_4, however, the thermal decomposition of N_2H_4 is probably a homogeneous reaction, because the propagation reactions are retarded by the collisions between the chain centers and the foreign gas molecules. The observed activation energy for the growth of silicon nitride films by the SiH_4-N_2H_4 process, about 54 kcal/mole, is close to the energy required for the N-N bond rupture of N_2H_4. So it is reasonable to assume that the N-N bond rupture is the rate-limiting step for the film growth at a temperature between 550° and 650°C. The silicon nitride films are probably formed according to

$$SiH_4 + N_2H_4 \rightleftarrows SiH_4 \cdot N_2H_4 \rightarrow Si(NH)_2 + 3H_2$$
$$2Si(NH)_2 \rightarrow (SiN)_2NH + NH_3$$
$$3(SiN)_2NH \rightarrow 2Si_3N_4 + NH_3$$

The growth rate of the films reaches a saturation value at about 750°C. This suggests that the supply of the reactants, in particular SiH_4, becomes rate determining above this temperature. The abrupt decrease in the growth rate at temperatures above 1000°C both for the SiH_4-N_2H_4 as for the SiH_4-NH_3 processes is probably caused by a decrease of the SiH_4 concentration near the substrate due to premature decomposition of SiH_4, as was suggested by Doo *et al.* (2).

The increase in etch rate with decreasing deposition temperature of silicon nitride films may be due to a decrease in the bond strength of Si-N. This is consistent with the infrared absorption data. The large decrease in etch rate after a heat-treatment at 900°C where the film does not show any shift of the absorption peak cannot be explained in the same way. No more can the effect be explained by assuming contamination of the silicon nitride films by oxygen because the reaction occurs in purified hydrogen atmosphere. The most probable cause for the large etch rates of films grown at lower temperatures will be a relatively large porosity of the films although the surface texture detected by electron microscopy does not clearly show the existence of a porous structure. The difference of etch rate between the films prepared by the SiH_4-N_2H_4 and the SiH_4-NH_3 process can also be explained by the difference of porosity.

A Water-Amine-Complexing Agent System for Etching Silicon

R. M. Finne[1] and D. L. Klein[2]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Ternary mixtures of water, amine, and complexing agent have been found to etch silicon. The silicon etch rate has been investigated as a function of variations in both solution and material parameters. A parallel investigation has been concerned with the etching characteristics of silicon samples coated with silicon dioxide films. Applications of this etching system to semiconductor device technology has provided a tool for the chemical shaping of silicon as well as the evaluation of protective surface films on silicon substrates.

It has been found that ternary mixtures of water, amines, and complexing agents dissolve silicon, with water being a necessary and active component of the etch. Significant among the properties of these etches are the large number of parameters on which the etch rate depends and the extremely low rate of attack on silica. It has been possible to etch silicon into unique shapes by the proper choice of etching parameters. These etches have also been used in the investigation of the etching characteristics of silica films on silicon substrates.

The etch rates in this ternary system have been found to exhibit a marked dependence on the crystallographic orientation and doping of the silicon. Due to the complex etch rate dependence and because there are also variations in etch rate related to the etch composition, a complete study of this system is extremely complicated. On the basis of data presented in this paper a reaction mechanism is proposed and some applications of the system are discussed.

An etch of this general type was first described by Crishal and Harrington (1) who reported the etch as a two-component mixture of hydrazine and pyrocatechol which etched silicon forming $(N_2H_5)_2[Si(C_6H_4O_2)_3] \cdot N_2H_4$ with accompanying evolution of nitrogen and hydrogen. The present study has shown that the silicon etch rate is a function of water content of the etch and falls to zero for anhydrous amine-pyrocatechol mixtures, and that the dissolution is accompanied by only the evolution of hydrogen.

Experimental Procedure

Equipment.—A glass refluxing system was used to prevent composition change by loss of volatile matter. A stream of nitrogen was bubbled through the etching solution to prevent air oxidation of the amine and complexing agent, and to provide agitation of the samples. Drying tubes were used to prevent moisture absorption from the air. The operating temperature was 110° ± 1°C. Reagent grade materials were used throughout.

Etch rate determinations.—The method selected for rate determination was an optical technique which utilized the extremely low etch rate on silica films (*i.e.*, ~200 Å/hr). Etch rates were determined as follows: polished silicon slices were masked with atmospheric steam-grown silica dots, etched, and the resulting step heights were measured microscopically using a focusing stage calibrated to one micron per scale division. The objective employed in the microscope had a depth of field of 1μ. The smallest step heights measured were in the order of 10μ.

Etch solutions.—For most of the etching studies described an etch composition was selected which would give close to the maximum etch rate on silicon. Although hydrazine was used for the initial experiments the majority of the work was performed with ethylenediamine. This choice was based on the higher etch rates exhibited by ethylenediamine systems, their higher stability and lower toxicity. The following composition was used for most of the work described in this paper:

Component	Formula	Amount	Mole %
Water	H_2O	8 ml	61.2
Ethylenediamine*	$NH_2(CH_2)_2NH_2$	17 ml	35.1
Pyrocatechol	$C_6H_4(OH)_2$	3g	3.7

* The abbreviation en will be used for ethylenediamine, pn for propylenediamine, hn for hexanediamine.

Etch solutions employing this molar ratio of components will be referred to as "solution 1". Solutions were freshly made for each run and stored under dry nitrogen prior to use.

Data and Discussion

Gas analysis.—The gaseous reaction products were collected from an argon flushed system and analyzed by mass spectrometry. Results of this analysis are shown below.

Major components	Concentration
Hydrogen	57%
Argon	43%
Trace components	
Nitrogen	450 ppm
Oxygen	110 ppm

The concentration ratio of nitrogen to oxygen (~4:1) suggests that their presence was due to a trace quantity of air in the system. A volumetric analysis of the hydrogen evolved for the total dissolution of weighed silicon samples in ethylenediamine-water mixtures showed the stoichiometry to be close to $2H_2$/Si both in the presence of and in the absence of pyrocatechol. For 0.0140g silicon samples (0.499 mM silicon) the following results were obtained:

Pyrocatechol content, mole %	Vol. H_2 evolved, mls at STP	Molar ratio H_2/Si
0	21.60	1.918
3.7	22.40	1.934

Product analysis.—On the basis of several known pyrocatecholato complexes of group IV elements (2) the expected empirical formula for the reaction product formed in the ethylenediamine system was $SiC_{22}N_4H_{30}O_6$. The following is a table showing the average values of three combustion analyses performed on the reaction product. This product, a white

[1] Present address: John O'Connell Associates K.K., 17-2 Akasaka 7-Chome, Minato-Ku, Tokyo, Japan.

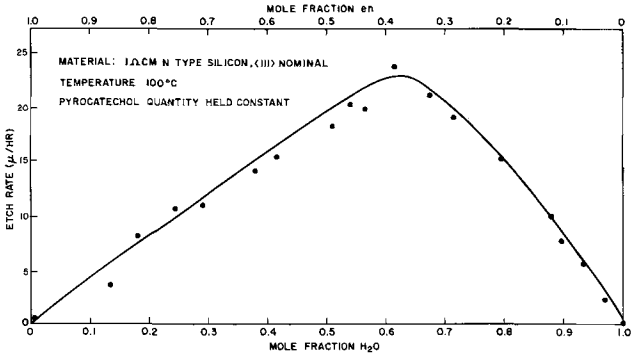

Fig. 1. Etch rate of silicon as a function of the water content of the etch with pyrocatechol content held constant.

crystalline solid, was isolated by the addition of ethanol to the reaction mixture.

Element	Found, %
C	54.31
H	6.41
N	11.05
Residue (assumed as SiO_2)	12.97

The empirical formula derived from these analyses is as follows: $Si_{1.0}C_{21.5}N_{8.7}H_{30.2}O_{5.7}$.[2]

Etching system parameters.—For the majority of the investigations in which the orientation of the crystal was not considered of fundamental significance, silicon was used which was nominally oriented; that is, within 3.5° of the major low index plane. In those cases where the orientation was considered significant, on-orientation samples within 0.5° of the plane were used.

Water content of the etch.—Figure 1 shows the etch rate of silicon as a function of the water content of the etch. The specific system considered was water-en-pyrocatechol, with 3g (0.03M) of pyrocatechol added to the water-en solutions. A maximum was observed for the etch composition corresponding to a mole ratio of water to en of approximately two. The silicon etch rates fall to zero for solutions with mole fractions of water equal to one and zero. This was found for all amines studied including hydrazine. The curve shape was found to be independent of the resistivity of the silicon in the resistivity range tested.

Pyrocatechol content of the etch.—Figure 2 shows the silicon etch rate as a function of pyrocatechol content of the etch. When the pyrocatechol was omitted the etch rate was reduced. However, the etch rate was finite in the absence of pyrocatechol. This fact, coupled with the data shown in Fig. 1, suggests that water and amine, unlike pyrocatechol, are the necessary components of the etching system.

Etchant components.—Figure 3 shows a plot of etch rate as a function of resistivity for etches using the

[2] The silicon was determined by considering the ignition residue to be SiO_2. The oxygen was determined by difference.

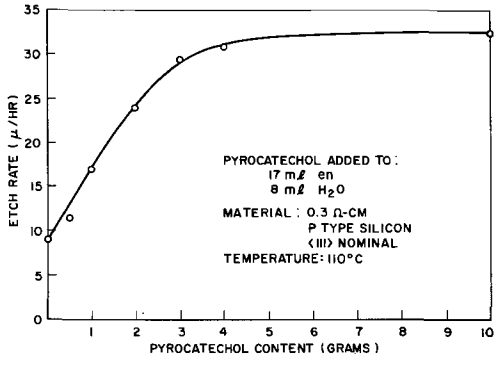

Fig. 2. Etch rate of silicon as a function of the pyrocatechol content of a constant composition en-water mixture.

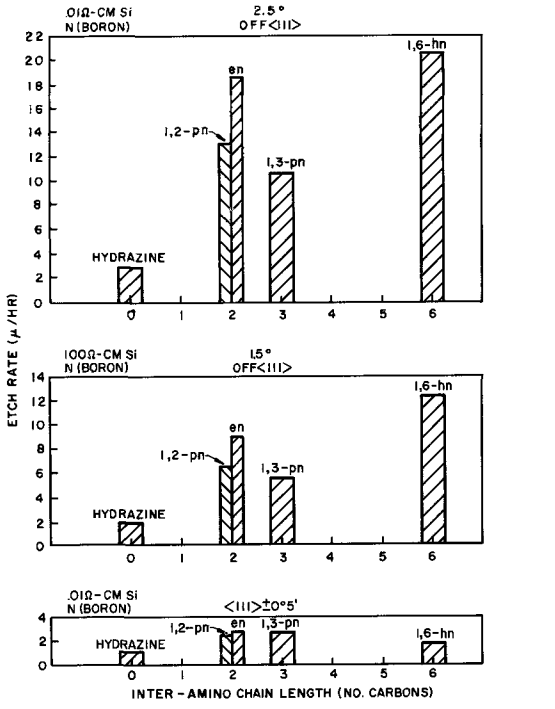

Fig. 3. Etch rate of 0.01 and 100 ohm-cm silicon as a function of the member of carbon atoms between amine groups for oriented and misoriented samples.

following amines:

Hydrazine	(NH_2-NH_2)
en	(NH_2-CH_2-CH_2-NH_2)
1,2-pn	(NH_2-CH_2-$CHCH_3$-NH_2)
1,3-pn	(NH_2-CH_2-CH_2-CH_2-NH_2)
1,6-hn	[NH_2-$(CH_2)_6$-NH_2]

The etching solutions were made using the molar composition cited in the section on etch solutions. The data shown in Fig. 3 suggest that for the amines tested the etch rate of nominally oriented silicon tends to increase with the number of carbon atoms between amine groups. For oriented silicon, no significant change in silicon etch rate was observed for the different amines tested. The behavior of 1,3-pn is discussed in the section on reaction mechanism. It is to be expected that the etch rates would be similar in the case of en and 1,2-pn since 1,2-pn can be considered a methyl-substituted en. Small differences in etch rate might be due to steric factors or electron donor properties of the substituted methyl group.

In the absence of pyrocatechol, 6 hr of etching produced a thin translucent layer on an exposed silicon surface. Figure 4 shows a photograph of such a surface layer. The dark areas are exposed regions of silicon viewed through openings in the film. The hexagonal shapes are etch pits formed in the silicon sur-

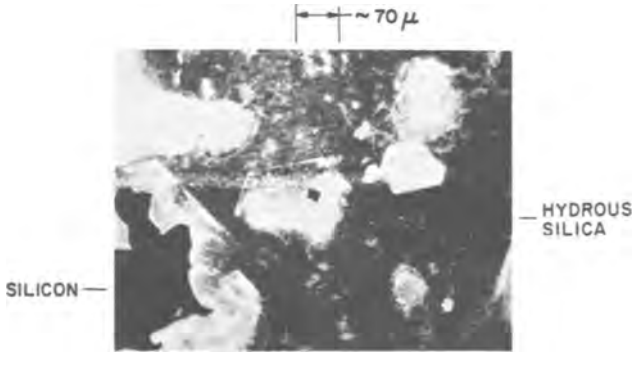

Fig. 4. Silicon surface after etching for 6 hr in an en-water mixture with no added pyrocatechol.

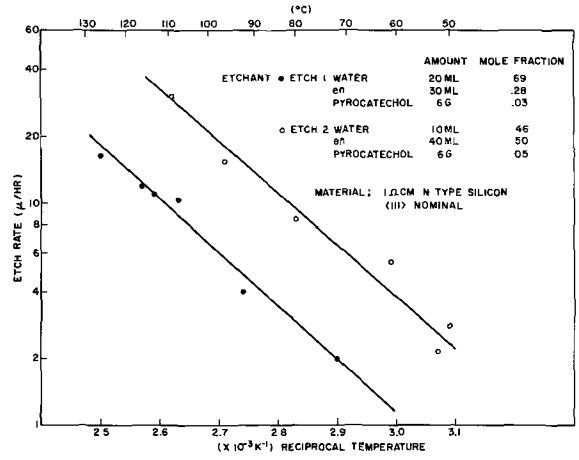

Fig. 5. Etch rate of silicon as a function of temperature for two compositions of etchant.

face. Since the crystallographic sensitivity of the etch persists in the absence of pyrocatechol it is concluded that the complexing agent does not control the sensitivity of the etch for various crystal planes.

Temperature.—A plot of etch rate as a function of temperature for two compositions of etchant is shown in Fig. 5. Etch rates were determined between approximately 50° and 127°C. From the Arrhenius equation, the apparent activation energy was determined to be approximately 11 kcal/mole (0.48 ev) for both concentrations. This indicates that the etching rate is probably not controlled by solution diffusion. The proposed etching mechanism, discussed in the following section, is based on the presence of OH^- groups. Some support for this is found in work done by Faust (3) who has determined the activation energy for the reaction between 10% NaOH solutions and silicon to be approximately 13 kcal/mole (0.56 ev). (The NaOH solution is also a preferential etch on silicon; however, it attacks silica rapidly whereas the present system does not.)

Chemical mechanism.—It has been suggested in this paper that water is a necessary etch component and plays an active part in the etching process. This is based on the observation that no silicon etching occurs for either anhydrous amine or anhydrous amine-pyrocatechol mixtures. Etching occurs only with the intentional or accidental introduction of water into the system.

The following reactions are proposed for the specific system water-en-pyrocatechol

Ionization

$$NH_2(CH_2)_2NH_2 + H_2O \rightarrow NH_2(CH_2)_2NH_3^+ + (OH)^- \quad [1]$$

Oxidation-Reduction

$$Si + 2(OH)^- + 4H_2O \rightarrow Si(OH)_6^= + 2H_2 \quad [2]$$

Chelation

$$Si(OH)_6^= + 3C_6H_4(OH)_2 \xrightarrow{\text{amine}} \left[Si(IV) \left(\begin{matrix} O \\ O \end{matrix} > C_6H_4 \right)_3 \right]^= + 6H_2O \quad [3]$$

Over-all Reaction

$$2NH_2(CH_2)_2NH_2 + Si + 3C_6H_4(OH)_2 \rightarrow 2NH_2(CH_2)_2NH_3^+ + [Si(C_6H_4O_2)_3]^= + 2H_2 \quad [4]$$

During the ionization step (Eq. [1]) hydroxyl and aminium (protonated amine) ions are formed. The hydroxyl ions, together with water, then oxidize the silicon to form hydrous silica with the evolution of hydrogen (Eq. [2]). The hydrous silica is converted to the complex pyrocatecholate which is soluble in the amine solution (Eq. [3]).

Examination of Eq. [4] shows that water does not appear in the over-all equation. This occurs because of the regeneration of water in the chelation step (Eq. [3]). Consequently, the reaction is not limited by water depletion, and the etch rate should remain constant over long periods of time in the presence of sufficient amine and complexing agent.

Several pyrocatecholato complexes of silicon were first reported by Rosenheim, Raibman, and Schendal (3). They isolated various *tris*(pyrocatecholato)silicon(IV) compounds by reacting freshly prepared silicic acid with pyrocatechol. In the present work the silicic acid was generated *in situ* at the silicon surface (Eq. [2]). The isolated ethylenediaminium compound has not been previously reported.

On the basis of the proposed mechanism we may account for the necessity for water in the system since in the absence of water no oxidation can take place. The suggested mechanism also explains the slow etch rate on silica films grown at high temperatures, since they contain few silanol (Si-OH) groups. These silica films must be converted to hydrous silica prior to their dissolution as the pyrocatecholato complex. This is apparently a slow step.

The addition of pyrocatechol to water-en solutions was found to increase the etch rate up to a limiting value (Fig. 2). At about 4 mole % pyrocatechol the rate saturates. This suggests that above this level of complexing agent the kinetics become limited by the oxidation step (Eq. [2]).

This mechanism can also account for the appearance of the silicon surface after etching in the absence of a complexing agent (Fig. 4). The limited etching of the silicon which takes place can be due to the slow dissolution of the hydrous silica by the en to form soluble *bis*(ethylenediaminium)silicate. However, the dissolution rate of the hydrous silica in this case is evidently slower than the rate of formation of the hydrous silica, resulting in a build-up of the hydrous silica layer. The dissolved areas of the surface layer may be explained as follows. Conversion of silicon to silica requires expansion of the lattice and can produce locally stressed areas which etch faster than unstressed areas. Alternatively, variations in the concentration of silanol groups on the silica surface of structural modifications of the silica may result in enhanced etching in localized areas.

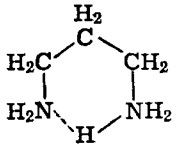
This mechanism differs from that proposed by Chrishal and Harrington (1), in which an oxidation of the silicon by hydrazine was postulated, with the evolution of nitrogen and hydrogen. Analysis of the gaseous reaction products in the present system showed hydrogen to be the sole gaseous reaction product. Volumetric analysis showed the hydrogen to be present in approximately the stoichiometrically predicted amount (Eq. [2]) both in the presence and absence of pyrocatechol.

If the reaction is performed in an open system, absorption of water by the hygroscopic anhydrous amine will result in the formation of a water-amine-pyrocatechol system of uncontrolled composition. Nitrogen evolution could then occur due to the decomposition of hydrazine in the presence of absorbed water and air.

With regard to the variation of silicon etch rate with amine, the base strength of the amine cannot be taken as an index of etch rate. Gero (4) has reported on the base strengths of polymethylenediamines. He found that en was the weakest base, and that 1,3-pn was abnormally strong due to chelate ring stabilization of the monocation. The present study has shown that en has the higher etch rate. The following explanations are proposed.

An amine environment is required for the pyrocatechol to dissolve (chelate) the hydrous silica. For small chain length diamines, where the amine separa-

tion is small, the positive charge on the monocation withdraws electrons from the second amine group, reducing its protophilic activity (amine nature). For hydrazine, the cation formed is NH_2-NH_3^+. In en the charge separation is greater, and the second amine retains its protophilic activity (Eq. [1]). For 1,3-pn, the second amine is thought by Gero (4) to be hydrogen bonded in the following manner



This type of cation would exhibit a lessening of amine character due to the utilization of the normally unbonded nitrogen electrons in the hydrogen bond. The succeeding cations of this diamine series should retain their amine nature and, therefore, provide a suitable environment for etching. A second possible explanation is based on the following information. Hooley (5) has observed that the dissolution rate of silica glass in aqueous solutions of alkali metal hydroxides is a function of effective cation size. The dissolution rates were found to be in the order Na > K > Li > Rb > Cs. In the present system, the protonated amine is a cation and is of an ionic size comparable to that of the alkali metal cations. Hooley (5) proposed no firm explanation of the rate variation as a function of cation size. Weiss *et al.* (6) have found that the kaolinite structure ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) is expanded from an initial planar spacing of ~10Å by exposure to hydrazine. On the basis of these investigations, a relation between etch rate of Si in a cation-hydroxide system, in which dissolution involves the intermediate formation of an oxide, and oxide bond distortion due to cation intrusion seems reasonable. This may relate directly to the silicon system under study in this paper. The silica structures proposed as intermediates may undergo bond distortion as a result of the intercalation of some amine species.

Silicon parameters.—Using solution 1 the etch rates for <111>, <110>, and <100> oriented silicon were found to be approximately 3:30:50 μ/hr for the samples tested. A plot of this data is shown in Fig. 6. The data scatter for the <111> oriented samples results from the limited precision of measuring the low etch rates. Samples were randomly selected with regard to dopant, utilizing such dopants as B, P, As, Sb, Al, Ga, and In.

For samples oriented off the three major low-index planes, the etch rates of the surface were found to be a function of the dopant concentration, and the degree and direction of misorientation. As the surface was misoriented from the plane, an increase in etch rate was observed. The variation in etch rate was marked near the <111> orientation, but much more gradual near the <100> orientation. This is now being investigated.

As is the case with most solid surface reactions, a

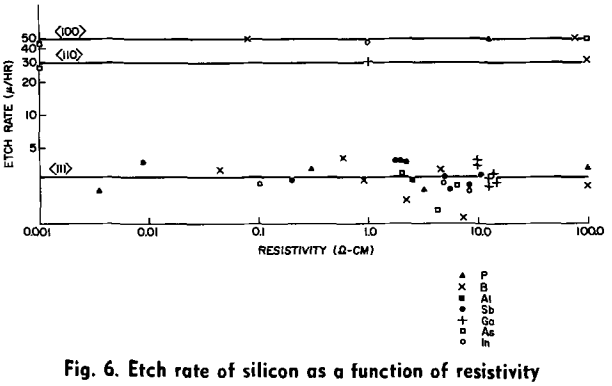


Fig. 6. Etch rate of silicon as a function of resistivity

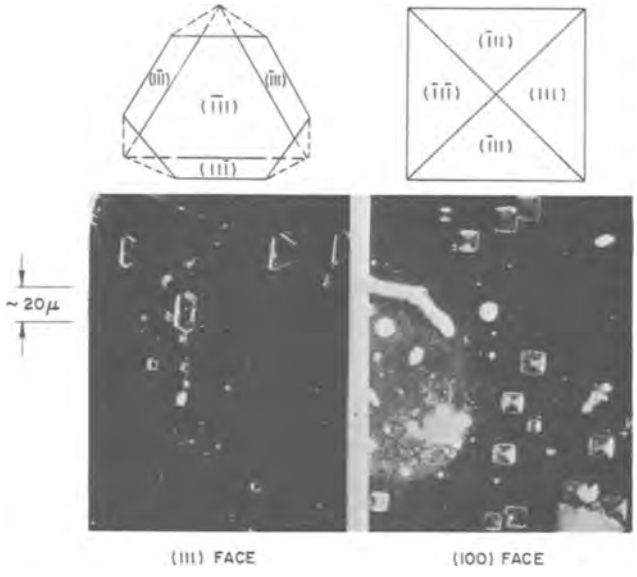

Fig. 7. Etch pit geometries in silicon for <111> and <100> oriented samples.

description of the detailed reaction mechanism is exceedingly difficult and cannot be based on kinetic studies of the gross reaction rate. Factors such as supply and movement of active surface sites on the silicon, reaction site spacing, activity of the reacting species in solution, and influence of impurities and/or absorbants on surface diffusion may all be significant. At present, evaluation of their respective roles is not possible. However, due to the diverse functional dependence of etch rate, a large amount of information can be gathered concerning this system. Because of this, it may eventually be possible to gain greater insight into the detailed reaction mechanism.

Silicon dioxide masking.—A parallel line of investigation has been concerned with etching studies on silicon substrates with a protective coating of silica. Structural inhomogeneities in the oxide may allow the etchant to penetrate to the silicon surface where localized etching takes place. Etch pits in the silicon were produced which were visible through the oxide film. These pits resulted from etching a concave surface which is bounded by slow etching planes (7). Schematic diagrams and photographs of the pits produced on two of the major low index planes of silicon are shown in Fig. 7.

Oxide porosity.—Oxide porosities were determined for various initial oxide thicknesses and various etching times. A plot summarizing this data is shown in Fig. 8. The samples used for these studies were oxidized at 1100°C in atmospheric pressure steam. The

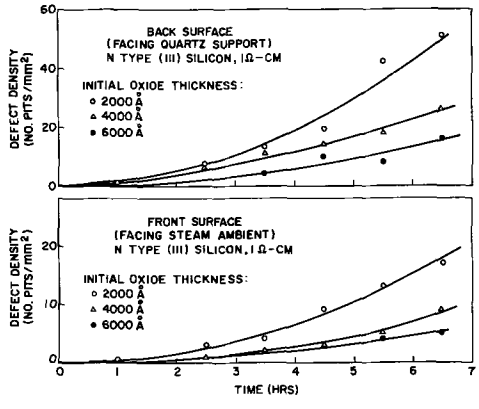

Fig. 8. Defect densities in silica films as a function of time of etching, initial oxide thickness, and surface exposure. The calibrated pinhole was formed using photolithographic techniques.

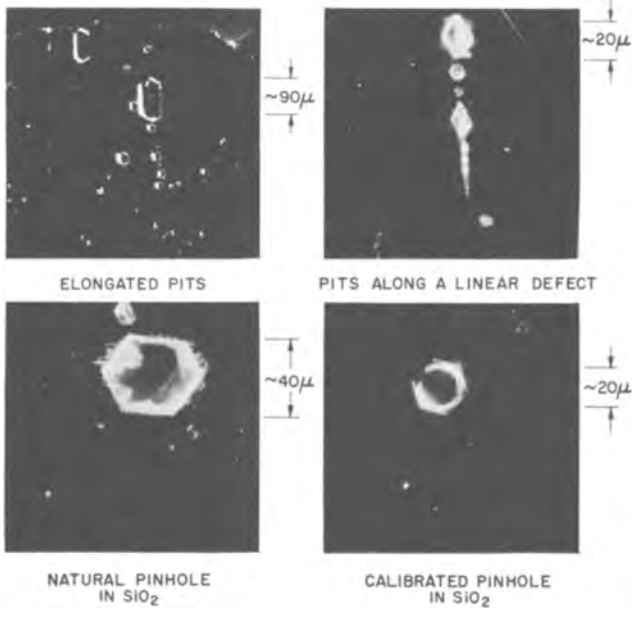

Fig. 9. Morphology of etch pits in <111> oriented silicon below silicon dioxide films.

oxide defect densities were found to be reproducible. An increase in etch pit density with time can be attributed to several causes. First, oxide defects which extend to within a few hundred angstroms of the substrate surface will etch through and initiate pits after extended etching. Second, the rate of growth of the etch pit is a function of the size of the oxide defect. Extremely small defects presumably will produce pits which are initially too small to be seen by optical microscopy. As the defect enlarges the pit size increases until the pit is visible. In addition, certain areas in the oxide may be structurally more susceptible to hydrolysis and subsequent dissolution. Of interest is the fact that while naturally occurring etch pits in <111> oriented silicon are not regular hexagons in shape, the pits formed beneath photolithographically produced round holes in the silica are. This indicates that the hexagonal shape of the pits is influenced by the geometry of the oxide defects. Examples of various etch pit shapes are shown in Fig. 9.

Oxide inclusions.—Also of interest have been the inclusions observed in silica films. These inclusions have etching characteristics grossly different from the oxide. They appear as "phantom crystals" which have unique etch pit shapes. Some of these phantom crystals manifest themselves as hexagonal shapes which disappear on further etching. Some appear as figures resembling dendritic crystals. Presumably these crystals are second phases in the silica (*e.g.*, devitrified areas) that etch at higher than the average rate of the film. Two examples of these shapes are shown in Fig. 10.

Applications

Application of the etching system described to device fabrication has shown promise in two general areas, the chemical shaping of silicon into unique shapes by utilizing the widespread control possible over the etch rate and studies of silica films. Significant in all applications is the low etch rate on silica, as well as on many metals. This allows silica or metals such as Ag, Au, Cu, or Ta to be used as etching masks, and differentiates this etch from alkali etches such as sodium hydroxide solutions which may be crystallographically sensitive but attack silica and many metals. The present etch is compatible with metals which cannot be used in HNO_3-HF systems. This may be explained by the fact that amine-soluble pyrocatecholates are formed predominantly with metals capable of attaining an oxidation state of IV (2).

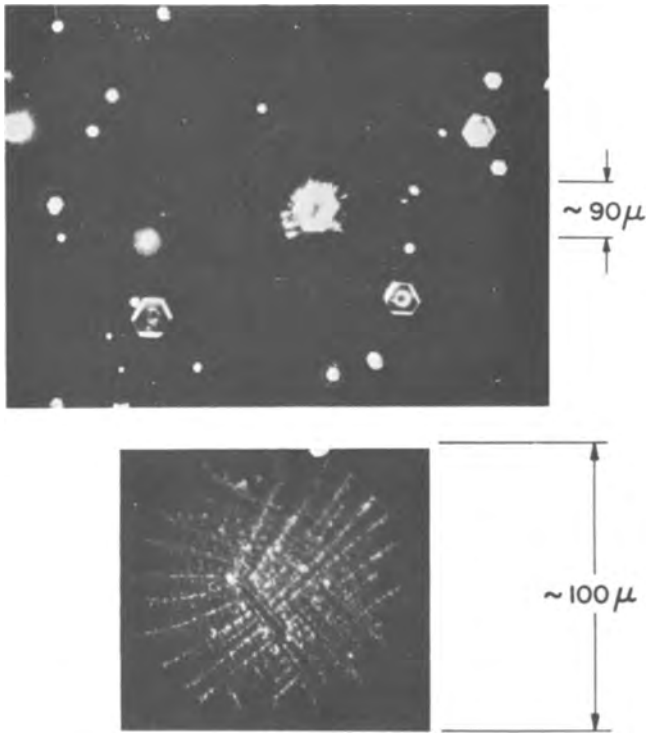

Fig. 10. Phantom crystals in silicon dioxide films

Chemical shaping with this etching system has produced silicon forms such as tapered mesas whose sides form an angle of 45° with respect to a (100) surface (Fig. 11). This is the natural shape of a mesa formed on a <100> oriented sample. Also, thin films of silicon alloys (~10μ) have been produced by etching slow or nonetching silicon alloys deposited on fast-etching silicon substrates. Germanium does not etch in this system. It has been found that silicon alloys containing as little as 5% germanium were not attacked by the etch. Therefore, when such alloys were epitaxially deposited on a silicon substrate, the substrate could be etched away leaving a nonetching film.

In the study of silica films on silicon substrates, the etch pit density in the silicon has been taken as an

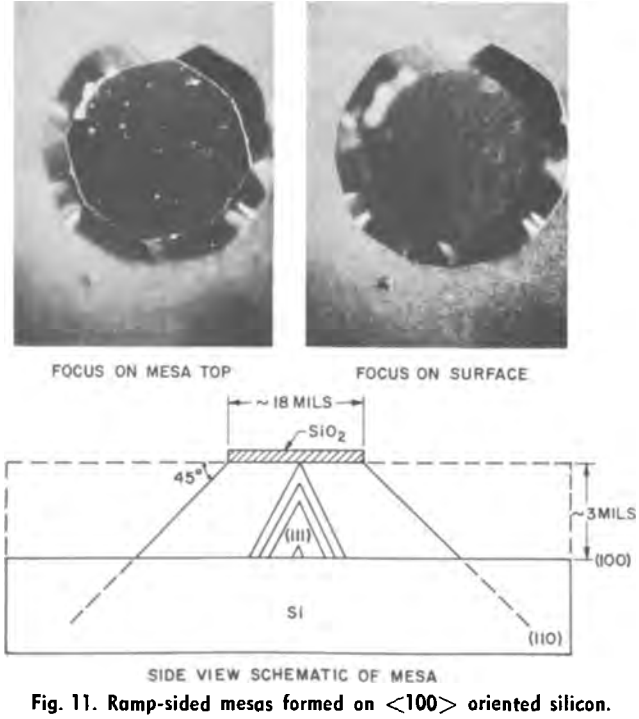

Fig. 11. Ramp-sided mesas formed on <100> oriented silicon.

index of the porosity of the silica film. This technique has been particularly applicable where low evaluation temperatures have been required. It has been shown that silica films formed by steam oxidation, plasma growth (8), and the CO_2 process (9) have approximately the same minimum porosity as determined by this technique. The chlorine gas etching system for oxide evaluation is generally used at a temperature of approximately 800°C, while the present system operates at approximately 110°C. Samples having etch pit densities of less than one and greater than 100 detectable pits per square millimeter have been observed after 2 hr of etching. In general, and in contrast to chlorine etching, individual pit growth may be observed since the etching action is slow and localized. Also, as previously mentioned, the etch pit shape is influenced by the shape of the oxide defect. Oxide inclusions or variations which have markedly different etch rates from the bulk oxide are delineated. Because of these factors, the system is a powerful tool for the study and evaluation of silica films.

Summary

It has been shown that the system water-amine-complexing agent will etch silicon and, to a much lesser extent, silica. For the specific system water-ethylenediamine-pyrocatechol, silica is etched at a rate of ~200 Å/hr while silicon etches at a rate approximately two orders of magnitude higher. The water appears to be an active component of the mixture and yields hydroxyl ions in the basic solvent system provided by the amine. Oxidation of the silicon by the water and hydroxyl ions forms hydrogen and hydrous silica at the silicon surface. The hydrous silica is removed from the silicon surface through the formation of the amine-soluble *tris*(pyrocatecholato)-silicon(IV).

For the specific etching system studied, the etch rates on <100>, <110>, and <111> oriented silicon were found to be approximately 50:30:3 μ/hr, respectively. For samples off the major low-index plane orientations the etch rates were found to be a function of resistivity and of the degree and direction of misorientation. Due to the large number of parameters which influence the etch rate, this system can be used for fundamental studies of the detailed reaction mechanism of silicon etching.

Because of the difference in etch rate on silica and silicon and the preferential nature of the etch on crystal planes, structural studies of silica films are feasible. In addition, protective oxides have been evaluated, and it has been possible to utilize the etching system for the chemical shaping of silicon to form tapered mesas and thin films of silicon.

Activation Energies in the Chemical Etching of Semiconductors in HNO_3-HF-CH_3COOH

A. F. Bogenschütz, W. Krusemark, K.-H. Löcherer, and W. Mussinger

Research Institute of TELEFUNKEN AG, Ulm, Germany

ABSTRACT

The intent of this paper is to clarify the reaction mechanism of the etching of (111)-oriented n-silicon and n-germanium in an etching solution of fum. HNO_3, conc. HNO_3, conc. HF, and glacial acetic acid. By comparing the temperature dependence of the etching rates and the temperature dependence of the viscosities of the etching solutions it was possible to show with some reliability that the investigated etching processes are diffusion controlled reactions. The performed mathematical calculations possibly allow the forecast of the effect of organic moderators and inhibitors in diffusion controlled etching systems, if the viscosity is known.

Mixtures consisting of several components are predominantly used for the chemical etching of semiconductor single crystals. Consequently the etching process generally comprises a number of parallel and secondary reactions which can be determined analytically only with difficulty. Without accurate knowledge of the chemical reaction mechanism it is difficult to produce etching solutions having the desired effect.

The activation energy yields some of the few criteria on etching mechanisms; it may be ascertained from the curve rise when the etching rate is entered logarithmically as a function of the reciprocal absolute temperature. Some attempts were described to draw conclusions on the reaction mechanism from such values (1-5). Since low activation energies around 4.5 kcal/mol (low dependence on temperature of corrosion rate) were measured in pure diffusion

processes according to Moelwyn-Hughes (6), it seemed obvious that a diffusion process dominates in etching processes with such activation energies. This means that either the diffusion of the components effective in etching to the semiconductor surface or the removal of reaction products determines the rate. As a rule oxidation reactions feature higher activation energies.

In previous investigations no direct comparison was made between the activation energy of the etching reaction and the activation energy of the diffusion process in the etching mixture. This paper describes such investigations. Since some technical difficulties are encountered in determining the activation energy of diffusion processes, we chose as standard of comparison the viscosity of the etching solution, which is easier to measure. This seems admissible since, according to the reasoning of Eyring (7), the viscosity, plasticity, and diffusion may be considered by virtue of the kinetic theory of liquids under the uniform aspect of a monomolecular reaction, whose elementary process is the transfer, for example, of a molecule from one equilibrium state to another through a potential threshold [*cf.* (8)]. Comparisons of the activation energy of the viscosity obtained in this manner, and thus the diffusion, and the activation energy of the etching process prove that the etching process actually is governed by a diffusion process in the systems Si/HF-HNO_3-CH_3COOH and Ge/HF-HNO_3-CH_3COOH which we investigated. The activation energy of the etching process and the activation energy of the viscosity, and thus the diffusion, agree within the error limit mainly.

Consequently it will be interesting to check, by further experiments on other diffusion controlled etching systems, whether or not the effect of an added organic moderator or inhibitor, such as acetic acid, tartaric acid, oxalic acid, formic acid, citric acid, tannic acid, ethylene glycol, propylene glycol, glycerin, butylamin, amylamin and n-butyl thiobutane, may be predicted by measuring the viscosity of the solution.

Experimental Part

As etching solution for our investigations a mixture was chosen which features a corrosion characteristic linear with time over a wide range of temperatures. The solution was 50 ml HNO_3 fum., 30 ml HNO_3 (65%), 20 ml HF (40%), and 80 ml glacial acetic acid. This mixture was used for etching on polished silicon and germanium wafers, the activation energy of the etching reaction resulting from the etching. In addition the activation energy of the viscosity was ascertained in the etching solution without semiconductor. These experiments are described next.

Etching experiments.—Single-crystal (111)-oriented n-silicon having a specific resistance of 25-35 ohm-cm and single-crystal (111)-oriented n-germanium ($g = 1$ ohm-cm) were used for the etching experiments described.

Following cutting and lapping the semiconductor wafers were polished chemically and mechanically as described in ref. (9) in such manner that a flat, structureless, pure surface was produced. The arrangement used for etching the semiconductor wafers is shown in Fig. 1. In this arrangement the semiconductor wafer is placed horizontally on a sievelike Teflon mount with a recess and immersed in the etching solution. The interference with the diffusion and thus the corrosion of the under surface, caused by the Teflon sieve, is much lower than 5% and may thus be neglected. As etching bath a covered Teflon can was used so that, by means of a thermostat, the temperature of the etching solution may be kept constant during the etching process. A magnetic stirrer rotating at 180 rpm was used to stir the etching liquid. In each etching process the volume of the etching solution was 100 ml.

In order to obtain reproducible test results the etching bath was first brought up to temperature without the etching solution over a period of 15 min prior to each etching process. Subsequently the freshly prepared solution was poured in the etching bath; its temperature was controlled thermostatically for a period of 15 min. Afterward the wafers were etched for 2 min, rinsed, dried, and weighed.

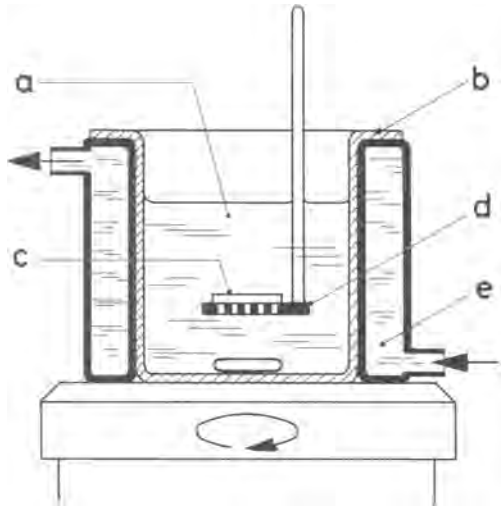

Fig. 1. Etching apparatus; (a) etching liquid, (b) Teflon container, (c) semiconductor wafer, (d) Teflon sieve, (e) thermostat.

The one-sided corrosion d followed from the equation

$$d = \frac{(G_1 - G_2)}{2F \cdot \gamma}$$

The weight $(G_1 - G_2)$ was determined by difference weighing. The surface of the wafers (F) was measured, and for the density γ the value 2.33 g/cm³ was inserted. The error caused by neglecting the narrow side surfaces of the wafer amounted to approximately 1%. The corrosion rate then corresponded to the quotient of corroded layer thickness on one side and etching time.

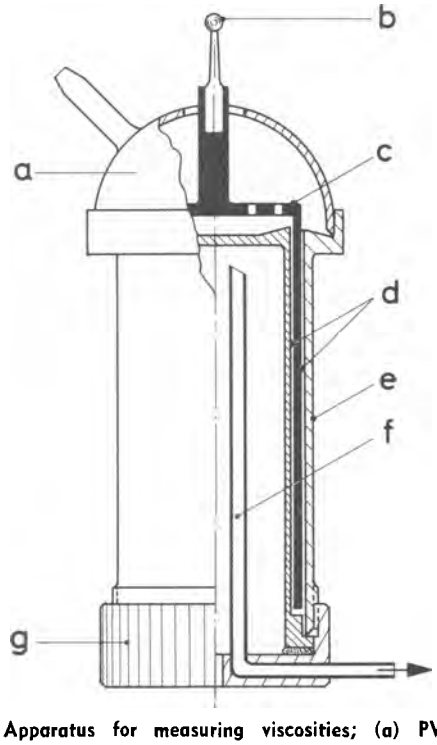

Fig. 2. Apparatus for measuring viscosities; (a) PVC-suction hood, (b) carrier ball (stainless steel), (c) measuring device (Teflon), (d) interspace for measuring solution, (e) Teflon case, (f) outlet tube to the thermostat, (g) Teflon-screw cap.

Values above 53°C were not used in the calculation of activation energy because at these temperatures the etching solution no longer features a defined composition due to the liberated nitrous gases and therefore does not yield reproducible results.

Viscosity measurements.—The viscosity measurements were performed on the same etching solution without semiconductor specimen using a Couette viscosimeter (Fig. 2). The etching solution was situated in the space between two cylinders arranged concentrically, in which a test body, likewise cylindrical, rotated. Teflon was chosen as the material for the test system. The shear force produced on the rotating test cylinder in consequence of liquid friction was measured by means of a torsion wire. In order to work at defined temperatures the test system was controlled thermostatically until the viscosity of the etching solution remained constant. Then the viscosity resulted in accordance with the equation $\eta = -\tau/D$. In this equation τ is the shear force in dyne · cm^{-2}, D is the gradient of shear force in sec^{-1}, and η is the viscosity in dyne ·-sec · cm^{-2}. This equation applies only for a Newton liquid (10), *i.e.*, for an etching solution in which the viscosity does not change under the influence of mechanical stress. Our etching solution complied with this requirement.

Evaluation of the Experimental Results

The dependence on temperature of the viscosity η is shown in Fig. 3. Accordingly ln η is a linearly rising function of $1/T$, the following thus applies

$$\eta \sim e^{\Delta E_{vis}/RT} \qquad [1]$$

For the magnitude of the activation energy ΔE_{vis} we obtained, in accordance with the Gaussian method of least squares

$$\Delta E_{vis} = 4.60 \pm 0.09 \text{ kcal/mol}$$

Equations like Eq. [1] were established empirically for liquids over fifty years ago (7). A corresponding theoretical equation

$$\eta = \frac{N \cdot h}{V} \cdot \frac{(2\pi mkT)^{1/2}}{h} \cdot \frac{6RT \cdot V^{1/3}}{\Delta E_{vap} N^{2/3}} \cdot e^{\Delta E_a/RT} \qquad [2]$$

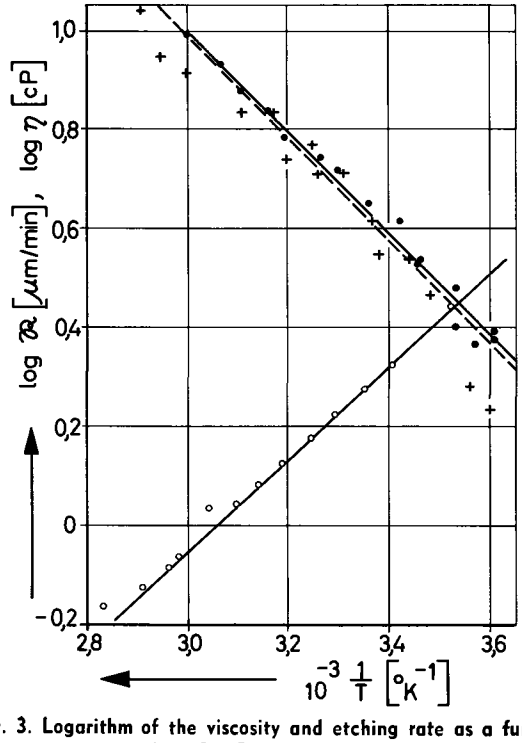

Fig. 3. Logarithm of the viscosity and etching rate as a function of temperature; • log $\mathcal{R}_1$ [µm/min] for silicon, × log $\mathcal{R}_2$ [µm/min] for germanium, ○ log η [cP].

was established by Eyring (7) [cf. (12)] by virtue of the kinetic theory of liquids. Here N is Avogadro's number, V the molar volume, h the Planck constant, k the Boltzmann constant, m the particle mass, ΔE_{vap} the molar evaporation energy, ΔE_a the activation energy per mol, R the gas constant and b the number 2 (for ordinary cube packing: for other packings the number is not very different).

If the dependence on temperature of the viscosity is determined primarily by the exponential factor in Eq. [2], then

$$\eta \sim e^{\Delta E_{vis}/RT}$$

applies in agreement with the empirical form [1] if $\Delta E_a = \Delta E_{vis}$. The dependence on temperature of the corrosion rates $\mathcal{R}_1$ and $\mathcal{R}_2$ is shown in Fig. 3 likewise. Accordingly ln $\mathcal{R}_1$ and ln $\mathcal{R}_2$ are linear falling functions of $1/T$, and it follows that

$$\mathcal{R}_{1,2} \sim e^{-\Delta E_{Etch\ 1,2}/RT} \qquad [3]$$

A connection with the form of Eq. [3] also follows from a theoretical formula by Camp (13), insofar as the etching process is characterized essentially by a single activation energy. For the magnitude of the activation energies $\Delta E_{Etch\ 1,2}$ we obtain by the Gaussian method of least squares

$$\Delta E_{Etch\ 1} = 4.72^{+0.5}_{-0.9} \text{ kcal/mol (for silicon)}$$

and

$$\Delta E_{Etch\ 2} = 4.96^{+0.1}_{-0.4} \text{ kcal/mol (for germanium)}$$

(The error was not calculated in this case but estimated only with reference to Fig. 3. It is much higher than in the findings from the viscosity measurements because the measurement of the corrosion rate is subject to a higher uncertainty.)

Within the measurement error ΔE_{vis} and ΔE_{Etch} agree for both silicon and germanium. From this fact we conclude that a diffusion determining procedure is primarily concerned in etching by the etching solution under consideration here, the type of etched semiconductor material playing only a minor part.

As regards diffusion-controlled processes it can be assumed with some justification that $\mathcal{R}$ is proportional to the diffusion coefficient D of the etching solution components effective in the corrosion process. Since according to the theory $\eta \cdot D = \text{const} \cdot T^n$ in addition, it follows that ΔE_{vis} must be equal to ΔE_{Etch} too according to [1] and [3]. The dependence on temperature of the product $\eta \cdot D$ in accordance with an exponential law, which is indicated by the theory, ought not to be significant in a small temperature range.

From the foregoing it will be seen that the condition $\eta \cdot \mathcal{R} = \text{const.}$ must be satisfied in diffusion-controlled processes. A graphic presentation of the product $\eta \cdot \mathcal{R}$ with the measured data indicates stability for both silicon and germanium over a temperature range from approximately 18° to 53°C (cf. Fig. 4 and 5). At lower temperature between 1° and 18°C possible induction periods in the corrosion may cause falsification of the test results. At temperatures above 53°C the nitrous gases start to be liberated from the

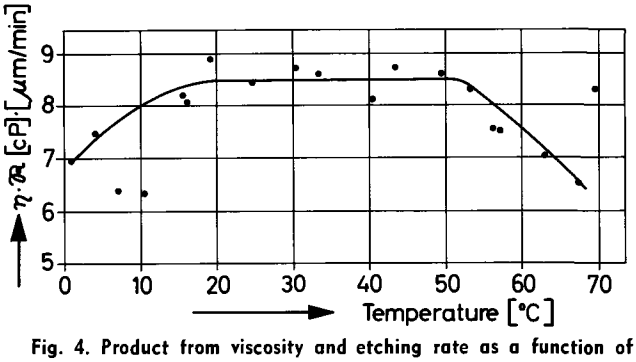

Fig. 4. Product from viscosity and etching rate as a function of temperature for the system silicon/etching solution.

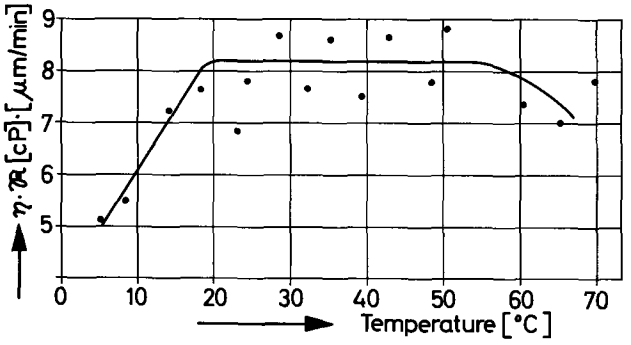

Fig. 5. Product from viscosity and etching rate as a function of temperature for the system germanium/etching solution.

etching solution thus causing a change in the composition of the etching solution.

Additional experiments, during which the glacial acetic acid moderating components were replaced by the same volumes of trichloracetic acid, o-phosphoric acid, or o-phosphoric acid saturated with P_2O_5, clearly confirm that the corrosion rate may drop by several decimal powers with increasing viscosity of the solution in diffusion-controlled etching systems. However, in such comparative cases it must be borne in mind that changes in the concentration of the moderating components may give rise to concentration shifts within the components effective in corrosion and thus alter the character of the etching system.

Technical Note

The Preparation and Electrical Resistance of Single Crystals of β-US_2

P. K. Smith and L. Cathey[1]

Savannah River Laboratory, E. I. du Pont de Nemours and Company, Aiken, South Carolina

Semiconducting compounds of alpha-emitting isotopes have potential applications as components of self-heating thermoelectric elements. Alpha-emitting actinide compounds with semiconductor properties are being sought, initially using uranium as a stand-in for elements with more highly radioactive isotopes.

Electrical properties of semiconductors are more meaningful when determined on single crystals. However, single crystals of pure compounds of the actinide elements with group V and VI elements are difficult to prepare because most decompose at high temperatures, have high melting points, and are incompatible with container materials. For example, orthorhombic β-US_2 transforms to tetragonal α-US_2 at 1350°C and vaporizes with a preferential loss of sulfur near 1500°C(1); thus single crystals cannot be made by melting or sublimation.

To avoid these difficulties, we have successfully used the vapor-transport technique described by Schäfer (2) to form small single crystals of orthorhombic β-US_2. Using this technique, polycrystalline US_2 was reacted with iodine at 940°C, and the gaseous uranium iodide and sulfur were transported down a temperature gradient and deposited at 700°C as single crystals of β-US_2. Resistance-temperature measurements on the β-US_2 crystals indicated that the crystals were semiconductors with a low activation energy for charge carrier generation.

Experimental

β-US_2 was prepared in two ways: (*i*) by reacting the elements, and (*ii*) by reacting H_2S with uranium. In the first method, a heavy-walled "Vycor"[2] transport tube (250 mm long x 19 mm OD and constricted to 8 mm ID in the center to minimize cross-contamination during handling) was outgassed at 1000°C under a vacuum of 10^{-4} mm. Stoichiometric quantities of electropolished, reactor-grade, natural uranium chips and reagent-grade sulfur were loaded into opposite ends of the transport tube. A thin-walled, glass ampule containing about 250 mg of spectroscopic-grade iodine (8 mg/cc to produce an iodine pressure of 2 atm at 1000°C in the tube) was placed in the transport tube. After the transport tube was sealed, the iodine was released by exploding the ampule with a torch. The sulfur was then distilled onto the uranium at 1000°C. By introducing the transport tube slowly into the fur-

[1] Present address: University of South Carolina, Columbia, South Carolina.

[2] Trademark of Corning Glass Works, Corning, New York.

nace, the rate of sulfur distillation was limited; thus the reaction rate and overheating were controlled. Thick heterogeneous layers of powdery β-US_2 and sulfur-rich phases were formed on small residual platelets of unreacted metal. This product was then transported to the other end of the tube in a controlled temperature gradient during long-term heatings.

In the second method, powdered β-US_2 was prepared by the reaction of flowing H_2S with uranium metal chips at 800°C in a tube furnace. X-ray diffraction analysis showed that the heterogeneous product was principally β-US_2, but contained small quantities of UOS. This material and iodine were loaded into the outgassed transport tube, and the β-US_2 was transported to the cool end of the tube where it deposited as single crystals.

An attempt was made to prepare US in the transport tube by the first preparative technique, using a stoichiometric ratio of the elements. The product formed on the uranium chips was predominantly β-US_2. Subsequent transport of this preparation produced β-US_2 crystals.

The crystal phases in the transported material were determined by x-ray diffraction using the Debye-Scherrer technique. The materials were analyzed chemically for uranium and sulfur and spectrographically for impurity metals. The needle crystals of β-US_2 in the product were analyzed for silicon by atomic absorption, and for iodine by spark-source mass spectrometry.

The electrical resistance of the crystals was measured from 113° to 472°K. These data were used to determine if the crystals were semiconducting and to estimate the energy gap for charge-carrier activation in the material.

The four-point mount shown in Fig. 1 was used to make resistance measurements on uniformly shaped needle crystals formed from US_2 prepared from H_2S and uranium. The back support is an epoxy-bonded, fiberglass circuit strip with copper foil on the two edges. The sample crystal spans the 1.1-mm gap between the two strips. The two potential contacts were made from No. 36 copper wire and were spaced 0.15 mm apart. All contacts with the crystal were made with gallium metal, which apparently wets the US_2 crystal and forms a nearly ohmic contact. The surface tension of the liquid gallium held the contacts in place above 300°K.

Results

In every experiment, the crystals formed at the cold end of the transport tubes were single-phase β-US_2. Two types of crystals were formed: about 80% was a fine microcrystalline powder; the remainder was needle crystals, 2-8 mm long and 0.2-0.5 mm in diameter (Fig. 2), which appeared to have grown as high-pitched spirals as if growth had proceeded along a screw dislocation.

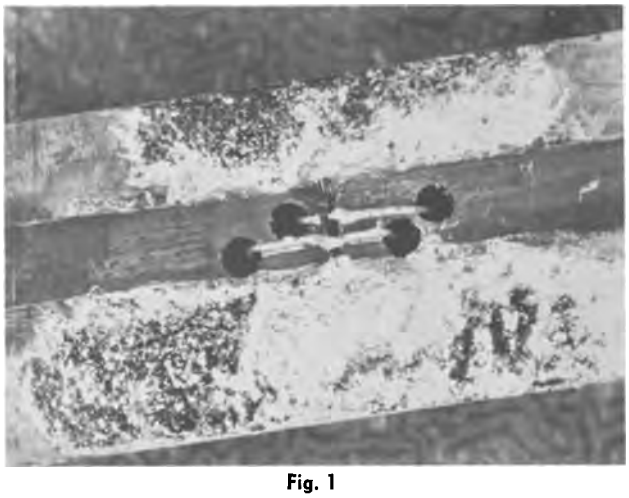

Fig. 1

Fig. 2

Transport rates were slow, about 20 mg US_2/hr for temperatures of 940°C at the hot zone and 700°C at the cold zones; only 0.3 mg/hr was transported in a 780°/600°C gradient. No transport was detected when the ΔT across the transport tube was below 140°C or when iodine was absent.

X-ray diffraction analysis of samples from both ends of the transport tubes indicated that the US_2 reacted with Vycor slowly at 700°C and more rapidly at 940°C to produce UOS. Analyses of the microcrystalline material from near the tube wall showed considerable UOS contamination in the β-US_2 after the 940°/700°C gradient heating; samples from the center of the material showed much less UOS. Much less UOS was observed in samples from the cold end of the tube relative to that in the hot end.

Chemical analyses were performed on the material transported in the 940°/700°C gradient. The composition of this acid-soluble, microcrystalline material was $US_{1.97\pm0.10}$. The total of the sulfur and uranium analyses combined with the 3.6 w/o (weight per cent) insoluble oxysulfide accounted for 100% of the sample. The principal impurities in the microcrystalline material were silicon, aluminum, and iron, as determined by emission spectroscopy (Table I). The silicon content was determined independently to be 1750 ±250 ppm.

The needle crystals by themselves were not analyzed for sulfur-to-uranium ratio. It was assumed that since the needle crystals were formed under the same pressure and temperature conditions as the microcrystalline product, the composition was the same.

The impurity concentrations in the needle crystals, particularly oxygen and silicon introduced from the reaction of US_2 with Vycor, were thought to be lower than for the microcrystalline material. The needle crystals were entirely soluble in sulfuric acid, in-

Table I. Emission spectrographic analysis of microcrystalline US_2. US_2 was formed by vapor transport in a 940°/700°C gradient

Element	Concentration, ppm	Element	Concentration, ppm
Si	>1000	Cr	15
Al	500-1000	Cu	10
Fe	500-1000	Mn	<10
Mo	500	V	1-10
Ni	50	Pb	7

Ca	10-50	Cd	1.2
Zr	<50	Sn	<1
Mg	15	Ag	<0.1

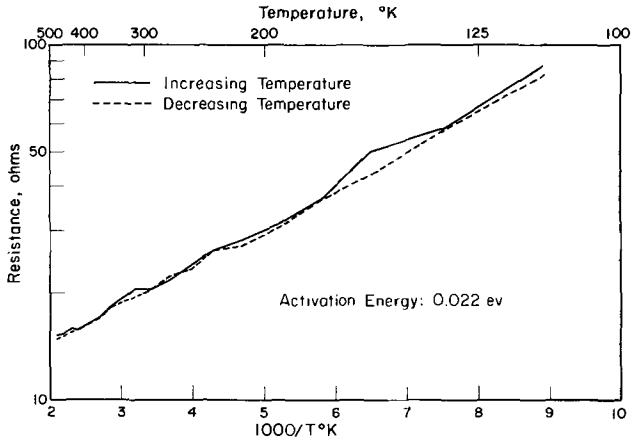

Fig. 3

dicating the absence of oxides or oxysulfides in the crystals. The iodine concentration in the needle crystals was 400 ppm.

The electrical resistance of the needle crystals decreased with increasing temperature, a behavior that is characteristic of a semiconducting material. The activation energy for charge-carrier formation was about 0.022 ev, as determined from the slope of the graph of R *vs.* $1/T$ (Fig. 3). Because of the relatively high impurity content of the crystals, it is not clear whether the conduction observed in β-US_2 is intrinsic or extrinsic. Resistance, rather than resistivity, is reported because the contacts were not uniform. Although the sample length and area could not be measured accurately, the sample areas were approximately 0.2 mm^2. The length was approximately the potential probe separation. The resistivity at 300°K is then near 25 ohm-cm. No other measurements on US_2 are reported for comparison.

Discussion

The transport of US_2 from higher to lower temperatures is consistent with either of two reactions:

$$US_2(c) + 3/2\,I_2(g) = UI_3(g) + S_2(g) \qquad [1]$$

$$US_2(c) + 2\,I_2(g) = UI_4(g) + S_2(g) \qquad [2]$$

The standard heats for the reactions in Eq. [1] and [2] at 298°K were estimated as 56 kcal and 34 kcal, respectively. Since the reactions are endothermic, transport of US_2 from high to low temperatures is expected in both cases.

Most effective transport will occur when the free energy of the reaction, $\Delta G°_T$, is near zero (2). Since the values for $\Delta H°_{298°K}$ are relatively large, transport can occur only if $\Delta S°_{298°C}$ for the reactions are positive; these values are estimated from data on analogous chemical systems to be about 38 and 17 eu, respectively. Values for $\Delta G°_T$, calculated assuming that $\Delta C°_P$ is zero, are given in Table II.

Table II. Estimated free energies *vs.* temperature for transport reactions

°C	$\Delta G°_T$, kcal	
	Reaction [1]	Reaction [2]
700	18	17
900	10	14
1200	0	9

These values are generally consistent with the observation that transport increases with an increasing average temperature and with increasing gradients. At 700°/600°C, little transport occurs by either reaction; at 940°/700°C, both reactions may contribute, with reaction [1] becoming more important as the temperatures are raised to 1200°C. Transport by a reaction involving formation of a ternary molecule such as $USI_2(g)$ may also be possible.

It should be easier to transport disulfides of transuranic elements or compounds of the actinides with the same stoichiometry combined with groups IVA, VA, and VIA elements lower in the periodic table. The heats of formation of these compounds should be lower than that of US_2. Consequently, $\Delta G°_T$ for reaction [1] stoichiometry will be closer to zero at lower temperatures than for US_2. Bro (3) has transported various rare earth ditellurides with I_2 in a 900°/700°C gradient, suggesting that ditellurides of actinide metals can be transported.

The transport of US was not observed in this work, but it should be possible. It is not immediately apparent how the transport criteria change for compounds with different stoichiometry. Generally, as the ratio of metal to nonmetal decreases, both $\Delta H°$ and $\Delta S°$ decrease. However, as $\Delta H°$ decreases, there is more amplitude to adjust the temperature to make $\Delta G°_T$ close to zero by varying the $T\Delta S°_T$ term. The transport of US_2 observed in the tube charged with equimolar amounts of uranium and sulfur (to produce US) probably is caused by the mixture of U, US_2, and higher sulfides in the US preparation.

Substituting Br_2 or Cl_2 for I_2 should increase transport rates of compounds with metal-to-nonmetal ratios of one-half, and should make possible transport of the more stable actinide compounds, *e.g.*, US. The heat of formation of $UX_3(g)$ increases from I_2 to Br_2 to Cl_2. Substitution of these halogens makes $\Delta H°_T$ smaller for reaction [1] without changing $\Delta S°_T$ significantly. Consequently, transport can be effected at a lower temperature since $\Delta G°_T$ will approach zero at a lower temperature, or transport rates should be higher for the same average gradient temperature.

Brief Communication

Liquid Encapsulation Zone Refining (LEZOR)

E. M. Swiggard

Naval Research Laboratory, Washington, D. C.

The use of a two-liquid zone melting system was anticipated by Pfann (1). He placed particular emphasis on the use of a liquid to support a large zone in a vertical ingot and to prevent contamination of the melt by a solid container. Metz *et al.* (2) and Mullin *et al.* (3) have applied the two-liquid system to growth of single crystals of decomposable solids in a conventional crystal puller. They used B_2O_3 as the second liquid and found that the B_2O_3, even though less dense than most semiconductor materials, wet the crucible and formed a liquid film between the crucible and the melt, hence the term "liquid encapsulation." In this work liquid encapsulation has been extended to zone refining. For the sake of brevity this author has adopted the acronym "LEZOR" to stand for liquid encapsulation zone refining. We report here a description of the vertical LEZOR technique and the results obtained with 40 ohm-cm Ge, InAs, Cd_3As_2, and Zn doped Ge.

A detailed schematic of the equipment used is shown in Fig. 1. The apparatus consisted of two resistance furnaces to keep the B_2O_3 liquid, an rf coil to maintain the molten zone, an open end capsule for the charge, a pedestal to support the capsule at the desired height, and an outer tube to contain the atmosphere. The charge was in rod form, the dimensions of which were such that it filled the capsule reasonably well but would slide readily. The capsule was heavy wall quartz (8 mm ID x 12 mm OD). One gram of previously dried B_2O_3 was placed at the bottom of the capsule and the charge on top of this. The tip of the capsule was initially positioned in the lower furnace. The system was then evacuated, and, while still pumping, the temperature of the furnace was raised to 650°C. This procedure was followed in order to remove surface moisture on the dried B_2O_3. In the case of Cd_3As_2 (mp 720°C) the furnace temperature was raised to only 550°C. The system was kept in this condition for about 1 hr before the pump was turned off and pure H_2 admitted. After a steady gas flow was established the rf generator was turned on and the tip of the capsule moved under the rf coil. During the pump out procedure the charge slowly dropped through the molten B_2O_3 until it rested on the bottom of the capsule. An inch or more of the charge was encapsulated in B_2O_3. The rf power was raised until a molten zone was established. The capsule was then lowered through the coil at 1-2 iphr. As the capsule was lowered the liquified charge, which was more dense than the B_2O_3, filled the lower part of the capsule leaving only a thin layer of B_2O_3 between the capsule and the charge. During the initial pass the furnace temperature was slowly lowered to 550°C, and minor adjustments in rf power were made. Proper shaping of the charge and careful observation during the initial pass to see that the travel did not exceed the speed with which the charge would drop through the B_2O_3 were the critical steps. If the charge was fragmented there was a tendency for the fragments to become wedged in the tube preventing them from falling into the melt. If the charge failed to fall properly, the zone separated and the B_2O_3 was left behind. Melting and refreezing of a charge not encapsulated in B_2O_3 usually resulted in a broken capsule. Sometimes the separation could be corrected by pushing with the quartz rod inserted through the top of the apparatus. Due to the high viscosity of B_2O_3 the charge was sluggish in its downward movement and occasionally had to be pushed with the rod mentioned above. If the travel exceeded the speed with which the charge would fall, the zone would separate and the same difficulties described above would occur. After the initial pass the zone refining process could be repeated without difficulty. The usual number of passes was 15-20, but in one case Cd_3As_2 was subjected to 35 zone refining passes. Figure 2 is a close-up of the liquid zone in Ge. The two solid-liquid interfaces are clearly visible. Bubbles such as the ones seen in Fig. 2 were observed, and they became more numerous on subsequent passes.

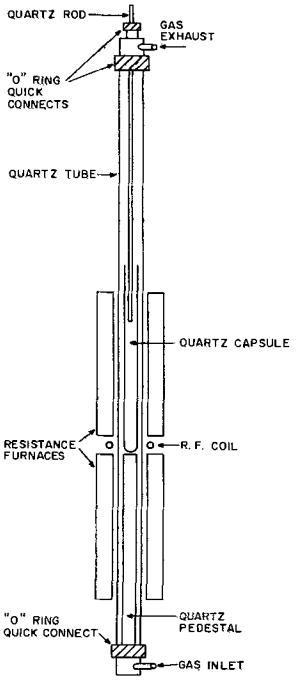

Fig. 1. Schematic of LEZOR apparatus

To complete the run the capsule was positioned so that the tip of the capsule was in the rf field, but the power was lowered so that the ingot was maintained at a temperature below its melting point but above the softening point of B_2O_3. The lower furnace was cooled to room temperature and the capsule lowered through the coil. As the tip of the capsule cooled, the B_2O_3 froze and broke the capsule and ingot. In order to evaluate the run it was necessary to dissolve the B_2O_3 in water and select unbroken pieces of the ingot for electrical measurements. Various cooling cycles were tried, but the ingot was always severely fractured.

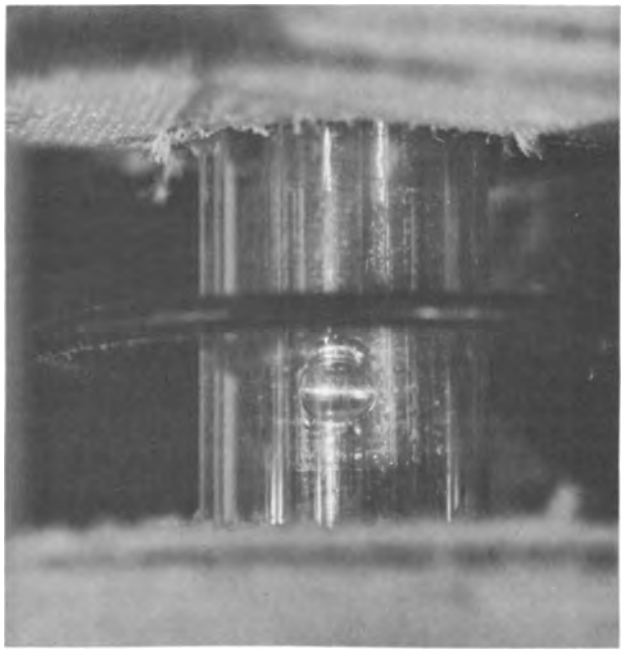

Fig. 2. Molten zone in B_2O_3 encapsulated Ge ingot

A summary of zone refining results is shown in Table I. The effectiveness of LEZOR was clearly seen in the case of Ge for which it was also observed that the low field breakdown emf at 4.2°K was 2.8 v/cm. Such a low value indicates that the concentration of compensating impurities is small. Despite the fact that high-purity InAs was zone refined 19 times it showed no change in carrier concentration. This probably indicates that the residual impurity has a segregation coefficient very close to one. The carrier concentration of Cd_3As_2 was reduced by a factor of 2. This result was achieved in both cases despite the fact that for the first ingot only a few passes were taken and the ratio of ingot length to zone length was only 6, while for the second ingot 35 passes were made and the ingot to zone length was 17. While the reduction in carrier concentration may be due to purification it is possible that improved stoichiometry or a combination of the two effects is responsible.

Table I. Impurity concentration, cm^3

Material	Starting material	After LEZOR	Zone melting phases
Ge*	8×10^{13} (p)	2.3×10^{12} (p)	18
InAs*	2×10^{16} (n)	2×10^{16} (n)	19
Cd_3As_2**	2×10^{18} (n)	1×10^{15} (n)	6
Cd_3As_2*	2×10^{18} (n)	1×10^{15} (n)	35

* Ingot length 23 cm—zone length 1.3 cm.
** Ingot length 11.5 cm—zone length 1.8 cm.

In order to study the liquid encapsulation technique with respect to volatile impurities a Zn doped Ge ingot was prepared. In this case the zinc was placed in the capsule under the B_2O_3 and the usual procedure followed. Only one zone melting pass was taken. Using the published value of the segregation coefficient of Zn in Ge (4×10^{-4}) the amount of Zn required to give an ingot containing 2×10^{17} carriers/cc was added. The resulting inogt had a uniform zinc concentration of 2.5×10^{17} carriers/cc. This result clearly shows that liquid encapsulation can prevent loss of volatile impurities and can eliminate vapor phase shunting of impurities during the zone refining process. Mullin (4) reports similar results pulling Zn doped Ge.

Severe fracture of the ingot presently limits the usefulness of LEZOR to material purification and exploratory investigations. It is possible that other encapsulating liquids and other capsule materials might be found to alleviate this problem. A possible solution would be to use a horizontal LEZOR process and remove the B_2O_3 by a gaseous reaction while it is still liquid. The reaction of B_2O_3 and methanol to form gaseous methylborate at 400°C was tried and showed considerable promise.

Acknowledgments

The author is indebted to O. Imber for technical assistance in the experimental work, E. D. Palik and B. Henvis for measurement of the carrier concentration in Cd_3As_2, and H. Shenker for valuable discussions. This work was performed under Project Defender, sponsored by the Advanced Research Projects Agency, Department of Defense, via the Office of Naval Research.

Corrections

In the paper "Structural Studies of Porous Electrodes" by E. Y. Weissman (July 1967 Journal, pp. 658-665), Equation [3] should read

$$T_s = \frac{6.6(\log_{10} p_s - 6.49594) - 255.821}{\log_{10} p_s - 6.49594} \qquad [3]$$

On the left hand side of Eq. [9] the exponent should read

$$(1 - \alpha)$$

High Activity Platinum Electrocatalysts for the Direct Anodic Oxidation of Saturated Hydrocarbons

E. J. Cairns[1] and E. J. McInerney[2]

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The fact that hydrocarbon fuels can be directly oxidized at reasonable current densities using fuel cells with platinum anodes and acidic electrolytes has been demonstrated previously. The next logical step was to reduce the amount of platinum electrocatalyst required for a given current density. Two approaches have been taken toward this objective: the preparation of higher activity unsupported electrocatalysts, and the use of conducting support materials to permit more effective utilization of the platinum. Results are reported for the anodic oxidation of both gaseous and liquid normal saturated hydrocarbons using a number of unsupported and carbon-supported electrocatalysts. Indications are that power densities of about 35 mw/cm^2 (resistance-free) are possible with a propane-oxygen fuel cell using 36 m/o (mole per cent) hydrofluoric acid at 105°C as the electrolyte with an anode containing 10 mg Pt/cm^2 as a carbon-supported electrocatalyst.

There has been a concerted effort during the last few years to accomplish the direct anodic oxidation of saturated hydrocarbons in fuel cells. This has been achieved by several investigators, all using platinum as the electrocatalyst. The amount of platinum used has ranged from 45 to 180 mg/cm^2 and the electrolytes used have been cesium carbonate (1, 2), sulfuric acid (3), phosphoric acid (4-6), hydrofluoric acid (7, 8), and cesium fluoride-hydrofluoric acid mixtures (7-9). The temperatures used in these investigations have ranged from 100° to 200°C. The normal saturated hydrocarbons which yielded the highest current densities were ethane, propane, and butane (2, 3, 5, 7, 10); consequently, most of the work has been done with them.

Even though acceptable performances have been obtained with the systems mentioned above, it has not been economically interesting to attempt the construction of practical power sources, largely because of the high cost of the large amounts of platinum necessary to obtain reasonable power densities. The next logical step after proving operational feasibility was to attempt to improve the economics of the system by reducing the amount of platinum required. Several approaches can be taken toward this goal:

1. Make more effective use of the platinum by preparing higher area blacks.
2. Prepare very high-area platinum on a support which can act as a current collector and perhaps also as an enhancement to the platinum activity.
3. Alloy the platinum with other metals in such a way that more activity per unit weight of platinum is obtained.
4. Replace the platinum with a less costly, but effective, electrocatalyst.

The first method listed above has not previously met with a great deal of success because platinum black with a specific surface area significantly above 15 m^2/g sinters under conditions of electrode preparation and may sinter with use at the higher fuel cell operating temperatures, resulting in a fairly rapid loss of area. The fourth method is generally considered the most difficult due to the multiple requirements placed on any successful electrocatalyst, not the least of which is excellent corrosion resistance to hot acids. The present work is concerned with approaches 1 and 2 above.

Experimental

Electrolyte.—The electrolyte chosen for this work was the maximum-boiling HF-H_2O azeotrope, containing approximately 36 m/o hydrofluoric acid which boils at approximately 112°C (7, 8, 11). This electrolyte has several advantages:

1. Because it is an azeotrope, its composition can be considered essentially uniform with time and position in the system.
2. It can support high current densities at a moderate temperature, allowing a wider range of current densities to be studied, thus simplifying the analysis of results.
3. It has provided for smooth, continuous operation with no cycling of the cell potential or current with any fuel under any of the test conditions.
4. It has fluid properties similar to those of water, so pumping and flow are not a problem.

The electrolyte was prepared from Baker and Adamson reagent grade 48 w/o (weight per cent) hydrofluoric acid having less than 20 ppm impurities, and from quartz-redistilled water. The temperature of operation was 105°C. This is near the maximum operational temperature attainable with this electrolyte at atmospheric pressure, and its selection is consistent with carbon deposition considerations (12, 13) and previously observed performance-temperature relationships (8). Under these conditions, the electrolyte has a resistivity of 1.8 ohm-cm (11).

Apparatus.—All portions of the apparatus which contacted the electrolyte were fabricated of Teflon in order to prevent any contamination of the electrolyte. The cell parts are shown in Fig. 1. The gas compartments were circular, 3 mm deep, and had an area

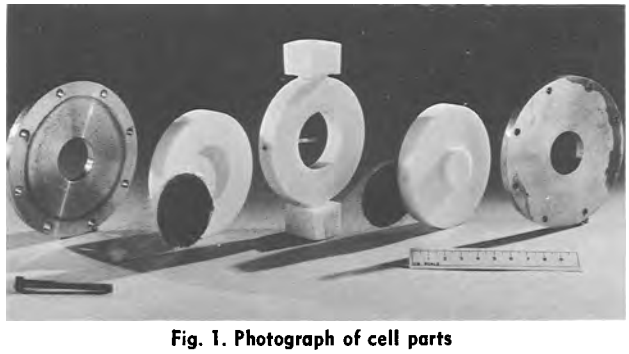

Fig. 1. Photograph of cell parts

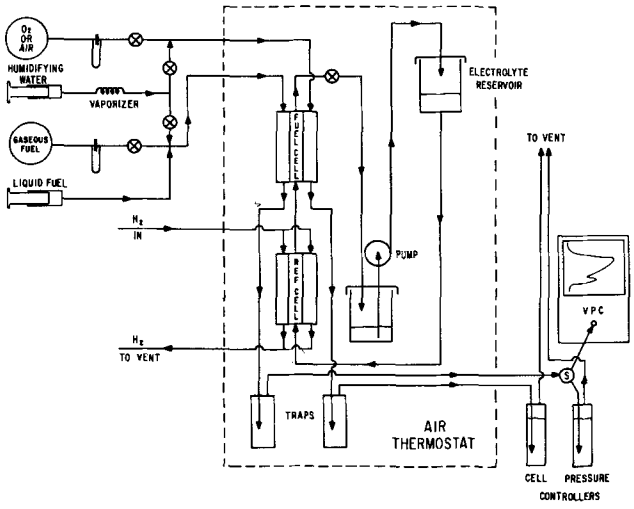

Fig. 2. Schematic diagram of fuel cell apparatus

of 11.38 cm^2. The electrolyte compartment had identical dimensions. The cell parts were assembled with electrodes as shown in Fig. 1. The assembly was held rigid by the Monel end plates and bolts.

A schematic diagram of the entire apparatus is shown in Fig. 2. This apparatus is similar to that discussed in ref. (2), (7), and (8). The fuel cell and an identical reference cell were operated in a forced-convection air thermostat maintained at 105°C. The reference cell contained two high-area reversible hydrogen reference electrodes of Teflon-bonded platinum black. Gaseous fuel and oxidant flows were controlled with needle valves and were monitored using capillary-tube flowmeters. The liquid fuel flow rate was set by use of a constant-speed (0.01%) syringe drive. The injection of humidifying water into either the fuel or oxidant stream was provided for, but this was not required with the azeotropic electrolyte. The exit gas streams from both cells passed through traps (which separated any liquid present) and then to water bubblers before venting. The exit fuel stream could be sampled and analyzed by a vapor-phase chromatograph as desired.

The electrolyte was circulated by gravity from an upper reservoir, passing upward through the reference cell and fuel cell at a flow rate of 2 or 3 cell volumes per minute. The effluent from the upper cell passed into a standpipe to eliminate any syphon action and was collected in a lower basin from which it was pumped to the upper reservoir by means of an all-Teflon microbellows pump. The electrolyte flow rate was controlled by varying the amount of head supplied by the upper reservoir.

Electrodes.—The electrodes were of the Teflon-bonded variety; 45 mesh platinum screen was used both for support and as a current collector. A porous Teflon wetproofing film was incorporated on the gas side of the electrodes. These electrodes were similar in structure to those originally reported by Niedrach and Alford (14), although the preparation techniques were sometimes different, as dictated by the physical properties and behavior of the electrocatalyst materials. When the platinum present in the electrode was in an oxidized rather than an elemental form, the removal of the aluminum foil used as a backing material during the fabrication was done electrochemically. The premature reduction of the catalyst to elemental platinum by the hydrogen generated during the chemical stripping processes was prevented by maintaining the electrode at a potential higher than that required for oxygen evolution. The hydrogen formed during the electrochemical reaction was evolved from a counter electrode sufficiently removed from the test electrode to prevent the hydrogen from diffusing back to the test electrode through the solution. The oxidized platinum present in the test electrode was subsequently reduced under carefully controlled conditions before testing in the fuel cell. This reduction was usually accomplished *in situ* by electrochemical and/or chemical methods.

Electrocatalysts.—Several electrocatalysts were tested, falling into two main categories: unsupported and supported.

The unsupported commercial electrocatalysts tested were platinum, palladium, iridium, and rhodium. The two remaining platinoid elements were not tested for the following reasons: ruthenium is corrosively attacked by the hot hydrofluoric acid electrolyte and osmium forms dangerous volatile oxides under the conditions of electrode preparation. All of the unsupported electrocatalysts were tested in the form of commercial blacks which were prepared by reduction from aqueous solution. The platinum black had a specific area of about 20 m^2/g; the palladium, iridium, and rhodium blacks had lower specific areas. Platinum was also tested by subjecting Adams catalyst ($PtO_2 \cdot H_2O$) to the previously mentioned *in situ* reduction procedures which result in a high-area platinum black. Adams catalyst from two sources was tested: commercial Adams catalyst, and some freshly prepared by the authors and denoted as PtO_2-Preparation A. The Adams catalyst was prepared by the usual procedure involving the oxidation of a platinum salt in a fused sodium nitrate bath (15-21).

Carbon is one of the few inexpensive materials which show excellent resistance to hot acidic electrolytes and is electronically conducting. Many types of carbon power are available, covering a wide range of physical properties. Not all of these powders, however, are compatible with the techniques used in the preparation of Teflon-bonded electrodes. The selection of the candidate substrates is limited to those powders which can be fabricated into useful electrode structures. The carbon powders with low specific areas (10-50 m^2/g) and particle sizes in the range 0.1-10μ have usually been employed with the most success. The one which most consistently yielded useful electrodes is a byproduct of the production of calcium cyanamid from calcium carbide. This carbon powder was obtained from the American Cyanamid Company and its properties are given in Table I (22).

Various carbon-supported electrocatalysts were prepared and evaluated. The carbon powder described in Table I was used as the substrate in every case. These electrocatalysts were prepared by various methods involving the deposition of a platinum salt from an aqueous solution onto the carbon surface. This deposition was followed either by room-temperature hydrogen reduction to elemental platinum (preparation 10) or by roasting in air to prepare an oxidized form of platinum on the carbon surface (preparations 20 and 21). When the oxidized form of platinum was present, the electrocatalyst was subjected to the previously mentioned *in situ* reduction process prior to testing.

Several commercially available carbon-supported electrocatalysts were also evaluated. Specific information concerning their preparation is proprietary and therefore was not available to the authors, but they were prepared by a variety of techniques involving the deposition of platinum black or a platinum salt on the surface of a carbon powder followed by reduction, as necessary.

Table 1. Properties of carbon powder (22)

Purity	99%
Impurities	SiO_2, CaO, Fe_2O_3, Al_2O_3
Particle diameter	0.25-2.0μ
Specific surface area	11.4 m^2/g
Resistivity @ 2000 psi	0.02 ohm-cm
Bulk density @ 2000 psi	1.28 g/cm^3
Porosity @ 2000 psi	40%
Structure	graphite

Fuels and oxidant.—Propane was chosen as the gaseous hydrocarbon fuel of primary interest and n-octane (bp = 125.7°C) was considered to be representative of the liquid hydrocarbon fuels. Matheson instrument-grade propane, 99.5 m/o minimum purity, and Philips research grade n-octane, 99.85 m/o minimum purity, were used. Other fuels tested were: Matheson ultra-high-purity methane, 99.95 m/o minimum purity; Matheson C.P. ethane, 99.0 m/o minimum purity; Matheson instrument grade n-butane, 99.5 m/o minimum purity; Phillips research grade n-pentane, 99.84 m/o minimum purity; Phillips research grade n-hexane, 99.85 m/o minimum purity; Phillips research grade n-decane, 99.49 m/o minimum purity.

The oxidant in every case reported was electrolytic grade oxygen, 99.6 m/o minimum purity.

Electrical measurements.—Electrical measurements were carried out using a 60 Hz modified Kordesch-Marko interrupter circuit (23, 24). The application of the 60 Hz interrupting frequency has been shown to have a limitation when rapid electrochemical reactions take place on electrodes containing only small amounts of active catalyst (25). The recovery of the cell potential during the period of interruption was checked using an oscilloscope to view the cell potential as a function of time during the operation of the interrupter. With an anode containing 8 mg Pt/cm^2 as a carbon-supported platinum electrocatalyst, the cell potential recovered about 5 mv at a current of 455 ma (40 ma/cm^2) when propane was used as the fuel. A high-loading (52 mg Pt/cm^2) platinum black cathode was used at all times, so this 5 mv recovery of the cell potential only reflected processes occurring at the low-loading anode used. This amounted to an error of less than 2%, within the limits of reproducibility of the results, so no correction was made.

The interrupter circuit yielded potential readings on a resistance-free basis and all results are reported on this basis unless otherwise specified. The potentials of the individual electrodes are reported with respect to a reversible hydrogen reference electrode in the same electrolyte at the same temperature. The current-potential data were taken at steady state (usually about 5 min after a change in current) and in the order of increasing current, starting at open circuit. No hysteresis effect was observed with decreasing current, except at low currents (less than 25 ma).

Resistance-included cell voltages (E_{cell}) can be estimated from the reported resistance-free ($E_{a\text{-}c}$) values using the expression

$$E_{cell} = E_{a\text{-}c} - i\rho l \qquad [1]$$

where i is the current density; ρ is the specific resistance of the electrolyte, 1.8 ohm-cm; and l is the interelectrode distance, 0.3 cm. This is only an estimate since it does not consider the (small) resistance of the electrodes.

Results and Discussion

Unsupported electrocatalysts.—The evaluation of commercially available platinoid element blacks was undertaken as a preliminary electrocatalyst survey. Emphasis was directed toward improving the specific activity of platinum when it became apparent that it was at least an order of magnitude better than the other three platinoid element blacks tested. This observation was not unexpected and is consistent with the results of other investigators (26, 27).

The sintering of high-area platinum black to a lower surface area under the conditions of electrode fabrication is one of the major problems obstructing the preparation of high-activity platinum electrodes. It was hoped that this problem could be avoided by starting with a more stable, highly oxidized form of platinum and reducing it to its elemental form after the electrode was prepared. Adams catalyst ($PtO_2 \cdot H_2O$) was selected as the starting material. An *in situ* reduction technique was then developed to accomplish the desired purpose. Initial successes prompted attempts to prepare a more optimal starting material and PtO_2-Preparation A was synthesized. A direct comparison of the propane performance in hydrofluoric acid at 105°C using the three most active unsupported electrocatalysts (Pt black, PtO_2-Commercial, and PtO_2-Preparation A) is shown in Fig. 3, where a loading of 25 mg Pt/cm^2 was used in each anode. It is evident that reduced PtO_2 is a much more active material than platinum black and the PtO_2-Preparation A electrode gave a cell performance (resistance-free) of about 150 ma/cm^2 at an anode *vs.* cathode potential of 0.4v. This was in contrast to 104 ma/cm^2 for commercial PtO_2 and 40 ma/cm^2 for platinum black. These anode *vs.* cathode potentials were calculated by determining the difference between the observed anode *vs.* reference potential and the cathode *vs.* reference potential obtained with a "standard" oxygen cathode (52 mg Pt black/cm^2) at the same current density. This standard oxygen cathode performance was determined by averaging about 15 representative cathode current density-voltage curves; this allowed cell-performance comparisons on the basis of anode performance only. The anode *vs.* cathode potentials for all the cells reported here were determined in a similar manner.

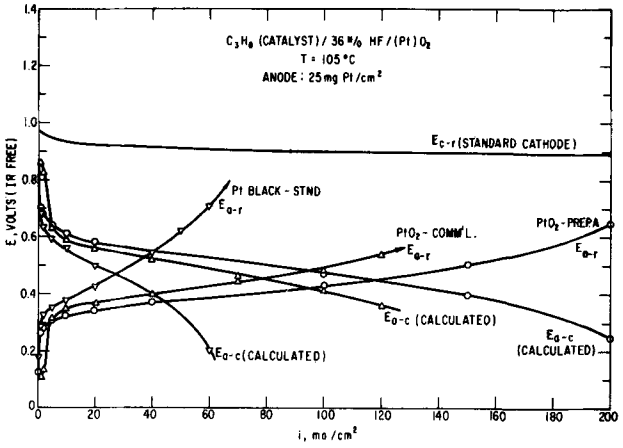

Fig. 3. Comparison of propane performance on the three most active unsupported electrocatalysts.

The propane performances with platinum black and reduced commercial Adams catalyst were determined at several levels of catalyst loading to evaluate the effect of catalyst loading on the specific performance (expressed as ma/mg Pt at an anode *vs.* reference potential of 0.5v). Figure 4 shows the results using

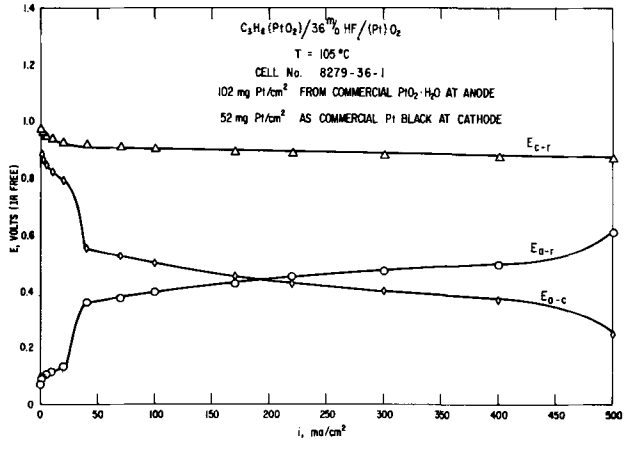

Fig. 4. Propane anode performance on reduced commercial PtO_2

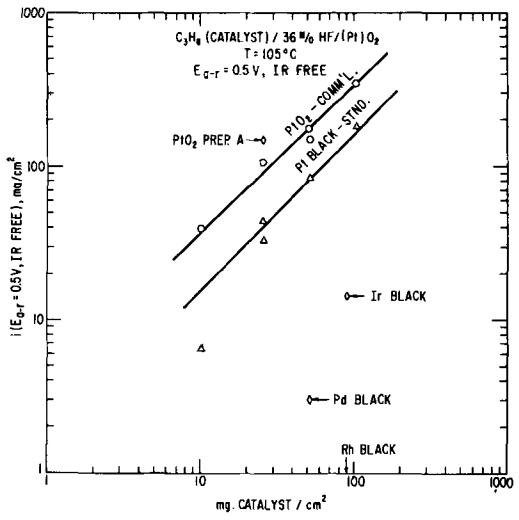

Fig. 5. Summary of the performance of propane on various unsupported electrocatalysts as a function of catalyst loading.

a high-loading anode containing 102 mg Pt/cm² reduced from commercial Adams catalyst. This cell had a limiting current density greater than 500 ma/cm², and a peak power point of about 140 mw/cm². The high platinum loading in this electrode is economically uninteresting, but the data do prove that very high levels of performance are possible with direct hydrocarbon fuel cells at 105°C using propane as the fuel.

All the results for the investigation of the unsupported electrocatalysts are presented in Fig. 5 in terms of the current density obtained with propane at an anode *vs.* reference potential of 0.5v as a function of platinoid element catalyst loading. Note that the data for commercial Adams catalyst and PtO_2-Preparation A fall above the data for commercial platinum black, indicating that these materials have higher specific activities than commercial platinum black, while the data for the other platinoid element blacks fall more than an order of magnitude below the platinum black data. It is also of interest that the data for commercial Adams catalyst and platinum black can be correlated with straight lines having a slope of nearly unity. Straight lines having a unit slope indicate that there is a direct proportionality between catalyst loading and current density. In other words, the specific activity of each of these electrocatalysts remained constant at loadings differing by an order of magnitude (10-100 mg Pt/cm²).

This invariance of the specific performance of an electrocatalyst allows all data to be related to a datum level of performance for ease of comparison. Commercial platinum black was chosen to represent this datum. A so-called "Effectiveness Ratio" was defined as the ratio of the specific performance observed with a given electrocatalyst to the specific performance observed with platinum black, both measured at the same anode *vs.* reference potential, that is

$$\text{Effectiveness Ratio} = \frac{\text{ma/mg catalyst}}{\text{ma/mg Pt black}}, \quad (E_{a\text{-}r} = \text{constant}) \qquad [2]$$

Table II presents this effectiveness ratio along with the data presented in Fig. 5, showing the comparison of propane performance using unsupported electrocatalysts at 105°C in hydrofluoric acid at an anode *vs.* reference potential of 0.5v (resistance-free). The value of the effectiveness ratio in Table II is an indication of the position (relative to platinum black) of a datum point on the current density scale of Fig. 5. As an example, a platinum electrode prepared by reducing PtO_2-Preparation A gave 3.5 times the current observed with a commercial platinum black electrode

at the same loading. This is verified by Fig. 3, where performance data are presented for this particular case.

The effectiveness ratio allows the direct comparison of data obtained with considerably different catalyst loadings and becomes considerably more useful when the supported electrocatalysts are considered.

Carbon-supported electrocatalysts.—Supported electrocatalysts are of interest because the small crystallites which can be obtained by use of supports should make a higher percentage of the platinum available at the surface and thus allow a higher specific area electrocatalyst to be prepared. Supported electrocatalysts also should be less susceptible to sintering because the active crystallites can be widely dispersed on the support surface.

The success of the high-activity platinum black prepared from PtO_2 prompted attempts to combine the expected enhancement produced by supporting the platinum on a substrate with the avoidance of sintering during electrode fabrication by starting with a highly oxidized platinum compound. This thought led to the development of Pt/C-Preparations 20 and 21. The propane performances with Pt/C-Preparation 20 and two commercially prepared carbon-supported electrocatalysts are shown in Fig. 6. The catalyst loadings are comparable, but not equal (4.7-7.1 mg Pt/cm²). The improvement of performance obtained with Pt/C-Preparation 20 is appreciable.

The results from all the electrocatalysts tested are presented in Fig. 7 in terms of the current density obtained with propane at an anode *vs.* reference potential of 0.5v, as a function of the platinoid element catalyst loading. The data for unsupported electrocatalysts previously presented in Fig. 5 are included as closed points for purposes of comparison, while the carbon-supported platinum electrocatalysts are shown as open points. Electrocatalyst Preparations 20 and 21 and Commercial Catalyst 4 show consider-

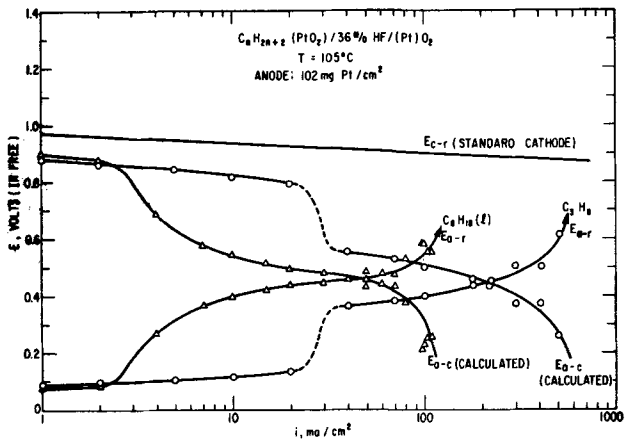

Fig. 8. Propane and n-octane anode performance on reduced commercial PtO_2.

ably higher specific activities than all the other electrocatalysts tested, but tend to deviate from a line of unit slope at the higher catalyst loadings, indicating a decrease in their specific activities. This loss of specific activity is also reflected by the reduction of the effectiveness ratios for propane performance with the carbon-supported platinum electrocatalysts at an anode *vs.* reference potential of 0.4v presented in Table III. This lower anode *vs.* reference potential is useful when comparing the carbon-supported platinum electrocatalysts because they operate at a higher voltage efficiency (28), and are approaching a maximum current condition at an anode *vs.* reference potential of 0.5v, as evidenced by the current density-voltage data presented in Fig. 6. The decrease in the specific activity of the carbon-supported electrocatalysts at high loadings should be alleviated by using substrates having higher specific surface areas. What should be noted is that effectiveness ratios near 10 have been obtained, indicating that a full order of magnitude improvement over the performance observed with commercial platinum black can be attained with these new carbon-supported platinum electrocatalysts. This means that a propane-oxygen fuel cell using 10 mg Pt/cm² at the anode as a carbon-supported electrocatalyst can deliver about 35 mw/cm²

(resistance-free) at 105°C using hydrofluoric acid as the electrolyte.

Other fuels.—A comparison of the performance of gaseous propane and liquid n-octane on reduced commercial PtO_2 is shown in Fig. 8. The propane data presented in this figure are the same as those presented in Fig. 4, and the anode catalyst loading is the same 102 mg Pt/cm². The maximum current density obtained with n-octane was about 120 ma/cm². The ratio of the performances for propane and n-octane shown in this figure is about the same as that reported earlier for platinum black (7). These data again demonstrate, as did Fig. 4, that high levels of performance can be obtained with direct hydrocarbon fuel cells at moderate temperatures, even when liquid hydrocarbons are used as the fuel.

The specific performances of several gaseous and liquid normal saturated hydrocarbon fuels (expressed as ma/mg Pt at an anode *vs.* reference potential of 0.5v, resistance-free) on commercial platinum black, reduced commercial PtO_2 and a commercial carbon-supported platinum are summarized in Fig. 9. The data presented for commercial platinum black in this

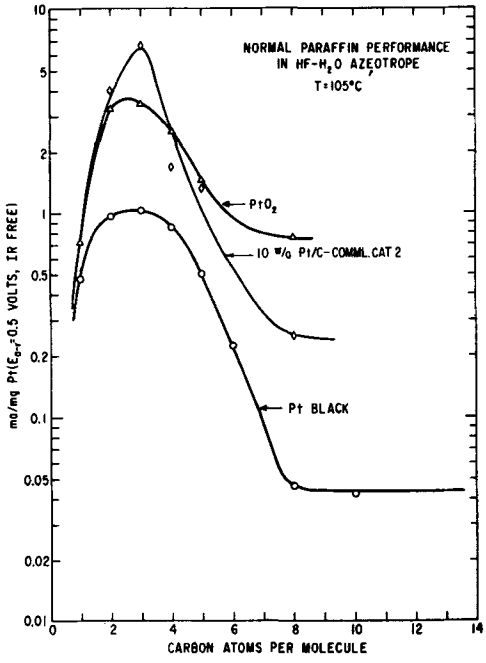

Fig. 9. Effect of molecular weight of normal saturated hydrocarbon fuels on specific performance at the anode. Platinum loadings were 52 mg commercial platinum black/cm²; 102 mg platinum (reduced from commercial $PtO_2 \cdot H_2O$)/cm²; 2.2 mg platinum/cm² as 10 w/o Pt/C, commercial catalyst 2.

figure are not the best performances observed at this catalyst loading (improvements in the electrode structure have allowed better performances to be achieved), but this was the only single electrode for which all the desired data were available. Ethane and propane give slightly higher current densities than butane, which gives higher current densities than the other hydrocarbons. Comparing the standard platinum black with the other two catalysts shows than an improved utilization of the platinum catalyst has been achieved with PtO_2 and Pt/C for all the hydrocarbon fuels tested.

In contrast to other strong-acid electrolytes (3, 29, 30) no cycling of the cell potential or current has been observed when using the hydrofluoric acid electrolyte with any fuel under any of the test conditions. This observation has previously been reported in connection with high-loading platinum black electrodes (7). The present work extends this observation to include other electrocatalysts, including low-loading carbon-supported platinum.

Conclusions

1. Both the use of higher activity forms of unsupported platinum, particularly the one reduced from Adams catalyst, and the use of carbon-supported platinum electrocatalysts are effective in reducing the amount of platinum required for a given amount of power from a direct hydrocarbon fuel cell.

2. Carbon-supported platinum electrocatalysts are effective in reducing the amount of platinum required for a given propane performance by about a factor of 10. Further improvements are likely.

3. A propane-oxygen fuel cell using 10 mg Pt/cm^2 as carbon-supported platinum at the anode can deliver about 35 mw/cm^2 (resistance-free) using a 36 m/o hydrofluoric acid electrolyte at 105°C.

4. No cycling of the cell current or potential has been observed with any saturated hydrocarbon fuel under any conditions when using the hydrofluoric acid electrolyte.

Acknowledgments

The authors wish to thank Dr. W. T. Grubb for information concerning deposition of platinum salts and Messrs. D. J. Surd and G. J. Holm for assistance in performing some of the experiments. Helpful discussions were provided by Dr. E. L. Simons and Dr. J. L. Holman. Mr. L. D. Sangermano, of the General Electric Company, Direct Energy Conversion Operation, supplied some of the Teflon binder used in these experiments.

This work is a part of the program under contracts DA-44-009-AMC-479(T) and DA-44-009-ENG-4909, ARPA Order No. 247 with the U. S. Army Engineer Research and Development Laboratories, Ft. Belvoir, Virginia, to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plants for operation on ambient air and hydrocarbon fuels.

Manuscript received May 23, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Complex Scale Formation on an Iron-18% Chromium Alloy

D. P. Whittle and G. C. Wood

Corrosion Science Division, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The oxidation of a pure Fe-18.0% Cr alloy in oxygen at 1 atm pressure in the temperature range 800°-1200°C has been studied using thermogravimetry, metallography, and electron probe microanalysis. Chromium oxide, containing minor amounts of dissolved iron, is the only oxide formed at 800° and 1000°C. This oxide is also formed initially at 1200°C, but its subsequent mechanical failure permits rapid oxidation of the underlying chromium-depleted alloy. Three types of scale formation are found in this second oxidation stage on different regions of the specimen surface. Each of these types of scale contains alternate layers of chromium-rich and iron-rich oxides. Two of the scale types are eventually healed by formation of a basal Cr_2O_3-rich layer; the third, occurring at the edges of the specimens, grows unimpeded. The mechanism of formation of these stratified scales and, where relevant, their subsequent healing, is explained by a theory involving the variation of the mobilities of Fe^{3+}, Fe^{2+}, and Cr^{3+} ions with composition in the spinel, $FeFe_{(2-x)}Cr_{(x)}O_4$, $(O \leq x \leq 2)$.

When chromium-rich iron-chromium alloys are oxidized in oxygen in the range 800°-1200°C, they form almost pure chromium oxide (1, 2) (subsequently designated Cr_2O_3 because it contains only minor quantities of dissolved iron). More dilute alloys containing 14-25% Cr also form this oxide under all but the severest conditions (1, 3, 4), when failure of the Cr_2O_3 scale allows thick stratified scale to develop. The mechanism of protective scale failure, proposed earlier (1-5), is substantiated here.

The nature of the stratified scales formed on the second class of alloys depends on the surface chromium content of the alloy when it is exposed by the protective scale failure. This critical dependence is exemplified in the present paper by the scales on Fe-18% Cr which vary according to their location around the specimen surface. Generally this type of variation (4) is expected where the bulk alloy chromium content is close to the border-line between protective and nonprotective behavior; in more dilute alloys the situation is not as critical (2, 3), and only one type of stratified scale is produced. Also, with the more dilute alloys, breakthrough and stratified scale growth are disastrous, and complete destruction of the specimen occurs, whereas with the 18% Cr alloy some self-healing of the scale is observed.

Experimental

The Fe-18.0 w/o Cr alloy was made from a base of special Swedish iron and pure chromium by vacuum melting, and subsequent hot and cold rolling to strip 0.040 cm thick (1). The impurity content of a similar alloy of the same batch was: C 0.017, N 0.023, S 0.014, P 0.002, Mn 0.02, Si 0.08, O 0.023, Al 0.04, Ni 0.01, Sn <0.002, Nb <0.006, W <0.05, Ti <0.04, Cu <0.01, Mo <0.005, V <0.004, B <0.0015 w/o.

Specimens 2.5 x 0.5 x 0.040 cm were annealed *in vacuo* (10^{-5} Torr) for 5 hr at 1000°C in order to remove any residual stresses in the alloy and to give a starting material of approximately constant grain size. Immediately prior to oxidation, specimens were individually electropolished for a total time of approximately 3 min in a mixture of glacial acetic acid and perchloric acid (sp gr 1.72) in the ratio 20 parts to 1 by volume. During polishing the current density was maintained in the range 0.4-0.8 amp cm^{-2} and the electrolyte cooled to 15°C. Specimens were then given a minimum cathodic etch at 10 μa cm^{-2} for 90 sec in 4*N* HCl producing a slightly etched but "clean" surface.

After a standard time of 30 min the prepared coupon was rapidly located in the hot zone of a previously heated silica spring thermobalance (sensitivity ± 0.05 mg cm^{-2}) containing slowly flowing dry oxygen (O_2 99.5%, A 0.5%, CO_2 5 ppm, H_2 50 ppm, hydrocarbons 10 ppm, N_2 trace, CO nil, H_2O < 0.15 g^{-3}). Loss of a volatile chromium oxide species [probably CrO_3 (6)] from the oxidizing sample was minimized by surrounding it with a Cr_2O_3-coated crucible. Weight gains were measured within several minutes of exposure and were continued for periods up to 50 hr. At the termination of the run the specimens were cooled to room temperature over a period of about 15 min.

The oxidized specimens were examined in plan by optical microscopy and also in cross section after standard metallographic preparation.

The prepared cross sections, made conducting by a thin carbon film, were also studied in a Cambridge Mark II "Microscan" microanalyzer at 29 kv. The results are presented as scanning x-ray images or as ultra slow-scanning line concentration profiles. The individual points on these traverses indicate where absorption and fluorescence corrections have been made, rather than the location of static probe measurements. The latter were occasionally used to check results. Distances marked on the abcissae scales are measured from the scale/atmosphere interface.

Results and Interpretation

Oxidation kinetics.—The over-all oxidation behavior can be divided into three stages, as shown in Fig. 1 which gives the weight gain/time curves at 1200°C. These three stages are: (*a*) an initial protective stage, shown in detail in the inset of Fig. 1, (*b*) a period of very rapid, apparently linear, oxidation, and (*c*) a further period of slow protective oxidation.

(*a*) During this period at 1200°C there was generally good agreement between the weight gains of the various specimens and of the time taken to breakthrough, (typically 1 hr, although it varied between 45 min and 2 hr). The scale thickened at an approximately parabolic rate, the mean rate constant being 8 x 10^{-10} g^2 cm^{-4} sec^{-1}. This is only slightly higher than that for alloys richer in chromium at this temperature (1, 2).

At 800° and 1000°C only this oxidation stage occurs, at least up to 50 hr. Growth occurs reproducibly with only a slight negative deviation from the parabolic law, as has been observed for alloys richer in chromium (1, 2). At 1000°C, the parabolic rate constant is 4.3 x 10^{-11} g^2 cm^{-4} sec^{-1} compared with 5.8 x 10^{-11} g^2 cm^{-4} sec^{-1} for an Fe-28% Cr alloy of similar purity (1, 2). Corresponding rate constants at 800°C are 1.0 x 10^{-12} and 4.7 x 10^{-12} g^2 cm^{-4} sec^{-1}.

(*b*) The linear oxidation rate during the second

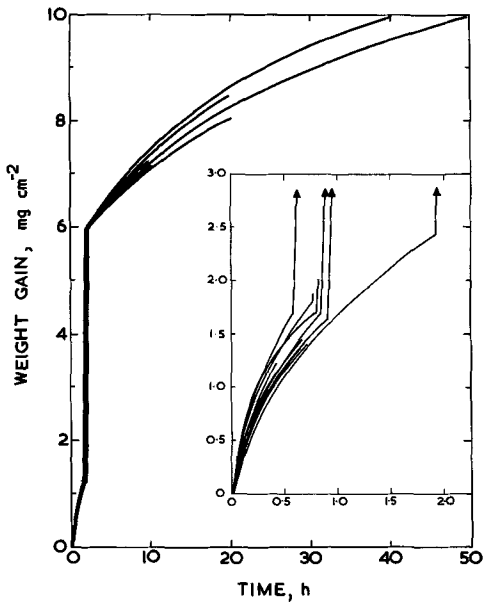

Fig. 1. Weight gain/time curves for the oxidation of Fe-18.0% Cr at 1200°C in oxygen.

stage was (5.1-6.5) x 10^{-6} g cm^{-2} sec^{-1}, corresponding approximately to a rate of increase in scale thickness of 0.6 μm min^{-1} which is considerably slower than the corresponding value for an Fe-14.0% Cr alloy (5 μm min^{-1}) (2). However, these rate constants carry very little meaning as they refer only to the very rapid localized nodular scale growth, as will be seen later. This stage of oxidation lasted in all cases until a weight gain of approximately 6.0 mg cm^{-2} had been obtained, this probably being when the whole specimen surface had been subjected to rapid oxidation.

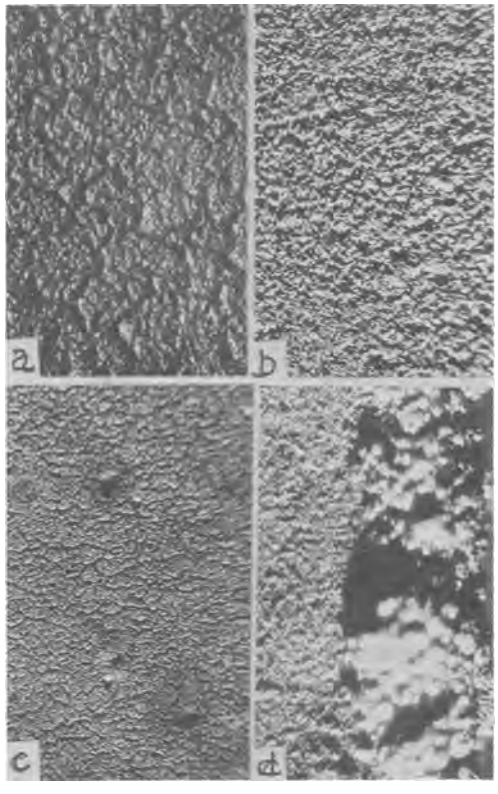

Fig. 2. Surface topography of scales formed on Fe-18.0% Cr; oblique illumination: a, 1 hr at 1000°C, magnification *ca.* 80X; b, 50 hr at 1000°C, magnification *ca.* 80X; c, 5 hr at 1200°C, magnification *ca.* 24X; d, 50 hr at 1200°C, magnification *ca.* 24X.

(c) During the final stage, the weight gain/time curves again apparently follow a parabolic law, with the parabolic rate constant slightly greater than that during the first stage. The absolute value of the rate constant is not important because the scale being formed shows marked differences around the specimen. However, metallographic examination shows later that a "healing" layer of Cr_2O_3 is growing over most of the surface, accounting for the similarity between the rate constant here and that during the first stage.

Surface metallography.—At 800° and 1000°C the superficial appearance of the scale was reasonably uniform except that the alloy grain boundaries were replicated in the scale, Fig. 2a. As oxidation proceeded, the scale surface became less angular in nature and the alloy grain boundaries were not observed, Fig. 2b; scales formed in the initial stages at 1200°C were similar. Occasionally, the scale formed at 1000°C showed nodular growths, Fig. 2c, approximately 50-80 μm in diameter and 10 μm high. This failure of the protective scale was always very localized and never showed any tendency to spread by disrupting adjacent areas of protective scale. Furthermore, nodular growth was always so slight at 1000°C as to be undetectable in the weight gain/time curves. At 1200°C, nodular growth was much more extensive and, once initiated, spread rapidly over the whole specimen. Generally, the scales at the edges of the specimen appeared much thicker than over the remainder of the surface and had a characteristic silvery appearance, Fig. 2d.

Metallography in cross section and electron probe microanalysis.—For ease of presentation this section is divided into three parts corresponding to the three stages noted in the oxidation kinetic curves at 1200°C.

Initial protective oxidation stage.—Only Cr_2O_3 was observed during this stage of the oxidation. However, the morphology of the scales formed at 800° and 1000°C was considerably different from that formed at 1200°C. At the lower temperatures, the Cr_2O_3 scale was a single layer and did not vary in thickness around the prepared cross section by more than about 30%. At 1200°C, the scale was highly irregular and contained many oxide balloons (Fig. 3). The extent to which the irregularities in the scale have been accentuated by the metallographic preparation and differential contraction between scale and alloy on cooling from the oxidation temperature is difficult to establish. The irregularity of the alloy/oxide interface is possibly indicative of scale lifting at temperature, but it is more likely to be due to plastic deformation of the alloy surface layers (7) by stresses in the specimen. In any event, the alloy/oxide interface was more rugged than that of other Fe-Cr alloys (27.4 and 59.5% Cr) when oxidized at this temperature (1, 2). Cracking at temperature of Cr_2O_3 scale lifted

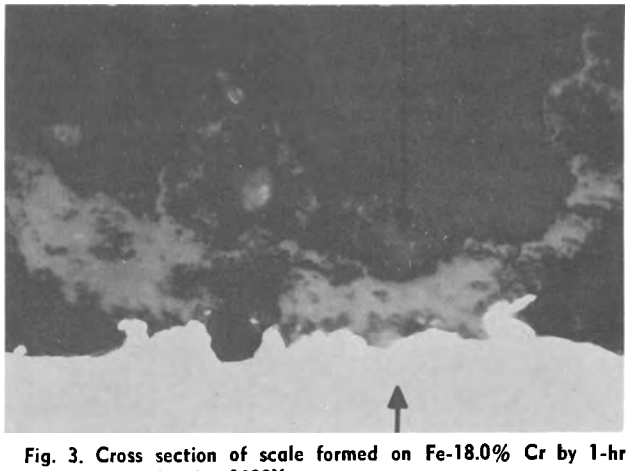

Fig. 3. Cross section of scale formed on Fe-18.0% Cr by 1-hr oxidation. Magnification 1000X.

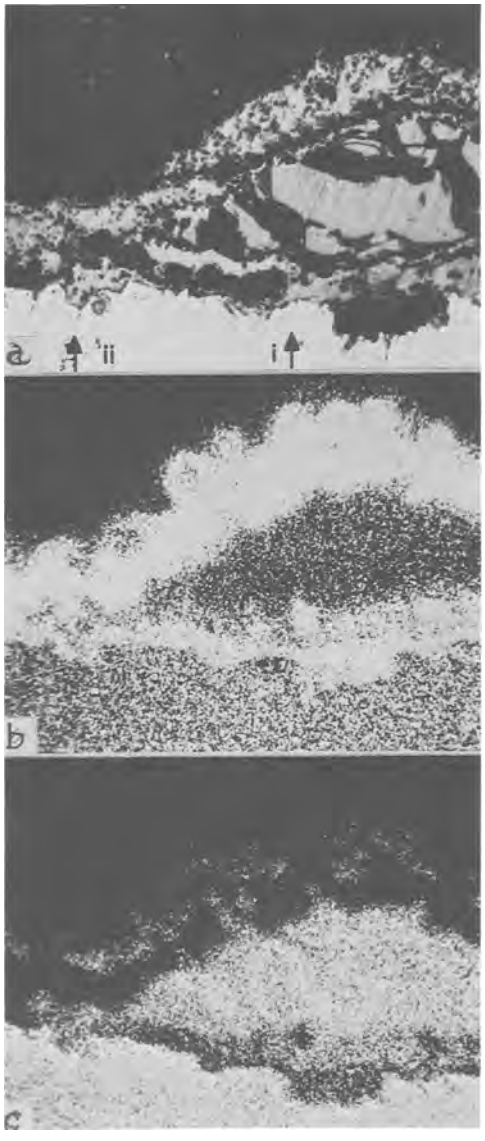

Fig. 4. Cross section of scale formed on Fe-18.0% Cr by 70-min oxidation at 1200°C: a, optical; b, KαCr image; c, KαFe image. Magnification *ca.* 400X.

from the alloy followed by re-formation of Cr_2O_3 is unlikely because the chromium concentration at the alloy/oxide interface is too low (5). Certainly the layered-type of Cr_2O_3 scales found on Fe-59.5% Cr oxidized at this temperature are absent (1, 2).

A typical electron probe microanalysis of a Cr_2O_3 scale formed after 50-hr oxidation at 1000°C gave 60.2% Cr and 1.5% Fe. These values can be normalized to a total metal content of 67.6% as most of the error is due to overlapping effects of the x-ray source in analyzing these thin films; normalized values are 65.9% Cr and 1.7% Fe. A similar analysis, 60.7% Cr and 1.1% Fe (normalized values 66.4% Cr and 1.2% Fe) was obtained for the scale formed for 1 hr at 1200°C.

The chromium concentration profile in the alloy, along the line shown in Fig. 3, indicates a relatively sharp decrease in chromium concentration near to the alloy/oxide interface down to a value of 9.5% Cr. Although not easily detectable in the microanalyzer the chromium-depleted zone should reach about 120 μm into the alloy because the alloy interdiffusion coefficient is relatively large (5).

Linear oxidation stage.—Generally, when the oxidation was terminated during this stage, there were areas of the specimen surface still covered by Cr_2O_3 and areas of fully developed stratified scale, described in the next section. As the linear oxidation stage proceeded, only the relative areas of the specimen surface covered by these two types of scale changed. The stratified scale must have grown extremely rapidly as it was very difficult to obtain examples of the scale at the start of its growth.

Figure 4a shows how the protective Cr_2O_3 separated away from the alloy surface and how stratified scale was formed beneath it. Other similar configurations of Cr_2O_3 and stratified scale are possible (1-4), but none shows the mechanism as clearly as Fig. 4a. The outer layer of Cr_2O_3 is visible over the whole field of view, Fig. 4b. At the left side of the micrograph, the Cr_2O_3 is adjacent to the alloy whereas over the remainder of the visible surface it is separated from the alloy by a mixed oxide nodule, Fig. 4b and 4c. The thickness of this outer Cr_2O_3 layer is independent of its position in the scale because it was formed during the first stage of oxidation. All the oxide layers are very porous, but this is largely connected with the poor metallographic preparation. The concentration profiles, Fig. 4d, across the line marked (i) in Fig. 4a confirm the general pattern of the elemental distribution shown in the x-ray images. The outer oxide is Cr_2O_3 as it contains 66.9% Cr and only 0.3% Fe. The remaining part of the scale is similar to the double layer scales observed on other alloys (1-3); an outer, almost pure iron oxide layer 30 μm thick, and inner, mixed layer containing undulating chromium and iron concentration profiles, also 30 μm thick. In order to identify these oxides completely, x-ray diffraction of the scales would be necessary. However, until a technique for microdiffraction becomes available, bulk analysis of scales stratified on such a fine scale is not very informative.

Traverses across lines such as (ii) in Fig. 4a show a simple Cr_2O_3 scale together with a chromium depletion in the underlying alloy.

Third stage of oxidation.—During this final stage, four general types of scale are found around the specimen cross sections: (i) over most of the specimen surface a stratified scale containing a chromium-rich layer at the alloy/oxide interface; (ii) a thicker stratified scale without the chromium-rich basal layer and usually confined to areas close to the specimen edges; (iii) a stratified scale intermediate between types (i) and (ii) also found near to specimen edges; and (iv) areas where the initial protective Cr_2O_3 scale still remained.

Figure 5a, together with its x-ray images 5b and c, shows a typical area where scales of type (i) and (iv) are adjacent. Clearly the thinner, protective oxide in these areas is Cr_2O_3 containing very little iron. The thicker, nodular oxide contains layers of chromium-rich and iron-rich oxides and is discussed more fully later.

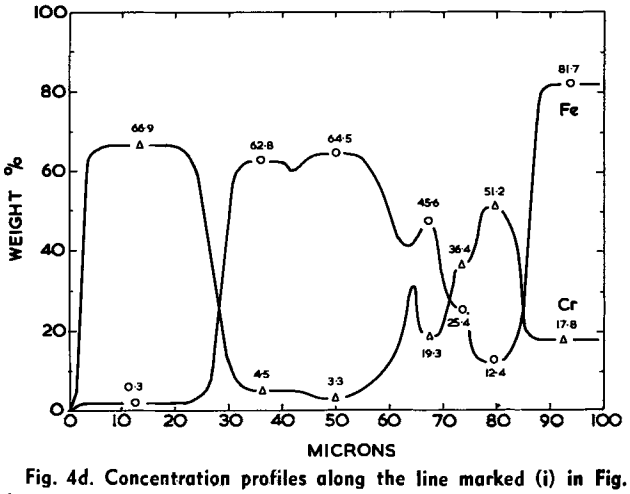

Fig. 4d. Concentration profiles along the line marked (i) in Fig. 4a.

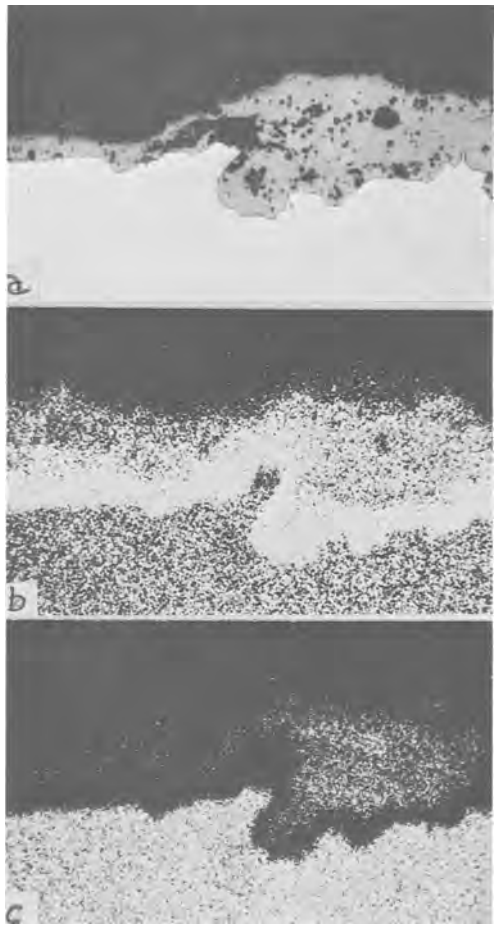

Fig. 5. Cross section of scale formed on Fe-18.0% Cr by 10-hr oxidation at 1200°C: a, optical, b, KαCr image; c, KαFe image. Magnification ca. 400X.

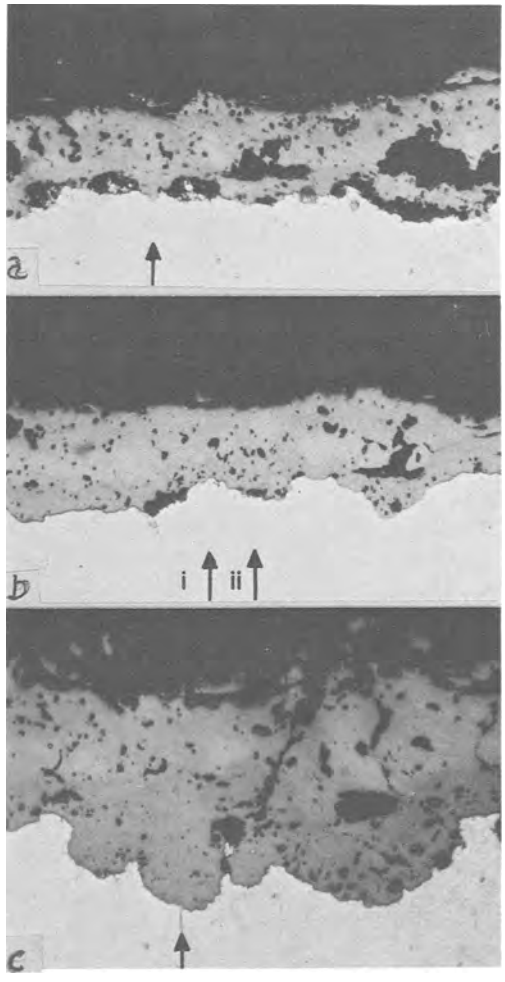

Fig. 6. Cross sections of scale formed on Fe-18.0% Cr by: a, 5-hr oxidation at 1200°C; b, 10-hr oxidation at 1200°C; c, 50-hr oxidation at 1200°C. Magnification ca. 400X.

Figure 6a, b, and c show the typical growth sequence of scales of type (i), these specimens having been oxidized for 5, 10, and 50 hr, respectively. The individual oxide layers are more easily distinguishable in the corresponding concentration profiles measured along the lines marked in Fig. 6a, b, and c and presented in Fig. 7a, b (i and ii) and c, respectively. Two traverses, (i) and (ii), are given in Fig. 7b corresponding to lines (i) and (ii) in Fig. 6b. In Fig. 7a two outer layers, not separable in the photomicrograph (Fig. 6a), are indicated, the outer one being richer in iron. Beneath these is an iron-rich, lighter-colored phase which does not form a continuous layer in the scale (Fig. 6a). The layer adjacent to the alloy/oxide interface is Cr_2O_3 and is approximately 3-4 μm thick. There is no internal oxide.

Scales of this type do not increase very greatly in thickness as oxidation proceeds. Figure 7b shows that all the increase in thickness after oxidation for 10 hr is associated with the thickening of the inner Cr_2O_3 layer, now 6-7 μm thick. The two traverses (i) and (ii) again show that the light-colored, iron-rich oxide does not form a continuous layer in the scale, being present in scan (i) but not in scan (ii). Furthermore, interdiffusion appears to have taken place between the two outer layers, although there is still an enrichment of iron at the scale/atmosphere interface.

After oxidation for 50 hr the inner Cr_2O_3 layer is about 30 μm thick (Fig. 6c). There is the expected distribution of iron and chromium across the scale (Fig. 7c) with interdiffusion between all the scale layers, except the innermost Cr_2O_3 layer, being well advanced. Again no internal oxide is present, although this is hardly surprising behind as stable an oxide as Cr_2O_3.

A typical scale of type (ii) which, as stated previously, occurs at the ends of the specimen cross sections, is presented in Fig. 8a. The darker colored oxide, typical of Fe_3O_4, is observed in these regions whereas it did not appear to be present in the other types of scales. Furthermore, this darker colored phase is surmounted by a lighter colored oxide, Fe_2O_3 while the inner scale is apparently porous. Reference to the x-ray images, Fig. 8b and c, indicates that there is no Cr_2O_3 layer at the base of this type of scale and as a result of this, the formation of internal oxide,

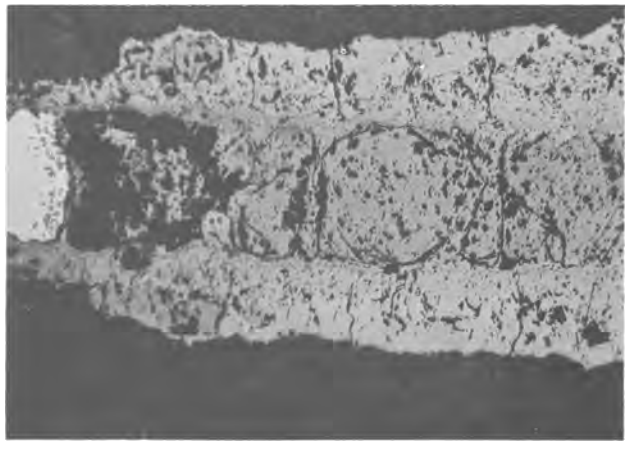

Fig. 9. Cross section of scale formed on Fe-18.0% Cr by 50-hr oxidation at 1200°C. Magnification 75X.

which is now possible, occurs. Figure 9 shows that the growth of type (ii) scale remains unchecked, causing the alloy to be completely converted into oxide. The inner region of this large nodule is again very friable and contains many pores. However, most of these are probably introduced during the metallographic preparation. Internal oxide particles do not appear to have increased in population with the increasing oxidation time.

Finally, the fourth type of scale, (iii), is shown in Fig. 10a, b, and c. The quantitative analyses of the scale (Fig. 10d) indicate the usual layered structure.

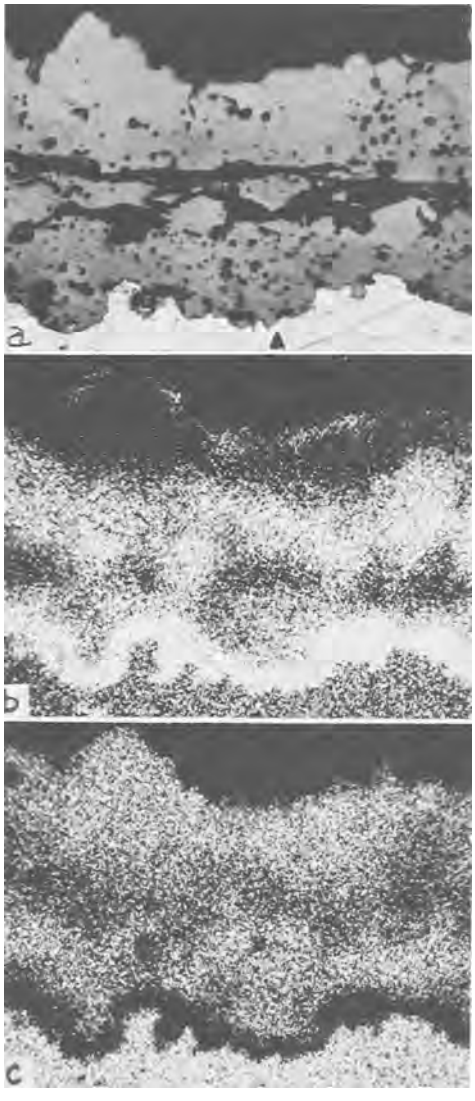

Fig. 10. Cross section of scale formed on Fe-18.0% Cr by 5-hr oxidation at 1200°C: a, optical; b, KαCr image; c, KαFe image. Magnification *ca.* 400X.

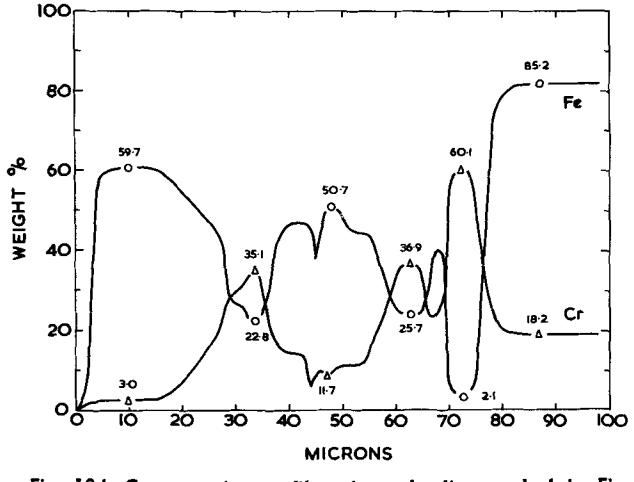

Fig. 10d. Concentration profiles along the line marked in Fig. 10a.

Comparison of these profiles with those for type (i) scale (Fig. 7a, b, or c) indicates a certain similarity. The three outer layers of type (i) scale appear in duplicate in this type (iii) scale, surmounting the usual Cr_2O_3 layer at the alloy/oxide interface. Again no internal oxide is present.

Discussion

Formation of the protective oxide Cr_2O_3.—The only oxide formed at 800° and 1000°C, and during the first stages of oxidation at 1200°C is Cr_2O_3. The growth mechanism of this oxide is presumably similar to that on alloys richer in chromium, namely, predominantly by cationic diffusion as discussed elsewhere (1, 2). Certainly, the parabolic rate constants are of a similar magnitude.

The iron content of the Cr_2O_3 scales was always small and decreased with time, the actual weight of iron in the scale remaining constant and equal to that present in the "initial film" as discussed previously (1, 2). No spinel, of the type $FeFe_{(2-x)}Cr_{(x)}O_4$ ($O \leq x \leq 2$), was ever observed metallographically, nor the associated higher iron contents by microanalysis. If this oxide were formed initially, then it must have been rapidly replaced by Cr_2O_3.

At 800° and 1000°C, there was in general no cracking of the protective oxide at temperature, no double layers of Cr_2O_3 were formed and very little roughening of the alloy/oxide interface occurred. At 1200°C, however, a roughened alloy/oxide interface was formed, and there was ballooning of the Cr_2O_3 scale, although this latter could have occurred on cooling the specimen from the oxidation temperature. When cracking of the Cr_2O_3 scale occurs at 1200°C, Cr_2O_3 is not re-formed as it is with alloys richer in chromium (1,2), because the chromium concentration at the alloy/oxide interface is too low (5). Instead rapid scaling or breakthrough occurs.

Mechanism of breakthrough.—At 1200°C, the end of the protective oxidation and commencement of rapid attack occurs at apparently random sites over the specimen surface. The suddenness of the onset of rapid oxidation, together with the observance of only protective Cr_2O_3 immediately prior to breakthrough, is indicative of a mechanical cracking mechanism (1, 3-5) rather than a "chemical mechanism" (8-10) for the transformation in oxidation rate. Providing that the Cr_2O_3 scale formed initially remains in contact with the alloy, or becomes detached without puncturing, there is no reason why it should not continue to grow. A simple calculation (5) shows that Cr_2O_3 is thermodynamically stable with an Fe-Cr alloy containing as little as 0.2% Cr at 1200°C. Calculated chromium concentration profiles (5) which, due to the assumptions made, give the minimum possible chromium concentrations, indicate that the interfacial chromium concentration at 1200°C increases from 4.8% after 10-min oxidation to 5.5% after 5-hr oxidation. Generally, experimentally measured values are not as low as this. Thus, the Cr_2O_3 scale formed at the start of oxidation never becomes thermodynamically unstable, and its subsequent failure is simply due to mechanical causes. This is further emphasized, in that at 1000°C where breakthrough does not generally occur, the chromium concentration at the alloy/oxide is calculated to be 2.5% after 10-min oxidation and 7.1% after 5 hr.

Apparently, the loosely attached protective scales balloon from the alloy surface before cracking open so that relatively large areas of the chromium-depleted underlying alloy are eventually exposed; rapid scaling through simple cracks in the protective scale would soon be stifled (1, 3). Presumably the punctured chromium oxide envelope is eventually lost completely from the specimen as it is never observed after breakthrough. In other instances it can stifle the growth of the stratified scale (4) or be slowly incorporated into the growing nodule (2).

Loss of the protective oxide need not occur simultaneously over the whole specimen surface. Cracking of one or two voids initially, followed by very rapid scaling there, would be sufficient to give the observed sudden increases in weight. Intermittent opening of other cavities in rapid succession would then result

in the smooth weight gain/time curves produced. Such failures would be expected randomly, but possibly the development of stratified scale in some places tends to disrupt the protective oxide in nearby locations. Overheating of the specimen may be important under catastrophic oxidation conditions.

It is extremely difficult to isolate one factor as the cause of the loss of protective scale, and probably it is a combination of factors: scale thickness, scale plasticity, alloy ductility, phase changes, adhesion between alloy and oxide and alloy and/or oxide grain growth. Detailed discussion of these factors is given elsewhere (1, 2).

Growth of stratified scale.—The scale formed at breakthrough depends implicitly on the chromium concentration at the surface of the underlying alloy when directly exposed to the atmosphere. Generally the higher the bulk alloy chromium content the higher is the chromium content at the alloy/oxide interface when it is exposed, although other factors, oxidation rate, alloy interdiffusion rate, time, are also important (5). Specimen geometry is also sometimes important because larger depletions of chromium are expected near to the specimen edges (chromium being used up from such regions by oxide growth on two or more nearby faces simultaneously) and at locations of thin section. With the present Fe-18% Cr alloy, the chromium concentration at the alloy/oxide interface when breakthrough occurs is near to the borderline between that for formation of type (i) and type (ii) scales. Thus, at the edges of specimens where lower chromium contents are likely type (ii) scales, typical of alloys of lower bulk chromium content, are formed. Over most of the remainder of the surface type (i) scales are formed, while at intermediate locations, type (iii) scales are formed.

At breakthrough, the chromium concentration at the alloy/oxide interface is never high enough for the immediate re-formation of a Cr_2O_3 scale as is observed for higher chromium alloys (1, 2) and a mixed iron and chromium oxide is formed. Whether this mixed oxide is the spinel, $FeFe_{(2-x)}Cr_xO_4$ ($O \leq x \leq 2$), or the rhombohedral oxide, $Fe_{(2-x)}Cr_xO_3$ ($O \leq x \leq 2$) or even mixtures of the two is relatively unimportant as both these oxides can vary continually with composition. For the purposes of this discussion, it is assumed that the spinel plays the major role in determining the subsequent oxidation behavior, particularly as this is the more favored phase at chromium levels of this magnitude (11).

Thus, the start of stratified scale growth is the formation of a spinel on the alloy surface exposed by the loss of protective Cr_2O_3. Initially the spinel is of uniform composition, but the chromium content of the spinel is dependent on the chromium concentration at the alloy surface when this is exposed; it is lower where type (ii) scales eventually develop than where type (i) scales are formed. The spinel produced in the chromium-rich areas may in fact be the normal spinel as evidenced by its composition (12). The situation at this stage is shown schematically in Fig. 11a, for scales of types (i) and (ii); type (iii) scales are similar to these and are discussed later.

Soon after the spinel is initiated, the faster diffusing iron ions start to segregate at the outer scale surface, leaving a chromium-rich region at the alloy/oxide interface (Fig. 11b), a distribution favored thermodynamically. If the scale is mainly spinel, then the value of x in the formula $FeFe_{(2-x)}Cr_xO_4$ varies through the scale, increasing as the alloy/oxide interface is approached (13). In general, the ionic mobilities in chromite spinels are lower than in ferrite spinels (14) making interdiffusion rates slower in type (i) scales than in type (ii) scales. Thus, in the former scales the segregation is not as complete as in type (ii) scales where the virtually pure spinel magnetite is formed at the surface of the scale, this being further oxidized to Fe_2O_3 in a manner similar

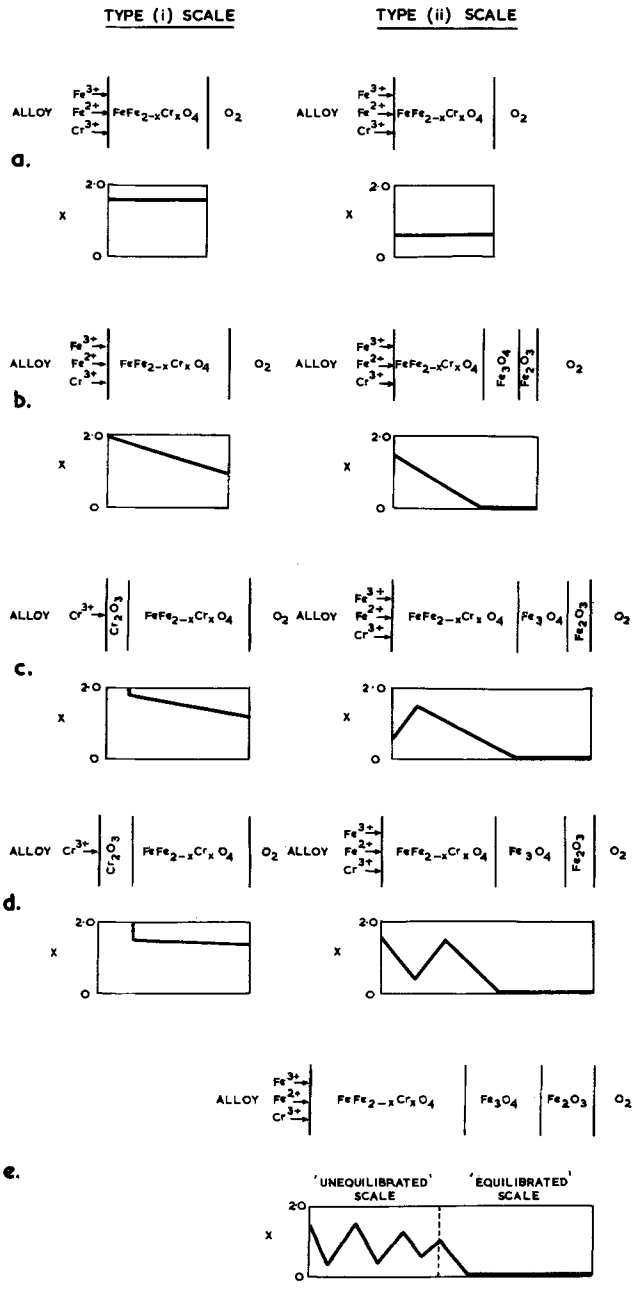

Fig. 11. Schematic diagram of the formation of scales of type (i) and (ii).

to that formed on pure iron. Clearly the over-all growth rate of type (ii) scales will be greater than the more chromium-rich type (i).

When the chromium content of the spinel in the vicinity of the alloy/oxide interface increases it acts as a partial barrier to the continued diffusion of iron ions to the outer scale layers. Consequently, a second iron-rich layer is formed beneath this barrier, resulting in a second chromium-rich barrier layer at the alloy/oxide interface. This is shown schematically for type (ii) scales in Fig. 11c and d. Further growth of type (ii) scales occurs by the continued formation of these iron-rich and chromium-rich oxides, resulting in the complex distribution of alternate iron-rich and chromium-rich layers found in these scales. With type (i) scales, the formation of the chromium-rich spinel at the alloy/oxide interface is closely followed by the formation there of the rhombohedral oxide, Cr_2O_3, containing only a very small amount of dissolved iron (Fig. 11c). Iron from the alloy cannot now enter this Cr_2O_3 layer at the base of the scale unless

the chromium concentration falls to about 0.2% at 1200°C (5), thus the supply of Fe^{2+} and Fe^{3+} ions to the outer scale layers is terminated. Further scale growth (Fig. 11d) of type (i) scale is, therefore, only the continued thickening of the Cr_2O_3 layer, the reaction at the Cr_2O_3/spinel interface being

$$3FeFe_{(2-x)}Cr_xO_4 + (6\square''' + 3\square'')_{spinel} = 4Cr_2O_3 + (8\square''')Cr_2O_3$$

where $(\square''')_{spinel}$, $(\square'')_{spinel}$, and $(\square''')_{CrO_3}$ represent trivalent and divalent cation vacancies in the spinel and trivalent cation vacancies in the rhombohedral oxide, respectively.

Scales of type (iii) are formed in an identical manner to those of type (ii) except that several pairs of iron-rich and chromium-rich layers are formed before the scale is healed by a Cr_2O_3 layer as described for type (i) scales. Further discussion of scale healing by Cr_2O_3 is reserved for the final section.

During later growth of all these scales the undulating chromium and iron concentration profiles tend to approach steady-state conditions. In type (i) scales this is seen in the sequence Fig. 7a-c where interdiffusion has reduced the compositional differences between the three layers. This process is essentially slow because ionic mobilities in the chromium-rich spinels are relatively low. However, it is assisted by the inner Cr_2O_3 layer preventing further thickening of the outer spinel layers. Possibly these outer spinel layers are oxidized further to the corresponding mixed rhombohedral oxide.

In type (ii) scales, the levelling out of the compositional differences between iron-rich and chromium-rich layers has to take place simultaneously with the continued growth of these layers. Thus, local activity gradients in the scale, which are not necessarily in the same direction as the over-all activity gradient, are gradually being removed as the scale grows under the over-all activity gradient between alloy and oxidizing atmosphere. Figure 11e shows this situation where the outer scale represents the steady state (a smooth activity gradient) and the inner scale the nonsteady state (an undulating activity gradient), the degree of "equilibration" decreasing as the alloy/oxide interface is approached.

Internal oxidation never occurs behind healed scales because the Cr_2O_3 at the alloy/oxide interface is thermodynamically very stable. In other instances, penetration of internal oxide particles into the alloy is never very great because the diffusion rate of oxygen into the alloy is not much faster than the rate of encroachment of the alloy/oxide interface. Incorporation of internal oxide particles into the surface scale would cause further stratification and local concentration gradients in the inner layers.

Mechanism of scale healing.—The reasons why stratified scale is healed along the sides of the specimen and not at the edges is not entirely clear. As soon as breakthrough occurs and rapid scaling starts, the chromium depletion established during the initial Cr_2O_3 formation is rapidly consumed. However, the alloy is not completely equilibrated as there is still a degree of selective oxidation of chromium during the rapid scaling.

Scale healing is associated with the formation of a continuous layer of the protective oxide, Cr_2O_3, in the present system, as opposed to a discontinuous layer or internal oxide of Cr_2O_3. After the start of rapid scaling, oxygen produced by dissociation of the surface scale at the alloy/scale interface diffuses into the alloy producing an internal oxide precipitate of Cr_2O_3. If the volume fraction of this internal oxide is above a certain critical level, then further formation of Cr_2O_3 will occur by sideways growth of the existing internal oxide particles (15). When the volume fraction is below the critical level, new Cr_2O_3 internal oxide precipitates are formed deeper in the alloy. Under the former conditions, continued sideways growth of the Cr_2O_3 particle results in a continuous "healing" Cr_2O_3 layer being formed, providing the rate of encroachment of the alloy/oxide interface is not so fast as to cause the Cr_2O_3 particles to be incorporated into the scale before they link up. Where continued nucleation of Cr_2O_3 particles occurs, a continuous layer will never be formed and scaling continues unchecked.

Factors governing the formation of this critical volume fraction of internal oxide include: (*a*) the chromium concentration profile in the alloy at the time of breakthrough; (*b*) the alloy interdiffusion coefficient which governs the flux of chromium atoms to the alloy/oxide interface; (*c*) the oxygen diffusion rate in the alloy; (*d*) the oxygen pressure at the alloy/external scale interface; and (*e*) the over-all oxidation rate. Comparing the edges of the specimens with the remainder of the surface, the interdiffusion coefficients, (*b*) and (*c*) above, will be the same. However, the other factors tend to favor healing along the sides of the specimens as compared to the edges of the specimens. Thus the lower local chromium concentrations at the edges of specimens, as discussed earlier, promote more iron-rich spinels in the external scale and therefore faster oxidation rates and higher effective oxygen pressures at the alloy/scale interface. Consequently Cr_2O_3 continues to be precipitated as internal oxide rather than form a continuous layer.

In order to understand more quantitatively the formation and healing of scales of this type, more information on diffusion and lattice defects in ternary oxides is required. Using thermodynamic and transport data it is possible at present to predict the final steady-state scaling conditions, but little can be said about the rate at which the steady state is approached or about the scaling behavior during the transient period. Presumably a more sophisticated theoretical approach will permit this.

Acknowledgments

The authors' thanks are due to Professor T. K. Ross for providing facilities and encouraging this study. They are also indebted to the Science Research Council for providing the electron probe microanalyzer and for a research studentship to one of them (D.P.W.) from October 1962 to September 1965.

Manuscript received May 15, 1967; revised manuscript received July 5, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Electron Diffraction Studies of Active, Passive, and Transpassive Oxide Films Formed on Iron

C. L. Foley, J. Kruger, and C. J. Bechtoldt

National Bureau of Standards, Washington, D. C.

ABSTRACT

Iron foil specimens were anodically polarized by means of a potentiostat in 1*N* H_2SO_4, 0.1*N* NaOH, and a sodium borate-boric acid solution (*p*H, 8.5). Both passive, active, and transpassive regions of the polarization curve were studied for each solution. The oxide films were examined while still in contact with the iron foil by selected area transmission electron diffraction. Five iron planes were studied: {100}, {110}, {111}, {210}, and {211}, and the epitaxial relationship of the oxide to the iron substrate determined. Evidence was found indicating that in all of the electrolytes used the passive film contained γ-Fe_2O_3, while the nonpassive films did not.

Of prime importance to our understanding of the nature of the phenomenon of passivity is a knowledge of the nature of the passive film. This includes its composition, structure, and relationship to the metal surface on which it was formed. There has not been a concentrated effort to discover the nature of the film, but there have been a few such studies (1-3) of the passive film on iron. Due to the thinness of the films, these studies have involved the use of electron diffraction. Two techniques, in particular, have been used. One is film stripping coupled with transmission electron diffraction; the other is reflection electron diffraction, leaving the film still in contact with the metal surface on which it was formed. The first technique has the advantage that the quality of the patterns obtained allows one to detect the weaker oxide reflections rather easily, but has the disadvantage that the film must be removed from the substrate under rather corrosive conditions. Mayne and Pryor (1) have evidence to show that the removal procedure does not chemically alter the film, although the possibility always exists that subtle changes may have occurred. Another problem associated with film stripping is that the film may change structurally during or subsequent to being detached from the metal surface. For example, stress existing in the film while it is attached to the metal may be relaxed upon stripping, thereby changing the lattice parameter and, as Mayne and Pryor (1) have suggested, may produce recrystallization of the film. The reflection technique, while it does look at films still in contact with the metal, is less able to detect weak oxide reflections because they may be hidden by the elongated stronger metal and oxide reflections.

This study attempts to combine the advantage of reflection diffraction (looking at the film while it is still on the metal) with that of transmission diffraction (greater sensitivity). This is accomplished by producing both passive and nonpassive oxide films on thin metal foils, of the type used so effectively in many recent transmission electron microscopy studies of metals (2). Selected area diffraction enables us to look at double layers of the film (one on each side of the foil) on metal grains of many different crystallographic orientations. The epitaxial relationships between the substrate iron and the film can thus be easily determined for many orientations without the necessity of using large iron single crystals. The film-metal-film "sandwich" doubles the amount of passive film studied and thus increases the possibility of detecting the weaker oxide reflections that are necessary to distinguish between Fe_3O_4 and γ-Fe_2O_3. This is of importance since a number of workers have indicated that the γ-Fe_2O_3 plays a role in passivity (3, 5). This "sandwich" would also increase the chances for double diffraction effects, but as will be mentioned later, this did not present a problem in our patterns. The technique now used suffers from the same disadvantage that is present with both of the aforementioned electron diffraction techniques, in that for examination the specimen must be removed from the environment where the film is formed. Thus, there is a possibility that the nature of the film itself has been altered by the time it is studied in the electron diffraction apparatus. Experiments described later indicate that this is not a serious difficulty.

These studies of films formed on pure iron foils have extended the range of systems studied by electron diffraction to include those formed in acidic and basic as well as neutral solutions. The prepassive and transpassive regions of the anodic polarization curve were studied, in addition to the passive region.

Experimental

The electrolytic cell used for polarizing thin foil specimens to selected potentials by means of a potentiostat is shown in Fig. 1. This cell enabled us to deaerate our solutions with Grade A, 99.99% helium during all experiments. Foil specimens were rolled to a thickness of 0.005 cm from an iron sample obtained

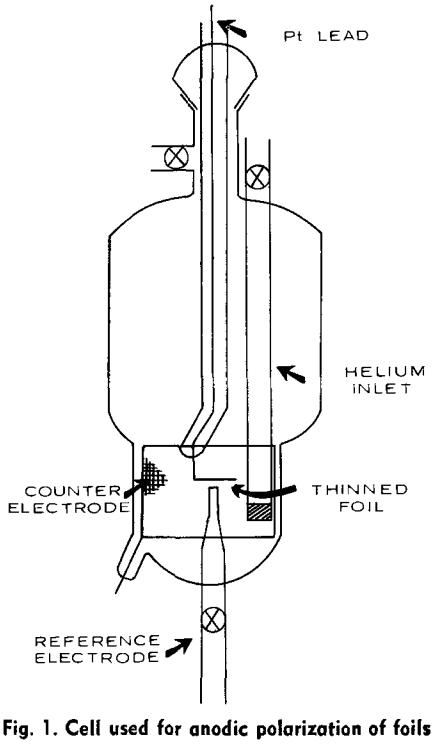

Fig. 1. Cell used for anodic polarization of foils

from the Battelle Memorial Institute.[1] After degreasing with ethanol and trichloroethylene, the foil was annealed for 1 hr at 1000°C in a hydrogen atmosphere. The foil specimens were thinned by the Bollman technique (2), using a mixture of one part 70% perchloric acid to twenty parts glacial acetic acid, for the electropolishing solution. Specimens were then rinsed in high-purity methanol and transferred immediately to the electrolytic cell. After 1 min of cathodic reduction to remove any oxide films, the specimen was brought to the desired potential and usually held at this potential for 2 hr. Longer exposures did not give significantly different results.

When the specimen was ready for inspection, it was rapidly removed from the cell, rinsed, and submerged in methanol. The foil was mounted for the electron microscope and selected area diffraction patterns were obtained at an operating voltage of 100 kv. In order to introduce as little contamination and heating into the specimens as possible, the diffraction patterns were taken, during the first 5 min of examination, then electron micrographs of the same area were made, if they were desired.

Three solutions were used in these experiments: a basic solution of 0.1*N* NaOH with a *p*H of 11.4, a nearly neutral solution, which we will refer to as "borate" consisting of 0.15*N* $Na_2B_4O_7 \cdot 10H_2O$ and 0.15*N* H_3BO_3 mixed in proportions giving a *p*H of 8.5, and an acidic solution of 1*N* H_2SO_4 with a *p*H of 1.1. Using each solution, there were four main groups of experiments: prepassive, passive, passive-decay (initially passive, but then driven potentiostatically to an active potential), and transpassive. The anodic polarization curves used to determine the potentials characteristic of these various regions were determined in a manner similar to that used by Nagayama and Cohen (3).

[1] Gaseous impurities (ppm): O_2 (vacuum fusion), 2.1; S (colorimetric), 4 ± 3; C (combustion-conductometric), 3 ± 3; N_2 (vacuum fusion), 0.5; H_2 (vacuum fusion), 0.3. Major metallic impurities (ppm): Al, 15; Cr, 5; Co, 5; Cu, 7; Ni, 20; P, 9; Si, 10.

The potentials used (*vs.* SCE) are listed in Tables I, II, and III.

A few studies were made on specimens that were formed by exposure to the inorganic passivating solution, 0.1*N* $NaNO_2$. Several other experiments were carried out using the borate and H_2SO_4 solutions containing chloride ions.

Results and Interpretation

The results of our study of oxide films formed in the acidic, basic, and neutral solutions for five of the iron planes are presented in Tables I, II, and III. Figure 2 shows that the patterns obtained for the passive films in the three solutions, plus $NaNO_2$, had the same geometric distribution and differed only in intensity. It should be noted that the observable differences in the patterns are due to the intensity distribution and the difference in thickness of the film. While this figure depicts one iron orientation, the relative quality was similar for all orientations studied.

Indexing and epitaxy.—The indexing of each negative plate was accomplished by the standard methods utilizing the sideline technique (6), the iron spots serving as an internal standard. As a check, the angles between various oxide spots were measured and compared with the standard cubic interplanar angles (7). Figures 3-7 show examples of both a passive and a nonpassive film for each plane listed in Tables I, II and III, with a corresponding indexed diagram. A comparison between the epitaxial relationships obtained in our work and other work done in this field is shown in Table IV. The comparison studies listed have all been concerned with films formed by gaseous oxidation.

There were some special problems associated with indexing. The principal one arises because the thickness of the oxide layer [≈ 30Å (8)], makes it possible for reciprocal lattice spikes (9) from more than one oxide layer to intersect the reflecting sphere. In fact,

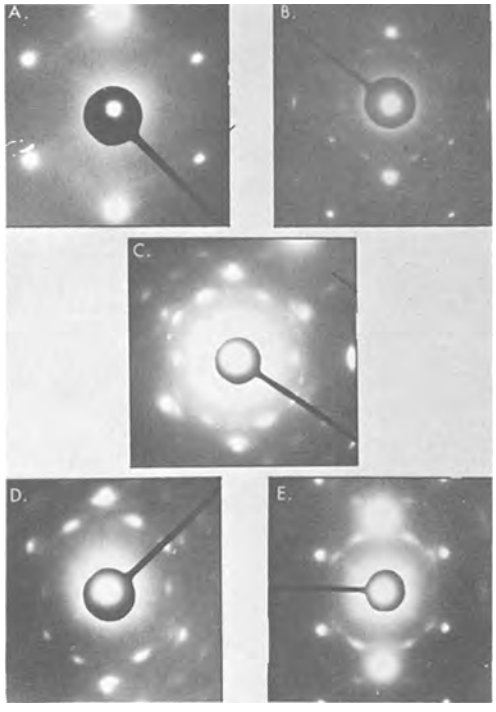

Fig. 2. Comparison of solutions: A, {111} plane shows no oxide after just submerging in borate; B, {111} plane, polarized at +0.75v in borate; C, {111} plane, polarized at +0.5 in NaOH; D, {111} plane, polarized at +1.4v in H_2SO_4; E, {111} plane, dipped in $NaNO_2$.

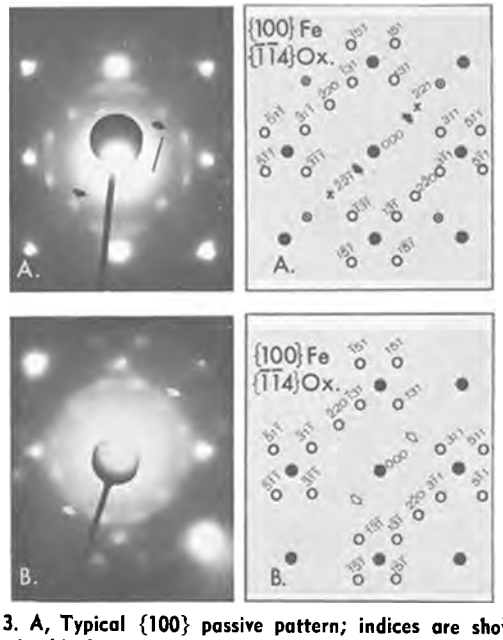

Fig. 3. A, Typical {100} passive pattern; indices are shown for oxide only; black arrows indicate γ-Fe_2O_3 reflections on a passive foil which disappear for nonpassive. B, Typical {100} nonpassive pattern; white arrows show sites where γ-Fe_2O_3 reflections have disappeared. Three oxide levels are represented in both A and B. Note: The oxide orientation is "nearly" $\bar{1}1\bar{4}$. It is composed of reflections on the zero level as well as reflections rel-rodded from above and below. Key: •, iron; ○, spinel Fe_3O_4 (or coincident γ-Fe_2O_3 spots in the passive case); X, γ-Fe_2O_3; ⊙, double diffraction.

a number of the patterns could be indexed only by taking this effect into account. An example of this can be seen for {210} iron, where three oxide levels are present (see Fig. 6). Some of the other planes are also interpreted in this manner.

Another difficulty was encountered in indexing films for the {100} substrate. As seen in Fig. 3 the passive

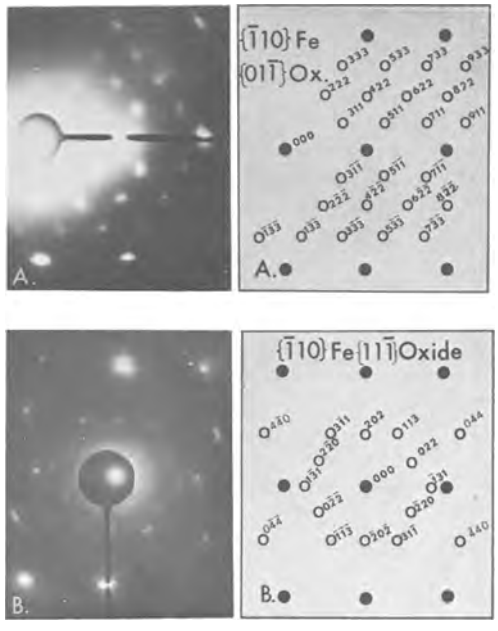

Fig. 4. A, Typical {$\bar{1}10$} passive pattern; only one oxide layer is represented. B, Typical {$\bar{1}10$} nonpassive pattern; again, the oxide is nearly {$11\bar{1}$}, being composed of reflections from more than one oxide layer. Key: •, iron; ○, spinel Fe_3O_4 (or coincident γ-Fe_2O_3 spots in the passive case).

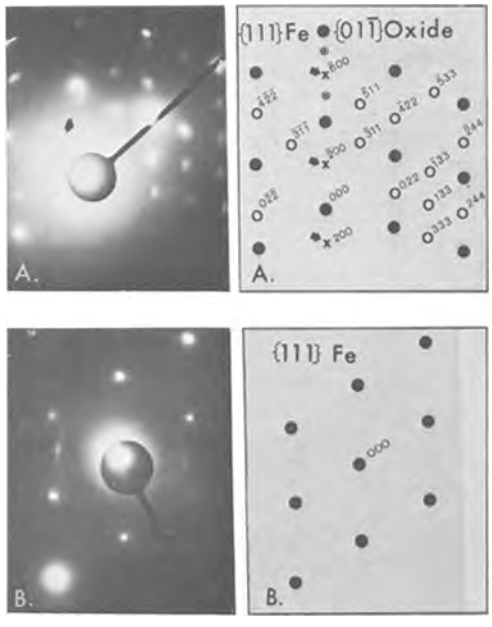

Fig. 5. A, Typical {111} passive pattern. B, The typical {111} nonpassive pattern showed either no oxide (as shown here), or a weaker version of the passive pattern, often incorporating oxide α-FeOOH rings. Only one oxide layer is represented in A. Key: •, iron; ○, spinel Fe_3O_4 (or coincident γ-Fe_2O_3 spots for the passive case); X, γ-Fe_2O_3.

film appears to have fourfold symmetry, indicating a {100} oxide orientation (this orientation was found in previous studies as indicated in Table IV). Nonpassive films for the {100} iron lose this symmetry, however. In order to explain the disappearance of only one pair of the center oxide spots (marked with arrows in Fig. 3), when the film became nonpassive, it was necessary to consider another orientation for the passive film. A close examination of the passive film pattern revealed a slight, but reproducible difference in the radial distances to the center oxide pairs. The closer pair, having a slightly higher d-value, could then be distinguished as a {221} reflection (d = 2.78), which

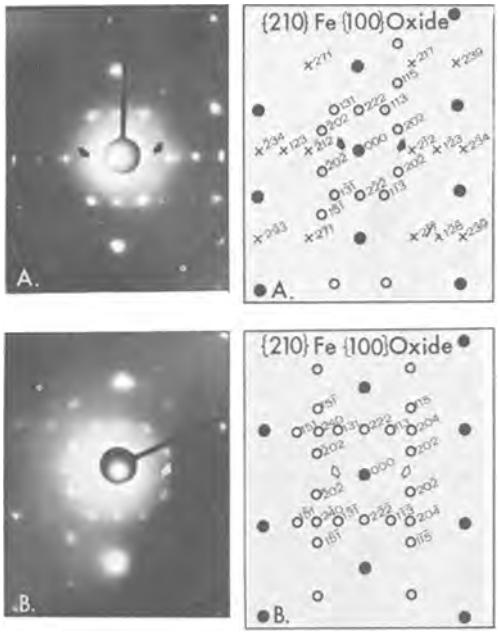

Fig. 6. A, Typical {210} passive pattern; black arrows indicate γ-Fe_2O_3 reflections. B, The {210} nonpassive pattern showed the same structure without the γ-Fe_2O_3 reflections (empty sites indicated by white arrows). Two oxide levels are represented in both A and B, thus the oxide orientation is "nearly" {100}. Key: •, iron; ○, spinel Fe_3O_4 (or coincident γ-Fe_2O_3 spots for the passive case); X, γ-Fe_2O_3.

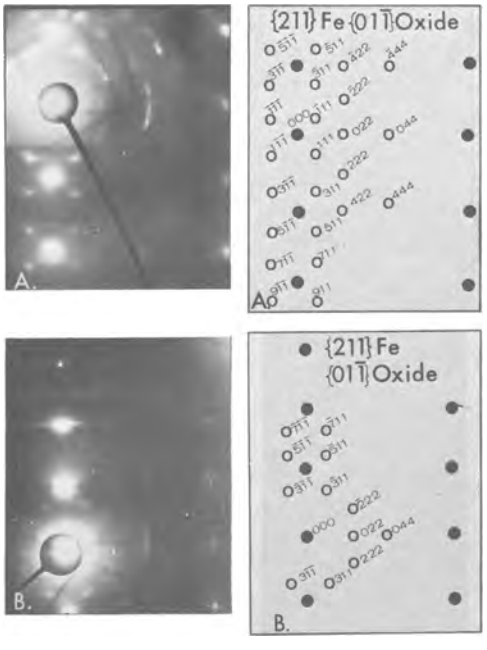

Fig. 7. A, Typical {211} passive pattern; and B, the weaker nonpassive version of the same structure. Only one oxide layer is represented. *Note:* This oxide relationship shows a resemblance to the super lattice reflections (27) perpetrated by partially coherent oxide precipitates. This particular oxide orientation consists of only one oxide level, however, while the super lattice reflections of this type will usually occur only when the foil is tipped a few degrees from a prominent matrix zone. Key: •, iron; ○, spinel Fe_3O_4 (or coincident γ-Fe_2O_3 reflections for the passive case).

would disappear when in the nonpassive state. This distinction between certain oxide reflections will be discussed further. When indexed in this manner, the oxide film orientation would be considered as {$\bar{1}\bar{1}4$} in both passive and nonpassive cases.

As seen in Table IV, our work showed the same oxide orientation for both passive and nonpassive films

* Determined by the authors from an indexed figure in ref. (6).

for all except the {$\bar{1}$10} substrate orientation. The problem of the {$\bar{1}$10} iron orientation will be discussed later, but it should be noted in Fig. 4 that there is a clear distinction between the passive film orientation and the nonpassive film orientation. This situation is not similar to the {100} substrate where, for reasons mentioned before, the difference between the passive and nonpassive patterns has not been ascribed to a difference in orientations.

Although other iron planes have been studied, *e.g.*, {113} and {301}, the results for these were not significantly different from those listed in Tables I, II, and III, and will not be given a detailed survey here in order to conserve space. The epitaxy for these two orientations is given in Table V.

Double diffraction.—Double diffraction effects from the iron were encountered only with the NaOH solution where films formed were relatively thick. The extraneous reflections due to this effect were easy to detect by the method mentioned by Hirsch *et al.* (10).

Table V. Epitaxy for the {113} and {301} iron orientations. These relationships hold for both the passive (P) and nonpassive (NP) cases.

{113} iron ||	{001} oxide P and NP
[$\bar{3}$01] iron	|| [111] oxide
[211] iron	|| [$\bar{3}$11] oxide
{301} iron ||	{100} oxide P and NP
[001] iron	|| [$\bar{1}$01] oxide
[312] iron	|| [$\bar{5}$11] oxide

The NaOH patterns were then used as a basis for determining all of the double diffraction reflections on each iron orientation. The double layer of oxide viewed (film-metal-film) did not seem to introduce extra reflections for the thinner oxide layers formed in neutral and acidic solutions since double diffraction was not detected for these films.

Lattice parameters.—The spinel lattice parameters for each negative were determined by using many d-values for different pairs of oxide spots and the parameter calculated for each. Many of the selected area diffraction patterns were found to suffer from a certain amount of pin-cushion distortion (11). In order to correct for the error in lattice parameter determinations introduced by this effect, we measured the degree of distortion using a Palladium standard and used the displacements calculated from this to determine the undistorted values of the radial distances for the oxides. These corrections were small (0-1.25%), but important in distinguishing between γ-Fe_2O_3 (8.32Å) and Fe_3O_4 [8.396Å (12)]. The "average" values of lattice parameters listed in Tables I, II, and III, represent values which have been "corrected" for the pin-cushion effect. A number of plates were used to determine each value. Since each oxide spot can be measured with the same absolute accuracy, it is necessary to weight any measurement error in the lattice parameter according to the value of $\sqrt{h^2 + k^2 + l^2}$. This practice has generally been neglected in previous error determinations of the lattice parameters in this system. (Note: A discussion of the structure of γ-Fe_2O_3 follows.) A statistical analysis of the lattice parameter data taking this weighting factor into account showed a maximum error of $\pm$ 0.02Å on the parameter values.[2]

It should be noted that, in general, the spinel parameters are much lower for the passive state (Tables I, II, and III, line 1) than for the transpassive or prepassive states. Whenever indications of γ-Fe_2O_3 have been found on most of the films for a particular group (see lines 5, 10, and 15), the lattice parameter is very near the γ-Fe_2O_3 value (8.32Å). Previous studies have verified this result for films formed in chromate solutions (1) and by gaseous oxidation (4).

The lattice parameters found for passive-decay films usually fall nearly midway between these for γ-Fe_2O_3 and Fe_3O_4, indicating a transition state. The decay patterns sometimes showed faint γ-Fe_2O_3 reflections, but not consistently.

Distinction between γ-Fe_2O_3 and Fe_3O_4.—The structures of the two oxides Fe_3O_4 and γ-Fe_2O_3 are closely related, γ-Fe_2O_3 being a pseudospinel probably having the lithium "spinel," $LiFe_5O_8$, type structure. γ-Fe_2O_3 has all of the reflections of the Fe_3O_4 spinel structure, plus additional reflections which probably result from ordered vacancies or ordered substitution of protons for ferrous ions in certain of the special positions, 16d, Fd3m of the spinel structure. This substitution has the effect of reducing the structure to primitive cubic and, as a result, introduces mixed even-odd indices reflections for the γ-Fe_2O_3 (12, 20). In some γ-Fe_2O_3 preparations (14, 15), including the standard sample used in this laboratory,[3] faint extra reflections can be detected which can be indexed using a tetragonal cell (with $c_o = 3\ a_o$, where a_o equals a_o of the cubic cell). However, the principal lines of this pattern occur in the order of magnitude one would expect for the $LiFe_5O_8$ type structure, and, therefore, a close relation is evident. Bloom and Goldenberg (21) claim that the tetragonal cell occurs with the incomplete removal by oxidation of ferrous ions. In this paper, γ-Fe_2O_3 is regarded as cubic. In addition to the additional mixed even-odd reflections the d-values and angles for γ-Fe_2O_3 reflections are sufficiently different from those of the nearby Fe_3O_4 reflections to be easily identified. The γ-Fe_2O_3 reflections obtained for our patterns were closely matched to the standard values (16) and were easily distinguished from the standard values for Fe_3O_4 (17). We would label the oxide film on a particular iron orientation as "γ-Fe_2O_3" only if it had these extra spots and a lower lattice parameter.

Validity of electron diffraction studies.—There have been objections raised to the study of passive films out-of-solution, no matter what the technique. The most serious of these involved the possibility that the films undergo chemical or structural changes in the interval between formation and observation.

For our work, this objection can be met in a number of ways. First, after a passive film has been formed by anodic polarization, the circuit can be open for a considerable length of time before the specimen's potential relative to SCE will drop below the value characteristic of the passive region. A series of experiments in H_2SO_4 showed a decay time of more than 7 min when left in an acidic environment. Since our specimens were removed from solution and mounted in an evacuated chamber within 5 min, it seems reasonable to assume that the passive film had remained intact. This hypothesis was checked by passivating a specimen, removing it from solution, treating it in the same manner as required for electron diffraction work, and then replacing it in solution: the potential still remained in the passive range.

Second, the films formed in NaOH were very thick and difficult to dissolve (as can be seen in the decay experiments for this group, Table III). Since the patterns found for foils prepared in H_2SO_4 and borate were similar to those for the NaOH prepared foils, it is again reasonable to assume that the passive condition exists for foils prepared in all three solutions when they are under examination.

Finally, prepassive and transpassive films gave different results from those observed for passive films. If the passive films were changed during handling and observation, it is most likely that they would have become nonpassive. This did not happen for any of the NaOH films and occurred only rarely for the other films.

The possibility that the γ-Fe_2O_3 is formed by exposure to air does not seem apparent here as the exposure of the specimens to air and the vacuum environment of the diffraction apparatus is not great enough to produce the sort of lattice parameter variations as noted by Sewell, Stockbridge, and Cohen (4). Since all of the specimens receive approximately equal exposure, the considerable lattice parameter variations found between passive and nonpassive films could not be explained in this manner.

Effect of chloride ions.—When chloride ions were added to the solutions used, rings were always detected in the diffraction patterns of the films formed. These rings were found to be due to γ-FeOOH, in agreement with the previous work of Mellors *et al.* (18) for passive films formed in the presence of chloride in inorganic inhibitor solutions. Table II indicates that γ-FeOOH was also detected in some cases when films were formed in the active region. Since the γ-FeOOH was randomly oriented, it seems likely that it formed by precipitation from the solution rather than by direct growth on the metal surface.

Discussion

This study shows that the structure and composition of the anodic passive film formed on iron is not dependent on the pH of the electrolyte, but only on the orientation of the surface on which it is formed. The

[2] The "weighting" factor is necessary since the lattice parameter is a function of $\sqrt{h^2 + k^2 + l^2}$ and the distortion is greater near the center and on the edges of the patterns. The negative plates were oriented and the same oxide and iron spots on each were used to approximate the actual distortion pattern. Then by casting an undistorted grid on the pattern, the percentage of "pull" on each spot could be calculated.

[3] This analysis was made from a sample kindly lent to the authors by Dr. M. C. Bloom, Naval Research Laboratory.

passive film gives electron diffraction patterns of γ-Fe_2O_3, whether it be formed by anodic polarization or by the use of an inorganic passivating solution and in each case shows the same epitaxial relationships to the iron substrate. Since the γ-Fe_2O_3 pattern contains all of the reflections of Fe_3O_4, it is possible that it is present along with the γ-Fe_2O_3. This assumption has its basis in the work of Nagayama and Cohen (2) who have suggested that it exists at the metal interface.

The interpretation of two oxide phases in the passive film is not new experimentally (1) nor is it unexpected theoretically (5). As was mentioned earlier, however, this study extends the *p*H range of the solutions studied from the neutral region of past studies to both the acidic and basic regions and shows that regardless of mode of formation, the nature of the film remains essentially the same.[4] More important, perhaps, than presenting evidence supporting the presence of γ-Fe_2O_3 in the passive film, are the results of this study obtained in the prepassive and transpassive regions showing the absence of γ-Fe_2O_3 and the presence of only Fe_3O_4. Had this not been found, the presence of γ-Fe_2O_3 in the passive film could be considered as only an interesting fact, but one not necessarily related to its being passive.

Since the presence of γ-Fe_2O_3 in the passive film appears related to the passive state of the metal, what special property does it have that differentiates it from the very similar Fe_3O_4 which we find in the nonpassive films? A recent suggestion has been made by Bloom and Goldenberg (21) who point out that a major difference between the two oxides is the great difference in their electrical conductivity, the Fe_3O_4 being a better conductor by many orders of magnitude. As Hoar (22) has pointed out, most current ideas concerning the conductivity of the passive film on iron consider it as being a good electrical conductor. This idea is mainly based on the fact that in going to the transpassive region large currents are easily passed, indicating a film of high conductivity. When the transpassive region is reached, this study shows that the film is no longer γ-Fe_2O_3, but is the relatively good conductor Fe_3O_4. In agreement with this we find that low conductivity γ-Fe_2O_3 is absent in these active films. Since γ-Fe_2O_3 is always associated only with a passive film, and it is a poor conductor, then passivity must require a film with an insulating outer layer if it has more than one layer. Recent kinetic studies from this laboratory (8) lend support to this hypothesis. However, no direct measurement, to our knowledge, has been made of the conductivity of the very thin outer γ-Fe_2O_3 layer in the passive film in order to settle this question. Another difference noted by Bloom and Goldenberg (21) is that γ-Fe_2O_3 does not have the formula, Fe_2O_3, but is probably similar to the lithium spinel $LiFe_5O_8$, the lithium being replaced by hydrogen to give HFe_5O_8. The structure of HFe_5O_8 can be derived from the Fe_3O_4 structure by systematically replacing four iron atoms in the special positions, 16d and Fd3m of the spinel structure with protons. The specific positions to be filled are: (5/8, 5/8, 5/8), (1/8, 7/8, 3/8), (3/8, 1/8, 7/8), and (1/8, 3/8, 7/8). These are the special positions 4b of the space group $P4_33$. The other positions of the spinel structure can be assigned to other sets of special positions of this space group (12). This revised structure would give, as does $LiFe_5O_8$, the extra reflections that were found in this study.

The other aspect of passivity dealt with in this study is the epitaxial relationship between films formed in the prepassive, passive, and transpassive regions of the anodic polarization curve and the iron substrate. The most unexpected finding is that a {110} iron surface bears a different epitaxial relationship to the film formed on it, depending on whether the film is passive or active. This is not true for any of the other substrate orientations studied, where both passive and nonpassive films gave the same epitaxial relationships. This special behavior of the {110} orientation agrees with previous studies which showed that, of all the other orientations studied, it exhibited greater pitting tendency (23) and that the passive films formed on it had larger numbers of breakdown sites (24). Both of these earlier findings also agree with the present result that the {110} plane showed a lesser tendency to retain the passive state on removal of the potential difference across the cell. This was usually not the rule for other substrate orientations, where the decay films would sometimes show similarities to the passive films.

The origin of this special behavior by the {110} plane (the closest packed plane in the bcc structure) is obscure. Attempts were made to establish any relationship between how well the metal ions in the oxide lattice matched the underlying atoms in the metal lattice and this change of orientation. Based on a simple matching of hard sphere crystal models, it appeared that the passive oxide orientation was a "better match" than the nonpassive. It is difficult, however, to relate the degree of misfit between oxide and substrate to film properties. This was shown by an investigation of the problem of misfit for another system (25), where it was not possible to relate the degree of oxide film-metal substrate misfit to protectiveness in a consistent manner. One would expect that the geometrical relationship between the film lattice and the metal lattice must determine the strain in the film and, hence, the grain size and the number and nature of imperfections. All of these will modify the intrinsic electrical characteristics of the film and determine the film's permeability to the movement of ions and, hence, its protective properties.

Conclusions

1. γ-Fe_2O_3 is present in all passive films independent of the *p*H of the solution in which the films are formed, or the orientation of the iron substrate.
2. Films formed in the prepassive or transpassive regions of the polarization curve contain the Fe_3O_4 spinel structure and not the γ-Fe_2O_3 structure.
3. The epitaxial relationships between spinel film and substrate on all the orientations studied are the same for both passive and nonpassive films, with the exception of the {110} plane, which has different oxide orientations for the two states.

Acknowledgments

The authors are grateful to D. Ballard for his help with the preliminary diffraction and to Mary Ann Giles who obtained the majority of the diffraction patterns used in this paper. They are also indebted to Brian Joiner for his aid in the statistical analysis of their data.

Manscript received Feb. 21, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Passivation of Aluminum by Chromate Solutions

M. A. Heine and M. J. Pryor

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

Passive films of γ-Al_2O_3 formed on aluminum by chromate solutions exhibit lower ionic resistance and higher electronic resistance than amorphous thermal films of the same thickness. The low ionic resistance is attributed to the formation of some crystalline γ-Al_2O_3 of very low ionic resistance at the oxide solution interface. The high electronic resistance is attributed to the inclusion of some protons in the passive film. A detailed mechanism for the passivation process is advanced.

Despite the numerous studies of the passivation of ferrous metals by chromate solutions, comparatively little has been published on the mechanism by which they inhibit the corrosion of aluminum. Mears and Brown (1) in an early study reported that chromates were effective in polarizing the local anodes on aluminum but did not specify a detailed mechanism. Later Edeleanu and Evans (2) suggested that chromate ions and aluminum underwent a redox reaction to form aluminum oxide and chromic ions. One of the authors (3) subsequently conducted an electrochemical-electronoptical study of inhibition of the corrosion of aluminum by sodium chromate solutions within the *p*H range of 2.5-9.5. The passive films were found to be somewhat thicker than the air-formed oxide film on aluminum and were duplex in nature, with an underlying layer of amorphous γ-Al_2O_3 being overlaid by a few angstroms of microcrystalline γ-Al_2O_3 exhibiting sharp spotty diffraction patterns.

It was deduced that passive films grew for a few hours on initially film-free aluminum with inverse logarithmic (or logarithmic) kinetics and thereafter thickened at a somewhat slower rate. This observation was considered to support a high field growth mechanism for the passive film with the enhanced field being supplied by the high adsorbed charge density in chromate solutions as compared with dry oxidation. Aluminum ions migrating to the oxide-solution interface were considered to be oxidized to γ-Al_2O_3, with the chromate ions being reduced to the trivalent condition. It was further suggested that passivation was a kinetic balance between film growth and film dissolution, the former being sensitive to chromate concentration and the latter to *p*H.

At the time when the former study (3) was conducted, techniques were not readily available to determine the ionic and electronic resistance of thin surface films on aluminum. Consequently, the earlier study was not able to throw light on any differences in conduction characteristics between passive (chromate) and amorphous thermal films of similar average thickness. In the intervening years such techniques have been developed in the writers' laboratory and chloride degradation of γ-Al_2O_3 films has been extensively studied (4-7). Accordingly, the primary purpose of the present work was to study the a-c resistance characteristics of passive films formed on aluminum by chromate solutions. The results have been compared with those obtained previously on thermal and barrier layer anodic films of similar thickness so that some more detailed view of the defect structure of passive films and its relation to the passivation process could be formed. The effects of chloride ions on the resistance of passive films has also been studied with a view to determining why chromates are so effective in preventing corrosion of aluminum by chloride ions.

Experimental

Materials.—The aluminum used was in the form of annealed 0.37 mm thick sheet having a purity of 99.997%. The impurities were 0.001% Cu, 0.001% Fe, 0.001% Si. All passivating chromate solutions were made up from A.R. grade chemicals and distilled deionized water and were adjusted to *p*H 6 by the addition of sodium dichromate unless otherwise indicated. All studies were carried out at 25° ± 0.05°C.

Experimental methods.—Passive films were mainly formed in 1.0M sodium chromate solution on aluminum specimens carrying an original air-formed oxide film and on caustic etched (and essentially film free) aluminum. The air-formed oxide films were formed by 24 hr exposure to dry air of 6 cm^2 aluminum specimens that had originally been etched in 0.5*N* NaOH solution at room temperature for 15 min followed by

less than 1 sec immersion in 50% nitric acid at 85°C. This surface pretreatment produces a slightly scalloped, reproducible, surface having a roughness factor of 1.2 and has been described in detail previously (8). The advantage of this particular surface is that reproducible, high resistance, contamination free, oxide films may be subsequently formed on it by a variety of oxidation processes. Essentially film-free aluminum surfaces were obtained as a starting condition by etching the specimens in 0.5*N* sodium hydroxide solution for 15 min, rapidly rinsing in distilled deionized water, and immediately inserting the specimens into the passivating chromate solution.

Film resistance studies were carried out at frequencies from 1-100 kc using a General Radio Type 716-C capacitance bridge and associated type 716-P4 guard circuit; the measurements were conducted in a separate solution of molar sodium chromate at *p*H 7 as has been described in earlier publications (6, 7). A 50 mv p-p signal was employed throughout with masked specimen areas of 0.02 cm². The neutral chromate solution will form thin films having a thickness greater than around 20-25Å (the passive film thickness) in a uniform manner, thereby permitting a-c resistance profiles to be obtained at various frequencies. In the case of passive films formed by simple immersion in 1.0M chromate solution, resistance profiles could not be obtained by this method because the initial films were already at their terminal passive thickness. Accordingly, after forming passive films by simple immersion for a period of 24 hr at 25°C they were thickened slightly by constant current anodizing in 1.0M sodium chromate solution at *p*H 6.0. Constant current anodizing was performed at 1 μa/cm². The potential of the specimen was monitored until the total film thickness was around 37Å. The times required to form the 37Å thick passive films varied between 45 and 90 min depending on the particular solution used and the surface condition prior to passivation. The additional passive film so produced was compact and quite dissimilar to the porous thick films produced at much higher voltages in chromates (3). Under no condition was the potential of the specimens during anodic polarization permitted to rise above +1.0v on the hydrogen scale. Such films could then be thinned back to around 20-25Å in 1.0M sodium chromate solution at *p*H 7, and resistance profiles developed for the exterior portions of the passive films. A simple analogue of a capacitor with a parallel resistance was used to represent the electrical behavior of the films. Corrections for solution resistance were made at all frequencies.

Some experiments were conducted on specimens carrying passive films that had not been thickened anodically. These films were formed in 1.0 and 0.01M sodium chromate both free from and containing one tenth and equal concentrations of sodium chloride solution. Passive films were formed on 6 cm² specimens carrying an original air-formed oxide film by simple immersion for 6 hr in the passivating chromate solution of varying chromate and chloride ion concentrations. The specimens were again masked to expose an area of 0.02 cm²; the thickness and a-c resistance of these films were determined at 1 kc only by immersion in fresh solutions of 1.0M sodium chromate solution at *p*H 6 since here, thinning rate of the films is at a minimum.

Results

Plots of parallel a-c resistance *vs.* thickness[1] at frequencies of 1, 10, and 100 kc are shown in Fig. 1-3. These results all pertain to passive films formed in 1.0M sodium chromate at *p*H 6 which had been subsequently thickened to around 37Å by constant current anodizing at 1 μa/cm². Each figure contains experimental points determined on quadruplicate specimens both freed from and carrying an original air-formed oxide film.

[1] From capacitance measurements at 1 kc.

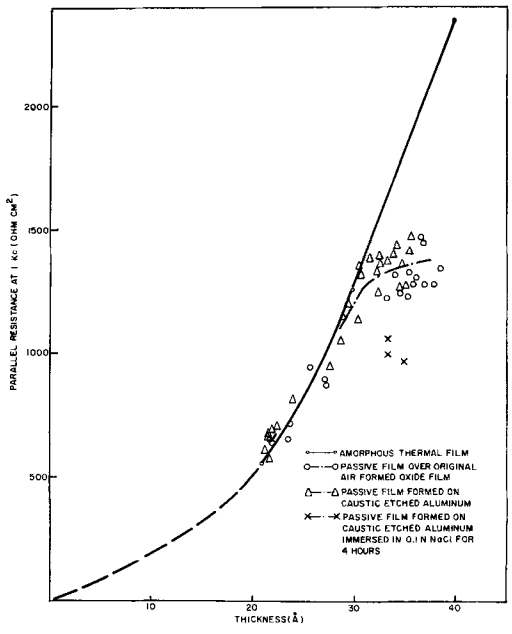

Fig. 1. Relation between parallel a-c resistance at 1 kc and thickness of an amorphous 350°C thermal film and of passive films formed on aluminum in 1.0M sodium chromate solution at *p*H 6 and at 25°C.

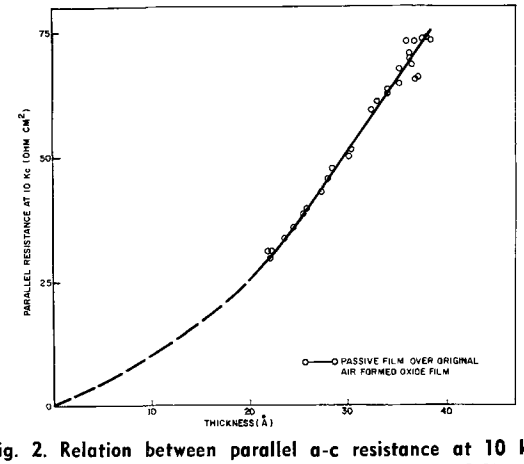

Fig. 2. Relation between parallel a-c resistance at 10 kc and thickness of passive films formed on aluminum in 1.0M sodium chromate solution at *p*H 6 and at 25°C.

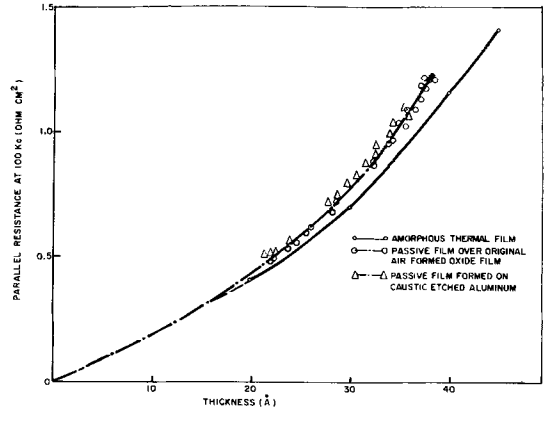

Fig. 3. Relation between parallel a-c resistance at 100 kc and thickness of an amorphous 350°C thermal film and of passive films formed on aluminum in 1.0M sodium chromate solution at *p*H 6 and at 25°C.

In Fig. 1 and 3 the parallel resistance results on the passive films are compared with previous results obtained on amorphous thermal films of the same average thickness (8) (350°C for 20 hr at P_{O_2} = 76 Torr). These in turn are identical to resistance results also obtained previously on amorphous barrier layer anodic films formed in neutral ammonium tartrate solution (6, 8). It may be seen from Fig. 1 that, at a frequency of 1 kc, the a-c resistance of the passive films is identical to that of thermal and barrier layer anodic films until a film thickness of around 30Å has been achieved; thereafter, and at higher thicknesses, the a-c resistance of the passive films becomes much less than that of amorphous thermal films. The resistance profile of passive films at 1 kc was not affected by whether the passivation was conducted on specimens carrying a 20Å air-formed oxide film or on essentially film-free aluminum. Also included in Fig. 1 are three points representing the total resistance of specimens carrying a 35Å thick passive film which has been formed as described above and which had then been immersed in 0.1M sodium chloride for 4 hr at 25°C. Such immersion is known to produce no change in the thickness, crystallographic structure or topography of γ-Al_2O_3 films on aluminum (5). A significant reduction in a-c resistance of the passive films at 1 kc was observed.

At the highest frequency studied in this work, *i.e.*, 100 kc, substantially different results were obtained (Fig. 3). Again, the results obtained on passive films were compared with results obtained previously on amorphous thermal films (8, 9) and on barrier films formed in neutral ammonium tartrate (6, 7). Figure 3 shows that the high-frequency a-c resistance of the passive films is significantly higher than that exhibited by amorphous thermal films. Again, the results in Fig. 3 are individual points from quadruplicate specimens with the two initial surface conditions. Also, the results obtained are independent of whether the passive films were formed on top of an original air-formed oxide film or on caustic etched aluminum. The experiment in which the passive film formed in 1.0M sodium chromate at pH 6 and the specimen then exposed for 4 hr to 0.1M sodium chloride solution at 25°C was repeated. At 100 kc, exposure to chloride solution produced no detectable lowering of film resistance.

At 10 kc (Fig. 2) the results on the passive films more closely parallel the results of 100 kc than at 1 kc. Such behavior has been noted previously in barrier layer anodic films exposed to sodium chloride solution (5).

It is also possible to obtain from the previous experiments information on the kinetics by which the various films are thinned by the 1.0M sodium chromate solution at pH 7.0 from their initial thickness of around 37Å to their terminal thickness of around 25Å. In such instances the measurement of capacitance as a function of time permits calculation of the average thickness of oxide removed at any interval of measurement. The thinning rates of the 350°C thermal film together with those of 37Å thick passive films grown on aluminum freed from and carrying an original air-formed oxide film are shown in Fig. 4.

A final series of experiments was conducted on passivation in 1.0 and 0.01M sodium chromate solutions at pH 6 with and without various additions of sodium chloride as described earlier. The a-c resistivity results on replicate specimens at 1 kc are shown in Fig. 5. In 1.0M sodium chromate solution at pH 6, the simultaneous presence of a chloride ion concentration of 0.1M resulted in, at best, a slight drop in film resistivity. A significant drop in film resistivity was observed when the chloride concentration in the chromate solution was increased to 1.0M. In all experiments, the aluminum remained passive throughout. In the absence of chloride the initial film resistivity in 0.01M sodium chromate was only around 70% of that in the 1.0M chromate solution. The presence of

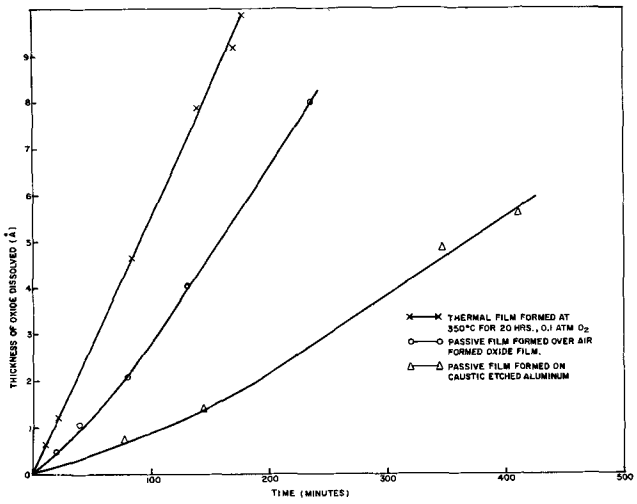

Fig. 4. Relation between time and average oxide thickness removed in 1.0M sodium chromate solution at pH 7 for an amorphous 350°C thermal film and for passive films formed in 1.0M sodium chromate solution at pH 6 on aluminum carrying and freed from its original air-formed oxide film.

chloride ions at a concentration in 0.001M resulted in no change in low-frequency film resistivity; further, the simultaneous presence of 0.01M sodium chloride resulted in a slight rise in film resistivity, although the magnitude of the rise is of somewhat dubious experimental significance. The addition of chloride to the passivating chromate solutions had no effect on film resistivity at 100 kc as had been observed in Fig. 3 and in past work (5-7).

Discussion

The primary objectives of the present work were: (*a*) to improve understanding of how chromate solutions alone passivate aluminum and (*b*) to obtain information on why chromate ions are so effective in preventing corrosion of aluminum by chloride solutions. The low-frequency (1 kc) a-c resistance profiles of passive films (Fig. 1) show that passive film resistance is identical to that of amorphous thermal films until the film thickness exceeds around 30Å. Thereafter and at higher thicknesses low frequency a-c resistance of passive films is substantially less than that of amorphous thermal and barrier layer anodic films. At best, at the natural passive film thickness of around 25Å a-c resistance at 1 kc can be no higher than that of the less protective thermal films and may well be less. Against this background it is not surprising that identical results were obtained at

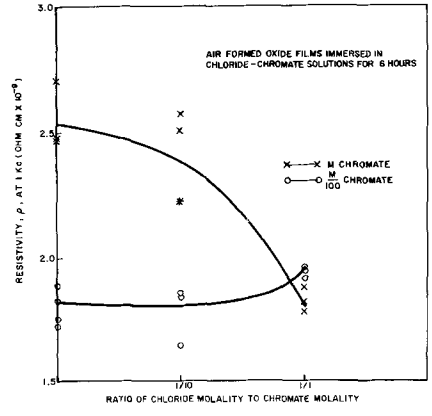

Fig. 5. Effect of chloride ion concentration on the parallel resistivity at 1 kc of passive films formed on aluminum by 1.0 and 0.01M sodium chromate solutions at pH 6.

1 kc irrespective of whether the aluminum specimens carried an air-formed oxide film or were initially freed from oxide by etching in caustic soda.

Very similar low-frequency resistance profiles have been observed previously on thermal films formed at high temperatures in excess of 450°C (8). A marked reduction in the slope of the resistance/thickness curves, almost identical to that in Fig. 1, occurred when well-defined crystals of γ-Al_2O_3 nucleated and grew at the amorphous oxide-metal interface. Electronoptical studies of the thermal γ-Al_2O_3 crystals (8) showed the presence of extensive faulting, and it was suggested that enhanced ionic conduction took place at these internal surfaces. Crystalline γ-Al_2O_3 also forms during passivation in chromates but at the oxide-solution interface. Figure 1 suggests that this crystalline oxide also has a very low resistivity at 1 kc compared with amorphous γ-Al_2O_3 and that a significant quantity in terms of average thickness must be present before it is easily detected by the capacitance-loss method. Since natural passive films, formed without auxiliary anodic polarization, also show crystals at the oxide-solution interface it is almost certain that these films do not have as high an a-c resistance at 1 kc as amorphous thermal films of identical thickness.

Considerable previous study has been devoted to clarifying the interpretation of the frequency dispersion of the a-c resistance of films of γ-Al_2O_3 (5-7). Most impurity defects in γ-Al_2O_3 appear to have characteristic relaxation times of around 10^{-4} sec (4). Accordingly, details in the a-c resistance *vs.* thickness curves seen at frequencies below 10 kc but not above 10 kc pertain to ionic relaxation effects and are related to d-c ionic conduction through the films. Details seen above 10 kc similarly are related to d-c electronic conduction through the films.

Against this background it appears that the amorphous part of the passive film has a virtually identical ionic resistance to that of a similar thickness of amorphous γ-Al_2O_3 formed thermally. When crystalline γ-Al_2O_3 forms at the outer surface of the amorphous film during passivation it exhibits much lower ionic resistance, similar to that of the crystalline portion of thermal films formed above 450°C and probably for the same reasons (8). This observation explains why a deviation from inverse logarithmic growth kinetics, calculated from potential data, was observed after a few hours in earlier work (3). The earlier corrosion potential measurement sensed ionic resistance of the film in a crude and approximate fashion (3). As long as the passive film grew by a high field mechanism and as long as the oxide so produced had ionic resistance characteristics similar to those of barrier layer anodic films, growth kinetics should be inverse logarithmic with time (10). However, as some crystalline oxide of much lower ionic resistivity was produced then the potential measurements will not sense this new oxide quantitatively and growth kinetics calculated from such electrochemical measurements will deviate from an inverse logarithmic law.

From the foregoing it is clear that considerations of ionic resistance alone provide no explanation for the unusually protective nature of passive films on aluminum. Indeed, the passive films will exhibit somewhat inferior ionic resistance to amorphous thermal films, the relative inferiority increasing with the proportion of crystalline γ-Al_2O_3 in the over-all passive film. However, Fig. 4 indicates one area of the complex process of passivation where the presence of crystalline γ-Al_2O_3 may be helpful. It may be seen that the dissolution rate of the outer crystalline portion of passive films formed on aluminum either carrying or freed from an original air-formed oxide film is much less than that of the underlying amorphous γ-Al_2O_3. Since passivation by chromates is believed to involve a kinetic balance between film formation and film dissolution (3) any factor that retards film dissolution should aid in increasing passive film thickness. Similar low dissolution rates of crystalline γ-Al_2O_3 have been observed previously in studies of duplex thermal films formed above 450°C and possible reasons for this behavior have been advanced (8). Similar reasons are believed to be valid for crystalline γ-Al_2O_3 formed during passivation. The linear slope of the dissolution curve for the passive film formed on aluminum carrying an original air-formed oxide film is only slightly less than that for the 350°C thermal film. The linear slope of the dissolution curve for the passive film formed on caustic etched (and essentially film-free) aluminum is much lower than either of the other two curves. No convincing explanation can be offered for this behavior at the present time. The effect cannot be related to an effect of surface preparation on the amount of crystalline phase because the low frequency resistance-thickness curves are identical for the two surface conditions (Fig. 1).

The high frequency (100 kHz) a-c resistance *vs.* thickness curves (Fig. 3) throw additional light on the reasons for the highly protective nature of passive films on aluminum. At all thicknesses studied a-c resistance at 100 kc was significantly higher for passive films formed in chromate solutions than for similar thickness amorphous films formed thermally at 350°C (8) or anodically in ammonium tartrate solution (6, 7). Crystalline γ-Al_2O_3 does not reduce high-frequency a-c resistivity of duplex thermal films formed above 450°C (8, 9) and from Fig. 3 exhibits similar behavior when formed in chromate solutions. Again no effect of initial surface condition was found in these experiments. The form of the a-c resistance *vs.* thickness curves at 100 kc for thermal and barrier layer anodic films is a very accurate parabola (9) for distances up to 90Å from the oxide-metal interface. At greater thicknesses the resistance is a linear function of thickness (6, 7). Heine and Sperry (9) interpreted these results as meaning that 90Å is the limit of thickness of γ-Al_2O_3 at which a conductivity effect due to excess metal arising from the proximity of the metal substrate disappears. At thicknesses lower than this value, conductivity is an inverse function of distance from the metal interface (on account of the parabolic nature of the R_p *vs.* thickness curve) and so the concentration of excess metal current carriers must also vary inversely with distance from the metal interface. Heine and Sperry (9) accepted the earlier model of Grunberg and Wright (11) for the probable defect structure in the vicinity of the oxide-metal interface, *i.e.*, an F′ center structure with excess metal existing as missing oxygen ions with two electrons trapped per oxygen vacancy. Since high-frequency a-c resistance singularities have been related to similar singularities in electronic d-c resistance (5-7) the foregoing implies that electronic conduction through these films to a thickness of 90Å is controlled primarily by the loosely bound electrons in the F′ center defect structure. The form of the 100 kc a-c resistance *vs.* thickness curve for passive films is also a parabola from Fig. 6 but with a greater slope than that for thermal films. This implies higher electronic resistance at any thickness due to the presence of somewhat fewer loosely bound electrons. Such defect structure could logically arise from the relatively uniform incorporation of some water or H^+ in the γ-Al_2O_3. γ-Al_2O_3 is a defect spinel with a close packed fcc oxygen lattice. The cation lattice is poorly understood, but could well contain a number of vacant sites. If a H^+ were to enter the oxide, either in one of the vacant cation sites or interstitially, one electron would have to be added for electrical neutrality and electronic resistance would decrease. Such is clearly not the case from Fig. 3. If however, a proton were to replace an aluminum ion, two electrons would have to be removed to maintain electrical neu-

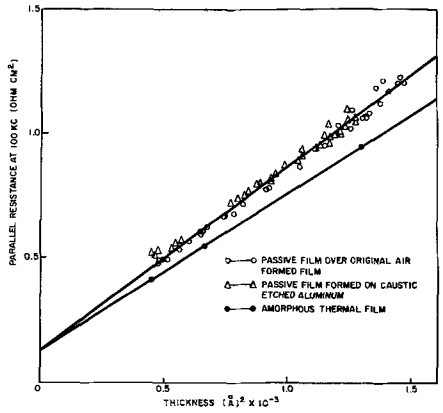

Fig. 6. Relation between parallel a-c resistance at 100 kc and (thickness)^2 of an amorphous 350°C thermal film and of passive films formed on aluminum in 1.0M sodium chromate solution at *p*H 6 and at 25°C.

trality, and electronic resistance would increase without any change in ionic resistance. This explanation is consistent with the experimental data in Fig. 1 and 3. Calculations from earlier data (4) would suggest a substituted H^+ concentration of around 1 pt in 10^5 or less. Similar explanations can be derived for the substitution of water, but the present work provides no means of distinguishing these alternatives.

From the foregoing considerations a more detailed mechanism for the passivation of aluminum by chromate solutions may now be advanced. First a redox reaction appears to be involved in passivation as suggested by Edeleanu and Evans (2). Chromate ions from solution are likely strongly and specifically adsorbed on the metal, if it is originally film free, or on an air-formed oxide film as is the more normal condition. This contention is supported by the earlier detection of Cr^{6+} on the surface of passivated iron (11). The adsorbed charge density from the small divalent $CrO_4^=$ ion should be higher than that pertaining during dry oxidation from the formation and adsorption of the energetically more probable O' ion. Accordingly, a higher than limiting field should exist across any pre-existing air-formed oxide film. Ionic migration will accordingly commence. As migrating aluminum ions arrive at the oxide-solution interface they become oxidized to γ-Al_2O_3 with Cr^{6+} ions becoming reduced to Cr^{3+} although the latter species has not been detected to date. The film will thicken until the limiting field of somewhat less than 10^7 v/cm is re-established. The amorphous portion of the passive film appears to be formed at field strengths significantly above the limiting field strength; the outer crystalline portion of the passive film appears to form at field strengths only slightly above or at the limiting field.

Because the passive film is duplex in nature the passivation reaction does not proceed in an identical manner to the more widely studied anodic film formation. During the time when the passive film is amorphous, electrochemical information indicates that the growth kinetics are logarithmic or inverse logarithmic, *i.e.*, in accord with a high field mechanism. The amorphous part of the passive film has the same ionic resistance at any thickness as a thermal or a barrier layer anodic film. Simultaneously it exhibits higher electronic resistance than comparable thermal films probably due to inclusion of small quantities of H^+ or water and so is more protective. As the low ionic resistance crystals appear at the outer surface of the passive film, electrochemical measurements do not sense the new low-resistance film adequately, and kinetics calculated from these measurements appear to deviate from the former growth law. However, the new crystalline film still contributes to the high electronic resistance of the passive film, being indistinguishable in this respect from the amorphous part of the passive film. It further dissolves in the passivating solution at a lower rate than the amorphous substrate and tends to protect against the competitive film dissolution process. Excellent evidence of this may be found from earlier work. Capacitance measurements (sensitive to the presence of both crystalline and amorphous γ-Al_2O_3) showed that passive film thickness was constant between *p*H 6 and 9 (6). Electrochemical measurements (3), not as sensitive to the presence of low ionic resistance γ-Al_2O_3 crystals, had been interpreted (erroneously) as meaning that passive film thickness is at a maximum at *p*H 6 and decreases with increasing or decreasing *p*H. These observations can now be reconciled as follows. Passive film thickness from capacitance measurements is not *p*H dependent between 6.0 and 9.0 (6). However, ionic resistance by electrochemical measurement (3) does decrease with increasing *p*H above 6.0. It appears that the proportion of low resistance crystalline γ-Al_2O_3 phase must be at a minimum at *p*H 6 and increases as the *p*H moves in the alkaline or acid direction. This contention is supported by earlier potential-time curves (3) which showed that serrated potential-time traces, characteristic of the formation of crystalline γ-Al_2O_3, initiated at lower potentials when *p*H was moved from 6.0 in either direction. Furthermore, the onset of these serrations (crystal formation) was dependent at constant *p*H on the chromate concentration, occurring at lower potentials as the chromate solution was diluted. Accordingly, the proportion of crystalline γ-Al_2O_3 in the film, being *p*H (minimum at *p*H 6.0) dependent and chromate concentration dependent (decreasing with increasing concentration) has a marked influence on the electrochemical properties of the over-all film. The proportion of crystals has little or no effect on the total thickness of film or on its very high electronic resistance both of which are important components of its unusual protective action. The proportion of crystalline phase profoundly modifies ionic resistance of the film which decreases with increasing proportion of crystals. This effects the electrochemical response of the passivated aluminum more than the protective action of the duplex film since an increasing proportion of crystalline γ-Al_2O_3 phase also implies a reduction of the rate of dissolution in the passivating medium.

Finally, there remains the question of the means by which chromate solutions prevent corrosion of aluminum by chloride ions in such an effective manner. The influence of chloride ions on aluminum covered with amorphous γ-Al_2O_3 has been studied in some detail earlier by the authors (5-7). In the absence of chromate, chloride ions can enter the γ-Al_2O_3 lattice, create cation vacancies and lower ionic (1 kc) resistance without changing electronic (100 kc) resistance. γ-Al_2O_3 containing small amounts of substituted Cl' also dissolves more rapidly in sodium chromate at *p*H 7 than unsubstituted γ-Al_2O_3. The effect of the simultaneous presence of chromate and chloride ions on aluminum is presented in Fig. 5 at chromate concentrations of 1.0 and 0.01M. The study was confined to one frequency (1 kc) which is sensitive to chloride inclusion in the film and to the natural passive film thickness (around 25Å in both solutions). First, it may be seen that the resistivity of the passive film in 0.01M chromate is only about 70% of that in 1.0M chromate. The passive film thicknesses are identical from capacitance measurements, and the difference in resistivity may be attributed to a higher proportion of crystalline γ-Al_2O_3 of low ionic resistance in the more dilute passivating solution. When the two chromate solutions contain sodium chloride at a concentration of one tenth the chromate concentration, *i.e.*, 0.1 and 0.001M, respectively, no significant change in passive film thickness or resistivity is seen at 1 kc. When passivation is conducted in the two chromate solutions with equal concentrations of sodium chloride (1.0 and 0.01M) the thickness of the

passive film again remains constant. However, passive film resistivity decreases in the concentrated (1.0M) solutions and remains essentially unchanged in the dilute (0.01M) solutions. The effects of the chloride in the simultaneous presence of chromate could be due to one of two causes: (*a*) a reluctance of chloride to enter the crystalline γ-Al_2O_3 and penetrate to the amorphous layer where its effect at 1 kc should be large. Such behavior has been noted in high-temperature crystalline γ-Al_2O_3 (8); and (*b*) an adsorption effect whereby chromate prevents simultaneous adsorption of chloride on the film surface. In the absence of specific adsorption of Cl' ions their entry into the γ-Al_2O_3 lattice is not considered possible.

In order to distinguish between these alternatives, passive films were formed in 1.0M chromate on aluminum as described earlier and thickened anodically to around 35Å thereby increasing the amount of crystalline γ-Al_2O_3. After this treatment the specimens were rinsed and immersed in chromate free 0.1M NaCl solution at *p*H6 for 4 hr. The low-frequency (1 kc) resistance of the total film was then measured in the standard manner at *p*H 6 in the absence of film thinning. The results in Fig. 1 show a marked decrease in ionic resistance for these specimens. If this result is compared with the fact that the same concentration of chloride (0.1M) when present in combination with 1.0M sodium chromate permitted growth of a passive film of undiminished resistivity at 1 kc (Fig. 5), it is clear that explanation (*a*) is untenable. Indeed the stability of passive film formed in the combined presence of chromate and chloride must be due to a relative adsorption effect whereby the chromate ions are specifically adsorbed on the growing oxide so strongly that they will displace chloride from the surface at least up to a certain critical concentration level. The fact that the relative critical chloride concentrations differ with the chromate concentration also supports such a view. This conclusion is consistent in part, with views expressed on chromate and chloride adsorption on passive iron by Matsuda and Uhlig (12). It receives direct experimental support from the zeta potential studies of O'Connor *et al.* (13) on corundum, γ-Al_2O_3 and Al·O·OH which indicated a much stronger specific adsorption for divalent CrO_4'' ions on these oxides. This conclusion also indicates that the protection against chloride corrosion is only obtained in the simultaneous presence of chromate and that once the latter is removed, film degradation by chloride ions can proceed in a normal fashion.

Theory of Organic Corrosion Inhibitors

II. Electrochemical Characteristics of Iron in Acidic Solutions Containing Ring-Substituted Anilines

Francis M. Donahue,[1] Akitane Akiyama,[2] and Ken Nobe

Department of Engineering, University of California, Los Angeles, California

ABSTRACT

The effect of aniline and aniline derivatives on the electrochemical characteristics of iron in H_2SO_4 has been studied using relaxation techniques. Armco iron corrosion was found to be inhibited primarily by an adsorption mechanism. However, evidence was noted which suggested a contribution from a "surface chelate." Evidence for surface chelation was more pronounced in the case of zone-refined iron which showed a transition from a nearly "pure adsorption" to a predominant surface chelation process. Subsequent loss of inhibition with time by some organics has been attributed to charge transfer processes associated with the surface chelate.

An understanding of the structure-corrosion inhibition relationship of organic compounds may be obtained by: (a) empirically correlating observed corrosion rates of metals in the presence of inhibitors with physico-chemical measurements or correlation parameters [e.g., see ref. (1-4)]; (*b*) a detailed study of the electrochemical behavior of inhibited metal dissolution (5, 6); and (c) measurement of adsorption properties of metal-solution interfaces (2, 7).

An unequivocal solution to the structure-corrosion inhibition relationship is not to be anticipated from any of these techniques alone. In fact, unless the nature of the dissolution reaction itself is well under-

stood, very little of fundamental significance can be gained from studies of inhibition. Therefore, this laboratory has undertaken the task of simultaneously studying the inhibited and uninhibited behavior of iron in acidic solution. The first paper in this series (4) was concerned with correlation of adsorption and inhibition behavior of organic compounds with phenomenological constants derived from physical-organic chemistry. Another paper (8) is associated with the detection and role of intermediates in the dissolution process. This paper and the one to follow (9) are associated with the electrochemical characteristics of inhibited dissolution and a study of empirical correlations of inhibitor data, respectively. A "final" paper (10) is a study of the uninhibited kinetics of iron. It is the authors' purpose to investigate in a systematic manner with several electrochemical techniques the structure-corrosion inhibition relationship of a series of organic compounds on two different iron samples.

The present paper considers the effect of the addition of organic compounds on the observed electrochemical behavior of iron. Thus, observations of the open-circuit potential (corrosion potential), polarization behavior, and differential capacitance will be used in the manner described below to deduce the role of the organic in the inhibition process.

The various theories of inhibition by organic compounds have been adequately reviewed in the literature (11, 12) and, hence, are not considered here. Whereas chemisorption was assumed as the mode of inhibition in the "Theoretical" aspect of this series (4), no assumptions are made with respect to the mode of inhibition here.

Kaesche (5) has suggested that observations of the shift of the open-circuit potential in the presence of an inhibitor permits the specification of which partial process is influenced by the inhibitor. In summary, his postulates are these: (*a*) shifts of the open-circuit potential in the positive direction indicate predominant interference with the anodic partial process; (*b*) shifts in the negative direction, the cathodic partial process is affected; and (c) no shift in open-circuit potential, both processes are affected to the same extent. The analysis tacitly assumes near constancy of the respective Tafel slopes, *i.e.*, no change in mechanism of the partial processes in the presence of the inhibitor. Therefore, mere measurements of open-circuit potentials cannot describe unequivocally the interaction of the organic with the partial processes, and it is necessary to polarize the electrode to verify the Tafel slope constancy.

Bockris (13) has suggested the following mechanism for iron dissolution

$$Fe + OH^- \rightleftarrows (FeOH)_{ads} + e^- \quad [1]$$

$$(FeOH)_{ads} \rightarrow (FeOH)^+ + e^- \quad [2]$$

$$(FeOH)^+ \rightarrow Fe^{+2} + OH^- \quad [3]$$

where step [1] is in quasi-equilibrium, step [2] is rate limiting, and step [3] is fast. In the light of this mechanism and techniques which have recently been developed (8), the rate constants for step [1] may be calculated from anodic charging curves under certain circumstances, *e.g.*, Armco iron in 1N H_2SO_4, and the rate of disappearance of the adsorbed intermediate may be deduced from decay measurements. In this manner the question of "deactivation" of the metal surface may find a partial resolution (5). Thus, an inhibitor which "stabilizes" the iron atom in the lattice will cause a shift in the equilibrium given by [1] and, thereby, change the ratio of the rate constants. From the theoretical development given before (8), this effect should be characterized by a decrease in adsorption pseudocapacitance (*i.e.*, surface coverage of intermediate) and an alteration of the shape of the charging curve.

If the effect of the inhibitor is on the adsorbed intermediate, *e.g.*, some sort of chelation mechanism, the evaluation is less direct. Consider the following

$$(FeOH)_{ads} + n\,I \rightleftarrows [(FeOH) \cdot I_n]_{ads} \quad [1a]$$

$$[(FeOH) \cdot I_n]_{ads} \rightarrow [(FeOH) \cdot I_n]^+ + e^- \quad [1b]$$

In step [1a] the adsorbed intermediate interacts with n molecules of inhibitor I (at this point it is unnecessary to stipulate whether the inhibitor is adsorbed) to form a complex which is adsorbed on the surface. To the extent that the complex can undergo charge transfer, *i.e.*, step [1b], and desorb as a complex ion, a postulated inhibitor may in fact be an accelerator (see Experimental Results below). Likewise, the value of the equilibrium constant of [1a] ought to determine the extent of inhibition provided that the rate of [1b] is much slower than [2]. In addition, the values of the rate constants for [1a] should intimately affect the measured values of the rate constants for [1]. For example, should the rate constants for [1a] be much less than those of [1], then the anodic charging curve would be insensitive to the presence of the inhibitor. On the other hand, if the rate constants for [1a] (especially the forward constant) are equal to or greater than those of [1], then the charging curve should undergo a significant change in shape. Unfortunately, no theoretical analysis of the scheme suggested here has been worked out. However, such an alteration of the charging curve would be partial support for such a mechanism.

Since the rate-determining step for hydrogen evolution on Armco iron has been shown to be the first electron transfer step (14), such an analysis for the cathodic partial process is precluded. However, "deactivation" of the surface for hydrogen evolution would reveal itself in an alteration of the cathodic Tafel slope.

A simple blocking of the surface by adsorption of the inhibitor would decrease the area available to the respective partial processes and thereby decrease the apparent exchange currents in an identical fashion. Therefore, the open-circuit potential and Tafel slopes would remain unaltered. However, the adsorption pseudocapacitance would decrease linearly with increasing adsorption of the organic [provided the surface coverage of (FeOH) was less than 0.1 (8)]. In the same manner, the apparent double layer capacitance would also decrease on increasing adsorption of organic.

The foregoing discussion gives a rather qualitative picture of how one might attempt to ascertain information pertinent to the mode of inhibition of organic compounds using electrochemical techniques. In the text to follow an example of this approach is given.

Experimental

The details of the experimental equipment and the procedure are given elsewhere (10). The materials used were Armco iron and a sample of zone-refined iron which was donated by the American Iron and Steel Institute (designated as Bar 65A) and prepared in rod form by Battelle Memorial Institute. The electrodes were of cylindrical form and were rotated at constant speed.

The organic compounds were purified before use by distillation at reduced pressure in a nitrogen atmosphere or by recrystallization (p-Toluidine). Boiling point ranges were $\leq$ 2°C and the melting point of p-Toluidine was 42°-43.5°C.

The determination of the rate constants was by the technique previously described (8).

Results and Discussion

Figure 1 shows the effect of the addition of organic compounds on the open-circuit potential of Armco iron. The solid line shows behavior of uninhibited iron (10) for comparison. Aniline and p-Toluidine show deviation in the negative direction, while the remainder exhibit positive deviations. However, with the exception of p-Toluidine, the deviations are smaller

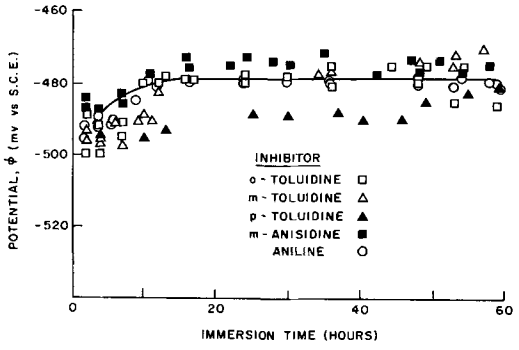

Fig. 1. Open-circuit potential of Armco iron in the presence of 0.3M aniline and ring-substituted anilines. The solid line describes the behavior of uninhibited iron (10).

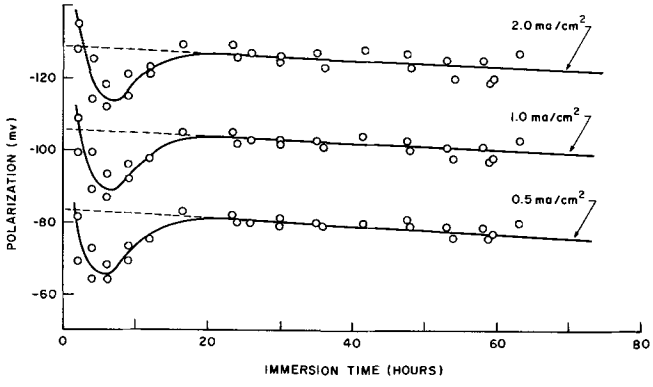

Fig. 2. Cathodic polarization behavior of Armco iron electrodes in the presence of 0.3M aniline.

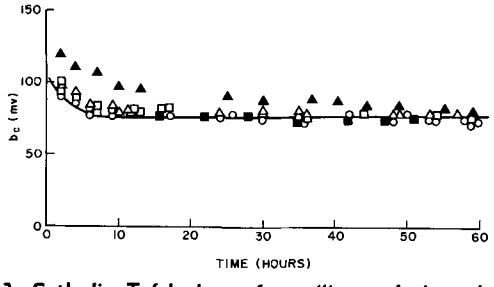

Fig. 3. Cathodic Tafel slopes for aniline and ring-substituted anilines as a function of time of immersion. Solid line shows the data for uninhibited iron (10). See Fig. 1 for designation of symbols.

than about 5 mv, which are smaller than those of Kaesche (5), and are not considered to be sufficient to permit ascribing any specific interaction with one or the other partial process.

Figure 2 shows the typical cathodic pulse polarization behavior observed for Armco iron. The minimum in polarization is characteristic of unannealed Armco iron electrodes (10) and does not reflect any effect of the inhibitor.

Figure 3 shows the variation of cathodic Tafel slope with time for inhibited Armco iron [again the solid line is presented to allow comparison with the uninhibited work (10)]. It can be seen that the inhibited samples (except p-Toluidine) follow the behavior of the uninhibited samples. This suggests that the cathodic partial process is essentially unaffected (in terms of reaction mechanism) by the presence of most of the organics. This is not true of p-Toluidine, which only approaches the uninhibited behavior as a limit at long immersion times. This behavior of p-Toluidine is consistent with other observations with this compound. Although it is chemically related to the other ring-substituted anilines, its behavior at the iron electrode seems to be quite anomalous.

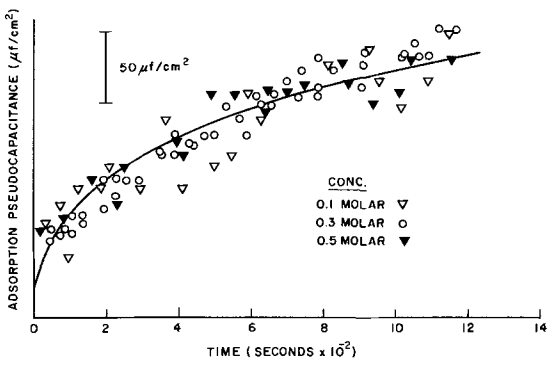

Fig. 4. Adsorption pseudocapacitance observed during anodic polarization of iron in the presence of aniline. Solid line is curve for uninhibited iron (8). Current density, 1 ma/cm².

One aspect of Fig. 3 which deserves comment at this time is the observation of rather low cathodic Tafel slopes. Values between 100 and 120 mv have been most frequently reported. In fact, previous work on this system (Armco iron/H_2SO_4) in this laboratory gave slopes of 100 mv (15). However, those experiments were usually completed within 2 hr after the samples were immersed. Those observations are in accord with the present work if one examines Fig. 3 at short times. Likewise, Kaesche (5) noted a range of Tafel slopes of 83-92 mv for uninhibited samples whose polarization data were obtained after 5 and 7 hr immersion time, again, in accord with the curve shown in Fig. 3. This underlines the need for investigators to stipulate at what time following immersion their data were obtained. Unless this is done, comparison of data among investigators may not be meaningful.

It has been shown elsewhere (8) that the slow achievement of a steady-state potential during anodic polarization is associated with the slow build-up of the surface concentration of the intermediate species (FeOH). It was also shown that an indirect measurement of this build-up could be made by determining the adsorption pseudocapacitance during the polarization by superimposing short galvanostatic pulses on the already existing signal. Figures 4 and 5 show the experimental results for aniline at three concentrations and some ring-substituted anilines, respectively. The agreement between the inhibited samples and their approximation to the uninhibited case is quite revealing as shown in Fig. 4 and 5. From this it may be surmised that the energetics of the initial electron transfer (see Eq. [1] above) seem to be independent of the presence of the organic or its chemical structure. Again it should be noted that p-Toluidine is an exception.

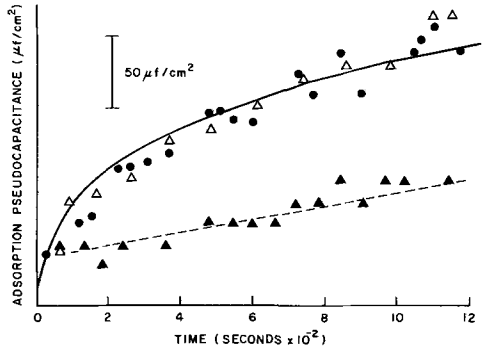

Fig. 5. Adsorption pseudocapacitance observed during anodic polarization of iron in the presence of some ring-substituted anilines. Solid line is curve for uninhibited iron (8). Current density, 1 ma/cm². Compounds are: 0.1M as-received aniline (●), 0.3M m-Toluidine (△), 0.3M p-Toluidine ▲.

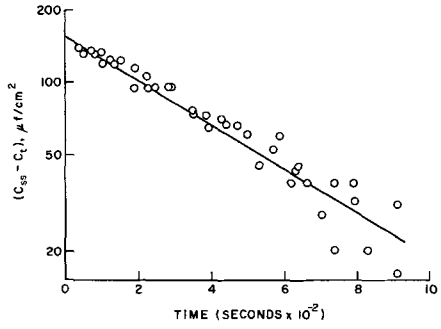

Fig. 6. Experimental test of Eq. (15), ref. (8) for an iron electrode in the presence of 0.3M aniline.

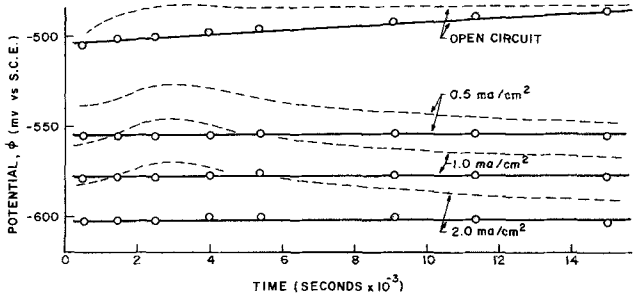

Fig. 7. Electrode potential (open circuit and cathodic pulse polarization) during the relaxation following anodic polarization. Inhibitor: 0.3M aniline. Dashed line shows the results for uninhibited iron (10).

From the comments in the preceding paragraph, it is anticipated that an estimation of the rate constants from the adsorption pseudocapacitance data would approximate that which has been found for the uninhibited case (8). Figure 6 shows the results which were obtained for two different Armco iron electrodes in the presence of 0.3M aniline. The slope of the line, *i.e.*, the sum of the rate constants of Eq. [1], was 2.1 x 10^{-3} sec^{-1}, which was within 10% of the average value obtained for the uninhibited samples (8).

Thus far all of the suggested electrochemical techniques have been able to supply answers to the specific questions which have been posed. In addition to the mere presentation of answers, the picture which the results suggest is self-consistent, *i.e.*, the open-circuit potential and both the anodic and cathodic polarization measurements suggest a nonspecific, "nondeactivating" mechanism for the effect of the organic on the electrochemical behavior of iron.[3] In addition, it has been possible to eliminate a fast "chelation" step (*e.g.*, see Eq. [1a]). However, the results have not been able to differentiate between a simple blocking mechanism such as might be envisioned in a chemisorption mechanism and a slow "chelation" step (Eq. [1a]).

The resolution of the problem is at least theoretically at hand. If the chelation process proceeds at a reasonable rate (from the rapid convergence of the inhibited and uninhibited cathodic Tafel slopes, it seems reasonable to assume that whatever process is operative it probably has a relaxation time which is less than an hour), then measurements of the decay of adsorption pseudocapacitance following the cessation of anodic polarization ought to show the presence of the chelate. Two pieces of information are available from the previous analysis for uninhibited iron (8): (*A*) The decay relaxation time is about an order of magnitude larger than the charging case; (*B*) the decay data are not as reproducible as charging data. The first observation suggests that it is possible to observe the equilibration of [1*a*] during decay even if we could not detect it during the charging process. The second observation suggests that at the present state of the experimental method one can, at best, only qualitatively evaluate the chelation effect. The experimental results obtained for the decay experiments [see Eq. (16) of ref. (8)] are not shown since the reproducibility was even poorer than those obtained in the uninhibited case (8) and would not lend anything to the discussion.

Another series of measurements are available during the decay process which has not been considered previously. Short (~5 sec) cathodic pulses can be applied to an electrode which is relaxing following the cessation of anodic polarization without perturbing the relaxation process and, thereby, determine the polarization characteristics during the relaxation (10). It has been suggested that (FeOH) catalyzes, *i.e.*, increases the apparent exchange current, the hydrogen evolution reaction (h.e.r.) (15). Since an electrode during the relaxation process has a varying amount of (FeOH) on its surface, the potential associated with a given current density should increase with decreasing (FeOH) if such an hypothesis is correct. On the other hand, if the (FeOH) does not catalyze the h.e.r. or is unavailable for such a catalysis, the potential for a given value of current density should remain constant. Figure 7 compares an uninhibited and an aniline-inhibited iron sample. In the uninhibited sample (dashed line) it can be seen that at times greater than 1 hr (the time corresponding to the achievement of a steady-state open-circuit potential) the previous hypothesis (15) finds experimental support, *i.e.*, the adsorbed (FeOH) affects the h.e.r. In the case of the inhibited sample, however, catalysis is essentially absent. It does not seem likely that such a result can be explained except in terms of a "surface chelation" process.

It was suggested at the outset that measurements of adsorption pseudocapacitance on open circuit should permit an estimation of the coverage of the inhibitor. However, capacitance measurements of Armco iron displayed a large intrinsic scatter from electrode to electrode which has tentatively been ascribed to "surface defects" (10). The same phenomena have been observed in the inhibitor study so that at present the capacitance technique is of no benefit in determining surface coverages of the inhibitor on unannealed Armco iron electrodes.

The zone-refined iron has not been considered in the preceding discussion. It has already been noted that the zone-refined sample undergoes a rather rapid equilibration of step [1], *viz.*, about 10^3 times more rapid than Armco iron (8). Therefore, it is not possible to evaluate the purer sample in the same manner as that given above.

It has been observed that zone-refined iron in 1*N* H_2SO_4 achieves a steady-state potential in less than 5 sec for anodic (8) and cathodic polarization (10). Therefore, in contrast to the Armco iron, it is possible to obtain steady-state polarization data for zone-refined iron with minimum perturbations of the quiescent (open-circuit) conditions of corrosion.

The open-circuit potentials of zone-refined iron were not as reproducible as those for Armco iron both in the presence and absence of aniline. However, in presence of aniline zone-refined iron was always more negative than in the uninhibited case. Consequently, from the analysis of Kaesche (5) it may be deduced that aniline affects the cathodic partial process more than the anodic partial process. This is a different result than had been obtained in the case of the Armco iron (see above).

Figure 8 shows the variation of cathodic Tafel slope for zone-refined iron in the presence and absence of aniline. At times greater than about 20 hr, the slope of the former deviates from that associated with the uninhibited case. Figure 9 shows the variation of the corrosion rate under the same circumstances. A com-

[3] These comments are not true for p-Toluidine, and for the present that compound will be omitted from any generalizations.

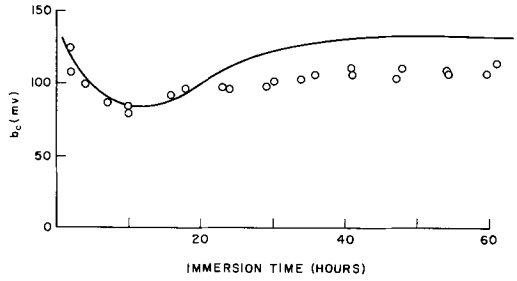

Fig. 8. Cathodic Tafel slope of zone-refined iron in the presence of 0.3M aniline. The solid line represents the behavior of the uninhibited iron (10).

parison of these two graphs is illuminating. In the vicinity of the deviation of cathodic Tafel slopes it is seen that the corrosion rate of uninhibited iron begins to "run away," *i.e.*, the shape of the curve for uninhibited iron in Fig. 9 suggests an autocatalytic process. Such a process and the conditions under which it could be realized have been considered elsewhere (10). Let it suffice here that inhibited iron behaves in a "regular" fashion, *i.e.*, at times beyond 20 hr it does not behave much differently than it did at shorter times, and that the "deviation" is more associated with uninhibited iron. Therefore, it is difficult to attempt to rationalize the significance of the Tafel slope deviations.

The rate-determining step for h.e.r. on high-purity iron in the absence of inhibitors has been shown to be slow discharge (16-18). If this is also the rate limiting step in the presence of the inhibitor (a question which remains unanswered), then an inhibitor which decreases the Tafel slope (see Fig. 8) and decreases the corrosion rate must simultaneously decrease the activation barrier and depress the exchange current. For the foregoing observations to prevail, the depression of the exchange current must be very large. An alternate possibility exists which is more intimately associated with the anodic partial process and, hence. will be considered further below.

The anodic Tafel slope for the uninhibited zone-refined iron has been found to be 47 ± 2 mv (10) while in the presence of 0.3M aniline, slopes of 55 ± 3 mv were obtained. This increase in Tafel slope suggests a mode of inhibition involving an interposition of organic into the charge transfer process for the anodic reaction. This is consistent with the mechanism suggested above if the equilibration of [1a] is fast and is shifted toward the right, *i.e.*, the surface concentration of free (FeOH) is low, and the bulk of the dissolution comes from [1b].

This suggestion of an interposition of the organic in the anodic charge transfer process may help clarify the observations of cathodic Tafel slope deviations and modes of inhibition. If one allows the possibility of the generation of surface sites, which are preferred for adsorption, during the natural corrosion process, then it does not seem unreasonable to suggest that the equilibrium by [1] will be adjusted such that the surface concentration of (FeOH) would increase. In turn the rate of the dissolution reaction would increase and, thereby, beget more surface sites, etc., until the process would tend toward autocatalytic behavior. Tentatively, the h.e.r. process has been neglected, but in fact its exchange current is also increased (10). Therefore, if one could introduce a species which could simultaneously trap the (FeOH) and consume the surface sites (by an appropriate adsorption mechanism) this "autocatalytic" process could be stifled. As was suggested above, the results indicate that the aniline does fill this dual role, *i.e.*, the aniline adsorbs on the surface and complexes with the (FeOH) on the surface.

In contrast to Armco iron, zone-refined iron has reproducible open-circuit capacitance behavior. Therefore, in the latter case, one may deduce the effective surface coverage of the inhibitor. If one assumes that the adsorption of the organic compound "insulates" that part of the metal-solution interface, then the relationship between the capacitance in the presence and absence of inhibitor and the surface coverage is

$$C_i = (1 - \theta)\, C_u \qquad [4]$$

where the subscripts i and u correspond to the inhibited and uninhibited cases, respectively, and θ is the surface coverage of inhibitor. Therefore, the ratio C_i/C_u is a measure of the surface coverage. If adsorption is the only mode of inhibition, then the ratio of the inhibited rate to the uninhibited rate (at any time) should be the same as that for the capacitance ratio.

The capacitance-time behavior of the inhibited zone-refined iron is shown in Fig. 10. It is seen that the capacitance of uninhibited iron has a higher C-t slope than inhibited iron. This is consistent with the suggestion that the inhibition process decreases the rate of appearance of the intermediate (FeOH).

Table I is a collection of data from Fig. 9 and 10 and provides an indication of the extent to which adsorption alone contributes to the inhibition. Considering the approximativeness of the numbers used in the calculation, the correspondence between the ratios of capacitance and corrosivity at times ≤ 20 hr is good and suggests a predominantly adsorption mechanism. However, at times greater than 20 hr, the differences between the two can be ascribed to surface chelation as described above.

A detailed tabulation of the observed corrosion rates with time for Armco iron as well as the LFER correlation of the data is given elsewhere (9). The data

showed that meta- and para-toluidine lost inhibition with time (para- before the meta-) until both were acting as accelerators. Mere loss of inhibition would derive from an exclusion of the organic from the surface; acceleration suggests a definitive role for the organic. These results may be explained in terms of reaction [1b] becoming the dominant dissolution reaction. The reason for the shift from [2] to [1b] is not clear, but is probably a complex interaction between the stability of the surface chelate and its oxidation propensity. This may be seen in Fig. 5 where the p-Toluidine is seen to deviate from the behavior of the other inhibitors and the uninhibited case. It is suggested that the rate of equilibration of [1] would be very slow due to the intervention of steps [1a] and [1b] to yield the complex ion with iron in the divalent state.

A final comment concerning purification of the organic should be made. During the course of this work, it was found that 0.1M aniline in the as-received state (brownish-colored liquid) gave nearly identical inhibition as 0.3M of the redistilled (clear) aniline. Therefore, it is suggested that only purified compounds should be used when studying the effect of organic compounds on electrochemical properties of metals.

Conclusions

The results of electrochemical measurements of Armco iron and zone-refined iron in the presence of aniline and its ring-substituted derivatives have shown that deactivation of the iron lattice (5) is not the model by which the anodic partial process is altered. Instead, there is an equilibrated "capture" of the monovalent intermediate, *i.e.*, (FeOH), in some sort of surface chelate. However, at low coverages of the intermediate, the inhibition is essentially a blocking (adsorption) mode.

The effect of aniline derivatives on the hydrogen evolution reaction is essentially an adsorption mode. In the case of the zone-refined iron the drastic alterations in h.e.r. exchange current were more associated with the absence of the intermediate (FeOH) due to the presence of surface chelate than any deactivation of the cathodic partial process, *per se*.

The work presented here shows the utility of the multifaceted electrochemical approach to the problems of ascertaining the effects of organics on the electrochemical properties of active metals. An analysis of the structure-inhibition relationship is given elsewhere (9).

Theory of Organic Corrosion Inhibitors

III. LFER Correlation of Inhibition of Armco Iron by Ring-Substituted Anilines

Francis M. Donahue[1] and Ken Nobe

Department of Engineering, University of California, Los Angeles, California

ABSTRACT

The corrosion rates of Armco iron in the presence of ring-substituted anilines were shown to obey a LFER predicated on inhibition by adsorption. Deviations from the adsorption correlation were shown for p-Toluidine at times greater than 20 hr and for m-toluidine in excess of 30 hr. These deviations tended toward an acceleration which has been attributed to an oxidative propensity of the "surface chelate." Since 0-Toluidine was found to follow the adsorption correlation, it was concluded that adsorption of the organic was parallel to the electrode surface. Adsorption data on Hg where the orientation was shown to be parallel to the electrode surface were also correlated by the LFER theory.

Recently, the authors have proposed a correlation between adsorption of and/or inhibition by organic compounds and physical-organic chemical substituent constants (1). Correlating such parameters was not completely new since Hackerman and Hurd (2) had plotted the degree of inhibition for ring-substituted N-methylanilines *vs.* the Hammett substituent constant as early as 1961. However, no previous formalism had been developed for plotting inhibition *vs.* substituent constants.

In essence, the "theory" states that, if inhibition (or adsorption) of organic compounds is determined by the electronic distribution in the "anchoring" group of the adsorbate, then it should be amenable to a "Linear Free Energy Relationship" treatment. The term "anchoring" has been placed in quotation marks here and previously (1) for two pragmatic reasons:

(*A*) If one is to investigate electron distributions in an organic molecule, he ought to focus his attention on one atom within that molecule and note variations in the electron density due to variations of a substituent elsewhere in the molecule. Therefore, the choice of the "marked" atom is somewhat arbitrary, although a certain atom in some molecules, *e.g.*, the nitrogen in alkyl substituted pyridines, suggests itself. In physical-organic chemistry the marked atom is invariably the reaction site.

(*B*) In studies of corrosion inhibition the term "anchoring" atom has been used extensively, and the authors feel that one may use such a term provided it is not taken literally [see Discussion, p. 888, of ref. (1)]. Therefore, to remove such an improper interpretation the quotation marks have been and will continue to be used.

Cox and co-workers (3) following the reasoning of Hackerman and Makrides (4) demonstrated a correlation between degree of inhibition for ring-substituted anilines and n.m.r. chemical shift for the amine hydrogens (a measure of the nitrogen electron density). This correlation should have lent considerable support to the authors' theory (1) since Suhr (5) and Dyall (6) had shown correlations between n.m.r. chemical shifts for amine hydrogens and the Hammett substituent constant. However, neither the corrosion inhibition data (3) using Eq. [15b] (1) nor the chemical shifts (3) were found to correlate with the substituent constants. Since Dyall (6) had studied six of the ring-substituted anilines which Cox (3) had observed, it is noteworthy that the results of the two investigators show essentially no correlation with each other. The difference in solvents between the two investigators is probably not the source of the discrepancy since Dyall's work in CCl_4 and acetonitrile gave good internal checks. Unfortunately, the authors cannot resolve the discrepancies in the n.m.r. work and, hence, will have to forego any further critique until more work in this interesting area is published.

However, the authors can address themselves to the corrosion inhibition data of Every and Riggs (7). The authors have observed previously that impure organics, *i.e.*, those used in the as-received state without further purification, yield misleading results (8). In neither the paper under discussion (7) nor in previous work by those investigators (9, 10) was mention made of purification of the organics prior to inhibition studies. Likewise, their representation of the degree of inhibition (7) is derived from an integral corrosion rate *i.e.*, the total weight loss after 24 hr in the presence of inhibitor is compared with the uninhibited weight loss for the same duration. Unless the weight loss-time curves have the same shape (an unsubstantiated assumption), such a measurement is not indicative of the over-all efficacy of the inhibitor. Consider Fig. 1 as an example. Using the integral corrosion rate technique, all three inhibitors (a, b, and c) show about a 25% protection at 24 hr. However, only "b" will show this degree at any other time while "a" will give a higher value of protection at longer times and "c" will soon be an accelerator.

From the previous derivation (1) the instantaneous rate, *i.e.*, the slope of the curves in Fig. 1 or the corro-

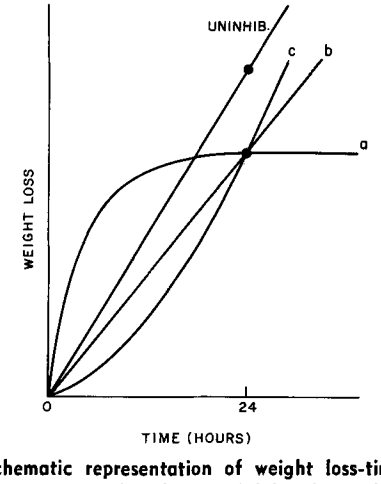

Fig. 1. Schematic representation of weight loss-time curves for three inhibitors compared with an uninhibited sample.

[1] Present address: Department of Chemical and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan.

sion current from polarization measurements, should be correlated with the substituent constant. Consequently, simple weight loss measurements are an unsatisfactory method of testing the theory unless a sufficient number of data points can be obtained such that a differentiation of curves like those shown in Fig. 1 may be effected. Electrical resistance probes (11) can be used effectively for this purpose under certain conditions.

An important aspect of the proposed theory (1) has been questioned recently (12). Due to an apparent misunderstanding of the usage of "anchoring" group (see comments above), it was suggested by Annand that observations such as those by Blomgren and Bockris (13), who concluded from their results that the adsorption of ring-substituted anilines on mercury was parallel to the electrode surface and was attached to the surface by π-bonds from the aromatic nucleus, negated our entire analysis. On the contrary, Fig. 2 shows that Eq. [9c] (1) correlates the data of Blomgren (13) quite well when the organic was at the high concentration. The deviations at the lower concentration could be due to slow adsorption or just the intrinsic reproducibility of their measurements coupled with the nature of the ordinate of Fig. 2. The main point here is that for a case which had already been shown to proceed by parallel adsorption the theory prevails. The data followed the correlation because the conjugated system which interacted with the surface was composed of the six carbon atoms and the nitrogen atom. Therefore, the electron density at nitrogen was directly coupled to the density at the aromatic nucleus [see p. 526 of ref. (4)]. This strongly suggests that the organic which adsorbs is unprotonated in support of Hackerman's hypothesis (4) which has been questioned by Blomgren (13). The latter's comments were perhaps premature since dissociative adsorption, *i.e.*, fragmentation of the anilinium ion into free amine and proton at the surface, cannot be ruled out provided equilibrium is maintained with the anilinium ions in the double layer.

Results and Discussion

Table I shows the instantaneous corrosion rate of Armco iron specimens as a function of immersion time in solutions containing 0.3M organic in 1*N* H_2SO_4 (8). It may be seen that all of the organics show a minimum in corrosion rate in the region of 20-30 hr immersion. From the previous discussions (8) it can be seen that the inhibition process is a combination of a number of coupled chemical and electrochemical processes. It is not known at present why this coupling should be optimum after this period of immersion. However, it is noteworthy (although perhaps fortuitous) that this same time was observed for the

transition from adsorption to "chelation" control in the case of zone-refined iron (8).

The previously suggested processes associated with the effects of organic compounds on the electrochemical properties of iron will be repeated here with the same notations as before for the convenience of discussion (8).

$$Fe + OH^- \rightleftarrows (FeOH)_{ads} + e^- \quad [1]$$

$$(FeOH)_{ads} + n\,I \rightleftarrows [(FeOH) \cdot I_n]_{ads} \quad [1a]$$

$$I + S_{ads} \rightleftarrows I_{ads} + S \quad [1a']$$

$$(FeOH)_{ads} + n\,I_{ads} \rightleftarrows [(FeOH) \cdot I_n]_{ads} \quad [1a'']$$

$$[(FeOH) \cdot I_n] \rightarrow [(FeOH) \cdot I_n]^+ + e^- \quad [1b]$$

$$(FeOH)_{ads} \rightarrow (FeOH)^+ + e^- \quad [2]$$

$$(FeOH)^+ \rightarrow Fe^{+2} + OH^- \quad [3]$$

$$[(FeOH] \cdot I_n]^+ \rightarrow [FeI_n]^{+2} + OH^- \quad [3a]$$

Steps [1a'] and [1a"] have been added for completeness. The symbol S denotes the solvent or any specifically adsorbed electrolytic ions.

In the previous analysis (8), step [1a'] would be the mode of inhibition which has been designated as "blocking" or adsorption. Steps [1a] and [1a"] are the surface chelate modes. If the process described by [1a"] was the dominant mechanism for the production of chelate, then the formation of chelate would be enhanced by increased coverage of both adsorbed inhibitor and reaction intermediate. Since increased coverage of intermediate leads to product formation via step [2], the chelation process, *i.e.*, [1a"], must be fast or the surface coverage of adsorbed inhibitor must be high for inhibition to be maintained. Assuming the foregoing to be correct, *i.e.*, chelate forms by [1a"] and that the equilibria of [1] and [1a'] are shifted toward the right as adsorption sites are generated by dissolution (8), then the importance of chelation ought to increase with increasing immersion time. The extent to which [1] and [1a'] are shifted to the right relative to each other and the stoichiometry of [1a"], *i.e.*, whether $n \geqq 1$, will determine whether inhibition will increase, decrease, or remain constant. Thus, until one may ascertain the critical parameters associated with [1], [1a'], and [1a"], only a qualitative discussion of the causes of the observed phenomena can be made.

From the foregoing discussion, it should not be assumed that the mechanism given by [1a] has been ruled out. On the contrary, such a mechanism is still attractive since organic is more readily available from the solution than it would be via some sort of surface diffusion mechanism. On the other hand, the fact that adsorbed organic is indeed present and the organic

and intermediate are assumed to gravitate toward the same surface sites suggest a preference for [1a"].

In the previous study it was noted that both adsorption and surface chelate functioned in a more or less concerted manner to achieve inhibition (8). Likewise, it was suggested that acceleration of corrosion was associated with the oxidative propensity of the surface chelate. The theory which was previously derived (1) predated the experiments, and, hence, did not anticipate stability of surface chelates as playing a role in inhibition. Therefore, the analysis was proposed on the basis of only an adsorption mechanism. Consequently, the theory must be re-evaluated in the light of the experimental observations.

Although the bulk of the "theoretical" paper (1) was associated with adsorption phenomena, the actual applicability of the concept is more universal than might be thought initially. Little and co-workers (14) have shown correlations between chronopotentiometric quarter wave potentials for substituted phenylferrocenes and directly substituted ferrocenes and substituent constants. As noted in the previous paper (1), correlations have likewise been observed for the fifth wave oxidation potential for substituted anilines (15). Chen (16) has demonstrated a Linear Free Energy Relationship (LFER) between complex ions and the pK's of the liquids. The authors mentioned most of this work in passing (1); however, it did not seem important at that time to dwell on areas which then seemed unrelated to corrosion inhibition. The subsequent experimental work (8) showed this view to be short-sighted.

In a very naive sense, [1a] and [1a"] may be viewed as "two dimensional complex ions" or surface chelate (8). Consequently, the stability constant for the complex will be intimately related to the pK of the ligand (organic) provided the three-dimensional work of Chen may be translated to the surface chelate. The pK's of these compounds parallel the Hammett substituent constant. Therefore, the shift in equilibrium of [1a] or [1a"] should vary directly with the substituent constant. Since it was postulated above that inhibition was dependent on the stability of the surface chelate, by deduction it was again seen that inhibition is directly correlatable to a substituent constant.

Likewise, the oxidative propensity of the complex ion may be viewed in the light of Little's work (14). Here the iron of the complex undergoes a single electron oxidative transfer with retention of the structure of the complex. This is identical in form to [1b]. Consequently, extrapolating Little's results to the case under consideration, one deduces that the oxidative propensity of the complex ought to be a function of the substituent constant as well.

In summary, it can be seen [and experimentally demonstrated to an extent (8)] that an organic such as a ring substituted aniline compound is capable of performing the following functions at a corroding electrode: (*a*) chemisorbing on the surface; (*b*) forming a more or less stable complex with a corrosion intermediate and effectively removing the intermediate from the dissolution sequence; (c) formation of a complex as in (*b*) with a finite oxidative propensity. Each of these processes taken alone is theoretically capable of being correlated with a substituent constant with an unique value of ρ for each process. Since each of these separate functions derive their stability (or lack of it) from the electronic distribution throughout the molecule, it seems reasonable to suppose that as the electron density is varied in a family of molecules the relative contribution to each of these possibilities will change in a monotonic fashion. For example, a molecule with the greatest tendency for adsorption will probably have a small tendency for formation of the surface complex (one may view this molecule as being in a "stable" state while adsorbed) and, consequently, will have a negligible contribution to oxidation of the complex. On the other end of the spectrum one may envisage a molecule with a great affinity for the lattice ion, but a negligible tendency for long-lived adsorption. Such a molecule would function as an accelerator to corrosion. It would be fortuitous, indeed, if the ρ's for these respective procesess were identical.

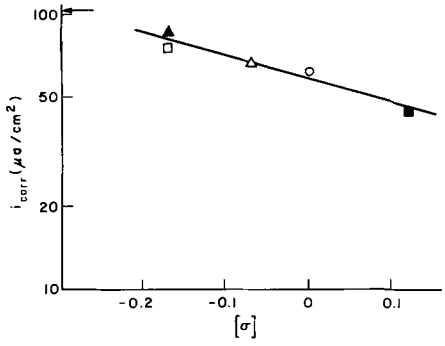

Fig. 3. Corrosion rate as a function of substituent constant for Armco iron electrodes after 2 hr immersion. Arrow denotes uninhibited rate. Symbols for compounds are given in Table I.

The comments immediately above suggest that attempts to formalize organic corrosion inhibitors in terms of a single correlation are not likely to succeed. Such a pessimistic outlook would be justified if the only data available to the investigator were the respective corrosion rates and correlation parameters. However, as was noted here and previously (8), each of these three functions, *viz.*, adsorption, complexation, and acceleration, can be determined to a degree by the supporting electrochemical measurements.

For electrodes in the solution for a short period of time, *e.g.*, 2 hr, it may be assumed that the adsorption step has essentially equilibrated. Since the results with most of the organics did not indicate a fast chelation process, even under conditions of high coverage as in the anodic charging experiments (8), it may be assumed that contributions from the chelate were minimal, thereby negating the oxidative mode as a contributor as well. Therefore, a LFER correlation under these conditions should describe the adsorption mode of inhibition and yield a value of ρ_{ads} for future use. Figure 3 is a correlation plot made under those conditions. It is noteworthy that the ortho substituent [a Taft σ^* was used for the correlation, see ref. (1)] obeys the adsorption LFER correlation. This rules out a perpendicular orientation with the nitrogen as the "anchoring" group. It suggests, but does not prove, a parallel orientation toward the surface.

Figure 4 shows a correlation plot for data after 25 hr immersion. This is the region where the minimum corrosion rate had been observed. The solid line, which was purposely drawn parallel to the line in Fig. 3, is meant to describe the adsorption "component" of the various functions described above. From the plot

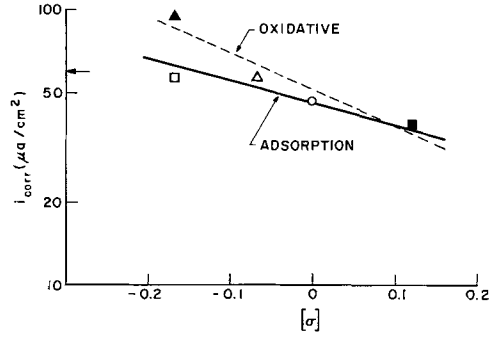

Fig. 4. Corrosion rate as a function of substituent constant for Armco iron electrodes after 25 hr immersion. Symbols for compounds are given in Table I.

it seems that an adsorption mode still describes the behavior of all the compounds except p-Toluidine which at this time is involved in an acceleration on the order of 50%. Therefore, it may be concluded that p-Toluidine is functioning in the oxidative mode. A second line (dashed) is drawn with the naive suggestion that this may describe the oxidative mode. However, such a correlation line cannot be drawn at this time. That adsorption is the main mode for the remaining organics corroborates the previous kinetic measurements (8).

Conclusions

The results presented herein show the validity of a LFER correlation for ring-substituted anilines in terms of corrosion inhibition. The results also demonstrated the necessity for supporting electrochemical measurements. This need was underlined when the analysis of the data suggested the existence of eight possible chemical and electrochemical reactions in the over-all scheme. Such a scheme could be deduced from corrosion rate measurements alone, but the supporting electrochemical measurements permitted definitive mechanisms to be ascribed to the various organics as a function of immersion time.

The observation that adsorption was the primary mode of inhibition by the organics studied lends support to an earlier hypothesis by Hackerman and Makrides (4); however, the results for the zone-refined iron in the presence of aniline (8) present a new challenge to this hypothesis which should be pursued further. The correlation of the work of Blomgren (13) with the current theory and the agreement of the O-Toluidine with the other compounds suggests parallel adsorption of free amine at the metal surface.

Mechanism of the Corrosion Inhibition of Stainless Steel in Sulfuric Acid by Sodium Molybdophosphate

E. A. Lizlovs

Research Laboratory, Climax Molybdenum Company of Michigan, Inc., A Subsidiary of American Metal Climax, Inc., Ann Arbor, Michigan

ABSTRACT

Sodium 12-molybdophosphate inhibits the corrosion of an actively corroding type 430 stainless steel sample in sulfuric acid by first polarizing the sample to the primary passivation potential. After this potential is reached, the stainless steel sample passivates spontaneously. From the potentiodynamic polarization curves it was deduced that the addition of sodium molybdophosphate to the sulfuric acid does not significantly alter the anodic characteristics of the type 430 steel in sulfuric acid. The experimental results were in agreement with the electrochemical theory for the passivator-type inhibitors.

The corrosion inhibiting properties of the molybdates are well known, and a considerable amount of research has been devoted to the subject. The inhibiting properties of the heteropolymolybdates, on the other hand, are far less known. Exploratory studies conducted at this Laboratory showed that sodium molybdophosphate or molybdophosphoric acid was an effective corrosion inhibitor for stainless steel in a sulfuric acid medium. In addition, the inhibition of corrosion of the actively corroding stainless steel sample was accompanied by the formation of the intensely blue reduced form of the molybdophosphate ion. Therefore, it was suspected that the molybdophosphates might be passivating-type inhibitors, the theory for which has been presented by Stern (1). Further work by Makrides and Stern (2) and by Makrides (3) demonstrated the validity of the theory for the inhibition of corrosion of type 410 stainless steel and pure iron by ferric sulfate. This investigation was undertaken to clarify the corrosion inhibition mechanism of the molybdophosphate ion.

Experimental Procedures

Commercial grade, type 430 stainless steel was used for all experiments. The construction and preparation of the electrodes is described elsewhere (4). All po-

tentials reported are for the saturated calomel electrode.

Two series of experiments were performed with type 430 stainless steel. One series consisted of the potentiodynamic polarization studies, and the other series was primarily concerned with the potential measurements of the corroding specimen.

Potentiodynamic studies were conducted in 1.05*N* H_2SO_4 containing 0.010, 0.100, 1.0, 3.0, and 6.0g of sodium 12-molybdophosphate ($Na_3PMo_{12}O_{40}\cdot nH_2O$) per liter of solution.[1] All experiments were performed in argon-purged solutions at 29.6°C, and the test solution was stirred magnetically. The potential scanning rate was approximately 0.15 mv/sec.

The minimum amount of the inhibitor necessary to passivate an actively corroding sample was determined by the slow addition of 1.05*N* H_2SO_4 solution containing 50 mg of $Na_3PMo_{12}O_{40}\cdot nH_2O$ per milliliter to 2100 ml of 1.05*N* H_2SO_4 test solution containing the corroding specimen. The potential of the sample was recorded on a strip-chart recorder. The transition from the active to the passive state was marked by a rapid and sharp potential rise from the active to the passive values.

The approximate amount of inhibitor necessary to maintain the passivity was established by passivating the type 430 electrode potentiostatically at +0.50v for 1, 10, and 60 sec, and 2 hr in a solution of 1.05*N* H_2SO_4 acid containing 0, 10, and 100 mg of the inhibitor per liter of solution. The potential decay was recorded after the discontinuation of passivation. The procedures for potentiostatic passivation and determination of the passive-film breakdown times are described elsewhere (4).

Results

The addition of sodium molybdophosphate to 1.05*N* H_2SO_4 resulted in a very pronounced change in the appearance of the potentiodynamic polarization curves for the type 430 stainless steel. The potentiodynamic curves for the pure 1.05*N* H_2SO_4 and for the sulfuric acid containing 0.100 and 6.0 g/l of sodium molybdophosphate are shown in Fig. 1 through 3. With an increased sodium molybdophosphate content, the oscillations in the polarization current became increasingly larger, the measured critical current density (I_{cr}') became smaller, and a progressively more extensive cathodic loop appeared on the polarization diagrams. For a sodium molybdophosphate concentration of 6 g/l, the measured polarization current remained negative up to the potential of +0.456v. The cathodic loop usually terminated at the equilibrium potential for the molybdophosphate/reduced molybdophosphate system, that is, at the potential exhibited by the platinum wire electrode in the test medium. This cathodic loop was due to the reduction of the molybdophosphate ion on the passive type 430 electrode. The oscillations in the cathodic current were dependent on the stirring rate of the solution. In stagnant solutions, no oscillations occurred and the current was considerably smaller.

The most striking feature of the polarization diagram was the presence of the anodic dissolution region even at the most concentrated solution used (Fig. 3). The increased amounts of sodium molybdophosphate depressed the anodic dissolution region; nevertheless, the height of this region was estimated as being unchanged and was approximately equal to that seen for pure sulfuric acid. The potentials (E_{pp}), corresponding to the measured critical current density, remained exactly the same for all concentrations of sodium molybdophosphate as for pure sulfuric acid. For the most concentrated solution (6 g/l of sodium molybdophosphate) no net anodic current was observed, and the measured critical anodic dissolution current was actually negative. The measured critical anodic current density and the corresponding primary passivation potentials are summarized in Table I. Average values are given when the current could not be determined exactly because of the oscillations.

The transpassive behavior of the type 430 stainless steel was not affected by the sodium molybdophosphate. The oxidation of the reduced molybdophosphate should occur in the transpassive region, but because of the small amount of the reduced form present, the oxidation current of this compound could not be de-

[1] Since the exact molecular weight of the $Na_3PMo_{12}O_{40}\cdot nH_2O$ is not known, the inhibitor concentrations are expressed in grams per liter rather than in molarity or normality. Approximate molarity can be calculated by assuming that the molecular weight of the $Na_3PMo_{12}O_{40}\cdot nH_2O$ is 2000 (see Table I).

tected in the presence of a much larger transpassive current.

Successive additions of sodium molybdophosphate to the 1.05*N* H_2SO_4 solution gradually polarized the corrosion potential of the freely corroding type 430 sample in the noble direction, until the critical potential was reached (Fig. 4). This critical potential was the same as the primary passivation potential determined by potentiodynamic studies, −0.440 to −0.435v. Once this potential was reached, passivation of the corroding electrode resulted. The passivation process was evident by a rapid change of the electrode potential from the active to passive values. The final potential of the electrode was about the same as the potential of a platinum electrode in the same solution, +0.492v. The minimum amount of sodium molybdophosphate needed to passivate freely corroding type 430 stainless steel in stirred 1.05*N* H_2SO_4 was determined to be 3.540 g/l (1.8×10^{-3}M). However, this amount was dependent on the stirring rate of the solution. In quiescent solutions the electrode continued to corrode even in solutions containing 6 g/l of sodium molybdophosphate.

The passive-film breakdown times for the type 430 stainless steel in 1.05*N* and in 1.05*N* H_2SO_4 containing sodium molybdophosphate are given in Table II. As Table II shows, the inhibitor concentration of 10 mg/l apparently represents the borderline concentration for maintenance of the passivity of type 430 steel after prior passivation. The experiments were not performed with more dilute solutions because of the increasing possibility of hydrolytic decomposition of more dilute solutions of molybdophosphate ion.

Discussion

The behavior of the type 430 stainless steel in sulfuric acid containing various amounts of sodium molybdophosphate is an agreement with Stern's electrochemical theory for the passivating-type inhibitors (Fig. 1 through 3). As the sodium molybdophosphate concentration is increased, the measured current becomes more negative because of the increased total reduction current. Nevertheless, the anodic dissolution region and the presence of the critical anodic current is clearly indicated even at sodium molybdophosphate concentrations of 6 g/l (Fig. 3), where the cathodic partial current at E_{pp} is greater than the critical anodic current, and consequently the total measured current is cathodic. The most striking feature is that E_{pp} remains unchanged for all concentrations of sodium molybdophosphate and is the same as for the pure sulfuric acid (—0.435v). The critical anodic current density can be estimated to be approximately the same in the presence of molybdophosphate as in the pure acid. Furthermore, the critical current densities for the two most dilute solutions, where the effect of the reduction current of the molybdophosphate is expected to be negligible at E_{pp}, are essentially the same as for the pure acid (Table I). Hence, it can be concluded that the anodic dissolution characteristics of type 430 stainless steel in 1.05*N* H_2SO_4 are not affected by the sodium molybdophosphate additions to the acid. The main function of the inhibitor is to polarize the steel until the corrosion potential coincides with the primary passivation potential. Further polarization then results in spontaneous passivation of the stainless steel sample (Fig. 4) with the final potential value being determined by the redox potential of the molybdophosphate/reduced molybdophosphate system. Thus, the molybdophosphate ion belongs to the passivating class of inhibitors. As the corrosion potential becomes more noble, corrosion rates increase until the critical value of 8.0 to 8.8 ma/cm² is reached. The corrosion rates at any corrosion potential up to E_{pp} in the presence of molybdophosphate ion should be the same as the corrosion rates at the corresponding potentials under potentiodynamic conditions in pure sulfuric acid. The corrosion rates of type 430 steel in the passive state are negligible as can be seen from the polarization diagram shown in Fig. 1, and these rates are also expected to be negligible in inhibited solutions.

According to well-known electrochemical principles, any corroding metal for which the measured critical current density is positive will corrode actively in that medium. On the other hand, if the measured critical current density is zero or negative, the metal will undergo spontaneously active-passive transition. Furthermore, if the potentiostatic (or potentiodynamic) polarization curve for a metal in a corrosive medium is characterized by a cathodic loop, a corroding metal can continue to corrode actively or remain passive, depending on the conditions under which it is exposed to the corrosive medium. No spontaneous transition from one state to the other can take place. The results from this investigation are again in agreement with the theoretical principles above. A spontaneous passivation occurred in a solution containing 6.0 g/l of molybdophosphate for which I_{cr}' is negative (Fig. 3). At the inhibitor concentration of 3.0 g/l no spontane-

ous passivation is expected; however, the value of I_{cr}' is close to zero (Table I), and small changes in experimental conditions can be expected to result in spontaneous passivation. Increase of sodium molybdophosphate concentration to 3.540 g/l indeed resulted in the spontaneous passivation (Fig. 4). No spontaneous passivation is expected for the 1.0 and 0.100 g/l concentrations, but if the sample were passivated in these solutions, a stable passive state should result because of the prominent cathodic loops present on the polarization curves for these solutions (Fig. 2). This conclusion was also verified by the experiments, and no breakdown of passivity was obtained in these solutions if the sample had been passivated. On the other hand, the specimen continued to corrode actively after cathodic activation and no repassivation occurred. The solution containing 0.010 g/l of the sodium molybdophosphate represents the borderline case. The potentiodynamic polarization curve has a cathodic loop, but this loop is not very pronounced. A small change in experimental conditions can be expected to result in the retention or loss of passivity after the passivation treatment. This again is in accord with experimental observations. In very dilute solution a partial hydrolytic decomposition of the molybdophosphate ion can be expected. Therefore, the retention of the passivity in a dilute solution such as 0.010 g/l (5×10^{-6}M) may be partially due to some form of molybdate ions.

The effectiveness of the molybdophosphate ion as a passivating agent depends on the ease of its reduction. Earlier observations in this Laboratory have shown that the molybdophosphate ion is very easily reduced to an intensely blue compound. Because of its ease of reduction it is quite corrosive to many metals, including molybdenum, tungsten, and copper. Because of the diffusion control of the reduction reaction in the important potential range around E_{pp}, the passivating process is drastically influenced by the rate of transport of the inhibitor to the surface of the corroding specimen. The minimum amount of the molybdophosphate necessary to passivate the specimen will therefore be strongly dependent on the hydrodynamic characteristics of the system. However, once the passivation occurs, the rate of mass transfer no longer has a significant effect and the passivity will be retained in quiescent solutions.

The minimum amount of molybdophosphate ion necessary to passivate any metal or alloy in acid solution, aside from the hydrodynamic considerations discussed above, will usually depend on the magnitude of the anodic critical current density. For stainless steels more alloyed than type 430, considerably smaller quantities of the sodium molybdophosphate will be needed for passivation. On the other hand, for metals with very large critical current requirements, no amount of the inhibitor will be sufficient to affect the active-passive transition, and the only effect will be the acceleration of the corrosion rate. Thus, for iron, which has a critical current density of about 600 ma/cm^2 in 1N H_2SO_4 (5), no amount of sodium molybdophosphate is expected to effect passivation. Exploratory studies showed that no passivation of iron electrode occurred in vigorously stirred 1.05N H_2SO_4 containing as high as 50 g/l of sodium molybdophosphate. The results from this investigation were in agreement with the results of Makrides and Stern, and Makrides for the ferric sulfate system (2, 3).

The Nonelectrolytic Deposition of Titanium on Columbium Alloys from Fused Salts

J. B. Steinman, R. V. Warnock, C. G. Root, and A. R. Stetson

Solar Division, International Harvester Company, San Diego, California

ABSTRACT

A high-temperature cell was designed for deposition of metallic coatings on refractory alloy substrates. The deposition of titanium from fused chloride and fluoride salts onto columbium alloys was investigated at several temperatures from 800° to 1100°C. The as-deposited coatings were generally dense and adherent and exhibited excellent side-to-side and edge uniformity. An explanation of the driving force and a mechanism for nonelectrolytic deposition is proposed, and an activation energy for deposition is calculated.

Considerable work has been directed toward the development of a process for the production of high-purity titanium and, alternatively, toward deposition of a uniform titanium coating from a molten salt bath. Studies at the National Bureau of Standards (1) produced titanium coatings 0.001- to 0.002-in. thick by electrolysis of a fused salt bath containing $NaTiCl_4$, KCl, and LiCl. Current densities up to 200 amp/ft^2 were used and the deposit was largely dendritic. Using an all-fluoride bath, K_2TiF_6 and NaF, Stetson was able to deposit a fairly uniform titanium coating by the electrolytic method (2). However, electrolytic deposition of titanium from a fused salt bath has produced primarily dendritic growths rather than smooth coatings.

Gill, Straumanis, and Schlecten first observed the corrosion of titanium in NaCl to form "pyrosols," and the subsequent use of these sols in the titanium coating of steels, copper, nickel, and cobalt (3-5). Alpert used scrap titanium, a partially reduced $TiCl_3$-$TiCl_2$ mixture, and NaCl to produce a titanium bath which reportedly gave coatings up to 0.02-in. thick on nickel,

iron, and tantalum (6). Stetson and Moore (7) successfully plated titanium on the columbium alloys, D43 and B66, with a K_2TiF_6, NaCl, LiF, Ti bath. This bath was run nonelectrolytically between 1010° and 1093°C and gave 0.0007 in. of titanium alloy plate in 20 hr.

The nonelectrolytic deposition of chromium, aluminum, nickel, titanium, silicon, and vanadium has been observed by the authors to occur from fused salt baths.

In the present work, an investigation of nonelectrolytic titanium plating was conducted. All fluoride, K_2TiF_6-LiF-NaF-Ti and all chloride, $TiCl_3$-NaCl-$BaCl_2$-Ti baths were investigated at two active salt concentrations and two temperatures. Additional work has shown that the baths will plate well without the addition of K_2TiF_6 or $TiCl_3$; however, the equilibration period before acceptable deposits and deposition rates can be obtained is approximately three days compared with one day for the baths with active salt additions. Two additional temperatures were investigated with a 5 m/o (mole per cent) K_2TiF_6 bath in an effort to determine the activation energy for deposition. Smooth, uniform, titanium alloy coatings up to 0.007-in. thick were obtained in 16 hr at 1093°C.

A special plating cell was designed for use in this project, and provisions were made for control of the atmosphere above the baths at all times.

Materials

All chemicals used in this work were of reagent or better grade. The barium chloride was vacuum dried at 150°C to eliminate hydrated water. All other chemicals were used as supplied. Commercially pure titanium sheet was used to fabricate the cylindrical titanium source used in each bath.

Cb752 (Cb-10W-2.5Zr) and D43 (Cb-10W-1Zr-0.1C) were used as the substrate alloys. Both alloys were obtained as 0.020-in. thick sheet and were in the duplex heat-treated condition (solution treated, cold reduced 25%, and aged). Table I shows chemical analyses of the as-received columbium alloys.

Two bath concentrations were investigated in the fluoride system and one in the chloride system. The fluoride baths consisted of 5 m/o K_2TiF_6, (28.0 w/o K_2TiF_6, 34.6 w/o LiF, 37.4 w/o NaF) and 20 m/o K_2TiF_6 (65.1 w/o K_2TiF_6, 16.8 w/o LiF, 18.1 w/o NaF) dissolved in LiF-NaF eutectic. The chloride baths were prepared by dissolving 5 m/o $TiCl_3$ in a eutectic mixture of $BaCl_2$-NaCl to give a 6.4 w/o $TiCl_3$, 27.8 w/o NaCl, and 65.8 w/o $BaCl_2$ bath. Sufficient titanium metal, in the form of a cylinder, was provided to effect reduction of the baths and to maintain metallic titanium in contact with the bath at all times. The melts weighed approximately 1600g and gave a bath depth of approximately 8 in.

Equipment

A high-temperature plating cell was designed for deposition of metallic coatings on refractory alloy substrates. Provisions were made to ensure positive control of the argon inert atmosphere and to prevent atmospheric contamination of the bath during insertion and extraction of specimens. The cell was designed to operate in the temperature range 427°-1150°C (800°-2100°F) in a gas fired furnace with a temperature control of ± 5°C. A schematic diagram of the cell is shown in Fig. 1.

The bottom part of the cell is 0.125-in. Inconel 600 tube that has been aluminized. The upper chamber

Cb752	52	6	42	10	9.97	2.5

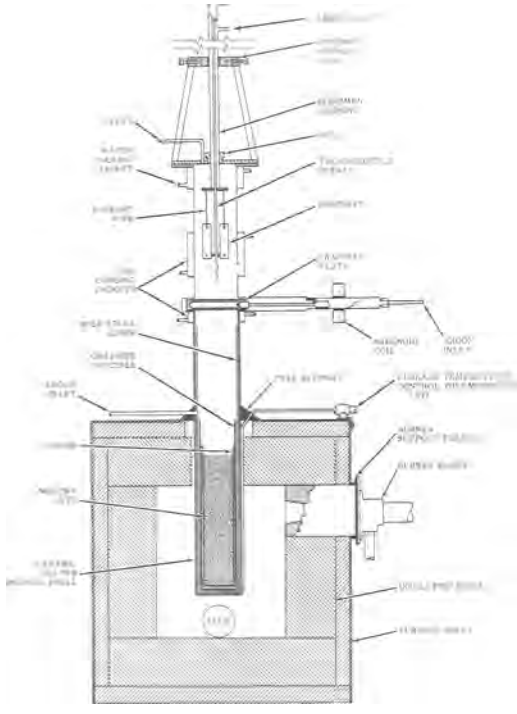

Fig. 1. Schematic diagram of fused salt plating cells

was fabricated from type 321 stainless steel and is separated from the lower bath chamber by a graphite gate valve actuated magnetically by a solenoid coil. This arrangement permits insertion and removal of specimens while continuously purging the lower chamber with argon.

The specimens, 2.0 x 0.5 x 0.020 in., are hung on tantalum wires welded to the Inconel specimen support rod which enters the cell through a Teflon compression seal. The cell top, through which the specimen support rod passes, is bolted to the upper chamber flange and is sealed with an O-ring.

The bath is contained in a National Carbon Company ATJ grade graphite crucible with an ID of 2.875 in. This grade of high-density graphite has proven impermeable to the salt mixtures at operating temperatures. The graphite crucible is placed in a mild steel liner which is, in turn, placed inside the Inconel retort. The bottom half of the crucible is wrapped in 0.002-in. molybdenum foil to prevent formation of the iron-carbon eutectic and subsequent fusion of the liner to the Inconel retort.

The furnace is gas fired using an Eclipse Tempered Air Burner. The temperature is controlled by a Barber-Coleman controller operating on the output of a chromel-alumel thermocouple in a protective sheath attached to the outside of the retort. The internal bath temperature is monitored by means of a tantalum-sheathed chromel-alumel thermocouple which enters the bath through the specimen support rod. Water and air cooling jackets are available for cooling the upper chamber but were not used in this work.

Procedure

The entire weighed salt mixture is placed in the graphite crucible into which has been inserted a cylindrical sheet of pure titanium (this is the titanium source in the deposition reaction). The molybdenum-wrapped crucible is then placed in a liner which is, in turn, placed in the cell. After assembly, the cell is purged with argon (99.997% argon) for 4 hr (the time required to decrease the oxygen level in the cell effluent to <5 ppm) with an argon flow of 8 cfh. The furnace is then fired and the cell temperature brought to about 450°C and held for 16 hr. This procedure permits elimination of volatile impurities present in the salt mixture. The temperature is brought to 1093°C

Table II. Titanium deposition on Cb752 from a 5 m/o K_2TiF_6 bath

Time, hr	Average weight gain in mg/cm²			
	799°C (1470°F)	872°C (1600°F)	982°C (1800°F)	1093°C (2000°F)

2	1.5	2.9	7.1	14.4
4	2.1	5.7	11.2	23.6
16	4.3	12.4	29.2	50.0

where the salt is fused and allowed to "equilibrate" (establish a uniform temperature, become homogeneous, and reach the proper valence state).

The bath preparation procedure is slightly modified in the case of the chloride baths. The anhydrous reagent grade $BaCl_2$ contains some water of hydration even after heating to 150°C in a vacuum drying oven. The remaining moisture is eliminated by heating the NaCl-$BaCl_2$ solvent to 1100°C in a stream of argon in the fused salt cell. The $TiCl_3$ is then added in a polyethylene bag suspended from the specimen support wires. The polyethylene decomposes and is vaporized.

To insert the specimens, the top of the cell is removed (with the gate valve closed). The specimens, hung on the tantalum support wires, are introduced into the upper chamber which is then sealed, and purged with argon for 15 min. The gate valve is then opened, and the specimens are lowered into the bath. For removal, the specimens are raised out of the bath into the upper chamber and the gate valve is closed. The specimens are allowed to cool in the argon atmosphere in the upper chamber for 5 min before the cell is opened and the specimens removed. The adherent salt is readily removed from the specimens after a short period of soaking in hot water.

Experimental Results

Titanium deposition studies were carried out in two different fused salt systems: the all-fluoride system and the all-chloride system. The carrier salt composition for a given system remained the same throughout the studies while the active salt percentage was varied.

The all-fluoride system.—A series of plating runs was made in both the 5 and 20 m/o K_2TiF_6 baths. Four temperatures were investigated in the case of the former and the two standard temperatures, 982° and 1093°C (1800° and 2000°F) for the 20 m/o bath. The temperatures studied in the 5 m/o bath included 799°, 872°, 982°, and 1093°C (1470°, 1600°, 1800°, 2000°F). The data from the runs in the 5 m/o K_2TiF_6 bath are shown in Table II and plotted in Fig. 2.

The series of plating runs in the 20 m/o K_2TiF_6 bath at 982° and 1093°C produced results very similar to those from the 5 m/o bath. The deposition ranged from a low of 4.4 mg/cm² in 1 hr at 982°C to a high of 80 mg/cm² in 16 hr at 1093°C. Both macroscopically and microscopically the coatings were similar to those deposited from the 5 m/o K_2TiF_6 bath.

	982°C (1800°F)	1093°C (2000°F)
1	2.5	6.5
2	4.5	8.4
4	7.5	14.9
16	16.6	36.0

Table IV. Titanium deposition on D43 alloy

Bath	Time, hr	Weight gain (mg/cm²)	
		982°C	1093°C
5 m/o K_2TiF_6	2	6.8	—
	4	7.6	—
5 m/o $TiCl_3$	2	4.7	6.3
	4	9.1	13.8

All-chloride system.—A 5 m/o $TiCl_3$ bath was investigated at 982° and 1093°C. A series of runs was completed at each temperature on the Cb752 alloy, and the data are presented in Table III and plotted in Fig. 3.

The deposition rate in this chloride bath was found to be somewhat lower than that found in the all-fluoride system.

Two- and four-hour runs were made in the baths studied using D43 specimens. Results are shown in Table IV.

Comparison of this data with that for Cb752 shows the rate of titanium alloy formation to be slightly higher on Cb752 in two of the three comparable cases. While substrate composition should have a considerable influence on diffusion controlled deposition, little substrate effect was seen in this case since the alloys are quite similar. There is a possible exception which might be caused by the only compositional difference in the alloys. This one notable difference is the carbon content of the D43 which makes this alloy precipitation hardened (ZrC precipitates). The carbon in the alloy could influence the initial titanium deposition rate because of the possible formation of TiC. However, this effect was not seen in the present work.

The deposition rate curves for all the baths are generally parabolic in shape and fit an equation of the form, $W^2 = kt$, where W is the weight gain, k is a rate constant, and t is the time. The rate constants are a function of temperature and for the 5 m/o K_2TiF_6 bath ranged from 1.1 at 799°C to 131 mg²/cm⁴ hr at 1093°C.

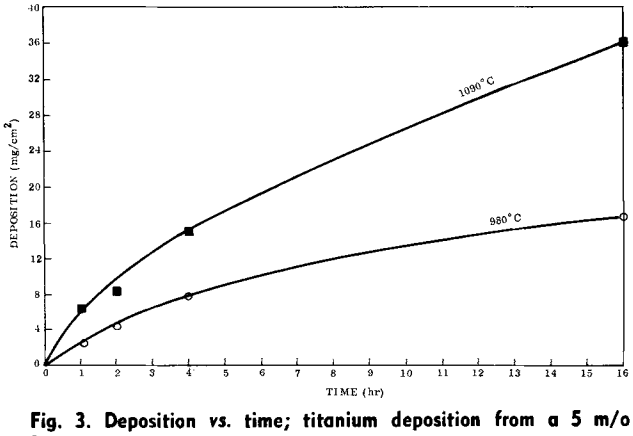

Fig. 3. Deposition vs. time; titanium deposition from a 5 m/o $TiCl_3$ bath on Cb752 alloy.

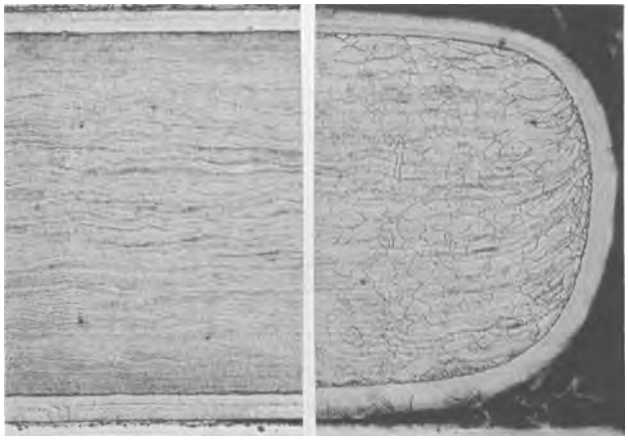

Fig. 4. Cb752 substrate (0.020 in.) with a titanium alloy coating applied in the all-fluoride bath at 1093°C (2000°F) in 4 hr: A (left), note the uniformity of thickness from side to side of the specimen; B (right), edge coating uniformity is shown. Magnification ca. 100X.

All of the deposits were smooth, adherent, and presented a shiny macroscopic appearance. Figure 4 shows a photomicrograph of a typical titanium-coated specimen. The side-to-side and edge uniformity should be noted.

Microhardness traverses were made on typical specimens from each of the baths studied in both fluoride and chloride systems. Results were similar for all baths, and a typical microhardness traverse is shown in Fig. 5. The average hardness of the as-received Cb752 alloy is 280 Knoop Hardness Number (50-g load).

A representative group of Cb752 specimens, coated with titanium in different baths, was subjected to bend ductility tests at minus 73°C. In all cases, the specimens bent without fracture or visible signs of cracking as did the uncoated standards. The titanium alloy coating remained intact.

As noted earlier, the baths were protected by an argon atmosphere at all times. It was found that any exposure of the bath to the air resulted in decreased plating rates. For example, exposure of the molten bath surface for less than 5 min resulted in as much as a 75% decrease in plating rates and a concomitant loss in coating quality. Shih and co-workers (8) claimed that the presence of oxygen in a Ti-NaCl or KCl bath was necessary for plating and indicated that poor coatings on iron resulted when no oxygen was present.

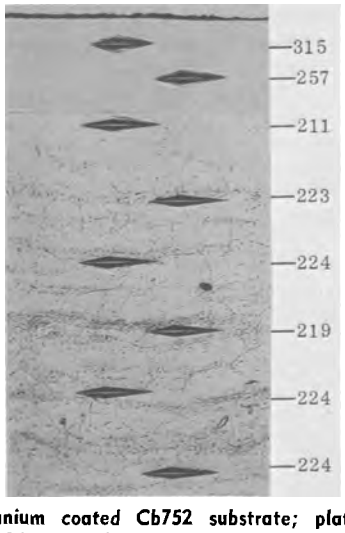

Fig. 5. Titanium coated Cb752 substrate; plated in 5 m/o $TiCl_3$ bath for 16 hr at 1093°C (2000°F). Magnification ca. 200X.

While it was not possible to completely exclude oxygen from the fused salt baths in this investigation, all practical precautions were taken to prevent its introduction. It should be noted that the titanium deposition rates in this study were two to four times greater than any reported in the literature.

Discussion of Results

The fused salt baths investigated in this work produced smooth, adherent titanium alloy deposits on both Cb752 and D43 alloys. Close examination of the specimen cross section seen in Fig. 4 shows two different structures. The single-phase region adjacent to the substrate is probably columbium-rich, beta titanium alloy. The outer, Widmanstatten-like structure is a very dilute solid solution of columbium in transformed beta titanium alloy and was not evident on thinner coatings which showed the single-phase, beta structure only.

The substrate was also affected by the coating treatment. Examination of the microhardness traverse in Fig. 5 shows a loss in substrate hardness. This loss, in all cases, was most pronounced in the area immediately adjacent to the coating and was as much as 25% in some cases. The decrease in hardness was greater at higher temperatures and longer times. This phenomena may be explained by the "interstitial sink effect" (9). This term is used to describe the potential for migration and the equilibrium partition of an interstitial element as a result of the difference in the partial molal free energies of the element in two adjacent metallic layers.

The Cb752 alloy is basically a solid solution strengthened alloy depending on oxygen in solution plus a small distribution of ZrO_2 precipitates. These precipitates are readily seen in the as-received alloy with the aid of electron microscopy. A similar examination of the titanium-coated alloy revealed a large reduction or complete elimination of this precipitate for varying depths below the coating-substrate interface depending on the coating time and temperature. The distribution of oxygen between columbium and titanium may be calculated by considering the partial molal free energies of solution. This partition at 1500 K (at equilibrium) in a titanium-coated Cb752 alloy is:

	Columbium	Titanium
Oxygen, ppm	1	1000

In an effort to fully characterize the plating chemistries, periodic chemical analyses were performed on the operating baths. Comparison of the observed data (weight per cent titanium in the bath) and theoretical weight per cents, as a function of oxidation state, gave an indication of the valence state of the titanium in a bath. Previous work reported in the literature (10, 11) indicated that the predominant reduction product in a K_2TiF_6 bath, similar to those used in this work, was Ti^{+3}. Analyses and calculations have shown the average valence in the fluoride baths to be generally between +2 and +3, while the predominant species in the $TiCl_3$ baths was found to have an average valence of +2.2. Kreye and Kellogg (12) reported Ti^{+2} as the dominant species in an NaCl-KCl-$TiCl_3$ melt at 760°C. They also observed a slightly lower Ti^{+2} concentration at 782°C with a corresponding increase in the Ti^{+3} species. These findings are in accord with the +2.2 average valence in the present work and might also explain the somewhat higher plating rates found in the K_2TiF_6 baths compared with the chloride system. With an average valence of +2.2, the chloride baths were not in as fully reduced a condition as were the fluoride baths when in the +3 or lower state.

The parabolic nature of the deposition rate indicates that the deposition is controlled by diffusion into the metal substrate. A diffusion controlled hypothesis is supported by considering the difference in chemical

activity between the titanium in the source and the titanium in solution in the columbium. The activity of the titanium in solution in the columbium is lower than the activity of the titanium in the source. The decrease in activity from the pure to the alloyed state is then the probable driving force for deposition. It was also noted that the deposition rate was highly temperature dependent, increasing with increasing temperature. This behavior would be expected in a diffusion-controlled reaction as the diffusivity increases with the temperature. Further, if the deposition were diffusion controlled, the rate constant, k, from the equation

$$W^2 = kt \quad [1]$$

could be described by the Arrhenius equation and expressed by:

$$k = A\ (\exp) -\frac{Q}{RT} \quad [2]$$

where A is a constant, Q might be called the "activation energy for deposition," R is the universal gas constant, and T is the absolute temperature. If the diffusion hypothesis is correct and Eq. [2] accurately describes the rate constant, an Arrhenius plot of ln k *vs.* $(1/T)$ should yield a straight line. Such a plot is shown in Fig. 6 for the 5 mole per cent K_2TiF_6 bath and is seen to be linear. An activation energy for deposition was determined graphically from Fig. 6 and is 46 kcal/mole. This may be compared to the activation energy for diffusion of titanium in columbium which ranges from about 61 kcal/mole in pure columbium to 39 kcal/mole in pure titanium (13) while the activation energy for diffusion of complex titanium ions in fused salt solutions is expected to be only 6-10 kcal/mole (14). This further supports the hypothesis that the rate-determining step is interdiffusion of the titanium and the basis metal.

Straumanis *et al.* (15) determined the activation energy for diffusion of titanium into an iron substrate. A value of 32 kcal/mole may be calculated from their reported data. This may be compared with the value of 46 kcal/mole determined in the present work and designated, "the activation energy for deposition." More precisely, the latter value, 46 kcal/mole, reflects the activation energy for diffusion of titanium in a columbium alloy, and a comparison of the two values indicates that a titanium alloy coating may be developed more easily on an iron substrate than a columbium substrate under similar conditions if nearly equal frequency factors (A) are assumed. Preliminary work was undertaken to substantiate this conclusion, and results are presented in Table V.

No runs were performed which lasted over 60 min; however, as might be expected, the initial titanium deposition rate is faster on iron than on columbium by a factor of 1.4 to 2. In general, diffusion activation energies of metals in substitutional solid solution are proportional to the melting point, and deposition rates should also be proportional to melting points. An approximately linear relationship between titanium deposition rate and substrate melting point has been observed (over an 1800°C substrate melting point range) in other work by the authors.

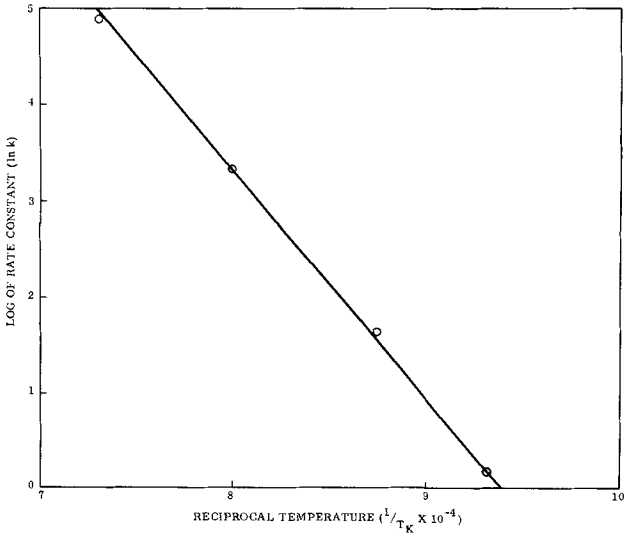

Fig. 6. Arrhenius plot ln k *vs.* reciprocal absolute temperature

Table V. Titanium deposition on 1010 steel from a 20 m/o K_2TiF_6 bath

Time, min	Average weight gain (mg/cm²) at 982°C
2	0.8
6	1.9
15	3.4
30	4.0
60	6.9

There are several possible mechanisms (of which three are most apparent) which could account for the deposition of titanium on columbium alloys with the subsequent formation of a titanium-rich titanium/columbium alloy at the specimen surface. One such mechanism is an oxidation reduction type in which reactions similar to the following might occur:

$$3Cb\ (\text{alloy}) + 5TiF_3 \rightarrow 3CbF_5 + 5Ti$$

or

$$2Cb\ (\text{alloy}) + 5TiCl_2 \rightarrow 2CbCl_5 + 5Ti$$

Interdiffusion of the titanium and columbium would then produce the observed alloy coating. The operation of this oxidation-reduction mechanism should result in a decreased substrate thickness, an over-all weight loss or slight weight gain (depending on the coefficients in the redox equation chosen), and the accumulation of columbium in the bath.

Another possibility is a disproportionation reaction leading to the production of titanium metal. A possible representation is:

$$Ti + 6F^- + 3TiF_6^{-2} \rightarrow 4TiF_6^{-3}$$

$$Cb + 4TiF_6^{-3} \rightarrow 3TiF_6^{-2} + 6F^- + (\text{Ti-Cb alloy})$$

This mechanism should be dependent on TiF_6^{-3} concentration and would presumably decrease to a negligible rate with decreasing temperature. As long as sufficient titanium is present to support the deposition rates observed, interdiffusion rates would still control the plating rate. It is possible that some TiF_4 would be lost from the bath as a gaseous species; however, it would more probably be retained as a complex F^- ion.

The remaining possible mechanism is the diffusion of dissolved or finely dispersed titanium in the melt into the columbium substrate; for example

$$Ti + Cb\ (\text{alloy}) \rightarrow TiCb\ (\text{alloy})$$

Again, the deposition rate should be a function of the ease of interdiffusion of titanium and the substrate material and should decrease with increasing alloy thickness. All of the suggested mechanisms would be temperature dependent.

The oxidation-reduction type mechanism can be eliminated because no decrease in substrate thickness occurs and a positive weight gain is always observed for a coated specimen.

Straumanis, Shih, and Schlecten (15) stated that they were able to differentiate between a disproportionation type reaction and one in which dispersed titanium metal or TiO_x reacted to form the alloy coating. They concluded that the coating was formed by direct impact of dispersed titanium or TiO_x particles in the melt with the surface to be coated.

When examining the possibility of the dissolved or finely dispersed titanium theory, it is interesting to note that recent work (16) has demonstrated the ex-

istence of true solutions of metals in their own halide salts at elevated temperatures. Although no data are available for solutions of titanium in titanium-fluoride or chloride melts, it is quite possible that such systems do exist. X-ray diffraction analysis of melt samples in the present investigation failed to show the presence of any free titanium or titanium oxides in the bath. This does not, though, eliminate the possibility of dissolved titanium metal.

Sufficient data are not available from the present work to determine whether disproportionation of a reduced titanium complex at the specimen surface or mechanical adherence of free titanium metal is the coating mechanism. Evidence for both mechanisms exist, and neither may be ruled out at this time.

Acknowledgments

The authors are indebted to Messrs. Warren Johnson and Gail Eichelman for helpful discussions and technical direction on this program. Electrolytic Reductive Coupling

XV. Electroreductions of Aqueous Concentrated Solutions of Diethyl Maleate in the Presence of Sodium or Tetraethylammonium Cations[1]

Manuel M. Baizer and John P. Petrovich

Central Research Department, Monsanto Company, St. Louis, Missouri

ABSTRACT

Concentrated solutions of diethyl maleate in dimethylformamide-water containing sodium or tetraethylammonium *p*-toluenesulfonate were electrolyzed at constant current. The yields of diethyl succinate and of tetraethyl butanetetracarboxylate were determined. At a given concentration of supporting cation and of bulk water less hydrodimer is formed in the presence of sodium than in the presence of tetraethylammonium cations. These results are related to previous suggestions concerning the influence of the degree of hydration of the supporting cations upon the nature of the electroreduction products.

It has been suggested (2) that during the electroreduction of concentrated aqueous solutions of acrylonitrile the presence of alkali metal cations (M^+), which are simultaneously discharged, leads to substantial yields of propionitrile [1] because of concomitant chemical reactions, whereas the replacement of M^+ by quaternary ammonium cations (R_4N^+), which are not discharged at the operating cathode potential, permits the attainment of very high yields of adiponitrile [2].

$$CH_2{=}CHCN + 2\bar{e} + 2H_2O \xrightarrow{M^+(H_2O)_x} CH_3CH_2CN + 2\,\overline{OH} \quad [1]$$

$$2CH_2{=}CHCN + 2\bar{e} + 2H_2O \xrightarrow{R_4N^+} NC(CH_2)_4CN + 2\,\overline{OH} \quad [2]$$

Recently Feoktistov and co-workers (3) and, independently, Gillet (4) have offered an alternate explanation for the change in the distribution of reduction products when one replaces supporting electrolytes containing M^+ by those containing R_4N^+. They have pointed out that alkali metal cations are hydrated while quaternary ammonium cations are not. As a consequence, Gillet has argued, when the acrylonitrile molecule, aligned with the β-carbon atom on

[a] Sodium p-toluenesulfonate.
[b] Tetraethylammonium p-toluenesulfonate.
[c] Initially 5.0 ml of diethyl maleate was included in the catholyte. The remainder, to a total of 25.8g (0.15 mole), was added in the course of the run. Acetic acid had to be added dropwise to maintain the desired pH.
* Identified by comparison of vpc retention time with samples previously prepared (7). Two isomers in a ratio of *ca* 93/7 (presumably meso-/dl) were obtained.

the cathode surface, is being reduced[2] the final anionic intermediate which is just leaving the cathode surface has an opportunity to react at the β-carbon atom with water when $M^+(H_2O)_x$ is the counterion [1], whereas it has an overwhelming opportunity to react with a second acrylonitrile molecule when R_4N^+ $(H_2O)_o$ is the counterion.

The purpose of the work reported here was to test the effect of (supporting) cation hydration on the yield of hydrodimer prepared from an activated olefin whose electroreduction occurs at a cathode voltage at which simultaneous cation discharge is unambiguously avoided. While several monoactivated olefins CH_2= CHX (where X is an electron-withdrawing group) are available which reduce at a considerably more positive cathode voltage than is required for $Na^+(H_2O)_x$ discharge, they may, like methyl vinyl ketone, undergo under the conditions of electrolysis various chemical side reactions which complicate the interpretation of the results. Because its reduction occurs at a voltage at least 0.7v more anodic than that of $Na^+(H_2O)_x$, its polarography has been extensively[3] studied (6), its electrolytic hydrodimerization to tetraethyl butanetetracarboxylate has been reported (7), and its side reactions during reduction are minimal, diethyl maleate was chosen as the model activated olefin for this study.

Experimental

Reagents.—Diethyl maleate (Matheson Scientific, Superior) was used as received. Vpc and nmr analyses showed that it contained about 8% diethyl fumarate. Tetraethylammonium p-toluenesulfonate (Alfred Bader Company) was recrystallized from acetone and dried *in vacuo* at 60°. Sodium p-toluenesulfonate was prepared from the acid and base and dried as above. The dimethylformamide (DMF) was redistilled through a Vigreau column at atmospheric pressure.

Equipment.—The electrolysis cell and associated apparatus have been described (1). A mercury cathode, area 55 cm^2, was used throughout. Vpc analyses of the products obtained from the electrolyses were carried out using an F and M Model 300 instrument; the column contained 1% silver nitrate and 18% Carbowax 20M on 35-48 mesh Chromosorb W and was used at 125° (for "low boilers") and at 225° (for "high boilers").

Procedures.—The electrolysis data are summarized in Table I. The catholytes contained 43.0g (0.25 mole) of diethyl maleate, 0.10 mole of sodium (19.4g) or tetraethylammonium p-toluenesulfonate (30.1g), and 96 ml of a DMF-water mixture; the total volume was *ca.* 150 ml. The anolytes were saturated aqueous solutions of the same electrolyte present in the catholyte. The electrolyses were conducted at a constant current of 1.00 amp for 3 hr. The cathode voltage in the several experiments was −1.19 to −1.30v (SCE). Acetic acid was available for dropwise addition to the catholyte in order to maintain the pH at 7-8 (measured externally on Alkacid paper). Usually no acid addition was needed, indicating that saponification of the ester was rapid enough to provide a buffering effect. No hydrogen was evolved. At the end of the electrolysis the catholyte was separated from the mercury, diluted with 200 ml of ice water, and extracted with three 100 ml portions of methylene chloride. The combined extracts were washed with three 100 ml portions of water and dried over anhydrous magnesium sulfate. The filtered solution was heated on a water bath to remove methylene chloride and then fractionated through a 2-ft Vigreau column to a vapor temperature of 50° (18 mm) to remove the bulk of the residual DMF. The remaining crude mixture of esters was fractionated through a semimicro apparatus having a vacuum-jacketed 6-in. Vigreau column. The following fractions were collected: (*i*) to 115° (20 mm), (*ii*) 115°-118° (20 mm), (*iii*) to 153° (0.25 mm), (*iv*) 156°-161° (0.25 mm), (*v*) pot residue.[4] Each fraction[5] was analyzed by vpc first at 125° to determine DMF, diethyl maleate, diethyl succinate, and diethyl fumarate and then at 225° to determine tetraethyl butanetetracarboxylate and its ratio to the lower boiling components.

Discussion of Results

At a given level of proton donor (water) concentration in the catholyte, all other conditions being the same, more hydrodimerization occurs in the presence of tetraethylammonium than of sodium (run 3 *vs.* 1; run 4 *vs.* run 2). The hydrodimerization is less sensitive to increasing water concentration when tetraethylammonium is used than when sodium is used, *e.g.*, the yield of hydrodimer in run 7 is 89.5% of its value in run 3, whereas the yield in run 6 is only 68.3% of its value in run 1. Further the addition of tetraethylammonium to a catholyte containing sodium (run 5) is capable of elevating the yield of hydrodimer substantially. These results lend support to the proposal (3, 4) that, in effect, adsorption of tetraalkylammonium on the mercury cathode leads to the establishment of a water-poor zone close to the cathode surface.[6] The substantial yield of hydrodimer ob-

[2] In the over-all two-electron process the acrylonitrile may during the uptake of the first electron react simultaneously at the -CN or α-carbon atom with a molecule of water from the bulk of solution [5].
[3] Professor Wawzonek has pointed out that the polarography of diethyl maleate in tetralkylammonium electrolytes has not been previously reported. While this information will be later presented separately in a paper describing work which is currently in progress, it may be stated now that in aqueous dimethylformamide no significant differences were found in the polarographic behavior using sodium or tetraethylammonium supporting electrolytes.
[4] This was always negligible, indicating that no oligomers higher than the hydrodimer had been formed.
[5] This procedure gave more satisfactory results than the attempted vpc analysis of the crude mixture directly.
[6] This may likewise explain the reported excellent yield of adiponitrile from acrylonitrile in an amalgam reduction in the presence of aqueous acid and tetraethylammonium p-toluenesulfonate (8).

tained (run 8) even when the concentration of diethyl maleate in the catholyte at a given time is relatively low and the concentration of water relatively high emphasizes again the need for caution in predicting the products of an electrochemical reduction; this is particularly true when activated olefins are involved.

Since all runs were carried out at the same constant current density, the rates of generation of the reduced intermediates were the same. If formation of hydrodimer occurred *via* radical coupling of anion-radicals or (after neutralization with water) their derived radicals, the yield of hydrodimer should not be affected by the nature of the supporting cation nor by the relatively small over-all changes in water concentration. The experimental results are better accommodated by the proposal (9) that the coupling is the result of an anionic attack of a reduced species upon an unreduced molecule. Whether this is a two-step (9) or a concerted process (1) is still a moot question. It is also not known at present whether the hydrodimerization of 1,2-diactivated olefins proceeds by the same mechanism as the hydrodimerization of monoactivated olefins: this problem is under investigation in this Laboratory.[7]

Finally, it is instructive to examine (Table I) the apparent losses of diethyl maleate and to compare these with the coulombic input not accounted for in the form of reduced products isolated. In run 1, *e.g.*, the "missing" 0.25 amp hr is equivalent to 0.81g diethyl succinate or 1.61g hydrodimer. Assuming complete loss of these reduced esters through saponification[8] there is still considerable diethyl maleate to account for. The facile saponification of the latter ester is well known (6); it was of interest to be able to estimate whether part of the saponified maleate (as half-ester or diacid) was being reduced in the course of the electrolysis and was causing a shift of the cathode v to a more negative value than it would have had in the absence of saponification, or whether part of the diethyl succinate already formed was being later saponified. A study[9] of the kinetics of diethyl maleate/diethyl succinate[10] saponification showed a rate ratio of $k_m/k_s = 20$. Even if all the diethyl succinate had been present from the start (run 1) and the cathode surface had a pH of *ca.* 13, less than 0.2g of diethyl succinate would have been saponified in 3 hr; however, all of the unrecovered ester can be accounted for by saponification of diethyl maleate under the same conditions. Therefore, the "excess" current was most probably used in the reduction of ethyl hydrogen maleate.

[7] After this manuscript was submitted for publication, a possibly relevant paper appeared (10) concerning the participation of the α-carbon atom in electrolytic reductive couplings of activated olefins. In 1,2-bis-activated olefins the α-β-carbon atoms are of course equivalent.

[8] The half-ester or diacid would not have been extracted by methylene chloride from slightly alkaline solution.

[9] The rates of ester saponification were followed to > 50% reaction by vpc analysis using an XE-60 on Teflon column at 115°. In a typical experiment the appropriate ester and diphenylmethane, the vpc internal standard, were dissolved in a DMF solution containing 30g of tetraethylammonium *p*-toluenesulfonate and 30 ml of 10% aqueous tetraethylammonium hydroxide and diluted to 100 ml with DMF. The reaction flasks were thermostated at 25°. At appropriate times a 1 ml aliquot was removed, neutralized with acetic acid, and analyzed directly by vpc for unreacted diester. The second order rate constants obtained by this method for diethyl maleate and diethyl succinate were 2.1×10^{-3} and 1.0×10^{-4} liter mole^{-1} sec^{-1}, respectively. The estimated error in k is $\pm$ 0.2.

[10] It was assumed that the rate of saponification of the hydrodimer was too low to affect the conclusions.

Electrolytic Oxidation of Aromatic Amines

S. Wawzonek and T. W. McIntyre

Department of Chemistry, University of Iowa, Iowa City, Iowa

ABSTRACT

The electrolytic oxidation of anilines at a rotating platinum electrode in acetonitrile in the presence of pyridine involved a two electron change and formed azobenzenes. Evidence for the mechanism was the voltammetric behavior of hydrazobenzenes, *p*-phenylenediamine and 4,4'-dimethoxyazobenzene and the formation of azobenzenes in macroscale oxidations. The behavior of anilines in the absence of pyridine was more complex since the amine acted as a base and formed a salt which was not easily oxidized. Exceptions were the weakly basic *o*-nitroaniline, *p*-nitroaniline, 2,4-dinitroaniline and the reversible systems, o-phenylenediamine and *p*-phenylenediamine; two electrons were involved for these examples.

The electrolytic oxidation of aromatic amines was studied in acetonitrile at a microrotating platinum electrode to determine whether this reaction could be used to prepare azobenzenes on a macroscale.

Voltammetric studies of aromatic amines in acetonitrile have been carried out with aniline (1), 2-aminoanthracene, 2-fluorenamine, 1- and 2-naphthylamine (2), *p*-phenylenediamine (3, 4), 9-amino-10-phenylanthracene (5) and dimethylanilines (4, 6). A stepwise oxidation is reported for *p*-phenylenediamine (3) and a one-electron oxidation change is suggested for the dimethylanilines (4, 6) and 9-amino-10-phenylanthracene (5).

Large-scale oxidations of anilines have been carried out mainly in aqueous acid and basic media. The former usually leads to polymeric products or nitrogen free compounds, (7-10). In alkaline solution *p*-toluidine and 2,4-dimethylaniline gave the corresponding

azobenzenes at an iron anode (11). If one or both of the N-hydrogens are replaced by alkyl groups, dimeric products result (12, 13).

Experimental

Apparatus.—The voltammetric data were obtained with a Sargent Model XXI polarograph and were corrected for *iR* drop across the cell. All measurements were made in a water thermostat at 25° ± 0.1°.

Resistances were measured with a Wheatstone bridge circuit which contained an audio oscillator signal generator and a head set as a null indicator. A variable capacitor was placed in one arm of the bridge circuit to balance the capacitance effects of the cell. An input voltage of 1v (a.c.) and a signal of 1000 Hz was used.

The indicator electrode was a platinum bead electrode, which had an exposed area of 1.0 mm^2. This microelectrode was constructed by sealing a No. 20 platinum wire into a 6 mm glass tube parallel to the axis of rotation; the exposed wire was then fused flush with the glass surface. The platinum electrode was rotated at 600 rpm with a Sargent Synchronous Rotator and cleaned before each run by the procedure of Kolthoff and Coetzee (14).

The solutions (25 ml volumes were used) were studied in a cylindrical shaped cell with an external Ag/0.1M $AgClO_4$ reference electrode connected to the cell through a fine glass frit.

The large-scale electrolyses were carried out in two different cells. One cell was an H-cell, which had a medium glass frit separating the two compartments of equal volume (100 ml). One compartment contained a cylindrical platinum gauze anode, which could be rotated at high speed, and the other compartment contained a stirred mercury pool cathode. This cell was also provided with a compartment for a reference electrode for controlled potential electrolysis.

The second cell consisted of a tall beaker 14.5 cm high and 7 cm in diameter. A Coors porous cup (7.5 by 2.6 cm with a wall thickness of 2 mm) was placed inside as the cathode compartment.

A Heath-Kit IP-12 battery eliminator was used as a direct current source with a variable voltage range of 0-15v. For controlled potential electrolysis the manual apparatus described by Lingane (15) was used. An L&N Student Potentiometer was employed as the voltage measuring device.

Infrared spectra of cast films were recorded using a Perkin-Elmer spectrophotometer.

Chemicals. Acetonitrile was purified by method E of Coetzee *et al.* (16).

Pyridine was purified by refluxing with solid potassium hydroxide and fractionally distilling through a Fenske column; the center fraction (60%) was collected.

Lithium and sodium perchlorate (G. F. Smith and Company) were dried under vacuum at 80° and stored over phosphorous pentoxide.

The various anilines, hydrazobenzenes, and azobenzenes studied were either obtained commercially or synthesized by appropriate methods given in the literature.

Electrolytic oxidations.—p-Nitroaniline. p-Nitroaniline (1.0g)) was dissolved in 90 ml of acetonitrile (0.5*M* pyridine, 0.5*M* sodium perchlorate) and electrolyzed in the H-cell using a rotating platinum gauze anode and a mercury pool cathode. The solution was degassed with nitrogen before and during the electrolysis. At an applied potential of 10v, a current of 0.3 amp was obtained, which decreased to a final value of 0.05 amp in 4 hr. The anolyte was concentrated to 20 ml and 30 ml of water was added. The precipitated material was collected and extracted with 100 ml of cold acetone. The acetone was removed, and the residue was chromatographed on alumina in benzene-chloroform mixtures. The first fraction gave reddish brown crystals (0.26g, 39.2%), mp 220°-222°. The infrared spectrum was identical with that of an authentic sample of 4,4'-dinitroazobenzene. The second fraction from the column was *p*-nitroaniline.

p-Chloroaniline.—Oxidation of *p*-chloroaniline (1.0g) was carried out under conditions similar to those used for *p*-nitroaniline. At an applied voltage of 10v a current of 0.15 amp was obtained which decreased to a final value of 0.01 amp in 14 hr.

The anolyte was concentrated to 10 ml and poured into 500 ml of methylene chloride. The methylene chloride was filtered and extracted with two 100-ml portions of cold 5% hydrochloric acid solution. The aqueous extract was evaporated to dryness and 0.32g of *p*-chloroaniline was recovered as the hydrochloride. The methylene chloride extract was dried over anhydrous sodium sulfate, concentrated and chromatographed on alumina with benzene-chloroform mixtures. The first fraction contained 0.165g (24.3%) of 4,4'-dichloroazobenzene, which was identified by comparison of its infrared spectrum with that of an authentic sample. The melting point of the product after recrystallization from methanol was 185°-187°. The second fraction from the column gave 0.053g (7.8%) of a red crystalline compound, which had a melting point of 258°-260d° after recrystallization from toluene. This product produced a violet color when dissolved in concentrated sulfuric acid and gave a NH band in the 3200-3500 cm^{-1} region in the infrared region. These properties agree with those of 2,5-di-*p*-chlorophenylaminobenzoquinonedi-*p*-chlorophenylimine [tetra-*p*-chloroazophenine (I)] (17).

A similar electrolysis of *p*-chloroaniline in the absence of pyridine and using 0.5*M* lithium perchlorate gave an acidic anolyte at the conclusion of the reaction. Products isolated were starting material (20%) and tar.

2,4-Dichloroaniline.—The electrolysis was conducted at 10v using the beaker cell with a platinum anode and a copper cathode. The initial current of 0.25 amp decreased to 0.05 amp in 4 hr. During the electrolysis the anolyte turned reddish brown and the azo compound precipitated. The mother liquor was concentrated and poured into water. The resulting product was extracted with hot benzene (200 ml) and chromatographed on alumina. The first fraction consisted of azo compound and was combined with the precipitated fraction. Recrystallization from methanol gave 2,4,2'4'-tetrachloroazobenzene; mp 161°-162°; yield, 30.0%. The infrared spectrum was consistent with this structure.

p-Anisidine.—Oxidation was carried out in a similar fashion to that used for *p*-chloroaniline using 0.5*M* lithium perchlorate. The residue in benzene was chromatographed on alumina and gave 4,4-dimethoxyazobenzene (5.2% yield) which melted at 162°-163° after recrystallization from a benzene-(30°-60°) petroleum ether mixture. The infrared spectrum was identical with that of an authentic sample.

The second fraction gave an 8.6% yield of dark red crystals melting at 236°-237°. These crystals gave a red-violet color with concentrated sulfuric acid and had an NH band in the 3200-3500 cm^{-1} region of the infrared. These properties are in agreement with di-*p*-anisidinobenzoquinone-di-*p*-methoxyphenylimine (I) (tetra-*p*-methoxyazophenine) (18). The remaining oxidation products were resinous in nature.

Aniline and p-chloroaniline.—A solution of *p*-chloroaniline (0.5g) and aniline (3.0g) in 60 ml of acetonitrile and 10 ml of pyridine containing 0.5*M* sodium perchlorate was electrolyzed in a beaker containing a porous cup cathode compartment. The anode was a platinum screen and the cathode was a copper wire. The solution was purged with nitrogen and a potential of 8.0v was applied to the cell. The original current of 0.1 amp decreased to 0.05 amp after 4 hr. In this period the anolyte changed from an orange to a reddish-

brown color, and the anode became coated with a brown-black tar.

The anolyte was concentrated to 30 ml and poured into ether (30 ml). The ether solution was filtered, concentrated to 50 ml and chromatographed on alumina (grade I). The first fraction consisted of azo compounds which were rechromatographed. The second fraction gave a dark red solid (0.21g) which, on recrystallization from benzene, melted at 234°-236° and gave a violet color in concentrated sulfuric acid. This compound was halogen free and agreed in all respects with di-(phenylamino) benzoquinone-diphenylimine (azophenine) (19). The mixed azo compounds when rechromatographed twice on alumina using a 1:1 mixture of benzene-(30°-60°)petroleum ether gave azobenzene (0.243g) which melted at 68°-69° and *p*-chloroazobenzene (0.86g) melting at 88°-89° [ref. (20), 87.5°]. The infrared spectrum was similar to that for azobenzene and 4,4'-dichloroazobenzene.

p-Chloroaniline and 2,4-dinitroaniline.—A solution of p-chloroaniline (0.5g), 2,4-dinitroaniline (1.0g) in acetonitrile (80 ml) and pyridine (5 ml) containing 0.5*M* sodium perchlorate was electrolyzed under nitrogen in the H-cell at a controlled potential of +0.80v *vs.* the Ag/0.1*N* $AgClO_4$ electrode, using a rotating platinum anode and a mercury pool cathode. The initial current of 0.15 amp decreased to 0.05 amp in 8 hr. The anolyte was concentrated to 20 ml, poured into water (50 ml), and extracted with ether (500 ml). The ether extract was washed with 100 ml of 5% hydrochloric acid and 100 ml of water. The acid extract gave the hydrochloride of *p*-chloroaniline (0.11g). Removal of the ether gave a solid which was dissolved in a minimal amount of 1:1 benzene-chloroform mixture and chromatographed on alumina. The first fraction gave 4,4'-dichloroazobenzene (0.102g) melting at 184°-186°, and the second fraction gave 2,4-dinitroaniline (0.921g) melting at 178°-179° after crystallization from ethanol (92.1% recovery). No cross product was isolated.

p-Chloroaniline and p-nitroaniline.—This mixture was treated in a similar fashion to that described in the preceding paragraph using a controlled potential of +0.7v, 4,4-Dichloroazobenzene (22.8%) and *p*-nitroaniline (90%) were obtained together with resinous material.

Hydrazobenzene.—This compound (2.0g) was oxidized in a beaker (100 ml) containing a porous cup cathode compartment. The cell was wrapped with aluminum foil to keep out light, and the solution was deaerated during the electrolysis with nitrogen. The resulting solution when processed in the usual manner gave azobenzene (0.216g), dark brown polymeric material and a black crystalline residue similar to aniline black.

4,4-Dichlorohydrazobenzene.—The electrolysis was performed in a similar manner to that for hydrazobenzene. The anode solution gave an 82% yield of 4,4'-dichloroazobenzene.

4,4-Dimethoxyazobenzene.—The electrolysis and processing of the oxidation product was similar to the above procedure. The anolyte gave starting material (55%) and brown resinous material.

Results

The voltammetric behavior of various anilines in acetonitrile containing 0.5*M* sodium perchlorate in the presence and absence of pyridine is given in Table I. Half-wave potentials corrected for the *iR* drop are reported against an external silver 0.1*M* silver perchlorate reference electrode.

Most of the compounds exhibited normal S-shaped waves in the absence of pyridine. In the presence of this compound the curves reached a current plateau which decreased near the end of the voltage scan. This behavior is associated with film formation on the electrode surface for, if the current-voltage curve is retraced without cleaning the microelectrode, the limiting current is substantially reduced. Waves were also encountered as peaks and are probably caused by an immediate coating of the electrode. The decrease in current was not caused by the oxidation of pyridine since this compound when pure does not give an oxidation wave in acetonitrile. In order to evaluate the number of electrons involved in the oxidation, hydroquinone and bromide ion were studied under similar conditions, and the data are given in Table I.

To aid in formulating an electrode mechanism a series of hydrazobenzenes and azobenzenes was studied under similar conditions, and the data are given in Table II.

Table III. Large-scale electrolytic oxidations of primary aromatic amines[a] and hydrazobenzenes[a]

Compound	Supporting electrolyte, 0.5M	Products (per cent yield)
p-Nitroaniline	$NaClO_4$	4,4'-Dinitroazobenzene (39.2%)
p-Chloroaniline	$NaClO_4$	4,4'-Dichloroazobenzene (24.3%); tetra-p-chloroazophenine (7.8%)
p-Chloroaniline[b]	$LiClO_4$	Tar
2,4-Dichloroaniline	$NaClO_4$	2,2',4,4'-Tetrachloroazobenzene (30.1%)
p-Anisidine	$LiClO_4$	4,4'-Dimethoxyazobenzene (5.2%) tetra-p-methoxyazophenine (8.6%)
Aniline and p-Chloroaniline	$NaClO_4$	Azophenine (7.0%); azobenzene (8%); p-chloroazobenzene (83%)
Hydrazobenzene	$NaClO_4$	Azobenzene (10.8%)
4,4'-Dichlorohydrazobenzene	$NaClO_4$	4,4'-Dichloroazobenzene (82%)

[a] The electrolysis were run in a nitrogen atmosphere, and pyridine (0.1M) was added unless otherwise indicated.
[b] No pyridine was added.

In further studies of the mechanism of oxidation macroscale oxidations of several anilines were carried out in acetonitrile, and the results are reported in Table III.

Discussion of Results

Comparison of the limiting currents for the oxidation of the anilines in the presence of pyridine with that for hydroquinone and bromide ion indicates that the majority of the examples involve a two-electron change. The lower values observed for aniline, o-nitroaniline, m-bromoaniline, m-phenylenediamine, and 2,2'-diaminobiphenyl were caused by coating of the electrode.

The electrode reaction suggested by the two-electron change using aniline as an example is the following

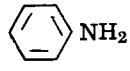
(a) $C_6H_5NH_2 - e \rightarrow C_6H_5NH_2^{+\cdot}$

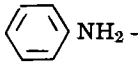
$C_6H_5NH_2^{+\cdot} + \text{pyridine} \rightarrow C_6H_5NH\cdot + C_5H_5NH^+$

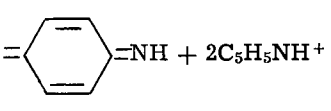
(b) $2C_6H_5NH\cdot \rightarrow C_6H_5NHNHC_6H_5$

$2C_6H_5NHNHC_6H_5 - 2e + 2\text{ pyridines} \rightarrow C_6H_5N = NC_6H_5 + 2C_5H_5NH^+$

(c) $C_6H_5NH\cdot \leftrightarrow HN=$ 
$C_6H_5NH\cdot +$ 

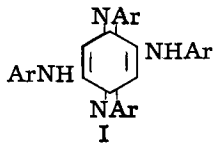






The extent to which reactions (b) and (c) occur will depend on the substituents present.

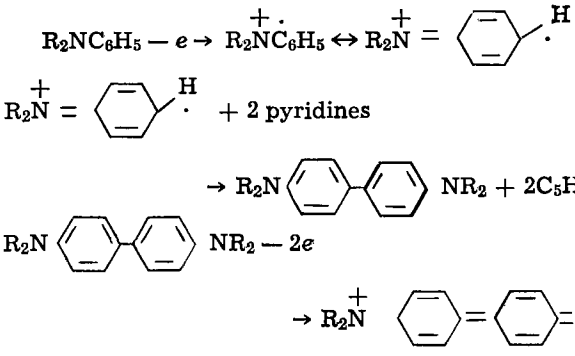
In agreement with this mechanism is the oxidation of hydrazobenzenes (Table II) and p-phenylenediamine (Table I) in the presence of pyridine at more negative potentials than those for the anilines, and the formation of azobenzenes and azophenines (I) in the macroscale oxidations (Table III)



I

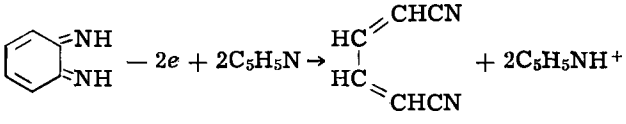
Further evidence is the appearance of a third wave in the oxidation of p-anisidine at approximately the same point as that for 4,4'-dimethoxyazobenzene. A similar wave was not observed for other azobenzenes because of coating of the electrode.

Diethylaniline and dimethylaniline in the presence of pyridine would involve coupling in the p-position in a manner to that suggested by Adams (6)



The oxidation of N-ethylaniline and N-p-nitrobenzylaniline could proceed in the same fashion or could give rise to a hydrazine which would be oxidized further. Large-scale oxidation of p-nitrobenzylaniline formed the hydrazine together with polymers (21).

p-Phenylenediamine and o-phenylenediamine which behave reversibly in aqueous medium are oxidized stepwise to the quinoneimine (3). In the presence of pyridine o-phenylenediamine behaves differently and shows an abnormally high wave. A similar behavior has been observed in aqueous acetate buffer solution (22) and has been ascribed to the formation of a diaminophenazine which is oxidized further. Another possible explanation is further oxidation of the resulting o-quinonediimine to muconitrile since



such a reaction is reported to take place in the oxidation of o-phenylenediamine by lead tetraacetate (23).

The oxidation of the anilines in the absence of pyridine is more complex. The aniline itself acts as a base and converts the cation radical into the free radical and a salt which would not be easily oxidized

$$ArNH_2 - e \rightarrow ArNH_2^{+\cdot}$$

$$ArNH_2^{+\cdot} + ArNH_2 \rightarrow ArNH\cdot + ArNH_3^+$$

Exceptions are the nitroanilines and are discussed later. The free radical thus formed would couple and form the corresponding hydrazobenzenes and N-arylphenylenediamines as mentioned earlier. The latter compound would lead to an N-arylquinonediimine which is considered to be the precursor of the varied products obtained in the oxidation of anilines (24). This formation of N-arylphenylenediamines may be favored in the absence of pyridine since tars were mainly formed on a large scale under these conditions.

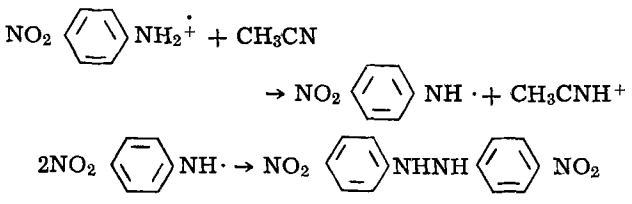
Hydrazobenzenes (Table II) formed under these circumstances would be oxidized further to azobenzenes. This process occurs in the absence of pyridine by a two step process.

$$C_6H_5NHNHC_6H_5 - e \rightarrow C_6H_5\overset{+}{N}HNHC_6H_5$$

$$C_6H_5\overset{+}{N}HNHC_6H_5 - e \rightarrow C_6H_5N = NC_6H_5 + 2H^+$$

These reactions would be modified to a certain extent by the aniline and would give oxidation waves with unequal heights. The second wave which occurs at the same point as azobenzene is not caused by this compound since the addition of pyridine to the same solution gave one oxidation wave. Azobenzenes under similar circumstances caused coating of the electrode and gave no oxidation waves except for 4,4'-dimethoxyazobenzene. The oxidation products formed from azo compounds are unknown since large-scale oxidations in acetonitrile gave tars.

o-Nitroaniline, *p*-nitroaniline, and 2,4-dinitroaniline gave a two electron wave in the absence of pyridine. This behavior suggests that the cation radical, because of the decreased basicity of these compounds, loses a proton easily and forms the radical which dimerizes to the hydrazo compound.



The latter would be oxidized further to the azo compound. A two-step process was actually observed with *p*-nitroaniline at higher concentrations.

Analyses of the current-voltage curves for *p*-bromoaniline and *p*-anisidine in the absence of pyridine gave values of 0.0645 and 0.049, respectively, for the slope which are in fair agreement with the initial one electron step postulated. The addition of pyridine causes the reaction to become more irreversible since *p*-bromoaniline gave a value of 0.0734. *p*-Anisidine is an exception under similar conditions since it gives a stepwise oxidation and a slope of 0.057 for the first wave. This value is in good agreement with the one-electron step involved.

Large-scale oxidations of the anilines at a platinum electrode in acetonitrile (Table III) were in agreement with the electrode mechanisms mentioned; azobenzenes, azophenines, and tars were obtained since the potential was not controlled. The potentials applied, however, gave similar initial currents to those obtained under controlled potential conditions.

Hydrazobenzenes on large-scale oxidation gave azobenzenes as expected. In the oxidation of hydrazobenzene itself, the product was accompanied by tar and aniline black since the potential was not controlled.

No products involving pyridine were isolated in the oxidation of the anilines, and this result eliminates the possible formation of a cation as the initial product

$$ArNH_2 - 2e \rightarrow ArNH^+ + H^+$$

Such an intermediate would be expected to react with pyridine, since pyridine is in excess, and form a hydrazonium salt. Further evidence against this cation is the crossed coupling of two anilines. A mixed azobenzene was obtained only with aniline and *p*-chloroaniline which are oxidized at approximately the same point. Mixtures of *p*-chloroaniline with *p*-nitroaniline and with 2,4-dinitroaniline when oxidized at controlled potential gave only 4,4'-dichloroazobenzene.

High-Temperature Oxidation

IV. Zirconium and Hafnium Carbides

Joan B. Berkowitz-Mattuck

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

The oxidation of ZrC was studied at temperatures of 1130°-2160°K and oxygen partial pressures around 3.9 and 20 Torr. The rate of oxidation was monitored with a thermal conductivity cell. Independent measurements were made of net weight gain and quantities of CO(g) and CO_2(g) evolved. Oxidation was shown to be nonpreferential, *i.e.*, zirconium was oxidized at the same rate as carbon. Gas phase diffusion control imposed by the experimental system was frequently encountered. Where it was possible to observe a true chemically controlled reaction rate, the kinetics appeared to be linear. Microscopic examination of the oxidized specimens revealed preferential oxidation along grain boundaries. Between 1130° and 1560°K this preferential oxidation resulted in intercrystalline fracture. At higher temperatures stresses were apparently sufficiently relieved so that the samples remained intact. The oxidation of HfC between 1790° and 2000°K, at oxygen pressures near 10 Torr, was also found to be linear and preferential along grain boundaries.

The oxidation of zirconium carbide was studied by Margrave and Kuriakose (1) at temperatures of 550°-650°C in oxygen at 1 atm. The oxidation was found to be linear, with an activation energy of 16.7 ± 1.7 kcal/mole.

Bartlett, Wadsworth, and Cutler (2) studied the weight gain of sized powders of zirconium carbide in air, oxygen, and oxygen-helium mixtures at temperatures of 450°-580°C, and oxygen pressures of 6.5 x 10^{-5} to 1 atm. Stoichiometric oxidation of ZrC to ZrO_2 and gaseous oxides of carbon was assumed. The data were interpreted on the basis of two parallel independent processes: a parabolic diffusion reaction involving the partial replacement of interstitial carbon in the ZrC lattice with oxygen, and a linear surface reaction occurring at the ZrC-ZrO_2 phase boundary. Both processes occur simultaneously, with the diffusion reaction predominating at short times and the surface reaction becoming rate controlling as oxidation proceeds. The activation energies were calculated as 53 kcal/mole for the diffusion process and 46 kcal/mole for the surface reaction. Water vapor, in the presence of oxygen, was found to accelerate the rate of the surface reaction while leaving its activation energy unchanged. The solid oxidation product was found to be cubic ZrO_2, a phase normally thought to be unstable, but which might be stabilized by small amounts of carbon.

Watt, Cockett, and Hall (3) made a single weight change measurement of 49.8 mg/cm² on a solid sample of ZrC of density 6.20 g/cc and 4.8% porosity, exposed to a stream of dry air flowing at 5.3 cm/sec, for 30 min at 800°C.

The present study was undertaken to investigate the oxidation of ZrC and the chemically related HfC at temperatures above 900°C.

Experimental Method

Cylindrical pellets of ZrC were cut from zone refined bars prepared as described by Westrum and Feick (4). The fabricated bars contained 11.2 w/o carbon. Hafnium carbide powder was prepared by the Carborundum Company from high-purity HfO_2 supplied by Wah Chang Corporation. The HfC powder was sintered into bars and arc-melted on a water-cooled copper hearth using a water-cooled tungsten electrode. In order to minimize loss of carbon during melting, the operation was conducted in an atmosphere of argon containing 3.14% of ethylene and 11.4% of hydrogen. The resulting material was carbon deficient, corresponding to a composition $HfC_{0.952}$ (5).

The anticipated products of the oxidation of ZrC and HfC were the permanent gases, CO(g) and CO_2(g), in addition to the refractory metal oxides. Due to the evolution of permanent gases, the thermal conductivity method described in previous publications (6-8) had to be modified to study the oxidation. A known mixture of helium and oxygen was passed through the reference side of a thermal conductivity cell (6) and over an inductively heated carbide pellet supported on ThO_2 fingers by three point contact. A portion of the oxygen in the gas stream reacted with the pellet to produce oxides of the metal and carbon. The effluent gas was therefore depleted in oxygen, but enriched in CO(g) and CO_2(g). The latter was removed by passage through a weighed Ascarite bulb, and the remaining mixture of CO(g), O_2(g), and He entered the sampling side of the thermal conductivity cell (6). Finally, the CO(g) was oxidized to CO_2(g) over copper oxide powder at 500°C, and the CO_2(g) produced was collected in a second weighed Ascarite bulb. The signal from the thermal conductivity cell in this case was therefore not directly related to the rate of oxygen consumption as in previously studied systems (6-8), but instead reflected the difference between the rate of total oxygen consumption and the rate of formation of CO(g). The calibration constant, relating the electrical signal to the difference in gas pressure on the two sides of the cell is the same for both CO and O_2 in He. Hence, evolution of CO depresses the signal, as compared to simple removal of oxygen.

Results

Zirconium carbide.—Oxidation kinetics.—The experimental data are summarized in Table I. The signal from the thermal conductivity apparatus was constant with time in every experiment. However, only in the case of experiment XII-1 did this reflect true chemically controlled linear oxidation kinetics. In the other experiments more than 90% of the oxygen passed over the carbide pellet reacted with it, and the controlling process was therefore probably the rate of arrival of oxygen gas at the sample surface. At higher pressures and/or higher gas flow rates, a greater proportion of the carbide would have been converted to oxides.

In Table I, the "initial" weights were taken after degassing at 2200°K in pure helium until the signal from the thermal conductivity cell indicated that no permanent gases were being evolved. The surface areas were calculated from micrometer measurements of the height and diameter of the cylindrical pellets. Temperatures were measured optically and corrected for an emissivity of 0.7, determined by comparing

surface temperatures with ultrasonically drilled black body cavity temperatures under oxidizing conditions. Oxygen partial pressures in helium are given; the total pressure was close to 1 atm in every experiment. The carrier gas flow rate was 58.6 cc/min in every experiment, corresponding to a linear flow velocity in the neighborhood of the sample of 1.9 cm/sec, except VII-8 where a flow of 51.5 cc/min was used.

From the measured net weight change of the carbide on oxidation, and the observed weight changes W_{CO_2} and W_{CO} in the Ascarite bulbs, the total amounts of carbon and zirconium consumed were readily calculated, on the assumption that the only oxidation products were $CO_2(g)$, $CO(g)$, and $ZrO_2(s)$. The formation of ZrOC(s) cannot be precluded, but since it is isostructural with ZrC, no positive evidence was obtained for its presence. The total weight of carbon consumed, W_c, is given by

$$W_c = \frac{[C]}{[CO_2]} \cdot W_{CO_2} + \frac{[C]}{[CO]} \cdot W_{CO} \qquad [1]$$

where the symbols in brackets represent molecular weights. The total weight of zirconium, W_{Zr}, that has been converted to oxide is calculated from the measured weight change, W_o, and the derived carbon consumption

$$W_{Zr} = \frac{[Zr]}{2[O]} (W_o + W_c) \qquad [2]$$

The ratio of the number of grams of zirconium consumed to the number of grams of carbon consumed during oxidation is shown in Table I to have an approximately constant value of 7.5 ± 0.2. Since the corresponding ratio in the ZrC starting material is 7.6, it would appear that the oxidation of ZrC is stoichiometric. That is, for each zirconium atom converted to oxide, a single carbon atom is also converted to oxide.

Structural changes during oxidation.—The reason that weight change data were not given for pellets XII-8, XII-5, and XII-3 is that at these relatively low temperatures the pellets were broken apart by the oxidation process. At the end of each experiment, the grain boundaries of the ZrC were seen to be outlined by a white material, identified by room temperature x-ray as monoclinic ZrO_2. The growth of the oxide in pre-existing cracks and grain boundaries of ZrC undoubtedly creates enough stress to fracture the carbide. At higher temperatures, as discussed below, significant grain boundary oxidation was observed, but stresses are apparently sufficiently relieved so that fracture does not occur.

Pellet XII-1 for which true kinetic data had been obtained was mounted and polished for metallographic examination.

Figure 1a shows the specimen at a magnification of ca. 4X. The gray outer rim is the oxide, and the inner white circular area is the surface of carbide. To the naked eye, the outer oxide coating looked white and chalky, and the inner surface from which the oxide coating was polished off, looked bright and metallic. A mottled rim is clearly visible along the oxide-alloy interface in the figure and the remaining photomicrographs focus on portions of this interface. In Fig. 1b, at a magnification of *ca.* 30X, the oxide fills the entire upper half of the photograph, and the alloy the lower. The oxide is obviously growing preferentially along grain boundaries in the carbide, and enveloping individual alloy crystallites. The structure of the bulk oxide is very different from that on ZrB_2 (8), although after cooling both showed only the x-ray lines for monoclinic ZrO_2. On ZrB_2 the oxide was seen to grow in a columnar structure; on ZrC, the ZrO_2 assumed an equiaxed grain structure very similar to that of the original alloy. Figures 1c and 1d show the oxide alloy interface at a still higher magnification, *ca.* 195X, and one sees even more clearly the preferential oxidation of grain boundaries, and the lateral fingerlike growth of oxide from the boundaries into the crystallite bulk. The reaction zone of intergranular attack was approximately 0.014 ± 0.002 cm in thickness. The outer oxide was about ten times thicker. The mechanism of oxide growth on ZrC at high temperatures appears to be rapid attack at grain boundaries, and slow oxidation of the alloy from the grain boundary surface inward. Figure 1e, at a magnification of *ca.* 345X, shows portions of the alloy completely enveloped by oxide. Finally, Fig. 1f is a view of the alloy surface at a magnification of *ca.* 345X. This surface had been covered with a dense oxide prior to polishing, and one sees here the penetration of the oxide into grain boundaries of the alloy. Between 1126° and 1559°K the grain boundary attack results in intergranular fracture of the alloy. Above 1580°K there is apparently enough plasticity in either alloy, oxide, or both, so that the sample remains intact during oxidation.

Hafnium carbide.—Oxidation kinetics.—The experimental data for HfC are summarized in Table II. Since the arc-melted samples were highly irregular in shape,

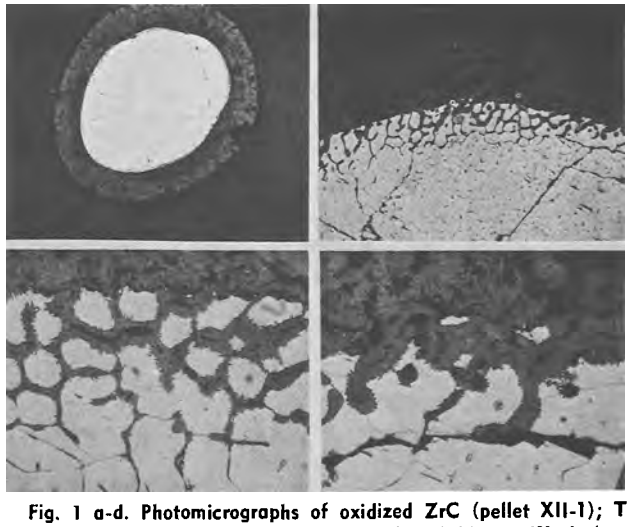

Fig. 1 a-d. Photomicrographs of oxidized ZrC (pellet XII-1); T 1960°K; P_{O_2} 25.9 Torr. Magnification: a (top left) ca. 4X; b (top right) ca. 30X; c (bottom left) ca. 195X; d (bottom right) ca. 195X.

Fig. 1 e-f. Photomicrographs of oxidized ZrC (pellet XII-1); T 196°K; P_{O_2} 25.9 Torr. Magnification: e (left) and f (right) ca. 345X.

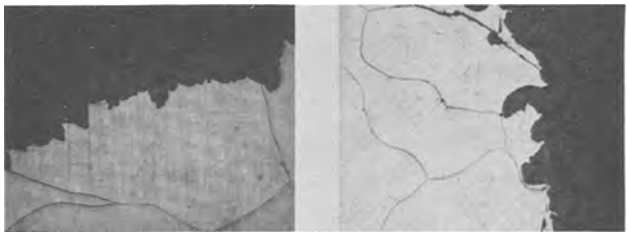

Fig. 2. Photomicrographs of oxidized hafnium carbide pellet XVI-19; temperature 1600°-2000°K; P_{O_2} 11.5 Torr. Magnification ca. 130X.

the geometrically calculated surface areas are only approximate. The surface oxide tended to flake and spall on removal of the sample from the apparatus; and, hence, the measured weight gains are minimum values. From the measured minimum net weight gains, and the weights of CO(g) and CO_2(g) in the product gas stream, the minimum ratio of hafnium to carbon oxidized can be calculated, as described above for the oxidation of ZrC. The experimental values of the ratio are given in Table II as 14.1, 10.1, and 15.9, to be compared to an Hf:C ratio in the original alloy of 15.6. Linear oxidation was observed in every case. Flow rates of 119 cc/min, approximately double those used for the ZrC experiments, were employed in order to maintain an adequate supply of oxygen.

At 1280°K in pure oxygen at 1 atm, a hafnium carbide specimen disintegrated into several pieces within 3 min in a manner very similar to that described above for zirconium carbide.

Metallographic examination of oxide films.—Pellet XVI-19 was imbedded in plastic and polished for microscopic observation. In the photomicrographs shown in Fig. 2, the oxide is seen to contain considerable porosity. As in the case of zirconium carbide, oxidation appears to be preferential along grain boundaries.

The photomicrograph in Fig. 3 is for a hafnium carbide pellet that had been exposed to a N_2-He mixture for an hour and a quarter at a temperature of 1960°K. The N_2 apparently contained a small quantity of oxygen, and white HfO_2(c) was identified on the surface of the sample by x-ray diffraction. The net weight change of the sample was 0.0024 g/cm², an order of magnitude less than that observed at an oxygen partial pressure of 11.5 Torr at about the same temperature. The oxidation rate was seen to decrease slightly with time, and, although grain boundary oxidation is

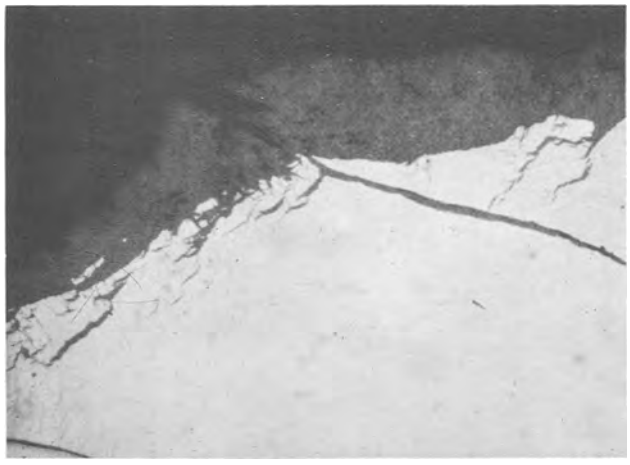

Fig. 3. Photomicrograph of oxidized hafnium carbide pellet XVI-22; temperature 1960°K, low oxygen pressure. Magnification ca. 230X.

apparent in Fig. 3, the oxide seems less porous than that shown in Fig. 2, for oxidation at a higher pressure.

Discussion

A recent report (9) suggests that grain boundary oxidation is characteristic of iron contaminated ZrC. For material with an impurity level about 1 v/o Fe_3C or about 1.1 w/o, the Fe_3C is found to be segregated at the grain boundaries, and to be oxidized at a much more rapid rate than the ZrC matrix.

A chemical analysis of the zone melted material used in the present study showed an iron contamination level of 0.07% by weight. In order to try to assess the possible influence of iron on the present results, the oxidized and polished ZrC sample shown in Fig. 1 was examined for iron with the electron probe.[1]

An $FeK_{\alpha 1}$ scanning image was taken of the sample, and iron was found to be concentrated in the small circular inclusions visible in Fig. 1, and inhomogeneously in the cracks. Point count analyses take in the inclusions, the cracks, the grain boundaries, and the matrix showed the presence of iron particles of less than 1μ in size distributed at random in the inclusions and cracks, but failed to reveal the presence of any iron at all in either the grain boundaries or the matrix. The preferential grain boundary oxidation observed in zirconium carbide, therefore, seems to be characteristic of the pure material.

Acknowledgment

It is a pleasure to thank John Engelke of Arthur D. Little, Inc., for his assistance in obtaining and interpreting the electron probe data, and to acknowledge the invaluable assistance of Richard F. Quigley and Walter Christensen with the experimental work.

Manuscript received Jan. 23, 1967; revised manuscript received May 31, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Fundamental Limitations on the Low-Temperature Operation of Electrolytic Devices

C. A. Angell

Department of Chemistry, Purdue University, Lafayette, Indiana

ABSTRACT

A new approach to the understanding of transport behavior in concentrated electrolyte solutions requires the recognition at low temperatures of a liquid state limiting temperature which is a thermodynamic constant of any solvent-electrolyte solution. The value of this constant, which determines service limits, is a function of electrolyte concentration except at low concentrations where solvent structure may dominate. In this paper the results of workers investigating electrolyte solutions for low-temperature battery applications are used to emphasize the usefulness of the concepts underlying this approach to low-temperature electrolyte problems.

This article considers briefly some implications of recent developments in electrolyte solution transport theory to the practical problems encountered in the use of electrolyte solutions at low temperatures.

Temperature and concentration dependence of solution transport properties.—In recent papers (1-3) it has been shown that the temperature dependence and composition dependence of electrical (equivalent) conductance, Λ, and viscous flow, η, processes in various concentrated aqueous electrolyte solutions at low corresponding temperatures may be described by equations of the following form

constant composition

$$\Lambda_{(N)}, 1/\eta_{(N)} = A \exp \frac{-k}{T - T_o} \qquad [1]$$

constant temperature

$$\Lambda_{(T)}, 1/\eta_{(T)} = A \exp - \frac{k/Q}{N_o - N} \qquad [2]$$

where A, k, and T_o in Eq. [1] and A, k/Q, and N_o in Eq. [2] are constants; T and N are, respectively, the absolute temperature and the equivalent concentration.

A plausible theoretical interpretation discussed in detail elsewhere (1, 4, 5) may be given these equations in terms of the controlling influence on the transport processes, of the liquid configurational entropy content (6). The constants T_o and N_o in this case represent the temperature at fixed composition, and the equivalent concentration at constant temperature, respectively, at which the configurational entropy vanishes.

Significance of low-temperature electrolyte solution behavior.—An important result of this treatment which we wish to emphasize in this paper is the realization that, provided crystallization has not already occurred, any electrolyte solution will lose its liquid character and become a glass at a temperature ($\sim T_o$) which in general will be well above 100°K. Where the electrolyte property of interest depends on, or is related to, the fluidity of the substance, this temperature therefore places an absolute lower limit to the serviceability of the material.[1]

Furthermore, it is found that, for many electrolyte mixtures and solutions at temperatures not too far above T_o, T_o itself is the only important variable in the transport equation, so that the low-temperature transport properties of such liquids are to a large extent known once T_o is known (3). Thus, the scaling factor to be used in comparing a given property amongst different solutions is, from Eq. [1], $(T - T_o)$.

To illustrate the usefulness of this point, we take an example from the work of Garrett *et al.* (7) who were investigating various strong (presumed fully dissociated) electrolyte solutions for suitability in low-temperature battery applications. Their (uninterpreted) data on the viscosity of some solutions, relative to the viscosity of water at 25°C, are reproduced in Fig. 1(i). The striking feature of the data is, of course, the very rapid rise in solution viscosity at the lower temperatures. In Fig. 1(ii) we show how the use of a T_o value appropriate to each solution in the scaling factor $(T - T_o)$ reduces the data approximately to a single curve. The remaining minor differences seem to be due mainly to variations in the value of the preexponential term A, as seen in the following.

According to Eq. [1], the values of T_o which reduce the solution viscosities as in Fig. 1(ii), should yield a linear plot for the relative viscosities when log η/η_o, (or log η_o/η to maintain Eq. [1] signs) is plotted against $1/(T - T_o)$. The appropriate semilogarithmic plots are shown in Fig. 2. The various plots are now seen to be differentiated by small changes in the values of the parameter A, the plots being linear with essentially equal values of the slope k. It must be said, however, that the available data are not sufficiently

[1] The limiting temperature usually imposed by the crystallization temperature is not an absolute limit insofar as suitable additives can usually make crystal nucleation a very improbable process even when thermodynamically favored.

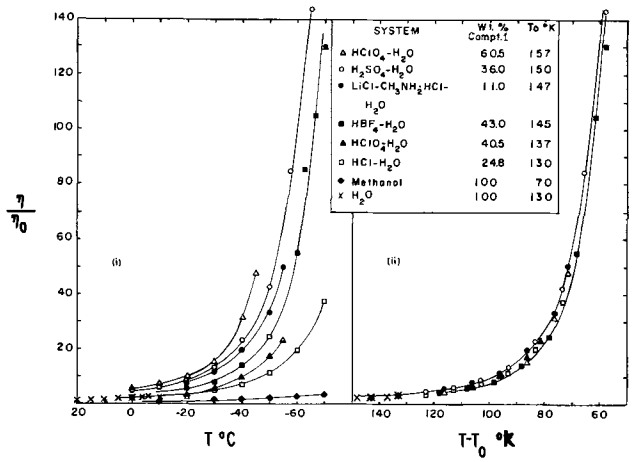

Fig. 1 (i). Viscosities of various electrolyte solutions relative to η_{H_2O} at 25°C (η_0) [after Garrett et al. ref. (7)]. Legend gives weight per cent (w/o) of the first component listed: in ternary system, weight per cent of $CH_3NH_2 \cdot HCl$ is 33%; Fig. 1 (ii). Data of (i) scaled by means of the vanishing entropy (S_c) temperature T_o [$S_c \rightarrow 0$ as $T \rightarrow T_o$, see ref. (5, 6)].

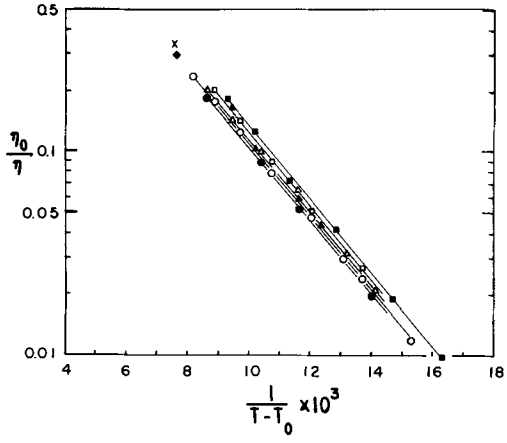

Fig. 2. Plot showing the linear dependence of log (relative viscosity) for the solutions of Fig. 1 on $1/(T-T_o)$ required by Eq. [1]. Points are identified in Fig. 1 legend.

accurate or extensive to conclude that k has the same value for each solution, though the differences apparently cannot be great.

Thus, the low-temperature electrolyte data of Fig. 1(i) are well accounted for by Eq. [1]; it follows that any theoretically guided quest for electrolytes serviceable to very low temperatures must focus attention on the property T_o of the material. We return to this matter shortly.

The Case of Specific Conductance

An interesting situation arises when the low-temperature property of interest is the electrical conductance. For the case of equivalent conductance, the viscosity and conductance at high concentrations follow essentially parallel paths except for small differences in the parameter k (2, 3). However, for practical applications it is the ability of a given volume of the electrolyte to conduct current which is of importance, and one is therefore concerned with the specific conductance, κ, which is related to the equivalent conductance by

$$\kappa = \frac{\Lambda N}{1000} \qquad [3]$$

whence, from Eq. [2],

$$\kappa = NA' \exp - \left(\frac{k/Q}{N_o - N} \right) \qquad [4]$$

Thus the equation for isothermal specific conductance contains the electrolyte concentration in both preexponential and exponential terms. The preexponential N leads to an increase in conductance with increasing N, due to the increase in number density of current carriers, while the exponential N opposes this increase, by raising the T_o value of the solution towards the isothermal temperature, T. Thus at $N = 0$, $\kappa = 0$, and eventually, as $N \rightarrow N_o$, $\kappa = 0$. Thus it is clear from Eq. [4] that the specific conductance must go through a maximum, provided the solubility limit of the salt is not first exceeded. The maximum in κ observed for many highly soluble salts is, of course, well known (8).

The not-so-obvious consequence of Eq. [4] which is of special interest to the present discussion, is the fact that since the influence of the preexponential N is independent of temperature (provided we are dealing with fully dissociated electrolytes) the maximum in the specific conductance isotherm must shift to lower concentrations at lower temperatures, since N_o decreases with decreasing temperature. Thus attempts to compensate for the low conductances encountered at the low temperatures by raising the electrolyte concentration, are increasingly frustrated the lower the temperature. To observe the effect of concentration on T_o, the data for the two compositions of perchloric acid treated in Fig. 1 and 2 may be referred to (see also Table I, discussed below). The effect of temperature on the specific conductance maximum is illustrated adequately by some data on zinc nitrate solutions due to Bak (9) shown in Fig. 3. The effect should be more dramatic at lower temperatures, but suitable data are not available to demonstrate this.

It should be pointed out, in view of the fact that most of the electrolyte solutions whose low-temperature properties were tested by Garrett and co-workers (7) were acids, that although the conductance exhibited is primarily proton conductance, the temperature dependence of the process should still be of the form of Eq. [1]. This will be true because proton conductance requires configurational freedom on the part of the water molecules (primarily freedom to rotate) which, like dielectric relaxation (10), requires an Eq. [1] type of description for the temperature dependence.

Factors Determining the Magnitude of T_o

The problem of what determines T_o is therefore fundamental to the question of low-temperature electrolytes. T_o is evidently a thermodynamic property of the material and a parameter of major importance to the understanding of liquid-solid relations. As discussed elsewhere (1) it appears to be the temperature

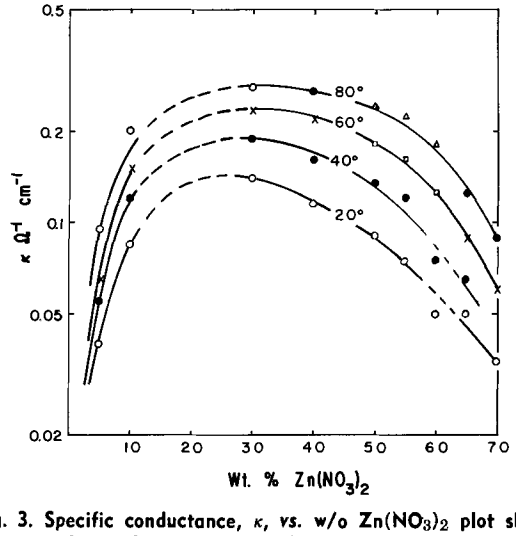

Fig. 3. Specific conductance, κ, vs. w/o $Zn(NO_3)_2$ plot showing movement of specific conductance maximum to lower concentrations as isotherm temperature decreases [after Bak, ref. (9)].

Table I.

Liquid		N equiv. l^{-1}, at $-70°C$[a]	T_0, °K

24.8	HCl	8.0	130
36.0	H_2SO_4	9.9	150
60.5	$HClO_4$	10.1	157

[a] Values of N are calculated using the densities at $-70°C$ quoted in ref. (7).

at which the "ideal metastable amorphous solid" (11) phase commences to exchange vibrational for configurational degrees of freedom, but it is not clear that this implies a dependence only on bond strength, or cohesive energy, as the interpretation of Turnbull and Cohen (12) suggests. Since the vibration frequencies of the amorphous solid are apparently involved it seems reasonable to enquire about the possible effects of the mass of the constituent particles on T_0. Investigations of such possible factors are currently in progress.

Certainly the cohesion among the particles of the material must play a role, and in this connection the difference in T_0 values between H_2O and methanol deserves comment.[2] The higher value for H_2O is evidently to be attributed to the more strongly hydrogen-bonded structure of water. The so-called "structure-breaking" solutes may therefore tend to lower T_0 at least at low concentrations, while at the same time supplying current carriers. Such properties would seem desirable for low temperature applications, but unfortunately these salts do not produce low eutectic temperatures with water.

It is notable that 24.8% HCl has the same value of T_0 as that assigned to H_2O. The reason is probably that chloride ion, unlike the oxy- and fluoro-anions of the other acids, can only participate weakly in configuration restricting hydrogen bonding to the water molecules, so that increases in cohesion due to electrostatic effects are largely nullified by a net reduction in hydrogen bonding. HBr and HI solutions may therefore reach still lower T_0 values. Apart from HCl, the values of T_0 correlate (approximately) with the equivalent concentration, N, (Table I) as Eq. [2] predicts. The hydrogen bond contribution will vary from acid to acid and a quantitative correlation is not to be expected.

Figure 1 (i) and (ii) show that the difference in limiting service temperatures (*e.g.*, maximum permissible viscosity, resistance, or relaxation time) is effectively the difference in T_0 values. Accordingly, for very low-temperature work, solvents with T_0 values lower than that of H_2O would be required, and a non-hydrogen-bonded structure would seem necessary. This leads to something of an impasse however, since a nonhydrogen-bonded structure appears to conflict with the requirement of a dielectric constant high enough to promote electrolyte dissociation. There is room for further experimental work in this area, with systems such as the fluorosulfonic acids in nitrile and mixed alcohol solvents offering interesting possibilities.

[2] The assignment of T_0 values to these liquids (see legend Fig. 1) is only approximate because in neither case does the available transport data approach T_0 closely enough to permit a solution of Eq. [1] for T_0 with confidence. (Solutions of Eq. [1] for H_2O viscosities yield the result $T_0 = 150°K$ [F. Gutmann and L. M. Simmons, *J. Appl. Phys.*, **23**, 977 (1952); A. A. Miller, *J. Chem. Phys.*, **38**, 1568 (1963)].) The value, $T_0 = 130°K$ assigned to H_2O in this work is based mainly on the observation of the glass transition at 139°K for vapor-deposited vitreous ice [J. McMillan and S. C. Los, *Nature*, **206**, 806 (1965)], (recently confirmed in this laboratory [C. A. Angell, E. J. Sare, and R. D. Bressel, *J. Phys. Chem.*, **71**, 2759 (1967)], and the experience that the experimental glass transition is always observed at a temperature higher than T_0 by 5 – 30% dependent partly on molecular complexity. The estimate for methanol is based on the experimental value for the observed glass transition, 110°K [J. A. Faucher and J. V. Koleske, *Phys. Chem. Glasses*, **7**, 454 (1966)] and the known value $T_0 = 73.5°K$ for n-propanol [see ref. (10)] for which the measured glass transition temperature is also 110°K.

A Generalized Expression for the Tafel Slope and the Kinetics of Oxygen Reduction on Noble Metals and Alloys

D. S. Gnanamuthu and J. V. Petrocelli

Applied Research Laboratory, Scientific Research Staff, Ford Motor Company, Dearborn, Michigan

ABSTRACT

The usually employed expression for the Tafel slope is modified to take into account the potential which is effective in charge transfer within the double layer. The exchange currents and cathodic Tafel slopes are obtained on noble metal electrodes having different number of holes in the d-band. Using the conventional and modified Tafel slopes, possible paths and rate-determining steps are suggested for the cathodic reduction of oxygen.

It has been well established that the oxygen electrode reaction

$$O_2 + 4H^+ + 4e = 2H_2O \quad \text{(acidic)}$$
$$O_2 + 2H_2O + 4e = 4\,OH^- \quad \text{(basic)}$$

is highly irreversible. In fact only a few investigators have been able to establish the thermodynamically reversible potential on the noble metals. In these cases the electrodes were pretreated by methods which produced oxide films on the surface (1-3).

It is very likely that much of the reported data on the cathodic reduction of oxygen and the anodic evolution of oxygen on the noble metals were obtained on oxide covered surfaces (1-5). Since the completion of this work Damjanovic *et al.* (6-8) have obtained cathodic Tafel lines on Pt and Rh. They report different Tafel slopes for prereduced and oxide covered surfaces.

The energetically unfavorable steps in the reduction of oxygen are the endothermic reactions, (*i*) breaking the oxygen bond which requires about 5 ev, and (*ii*) the addition of a second electron to an oxygen atom which requires about 7.0 ev (8a). Although the addition of the first electron to the oxygen atom is exothermic by 1.0 ev, it should be noted that this electronic level

$$O(g) + e \rightarrow O^-(g)$$

lies about 3-4 ev above the Fermi level, when the metal electrode is at equilibrium for the over-all reaction, with reactants and products in their standard states. The reaction path should be dictated by these energetic requirements, and it is reasonable to assume that the chemisorption of the proper species will play a large role in reducing the activation energy. The adsorption energy will, of course, depend on the bond strength and, whether we consider a valence bond or an electrostatic bond, the number of electrons in the d-levels may play an important role.

The object of this study was to determine the effect of the number of holes in the d-band of the electrode on the Tafel parameters and over-all activity for the reduction of oxygen. Since the presence of an oxide on the metal surface may well obscure any metallic electronic structure effects, the data was obtained on prereduced electrodes of Au, Pt, Pd, Ir, Rh, Os, Ru, Pt-Au, and Pd-Au alloys.

It may be noted that McDonald and Conway obtained Tafel slopes for oxygen evolution on a series of Pd-Au alloys, but concluded that any possible effects of d-band structure were probably obscured by the role of surface oxides (5).

Tafel Slopes

It is difficult, if indeed possible, to determine a unique reaction path by means of only Tafel parameters. However, if one reaction path is predominant and one of the elementary reactions (step) in the sequence of elementary reactions is rate determining, the Tafel slope, b_c, will be characteristic of the rate-determining step (rds).

The assumption usually made in obtaining the "expected slope" is that the symmetry factor for the rds is 0.5. Riddiford has shown that this assumption may not be in accord with the experimental facts (9). McDonald and Conway have pointed out the possible effect of oxide films on the symmetry factor (5).

We suggest that even if the symmetry factor of the rds is 0.5 and oxide films are absent, the expression generally used to obtain the "expected" Tafel slope (7-13)

$$-b_c = \frac{2.303\,\nu_j}{n_c + \beta_c\, n_j}\,\frac{RT}{\mathbf{F}} \qquad [1]$$

may not be correct in some cases. In this expression n_c is the total number of electrons transferred before the rds, n_j is the number transferred in the rds, β_c is the symmetry factor of the rds, and ν_j is the number of times that the rds must occur in order for the over-all reaction to take place once, usually designated the stoichiometric number of the rds.

Although this expression is usually employed, the derivation has not been given (7, 10). For purposes of clarity we shall designate this b_c as the "conventional expected" Tafel slope, (CTS) and present a derivation in order to indicate its limitations and finally derive a more general expression. The latter will be more satisfactory especially for some reaction paths which have been postulated for the oxygen reaction (7).

When the over-all reaction is governed predominantly by one reaction path, and one of the consecutive elementary reactions, a step, is rate determining, the slope may be obtained by assuming "quasi-equilibrium" for all reactions preceding the rds (12) or by considering the passage of the reactants over a series of energy barriers (11). We shall follow the latter approach.

If we have an over-all reaction

$$xX + bB^z + ne \rightarrow wW + cC^{(bz-n)/c} \qquad [2]$$

it is assumed that the completion of this over-all reaction requires the formation and decomposition of ν identical activated complexes A^*, where ν is an integer. The rate-determining reaction may then be written as

$$\frac{x}{\nu}X + \frac{b}{\nu}B^z + \frac{n}{\nu}e \rightarrow \frac{w}{\nu}W + \frac{c}{\nu}C^{(bz-n)/c} \qquad [3]$$

and ν is usually called the stoichiometric number of the reaction.

The four states to be considered are: the initial state *I*, the state immediately before the highest energy barrier *P*, the state immediately after this barrier, *Q*, and the final state *F*. A cross section of the energy surface indicating the reaction path is shown, schematically, in Fig. 1.

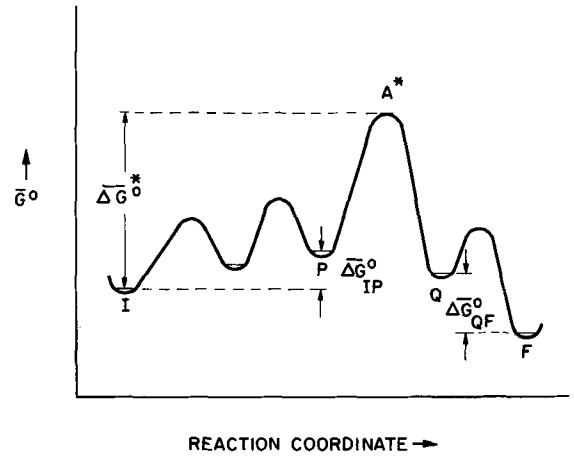

Fig. 1. Standard free energy change in a consecutive reaction path (schematic).

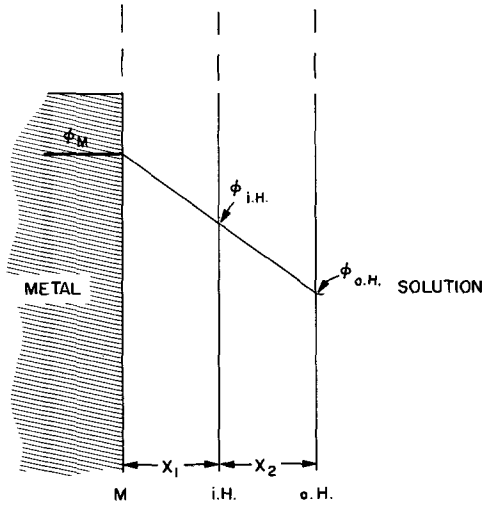

Fig. 2. Distribution of potential in the double-layer (schematic)

The electrical part of the standard free energy of activation in the forward direction is given by

$$\Delta G^{*o}_{Elec} = \sum_i Z_{IP} F \Delta\phi_{IP} + Z_{PQ} F \Delta\phi_{PA^*} \quad [4]$$

where Z_{IP} is the charge of a particle which is transferred from state I to P, $\Delta\phi_{IP}$ is the electrical potential difference through which the particle moves in going from I to P and the summation is over all charged particles i which react in order for the rds to occur once. Similarly the second term is for the charged particles which react to form the transition complex A^*.

If we let

$$\beta_c = \frac{\Delta\phi_{PA^*}}{\Delta\phi_{PQ}} \quad [5]$$

where β_c is the fraction of the potential difference between state P and Q which is effective for the activation of a charged particle i. We may write:

$$\Delta G^{*o}_{Elec} = \sum_i Z_{IP} F \Delta\phi_{IP} + Z_{PQ} F \beta_c \phi_{PQ} \quad [6]$$

β_c is then the conventional symmetry factor.

If we now identify the electric inner potentials which occur in the various states with those of the metal, ϕ_M, and the solution, ϕ_S, and consider only the transfer of electrons, we can write Eq. [6] as

$$\Delta G^{*o}_{Elec} = \frac{n_{IP}}{\nu_j} F [\phi_M - \phi_S] + \frac{n_{PQ}}{\nu_j} F \beta_c [\phi_M - \phi_S] \quad [7]$$

where effectively we assume that the electric potential difference across each barrier is that between the metal and the solution. n_{IP}/ν_j and n_{PQ}/ν_j are the number of electrons which are transferred from the metal to the solution prior to the rds and in the rds, respectively, in order for the rate-determining reaction, Eq. [3], to take place once.

For the complete reaction we have

$$\frac{n}{\nu_j} F [\phi_M - \phi_S] = \frac{n_{IP}}{\nu_j} F [\phi_M - \phi_S] + \frac{n_{PQ}}{\nu_j} F [\phi_M - \phi_S] + \frac{n_{QF}}{\nu_j} F [\phi_M - \phi_S] \quad [8]$$

The rate of the forward reaction in terms of current density is

$$i = \frac{n}{\nu} F\kappa \frac{kT}{h} a^{x'}{}_X a^{b'}{}_B e^{\frac{-\Delta G^{*o}_{Chem}}{RT}} e^{\frac{-\Delta G^{*o}_{Elec}}{RT}} \quad [9]$$

where

$$x' = \frac{x}{\nu} \text{ and } b' = \frac{b}{\nu}$$

which for a given reaction may be written as

$$\Delta G^{*o}_{Elec} = -RT \ln i + C \quad [10]$$

substituting Eq. [7] into [10] we obtain

$$\frac{n_{IP}}{\nu_j} F [\phi_M - \phi_S] + \frac{n_{PQ}}{\nu_j} F \beta_c [\phi_M - \phi_S] = -RT \ln i + C \quad [11]$$

and

$$-b_c = \frac{2.303\,\nu_j}{n_{IP} + \beta_c n_{PQ}} \frac{RT}{F} \quad [12]$$

which is identical with Eq. [1], the expression for the CTS.

It will be obvious that Eq. [11] and [12] are only true when the electrons or charges, are transferred from the metal to the solution or *vice versa*. This may not always be the case. In some of the elementary reactions, charges may not cross the total double layer. If the electrons are transferred from the metal to the adsorbed species and the ions are transferred from the adsorbed sites to the solution, or *vice versa*, the above equations must be modified.

Recalling the relative positions of the metal-plane, the inner Helmholtz plane, iH, and the outer Helmholtz plane, oH, shown schematically in Fig. 2, we may designate ϕ_M, ϕ_{iH}, and ϕ_{oH} as the inner electric potential of these planes (13-15). The diameter of an adsorbed radical or ion in the oxygen electrode reaction will be approximately equal to that of an oxygen atom or ion and will lie in the iH plane.

If we go back to Eq. [6] and substitute it into Eq. [10], the following general expression is obtained

$$\sum_i Z_{IP} F \Delta\phi_{IP} + Z_{PQ} F \beta_c \Delta\phi_{PQ} = -RT \ln i + C \quad [13]$$

Let

$$\Delta\phi_{IP} = f_{IP} \Delta\phi_{MS}$$
$$\Delta\phi_{PQ} = f_{PQ} \Delta\phi_{MS} \quad [14]$$

We have from Eq. [13] and [14]

$$-b_c = \frac{2.303}{\sum_i Z_{IP} f_{IP} + Z_{PQ} \beta_c f_{PQ}} \frac{RT}{F} \quad [15]$$

By this treatment we have retained the conventional definition and concept of the symmetry factor β_c as the portion of the change in the standard free energy of the rds which is effective in the activation process. The quantities f_{IP} and f_{PQ} then indicate the fraction of the total electrical potential difference at the metal-solution interface involved in the charge transfer process.

The transfer coefficient for the reaction will be given by

$$\alpha_c = \sum_i Z_{IP} f_{IP} + Z_{PQ} \beta_c f_{PQ} \quad [16]$$

As a first approximation we will let $\phi_{oH} = \phi_S$ (neglect p·d of the diffuse layer), take $\partial\phi/\partial X$ in the double layer as constant, and take the distance from the metal to the iH plane equal to that from the iH plane to the oH plane.

With these approximations and the usual reasonable assumption that $\beta_c = 0.5$, the "corrected" Tafel slopes, b'_c, have been calculated from Eq. [15] for the reaction paths given in Table I. Values of the "conventional" Tafel slopes, b_c, are included for comparison. The paths I through XIV have been listed by Damjanovic *et al.* (7); paths XV and XVI have been added.

Since Eq. [15] will yield the "conventional" slope when the values of f_{IP} and f_{PQ} are equal to unity, only paths VI, X, XI, XIII, XIV, XV, and XVI are affected.

To illustrate and clarify the concepts developed here, let us apply Eq. [15] to the Hoar's alkaline path, section VI in Table I, which has received support from Hoar (10) and Damjanovic *et al.* (7).

We assume that step 3 is rate determining so that $\nu_j = 2$. First it should be noted that since this step does not involve electron transfer, the conventional treatment assumes that this is not directly potential dependent. Yet the elementary reaction as written indicates the transfer of charge from the adsorbed site to the solution. Certainly this transfer should depend on $(\phi_{iH} - \phi_S)$, and Eq. [15] takes this into account.

The electrical part of the standard free energy of the various states *I*, *P*, *Q*, and *F* are

State	G°_{Elec}
I	$-2F\phi_M$
P	$-F\phi_{iH} - F\phi_M$
Q	$-F\phi_S - F\phi_M$
F	$-2F\phi_S$

The total electrical standard free energy change for the rate-determining reaction

$$\tfrac{1}{2}\,O_2 + 2e + H_2O \rightarrow 2\,OH^-$$

is

$$(\Delta G^\circ_{Elec})_{Total} = 2F\Delta\phi_{MS}$$

as it should be, and the electrical part of the standard free energy of activation for the forward reaction is

$$\Delta G^{*\circ}_{Elec} = F[\phi_M - \phi_{iH}] + F\beta_c[\phi_{iH} - \phi_S] = 0.5F\Delta\phi_{MS} + 0.25F\Delta\phi_{MS}$$

so that

$$\alpha_c = 0.75$$

$$-b'_c = 0.079V \text{ @ } 25°C$$

whereas the conventional slope = —0.059v.

If the reacting species are in fact adsorbed on the metal surface as indicated by the reaction equations, the conventional expected values of b_c used by investigators in their analysis would not yield a correct slope.

Experimental

The experiments were performed in highly purified solutions at 25°C. The techniques and methods of purification were similar to those described in the literature. Oxygen was maintained at unit pressure and at a constant rate of bubbling. Some data were obtained on rotating electrodes, but they were essentially the same as in the solutions stirred only by oxygen bubbling, except for larger limiting current densities in some cases.

The solutions were 1*N* H_2SO_4, 0.1*N* NaOH and various concentrations of Na_2SO_4 which were of constant ionic strength but various pH values by adding a few drops of diluted H_2SO_4 or NaOH.

Pt, Pd, and Au electrodes were 99.999% pure and the other electrodes were 99.9% pure. The Pd-Au and Pt-Au alloys were made in an induction furnace using recrystallized alumina crucible and helium atmosphere. They were cast and rolled to 50% reduction at room temperature, except for some of the Pt rich Au-Pt alloys which were rolled at 1100°C. All alloys

were homogenized for 12 hr at the proper temperature and quenched in water to obtain a homogeneous, single phase solid solution. Au-Pt alloys having the following compositions were used (w/o Au): 4.72, 9.66, 17.35, 27.38, 37.25, 49.84, 60.35, 70.13, 80.03, and 89.64. Au-Pd alloys were of the following composition (w/o Au): 9.47, 23.96, 53.89, 67.06, 71.01, 76.90, and 85.8.

The alloy electrodes were cut from the inside of the specimen in order to avoid any possible surface inhomogeneity. The homogeneity of the surface was checked by the electron probe microanalyzer.

Electrodes were metallographically polished, thoroughly cleaned, rinsed, and dried. Acid pretreatments were omitted in order to avoid possible preferential dissolution of alloy constituents. Experiments on pure metals with and without acid treatment showed the same final results.

All the electrodes were prereduced at +0.20v in H_2SO_4 and —0.60v in NaOH for 15 min. Since the final results were the same whether the solutions were saturated with oxygen or nitrogen during the reduction, most prereductions were done in an oxygen saturated solution. After prereduction the circuit was opened and the electrode assumed an open-circuit potential, E_o, which became steady in about 10 min. The electrode was then cathodically polarized, galvanostatically, from low to high current densities, then from high to low current densities without opening the circuit.

Electrode potential values are given on the standard hydrogen electrode scale.

Results

Pure metals.—The η log i curves for oxygen reduction showed a reproducible Tafel relation for all the electrodes in H_2SO_4 and NaOH from about 10^{-6} amp/cm^2 to about 10^{-3} amp/cm^2. Concentration polarization became noticeable at these higher current densities under the stirring conditions used. The curves were the same whether obtained from low to high currents or *vice versa*.

Except for Au in H_2SO_4 the potential changed very little from the open-circuit value, E_o, until the current density reached about 10^{-6} amp/cm^2. The η-log i relation was not linear in this low current density range. The results for Pt, Pd, and Au are typical and are shown in Fig. 3.

The Tafel parameters are given in Table II. The reported values are the mean of at least six experiments. The values of the slope, b_c, were reproducible to better than ±0.005v for all metals in NaOH, to about the same value for Pt and Pd in H_2SO_4, and about ±0.01v for the other metals and alloys in H_2SO_4. The values of i_o could be reproduced by a factor of ten. Except for Au in H_2SO_4, E_o varied by about ±0.02v in H_2SO_4 and ±0.01v in NaOH. The E_o of Au varied by about ±0.05v in acid. The overpotential at 10^{-5} amp/cm^2, η^o, was chosen as a relative index of the "over-all activity" of the electrode for the reduction reaction.

Pt has the highest i_o and activity (lowest η^o) in both acid and alkaline solutions. Except for Pt, the activity of the metals is greater in NaOH. Since the values of i_o are all quite low, b_c plays the greater role in determining η^o.

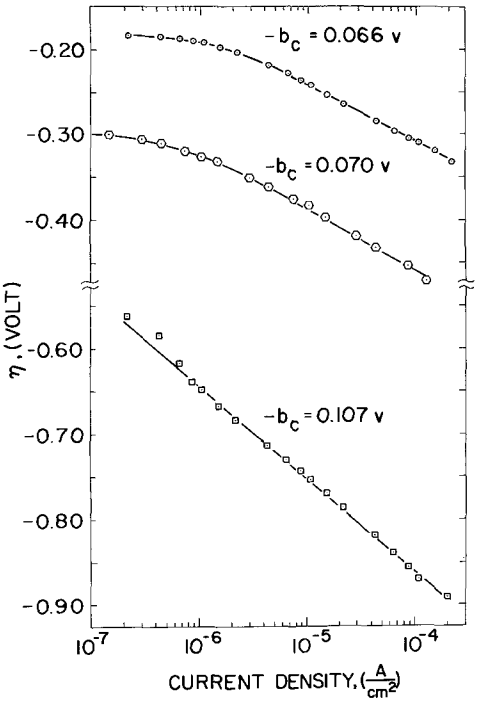

Fig. 3. Overvoltage, η — log i relationship in 1*N* H_2SO_4. ⊙ Pt; ⊙ Pd; ⊡ Au.

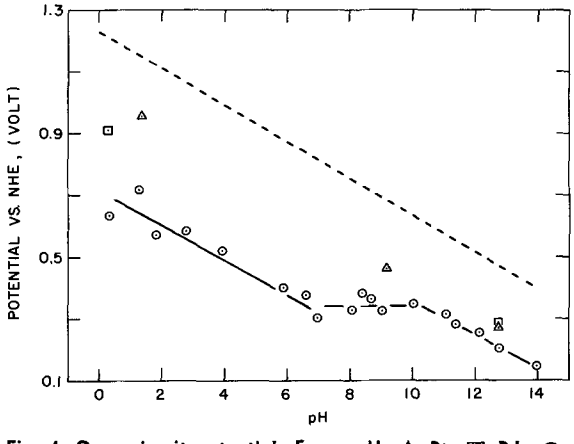

Fig. 4. Open-circuit potential, E_o vs. pH. △ Pt; ⊡ Pd; ⊙ Au. Dashed line indicates theoretical potential-pH relationship, calculated from the equation

$$E = 1.23 - \frac{RT}{4F} \ln \frac{(a_{H_2O})^2}{(a_{H^+})^4 (P_{O_2})}$$

Since the values of b_c and η^o for Au were significantly different in H_2SO_4 and NaOH, more detailed data were obtained for this metal with solutions of different pH values. The results are shown in Fig. 4, 5, and 6.

Alloys.—The data for the alloys are shown in Fig. 7, 8, and 9. These figures also include parameters of

the pure metals in order to show the effect of the d-band structure as well as composition.

Pt-Au *alloys in* H_2SO_4.—E_o remains close to the value for Pt until about 85 a/o (atomic per cent) Au. The value of i_o remains close to that of Pt until about 60 a/o Au. Surprisingly, b_c changes to that of Au at only about 5 a/o Au. The net effect is a decrease of activity with Au content.

Pt-Au *alloys in* NaOH.—i_o decreases with Au content, while E_o remains close to that of Au for all compositions. η° and b_c do not vary with alloy composition.

Pd-Au *alloys in* H_2SO_4.—E_o remains close to that of Pd until about 70 a/o Au. The values of b_c, i_o, and η° change approximately linearly with Au content from the values of Pd to those of Au, with considerable scatter in the values.

Pd-Au *alloys in* NaOH.—E_o remains close to that of Pd until about 60 a/o Au. The values of b_c and η° are

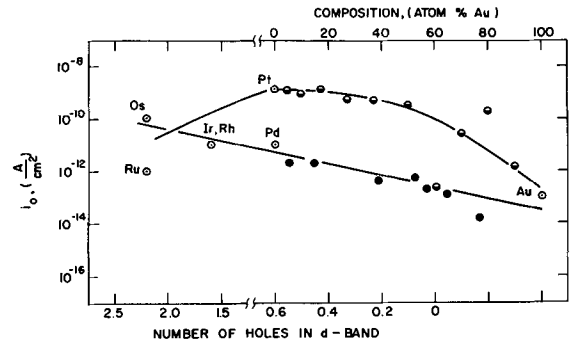

Fig. 8. Exchange current, i_o *vs.* composition and number of holes in d-band; in 1*N* H_2SO_4. ◒ Pt-Au alloys; ● Pd-Au alloys.

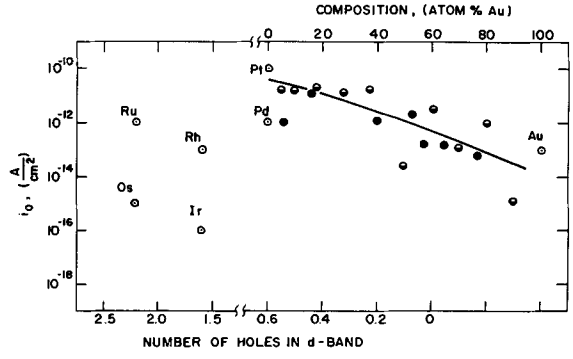

Fig. 9. Exchange current, i_o *vs.* composition and number of holes in d-band; in 0.1*N* NaOH, ◒ Pt-Au alloys; ● Pd-Au alloys.

about the same for the two pure metals and show no significant dependency on composition, considering the reproducibility. The i_o values for Pd and Au are about 10^{-12} amp/cm^2 and 10^{-13} amp/cm^2, respectively. The value for the alloys changes approximately linearly with Au content between these two limits.

Any effects due to the number of holes in the d-band (nhd) may be seen from Fig. 7, 8, and 9, by considering the data for the pure metals along with that for the alloys. The large scatter in the values does not allow precise evaluation, but certain consistent trends of the variation of the Tafel parameters η° and i_o are indicated. These trends are shown by the curves drawn in the figures. The trends are much more with the chemical composition-surface structure than with the nhd.

Discussion

Open-circuit potential.—The nonlinear character of η-log i and the very low rate of change of η with log i in the low current density range strongly indicates that the open-circuit potential is either a mixed potential with a "reaction current density" of about $10^{-6.5}$ amp/cm^2 or that it is a reversible potential for some reaction with an exchange current density of the same value. We believe that the former is the case, in agreement with Hoar and others (16, 16a).

Reaction mechanisms.—It is not possible to determine reaction mechanisms by means of b_c and i_o. Since the anodic reaction occurs on an oxide surface (5, 6), the anodic slope b_a and ν could not be obtained on prereduced surfaces. Moreover E_o is about 1V, and hence one cannot use the linear relation between η and i to calculate ν (11).

Values of b_c may be used to eliminate certain reaction paths and indicate possible paths. Many reaction paths can be devised for the oxygen electrode, but we will limit our discussion to those listed in Table I. Taking into account the variations in the reproducibility of the b_c values the possible paths for the metals are summarized in Table III.

Table III. Possible reaction paths and rate-determining steps corresponding to experimental b_c

No.	System	Possible paths and rds**	Remarks
1	Pt in H_2SO_4	III(2), IV(2), VI(2), VII(2), V(4),* VII(4)*	Damjanovic *et al.* (6) obtained 0.054v on oxide free Pt. Bianchi *et al.* (3) obtained 0.06v on oxide free Pt.
2	Pt in NaOH	III(2), IV(2), VI(2), VII(2), XV(4),* XVI(3)*	Damjanovic *et al.* (7, 8) obtained 0.065v on oxide covered Pt. Hoar (16) obtained 0.048v

* In these steps electrons are transferred.
** Roman numeral indicates the reaction path and the numeral in parenthesis indicates the rds; refer to Table I.

The continuous variation of b_c with pH for Au is noteworthy. Although data were not obtained for Ru, Rh, Ir, and Os, which also show a fairly large change in slope from acidic to alkaline solutions, it is likely that a similar variation of b_c with pH occurs on these metals. The continuous variation in b_c with pH is very likely due to the presence of at least two alternate reaction paths whose rates are close in value with one path being pH dependent.

There is no apparent relationship of the number of holes in the d-band (nhd) with the activity in NaOH or with b_c in H_2SO_4 and NaOH. The exchange current density, i_o, does show a trend with nhd in H_2SO_4. It does not appear significant, however. The trend in NaOH is even less significant. The activity in H_2SO_4 does show a definite trend (Fig. 7), with a maximum activity (minimum η^o) at Pt and Pd. Our general conclusion is that composition, hence geometric and chemical factors, play the predominant role in this series of metals. These results and conclusions are not at variance with some current views on the role of electronic structure on catalysis (17). It is interesting to note that Brennan *et al.* found that the integral heat of adsorption for oxygen on Pt, Pd, and Rh varied almost linearly with atomic radii (18). On the other hand, Rao *et al.* have reported an increase in surface coverage of oxygen with an increase in the nhd for the same metals used in this work (19).

Technical Notes

The Kolbe Electrosynthesis of Polydifluoromethylene

Madeline S. Toy

Douglas Aircraft Company, Missile and Space Systems Division, Astropower Laboratory, Newport Beach, California

In general, dicarboxylic acids, such as malonic acid, do not undergo reactions of Kolbe type, but oxidize to degradation products at anode electrode in an alkaline medium. However, the alkaline salts of the monoester dicarboxylic acids have been reported to give Kolbe type reactions with products being higher dicarboxylic acid esters (1). The electrolysis of dibasic acids in methanol have been reported by Garrison (2) to form polymers, and Kolbe couplings of perfluorinated monobasic acids have been reported by Levin, Chechina, and Sokolov (3). A recent patent describes the production of long-chain perfluoromono- and perfluorodicarboxylic acid esters also through Kolbe couplings (4).

This note reports the anodic synthesis of polydifluoromethylene from a perfluorodicarboxylic acid. Polydifluoromethylene has been prepared by electrolysis of solutions of commercial perfluoroglutaric acid (mp 85°-90°C) with sodium in methanol. The temperature of the experiments ranged from 25° to 55°C and the monomer concentration in absolute methanol ranged from 5 to 25 w/o. The electrolytic cell was equipped with two smooth platinum electrodes. A typical run employed 10% monomer by weight, current density of 40 to 100 ma/cm², and applied voltage up to 40v (depending on the distance between the electrodes and salt concentration). A white loosely adhering coating was formed on the anode in 4 hr. The current density could not be maintained but gradually decreased. After a few hours of electrolysis, a small amount of white flocculent precipitate was observed around the anode. The flocculent precipitate can be slightly increased by occasionally reversing the polarity of the electrodes. The white solid scraped from the anode partially softened at 300°C and was insoluble in solvents, including hexafluorobenzene, chloroform, dimethyl formamide, dimethyl sulfoxide, concentrated sulfuric acid, while the small amount of white solid recovered from the suspension was partially soluble in concentrated sulfuric acid, but not in the other tested solvents. The very strong broad absorption band between 7.9 and 8.7μ (5) for "Teflon" (trademark of du Pont's polytetrafluoroethylene) is observed in Fig. 1. The anodically synthesized polydifluoromethylene also shows another strong absorption band at 5.6μ with a weak peak at 2.9μ, indication typical of COOH in fluorocarbons (6). The infrared spectrum (Fig. 1) and the absolutely insoluble characteristics of the white solid scraped from the anode indicate that the polymer is essentially a long perfluorocarbon chain as Teflon, but with carboxylic terminal groups. The estimated molecular weight is low at approximately one thousand by the relative intensities of the CF and CO groups in the infrared spectrum.

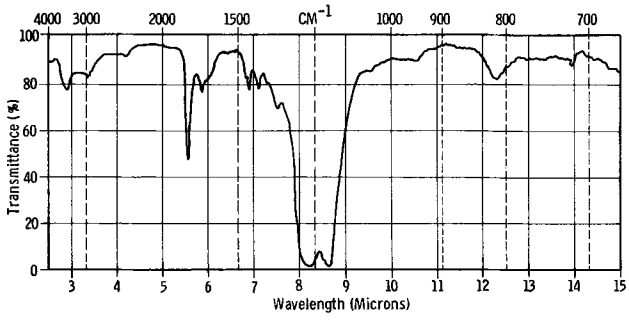

Fig. 1. Infrared spectrum of anodically synthesized polydifluoromethylene.

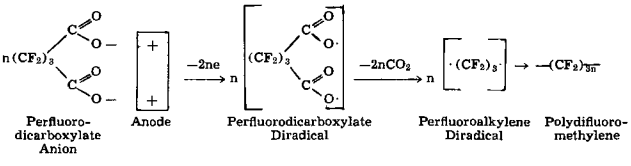
The mechanism of anodic synthesis of polydifluoromethylene from perfluoroglutaric acid appears to involve diradical couplings on the electrode surface.



During electrolysis, the perfluorodicarboxylate anions are impelled to the anode, where they give up the ionic charges and possibly exist in a transient phase as a perfluorodicarboxylate diradical having an odd electron on both ends. This diradical at once loses carbon dioxide molecules and gives an equally transient trivalent carbon radical on both ends. This perfluoroalkylene diradical finally achieves stabilization by radical combinations with adjacent diradicals to form a polydifluoromethylene coating on the metal surface.

Oxygen Reduction on a Partially Immersed Rotating Platinum Cathode

R. J. Roethlein and H. J. R. Maget

DECO Research & Development Laboratory, General Electric Company, West Lynn, Massachusetts

Reaction rates for an electrochemical process occurring on stationary electrodes in a diffusion controlled region having essentially the same interphase between the conducting electrolyte and the gas phase reactant have been shown by many authors to be associated with mass transport processes through thin electrolyte films (1-5). The reaction zone is confined to a small region near the film-meniscus interphase, and it is evident that these electrodes utilized only a fraction of the total electrode surface area. The bulk electrolyte presents a longer path for the mass transport of the reactant (gas) species to the electrode surface, and the reaction zone is further limited by the increased resistance to ionic flow encountered in the thin film region as the distance from the bulk electrolyte region increases. In order to facilitate a larger portion of the electrode surface area for mass transport processes a rotating electrode structure was investigated.

A circular hydrophobic electrode structure was rotated intermittently through an aqueous electrolyte and a depolarizing gas (oxygen). This procedure extends the region of thin film formation above the electrolyte level causing an increase in the total electrode current. Similar investigations have been carried out by Bonnemay *et al.* (6) in an attempt to separate adsorption from mass transport in electrochemical studies, and Weber *et al.* (7) have used a rotating copper electrode to investigate the mechanism of metal oxidation. The increased currents observed on partially immersed porous electrode has been employed by Bianchi (8) as a convenient basis for a comparative study of electrocatalytic activity of noble metals and for investigations of electrocatalytic processes of various reactant gases.

Therefore this novel electrode structure may not only provide higher diffusion controlled currents but also serve as an effective tool in catalyst evaluation. Further by variation of the rotational speed and depth of immersion this device could be used to determine the relative rates of:

1. The diffusion of a reactant gas across an electrolyte film.
2. Migration parallel to the electrolyte film.
3. Reaction and desorption of reactants into the electrolyte.
4. Adsorption on a dry surface or below the electrolyte film level.

Experimental

Experiments were carried out in a specially modified Pyrex glass test cell, which contained reference and counter electrode compartments separated from the study electrode section of the cell, Fig. 1. The counter electrode consisted of a large section of platinum black screen, and the reference system contained a dynamic hydrogen reference electrode, which maintained a steady potential near the reversible H^+/H_2 potential. The test electrode consisted essentially of a Teflon-bonded platinum black electrode (9) which was cut into a circular disk and then mounted on a tantalum shaft. The shaft was connected by means of an insulated bushing to a multi-speed transmission which has a 600 rpm reversible synchronous motor and a gear train with twelve steps of reduction. By the use of this motor various speeds of rotation could be imposed upon the

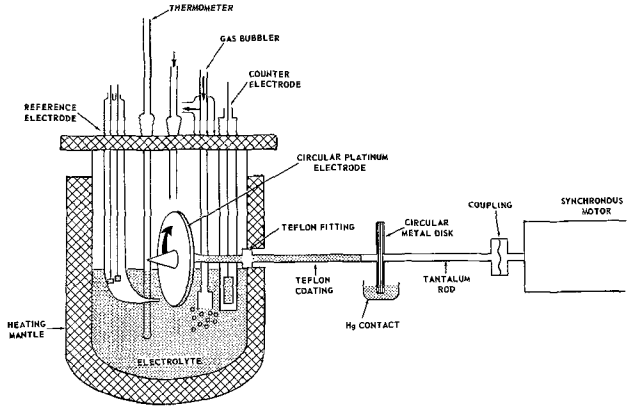

Fig. 1. Experimental apparatus

electrode. The study electrode was held vertical on the shaft with two circular Teflon disks which were threaded into the tantalum rod.

Electrical contact was accomplished by having a metal disk connected to the shaft outside of the test cell which then rotated through a pool of mercury. Teflon couplings mounted on the glass inlet port for the tantalum shaft prevented electrolyte leakage from the test cell, but still permitted the metal shaft to rotate freely. Temperature was maintained constant to within a few degrees by means of a variac controlled heating mantel. The study electrode was composed of the same materials generally employed in making Niedrach-Alford-type electrodes, nine parts platinum black to one part of weight of Teflon; pressed on platinum screening. The electrode was pressed at approximately 6200 psi at 700°F for a period of 7.5 min. A thin film of Teflon was sprayed on both sides of the electrode with an aqueous dispersion of (T-30). The actual electrode area on both faces of the disk was approximately 42 cm^2 with an average thickness of 10 mils. Measurements of the electrochemical reduction of oxygen were made in 10*N* H_2SO_4 at 25°C; both the electrolyte and surrounding atmosphere inside the test cell were kept completely saturated with oxygen gas. The electrolyte was presaturated with oxygen by means of the gas bubbler; however, during test the oxygen was admitted above the electrolyte level. Electrode potential was held constant by means of a Wenking potentiostat.

Results and Discussion

Performance studies were made of the rate of the electrochemical reduction of oxygen under various conditions. The electrode was held at a constant potential of +0.600v *vs.* H^+/H_2 and the current recorded for various conditions of electrode immersion and rotational speed. Figure 2 shows a plot of variation in current with the square root of rotational speed for six different immersion depths, 10, 15, 30, 50, 75, and 100% of the total electrode surface below the electrolyte level. When the electrode is totally immersed the electrochemical process is controlled by the bulk diffusion of oxygen through the electrolyte; hence only low currents are obtainable which show only slight increases with rotational speed. As

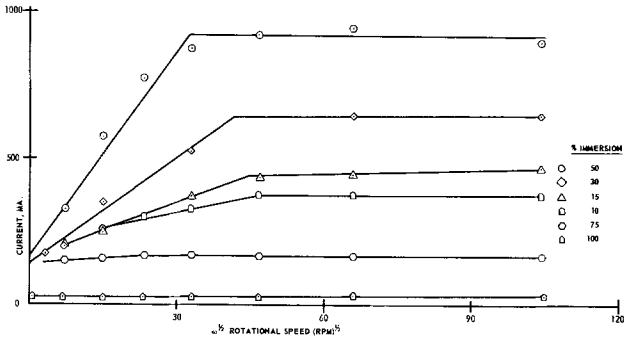

Fig. 2. Effect of rotational speed and immersion depth on electrode current. O_2 reduction; ion-H_2SO_4. 25°C; applied potential +0.600v vs. H^+/H_2.

the electrode is raised out of solution there is an immediate increase in current even while the electrode is at rest. This is due to the formation of a thin film of electrolyte in the exposed portion of the electrode matrix, which provides a shorter path for diffusion of oxygen molecules to the catalyst surface (10). Increasing the amount of exposed surface area has no substantial effect on the current while the electrode is at rest. This is due to the fact that the effective "active" area of the thin film portion of the electrode is virtually the same no matter how much of the total electrode surface is above the electrolyte level. The "active" length of the film is dependent mainly on the thickness of the electrolyte film which can produce large ionic resistance variations during current flow. At rest, gravitational forces will cause the liquid film to drain to a constant thickness which is independent of the amount of exposed surface area. When the electrode is rotated a linear increase in current is obtained with the square root of rotational speed up to an optimum value above which there is no subsequent current change with increasing rotational speed.

Observations made of the electrode surface at rest and during rotation show a distinctly hydrophobic surface in that the contact angle is greater than 90° and liquid does not cling to the exposed electrode surface during rotation. However the catalyst matrix beneath the Teflon film does wet, and rotating the electrode brings this wetted section above the electrolyte level. At this point electrolyte in the catalyst matrix drains downward, but has the immediate effect of providing an electrolyte film in the exposed section of the electrode above the level of the electrolyte. Increasing the speed of rotation will tend to counter balance the force of gravity providing a temporary greater film thickness in the region above the electrolyte level. Thus a larger portion of the thin film will be able to support current due to the decreased ionic resistance provided by the increase in film thickness. Eventually increasing the rotational speed will no longer have any effect on the film thickness and electrode current will reach a plateau.

Variations in the amount of electrode surface partially immersed reflect changes in the electrode current during rotation. There is a steady increase in current as the depth of immersion increases up to approximately 50% of the total electrode area; subsequent increases in the per cent of immersion produce a decrease in total electrode current. For immersion depths less than half of the total electrode area smaller portions of the outside perimeter of circular electrode surface are wetted by electrolyte during rotation. As the immersion depth increases the total current increase is due to a geometric increase in electrode area on which the active area of the thin film can be formed. The lower currents obtained for immersions depths greater than approximately 50% are caused by a decrease in the active area of the thin film region since a larger portion of the electrode surface is below the electrolyte level and bulk diffusion controlled.

Brief Communication

Conductivity of KOH and KOH-ZnO Electrolytes from 36° to -66°C

Charles T. Baker and Isaac Trachtenberg

Texas Instruments, Incorporated, Dallas, Texas

Currently, emphasis is being placed on the research of alkaline batteries using the negative zinc electrode, and more information is needed on the KOH and KOH-ZnO electrolyte systems which are used in such batteries. In this note data are presented on the specific conductivities of various KOH and KOH-ZnO solutions as a function of temperature between 36° and —66°C and on the solubility of ZnO in these KOH solutions. These latter data are in agreement with those of other investigators (1, 2).

All KOH and KOH-ZnO solutions were prepared using reagent grade KOH and ZnO and deionized water. During the preparation and utilization of these solutions, precautions were taken to prevent the introduction of CO_2. A Tenney, Jr., Environmental Chamber, Model TJR, was used to control the temperature of the experiments to ±0.5°C. The conductivity measurements were made with an L&N model 4805-50 conductivity cell assembly in conjunction with a General Radio Company impedance comparator, model 1605, using General Radio Company precision resistance and capacitance decade boxes. The cell constant for the conductivity cell was determined by using the solutions and data given by Jones and Bradshaw (3).

In the ZnO solubility studies, at each temperature the sample solution was agitated periodically by means of an ultrasonic bath over a three-day span in order to insure that equilibrium had been established. When samples were needed for analysis, the required amount of solution was extracted from the vessel in the environmental chamber by means of a reduced pressure system.

Results of the conductivity experiments are reported in Fig. 1 and Fig. 2 for 39, 34, 30, and 25% KOH and for 36.3% and 30% KOH saturated with ZnO at temperatures from 36° to —66°C. Both Dirkse (4) and Bodamer (1) have shown that for a particular KOH concentration and temperature, the specific conductivity decreases as the concentration of zinc in solution increases.

The conductivity data point out one major problem which must be considered in the use of alkaline batteries at low temperatures. There will be about a 100 fold change in the internal resistance of the battery which in itself can grossly affect the charge-discharge characteristics of the battery. For the pure KOH solutions, the 30% KOH solution exhibits the best behavior over the temperature range investigated. The 25% KOH solution is equally conductive at temperatures down to —23°C and is slightly more conductive for temperatures down to —36°C, but is limited by a freezing point in the neighborhood of —41°C. The conductivity data for the KOH solutions saturated with

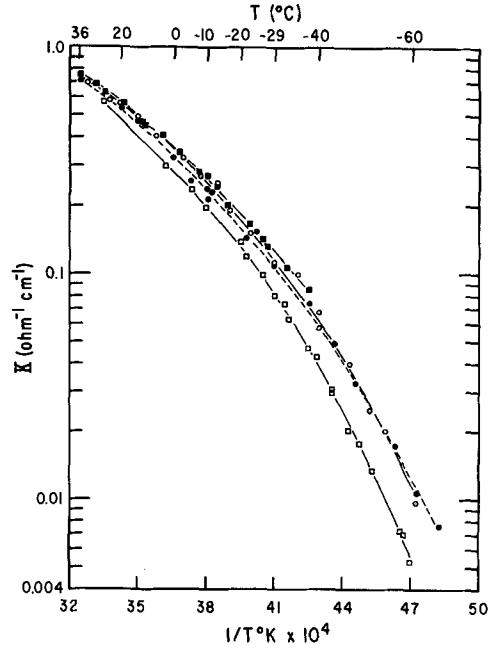

Fig. 1. Specific conductivity of KOH solutions as a function of temperature. ■ 25% KOH; O 30% KOH; ● 34% KOH; and □ 39% KOH.

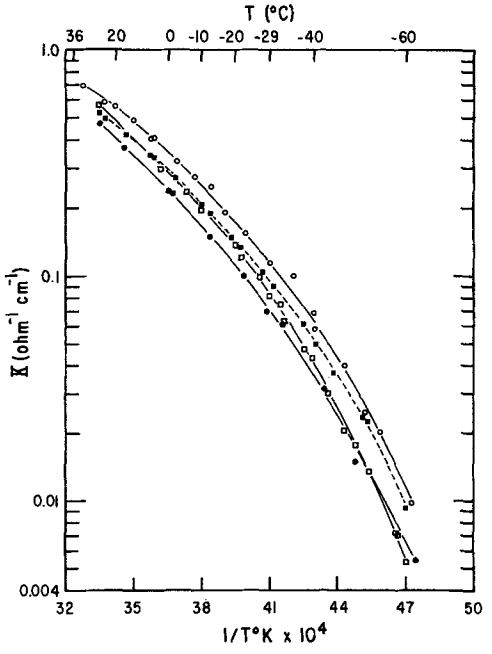

Fig. 2. Specific conductivity of KOH and KOH-ZnO solutions as a function of temperature. O 30% KOH; □ 39% KOH; ● ZnO saturated 36.3% KOH; and ■ ZnO saturated 30% KOH.

Table I. Solubility of ZnO in KOH at 25°C

% KOH (before saturation)	*M* Zn ions in solution
25 (5.5*M* KOH)	0.45
30 (6.9*M* KOH)	0.64
34 (8.1*M* KOH)	0.83
36.3 (8.7*M* KOH)	0.95

ZnO at these low temperatures are consistent with that reported by Bodamer at the higher temperatures. Addition of ZnO to a KOH solution decreases the conductivity of the solution.

Results of the solubility studies of ZnO in 25, 30, 34, and 36.3% KOH at 25°C are given in Table I and are in agreement with the values reported by Bodamer (1) and Dirkse (2). The effect of temperature on the solubility of ZnO in 36.3% KOH is shown in Table II. As the temperature decreases from 26° to −62°C, the solubility of ZnO appears to be invariant. Bodamer observed the same effect for temperatures between 10° and 95°C. Based on these two sets of data, the over-all heat of solution appears to be close to zero.

Manuscript received July 25, 1967.

Characterization of Energy Transfer Interactions between Rare Earth Ions

L. G. Van Uitert

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Energy transfer studies employing the sodium rare earth tungstates (scheelite structure) indicate a number of modes of, and requirements for, nonradiative interaction. Direct dipole-dipole interactions are prevalent. However, dipole-quadrupole interactions are observed for the states of the larger rare earth ions that lie high in energy. The relation of lifetime (τ_e) to intensity changes with the mode of transfer. Phonon assisted transfer is enhanced by exchange coupling between rare earth ions in nearest or next nearest neighbor positions. Excitation may migrate between Tb ions in such positions when thermally activated and provided a suitable quenching center (*e.g.*, Nd, Eu) is present. Such migration appears to be directional in comparison to transfer by radiation reabsorption. The latter is essentially random. Methods for analyzing lifetime data for transfer interactions are also discussed.

Energy transfer between rare earth (RE) ions is a subject of appreciable current interest for practical as well as theoretical reasons. The use of rare earths for laser and colored television applications have stimulated a desire for a better understanding of transfer. Early work in this field has been discussed by Botden (1). More recent work has been summarized elsewhere (2). Much of the previous work has been limited to demonstrations that transfer does occur and general statements as to the probable mechanisms involved. In fact, however, a sufficiently strong theoretical basis exists for more exacting results to be obtained (3-6). The RE ions are particularly suitable for the study of energy transfer as the absorption and emission due to f-electrons is sharp and the associated oscillator strengths are weak.

Energy transfer is generally associated with multipolar interactions, radiation reabsorption, or exchange. These effects can be identified by examining intensity and lifetime data as a function of the excited (E) and/or the quenching (Q) ion concentration. Intensity values can be obtained by direct measurement under equilibrium conditions, but lifetime is obtained under transient conditions and is somewhat subject to interpretation. Procedures for analyzing lifetime data and the significance of various correlations of intensity and lifetime with E-ion and/or Q-ion concentration are discussed.

Materials and Measurements

Crystals of various members of the series $Na_{0.5}(Y,RE)_{0.5}WO_4$, where RE = Pr, Nd, Sm, Eu, Tb, Dy, and or Er in the combinations indicated in the accompanying figures, were grown from a $Na_2W_2O_7$ flux as described previously (7). The crystals have the scheelite ($CaWO_4$) structure; however, the Na, Y, and RE ions are distributed somewhat randomly over the dodecahedral sites normally occupied by Ca. The compositions were analyzed by x-ray fluorescence methods.

Intensity comparisons were obtained using a standard plaque technique. The intensity of emission of Pr (at 0.487μ for Pr^3P_0), of Sm (at 0.598μ for $Sm^4F_{5/2}$), of Eu (at 0.614μ for Eu^5Do), of Tb (at 0.544μ for Tb^5D_4), of Dy (at 0.574μ for $Dy^4F_{9/2}$) and of Er (at 0.552μ for $Er^4S_{3/2}$) was obtained under ~0.365μ excitation as provided by a CH4 spotlamp and CS7-54 longwave uv pass filter. The intensity of emission of Er (at 1.56μ for $Er^4/I_{13/2}$) or Nd (at 1.06μ for $Nd^4F_{3/2}$) was obtained under 0.43-0.62μ excitation isolated from the CH4 lamp by a CS3-72 cut-off filter and a $CuSO_4$ solution before the sample. A Gaertner high dispersion spectrometer equipped with an AMINCO microphotometer and S11 detector were employed to record data for the visible region. A Bausch and Lombe No. 33-86-03 monochromator, with a CS7-56 filter at the input, and S1 detector at the output, was used to record data at 1.06μ; and a Bausch and Lombe No. 33-86-04 monochromator, with a CS7-56 filter at the input, and a InAs detector at the output, was used to record data at 1.56μ.

Lifetime data were obtained employing a confocal ellipse laser housing with an EG&G FX12 flashlamp at one focus and the sample at the other. One side of the ellipse was slotted so that the output of the sample could be viewed. A Bausch and Lombe No. 33-86-02, -03 or -04 monochromator equipped with an S1, cooled S11 (~217°K), or cooled InAs (~77°K) detector and oscilloscope were used to obtain photographic recordings of the decay curves. A CS-7-54 filter was placed between the flashlamp and sample when obtaining data in the visible region. A CS-3-72 filter was placed between the lamp and sample in measuring at 1.06μ, but none was used in obtaining data at 1.56μ A CS-7-56 filter was placed in front of the monochromator for all infrared measurements.

Intensity and Lifetime

The emission spectra of RE ions change little with concentration provided that increasing substitution does not appreciably change the effective crystal field seen by the RE ions. This condition is satisfied when substituting RE ions for others of equivalent radius and valence in the sodium rare earth tungstates.

The probability for de-excitation of the E-species (P_3) is equal to the sum of the probabilities for emission (P_1) and nonradiative loss (P_2). Therefore emission per E-ion (I) relative to that obtained under dilute conditions (I_o) is

$$I/I_o = P_1/P_3 = P_1/(P_1 + P_2) \qquad [1]$$

If the nonradiative losses are attributable to multipolar transfer, $P_2 \propto (C/C^*)^{\theta/3}$ where C is the Q-ion concentration, C^* is the critical transfer concentration of Q-ions and θ = 6, 8, or 10 for dipole-dipole, dipole-quadrupole, or quadrupole-quadrupole interactions, respectively (3-6). Substituting into relation [1] and rearranging, one obtains

$$I/I_o = [1 + \beta(C/C^*)^{\theta/3}]^{-1} \qquad [2]$$

where β is a constant for each interaction.

Lifetime measurements are obtained under transient conditions and can involve various modes of decay that complicate their interpretation. When there is no interaction between RE ions, the emission decay curve is a single exponential. Lifetime can then be

taken to be the time (t) required for the transient intensity (Φ) to fall to 1/e (or 0.368) of the value it has at $t = 0$. This relation defines τ_e. If direct multipolar interactions quench the E-species, the decay curve is much more complex. τ_e/τ_o, where τ_o is the value of τ_e under dilute conditions, cannot then be substituted directly for I/I_o in relation [2]. However, this relation can be employed to define an arbitrary lifetime τ_a

$$\tau_a/\tau_o = [1 + \beta'(C/C^*)^{\theta/3}]^{-1} \qquad [3]$$

The relation of τ_e to τ_a and the procedure for determining a lifetime (τ_i) which approximates τ_a from the initial or early slope of the decay curve is discussed in the Appendix. Properly selected values of τ_i correlate with I and are therefore helpful in characterizing energy transfer interactions.

Interactions

Exchange is generally limited to interactions between RE ions in nearest neighbor (nn) or next nearest neighbor (nnn) dodecahedral sites in the scheelites. Six such interactions are permissible (8). Therefore, the fraction of RE ions which, in any event are little affected by exchange is $(1 - x)^6$, where x is the fraction of dodecahedral sites occupied by RE ions. Where RE ions that are exchange coupled (but no others) are quenched, intensity of emission per ion (I) will follow this relation and a peak in total emission will be obtained at $\sim x = 0.14$. When direct multipolar interactions are involved, quenching is generally more extensive and relations [2] and [3] tend to be obeyed (8-14). Quenching is even greater when excitation migrates over the E-ion set. If migration is rapid compared to direct transfer, quenching tends to be proportional to Q-ion concentration ($\theta = 3$), since transfer to Q-ions from close lying E-ions becomes the rate limiting step (8-14). Lifetime tends to be a single exponential, but decreases rapidly with Q-ion concentration under these conditions. If radiation reabsorption, self-quenching, or internal relaxation is strong, the foregoing intensity and/or lifetime relations can be altered significantly. Examples are cited under results.

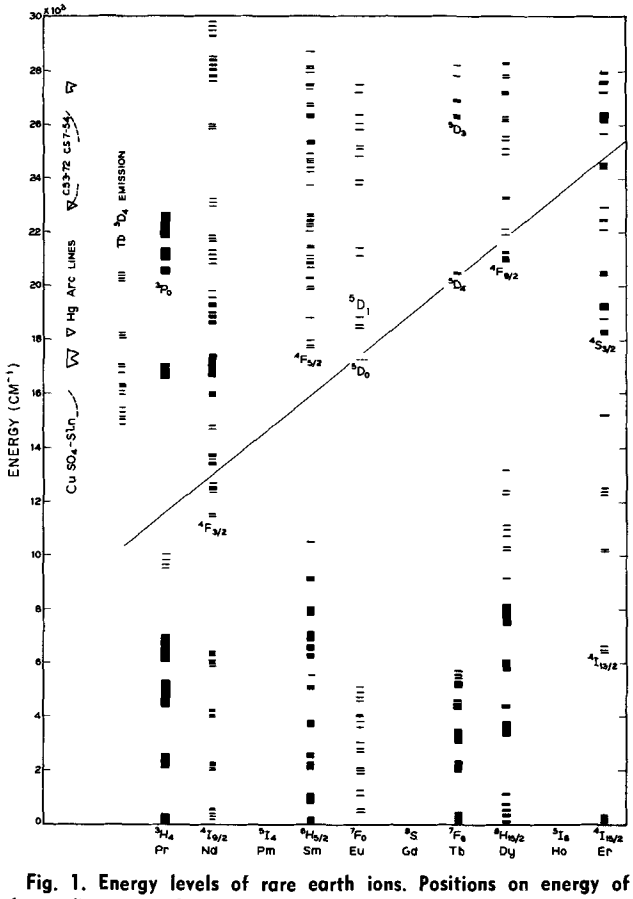

Fig. 1. Energy levels of rare earth ions. Positions on energy of the radiation peaks from the mercury arc source, of emission lines of Tb from Tb^5D_4, and of the cut-off frequencies for the CS7-54, CS3-72, and $CuSO_4$ solution filters are also indicated. The diagonal line is a somewhat arbitrary demarcation between manifolds which have been observed to participate in dipole-quadrupole interactions (upper part) and those for which only dipole-dipole interactions have been observed.

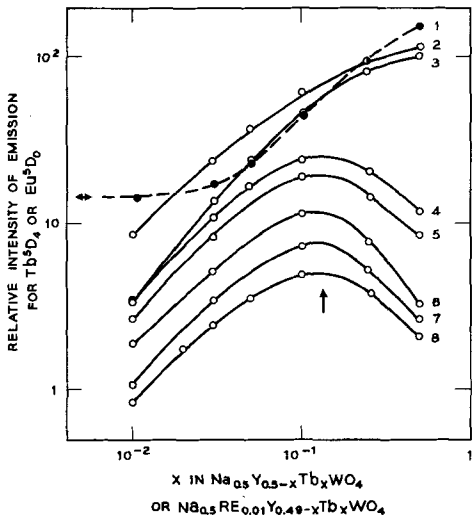

Fig. 2. Relative intensity of emission of Tb from Tb^5D_4 (O) at 295°K *vs.* Tb concentration for the following series: curve 3, $Na_{0.5}Y_{0.5-x}Tb_xWO_4$; curves 2, 4, 5, 6, 7, and 8, $Na_{0.5}RE_{0.01}Y_{0.49-x}Tb_xWO_4$ where RE = Dy, Eu, Pr, Sm, Nd, and Er respectively. Curve 1 represents emission from Eu^5D_0 (●) for series 4. The reference mark (↔) indicates the intensity of emission for Eu in $Na_{0.5}Eu_{0.01}Y_{0.49}WO_4$.

Results

The positions in energy of significant excited states of Pr, Nd, Sm, Eu, Tb, Dy, and Er in the tungstates are shown in Fig. 1. The energies of the spectral lines for emission from Tb^5D_4 and for emission from the CH4 Hg arc lamp and the cut-off frequencies of the CS7-54, CS3-72, and $CuSO_4$ solution filters employed are also indicated. The diagonal line represents a somewhat arbitrary demarcation between states that have been observed to participate in dipole-quadrupole ($\theta = 8$) interactions (upper part) and those for which only dipole-dipole ($\theta = 6$) interactions have been observed (see Discussion). The manifold designations are those given by Dieke for chlorides (15).

Intensity of emission from Tb^5D_4 at 295°K under 0.365μ excitation is shown *vs.* Tb concentration in various series in Fig. 2. All of the Tb intensity data is relative to 100 for $Na_{0.5}Tb_{0.5}WO_4$. Curve 3 is for the series $Na_{0.5}Y_{0.5-x}Tb_xWO_4$ and curves 2, 4, 5, 6, 7, or 8 are for the series $Na_{0.5}RE_{0.01}Y_{0.49-x}Tb_xWO_4$ where RE equals Dy, Eu, Pr, Sm, Nd, or Er, respectively. Dy transfers excitation from $Dy^4F_{9/2}$ (20,900 cm^{-1}) to Tb^5D_4 (20,500 cm^{-1}) and has little quenching effect on Tb^5D_4 for the indicated Dy concentration. This is shown by curve 2 lying above curve 3. Eu, Pr, Sm, Nd, and Er, however, increasingly quench Tb^5D_4 in the given order. If only direct Tb to Q-ion multipolar interactions occurred, curves 4-8 would all be parallel to curve 3 as the average distance from Tb to Q-ion is not dependent on Tb concentration. In general, the strengths of the multipolar interactions responsible increase with the overlap of Tb emission and RE absorption. However, discrepancies do occur (2, 12).

At high Tb concentrations, excitation may migrate from remote Tb ions to those that are close to Q-ions and thereby enhance the probability for transfer to the latter. This effect accounts for the increased displacement of curves 4-8 from curve 3 at high Tb concentrations. Although Eu, Pr, Sm, Nd, and Er are quite different in quenching power, curves 4-8 all peak at

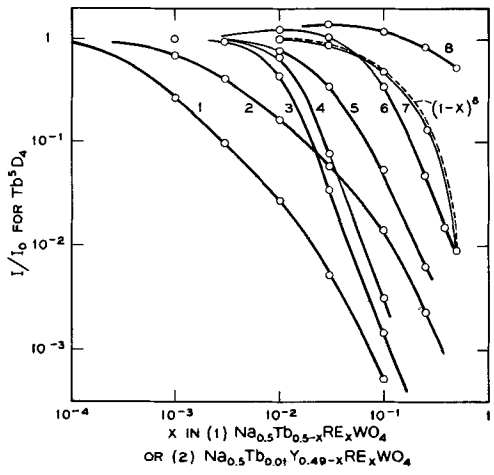

Fig. 3. Normalized emission *per* Tb (I/I_o) for emission from Tb^5D_4 *vs.* RE concentration for the series 1 $Na_{0.5}Tb_{0.5-x}RE_xWO_4$ and 2 $Na_{0.5}Tb_{0.01}Y_{0.49-x}RE_xWO_4$ where RE = Nd, Eu, or Dy. Curves 1 and 4 are for series 1 Nd at 295°K and 4.2°K, respectively. Curve 3 is for series 2 Nd at 295°K. Curves 2 and 5 are for series 1 Eu and series 2 Eu, respectively, at 295°K. Curve 7 represents both series 1 Eu and series 2 Eu at 4.2°K. The data for both of the latter series fit the relation $(1-x)^6$. Curve 6 represents both series 1 Dy and series 2 Dy at 295°K, and curve 8 represents the comparable data for Dy at 77°K (or 4.2°K).

$x \simeq 0.14$ indicating that the migration is dominated by exchange (8-13). That is, energy may move between Tb^5D_4 manifolds only when the Tb-ions are in nearest or next nearest neighbor dodecahedral sites in the tungstates and therefore the chances for such excitation migration depends directly on Tb concentration. When Eu is the Q-species, the excitation lost to Eu by Tb appears as emission from Eu^5D_0 (16). The effect on Eu emission is indicated by curve 1 of Fig. 2. Since multipolar transfer from Tb to $Eu_{0.01}$ is rather weak, the large increase in Eu emission at high Tb concentrations is almost entirely due to enhanced transfer due to migration between exchange coupled Tb ions.

I/I_o for emission *per* Tb from Tb^5D_4 under 0.365μ excitation is shown *vs.* RE concentration in Fig. 3 for the series 1 $Na_{0.5}Tb_{0.5-x}RE_xWO_4$ and 2 $Na_{0.5}Tb_{0.01}Y_{0.49-x}RE_xWO_4$ where RE = Nd, Eu, or Dy. Curves 1 and 4 are for series 1 where RE = Nd, 1 Nd, at 295°K and 4.2°K, respectively. Curve 3 is for series 2 Nd at 295°K, curves 2 and 5 are for series 1 Eu and series 2 Eu, respectively, at 295°K while curve 7 which fits the relation $(1-x)^6$, represents both series 1 Eu and series 2 Eu at 4.2°K. Curve 6 represents both series 1 Dy and series 2 Dy at 295°K, and curve 8 represents the comparable data for series 1 Dy and series 2 Dy at 77°K (or 4.2°K). The curves for RE = Nd, Eu, and Dy have been selected as representative of three different energy relations between the E- and Q-ions. For the first Q-species (Nd), there is an exact match between an emission transition of Tb and an absorption transition of Nd originating from the ground state. Therefore transfer from Tb to Nd is not dependent on temperature. The data of curve 3, for series 2 Nd, is fitted by a $\theta = 8$ relation showing that the transfer from Tb to Nd is dipole-quadrupole in character. Curve 1, for series 1 Nd at 295°K shows the additional quenching due to excitation migration between Tb ions in nn or nnn sites (2,12). This migration no longer occurs at 4.2°K as shown by the near coincidence of curves 3 and 4 of Fig. 3.

For the second Q-species (Eu), Tb emission overlaps Eu absorption at 295°K but not at 4.2°K. However, transfer can occur at the lower temperature through simultaneous interaction with the phonon spectrum. The data of curve 5 of Fig. 3, for series 2 Eu, is fitted by a $\theta = 6$ relation indicating that transfer from Tb to Eu is by dipole-dipole interactions at 295°K. Curve 2, for series 1 Eu, shows that excitation migration between Tb-ions is also prevalent at 295°K when Eu is the Q-ion species. At 4.2°K, however, the data for both series 1 Eu and series 2 Eu lie along curve 7 of Fig. 3. This curve follows the relation $(1-x)^6$, indicating that at 4.2°K transfer from Tb to Eu only occurs when these ions are in nn or nnn positions (9).

Dy, the third Q-ion, only acts as a quenching center for Tb^5D_4 when quenched itself. The receiving manifold ($Dy^4F_{9/2}$) lies $\sim$400 cm^{-1} above Tb^5D_4 (see Fig. 1). Emission from Tb^5D_4 to the ground state, the highest emission line in Fig. 1, can match an absorption transition to $Dy^4F_{9/2}$ when Dy (400 cm^{-1}) is thermally populated. This occurs at 295°K but not at 77°K. At low Dy concentrations, transfer is predominantly from $Dy^4F_{9/2}$ to Tb^5D_4, as indicated in connection with Fig. 2. However, at high Dy concentrations, where Dy is strongly self-quenched, the reverse transfer can be important. Lifetime data show that transfer from Tb^5D_4 to $Dy^4F_{9/2}$ is by dipole-dipole ($\theta = 6$) interactions (10). Curve 6, however, is altered by transfer from Dy to Tb for low Dy concentrations. The extent of this transfer is apparent from curve 8, which represents the data for series 1 Dy and series 2 Dy at 77°K where transfer from Tb to Dy is negligible. It is apparent that I/I_o is not dependent on Tb concentration when Dy is the Q-species, even at 295°K.

I/I_o for emission *per* E-ion is shown *vs.* concentration for self-quenching of $Dy^4F_{9/2}$, $Er^4S_{3/2}$, $Sm^4F_{5/2}$, $Nd^4F_{3/2}$, Pr^3P_o, and Tb^5D_3 by curves 1-6 of Fig. 4A, respectively (8-14). Similar curves for the quenching of Tb^5D_4 by multipolar interactions with Er, Sm, Pr, Nd, Eu, and Dy in the series $Na_{0.5}Tb_{0.1}Y_{0.4-x}RE_xWO_4$ are shown by curves 7-12 of Fig. 4B, respectively. Curve 12′ fits the data of curve 12 when the latter are corrected for Dy to Tb transfer (10). The data for curves 1, 2, 4, 7, 11, and 12′ are fitted by $\theta = 6$ relations indicating that the corresponding interactions are dipole-dipole in character. The data for the remaining curves are fitted by $\theta = 8$ relations, indicating that dipole-quadrupole interactions are responsible for transfer in these instances. Curve 2 deviates from a $\theta = 6$ relation toward $\theta = 8$ at high Er concentrations. This is attributable to the combined effects of radiation reabsorption and rapid internal relaxation (13).

Examples of the relation of τ_i/τ_o to I/I_o for emission per E-ion are given in Fig. 5. Curves 1 and 2 represent τ_i/τ_o and I/I_o, respectively, for emission from Tb^5D_4 in the series (*a*) $Na_{0.5}Tb_{0.1}Y_{0.4-x}Nd_xWO_4$ (for Tb^5D_4, τ_o = 565 μsec). Curves 3 and 4 represent I/I_o and τ_i/τ_o, respectively, for emission from Tb^5D_4 in the series (*b*) $Na_{0.5}Tb_{0.1}Y_{0.4-x}Eu_xWO_4$ and curves 5 and 6

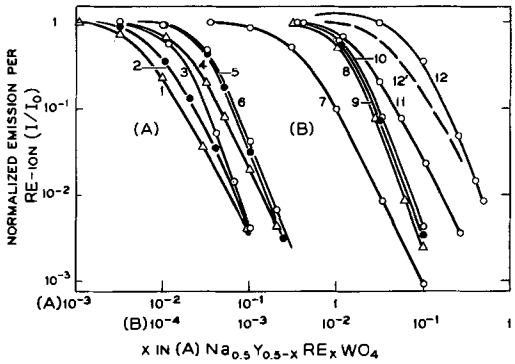

Fig. 4.(A) Normalized emission per E-ion (I/I_o) *vs.* E-ion concentration in series (A) $Na_{0.5}Y_{0.5-x}RE_xWO_4$. Emission is from $Dy^4F_{9/2}$, $Er^4S_{3/2}$, $Sm^4F_{5/2}$, $Nd^4F_{3/2}$, Pr^3Po, or Tb^5D_3 for curves 1-6, respectively. *(B)* Normalized emission *per* Tb (I/I_o) for emission from Tb^5D_4 *vs.* RE concentration for the series *(B)* $Na_{0.5}Tb_{0.1}Y_{0.4-x}RE_xWO_4$ where RE — Er, Sm, Pr, Nd, Eu, or Dy for curves 7-12, respectively.

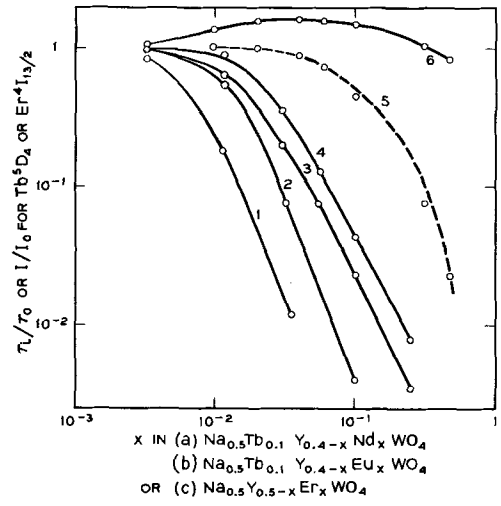

Fig. 5. Normalized initial lifetime (τ_i/τ_0) or normalized emission per E-ion (I/I_o) for emission from Tb^5D_4 or $Er^4I_{13/2}$ vs. Nd, Eu, or Er concentration. Curves 1 and 2 represent τ_i/τ_0 and I/I_o, respectively, for Tb emission from series (a). Curves 3 and 4 represent I/I_o and τ_i/τ_0 respectively for Tb emission from series (b) and curve 6 and the data following curve 5 are for τ_i/τ_0 and I/I_o respectively for Er emission from series (c). Curve 5 is the relation $(1-x)^6$.

approximate I/I_0 and τ_i/τ_o, respectively, for emission from $Er^4I_{13/2}$ in the series (c) $Na_{0.5}Y_{0.5-x}Er_xWO_4$. All data are for 295°K. Moderately high Tb concentrations were employed for series (*a*) and (*b*) to insure fast internal relaxation to Tb^5D_4 (11, 12, 17). Further, radiation reabsorption by Tb^5D_4 is minimal since less than 10% of the emission from Tb^5D_4 is to the ground state. Hence, the relations between τ_i/τ_0 and I/I_0 for these series [(*a*) and (*b*)] are relatively uncomplicated. It can be observed that τ_i/τ_0 falls outside I/I_o for series (b), which follows a $\theta = 6$ relation, and inside I/I_o for series (*a*), which follows a $\theta = 8$ relation.

All of the strong emission transitions of Er appear to be to the ground manifold. Further, the drain time from higher lying manifolds to $Er^4I_{13/2}$ is small compared to the lifetime of the latter (~4,500 μsec) (13). Hence, the prolonged lifetimes where $\tau_i/\tau_0 > 1$, indicated by curve 6 of Fig. 5, for intermediate values of Er in series (c), can be attributed to radiation reabsorption. The I/I_o data for series (c) follows the $(1-x)^6$ relation indicated by the broken line (curve 5). This indicates that quenching is associated with interactions between Er ions in nn or nnn positions. The quenching may involve nonradiative excitation migration between exchange coupled Er-ions to Q-ions present as impurities or it may be due to pairing enhancing interaction with the phonon spectrum. In either case, radiation absorbed by the paired Er-ions is not emitted and therefore beyond ~$Er_{0.1}$, the chances for absorption and re-emission of resonance radiation decreases with increasing Er concentration, resulting in a decline in τ_i/τ_0 back to ~1.0.

Discussion

The lifetime τ_a defined by relation [3] can be approximated by measuring τ_i from the initial or early slope of the decay curve for emission, as outlined in the Appendix. τ_i/τ_0 has the same dependence on C/C^* as the corresponding equilibrium intensity measurement I/I_o. However, for multipolar interactions where other things are equal τ_i/τ_0 lies at decreasing values of C/C^* relative to the comparable I/I_0 curve as θ increases (see Fig. 5). This displacement is consistent with the fact that, when quenching is strong, the fraction of the total emission yielded up to $t = \tau_e$ (or τ_i) changes from 0.28 to 0.10 to 0.045 on changing from a $\theta = 6$ to 8 to 10 mechanism. Quadrupole effects tend to shift τ_i/τ_0 to the inside of the comparable I/I_o curve while prolonged drain time to the emitting manifold or radiation reabsorption by this manifold have the opposite effect.

Multipolar interactions generally increase with the overlap of E-ion emission and Q-ion absorption. However, when the overlap is small, processes involving the simultaneous release of energy to the phonon spectrum become competitive. Single phonon processes, for energies up to that of the fundamental stretching frequency (~850 cm^{-1} in the tungstates), do not appear to have drastically reduced probabilities for transfer (12, 13). Further, these and more complex interactions can be facilitated by the mixing effects of exchange.

As shown in Fig. 1, the positions in energy of Eu^5D_1 and Eu^5D_0 and the emission lines originating from Tb^5D_4 are mismatched by ~100 cm^{-1}, with the closest emission lines lying below the Eu levels. The closest to a match for a Tb emission line that lies higher in energy than a Eu level (Eu^5D_0) is out by ~900 cm^{-1}. At 295°K, however, Eu^7F_1 (~500 cm^{-1}) is populated from Eu^7F_0, permitting a match of the Tb emission line at ~16,800 cm^{-1} to the Eu absorption transition Eu^5D_0 (17,300 cm^{-1}) ← Eu^7F_1 (~500 cm^{-1}). As a result, multipolar transfer takes place at this temperature (curve 5 of Fig. 3). However, at 4.2°K, Eu^7F_1 is not populated, and transfer requires the release of ~900 cm^{-1} to the phonon spectrum. I/I_o follows the relation $(1-x)^6$ under these circumstances, indicating that the mixing effects of exchange facilitate transfer from Tb to Eu (curve 7 of Fig. 3).

Excitation migration between Tb-ions in nn or nnn positions at 295°K is evident for series 1 Nd and series 1 Eu (curves 1 and 2 of Fig. 3, respectively) but not for series 1 Dy (curve 6 of Fig. 3). Nd and Eu can act as quenching centers as single Q-ions while Dy only does so when it, itself, is quenched. However, as Dy is self-quenched at intermediate concentrations (see curve 1 of Fig. 4) and, therefore, dissipates excitation received from Tb^5D_4 by multipolar transfer, it is evident that excitation migration does not occur, even at 295°K, unless a sink that acts directly is present. In contrast to the essentially random movement of excitation by emission and reabsorption, this implies that migration by nonradiative interactions can be directed toward the Q-ion promoting the transfer.

It is apparent from Fig. 4 that both $\theta = 6$ and $\theta = 8$ relations are observed for interactions between RE-ions in the scheelite structure. The manifolds Pr^3P_0, $Sm^4F_{5/2}$, Tb^5D_3 and Tb^5D_4 have been found to participate in dipole-quadrupole interactions. These lie above the diagonal in Fig. 1. The manifolds $Nd^4F_{3/2}$, Eu^5D_0, $Dy^4F_{9/2}$, and $Er^4S_{3/2}$ lie below the diagonal. So far the latter have only been found to participate in dipole-dipole transfers. Such interactions may be typical for smaller RE-ions and for the lower lying levels of the larger RE-ions. Dipole-quadrupole interactions seems more likely for the higher lying levels of the larger RE-ions. There seems to be an increased probability for quadrupole interactions when the states involved are strongly perturbed. Perturbation increases with the tightness of the fit of the rare earth into the site it occupies and with the proximity of the manifold involved to the continuum.

APPENDIX

Analysis of Lifetime Data

The intrinsic lifetime for fluorescence (τ_0) of an excited E-ion state is equal to the time (τ_e) required for the transient intensity of emission (Φ) to decay to $1/e$ (or 0.368) of its initial value when there is no interaction between E-ions or with Q-ions by radiative or nonradiative means. When conditions are ideal, Ln Φ is linear with time (t). However, if multipolar transfer occurs τ_e will be less than τ_0 and, if emission, corresponding to transitions to the ground manifold of

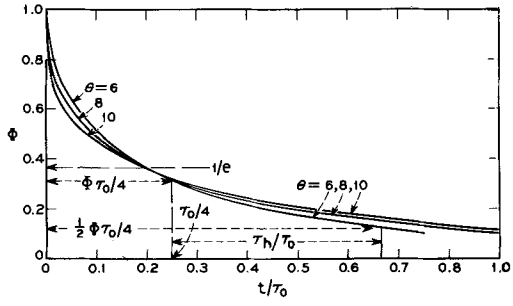

Fig. 6. Transient intensity (Φ) vs. normalized time (t/τ_o) for relation [5] when $C = C^*$ and θ is the value indicated. Markings relevant to determining τ_h/τ_o are also present.

the E-ion, is reabsorbed τ_e will tend to be greater than τ_o.

The probability for de-excitation of the E-species (P_3) is equal to the sum of the probability for emission (P_1) and the probability for nonradiative transfer (P_2)

$$P_3 = P_1 + P_2 \qquad [4]$$

P_1 is inversely related to τ_o (or $P_1 \propto 1/\tau_o$); $P_2 \propto (C/C^*)^{\theta/3}$ as indicated previously; and P_3 is inversely related to τ_a, the representative lifetime when both radiative and nonradiative de-excitation occurs. Substituting for P_1, P_2, and P_3 in relation [4] and rearranging, one obtains relation [3] which has the same form as that for intensity, relation [2]. θ and β/C^* can be determined from relation [2]. θ can also be determined from relation [3] provided one measures the proper lifetime, *i.e.*, τ_a.

θ and an independent value for C^* can be obtained by fitting accurately measured decay curves to the theoretical expression for decay given by Inokuti and Hirayama (6).

$$\Phi(t) = \exp\,[-t/\tau_o - \Gamma(1 - 3/\theta)\,(C/C^*)\,(t/\tau_o)^{3/\theta}] \qquad [5]$$

However, for most materials such a procedure would require greater measurement accuracy than can generally be relied on. Φ for relation [5] is plotted *vs.* t/τ_o in Fig. 6 for $C = C^*$ and $\theta = 6$, 8, or 10. The value of $\Gamma(1 - 3/\theta)$ is 1.77, 1.43, and 1.30, respectively, for these curves. The markings relating to $\tau_o/4$ and τ_h are discussed below. It can be seen that relatively small errors in measuring Φ can seriously affect one's ability to determine the correct value of θ. It is easier to determine θ from the concentration dependence of intensity by relation [2] or from the concentration dependence of lifetime by relations 3 or 5.

The dependence of τ_e/τ_o on C/C^* for $\theta = 6$, 8, or 10 is shown in Fig. 7 by set (A) curves 1, 2, and 3, respectively. The comparable relations for τ_a/τ_o (or I/I_o are shown by set (B), curves 4, 5, and 6, respectively. Curves 1, 2, and 3 were obtained from relation [5] by setting $\mathrm{Ln}\Phi = -1$.

$$\mathrm{Ln}\Phi = -1 = -t/\tau_o - \Gamma(1 - 3/\theta)\,(C/C^*)\,(t/\tau_o)^{3/\theta} \qquad [6]$$

while curves 4, 5, and 6 were obtained from relation

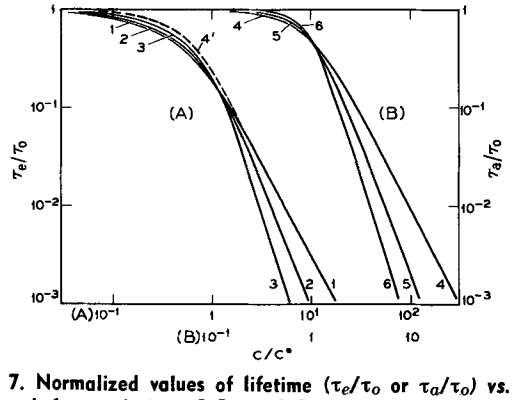

Fig. 7. Normalized values of lifetime (τ_e/τ_o or τ_a/τ_o) vs. C/C^* calculated from relations [6] or [3], respectively. Curves 1, 2, and 3 are for τ_e/τ_o for $\theta = 6$, 8, or 10, respectively, and curves 4, 5, and 6 are for τ_a/τ_o for $\theta = 6$, 8, or 10, respectively, when $\beta' = 1.0$. Curve 4' is obtained from relation (7). Normalized intensity I/I_o follows the τ_a/τ_o relation.

[3] by setting $\beta' = 1$. Curve 4' is curve 4 brought into coincidence with curve 1 (for $C > C^*$) by assigning $\beta' = 3.2$

$$\tau_a/\tau_o = [1 + 3.2(C/C^*)^2]^{-1} \qquad [7]$$

Curve 1, for τ_e/τ_o when $\theta = 6$, deviates up to 30% from curve 4', τ_a/τ_o for $\theta = 6$, over the first order of magnitude of quenching. However, for $C > C^*$, the slope of the curve for either τ_a/τ_o or τ_e/τ_o, from relation [3] or relation [5], respectively, is about equal to θ. For the first order of magnitude of quenching τ_e/τ_o can be corrected to τ_a/τ_o by comparing the above curves. For stronger quenching, where discrimination between θ values is much clearer, τ_e can be employed as a measure of τ_a. However, τ_e is difficult to determine directly in this region. Therefore, if intensity measurements are impractical, other methods for obtaining lifetime data at high Q-ion concentrations should be considered.

It can be seen from relation [6] that when $t < \tau_o$ and $C > C^*$ the second term of the exponent is dominant and the first can be ignored. Under these circumstances, if θ is fixed the decay curves for various C/C^* ratios can be reduced to a single representative curve by multiplying the values along the t/τ_o coordinate (see Fig. 6) by $(C/C^*)^{\theta/3}$. Such relations are shown by curves 4, 5, and 6 of Fig. 8.

Figure 8 has been constructed by plotting Φ from relation [5], on a logarithmic scale *vs.* $n(t/\tau_o)$, on a linear scale, where n is the scaling factor required to position $\Phi = 0.1$ at $n(t/\tau_o) = 1.0$. The parameter $n(t/\tau_o)$ is only used to graph the theoretical decay curves. In practice, the abscissa is t alone on a scale that suitably displays curve symmetry. Curve 1 is the exponential relation for $C/C^* = 0$. Curve 2 is for $C = 0.28C^*$ and $\theta = 6$, curve 3 is for $C = C^*$, and $\theta = 6$ and curves 4, 5, and 6 are representative for Q-ion concentrations where $C > 2C^*$ when $\theta = 6$, 8, or 10, respectively.

Lifetime calculated from the tangent (1, 2'-5' or 6') to the respective curve as drawn is equal in value to τ_a. This value also equals τ_e for 1, 4', 5', and 6'. It is 25% larger than τ_e for 2' and 20% larger than τ_e for 3'. In practice, for the first factor of 5 of quenching, τ_a can be estimated from τ_e by adding the correction indicated by superimposing the calculated relations between τ_e/τ_o and τ_a/τ_o. The corrections required are essentially independent of θ as τ_a/τ_o varies in the same manner as τ_e/τ_o with θ (see Fig. 7). However, if there is some question as to the value of Φ at $t = 0$, the decay curve can be plotted as in Fig. 8 and τ_a inferred from the proper tangent. For weak interactions (curves 1 and 2) the tangent required to obtain τ_a averages the points of the curve lying between 10 and

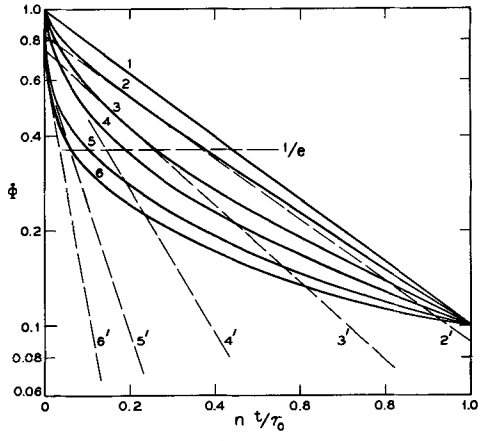

Fig. 8. Transient intensity (Φ) from relation [5] vs. adjusted time, $n(t/\tau_o)$, where n is the scaling factor required to position $\Phi = 0.1$ at $n(t/\tau_o) = 1.0$. Curve 1 is for $C/C^* = 0$; curve 2 is for $C = 0.28C^*$, $\theta = 6$; curve 3 is for $C = C^*$, $\theta = 6$; and curves 4, 5, and 6 are characteristic for $C > 2C^*$ for $\theta = 6$, 8, or 10, respectively. The tangents 2'-6' are drawn to indicate the correct value of τ_a. As an aid to reading the theoretical curves, it is noted that for the intercept of Φ with, i.e., $\tau_e/\tau_o = (1/n)[n(t/\tau_o)$ for the intercept] and for the tangents $\tau_a/\tau_o = [1/(2.3n)]n(t/\tau_o)_{10}$, where $n(t/\tau_o)_{10}$ is the time period elapsed for a tenfold decrease for the coordinate of the tangent along Φ.

30% of the way along the time coordinate to $\Phi = 0.1$. When quenching is by a factor greater than 5 (*i.e.*, $\tau_e/\tau_o < 0.2$ or $C > C^*$), Φ at $t = 0$ is generally so obscured by the excitation flash, or in some instances by the rise in Φ on excitation being prolonged by a finite drain time from higher lying states, that it is difficult to estimate its value accurately. Under these circumstances, the tangent to the initial measurable slope of the decay curve provides a good estimate of τ_e or τ_a as long as the lifetime for emission exceeds the decay time of the flash lamp. The symmetry of the appropriate curve of Fig. 8 should be kept in mind when choosing the tangent or otherwise estimating lifetime. The tangents shown in Fig. 8 indicate the slopes to measure to obtain τ_a in each case. The lifetime derived in this way from the early or initial slope of the decay curve, or by correcting τ_e, is termed τ_i and is the estimate of τ_a obtained by observing the foregoing procedures.

Other Measures of τ

As shown in Fig. 7 there is less than 5% difference in τ_e/τ_o for $\theta = 8$ and either the neighboring curve for $\theta = 6$ or for $\theta = 10$ over the first order of magnitude of quenching. Obviously it is difficult to characterize transfer interactions from such data alone. Further, even if τ_e or a comparable defined lifetime is accurately measured the results would be deceiving unless they were properly analyzed. For example τ_e values employed in place of τ_a values in relation [3] may indicate the wrong value of θ. As can be seen from Fig. 7, τ_e/τ_o for $\theta = 10$, indeed, lies closer to τ_a/τ_o for $\theta = 6$ than does τ_e/τ_o for $\theta = 6$ itself over the first order of magnitude of quenching.

Nakazawa and Shionoya employ a lifetime (τ_h) which is defined as the time (t) required for Φ to fall from its value at $\tau_o/4$ to one-half of that value, as illustrated for the $\theta = 6$ curve of Fig. 6 (18). This definition effectively limits measurement to the first order of magnitude of quenching. τ_h/τ_o bears a relation to I/I_o that is susceptible to analysis. However, the shape of the curve follows a $\theta = 3$ relation regardless of the actual mechanism of quenching. These results are quite similar to those obtained by taking lifetime from the tangent to the decay curve (Ln Φ *vs.* t) at a fixed value of t. As can be seen from relation [5], θ appears in the exponent of t/τ_o not C/C^*; hence, the curves obtained by plotting such data *vs.* C/C^* only change in displacement along the latter coordinate as θ changes.

Unfortunately, most of the literature concerning lifetime measurements connected with transfer interactions is not clear as to the actual procedure for analyzing data. It is therefore not easy to draw significant conclusions concerning the mechanism of energy transfer involved from such lifetime data alone.

Photovoltaic Behavior of the TCNE-THF Solution Charge-Transfer Complex

P. J. Reucroft, P. L. Kronick, and E. E. Hillman

Chemistry Department, The Franklin Institute Research Laboratories, Philadelphia, Pennsylvania

ABSTRACT

Reversible photoinduced electron transfer in solutions of tetracyanoethylene (TCNE) in tetrahydrofuran (THF) has been shown to lead to a voltaic effect. The photovoltage spectral response peaks at the absorption edge of the charge-transfer band, demonstrating that light capable of promoting charge-transfer must penetrate to the vicinity of the electrode. Maximum power output recorded is in the region of 10^{-10} watts for monochromatic light input intensity of 10^{-3} w/cm^2. A sublinear dependence of photovoltage on light intensity suggests a mechanism of photovoltage production whereby photogenerated ionic species distribute to give concentration gradients, or alternatively a process involving the preferential adsorption of the negative ion species.

The production of photovoltages in organic systems has been widely reported. Thin films of organic solid sandwiched between semitransparent layers of metal have been most commonly investigated (1g). Organic solids studied in this way include aromatic hydrocarbons (1a), organic dyes and pigments (1b, c) and organometallics (1d). Photovoltaic effects in organic crystals in contact with electrolyte solutions as electrodes have also been reported (1e). Photovoltages obtained in layers of electron-donor organic solids in contact with electron-acceptor organic solids have been attributed to photoinduced donor-acceptor interaction (1f). Photovoltages in these systems usually fall in the range 10^{-6} to 1v and power outputs in the range 10^{-8} to 10^{-17}w.

In order to explore more fully the role of donor-acceptor interaction in photovoltage production in organic systems and evaluate the potential of organic systems for significant power output, we have investigated the photovoltaic behavior of molecular complexes in solution. The present work deals with the photovoltaic behavior of solutions of tetracyanoethylene (TCNE) in tetrahydrofuran (THF). This system was chosen for the investigation as previous studies on photoinduced electron spin resonance (2a, b) and photoconduction (2b) have provided some understanding of the fundamental processes which take place on illumination. In addition, complicating photochemical reactions are minimal in this system (2c), the main effect of illumination being to promote a reversible photoinduced electron transfer from the electron-donor molecule (THF) to the electron-acceptor molecule (TCNE). Reversible photovoltaic effects were thus expected and were, in fact, found.

Experimental

Photovoltaic measurements were carried out by illuminating platinum electrodes immersed in the TCNE-THF solutions. A typical cell, used in initial studies, is shown in Fig. 1. The electrodes were constructed from platinum sheet, 0.5 mm in thickness, welded to 2 mm diameter platinum rod. The electrode area and spacing was 2 cm^2 and 1 cm, respectively. Solution was introduced into the cell and was in contact with platinum and glass only. After successive freeze-thaw cycles, evacuating after each freezing procedure, the cell was sealed off under a vacuum of 5 x 10^{-3} mm Hg. In later experiments, an all-glass cell was used to eliminate solvent attack on the O-ring.

THF, supplied by Matheson, Coleman, and Bell, was purified by distillation from a sodium dispersion under 1 atm of nitrogen. Eastman Kodak White Label TCNE was vacuum sublimed. All measurements were made on freshly prepared solutions.

The experimental arrangement for measuring photovoltage is shown in Fig. 2. A Keithley 610 electrometer, or a Cary vibrating-reed electrometer operating in the 31V mode, was used to measure the photoinduced voltages. Open-circuit photovoltages were usually measured. The power output of the photocell was determined by measuring the photovoltage across a series of shunt resistors, varied from 10^{11} to 10^2 ohms. An Osram 900-W or 150-W xenon light source was used for illumination. Monochromatic light could be obtained from these sources in conjunction with Bausch and Lomb monochromator gratings, Nos. 33-86-07 and 33-86-02. Illumination conditions were arranged so that one electrode received the full

illumination. Illumination intensities were measured by means of a bismuth-silver thermopile supplied by Eppley Laboratory Inc. Solution spectra were measured with a Cary 14R recording spectrophotometer.

Results

The photovoltage response is shown in Fig. 3 at three illuminating wavelengths for a 10^{-1}M solution of TCNE in THF. The fast rise observed at 450 and 500 mμ reflects the response time of the external circuit. A slower rise was observed at 400 mμ, however, which appears to be a property of the solution system. The electrode attached to the electrometer input (the illuminated electrode) always acquired a negative voltage. Reproducibility and reversibility of the photovoltage is illustrated in Fig. 4.

Similar results were obtained with 10^{-3} and 7 x 10^{-1}M solutions of TCNE in THF. The 10^{-3}M solution responded more slowly and required a dark period for regeneration.

The spectral dependence of the photovoltage for three solution concentrations is shown in Fig. 5. The photovoltage magnitude is corrected to a uniform incident light intensity throughout the spectral region. The absorption spectra of the various solutions is also shown in Fig. 5 illustrating that the photovoltage increases sharply with decreasing wavelength at the absorption edge for each solution. The absorption of TCNE-THF solutions in this spectral region is due to the TCNE-THF charge-transfer band (2b, c, 3). The maxima in the photovoltage curve for the more concentrated solutions demonstrate that light capable of producing charge-transfer must be able to penetrate to the vicinity of the electrode in order to promote photovoltage production. This is only possible at the absorption edge, in the case of concentrated solutions, since wavelengths at the absorption peak are completely absorbed by the solution and do not penetrate to the electrode region. Thus, the photovoltage spectrum decreases again at the onset of strong absorption, the peak photovoltage shifting to longer wavelengths as the concentration increases. The results for the 10^{-1} and 7 x 10^{-1}M solutions indicated that the peak voltage increases as the TCNE concentration decreases. The peak photovoltage in the case of the 10^{-3}M solution was not determined in view of experimental difficulties due to the reduced light output of the source below 380 mμ. A trend toward a peak voltage at least as high as the peak observed for the 10^{-1}M solution is suggested, however, from the data at wavelengths longer than 380 mμ.

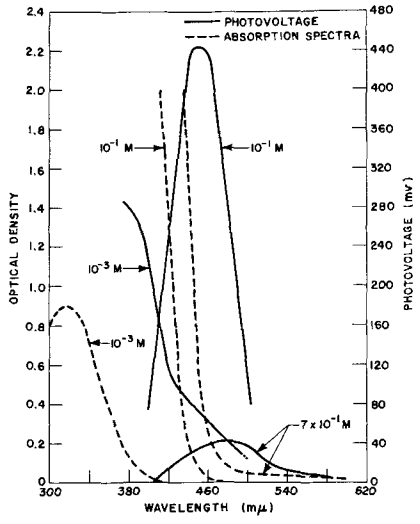

Fig. 5. Photovoltage spectral response and absorption spectra of TCNE-THF solutions (photovoltage corrected to incident light intensity 3.4 mw/cm^2).

Maximum power output was obtained from the 10^{-3}M solution at 1.6 x 10^{-10}w, illuminating with monochromatic light. Maximum power output from the 7 x 10^{-1}M solution with polychromatic light intensity 0.13w/cm^2 was 4 x 10^{-11}w. The photovoltage-current characteristic for a 10^{-3}M solution is shown in Fig. 6.

A sublinear dependence of photovoltage on light intensity was generally observed, *i.e.*, $V = K(I)^n$ where

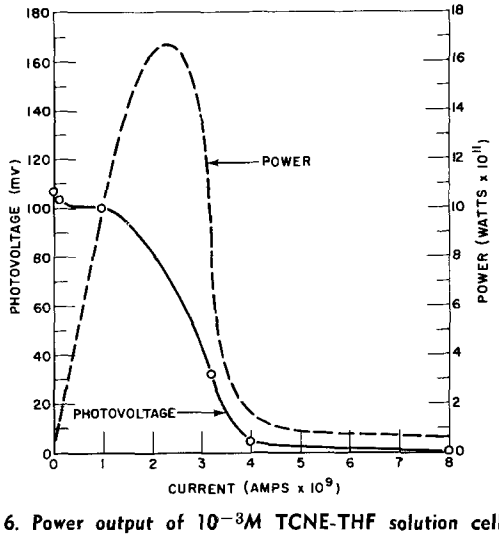

Fig. 6. Power output of 10^{-3}M TCNE-THF solution cell (illuminating wavelength 450 mμ; incident light intensity 1.7 mw/cm^2).

Table I. Effect of illumination intensity on photovoltage of 10^{-3}M TCNE-THF solution

Wavelength, mμ	Intensity, μw/cm²	Photovoltage, mv	Intensity, μw/cm²	Photovoltage, mv	Intensity ratio	Photovoltage ratio
375	—	(−) 40	202	(−) 70	—	1.7
400	54	(−) 70	832	(−) 115	15	1.6
425	112	(−) 54	1370	(−) 68	12	1.3
450	141	(−) 15	1662	(−) 58	12	3.8
475	204	(−) 10	2485	(−) 40	12	4.0
500	183	(−) 2	2080	(−) 18.5	11	9.2

$n < 1$. This is illustrated by the photovoltage data in Table I at two incident light intensities and the plot of photovoltage against incident light intensity shown in Fig. 7. In this plot $n = 0.62$.

Discussion

ESR and photoconductiviy studies have shown that the TCNE negative-ion radical and, presumably, the THF positive-ion radical are formed on illuminating TCNE-THF solutions in the TCNE-THF charge transfer band. The TCNE negative-ion radical was identified from the hyperfine splitting of the ESR signal. The positive-ion radical was not detected, possibly because hole migration from $THF^{+}\cdot$ to THF neutral species (present in large excess) leads to broadening of the ESR signal (4). Chemical reaction of $THF^{+}\cdot$ is unlikely, since no permanent changes are detected.

The present data suggest two possible explanations for the production of photovoltages in charge-transfer solutions. In one view the photogenerated ions distribute to give concentration gradients in the vicinity of a platinum electrode yielding a net emf which can be sensed by the electrode. Evidence for this was provided by measurements of photovoltages with the charge-transfer solution stirred and unstirred. An unstirred 10^{-3}M solution of TCNE in THF gave a photovoltage of 126 mv at 425 mμ. On commencement of stirring, with a Teflon-coated magnetic stirring bar incorporated in the cell, the voltage dropped immediately to 96 mμ and dropped almost to zero on increasing the stirring speed. Assuming that the photovoltage (V) follows the Nernst relation

$$V = A \log C + B \qquad [1]$$

where C is the concentration of ionic species and A and B are constants, then taking $C = K'(I)^{1/2}$ (2b, c), where I is the intensity of incident illumination, we have

$$V = \frac{A}{2} \log I + B' \qquad [2]$$

which is a sublinear dependence of photovoltage on illumination intensity. The observation of a sublinear dependence of photovoltage on illumination intensity is thus consistent with this picture, although the intensity data shown in Fig. 7 does not give a good fit to Eq. [2].

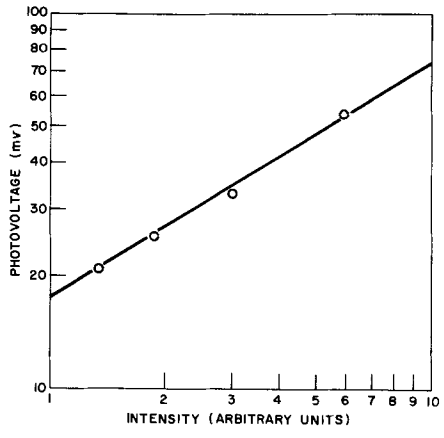

Fig. 7. Photovoltage-illumination intensity relationship for 10^{-1} TCNE-THF solution (illuminating wavelength 500 mμ).

Alternatively the photovoltage may arise from the preferential adsorption of one ionic species on the platinum electrode. This would explain the negative potential if it is assumed that the TCNE negative radical-ion is preferentially adsorbed. When light was confined to the solution between the electrodes, erratic results were obtained. This is further evidence that the interaction between the illumination and the charge-transfer species must take place in the vicinity of the electrode for photovoltage production.

Assuming that the photovoltage is directly proportional to the number of ions adsorbed and that Henry's law obtains, *i.e.*, number of ions adsorbed is directly proportional to the ionic concentration in solution, we have

$$V = K(I)^{1/2} \qquad [3]$$

An approximate fit to such a relationship is shown in Fig. 7. This model predicts a saturation effect with increased intensity as a monolayer of adsorbed ions is approached (Langmuir isotherm). Some evidence for this was found at the highest intensities with polychromatic light. The weight of evidence can thus be considered to favor the second explanation.

Further studies on the interaction of ion radical species with the electrode surface and measurements of photovoltages with reference electrodes are needed to settle some of these points, however.

Maximum power output of the TCNE-THF solution cell was on the order of 10^{-10}w, obtained with the 10^{-3}M solution. This value is on the upper limit of the range of values reported for organic solid photovoltaic systems (1) and suggests that organic solution systems may have more potential than organic solid systems for significant power output. Attempts were made to improve the power output by supplying ionic additives to the solution which would decrease the internal cell resistance without affecting the photovoltage magnitude or reversibility. This approach was largely unsuccessful.

Summary and Conclusions

Reversible photoinduced electron transfer in solutions of TCNE in THF leads to the production of voltages which can be sensed by platinum electrodes. The mechanism of photovoltage production is not well understood, but probably involves distribution of photogenerated ionic species leading to a voltaic cell effect, or an effect related to the adsorption of ionic species on the electrode.

Maximum power output from these systems is in the region of 10^{-10}w for monochromatic illumination intensities of 10^{-3} w/cm². This is an extremely low conversion efficiency compared to the values reported for the best inorganic photovoltaic devices (5). Power output is on the high range of values reported for organic systems, however. Solution photovoltaic cells of this type may thus have greater potential in the development of organic photovoltaic devices than the solid systems investigated previously.

Bismuth in Yttrium Vanadate and Yttrium Europium Vanadate Phosphors

R. K. Datta

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

Activation of rare earth vanadate by ions other than rare earths is successfully attempted in the present investigation. Bi^{+3} can be incorporated in the YVO_4 and $GdVO_4$ lattice by solid-state reaction. The phosphor $R_{1-x}Bi_xVO_4$ (R = Y,Gd), excited by cathode rays or uv radiation, shows luminescence with a continuous emission band extending from 4000 to 7000Å and peaking at 5670Å. Under 2537Å excitation, the energy is absorbed essentially by Y-O components of the matrix and transferred to the emission centers (Bi^{+3}). Under 3650Å excitation, energy absorbed by charge-transfer processes involving (V-O) and (Bi-O) components of the phosphor is transferred to the emission centers (Bi^{+3}). The transmission of energy from the absorption to the emission centers under 2537 and 3650Å excitations involved a radiationless process. The phosphor YVO_4:Bi can be modified by incorporating Eu^{+3} in the lattice. YVO_4:Eu:Bi, when excited by short- or long-wavelength uv radiation, shows emission spectra with sharp Eu^{+3} emission peaks. Under cathode-ray or 3650Å excitation, the Bi^{+3} emission is gradually quenched when Eu^{+3} is incorporated in the YVO_4:Bi lattice with a constant level of Bi^{+3} concentration; on the other hand, under 3650Å excitation, the Eu^{+3} emission is enhanced when Bi^{+3} is incorporated in the YVO_4:Eu lattice with a constant level of Eu^{+3} concentration. This indicates a radiationless transfer of energy from Bi^{+3} to Eu^{+3} under 3650Å radiation.

In recent years activation of yttrium vanadate (YVO_4) by various rare earth ions has become of considerable scientific (1-5) and technological (6-7) interest. The phosphor YVO_4:R (R = rare earth), when excited by cathode rays, 2537 or 3650Å radiation, shows a typical, narrow-band spectrum of the corresponding rare earth fluorescence. Datta (8) studied the mechanism of absorption and photoluminescence and postulated that YVO_4:Eu is a host-sensitized phosphor. The excitation of the phosphor by uv radiation is due to absorption by two separate processes in the matrix (YVO_4). The energy absorbed by the matrix is transferred by a resonance process to the activator (Eu^{+3}) which causes excitation of Eu^{+3} ions among levels of the $4f^6$ configuration and thence the final emission from them. O'Connor (5) investigated the laser properties of YVO:Nd^{+3} and suggested transfer of energy from the lattice (YVO_4) to Nd^{+3}. Although these investigations indicate that YVO_4 is a promising matrix which can be activated by various types of activator ions, published reports list phosphors where YVO_4 is activated by rare earth ions only. This is probably due to recent interest in color-television phosphor and solid-state laser studies. YVO_4:R shows fluorescence of rare earth ions where transitions among the $4f^6$-electron energy levels result in line emission because the shielding effects of outer electrons minimize the perturbing influence of the crystal field. However, possibilities of activating YVO_4 with activator ions involving s-, p-, or d-electrons, where considerable perturbation occurs resulting in broad emission bands, cannot be ruled out.

In the present investigation, Bi^{+3} among other trivalent activators (other than the rare earth ions) was substituted for Y^{+3} in the YVO_4 lattice in various concentrations. It has been found that YVO_4, $GdVO_4$, and their various solid solutions, when activated with Bi^{+3}, show a broad emission band under cathode-ray, short- and long-wavelength uv excitations. It has been observed that the function of Bi^{+3} in the phosphor is manifold. It acts as absorption and emission centers in the phosphor. In addition, when coactivated with Eu^{+3} in the YVO_4 or $GdVO_4$ matrix, Bi^{+3} acts as a sensitizer for Eu^{+3} emission.

This report (*i*) characterizes the phosphors YVO_4:Bi $GdVO_4$:Bi and YVO_4:Eu:Bi; (*ii*) qualitatively describes the general function of Bi^{+3} ions in terms of absorption, emission, and excitation of the phosphors under uv radiation with special emphasis on YVO_4:Bi and YVO_4:Eu:Bi.

Experimental Procedure

Sample preparation and composition.—The raw materials used in this investigation consisted of luminescent grade (99.99-99.999% pure) oxides, such as yttrium oxide, Y_2O_3, gadolinium oxide, Gd_2O_3, europium oxide, Eu_2O_3, bismuth oxide, Bi_2O_3, and vanadium pentoxide, V_2O_5. In order to obtain the optimum

brightness of luminescence and high reflectance in the visible region, the vanadate should preferably be of stoichiometric composition. The activator(s) was incorporated with Y_2O_3 (Gd_2O_3) by coprecipitation as the oxalate, which was ignited at about 830°C to form the oxide. This insured uniform distribution of the activators in the phosphor. This oxide and V_2O_5 were mixed essentially in stoichiometric proportion (1:1 mole ratio) and fired at about 1000°C for 1½ hr. Additional 1-2 m/o (mole per cent) of V_2O_5 in the mixture insures compensation of the loss of V_2O_5 due to volatilization during firing. After cooling, the mixture was ground and washed in an ammonia solution to remove any excess V_2O_5. The washed and dried phosphor was reheated at ~1100°C for 1 hr. The firings of the phosphors were done in silica crucibles, and the homogeneity of the final products checked by x-ray diffraction analysis. CuK_α reduction from a G.E. diffractometer with a nickel filter was used to investigate all compounds. For precise determination of the change of d-spacing with change in composition of the solid solution series of the system YVO_4-$BiVO_4$, diffraction patterns were run at high angle ($2\theta \sim 65°$) region at slow speed (¼ deg/min/in.). Reproducibility of measurement was within ±0.0125°. Composition of the finished phosphors were periodically analyzed by wet chemical method in order to determine the loss of bismuth during firing. The loss ranged from 2 to 6% of bismuth added in the starting compositions; the amount of bismuth in the phosphors described throughout this paper is based on the formulated compositions.

Spectroscopic measurements.—Diffuse reflectance spectra of the samples within the range 2500-7000Å were obtained by using CaF_2 [1] as standard in a Cary Recording Spectrophotometer, Model No. 14. The emission spectra and the intensity of emission (peak height) measurements were obtained with a direct recording spectroradiometer (10) with a grating monochromator with nearly constant dispersion. The details involved are described elsewhere (8). The excitation spectra were measured using sodium salicylate as standard.

Cathodoluminescence spectra were obtained using a demountable cathode-ray tube operating at a 20 kv anode potential at 17.5 μa beam current over a standard scan TV raster of 35 cm^2 area. Brightness and color points of emission under these conditions were measured using an eye-corrected Weston foot-Lambert meter and G.E. colorimeter (JB 1E), respectively.

Compositions of the phosphors studied.—Since the absorption and emission spectra of phosphors may not always be independent of the relative amounts of the activator and coactivator, phosphors with wide range of concentration of Bi^{+3} and rare earth ions were prepared. The compositions of the phosphors can be expressed by the general formula

$$Y_{1-(x+y)}Bi_xEu_yVO_4$$

x and y can vary from 0.000025 to 0.1 and 0 to 0.1, respectively.

The subsequent discussion on the properties of phosphors is generalized and does not pertain to one specific phosphor composition. The exact compositions of the phosphors are described in the text whenever such descriptions are necessary and meaningful. However, reflectance, emission, and excitation spectra are given along with the exact composition of the corresponding phosphor.

Results and Discussion

Phase equilibrium relationship.—Subsolidus studies showed at least 7 m/o of $BiVO_4$ can be dissolved in the YVO_4 lattice within the temperature range (830°-1100°C) of sample preparation. This is well within the range of activator concentration used in the present investigation.

Reflectance spectra.—(YVO_4:Eu:Bi).—Figures 1 and 2 show the effects of Bi^{+3} incorporation on the diffuse reflectance spectrum of the phosphor YVO_4:Eu. Except for the sharp Eu^{+3} absorption lines in the visible region, the diffuse reflectance spectra of YVO_4 and YVO_4:Eu are essentially alike. Figure 1 shows the reflectance spectra of samples having a constant concentration (5 a/o [atom per cent]) of Eu^{+3} but different amounts of Bi^{+3}, whereas Fig. 2 shows the reflectance spectra of samples having a fixed amount of Bi^{+3} (2 a/o) but different levels of Eu^{+3} concentration. These spectra show that the absorption of the phosphor YVO_4:Eu:Bi in the uv region is essentially independent of Eu^{+3} concentration. However, incorporation of Bi^{+3} enhances the absorption at long-wavelength uv radiation. On the basis of the spectra shown in Fig. 1, 2, and 3, it may be suggested that the mechanisms of absorption in the uv region by the phosphors YVO_4:Bi (discussed below) and YVO_4:Eu:Bi are essentially similar.

(YVO_4:Bi).—The diffuse reflectance spectra of some of the YVO_4:Bi samples studied are shown in Fig. 3. YVO_4 shows two absorption bands, namely, at 2500

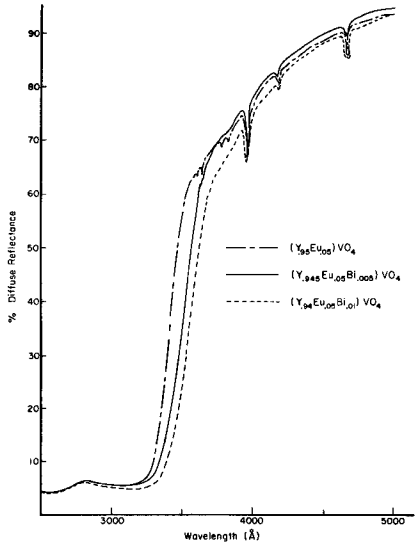

Fig. 1. Diffuse reflectance spectra of YVO_4:Eu:Bi samples (constant Eu content).

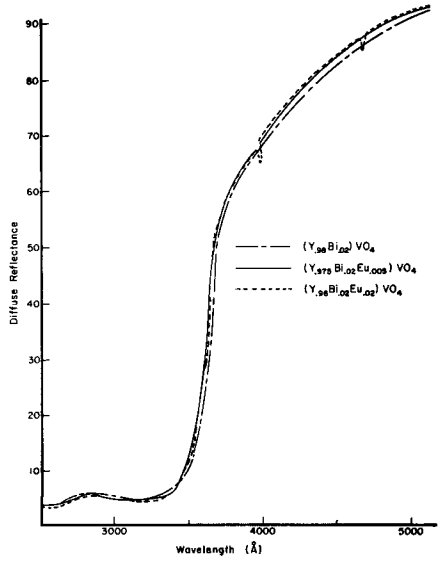

Fig. 2. Diffuse reflectance spectra of YVO_4:Eu:Bi samples (constant Bi content).

[1] In addition to higher reflectance in the region 2500-4000A, CaF_2 shows better chemical stability in room conditions than the usual reflectance standards, such as MgO, $MgCO_3$, which partly react with atmospheric moisture and lower their reflectance in the uv region even further (9).

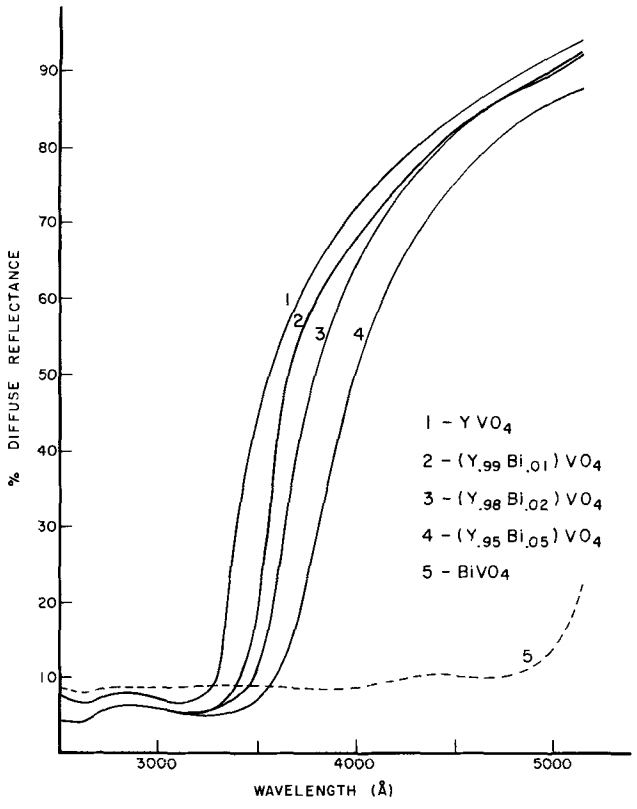

Fig. 3. Diffuse reflectance spectra of YVO_4:Bi samples

and 3200Å. These are attributed to charge transfer processes involving Y-O and V-O components of the matrix, respectively (8, 16). Addition of Bi^{+3} in YVO_4 shifts the absorption edge toward longer wavelength, whereas the absorption band at 2500Å region remains essentially unchanged. Pure YVO_4 shows an absorption edge at about 3200Å with about 60% absorption at 3400Å. Addition of 1 and 2 a/o of Bi^{+3} shifts the edge to 3300 and 3450Å and increases the absorption at 3400Å to about 85 and 90%, respectively (Fig. 3). From a study of the reflectance spectra of BiF_3 and Bi_2O_3, it has been shown (11) that the absorption of long-wavelength uv radiation due to incorporation of Bi^{+3} in an oxide matrix is mainly caused by charge-transfer states involving bismuth and oxygen. The shift in the absorption edge of YVO_4 to longer wavelength due to Bi^{+3} addition, as observed in the present investigation, may be ascribed to the absorption caused by charge-transfer states involving Bi^{+3} and the neighboring eight oxygen atoms of $(YBi)VO_4$ (12).

It can be summarized that YVO_4:Bi and YVO_4:Eu:Bi show strong absorption of short- and long-wavelength uv radiations. The absorption of short-wavelength uv radiation is due to a charge-transfer process involving the Y-O components (8), whereas the charge-transfer process involving Bi-O and V-O component (8) of the phosphor are responsible for absorption in the 3000-3400Å region. In addition, increase in Bi^{+3} content of the sample causes increased absorption at wavelengths about 3400Å and higher. For the sake of brevity, in the subsequent sections of this paper absorption due to charge-transfer processes involving the Bi-O components is referred to as Bi^{+3} absorption.

In the foregoing discussion little emphasis has been placed on the absorption of short-wavelength uv radiation by the Bi-O components of YVO_4:Eu:Bi and YVO_4:Bi. However, it is not suggested that such absorption by Bi^{+3} and/or Bi-O is either not taking place or is not important. On the contrary, the absorption of short-wavelength uv radiation by Bi^{+3} incorporated in the Y_2O_3 matrix is shown by the

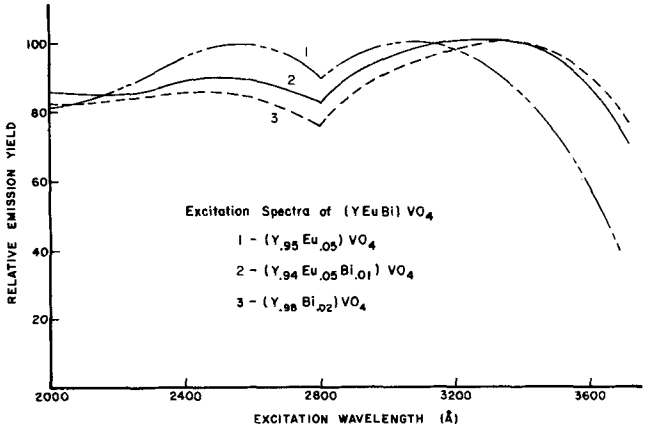

Fig. 4. Excitation spectra of $(YEuBi)VO_4$

diffuse reflectance spectra of Y_2O_3:Bi samples (11). The only suggestion made here is that although some (about 20%) absorption of short-wavelength uv radiation is probably caused by Bi and/or Bi-O, such process is not the underlying cause for high efficiency of the phosphor YVO_4:Bi under 2537Å excitation. This idea may be indirectly supported by the fact that as the concentration of Bi^{+3} in the phosphor YVO_4:Bi increases from 0.75 to 2 a/o, the absorption of the short-wavelength (2537Å) uv radiation and the intensity of emission under 2537Å remain essentially constant.

Excitation spectra.—Normalized excitation spectra of the samples YVO_4:Bi, YVO_4:Eu, and YVO_4:Eu:Bi are shown in Fig. 4. The emission spectra of samples with and without Eu^{+3} are quite different. Hence, their response to the photomultiplier tube used in obtaining excitation spectra are also different. Any quantitative comparison of the excitation spectra should be made after necessary correction. However, it may be generalized that these phosphors have continuous broad excitation spectra with two wide maxima at 2600 and 3200Å. These samples respond efficiently to 2537 and 3650Å excitations.

Emission spectra.—$(YVO_4:Bi)$.—When excited by cathode-rays, short (2537Å)- or long (3650Å)-wavelength uv radiations, Bi^{+3}-activated YVO_4 shows luminescence with an emission band extending from 4000 to 7000Å and peaking at 5670Å (Fig. 5). The present investigation does not include any quantitative measurement of the quantum efficiency of the phosphor under different excitations. However, a qualitative evaluation of the emission process can be attempted.

The band shape of the emission spectra of the phosphor YVO_4:Bi (Fig. 5) is independent of the exciting source and amount of Bi^{+3}. The question now arises whether the emission is from the lattice (YVO_4), Bi^{+3} ions or from the excited Bi-O components. The emis-

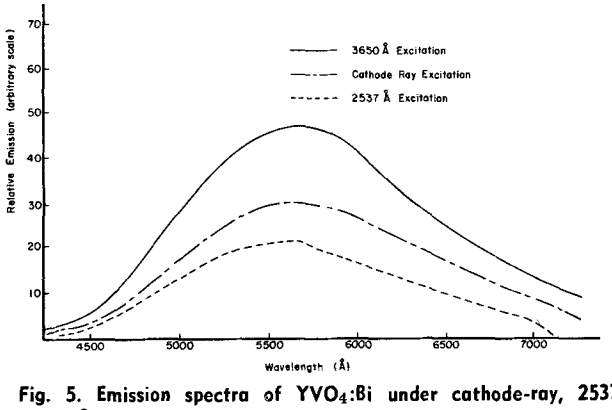

Fig. 5. Emission spectra of YVO_4:Bi under cathode-ray, 2537 and 3650Å excitations.

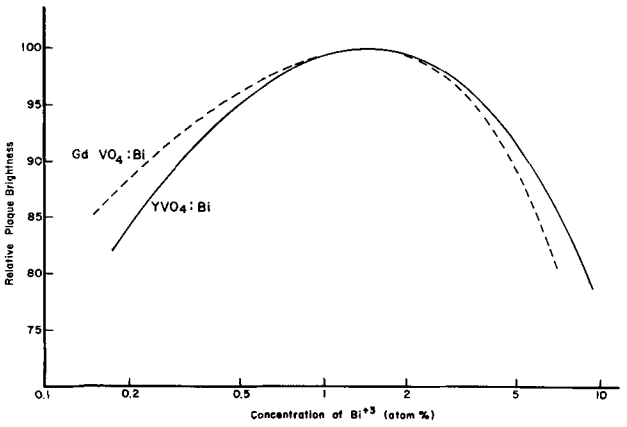

Fig. 6. Plaque brightness vs. activator concentration of RVO_4:Bi (R = Gd, Y), 2537Å excitation.

sion spectrum of pure YVO_4, excited by cathode rays, 2537 or 3650Å radiations, shows a broad weak emission extending from 4000 to 5500Å region and peaking at about 4375Å. The position of the peak of this emission spectrum is quite different from that of YVO_4:Bi. In addition, the intensity of emission of YVO_4:Bi is a function of Bi^{+3} concentration. Normalized plots of plaque[2] brightness against logarithm of Bi^{+3} concentration in YVO_4 and $GdVO_4$ under 2537Å excitation are shown in Fig. 6. When excited by uv radiation, the optimum concentration of Bi^{+3} is independent of the wavelength of the exciting source. The concentration of Bi^{+3} may be chosen within wide limits (1-10 a/o), the optimum being 1-3 a/o of bismuth substituted for Y or Gd in YVO_4 and $GdVO_4$, respectively. When excited under cathode rays, the optimum Bi^{+3} concentration ranges from 0.1 to 0.5 a/o. These indicate that the emission in YVO_4:Bi is not a matrix fluorescence; it is related to Bi^{+3} ions and/or Bi-O components.

Most of the Bi^{+3}-activated phosphors (sulfides, selenides, carbonates, oxides, silicates, etc.) emit in the blue region, although other emissions, such as green, yellow, red, etc., are known (13). The absorption and emission of trivalent metal ions of the sixth period with $^1S_0$ ($5d^{10}6s^2$) ground state have been discussed in considerable detail by McClure (14). However, no simple correlation between the Bi^{+3} emission and composition and structure of the matrix could be obtained from available literature. McClure (14) suggested a $6s6p \rightarrow 6s^2$ transition for Bi^{+3} fluorescence. These outer sp orbitals of post-transitional metal ions are also actual bonding orbitals. Hence, the energy levels of Bi^{+3} ions are highly perturbed by the anions (O^{-2}) of the matrix. In the subsequent discussion this emission is referred to as Bi^{+3} emission.

It should be noted that the emission spectrum of pure YVO_4 which extends from 4000-5500Å, is in part coincident with that of the phosphor YVO_4:Bi (4000-7000Å region), although their peak positions are different. From the symmetric nature of the emission spectrum of YVO_4:Bi, even when the concentration of Bi^{+3} is very low (about 0.7 a/o of yttrium), it can be suggested that the lattice emission (YVO_4) is essentially absent. Hence, it can be suggested that the excitation energy absorbed under short (2537Å)- or long (3650Å)-wavelength uv radiation is emitted mostly as Bi^{+3} fluorescence.

(YVO_4:Eu:Bi).—When Eu^{+3} is incorporated in the YVO_4:Bi lattice with a fixed concentration of Bi^{+3}, the broad Bi^{+3} emission under cathode rays, 2537 and 3650Å excitations is gradually quenched, and sharp, line emissions of Eu^{+3} appear. The relative intensity of these two emissions are dependent on the relative concentration of these two activators so that concentrations can be varied within a wide range depending on the nature of emission desired.

[2] Powdered samples tightly packed in a flat holder.

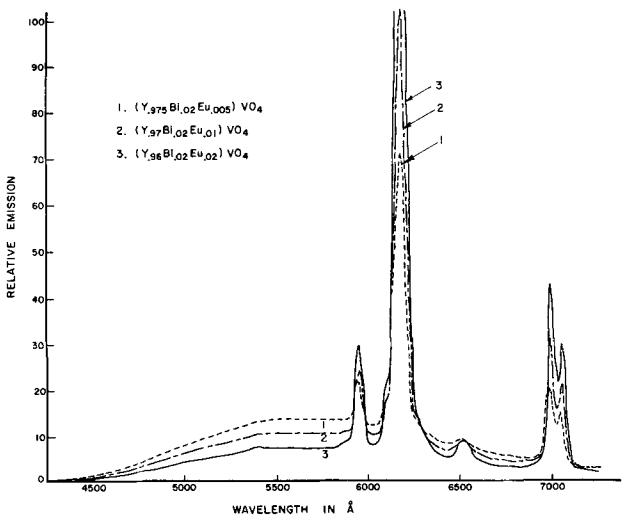

Fig. 7. Emission spectra of YVO_4:Eu:Bi under 2537Å excitation

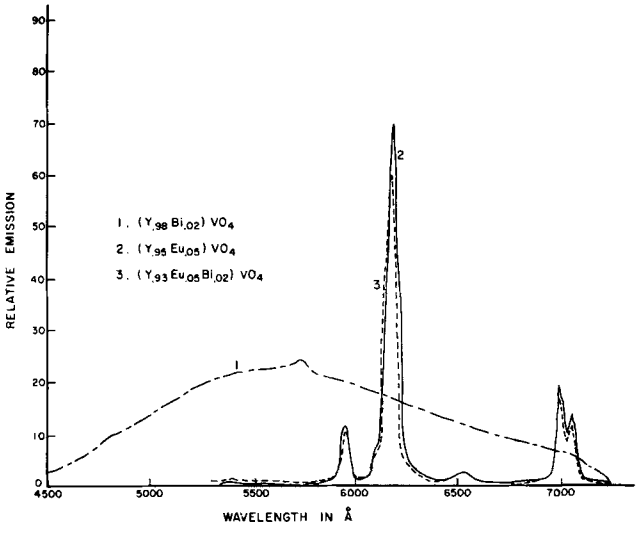

Fig. 8. Emission spectra of YVO_4:Eu:Bi under 2537Å excitation

The phosphor YVO_4:Eu:Bi behaves differently under different uv excitations, namely, 2537 and 3650Å radiations. These are discussed separately below.

2537Å *excitation.*—When Eu^{+3} concentration is gradually increased in the $Y_{0.95}Bi_{0.02}VO_4$ lattice, the broad Bi^{+3} emission under 2537Å excitation is gradually quenched without any change in the band shape of Bi-emission, and narrow-band Eu^{+3} emissions appear (Fig. 7). When Bi^{+3} is incorporated in the $Y_{0.95}Eu_{0.05}VO_4$ lattice, a very faint Bi^{+3} emission is noticed, and there is little effect on the intensity of Eu^{+3} emission (Fig. 8, 12). With further increase in Bi^{+3} concentration (above 2 a/o) the intensity of Eu^{+3} emission is gradually decreased without any enhancement of Bi^{+3} emission. At higher concentration, Bi^{+3} acts as "killer" for Eu^{+3} emission.

3650Å *excitation.*—When Eu^{+3} concentration is gradually increased in the $Y_{0.98}Bi_{0.02}VO_4$ lattice, the intensity of broad Bi^{+3} emission under 3650Å excitation is decreased, and narrow-band Eu^{+3} emissions appear (Fig. 9, 10). Even 0.5 a/o Eu^{+3} can considerably decrease Bi^{+3} emission of $Y_{0.98}Bi_{0.02}VO_4$ (curve 2, Fig. 10). However, Bi^{+3} emission is never completely quenched, even with Eu^{+3} concentration as high as 5 a/o (curve 5, Fig. 11). When Bi^{+3} is gradually incorporated in the $Y_{0.95}Eu_{0.05}VO_4$ lattice, the emission lines of Eu^{+3} show enhanced intensity, especially the main emission peak at 6190Å. The intensity of this peak shows an increase of almost 200% as Bi^{+3} content of $Y_{0.95}Eu_{0.05}VO_4$ is increased from 0 to

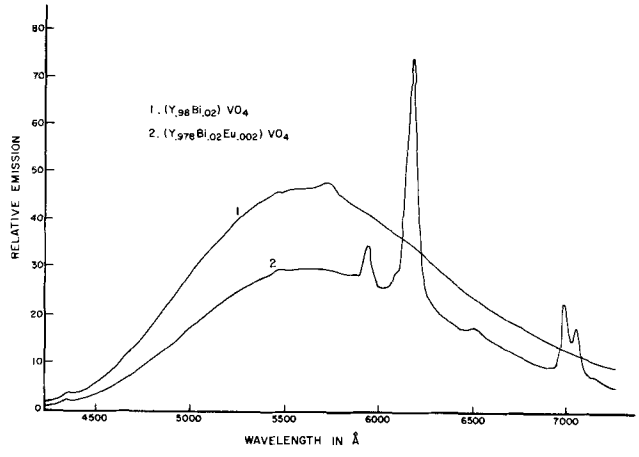

Fig. 9. Emission spectra of YVO_4:Eu:Bi under 3650Å excitation

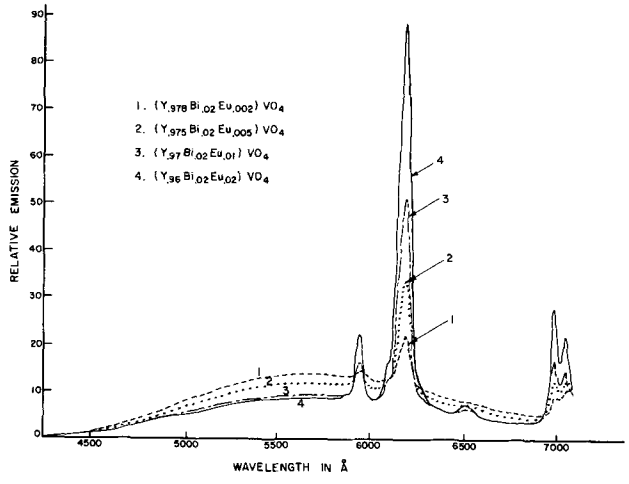

Fig. 10. Emission spectra of YVO_4:Eu:Bi under 3650Å excitation

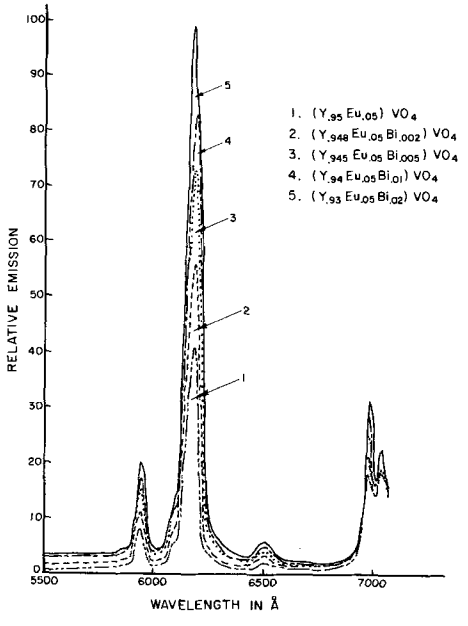

Fig. 11. Emission spectra of YVO_4:Eu:Bi under 3650Å excitation

2 a/o. That is, the composition of the phosphor is changed from $Y_{0.95}Eu_{0.05}VO_4$ to $Y_{0.93}Eu_{0.05}VO_4$ to $Y_{0.93}Eu_{0.05}Bi_{0.02}VO_4$ (Fig. 11). Figure 12 shows the effects on the main Eu^{+3} emission peak at 6190Å under 2537 and 3650Å excitations due to incorporation of Bi^{+3} in $Y_{0.95}Eu_{0.05}VO_4$. Because of the difference in

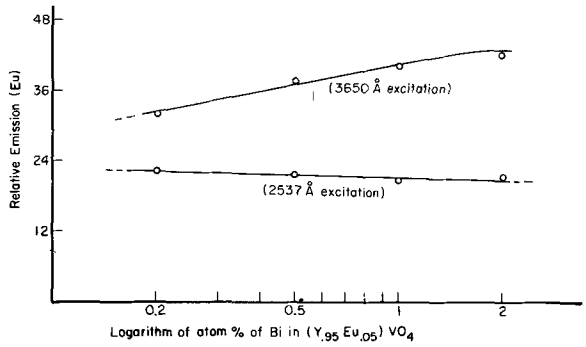

Fig. 12. Relative Eu^{+3} emission of YVO_4:Eu:Bi under 2537 and 3650Å excitations vs. Bi^{+3} content of the samples. (The emission is measured from the total area of the peak at 6190Å.)

the intensities of the two exciting sources used in the present investigation, the relative response of the phosphor, $(YEuBi)VO_4$ to these two excitations should not be deduced from Fig. 12 and compared with the data presented in Fig. 4.

Mechanism of Energy Transfer

It has been suggested in the reflectance spectra section of this paper that in the phosphors YVO_4:Bi and YVO_4:Eu:Bi the short-wavelength uv radiation is absorbed essentially by the lattice, whereas the long-wavelength uv radiation is absorbed jointly by the lattice (V-O components) and the impurity (Bi-O components) elements. The question now arises: What are the mechanisms involved in the transfer of energy from the absorber to the emitting centers, *i.e.*, Bi^{+3} and Eu^{+3} ions in YVO_4:Bi and YVO_4:Eu:Bi, respectively? Klick and Schulman (15) discussed two different methods by which energy from the absorbing components can be transferred to the emission centers in photoluminescent phosphors: (*i*) a radiative transfer of energy through the emission of photons from the absorbing matrix and reabsorption by the final emitter; (*ii*) a nonradiative or exchange process associated with resonance between the absorber and emitter.

In the former case, the absorbing species of the phosphor system must be a very good emitter, and the emitting species must be an efficient absorber. In addition, for any significant amount of energy transfer by the radiative process, the emission spectrum of the absorbing species must substantially overlap the absorption band of the emitting species.

In the phosphor YVO_4:Bi, the weak emission of the matrix (YVO_4) which extends from 4000-5500Å region under uv radiations does not overlap significantly the Bi^{+3} absorption band (3200-4200Å region) of the phosphor. In the phosphor YVO_4:Eu:Bi, the emission of YVO_4:Bi which extends from 4000 to 7000Å under uv excitations does not overlap the main absorption band (at about 2500Å) of Eu^{+3} ions. Hence, any substantial transfer of energy by a radiative process from YVO_4 and YVO_4:Bi to the emitting centers, such as Bi^{+3} and Eu^{+3} of the phosphor systems YVO_4:Bi and YVO_4:Eu:Bi, respectively, can be ruled out.

It may be emphasized that two steps are involved in case of energy transfer by a radiationless or resonance process in photoluminescent phosphors (16): (*i*) energy transfer through the matrix, *i.e.*, from one absorbing group to the other, and (*ii*) energy transfer from the absorbing groups to the activators or emitting centers. Dexter (17) studied the mechanisms and conditions required for a nonradiative transfer of energy through the matrix. The probability of such transfer is a function of the overlap of the wave functions of the absorbing groups and the overlap of the absorption and emission bands of the absorbing groups. It has been shown that such conditions are well satisfied in the YVO_4 matrix (16). Blasse (16) studied many host-sensitized Eu^{+3}-activated phosphors and suggested several requirements for energy transfer from

the matrix to the emitting centers (activators): (a) overlap between the orbitals of the central cation of the absorbing group and the neighboring activator ions, and (b) some overlap of the emission and absorption of the absorbing and emitting groups, respectively.

Blasse (16) further suggested that by virtue of the arrangements of the ions in the lattice, the requirement of orbital overlap betwen yttrium and vanadium is very well satisfied in YVO_4. As a result, YVO_4-based phosphors where part of the yttrium is randomly substituted by the activator ion show efficient energy transfer from the absorbing centers (VO_4^{-3}) to the emitters. In YVO_4:Bi a part of the emission spectrum of YVO_4 is overlapped by the absorption band of Bi^{+3}. Hence, in case of YVO_4:Bi, the short-wavelength (2537Å) uv radiation absorbed by the matrix (YVO_4) may well be transferred by a radiationless process (15, 17) to the emitting centers (Bi^{+3}) resulting in the excitation of Bi^{+3} ions and the final emission from them ($6s6p \rightarrow 6s^2$ transition). The mechanism of excitation of Bi^{+3} ions under 3650Å radiation is slightly different. In this case, in addition to the transfer of energy from the matrix to the activator centers (Bi^{+3}), Bi^{+3} ions themselves absorb the excitation energy and undergo excitation directly. In YVO_4:Eu:Bi, the requirement for energy overlap for the transfer of energy from the matrix to the emission centers is satisfied. This is because Eu^{+3} ions show small, sharp absorption lines within the region (4000-7000Å) of continuous emission spectrum of YVO_4:Bi under uv excitations. It can be recalled here that both YVO_4:Bi and YVO_4:Eu are essentially host-sensitized phosphors under 2537Å excitation. The energy absorbed by the matrix is transferred to the emission centers Eu^{+3} and Bi^{+3}. When these two activators are present together, as observed in the present investigation, energy absorbed by the matrix is transferred preferentially to Eu^{+3} ions which undergo excitation and the final emission. Since Eu^{+3} and Bi^{+3} ions randomly substitute part of yttrium in the YVO_4 lattice[3] and their probabilities of being near the absorption matrix are equal, it is not yet understood why only Eu^{+3} ions are excited. On the other hand, it could be a multistep transfer, *i.e.*, energy from the host is transferred to Eu^{+3} *via* Bi^{+3}. However, even with increased Bi^{+3} concentration very little energy absorbed by the matrix is emitted from Bi^{+3}.

The emission of YVO_4:Eu:Bi under 3650Å excitation is an example of simultaneous host- and impurity (coactivator)-sensitized luminescence (15). In case of impurity-sensitized phosphor, such as $CaSiO_3$:Pb:Mn, energy absorbed by Pb is transferred by a radiationless process to Mn^{++} which undergoes excitation and the final emission (18). In case of host-sensitized phosphors, such as YVO_4:Eu and Y_2WO_6:Eu, energy absorbed by the matrix (VO_4^{-3}, WO_6^{-6}) is transferred by a radiationless process to the emission centers (Eu^{+3}) (8, 19). In YVO_4:Eu:Bi, as observed in the present investigation, energy absorbed by the lattice (VO_4^{-3}) and the impurity centers (Bi-O) under 3650Å excitation is transferred to Eu^{+3} ions by a nonradiative or resonance process (15, 20). The idea of transfer of energy is supported by the following observations under 3650Å excitations: (*i*) The broad Bi^{+3} emission of $Y_{0.98}Bi_{0.02}VO_4$ is gradually quenched as Eu^{+3} concentration is increased in the lattice. (*ii*) The Eu^{+3} emission of $Y_{0.95}Eu_{0.05}VO_4$ is enhanced markedly with gradual increase in Bi^{+3} content.

Sensitization of Eu^{+3} emission by other rare earths, such as Tb, is known (21). YVO_4:Eu:Bi is probably the first phosphor reported where Eu^{+3} emission is sensitized by a nonrare earth ion (Bi^{+3}). This paper describes the photoluminescence of the phosphors YVO_4:Bi and YVO_4:Eu:Bi. However, for the sake of completeness, the effects of Bi^{+3} addition on color point and brightness of $Y_{0.95}Eu_{0.05}VO_4$ emission under cathode-ray excitation are shown (Table I). Although, because of instrumental limitations, no Bi^{+3} emission was detected in the emission spectra of (YEuBi)VO_4 under cathode-ray excitation, data in Table I are more consistent with the introduction of a Bi^{+3} emission (hence the color shift) with little effect on the Eu^{+3} emission intensity.

[3] X-ray diffraction patterns obtained with carefully prepared samples of YVO_4 and $Y_{1-(x+y)}Bi_xEu_yVO_4$ to avoid preferred orientation were compared. Absence of any additional reflection in the activated samples was interpreted as a lack of superlattice or long-range order of Bi-Eu or Bi-Y-Eu in $Y_{1-(x+y)}Bi_xEu_yVO_4$. However, short-range order, usually indicated by preferential increase or decrease of intensities of certain reflections over others in a randomly oriented sample, cannot be unequivocally ruled out due to very small concentration of Bi involved.

Table I. Cathode-ray brightness of YVO_4:Eu:Bi samples

Composition	A/O Eu	A/O Bi	Relative brightness	Color coordinates* X	Y
(YBi)VO_4	—	0.2	100	378	537

Summary and Conclusion

Yttrium vanadate (YVO_4) is a well-known matrix for fluorescence of rare earth ions. In the present investigation it has been activated with Bi^{+3}. YVO_4:Bi is a new phosphor with a broad excitation band extending from 2000 to 3600Å. The phosphor responds very well to cathode rays, 2537 and 3650Å excitation and emits a broad emission band extending from 4000 to 7000Å with a peak at 5670Å. Under 2537Å excitation, energy is absorbed by the Y-O components of the matrix and transferred to Bi^{+3} ions (emission centers) by a radiationless process. The emission of YVO_4:Bi is attributed to the $6s6p \rightarrow 6s^2$ transition of Bi^{+3} ions. These sp orbitals are also bonding orbitals. Hence, influence of the oxygen ions surrounding Bi^{+3} ions on emission cannot be ruled out. Under 3650Å excitation, energy is absorbed by charge-transfer processes involving the V-O and Bi-O components of the phosphor. The energy from the matrix (V-O) is transferred by a radiationless process to Bi ions resulting in their excitation and the final emission from them.

When Eu^{+3} is incorporated in the YVO_4:Bi lattice, the broad Bi^{+3} emission is gradually quenched under cathode rays, 2537 and 3650Å excitation, and the line emission of Eu^{+3} ions appears. With proper selection of concentration of Eu^{+3} and Bi^{+3}, the Eu^{+3} emission is enhanced under 3650Å excitation without showing any appreciable emission of Bi^{+3}.

On the basis of these observations, it can be suggested that the photoluminescence of YVO_4:Eu:Bi under 3650Å excitation is a result of host and impurity sensitization. The energy absorbed by the matrix (V-O) and the impurity centers (Bi-O) is transferred by a resonance process to the emission centers (Eu^{+3}) resulting in the excitation of Eu^{+3} ions among the energy levels of the $4f^6$ configuration and final narrow band emission from them with a peak at 6190Å involving mainly $^5D_0 \rightarrow {}^7F_2$ transition of Eu^{+3}. This investigation shows that Bi^{+3} in YVO_4:Eu:Bi and YVO_4:Bi acts as absorber, emitter, and sensitizer.

Acknowledgments

The author acknowledges the assistance of Dr. R. L. Brown, T. E. Lusk, and B. Walsh in obtaining emission and excitation spectra, of M. Brines and F. Geraghty who measured cathode-ray brightness. The author also wishes to express his thanks to L. S. Staikoff for x-ray measurements, to T. Luscher for preparing the phosphor and measuring uv brightness, and to Dr. E. F. Apple for many helpful discussions. Dr. T. S. Davis and

V. Thelian helped in preparing the manuscript in the final form.

Manuscript received May 23, 1967; revised manuscript received *ca.* July 3, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Ohmic Electrical Contacts to P-Type ZnTe and $ZnSe_xTe_{1-x}$

M. Aven and W. Garwacki

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Low resistance electrical contacts to p-type ZnTe and $ZnSe_xTe_{1-x}$ can be made by diffusing Li from a Li salt into the area of the crystal to be contacted and forming an electroless Au deposit on top of the Li-diffused area. The Li-Au contacts stay nearly ohmic down to 35°K and have been used on crystals having carrier concentrations below 10^9 cm^{-3}. It is suggested that the superior behavior of the Li-Au contacts arises from high concentrations of shallow acceptors in the Li-diffused region which narrows the potential barrier between the valence band of ZnTe and the filled band of the contacting material sufficiently to allow tunneling of carriers even at low temperatures.

Fundamental studies as well as device applications of II-VI compounds, particularly the Zn chalcogenides, have been seriously hindered by the difficulties in making low resistance, low noise, ohmic contacts to these materials. In a recent paper Blount *et al.* (1) have reviewed the requirements for obtaining such contacts. In brief, these requirements call for a material for the contact electrode which has a smaller work function than that of the semiconductor if the semiconductor is n-type or larger if the semiconductor is p-type, and which, when diffused into the semiconductor, will act as a dopant providing majority carriers.

Following these guidelines, satisfactory ohmic contacts can be produced to n-type CdS, CdSe, and CdTe by using In or Ga as the contact metal (2). The contacting of n-type ZnS and ZnSe, which have lower work functions (3) and show a greater tendency toward compensation is more difficult. Nevertheless, satisfactory ohmic contacts have been found for low and high resistivity ZnSe (4), low resistivity ZnS (5), and, more recently, even for high resistivity ZnS (1). Low resistivity p-type CdTe and ZnTe have been electroded with moderate success with electroless gold (6-7). The contacting of these compounds in high or even moderate resistivity form, however, has been very difficult. As a consequence, low-temperature electrical transport studies of these materials in high-purity p-type form are very scarce.

In this paper the authors wish to describe the preparation and some characteristics of Li-diffused contacts to high resistivity p-type ZnTe and $ZnSe_xTe_{1-x}$ crystals. Such contacts stay ohmic and noiseless to quite low temperatures and can be used on crystals having very low carrier concentrations.

Preparation

The crystal to be electroded is etched for 10 to 60 sec in boiling 50% NaOH, rinsed first with hot dilute NaOH, and then with hot distilled water. A small drop of $LiNO_3$ solution (10^{-4} mol/ml) is placed on the crystal in the desired electrode location while the crystal is heated to 40°C in air. The heating is not a necessary requirement, but promotes the evaporation of the solution to dryness. This is particularly useful when applying several electrodes to different sides of the crystal. The crystal is then slowly heated to 320°-350°C in H_2 and held there for 20 to 60 sec. As the crystal is heated, the dry $LiNO_3$ deposit melts at 250°C. At about 300°C the liquid melt suddenly reacts with the substrate and appears to penetrate into the crystal, leaving a barely visible gray spot on the surface. Lateral spreading causes the spot to increase to several times the size of the contact area of the original liquid salt droplet. After cooling to room temperature, the crystal is rinsed with distilled water, dried, and an electroless Au deposit is formed (6) on top of the Li-reacted area. If desired, wires can be soldered to the Au deposit with an In or In-Ag alloy, or fastened to it with silver paste.

In a few instances, while electroding very small bar-shaped ZnTe crystals for Hall effect measure-

ments, the lateral spread of the Li-diffused area or, possibly, a fine spray of droplets from the Li solution caused a partial shorting of some of the electrodes to each other. To safeguard against such low resistivity surface channels, the following procedure was adopted for crystals with closely-spaced (less than a few mm) contacts. After forming the Li-contacts, each was covered with a small drop of thermosetting resin (*e.g.*, GE 7031 "Adhesive and Insulating Varnish"). After the resin had set for 30 to 60 min, the crystal was etched for 30 to 45 sec in boiling concentrated NaOH. This removed some 20-50μ of material from the crystal surface in locations not covered by the resin. After rinsing, the resin was dissolved in a 1:1 mixture of ethyl alcohol and toluene, and a gold dot was deposited on each of the small Li-diffused mesas left by the etching of the surrounding areas. Crystals electroded in such fashion rarely showed any signs of interelectrode shorting. With contacts that were more than a few mm apart, this more complicated procedure was, in most cases, unnecessary.

Electrical Properties

Figure 1 shows a series of oscilloscope I-V traces obtained between a pair of Au and pair of Li-Au contacts on two ZnTe crystals from the same boule at several temperatures. The resistivity of the crystals was about 10 ohm-cm at room temperature and 200 ohm-cm at 55°K. It can be seen that whereas the Au contacts show a considerable contact resistance already at 300°K (note the different current scales for the Li-Au and the Au sequences), the Li-Au contacts

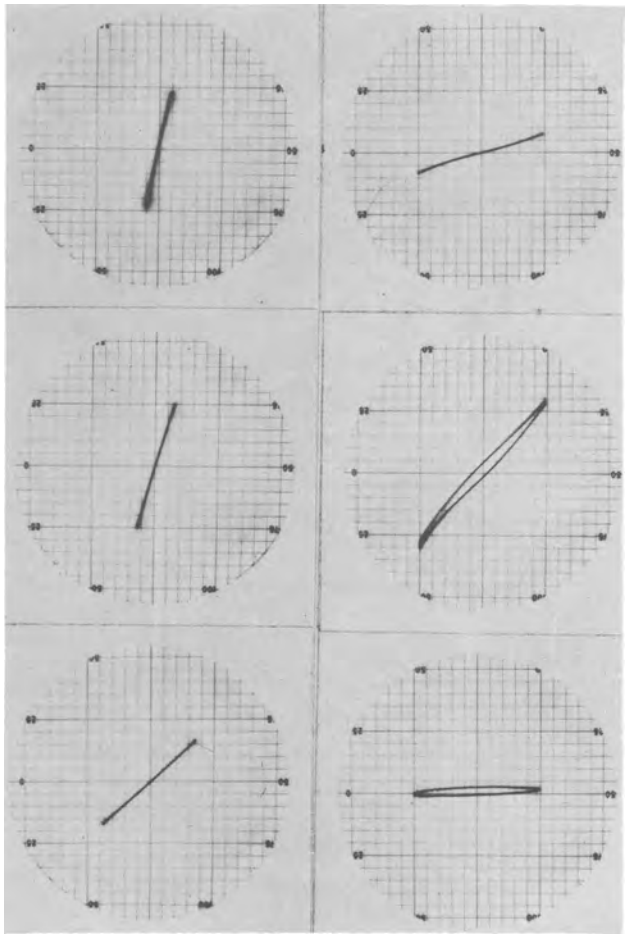

Fig. 1. Current-voltage characteristics obtained between a pair of Li-Au (left sequence) and a pair of Au (right sequence) contacts on ZnTe. Horizontal scale 1v/in. (1 in. corresponds to one large division). The temperatures and vertical scales are, from top to bottom: Li-Au sequence, 300°K, 10^{-3} amp/in.; 232°K, 10^{-3} amp/in.; 55°K, 10^{-6} amp/in.; Au sequence, 300°K, 10^{-4} amp/in.; 232°K, 10^{-5} amp/in.; 70°K, 10^{-7} amp/in.

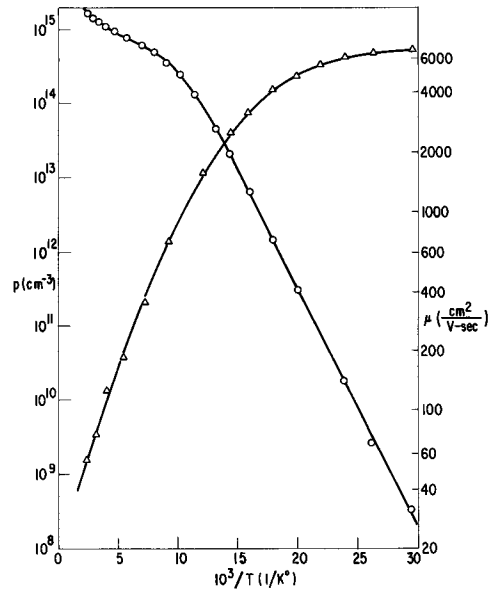

Fig. 2. Temperature dependence of the free hole concentration (circles) and of the Hall mobility (triangles) of an undoped ZnTe crystal.

stay relatively low resistance down to 55°K. At 70°K the contact resistance of the Au electrode is so high as to make the current through the crystal unobservably low on the scale employed. Frequently the Au contacts to ZnTe have displayed strongly nonohmic behavior even at room temperature. Investigation of the conditions which produce optimum room temperature Au contacts showed that a 60-sec heating period at 80°-100°C after the forming step led to best results. No heating or heating at higher temperatures produced much inferior contacts. However, Au contacts with even the best room temperature characteristics started rapidly deteriorating at about 150°C and were unusable for Hall effect measurements on high resistivity ZnTe crystals below liquid N_2 temperature. The significance of this finding is discussed below.

Figure 2 shows the temperature dependence of the free hole concentration and of the Hall mobility of an undoped p-type ZnTe crystal. Measurements of this type at temperatures below the liquid N_2 range have been very difficult before due to the unavailability of suitable contacts. The data in Fig. 2, obtained with a crystal with five Li-Au contacts, have enabled us, for the first time, to extend the measurements to about 35°K. On a reciprocal temperature scale this provides an additional range extending from about $10^3/T = 14$ (pumped N_2 temperature) to $10^3/T = 29$. As can be seen in the figure, this is the range in which the log p *vs.* $1/T$ relationship has become linear, and which, therefore, enables one to obtain the acceptor ionization energy with good accuracy. Hall mobility measurements between the liquid N_2 temperature and 35°K indicate increasing departure from pure LO phonon scattering (4). Mobility studies in this temperature range thus make it possible to investigate the scattering due to low concentrations of charged impurities.

The forward I-V characteristics at 77°K of a $ZnSe_{0.36}Te_{0.64}$ light emitting p-n junction diode (8) with an In-Hg electrode on the n-type side and either a Li-Au or a Au electrode on the p-type side of the diode are compared in Fig. 3. It can be seen that the Li-Au contact allows a substantially higher current to pass through the diode than the Au contact. The strongly nonideal I-V characteristic of this particular diode even with the Li-Au contacts is due to the high bulk resistance of the p- and n-type sides of the diode.

It has been reported (7) that originally low resistivity Li-doped ZnTe crystals gradually become high re-

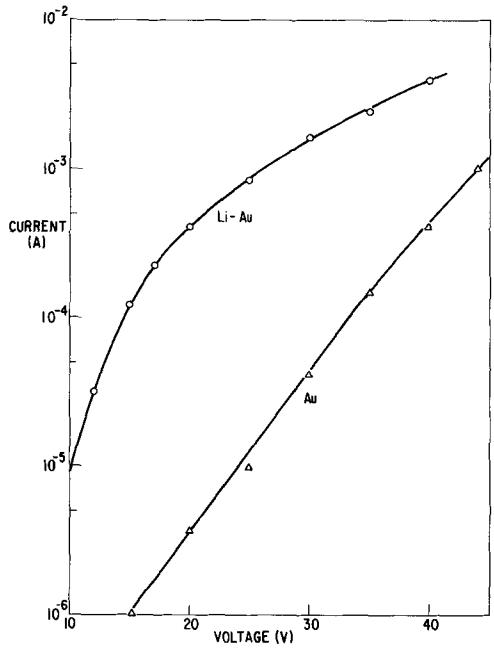

Fig. 3. Forward I-V characteristics of a $ZnSe_{0.36}Te_{0.64}$ light emitting p-n junction diode with an In-Hg electrode on the n-type side and either a Li-Au (circles) or a Au (triangles) electrode on the p-type side.

sistivity when annealed at even relatively low temperatures. The high ionic mobility of Li and its tendency to associate with other lattice defects in semiconductors is well known (9). In view of this a life test was conducted with a $ZnSe_{0.36}Te_{0.64}$ p-n junction diode in which the I-V characteristic was measured originally, and after (*a*) 264 hr in liquid N_2; (*b*) 312 hr at room temperature in vacuum; (c) 640 hr at room temperature in air; and finally (*d*) 93 hr at liquid N_2 temperature in vacuum, with 30v forward bias. The I-V characteristic was found to be essentially unchanged after each of the indicated periods, indicating the electrical stability of the Li-Au contacts under the test conditions employed.

Discussion

The shallow acceptor activity in undoped ZnTe and CdTe has generally been attributed to doubly ionizable Zn vacancies (4, 10, 11), which have their first charge state about 0.05 ev above the valence band edge. Acceptor states with ionization energies comparable to that of the Zn vacancy have been observed in Li- and Na-doped ZnTe and CdTe (7). The noble metals Ag, Cu, and Au, on the other hand, have been found to introduce deeper acceptor states, 0.11, 0.15, and 0.22 ev, respectively (4). Using this information in conjunction with the results of the present study leads to the following characterization of the Au and Au-Li contacts.

As shown in Fig. 4a the relative work functions of Au and ZnTe are such (3) as to suggest a barrier of about 0.66 ev between the Fermi level in Au and the valence band edge in ZnTe. Although the presence of surface contamination, surface states, etc., often does not allow one to rely on simple calculation of barrier heights from work function data, it has been shown by several workers (3, 12) that in the case of II-VI compounds this is often not a bad approximation. The band structure resulting from an essentially noninteracting contact (in the sense that the barrier shape and height depends only on the work function difference of Au and ZnTe and the charge density in ZnTe) on undoped ZnTe would then look as shown in Fig. 4b. Due to a moderate concentration of shallow Zn vacancy acceptor states, the barrier height and width are such as to allow a small but measurable current of holes from the metallic contact into the valence band of ZnTe, and *vice versa*, at room temperature. At low temperatures, however, the barrier becomes a serious obstacle to current passage, and the contact becomes high resistance. We believe that the Au contact on undoped ZnTe, processed under optimum conditions, comes close to this case. Figure 4c schematically represents an Au contact in which Au has diffused too far into the crystal and replaced the shallow Zn vacancy acceptors by the deep Au acceptors. In addition to the barrier one now has a high resistivity region under the contact. The structure of the Li-diffused contact is shown in Fig. 4d. Here the high concentration of shallow acceptors in the surface region significantly reduces the barrier width and allows a tunneling current of holes to pass from the external Au electrode into the valence band of ZnTe even at low temperatures. Gold contacts to Li, Na, or P-doped ZnTe work in a similar fashion, except that now the high p-type doping exists uniformly throughout the bulk of the ZnTe crystal rather than just in the Li-diffused surface region.

The external contacts of chemically deposited Au are much superior to simple mechanical electrodes such as silver paste, colloidal graphite, or tungsten wire even on Li-diffused areas on ZnTe crystals. This suggests that the chemical reaction between ZnTe and the solution used to form the electroless Au contacts ($HAuCl_4$ · aq) which consumes a small layer of the ZnTe crystal under the Au solution drop thereby effects a clean-up of the surface immediately beneath the Au deposit. Evidence of the etching action of $HAuCl_4$ · aq is revealed by microscopic examinations of Au-contacted ZnTe crystals, which show that the Au deposits reside in slightly depressed areas having the appearance of shallow negative mesas.

Conclusion

It has been shown that electrical contacts to ZnTe and $ZnSe_xTe_{1-x}$ crystals fabricated by a method in which Li is first diffused into the area to be contacted and then an electroless Au deposit is formed on top of the diffused area, are significantly superior to electroless Au contacts. Using the Li-Au electroding technique on undoped ZnTe crystals it has been possible to investigate the electrical transport properties of this material at considerably lower temperatures than has been done previously. $ZnSe_xTe_{1-x}$ p-n junction diodes

electroded with the Li-Au contact on the p-type side have been found to pass substantially higher current at comparable voltages than diodes electroded with the Au alone. It has been suggested that the low contact resistance of the Li-Au contacts arises from the highly Li-doped surface regions of the ZnTe crystals being electroded. In such regions the shallow acceptor concentration is considerably higher than in undoped ZnTe, and hence the barrier separating the valence band of ZnTe from the filled band of the external contacting material is much narrower. This allows a tunneling current to communicate between the crystal and the external electrode even at low temperatures.

Acknowledgments

The authors wish to thank R. K. Swank and H. H. Woodbury for the many helpful suggestions and stimulating discussions during the course of this work. Work on this paper was sponsored by the Air Force Cambridge Research Laboratories under Contract No. AF-19(628)-4976.

Manuscript received May 22, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

The Effects of Double Insulating Layers on the Electroluminescence of Evaporated ZnS:Mn Films

M. J. Russ and D. I. Kennedy

Bowmar Canada Limited, Ottawa, Ontario, Canada

ABSTRACT

The performance of ZnS:Mn electroluminescent layers deposited between double SiO insulating films is described. The dependence of emission properties on SiO and ZnS film thickness and Mn content are outlined. The relatively bright (700 ft-L) and efficient (1 lpw) emission is interpreted in terms of excursions from equilibrium trap occupation under high field conditions.

A considerable number of investigations of EL (electroluminescence) in thin ZnS films have been carried out using direct contact between the ZnS films and the conducting electrodes. In some investigations a single thin insulating layer has been used between the films and one of the electrodes. In most of the cases the results have shown marked asymmetry with respect to changes in polarity of the applied voltage. This situation has frequently led to difficulties in interpretation of the results. The present experiments were designed to eliminate some of the complexity by using thin insulating layers on both sides of the ZnS films.

In the past there have been a number of reports (1-11) on a-c EL in ZnS thin films. These reports have covered a variety of preparation techniques. Halsted and Koller (1) prepared EL (electroluminescent) ZnS:Mn films by the vapor reaction technique of Studer and Cusano (12), whereas Thornton (2) used the diffusion method of Feldman and O'Hara (13) to prepare ZnS:Mn:Cl and ZnS:Cu:Cl films. Vlasenko and Popkov (4) prepared ZnS:Mn films by separate evaporation and subsequent high-temperature diffusion of the constituents. Using a technique of coevaporation on a heated substrate proposed by Koller and Coghill (14), Antcliffe (15) has prepared EL ZnS:Mn films. Apart from variations in methods of producing the phosphor layer, various types of composite device have been investigated. Several authors (4, 6) have utilized an insulating layer between the phosphor film and the metal electrode. Harper (6) has reported that improved efficiencies and over-all brightness levels can be obtained by the use of an SiO_2 film of thickness between 7 and 160Å in this position.

The technique of coevaporation of ZnS and Mn on a heated substrate was adopted for the present experiments because of the simple, one-stage process.

Film Preparation

High-purity ZnS in either single crystal or compressed polycrystalline form was used as source material and, in the majority of experiments, Mn powder was added to the ZnS crystals in a range of concentrations from 0.04 to 6.0 w/o. To maintain uniform conditions in successive depositions the accurately weighed charges were evaporated to completion.

It was found that in order to obtain high-brightness EL the deposition conditions were critical. Substrate temperatures had to be maintained in the range 250°-300°C. Above 300°C significant crystallization of the ZnS film occurred and this resulted in the formation of an opaque white layer. For substrates maintained at temperatures between 20° and 250°C, only low-level emission was obtained. The critical deposition rate was found to be 1000 Å/min at a pressure of 10^{-5} Torr. The source temperature required to maintain this deposition rate at a distance of 7 in. from the substrate was 1230°C as determined by an optical pyrometer. The use of a lower evaporation rate did not permit sublimation of the added Mn, and a higher rate led to poor incorporation of the Mn in the film. This latter condition resulted in the deposition of a film having a black metallic coloration.

When the critical deposition conditions were met it was possible to obtain emission from panels with a range of ZnS film thicknesses and Mn concentrations. In order to obtain panels with a usable brightness, however, it was necessary to control the latter parameters also.

Prior to deposition of the ZnS film a layer of SiO was evaporated onto the unheated tin-oxide coated glass substrate. SiO thicknesses which were varied from 600 to 5000Å were used. Subsequent to the deposition of the phosphor film a second SiO layer was evaporated and finally metal electrodes were deposited. The properties of devices made with this structure were found to be independent of the metal electrode used (Al, Au, and In were each investigated). The results are based on an evaluation of at least 36 devices for each experiment.

Results

The emission resulting from a-c excitation of the ZnS:Mn films was located in the same region of the spectrum as reported by previous authors. Using a DK-2A spectrophotometer it was found that the peak occurred at 5780Å and the half-width was 450Å.

On first application of voltage to these devices it was found that the emission would grow steadily to a uniform brightness over the active area. This behavior contrasted strongly with previous experiments carried out in this laboratory and elsewhere on structures with no insulating layers or a single such layer. In the latter cases it was found that a "forming" process, in which the phosphor was subjected to a critical near-breakdown electric field, was required to produce over-all luminescence. This "forming" process was attended initially by high currents without the presence of EL, and the emission appeared gradually as the currents fell to lower values. These processes have been discussed by Goldberg and Nickerson (16) and Cusano (17). The use of single insulating layers reduces the severity of the break-in process, and the double layers described in this report virtually eliminate the effect.

Effects of SiO *layers.*—Using the deposition conditions described above a 1000Å film of SiO was evaporated on tin-oxide coated glass followed by deposition of a 1.5μ ZnS:Mn film (Mn concentration in source of 0.6 w/o). This was followed by deposition of SiO stripes which increased in thickness in steps over the range from 220 to 5000Å. Metal electrodes of area 6 x 10^{-2} cm^2 were then evaporated to complete the devices.

Figure 1 shows the results obtained on a-c excitation of these films at a frequency of 13 kHz in terms of the dependence on surface brightness on the rms electric field applied across the ZnS film. (This latter parameter was estimated from the total applied voltage using measured results for the dependence of the dielectric constants of ZnS and SiO on film thickness at the frequencies used.) The brightness was measured using a Spectra-Spot brightness meter. All results show a marked dependence of brightness on SiO thickness. As the SiO thicknesses were gradually increased it was found that the observed emission for a given field across the ZnS layers passed through maxima and minima. Although the emission process may be influenced by SiO thickness to some extent, the oscillatory nature of the characteristics pointed strongly to the existence of optical interference effects in the composite structure.

To maximize the observed emission in the above structure it was necessary to use particular values of SiO layer thickness. Utilization of data similar to that shown in Fig. 1 for dependence of brightness on SiO thickness at fixed values of ZnS field showed that the maximum brightness is obtained for an SiO thickness of 650Å. This differs from the theoretical value of 730Å calculated from reported refractive indices for the various layers; the difference probably

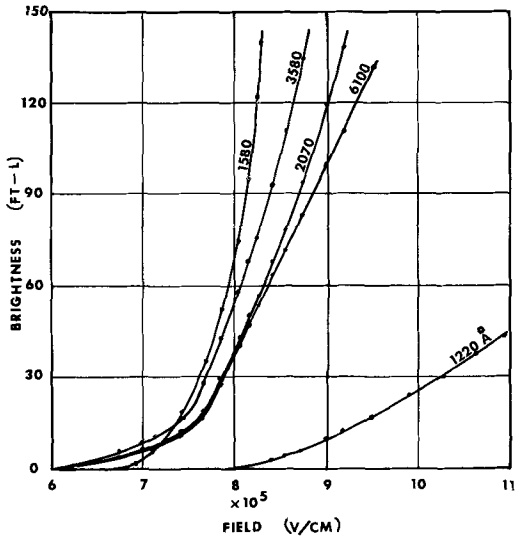

Fig. 1. Dependence of brightness on ZnS field at 13 kHz for various SiO layers. 1000Å SiO films were used between the ZnS and SnO_2 and thicknesses of 220-5100Å of SiO were used between the ZnS and Al.

results from the complex dependence of refractive index on film composition and thickness in the materials used. By varying the thickness of the SiO layer between the tin-oxide electrode and the ZnS film while maintaining the second SiO layer constant, it was possible to establish an optimum thickness value of 1300Å for the internal SiO layer. This value is in agreement with theory assuming $n_{SiO} < n_{SnO_2}$. A further increase in observed emission would be anticipated if the SiO or tin-oxide layers were replaced with materials with more ideally matched refractive indices.

It is interesting to note that the field strengths applied to the ZnS layers in our devices under routine operating conditions appear to be equal to or slightly higher than values normally used in this type of experiment and also than the reported dielectric breakdown strength for ZnS (4, 18). The calculated field strength values were obtained from separate measurements on SiO and ZnS layers of equivalent thicknesses and may not correspond exactly to the values which occur in composite structure. Nevertheless, the possibility exists that the double SiO layers eliminate one form of breakdown which occurs when direct metal/ZnS contact exists. The highest-efficiency EL in this work was observed when devices were operated in this field regime.

The dependence of brightness on frequency in the range from 1-20 kHz, showed, for all values of SiO thicknesses, a saturation effect above 8 kHz. As the frequency was increased above 13 kHz the average brightness at a given applied field decreased. Although this decrease may be associated with impedance effects in the various layers or with internal heating there is some evidence that it could be caused by failure of the excitation and recombination processes to reach completion within individual half cycles of the applied field.

Effect of manganese concentration.—There is little information in the literature on the dependence of ZnS film emission properties on Mn concentration. The majority of published work has been carried out on single values of Mn content in a range between 0.1 and 1 w/o. Vlasenko and Popkov (4) carried out experiments with several Mn concentrations and reported an optimum value of 0.6 w/o. In the present work a range of samples were prepared from sources containing from 0.04 to 6.0% Mn. In all cases the ZnS film thickness was maintained at 1.5μ, and a symmetrical structure with double SiO layers of 700Å thickness was used.

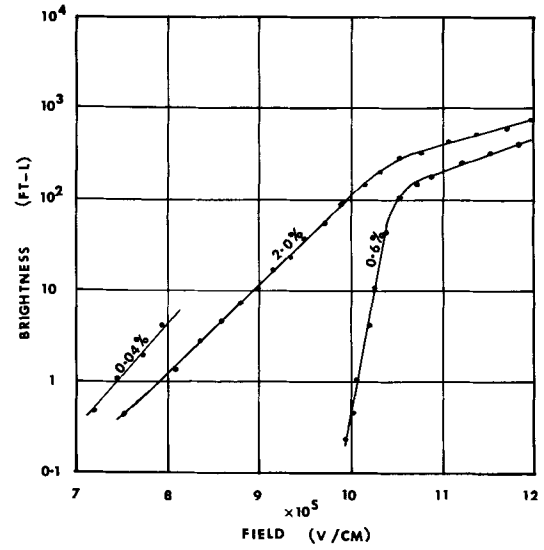

Fig. 2. Dependence of brightness on ZnS field at 13 kHz for various Mn concentrations. A ZnS thickness of 1.5μ was used in conjunction with double 700Å SiO layers.

Figure 2 shows the dependence of integrated brightness on the applied field at 13 kHz for three Mn concentrations. A considerable improvement in brightness levels was obtained as the Mn concentration increased. The maximum brightness for a phosphor containing 2 w/o Mn was in excess of 700 ft-L compared with 5 ft-L for a 0.044 w/o phosphor. If the Mn concentration was increased to 6%, the maximum brightness was reduced to 10 ft-L, and the panels were found to burn out at low applied voltages; this would appear to be due to the reduction in the resistivity of the phosphor with high Mn content. At 6 w/o Mn the films had a metallic black rather than yellow coloration. In the concentration range from 0.04 to 2.0 w/o the maximum brightness and discrimination ratio increased with increasing Mn content. Although 2% Mn was the maximum level of incorporation which led to repeatably good results using the described procedures it is felt that higher concentrations could be achieved using more sophisticated source materials and deposition procedures. In this case it should be possible to obtain even brighter emission from the devices. The present results are in agreement with Kodzhespirov *et al.* (8) who reported that emission intensities of ZnS:Mn devices increased with increasing Mn content. The maximum concentration used by these authors was 4.0 w/o and the ratio of emission intensity in the high-concentration devices to those with 0.04 w/o Mn was reported to be 10^3:1.

The dependence of the El output on frequency exhibited little variation as the Mn concentration was altered.

Effect of ZnS *thickness.*—There is little information in the literature on the effects of variation of phosphor film thickness on device performance. The results from the present work are shown in Fig. 3. In these experiments the concentration of Mn was maintained at 0.6 w/o, and the film was again sandwiched between 700Å SiO layers. The maximum obtainable brightness increased with ZnS thickness to 1.3μ, but did not increase appreciably thereafter. The discrimination ratio attained a maximum value for films in the region of 1.3μ in thickness. The figure also demonstrates that the field strength required to develop a given emission intensity falls towards a lower limit as the ZnS film thickness is increased. Vlasenko and Popkov (4) observed that emission intensity increased with increasing film thickness and the field strength at which emission was first discernible to the eye decreased with increasing thickness. The latter authors interpreted the results to be evidence

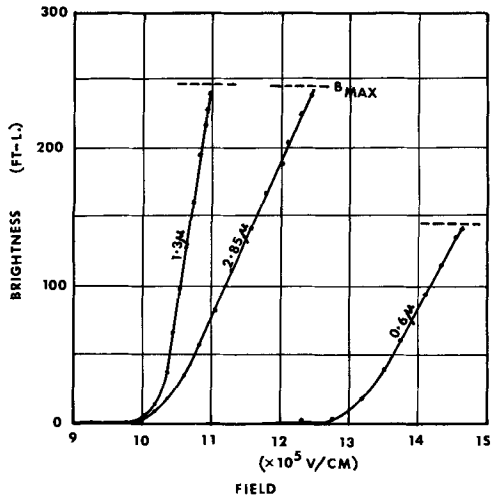

Fig. 3. Dependence of brightness on ZnS field at 13 kHz for various ZnS film thicknesses. A Mn concentration of 0.6 w/o was used and double 700Å SiO layers were employed.

of recombination throughout the bulk of the phosphor.

The dependence of electroluminescent output on frequency was found to saturate for all thicknesses of ZnS layers but, as the ZnS thickness was increased beyond 1.3μ, saturation occurred at successively lower frequencies.

In measurements of I-V curves on a number of panels over a brightness range from 1 to 700 ft-L it was found that the current increased linearly with voltage. As the SiO thickness was decreased or as the Mn content was decreased a given change in applied voltage would produce a greater change in current.

The relationship between brightness and rms applied voltage was measured for a number of films and was found to consist of two exponential regions. The curves, which are illustrated in Fig. 4 for several ZnS thicknesses, obey the following relation

$$B = B_1\left(\exp\frac{V}{V_1} - 1\right) + B_2\left(\exp\frac{V}{V_2} - 1\right)$$

where B is the surface brightness, V is the rms applied voltage, and B_1, B_2, V_1, and V_2 are constants. Kolomeitsev *et al.* (9) also found their results to obey this expression.

Efficiency-voltage characteristic.—Figure 5 shows the efficiency-voltage curves for several typical de-

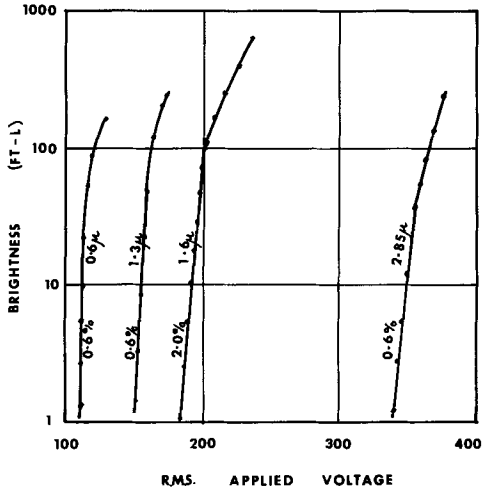

Fig. 4. Dependence on brightness on rms applied voltage for various ZnS film thicknesses and Mn concentrations using 700Å SiO layers.

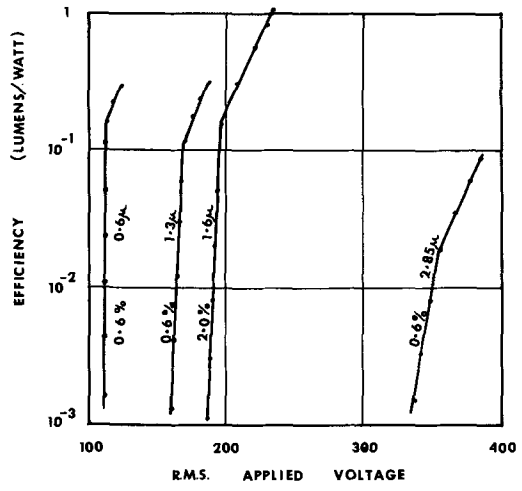

Fig. 5. Efficiency vs. rms applied voltage for various ZnS film thicknesses and Mn concentrations using 700Å SiO layers.

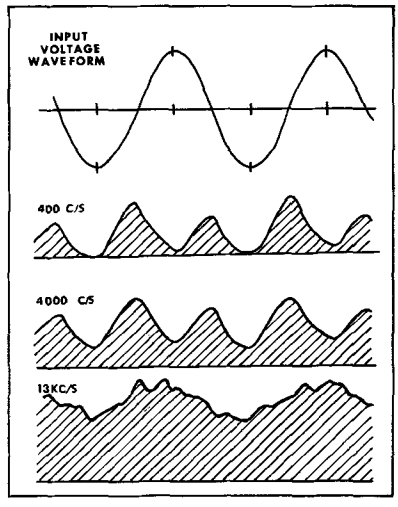

Fig. 6. Tracings of the emission waveforms obtained under sinusoidal excitation at several frequencies from a typical 2% Mn 1.6μ ZnS film.

vices. Once again double SiO layers were used and an excitation frequency of 13 kHz was employed. Emission efficiencies in the range from 0.1 to 1.0 lpw were regularly obtained; the higher efficiency results usually occurred when ZnS with 2 w/o Mn was evaporated, and the devices had the optimum SiO thicknesses for maximum emission.

The reduction in rate of increase of efficiency with applied voltage shown in Fig. 5 was also reported by Kodzhespirov and Kostylev (8). The dependence of efficiency on SiO thickness attained a maximum for values similar to those described in the section dealing with optical effects in these layers. Therefore, the improvement in efficiency can also be associated with these effects. The improvements in efficiency reported by Harper (6) for SiO_2 layers were associated with tunneling and accumulation effects in these layers; for these thin films (7-160Å) significant optical enhancement would not be anticipated.

In comparing the performance of thin-film and powder El phosphors it is significant that the efficiency of films increases with applied voltage whereas the efficiency of powder phosphors reaches a peak at approximately one-half of the desirable operating brightness and falls off with further increase of voltage. Although powder cells have exhibited maximum efficiencies of 14 lpw at low brightness, a value of 3 lpw is a more typical efficiency under normal operating conditions. The efficiency of thin-film panels of the type described here operating under similar conditions compares favorably with this value.

Emission characteristics under sinusoidal and pulsed excitation.—The shapes of the emission output waveforms were detected by a type 7625 photomultiplier and displayed on a Hewlett-Packard 175A dual-trace oscilloscope. Tracings of photographs of the waveforms obtained under sinusoidal excitation are shown in Fig. 6; the wavetrains progress from left to right of the diagrams. It was noted at low frequencies that there were two emission pulses per cycle of applied voltage and that the maximum emission lagged the maximum voltage for both polarities by 0.6 to 0.8 msec. At 400 Hz the two pulses were distinct but at 4 kHz the emission from a particular pulse did not decay to zero before onset of the succeeding pulse. At 13 kHz the emission pulses appeared only as a slight structure superimposed on a continuous level of emission.

It was found in a number of devices that, although similar time and frequency dependence of the emission peaks occurred, their amplitudes were not always equal. In these cases where the emission pulses were not equal in amplitude it was found that the light output corresponding to positive voltage applied to the tin oxide electrode could exceed the reverse case by up to 50%. Because of the similarity of behavior of the two peaks in all other aspects and because of the independence of results on the nature of the electrodes it is felt that the asymmetry results from nonuniform excitation or emission properties through the ZnS layer or at its interfaces with SiO. The nature of the device fabrication unfortunately introduces asymmetry in two respects. First, the distribution of Mn through the depth of the ZnS film may be nonuniform due to rapid depletion of Mn at the start of evaporation or deposit of an excess at the completion [in previous work (14) the Mn:Zn ratio has been shown to vary from 0.003 to 0.007 to 0.011 in subsequent 1-min deposition intervals]. A second factor arises from the sequential film deposition procedures which involve substrate heating during the ZnS evaporation. This process inevitably introduces inequalities in the properties of the initial and final SiO layers.

Figure 7 shows the response of a panel to symmetrical pulse excitation. Again two pulses per cycle were observed, and the maximum light emission lagged the voltage switching time by about 0.6 msec. Similar results were obtained for the cases where the tin-oxide electrode was pulsed positive and negative with respect to the metal electrode; the only slight distinction occurred in cases where the two emission

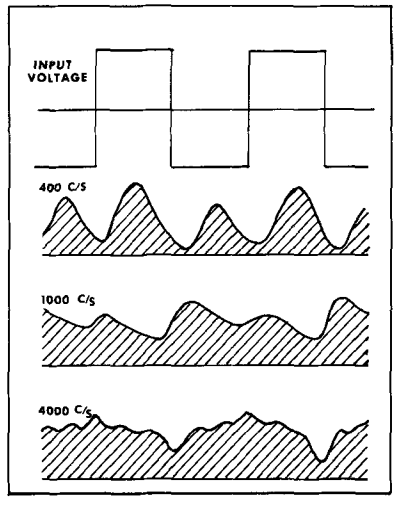

Fig. 7. Tracings of the emission waveforms obtained under symmetrical pulse excitation at several frequencies.

pulses were unequal in amplitude. In the latter case the larger pulse would occur when the tin-oxide layer was switched positive with respect to the metal electrode regardless of the potential at which the metal electrode was held (0 volts or full negative potential). At 400 Hz the two pulses per cycle were distinct but, as higher frequencies were applied, the light emission did not decay to zero between field reversals.

An interesting result was obtained by varying the mark: space ratio of the pulse waveform at a repetition rate in the region of 400 Hz, *i.e.*, below saturation frequencies. At a 50:50 duty cycle it was found that two approximately equal pulses per cycle were obtained, but as the ratio was moved to 85:15 the amplitude of one pulse decreased and the second pulse increased. At 85:15 only a single pulse occurred each cycle and this was approximately twice the size of its counterpart in the 50:50 duty cycle case. The single pulse was found to reach a peak approximately 0.6 msec after the termination of the 85% part of the cycle.

A series of experiments were performed in which the metal electrode was held at ground potential and the tin oxide was pulsed to full positive potential for 15% of each cycle. These experiments were repeated for the same pulse durations but with application of negative pulses to the tin oxide. Both sets of experiments were repeated using longer pulse durations so that the pulse occupied 85% of the cycle times. In all cases the results were similar, and the samples behaved as if the condition in which 85% of the time was spent was the equilibrium state and emission took place only after the applied voltage switched to the 15% state. Figure 8 illustrates two of these cases. It can be seen that the decay to zero emission following each light pulse takes several milliseconds.

Ageing.—One major disadvantage of thin-film El panels is their extremely rapid ageing characteristic. Apart from exceptional cases, thin films prepared by the above techniques show a reduction to half initial brightness within tens of operating hours. This figure is similar to values obtained by other authors. Ageing was accelerated by elevating the ambient temperature. It was noted, however, that the lifetime parameter showed distinct variations from one batch of devices to another prepared at a different time but in ostensibly the same manner, whereas from one device to another within any one particular batch there was consistency in ageing characteristics. There is evidence to suggest that this property is related to controlled and uniform manganese incorporation and that the use of more sophisticated material preparation and evaporation procedures may yield significant improvements. It was found that the lifetime of panels capable of several hundred foot-Lamberts could be extended by operation at lower brightness levels. The initial decay of brightness is not truly exponential, and a fast decay occurs during the application of the first few cycles of voltage. Because of this it is almost impossible to establish the true starting time for the decay process and therefore to state the true half-life. In our work we have taken the initial brightness as a value measured within the first minute of field application.

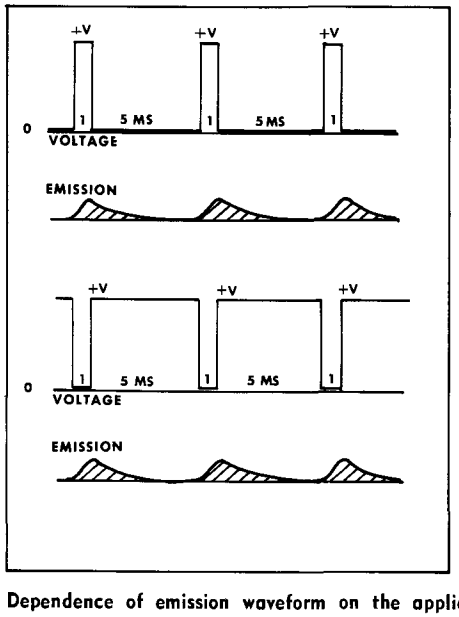

Fig. 8. Dependence of emission waveform on the applied pulse duty cycle.

Discussion

A great deal of controversy is apparent in recent published work on ZnS films. The majority of workers suggest that the best structure for obtaining efficient emission has a blocking layer at the positive metal electrode while others report that blocking contacts at the cathode are advisable [these points are reviewed in ref. (19)]. In the present work using relatively thick double insulating layers the emission was found in almost every case to be similar for both applied polarities regardless of the nature of the metal electrodes. This result implies that the metal/insulator interface properties are of secondary importance and that the carriers required for the recombination process originate either in the ZnS film itself or in the ZnS/SiO interface barriers, for example, in an accumulation layer of the type described by Harper (6).

The most favored mechanisms for explaining electroluminescence in Zns films include injection effects from adjacent layers (16, 20) or internal p-n junctions (5),and electronic impact ionization (6, 21). It is almost certain that light emission can and does result from these and other processes depending on the film preparation and contact properties. In the case of the present devices where average fields of 10^6 V/cm exist in the films under the optimum operating conditions one would anticipate a high-field mechanism to be operative. Impact excitation is likely to occur at these fields. The source of carriers for the emission process may be thermally generated electrons, but it is also possible that field effects lead to depopulation of traps in the various parts of the devices and that these could represent a significant contribution (23, 25). It should be noted that an average field of 8×10^5 V/cm was normally required for the efficient emission process in our layers and that the light output increased typically from 1 to 600 ft-L with a minor increase of field to 1.2×10^6 V/cm. Although inefficient emission was detected at lower fields its characteristics were different; the bright emission process appeared to have a definite field threshold. (Since there was evidence of space-charge effects in the devices it was possible that nonuniform field distribution occurred within the layers and that considerably higher than the average local fields may have been present.)

The emission from the films was similar to emission from a variety of ZnS:Mn devices and is believed to result from excitation of Mn centers by collision or resonance transfer. It is unlikely that direct field excitation of the Mn center itself occurred because of the high calculated field strength required for this process (22).

The emission waveform was considerably simpler than described results from ZnS films with other activator systems. The secondary peaks often described in work with other films were not observed in the present experiments. After a single step increment in voltage the emission was found to grow to a peak after 0.6 to 0.8 msec and then to decay over a considerably longer time interval. This behavior together with the observations under various applied waveforms could be explained in the following manner.

It is a well-established fact that ZnS films, interfaces, and oxide insulators possess a number of trapping levels with time constants ranging from microseconds to hours. The degree of occupation of these levels in structures such as the present panels is a complex function of applied voltage, ambient temperature, illumination, and past history. On changing the applied voltage a series of events occurs which leads to a new distribution of the carrier population throughout the devices. At first the free carriers and easily excited carriers flood toward their new positions and, more gradually, the deeper levels adjust in population according to a complex time dependence. Some of the adjustment occurs at a rate determined by thermal detrapping, but additional field-enhanced detrapping at fields as low as 5×10^3 V/cm could also occur (23). The internal field in each part of the structure cannot instantaneously acquire a new equilibrium value when the applied voltage is increased, but rather it will rise to a new value according to a time dependence determined by the level repopulation processes. Based on these premises it is tempting to conclude that it is this gradual field growth after a change in applied voltage which leads to the 0.6 msec delay before peak emission occurs. In other words the required field for the collision process does not appear across the total volume of the main emitting regions until 0.6 msec after application of the required voltage (the 0.6 msec time being a particular property of the present panels under these applied conditions).

As equilibrium is approached the flow of carriers diminishes and this leads to a gradual reduction in the number of excitations and recombinations. This is likely to be the explanation for the observed decay in emitted brightness after the peak value at 0.6 msec. A small residual light emission after equilibrium is established caused by thermally generated carriers entering the high-field regions might also be expected.

The above picture provides a simple and self-consistent explanation of the observed emission waveforms. Under sinusoidal or symmetrical pulse excitation there are equal excursions about each side of an average condition. This creates two major disturbances of equilibrium per cycle and could be expected to lead to two emission pulses per cycle. If the symmetry of the pulse excitation is altered to an 85:15 duty cycle, the equilibrium will be biased predominantly to the 85% condition. This being the case only one major excursion from equilibrium per cycle occurs. The excursion will be larger in magnitude than in the 50:50 duty cycle, and the result would be the observed single emission pulse of larger amplitude following the onset of the 15% parts of the waveform. This situation would occur regardless of the actual voltage experienced by the panel during the 85% part of the cycle.

The frequency dependence of the results is also explained. At high frequencies the 0.6 msec required by the present devices to reach full emission is not available. Instead the emission only grows to part of the maximum value. As the frequency is raised, however, the number of partial emissions per second is increased. These two effects counterbalance until, above 15 kHz the emission per pulse is so weak that the increased repetition rate no longer compensates and the output falls off. At low frequencies the growth of emission to a peak after 0.6 msec followed by a decay may be completed before the end of the applied voltage pulse. The total emission would in this case be simply determined by the pulse repetition rate. This linear emission fall off with reduced frequency was in fact observed.

With no applied field the distribution of occupied traps takes on its field-free form. Under sinusoidal or pulse excitation, parts of the ZnS films and adjacent layers become depopulated during a fraction of each voltage cycle and the population of deeper levels slowly adjusts to a value determined by the average occupation of the shallow levels. This operational equilibrium is different from the field-free case, and the transition from one situation to the other is believed to be responsible for the gradual build-up of emission during the first few cycles of voltage which is frequently described in the literature (26-28).

Conclusion

The experiments that have been reported have shown that the use of insulating layers on both sides of a ZnS:Mn film can lead to bright and relatively efficient electroluminescence (700 ft-L at 1 lpw). It is considered that the emission results from an impact excitation process which occurs when the various energy states in the device are disturbed from equilibrium under high-field conditions. It is also believed that the present efficient emission occurs in a regime of electric field in which the ZnS layer would normally experience breakdown if placed in direct contact with a metal electrode.

The proposed mechanism for the EL provides a consistent and straightforward explanation of the present observations, and it can also be shown to provide a simple alternative explanation of several other experiments which are described in the literature. The mechanism is amenable to experimental verification although the procedures are complex because of the small range of applied voltage during which the panels pass from 1 to 700 ft-L emission. A study of the time-dependence of the repopulation effects and their relation to ambient temperature, field, and illumination will clarify the situation.

The critical nature of the film deposition parameters required to produce efficient devices can be attributed to two factors. First, the required electrical properties of the ZnS layer are strongly dependent on the degree of crystallinity and the structural properties of the film. Second, the incorporation of high concentrations of Mn without serious disruption of the film must be achieved.

The brightness, efficiency, and ageing characteristics of the ZnS devices all appear to be related to the successful incorporation of Mn without film disruption. The present films improved in these characteristics as the Mn content in the source material was increased from 0.04 to 2.0 w/o. There is every reason to believe that further improvements will be possible when more sophisticated deposition techniques are used.

Acknowledgment

The authors would like to thank Mr. W. Carkner for his assistance in the fabrication of the ZnS devices and the Bowmar Instrument Corporation for permission to publish information contained in the First and Second Annual Research Reports on DIR Grant E54. The work was carried out as part of a research program jointly supported by Bowmar Canada Limited and the Defence Industrial Research Program operated by the Canadian Defence Research Board.

Technical Notes

(Cd,Zn)S Photoconductive Sintered Layer

Miyoshi Haradome and Hirokuni Kawashima

The Physical Science Laboratories, Nihon University at Narashino, Chiba-ken, Japan

As is widely known, light-sensitive sintered layers of CdS show a remarkable fall-off of photoconductive sensitivity in the spectral region below 520 mμ, because of surface recombination of carriers. In order to remove such a fault, one of the authors (1) previously examined the preparation of (Cd,Zn)S solid solution layers in the way similar to that for usual CdS layers (2). It must be noted, however, that such a conventional method was unsuccessful in producing satisfactorily adherent and uniform layers of recrystallized (Cd, Zn)S, especially in the Zn-rich region.

In the present study, the authors have succeeded in developing a new sintering technique for the (Cd, Zn)S, layer by making use of a high-temperature, high-pressure argon atmosphere and of NaCl solvent flux. The resultant product exhibits high sensitivity even in the spectral region from 520 down to 400 mμ.

Experimental

The sintering apparatus utilized in this work is shown schematically in Fig. 1. In a stainless steel tube an impurity protector and sample chamber both made of quartz are enclosed, and the whole system is put in a SiC resistance furnace for heat-treatment. The sample chamber is loosely sealed with a quartz cap. Fluorescent powder of (Cd, Zn)S solid solution activated with a small amount of Ag or Cu (product of the Dai-Nippon Paint Company, Ltd.) was used as starting material. A mixture of 3×10^{-2} mole of the fluorescent powder and 9×10^{-3} mole of high grade NaCl was blended with 3 cc of distilled water and was ground in a quartz mixer for 5 hr. This suspension was sprayed on the surface of high-purity alumina plates by a quartz spray-gun. The sprayed layer was dried for 2 hr at 80°C and was then enclosed in the stainless steel tube which was evacuated to 10^{-4} Torr. After introducing high-purity argon gas (oxygen content of 0.2 ppm) into the tube, the heat-treatment for sintering was started. It took about 20 min to raise the temperature to 1100°C, at which the sintering was most appropriately conducted.

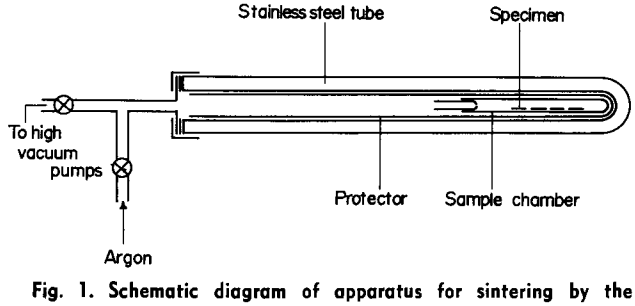

Fig. 1. Schematic diagram of apparatus for sintering by the high-pressure sintering method.

Results and Discussions

From grain size observation with an optical microscope, the average grain size of the (Cd, Zn)S solid solution layers prepared in the pressure range above 30 atm has been found to indicate a monotonic increase with increasing sintering temperature (1000°-1150°C) and time (0-100 min). It must be noted that the evaporation of the specimen takes place under pressures below 30 atm. It may be emphasized, in addition, that x-ray diffraction data indicate no change in composition of (Cd, Zn)S solid solutions if the sintering is done at temperatures below 1150°C, under pressures exceeding 30 atm, and within times less than 100 min.

Figure 2 gives the sintering temperature dependence of the photocurrent and dark current produced in

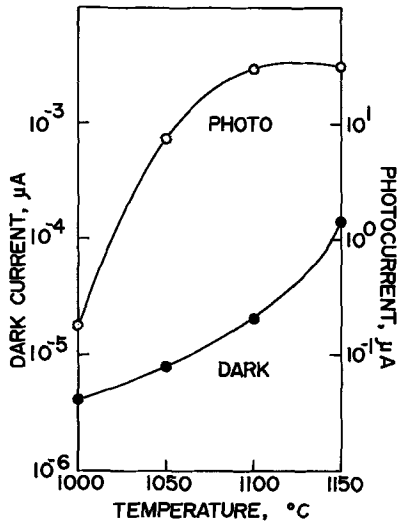

Fig. 2. Sintering temperature dependence of the photocurrent and dark current for the 30 m/o Zn, sintered for 60 min under 50 atm Ar.

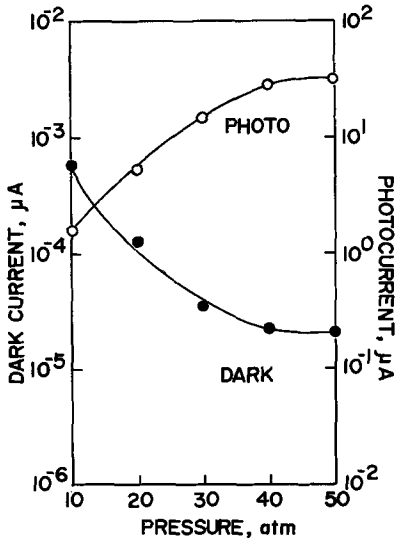

Fig. 3. Pressure dependence of the photocurrent and the dark current for the 30 m/o Zn, sintered for 60 min at 1100°C.

the specimens containing 30 m/o ZnS, while the sintering was done under a pressure of 50 atm for 60 min. A maximum of the photocurrent curve is found at 1100°C, making a sharp contrast to the monotonic increase of dark current. In Fig. 3 is presented the pressure dependence of the photocurrent and dark current for the specimen containing 30 m/o Zn when heat treated at 1100°C for 60 min. With increasing pressure, the photocurrent increases remarkably, while the dark current decreases, both showing leveling-off in the high-pressure range above 40 atm. The maximum position in the photoconductivity spectrum for a number of (Cd, Zn)S:Ag, Cl layers sintered at 1100°C for 60 min under 50 atm is shown schematically in Fig. 4. The shift of the photoconductivity peak with change in composition is almost parallel to that of the emission peak (3), which may suggest that composition of those (Cd, Zn)S layers has not changed during the heat-treatment. In Fig. 5, the decay time of the photocurrent when the same specimens were exposed to 100 Lx radiation is plotted against the composition. For the

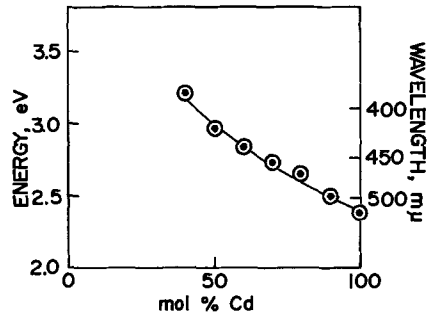

Fig. 4. Maximum of the photoconductivity spectrum of the (Cd,Zn)S:Ag, Cl solid solution sintered layers.

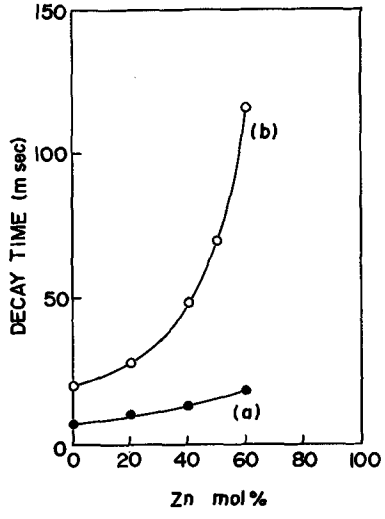

Fig. 5. Decay time of the photocurrent for the (Cd,Zn)S:Ag,Cl solid solution sintered layers. (a): high-pressure sintering method; (b) conventional sintering method.

sake of comparison, the behavior of specimens prepared by the conventional sintering method (1) is also shown in Fig 5. On the basis of these data, one can conclude that the much shorter decay times exhibited by the layers prepared at high pressures may be ascribed to the presence of fewer grain boundaries, causing less scattering of the photoconductivity carriers. On the other hand, the decay time is found to increase almost linearly with the content of Zn. Through a preliminary investigation of the behavior of thermally stimulated current and decayed thermally stimulated current, such an increase of the decay time has been concluded to arise from the increase of the density and depth of the electron traps.

Further studies, especially of electron and hole traps are being pushed forward and will be published in the not too far distant future.

Manuscript received June 12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

Cd_4SiS_6 and Cd_4SiSe_6, New Ternary Compounds

Synthesis, Photoconductive and Fluorescent Properties

E. Kaldis,[1] L. Krausbauer, and R. Widmer

Laboratories RCA Ltd., Zurich, Switzerland

In the course of a program aimed at the synthesis of new photoconductors and phosphors attempts were made to synthesize ternary cadmium and zinc chalcogenides with silicon and germanium. Accordingly the following systems were examined: Cd-Si-S, Cd-Si-Se, Cd-Si-Te, Zn-Si-S, Zn-Si-Se, Zn-Si-Te, Zn-Ge-S, Zn-Ge-Se, Zn-Ge-Te. Ternary phases could be found only in the first two of these systems. The compounds Zn_2GeS_4 and Zn_2GeSe_4 which have been reported in the literature (1) could not be synthesized.

Since the compound Cd_4GeS_6 had been found to be a good photoconductor (2-5), it could be expected that metal silicon chalcogenides might also show photoconduction. Due to the lighter atomic weight of silicon the peak sensitivity was expected to be at shorter wavelengths than in the corresponding metal germanium chalcogenides (6).

This paper deals with the synthesis, crystal growth, and preliminary measurements of the photoconductivity and fluorescence properties of Cd_4SiS_6 and Cd_4SiSe_6.

Cd_4SiS_6 was synthesized by reacting stoichiometric quantities of cadmium sulfide, silicon, and sulfur (5*N* purity, Light, England) in evacuated quartz tubes. The tube with the well mixed starting materials was put in a furnace with a flat temperature profile and was slowly heated up to 850°C within 2 days. This slow heating rate was necessary to avoid explosions.

Guinier powder diagrams showed that the reaction product was isomorphous to the germanium compound which a new chemical analysis (3) showed to have the formula Cd_4GeS_6. The latter was found to crystallize in the C_c space group with unit cell dimensions $a = 12.303$Å, $b = 7.056$Å, $c = 12.335$Å, and $\beta = 110°02'$ (4). The x-ray diagrams of Cd_4SiS_6 showed only the lines corresponding to those of Cd_4GeS_6. No additional lines could be detected. The angle β for Cd_4SiS_6 was measured with the optical goniometer to $\beta = 110°30'$.

The Cd_4SiS_6 powder synthesized as described above looks very homogeneous but has a light olive green color, although the fundamental absorption edge of the compound lies at 4300Å (see below). Material synthesized in the presence of iodine or crystals grown by iodine transport have a lemon yellow color. Also, the powder synthesied in the presence of excess of sulfur is yellow. All these materials have the same x-ray diagram. The yellow color could not be restored by adding small amounts of excess cadmium sulfide, silicon, or a mixture of silicon and sulfur to the starting material. Yellow crystals of Cd_4SiS_6 heated at 1250°C in a small evacuated quartz ampoule become greenish. In the presence of a partial sulfur pressure of 1 atm the color of the crystals remains yellow.

It is possible that the green color is the result of a slight decomposition taking place only at the surface of the powder. At 1250°C this decomposition can obviously be suppressed by 1 atm of sulfur pressure. A partial sulfur pressure which is probably high enough to prevent decomposition is also built up during the iodine transport.

Cd_4SiSe_6 was synthesized from the elements in the presence of iodine at 800°C in an evacuated quartz ampoule.

Crystals of Cd_4SiS_6 with dimensions up to 10 x 5 x 6 mm^3 were grown by iodine transport at 800°C in a closed system. The iodine concentration in the ampoules was 4 mg/cm^3. Using values of undercooling (4) between 5° and 30°C and growth times of two to ten days crystals with varying dimensions and highly reflecting natural faces could be grown.

Doped crystals were grown by mixing the starting materials with the dopant in the form of the metal iodides.

Black crystals of Cd_4SiSe_6 with dimensions of a few millimeters were grown by iodine transport at 800°C.

The optical measurements were made with conventional apparatus. For photoconductivity and absorption measurements in the visible part of the spectrum a xenon high-pressure lamp was used as light source in connection with a Leiss single prism monochromator and a Zeiss double prism monochromator, respectively. In the near uv a hydrogen lamp was used. A high impedance Keithley micromicroammeter in connection with a Moseley X-Y-recorder was used to register photocurrent *vs.* wavelength and current-voltage curves.

Reflectivity measurements were carried out with a tungsten or hydrogen lamp, a Bausch and Lomb grating monochromator, and a RCA 1P28 phototube as detector.

For luminescence measurements the samples were irradiated with the 3660Å-Hg-line, the luminescent light was focussed onto the entrance slit of a single prism Leiss monochromator. An RCA 7265 photomultiplier was used as detector of the light at the exit slit of the monochromator. The output of the photomultiplier was fed into a Varian chart recorder, the speed of which was synchronized with the prism rotation of the monochromator. The curves so obtained were corrected for the multiplier sensitivity and the dispersion of the prism to give the true spectrum in arbitrary units.

It was found that as-grown crystals were covered with an insulating surface layer. To remove this surface layer the crystals were washed immediately after they had been taken out of the ampoule, first with hot hexane to dissolve silicon iodide and then with alcohol to dissolve cadmium iodide. In cases where this treatment was not successful the insulating layer could be removed mechanically by grinding and polishing the crystal surface. After these treatments evaporated contacts of silver, cadmium, indium, gallium, and aluminum were found to be ohmic and to give the same wavelength dependence of the photocurrent. Throughout this work indium electrodes were used unless otherwise stated. The electrodes were evaporated in a vacuum of $5 \cdot 10^{-5}$ Torr, the electrode separation d being 0.3 to 0.8 mm.

Annealing experiments were made in air and hydrogen at different temperatures. For each experiment the crystals were kept at the annealing temperature for 30 min. All dark and photocurrent measurements were done at room temperature.

Results

Undoped Cd_4SiS_6 crystals without any heat-treatment show good photoconductive properties. Measurements with a thermoelectric tester (7) showed n-type conductivity, both in the dark and under illumination. The crystals have a dark conductivity between 10^{-12} and 10^{-10} ohm-cm^{-1}. A typical wavelength dependence of the photoconduction is shown in Fig. 1. There

[1] Present address: Laboratorium für Festkörperphysik, ETH, Zürich, Switzerland.

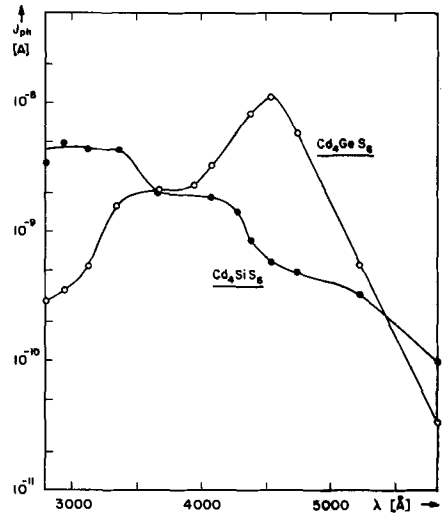

Fig. 1. Wavelength dependence of the photocurrent for unannealed Cd_4SiS_6 and Cd_4GeS_6 crystals. The photocurrent is corrected for equal numbers of incident light quanta under the assumption that $J_{Ph} \alpha B$ (B = light intensity).

are three regions in the response curve: All Cd_4SiS_6 crystals show a photoconductivity shoulder around 5000Å, another one at about 4200Å, and a third one around 3300Å. Typical values for the photoconductivity of Cd_4SiS_6 crystals at 4200Å with a light intensity of $N = 10^{12}$ quanta/cm^2 sec lie between 10^{-6} ohm-cm^{-1} and 10^{-7} ohm-cm^{-1}. At 3000Å and for the same light intensity the photoconductivity values vary between 10^{-7} and 10^{-5} ohm-cm^{-1}. The ratio of the photoconductivity to the dark conductivity lies between 10^3 and 10^4. The sensitivity defined by Bube (8) as $S = \Sigma_{Ph} \cdot d^2$/absorbed power ($\Sigma_{Ph} = I_{Ph}/U$, U = applied voltage) reaches values of 10^{-2} mho cm^2/w, which is of the same order of magnitude as the values for cadmium sulfide and Cd_4GeS_6. The Cd_4SiS_6 crystals show a gain of several hundreds for a field strength of 10^3 v/cm. The response time of these crytals is of the order of a few seconds for a light intensity of $N = 10^{12}$ quanta/cm^2 sec. It increases with decreasing light intensity.

Absorption measurements on Cd_4SiS_6 crystals showed the fundamental optical absorption edge to lie at about 4300Å. The absorption coefficient shows an exponential increase for wavelengths shorter than 4550Å and reaches a value of $k = 5 \cdot 10^3$ cm^{-1} for λ = 4360Å. We conclude therefore that the photoconductivity shoulder around 4200Å corresponds to the fundamental optical absorption edge and the shoulder around 5000Å is due to impurity photoconduction.

The question arises as to the origin of the third shoulder in the photoconductivity response around 3200Å. To our knowledge so far an increase in photoconductivity for energies higher than the fundamental absorption edge has only been observed for GaP (9). CdS and especially Cd_4GeS_6 do not show such an effect. (The fundamental absorption edge of Cd_4GeS_6 lies at about 4700Å). The increase in photoconductivity in the uv for Cd_4SiS_6 could be due to a change in the physical properties of Cd_4SiS_6 (absorption coefficient, mobility, carrier lifetime a.s.o.) as a function of light frequency or intensity, as is invoked to explain the anomalous photoresponse in GaP (9), or it could be due to a surface effect caused either by surface states, or by a surface of different chemical composition on top of the Cd_4SiS_6 crystals.

Reflectivity measurements have been made on a Cd_4SiS_6 and a Cd_4GeS_6 crystal from λ = 5000Å to 2200Å (Fig. 2). Both curves show a maximum at the fundamental optical absorption edge and a weak peak around 3400Å in the case of Cd_4SiS_6 and around 3300Å in the case of Cd_4GeS_6. Similar results are known for GaP (10). Therefore the uv photoresponse in Cd_4SiS_6 could be due to strong direct optical transitions similar to the explanation presented by Nelson *et al.* for GaP (9).

It might be worthwhile mentioning that the photoconductivity response for Cd_4GeS_6 also shows a shoulder for energies higher than the fundamental absorption edge (Fig. 1). Therefore similar transitions might occur in Cd_4GeS_6, but different surface states in this material might cause a decrease in the carrier lifetime and by this a decrease in photoconductivity.

It is generally known that silicon-sulfur compounds hydrolyze easily (11-13). A colorless insulating layer has been found on the surface of the as-grown crystals. Although the greater part of this layer is removed by chemical or mechanical means, in order to get ohmic contacts on the crystal, it is probable that a thin layer still exists on the surface of the crystals. However, this layer must inhibit further hydrolysis because the photoconductive properties of as-grown and ground Cd_4SiS_6 crystals do not change after a treatment with hot water (100°C, for 30 min). An amorphous, hydrolyzed surface layer on the Cd_4SiS_6 crystals could be responsible, either alone or in conjunction with the Cd_4SiS_6 lattice, for the observed high uv-sensitivity if one assumes a high absorption coefficient of this surface layer for wavelengths between 3000 and 4000Å. Bradford *et al.* (14) have found a fairly high absorption coefficient for SiO_{2-x} layers depending on the amount of oxygen and the degree of disorder of the layers. The higher the silicon to oxygen ratio or degree of disorder the higher the absorption coefficient around 3000Å was found to be.

Some indication for such an explanation of the uv photoconductivity can be found in annealing experiments in air and hydrogen. Annealing Cd_4SiS_6 crystals at 300°C in air, *e.g.*, decreases the uv sensitivity considerably whereas it is unchanged or increased for crystals annealed in hydrogen. In the first case the decrease of the uv sensitivity could be the result of a decrease of the silicon to oxygen ratio due to a partial surface oxidation which in its turn might lead to a decrease of the absorption coefficient. On the other hand annealing in hydrogen is not expected to decrease the silicon to oxygen ratio.

So far no final decision can be made about the origin of the uv photosensitivity of untreated Cd_4SiS_6 crystals. Further experiments are necessary to show if the uv photoresponse in Cd_4SiS_6 has a similar origin to that in GaP or to give direct evidence for the ex-

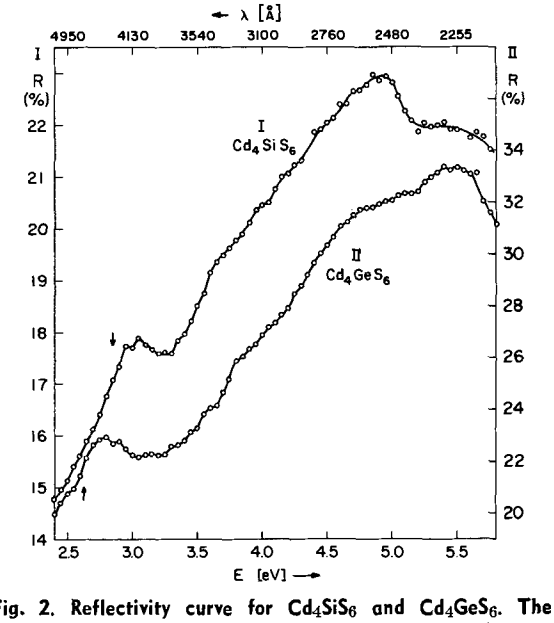

Fig. 2. Reflectivity curve for Cd_4SiS_6 and Cd_4GeS_6. The arrows indicate the approximate positions of the fundamental optical absorption edge.
