The cell and electrodes were cleaned by rinsing in boiling 1N HCl, and rinsing at least twice with distilled water and dried under flowing chlorine at 800°C for several hours. The cell was then cooled and solvent (2 moles) added to the crucible. After melt preparation was complete, solute was added and cell potentials were measured as a function of temperature, the usual sequence being intermediate, high, and low temperatures. Linearity and reproducibility of the cell emf as a function of temperature was taken as one indication of reversible behavior. Nickel electrodes were left in the melt only long enough for steady potentials to be obtained, usually a few minutes.

After each potential measurement a melt sample was taken by means of a flamed 6 mm Vycor tube. Nickel was determined spectrophotometrically in aqueous solution as the tetracyano complex (7). Aqueous solutions of known concentration of NiCl<sub>2</sub> were used to establish the absorbance curve. The method of least squares was applied to determine the best relationship between absorbance and concentration for 18 known samples. The standard deviation,  $\sigma$ , from the least squares line was  $\sigma = 4 \times 10^{-3}$  absorbance units. Bath samples were usually diluted to give absorbance values between 0.200 and 0.700. Thus, the limit of error (99% confidence level) of bath concentrations calculated on the basis of one sample is taken to be  $2.6 \sigma = 0.010$  absorbance units or approximately  $\pm 3\%$  of bath concentration for intermediate absorbance values. Usually three potential measurements and three samples were taken at each nominal concentration. The analytical data were averaged to establish the bath concentration.

Solute additions were made both electrolytically and as the dry powder. A positive pressure of chlorine or inert gas was maintained in the cell at all times and care was taken to open the cell to air for only minimal lengths of time in carrying out changes of electrodes, solute additions, and sampling operations.

Some modifications were made in equipment or procedure as the work progressed. For the most part these were aimed at decreasing the possibility of atmospheric contamination of the melt during cell operation: (a) mechanical stirring (Ni cells only) using a Teflon bearing at the cell top was discontinued after cell III; (b) provision of an air lock at the top of the cell for sampling was provided after cell III; (c) in the initial experiment with KCl the metal electrode compartment was changed after each potential measurement. Subsequently, this compartment was changed as infrequently as possible. Equalization of melt concentration inside and outside the metal electrode compartment was achieved by purging with dry argon and allowing the compartment to refill.

## Results

*The AgCl formation cell.*—The results from work on the AgCl formation cells A and B are illustrated in

Fig. 2, 3, and 4. The cell emf's have been corrected for thermoelectric effects.

Polarization of the chlorine electrodes (Fig. 2) as a test of electrode reversibility was carried out by passing current between the chlorine electrode and an auxiliary graphite electrode. Potential differences were measured between the chlorine electrode and a non-current-carrying Ag electrode (design C, Fig. 1). Only resistive polarization was evident, and hysteresis ef-

Fig. 2. Polarization data for two chlorine electrodes. Porous electrode design: ●, increasing positive current, ○, decreasing positive current. Nonporous electrode design: ● decreasing positive current.

Fig. 3. Cell voltage,  $E$ , for AgCl formation cell A; Ag electrode housed in protection tube C, ●, tube B, ●, tube A, ○. The solid line represents the data of Senderoff and Mellors.

Fig. 4. Cell voltage,  $E$ , for AgCl formation cell B; Ag electrode housed in protection tube C, ●, tubes D or E, □. The solid line represents the data of Senderoff and Mellors.

fects were absent to within ±1 mv. Potential differences between unpolarized chlorine electrodes of different design in the same cell were generally less than 1 mv.; short term (order of seconds) fluctuations were of the order of 0.1 mv. No dependence of chlorine electrode potential on design could be established.

The flow rate of chlorine was varied by factors up to 30 to 1, but the effect upon the emf was always less than 1 mv. Termination of chlorine flow was made apparent within minutes by a decrease in cell emf; however, the cell emf's regained their initial values within minutes after resumption of Cl<sub>2</sub> flow. Intermediate Cl<sub>2</sub> flow rates were adopted as standard.

The effect on cell emf of the degree of shielding of the Ag electrode is illustrated in Fig. 3. Cells utilizing Ag electrodes housed in the open well protection tube (A, Fig. 1) gave emf's which were scattered, and on the average, less than those observed by Senderoff and Mellors (8) whereas cells utilizing Ag electrodes housed in constricted or "scavenged" (B, C, Fig. 1) tubes were found to yield cell emf's more in agreement with Senderoff and Mellors' data.

The data in Fig. 4 were obtained from a freshly prepared cell (cell B) utilizing scavenged or capillary (D and E, Fig. 1) protection tubes. The agreement with Senderoff and Mellors' data is excellent.

*The cells Ni | NiCl<sub>2</sub>, MCl | Cl<sub>2</sub>, C.*—Current reversibility of the chlorine electrodes used in each cell was verified; curves similar to those shown in Fig. 2 resulted in all cases. Potential differences between chlorine electrodes of different design in the same cell were near 1 mv, or less, with short term fluctuations of the order of 0.1 mv. Current reversibility of the Ni electrodes was verified in cells II through VI at NiCl<sub>2</sub> concentrations near  $N = 10^{-2}$ . An example of these tests is shown in Fig. 5.

The data from each cell were plotted as cell emf,  $E$ , vs. temperature at each concentration. From these curves, emf's were read at a series of fixed temperatures to prepare the graphs shown in Fig. 6. Below  $N = 10^{-2}$ ,  $E$  at constant temperatures may be represented by

$$E = a - b \log N$$

where  $b = 2.303 RT/2F$ . The solid straight lines in Fig. 6 were drawn with slopes  $b$  below  $N = 10^{-2}$  and the intercept  $a$  was chosen to give the best fit with the data points for  $N < 10^{-2}$ . Table I gives the values of the constants  $a$  and the average deviations of the data

points from the straight lines in the low concentration range.

An attempt was made to obtain cell data at  $N < 10^{-4}$ ; however, stable emf's (i.e., short-term fluctuations in  $E$  less than 1 mv) were not achieved in this concentration range. Furthermore, the variation of  $E$  with temperature was usually nonlinear, uncertainties in concentration were large, and the values of  $E$  were larger than would be predicted on the basis of the data at higher concentrations. These effects are attributed to the appreciable solubility of chlorine in these melts and to the presence of impurities, e.g., oxygen, in the cell which seriously effect the nickel electrode potential when the exchange current for the desired reaction is low.

For NaCl, KCl, and NaCl-KCl melts, the electrolyte containers and glass cell components were observed to suffer only slight surface etching during experiments lasting as long as seven days. In the case of LiCl, rapid etching of glass components was noted for melts prepared by both techniques mentioned above. However, the rate of attack was observed to decrease as NiCl<sub>2</sub> concentration increased, becoming insignificant as solute concentration passed  $10^{-4}$  mole fraction. Evidently, oxygen was removed by precipitation as NiO (9, 10).

The thermodynamic functions for the cell reaction

have been calculated on the basis of the definitions

Table I. Values of the constants  $a$

	$a$ , °C			Avg dev., mv		
	700	800	900	700°C	800°C	900°C
LiCl	0.798	0.759		2	2	
NaCl		0.864	0.824	5	5	8
KCl		0.982		3	3	6
1:1 NaCl-KCl	0.973	0.930	0.946	2	4	

$$\lim_{N \rightarrow 1} \frac{a}{N} = 1$$

$$a = N\gamma$$

where  $a$ ,  $N$ , and  $\gamma$  refer to the solute,  $\text{NiCl}_2$ . Thus, the standard and reference states of the solute are chosen as the pure liquid with the properties of the pure liquid at the temperature of the experiment. The partial molar Gibbs function of mixing and the partial molar enthalpy and entropy of mixing are given by

$$\bar{G} = -nFE - \Delta G^\circ$$

$$\bar{H} = \Delta H - \Delta H^\circ$$

$$\bar{S} = nF \left( \frac{\partial E}{\partial T} \right)_P - \Delta S^\circ$$

where  $\Delta G^\circ$ ,  $\Delta H^\circ$ ,  $\Delta S^\circ$  are the standard changes for reaction [1]. The excess free energy of mixing is given by

$$\bar{G}^E \equiv \bar{G} - RT \ln N = RT \ln \gamma$$

Equations describing the temperature dependence of  $\Delta G^\circ$  and  $\Delta H^\circ$  have been derived with the aid of the thermochemical data tabulated by Wicks and Block (11) and Kubaschewsky and Evans (12).

$$\Delta H^\circ = 6.14 \times 10^4 + 9.35T$$

$$- 1.05 \times 10^{-3}T^2 - 0.68 \times 10^5T^{-1}$$

$$\Delta G^\circ = 6.14 \times 10^4 + 9.19T - 2.15T \log_{10}T$$

$$+ 1.05 \times 10^{-3}T^2 - 0.34 \times 10^5T^{-1}$$

Calculated values of  $\Delta G^\circ$ ,  $\Delta H^\circ$ , and  $\Delta S^\circ$  at selected temperatures are listed in Table II. The curves of Fig. 6 have been extrapolated to  $N = 1$ ,  $E^\circ$ , on the basis of the values of  $\Delta G^\circ$  at the temperature of the experiment. These values of  $E^\circ$  are shown in Fig. 6. Values of  $E^\circ$  calculated on the basis of the earlier compilation of Hamer *et al.* (13) lie more than 100 mv higher than those used here and are in conflict with the present cell data.

Table II. Calculated values of  $\Delta H^\circ$ ,  $\Delta G^\circ$ ,  $\Delta S^\circ$ 

	650°C	700°C	750°C	800°C	850°C	900°C
$\Delta H^\circ$ (kcal)	-53.8	-53.4	-53.0	-52.7	-52.3	-52.0
$\Delta G^\circ$ (kcal)	-34.7	-33.6	-32.7	-31.6	-30.7	-29.7
$\Delta S^\circ$ (eu)	-20.7	-20.3	-19.8	-19.7	-19.2	-19.0
$E^\circ$ (v)	0.756	0.727	0.709	0.685	0.675	0.644

Emf values were read at selected concentrations from the curves of Fig. 6 and used to calculate the values of the functions given in the Tables III through VI. Values of  $\bar{S}$  given in tables are smoothed values based on graphs of  $\Delta S$  as a function of concentration.

*Ag reference electrodes.*—The Ag reference electrodes incorporated in cells III, IV, and VI are described in Table VII.

$E'_{\text{Ag}}$  was found to be independent of  $N_{\text{NiCl}_2}$  up to  $N_{\text{NiCl}_2} = 10^{-2}$ . Values of  $E'_{\text{Ag}}$  given in the table are average values, corrected for thermoelectric emfs, taken over the duration of the experiment  $E'_{\text{Ag}} - E_{\text{Ag}}$ , at  $\text{NiCl}_2$  concentrations up to  $N_{\text{NiCl}_2} = 10^{-2}$ . The maximum limits of deviation from the averages are given. Values of  $\Delta E'$ , that is,  $E'_{\text{Ag}} - E_{\text{Ag}}$ , were detectable at higher  $\text{NiCl}_2$  concentrations; these values are plotted in Fig. 7.

### Discussion

Various aspects of the behavior of nickel electrodes in fused media have been studied by other investigators (14-19). Equilibrium electrode potentials in 1:1 NaCl-KCl have been measured by Flengas and Ingrahm (14, 15) and some of their data may be compared with the present results. Flengas and Ingrahm used the reference electrode

where the double line represents an asbestos fiber, to measure the potential of the Ni electrode as a function of  $\text{NiCl}_2$  concentration up to  $N = 6.2 \times 10^{-2}$  at 705°C in 1:1 NaCl-KCl. In an independent experiment the potential of the reference electrode was compared with that of the chlorine electrode in the same solvent. Thus, potential differences between nickel and chlo-

rine electrodes may be calculated from Flengas and Ingrahm's data. Corrections for thermoelectric effects were included in a later publication (15); however, the polarity of the stated correction for a Ni, Ni-Ag, Pt combination is opposite that expected on the basis of the tabulated (20) thermal emfs of various elements relative to platinum. Flengas and Ingrahm's data without thermoelectric corrections has been included in Fig. 6. It is believed that proper correction for thermoelectric effects would bring the two sets of data into agreement at concentrations near  $10^{-2}$  mole fraction.

Flengas and Ingrahm observed a non-Nernstian slope, 0.107 as opposed to an expected 0.097, in their work with the Ni electrode. Similar effects have been reported by Maricle and Hume (16) in polarographic work and a tendency toward high emf values at low concentrations was observed in the present work. The authors believe that this tendency is due to a mixed potential at the nickel electrode arising from the presence of small amounts of oxygen in the cell. Attention is called to the difference in the data for cells I and VI, Fig. 6, both involving KCl solvent. Changes in experimental procedures decreased the possibility of oxygen contamination of the cell and resulted in decreased values of cell emf at low NiCl<sub>2</sub> concentrations.

Yang and Hudson (21) reported on the error involved in calculating the emf for a cell containing the chlorine electrode from that of a cell in which the chlorine electrode was replaced by the Ag|AgCl, MCl|| reference electrode. Here we have shown, by direct measurement, that the potential difference between the reference electrode and the chlorine electrode is constant for  $N_{\text{NiCl}_2} < 10^{-2}$  (Fig. 7). Thus, potentials arising from differences in chloride ion activity on either side of the membrane and from the membrane itself are constant at sufficiently low NiCl<sub>2</sub>

concentration. If this result is taken to be valid generally, the Ag | AgCl, MCl || reference electrode may be reliably used in place of the chlorine electrode to study, at low concentrations, solutes such as FeCl<sub>2</sub>.

It is also of importance that the data of Fig. 7 indicate no measurable change of the chlorine electrode potential with solute concentration up to  $2 \times 10^{-2}$  mole fraction solute unless there are compensating effects that render  $\Delta E'$  negligible below this concentration.

The measure of solute deviation from ideal behavior, on the basis of the chosen standard and reference states, is given by the excess partial molar free energy,  $\bar{G}^E = RT \ln \gamma$ . The magnitude of  $\bar{G}^E$  at any fixed solute concentration varies with solvent in the order KCl > NaCl-KCl > NaCl > LiCl which follows the order established in numerous previous studies which include the solutes PbCl<sub>2</sub>, CdCl<sub>2</sub>, ZnCl<sub>2</sub>, MgCl<sub>2</sub>, CeCl<sub>3</sub>, FeCl<sub>2</sub>, BeCl<sub>2</sub>, in the alkali chlorides (22, 24). The order of variation of  $\bar{G}^E$  with solvent is commonly explained on the basis of a competition for anions between the solute and solvent cations. The solvent cation of largest charge-to-size ratio, Li<sup>+</sup>, is considered to be the most effective competitor for chloride ions, and its presence results in the smallest degree of bonding between the solute cations and solvent anions.

Table VII. Ag reference electrodes

Cell	$N_{\text{AgCl}}$	Solvent	$E'_{\text{Ag}}$	
			700°C	800°C
III	$6.6 \times 10^{-2}$	1:1 NaCl-KCl	$1.063 \pm 6$ mv	
IV	$7.3 \times 10^{-2}$	LiCl	$0.978 \pm 2$ mv	
VI	$5.5 \times 10^{-2}$	KCl		$1.136 \pm 4$ mv

Fig. 7. Values of  $\Delta E' = E'_{\text{Ag}} - E_{\text{Ag}}$  vs.  $\log N_{\text{NiCl}_2}$ . Sizes of the symbols representing the data points were chosen to reflect the limits of deviation given in Table VII. Symbols are related to cells and solvents as in Fig. 6.

A comparison of  $\overline{G}^E$  for  $\text{NiCl}_2$  and  $\text{MgCl}_2$  in  $\text{KCl}$  and in  $\text{NaCl-KCl}$  mixture is of interest (Fig. 8) because of the similarity in the ionic size of nickel and magnesium ions. The crystal radii of hexacoordinated  $\text{Ni}^{2+}$  and  $\text{Mg}^{2+}$  ions are 0.69 and 0.66 Å, respectively (24). In Fig. 8 our results for  $\text{NiCl}_2$  are compared with those of Neil and Clark (25) for  $\text{MgCl}_2$ . Except at concentrations below  $N = 0.1$ , where  $\text{NiCl}_2$  is significantly less ideal, the two solutes exhibit about the same departure from ideality. There is good evidence (25-29) that both nickel and magnesium exist as chloro-complexes in the alkali chloride melts; this is likely a major cause of nonideal behavior both with respect to the heat of mixing and the entropy of mixing. We return to this point later in connection with the entropy of mixing.

In Fig. 9 the variation of the partial molar entropy of mixing of  $\text{NiCl}_2$ ,  $\overline{S}$ , is shown as a function of  $\log N_{\text{NiCl}_2}$ , for all of the solvents investigated. If the solutions of  $\text{NiCl}_2$  in the alkali halides are ideal, then according to Raoult's law, we can assert that  $\overline{S}$  follows the equation

$$\overline{S} = [\partial \Delta S_{\text{mix}} / \partial n_{\text{NiCl}_2}]_{T,p,n_{\text{MCl}}} = -R \ln N_{\text{NiCl}_2} \quad [2]$$

where  $\Delta S_{\text{mix}}$  is the ideal entropy of mixing and  $n$  is the number of moles. The ideal curve is shown as the solid

Fig. 8. Excess partial molar free energy,  $\overline{G}^E$ , vs. mole fraction for the solutes  $\text{MgCl}_2$ ,  $\nabla$ ,  $\nabla$ , and  $\text{NiCl}_2$ ,  $\circ$ ,  $\circ$  in the indicated solvents at  $800^\circ\text{C}$ . The  $\text{MgCl}_2$  data are those of Neil.

Fig. 9. Partial molar entropy of mixing for  $\text{NiCl}_2$ ,  $\overline{S}$ , as a function of  $\log N_{\text{NiCl}_2}$ , compared with the value predicted on the basis of the Temkin model. Symbols are related to cells and solvents as in Fig. 6.

line in Fig. 9. The deviations from ideality are not severe, probably lying within the experimental error in the case of the  $\text{LiCl}$  solutions. Deviation is most pronounced in  $\text{KCl}$  solutions, with  $\text{NaCl}$  and  $\text{NaCl-KCl}$  solutions intermediate.

Several causes for nonideal mixing suggest themselves and merit comment. First there is the excess entropy of mixing, present even in the case of perfect random mixing, which derives from the temperature coefficients of the intermolecular interaction energies. This is usually small, and in any case can only be found empirically. In the absence of specific chemical interactions, e.g., complex formation, it may be shown that incorporation of cation vacancies to balance the excess charge of the  $\text{Ni}^{2+}$  ion and maintain a pseudo-lattice structure leads to nonideality. The degree of departure from ideality depends on the degree of association between  $\text{Ni}^{2+}$  and the vacancy. The formation of a complex also leads to a deviation from [2] as shown below; in addition, vacancy incorporation may also occur together with complex formation, with the possibility of vacancy association, so that the functional dependence of  $\overline{S}$  on  $N_{\text{NiCl}_2}$  may be extremely complicated even if simple models are used for the statistical calculation of the configurational entropy.

Lattice models for the mixing of liquid  $\text{NiCl}_2$  with a liquid alkali halide (in which the formation of halo-complexes is not considered) have been reviewed (22, 30), and lead to the following results:

(a) Temkin model:  $\overline{S} = -R \ln N$ ; (b) vacancy model:  $\overline{S} = -2R \ln N'$ ; (c) associated vacancy model

$$\overline{S} = -R[-N'_s + \ln N' - (N'^2_s/Z) \ln 2]$$

where  $N = N_{\text{NiCl}_2} = n_{\text{Ni}} / (n_{\text{Ni}} + n_s)$ ,  $N' = 2n_{\text{Ni}} / (2n_{\text{Ni}} + n_s)$ ,  $N'_s = 1 - N'$ , with  $n_{\text{Ni}}$  and  $n_s$  representing the number of moles of  $\text{NiCl}_2$  and the number of moles of the alkali halide, respectively, and  $Z$  is the number of nearest cation sites surrounding a cation site. We take  $Z = 4$  for molten alkali halides (31).

In each case the assumption has been made that only one anion,  $\text{Cl}^-$ , exists in solution; thus, its mole fraction is unity, and there is no anion contribution to the partial molar configurational entropy. The Temkin entropy is calculated from the number of ways one can distribute a given number of distinguishable sites among a certain number of cations; no provision is made for charge compensation in the case of mixing mono- and divalent cations. The entropy of the Temkin model is that of an ideal mixture. The vacancy model allows for charge compensation by requiring that one vacant site be created per divalent cation, but assumes no association between vacancies and divalent cations. The associated vacancy model, on the other hand, assumes complete association.

In Fig. 10, the observed values of  $\overline{S}$ , plotted against  $\log N_{\text{NiCl}_2}$ , are compared with the predictions of models (b) and (c). The data are clearly inconsistent with the vacancy model, but agree about as well with the associated vacancy model as with the Temkin model. This is not surprising, as the slope of  $\overline{S}$  calculated for the associated vacancy case vs.  $N'$ , is, except at  $N' > 0.2$ , virtually indistinguishable from that of  $\overline{S}$  calculated for the ideal case vs.  $N$ .

We turn next to the effect of complex formation. The absorption spectrum of  $\text{NiCl}_2$ - $\text{KCl}$  solutions bears a close resemblance to that of crystalline  $\text{Cs}_2\text{ZnCl}_4$  in which  $\text{Cs}_2\text{NiCl}_4$  is isomorphically substituted (26), which is good evidence that tetrahedral  $\text{NiCl}_4^{2-}$  complexes exist in the solutions. The same species is also found in  $\text{RbCl}$  and  $\text{CsCl}$  (32). The coordination geometry is evidently considerably altered in  $\text{NaCl}$  and  $\text{LiCl}$  (26, 32, 33). In  $\text{LiCl}$ , for example, an octahedral form appears to exist in equilibrium with the tetrahedral form (33). A pronounced distortion also occurs in  $\text{KCl}$  solutions to which a third electrolyte such as  $\text{ZnCl}_2$  is added (34). One may assume that a high concentration

Fig. 10. Partial molar entropy of mixing for NiCl<sub>2</sub>,  $\bar{S}$ , as a function of  $\log N'_{\text{NiCl}_2}$ , compared with values predicted on the basis of the vacancy and associated vacancy models. Symbols are related to cells and solvents as in Fig. 6.

of NiCl<sub>2</sub> itself would have an effect similar to addition of ZnCl<sub>2</sub> on the coordination geometry of NiCl<sub>4</sub><sup>2-</sup>. For simplicity, we consider only the tetrahedral case, applicable strictly only to NiCl<sub>2</sub> in KCl among the solutions we report on here. Further, we anticipate that, at high NiCl<sub>2</sub> concentration, even in KCl the assumption of tetrahedral coordination about nickel may be subject to later modification; however, here we will assume the tetrahedral complex to be the only nickel species present at all compositions having  $N_{\text{NiCl}_2} < 1/3$ , that is, the composition corresponding to the double salt K<sub>2</sub>NiCl<sub>4</sub>.

Let us consider the mixing to occur in two steps. The first is the formation of the complex liquid salt according to

The second step consists of mixing the complex liquid salt with an excess of KCl to give the desired solution. Let the entropy change for the complex salt formation be  $\Delta S'$ . The partial molar entropy of K<sub>2</sub>NiCl<sub>4</sub> for mixing K<sub>2</sub>NiCl<sub>4</sub> with KCl will then be given by

$$\begin{aligned} \bar{S}_{\text{K}_2\text{NiCl}_4} &= [\partial \Delta S_{\text{mix}} / \partial n_{\text{K}_2\text{NiCl}_4}]_{T,p,n_{\text{KCl}}} \\ &= nF \left( \frac{\partial E}{\partial T} \right)_p - \Delta S^{\circ} - \Delta S' = \bar{S} - \Delta S' \end{aligned}$$

where  $n_{\text{KCl}}$  is the number of moles of KCl in excess of that consumed in forming the double salt. For pure liquid K<sub>2</sub>NiCl<sub>4</sub> (that is, at  $N_{\text{NiCl}_2} = 1/3$ ),  $\bar{S}_{\text{K}_2\text{NiCl}_4}$  is zero, and  $\Delta S'$  is thus just the value of  $\bar{S}$  at  $N_{\text{NiCl}_2} = 1/3$ . According to Fig. 9,  $\Delta S'$  is about 2 cal/mole deg. This is not far from the value for ideal mixing of NiCl<sub>2</sub> and KCl; this may be largely fortuitous, as  $\Delta S'$  certainly must be composed of significant contributions from vibrational frequency changes as the complex ion is formed from NiCl<sub>2</sub>.

For the second step, that is, mixing of K<sub>2</sub>NiCl<sub>4</sub> with more KCl, we may again obtain certain results based on ideal mixing or on pseudolattice models of the kind already discussed.

For ideal mixing,  $\bar{S}_{\text{K}_2\text{NiCl}_4}$  is given by

$$\bar{S}_{\text{K}_2\text{NiCl}_4} = -R \ln N_1$$

where  $N_1$ , the mole fraction of K<sub>2</sub>NiCl<sub>4</sub>, is given by

$$N_1 = n_{\text{Ni}} / (n_s - n_{\text{Ni}}) = N / (1 - 2N)$$

Note that  $N_1$  can exceed unity; if so, however, the solution is then a mixture of K<sub>2</sub>NiCl<sub>4</sub> and NiCl<sub>2</sub>. The partial molar entropy of mixing for NiCl<sub>2</sub>, is, then, according to the assumption of ideal mixing of K<sub>2</sub>NiCl<sub>4</sub> with KCl, given by

$$\bar{S} = \Delta S' - R \ln N_1$$

Fig. 11. Partial molar entropy of mixing for NiCl<sub>2</sub> in KCl as a function of  $\log N_{\text{K}_2\text{NiCl}_4}$ , compared with predictions based on ideal mixing of K<sub>2</sub>NiCl<sub>4</sub> with KCl (curve A) and models (d) and (e) as indicated (see text). See Fig. 6 for symbols.

In Fig. 11, the observed values of  $\bar{S}$  for NiCl<sub>2</sub> in KCl are presented as a function of  $N_1$ , together with the ideal-mixing curve drawn so as to pass through  $\Delta S' = 2.00$  eu at  $N_1 = 1.00$ . The considerable deviation from the ideal curve for  $N_1 > 0.1$  is not unexpected, since both K<sub>2</sub>NiCl<sub>4</sub> and KCl contribute K<sup>+</sup> ions to the mixture.

Next we consider some pseudolattice models for the mixing of K<sub>2</sub>NiCl<sub>4</sub> with KCl, as follows:

(d) The NiCl<sub>4</sub><sup>2-</sup> ion replaces one K<sup>+</sup> ion and four surrounding Cl<sup>-</sup> ions on the KCl pseudolattice. The excess charge of nickel is not compensated by vacancies. This model is physically identical to the Temkin model (a) with, however, the restriction that two additional K<sup>+</sup> ions are added to the lattice for each NiCl<sub>4</sub><sup>2-</sup> ion added. The partial molar entropy of mixing, for K<sub>2</sub>NiCl<sub>4</sub>, is

$$\bar{S}_{\text{K}_2\text{NiCl}_4} = -R \ln N_1 (N_1 + 1)^2 + R \ln (2N_1 + 1)^3$$

This model, although plausible, has some questionable features in addition to the artificiality of assigning lattice positions to ions in the liquid state. The coordination number of K<sup>+</sup> in fused KCl is about four (31), and it may be inferred from the isotropic properties of the liquid that the coordination is tetrahedral, but the Cl-Cl distance in the solvent is probably larger than that in the complex (26, 31) so that the fit of the complex upon the pseudolattice is not very close.

(e) The NiCl<sub>4</sub><sup>2-</sup> is accommodated as in (d), but one vacancy is created on the positive-ion sublattice for each NiCl<sub>4</sub><sup>2-</sup> ion. In this case  $\bar{S}_{\text{K}_2\text{NiCl}_4}$  is given by

$$\bar{S}_{\text{K}_2\text{NiCl}_4} = -2R \ln \frac{8N_1(N_1 + 1)}{(3N_1 + 1)^2}$$

(f) If the vacancies in model (e) are assumed to be completely associated with the complex ions, the result differs, as before, only slightly from that of model (d).

On Fig. 11 are also shown curves for  $\bar{S}$  corresponding to the predictions based on model (d) and (e), with  $\Delta S' = 2.00$  eu. The observed values for KCl are most nearly in accord with model (e). It is noteworthy that all the pseudolattice models investigated predict the observed negative deviation from ideal mixing for  $N > 0.10$ . Comparison of the data for the LiCl, NaCl, and NaCl-KCl solutions (Fig. 9) with the calculated curves of Fig. 11 will show that models (d) and (e) apply about as well to these cases as do models (a) and (c). For clarity, and because of doubt about the actual nature of complexes in these solutions, we have not included these data on Fig. 11.

Although the number of plausible models which may be tested is large (including, for example, those in which complex ions are distributed on the anion sublattice either with or without vacancy-compensation) the examples above suffice to allow us to state some conclusions.

First, the entropy-of-mixing data, which we estimate to be within about  $\pm 2$  eu, is insufficiently accurate, and the calculated entropies insufficiently sensitive to variations in the model, to permit one to select unambiguously the most representative model for each of these solutions.

Second, the Temkin or ideal model for mixing  $\text{NiCl}_2$  with the alkali halides (as well as the associated vacancy model) is satisfactory for  $\text{LiCl}$ , but less so for  $\text{NaCl}$ ,  $\text{KCl}$ , and  $\text{NaCl-KCl}$ , while the vacancy model is unsatisfactory for any of the solutions.

Third, the entropy of mixing in  $\text{KCl}$  is reasonably consistent with the predictions based on a model in which tetrahedral  $\text{NiCl}_4^{2-}$  complex ions and an equal number of positive-ion vacancies are distributed on the cation pseudolattice.

#### Acknowledgments

The initial encouragement by W. J. Kroll to undertake this research, and his continued interest is acknowledged with thanks. The authors are also indebted to D. A. Nissen, K. Stern, R. D. Walker, and Robert Stromatt for useful discussions and information, and to the Tektronix Foundation for valued support.

Manuscript received Nov. 30, 1967; revised manuscript received March 19, 1968. This paper was taken from the Ph.D. thesis of one of the authors (D.C.H.), Oregon State University, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# On the Mechanism of Anodic Chlorate Formation in Dilute NaCl Solutions

N. Ibl\* and D. Landolt\*<sup>1</sup>

Department of Industrial and Engineering Chemistry,  
Swiss Federal Institute of Technology, Zurich, Switzerland

## ABSTRACT

The rates of anodic chlorate formation were measured under a variety of well-defined hydrodynamic conditions. In dilute NaCl solutions (<0.1M) these rates are up to 60 times larger than those calculated for mass transport control as hitherto postulated. The rates of chlorate formation were calculated using a model which involves the coupling of mass transfer with a chemical reaction (chlorine hydrolysis) proceeding in the diffusion layer. The agreement between the calculated and the experimental values is satisfactory. The model used describes adequately the mechanism of anodic chlorate formation in the range of conditions investigated. In dilute NaCl solutions the rate of chlorate formation is governed by the kinetics of the chlorine hydrolysis. At higher chloride concentrations equilibrium may limit the hydrolysis and the mechanism of the process then changes accordingly.

Chlorate is manufactured industrially by electrolysis of neutral sodium chloride solutions in cells without a diaphragm. The reactions taking place in a chlorate cell were formulated by Foerster and Mueller (1, 2) as follows:

Solution:

Anodic loss reactions:<sup>2</sup>

Reaction (G) plays a minor role, as long as the solution does not become too alkaline, or the chloride concentration too low.<sup>3</sup> According to reactions (E) and (F) chlorate may be formed in two ways, either by a purely chemical reaction of the hypochlorite ion with hypochlorous acid in the bulk solution (chemical chlorate formation) or by electrochemical oxidation of the hypochlorite at the anode under simultaneous oxygen evolution (anodic chlorate formation). If all chlorate is formed by the chemical reaction (E), six Faradays are consumed in the oxidation of one mole chloride to chlorate. This is said to correspond to a maximum current efficiency  $\tau_{\text{ClO}_3}$  of 100%. If all chlorate is formed by reaction (F) the current efficiency cannot be higher than 66.7% since one third of the current is used for the evolution of oxygen.

Only little is known about the rate-determining step of the anodic loss reaction (F) which limits the current efficiency in technical cells. As was already observed by Foerster (2) the concentration of hypochlorite in the bulk solution increases during electrolysis until a steady state is reached (see Fig. 2). According to this author there is approximate proportionality between the rate of oxygen evolution result-

ing from reaction (F) and the hypochlorite concentration in the solution, both for the steady and the unsteady state (2). This was confirmed later by Knibbs and Palfreeman (4). From a discussion of Foerster's results, de Valera (5) and Beck (6) concluded that the anodic chlorate formation is controlled by the mass transport of the hypochlorite from the bulk solution toward the anode. In his treatment of Foerster's data, Beck took into account the complication that under transport control the rate of chlorate formation and therefore the rate of oxygen evolution should increase somewhat faster than would correspond to proportionality with the hypochlorite concentration, because the thickness  $\delta$  of the diffusion layer decreases when the stirring by the gas bubbles becomes stronger owing to a faster gas evolution. Whereas Foerster worked mainly with platinum electrodes, Hammar and Wranglén (7) have recently made a comprehensive study of the rate of oxygen evolution in chlorate electrolysis with graphite electrodes. They also found that the rate of oxygen evolution is proportional to the hypochlorite concentration if the influence of the gas bubbling on  $\delta$  is taken into account, and they concluded that mass transport of the hypochlorite is the rate-determining step of the anodic chlorate formation.

Most of the afore-mentioned experiments of the literature were carried out with concentrated NaCl solutions (>1M). Recently, Selvig and Ibl made measurements in dilute solutions where the rates of chlorate formation were up to ten times larger than those expected for a diffusion controlled process (8). The latter values were calculated from the measured oxygen evolution rate by means of the following correlation for mass transfer at gas evolving electrodes, given by Ibl and Venczel (9, 11).

$$k_L = \frac{DV^{0.5}}{1.50 \times 10^{-3}}$$

where  $k_L$  = mass transfer coefficient (cm/sec);  $D$  = diffusion coefficient (cm<sup>2</sup>/sec);  $V$  = gas evolution rate (cm<sup>3</sup>/cm<sup>2</sup> min).

Electrolyzing acid sodium chloride solutions of various concentrations, Selvig found a strong dependence of the steady state hypochlorite concentration on the chloride concentration. Figure 1 shows results similar to those of Selvig, but obtained in slightly alkaline solutions (10). Steady-state hypochlorite concentrations and chlorate formation rates are given for a variety of experiments performed by electrolyzing sodium chloride solutions of various concentrations at constant current density in the absence of forced con-

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Lawrence Radiation Laboratory, University of California, Berkeley, California.

<sup>2</sup> Loss reactions at the cathode may be suppressed almost entirely by adding small amounts of potassium bichromate to the solution (3).

<sup>3</sup> Formation of perchlorate is another possible anodic loss reaction. It may occur at platinum electrodes but under extreme conditions only.

Fig. 1. Steady-state hypochlorite concentrations and chlorate formation rates at various chloride concentrations in unstirred solutions: ● hypochlorite concentration,  $i = 5$  ma/cm<sup>2</sup>; □ hypochlorite concentration,  $i = 20$  ma/cm<sup>2</sup>; ○ chlorate yield,  $i = 5$  ma/cm<sup>2</sup>;  $i = 20$  ma/cm<sup>2</sup>.

Fig. 2. Variation of hypochlorite and chlorate concentration with time during electrolysis of NaCl solution: ○ concentration of NaCl = 4 mole/liter; □ concentration of NaCl = 0.05 mole/liter, maintained approximately constant during experiment.

vection.<sup>4</sup> Bichromate was added to the solution to reduce cathodic losses. pH and chloride concentration were kept constant by adding concentrated HCl or NaOH during the experiments. Hypochlorite and chlorate concentrations were followed over time by potentiometric titration (see below). Oxygen and hydrogen evolution rates in the steady state were measured using a standard oxygen absorption method.

The history of a typical experiment is shown in Fig. 2. Starting with no hypochlorite in the solution hypochlorite is built up in the bulk at the beginning of the experiment. Gradually more chlorate is formed until a steady state is reached after some time when hypochlorite concentration and chlorate formation rate remain constant. The steady-state values given in Fig. 1 as a function of the NaCl concentration show a sharp decrease in the hypochlorite concentration at chloride concentration below about 400 mM/liter. On the other hand, the chlorate formation rate decreases only slightly, the decrease being possibly due to increased oxygen evolution according to reaction (G).

<sup>4</sup> The cell was constructed in a way to allow circulation of the electrolyte for good mixing. It contained two graphite electrodes (AGLX 58, Union Carbide) of 100 cm<sup>2</sup> surface area. The electrolyte volume was between 170 and 200 ml.

Fig. 3. Concentration profiles near the anode (schematically)

All the experiments of the literature mentioned so far were carried out without external stirring, the only convection present being that due to gas evolution and to the density differences in the solution. The hydrodynamic conditions were thus not well defined, and an accurate comparison with theoretical relationships is therefore difficult. This also applies to Selvig's results. However, in the latter case the discrepancy with the values calculated for mass transport control are so large that at least under the conditions of Selvig's experiments, the rate of chlorate formation can hardly be interpreted in terms of mass transport alone. Furthermore, the results of Fig. 1 (i.e., the large difference between the steady-state hypochlorite concentration measured in dilute and concentrated NaCl solutions in spite of the almost unchanged rate of chlorate formation) strongly suggest that the kinetics of chlorate formation are more complicated than would correspond to a simple transport mechanism. In the mass transfer theory of chlorate formation, as hitherto developed in the literature, only the diffusion of the hypochlorite toward the anode is considered, without taking into account the possible influence of the kinetics of the hypochlorite formation, i.e., it is more or less tacitly assumed that the chlorine hydrolysis [reaction (C)] does not take place in the diffusion layer but only in the bulk solution and does not affect the rate of the anodic chlorate formation. However, as we have pointed out in an earlier paper (11), the chlorine hydrolysis is a relatively fast reaction. One should therefore expect that it takes place within the diffusion layer, close to the anode where the chlorine is generated. In the next section the rate of chlorate formation will be calculated using a model which involves the coupling of mass transfer with a chemical reaction (chlorine hydrolysis) in the diffusion layer, and in a later section the computed values will be compared with measurements carried out under well-defined hydrodynamic conditions.

#### Theoretical

Schematic concentration profiles near the anode as they may be expected according to the reactions (A) and (F) are shown in Fig. 3; chloride and hypochlorite<sup>5</sup> are consumed at the anode and must therefore be transported towards it. Molecular chlorine and hydrogen ions are generated and must be transported away from the anode.

The differential equations describing the system are obtained from a balance of mass for an infinitely small volume element in the diffusion layer. Neglecting migration we may write the general equation

$$\frac{\partial c_i}{\partial t} = -U \nabla c_i + D_i \nabla^2 c_i + R_i \quad [1]$$

where  $c_i$  = concentration of species  $i$  (mole/cm<sup>3</sup>) where  $i = 1$  stands for molecular chlorine,  $i = 2$  for hydrogen ion,  $i = 3$  for hypochlorite (sum of hypo-

<sup>5</sup> It is assumed that the dissociation equilibrium of the hypochlorous acid is established infinitely fast, and the term hypochlorite is used here as the sum of hypochlorous acid and hypochlorite ions.

chlorite ions and hypochlorous acid);  $t$  = time (sec);  $U$  = velocity vector (cm/sec);  $D_i$  = diffusion coefficient of species  $i$  (cm<sup>2</sup>/sec);  $R_i$  = rate of production of species  $i$  by chemical reaction (mole/cm<sup>3</sup> sec).

In applying Eq. [1] to our system, the following simplifications were made: The steady state only ( $\partial c/\partial t = 0$ ) was considered. The concept of a stagnant diffusion layer was used, thereby dropping the convection term and only considering the dimension perpendicular to the electrode. The chlorine hydrolysis was treated as a first order irreversible reaction following the rate law

$$-\frac{dc_1}{dt} = kc_1$$

The differential equation for the chlorine profile in the diffusion layer thus becomes

$$D_1 \frac{d^2c_1}{dx^2} - kc_1 = 0 \quad [2]$$

Boundary conditions are:  $x = 0$ ;  $D_1(dc_1/dx) = -i\phi_1/2F$ ; and  $x = \delta$ ,  $c_1 = 0$ . The first boundary condition states that the chlorine flux at the anode surface is proportional to the density of the current used for the oxidation of chloride ions to chlorine ( $\phi_1$  = fraction of total current used for reaction A). The second boundary condition states that the chlorine concentration in the bulk is essentially zero as it may be expected if the solution is neutral. Equation [2] was first applied to the calculation of the chlorine profile at the anode by Beck (12). Its solution may be expressed as an exponential function<sup>6</sup>

$$c_1 = \frac{i\phi_1}{2FD_1a} \exp(-ax) \quad \text{with } a = \sqrt{\frac{k}{D_1}} \quad [3]$$

Equation [3] holds for the case where the thickness of the layer in which the chemical reaction occurs, is small as compared with the thickness  $\delta$  which the diffusion layer would have under the same hydrodynamic conditions but without a concomitant chemical reaction. Hydrogen ion and hypochlorite concentration profiles are calculated by integrating the equations

$$D_2 \frac{d^2c_2}{dx^2} + kc_{1(x)} = 0 \quad [4]$$

$$D_3 \frac{d^2c_3}{dx^2} + kc_{1(x)} = 0 \quad [5]$$

in which  $c_{1(x)}$  can be expressed by means of Eq. [3]. Equation [4] implies that all the hydrogen ions generated in the diffusion layer result from reaction (C), i.e., that no hydrogen ions are produced by reaction (D). This is a reasonable assumption since in the present model the diffusion layer is quite acid (see below) and the dissociation constant (13) of HClO is  $4 \times 10^{-8}$  mole/liter at 25°C, so that all the hypochlorite is virtually present as HClO in the diffusion layer. Boundary conditions for Eq. [4] are  $D_2(dc_2/dx) = i\phi_2/F$  at  $x = 0$  and  $c_2 = 0$  at  $x = \delta$ . The flux of the hydrogen ions at the anode surface is given by the density of current corresponding to the evolution of oxygen according to reactions (F) and (G) ( $\phi_2$  = fraction of total current used for oxygen evolution).<sup>7</sup> For a neutral solution the hydrogen ion concentration in the bulk solution is virtually zero. Boundary conditions for Eq. [5] are:  $c_3 = 0$  at  $x = 0$  and  $c_3 = c_0$  at  $x = \delta$ . Outside the diffusion layer the hypochlorite

<sup>6</sup> The exact solution of Eq. [2] is

$$c_1 = \frac{i\phi_1}{2FD_1a} \left( \frac{e^{-ax}}{1 + e^{-2a\delta}} - \frac{e^{ax}}{1 + e^{2a\delta}} \right) \quad (3')$$

which for  $a\delta \gg 1$  takes the form of Eq. [3]. The assumption  $a\delta > 1$  must be made anyhow if the convection term of the fundamental differential Eq. [1] is to be neglected in the integration.

<sup>7</sup> The boundary condition at the interface implies the validity of the stoichiometry of the anodic chlorate formation given by reaction (F). This question will be discussed in the section on Experimental results.

concentration equals the bulk concentration which may be determined experimentally. The hypochlorite concentration at the interface is taken as zero, i.e., it is assumed that it is oxidized at the limiting rate. At potentials where  $\text{Cl}^-$  is discharged this assumption appears justified since various authors (2, 4) have reported that hypochlorite reacts at substantially less positive potentials than  $\text{Cl}^-$ .

The corresponding solutions of Eq. [4] and [5], describing the concentration profiles of hydrogen ion and hypochlorite in the diffusion layer, are

$$c_2 = \frac{i\phi_1}{2FD_2a} (e^{-a\delta} - e^{-ax}) + \frac{i(\delta - x)}{FD_2} \left( \frac{\phi_1}{2} + \phi_2 \right) \quad [6]$$

$$c_3 = \frac{i\phi_1}{2FD_3a} (1 - e^{-ax}) + \frac{x}{\delta} \left\{ c_0 - \frac{i\phi_1}{2FD_3a} (1 - e^{-a\delta}) \right\} \quad [7]$$

The hypochlorite flux at the anode, which corresponds to the rate of anodic chlorate formation, is obtained by differentiating Eq. [7] at  $x = 0$

$$j_h = -D_3 \left( \frac{dc_3}{dx} \right)_{x=0} = \frac{i\phi_1}{2F} \left( \frac{1}{a\delta} - 1 \right) - D_3 \frac{c_0}{\delta} - \frac{i\phi_1}{2Fa\delta} e^{-a\delta} \quad [8]$$

The above calculations show that the chlorine hydrolysis proceeding within the diffusion layer has two consequences: (i) the pH in the diffusion layer, being already lower than that of the bulk solution due to the electrochemical hydrogen ion generation by reaction (F) and (G), is lowered even further by the chemical reaction as may be verified by comparing the hydrogen ion concentration at the anode surface calculated by Eq. [6] with that expected for a diffusion controlled process according to

$$(c_2)_{x=0} = \frac{i\phi_2\delta}{D_2F} \quad [6']$$

To illustrate the increased acidity of the diffusion layer we calculate from Eq. [6] the concentration of the  $\text{H}^+$  ions at the interface for the conditions of the experiment B indicated in Table I. With  $k = 6.3 \text{ sec}^{-1}$  ( $t = 13^\circ$ );  $D_1 = 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$  and  $D_2 = 5 \times 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$  we obtain  $(c_2)_{x=0} = 2.65 \times 10^{-2}$  mole/liter. If we make the corresponding calculation with Eq. [6'], i.e., without taking hydrolysis into account, we get  $(c_2)_{x=0} = 1.83 \times 10^{-2}$  mole/liter. (ii) The concentration gradient of hypochlorite at the anode is increased [Eq. (8)], and hence the rate of anodic chlorate formation becomes higher than expected for a process controlled by diffusion alone.

The shape of the hypochlorite concentration profile in the stagnant diffusion layer is illustrated in Fig. 4. Curve 1 in Fig. 4 was calculated from Eq. [7] for the data of experiment B (Fig. 2) which are given in Table I. The values of the diffusion coefficients of chlorine and hypochlorite were assumed as  $10^{-5} \text{ cm}^2/\text{sec}$ ; the rate constant of the chlorine hydrolysis at  $13^\circ\text{C}$  was obtained by interpolation of literature values (14) as  $6.3 \text{ sec}^{-1}$ . The dotted line in Fig. 4 represents the concentration profile for a diffusion controlled process. It follows from the two curves that the hypochlorite concentration in the diffusion layer is shifted upward by the chemical reaction and a steeper concentration gradient at the anode results. Curve 2 illustrates the interesting fact that the concentration in the diffusion layer may even exceed the bulk concentration. It was calculated in the same way as curve 1 but under the assumption of zero bulk hypochlorite concentration. The concentration max-

Table I. Data of experiments A and B used in the calculation of concentration profiles and equilibrium concentrations

	A	B
Sodium chloride concentration (mole/liter)	4.0	0.056
Current density (ma/cm <sup>2</sup> )	20	20
Average temperature (°C)	20	13
Average pH	9.3	9.0
Steady-state hypochlorite concentration (mM/liter)	134	10
Steady-state chlorate formation rate (mole/cm <sup>2</sup> sec)	$20 \times 10^{-9}$	$17.6 \times 10^{-9}$
Current efficiency for chlorate formation (%)	57.8	50.8
Thickness of diffusion layer (cm) calculated from oxygen evolution rate	$1.1 \times 10^{-3}$	$0.9 \times 10^{-2}$

imum within the diffusion layer may be interpreted in such a way that in the absence of hypochlorite in the bulk solution part of the hypochlorite generated within the diffusion layer reacts at the anode and part of it diffuses toward the bulk. In the absence of hypochlorite losses in the bulk curve 2 does not represent a true steady state, because the bulk concentration increases with time. The steady-state approach is appropriate, however, for large bulk volumes, where the hypochlorite concentration changes only very slowly. In the absence of hypochlorite losses other than anodic, a true steady state would be reached when the bulk hypochlorite concentration reaches a value equal to the corresponding maximum concentration of the diffusion layer.

In order to test the above ideas about the mechanism of anodic chlorate formation, chlorate formation rates were measured under well defined conditions of hydrodynamic flow, of pH, and of temperature.

#### Experimental Procedure and Apparatus

The experimental set-up is shown schematically in Fig. 5a. The electrolyte was pumped continuously through a channel cell at flow rates between 10 and 160 cm/sec. The Lucite cell (Fig. 5b) contained compact impregnated graphite electrodes (EK 200 Ringsdorf, Germany) with smooth surfaces of a length (in the direction of flow) of 5, 10, or 20 cm, the breadth being 5 cm in all cases. A diaphragm (porous polyethylene) could be inserted between anode and cathode. The distance between anode and cathode (or diaphragm) was 2.25 or 9 mm. Potentials at the anode were measured vs. a saturated calomel electrode using a backside capillary drilled through the graphite. If a diaphragm was inserted in the cell, the cathodically evolved hydrogen could escape from a glass tube connected to a mercury valve. The temperature of the system was kept low by means of a cryostat in order

Fig. 4. Calculated hypochlorite concentration profiles in the diffusion layer (experiment B). Curve I,  $c_0 = 10 \times 10^{-6}$  mole/cm<sup>3</sup>, curve II,  $c_0 = 0$ , both curves, diffusion coupled with chemical reaction, and curve III, diffusion controlled process,  $c_0 = 10 \times 10^{-6}$  mole/cm<sup>3</sup>.

to suppress the chemical chlorate formation (reaction E). Most experiments were performed at a constant temperature of  $7^\circ \pm 0.5^\circ\text{C}$ . The pH of the electrolyte was measured with a glass electrode. It was kept constant by automatically adding conc NaOH or conc HCl with the help of an "Impulsomat" (Metrohm, Herisau, Switzerland). The flow rate was measured with a rotameter and regulated by two PVC valves and a bypass. A nonpulsating ceramic pump was used (Chemiepumpenbau, Zofingen, Switzerland). The flow of the solution was quieted by passing through 20 to 80 channels, 2 mm in diameter, drilled through Lucite block S. The whole system contained no metallic parts in contact with the electrolyte. The electrolyte volume used varied from 1.6 to 2.0 liter. The electrolysis was performed at constant current density, usually 5 ma/cm<sup>2</sup>.<sup>8</sup> The absence of chemical chlorate formation during the experiments was confirmed by circulating hypochlorite solutions in the flow system under the same conditions, but in the absence of current, and measuring hypochlorite and chlorate concentrations as a function of time.

<sup>8</sup> Further details of the experimental arrangement and of the results are given in the thesis of one of the authors (10).

Fig. 6. Potentiometric titration of hypochlorite and chlorate

**Analytical.**—Two samples of 2 ml were taken from the electrolyte solution at suitable intervals. One sample served for the determination of the chloride ion concentration by a conventional titration method using silver nitrate as titrant and potassium bichromate as indicator. In the second sample the sum of the concentrations of hypochlorite, hypochlorous acid, and molecular chlorine and the concentration of chlorate were determined using an improved potentiometric titration method, based on a procedure given by Norkus and Prokopchik (15). These authors determined hypochlorite by potentiometric titration with  $As_2O_3$ . The chlorate was then reduced by excess  $As_2O_3$  by heating the sample for several minutes to  $90^\circ C$  after  $OsO_4$  has been added as catalyst. The excess arsenic oxide was titrated with potassium bromate solution using methyl orange as indicator [cf. Peters and Deutschländer (16)].<sup>9</sup> In our experiments the following procedure was found to give rapid and sufficiently accurate results: After the addition of some 1N sodium bicarbonate solution to the sample, hypochlorite was titrated potentiometrically with a solution of usually 0.05 or 0.005 mole/liter  $As_2O_3$ . A 100 ml beaker containing a platinum ring electrode and a calomel electrode with ceramic double diaphragm was used. Before each run the platinum electrode was immersed briefly in conc sulfuric acid containing chromate. After reaching the hypochlorite endpoint excess arsenic oxide was added, then some potassium bromide (about 30 mg) and a volume of chemically pure concentrated hydrochloric acid approximately equal to the solution volume already present. The solution which had to contain now at least 20% HCl was then allowed to stand for 3 to 5 min. After that time the excess  $As_2O_3$  was titrated potentiometrically with  $KBrO_3$ . The relative potential change was followed using a potentiometer range of 0–140 mv. The shape of the potentiometric titration curves is illustrated in Fig. 6. The accuracy of the chlorate concentration values determined by the described method was better than  $\pm 2\%$  for chlorate concentrations not smaller than 0.001 mole/liter. In view of its great importance for the present study the analytical procedure was tested in some detail. A more complete report of the experiments carried out has been given elsewhere (10).

### Experimental Results

In each run the change of the hypochlorite concentration with time was followed, until a steady state

<sup>9</sup> Norkus and Prokopchik give a procedure by which  $ClO_2^-$  can be determined in the same sample. Hypochlorite is then titrated in alkaline medium, chlorite in neutral medium with  $OsO_4$  as catalyst. The complete determination of hypochlorite, chlorite, and chlorate was found by us to be rather uncertain and lengthy, because of the slowness of potential changes in alkaline medium. The determination of chlorite was not necessary, however, in our experiments, since tests showed that in chlorate electrolysis chlorite is never present in measurable amounts.

with a constant hypochlorite concentration was reached (Fig. 2). The values of the hypochlorite concentrations and of the rates of chlorate formation measured in the steady state with dilute NaCl solutions are summarized in Table II. Measured and calculated rates of chlorate formation are compared in Table III in terms of the corresponding hypochlorite fluxes at the anode.

The linking of the rate of chlorate formation with the hypochlorite flux at the anode requires the knowledge of the stoichiometry of the anodic chlorate formation. According to reaction (F) three moles of hypochlorite, oxidized anodically, yield one mole of chlorate. Stoichiometric ratios different from those given by reaction (F) have been found by Rius and Llopis (17, 18). According to these authors their experiments fit best the equation

In this case only 1.7 moles of hypochlorite are needed to yield 1 mole chlorate. It seems that reaction (F) applies to acid baths, reaction (H) to strongly alkaline solutions. The great influence of pH on the stoichiometry of the anodic chlorate formation is apparent from Foerster's results (2) as well as from those of Rius and Llopis (17, 18). It was also observed in a series of stoichiometric measurements carried out in our laboratory. Now, we have seen that with the model discussed earlier the pH at the interface is quite low. We therefore use the stoichiometric ratios given by reaction (F). The formation of one mole chlorate then corresponds to the diffusion of three moles of hypochlorite to the anode. We thus have  $j_e = 3v_{ClO_3}$ , where  $v_{ClO_3}$  is the measured rate of chlorate formation (mole  $cm^{-2} sec^{-1}$ ). We will regard  $j_e$  as an experimental value of the hypochlorite flux at the interface.

The hypochlorite flux for a diffusion controlled process (without influence of a chemical reaction) may be calculated from the bulk concentration  $c_0$  by

$$j_d = -D_3 \frac{c_0}{\delta}$$

For the case that mass transfer is coupled with a first order chemical reaction (chlorine hydrolysis) the hypochlorite flux at the anode  $j_h$  is related to the bulk concentration by Eq. [8]. In the calculation of  $j_d$  and  $j_h$  the diffusion coefficient of hypochlorite was assumed as  $10^{-5} cm^2/sec$  since no measured values were available in the literature. The value of the rate constant for chlorine hydrolysis at  $7^\circ C$  was interpolated from an Arrhenius plot given in ref. (14) as  $k = 3.6 sec^{-1}$ . The diffusion layer thickness was evaluated experimentally by measuring limiting currents for the reduction of ferricyanide to ferrocyanide at various flow rates. The measurements were performed at  $25^\circ C$  with a solution containing 0.05 mole/liter potassium ferricyanide, 0.01 mole/liter potassium ferrocyanide, and 1.0 mole/liter potassium chloride. The cell geometries and electrodes were the same as in the chlorate experiments. Figure 7 shows Nusselt numbers calculated from the measured limiting currents according to

$$Nu = \frac{i_0 L}{F c_{Fe} D_{Fe}}$$

as a function of the Reynolds number  $Re = uL/v$ , where  $i_0$  = limiting current density;  $L$  = length of electrode<sup>10</sup> (here always 20 cm);  $F$  = Faraday con-

<sup>10</sup> For fully developed channel flow the quantity  $L^* = 4 \frac{\text{cross section}}{\text{perimeter}}$  would be more appropriate in forming the dimensionless numbers  $Nu$  and  $Re$  than the quantity  $L$  which is used in describing the flow past a flat plate. Since in the chlorate experiments the ratio electrode area/electrolyte volume must not be too small, the entrance length in our experiments was usually shorter than that required for the two hydrodynamic boundary layers to merge. The calculated value of the average diffusion layer thickness is not affected by the choice of the characteristic length as long as only experiments performed under equal geometrical conditions are compared as it was done here.

δ Average thickness of diffusion layer, calculated from limiting current measurements for ferricyanide reduction.

c<sub>o</sub> Concentration of hypochlorite and hypochlorous acid in the steady state. c<sub>o</sub> is related to the total concentration of chlorine, hypochlorous acid, and hypochlorite c<sub>st</sub> by

$$c_o = \frac{K_1 c_{st}}{(Cl^-)(H^+) + K_1} \times 10^{-3} \text{ [mole/cm}^3\text{]}$$

where K<sub>1</sub> is the equilibrium constant of the chlorine hydrolysis

$$K_1 = \frac{(HOCl)(Cl^-)(H^+)}{(Cl_2)} \text{ in mole}^2\text{/liter}^2$$

j<sub>e</sub> Hypochlorite flux at the anode determined from experimentally measured chlorate formation rates:  $j_e = 3v_{ClO_3}$  [cf. reaction (F)].

j<sub>a</sub> Hypochlorite flux at anode calculated from steady-state hypochlorite concentration assuming a diffusion controlled process:  $j_a = -D_3 c_o / \delta$ .

j<sub>h</sub> Hypochlorite flux at anode calculated by taking into consideration the chlorine hydrolysis within the diffusion layer (Eq. [8]).

### Discussion of Results

Table III shows that the ratio  $j_e/j_a$  strongly varies with the conditions and is always much larger than 1. The experimental rate of chlorate formation is up to 64 times larger than the value calculated for transport control without influence of a chemical reaction. This confirms our earlier results (8, 11) and is strong evidence that under the conditions of the experiments in Table II the rate of anodic chlorate formation is not controlled by a simple mass transport of hypochlorite by diffusion and convection from the bulk to the anode.<sup>11</sup> The calculation considering the influence of the chlorine hydrolysis in the diffusion layer, on the other hand, fits the experimental results much better; the ratio  $j_e/j_h$  remains nearly constant and is close to 1, except for very high flow rates. This departure from the value of 1 observed at high flow rates is not surprising, however. In the fundamental differential equation for the mass transport (Eq. [1]) the convection term was dropped before carrying out the integration which finally yielded the relationship  $j_e/j_h$  (Eq. [8]). This procedure can lead to a good ap-

<sup>11</sup> Mass transfer due to migration, although not entirely negligible in some of the experiments, played a minor role, since excess chloride was always present in the solution. Also the uncertainty in the assumption of a value of the diffusion coefficient does not alter the conclusions, since the uncertainty is expected to be smaller than a factor of 2 whereas  $j_a$  and  $j_h$  differ by an order of magnitude. Furthermore, if the estimated value of D was wrong,  $j_e/j_a$  would be different from 1 but would be constant in a transport controlled process.

Fig. 7. Evaluation of mass transfer conditions in flow cell by measuring limiting current for the reduction of ferricyanide. O gap width 9 mm, + gap width 2.25 mm.

proximation only if the thickness  $\delta_R$  of the zone in which the hydrolysis takes place (reaction layer) is small as compared to the normal thickness which the diffusion layer would have in the absence of a chemical reaction. Let us consider as representative for  $\delta_R$  the distance from the anode at which the chlorine concentration has dropped to 1% of its value at the interface.<sup>12</sup> With  $k = 3.6 \text{ sec}^{-1}$  we obtain for this distance (from Eq. [3]) a value of  $3.8 \times 10^{-3} \text{ cm}$ . At flow rates of 13 and 44 cm/sec this is smaller than the normal thickness of the diffusion layer  $\delta$ , but not at flow rates of 145 and 154 cm/sec (Tables II and III). These two latter flow rates are precisely those at which the ratio  $j_e/j_h$  becomes substantially larger than 1.

From all this we can conclude that the model involving the coupling of mass transfer with a first order chemical reaction proceeding in the diffusion layer describes adequately the mechanism of anodic chlorate formation under the conditions of the experiments of Table II and Table III. In dilute NaCl solutions the rate of the anodic chlorate formation is governed by the kinetics of the chlorine hydrolysis in the immediate vicinity of the electrode.

In concentrated NaCl solutions, however, the ratio  $j_e/j_h$  is systematically substantially smaller than 1 (23) and, as we have seen in Fig. 1, the steady-state bulk concentration of hypochlorite is much larger than in dilute solutions. This suggests that the mechanism of chlorate formation is not the same in dilute and concentrated NaCl solutions: The model developed in this paper appears to be restricted to dilute solutions. This can be readily understood by considering the chemical equilibrium of reaction (C) in the diffusion layer.<sup>13</sup> For the purpose of illustration the equilibrium HOCl concentration at the point where the HOCl concentration reaches a maximum in the diffusion layer, is calculated for the two experiments A and B listed in Fig. 2 and Table II. The bulk hypochlorite concentration is assumed to be zero in both cases. The distance from the anode at which the maximum is located, is obtained by differentiating Eq. [7] and setting  $dc_3/dx = 0$ ,

$$X_m = -\frac{1}{a} \ln Z$$

with

$$Z = \frac{1}{a\delta} (1 - e^{-a\delta}) - \frac{2c_0 D_3 F}{\delta i \phi_1}$$

The corresponding numerical values are  $X_m = 2.18 \times 10^{-3} \text{ cm}$  for A and  $2.49 \times 10^{-3} \text{ cm}$  for B. The hydrogen ion concentrations at  $X_m$  are  $25.89 \times 10^{-3} \text{ mole/liter}$  for A and  $19.98 \times 10^{-3} \text{ mole/liter}$  for B, calculated from Eq. [6], setting  $\phi_2 = 1 - \phi_1$  and  $D_2 = 5 \times 10^{-5} \text{ cm}^2/\text{sec}$ . The equilibrium concentration of HOCl is given by

$$(\text{HOCl})_{\text{eq}} = \frac{K(\text{Cl}_2)}{(\text{Cl}^-)(\text{H}^+)}$$

where  $K \approx 3 \times 10^{-4} \text{ mole}^2/\text{liter}^2$  at the temperature of the experiments (22). Setting for the chlorine concentration the maximum possible value corresponding to the saturation concentration  $(\text{Cl}_2)_{\text{sat}} \approx 0.06 \text{ mole/liter}$  one obtains the maximum possible values of the

<sup>12</sup> The definition of the thickness of the reaction layer is somewhat arbitrary. One can also define an effective thickness of the reaction layer in a way quite similar to the definition of the usual effective or equivalent thickness of the adhering diffusion layer of Nernst. From Eq. [3] it can be easily derived that the effective thickness of the reaction layer is equal to  $0.5\sqrt{D_1/k}$  if the influence of convection is entirely disregarded. With  $D = 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$  and  $k = 3.6 \text{ sec}^{-1}$  this effective thickness is about  $2 \times 10^{-3} \text{ cm}$ . Comparison with the values of  $\delta$  shown in Table III leads to the same conclusions as above, i.e. that the departure of  $j_e/j_h$  takes place at flow rates which appear as very reasonable from the viewpoint of the simplifications made.

<sup>13</sup> The outlined considerations based on the dependence of the rate of the chlorine hydrolysis and of the hydrolysis equilibrium in the diffusion layer on chloride concentration and pH may explain why there has to be a difference in the bulk hypochlorite concentration in dilute and concentrated chloride solutions. But there are also differences between the two cases with respect to the electrode reactions which will be discussed elsewhere (23).

HOCl equilibrium concentration at  $X_m$

$$c_{3 \text{ eq}} = 0.17 \times 10^{-6} \text{ mole/cm}^3 \quad (\text{A})$$

$$c_{3 \text{ eq}} = 16.1 \times 10^{-6} \text{ mole/cm}^3 \quad (\text{B})$$

These concentrations may then be compared to the concentrations at  $X_m$  calculated from Eq. [7] for a first order irreversible reaction

$$c_{3h} = 3.69 \times 10^{-6} \text{ mole/cm}^3 \quad (\text{A})$$

$$c_{3h} = 3.88 \times 10^{-6} \text{ mole/cm}^3 \quad (\text{B})$$

Comparison shows that for the dilute sodium chloride solution (experiment B) the value  $c_{3h}$  lies well below the equilibrium value. In concentrated sodium chloride solution (experiment A), on the other hand, the value of  $c_{3h}$  is about 20 times larger than the equilibrium value. The above comparison illustrates the fact that in concentrated NaCl solutions the chlorine hydrolysis cannot proceed in the diffusion layer in the same way as in dilute solutions, because the equilibrium value is reached much earlier and the hydrolysis is therefore stopped. Our study of the concentrated solutions will be reported in more detail in a subsequent paper (23).<sup>14</sup>

## Technical Notes

### The Hydrothermal Corrosion and Recrystallization of Noble Metals

V. G. Hill

*Tem-Pres Research, Inc., A Carborundum Subsidiary, State College, Pennsylvania*

During a research program on the hydrothermal growth of oxide crystals, it was observed that in some cases the solutions used dissolved parts of the noble metal liners of the autoclaves and produced small crystals of these metals. The understanding and preventing of this type of corrosion is important because it is necessary to protect the autoclaves from the corrosive solutions often used by containing them inside noble metal liners. The deterioration of the liner often results in the loss of the autoclave by the escape of the solution through holes formed in the liner. The increased application of the hydrothermal method, particularly with concentrated solutions for the growth of various single crystals including some higher valence compounds and nonstoichiometric oxides, makes this an urgent problem.

The growth of metal crystals by the hydrothermal technique is also of interest because there are few reported examples of the application of the method for producing metal crystals hundreds of degrees below their melting points (1, 2). Levinson and Carter obtained silver crystals during the growth of  $\alpha\text{-Al}_2\text{O}_3$  using 4N NaOH as the hydrothermal solution. Similar results were obtained by Monchamp, Putzbach, and Nielsen (3) during the growth of ruby and  $\text{Y}_3\text{Fe}_5\text{O}_{12}$  from  $\text{K}_2\text{CO}_3$  solution and ZnO crystals using 5M KOH as the hydrothermal solution. They found that the crystallization of the silver liner could be prevented by suspending in the solution a small piece of the metal whose oxide is being grown.

We found that silver, gold, and platinum dissolved in some hydrothermal solvents and grew as small crystals. In the case of silver, 4N KOH solution dissolved and recrystallized it at an appreciable rate in the presence of only small amounts of oxygen at temperatures above 400°C. The solution of the metal occurred in the nutrient part of the vessel where a liquid phase (KOH solution) was present. The growth of the silver crystals was primarily in the liquid phase, particularly at the interface of the liquid and vapor phases. This suggested that silver was much less soluble in the vapor phase than in the liquid. The crystals grew out from the walls of the vessel toward the center and were up to 5 mm in length. The silver crystals were of rhombic outline. These rhombs were often elongated forming laths, or grew as stepped clusters to form hollow rhombs (Fig. 1). Confirmation of the role of oxygen was obtained by comparing the results obtained from runs in which oxygen was deliberately introduced with those made in an oxygen-free environment. The former yielded copious silver dendrites, while the latter did not produce any silver crystals at all. The presence of only a small amount of oxygen

in the vessels resulted in a slower growth rate, but much better crystals. Silver was also attacked and recrystallized by 2N LiCl solution. The results appear to be similar to those produced by KOH solutions.

The best gold crystals were formed by the attack of 2N LiCl on the walls of the sealed gold capsules at temperatures between 350° and 450°C. Most of the crystals were needles, but a few were cube faces truncated by octahedron faces (Fig. 2). Roughly similar results were obtained with NaCl solution, but the degree of attack was much less. KCl solutions barely attacked it. HCl solutions also attacked gold in the presence of oxygen. Platinum was attacked by LiCl solutions, but much less so than either gold or silver, and in fact only a thin coating of platinum was deposited on the walls of the gold tube used to contain the reactants.

The attack on the silver by alkali hydroxide was due to the presence of oxygen in the vessel. The transport mechanism was probably through the formation of an unstable oxide. In reactions with amphoteric oxides in an alkali hydroxide solution, oxygen can be readily eliminated by suspending a small piece of the corresponding metal of the oxide in the alkaline solution. The hydrogen produced combined with any oxygen in the vessel and made the environment reducing. In other cases, a simple hydrogen generator was placed inside the autoclave. This was a sealed platinum tube crimped in the center initially to separate the charge of sodium hydroxide solution and metallic zinc. When the autoclave was heated, the contents of the tube expanded and reacted. The hydrogen gener-

Fig. 1. Hydrothermally grown silver crystals

Fig. 2. Hydrothermally grown gold crystals

ated diffused through the walls of the tube into the autoclave. Attack on the silver by the strong alkali did not occur in a reducing environment. It is essential that the last traces of free oxygen be eliminated from the vessel. The amount of metal needed for the scavenging of all the oxygen can be reduced by making up the solution with freshly boiled water and flushing out the autoclave with nitrogen.

The crystallization of gold in chloride solutions appears to be related to the increase in the activity of oxygen with temperature. In fact, the experimental evidence suggests that oxygen becomes a very strong oxidizing agent, and may severely corrode gold under certain conditions. It should be pointed out however that although the attack on gold increases with increased oxygen pressure, very little oxygen is required to initiate the attack. It is thus possible for gold to be transported across a thermal gradient and redeposited in the presence of only trace amounts of oxygen. The mechanism of the reaction is probably due to the formation of complex gold halide anions which decompose to give metallic gold. The mechanism

of the attack on platinum appears to be also related to the change in activity of the oxygen with temperature. The result is much less severe than in the case of either silver or gold.

Other metals and alloys are also dissolved and re-crystallized by solutions under hydrothermal conditions. For example, the alloy, Stellite 21, which is used to fabricate the autoclaves was attacked by KOH solution in some runs and small cobalt crystals grew in the cooler parts of the vessel.

These results serve to emphasize the limitations in the use of noble metal liners in current hydrothermal research. These are more suitable for work under reducing rather than oxidizing conditions. The use of halogens, particularly chlorides, should be avoided. Platinum appears to be best for working under oxidizing conditions, but the severity of attack may increase under high oxygen pressures, particularly in runs of long duration. Silver appears to be the most serviceable in strongly alkaline solutions under reducing conditions.

#### Acknowledgments

The author wishes to express his thanks to Dr. R. I. Harker for his interest in the work and for critically reading the manuscript. This work was done as part of a research project on hydrothermal crystal growth sponsored by the U.S. Air Force Materials Laboratory, Wright-Patterson Air Force Base, Ohio. Mr. Paul W. Dimiduk was the Project Engineer.

Manuscript received July 31, 1967; revised manuscript received March 26, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## A Stress Corrosion Cell for Uniaxial Tensile Tests

F. H. Cocks and W. M. Krebs\*

*Tyco Laboratories, Inc., Waltham, Massachusetts*

There is at present great interest in studying the phenomenon of stress corrosion cracking, particularly in aluminum and titanium alloys, and a variety of test methods are being used to determine the susceptibility of metals to failures of this kind (1, 2). Most of these methods may be considered as either constant strain or constant load tests. In almost all cases what is measured, in addition to electrochemical data such as current density or potential, is the time to failure or to the first appearance of surface cracks. In constant load tests a weight is hung from the specimen either directly or through levers. In the more usual constant strain tests, the specimen is bent to a fixed radius or loaded uniaxially by a bolt and nut mechanism. These methods have the advantage of simplicity of construction so that they are well suited to situations where large numbers of samples are to be tested and multiple testing jigs are necessary. They fail, however, to take advantage of the greater amount of information concerning mechanical properties that can be obtained through the use of modern tensile testing equipment. To utilize to the full extent the capabilities of the model TTDL Instron Universal Testing Machine a special stress corrosion cell was built. Although designed for use with an Instron, this cell can equally

well be used with any vertical tensile machine having a 6-in. clearance, or for any constant deadweight load experiment. As will be discussed, this cell has the particular advantage of being fully sealed from the atmosphere and has facilities for thermostating and for mass transport control.

The cell consists, as shown schematically in Fig. 1 and in the photographs of Fig. 2, of a heavy walled Pyrex tube, fitted with smaller inlet and outlet tubes which terminate in ball joints. The working volume is about 70 ml. The inlet tube is fitted with a perforated ring of glass which directs the incoming flow uniformly against the gauge section of the specimen. Provision for controlled stirring is not commonly provided in stress corrosion studies, but it has been found that under certain circumstances the stirring rate can be an important variable (3). The outlet has an extension tube which is bent upward to draw off any gas produced during the corrosion process. The solution is circulated by means of a Masterflex peristaltic pump<sup>1</sup> operating on Viton tubing and connected to the system via Teflon tubing and ground glass ball joints. Before entering the cell, this solution is thermostated by being passed through a water-jacketed

\* Electrochemical Society Active Member.

<sup>1</sup> Cole-Parmer Institute and Equipment Corporation, Chicago, Illinois.

Fig. 1. Schematic diagram of the stress corrosion cell

Fig. 2. Stress corrosion cell (a) as assembled, including specimen, and (b) disassembled.

reaction kettle. There it is also deoxygenated by purging with nitrogen before being pumped into the cell itself. Using a Haake<sup>2</sup> thermostat to control the temperature in the jacket, the cell has been operated with solution temperatures up to 75°C. The peristaltic pump system is completely reversible and can supply continuously variable flow rates of from 0 to 700 cc/min.

A ring of fine mesh platinum screen serves as the counter electrode. The reference electrode, against which the specimen potential is measured, is contained in a separate unit which is joined to the cell via an O-ring joint. From this reference electrode a Luggin capillary extends into the cell close to the working electrode. This capillary not only reduces the "uncompensated" resistance between the reference and working (specimen) electrode, but also virtually eliminates agitation in the reference compartment due to stirring in the body of the cell. Such a design also permits the rapid and easy exchange of reference electrodes as would be required, for example, in changing from chloride to sulfate solutions.

<sup>2</sup> Poly Science Corporation, International Division, Evanston, Illinois.

Fig. 3. Load vs. time during stress corrosion tests on the aluminum alloys 2219-T37 and 7075-T651.

The sample itself is a short 1½-in. standard tensile specimen which is threaded at each end into ⅜-in. steel extension rods. By using small specimens, samples from the short transverse direction of rolled material can be tested, and this is usually the direction of interest in stress corrosion studies. This assembly, sample and grips, is dipped into a molten mixture of Kel-F No. 200 and No. 210 waxes to mask off all but a ⅜-in. section on the gauge length, to which corrosion is consequently restricted. Masking the grips is necessary in order to eliminate corrosion of the steel extension rods. These are passed through the Teflon end pieces of the cell by means of deformable O-ring seals, as shown in Fig. 1. Because the end pieces are threaded, these seals can be independently tightened even after the cell is fully assembled (Fig. 2). The Teflon end pieces are also sealed onto the flat ends of the cell by means of O-rings together with three long bolts which pass through circular aluminum clamping plates at each end of the cell. The O-ring seals have been found to be extremely effective, and leakage of solution does not occur, even after violent specimen failure. The use of a sealed and purged system eliminates effects due to dissolved air or oxygen<sup>3</sup> and is, therefore, an improvement over other cells for use with testing equipment which have been open to the air (4). By using standard tensile bar samples, many of the problems associated with the use of wire specimens are avoided (3, 5).

In operation, the cell is mounted vertically in the Instron by threading the steel extension rods into tensile grips. The current through the cell (between working and counter electrodes) is monitored on a multirange strip chart recorder, and the load applied to the sample is continuously monitored by means of the Instron load cell. The strain is calculated from the known cross-head position. With this apparatus, it has been possible to make constant strain, continuous straining, and variable strain rate tests. The latter two types of tests in particular can provide information, especially on oxide film ductility (6), which cannot be obtained either from constant strain or constant dead weight load tests alone. By continuously monitoring the load, the amount of stress relaxation which occurs before failure can be quantitatively determined. This is a useful parameter because the stress is a critical factor in determining the time to failure, and if considerable relaxation occurs, the time to failure will be greatly increased. This could lead to an erroneous conclusion as to susceptibility, if not taken into account. Also, any discontinuities, such as might occur during sudden crack propagation, can be observed.

Figure 3 shows results obtained using this system. Here, the applied load vs. time during a stress corro-

<sup>3</sup> As was noted by Dr. H. Lee Craig at the workshop on stress corrosion held at the Naval Air Materials Laboratory, Philadelphia, June 6-7, 1967, the change in solubility of dissolved oxygen can account for most of the temperature dependence reported for stress corrosion of aluminum alloys.

Table I. Nominal compositions and yield strengths of the aluminum alloys 7075-T651 and 2219-T37

Alloy	Nominal composition	Yield strength, psi
7075-T651	Al-5.6 Zn-2.5 Mg-1.6 Cu-0.3 Cr	73,000
2219-T37	Al-6.3 Cu-0.3 Mn-0.18 Zr-0.1 V-0.06 Ti	44,000

sion test was measured for two different aluminum alloys, 7075-T651 and 2219-T37. The properties and compositions of these alloys are shown in Table I. The initial applied stress in each case was 90% of the 0.2% offset yield stress. Each test was carried out in 1M NaCl buffered to a pH of 4.7 with acetic acid and sodium acetate and corrosion was carried out galvanostatically with a current density of 0.3 ma/cm<sup>2</sup>. It is evident that there are different modes of failure of each alloy.

For 7075-T651, failure is catastrophic, and only a very brief period of rapidly decreasing load immediately preceding failure can be seen. Hence, a single stress corrosion event occurred, *i.e.*, once the crack reaches a critical length it causes immediate (probably purely mechanical) failure.

For 2219-T37, however, failure occurs in a stepwise manner, with several points of discontinuous load change separated by regions in which the load decreases relatively slowly. This stepwise failure can be interpreted in two ways; on the one hand, the intermittent decreases in load could represent discontinuous propagation of a single crack; alternatively, they could represent the periodic initiation of new cracks. To determine which of these possibilities was correct, specimens of high-purity Al-4 Cu alloy were prepared. After solution heat-treatment for 6 hr at 520°C, these specimens were quenched and aged for 20 hr at 200°C to render them susceptible to stress corrosion cracking. The 6-hr solutionization treatment gave rise to sufficiently large grain size (0.2 mm) that the mode of crack propagation could be observed directly. The specimens were also cut so as to have a rectangular cross section with a width to thickness ratio of six to one, thus allowing the progress of crack propagation to be observed over the full length of specimen life. These specimens cracked in the same stepwise manner as did the commercial 2219-T37 specimens, and in each case failure was observed to propagate via a single crack. The regions of discontinuous fall in load were observed to coincide with the advancement of a crack along a grain boundary. Similarly, the intervening regions of relatively slowly decreasing load resulted from the halting of crack advance at grain boundary intersections. It could be concluded, therefore, that cracking occurs in this alloy by a periodic-electrochemical-mechanical mechanism (7), and that the electrochemical stage is associated with the reinitiation of mechanical failure at grain boundary intersections.

This stress corrosion cell, and the capability of the Instron for setting load or strain, are particularly useful in a relatively new area of interest, of great relevance to stress corrosion, recently brought out by the work of Bubar and Vermilyea (6). In their preliminary studies they explored oxide ductility on a number of metals; the rupture of surface oxides is of crucial importance to many theories of aluminum stress corrosion. In our system studies of the oxide film ductility on aluminum alloys were made by varying the strain, while the specimen was under potentiostatic control. The principle of the method is as follows: If the oxide is completely nonductile, increasing the strain results in its continual rupture. This exposes oxide film-free metal surface. The process of "repairing" the surface via its anodic oxidation will then give rise to a current which adds to the steady corrosion current. With a ductile oxide, the film thins and rupture will occur sometime after the strain is

applied, depending on the ductility. The rate of current increase after this point will be not only a function of the rate of film rupture, but also will depend on the rate of film repair.

Figure 4 presents results obtained on a tensile specimen of 2219-T37 which had been potentiostatically controlled at a sufficiently anodic potential to result in a corrosion current of about 0.4 ma/cm<sup>2</sup>. The strain was applied after the current had become nearly steady. Unloading was carried out at the same strain rate as the loading. Slight load relaxation (creep) occurred during the period of constant strain. Thus, the time required for unloading was slightly smaller than that for loading. From Fig. 4, the delay between the time at which the load was applied and the point at which the current increased can be seen to correspond to a strain of  $1.5 \times 10^{-3}$ . Beyond this point the increase in current with time is unmistakable. The rate of increase in current with strain (time) does not remain constant but increases. At constant strain there is a small decrease in the current, which becomes very rapid as the sample is unloaded. The final current is approximately the same as that before the strain was applied. We should emphasize that the specimen of 2219-T37 underwent less than a 1% change in exposed area during straining, which alone is insufficient to account for the factor of two change in the current.

It is evident, therefore, that during straining the oxide film becomes less protective through thinning and/or fracture. This metal undergoes rapid dissolution and there is an increase in current. Repair of the film at these cracks undoubtedly occurs, but the low rate of current decrease at constant strain indicates that this repair occurs only slowly and inefficiently in chloride. The decrease in current upon unloading corresponds to the closure of these fissures. Had the sample been plastically deformed substantially such a process would have been markedly retarded. From the length of time between loading and current increase, at least an indication of the over-all strength of the oxide film can be obtained. It is thought that the oxide film is of a different character above grain boundaries and precipitate phases than above the solutionized matrix. This technique promises to provide a quantitative picture of these properties.

These experiments are indicative of the range of this technique. Using it, we can expect critical tests of oxide rupture theories of stress corrosion and detailed studies of flaws in their passive layers. Further studies on age-hardened aluminum alloys are in progress.

In summary, we have described a new stress corrosion cell. This cell has the advantages of being sealed, leak-free, easy to assemble, and suitable for electrochemical measurements under controlled load and strain conditions. With this cell we have explored the mode of cracking of two aluminum alloys. Specifically, we have shown that in the Al-Cu system, cracks

Fig. 4. Relation between strain and current density for 2219-T37.

progress rapidly along grain boundaries but can be halted at grain boundary intersections. Exploratory experiments have indicated the application of this system to the study of oxide ductility and film repair.

## The Role of Gaseous Oxygen during HNO<sub>3</sub> Treatment of Platinum

Stuart G. Meibuhr\*

Research Laboratories, General Motors Corporation, Warren, Michigan

The nitric acid treatment (1-3) of bright Pt has been found to give a Pt electrode that will exhibit the reversible O<sub>2</sub> electrode potential of 1229 mv (4) in sulfuric acid and in phosphoric acid solutions (3). The treated, bright Pt electrode also has been shown to exhibit a higher double layer capacity (5) and a lower cathodic polarization (2, 6) than an untreated Pt electrode. The increased activity of the treated electrode has been maintained for several days despite severe cathodic polarization (6). Vacuum fusion analysis indicated a greater amount of oxygen to be associated with treated Pt than with untreated Pt (6); however, the quantity of nitrogen remained virtually unchanged.

The work reported here was concerned with the question of whether atmospheric oxygen was the source of the excess oxygen previously found in HNO<sub>3</sub> treated Pt.

The open-circuit oxygen potentials of three Pt wires were measured with an electrometer in a 3.25M H<sub>2</sub>SO<sub>4</sub> solution contained in a three-compartmented glass cell maintained at room temperature. Experiments were performed in triplicate. The electrolyte was preelectrolyzed cathodically and anodically at 200 ma/cm<sup>2</sup> in a manner similar to one described before (7). The H<sub>2</sub> counter and reference electrode was a small piece of American Cyanamid Company's AA-1 electrode material that was spot-welded to a Pt wire.

All three test electrodes were cleaned by repeated flaming followed by quenching in HNO<sub>3</sub>. After cleaning, the electrodes were washed well. The electrodes were then sealed in glass tubing with polypropylene. This technique was simpler than sealing the Pt wire directly to glass. Electrode number 1 was tested immediately without HNO<sub>3</sub> treatment. Electrodes 2 and 3 were HNO<sub>3</sub> treated for 4 days in a closed system. Electrode 2 was treated in acid through which oxygen was bubbled. This procedure simulated the open-air treatment described earlier (1). Electrode 3 was

# The Use of Discontinuous Metal Films in Determining the Rate of Formation of Very Thin Oxide Films

Francis P. Fehlner

Research and Development Laboratories, Corning Glass Works, Corning, New York

## ABSTRACT

A new method for determining the low-temperature oxidation-rate constants of metals has been developed. The method is based on measuring the change in d-c resistance of a discontinuous metal film when it is exposed to oxygen. Values of the logarithmic oxidation-rate constant ( $10^{-9}$  cm) for zirconium (1.8-10.3), titanium (0.2-4.0), niobium (0.8-3.2), and nickel (0.2-2.0) have been determined under the following conditions: 77°-298°K and  $10^{-6}$  to  $10^{-8}$  Torr oxygen.

A new method has been developed to measure the tarnishing rate of a metal at or below room temperature. The method is based on the change in d-c resistance of a discontinuous metal film when it is exposed to a reactive gas such as oxygen. Using this method, oxidation rates for titanium (1, 2), nickel (2), and zirconium (3) have been found which are smaller than rates obtained by other investigators. In the present work, the low-temperature oxidation of niobium is examined.

This new technique is a direct outgrowth of a detailed study of the electrical properties of discontinuous thin films of metals on glass (1-3). Formation of such films occurs initially by the nucleation of discrete islands which, after a certain growth period, coalesce into a physically continuous film. For example, a metal film may be deposited on a glass substrate by evaporation in a vacuum system. The condensing atoms exhibit large surface mobilities, arising primarily from their still-high kinetic energy. The magnitude of this mobility will depend on the materials involved and on the temperature and condition of the substrate. The migrating atoms undergo mutual collisions, resulting in the formation of clusters and embryos. Finally, large stable islands of metal are formed on the glass surface. These islands subsequently grow both horizontally and vertically until they coalesce into a continuous film. If metal evaporation is halted before the islands join together, a discontinuous film is left on the glass surface. Pashley (4, 5) and others have described this process in much greater detail.

Discontinuous metal films have several outstanding electrical characteristics which differentiate them from thicker films, although film conductivity in both cases can be explained on the basis of electron transport. The temperature coefficient of resistance for discontinuous films is negative; they show a decrease in a-c resistance with increasing frequency, and their mode of electron transport is by tunneling of electrons from island to island through insulating gaps.

There has been a continuing discussion of the role of thermionic emission *vs.* tunneling in the electron transfer process, but for the present study, the "activated tunneling" mechanism proposed by Neugebauer and Webb (6, 7) best fits the experimental conditions in a quantitative manner. The following equation is a condensed version of their expressions for film conductivity in terms of the geometrical characteristics and energy considerations of the islands and gaps (Fig. 1).

$$\sigma = Ad\phi^{1/2} \exp \left[ -\frac{\epsilon}{kT} - Bd\phi^{1/2} \right] \quad [1]$$

where  $\sigma$  = film conductivity, A, B = constants dependent on island size,  $k$  = Boltzmann constant,  $d$  = interisland distance,  $\phi$  = energy barrier to electron

transfer,  $\epsilon$  = activation energy for conduction, and  $T$  = temperature.

In the study of oxygen adsorption on titanium (1, 2), nickel (2), and zirconium (3), the relationships between  $\sigma$ ,  $\phi$ , and  $d$  in Eq. [1] were examined. In brief, it was found that the initial chemisorption of an oxygen monolayer caused an increase in  $\phi$ , while the subsequent oxidation of the metal islands led to an increase in  $d$ . Both changes caused a decrease in  $\sigma$  or, conversely, an increase in film resistivity  $\rho$ .

The increase in  $d$  occurring during film exposure to oxygen can be directly related to the low-temperature oxidation-rate constant by combining the empirical expression (8a)

$$s = K \log (at + t_0) \quad [2]$$

where  $s$  = oxide thickness,  $t$  = time,  $K$  = oxidation rate constant,  $a$ ,  $t_0$  = constants, with the assumption that the interisland distance after oxidation equals the interisland distance prior to oxidation plus twice the oxide thickness. This is illustrated in Fig. 1, where the small correction due to the oxide-metal volume ratio has been ignored. Under the conditions of large interisland distances and long exposure times, the following equation has been derived (3) for determining  $K$

$$\frac{\Delta \log \rho}{\Delta \log t} = 8.06 \times 10^7 \phi^{1/2} K \quad [3]$$

where  $\Delta$  has been used in place of the differential.

The determination of  $K$  from Eq. [3] requires both low pressures and low temperatures, so that the reaction will proceed slowly. At oxygen pressures below  $10^{-6}$  Torr, both the formation of an oxygen monolayer and the oxidation process have been observed. From the latter, rate constants for the low-temperature oxidation of titanium (1, 2), nickel (2), zirconium (3), and niobium have been calculated. The resulting rate constants are smaller than those obtained by other investigators (see Table I). This difference can be attributed to the restrictive experimental conditions of  $10^{-8}$  to  $10^{-6}$  Torr, and 77°-298°K.

Fig. 1. Idealized cross section of a discontinuous thin film of metal;  $s$ , oxide thickness;  $d$ , interisland distance.

Table I. Comparison of experimental values for low-temperature oxidation-rate constants

Metal	Temp. range, °K	This work		Temp. range, °K	Literature		Refer.
		K, $10^{-9}$ cm	$E_a$ , kcal mole $^{-1}$		K, $10^{-9}$ cm	$E_a$ , kcal mole $^{-1}$	
Nickel	77-298	0.2-2.0	0.2	195-299 293	3-11 10	1.5 —	(26) (27)
Niobium	$\approx 50$ -298	0.8-3.2	0.01	—	—	—	—
Titanium	77-298	0.2-4.0	0.2	298 298	65 60	— —	(23) (28)
Zirconium	77-298	1.8-10.3	0.3	323-373	39-59	1.9	(23)

The discontinuous film method does not work well with low-melting-point metals, such as copper or aluminum (2), unless the metal film is first stabilized against thermal rearrangement. Such island rearrangement is responsible for a change in film resistivity which interferes with the resistivity change caused by oxygen exposure.

### Experimental Method

An ultrahigh-vacuum system was used for the experiments, to avoid contamination of the films before they were exposed to oxygen. The basic parts of the stainless-steel, copper-gasketed system are shown in Fig. 2. An 8-hr bakeout at 225°C led to a base pressure of  $10^{-9}$  Torr. Pressure readings taken with the Bayard-Alpert ion gauge were corrected to the substrate position.

Evaporations were carried out at  $2 \times 10^{-8}$  Torr from tungsten filaments. The films were deposited on Corning Code 7059 glass substrates held at the temperature at which the experiment was to be run. The only exception was the  $\approx 50^\circ\text{K}$  run in which film deposition took place at 77°K. Initial film resistance was used as a measure of film reproducibility, since the temperature coefficient of resistance for the films was close to zero. The metals were better than 99.9% pure. The films used in the present study were almost continuous, since films made up of very small islands would be completely oxidized during the formation of a monolayer of oxygen. Further experimental details are to be found in ref. (2) and (3).

### Results

The present work on the low-temperature oxidation of niobium illustrates the potential of the discontinuous thin film method. The log-log dependence of niobium film resistance on time at constant oxygen pressure is shown in Fig. 3, 4, and 5. Substrate temperatures were 297°, 77°, and  $\approx 50^\circ\text{K}$ , while the oxygen pressure was  $9 \times 10^{-8}$  Torr in all but one case. Initial film resistance was  $\approx 11$  kohm sq $^{-1}$  except in Fig. 5 where a value of 715 kohm sq $^{-1}$  was used. No unusual effects (3) due to heat of adsorption or impurities were encountered. The sudden rise in resistance caused by monolayer formation was followed by the log-log linear behavior resulting from island oxidation.

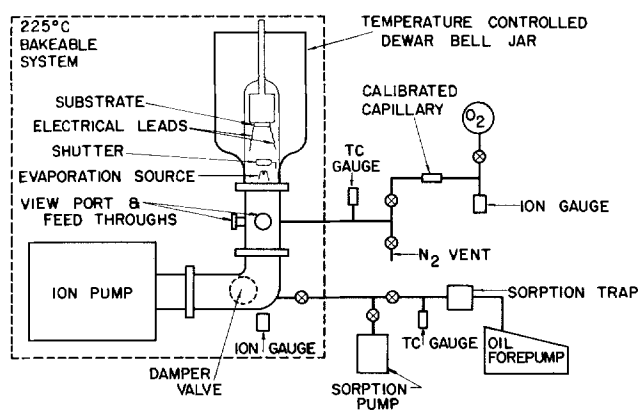

Fig. 2. Ultrahigh-vacuum system used for film evaporation, d-c resistance measurements, and oxygen exposure.

The slight increase in resistance with time found during the blank runs was due to adsorption of residual gases remaining in the vacuum chamber. This was especially true during the cool-down period for the  $\approx 50^\circ\text{K}$  runs.

The value of the change in niobium work function caused by oxygen adsorption is still unknown. Hence, the value of  $\phi$  in Eq. [3] was estimated to be 5 eV from comparison with the behavior of other refractory metals (9). Values of the rate constant  $K$  were then calculated from the slope of the  $\log R - \log t$  plots.

The value of the low-temperature oxidation-rate constant for niobium is compared with values for other metals in Table I. The relative oxidation rates follow the order:  $\text{Zr} > \text{Ti} > \text{Nb} > \text{Ni}$ . The rates found in the present work, when compared with those determined by other investigators, are found to be lower by a factor of approximately ten. The experimental activation energy shown in Table I is very small and may actually be zero, since the small difference in film structure caused by changes in deposition temperature was not taken into account.

### Discussion

The manner in which oxide films form at low temperature is still subject to various interpretations since definitive experimental data is lacking. Several theories (8b) have been developed to account for observations which include no oxygen diffusion into the metal (10), logarithmic kinetics (8a), and a very thin, adherent oxide film. The proposed mechanisms are

Fig. 3. Blank runs for niobium films in a vacuum of  $5 \times 10^{-9}$  Torr. X, Nb1A-1 at 297°K, O, Nb2A-1 at 77°K.

Fig. 4. Change in niobium film resistance caused by oxygen exposure at  $9 \times 10^{-8}$  Torr. X, Nb1A-1 at 297°K; O, Nb2A-1 at 77°K.

Fig. 5. Change in niobium film resistance caused by oxygen exposure at  $\approx 50^\circ\text{K}$ . X, cool down and O, oxygen run for Nb4A-1 at  $9 \times 10^{-8}$  Torr.  $\Delta$ , cool down and  $\square$ , oxygen run for Nb3A-1 at  $2 \times 10^{-7}$  Torr.

similar, since they all depend on electron transfer from the metal to oxygen adsorbed on the oxide surface. The electric field set up by the resulting charge separation causes ions to migrate through the oxide with a subsequent increase in oxide thickness.

The proposed oxidation mechanisms differ in the choice of a rate-limiting process: ion or electron transport. Cabrera and Mott (11) consider ion migration through the oxide under the influence of the electric field to be the most important process. Hauffe and Ilshner (12) hold that electron tunneling through the oxide is initially rate limiting with ion migration becoming subsequently more important. Fromhold and Cook (13) postulate a transition from ionic to electronic rate control. Uhlig (14) interprets the process as electron transfer across the metal-oxide interface, with a subsequent buildup of space charge in the oxide. These varied approaches to low-temperature oxidation predict either a direct or indirect logarithmic relationship between oxide thickness and time during the early stages of reaction, with a change in kinetics occurring after formation of a thin oxide film (in the range, 20-100Å thick). A direct logarithmic relationship (12, 14) is often observed, although the closely related inverse relationship is also possible (11). However, it is very difficult to differentiate experimentally between these two logarithmic relationships (15). Hence, the direct logarithmic expression has been adopted in the present work.

The interpretation of the experimental curves is based on the assumption that the Neugebauer-Webb conduction mechanism in discontinuous thin films involves direct tunneling from island to island through the vacuum gap. As a result, the sudden rise in resistance from B to C in Fig. 6 is interpreted as being due to an increase in the work function of the metal island surfaces. In other words, a monolayer of oxygen forms. The subsequent log-log linear portion of Fig. 6 (C to D) is then due to the oxidation of the islands.

Recently (16-19) conduction in discontinuous thin films has been reinterpreted in terms of electron tunneling from island to island through the substrate. This does not change the form of the conduction equation (Eq. [1]) but it does change the interpretation of the energy barrier  $\phi$ . No longer is  $\phi$  the vacuum work function of the metal islands, but it becomes the barrier to electron transfer at the metal-substrate in-

Fig. 6. Change in film resistance caused by oxygen exposure at constant pressure.

terface. Adsorption of a monolayer of oxygen can no longer affect film conductivity since  $\phi$  is not changed. However, oxidation of the metal islands still causes an increase in interisland distance and, as a result, an increase in film resistance. Hence, rate constants determined using Eq. [3] are still valid.

If substrate conduction is assumed, Fig. 6 must be reinterpreted. A to B now represents monolayer formation; B to C, a fast oxidation with a transition at C to a slow oxidation. These two oxidation rates may well correspond to the regions of ionic and electronic control postulated by Fromhold and Cook (13).

It is still too soon to discard the vacuum tunneling hypothesis, since substrate conduction has been shown to hold only for films with large interisland distances. The films used in the present work have very small interisland distances, so that it is still possible for direct tunneling to occur through the vacuum gaps (17). Experiments to resolve this point should be carried out in the near future. In any case, values of  $K$  calculated from the C to D linear portion of Fig. 6 would only be affected by a factor of two ( $\phi^{1/2}$ ) if the initial portion of the curve were reinterpreted.

The oxidation rate constants in Table I are based on an increase in the size of the interisland gaps and hence may be compared with the slow oxidation rate constants obtained by other investigators. The values of the oxidation rate constants found using the present method are smaller than those reported in the literature. Various factors can account for this difference.

Oxygen pressure was not an important variable in the discontinuous thin film work, but the range in which the pressure varied ( $10^{-6}$  to  $10^{-8}$  Torr) was far removed from that used to obtain the literature values (5-760 Torr) in Table I. Cabrera (20) has pointed out that pressures below  $10^{-4}$  Torr can lead to a reduction in the number of negatively charged oxygen ions adsorbed at the oxide-oxygen interface. As a result, the Mott potential and consequently the rate of oxidation will be reduced. Grimley (21) has also commented on this aspect of the oxidation process.

Low-temperature oxidation rates measured in high vacuum could not be found in the literature, so the effect of a ten-decade decrease in oxygen pressure can only be based on the present work. If the measured variation in  $K$  is attributed to oxygen pressure alone, then the rate constant must vary directly with the logarithm of pressure.

The above relationship may not be completely correct, since there is another factor which can modify the rate constant. Much published work has been done in a poorly controlled environment or at best, in a poor vacuum. It has been well established (8c, 15, 22, 23) that water vapor can affect the oxidation behavior of a metal, both decreasing and increasing the rate depending on conditions. Revesz (24) has also pointed out the influence of sodium and/or hydroxyl ions in increasing the rate of thermal oxidation of silicon. In fact Revesz and Evans (25) feel that silicon oxidation is normally an impurity controlled process.

Hence, the elimination of water and other impurities from the ultrahigh-vacuum work may well have changed the oxidation process, thereby reducing the oxidation rate.

### Summary

The oxidation of discontinuous metal films offers a simple and sensitive method for measuring low-temperature oxidation rate constants. The advantages of the method include control of variables such as impurities and heat of adsorption which can change the experimentally measured rates. These factors must be eliminated, or at least controlled, since they do not appear in the theoretical expressions for oxidation rate constants.

In addition, the surface structure of the metal can be controlled, and even single crystal surfaces can be utilized in films grown by epitaxial techniques. Uniform island size can be obtained by annealing the films for a long time, provided, of course, that the vacuum is high enough to prevent formation of a monolayer of gas.

The discontinuous film method is limited to the examination of tarnishing reactions, i.e., to temperatures below  $\approx 500^\circ\text{K}$ . Experimental techniques are relatively difficult, and all the interfering effects, such as film rearrangement, have not yet been eliminated. Despite these complications, the method offers a powerful tool for measuring tarnishing rates under very difficult conditions of pressure and temperature. Refinements in both theory and practice will allow the experimental results to be directly related to the microscopic parameters used in deriving reaction rate constants.

## Refractive Indices of ZnO, ZnS, and Several Thin-Film Insulators

J. C. Burgiel, Y. S. Chen, F. Vratny,\* and G. Smolinsky

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

### ABSTRACT

Optical constants of ZnO and ZnS near the band edges have been measured with an interference technique. Measurements on ZnO were performed on dielectric coated single crystals while those in ZnS were performed on thin films. Using a related method, we have also determined the refractive indices of insulating thin films of Ta<sub>2</sub>O<sub>5</sub>, Nb<sub>2</sub>O<sub>5</sub>, Si<sub>3</sub>N<sub>4</sub>, and a glow-discharge deposited silicone polymer. The significant features are discussed and related to the work of others.

Increasing studies of luminescence in II-VI semiconducting compounds have made detailed knowledge of the optical constants of these materials essential. Furthermore, efforts toward the development of luminescent devices using these compounds have made information concerning the optical constants of certain

Key words: refractive indices, insulator films, thin films, ZnO, ZnS.

\* Electrochemical Society Active Member.

dielectric films desirable. We have investigated at room temperature the II-VI compounds ZnO and ZnS together with thin films of the insulators Si<sub>3</sub>N<sub>4</sub>, Ta<sub>2</sub>O<sub>5</sub>, Nb<sub>2</sub>O<sub>5</sub>, and a glow-discharge deposited silicone polymer (1).

For ZnO we have measured both the real and imaginary parts of the ordinary refractive index as a function of wavelength at energies above as well as below

Fig. 1. Schematic diagram of samples used for determining the optical properties of the thin film. The optical properties of the substrate are known in this case.

the band gap. While there exist measurements of the refractive index below the band gap (2, 3), we believe our results are the first for the region near and above the band gap. For ZnS we have extended and corrected existing data on the real part of the refractive index in the region above the band gap. While ZnO measurements were performed on single crystal material (4), the ZnS measurements were performed on evaporated and crystallographically oriented sputtered films (5).

We have also measured the refractive indices of insulating thin films of chemically deposited  $\text{Si}_3\text{N}_4$  (6), reactively sputtered  $\text{Ta}_2\text{O}_5$  and  $\text{Nb}_2\text{O}_5$  (7), and a glow-discharge deposited silicone polymer. These measurements were performed over the respective wavelength regions in which these materials are transparent. These films are interesting because of their applications not only in electroluminescent cells, but also in light-trapping and waveguiding structures for use in second-harmonic generation and optical mixing (8), and in possible lasers.

### Methods

The optical constants reported here were determined from light interference in either the transmission or the reflection spectra of thin films. Previous workers (9-14) have employed such methods extensively to determine the optical constants of various materials. Our experiments can be divided into two categories, transparent film on transparent bulk substrates and on absorbing substrates.

*Transparent film on transparent bulk substrate.*—Figure 1 depicts a schematic diagram of a typical sample: a thin film A of thickness  $d$  on a bulk substrate B. Since both A and B are nonabsorbing, they are characterized by their respective refractive indices,  $n_f$  and  $n_s$ . The transmittance is given by (14)

$$T = \frac{I_T}{I_0} = \left\{ \frac{r_B^2}{1 - r_B^2} + \frac{1 + (r_A \cdot r_{AB})^2 - 2r_A r_{AB} \cos \phi}{(1 - r_A^2)(1 - r_B^2)} \right\}^{-1} \quad [1]$$

where  $r_A = \frac{n_f - 1}{n_f + 1}$ ,  $r_B = \frac{n_s - 1}{n_s + 1}$ ,  $r_{AB} = \frac{n_f - n_s}{n_f + n_s}$ , and

$\phi = \frac{4\pi n_f d}{\lambda}$  with  $\lambda$  being the wavelength of the incident light.

When  $\phi = m\pi$ , or equivalently when

$$\lambda_m = \frac{4n_f d}{m} \quad (m = 1, 2, 3, \dots) \quad [2]$$

the transmittance goes through a maximum or a minimum depending upon whether  $(-1)^m r_{AB}$  is positive or negative. Also the transmittance of this sample at  $m = 2, 4, 6, \dots$  can be shown to be equal to that of the substrate alone, and in turn gives an excellent check on the uniformity of the deposited film.

In a region in which  $n_f$  and  $n_s$  do not vary too rapidly with  $\lambda$ , the ratio of transmittance at neighboring maximum and minimum is given by

$$\frac{T_{\max}}{T_{\min}} = 1 + \frac{4r_A |r_{AB}| (1 - r_B^2)}{(1 - r_A |r_{AB}|)^2 - (r_A - |r_{AB}|)^2 r_B^2} \quad [3]$$

This function contains only two variables, i.e.,  $n_s$  and  $n_f$ ; therefore, given one, the other can be determined from the measured value of the ratio at a particular  $\lambda_m$ . Thus given the values of  $n_s$ , the film thickness  $d$  as well as the values of  $n_f$  as a function of  $\lambda$  can be determined through Eq. [2] and [3].

The fact that the wavelength at which the extremes occur can be accurately read and that the ratio of  $T_{\max}/T_{\min}$  does not require absolute measurements makes this method quite accurate for measuring  $n_f$  and  $d$ . This type of experiment can also be carried out using a measurement of reflection.

*Transparent film on absorbing substrate.*—Figure 2 gives the schematic diagram of a typical sample: a thin transparent film A of thickness  $d$  and index of refraction  $n_f$ , on a substrate C, bulk or film, whose optical constants are  $n_s$  and  $k_s$ , the latter being the extinction coefficient. In this case, the values of  $n_f(\lambda)$  are known either using the method of the previous section or from the literature; the unknowns are  $n_s(\lambda)$  and  $k_s(\lambda)$ .

The reflectivity at normal incidence is given by (9)

$$R = \frac{I_R}{I_0} = \frac{r_A^2 + |r_{AC}|^2 - 2r_A |r_{AC}| \cos(\phi + \theta)}{1 + r_A^2 |r_{AC}|^2 - 2r_A |r_{AC}| \cos(\phi + \theta)} \quad [4]$$

where  $r_A$  and  $\phi$  have already been defined, and where

$$|r_{AC}| e^{i\theta} = \frac{n_f - n_s + ik_s}{n_f + n_s - ik_s} \quad [5]$$

From Eq. [5] one obtains

$$|r_{AC}|^2 = 1 - \frac{4(n_s/n_f)}{\left(1 + \frac{n_s}{n_f}\right)^2 + \left(\frac{k_s}{n_f}\right)^2} \quad [6]$$

and

$$\theta = \tan^{-1} \frac{k_s/n_f}{1 - \frac{n_s}{n_f}} + \tan^{-1} \frac{k_s/n_f}{1 + \frac{n_s}{n_f}} \quad [7]$$

Experimentally, the quantities  $R$  and  $\theta$  can be determined from the reflectivity spectrum; the former is trivial and the latter is determined from the relationship

$$\frac{4\pi n_f d}{\lambda_m} + \theta = m\pi \quad [8]$$

at the extreme of the spectrum.  $n_f(\lambda)$  is already known and the thickness  $d$  can be determined from the  $n_f d$  product in a region where both film and substrate are transparent. Once  $R$  and  $\theta$  are known at various  $\lambda_m$ 's the values of  $n_s$  and  $k_s$  can be determined with the aid of a computer.

This method does rely on the absolute magnitude of the reflectivity; however, it does not contain the error one usually gets from a Kramers-Kronig anal-

ysis of the reflectivity spectrum arising from either insufficient coverage or from important nearby optical structure.

To assume good sensitivity and accuracy using this method, it is necessary that  $n_t$  and  $n_s$  not be too different and that  $k_s$  not be very large; in other words, as can be seen from Eq. [5],  $|\tau_{AC}|$  should not be near unity. This method therefore should be very good in determining the optical constants of the II-VI compounds near the band edge using dielectric films of similar refractive indices, but is not well suited for studying these constants in metals or in some of the homopolar semiconductors (12, 13).

### Results

Details concerning our samples are listed in Table I.

**Insulating films.**—An important problem arising in the production of certain insulating films is reproducibility. Slight variations in preparation conditions can cause variations in the properties of the resulting films. These problems are well under control for Ta<sub>2</sub>O<sub>5</sub> (7), Si<sub>3</sub>N<sub>4</sub> (6), and ZnS (5).<sup>1</sup> The glow-discharge technique used in preparing our silicone polymer films seems relatively free from such difficulties. Our Nb<sub>2</sub>O<sub>5</sub> films, however, were deposited under preliminary conditions and further experiments are necessary to show that we have indeed achieved reproducible films.

The refractive indices of our Ta<sub>2</sub>O<sub>5</sub> and Nb<sub>2</sub>O<sub>5</sub> sputtered films are plotted in Fig. 3. For both oxides our measured refractive indices are about 10% smaller than corresponding results for anodic films of these same materials (15). This discrepancy is well outside our limits of error and we conclude that for Ta<sub>2</sub>O<sub>5</sub> and Nb<sub>2</sub>O<sub>5</sub>, anodic and sputtered films are optically quite different.

The refractive indices for Si<sub>3</sub>N<sub>4</sub> and the silicone polymer are plotted in Fig. 4. Our results for Si<sub>3</sub>N<sub>4</sub>

<sup>1</sup> We have studied more than a dozen ZnS films and found excellent consistency and reproducibility. In particular, below the band gap at least, we get the same results for both sputtered and evaporated films; this fact alone argues strongly that the properties of our film are not being affected by variations in our method of deposition.

Fig. 3. Refractive indices of Ta<sub>2</sub>O<sub>5</sub> and Nb<sub>2</sub>O<sub>5</sub> sputtered films

are in good agreement with the value  $n = 2.00$  to  $2.05$  obtained by Bean *et al.* (16) at a wavelength of 5461 Å.

The refractive index of the silicone polymer was measured for films deposited on two optically very different substrates, KTaO<sub>3</sub> (17) and Al<sub>2</sub>O<sub>3</sub>. This was necessary in order to resolve the ambiguity arising because in this case Eq. [3] has two possible solutions. It seems worth mentioning that the glow-discharge method of preparing polymer films (1) is a very simple one requiring relatively little specialized equipment. Using this method, polymer films can be produced from most reasonably volatile organic compounds; and by changing the raw materials, it is possible to tailor the properties of the resulting film.

ZnO.—Figure 5 shows  $n$  and  $k$ , the real and imaginary parts of the ordinary complex refractive index, for ZnO for photon energies ranging from 2 to 4 eV. The measurements were made by coating the ZnO single crystal (4) with a thin film of Ta<sub>2</sub>O<sub>5</sub>, the refractive index of which is obtained from Fig. 3. At energies sufficiently below the band gap of ZnO that  $k$  is very small,  $\theta$  in Eq. [8] is zero. From the magnitude of the interference fringes, and from the shift in their positions, *i.e.*, from the value of  $\theta$ , we are able to determine both  $n$  and  $k$  for the ZnO substrate. The chief uncertainty in this procedure is the slight possibility that due to different surface mobility or to somewhat different heat transfer conditions the Ta<sub>2</sub>O<sub>5</sub> film deposited on ZnO may have a slightly different density than the Ta<sub>2</sub>O<sub>5</sub> deposited on sapphire. For this reason we have also performed the experiment using a sputtered ZnS film in place of the Ta<sub>2</sub>O<sub>5</sub> to determine the refractive index of ZnO below 3.0 eV. The results are also given in Fig. 5 and are in reasonable agreement with those from Ta<sub>2</sub>O<sub>5</sub> coated

Fig. 4. Refractive indices of Si<sub>3</sub>N<sub>4</sub> and silicone polymer thin films.

Fig. 5. Real and imaginary parts of the ordinary complex refractive index ( $\bar{n} = n + ik$ ) of ZnO.

samples. The refractive index at 2.5 eV is 1.94 as compared to 2.05 in ref. (3).

The structure between 3.0 and 4.0 eV in the curves of Fig. 5 is an interesting new feature of ZnO. Admittedly our data points are too far apart to adequately resolve this structure, however we are continuing our studies of this phenomenon. Neither of the authors of ref. (2) and (3) give results to this high an energy. It is tempting to associate the peaks in  $k$  at 3.4 and 3.7 eV with exciton transitions (18, 19). Unfortunately extrapolation of the temperature dependence of the  $A$  ( $n = 1$ ) exciton (19) to room temperature is at best an uncertain procedure; however, if such an extrapolation is made, the numbers appear reasonable. We hope that an experiment of ours currently in progress will clarify the nature of this structure.

ZnS.—There is serious disagreement between the results of Coogan (20) and of Hall (21) for the refractive index of thin ZnS films at energies about 3 eV. Both sets of data were obtained from fitting the transmission and the reflection spectra of thin ZnS films. The data of Coogan show significant structure at 4.4 eV, while those of Hall increase monotonically with photon energy. We have applied the method described in this paper to determine the refractive index of ZnS films, both sputtered and evaporated. The results are given in Fig. 6. Data below 3.0 eV was obtained from ZnS films on c-cut sapphire substrates. No difference was found between the sputtered films (predominantly cubic ZnS with the (111) plane in the plane of the film) and the evaporated films. Data above 3.5 eV was obtained using [sapphire] — [ $\text{Si}_3\text{N}_4$  film] — [ZnS film] samples by the method stated in the section on Transparent film on absorbing substrate. Both types of sample yielded similar results. Although the results above the ZnS gap are somewhat scattered, it is certain that they are much closer to those of Hall than of Coogan. Recently, similar results were reported by Cardona (22) in a Kramers-Kronig analysis of the reflectivity spectra of ZnS single crystals, both cubic and hexagonal.

#### Symbols

- $d$  = film thickness.  
 $k$  = extinction coefficient.  
 $k_s$  = extinction coefficient of substrate.  
 $m$  = integer giving the order of reflectivity or transmittance extremum.  
 $n$  = refractive index  
 $n_f$  = refractive index of thin film.  
 $n_s$  = refractive index of substrate.  
 $R$  = reflectivity of entire sample.

Fig. 6. Refractive index of ZnS thin films. Below the band gap the results for both sputtered and evaporated films agree; however, above band gap some differences occur.

- $r_{AB}$  = complex reflectance of interface between material A and B.  
 $T$  = transmittance of entire sample.  
 $\theta$  = phase of complex reflectance.  
 $\lambda$  = wavelength of incident light.  
 $\lambda_m$  = wavelength corresponding to extremum of order  $m$ .  
 $\phi = (4\pi n_f d) / \lambda$

Manuscript received Jan. 8, 1968; revised manuscript received ca. March 5, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Abstract 18.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## ABSTRACT

The incorporation of divalent europium in the compounds  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ , and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  produces phosphors of high luminescence yield. These phosphors respond well to both long and short wavelength ultraviolet excitation, as well as to cathode ray bombardment. The peak of the emission band occurs at progressively shorter wavelength and narrows as the radius of the major alkaline earth ion (Ca, Sr, or Ba) is increased. A  $1200^\circ\text{C}$  isotherm on compositions intermediate to  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  shows a complete series of crystalline solutions to exist at this temperature. Using an orthorhombic cell the d-spacings of the (222) reflection vary continuously from 1.956 Å for  $\text{Sr}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$  to 2.012 Å for  $\text{Ba}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$ . The emission spectra of these samples, however, vary in a discontinuous manner. Complete crystalline solution is likewise observed in a  $1200^\circ\text{C}$  isotherm for compositions intermediate to  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ . Here the d-spacings of the (222) reflection from the orthorhombic cell vary continuously from 1.909 Å for  $\text{Ca}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$  to 1.956 Å for  $\text{Sr}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$ . Again the peak of the emission spectra varies discontinuously with composition even for the complete crystalline solution series.

Emission spectra and x-ray diffraction data collected on samples prepared in the  $1200^\circ\text{C}$  subsolidus isotherm intermediate in composition to  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  show an intermediate compound to be formed. This compound  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  has luminescent properties which more closely resemble those of the calcium end-member. Several compositions were prepared in the subsolidus,  $1200^\circ\text{C}$ , isothermal, ternary section bounded by  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ , and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . The samples prepared show the major feature of the section to be a large single phase region. In general, broadening of spectral energy distributions is observed as compositions move into the ternary section. All the compositions prepared resulted in phosphors of relatively high efficiency.

Several other works on subsolidus equilibria cover various parts of the phase data presented here. Klasens, Hoekstra, and Cox (1) in an extensive work on lead activation of ternary silicates mention the complete crystalline solubility of ( $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ ) and ( $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ ). They also report that x-ray data from a 1:1 composition between  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  prepared subsolidus shows that substantial  $\text{Ca}^{2+}$  in  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  can be replaced by  $\text{Ba}^{2+}$ , while very little  $\text{Ba}^{2+}$  in  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  can be replaced by  $\text{Ca}^{2+}$ . Regarding the fluorescence of the compounds they report all three to be of little importance. Aside from Pb, they tried many of the other usual activators such as Mn, Tl, Bi, Sb, Sn, etc., in the ternary compounds. Although some did show a weak fluorescence, none of the others led to phosphors of any appreciable efficiency.

Nadachowski and Grylicki (2) in a study of the phase equilibria in the  $\text{Ba}_2\text{SiO}_4\text{-Ca}_2\text{SiO}_4\text{-Mg}_2\text{SiO}_4$  system reported two compounds,  $\text{BaMgSiO}_4$  and  $\text{BaMg}_3\text{Si}_2\text{O}_8$ , existed in the bounding system  $\text{Ba}_2\text{SiO}_4\text{-Mg}_2\text{SiO}_4$ , which they represent as binary. They did not report the compound  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . One ternary compound ( $\text{BaCa}_2\text{MgSi}_2\text{O}_8$ ) was reported to exist in the system.

Argyle (3) redid the phase relations in the  $\text{BaO-MgO-SiO}_2$  system. He reports the compound  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  found earlier by Klasens *et al.* (1) but not by Nadachowski and Grylicki (2). X-ray data from his work and that of Klasens state that the com-

pound  $\text{BaMg}_3\text{Si}_2\text{O}_8$  reported by Nadachowski and Grylicki is really a mixture of  $\text{BaMg}_2\text{Si}_2\text{O}_7$  and  $\text{MgO}$ .

## Experimental

**Starting materials.**—The alkaline earth carbonates of the large alkaline earth ions and the silicic acid used in this study were luminescent grade chemicals. The basic magnesium carbonate was a Mallinckrodt analytical reagent containing less than 0.005% sulfate as an impurity. The europium oxide was of 99.9% purity. Analysis of the europium oxide, as given by the American Potash and Chemical Corporation, showed only trace amounts of other rare earth ions. The ammonium chloride used was a commercially available reagent grade chemical. Assays were run on basic magnesium carbonate, manganese carbonate, and silicic acid to allow compensation for sorbed water in formulating the blends.

**Preparation of starting mixtures.**—Starting mixtures were prepared by dry blending the appropriate proportions of the raw materials in a model 8000 Spex Mixer/Mill for 15 min. The addition of a few glass beads to the raw blend greatly facilitates the mixing process.

**Firing procedure.**—The blended mixtures were fired in alumina boats at  $600^\circ\text{C}$  in air. This firing initiates the decomposition of the alkaline earth carbonates and reaction with the ammonium chloride flux.

The prefired samples were then fired at  $1200^\circ\text{C}$  in an atmosphere of 4 parts nitrogen to 1 part hydrogen. Firing times of 2 to 12 hr and temperatures ranging between  $1100^\circ$  and  $1300^\circ\text{C}$  were used at various times,

**Key words:** Phosphors alk earth silicates, emission spectra, europium ( $2+$ ) activation, fluorescence europium ( $2+$ ), equil subsolidus, energy transfer Eu ( $2+$ ) to Mn ( $2+$ ), luminescence alk earth silicates.

the routine combination being 4 hr at 1200°C. After firing the samples were allowed to cool to room temperature in the reducing atmosphere.

The optimum flux concentration was about 0.20 moles of  $\text{NH}_4\text{Cl}$  per mole of silicic acid. The presence of the  $\text{NH}_4\text{Cl}$  flux effects both the reaction rate and the luminescence of a particular composition at a given temperature. Samples fired without flux yield a product of considerably poorer crystallinity, as evidenced in x-ray diffraction patterns, and give emission curves much broader and substantially less intense than that characteristic of the equilibrium assemblage.

**Characterization of products.**—Both fast ( $2^\circ/\text{min}$ ) and slow ( $0.25^\circ/\text{min}$ ) scans using a Norelco x-ray diffractometer with filtered  $\text{CuK}\alpha$ -radiation were useful in phase identification. Fluorescent properties (excitation spectra and spectral energy distribution curves) were determined using equipment and techniques, which have been fully described elsewhere (4).

### Results and Discussion

**End-member phases.**—The three compounds which delimit the compositions covered in this study all produce highly efficient, narrow band, blue emitting phosphors when activated by divalent europium. They exhibit a brilliant blue fluorescence when excited by u.v. radiation or cathode rays. They respond well to 2537Å radiation as well as to radiation from a blacklite lamp, which has a broad u.v. spectrum from 3250 to 4000Å. These phosphors possess band widths about one-third as wide as most commercial blue phosphors. Activator concentrations between 0.005 and 0.10 atom fraction europium were all found to produce efficient phosphors. A value of 0.04 was commonly used in this study. The spectral properties of these phosphors are given in Table I. The intensity factors given in Table I are the product of the peak height, the scale factor, and the width at half height. The factors given for individual members of the compositional series include experimental variables. They are only a qualitative measure of intensity variations and are given in order to compare the compounds themselves and also subsequent compositions to follow. Figure 1 gives the spectral energy distribution curves for the three compounds run at different instrument settings, as indicated by the intensity factors. The narrowing of the emission band and the shifting to shorter wavelengths as the ionic radius of the major alkaline earth ion is increased is obvious in these curves.

Figure 2 gives plots of peak wavelength vs. the ionic radii of the large alkaline earth ions. Plots are given for both Ahrens' and Goldschmidt radii. Both plots indicate a nearly linear relationship with a slight positive deviation for one set of radii and a slight negative deviation for the other. This indicates the structures of the three compounds to be quite closely related if not isomorphous. Klasens *et al.* (1) reported that an isomorphous relationship appeared to exist for  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ , and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . They thus indexed the x-ray lines for all three compounds on the basis of an orthorhombic cell. Their cell dimensions for the three orthorhombic cells are given in Table II. An earlier work by Nurse (5) states that merwinite,  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ , is monoclinic with cell dimensions

$$a_0 = 10.77, b_0 = 9.20, c_0 = 13.26\text{Å}; \beta = 91^\circ$$

In addition Argyle (3) states that x-ray patterns of

Fig. 1. Spectral energy distribution curves for  $\text{Ba}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$ , and  $\text{Ca}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$  (2537Å excitation).

Fig. 2. Peak wavelength vs. ionic radii of large alkaline earth ions.

$\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  were not sufficiently alike for them to have the same structures. Using the orthorhombic cell of Klasens for  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ , lines from this compound were used to assign indices to lines in  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . These indices were then used to obtain lattice parameters for the orthorhombic cell. However, these lattice parameters could not be used successfully to index all the remaining lines.

The diffraction data collected in this study agreed with the works of Nurse (5) and Argyle (3). The monoclinic distortion of the orthorhombic structure was very clearly in evidence in some of the crystalline solution phases prepared. However, the orthorhombic cells proposed by Klasens *et al.* (1) approximate the true structures fairly closely, as the monoclinic distortions are slight, and were used in assigning indices to the x-ray peaks used in defining crystalline solubility in this study. The monoclinic distortion was very pronounced in the  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ - $\text{Sr}_3\text{MgSi}_2\text{O}_8$  complete solution series and slight in the  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ - $\text{Sr}_3\text{MgSi}_2\text{O}_8$  series.

Table I. Fluorescent data on compounds

Phosphor composition	Wavelength of maximum emission, nm	Width of band at half intensity, nm	Intensity factor
$\text{Ca}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$	475	52	21.8
$\text{Sr}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$	458	39	50.3
$\text{Ba}_3\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}$	437	31	60.5

	$a_0$ , Å	$b_0$ , Å	$c_0$ , Å
$\text{Ca}_3\text{MgSi}_2\text{O}_8$	5.2	9.2	6.8
$\text{Sr}_3\text{MgSi}_2\text{O}_8$	5.4	9.6	7.2
$\text{Ba}_3\text{MgSi}_2\text{O}_8$	5.5	9.8	7.6

The subsolidus  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ - $\text{Sr}_3\text{MgSi}_2\text{O}_8$  join.—A subsolidus isotherm at  $1200^\circ\text{C}$  was run on samples prepared at 10 m/o (mole per cent) intervals for compositions varying between  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ . Using the (222) reflection from the orthorhombic cell, described above, the change in x-ray d-spacing with composition was followed. This plot is given in Fig. 3. The continuous variation in d-spacing of the (222) reflection from a value of  $1.956\text{\AA}$  for  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  to  $2.012\text{\AA}$  for  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  shows complete crystalline solution to exist between these two compounds. Spectral energy distribution curves were obtained on these samples when divalent europium was employed as the activator. The variation of peak wavelength with composition is given in Fig. 4. This figure shows that the replacement up to 50 m/o of  $\text{Ba}^{2+}$  by  $\text{Sr}^{2+}$  in  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  has essentially no effect on the position of the emission band. However, broadening of the band does occur. Beyond the 50-50 composition on up to  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  the emission peak does shift in a fairly continuous manner with composition and the width of the emission band narrows. The fluorescent data obtained on the samples prepared are given in Table III.

The scatter of the points in the 30-50 m/o  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  region in Fig. 3 and 4 is due to the presence of a small amount of a nonequilibrium second phase, which is not characteristic of this join. Extreme examples of the formation of metastable phases which can arise when compositions along this join are sought are given below.

Since this join has previously been established as one of complete crystalline solution (1), the spectral energy distribution (S.E.D.) curves for finished phosphors, activated by divalent europium, should

yield single band emissions, intermediate to those of the two end-members as presented above. When two compositions represented by the following formulations ( $\text{Ba}_2\text{Sr}$ ) $\text{MgSi}_2\text{O}_8$  and ( $\text{BaSr}_2$ ) $\text{MgSi}_2\text{O}_8$  were prepared, S.E.D. curves showed a double peak which was in direct contrast to the single peak observed for other members prepared along this join. This so-called doublet, in the case of ( $\text{Ba}_2\text{Sr}$ ) $\text{MgSi}_2\text{O}_8$ , is actually composed of two overlapping bands in the blue region (due to one of the metastable phases and the equilibrium crystalline solution) and a band in the green region due to the second metastable phase. However, these formulations may be represented by other joins which intersect the  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ - $\text{Ba}_3\text{MgSi}_2\text{O}_8$  join at the respective points. Thus, other phases, which are indicative of this other join, may form metastably. This is exactly what happens to these two mixtures. Thus, instead of forming a single phase crystalline solution which may be formulated as ( $\text{Ba}_2\text{Sr}$ ) $\text{MgSi}_2\text{O}_8$ , two additional phases ( $\text{BaMgSiO}_4$  and  $\text{SrBaSiO}_4$ ) form metastably and these are readily seen in the S.E.D. curves, since the spectra obtained for the fired sample contains peaks of the two metastable components and differs from the single peak which is characteristic of the crystalline solution. The same holds for the ( $\text{BaSr}_2$ ) $\text{MgSi}_2\text{O}_8$  formulation except different phases are metastably formed. This was quickly established, as all the compounds as well as other selected compositions have been prepared and S.E.D. curves obtained for each sample.

This trend is not so easily observed in x-ray diffraction patterns of these compositions because of poor crystallinity of the metastable phases formed and the resultant low intensity broad lines of the patterns obtained. Also, reheating the initial samples obtained by firing 3 hr at  $1200^\circ\text{C}$  in 20%  $\text{H}_2$  for 12 hr more in the same atmosphere and at the same temperature greatly diminished the intensity of the emission peaks of the metastable phases and increased that of the stable crystalline solution.

Various compounds have been employed as starting materials in preparation of the crystalline solutions in this system. Drastic changes in the kinetics have been observed with different starting materials formulated to yield the identical result after firing. In samples prepared incorporating a hydrated magnesium silicate,  $\text{MgO}\cdot 2.5\text{SiO}_2\cdot 1.5\text{H}_2\text{O}$ , as a starting material equilibrium was difficult to obtain in many instances even by prolonged heating ( $\sim 60$  hr at  $1200^\circ\text{C}$ ). However, when this compound is replaced in the blend by basic magnesium carbonate ( $3\text{MgCO}_3\cdot \text{Mg}(\text{OH})_2\cdot 3\text{H}_2\text{O}$ ) plus partially decomposed silicic acid ( $\text{SiO}_2\cdot \text{XH}_2\text{O}$ ), equilibrium was obtained within 4 hr at  $1200^\circ\text{C}$ , except for the specific compositions previously noted. The same type of metastable relations observed above apply here.

The subsolidus  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ - $\text{Sr}_3\text{MgSi}_2\text{O}_8$  join.—The  $1200^\circ\text{C}$  subsolidus isotherm run between these compounds also showed a join of complete crystalline solution. The variation of the (222) reflection with composition, again on the basis of the orthorhombic cell, resulted in a continuous curve varying from  $1.956\text{\AA}$  for  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  to  $1.909\text{\AA}$  for  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ . This plot is

Fig. 5. X-ray  $d$ -spacing vs. composition for  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ - $\text{Ca}_3\text{MgSi}_2\text{O}_8$  crystalline solutions.

Fig. 6. Peak wavelength vs. composition for  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ - $\text{Ca}_3\text{MgSi}_2\text{O}_8$  crystalline solutions.

given in Fig. 5. A curve of the emission wavelength at maximum intensity vs. composition (for divalent europium activation) is given in Fig. 6. This shows that emission peak to be sensitive to composition in the regions near the end-members. The center of the diagram shows a large compositional region (30 to 80 m/o  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ) in which both the position and width of the emission peak are relatively insensitive to composition. The data on the fluorescent samples are given in Table IV. In general, the intensity factors above show a substantial increase in fluorescent output for the crystalline solution phases.

*The subsolidus  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ - $\text{Ba}_3\text{MgSi}_2\text{O}_8$  join.*—Evaluation of both x-ray and fluorescent (S.E.D.) data collected on samples prepared in the subsolidus region

between the compounds  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  revealed the existence of an intermediate compound. The chemical formula of this compound is  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  and its x-ray pattern is distinctly different from that of either  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  or  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . The spectral energy distribution curve of this compound (when divalent europium is employed as the activator) although different from both compounds is more similar to that of  $\text{Ca}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$ .

X-ray diffraction studies of subsolidus compositions intermediate to  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  indicate a very limited solubility of  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  in  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  probably of the order of 10 m/o. Patterns of compositions between 10 and 40 m/o  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  exhibit two distinct phases, one a  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  crystalline solution and the other a  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  crystalline solution. Between 40 and 80 m/o  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ , a large single phase region with the  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  structure exists. From 80 m/o  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  on up to the pure compound itself two crystalline phases co-exist, one a  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  crystalline solution, and the other essentially pure  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ . The fluorescent data on these samples are given in Table V.

It can be seen in the table that the emission peak broadens from the compound  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ , narrows again with further increase in the  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  concentration, rebroadens, and is finally very sharp for the pure  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  compound. It has been reported by Klasens *et al.* (1) that a substantial amount of  $\text{Ca}^{2+}$  can be replaced by  $\text{Ba}^{2+}$ , while little  $\text{Ca}^{2+}$  seems to be taken up by  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . If these data represented the complete picture of what occurs between these two ternary orthosilicate compounds, then the two crystalline solution fields would be separated by a two phase region in which two crystalline solution phases (varying in amount with composition) would be in equilibrium with one another at a constant temperature. Thus, it would not be possible for an intermediate composition to yield an emission spectrum with a band any narrower than that of the sum of the two crystalline solutions in equilibrium at the given temperature. The narrowing of the emission spectrum for the intermediate compositions evidenced in Table V clearly demonstrates that this is not the case. The fluorescence spectra of the divalent europium incorporated in these specimens make obvious the intermediate compound formed. The divalent europium employed in this study yields more efficient phosphors with spectral energy distributions which are much more definitive as an aid in interpreting the phase relations for these compositions than the divalent lead employed by Klasens *et al.* (1). A search of the literature revealed this intermediate compound ( $\text{BaCa}_2\text{MgSi}_2\text{O}_8$ ) had been reported in a phase equilibrium study of the so-called ternary system  $\text{Ba}_2\text{SiO}_4$ - $\text{Mg}_2\text{SiO}_4$ - $\text{Ca}_2\text{SiO}_4$  by Nadachowski and Grylicki (2).

*Ternary compositions bounded by  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ , and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ .*—Several divalent europium activated fluorescent compositions have been prepared at  $1200^\circ\text{C}$  in the orthosilicate plane bounded by the compounds  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ,  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ , and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . The compositions studied are represented by lines joining one pure compound with the 1:1 com-

position between the other two compounds. In general, broadening of spectral energy distributions of intermediate compositions occurs as we move away from the compositions representing the pure compounds. This can be seen in Table VI which gives the emission peak and the width at half height for compositions intermediate to  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ .

Table VII presents the same data for compositions intermediate to  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and the 1:1 composition between  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ .

The data obtained for samples prepared along the third join between  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and 1:1 composition between  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$  are tabulated in Table VIII.

The data in Tables VI-VIII indicate that if the divalent europium ( $r^{2+} = 1.12\text{\AA}$ ) is substituting for the large divalent alkaline earth ions, the emission spectra, in regard to shifting and broadening, are least sensitive when the dominant alkaline earth ion is larger than divalent europium as in the case of  $\text{Ba}^{2+}$  ( $r^{2+} = 1.34\text{\AA}$ ), most sensitive when it is smaller as  $\text{Ca}^{2+}$  ( $r^{2+} = 0.99\text{\AA}$ ), and intermediate when the disparity is minimum such as for  $\text{Sr}^{2+}$  ( $r^{2+} = 1.12\text{\AA}$ ) (6).

X-ray diffraction patterns of the compositions run in this study indicate very extensive ternary crystalline solution to exist. Only a single phase was present in the ternary compositions presented here.

#### Co-activation with Manganese

Attempts at incorporating both divalent europium and divalent manganese in the three bounding phases of this study were conducted. Manganese alone does not activate these compounds. Previous works on co-activation in alkaline earth phosphate systems have reported such phenomena (7, 8). It was found that co-activation with europium and manganese occurred quite efficiently in the compound  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ . An S.E.D. curve showing both europium and manganese emission is given in Fig. 7. A substantially less efficient co-activation was found in the S.E.D. curves of the compounds  $\text{Ca}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ . The S.E.D. curves for the three compounds (activated by divalent europium alone) given in Fig. 1 show the large variation in peak position for the three compounds. The peak for  $\text{Ba}_3\text{MgSi}_2\text{O}_8$  falls at a considerably lower wavelength than the other two. The wavelength at which maximum intensity occurs may be the key to co-activation for the europium-manganese pair

Fig. 7. Spectral energy distribution curve showing co-activation with  $\text{Eu}^{2+}$  and  $\text{Mn}^{2+}$  in  $\text{Ba}_3\text{MgSi}_2\text{O}_8$ .

in these compounds. It was also observed that the wavelength at which maximum intensity of the manganese emission occurs shifts to longer wavelength as the average ionic radius of the large alkaline earth ion is decreased by substitution of ( $\text{Sr}^{2+}$ ), or ( $\text{Sr}^{2+} + \text{Ca}^{2+}$ ) for  $\text{Ba}^{2+}$ . Examples illustrating this shifting are given in Table IX.

Figure 8 shows the decrease in europium emission as the manganese concentration is increased and a corresponding increase in the manganese emission up to the point where concentration quenching sets in. This type of relationship is characteristic of an energy transfer process.

#### Conclusion

Divalent europium activation of  $\text{A}_3\text{MgSi}_2\text{O}_8$  phases (where A = Ca, Sr, and Ba, or any combination of the three) has produced a series of narrow band, high-luminescent yield phosphors in which the emission band can be shifted over the blue region of the spectrum. These phosphors have potential application in photocopy devices where the energy delivered must fall within specific wavelength limits. They may also find application as color correction phosphors, as they are capable of supplying more energy at the key wavelengths necessary to achieve the desired result. This would also allow some variations in the other phosphors in the blend because of the narrow spectral region covered by the blue color corrector.

This work agrees with that of Klasens *et al.* (1) on the complete crystalline solubility of ( $\text{Ba}_3\text{MgSi}_2\text{O}_8$  and  $\text{Sr}_3\text{MgSi}_2\text{O}_8$ ) and ( $\text{Sr}_3\text{MgSi}_2\text{O}_8$  and  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ ). In these two pseudobinary systems where complete crystalline solution exists, the luminescence of intermediate phases has been shown to be enhanced. Also, the emission wavelength at which maximum intensity occurs does not vary in a continuous manner even for the systems with complete crystalline solution. However, the divalent europium served as a more definitive probe in establishing the existence of the compound  $\text{BaCa}_2\text{MgSi}_2\text{O}_8$  not reported by them in the  $\text{Ca}_3\text{MgSi}_2\text{O}_8$ - $\text{Ba}_3\text{MgSi}_2\text{O}_8$  pseudobinary system.

Reaction kinetics are greatly affected by the starting materials and also may be characteristic for specific compositions.

Table IX. Emission data on some  $\text{Eu}^{2+}$ ,  $\text{Mn}^{2+}$  co-activated crystalline solution phases

Composition	Blue band $\lambda_{\text{Peak}}$ , nm	Red band $\lambda_{\text{Peak}}$ , nm

$(\text{Ba}_{2.11}\text{Sr}_{0.75})\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}, \text{Mn}_{0.10}^{2+}$	437	645
$\text{Ba}_{1.36}\text{Sr}_{0.75}\text{Ca}_{0.75})\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}, \text{Mn}_{0.10}^{2+}$	443	670
$\text{Sr}_{2.86}\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}, \text{Mn}_{0.10}^{2+}$	458	685
$\text{Ca}_{2.86}\text{MgSi}_2\text{O}_8:\text{Eu}_{0.04}^{2+}, \text{Mn}_{0.10}^{2+}$	475	>700

Fig. 8. Effect of manganese concentration on the energy transfer in  $(\text{Ba}_{0.224-x}\text{Sr}_{0.75})\text{MgSi}_2\text{O}_8:\text{Eu}_{0.01}^{2+}, \text{Mn}_x^{2+}$ .

Co-activation with manganese produces a phosphor with two distinct emission bands. One characteristic of the particular composition activated by europium alone and a second band in the red region of the spectrum whose position may be regulated by the formulation of A in  $\text{A}_3\text{MgSi}_2\text{O}_8$ . The spectral energy distribution curves of these co-activated phosphors (Fig. 7) conform fairly well to the action spectra of chlorophyll synthesis and photosynthesis. Thus, they may potentially be useful as "Gro-Lux" phosphors. This possibility is enhanced because of the latitude allowed in shifting both the blue and red emission bands.

### Acknowledgments

The author wishes to express his thanks to Dr. K. H. Butler and Dr. M. J. B. Thomas for their encouragement and valuable discussions during the course of this investigation. Appreciation is also extended to Mr. A. Rudis for the preparation and spectral determinations on many of the samples and to Miss M. Skeadas for the x-ray diffraction data.

Manuscript received Feb. 9, 1968; revised manuscript received March 18, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Fluorescence of Uranium-Activated Compounds with Rocksalt Lattice

G. Blasse

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

### ABSTRACT

The green fluorescence of the following phosphors is reported:  $\text{Li}_3\text{NbO}_4\text{-U}$ ,  $\text{Li}_3\text{SbO}_4\text{-U}$ ,  $\text{Li}_2\text{SnO}_3\text{-U}$ ,  $\text{LiScO}_2\text{-U}$ , and  $\text{MgO-U}$ . Their crystal structures are based on the rocksalt lattice. It is found that for increasing lithium content of the host lattice the position of the maximum of the emission band shifts to shorter wavelengths and the quantum efficiency increases. This relation is discussed. Concentration quenching occurs at low activator concentration.  $\text{Y}_6\text{WO}_{12}\text{-U}$  with regular  $\text{UO}_6$  octahedra emits also in the green. For some other compounds red emission was found. Green uranium emission is assigned to  $\text{UO}_6$  groups and uranyl ( $\text{UO}_2$ ) groups, red emission to  $\text{UO}_4$  groups. It is shown that this assignment is consistent with the structural data for a large number of uranium-activated oxides. Energy transfer was observed between the uranium center and  $\text{Eu}^{3+}$ . Addition of  $\text{Cr}^{3+}$  or  $\text{Rh}^{3+}$  quenches the uranium fluorescence drastically.

The fluorescence of hexavalent uranium centers is well known. In glasses this fluorescence is usually ascribed to the uranyl ( $\text{UO}_2^{2+}$ ) group (1). In solids two types of emission occur, viz., green and/or red emission. This difference was earlier noted by Kröger (2), who ascribed the green emission to uranyl groups and the red emission to uranate groups (i.e., hexavalent uranium ions substituted at a crystallographic site of the host lattice, for example, for tungsten). Runciman (3), however, ascribed the green emission of  $\text{CaO-U}$  and  $\text{Ca}_2\text{MgWO}_6\text{-U}$  to the uranate ( $\text{UO}_6$ ) group.

Gobrecht and Weiss (4) investigated thoroughly the uranium-activated scheelites and concluded that the green emission originates from the uranyl group and the red emission from the uranate ( $\text{UO}_4$ ) group. Effi-

cient green uranium fluorescence in the solid state was reported by Leonov (5) for  $\text{Li}_4\text{WO}_5\text{-U}$  and  $\text{Li}_4\text{MgWO}_6\text{-U}$  and by Mooney (6) for  $\text{Li}_6\text{Mg}_5\text{Sb}_2\text{O}_{13}\text{-U}$ . These host lattices are related to the rocksalt lattice. Therefore we decided to investigate the uranium fluorescence in other compounds with rocksalt-like lattices. On the other hand we looked for a host lattice that could offer only a regular octahedral coordination for hexavalent uranium in order to study the emission of regular  $\text{UO}_6$  groups.

### Experimental

Samples were prepared by usual ceramic methods, firing intimate mixtures of highly pure oxides and/or carbonates in air at  $950^\circ$  for lithium-containing ma-

materials and at 1350° for  $Y_6WO_{12}$ . Uranium was used as uranyl nitrate or acetate and introduced into the host lattice according to stoichiometric equations, using  $Li^+$  as charge compensator if necessary (e.g.,  $W^{6+} \rightarrow U^{6+}$ ,  $5Nb^{5+} \rightarrow 4U^{6+} + Li^+$ ,  $5Sn^{4+} \rightarrow 3U^{6+} + 2Li^+$ ,  $5Mg^{2+} \rightarrow U^{6+} + 4Li^+$ , etc.).

The uranium concentration was varied from 0.1 to 1.0 a/o (atomic per cent) per formula unit of the host lattice. Samples were checked by x-ray analysis. The performance of the optical measurements has been described elsewhere (7).

### Results

The following uranium-activated materials were studied:  $Li_3NbO_4-U$ ,  $Li_3SbO_4-U$ ,  $Li_2SnO_3-U$ ,  $LiScO_2-U$ ,  $MgO-U$ ,  $LiNbO_3-U$ ,  $LiSbO_3-U$ ,  $NaSbO_3-U$ , and  $Y_6WO_{12}-U$ . Only  $Li_3NbO_4-U$  shows a green fluorescence of reasonable intensity at room temperature.  $Li_3SbO_4-U$  and  $Li_2SnO_3-U$  show a weak green fluorescence and  $LiSbO_3-U$  a weak orange fluorescence at room temperature. The other compounds do not fluoresce at room temperature, but they fluoresce at liquid  $N_2$  temperature. The emission color of the last group of materials is green, except for  $NaSbO_3-U$  which shows an orange fluorescence. The excitation source in all these cases is long- and/or short-wave ultraviolet radiation.

The spectral energy distribution of the emission of part of the samples studied is given in Fig. 1-3. Tables I and II indicate the position of the maximum of the

Fig. 1. Spectral energy distribution of the fluorescence at room temperature of  $Li_3NbO_4-U$ ,  $Li_3SbO_4-U$ , and  $LiSbO_3-U$  (365 nm excitation). Along the ordinate the radiant power per constant wavelength interval ( $I$ ) has been plotted in arbitrary units.

emission band of all phosphors studied. The quantum efficiency of the fluorescence of the more efficient phosphors at room temperature is given in Table I.

The excitation spectrum of the green fluorescence of  $Li_3NbO_4-U$  is given in Fig. 4 and resembles that of  $Li_6Mg_5Sb_2O_{13}-U$  (6). Under cathode-ray excitation  $Li_3NbO_4-U$  shows blue and green emission with an energy conversion factor of about 1%. This blue emission was also observed for the unactivated  $Li_3NbO_4$  (8), so that energy transfer from host lattice (niobate group) to uranium center is inefficient.

The variation of quantum efficiency with uranium concentration was studied for  $Li_3NbO_4-U$ . The highest observed quantum efficiency in the u.v. region amounts to 45%, 30%, and 20% for uranium concentrations of 0.1, 0.5, and 1.0 a/o per formula unit  $Li_3NbO_4$ , respectively. Although values for still lower U-concentrations varied too much to give reliable data, it is clear that concentration quenching of the fluorescence occurs at very low concentrations. For increasing U-content the emission band becomes

Fig. 4. Relative excitation spectrum of the emission with  $\lambda > 500$  nm of  $\text{Li}_3\text{NbO}_4\text{-U}$ .

steeper on the short-wavelength side and its maximum shifts to longer wavelength.

Energy transfer from the uranium center  $\text{Eu}^{3+}$  was observed in  $\text{Li}_3\text{SbO}_4\text{-U}$ , Eu. The excitation spectrum of the  $\text{Eu}^{3+}$  fluorescence shows also the uranium excitation bands of  $\text{Li}_3\text{SbO}_4\text{-U}$  [these are similar to these of  $\text{Li}_3\text{NbO}_4\text{-U}$  (Fig. 4)]. Energy transfer from the uranyl group to  $\text{Eu}^{3+}$  in glasses and solutions has been observed before (9, 10).

Addition of  $\text{Cr}^{3+}$  or  $\text{Rh}^{3+}$  to  $\text{Li}_3\text{NbO}_4\text{-U}$  or  $\text{Li}_3\text{SbO}_4\text{-U}$  quenches the fluorescence drastically. On addition of 0.5 a/o of  $\text{Cr}^{3+}$  per formula unit  $\text{Li}_3\text{SbO}_4\text{-U}$  (1 a/o), for example, the light output of the uranium fluorescence decreases to 5%. For the same  $\text{Rh}^{3+}$  concentration this figure is 35%.  $\text{Rh}^{3+}$  shows weak absorption bands at 400 and 525 nm in  $\text{Li}_3\text{NbO}_4$  and at 345 and 460 nm in  $\text{Li}_3\text{SbO}_4$ .

### Discussion

*Compounds with rocksalt-like lattices.*—A number of the host lattices investigated have the rocksalt structure or a structure based on a superstructure of this structure (ordering of cations):  $\text{MgO}$  has rocksalt structure,  $\text{Li}_2\text{SnO}_3$  (12),  $\text{Li}_3\text{SbO}_4$  (13), and  $\text{Li}_4\text{WO}_5$  (14) have ordered rocksalt structures. Table I shows that the uranium emission of these compounds shifts to longer wavelengths and the quantum efficiency decreases for decreasing lithium content of the host lattice.

$\text{Li}_4\text{MgWO}_6\text{-U}$  and  $\text{Li}_6\text{Mg}_5\text{Sb}_2\text{O}_{13}\text{-U}$  are also included in this table for the following reason.  $\text{Li}_4\text{MgWO}_6$  is a compound in the system  $\text{Li}_4\text{WO}_5\text{-MgO}$ . Both compounds have rocksalt structure and the cations involved have about equal radii. Therefore the structure of  $\text{Li}_4\text{MgWO}_6$  is probably also of the rocksalt type. In the analogous  $\text{Re}^{6+}$  system it has indeed been found that  $\text{Li}_4\text{ReO}_5$  as well as  $\text{Li}_4\text{MgReO}_6$  have rocksalt-like structures (12, 15).  $\text{Li}_6\text{Mg}_5\text{Sb}_2\text{O}_{13}$  is a composition in between  $\text{MgO}$  and  $\text{Li}_3\text{SbO}_4$  (both with rocksalt structure and cations with equal radii), so that the structure of this compound can probably also be described as a superstructure of the rocksalt structure. From Table I it follows that only  $\text{Li}_4\text{MgWO}_6\text{-U}$  seriously disagrees with the correlation mentioned above.

The correlation of Table I recalls two other correlations given by us before: for niobates the quantum efficiency at room temperature, and the quenching temperature, of the fluorescence increases if the absorption edge (and the emission band) shifts to shorter wavelength (8, 16); for  $\text{Eu}^{3+}$ -activated mixed metal oxides the quantum efficiency and the quenching temperature of the  $\text{Eu}^{3+}$  fluorescence increase if the charge-transfer absorption band of the  $\text{Eu}^{3+}$ -center shifts to shorter wavelengths (17, 18). We could account for these correlations by assuming that charge-transfer absorption bands move to shorter

wavelengths if the potential field at the  $\text{O}^{2-}$  ion due to the cations increases. This assumption is not unreasonable. In the present case it can only be relevant if a charge-transfer process is indeed involved in the uranium fluorescence. For the uranyl group it has been shown that this is the case (19). The lowest absorption band is ascribed to an electron transfer from the highest filled molecular orbital (m.o.) of the complex (which is localized mainly on the oxygen ions) to the lowest empty molecular orbital (which consists mainly of the 5f orbital of the uranium ion). It seems probable that this is also the case for uranium centers in oxides (uranate groups). The highest filled m.o. is a nonbonding oxygen orbital, the lowest empty m.o. is the 5f orbital [ $\text{U}^{5+}$  in the solid state has  $5f^1$  configuration; see, e.g. (20)]. The nonbonding orbitals and the 5f orbital will not depend strongly on the type of uranium center, so that their energy difference is mainly determined by the field at the oxygen ions (the higher this field, the lower the oxygen orbitals are situated).

Elsewhere we have shown that for ordered structures the potential field at the  $\text{O}^{2-}$  ions around the higher charged cations is always relatively high (8). We feel, therefore, that the results of Table I are in a physical sense closely connected with our results for niobates and europium-activated oxides in spite of the chemical differences. If the  $\text{Li}^+$  content of the host lattice increases, the cationic charge is distributed less homogeneously. The field at a part of the anions becomes stronger, the charge transfer bands shift to shorter wavelengths, and the fluorescence efficiencies and quenching temperatures increase. Since these relations can now no longer be considered to be accidental, further investigation of them seems highly desirable.

We will now discuss the nature of the fluorescent center in these compounds with rocksalt lattice. In view of the green fluorescence of the uranyl group it is tempting to assign the green fluorescence of the present phosphors to uranyl groups as well. It is difficult, however, to imagine how the  $\text{U}^{6+}$  ion can be introduced in the rocksalt lattice as a linear  $\text{UO}_2$  group. Moreover the  $\text{U}^{6+}$  ion in oxides is not in all cases present in the form of a  $\text{UO}_2$  group. In  $\text{CaUO}_4$  and  $\text{UO}_3$  (21) one can clearly distinguish separate  $\text{UO}_2$  groups. In  $\text{Li}_4\text{UO}_5$ , however,  $\text{UO}_6$  octahedra are present with four shorter and two longer U-O distances (22) and in  $\text{Y}_6\text{UO}_{12}$  even regular  $\text{UO}_6$  octahedra have been found (23).  $\text{Y}_6\text{WO}_{12}$  is isomorphous with  $\text{Y}_6\text{UO}_{12}$ . For this reason we decided to study  $\text{Y}_6\text{W}_{1-x}\text{U}_x\text{O}_{12}$ , because materials of this composition will contain regular  $\text{UO}_6$  octahedra.

*Color of the uranium emission in oxides.*—The emission of  $\text{Y}_6\text{WO}_{12}\text{-U}$  (Fig. 2) consists of a broad band in the green with a pronounced structure. Runciman (3) also observed structure in the uranium emission of  $\text{CaO}$ ,  $\text{Ca}_2\text{MgWO}_6$ , and other compounds. The emission band of  $\text{Li}_3\text{NbO}_4\text{-U}$  shows also structure at liquid nitrogen temperature. These phenomena will not be discussed in this paper. What is of interest here is that the emission is in the green part of the spectrum. This shows that green uranium emission originates not only from uranyl groups ( $\text{UO}_2^{2+}$ ), but also from  $\text{UO}_6$  octahedra. Only Runciman (3) seems to have recognized this fact. The red uranium emission must then be ascribed to  $\text{UO}_4$  groups. In Table II which contains also a number of data from the literature the emission color of a number of uranium-activated phosphors are compared. We will attempt to correlate these with the crystal structure.

Compounds with rocksalt lattice show green uranium fluorescence without exception. This lattice consists of a cubic close-packed array of anions in which all the octahedral holes are occupied by cations. In this situation it is very unfavorable for a cation to occupy one of the tetrahedral holes, since each tetrahedral hole has a large number of occupied octahedral holes

at short distances ( $\sim 1.8\text{\AA}$ ). No crystal structures are known that are based on a close-packing with not only all octahedral but also part of the tetrahedral holes occupied (21, 24). In accordance with this, no red  $\text{UO}_4$  emission is observed. Since the rocksalt lattice does not give favorable opportunities for linear  $\text{UO}_2$  groups, it seems probable that the emission from uranium-activated compounds with rocksalt lattice is due to  $\text{UO}_6$  groups, *i.e.*, the  $\text{U}^{6+}$  ion occupies the normal crystallographic sites of the cations.

$\text{LiNbO}_3$ ,  $\text{LiSbO}_3$ , and  $\text{NaSbO}_3$  have a structure based on a hexagonal close-packed array of anions with two thirds of the octahedral holes filled (21). The distribution of the cations among these holes is different for the three compounds. In these structures the  $\text{U}^{6+}$  ion can occupy octahedral holes. However, occupation of tetrahedral holes is not so unfavorable as in the rocksalt lattice, because not every tetrahedral hole is surrounded by a large number of octahedral ions at short distances (compounds with crystal structures in which part of the octahedral and part of the tetrahedral sites are occupied are well-known, *e.g.*, spinels and olivines). It is therefore not surprising that the uranium-emission color is green in  $\text{LiNbO}_3\text{-U}$  ( $\text{UO}_6$  groups), green and red in  $\text{LiSbO}_3\text{-U}$ , ( $\text{UO}_6$  and  $\text{UO}_4$  groups; see Fig. 1), and red in  $\text{NaSbO}_3\text{-U}$  ( $\text{UO}_4$  groups). Why the emission color is different for these three cases cannot be explained at the moment. However, there are at least no serious objections against the presence of  $\text{UO}_4$  groups in this structure.

In the uranium activated scheelites (*e.g.*,  $\text{CaWO}_4$ ) red and green fluorescence have both been observed. In our interpretation the red emission is due to  $\text{UO}_4$  groups ( $\text{U}^{6+}$  on a  $\text{W}^{6+}$  site). The scheelite structure has a large number of unoccupied octahedral holes the centers of which are situated midway between each pair of next-nearest tungsten neighbors. We propose, therefore, that the green uranium emission in scheelites is due to  $\text{UO}_6$  groups which are formed by occupation of the empty octahedral holes by  $\text{U}^{6+}$  ions. This is at least as probable as the assumption of the interstitial uranyl groups proposed by Gobrecht and Weiss (4).

In wolframites (*e.g.*,  $\text{CdWO}_4$  and  $\text{MgWO}_4$ ) only red uranium fluorescence has been observed. In all the papers in the literature this emission is assigned to a  $\text{UO}_4$  group. This agrees with the present hypothesis. However, the  $\text{W}^{6+}$  ion in the wolframite structure is in six-coordination. Two explanations can be offered: (a) only half of the octahedral holes in the hexagonal close-packed array of  $\text{O}^{2-}$  ions of this structure are occupied, so that the  $\text{U}^{6+}$  ion may occupy tetrahedral sites, and (b) the  $\text{WO}_6$  octahedron is strongly elongated in the wolframite structure. In  $\text{CdWO}_4$  for example, the  $\text{W}^{6+}$  ion has four  $\text{O}^{2-}$  ions at 1.80-1.87 $\text{\AA}$  and two  $\text{O}^{2-}$  ions at 2.22 $\text{\AA}$  (25). For  $\text{NiWO}_4$  these values are 4 x 1.79 $\text{\AA}$  and 2 x 2.19 $\text{\AA}$  (26). If  $\text{U}^{6+}$  substitutes for  $\text{W}^{6+}$  on a  $\text{W}^{6+}$  site, something like a  $\text{UO}_4$  is formed.

$\text{Li}_2\text{WO}_4$  and  $\text{Li}_3\text{PO}_4$  have both structures with the metal ions in four coordination. The oxygen lattice of  $\text{Li}_2\text{WO}_4$  (phenacite structure) is not close-packed and contains large octahedral holes in which the  $\text{U}^{6+}$  ion would fit. This possibility was previously suggested by Van Arkel (27). The green fluorescence of  $\text{Li}_2\text{WO}_4\text{-U}$  would then be due to centers of this type. The structure of  $\text{Li}_3\text{PO}_4$  is again based on a hexagonal close-packed array of  $\text{O}^{2-}$  ions (28). Half of the tetrahedral holes are occupied, whereas the octahedral holes are empty. The  $\text{U}^{6+}$  ion can therefore occupy octahedral sites (green luminescence as found experimentally).

In conclusion we see that the assignment of green emission to  $\text{UO}_6$  and uranyl groups and of red emission to  $\text{UO}_4$  groups does not contradict the structural data and that it is not necessary in many cases to assume interstitial uranyl groups to explain a green emission. This assignment is the same as proposed by

Runciman (3) but differs from that given by Kröger (2) and Gobrecht and Weiss (4).

*Concentration quenching.*—From our results it follows that concentration quenching of the uranium emission occurs at low uranium concentration ( $<1$  a/o) as has been observed before by other workers [see, *e.g.* (4)]. Dexter and Schulman (29) have proposed a theory of concentration quenching. They assume that energy is transferred from activator to activator center until it reaches a sink or is emitted as radiation. Therefore the efficiency of the energy transfer between the activator centers is one of the factors determining the critical concentration at which concentration quenching starts [see also (30)]. Dexter and Schulman estimate this critical concentration at 0.1-1.0 a/o, if the transitions involved are allowed electric dipole transitions.

From the fact that the emission band of  $\text{Li}_3\text{NbO}_4\text{-U}$  moves to longer wavelengths and becomes steeper on the short wavelength side we conclude that the energy transfer occurs partly radiatively (self-absorption).  $\text{Li}_3\text{NbO}_4\text{-U}$  in fact shows an absorption band peaking at about 500 nm (data from diffuse reflection spectra), so that the energy overlap of emission and absorption band is large. This is required for radiative transfer. Moreover it is very probable that the transfer will also occur by nonradiative electric dipole-dipole interaction, since the optical strength of the transition involved is by no means weak (charge-transfer) and the energy overlap large.

In conclusion we see that the energy transfer from one uranium center to another is efficient and that the critical concentration for quenching is therefore low.

*Energy transfer to other centers.*—Finally we shall briefly discuss some other cases of energy transfer which were observed during this investigation.

Under short-wave u.v. and especially cathode-ray excitation the phosphor  $\text{Li}_3\text{NbO}_4\text{-U}$  emits not only a green fluorescence, but also a strong blue fluorescence. The latter emission originates from the host lattice itself (8). It may therefore be concluded that the energy transfer from host lattice to uranium center is far from efficient. This follows also from the excitation spectrum of the fluorescence (Fig. 4): the excitation band of the host lattice at about 240 nm is absent. There are two possible reasons for this inefficient transfer: (a) Transfer through the host lattice will not be efficient, since the energy overlap condition is badly fulfilled: the emission band of  $\text{Li}_3\text{NbO}_4$  almost fails to overlap the absorption band (8). A similar phenomenon has been observed for  $\text{YNbO}_4\text{-Eu}$ , where large amounts of Eu are needed to quench the niobate emission (31). However, the total quantum efficiency (of niobate and  $\text{Eu}^{3+}$  emission) remains constant. This points to inefficient energy transfer through the niobate lattice. Since in our case the activator concentration is necessarily low to prevent concentration quenching, this effect will be important. (b) It is also possible that energy transfer from niobate group to uranium center is not very efficient, since the  $\text{Li}_3\text{NbO}_4$  emission (peaking at 370 nm) lies in between two absorption bands of the uranium center (peaking at 500 nm at 340 nm). The energy overlap with these two bands is certainly not sufficient to allow transfer over large distances, so that the transfer through the host lattice indeed determines the total transfer efficiency from host lattice to activator. The situation is contrary to that in  $\text{Li}_3\text{NbO}_4\text{-Cr}$ , where the transfer from niobate to  $\text{Cr}^{3+}$ -center is extremely efficient (32). This explains why a very small amount of  $\text{Cr}^{3+}$  ions quenches the niobate emission completely, although the transfer through the lattice is inefficient.

In  $\text{Li}_3\text{SbO}_4\text{-U}$ , Eu transfer from the uranium center to  $\text{Eu}^{3+}$  was observed. It was shown above that the transfer between the uranium centers is efficient. The transfer from uranium center to  $\text{Eu}^{3+}$  is possible, since the uranium emission overlaps the  $^5\text{D}_1$  and  $^5\text{D}_0$  levels

of the  $\text{Eu}^{3+}$  ion (at about 525 and 580 nm, respectively). In view of the low optical strength of the transitions involved this transfer does probably not occur by electric multipole interaction but by exchange interaction. This was also found for the uranyl  $\rightarrow \text{Eu}^{3+}$  transfer in solutions (10) and other transfer processes to  $\text{Eu}^{3+}$  (33).

The strong quenching effect of  $\text{Cr}^{3+}$  on the fluorescence of  $\text{Li}_3\text{NbO}_4\text{-U}$  will be partly due to efficient energy transfer from the uranium center to  $\text{Cr}^{3+}$ . The uranium emission (530 nm) overlaps the intense, broad charge-transfer band of the  $\text{Cr}^{3+}$  center in  $\text{Li}_3\text{NbO}_4$  (380 nm) reasonably well (32). Both optical transitions are of a charge-transfer type and are therefore allowed electric-dipole transitions, so that transfer by electric dipole-dipole interaction is expected to be efficient. The shape of the emission band of the uranium center does not depend on the  $\text{Cr}^{3+}$  concentration. Therefore we exclude radiative transfer.

The quenching effect of  $\text{Rh}^{3+}$  is less than that of  $\text{Cr}^{3+}$ . The uranium emission overlaps the  $\text{Rh}^{3+}$  absorption in  $\text{Li}_3\text{NbO}_4$  at 525 nm very well, but the optical strength of this absorption is expected to be much lower than that of the absorption of  $\text{Cr}^{3+}$  in  $\text{Li}_3\text{NbO}_4$  (in the case of  $\text{Rh}^{3+}$  we are concerned with a parity-forbidden d-d transition, viz.,  ${}^1\text{A}_{1g} \rightarrow {}^1\text{T}_{1g}$ ). This weaker interaction causes a less efficient transfer.

In the case of  $\text{Li}_3\text{NbO}_4\text{-U,Rh}$  and especially of  $\text{Li}_3\text{NbO}_4\text{-U,Cr}$  it must be kept in mind that under short-wave as well as under long-wave u.v. excitation part of the exciting energy is already absorbed directly by the  $\text{Rh}^{3+}$  and  $\text{Cr}^{3+}$  centers, so that even without any energy transfer at all the green uranium output is expected to decrease with the addition of  $\text{Cr}^{3+}$  or  $\text{Rh}^{3+}$ .

Finally we note that the crystal-field splitting of the  $\text{Rh}^{3+}$  ion in  $\text{Li}_3\text{NbO}_4$  is relatively small. From the position of the two absorption bands we find the following approximate values for  $\Delta$  (crystal-field splitting) and B (electrostatic interaction parameter):  $\Delta = 17,500 \text{ cm}^{-1}$  and  $B = 400 \text{ cm}^{-1}$ . For  $\text{Li}_3\text{SbO}_4$   $\Delta = 20,000 \text{ cm}^{-1}$  and  $B = 450 \text{ cm}^{-1}$ . The calculation procedure has been described previously (34). For  $\text{Al}_2\text{O}_3\text{-Rh}$  these values are  $26,400 \text{ cm}^{-1}$  and  $400 \text{ cm}^{-1}$ , respectively (34). Low values of the crystal-field splitting of  $\text{Cr}^{3+}$  in niobates were observed and have been discussed elsewhere (32).

#### Acknowledgment

The author is greatly indebted to Dr. A. Bril, who obtained all the optical data reported.

Manuscript received Feb. 13, 1968; revised manuscript received March 19, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Abstract 47.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Electroluminescent Properties of ZnSe-Type Phosphors

T. Hariu, T. Seki, K. Miyashita, and M. Wada

Department of Electronic Engineering, Tohoku University, Sendai, Japan

## ABSTRACT

Electroluminescent properties of ZnSe-type phosphors, including host crystals of modified compositions, were examined, especially temperature dependence and Mn-band characteristics. The variation in frequency dependence with temperature and composition was interpreted by considering the temperature quenching factor of electroluminescence,  $q = [1 + (D/f) \exp(-E_c/kT)]^{-1}$  ( $E_c$ , the activation energy of temperature quenching). On the contrary, the Mn-band, which is not due to the delayed recombination, did not have a superlinear frequency dependence, even in the temperature quenching region. Consideration in which the  $c$ -value was assumed to be constant with time was not sufficient to explain the  $c$ -value variation in each band with temperature and frequency, and the excitation process characteristics obtained by the Mn-band.

The mechanism of electroluminescence (EL) investigated so far has been based mainly on the experimental results of ZnS. The results of host crystals with different compositions (Zn,Cd)(S,Se) will add further aspects to the discussion of the mechanism in the sense that the parameters involved, *e.g.*, the position of luminescent centers and donors in energy diagram, can be changed continuously.

In the case of EL, contrary to the photoluminescence (PL), the excitation occurs in the different course of time of recombination. Contrary to this fact, generally observed characteristics involve both of them, at least in the case of light emission from the Cu center. On the contrary, properties of light emission from the Mn center are characterized by the excitation process and the same recombination process as that of PL, because the excited electron does not become free and therefore the recombination is not delayed.

This paper describes EL properties of ZnSe-type phosphors including host crystals of modified compositions, paying special attention to effects of temperature and the Mn band.

## Experimental Procedure

Phosphor preparation procedure has been described in another paper (1). Light emission from an EL cell in a vacuum chamber was measured using a Hitach EPU-2 type spectrometer and R136 photomultiplier. The phosphors were bound with paraffin, the electric property of which is almost constant up to room temperature.

## Results

Emission spectra are shown in Fig. 1. ZnSe:Cu,Cl has two emission bands with peak wavelength at 530 and 640 m $\mu$  (which will be called band 1 and band 2, respectively). In addition to them, ZnSe:Cu, Mn, Cl has the Mn band with peak wavelength at about 585m, which is the same as the Mn band in ZnS, though in contradiction with the results in literature (2). Emission color varies with excitation frequency in the temperature range where temperature quenching occurs, *i.e.*, high frequency and low temperature make band 1 increase. In the temperature range where band 1 has been quenched, the emission color did not change with frequency and temperature up to about 0°C, although temperature quenching of the Mn band occurred in this range. Above this temperature at which band 2 begins to be quenched, high frequency and low temperature make band 2 greater compared with the Mn band. High applied voltage makes the Mn band greater relatively.

The activation energy of quenching of PL ( $B = B_0 / [1 + \nu \exp(-E_c/kT)]$ ) obtained from the brightness dependence on temperature is shown in Table I for each band.

Frequency dependence of emission intensity of EL for each band is shown in Fig. 2 for ZnSe:Cu,Cl and in Fig. 3 for ZnSe:Cu,Mn,Cl. As for band 1 and band 2, in the temperature range in which temperature quenching occurred, the intensity increased superlinearly with frequency as expected. However, the intensity of the Mn band increased a little sub-linearly in the whole temperature range measured, even in the range in which temperature quenching occurred.

As expected, in the case where some Se in the crystal base was substituted with S and the quenching temperature was made higher, the temperature at which superlinear increase would appear became higher, as shown in Fig. 4 for the sample composed of 10% substitution for Se.

In connection with the frequency dependence, the temperature dependence of brightness was measured with frequency as parameter, shown in Fig. 5 for ZnSe:Cu,Cl and in Fig. 6 for the Mn band in ZnSe:Cu,Mn,Cl.

Fig. 1(a). Emission spectra of ZnSe:Cu, Cl. Curve A, -100°C, 10 kc; curve B, -100°C, 1 k(kHz); curve C, 12°C, 10 k(kHz); curve D, 12°C, 1 k(kHz).

Table I. Activation energy of quenching

Sample	Emission band	$E_c$ , ev
ZnSe:Cu,Cl	Band 1	0.17
	Band 2	0.29
ZnSe:Cu,Mn,Cl (9.5ZnSe) (0.5CdSe) :Cu,Cl	Mn band	0.39
	Band 1	0.17
	Band 2	0.29
(9ZnSe) (1CdS) :Cu,Cl	Band 1	0.25
	Band 2	0.35

Luminescence intensity depended on voltage according to the law usually observed in ZnS ( $B = B_0 \exp(-c/V^{1/2})$ ), with  $c$ -value variation with frequency and temperature shown in Tables II, III, and IV. In ZnSe-type phosphors, the  $c$ -value tended to increase with frequency, and decrease with temperature, but it tended to increase at near room temperature. This tendency was not found in the sample composed of 10% substitution for Se, as shown in Table III. Voltage dependence of emission intensity for the Mn band and band 2 of (9ZnSe) (1CdS):Cu,Mn,Cl is shown in Fig. 7. For the Mn band, the  $c$ -value changed to a greater value at about 500v, but the smaller  $c$ -value is still greater than that of band 2.

## Discussion

**Excitation process.**—The voltage dependence of brightness allows us to discuss the excitation process. The familiar relation between brightness and voltage

$$B = B_0 \exp(-c/V^{1/2}) \quad [1]$$

which is deduced theoretically by considering the supply of primary electrons, and the probability of impact ionization in the Mott-Schottky type barrier region (3), can explain the experimental results. A small deviation from [1] does not provide sufficient information to find out how primary electrons are supplied: tunneling from  $\text{Cu}_2\text{S}$  phase, thermally or

$$-\frac{dN_c^+}{dt} = SvnN_c^+ \quad [4]$$

where  $N_c^+$  is the unoccupied emission center,  $S$  the capture cross section,  $n$  the density of electron in the conduction band, and  $v$  the thermal velocity of free electron. This equation also applies to the case where the emission process is the transition from donor state to emission center, if the unoccupied donor is easily occupied.

Considering that generally  $n \gg N_c^+$  (monomolecular recombination), it can be written as follows

$$N_c^+ = N_{co}^+ \exp\left(-\frac{t}{\tau}\right) \quad [5]$$

where  $\tau = 1/Svn \approx \text{const.}$ , and  $N_{co}^+$  is the number of excited emission centers. Consequently, the emission intensity per unit time  $B$  is expressed as follows

$$B = N_{co}^+ f \left[ 1 - \exp\left(-\frac{1}{\tau f}\right) \right] \quad [6]$$

which is apparently the same result as that of Zalm (3), Thornton (6), and Miyashita (5). Of course, in the low frequency region

$$B \propto f \quad (\tau f \ll 1) \quad [7]$$

As the temperature rises, holes begin to escape from the emission center and  $N_{co}^+$  decreases with time after excitation at the following rate

$$-\frac{dN_c^+}{dt} = \nu N_c^+ \exp(-E_c/kT) \quad [8]$$

If we simplify the process so that recombination will not occur during  $t = 0 \sim t = mT_o/4$  and will begin at  $t = mT_o/4$ , as shown in Fig. 9, the decreased excited emission center  $N_{co}^+$  is calculated as follows

$$N_{co}^+ = N_{co}^+ \exp\left(-\frac{\gamma mT_o}{4}\right) = N_{co}^+ \exp\left(-\frac{D\gamma}{f}\right) \quad [9]$$

where  $\gamma = \nu \exp(-E_c/kT)$

In the recombination process

$$-\frac{dN_c^+}{dt} = \gamma N_c^+ + SvnN_c^+ = \left(\gamma + \frac{1}{\tau}\right) N_c^+ \quad [10]$$

and a similar calculation as the above leads to

$$B \propto N_{co}^+ f \frac{1}{\gamma + \frac{1}{\tau}} \left[ 1 - \exp\left\{-\left(\gamma + \frac{1}{\tau}\right) / f\right\} \right] \quad [11]$$

The temperature quenching factor  $q$  affecting brightness dependence on frequency at the low-frequency region is obtained by expanding Eq. [9] as follows

$$q = [1 + (D/f) \exp(-E_c/kT)]^{-1} \quad (D\gamma/f < 1) \quad [12]$$

This result was also suggested by Ivey (7). Equation [12] indicates that superlinear characteristics are ob-

Fig. 9. Simplification of process

Fig. 10. Effect of temperature quenching on frequency dependence [ $b=f/(1+f_o/f)$ ].

served, as expected. In Fig. 10 frequency characteristics are given for several values of  $f_o = D \exp(-E_c/kT)$ .

Using Fig. 5 and Eq. [12], an approximate value of  $D$  is obtained from the temperature at which brightness is half of the maximum, to be  $\sim 10^8 \text{ sec}^{-1}$ . This is reasonable, considering  $\gamma = 10^8 \sim 10^9 \text{ sec}^{-1}$  (8-10).

It is noted that the above consideration of temperature quenching applies to the frequency characteristics of the delayed recombined emission center as the Cu center, but not to the Mn center; that is, superlinear dependence should not be observed even if temperature quenching occurs, as shown in Fig. 3. This result also suggests that energy transfer from the Cu center to the Mn center does not occur in this case and the Mn center is excited directly. It is clear here that characteristics of the Mn band enables us to look into the excitation process.

# Impurity Distribution in Single Crystals

## IV. Growth Characteristics and Impurity Incorporation During Facet Growth

K. Morizane,<sup>1\*</sup> A. F. Witt,\* and H. C. Gatos\*

Department of Metallurgy and Center for Materials Science and Engineering,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

### ABSTRACT

Impurity heterogeneities in the "core" region of InSb single crystals pulled from the melt were shown to be sensitive to thermal asymmetry, the location of the facet in the crystal, and the orientation of the facet relative to the growth axis. This behavior was explained assuming that the lateral growth rate which controls the incorporation of impurities in the core region is markedly modified by the extent of kinetic supercooling.

Theoretical treatments of the effective impurity distribution ( $k_{\text{eff}}$ ) during crystal growth are based on two different operating mechanisms. According to one, partition equilibrium is assumed at the solid-liquid growth interface and the effective impurity incorporation is considered as a process controlled by solute diffusion in the melt (1-4). The other mechanism postulated specific adsorption and solute diffusion in the solid immediately upon solidification as the principal parameters controlling the impurity incorporation (5, 6). This latter point of view was formulated to account for the observed orientation dependence of the effective distribution coefficient (5). It also explained differences in the growth rate dependence of  $k_{\text{eff}}$  for donor and acceptor impurities in semiconductor crystals; this behavior cannot be explained readily by solute diffusion in the melt.

At the time the above theories were published the "facet effect" had not as yet been discovered (7-9). Its discovery revealed that facet growth leads to a "core" formation which constitutes a major impurity heterogeneity in semiconductor crystals such as Ge, InSb, and others. This effect is most likely responsible for the earlier observed orientation dependence of  $k_{\text{eff}}$ . In the core the actual impurity concentration is reported (10) to differ in some systems by almost an order of magnitude from the rest of the crystal. Furthermore, the extent of coring may vary widely depending on growth conditions (11). For this reason all experimentally determined effective distribution coefficients reported prior to the discovery of the facet effect should be considered with caution.

The presence of macroscopic (111) growth facets on InSb single crystals pulled from the melt led to the conclusion that impurity cores are formed as a result of nonequilibrium conditions prevailing during impurity incorporation at the facet ( $k_{\text{interface}} \neq k_0$ ). These conditions were related to specific adsorption (6) in conjunction with lateral layer growth. The many attempts to examine the actual morphology of the growth interface (detection for example, of growth steps) by rapid removal of the growing crystal from the melt were not completely conclusive because of solidification of the layer of melt adhering to the crystal during removal. More direct information concerning the shape of the growth interface and facet growth was first obtained by Dikhoff (9) in his investigation of rotational impurity striations in core regions of doped germanium and silicon crystals.

The purpose of the present communication is to reconsider "facet growth" and the associated mechanism of impurity incorporation in the light of the recent findings on microscopic growth rates and the microscopic distribution of impurities as revealed by high resolution etching techniques (12).

### Experimental Findings Regarding Facet Growth

In a recent study concerned with the determination of microscopic growth rates in InSb single crystals by means of "rate striations" it was shown that under constant pulling rate (with and without rotation) the microscopic rate of growth in the facet region (core region) remains virtually constant in contrast to the rate in the off-facet region which exhibits rather pronounced growth rate fluctuations. These findings are shown in Fig. 1 where an "off-core" to "on-core" transition region of an InSb single crystal grown with seed rotation is depicted.

It was found in the present investigation that, depending on growth conditions, the core regions usually exhibit impurity fluctuations of varying geometric configuration. In single crystals pulled with seed rotation the intensity of these concentration fluctuations appears to increase with thermal asymmetry and is most pronounced in the core periphery. In all instances these fluctuations exhibit the periodicity of seed rotation; however, their detailed pattern depends on the location and relative orientation of the growth facet. Under "ideal" growth conditions (*i.e.*, the pulling direction coincides with the  $\langle 111 \rangle$  crystallographic direction) the facet (core) appears in the center of the crystal and normal to the growth direction. At slow rotational rates (about 10 rpm for pulling rates in the vicinity of 1 iph), the impurity fluctuations assume a helical pattern (Fig. 2). In crystals in which the growth direction deviates by an

Fig. 1. Off-core to core transition region in InSb single crystal. Note the microscopic growth rate fluctuations in the off-core region and the constancy in growth rate in the core region. Magnification 900X.

<sup>1</sup> Present address: Texas Instruments Inc., Dallas, Texas.

Fig. 2. Rotational impurity striations in the core region of an InSb single crystal. The helical pattern is characteristic of slow rates of rotation (4 rpm) (in centrally located facets). See text. Magnification 12X.

order of degrees from the  $\langle 111 \rangle$  direction, the (111) growth facet is shifted from the crystal center. The corresponding rotational core heterogeneities no longer exhibit a helical pattern but instead a more or less pronounced banded structure (Fig. 3). In either case, the heterogeneities are not associated with corresponding fluctuations in the vertical growth rate. As demonstrated unambiguously by means of rate striations (13) the microscopic rate of growth in the core is virtually constant.

Single crystals pulled without seed rotation exhibit nonrotational striations which are continuous across the off-core and the core regions but have no helical component (Fig. 4). Here again, the fluctuations in impurity concentration are associated with growth rate fluctuations in the off-core region whereas in most instances no corresponding microscopic growth rate variations are observed in the core region. Very small growth rate variations occasionally observed in the core region are invariably much smaller than those in the off-core region.

#### Discussion

A comparison of the impurity distribution in the off-core and in the core regions of single crystals pulled from the melt reveals differences in impurity

Fig. 3. Rotational impurity striations in the core region of an InSb single crystal. The observed band-like pattern is characteristic of rotational pulling with the growth facet shifted from the center to the periphery of the crystal. Magnification 90X.

Fig. 4. Nonrotational impurity striations in InSb single crystal. Note the continuity of striations across the off-core and the core region. Magnification 40X.

incorporation which indicate the operation of different growth mechanisms in the two regions.

Employing rate striations (13) it was demonstrated that in the presence of thermal asymmetry (which can never be completely eliminated) the off-core region grows at varying growth rates. These growth rate fluctuations are responsible for the observed rotational impurity striations, i.e., the parameter primarily controlling the effective impurity distribution is the microscopic growth rate.

In the core region of crystals pulled with rotation it has been reported (10) that the impurity concentration is substantially greater than in the off-core region. Yet it has been recently shown (13) that the microscopic rate of growth in the core region is in most instances smaller (never greater) than in the off-core region. Thus, if the controlling parameters of crystal growth and impurity incorporation were the same in both regions, then a decreased impurity concentration would be expected in the core region. The increased impurity concentration in the core was attributed (6) to a rapid sheet growth across the facet which leads to an increased nonequilibrium incorporation of impurities. According to this treatment the rate of the sheet growth is independent of the speed of movement of the isotherms and dependent only on the rate of incorporation of liquid atoms into the growing solid and the rate of dissipation of the latent heat of fusion. Accordingly, the concentration of impurities should be uniform across the facet.

As shown in the present and earlier results (13) the impurity concentration, however, can vary markedly across the facet. In fact the patterns of impurity heterogeneities observed in the core region of crystals grown under rotation are sensitive to thermal asymmetry, the location of the core in the crystal and the orientation of the facet relative to the growth axis. This behavior cannot be explained by any of the proposed theories of impurity incorporation during facet growth.

Moreover it has been shown theoretically (14) and experimentally (13) that rotational striations in pulled crystals are caused and controlled by thermal asymmetry. In the presence of thermal asymmetry the temperature at the facet-melt interface (region of kinetic supercooling) must vary asymmetrically about the axis of rotation, as shown schematically in Fig. 5. The observed nonuniform impurity incorporation across the growth facet can thus be related to a nonuniform lateral growth rate resulting from the nonuniform interfacial temperature. Under usual growth conditions the location and shape of the solidification isotherm remains geometrically fixed (14). Thus, nonrotational pulling under thermally asymmetric conditions will result in a radial decrease in impurity dis-

Fig. 5. Schematic presentation of thermal conditions across the growth facet in the presence of thermal asymmetry. Note varying amount of kinetic supercooling ( $\Delta T_2 > \Delta T_3 > \Delta T_1$ ).

tribution emanating from the thermal axis. Convectively induced temperature fluctuations in the melt near the growth interface (15) will result in random changes in the amount of supercooling at the facet and, thus, in the formation of random nonrotational striations although the vertical growth rate remains virtually constant.

Under the above interface configuration it is apparent that in crystals pulled with seed rotation the periodic displacement of the thermal axis about the axis of rotation will result in the observed helical patterns of rotational striations (Fig. 2). If the direction of pulling does not coincide with the say,  $\langle 111 \rangle$  crystallographic direction, then the facet is not exactly horizontal and thus it does not rotate on its own plane. With such a deviation of the facet from the horizontal position the axis of rotation does not intersect the facet at its center. For relatively excessive deviations (of the order degrees) the axis of rotation will not intersect the facet at all and thus the conditions leading to the formation of the helical patterns of impurity fluctuations in the core no longer prevail. The

impurity fluctuations must then assume the observed band-like pattern (Fig. 3).

### Summary

In summary, it was shown that in crystals pulled from the melt (in the present case InSb) the mechanism of facet growth is significantly different from that prevailing in the off-facet region. The incorporation of impurities in the facet region is controlled by the lateral growth rate. This rate was taken to be affected by the profile of kinetic supercooling and its fluctuations. On this basis the experimentally observed impurity fluctuations in the core region were satisfactorily explained.

# Accommodation of Lattice Mismatch at Heterojunctions

R. S. Mroczkowski,<sup>1</sup> A. F. Witt,\* and H. C. Gatos\*

Department of Metallurgy and Center for Materials Science and Engineering,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

## ABSTRACT

The accommodation of lattice mismatch at heterojunctions grown by back-melting and subsequent regrowth was investigated employing the InSb-GaSb system. Single crystals of either GaSb or InSb served as the one component (substrate) of the heterojunctions and the regrown part was an alloy of the general formula  $Ga_xIn_{1-x}Sb$ . The lattice mismatch at the heterojunction was varied by varying the composition of the regrown alloy. It was found that the accommodation of the lattice mismatch takes place by the generation of dislocations the number of which is consistent with a simple linear lattice model.

The recent interest in the electrical properties of semiconductor heterojunctions has precipitated the need for studying the structural aspects of such junctions. In a previous report (1) we have discussed the implications of the phase diagram of the binary (or pseudobinary) system involved. Attempts to study dislocation distribution and propagation across such heterojunctions made it apparent that the density of dislocations originating at the heterojunction was too high for any meaningful examination. A first step in approaching the study of dislocations at heterojunctions was the investigation of their behavior at "homojunctions" formed by back-melting under conditions prevailing during the formation of heterojunctions (2). It was shown that the thermal conditions during back-melting do not lead to the formation of new dislocations. In the back-melted portion of the crystal all of the observed dislocations originated in the parent crystal.

In the light of these results and the unique characteristics of semiconductor heterojunctions it was felt that it would be of interest to study the dependence of the density of dislocations at the plane of the grown heterojunctions on the lattice mismatch between the two component semiconductors. The lattice mismatch would be varied by varying the composition of  $Ga_xIn_{1-x}Sb$  solid solutions grown in single crystal form on single crystal substrates of either InSb or GaSb.

## Experimental Techniques

The heterojunctions consisting of pure GaSb, or pure InSb, and  $Ga_xIn_{1-x}Sb$  alloys were prepared as follows: the single crystal rectangular substrate, say GaSb, measuring  $1\frac{1}{2} \times 2 \times 3$  mm, was positioned between two resistively heated carbon strips. A small piece of InSb was placed on the substrate. The upper strip was first heated to approximately  $1000^\circ C$  and held at this temperature. In this way the InSb piece and the upper surface of the substrate were melted. The lower strip was then heated in a carefully controlled manner until just the desired amount of the substrate could be melted. At that moment the melting process was arrested and regrowth allowed to occur by decreasing the power input in the lower and then the upper carbon strip. By employing different size pieces of InSb and remelting the same amount of the GaSb substrate it was possible to grow  $Ga_xIn_{1-x}Sb$  of varying composition on a GaSb substrate.

Since the melting point of GaSb ( $706^\circ C$ ) is appreciably higher than that of InSb ( $525^\circ C$ ) it was found that heterojunctions of  $Ga_xIn_{1-x}Sb$  on InSb substrates

could not be prepared satisfactorily by melting pure GaSb pieces onto the InSb. The molten interface could not be controlled and the regrowth process was erratic. The difficulties were, to a large extent, overcome by employing pieces of an alloy of approximately 50% GaSb-50% InSb which were placed on the InSb substrates. In this way the same procedure as for the GaSb substrates could be followed.

From the relative amounts of the melted substrate and alloying material it was possible to obtain only an estimate of the alloy composition at the heterojunctions. The actual composition was determined by means of electron probe microanalysis.

Dislocations and their networks were studied by etching and by x-ray techniques employing a Lang camera. The etchant employed was a 5:3:3 mixture by volume of concentrated  $HNO_3$ , concentrated HF and glacial acetic acid, respectively. A microfocus x-ray source was employed in conjunction with the Lang camera to obtain the x-ray transmission topographs. The various  $\langle 220 \rangle$  reflections of  $AgK\alpha$  radiation were recorded on Ilford nuclear emulsion plates.

## Results and Discussion

A typical photomicrograph of an alloy heterojunction is shown in Fig. 1. The substrate (lower part) is GaSb and the alloy at the heterojunction contains 0.4% In ( $Ga_{0.996}In_{0.004}Sb$ ). It is seen that the back-melt interface is delineated by an increased concentration of dislocation etch pits resulting from the accommodation of the existing lattice mismatch. No such line of dislocation pits was observed at the interface of par-

Fig. 1. Dislocations across an alloy heterojunction of  $Ga_{0.996}In_{0.004}Sb$  (top section) on a GaSb substrate. Magnification ca. 150X.

<sup>1</sup> Present address: RCA Research Laboratories, Somerville, New Jersey.

tially melted and regrown single crystals (2) (homojunctions). It is further seen in Fig. 1 that these dislocation pits are also present in the regrown region. No such pits were evident in the regrown region near the homojunctions (2). It was indicated that in the case of the homojunctions no dislocations were formed during the regrowth process apparently because no thermal stresses were present. Among the dislocations in the substrate crystal only those which had a component parallel to the direction of regrowth propagated into the regrown section. In the present case a fraction of the dislocations generated to accommodate the lattice mismatch are propagated in the regrown region. At some distance from the interface there is a marked increase in dislocation density apparently resulting from the increased concentration of In [consistent with the GaSb-InSb phase diagram (3)] which imposes the accommodation of an increased lattice mismatch.

An x-ray topograph is shown in Fig. 2. The substrate is again GaSb (lower part) and the In content at the junction is 0.8% ( $\text{Ga}_{0.992}\text{In}_{0.008}\text{Sb}$ ). The heterojunction is clearly visible. However, the dislocation network is not seen since the dislocation lines are predominantly parallel to the interface. As in the case of the "homojunction" (2) here, also, dislocations with their lines primarily parallel to the direction of solidification are propagated indicating that no dislocations are generated in the regrowth region as a result of thermal stresses. The black area at some distance from the interface is again due to the increased In content resulting in an increase in dislocation density to accommodate the increased lattice mismatch. The x-ray topograph of Fig. 3 was taken parallel to the junction interface. The dislocation networks at the heterojunctions not visible in Fig. 2 are visible here as a crossed grid. The spacing in the grid is not completely uniform, apparently reflecting a lack of complete uniformity in composition on a microscale. The InSb content at the interface was too low to be measured by electron probe microanalysis.

The dislocation density expected for the accommodation of an abrupt lattice mismatch in single crystal growth can be readily calculated on the basis of a simple linear lattice model. If onto a linear lattice, with a constant  $a_0$ , another lattice with a constant  $a_0 + \delta$ , where  $\delta$  is a positive increment, is epitaxially superimposed, a dislocation will be required to obtain perfect registry of the lattices every  $n$  unit cells where  $n$  is calculated from the self-explanatory relationship

$$(n+1)a_0 = n(a_0 + \delta) \quad [1]$$

or

$$n = a_0/\delta \quad [2]$$

Fig. 2. X-ray topograph of an alloy heterojunction of  $\text{Ga}_{0.992}\text{In}_{0.008}\text{Sb}$  (top) on a GaSb substrate;  $\text{AgK}\alpha$  radiation, (220) reflection. Magnification ca. 40X.

Fig. 3. X-ray topograph of an alloy heterojunction shown in the plane of the interface. The crossed dislocation grid is considered to be due to the accommodation of the lattice misfit; the In content in the  $\text{GaInSb}$  alloy grown on GaSb was too small to be determined analytically;  $\text{AgK}\alpha$  radiation (220) reflection. Magnification ca. 40X.

The dislocation spacing,  $\Delta$ , is then given by

$$\Delta = na_{uvw} \quad [3]$$

where  $a_{uvw}$  is the lattice translation in the  $\langle uvw \rangle$  direction. For example  $a_{110} = \sqrt{2}a_0$ . In general

$$a_{uvw} = Sa_0 \quad [4]$$

where  $S$  is a geometric relation between the  $\langle uvw \rangle$  direction and the  $[100]$  direction. Thus,

$$\Delta = nSa_0 \quad [5]$$

and from Eq. [2]

$$\Delta = Sa_0^2/\delta \quad [6]$$

In the alloy heterojunctions of the present investigation the polished surface used for the dislocation count was parallel to a (111) crystallographic plane, the growth axis was parallel to a  $\langle 211 \rangle$  direction and the melt interface was parallel to a  $\langle 110 \rangle$  direction. Accordingly,  $S$  in the present case is  $\sqrt{2}$  giving

$$\Delta = \sqrt{2}a_0^2/\delta \quad [7]$$

Assuming the Vegard law is obeyed in this system it is apparent that

$$\delta = a_0(\text{InSb}) - a_0(\text{GaSb}) = 6.485 - 6.095 = 0.390 \text{ \AA} \quad [8]$$

and for the alloys

$$\delta = \delta_{100\%} (1/100) (\text{InSb}\%) = 3.90 \times 10^{-3} (\text{InSb}\%) \text{ \AA} \quad [9]$$

Then,  $\Delta$ , can be expressed in terms of the molar per cent of InSb in the alloy

$$\Delta = \sqrt{2}a_0^2/\delta = \sqrt{2}(6.095)^2/3.90 \times 10^{-3} (\% \text{InSb}) = 1.34/(\text{InSb}\%)$$

where  $\Delta$  is in microns.

The dislocation spacing in the present alloy heterojunctions was determined by etch pit counting at 1000X. Typical photomicrographs of some GaSb based heterojunctions are shown in Fig. 4. The experimentally measured dislocation spacings and the calculated values are plotted for comparison in Fig. 5.

The quantitative agreement between the calculated and experimental dislocation spacings is quite good. The experimental spacings tend to be somewhat less than the calculated values. This result suggests that

Fig. 4a. Photomicrograph of alloy heterojunctions,  $\text{Ga}_{0.9965}\text{In}_{0.0035}\text{Sb}$  on GaSb. Magnification 300X.

Fig. 4b. Photomicrograph of alloy heterojunctions,  $\text{Ga}_{0.992}\text{In}_{0.008}\text{Sb}$  on GaSb. Magnification 300X. Note increased density of dislocations at the junctions with increased InSb content in both a and b.

little, if any, of the lattice mismatch is accommodated by strain, after the model of van der Merwe (4). The somewhat smaller experimental dislocation spacing than the calculated values may be attributed to some dislocation generation during the growth process. The

Fig. 5. Dislocation spacing vs. the reciprocal of alloy composition: ● (% In Sb)<sup>-1</sup>; ■ (% Ga Sb)<sup>-1</sup>.

thermal expansion coefficients of the substrate and the alloy are slightly different, and thus some thermal stresses may occur on cooling. The dislocation network at the interface and the dislocation propagation from the substrate provide the dislocation interactions necessary for Frank Read sources which can then be activated by the differential thermal expansion stresses. Such dislocation generation might account for the dislocations observed near the remelt interface in alloy heterojunctions and which are not associated with the accommodation of the lattice mismatch. It will be recalled that no dislocations are observed near the remelt interface in back-melted GaSb wafers (homojunctions) where no differences in thermal expansion or interface dislocation networks exist.

# The Distribution Coefficient of Oxygen in Germanium

W. D. Edwards

Defence Research Telecommunications Establishment, Ottawa, Ontario, Canada

## ABSTRACT

An indirect method has been used to obtain a value for the distribution coefficient of oxygen in germanium. The method requires a knowledge of the distribution coefficient of aluminum in germanium and also information upon the state of oxidation of aluminum in germanium. If aluminum oxide in liquid germanium is assumed present as  $Al_2O_3$  then a distribution coefficient  $k$  for oxygen in germanium of 0.11 is indicated.

The effects of oxygen dissolved in germanium have been studied by a number of people (1, 2). The presence of oxygen can lead to a change from p to n type when the germanium is subjected to heating cycles such as are involved in the production of alloy type devices. Recently Fox (3) has shown that the presence of oxygen in germanium is detrimental to the production of lithium drifted gamma-ray spectrometers from such germanium.

It is therefore of interest to know the distribution coefficient of oxygen between liquid and solid germanium. The effective distribution coefficient of oxygen at the growth rate used is given by

$$k_{\text{eff}} = C_S / C_L$$

where  $C_S$  and  $C_L$  are the oxygen concentrations in the germanium solid and liquid, respectively. While the concentration of oxygen in solid germanium is readily calculated from the optical absorption coefficient at  $11.7\mu$  the concentration of oxygen in liquid germanium is not easily ascertained. An indirect method has therefore been used to obtain the oxygen concentration in liquid germanium and thence the distribution coefficient.

An equilibrium oxygen concentration is established in a germanium melt and this is then removed by the addition of aluminum. A reaction of the form

takes place. Both reaction products are subsequently incorporated into the growing crystal. While the aluminum dopes the germanium p type in the normal manner the aluminum oxide does not dope the crystal (4).

The amount of aluminum added to the melt,  $(x + m)Al$ , is known and from resistivity and Hall coefficient measurements the quantity,  $xAl$ , may be calculated. Hence the amount of aluminum neutralized by the oxygen,  $mAl$ , is known and from this the required concentration of the oxygen in the germanium melt may be calculated.

## Experimental

Germanium crystals were grown at 1 mm/min and 30 rpm in the  $\langle 111 \rangle$  direction by the Czochralski method. Intrinsic grade germanium was used and was contained in a fixed carbon crucible which was heated by a slotted carbon heater. The whole enclosure was continually flushed by helium maintained at 1 atm pressure.

After the growth of an initial portion of crystal, to allow for a check on the residual impurity concentration, see Fig. 1, section one, oxygen was slowly added to the system. This was continued for 15 min in order to establish an equilibrium oxygen concentration in the melt. Sufficient aluminum was then added to the melt, see Fig. 1, to both neutralize the oxygen in the melt and to dope the melt p type. The oxygen supply

Key words: Germanium, oxygen in germanium, distribution coefficient of oxygen in germanium.

was cut off a few seconds before the aluminum was added. Previous work (5) on crystals doped with oxygen alone has shown that there is no significant change in the oxygen content of the crystal grown in the first minute after the oxygen supply is cut off. The reaction between the aluminum and oxygen in the melt was rapid. To reduce the possibility of the oxidation of the aluminum by the oxygen still in the helium-oxygen atmosphere the system was evacuated to approximately  $10^{-5}$  Torr within minutes of the aluminum addition. Crystal growth was continued at the 1 mm/min rate for approximately 50 min and then the crystal was withdrawn from the melt. The crystal was cooled to room temperature over a 2-hr period.

The crystal was sectioned to provide samples for resistivity plots by the two probe method, infrared measurements to determine the oxygen concentration, and for Hall coefficient and conductivity measurements. Etching studies on the sectioned crystal established that the solid-to-liquid interface shape was very slightly convex toward the liquid.

## Results and Discussion

Kaiser and Thurmond (6) have shown that oxygen in germanium gives rise to a sharp optical absorption at  $11.7\mu$ . The magnitude of the absorption coefficient,  $\alpha$ , at this wavelength has been shown to be proportional to the oxygen concentration, the relationship being (7)

$$\alpha = 1 \text{ cm}^{-1} \equiv 1.25 \times 10^{17} \text{ oxygen/cc}$$

where  $\alpha$  is in units of  $\text{cm}^{-1}$ . This relationship was obtained by comparison of the infrared absorption coefficient with the corresponding concentrations obtained directly by vacuum fusion analysis. Corbett *et al.* (8) have shown that the absorption at  $11.7\mu$  is

Fig. 1. Plots of resistivity and absorption coefficient vs. distance along the crystal. The relevant position in the crystal is indicated. The growth rate was 1 mm/min. The effective distribution coefficient at this growth rate, is given by  $\frac{C_S}{C_L} = \frac{\text{column three value}}{3/2 (\text{column seven value})}$

\* Columns 5, 6, and 7 are expressed in these units to avoid the introduction of the density ratio of liquid to solid germanium.

due to interstitial oxygen. Provided that  $\alpha < 1 \text{ cm}^{-1}$ , errors due to the presence of oxygen in other forms remain small (5).

Samples were cut from section two of the crystal, see Fig. 1, and their absorption coefficients,  $\alpha$ , were measured. The values obtained are plotted in Fig. 1. It is seen that the addition of oxygen for a period of 15 min is sufficient to establish an equilibrium oxygen concentration in the growing crystal. At this concentration the presence of donors due to the oxygen (5) is barely detectable as a small reduction of the resistivity below the intrinsic value. The values of  $\alpha$  for the slices taken immediately prior to the cut-off of the oxygen supply, for three different crystals, have been entered in column two of Table I. From these values of  $\alpha$  the oxygen concentration in the solid,  $C_S$ , may be calculated. The values found are given in column three of Table I.

Hall coefficient and conductivity measurements were made in the temperature range 77°-373°K on samples cut from section three, see Fig. 1, of the crystals. The aluminum acceptor concentrations in the solid were calculated from these measurements. The aluminum acceptor concentrations in the material grown just after aluminum doping of the liquid are entered in column four of Table I. The equivalent concentrations in the liquid, based on the assumption of a distribution coefficient for aluminum of 0.073 (9), are entered in column five. In column six are the total aluminum concentrations in the liquid calculated from the known melt volumes and amounts of aluminum actually added.

When the aluminum is oxidized it no longer acts as a p-type dopant. The amount of aluminum that has been oxidized is given by the differences between that which was added to the melt and that which was calculated from the Hall coefficient measurements on the crystal as present in the melt, i.e., the difference between columns six and five of Table I. This difference is given in column seven and is the amount of aluminum required to "getter" the oxygen present in the liquid in concentration  $C_L$ .

Although the inclusion of the aluminum oxide in the germanium crystal has been demonstrated (5), the aluminum-to-oxygen ratio has not been measured. The quantitative analysis for aluminum and oxygen at a few parts per million or less in germanium is marginal. With the assumption that the formula for the aluminum oxide formed is Al<sub>2</sub>O<sub>3</sub> a value for  $k_{\text{eff}}$  for oxygen in germanium,  $C_S/C_L$ , is readily calculated. The values found are given in column eight of Table I.

The value found for  $k_{\text{eff}}$  is approximate and is probably a minimum value. We have a condition of dynamic equilibrium which involves oxygen exchange at the interface between the melt and furnace atmos-

phere. As a result the oxygen content in the melt is probably not uniform. As the method described gives an average value for the oxygen concentration in the melt, this is a source of uncertainty. When the aluminum is added to the melt impurity oxides may well be reduced but as the germanium used was intrinsic grade this source of error should be very small. Another more serious source of error is the unknown contribution of the oxygen present in the furnace atmosphere before the evacuation takes place. The rate of oxidation of the aluminum in the melt immediately after aluminum doping and before evacuation takes place is not excessive, see Fig. 1, and the error due to this is not expected to be more than several per cent. An accurate calculation of the equilibrium value of the distribution coefficient (10), i.e., the value for an infinitely slow growth rate, is not feasible at the present time because of the many uncertainties in the parameters involved, e.g., the diffusion coefficient of oxygen in liquid germanium.

In summary, the distribution coefficient of oxygen in germanium for a crystal growth rate of 1 mm/min is approximately 0.11. This value is calculated on the assumption that the formula for the aluminum oxide formed is Al<sub>2</sub>O<sub>3</sub>, and that the distribution coefficient of aluminum in germanium is 0.073.

# The Synthesis and Epitaxial Growth of GaP by Fused Salt Electrolysis

J. J. Cuomo\* and R. J. Gambino

IBM Watson Research Center, Yorktown Heights, New York

## ABSTRACT

Single crystals of GaP have been deposited epitaxially on silicon substrates ( $\langle 111 \rangle$ ,  $\langle 100 \rangle$ , and  $\langle 110 \rangle$ ) by fused salt electrolysis. A  $100\mu$  thick layer of GaP was cathodically deposited at a current density of  $50 \text{ ma/cm}^2$  from a fused salt solution consisting of  $2 \text{ NaPO}_3$ ,  $0.5 \text{ NaF}$ , and  $0.25 \text{ Ga}_2\text{O}_3$ , maintained at  $800^\circ\text{C}$ . The deposits have been doped, both p- or n-type, during growth by adding small concentrations of  $\text{ZnO}$  or  $\text{Na}_2\text{SeO}_4$  into the solution. Electroluminescent p-n junctions have also been fabricated by growing a layer of one carrier type, then overgrowing a layer of the other carrier type. Preliminary experiments on the deposition of AlP and ZnSe indicate that the fused salt electrolysis method can be applied to the synthesis of many compound semiconductors.

Considering the nature of electrodeposition, it is somewhat surprising that electrolytic techniques have not been utilized more frequently in the technology of crystal growth. One of the essential features of all methods of single crystal growth is a small, controlled displacement of the system from thermodynamic equilibrium in the direction of the desired solid phase. This condition can be obtained in an electrolytic cell by applying a potential slightly greater than the equilibrium potential for the reaction of interest. The rate of growth, moreover, is simply dependent on the current density and the current efficiency of the electrode reaction. In addition, since the growth is constrained to occur at an electrode, the seeding and geometry of the crystal should be more readily controllable.

High quality single crystals of a few metals, notably silver and copper (1) have been prepared electrolytically from aqueous solutions. A number of intermetallic compounds have been obtained as small, randomly oriented single crystals during the course of their synthesis from fused salts (2-4) but, in general, electrolytic methods have rather rarely been applied to single crystal growth. Single crystals of a number of oxides, such as vanadate spinels (5) and  $\text{Mn}_2\text{O}_3$  (6), have been grown electrolytically, but these methods apparently depend on changes in the oxidation state of the molten salt solvent rather than on electrodeposition so that they are not pertinent to the present discussion.

This paper deals with the synthesis and epitaxial crystal growth of GaP by electrodeposition from fused salt solutions. GaP was studied because of its importance as an electroluminescent device material and because it is representative of a whole class of large band gap III-V and II-VI semiconductors. This work demonstrates the feasibility of growing single crystals of GaP by fused salt electrolysis of sufficient quality to be of interest for electronic device applications. The experimental approach was to study the cathode deposits obtained by the electrolysis of several molten salt solutions. After achieving the synthesis of GaP, single crystal substrates were used as the cathode and the operating conditions necessary for epitaxial crystal growth were determined. The products were studied primarily by x-ray diffraction and metallographic methods. In a few cases spectrochemical analysis and electrical properties studies were made.

## Experimental Procedure

A schematic of the apparatus is shown in Fig. 1. It consists of a quartz chamber heated by a resistance

\* Electrochemical Society Active Member.

furnace. A graphite crucible, which contains the melt, is placed within the chamber. Electrical contact was made to the crucible which also serves as the anode of the cell.

Two types of cathodes were used. In the synthesis experiments, the cathode consisted of a  $\frac{1}{4}$  in. diameter, spectrographic grade graphite rod which was immersed into the melt to a depth of about 1 in. In the crystal growth experiments, single crystal wafers, usually of silicon, were used as the cathode. Substrates with  $\langle 111 \rangle$ ,  $\langle 110 \rangle$ , and  $\langle 100 \rangle$  crystallographic orientations were used. The wafers were attached to a graphite rod, which provided electrical contact to the wafer by means of the assembly shown in the inset of Fig. 1. With this assembly, approximately  $10 \text{ cm}^2$  of a 1.25 in. diameter wafer could be exposed to the solution. During this investigation both constant current and constant voltage supplies were used to obtain the electrodeposits. The compositions (in molar ratio) used to effect the synthesis and epitaxial growth of GaP were as follows:

1.  $2.0 \text{ NaPO}_3$ ,  $0.5 \text{ NaF}$ , and  $0.125$  to  $0.25 \text{ Ga}_2\text{O}_3$
2.  $1.2 \text{ LiCl}$ ,  $0.8 \text{ KCl}$  (eutectic composition),  $0.1 \text{ Ga}_2\text{O}_3$ , and  $0.2 \text{ NaPO}_3$
3.  $1.0 \text{ NaCl}$ ,  $1.0 \text{ KCl}$ ,  $0.05 \text{ Ga}_2\text{O}_3$ , and  $0.1 \text{ NaPO}_3$ .

The chemicals used were of reagent grade with the exception of  $\text{Ga}_2\text{O}_3$  which had a purity of 99.999%.

In all compositions, the sodium metaphosphate and gallium oxide act as the source of phosphorus and gallium respectively. In the first composition the sodium metaphosphate also acts as the solvent. The latter two

Fig. 1. Schematic of the apparatus for the preparation of GaP by fused salt electrolysis.

compositions allow for lower temperature operation and compatibility with quartz. The sodium metaphosphate bath will severely attack quartz, and it was therefore necessary to use graphite crucibles for this system. It was found that a thin layer of pyrolytic graphite on the inner wall of the quartz crucible would also act as an effective barrier against sodium metaphosphate attack. A dry, inert atmosphere was provided largely to prevent the oxidation of the graphite components and to prevent moisture from reacting with the melt.

The procedure used was to add the premixed composition to the crucible, allow the contents to come up to a predetermined temperature under an inert atmosphere, then lower the substrate into the melt with the potential on. The graphite portion of the cathode should not be introduced into the melt for this will produce a dendritic mass of GaP on the graphite making it difficult to remove the substrate.

When the deposition was completed, the substrate was slowly removed from the bath. This procedure allows for most of the solution that has been dragged out with the substrate to run off and for the phosphate glass that forms on the surface to cool slowly thus preventing cracking of the epitaxial layer.

The gallium phosphide layer was readily removed from the silicon substrate by dissolving the silicon in a solution of  $\text{HNO}_3$  and HF. The GaP surface was protected from the etch by a coating of apiezon wax which was also used to bond the wafer to an alumina disk for support. The dissolution of the silicon is rapid, whereas GaP is only slowly attacked by the etchant. After the silicon was removed, the epitaxial layer of GaP was detached from the alumina-supporting wafer with trichlorethylene. Thorough rinsing with trichlorethylene, then acetone, and finally with water and alcohol produced clean crystals. When a single wafer of silicon was used as a substrate, it was somewhat difficult to expose the silicon to the etch because it was covered on both sides with GaP. On occasion, the wafer split parallel to its surface exposing a silicon surface so that the above technique was readily employed. If two silicon wafers, back to back, are used as a substrate, the subsequent removal of the silicon from the GaP is greatly facilitated.

## Results

Some of the operating parameters and results of experiments with the  $\text{NaPO}_3$ -NaF solutions are shown in Table I. In the initial experiments, a graphite rod

was employed as a cathode and the deposits consisted of polycrystalline GaP of various grain size and shape. Powdery yellow deposits were obtained at high cell currents (i.e., 5000 ma) and rather coarsely crystalline products with crystallites up to 0.1 mm diameter and 0.5 mm long were produced at cell currents of about 100 ma. The bath was operated at temperatures between 800° and 1000°C. The lower limit was determined by the liquidus temperature of the mixture which became a clear liquid at about 750°C. The melt begins to vaporize quite rapidly at about 1000°C so this temperature was selected as an upper limit. Within this temperature range, the quality of the GaP product appears to be fairly independent of temperature.

At low cell voltages, below about 0.6v, no solid products were observed at the cathode but a gas, believed to be phosphorous vapor, was evolved. When the cell was operated in air, bubbles of this gas ignited on reaching the surface of the melt, resulting in a puff of white smoke, indicating the presence of phosphorous vapor. At higher voltages, about 0.6v, GaP is deposited at the cathode as well as phosphorous vapor. The cell current increases rapidly with increasing cell voltage at about this value of cell voltage.

It was found that p or n doping of the GaP deposit can be achieved by incorporating small amounts of compounds of the appropriate doping elements in the bath. Zinc in the form of ZnO was used for p-type doping. Selenium in the form of  $\text{Na}_2\text{SeO}_4$  and tellurium in the form of  $\text{Na}_2\text{TeO}_3$  were used to produce n-type doping. Table I shows some of the concentrations used and the effect on the resulting GaP layers. Experiments 4A and 4B were run under identical conditions with the exception of the cell potential. From the photoluminescence results it appears that the dopant concentration in the product depends on the cell voltage as well as on the concentration of the dopant in the bath.

The initial results, which showed that rather large crystallites of GaP could be deposited from this bath, suggested that with suitable control of nucleation, single crystals could be obtained. The method seemed well suited for an epitaxial growth approach if a suitable substrate could be found which would also serve as a cathode. Silicon was selected because of its availability as high quality single crystal wafers, crystallographic compatibility with GaP, high electrical conductivity, and high melting point. Epitaxial single crystal layers of undoped GaP were obtained when the graphite cathode was replaced by a silicon wafer

Table I. Typical GaP deposition experiments with  $\text{NaPO}_3$ -NaF melts

No.	Melt composition			Temp, °C	$E_{\text{cell}}$ , v	$I_{\text{cell}}$ , ma	Time, hr	Cathode composition	Orientation	Cathode products
	$\text{NaPO}_3$ , moles	NaF, moles	$\text{Ga}_2\text{O}_3$ , moles							
1	2	1/2	1/6	850	5.00	5000	3/4	Graphite	Random (polycrystal)	Fine yellow powder
2	2	1/2	1/4	900	0.60	100	16	Graphite	Random (polycrystal)	Yellow dendrites, needles and small crystals

13	2	1/2	1/4 + 0.5g ZnO	800	0.75	410	16	GaP	<110>	20μ epitaxial layer
14	2	1/2	1/4 + 0.5g ZnO	850	0.90	55	1	GaP	Poly—large grain	Epitaxial p-type overgrowth found
15	2	1/2	1/4 + 0.5g ZnO	850	0.96	64	10	GaP	Poly—large grain	Epitaxial p-type overgrowth found
16	2	1/2	1/4 + 0.5g ZnO	850	1.02	250	4	Si	<100>	p-type GaP epitaxial
17	2	1/2	1/4 + 0.59 $\text{Na}_2\text{SeO}_4$	850	1.10	800	13	Si	<100>	Epitaxial GaP
18	2	1/2	1/4 + 0.59 $\text{Na}_2\text{SeO}_4$	900	1.33	470	4	Si	<111>	n-type GaP epitaxial deposit
19	2	1/2	1/4 + 0.59 $\text{Na}_2\text{TeO}_3$	810	1.08	400	6	Si	<111> <100>	n-type epitaxial growth

with  $\langle 111 \rangle$  orientation. Typically the deposits consisted of an epitaxial layer about  $25\mu$  thick which was covered with a rather dendritic, polycrystalline overgrowth. The GaP single crystal was usually cracked in many places along cleavage planes. Subsequent experiments were aimed at obtaining thicker single crystal layers, eliminating the polycrystalline overgrowth, and reducing the number of cracks.

The rate of growth of the epitaxial layer is rapid initially,  $10\text{--}20\ \mu/\text{hr}$ , but decreases with time. This time dependence may be related to the relatively high electrical resistivity of the GaP which causes a substantial voltage drop across the product layer. Eventually, the potential at the surface of the GaP layer may become too low for GaP synthesis. The fact that doped GaP, which has a lower resistivity, grows to a greater thickness tends to support this argument (see sample 8, Table I).

The amount of polycrystalline overgrowth was somewhat reduced by using orientations other than  $\langle 111 \rangle$  such as  $\langle 100 \rangle$  and  $\langle 110 \rangle$  substrates. Doping, however, had an even more noticeable effect on the smoothness of the growth surface. For example, Zn-doped GaP on  $\langle 111 \rangle$  Si was essentially free of overgrowth and uniform in thickness. Undoped GaP was found to vary in carrier type from point to point on the surface, and this nonuniformity could contribute to dendritic growth.

Cracking of the GaP layer was substantially reduced by carefully cooling the crystal layer after its removal from the molten salt bath. When the electrolysis was completed, the cathode was raised out of the melt and left suspended just above the melt surface in the hot zone of the furnace. The furnace power was turned off and the crystal allowed to cool with the furnace over a period of several hours. The crystal was removed from the furnace when the temperature reached  $300^\circ\text{--}400^\circ\text{C}$ .

Figure 2 is a photomicrograph of a GaP crystal taken with transmitted light. The crystal was removed from the silicon substrate by the method described previously. The characteristic  $\langle 111 \rangle$  cleavage planes of the crystal are indicative of epitaxial growth of the GaP on the Si substrate with the same orientation. Figure 3 shows a cross-sectional view of a cleaved wafer taken with transmitted light. The silicon-GaP interface is clearly seen and is sharp. The layer above the epitaxial GaP is the dendritic overgrowth. The thickness of the epitaxial GaP layer is about  $100\mu$ .

A back reflection Laue pattern of a GaP crystal removed from the silicon substrate is shown in Fig. 4. The substrate had a  $\langle 111 \rangle$  orientation and as can be seen from the three-fold symmetry of the pattern, the GaP also has a  $\langle 111 \rangle$  orientation. The crystalline quality is good as indicated by the sharpness of the spots in the pattern.

Fig. 3. Photomicrograph of a cross-sectional view of a cleaved wafer. The GaP is about  $100\mu$ . Magnification 110X.

Fig. 4. Back reflection Laue pattern of epitaxial GaP

The lattice constant of the GaP prepared by this process was determined by the powder method using silicon as an internal standard. The value measured was  $5.4504 \pm 0.0008\text{\AA}$  in good agreement with the previously reported value  $5.447 \pm 0.006\text{\AA}$  (17).

The results of an emission spectrographic analysis of the GaP are shown in Table II. Sample A was measured with the silicon substrate attached to the GaP. Sample B had the substrate removed by the process previously described. The low silicon concentration in sample B is somewhat surprising in view of the fact that silicon substrates were used and considering that reagent grade NaF typically has 0.10%  $\text{Na}_2\text{SiF}_6$  as an impurity. Apparently, the deposition potential of silicon from this melt is so high that it does not electrodeposit with the GaP. The relatively high gold concentration in sample A may be explained by the fact that gold plated tweezers were used in handling the GaP wafers after growth. As can be seen by comparing sample A and B the impurity elements which are high in one sample are at very low levels or not detected in the other sample. This leads to the conclu-

Table II. Spectrographic analysis of GaP in a/o

Impurity	Sample A (with substrate)	Sample B (without substrate)
Si	Major	0.001
Au	0.01	N.D.

Fe	N.D.	0.01
Al	0.05	N.D.
Cu	0.001	0.001

Fig. 5. I.V. characteristics of a GaP diode prepared by fused salt electrolysis.

sion that certain impurities, for example Mg and Al which deposit at high potentials, can be avoided by using lower cell voltages. The heavy metal impurities, which deposit at very low potentials, can probably be removed by a preplating treatment. The gallium phosphide product is relatively pure considering the purity of the starting materials and crucibles.

The resistivity, Hall mobility, and carrier concentration of sample 9 (see Table I) were determined by the van der Pauw method. An indium-gold alloy was used to make contact to the GaP crystal. The room temperature measurements on p-type GaP show  $\rho = 0.0703$  ohm-cm;  $\mu = 27$  cm<sup>2</sup>/v-sec;  $N_a - N_d = 3.3 \times 10^{18}$  carriers/cc. The value of the Hall mobility suggests a total impurity concentration ( $N_a + N_d$ ) of the order of  $10^{19}$ /cc.

Electrodeposited overgrowths on GaP substrate-cathodes were obtained using wafers of GaP cut from Bridgeman-grown crystals (8). The deposits consisted of a thin epitaxial layer about  $20\mu$  thick covered by a thicker polycrystalline overgrowth. The epitaxial layer was thickest near the electrical contact to the wafer, indicating a large potential gradient in the plane of the wafer. The deposited layer was doped p-type by adding ZnO to the solution and the wafer was n-type so that a p-n junction was formed. The diode characteristics of such a junction are shown in Fig. 5. The turn-on voltage is about 1.8v. The light emitted from these diodes was red both at room temperature and at 77°K. The efficiency was estimated to be of the order of  $10^{-4}$ . Light-emitting diodes were also prepared by the solution regrowth technique (9) on electrodeposited GaP chips. The light emitted from these diodes was usually orange-red. In these preliminary experiments, the feasibility of fabricating light-emitting diodes has been demonstrated but not optimized.

The main emphasis of this work was on the NaPO<sub>3</sub> melt compositions; the two other molten salts mentioned previously were, however, studied briefly. Alkali halide mixtures were selected as the solvents because of their low melting points, compatibility with quartz, and high decomposition potentials (10). Gal-

lium oxide and sodium metaphosphate were dissolved in these molten salts. The melt compositions studied and some typical results are shown in Table III.

The cathode product from both the NaCl-KCl and the LiCl-KCl solutions was a mixture of Ga and GaP. Apparently in these solutions Ga deposits at a lower potential than phosphorus, at least when the Ga<sub>2</sub>O<sub>3</sub> and NaPO<sub>3</sub> concentrations in the solutions are those shown.

Evidence of epitaxial growth of GaP from the LiCl-KCl eutectic solution was obtained in that small oriented triangles were observed to form on the <111> silicon substrate-cathode. A possible explanation for the fact that the GaP deposited only in isolated spots is that the silicon wafer was passivated by a layer of SiO<sub>2</sub> and the GaP only grew at the location of pin holes in the passive layer. In the fluoride-containing melt, the SiO<sub>2</sub> layer is probably quickly dissolved but since the chloride melts do not attack quartz, the SiO<sub>2</sub> layer would not be removed by contact with the solution.

### Discussion

The exact mechanism for the formation of GaP by fused salt electrolysis was not explicitly studied during the course of this investigation; however, a number of tentative conclusions about the mechanism can be drawn from the observations presented under Results. The evidence suggests that in the NaPO<sub>3</sub>-NaF electrolyte, GaP is formed by the codeposition of the elements at the surface of the cathode, with phosphorus in excess. The fact that the deposits are coherent epitaxial layers supports the codeposition-surface reaction mechanism. The cathode reaction which liberates gallium is most probably the reduction of Ga<sup>+3</sup> ions to metal. The reduction of metaphosphate ions to elemental phosphorus at the cathode is more difficult to explain, particularly because it occurs at such a low cell potential. Yocom (4) has proposed the following cathode reaction

based largely on the observations that phosphorus and sodium orthophosphate were the cathode products observed after the electrolysis of a NaPO<sub>3</sub> melt. He concluded, therefore, that the reduction does not take place through the intermediate formation of sodium. The glassy phase, which surrounds the cathode and the GaP product after electrolysis in our experiments, is also believed to be Na<sub>3</sub>PO<sub>4</sub>.

Plots of cell voltage vs. cell current were found to be useful for establishing the necessary conditions for codeposition. The curves for the metaphosphate melt had the general shape shown in Fig. 6. The low potential portion of the curve is believed to be due to the metaphosphate cathode reaction. If the cell is operated at voltages that correspond to this portion of the curve, phosphorus is evolved but no GaP deposits. At a somewhat higher cell potential, the slope of the curve increases fairly sharply and GaP begins to deposit. The voltage at which the change in slope occurred varied slightly with melt composition, tempera-

Table III. Deposition experiments with alkali halide melts

Melt composition	Temp, °C	$E_{\text{cell}}$ , v	$I_{\text{cell}}$ , ma	Time, hr	Cathode composition	Cathode orientation	Cathode products

Fig. 6. Typical dependence of cell current on cell voltage for the sodium metaphosphate bath with graphite electrodes.

ture, and the experimental setup used. However, the break in the current-voltage curve was a reliable indication of the minimum voltage for GaP formation. At the beginning of each run, therefore, a current-voltage curve was plotted and the operating voltage set at a value somewhat above the change in slope.

The cathode reactions in the halide melts are apparently different in that the GaP product is sometimes contaminated with elemental gallium (see Table III). The deposition potential of gallium is apparently lower than that of phosphorus in the compositions studied. The halide solutions warrant further investigation because they have a number of desirable properties. Their lower melting temperatures are advantageous from the point of view of experimental flexibility: for example it might be possible to use germanium substrates with a lower melting halide solution. The problem of thermal shock cracking would also be greatly reduced by a lower operating temperature. Perhaps most important from the point of view of semiconductor technology is the fact that the halides are relatively easy to purify and are in fact commercially available in high purity form.

The deposition potentials of many elements from halide melts have been determined in recent years (11, 12). This data should be useful in extending the method of fused salt electrolysis to other III-V and II-VI compounds. The metaphosphate solution is not as readily extended to other compounds other than phosphides. We have shown that AlP and InP are obtained from the metaphosphate melt when  $\text{Ga}_2\text{O}_3$  is replaced by  $\text{Al}_2\text{O}_3$  or  $\text{In}_2\text{O}_3$ . ZnSe and ZnTe have been deposited epitaxially on Si from halide melts (see Table III). The success of these initial experiments suggests that most of the III-V and II-VI compounds can be deposited by fused salt electrolysis.

A number of applications for the method of fused salt electrodeposition suggest themselves. In device

fabrication especially, the flexibility and controllability of an electrolytic method should find applications. It should be possible, for example, to produce p-n junctions in the growing crystal simply by changing the cell potential. Plating through masks also appears to be feasible, at least in the halide melts, using  $\text{SiO}_2$ , for example, as a mask material.

The method of fused salt electrolysis may have a substantial economic advantage over other methods of semiconductor device fabrication. Conventional methods require the separate steps of extracting and purifying the constituent elements, growth of single crystals, slicing the crystals into wafers, and doping the wafers to produce a p-n junction. The method of fused salt electrolysis accomplishes the extraction, crystal growth, and junction formation in one operation. This method may become important therefore in such areas as the production of electroluminescent devices and the fabrication of solar cells (13).

#### Acknowledgment

The authors wish to express their appreciation to S. Blum for providing GaP substrates, C. Kelly and M. Lorentz for fabricating and characterizing diodes, and J. Woods for the electrical measurements. The technical assistance of Miss J. Bartivic, H. G. Schaefer, and R. Wnuk is gratefully acknowledged.

Manuscript received Dec. 26, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Si-SiO<sub>2</sub> Fast Interface State Measurements

Dale M. Brown\* and Peter V. Gray

General Electric Company, Research & Development Center, Schenectady, New York

## ABSTRACT

The low-temperature (77°K) MOS-C(V) curves previously utilized to measure the number of fast interface states are analyzed. Quantitative variations in the number of fast states with variations in crystal orientation, oxidation atmosphere, vacuum and hydrogen annealing, together with some results of MOS-FET vacuum annealing are presented. For instance, high-temperature vacuum annealing of oxidized silicon wafers is shown to be capable of producing a very high density of donor and acceptor type fast interface state levels of the type previously identified by measuring MOS-C(V) flat-band voltage at low temperatures. These results suggest that these bands of donor and acceptor levels arise from a single type of defect which is electrically amphoteric.

Cooling MOS samples to low temperatures and measuring resultant changes in the samples' flat band voltage as determined from capacitance *vs.* voltage [C(V)] curves has previously been shown to be a simple and direct method of measuring the number of fast interface state levels at the Si-SiO<sub>2</sub> interface (1). This method, of course, normally detects only those states between the high- and low-temperature Fermi levels. In order to scan both sides of the band gap, these experiments were performed on identically oxidized pairs of n- and p-type samples. The results of these previous experiments suggested that the acceptor- and donor-type interface state levels detected using these sample pairs are caused by a single type of defect which is electrically amphoteric. The amphoteric nature of the fast interface defect discussed in ref. (1) and the symmetry of the interface state levels suggests that they can be thought of as being levels taken out of the conduction and valence band continuum by the discontinuities experienced by the Si bonds at the surface. In order to explain the increases in surface channel conductance that occurred when thermal oxides were formed in dry O<sub>2</sub> and subsequently annealed in H<sub>2</sub> or whenever steam oxidation was performed, Balk has proposed that a fast interface state consists of an oxygen vacancy defect at the Si-SiO<sub>2</sub> interface whose chemically unsaturated bonds can be saturated with H which in turn causes the annihilation of the fast state (2).

The charge within these fast interface states at any particular value of surface potential must not be confused with the amount of fixed charge,  $Q_{so}$ .  $Q_{so}$  has usually been determined by measuring the room temperature MOS-C(V) flatband voltage. This type of determination for  $Q_{so}$  is, of course, correct only in the absence of fast interface states even at measurement frequencies high enough to eliminate all the fast state capacitance if interface states are present. In fact, it is very difficult to distinguish, especially for very low values of surface charge, the fixed charge component and the fast interface state component from one another. This is because such a separation requires detailed information about the nature and distribution of fast states. The fixed charge has been attributed to positive alkali ion contamination, oxygen ion vacancies and/or excess positively charged Si at the Si-SiO<sub>2</sub> interface, or even in some special instances to negative ion complexes.

It is the purpose of this paper to explain the low-temperature (77°K) MOS-C(V) curves utilized to measure the total number of fast states and to show how the number of fast states can be varied over a very wide range. For instance, the dependence of the interface state density on how "wet" the oxide is has often been alluded to but never directly measured.

Furthermore, if fast surface states are due to the presence of unsaturated Si bonds at the interface, their number should be greatly increased by vacuum annealing since the reduction of SiO<sub>2</sub> by Si should produce more unsaturated bonds at the interface and/or the vacuum annealing might also eliminate any Si-H bonding within the oxide.<sup>1</sup> In addition, experiments with MOS-FETs show that fast interface states when present inhibit surface inversion and drastically reduce the mobility of the free carriers in the channel.

## Experimental Techniques

One ohm-cm n- and p-type wafers 2.5 cm in diameter and 0.15 cm thick were lapped and etched in white etch<sup>2</sup> and rinsed in distilled H<sub>2</sub>O. Following this treatment they were placed in a double-walled quartz thermal-oxidation chamber. The complete oxidation system is shown schematically in Fig. 1. The oxygen used for oxidation was an extra dry grade<sup>3</sup> but was initially passed through a quartz tube heated to 1000°C by a simple resistance furnace. This preheating preburned any hydrocarbons present in the oxygen, and the resulting water was trapped. Known amounts of H<sub>2</sub>O could then be introduced by subsequently passing this dry O<sub>2</sub> through water (or ice) and a trap, both of which were held at fixed temperatures. In this manner the O<sub>2</sub> oxidation atmosphere could be varied between 1 atm O<sub>2</sub> + 80 ppm H<sub>2</sub>O and 0.9 atm O<sub>2</sub> + 10<sup>5</sup> ppm H<sub>2</sub>O. The O<sub>2</sub> dew point was measured at the exhaust of the oxidation chamber. After oxidizing the samples at 1000°C for either 2 or 3 hr depending on orientation, the sealed oxidation chamber was removed from the oxidation furnace and allowed to cool in the oxidation atmosphere. The resultant oxides were about 1200Å thick.

Vacuum annealing could be performed by placing one of these previously oxidized samples inside a Si vacuum furnace. This is shown in Fig. 2. The Si furnace cavity was enclosed in a quartz bell jar which is attached to a high vacuum ion pump system and the Si furnace was heated by an RF induction heater. The sample's temperature was monitored by using a Pt-Pt 10% Rd thermocouple connected to a potentiometric recorder<sup>4</sup> through an RF filter.

Al dots about 2 mm in diameter were formed on the surface of the oxide by evaporating Al from a W filament through a nonintegral metal mask. The wafers were not heated during the formation of the Al dots or at any time previous to the taking of C(V) curves. The C(V) curves were then measured at 300° and

<sup>1</sup> A number of possible reactions which could occur within oxides and alter the number of interface states has been extensively discussed by E. Kooi, *IEEE Transactions on Electron Devices*, 13, 238 (1966); E. Kooi and M. V. Whelan, *Appl. Phys. Letters*, 9, 314 (1966).

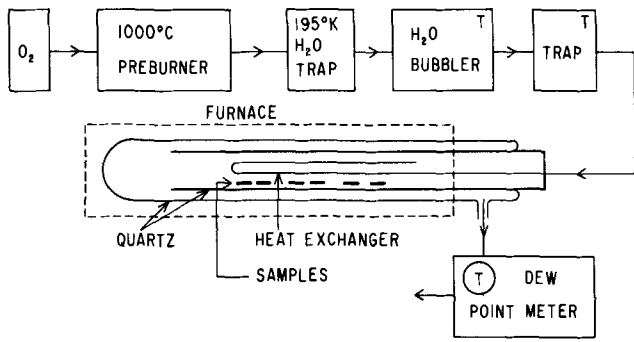

Fig. 1. Oxidation apparatus. The internal quartz heat exchanger is used to preheat the oxidation ambient before it enters the sample chamber. The H<sub>2</sub>O bubbler and trap both at temperature T are used to introduce fixed amounts of H<sub>2</sub>O into the O<sub>2</sub> stream.

Fig. 2. High-purity Si high vacuum RF furnace used to vacuum anneal oxidized samples.

78°K to determine the number of fast interface states produced by the initial oxidation or by subsequent vacuum annealing.

The C(V) curves were obtained by using a continuously recording capacitance vs. voltage bridge which utilizes a lock in amplifier<sup>5</sup> as a phase detector and a-c to d-c converter. A schematic diagram of this apparatus is shown in Fig. 3. The a-c signal frequency was either 100 or 150 kc unless otherwise noted.

**Results**

**C(V) curve analysis.**—A typical set of room temperature and liquid nitrogen temperature C(V) curves is shown in Fig. 4. Also presented are the calculated C(V) curves using methods of analysis described later in the text.

The 300°K curve of Fig. 4 resembles the theoretical MOS-C(V) curve for no interface states and shows little evidence of the  $\sim 10^{13}/\text{cm}^2$  states actually present. The "flat band capacitance" in this sample does not occur at the flat band condition but actually for about 0.1 ev of band bending (slight depletion). This is because the 100 kc capacitance due to interface states,  $C_{FS}$ , is quite large at this point. And by the time that the true flat band condition is reached, the interface state capacitance is so large that the total capacitance is nearly that of the oxide,  $C_o$ . There are two evidences of this high interface state density at room temperature. (A) The C(V) plot is frequency dependent with the "apparent" flatband voltage moving in the negative voltage direction as the frequency

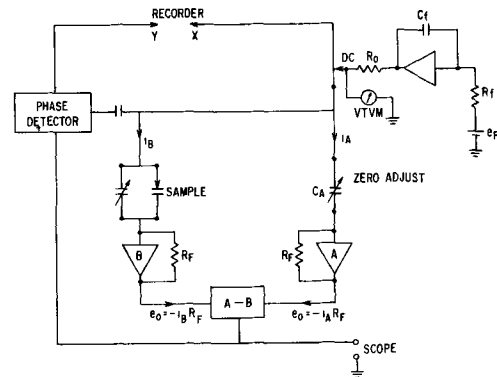

Fig. 3. Schematic diagram of continuous scanning MOS-C(V) bridge.

Fig. 4. Representative set of 300° and 77°K MOS-C(V) curves for samples with large amounts of fast interface states. The 300°-77°K curve voltage shift,  $\Delta V$ , gives the number of fast states  $N_{FS} \approx \Delta VC_o / Aq$  where  $C_o$  is the oxide capacity,  $A$  is the electrode area, and  $q$  is the electronic charge; 5 v/sec sweep speed. Experimental curves are solid lines, calculated are dashed and dash-dotted (see Fig. key). All theoretical curves are for  $\phi_{MS} = 0$  and  $Q_{so} = 0$ . 300°K curve assumes  $N_{FS} = 0$ . But the 77°K depletion curve is appropriately displaced in voltage.

is decreased and (B) if the vertical scale is greatly expanded near  $C_o$ , and C(V) is plotted between -10 and +70v bias the variations in interface state capacitance and that due to surface accumulation can be observed.

The 77°K plot of C(V) exhibits two phenomena not seen at 300°K, namely very strong hysteresis and photosensitivity effects. Most pronounced is a "ledge" of nearly constant capacitance shown in Fig. 4 from +20 to -40v which will occur whenever the bias is swept from negative to positive values. The ledge occurs over the same bias range as the plotted hysteresis loop made up of the lower outgoing trace and the plateau return trace. Both indicate that over this bias range the sample is not in thermodynamic equilibrium. During the plotting of this ledge, interface states below the Fermi level are being filled with electrons from the conduction band. The nearly constant capacitance corresponds to the degree of band bending (depletion) required to provide electrons at the surface to fill interface states at the voltage sweep speed. Thus, increasing the sweep speed will slightly increase the ledge capacitance since electrons are required at a greater rate and depletion type band bending must accordingly decrease. The nature of this ledge in no way gives information about the distribution of interface states even though its extent does depend on the total number present. It is, in fact, possible to observe a similar plateau or ledge and hys-

<sup>5</sup> Princeton Applied Research JB-5.

teresis loop (but at negative bias) in samples with no interface states if the surface is initially inverted. In this case, electrons are being provided to recombine with surface valence band holes and the ledge capacitance is slightly smaller than shown here. In the present sample, the ledge extends from large negative bias values whenever the surface is inverted by sweeping the sample to negative bias values and waiting for electrons to accumulate at the surface. Of course, this process can be enhanced by the presence of light or by going to sufficient fields to produce avalanching.<sup>6</sup>

On the lower trace shown in Fig. 4 the surface goes into strong depletion at 77°K because once the traps have become charged by sweeping the sample into accumulation they require minority carriers (holes) for neutralization. Therefore, as the charge on the field plate is reduced, the charge trapped in the fast interface state traps creates a strong internal field which forces the surface into depletion. This, of course, is a nonthermal equilibrium condition because the quasi-Fermi level is pinned above the charged acceptor states at the Si-SiO<sub>2</sub> interface. This condition can be maintained for hours because of the extremely small number of holes present in the n-type material at 77°K. Flashing light on the sample produces hole-electron pairs and the holes rapidly recombine with the negatively charged acceptor interface states which in turn extinguishes the internal field and the depletion region collapses. The capacity therefore rises toward the plateau value.

All of the effects observed here for this n-type MOS structure are also observed (with appropriate sign changes) for p-type samples. The number of fast states is of course approximately given by the voltage spacing between the 300° and 78°K flatband voltages.<sup>7</sup> This is indicated by the equation in Fig. 4 where  $N_{FS}$  is the number of fast states in the upper half of the band gap between the 300° and 78°K Fermi levels and  $\Delta V$  is the change in flatband voltages.<sup>8</sup>

The experimental curves shown in Fig. 4 were obtained by sweeping the sample past -60v where a type of avalanche breakdown repeatedly occurred which is not well understood because at this point the oxide became conductive enough to load the sweep circuit. This type of 77°K surface carrier generation, which stresses the oxide without destructively breaking it down, apparently produces the spacing between the capacitance curves above the plateau which are traced as the flatband condition is approached from the left and as the sample is swept away from accumulation into strong depletion. This spacing has been observed to decrease and even disappear in some samples if the extent of the voltage sweep is limited and the plateau is reached from the depletion curve either by reversing the direction of sweep or by illuminating the sample. Continuous illumination with strong light maintains a level of capacitance near the plateau value for both the outgoing and returning trace but this does not imply that the samples' capacitance in this case is even close to the thermal equilibrium value. A great

variety of curves can be obtained from samples of this nature at low temperatures depending on how the traces and retracings are made. But Fig. 4 amply illustrates all the main features of these situations.

As described above, the low-temperature ledge capacitance is controlled by the rate at which free carriers can fill interface states or by the rate of recombination of holes and electrons near the surface through recombination centers. And in fact, the primary recombination centers for carriers near the surface may be these fast interface state levels whenever they are present. An analytical formulation for the value of the interface state ledge capacitance is given below.

The rate of interface state filling is controlled by the interface state capture cross section  $\sigma$ , and the free carrier concentration,  $n$ , at the interface

$$1/\tau = \sigma \bar{v} n \quad [1]$$

where  $\bar{v}$  is the average free carrier thermal velocity. The instantaneous surface current is then

$$i_s = N n \sigma \bar{v} q \quad [2]$$

where  $N$  is the number of surface states not in equilibrium, and  $q$  is the electronic charge. This current can be related to the rate at which one adds charge to the interface during the filling of these states

$$i_s = C_o \frac{dV}{dt} = C_o S \quad [3]$$

where  $C_o$  is the capacitance of the dielectric layer and  $S$  is the sweep speed.

Since  $n = AT^{3/2}e^{-q\phi_s/kT}$  where  $A$  is the effective density of states divided by  $T^{3/2}$  and  $q\phi_s$  is the energy difference between the majority carrier band edge and the Fermi level at the surface, the surface potential which establishes the low temperature capacitance plateau is given by

$$\phi_s = \frac{kT}{q} \ln \left[ \frac{AT^{3/2}N\sigma\bar{v}q}{C_o S} \right] \quad [4]$$

Notice that the value of surface potential required to fill the fast states decreases as the sweep speed increases (the band edge moves towards the Fermi level). This, in turn, means that the ledge capacitance will increase slightly as the sweep speed increases. The ledge or plateau capacitance should also increase slightly as the empty interface states are filled, that is, as  $N$  in Eq. [4] decreases.

This analysis is compared with experiment in Fig. 4. The procedure for this comparison was as follows. The material used in these studies was specified as being  $1 \pm 0.25$  ohm-cm.<sup>9</sup> However, the actual surface concentration was determined by using the value of the 300°K zero sweep speed high-frequency minimum capacitance,  $C_{min}(S=0)$ , shown in Fig. 4. (The set of equations used to compute the differential capacitance curves are presented in the Appendix.) This value of  $N_D$  was then utilized in the  $C(V)$  equations to compute the 77°K depletion curve and the 77°K capacitance plateau. The fact that the theoretical depletion curve fits the experimental data so well is an indication that this particular sample is not heavily compensated with boron. If it were, the  $N_D-N_A$  value near the surface would be higher than that many depletion lengths away from the surface. This is because boron is segregated out of the surface during thermal oxidation (4).

The fit between the experimental ledge capacitance and the one calculated using Eq. [4] is within experimental error.<sup>10</sup> Furthermore, the slow increase in the capacitance, which occurs along the plateau as the empty interface states near the conduction band edge

<sup>6</sup> Similar 78°K  $C(V)$  curves have just recently been described by A. B. Kuper, E. Greenstein, and H. P. Caban-zeda. Recent News Paper given at the Chicago Meeting of the Society, Oct. 16, 1967. Electronics Division Abstract RN-3. Minority carrier generation by avalanche breakdown in MIS capacitors has also been observed by A. Goetzberger and E. H. Nicollian, *Appl. Phys. Letters*, 9, 444 (1966).

<sup>7</sup> The approximation here is largely due to the difficulties in determining the 300°K flatband voltage when  $N_{FS}$  is very large. This is because the fast state capacitance shifts the apparent flatband voltage (see text). The degree of uncertainty in  $N_{FS}$  can be estimated by examining n-type samples if we assume that the oxide space charge in all samples is positive or zero,  $Q_{so} \geq 0$ . For example, measurements on an n-type sample with  $N_{FS} \approx 5 \times 10^{12}/\text{cm}^2$  give an apparent 300°K flatband voltage at  $10^5$  and  $10^7$  Hz of -5 and -2v, respectively, but +28v at 78°K for both frequencies. The maximum error in  $N_{FS}$  is therefore about 20% if it is assumed that  $Q_{so} = 0$ . Because of this difficulty the  $Q_{so}$  values quoted in this article are approximate and are labeled " $Q_{so}$ ".

<sup>8</sup> Another method of detecting interface states which is based on measuring the conductive component of the MOS varactor impedance has been described by Nicollian and Goetzberger (3). This method is particularly effective for measuring interface state densities near the middle of the band gap and when the total number of interface states is low.

<sup>9</sup> TI LOPEX—Texas Instruments, Inc., Dallas, Texas.  $1 \pm 0.25$  ohm-cm n-type corresponds to an  $N_D-N_A = (5.8 \pm 1.8) \times 10^{15}/\text{cc}$ .

<sup>10</sup> The capture cross section and average thermal velocity used in these calculations are those used by Nicollian and Goetzberger (3):

$\sigma_n = 1 \times 10^{-15} \text{ cm}^2$  and  $\bar{v} = 10^7 \times (T/300^\circ\text{K})^{1/2}$ .

are filled, is also accounted for. Variations in the height of the plateau with sweep speed have also been verified; however, this correlation is not shown here.

The calculated 77°K high frequency minimum ledge capacitance (equilibrium theory) is also shown in Fig. 4. This was done to emphasize the fact that this capacitance, which is determined and maintained by minority carrier surface inversion, is very difficult to achieve at this low temperature. In fact, no practical combinations of sweep speed and/or illumination levels can be expected to maintain it while the MOS applied voltage is varied.

*$N_{FS}$  Variations with oxidation atmosphere ( $O_2 + H_2O$ ) and surface orientation.*—The variation in fast interface state density as a function of ppm  $H_2O$  added to the oxidation atmosphere can be found from Fig. 5, 6, and 7 which are plots of flatband voltage [assuming  $C_{FS}$  (150 kc)  $\approx 0$ ] for sample temperatures of 300° and 78°K for a range of  $H_2O$  concentrations between 80 and  $10^5$  ppm. Figure 5 gives the data for (111) orientated crystal surfaces, Fig. 6 gives it for (110) surfaces and Fig. 7 gives the data for (100) surfaces. Although the samples were all about  $1200 \pm 100\text{\AA}$  in thickness the data have been normalized for 1000Å of oxide. Note that the numbers of fast in-

Fig. 5. Flatband voltages for (111) 1 ohm-cm n- and p-type oxidized Si wafers at 300° and 78°K vs. ppm  $H_2O$  added to oxygen oxidation ambient.

Fig. 6. Flatband voltages for (110) 1 ohm-cm n- and p-type oxidized Si wafers at 300° and 78°K vs. ppm  $H_2O$  added to oxygen oxidation ambient.

Fig. 7. Flatband voltage for (100) 1 ohm-cm n- and p-type oxidized Si wafers at 300° and 78°K vs. ppm  $H_2O$  added to oxygen oxidation ambient.

terface states as measured by the change in flatband voltage between 300° and 78°K occur in almost identical numbers for any pair of n- and p-type samples oxidized in the same ambient. This holds for each of the three orientations. The number of fast states in both halves of the band gap increase monotonically as the oxygen is dried out. At 30,000 ppm  $H_2O$ , the fast state density,  $N_{FS}$ , is  $\leq 10^{10}/\text{cm}^2$  while for lower concentrations it increases until at the 80 ppm  $H_2O$  level  $N_{FS}$  is about  $3.8 \pm 0.3 \times 10^{12}/\text{cm}^2$  for n- and p-type (111) samples,  $2.5 \times 10^{12}/\text{cm}^2$  for (110) samples and  $9.3 \pm 2 \times 10^{11}/\text{cm}^2$  for (100) samples.<sup>11</sup>

*Increases in  $N_{FS}$  with vacuum annealing.*—As pointed out previously, vacuum annealing could be expected to produce even larger amounts of interface states by producing more unsaturated Si bonds through the reduction of  $SiO_2$  by Si at the  $SiO_2$ -Si interface and/or by elimination of Si-H bonds. The results of some high-temperature vacuum annealing experiments (pressure  $\sim 5 \times 10^{-7}$  Torr) done on a variety of (111) samples are shown in Table I. Samples 1 and 2 are identically treated n- and p-type samples. Notice that the additional vacuum annealing treatment has greatly increased the fast interface state density in these two samples, and yet the number of donor and acceptor levels still appear in almost identical numbers. Vacuum annealing can also increase the number of fast states in "wetter" oxides too, as is shown by the results obtained from sample 3. Sample 4 is a dry oxide that was first vacuum annealed and then  $H_2$  annealed, and the results show that  $H_2$  annealing eliminates the fast interface state defects as originally proposed by Balk (2). As mentioned previously, an exact interpretation of the "apparent" room temperature flatband condition is made difficult when the number of interface states is very large and the measuring frequency is too low to eliminate interface state capacity. However, the  $Q_{50}$  values in Table I indicate that  $H_2$  annealing which eliminates the states does not increase the amount of fixed positive charge. Therefore, the enhanced surface inversion observed by Zaininger and Warfield using  $H_2$  annealed p-type MOS varactors (5) was probably caused by the elimination of the fast interface states produced by the initial dry oxidation.

These results therefore show that the respective donor and acceptor fast state levels appear in equal numbers (within experimental accuracies) on identically treated pairs of p- and n-type samples. This fact is necessary to conclude that the fast state defect center is electrically amphoteric. It is not sufficient,

<sup>11</sup> It is interesting to note that the oxide growth rate is virtually unaffected by additions of water below 10,000 ppm  $H_2O$ . This fact can also be deduced from the wet and dry oxide growth rate constants given by B. E. Deal and A. S. Grove, *J. Appl. Phys.*, **36**, 3770 (1965).

however. One could still maintain that only one type of level occurs in either n or p-type samples. To prove that both types of levels appear in a single sample, it is necessary to look at inverted surfaces.

**Effects of N<sub>FS</sub> on surface inversion.**—Figure 8 shows a schematic picture of how the fast interface state levels in the minority carrier half of the band gap are charged whenever the surface is inverted. In this case, the surface of n-type Si has been inverted to produce a p-type channel. This, of course, is the surface condition required to turn on a p-channel enhancement mode MOS-FET. Charging these defect states is expected to have two effects: increase the threshold voltage, and reduce the channel carrier mobility by charge scattering (6). In order to demonstrate this effect clearly, a p-channel enhancement mode MOS-FET was fabricated. The threshold and carrier channel mobility as determined by measuring the small a-c signal channel conductance are shown in Table II. The thresholds given in Table II are defined as the gate voltage at which the surface conductivity of the channel is 1 μmho/square. The initial 300°K characteristics were: threshold -6v and channel mobility, 190 cm<sup>2</sup>/v-sec as determined by the slope of the channel conductance curve well beyond threshold. (It is assumed that well beyond threshold all the fast states are filled and that all the additional charge added to the surface adds free mobile charge to the channel.) The Al contacts were next removed and the device vacuum annealed at 1000°C to produce a large number of interface states. After reapplying the Al contacts the device characteristics were redetermined. Initially the 300° and 78°K thresholds were -6 and -7v, respectively, and N<sub>FS</sub> ≈ 4 × 10<sup>10</sup>/cm<sup>2</sup>. (Even without fast states, about a 1v shift in threshold is

Fig. 8. Schematic representation of how the fast interface state levels in the minority carrier half of the forbidden band are charged when the surface is inverted. In this case, n-type Si bulk material is inverted to produce a p-type surface.

expected for this change in temperature because  $kT$  at 77°K is much smaller and because of the shift in bulk Fermi level.) Following vacuum annealing, the LN<sub>2</sub> threshold had increased to -34v which indicates a N<sub>FS</sub> ≈ 5.9 × 10<sup>12</sup>/cm<sup>2</sup>, and the LN<sub>2</sub> channel mobility has decreased from 340 to 45 cm<sup>2</sup>/v-sec. The room temperature characteristics are now greatly degraded giving a threshold of -18.5v and a channel mobility of only 60 cm<sup>2</sup>/v-sec. Thus, as expected, surface inversion now requires additional surface charge to charge the defect centers, which when charged, greatly decrease the channel carrier mobility by introducing large amounts of additional scattering.<sup>12</sup> The temperature dependence of the mobility has also been altered. Before annealing, the channel mobility increased with decreasing temperature which suggests that phonon scattering was dominant; after annealing, however, the mobility at 78°K is slightly lower than it is at 300°K. This suggests that charged interface states reduce the channel mobility by coulomb potential scattering of the free carriers in the channel.

### Summary

The technique of cooling samples to 77°K and measuring the resultant shift in flatband voltage has been shown to be an excellent method of detecting and measuring the total number of fast states between the 300° and 77°K Fermi levels. And in fact, the range of detection is approximately 0.1 to greater than 200 × 10<sup>11</sup>/cm<sup>2</sup>. The 77°K C(V) curves have been explained and analyzed, and the so-called 77°K plateau or ledge capacitance explained. The results show that the fast interface state donor and acceptor levels always appear in nearly equal numbers. For example, the number of acceptor and donor levels measured on similarly treated n- and p-type samples, respectively, are essentially equal before and after their number has been greatly increased by vacuum annealing. These same levels are eliminated by H<sub>2</sub> annealing. These defect centers when present can drastically raise even the room temperature performance of MOS-FETs since their production has been shown to alter the threshold and greatly reduce the channel mobility of a MOS-FET. Furthermore, these two sets of defect levels are observed to delay both surface

<sup>12</sup> The presence of interface states is of course also apparent in the difficulty of attaining the characteristic very low-frequency surface inversion curve in standard MOS varactors. However, it is more difficult to make this effect in varactors as quantitative as the measurement of FET thresholds at low temperatures.

accumulation and surface inversion.<sup>13</sup> All these results suggest that these levels are caused by a single type of defect which is electrically amphoteric.

### Acknowledgments

The authors wish to acknowledge the fine technical help given by George Charney, Cliff Circe, and Lloyd Keifer in preparing wafers and in running the oxidation and vacuum systems used in this study.

Manuscript received Nov. 20, 1967; revised manuscript received March 4, 1968. This paper was presented in part at the Philadelphia Meeting, Oct. 9-14, 1966, as Recent News Paper 13.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

<sup>13</sup> Preliminary experiments on self-registered Mo gate MOS-FETs (D. M. Brown, W. Engeler, M. Garfinkel, P. V. Gray, Recent News Paper presented at the Chicago Meeting of the Society, Oct. 16, 1967, Electronics Div. Abstract RN-7) also show this correlation. That is, large shifts in MOS-FET threshold and in the MOS-C(V) flatband condition have been observed to occur simultaneously when the samples are cooled. Furthermore, as these shifts are reduced by hydrogen annealing, the FET thresholds are lowered, and the channel mobilities are increased.

### APPENDIX

#### Analytical Model for the Semiconductor Surface Varactor<sup>14</sup>

A brief presentation of the equations used to compute the theoretical C(V) curves in the text follows.

Several analytical papers have appeared which have treated various aspects of the surface properties of semiconductors with varying degrees of accuracy and completeness. Specialized solutions for the electric field at the semiconductor's surface have been presented by Kingston and Neustadter (7) for the case of fully ionized impurity states and nondegenerate free carrier distribution. These specialized solutions of Kingston and Neustadter have been used by Frankl (8) and by Grove, Deal, Snow, and Sah (9) to develop MOS capacitance calculations. Similar sets of equations have been developed by Garrett and Brattain (10), Lindner (11), and also by Marcus (12) who has included the effects of the hypothetical midband gap interface states. Stratton (13) has developed a specialized solution for the surface field for the limiting case of extreme degeneracy. Seiwatz and Green (14) have presented an exact equation for the surface field using Fermi-Dirac functions, and their equation is similar to ours in this respect. However, they did not develop the appropriate equations for the capacitance of the MOS varactor.

<sup>14</sup> Partial reproduction of "MOS Science and Technology, I. Analytical Model for the Semiconductor Surface Channel and the MOS Varactor and Field Effect Transistor," by D. M. Brown and P. V. Gray; General Electric Report No. 67-C-026, March (1967).

The assumptions are that: (i) the semiconductor bulk band structure can be characterized by parabolic bands and a density of states effective mass and a forbidden energy gap, all of which are continuous in value right up to the insulator-semiconductor interface; (ii) thermodynamic equilibrium holds throughout the semiconductor; and (iii) the insulator and insulator-semiconductor interface is perfect and does not contain any electronic traps nor does the insulator contain any ionic space charge.

The development of the formula for the electric field at the surface of the semiconductor for any degree of band bending parallels that given by Seiwatz and Green (14). The only difference is that the zero of energy in our calculations is taken at the valence band edge whereas Seiwatz and Green use the so-called intrinsic Fermi level which is very close to the middle of the forbidden band. Having zero energy at a band edge simplifies the situation somewhat.

The surface field is calculated by integrating Poisson's equation. The surface field is supported by a space charge region near the semiconductor's surface. The charge density,  $\rho$ , is given by

$$\rho = \rho_D - \rho_A + q(p-n) \quad [\text{A.1}]$$

where  $\rho_A$  and  $\rho_D$  are the densities of ionized acceptors and donors, and  $p$  and  $n$  are the densities of electrons and holes given by

$$n = A_C T^{3/2} F_{1/2}(U - E_G) \quad [\text{A.2}]$$

and

$$p = A_V T^{3/2} F_{1/2}(-U) \quad [\text{A.3}]$$

where  $E_G = \epsilon_G/kT$  is the reduced band gap,  $U$  is the reduced potential and

$$A_i = 2(2\pi m_i^* k/h^2)^{3/2} \quad \begin{array}{l} i = C(\text{conduction band}) \\ i = V(\text{valence band}) \end{array} \quad [\text{A.4}]$$

is the density of states divided by  $T^{3/2}$  with  $m_i$  being the density of states effective mass and  $F_{1/2}$  is the Fermi Dirac integral to the 1/2 order.<sup>15</sup> Fixed charge densities of ionized impurities are

$$\rho_A = qN_A [1 + 2 \exp(E_A - U)]^{-1} \quad [\text{A.5}]$$

$$\rho_D = qN_D [1 + 2 \exp(U + E_D - E_G)]^{-1} \quad [\text{A.6}]$$

where  $N_A$  and  $N_D$  are the density of acceptors and donors, respectively, and  $E_A$  and  $E_D$  their activation energies measured from the nearest band edge divided by  $kT$ .

Integrating Poisson's equation gives the semiconductor surface field

$$\epsilon_S^2 = \frac{8\pi}{K_S} kT \left\{ N_A \ln \left| \frac{2 + \exp(U_S - E_A)}{2 + \exp(U_B - E_A)} \right| \right. \quad [\text{A.7}]$$

$$\left. + N_D \ln \left| \frac{2 + \exp(E_G - E_D - U_S)}{2 + \exp(E_G - E_D - U_B)} \right| \right.$$

$$\left. + A_C T^{3/2} [F_{3/2}(U_S - E_G) - F_{3/2}(U_B - E_G)] \right.$$

$$\left. + A_V T^{3/2} [F_{3/2}(-U_S) - F_{3/2}(-U_B)] \right\}$$

where  $\epsilon_S$  is in statvolts/cm and  $U_S = q\phi_s/kT$  and  $U_B = q\phi_B/kT$  are the reduced surface and bulk potentials, respectively, and  $K_S$  is the semiconductor's dielectric constant. The total net semiconductor space charge is then

$$Q_S = K_S \epsilon_S / (4\pi) \quad [\text{A.8}]$$

The semiconductor's differential a-c capacitance is given by differentiation of Eq. [A.8]. This gives

$$C_S (\text{low frequency}) = - \frac{\partial Q_S}{\partial \phi_S} = \frac{q}{\epsilon_S} \left\{ N_A [1 + 2 \exp(-U_S + E_A)]^{-1} \right. \quad [\text{A.9}]$$

$$\left. - N_D [1 + 2 \exp(U_S + E_D - E_G)]^{-1} \right. \left. + A_C T^{3/2} F_{1/2}(U_S - E_G) - A_V T^{3/2} F_{1/2}(-U_S) \right\}$$

statfarads/cm<sup>2</sup>

<sup>15</sup> J. S. Blakemore, "Semiconductor Statistics," Pergamon Press, New York (1962). Blakemore's  $\mathcal{F}$  is used here.

Equation [A.9] then is the capacitance equation for the low-frequency limit because it includes the contributions of all charges to the differential a-c capacitance.

At sufficiently high frequencies, minority carriers cannot respond to the a-c signal, but as the surface is inverted by the d-c bias, the depletion width increases toward a maximum. This maximum occurs when the concentration of minority carriers at the surface is large enough to determine the size of the depletion region. In other words, at high frequencies, the minority carriers act like fixed charges concentrated at the surface. Deal *et al.* (4) have decided that this maximum depletion width occurs when the surface potential reaches the value

$$U_S = E_G - U_B \quad [A.10]$$

This is a guess which is based on physical reasoning. It agrees quite well with experiment. When this condition is reached, the depletion width and the high-frequency capacity remain constant. A solution for the high-frequency capacity can be obtained by dropping one of the two last terms, the minority carrier term, in Eq. [A.9] and specifying that for the inversion region, the semiconductor space charge capacity is constant and is equal to

$$C_S(U_S) = C_S(E_G - U_B) \quad [A.11]$$

The depletion capacity occurs when minority carriers cannot accumulate near the surface even in the bias range corresponding to inversion. This occurs,

for instance, when the MOS bias is rapidly switched from an accumulation value to an inversion value, and the capacitance is measured before minority carriers can accumulate at the surface; this case can also occur if the oxide leaks electrically. This transient non-equilibrium condition gives rise to a very wide depletion region, and evaluations for this situation are obtained by dropping the minority carrier terms in Eq. [A.7] and [A.9] and making evaluations for very large amounts of band bending.

The MOS capacitance is given by

$$C(U_S) = \frac{C_o C_S(U_S)}{C_o + C_S(U_S)} \quad [A.12]$$

where  $C_S(U_S)$  is any one of the three semiconductor capacities described above, and  $C_o$  is the capacitance of the dielectric.  $C_S$  is, of course, dependent on the applied voltage. The applied voltage for any given value of surface potential is

$$V(U_S) = (kT/q)(U_S - U_B) - Q_S/C_o + \phi_{MS} \quad [A.13]$$

where  $\phi_{MS}$  is the metal-semiconductor work function difference.

These equations are easily programmed for computer calculations of  $C(V)$  using the surface potential,  $\phi_s$ , which specifies the amount of semiconductor band bending at the surface, as the running variable. Such a set of straightforward and exact solutions for the MOS surface capacitance varactor is perhaps easier to understand and use than the specialized analytical solutions developed by others.

## Preparation of High-Purity Nickel

### II. Zone Melting

R. R. Soden and V. J. Albano

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

#### ABSTRACT

Nickel single crystals have been prepared by electron beam float zone melting with resistance ratios ( $R_{273^\circ\text{K}}/R_{4.2^\circ\text{K}}$ ) of 4000. These ratios were obtained by the selective removal of carbon by an oxygen treatment during the zone melting of specially prepared electrolytic nickel. Our data suggest that carbon and iron have a nearly equal contribution to the residual resistivity of Ni ( $\cong 4 \times 10^{-10}$  ohm-cm/atomic ppm). Thus, the total carbon and iron content of nickel, neglecting all other contributions to the residual resistance, must be less than 5 atom ppm to obtain a 4000 resistance ratio. Several commercial sources of nickel were zone melted and found to contain too much iron to approach this purity level.

Very high-purity metal single crystals are necessary for experiments directed toward an understanding of their intrinsic electronic properties. For this end, we have employed electron beam zone melting, together with chemical purification techniques, to obtain nickel single crystals of purities heretofore not obtained. One result of this work is that galvanomagnetic measurements by Reed and Fawcett (1) were allowed to be made to obtain information regarding the electronic structure of nickel.

The major requirement of a metal for high-field Fermi surface measurements is that  $\omega_c \tau \gg 1$ , where  $\omega_c$  is the cyclotron frequency for the electron and  $\tau$  is the electron relaxation time. Since  $\omega_c$  is proportional to the magnetic field strength which is applied to a sample and  $\tau$  is inversely proportional to the resistivity of the metal, either large fields must be available or the purity of the metal must be improved to lower the residual resistivity and thus increase  $\tau$ . It is now more feasible to increase the purity of the metal than to obtain the very high fields that are required.

Resistance ratios ( $R_{273^\circ\text{K}}/R_{4.2^\circ\text{K}}$ ) as high as 4000 have been obtained on nickel single crystals. These crystals were prepared by the floating zone melting of specially prepared electrolytic nickel. The preparation of this high-purity electrolytic nickel has been previously described (2). Resistance ratio data for zone melted commercial nickels are also reported and compared with the above data. The effect of carbon and iron on the ratio is reported and discussed.

#### Experimental

*Evaluation of purity.*—The primary difficulty in an investigation of this type is determining the impurities which contribute significantly to the residual resistivity. We employed spark spectra, vacuum fusion, and mass spectra analytical techniques to obtain data to complement the resistance ratio information.

*Source material, zone melting, and crystal growth.*—High-purity nickel was obtained from various commercial sources as sponge and rod. Table I contains the emission spectrographic analysis on these mate-

rials, as well as the electrolytic nickel prepared in these laboratories. The approximate carbon content of the as-plated electrolytic nickel is also shown. The carbon present in this material is thought to be due to pickup during the purification of the electrolyte. Nickel from source 1 was in the form of prefabricated rods ¼ in. diameter by 6 in. long. Nickel from sources 2, 3, and 4 were in sponge form. The preparation of the electrolytic nickel was previously described and was in the form of rods or rectangular plates of various dimensions.

The sponge materials were preformed into ¼ x ¼ x 3 in. bars by pressing at approximately 30,000 psi in a hardened steel die. The bars were not fragile and could be suspended in the zone melting apparatus without presintering.

The electrolytic nickel plates required cutting into rods. After cutting, the rods were vigorously etched with a 50% H<sub>2</sub>O-50% H<sub>2</sub>SO<sub>4</sub> anodic etch to remove iron which may have been picked up during cutting and washed with deionized water. Electrolytic nickel already in the form of rods was also subjected to this cleaning treatment.

The vacuum float zone melting apparatus employed in this work has been described (3). However, for this work, the rf coil was replaced by an electron gun which consists of a circular 0.0115-in. diameter thoriated tungsten filament and molybdenum focusing plates on the top and bottom. A mechanically driven variac control similar to that described by Schadler (4) was used to control the emission current.

All the nickel samples were suspended in the vacuum station from a quartz hook by cutting a notch in the top of a given sample and attaching a loop of 10 mil nickel wire of good purity. The bottom of each sample was placed in contact with a nickel rod which was held by an adjustable chuck. Focusing plates for the gun were selected on the basis of the experiment being conducted and usually had openings of 1 to 2 times the sample diameter. Before the start of zone melting, the sample was electron beam welded to the nickel crystal. Zone melting of the sample was started ½ in. up from the weld. Progressive melting-in from the surface of the rod was usually done on each sample to remove gaseous contaminants which were initially present in most of the materials. Up to ten passes were made on the samples at rates of either 0.001 or 0.0005 in./sec. The vacuum ranged between 2 x 10<sup>-5</sup> and 4 x 10<sup>-7</sup> mm of Hg depending on the contaminants present in the nickel and/or on the diameter of the rod.

### Results

Purification by zone melting can take place by selective vaporization and/or segregation. The ease of removal of a solute impurity from a host metal by selective vaporization can be qualitatively estimated from the available thermodynamic data (5). Table II shows the equilibrium vapor pressures  $p_i^*$  at 1725°K, for the impurities which were detected in our original nickel samples (Table I). Assuming that the partial pressure,  $p_i$  of the impurity in the vapor is given by  $X_i p_i^*$  (ideal solution), where  $X_i$  is the atom fraction, selective vaporization may occur when  $(p_i^* X_i) / (p_{Ni} X_{Ni}) > 1$ . That is, selective vaporization resulting in purification may occur when the escaping tendency of the impurity is greater than that of the solvent. On this basis, the third column in

Table II. Equilibrium vapor pressures ( $p_i^*$ ) at 1725°K for impurities detected in the original nickel samples compared to the vapor pressure of pure nickel

Impurity	$p_i^*$ atm	$X_i = \frac{p_{Ni} X_{Ni}}{p_i^*}$
Ni	4.3 x 10 <sup>-6</sup>	—
Cu	2.4 x 10 <sup>-4</sup>	0.018
Al	8 x 10 <sup>-4</sup>	0.0054
Mg	>5	<10 <sup>-6</sup>
Si	2 x 10 <sup>-6</sup>	1
Fe	1.15 x 10 <sup>-5</sup>	0.37
Ca	~1	<10 <sup>-6</sup>

Table II shows the approximate limiting impurity level obtainable by selective vaporization. It appears that only Mg and Ca can be removed from nickel to a low level by selective vaporization. If the growth conditions were such that the amount of vaporization of Ni from the molten zone was increased, the impurity elements Fe, Cu, and Si could be concentrated.

Purification by segregation appears to be limited for the materials studied in this work because the segregation coefficients for the impurities encountered are apparently unfavorable. However, we will show that selective oxidation, in addition to selective vaporization, coupled with floating zone melting, is effective in obtaining nickel having high resistance ratios.

#### Initial Results on Electrolytic Nickel

Table III shows representative  $R_{273^\circ K} / R_{4.2^\circ K}$  data on zone melted electrodeposited nickel obtained early in this investigation. It is important to note the large variation in ratio even though the metallic impurity contents on these materials, based on emission spectroscopy, were not initially very different in all the samples.

The data on plate IV, which was the first material investigated, were particularly baffling. The plate was approximately 6 x 3 x ⅛ in. thick. The edges were rounded due to the higher effective current density during plating and had a diameter of ~3/16 in. Each section was zone refined separately. Although the as-plated material showed only a slight increase in resistance ratio from top to bottom, the ratios of the zone melted rods were completely inconsistent compared to the starting ratios.

#### Initial Results on Commercial Nickels

Zone melting of commercial nickel samples, the analysis of which is given in Table I, was done concurrently with the electrolytic nickel. Results are shown in Table IV. Increasing the number of zone passes did not affect the ratios so dramatically as in

the case of the electrolytic samples. Also, the zone melting behavior was different. Large fluffy deposits were found on the focusing plates of the electron gun assembly which were not observed during the zoning of the electrolytic nickel. An x-ray powder pattern was taken of this deposit. It revealed approximately 80-90% nickel and 10-20% nickel oxide (estimated by relative line intensity). Since the surfaces of the zone refined rods were not smooth, several samples were sectioned, electropolished in  $H_2O-H_2SO_4$ , electro-etched, and examined. A cellular-type microstructure was observed which was not found in the zone melted electrolytic nickel. A cellular structure is a consequence of impurity segregation during unidirectional solidification. Since the sponge nickel samples contained adsorbed oxygen and the electron beam interacts with back streaming diffusion pump oil to form a polymer on the nickel surface (6), oxygen and carbon were suspected as serious contaminants. Even additional trapping in the chamber was insufficient to prevent carbon pickup. Several samples were analyzed for carbon to test this hypothesis; results are summarized in Table V.

The amount of carbon present did not correlate exactly with the resistance ratios since other impurities were present in varying amounts, but the trend toward increasing ratio with decreasing carbon content was in the proper direction. It was thus apparent that carbon must be removed to ascertain better the effect of metallic impurities on the resistance ratios.

#### Removal of Carbon

The removal of carbon from nickel by the use of oxygen during vacuum zone melting is relatively easy due to the following fortuitous circumstances:

1. Nickel can be readily oxidized.
2. Oxygen is soluble in nickel to the extent of 1 w/o (weight per cent) at its melting point.
3. The free energy change for the reaction of carbon with oxygen is much more negative than that of nickel with oxygen. Thus, the removal of carbon by oxygen is thermodynamically favorable.

Prior to zone melting, the nickel rods were heated at  $900^\circ C$  in air forming a coating of green NiO on the rod surface. This treatment results in an oxygen pickup of up to 1 w/o depending on the rod diameter. During the first pass or two, the heat input is controlled manually since the high oxygen content makes the molten zone somewhat unstable. A metallographic cross section of this part of a zone melted nickel rod shows a uniform NiO precipitate in the nickel matrix. Repeated zone melting was continued until the surface of the molten zone became stable and the surface of the rod appeared smooth. At this stage, no precipitate was observed metallographically. It thus takes 4 to 6 zone passes at 0.001 in./sec to remove the oxygen. A typical analysis of the zone melted nickel after the above treatment shows <20 atom ppm carbon and <8 atom ppm oxygen. By utilizing the above treatment, the resistance ratio of electrolytic nickel having the lowest metallic impurity content was raised from ~500 to 4000.

Increasing the number of zone melting passes beyond 6 now results in a decrease in the resistance ratio of the nickel, an observation made earlier. This is probably due to pickup of carbon from the diffusion pump oil vapor which now is important since there is

little excess oxygen present for oxidation of the carbon. The Octoil "S," which had been used as the diffusion pump oil, was therefore changed to DC-704 oil to decrease the carbon pickup. This silicone oil has a lower vapor pressure and was deemed to be less prone to fractionation problems. Indeed, the ratio did not decrease, after reaching a maximum, as rapidly with this oil. However, we were not able to restore the high ratio by re-oxidation and zone melting as we could when the pure hydrocarbon oil was used. This result suggested silicon contamination from the DC-704 oil. In addition, more passes were required to remove all the nickel oxide which suggested that oxygen removal is also enhanced by the higher concentration of hydrocarbon vapors in the system when pumped with Octoil "S."

Shapiro (7) performed residual gas analysis to determine the decomposition reaction for DC 704 oil and found the reaction to be

Thus silicon appears to be readily available for contamination of nickel. However, we have not performed any analysis to determine the amount of silicon contamination. It appears that the choice of diffusion pump oil is important for purification of nickel, therefore it would appear that an oilless vacuum system may be desirable for achieving even higher ratios for Ni.

#### Results of Removal of Both Carbon and Oxygen

The analysis of the electrolytic nickel before zone melting showed carbon contents of 20-100 atom ppm (2). Since the amounts of the metallic impurities did not correlate with the resistance ratios shown in Table III, it was postulated that the as-plated materials contained a carbon-to-oxygen ratio which depended on the current density at the particular region of the electrodeposit. This thought was also suggested by the anomalous results shown in Table III for the electrodeposited plate number four after zone melting. In order to verify this, sections of plate IV having low resistance ratios were oxygen treated and then zone melted. Resistance ratios of 3200 to 3500 were consistently obtained. Thus, it appears that an oxygen-bearing compound of nickel is being obtained at the high current density areas of the plate and it reacts with the carbon during zone melting. The amount of reaction, of course, depends on the concentration of oxygen. An alternative explanation is that stratification of metallic impurities was occurring in the plating bath. However, our observation of the effect of carbon appears to eliminate this as a plausible explanation.

Mass spectroscopic analysis of the nickel having a 4000 ratio had shown the sum of the metallic impurities to be about 1 atom ppm and hence the resistance ratio seemed to be dependent on the carbon content; therefore, to determine the effect of carbon on the resistance ratio, several samples of source 2 nickel sponge with a resistance ratio of 1500 were mixed with various amounts of spectroscopically pure carbon. The samples were compacted and given one zone pass. The resistance ratio was obtained for each sample. They were then analyzed for carbon. Figure 1 shows the plot of these data. From the slope of the curve and the resistivity of nickel at  $273^\circ K$ , a contribution to the residual resistance of  $3.0 \times 10^{-10}$  ohm-cm per atomic ppm carbon in nickel is obtained.

Figure 2 shows a plot of the reciprocal of resistance ratio vs. concentration in parts per million for iron in nickel. The accurate fit of the points reflects the sensitivity of the analysis for iron in nickel and the dominant contribution of iron to the helium temperature resistivity once the carbon content is minimized: The

Table V. Comparison of resistance ratio vs. carbon content for various samples

Sample	Number of passes	$R_{273^\circ K}/R_{1,3^\circ K}$	Carbon content in weight ppm
Electrolytic	0	554	94
Rod 23	1	1530	41
Electrolytic	1	685	63
Rod 37	6	800	12
Source 2	1	1500	28
Source 3	1	2000	5

Fig. 1. Plot of the reciprocal of the resistance ratio vs. carbon concentration in commercial sponge nickel.

Fig. 2. Plot of the reciprocal of the resistance ratio vs. iron concentration. Each Ni sample was given an oxygen treatment to bring the C content to the same level.

six points represent different nickel samples all of which have had the same oxygen treatment to remove carbon. Each nickel sample was obtained from the various sources as noted. The contribution to the helium temperature resistivity of nickel per atom ppm Fe is calculated from this curve to be  $4 \times 10^{-10}$  ohm-cm. It appears that carbon and iron are equally as effective in scattering electrons in Ni.

#### Discussion

Since electrolyte purification techniques coupled with electroplating reduces the total metallic impurities to about 1 atom ppm in nickel, it is desirable to consider more closely what may be inhibiting attainment of a much higher resistance ratio.

A generalization of Matthiessen's rule would make one suspect that ratios much larger than 4000 can be obtained for Ni. However, some transition metals show appreciable deviations from a  $T^5$  scattering law, i.e., their resistivities vary more slowly than  $T^5$ . This has the effect in nickel of perhaps limiting the resistance ratio, as defined by  $R_{273^\circ\text{K}}/R_{4.2^\circ\text{K}}$ , by a significant lattice contribution at 4.2°K. This contribution is given as about  $5 \times 10^{-10}$  ohm-cm at 4.2°K (8). By simply dividing this number into the room temperature resistivity of nickel, a ratio no better than 13,000 is expected if lattice scattering is the dominant mechanism.

According to Matthiessen's rule the residual resistivity ( $\rho_r$ ) is related to the thermal contribution ( $\rho_L$ ), the chemical contribution ( $\rho_i$ ), and the contribution due to physical imperfections ( $\rho_D$ ) by the relation  $\rho_r = \rho_L + \rho_i + \rho_D$ . The value of  $\rho_{4.2^\circ\text{K}}$  for our nickel with a 4000 ratio is  $2 \times 10^{-9}$  ohm-cm. Using this value and the value obtained for the thermal contribution (8), the following expression is obtained

$$\rho_i + \rho_D = 15 \times 10^{-10} \text{ ohm-cm}$$

Several investigators (9) have shown the average resistivity contribution per dislocation line to be of the order of  $10^{-19}$  ohm-cm. Well annealed metal crystals usually contain about  $10^7$  lines per  $\text{cm}^2$ . Thus, the contribution of the physical imperfections to the residual resistivity, assuming that the dislocations are the only type of defect of importance, will be small and  $\rho_i$  will be of the order of  $15 \times 10^{-10}$  ohm-cm. Since carbon is the major contaminant in our materials, it is the only impurity which we presently consider important. Therefore,  $\rho_i = 3 \times 10^{-10} C_c$  where  $C_c$  is the carbon concentration in atom ppm so that our material having a ratio of 4000 appears to have 5 atom ppm of carbon present. This carbon level is below the capability of present analytical detection techniques. To double the ratio will require a carbon content of about 2 atom ppm or in more conventional notation approximately 0.4 ppm by weight. The attainment of this carbon level cannot be obtained in an oil system.

#### Acknowledgment

The authors would like to thank E. Buehler and E. Berry for their early contribution to this work. The mass spectra analysis performed by D. L. Malm and the resistance ratio measurements by G. F. Brenner are gratefully acknowledged, as are many helpful discussions with W. A. Reed. Thanks are also due to J. H. Wernick for discussions and comments on the manuscript.

Manuscript received Oct. 27, 1967; revised manuscript received ca. March 4, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Selected Area Electron Diffraction Study of Twinned $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> Bladelike Platelet Growths on Iron

Richard L. Tallman\* and Earl A. Gulbransen\*

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

## ABSTRACT

The structure of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> bladelike platelets formed on iron at 450°C in atmospheres containing both water vapor and a trace of oxygen was studied. Single crystal electron diffraction patterns show the blade axis to be  $[\bar{1}120]$ . The collection of all of the patterns indicates a structure of twinned crystals whose orientations are related by mirroring on the blade face plane,  $(\bar{1}101)$ . Arguments are presented in favor of a growth mechanism involving the diffusion of iron atoms or ions along the twin interface to the tip, where reaction occurs with oxygen.

When annealed or cold-worked iron is reacted with water vapor atmospheres containing a trace of oxygen at 400°C, pointed bladelike oxide platelets form and predominate over whisker growths (1, 2). These oxide platelets are about 150Å thick, 2500-6000Å wide at the base, and grow to lengths up to 100,000Å. Electron diffraction patterns show the platelets to be  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (1, 2). Bigot (3) and Talbot and Bigot (4) in a recent study suggest that the bladelike oxide platelets are cubic  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>. Numerical data to substantiate this were not presented, however.

This paper presents: (i) new selected area electron diffraction studies on iron oxide bladelike platelets; (ii) evidence that the bladelike platelets consist of twinned oxide crystals of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>; and (iii) a likely growth mechanism for bladelike oxide platelets on iron. A similar study has been made of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> whisker growths in iron oxidation (5, 6).

## Experimental

A number of 99.99% pure iron wires carefully oxidized in a mixture of 10% water vapor and 90% argon containing a trace of oxygen (from the system and the <0.005% in commercial argon) were available from earlier studies (1). Before oxidation the iron wires had been carefully annealed and cleaned. Bladelike platelets have been found in our laboratory to grow in atmospheres ranging at least to 3% water in oxygen, where rounded whisker growths predominate. Such platelets have been obtained in our laboratory in many experiments over a period of years, on specimens of high-purity irons from Battelle, the National Bureau of Standards, and Westinghouse ("Puron" iron), and on a less pure iron from Armco.<sup>1</sup> Annealing, cleaning, and oxidation procedures have varied. Annealing at 850°-890°C commonly resulted in grain dimensions in the range 10-200 $\mu$ . Some effort has been made to find out how the controlled variables produce effects on the growths. The results obtained, however, are not sufficient to show that the whisker and platelet growths obtained do not result from some impurity effect, or do not show impurity effects.

An RCA EMU-3D electron microscope with selected area diffraction was used at 100 kV electron energy. The relative rotation of the selected area electron diffraction patterns was determined by use of the selected area images and the selected area diffraction patterns of asbestos fibers.

## Results and Discussion

*Description of the bladelike platelets.*—Figure 1 shows an electron micrograph of an assembly of bladelike oxide platelets formed on annealed pure iron when reacted in 10% water vapor and 90% argon con-

taining a trace of oxygen for 25 hr at 400°C. Bladelike platelets grown under other reaction conditions using water vapor and oxygen exhibit similar lengths, thicknesses, and ratios of width to length. Differences are found in the tip shapes, in the presence of striated growth patterns on the faces, and in the presence of curvature in the plane of the oxide platelet. Electron diffraction analyses of many of these platelets suggest that all of such platelets have essentially the same structure.

Figure 2 shows a selected area diffraction pattern for a number of bladelike platelets at one edge of an oxidized wire. Such fiber texture patterns are satisfactorily indexed by the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> cell. Measurements on these patterns provide the instrument constant (effectively the scale in Å<sup>-1</sup>) for the selected area diffraction patterns from specimens at the same distance from the objective lens. This use of the platelets as a standard was justified by the establishment in an earlier study (2) that the platelets are  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. In that work, no lenses were used between the specimen and the plate, and patterns of a standard were used to establish the instrument constant. The  $d$ -spacings calculated from the measured dimensions of the platelet diffraction patterns are all  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>  $d$ -spacings (2).

The possibility that a metallic impurity is concentrated in these growths has not been eliminated because only small changes in lattice dimensions would

Fig. 1. Pointed bladelike platelets at the edge of an iron wire after 24 hr at 450°C in 10% H<sub>2</sub>O in argon with a trace of oxygen.

Fig. 2. Selected area mode,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> pointed bladlike platelets at the edge of a wire.

result for some impurities. (A special analytical technique would be required to obtain the platelet analysis.)

Table I shows the  $d_{hkl}$  values, the intensities, and the three indexing systems for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. The conventional structural rhombohedral P and hexagonal index systems and the face-centered rhombohedral F or morphological system are given (5, 6). The geometry of the rhombohedral F lattice is readily understood as a small distortion of cubic geometry. The indices used, unless otherwise indicated, refer to the rhombohedral F system.

In Fig. 2 the regions of greatest intensity lie in the 202 ring. Arcs of weak 111 reflections together with possible 111 spots, both forbidden, are apparent near the center.

<sup>a</sup> Absent for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>—for hh0l: 1 = 2m required.

<sup>b</sup> Calculated from the hexagonal dimensions (7),  $a = 5.0317$ ,  $c = 13.737\text{\AA}$ .

*Selected area diffraction patterns.*—Eight different selected area patterns have been indexed. Six of these are shown in Fig. 3, 4, and 5. The axis of the blades was found to be  $[110]$ , i.e.,  $[\bar{1}\bar{1}20]$  and  $[\bar{1}01]$  in the conventional structural hexagonal and rhombohedral systems, respectively. This axis is the fiber axis of the fiber texture patterns from surfaces with dense growths of blades.

The most striking characteristic of the blade diffraction we would characterize by continuous reciprocal lattice rods normal to the blade face. This face is  $(11\bar{1})$ , and the rods show a distorted hexagonal pattern corresponding to the three-fold symmetry of the  $\langle 111 \rangle$  body diagonal of a cube. Figure 6 shows at lower left the nearly hexagonal electron diffraction pattern, or cross section of the reciprocal lattice, obtained with the beam normal, or nearly normal, to the blade face as in Fig. 3a. None of the unindexed spots of Fig. 3a can be ascribed to double diffraction. All the rods produce spots in all the patterns, and all the spots correspond to rods. This experimental fact we have indicated in Fig. 6 by showing continuous rods. Some, but not all, of the unindexed spots, of patterns in general, can be indexed as double diffraction spots. Thus the diffraction patterns in general result from a tilt of the rods in the beam and are based on a correspondingly distorted and enlarged hexagon. To be precise, however, the curvature of the reflecting sphere results in the rows of the pattern being concave in the direction of the tilt of the blade face from the position normal to the beam.

The concept of a reciprocal lattice rod seeming to be sufficiently broad, we have used it to describe the diffraction spot positions, as distinct from its use in describing a theoretical result. The theoretical result most commonly referred to, loosely, by the reciprocal lattice rod is the absolute square of the shape transform of a thin crystal. The first zero of the shape transform, limiting the extent of its principal maximum from the index point, is at the reciprocal of the crystal thickness (8). The weak diffraction spots we do not index do not result from this theoretical extension of the principal maxima. Whether a theoretical calculation of the intensities from subsidiary maxima can be devised to predict the intensities of these observed spots we cannot say.

Hirsch *et al.* (9), referring to the extension of reciprocal lattice points, state, "No reliable estimate of the absolute length of these spikes can be given, because for all but the smallest of crystals the heavy scattering causes a breakdown of the kinematical diffraction treatment." The  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> platelets are so thin that the diffraction effects should be essentially kinematic.

Hirsch *et al.* (10) show a diffraction pattern from (111) gold film very much like that of Fig. 3a. Pashley and Stowell (11) found the anomalous spots of this pattern to give dark field images of the double positioning twin boundaries. Such boundaries are essentially parallel to the beam, whereas the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> boundaries are essentially perpendicular to the beam (otherwise they would have been observed). Pashley and Stowell suggest that the unindexed spots may be double diffraction even in the absence of the required primary beams. This suggestion seems to rely on a dynamic interaction between beams traveling parallel to the boundary. Nevertheless, it may be that the interface and/or the surface structures of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> platelets are involved in the anomalous diffraction we find.

The angle measured between the tip edges of the blade image compares well with the angle calculated for the blade projection from the blade orientation in the beam, which can be calculated from the dimensions of the pattern. In this way, the tip edge directions have been confirmed by measurements on several blade images and diffraction patterns.

Fig. 3. Selected area electron diffraction of  $\alpha$ - $\text{Fe}_2\text{O}_3$  platelets, indexed with face-centered rhombohedron,  $\alpha = 85.7^\circ$ . Images rotated  $+145$  to  $148^\circ$  relative to diffraction.

Fig. 4. Selected area electron diffraction of  $\alpha$ - $\text{Fe}_2\text{O}_3$  platelets, indexed with face-centered rhombohedron,  $\alpha = 85.7^\circ$ . Images rotated  $+145$  to  $148^\circ$  relative to diffraction.

Fig. 5. Selected area electron diffraction of  $\alpha\text{-Fe}_2\text{O}_3$  platelets, indexed with face-centered rhombohedron,  $\alpha = 85.7^\circ$ . Images rotated  $+ 145$  to  $148^\circ$  relative to diffraction.

The indexing of the selected area diffraction patterns can be accomplished with the aid of a reciprocal lattice model, together with drawings of each twinned reciprocal lattice net normal to the growth axis. Each drawing, or net, corresponds to a row of spots of the diffraction pattern, a row normal to the projection of the blade axis onto the diffraction pattern; and each rod of a drawing, to a point in the corresponding row.

Figure 3a shows the pattern obtained when the beam is nearly normal to the blade face, also illustrated in Fig. 6. Figure 3b shows the pattern when the blade is tilted about its axis so that the beam is nearly normal to the threefold axis. The twin indices, where they are necessary, are underlined in all these patterns.

Figure 4a results from a slight tilt of the blade approximately about  $[11\bar{2}]$  (normal to the blade axis and

in the blade face). It is thus closely related to Fig. 3a in dimensions and indexing. Figure 4b results from a slightly greater tilt approximately about  $[11\bar{2}]$ . The four central indexed spots are indexed the same in each case. Such anomalies are explained as follows: Only two geometrical (infinitesimal) points and the origin can lie on the reflecting sphere at once, and in general none lie exactly on the sphere (except the origin). The extent along the rods of the interference regions associated with the index points is believed to be the principal cause of the high intensities observed in so many spots. No tilting of the specimen stage was attempted; the patterns are for different blades as they were found.

The pattern of Fig. 5a shows indexed point rows at a little less than  $90^\circ$  which would be found normal to one another (and indexed otherwise) in the untwinned lattice. Extreme distortion of the hexagonal pattern is illustrated in this figure. The "first layer line" in this pattern passes through  $\bar{2}02$  and  $200$ . Figure 5b shows another distorted hexagonal pattern. In this pattern,  $\bar{4}00$  to  $400$  is the zero layer line.

We conclude that most of the selected area diffraction patterns can be indexed only by the use of two crystals whose orientations are related by mirroring on the blade face plane  $(11\bar{1})$ . The blade face has the corresponding indices,  $(\bar{1}101)$  and  $(010)$ , using the conventional structural hexagonal and rhombohedral unit cells. The twinning is not required in indexing the patterns for a few special orientations, e.g., Fig. 3a. In order that the indices given refer to right-handed coordinate systems, the twin orientations are related by a twofold rotation about the normal to the twin plane.

The  $\alpha\text{-Fe}_2\text{O}_3$  bladelike platelet morphology is shown in Fig. 7. In Fig. 7, we use the more conventional

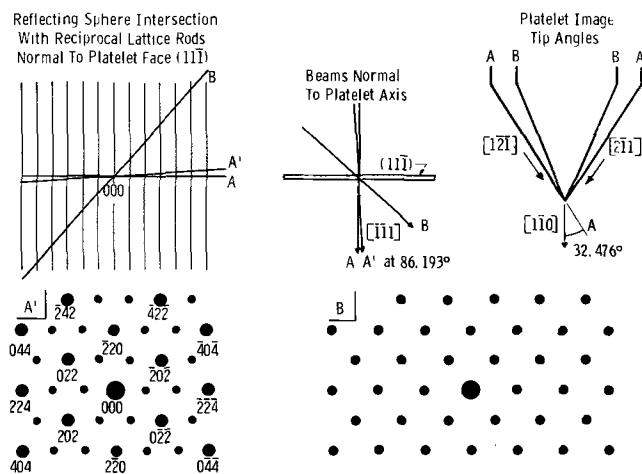

Fig. 6. Indexed spots in net normal to  $[111]$  ( $\alpha\text{-Fe}_2\text{O}_3$  rhombohedral F indexing); all other spots also observed.

Fig. 7.  $\alpha$ - $\text{Fe}_2\text{O}_3$  pointed bladelike platelet morphology (actual number of twins is undetermined). Structural rhombohedral unit cell pictured,  $a = 5.4228\text{\AA}$ ,  $\alpha = 55^\circ 17'$ .

structural rhombohedral unit cell for presenting the results. The blade face and blade axis are indexed also by the structural hexagonal unit cell.

The orientation of the twins is shown in Fig. 7. The blade tip angle, roughly determined from electron micrographs, indicates that the blade tip edges can be described as follows: In the face-centered rhombohedral  $F$  unit cell, the blade tip edges lie along  $[\bar{1}2\bar{1}]$  and  $[2\bar{1}\bar{1}]$  directions. The blade tip angle is calculated to be  $64^\circ 57'$ , which compares to the  $60^\circ$  angle found in the cubic system. Figure 6 shows the blade tip edges lying along  $[20\bar{1}]$  and  $[\bar{1}0\bar{2}]$  in the structural rhombohedral unit cell.

The two blade tip edge directions are equivalent, but not with respect to the blade. The tip edge directions given are the intersections of planes in mirror orientation to one another which intersect in reentrant edges at one tip edge and nonreentrant edges at the other. These planes are indexed  $(202)$  and  $(0\bar{2}\bar{2})$  in the face-centered rhombohedral system, planes which are normal to  $(11\bar{1})$  in the cubic system. Figure 7 shows the indexing of the tip edge in the structural rhombohedral unit cell. The reentrant edge angle is  $173^\circ 24.3'$ .

**Discussion of platelet morphology.**—General features of the bladelike platelet structure remain undetermined. First, the number of twins has not been determined. There may be more than one twin interface. Second, the atomic structure of the twin interface has not been determined. It is not known whether a mirror plane exists in the structure. Third, the tip faceting has not been observed. The planes shown as facets in Fig. 7 do not necessarily occur as facets.

The asymmetry of the tip could explain an asymmetrical tip image for the case of a two-twin blade. For three twins, the structure would have a twofold axis along its length, so that no asymmetry in the tip would be predicted.

Many blade images show a line down the center to the tip with usually uniform but different transmission of electrons on opposite sides of the line. This line appears to be the trace of the tip point. The asymmetry of the tip may result in a thickness difference because the growth mechanisms at the two tip edges are not identical. For example, growth steps may nucleate more readily at the reentrant edge. That the center line results only from the tip growth mechanism is suggested by the absence of this line for blades with rounded tips. The features of the blade faces result from thickness contrast and some thickness variations are traces of the tip edges.

Except for the effect of the apparent thickness variation across the center line, the uniform thickness contrast of the well-formed unbent blades and the bend contours of the few highly bent blades suggest nothing more

complex than the simple twinned morphology. The dark field images obtained show either the whole blade in nearly uniform contrast or bend contours, further confirming that the twins extend across the whole surface of the blade.

**More anomalous diffraction.**—In addition to the reciprocal lattice rods on which lie all the  $\alpha\text{-Fe}_2\text{O}_3$ -indexed points, it appears from weak unindexed spots that parallel to each of these rods are two satellite rods. These satellite rods are positioned along the blade axis at one sixth of the repeat distance between the index rods. The reflections associated with these rods appear slightly elongated normal to the blade axis.

**Comparison with previous morphological studies.**—Bigot (3) and Talbot and Bigot (4) failed to analyze correctly their selected area electron diffraction patterns of  $\alpha\text{-Fe}_2\text{O}_3$  bladelike platelets. Bigot (3) attributes diffraction patterns of bladelike platelets to  $\gamma\text{-Fe}_2\text{O}_3$  without presenting numerical data. They comment that the pattern dimensions are too small for the  $(0001)$  structural hexagonal plane of  $\alpha\text{-Fe}_2\text{O}_3$  (for which, pattern rows would be at  $60^\circ$ ). Their indexing corresponds to a beam direction along  $[\bar{1}10]$  of cubic  $\gamma\text{-Fe}_2\text{O}_3$  (pattern rows at  $54^\circ 44'$ ).

The relative pattern dimensions are, however, only slightly distorted from those to be expected for orientation of the beam parallel to the  $\alpha\text{-Fe}_2\text{O}_3$   $[\bar{1}10]$  face-centered rhombohedral direction. A curvature of the rows parallel to  $[\bar{1}120]$  or  $[\bar{1}10]$ , (structural hexagonal and rhombohedral  $F$  indices, respectively) results from the angle of the beam to the reciprocal lattice rods. This curvature is expected for a thin  $\alpha\text{-Fe}_2\text{O}_3$  crystal with  $(11\bar{1})$  faces and with the beam along  $[\bar{1}10]$ . The direction of curvature indicates the  $(11\bar{1})$  orientation in the beam. The misalignment of the beam from  $[\bar{1}10]$  is not in the  $(1120)$  structural hexagonal plane as the symmetry of the intensities is lost and the pattern is skewed, or sheared, two degrees. The angle of  $022$  to  $422$  in the  $(011)$  plane of the cubic system is  $54^\circ 44'$ , whereas the corresponding angles by Bigot's indexing measured in Bigot's pattern are about  $51^\circ 25'$  and  $54^\circ 30'$ . The corresponding angles in  $\alpha\text{-Fe}_2\text{O}_3$  should be  $53^\circ 49'$ . The measured angles differ from  $53^\circ 49'$  as a result of the skewed nature of the pattern. This distortion also results in discrepancies of up to 3% in the relative  $d$ -spacings calculated from the pattern.

The corresponding spacings for  $\gamma\text{-Fe}_2\text{O}_3$  are about 13–16% greater than those for  $\alpha\text{-Fe}_2\text{O}_3$ . It would appear that such a variation in the instrument constant for selected area diffraction was accepted by Bigot in indexing the pattern as  $\gamma\text{-Fe}_2\text{O}_3$ .

Some of the details of the intensities in Bigot's pattern are not simply interpreted; but otherwise, the pattern is indexed by  $\alpha\text{-Fe}_2\text{O}_3$ . Twinning is neither required nor precluded by this indexing.

**Novel character of the  $\alpha\text{-Fe}_2\text{O}_3$  platelet structure.**—Palache *et al.*, (12) state that lamellar twinning on  $\{10\bar{1}\}$  is common in natural corundum ( $\alpha\text{-Al}_2\text{O}_3$ , sapphire) and natural hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ). The indices used are morphological hexagonal and are the indices of the morphological rhombohedral surfaces  $\{100\}$ . The twinning we have studied in  $\alpha\text{-Fe}_2\text{O}_3$  bladelike platelets is on the structural rhombohedral surfaces. These are the morphological hexagonal  $\{02\bar{2}\}$  and morphological rhombohedral  $\{11\bar{1}\}$  planes.

We have not found any evidence in the literature for growth twinning on the rhombohedral planes of the structural rhombohedron for  $\alpha\text{-Fe}_2\text{O}_3$  or isomorphous minerals. We conclude that this is not a common twinning relation for the crystal growth mechanisms of minerals, which involve some type of deposition. We suggest that if the bladelike platelet growth proceeded by a surface transport mechanism, the same morphology would be found in minerals.

Scanning electron microscopy (13) has provided micrographs of hematite platelets a few microns thick and about  $10\mu$  across. These platelets grew in many orientations on mild steel in a 7-hr oxidation in 13% sodium hydroxide solution at  $300^\circ\text{C}$  and also by anodic polarization in sodium hydroxide solutions. The morphology of these platelets was not described, but their somewhat equilateral triangular appearance suggests the common (0001) tabular habit.

*Transport mechanisms for platelet growth.*—The bladelike platelets we believe to grow by the internal transport of iron to the tip. Takagi (14) has observed that such growths grow from the tip. The blades are too perfect to have been formed by extrusion. Surface diffusion seems highly unlikely because growth should occur readily in areas closer to platelet bases. Some arguments for internal diffusion in such growths we have given in more detail in previous publications (5, 6).

An additional and more powerful argument can be based on Coble's data on the shrinkage of  $\alpha\text{-Fe}_2\text{O}_3$  compacts on sintering (15). Coble shows that the shrinkage rate is limited by the iron lattice diffusion process. Surface diffusion would reduce the surface area which provides the driving force for the shrinkage, thereby decreasing the apparent iron lattice diffusion coefficient. An upper limit on the surface diffusion coefficient for iron can be estimated from Coble's data at  $750^\circ\text{C}$  to be  $10^4$  to  $10^6$  times smaller at  $750^\circ\text{C}$  than the surface diffusion coefficient required to provide the iron transport for the growth at  $1\text{-}100\text{\AA}$   $\text{sec}^{-1}$  of  $\alpha\text{-Fe}_2\text{O}_3$  whiskers and platelets.

It can be argued that the presence of  $\text{Fe}_3\text{O}_4$  or  $\gamma\text{-Fe}_2\text{O}_3$  may provide for whisker and platelet growth a surface transport mechanism not present in the sintering experiments on pure  $\alpha\text{-Fe}_2\text{O}_3$ . And further, that any sites for growth on the  $\alpha\text{-Fe}_2\text{O}_3$ ,  $\gamma\text{-Fe}_2\text{O}_3$ , and  $\text{Fe}_3\text{O}_4$  surfaces other than those producing the whisker and platelet growth may be poisoned. These arguments seem excessive to us.

In the case of platelets, the limited thickness can readily be understood as a result of internal diffusion along a plane interface. Platelet thickness would be expected to taper from the base if platelets grew by surface diffusion. Platelet surfaces, as revealed by thickness contours, are commonly at least slightly imperfect, so that further growth could occur readily; but platelets generally appear uniform in thickness along the lengths observed.

The model for growth of blade-shaped oxide platelets is shown in Fig. 7. The platelet must contain one or more twin interfaces. These provide paths for the internal diffusion of iron atoms which results in the growth.

The flat elongated structure of the bladelike platelets indicates that there are several ionic diffusion coefficients operating. The lattice diffusion of iron normal to the blade face is small, so that the blade remains thin. The transport at the twin interface and normal to the blade axis may be greater; so that the blade grows more broad as it grows longer. The transport at the twin interface and along the blade axis is greatest, so that the blade grows long. Transport over the tip surface is small, so that the blade grows thin.

We have reported in an earlier work (1) that in dry oxygen and in water vapor atmospheres with a trace of oxygen, oxide whiskers are the first growths to be observed. In water vapor atmospheres with a trace of oxygen, only bladelike platelets are found later in the oxidation process. The platelets may ob-

struct the view of the original whisker growths. No platelets grow in water vapor free of oxygen. The whiskers are distinguished from the platelets by their whiskerlike shape. These shape differences are believed to correspond to structural differences we have determined, the whiskers having axial screw dislocations without twinning (5), and platelets having twinning without dislocations. The role of water vapor in the growth mechanism remains to be determined.

### Summary

The bladelike iron oxide platelets observed by electron microscopy to have grown so as to extend out of the oxide film on the surface of pure iron have been studied. Electron diffraction from the oxidized surface by large numbers of these growths is characteristic of  $\alpha\text{-Fe}_2\text{O}_3$ . Such fiber-texture patterns show the fiber axis to be  $[\bar{1}120]$ , in agreement with the selected area electron diffraction patterns. The latter show also that the blades are twinned on the blade face plane, the (010) structural rhombohedral surface. The straight edges at the blade tip have prominent crystallographic directions. The asymmetry of the blade image in outline and in contrast corresponds to the asymmetry of the twinned structure.

Anisotropy in the diffusion of iron in the twin interface, together with apparently negligible lattice diffusion of iron, is believed to result in the blade shape. Iron leaving the interface at the tip is incorporated into growth on the tip edge surfaces.

Determination of the nature of the growth site and the driving forces would permit a more satisfactory appraisal of the significance of these growths.

Manuscript received Sept. 8, 1967; revised manuscript received ca. Feb. 6, 1968. This work was supported in part by the Office of Naval Research under Contract No. Nonr-4949(00).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Tb, A Bluish-White Emitting Cathode-Ray Phosphor with a Long Decay Time

A. Brill, W. L. Wanmaker, and J. W. ter Vrugt

N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

When terbium-activated phosphors are excited with ultraviolet radiation or cathode rays, the terbium ion is raised from the <sup>7</sup>F<sub>6</sub> ground state into the <sup>5</sup>D<sub>3</sub> or higher levels. Generally speaking emission is only found from the lower lying <sup>5</sup>D<sub>4</sub>-level, corresponding to the transitions <sup>5</sup>D<sub>4</sub> → <sup>7</sup>F<sub>j</sub> (j = 0–6). The blue emission originating from the transitions <sup>5</sup>D<sub>3</sub> → <sup>7</sup>F<sub>j</sub> has been found by Van Uitert (1) in CaWO<sub>4</sub>-Tb and Ca<sub>1-2x</sub>Na<sub>2x</sub>Tb<sub>2</sub>WO<sub>4</sub>, especially for low terbium concentrations, by Nelson (2) for SiO<sub>2</sub>-Tb and by Blasse and Brill (3) for LaOBr-Tb and YOCl-Tb. For high Tb concentrations the large transition probability <sup>5</sup>D<sub>3</sub> → <sup>5</sup>D<sub>4</sub> with high activator concentration was ascribed by Pearson, Peterson, and Northover (4) to a transfer process: the transition of an electron from the <sup>5</sup>D<sub>3</sub> to the <sup>5</sup>D<sub>4</sub> level of one ion is matched by the promotion of an electron from the <sup>7</sup>F<sub>6</sub> to the <sup>7</sup>F<sub>0</sub> level of another ion, the corresponding energies being about equal.

In this paper we report on the blue cathodoluminescence and photoluminescence of Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Tb phosphors, which were not described before. Nazarova (5) studied the influence of Tb-addition on the Eu<sup>2+</sup> luminescence in Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Eu<sup>2+</sup>, whereas the photoluminescence of Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> activated with Tb + Sn or Cu was described in a patent (6). In another patent (7) the influence of Tb addition on the luminescence of Dy activated alkaline earth phosphates was reported.

### Experimental

The phosphors were prepared by heating twice an intimate mixture of luminescent grade SrHPO<sub>4</sub>, SrCO<sub>3</sub>, and TbPO<sub>4</sub> for 2 hr at temperatures ranging from 1100° to 1400°C in a slightly reducing atmosphere. In between the two firings the mixture was ground. Up to firing temperatures of 1350°C only the α-Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> phase was found. Above this temperature also the β-phase appears (8). With 0.32g at. terbium added per mole of Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, diffraction lines from a new phase appears in the x-ray diagrams. The optical properties of the phosphors were determined in a way described already before (9).

### Results and Discussion

With ultraviolet (uv) excitation the maxima in the excitation spectra are located below 240 nm for both the α- and the β-Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Tb.

With the 254 nm line of a low pressure mercury discharge lamp they are only weakly excited. Especially the emission originating from the <sup>5</sup>D<sub>3</sub>-level was very poor. The intensities of the <sup>5</sup>D<sub>4</sub> → <sup>7</sup>F<sub>4</sub>, <sup>7</sup>F<sub>5</sub> and <sup>7</sup>F<sub>6</sub> emissions are nearly independent on the crystal structure of the host lattice and on the terbium concentration.

With cathode-ray excitation, however, also a strong emission from the higher lying <sup>5</sup>D<sub>3</sub>-level was observed up to high terbium concentrations [more than 0.32g at. per mole Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>] as may be seen from Fig. 1 and Table I. The lines originating from the <sup>5</sup>D<sub>3</sub>-level are found near 380 nm (<sup>5</sup>D<sub>3</sub> → <sup>7</sup>F<sub>6</sub>), 415 nm (<sup>5</sup>D<sub>3</sub> → <sup>7</sup>F<sub>5</sub>),

440 nm (<sup>5</sup>D<sub>3</sub> → <sup>7</sup>F<sub>4</sub>), and 460 nm (<sup>5</sup>D<sub>3</sub> → <sup>7</sup>F<sub>3</sub>). Longer wavelength <sup>5</sup>D<sub>3</sub>-fluorescence, if present, is obscured by the <sup>5</sup>D<sub>4</sub> → <sup>7</sup>F<sub>6</sub> emission.

Due to the presence of both the <sup>5</sup>D<sub>4</sub> and the <sup>5</sup>D<sub>3</sub>-emission Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Tb shows a bluish-white fluorescent color with cathode-ray excitation. The radiant efficiency (*i.e.*, the energy conversion efficiency, see Table I) is high for an oxidic phosphor, but it is much lower than those of ZnS-Ag and (Zn, Cd) S-Ag, which are normally used in TV receiving tubes (10). The highest value we obtained was 8% for the α-phase phosphor (the β-phase phosphors had a lower efficiency, less than 1%). Because of the emission near 380 nm, the radiant efficiency of the fluorescence emitted in the visible region is lower, *viz.*, about 6%.

Another interesting property of the Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-Tb phosphor is the behavior of the rise and decay times of the <sup>5</sup>D<sub>3</sub> and <sup>5</sup>D<sub>4</sub> emission. The lower the probability of the <sup>5</sup>D<sub>3</sub> → <sup>5</sup>D<sub>4</sub> transition, the stronger is the blue <sup>5</sup>D<sub>3</sub> emission, the longer its decay and the slower the rise of the green <sup>5</sup>D<sub>4</sub> emission due to the slower population of the latter level. This is demonstrated in Fig. 2, where a pulse of cathode rays is irradiating the phosphor. The blue emission has its maximum at the end of the exciting pulse as is normally found, but the maximum of the green emission shows a delay of 2 msec with respect to the end of the pulse. Theoretically (11) this delay δ is

$$\delta = [\tau(^5D_4) \cdot \tau(^5D_3) / \{\tau(^5D_4) - \tau(^5D_3)\}] \cdot \ln[\tau(^5D_4) / \tau(^5D_3)]$$

where τ(<sup>5</sup>D<sub>3</sub>) and τ(<sup>5</sup>D<sub>4</sub>) are the decay times of the <sup>5</sup>D<sub>3</sub>- and <sup>5</sup>D<sub>4</sub>-emissions. These have been measured separately and are found to be 4 and 9 msec, respectively. The formula gives a still larger delay (*viz.* 5 msec) than experimentally observed. Similar results

Fig. 1. Emission spectrum of α-Sr<sub>2.86</sub>(PO<sub>4</sub>)<sub>2</sub>-0.08 Tb with cathode-ray excitation. Along the ordinate the radiant power (I) per constant wavelength interval has been plotted in arbitrary units.

## Effects of Vapor Composition on the Growth Rates of Faceted Gallium Arsenide Hole Deposits

Don W. Shaw

Materials Science Research Laboratory, Texas Instruments Incorporated, Dallas, Texas

In an earlier study (1) it was demonstrated that GaAs could be epitaxially deposited in holes etched into GaAs substrates. These deposits had faceted upper surfaces which were extraordinarily smooth. When viewed by Nomarski interference contrast microscopy (2) the surfaces were apparently stepless. The same results were obtained using an electron microscope with shadowed replicas.

Due to the availability of semi-insulating GaAs, it is possible to use this selected area technique to produce planar integrated circuit structures (3). In this case holes etched into a semi-insulating substrate would be refilled with semiconducting GaAs of the desired electrical properties. Obviously it is important to be able to control the morphologies of the hole deposits, e.g., to be able to stop the deposition when the upper surface of the hole deposit is nearly flush with the surrounding substrate surface. In ref. (1) it was found that by depositing in holes etched into {111}B substrates this condition was fulfilled. However, later studies showed that this was not true for all reactor systems or designs. With some deposition conditions the {111}B hole deposits were as high as 30-50 $\mu$  above the substrate surface.

In view of the above, a study of the effects of vapor composition on the growth rates of faceted GaAs deposits was undertaken. The principal goal of this investigation was to define conditions necessary to obtain GaAs hole deposits of the desired morphologies. However, the faceting nature of GaAs hole deposits also allowed a study of GaAs epitaxial deposition rates on precisely defined orientations (facets). The mechanism which accounts for facet formation with hole deposits has been previously described in detail (1). Growth on these facets may be considered as growth on relatively "stepless," precisely oriented surfaces.

The investigation was divided into four parts. First, a series of runs was made using the "arsenided gallium" (Ga/AsCl<sub>3</sub>/H<sub>2</sub>) deposition system, and growth rates were obtained for each of the four major orientations ({111}A, {111}B, {110}, {100}). This was to establish a reference point using a well-known, reliable deposition system and to develop our experimental techniques so that reproducible growth rate data could be obtained. Next, the deposition rates were studied as a function of the Ga/As ratio with the total molar flux (GaCl and As<sub>4</sub>) held constant. For this and the remaining parts of the study an elemental dep-

osition system was employed which will be described later. In the third phase of the investigation the effect of the GaCl concentration on the deposition rate was studied at a constant As<sub>4</sub> concentration. Finally, the effects of the As<sub>4</sub> concentration were studied at constant GaCl concentration.

### Experimental

Chromium doped substrates, oriented to <0.5° from the principal direction, were employed for all runs. The substrates were polished with sodium hypochlorite on a rotating Pellon cloth in the manner described by Reisman and Rohr (4). A 3000-3500Å silica etch and deposition mask was applied by the oxidative TEOS process and circular windows, 3 and 6 mils in diameter, were cut into the mask. Holes 3-6μ deep were then etched into the substrate at the sites defined by the mask windows. Sodium hypochlorite (Clorox) was used to etch holes in {111}A substrates. For all other orientations either a 1:1000-Bromine:Methanol or 0.7M H<sub>2</sub>O<sub>2</sub>-1.0M NaOH solution (5) was employed. The holes were always etched just prior to deposition.

The deposition conditions employed with the "arsenided gallium" system were identical with those previously described (1).

For the vapor composition studies the reactor design illustrated in Fig. 1 was utilized. The purity of the elemental source materials was rated at 99.9999%. Gallium is transported as GaCl formed by the reaction of HCl with the Ga source which is maintained at 900°C. Experimental transport measurements showed that essentially 1 mole of GaCl is formed for each mole of HCl entering the Ga source zone at this temperature. Consequently the amount of the gallium species in the vapor was computed from the HCl flux over the gallium source. Hydrogen chloride was generated by the reduction of redistilled AsCl<sub>3</sub> by H<sub>2</sub> in a reduction tube filled with crushed quartz (6). The temperature of this tube was 950°C. The HCl flux was computed from the flow rate of H<sub>2</sub> through the bubbler and the vapor pressure of AsCl<sub>3</sub> at the bubbler temperature. The AsCl<sub>3</sub> bubbler was always placed in a water filled Dewar to prevent temperature fluctuations.

The amount of arsenic in the vapor stream was computed from the flow rate of H<sub>2</sub> over the arsenic source and the vapor pressure of arsenic at the source zone temperature. The vapor pressure of arsenic was calculated from the following equation (7)

$$\log P_{As_4} = \frac{-6777}{T} + 10.559$$

where  $P_{As_4}$  is the arsenic vapor pressure (Torr) and  $T$  is the absolute temperature. Complete saturation of the H<sub>2</sub> carrier gas with arsenic is assumed in calculating the arsenic content in the vapor stream. The temperature variation along the length of the arsenic source boat was less than three degrees. The arsenic source temperature was varied between 435° and

485°C depending on the desired vapor pressure. A substrate temperature of 825°C was used in all cases unless otherwise specified. The substrate holder was capable of holding four 1 x 1 cm slices inclined at an angle of approximately 45° from the tube axis.

All depositions were made under conditions in which the amount of extraneous deposition on the substrate holder, the deposition mask, and the surrounding tube walls was minimized or eliminated altogether. When deposition occurs only on the substrate and not on the surrounding areas which are at the same temperature, the reactions which lead to deposition may then be described as catalyzed by the substrate surface. In addition, it was found that the deposition rate is significantly reduced by the presence of extraneous GaAs on the tube walls. This is probably due to depletion of reactant species from the vapor stream by the extraneous material.

The deposition rate measurements were obtained by measuring the height of the upper surface facets above the substrate surface. Usually 10-15 facets were measured on each slice with the average value being recorded. An interferometer was used to measure facet heights less than 6μ. White light was used to follow the fringes from the substrate surface to the facet surface. The facet heights above 6μ were measured by the change of focus technique with a microscope micrometer scale. In this case high magnifications and wide objective apertures were used to minimize depth of field. The accuracy of this technique was estimated to be ±2μ while a precision of ±1μ was obtained. The depth of the hole did not significantly influence the measured facet growth rates. This is because the holes fill from the walls inward as well as from the bottom upward so that a small peripheral facet forms early in the deposition around the top of the hole. The parameter of interest was the height of this facet above the substrate surface. Thus it was not necessary to fill the hole completely to obtain a valid measurement [e.g., see Fig. 8 of ref. (1)]. Only those hole deposits with smooth surface facets were utilized for measurements.

### Results and Discussion

The effects of orientation on the facet growth rates were first investigated with the "arsenided-gallium" system. Table I shows the results for four runs in which the seed holder was loaded with specimens of each of the four orientations. The position of the {111}B as the slowest growing orientation is also observed with systems using precompounded GaAs source material (8-10). Bobb *et al.* (11) determined epitaxial growth rates as a function of substrate orientation with the arsenided gallium system using large area substrates. They found the rates to be in the ratio 5:2:2:1—{111}A:{100}:{110}:{111}B. This agrees qualitatively with the results shown in Table I. However, the rate differences are much more pronounced for faceted deposition than for the large area deposition. This is probably due to the increased emphasis on nucleation of new growth steps with faceted epitaxial growth. Due to small orientation errors, steps are inherently present in the substrate prior to deposition. During large area deposition, growth of the epitaxial

		{111}A	{100}	{110}	{111}B
Average rate μ/hr		60	16	8	1.5
Relative rates		40	10	5	1

layer in the direction perpendicular to the substrate is considered to be the result of the lateral propagation of these growth steps over one another. However, with limited area deposition such as observed with the hole deposits, the growth steps may propagate across the entire area before very many new growth steps are formed (1). Thus growth on facets should be more dependent on the rate of growth step nucleation than on the rate of propagation of steps already formed. This is also consistent with the absolute deposition rates.

During the next series of experiments the Ga/As ratio was varied while the total molar flux ( $\text{GaCl} + \text{As}_4$ ) was held constant. Within experimental error no pronounced effects on the growth rate were observed with either  $\{100\}$  or  $\{110\}$  as the Ga/As ratio was varied from 0.5 to 11. However, the Ga/As ratio was found to influence the deposition rates strongly on the polar  $\{111\}$  facets. This is illustrated for the  $\{111\}$ B in Fig. 2. The rate decreases gradually with decreasing Ga/As ratios down to a value of approximately 2:1 after which the rate decreases more rapidly. It is only at Ga/As ratios  $< 1:1$  that the  $\{111\}$ B facet growth rate drops below  $2\mu/\text{hr}$ . This defines the conditions necessary to obtain planar type selected area deposits with  $\{111\}$ B substrates—relatively low Ga/As ratios. In contrast to the  $\{111\}$ B, the  $\{111\}$ A facet growth rates show a negative dependence on the Ga/As ratio, i.e., the growth rate decreases with increasing Ga/As ratio. This is illustrated by Fig. 3. Indeed, with a Ga/As ratio of 11:1 the  $\{111\}$ A facet growth rate is less than  $2\mu/\text{hr}$ . Thus it would be possible to fabricate planar selected area structures using  $\{111\}$ A substrates if the Ga/As ratio were high.

In another series of depositions the  $\text{As}_4$  flux was held constant at a value of  $6.1 \times 10^{-5}$  mole/min while the GaCl flux was varied between  $5.0 \times 10^{-5}$  and  $30 \times 10^{-5}$  mole/min. The results are shown in Fig. 4 for all four orientations. Each orientation exhibits increasing deposition rates with increasing GaCl flux. The  $\{111\}$ A rate is apparently considerably more sensitive to variations in the GaCl flux than the other orientations. The nonpolar  $\{110\}$  and  $\{100\}$  facet growth rates exhibit similar dependencies on the GaCl flux.

Figure 5 presents a log-log plot of the deposition rate for  $\{100\}$  and  $\{110\}$  facets vs. the  $\text{As}_4$  flux at constant GaCl flux. As can be seen, the rates are independent of the  $\text{As}_4$  flux, and the deposition may be described as zero order with respect to the arsenic species. Comparison of the absolute rate values with those from Fig. 4 shows that the rates are approximately those predicted from the GaCl flux. Note from Fig. 4 and 5 that there is always approximately a factor of ten difference between the rates of  $\{100\}$  and  $\{110\}$  facets. The effects of varying the  $\text{As}_4$  fluxes on the growth rates of the polar  $\{111\}$  facets are shown in

Fig. 2. Variation in  $\{111\}$ B facet growth rate as a function of the Ga/As ratio.

Fig. 3. Variation in  $\{111\}$ A facet growth rate as a function of the Ga/As ratio.

Fig. 4. Variation in facet growth rates as a function of the GaCl flux.

Fig. 6. The  $\{111\}$ A rate exhibits a normal dependence on the  $\text{As}_4$  flux, while the  $\{111\}$ B rate shows a negative dependence on the  $\text{As}_4$  flux, i.e., its growth rate is inhibited by increasing  $\text{As}_4$  concentrations. Although two lines of different slope are drawn through the points in Fig. 6, the dependence may not be linear. The experimental accuracy does not exclude a nonlinear relationship.

Surface catalyzed reactions may be divided into the following series of steps: (a) mass transport of the reactants up to the catalyst (crystal) surface, (b) adsorption of the reactants on the surface, (c) reactions of the adsorbed species on the surface, (d) surface diffusion of the species to steps and incorporation into the lattice, and (e) mass transport of the products away from the surface. With respect to steps c and d, it should be noted that the adsorbed reactants may also diffuse to the crystal step and then react at that site. If any step is significantly slower than the others it becomes the rate limiting step. If any one of the mass transport steps were the rate-limiting step, the reaction rate would be strongly influenced by the flow rate but would be relatively independent of substrate orientation (12). Since in all of the experiments described above the rate was strongly orientation dependent, it is probable that the deposition rate is not mass transport limited. This indicates that the rate is probably determined by either an adsorption-desorp-

Fig. 5. Variation in {100} and {110} facet growth rates as a function of the arsenic flux.

Fig. 6. Variation in {111}B and {111}A facet growth rates as a function of the arsenic flux.

tion process or by the surface reaction itself. In order to completely describe the epitaxial mechanism, many more experiments would be required.

The negative growth rate dependence of the {111}B facets on the arsenic concentration explains the necessity of having low Ga/As ratios in order to obtain low {111}B facet growth rates. The initial step in the nucleation of a {111}B layer is addition of a singly bonded gallium. However, at high arsenic concentrations the arsenic species may compete with the gallium species for surface sites.

The deposition rate of {111}A facets exhibited a positive dependence on both the gallium and the arsenic species. However, as is shown by Fig. 3, the deposition rate decreased with increasing Ga/As ratio. This appears to be a contradiction until it is realized that while the Ga/As ratio increased it did so by a small increase in the GaCl flux and a relatively large decrease in the As<sub>4</sub> flux. Thus at a ratio of 2:1 the GaCl flux was  $29.3 \times 10^{-5}$  mole/min and the As<sub>4</sub> flux was  $3.9 \times 10^{-5}$  mole/min. When the Ga/As ratio was increased to 11:1 the GaCl flux was increased to  $32.2 \times 10^{-5}$  mole/min, while the As<sub>4</sub> flux decreased to  $0.73 \times 10^{-5}$  mole/min. This also explains the relative independence of the {100} and {110} facet growth rates on the Ga/As ratio for that series of experiments. The data shown in Fig. 6 indicate that it would be possible to use the {111}A orientation for planar selected area deposition if relatively low arsenic concentrations were employed.

The relatively high {100} rates and the independence of the rate on the arsenic concentration makes it the least desirable orientation for planar hole deposition. The high {100} growth rates are probably due to the ease of nucleation of {100} layers. In every case the addition of atoms onto a {100} surface results in double bonded atoms. It is again stressed that nucleation of new layers is considerably more important with facet growth than with the usual large area deposition.

#### Acknowledgment

Appreciation is expressed to Mr. D. G. Vieaux, Jr., for his assistance with the experimental work. Thanks are also extended to Dr. L. G. Bailey for helpful discussions of possible deposition mechanisms. The initial portions of this work were supported by the Air Force Avionics Laboratory, Electronics Technology Division, under Contract AF 33(615)-2101.

Manuscript received Feb. 2, 1968; revised manuscript received April 3, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Dependence of Sheet Resistance on SiO<sub>2</sub> Masking Geometry in Diffused Si Regions

J. P. Décosterd, D. Chauvy, and K. Hübner\*

Centre Electronique Horloger S. A., Neuchâtel, Switzerland

We have observed systematic differences in sheet resistance within the same IC chip depending on the width of the SiO<sub>2</sub> strip surrounding a particular diffusion window. A large meander-type boron diffused resistor of several hundred squares with line width and spacing of 10 $\mu$ , will show up to 20% lower sheet resistance than a short straight resistor surrounded by wide SiO<sub>2</sub> stripes. This applies for diffusion conditions as they are commonly used for resistors and bases in IC's. Under special conditions the difference can be much more pronounced.

In a series of specific experiments, including various masking patterns, we could convince ourselves, that the observed effect is not due to: (a) leakage current, (b) lateral impurity diffusion within the Si, (c) variation in SiO<sub>2</sub> thickness, (d) corner effects in resistor surface geometry, (e) particular surface preparation including chemical HNO<sub>3</sub> preoxidation, (f) any process following the predeposition, (g) choice of a particular diffusion system, (h) choice of a particular impurity (effect observed for boron and phosphorus, other doping elements not investigated). The effect does however depend on: (i) SiO<sub>2</sub> strip width around the diffusion window, (ii) size of the masking window, in particular line width of a diffused resistor, (iii) predeposition time.

Samples for the experiments reported below were prepared from 1-2 ohm cm, (111) orientation, n-type wafers. Customary cleaning procedures were employed, the final chemical treatment before oxidation or predeposition being an HF or buffered HF dip, respectively.

Oxidation was carried out at 1200°C in a 90-min wet, 5-min dry O<sub>2</sub> cycle, with the water temperature for the wet O<sub>2</sub> being 95°C. The type of masking pattern for the boron predeposition employed to obtain the results of Fig. 2 and 3 is shown in Fig. 1. It consists of 8 simple one-line windows for diffused resistors measuring 200 $\mu$  in length and 10 $\mu$  in width. The ends are formed by 50 x 50 $\mu$  square pads for the Al contacts. The individual resistors differ only in the width (not thickness) of the surrounding SiO<sub>2</sub> strip delineating the diffusion windows. This width of SiO<sub>2</sub> varies in Fig. 1 from 4 $\mu$  for the resistor in the upper left hand corner to 150 $\mu$  for the second resistor from the left in the bottom row. Each resistor is therefore surrounded by a different SiO<sub>2</sub> strip width. The space between these oxide surfaces surrounding each resistor is bare silicon. The photoresist used was centrifuged KMER.

The boron predeposition for most experiments was carried out in a Pt box system with a pure liquid B<sub>2</sub>O<sub>3</sub> glass as a source in a dry N<sub>2</sub> ambient, at 910°C. Control runs made in a more conventional BBr<sub>3</sub> liquid source system at 950°C yielded the same results. Right after boron predeposition contact windows were cut and Al evaporated from a stranded tungsten wire. After photoetching the remaining Al was alloyed at 578°C in N<sub>2</sub> for 6 min to assure good contact.

Typical results for a predeposition cycle likely to be used for a base diffusion are shown in Fig. 2. Plotted is sheet resistance in ohms per square as a function of the width of the surrounding masking oxide. The point for SiO<sub>2</sub> width equal to zero is the four-point probe measurement taken on the back side of the wafer.

The scatter indicated is for all chips measured on an entire wafer, the points being the averages. It is clearly visible that the width of the SiO<sub>2</sub> strip surrounding the diffused resistors influences sheet resistance by about 17%. The wider the SiO<sub>2</sub> strip surrounding the diffused silicon, the higher is the sheet resistance or the lower is the electrically active impurity concentration. For the conditions represented in Fig. 2 sheet resistance becomes constant for SiO<sub>2</sub> widths larger than about 50 $\mu$ .

This result expresses what we have been observing on diffused resistors in integrated circuits. Large me-

Key words: diffusion in Si, masking against diffusion, sheet resistance of diffused layers.

ander-type resistors have very little  $\text{SiO}_2$  surface between individual lines of the same resistor. Their sheet resistance is therefore lower than that of a simple one-line resistor with large  $\text{SiO}_2$  surfaces around it.

We have no specific model to explain our experiments, but suggest the following mechanisms which might account for most of our observations:

The affinity of the dopants ( $\text{B}_2\text{O}_3$ , but also  $\text{P}_2\text{O}_5$ ) to deposit on the  $\text{SiO}_2$  surface is larger than for the bare Si. This leads to a disturbance of the dopant distribution in the gas phase close to the edge of a diffusion window, where the oxide is thus preventing the  $\text{B}_2\text{O}_3$  molecules from depositing on the Si.

The molecules of the dopants deposited on the bare Si diffuse laterally on the Si surface to the oxide so that only part of these molecules supply doping atoms to the bulk.

Precipitation of the dopants in the Si on crystal imperfections in the strained regions along the edges of the diffusion windows cannot be ruled out. It is conceivable that less crystal disorder and therefore less precipitates are generated along the window edges, if the surrounding oxide frame is very narrow. This would explain our findings without further postulates.

To examine this last mechanism we varied the  $\text{SiO}_2$  thickness from 2500 to 20,000 Å, which should influence the strain generated, and found no influence. In separate experiments we established that lateral diffusion is a sensitive test to determine the presence of crystal imperfections at window edges. They reduce the lateral diffusion close to the surface of boron and enhance that of phosphorus. This is in agreement with the diffusion behavior of these elements along small angle grain boundaries in Si and suggests the presence of dislocations along the window edges. All our measurements presented here have been carried out on surfaces which exhibit a normal lateral diffusion behavior. It can therefore be assumed, that no excessive crystal disorder is responsible for the effect reported, but precipitation phenomena cannot be excluded as a possible mechanism to explain our observations.

Furthermore we established experimentally that:

(A) The effect is more pronounced if the predeposition time is small. Boron predepositions were carried out for only 3 min at 910°C. The results are shown in Fig. 3. While in Fig. 2 the difference in sheet resistance for  $\text{SiO}_2$  width of  $4\mu$  and  $150\mu$  was 17%, it is 26% in Fig. 3.

For such short predeposition times the resulting diffusion length is much smaller than the surface dimensions of the patterns. Two-dimensional diffusion effects can therefore be excluded as explanation. For longer predeposition times (60 and 120 min) the effect gradually gets smaller.

Fig. 3. Same measurement as in Fig. 2, but for a predeposition in a Pt box system with  $\text{B}_2\text{O}_3$  as a source at 910°C for 3 min.

A chemical  $\text{HNO}_3$  preoxidation does not attenuate the effect. This observation however is not in good agreement with our first proposed model.

One would also expect for the models suggested the line width of the diffused resistors to influence the observed effect. We also could confirm this point experimentally and repeatedly on a set of one-line resistor pairs of different line and  $\text{SiO}_2$  width. The effect gets smaller the wider the resistor lines are.

In conclusion we can state that we have found experimental evidence of  $\text{SiO}_2$  masks influencing sheet resistance during B (and P) predeposition in Si. The effect is most pronounced for small windows (order  $10\mu$ ) and short predeposition times.

# Double Layer Capacitance of Zinc Electrodes in KOH Solutions

T. P. Dirkse\* and R. Shoemaker

Calvin College, Grand Rapids, Michigan

## ABSTRACT

The double layer capacitance of amalgamated and nonamalgamated zinc electrodes has been measured in a range of KOH solutions at room temperature. The presence of zincate ions and of surface active materials modifies the capacitance values. There appears to be some correlation between the extent to which a surface active material modifies the double layer capacitance and its effectiveness in increasing the cycle life of the zinc electrode.

In zinc-alkaline batteries the zinc electrodes are usually amalgamated. This is done to improve the stand or shelf-life characteristics of the zinc electrode. Amalgamation raises the hydrogen overvoltage on zinc and thus reduces considerably the corrosion rate of zinc in highly alkaline solutions. However, amalgamation does more than raise the hydrogen overvoltage. It also modifies the anodic behavior of the zinc (1). It was suggested that this is due to a change in the surface of the zinc electrode. As a result, the anodic reaction may proceed by a somewhat different mechanism at these amalgamated electrodes (1). The work reported here was undertaken in an effort to get more information about this suggested mechanism.

One way to obtain information about the electrode/electrolyte interface is to measure the double layer capacitance at the electrode. This is difficult with an electrochemically active electrode such as zinc. Passage of current alters the nature of the electrode surface. Furthermore, any current used in making double layer capacitance measurements may also be accompanied by Faradaic current, i.e., chemical changes. In spite of this difficulty, attempts to measure double layer capacitance were nonetheless made because similar work with the silver electrode had proven fairly successful (2).

## Results

The method used was the one suggested by McMullen and Hackerman (3). The electrode surface was the cross-sectional area of a 0.063 in. diameter zinc wire encased in a Teflon tube. Further experimental details have been described earlier (2). The square wave frequency was 50,000 Hz, and the value of the current was of the order of 0.1 ma.

Some typical results are given on Fig. 1 and 2. The arrows on these figures designate the open circuit potential of the electrode in that solution. The values for the nonamalgamated zinc electrodes, Fig. 1, are in good agreement with those obtained by others (4). The reproducibility is also good for an electrode such as zinc.

One outstanding feature of these results is that amalgamation alters the surface characteristic of the zinc electrode. The presence of zincate ions alters the values at potentials cathodic to that at open circuit. This is to be expected because at these potentials metallic zinc is deposited and this introduces an appreciable Faradaic current which has the effect of increasing the value of the calculated double layer capacitance.

At potentials anodic to the open circuit value there is a marked difference in the behavior of amalgamated and nonamalgamated electrodes. The amalgamated electrodes give values close to the generally accepted ones ( $20 \mu\text{f}/\text{cm}^2$ ). It should be noted here that no correction was made for a roughness factor for zinc. Consequently, the data reported in Fig. 1 and 2 are

somewhat higher than the actual values for the non-amalgamated zinc.

A summary of the results is presented on Fig. 3. The capacitance values plotted on this graph are those obtained at the open circuit potential of the zinc electrode in that electrolyte. There is a maximum in the double layer capacitance values at 30-35% KOH for both types of electrodes. The presence of zincate ion has no effect on amalgamated electrodes but has a slight effect on nonamalgamated zinc.

In recent years it has been found that certain surface active materials increase the cycle life of the zinc electrode (5). The double layer capacitance of zinc electrodes was also measured in the presence of some such materials, Fig. 4-6. Ordinarily, the presence of Emulphogene BC-610 does not shift the equilibrium potential as much as is shown in Fig. 6. These open circuit or equilibrium potentials were somewhat random. There was no zincate in these solutions. However, there is a tendency to shift the equilibrium potential to more positive values. This phenomenon has been observed by others also (6).

## Discussion

At potentials cathodic to the open circuit value, the difference between amalgamated and nonamal-

gated electrodes decreases. This is noted particularly in zincate-free solutions where the reduction of zincate cannot occur. As the potential of the electrode increases in the anodic direction, the difference in behavior of the two types of electrodes increases.

The behavior represented on Fig. 1 is consistent with other work on the anodic and cathodic processes of the zinc electrode (1). The effect of amalgamation on the overvoltage for the zinc/zincate reaction and on the limiting current density at the zinc electrode is more pronounced for the anodic than for the cathodic processes.

The double layer capacitance value can be considered as the current necessary to bring about a given

rate of voltage change on the electrode. The current necessary to do this, then, is much greater for the nonamalgamated electrodes. This can be explained by assuming the adsorption of  $\text{OH}^-$  ions on the zinc adatoms (4). It is then more difficult to increase the potential of the zinc electrode anodically. It follows from this that no such adsorption (or a considerably smaller amount) takes place at amalgamated electrodes. Amalgamation may make the surface of the zinc more like a liquid, i.e., more homogeneous. It may remove screw dislocations and other imperfections. As a result there are no adatoms (adsorbed atoms with a low coordination number) on an amalgamated surface (1).

The variation of the double layer capacitance with KOH concentration, Fig. 3, has been noted before (2) and will be discussed in another paper. The presence of zincate ion has but little effect on the double layer capacitance, Fig. 3. There appears to be a slight difference at the nonamalgamated electrodes, but most of this is within the experimental uncertainty. The biggest difference is in 35% KOH. This difference is real but no satisfactory explanation for it is available.

The effect of additives to the electrolyte is especially interesting. The presence of maleic anhydride was found to have no significant effect on the cycle life of the zinc electrode. In the presence of this material the double layer capacitance of zinc electrodes was not changed except for some displacement, Fig. 4.

The use of Igepal CO-730 did not increase the cycle life of the zinc electrode (5). It did have an effect on the shape of the double layer capacitance curve of the nonamalgamated zinc electrode, Fig. 5. The double layer capacitance value is lower and it does not rise as abruptly at anodic potentials.

The cycle life of the zinc electrode was increased most by the use of Emulphogene BC-610 (5). Cell failure was often due to loss of zinc electrode capacity rather than to the formation of shorts (dendrites). Emulphogene BC-610 also had the greatest effect on the double layer capacitance of both types

Fig. 4. *dlc*-potential curve for zinc electrodes in 30% KOH. Circles, zinc; triangles, amalgamated zinc; open symbols, no additive; closed symbols, 0.01% maleic anhydride.

of zinc electrodes, Fig. 6. It altered the shape of the curve for the nonamalgamated electrodes completely and even lowered that of the amalgamated electrodes significantly.

These phenomena can again be accounted for in terms of surface adsorption. The surface active materials are adsorbed on the electrode surface. The Igepal CO-730 and the Emulphogene BC-610 are preferentially adsorbed on the electrode surface, the latter more so. This displaces or prevents  $\text{OH}^-$  ion adsorption. In fact, with Emulphogene BC-610, Fig. 6, the double layer capacitance of the nonamalgamated electrode becomes similar to that of the amalgamated electrode.

Such preferential adsorption of the surface active materials is undoubtedly associated with the increased cycle life of the zinc electrodes. The adsorption of the additives takes place on the most active reaction sites and prevents electrochemical reaction from occurring preferentially at these sites. This may prevent or delay the growth of zinc dendrites, which is a common mode of failure in the silver-zinc batteries. The anodic reaction mechanism may also be changed somewhat (1). The adsorption of the surface active materials at the preferred reaction sites forces the electrochemical reaction to take place over the rest of the electrode surface. This results in a more complete electrochemical use of the entire electrode surface instead of only certain parts of the surface. Thus treeing and dendrite growth are at least delayed.

In silver-zinc batteries the zinc electrodes are amalgamated. Consequently, if the above explanation is correct, it would appear unsuited to account for the extended cycle life of these batteries. However, it is likely that during cycling the deposits of zinc formed on charge are not amalgamated, at least to the extent of the original electrode. As a result, the

Fig. 6. *d/c*-potential curve for zinc electrodes in 30% KOH. Circles, zinc; squares, amalgamated zinc; open symbols, no additive; closed symbols, saturated with Emulphogene BC-610.

beneficial effects of amalgamation then cease to exist as cycling continues. Under such conditions it is very likely possible that the surfactants then exert their beneficial effect on the nonamalgamated or slightly amalgamated zinc deposits, and in this way serve to extend the cycle life of the zinc electrodes.

As a practical matter, the results reported here suggest that, in seeking additives to improve the zinc electrode behavior, the measurement of the double layer capacitance of the zinc electrode in the presence of such additives may serve as a useful tool in selecting substances which will be most effective. Furthermore, the results of this work are consistent with the mechanisms that have previously been suggested for the anodic zinc processes (1, 4).

# Self-Discharge in Alkali Metal-Containing Bimetallic Cells

J. C. Hesson, M. S. Foster, and H. Shimotake

Argonne National Laboratory, Argonne, Illinois

## ABSTRACT

The self-discharge rate of a concentration cell is considered to be due to the dissolution and ionization of alkali metal atoms in the fused-salt electrolyte. Assuming that an equilibrium exists between dissolved alkali metal atoms and alkali metal ions and electrons, an expression was derived which relates the self-discharge rate as a function of current. This expression was used to construct graphs showing the effect of cell current on the self-discharge rate for a variety of conditions. It is demonstrated that the open-circuit potential of such a cell will be less than that predicted from theoretical thermodynamic considerations.

Thermally regenerative bimetallic cells with alkali metal anodes have been considered as a means to convert heat energy into electrical energy (1-4). In these cells, the anode consists of an alkali metal such as lithium, sodium, or potassium, and the cathode consists of a binary alloy of the alkali metal and a more noble metal, such as lead, bismuth, or tin. An electrolyte consisting of a mixture of molten salts of the anode alkali metal is used. The open circuit potentials of such cells have been used to calculate the thermodynamic properties of binary alloys (5-7).

In this laboratory, it has been noted that, in the case of sodium-bismuth bimetallic cells using a molten sodium fluoride-sodium chloride-sodium iodide electrolyte, a non-faradaic or "irreversible" transfer of sodium from the anode to the cathode takes place. Since this transfer of sodium takes place without producing an electrical current in the external circuit, it is also called self-discharge of the cell. The self-discharge rate is much too large to be explained simply by the diffusion of dissolved sodium atoms through the electrolyte. In addition, it has been noted that the rate of self-discharge decreases as the current drawn from the cell is increased.

## Theoretical Analysis

In order to explain the observed self-discharge rate and its anomalous behavior with current, a theoretical analysis has been made. In this analysis, it is assumed: (a) that the self-discharge of the cell is in part due to electronic conductivity of the electrolyte which in turn results from dissolved alkali metal, and (b) that an equilibrium exists between dissolved alkali metal atoms and alkali metal ions and electrons.

We shall consider the cell of unit cross sectional area with parallel anode and cathode. The electrolyte thickness is  $L$  cm and it is postulated that no convective stirring takes place in the electrolyte.

The concentration cell to be considered is typified by the sodium-bismuth cell:

where all concentration changes occur in the region between the imaginary boundaries 1 and 2. The electrolyte immediately adjacent to the anode will be saturated with sodium metal, and the solubility of sodium is defined to be  $X_{\text{Na}}^A$ . The electrolyte immediately adjacent to the cathode will also contain dissolved sodium. Since the activity of sodium in the cathode alloy is much less than the activity of sodium in the anode, the concentration of sodium in the elec-

trolyte adjacent to the cathode,  $X_{\text{Na}}^C$ , will be much less than  $X_{\text{Na}}^A$ .

In the region between 1 and 2, the equivalent current density of sodium atoms, in amp/cm<sup>2</sup>, through the electrolyte and toward the cathode will be

$$i_o = \frac{-FD\rho X_{\text{Na}}}{MRT} \frac{d\mu_{\text{Na}}}{dx} \quad [1]$$

where  $F$  is the Faraday constant,  $D$  the effective diffusion coefficient of sodium atoms,  $\rho$  the density of the electrolyte solution,  $X_{\text{Na}}$  the mole fraction of sodium dissolved in the electrolyte,  $M$  the molecular weight of the electrolyte solution,  $R$  the universal gas constant,  $T$  the absolute temperature,  $\mu_{\text{Na}}$  the chemical potential of sodium due to concentration effects, and  $x$  the distance toward the cathode from the anode-electrolyte interface. The partial current density of sodium ions,  $i_i$ , is

$$i_i = \frac{-\kappa_i}{F} \frac{d\mu_i}{dx} - \kappa_i \frac{d\psi}{dx} \quad [2]$$

where  $\kappa_i$  is the partial sodium ion conductivity of the electrolyte (assumed constant),  $\mu_i$  the chemical potential of the sodium ions due to concentration effects, and  $\psi$  the local electric potential in the electrolyte. The partial electrical current density due to electrons in the electrolyte,  $i_e$ , is

$$i_e = \frac{\kappa_e}{F} \frac{d\mu_e}{dx} - \kappa_e \frac{d\psi}{dx} \quad [3]$$

where  $\kappa_e$  is the partial electronic conductivity of the electrolyte and  $\mu_e$  the chemical potential of the dissolved electrons. Note that the current carried by electrons is considered to be positive when the electrons themselves flow toward the anode (in the negative direction of  $x$ ). The total electrical current density,  $i$ , is the sum of the partial currents

$$i = i_i + i_e = \frac{1}{F} \left( \kappa_e \frac{d\mu_e}{dx} - \kappa_i \frac{d\mu_i}{dx} \right) - (\kappa_i + \kappa_e) \frac{d\psi}{dx} \quad [4]$$

The apparent self-discharge rate is

$$J_{\text{Na}}^* = i_o - i_e = (i_o + i_i) - i \quad [5]$$

It is assumed that steady-state conditions apply at any fixed current, i.e., (i) the current through any plane bisecting the electrolyte and parallel to the electrode-electrolyte interfaces is constant, and (ii) the total number of sodium nuclei in the electrolyte is constant. Therefore, Eq. [5] shows that  $J_{\text{Na}}^*$  is independent of position and is constant for a given  $i$ .

The dissolved sodium atoms in the electrolyte are assumed to be in equilibrium with sodium ions and

electrons, and, therefore, from the equilibrium

we know

$$\mu_{\text{Na}} = \mu_i + \mu_e \quad [6]$$

Equations [4] and [6] may be combined to yield the expression

$$\frac{d\mu_e}{dx} = \frac{\kappa_i}{\kappa_i + \kappa_e} \frac{d\mu_{\text{Na}}}{dx} + \frac{F i}{\kappa_i + \kappa_e} + F \frac{d\psi}{dx} \quad [7a]$$

This equation may be combined with Eq. [3] to eliminate the dependence of  $i_e$  on  $\psi$

$$i_e = \frac{\kappa_i \kappa_e}{F(\kappa_i + \kappa_e)} \frac{d\mu_{\text{Na}}}{dx} + \frac{\kappa_e i}{\kappa_i + \kappa_e} \quad [7b]$$

The concentration of sodium atoms dissolved in the electrolyte is small, allowing us to use dilute solution theory.

If the activity coefficient of sodium atoms dissolved in the fused electrolyte is constant for the dilute solutions involved, we may write

$$\frac{d\mu_{\text{Na}}}{dx} = RT \frac{d(\ln X_{\text{Na}})}{dx} \quad [8]$$

Bredig's results (8) suggest that for dilute solutions of sodium in molten sodium halides, the partial electronic conductivity,  $\kappa_e$ , is proportional to the mole fraction of sodium metal in the solution, or

$$\kappa_e = K_e X_{\text{Na}} \quad [9]$$

Using these assumptions and the basic differential relationships, the following equation is obtained

$$J_{\text{Na}}^* = - \left[ \frac{FD\rho}{M} + \frac{K_e RT \kappa_i}{F(\kappa_i + K_e X_{\text{Na}})} \right] \frac{dX_{\text{Na}}}{dx} - \frac{K_e X_{\text{Na}} i}{(\kappa_i + K_e X_{\text{Na}})} \quad [10]$$

As the imaginary boundaries 1 and 2 are considered to approach the electrode-electrolyte interfaces, Eq. [10] may be integrated to yield

$$J_{\text{Na}}^* + i = \left[ \frac{\kappa_i RT}{FL} + \frac{FD\rho \kappa_i i}{LMK_e(i + J_{\text{Na}}^*)} \right] \ln \left[ \frac{J_{\text{Na}}^* \kappa_i + (J_{\text{Na}}^* + i)K_e X_{\text{Na}}^A}{J_{\text{Na}}^* \kappa_i + (J_{\text{Na}}^* + i)K_e X_{\text{Na}}^C} \right] + \frac{FD\rho(X_{\text{Na}}^A - X_{\text{Na}}^C)}{LM} \quad [11]$$

Two interesting cases of Eq. [11] may be mentioned. If the current,  $i$ , in the external circuit is zero, then

$$J_{\text{Na}}^* = q_0 = \frac{\kappa_i RT}{FL} \ln \left( \frac{\kappa_i + K_e X_{\text{Na}}^A}{\kappa_i + K_e X_{\text{Na}}^C} \right) + \frac{FD\rho(X_{\text{Na}}^A - X_{\text{Na}}^C)}{LM} \quad [12]$$

and if the self-discharge rate,  $J_{\text{Na}}^*$  is zero

$$i = p_0 = \left[ \frac{\kappa_i RT}{FL} + \frac{FD\rho \kappa_i}{LMK_e} \right] \ln \left( \frac{X_{\text{Na}}^A}{X_{\text{Na}}^C} \right) + \frac{FD\rho(X_{\text{Na}}^A - X_{\text{Na}}^C)}{LM} \quad [13]$$

These equations will be used later in demonstrating some typical results of this treatment.

The cell reaction producing current in the external circuit may be written

where the subscripts An and Ca refer to the anode and cathode themselves and A and C to the electrolyte immediately contiguous with the anode and cathode,

respectively. The Gibbs free energy change,  $\Delta G$ , for reaction [14] is

$$\Delta G = (\mu_{\text{Na,Ca}} - \mu_{\text{Na,An}}) + (\mu_{\text{i,A}} - \mu_{\text{i,C}}) + F(\psi_{\text{A}} - \psi_{\text{C}}) + (\mu_{\text{e,An}} - \mu_{\text{e,Ca}}) - F(\psi_{\text{An}} - \psi_{\text{Ca}}) \quad [15]$$

Because the chemical potentials of electrons in the anode and cathode,  $\mu_{\text{e,An}}$  and  $\mu_{\text{e,Ca}}$ , are only a function of concentration (9) and are very nearly equal, we may write

$$\mu_{\text{e,An}} = \mu_{\text{e,Ca}} \quad [16]$$

Likewise, because the composition of the electrolyte varies only slightly

$$\mu_{\text{i,A}} = \mu_{\text{i,C}} \quad [17]$$

The cell terminal voltage is defined as

$$E = \psi_{\text{Ca}} - \psi_{\text{An}} \quad [18]$$

Thus, if only equilibrium processes take place,  $\Delta G = 0$ , and Eq. [15] becomes

$$\Delta G = (\mu_{\text{Na,Ca}} - \mu_{\text{Na,An}}) + F(\psi_{\text{A}} - \psi_{\text{C}}) + FE = 0 \quad [19]$$

Writing the theoretical thermodynamic open-circuit potential,  $E^\circ$ , as

$$E^\circ = -\frac{1}{F} (\mu_{\text{Na,Ca}} - \mu_{\text{Na,An}}) \quad [20]$$

and substituting into Eq. [19] results in

$$E = E^\circ + (\psi_{\text{C}} - \psi_{\text{A}}) \quad [21]$$

Combining Eq. [4] and [7], we find

$$d\mu_i = \frac{\kappa_e}{\kappa_i + \kappa_e} d\mu_{\text{Na}} - F d\psi - \frac{F i}{\kappa_i + \kappa_e} dx \quad [22]$$

Using the definition of  $J_{\text{Na}}^*$  in Eq. [10], we convert Eq. [22] to the integrable equation

$$d\mu_i = -\frac{F}{\kappa_i} \left[ (J_{\text{Na}}^* + i) dx + \frac{FD\rho}{M} dX_{\text{Na}} \right] - F d\psi \quad [23]$$

Integrating from  $x = 0$  to  $x = L$  and using Eq. [17]

$$\psi_{\text{C}} - \psi_{\text{A}} = -\frac{1}{\kappa_i} \left[ (J_{\text{Na}}^* + i) L + \frac{FD\rho}{M} (X_{\text{Na}}^C - X_{\text{Na}}^A) \right] \quad [24]$$

The terminal voltage of the cell is, in general, given by

$$E = E^\circ - \frac{1}{\kappa_i} (J_{\text{Na}}^* + i) L - \frac{FD\rho}{\kappa_i M} (X_{\text{Na}}^C - X_{\text{Na}}^A) \quad [25]$$

Several interesting results of Eq. [25] may be noted. One of these is the fact that the open-circuit terminal voltage of the cell is less than the theoretical thermodynamic open-circuit potential by an amount

$$E - E^\circ = -\frac{q_0 L}{\kappa_i} - \frac{FD\rho}{\kappa_i M} (X_{\text{Na}}^C - X_{\text{Na}}^A) = -\frac{RT}{F} \ln \left( \frac{\kappa_i + K_e X_{\text{Na}}^A}{\kappa_i + K_e X_{\text{Na}}^C} \right) \quad [26]$$

Therefore, it is not possible to measure the theoretical thermodynamic open-circuit potential of the above cell by direct means.

Another is the fact that the terminal voltage of the cell when the self-discharge rate is zero is

$$E = -\frac{FD\rho}{MK_e} \ln \frac{X_{\text{Na}}^A}{X_{\text{Na}}^C} \quad [27]$$

where we have utilized the assumptions that equilibrium exists and the activity coefficient is constant so that

$$E^\circ = -\frac{RT}{F} \ln \frac{X_{\text{Na}}^C}{X_{\text{Na}}^A} \quad [28]$$

Equation [27] shows that a negative terminal voltage will exist when the self-discharge rate is reduced to zero.

**Results**

Equation [11] was solved by putting it into the form

$$\frac{L}{\kappa_i} J_{Na}^* = \frac{1}{1+N} \left[ \frac{RT}{F} + \frac{FD\rho N}{MK_e(1+N)} \right] \ln \left[ \frac{1 + (1+N) \frac{K_e X_{Na}^A}{\kappa_i}}{1 + (1+N) \frac{K_e X_{Na}^C}{\kappa_i}} \right] + \frac{FD\rho(X_{Na}^A - X_{Na}^C)}{\kappa_i M(1+N)} \quad [29]$$

where  $N = i/J_{Na}^*$ . Values of  $N$  were assumed and values of  $L/\kappa_i J_{Na}^*$  and  $Li/\kappa_i$  were calculated for values of  $K_e X_{Na}^A/\kappa_i$  of 0.4, 0.8, and 1.6. For a temperature of 858°K, values of  $X_{Na}^A/X_{Na}^C$  of 10, 100, 1000, and 10,000 were chosen. By Eq. [28] these values of  $X_{Na}^A/X_{Na}^C$  correspond to  $E^\circ$  values of 0.1702, 0.3404, 0.5107, and 0.6809v, respectively. Other constants assumed for these calculations were:

- $\rho = 2.5 \text{ g/cm}^3$
- $M = 105$  (typical for NaF-NaCl-NaI mixtures) g/mole
- $D = 1 \times 10^{-4} \text{ cm}^2/\text{sec}$  (the Stokes-Einstein equation gives  $2.01 \times 10^{-5}$  and the Eyring equation,  $1.9 \times 10^{-4}$ )
- $K_c = 100, 200, 400 \text{ ohm}^{-1} \text{ cm}^{-1}$
- $X_{Na}^A = 0.004 \text{ mole/mole}$
- $\kappa_i = 1 \text{ ohm}^{-1} \text{ cm}^{-1}$

The calculated values of  $LJ_{Na}^*/\kappa_i$  and  $Li/\kappa_i$  are shown in Fig. 1, 2 and 3. It was noted that contributions by the terms involving  $FD\rho/M$  in Eq. [29] are negligible. This result indicates that the self-discharge rate is due

Fig. 1. Theoretical self-discharge rate as a function of cell current density.  $K_e/\kappa_i = 100$ ,  $K_e X_{Na}^A = 0.4$ ,  $X_{Na}^A = 0.004$ .

Fig. 2. Theoretical self-discharge rate as a function of cell current density:  $K_e/\kappa_i = 200$ ,  $K_e X_{Na}^A = 0.8$ ,  $X_{Na}^A = 0.004$ .

Fig. 3. Theoretical self-discharge rate as a function of cell current density:  $K_e/\kappa_i = 400$ ,  $K_e X_{Na}^A = 1.6$ ,  $X_{Na}^A = 0.004$ .

primarily to the electronic conductivity of the electrolyte solution and not to the diffusion of neutral sodium. Further, it was noted that the self-discharge rate decreases with increasing cell current.

The variation of  $X_{Na}$  (mole fraction of sodium dissolved in the electrolyte) with distance,  $x$ , from the anode-electrolyte interface was computed for  $i = 0$  ( $J_{Na}^* = q_0$ ) and  $J_{Na}^* = 0$  ( $i = p_0$ ); for  $K_e X_{Na}^A/\kappa_i = 1$ ; and for  $X_{Na}^A/X_{Na}^C = 10$  and 10,000. These values

Fig. 4. Calculated sodium concentration in the electrolyte as a function of distance from anode:  $\frac{K_e}{\kappa_1} = 250$ ,  $\frac{K_e X_{Na}^A}{\kappa_1} = 1$ ,  $X_{Na}^A = 0.004$ .

are shown in Fig. 4 as  $X_{Na}/X_{Na}^A$  vs.  $x/L$ . It can be seen from the figure that the concentration of dissolved sodium in the vicinity of the anode decreases more rapidly than elsewhere as the cell current is increased.

The efficiency of solid-electrolyte fuel cells has been discussed by Takahashi *et al.* (10). They assumed that the electronic component of the conductivity of the electrolyte is always uniform. Therefore, the electronic current in the electrolyte must decrease linearly with increasing current output.

Similarly, Suski and Kubisz (11) discuss the current efficiency of the electrolysis of molten sodium chloride with a liquid metal after assuming that all sodium atoms in the electrolyte are there by diffusion through the boundary layer. No allowance is made for the equilibrium ionization reaction

in the electrolyte. Thus, their treatment attributes a greater portion of the self-discharge to the diffusion term and gives a linear change of self-discharge with cell current. It can be seen from Fig. 1 and Eq. [25] that the terminal cell voltage predicted by our treatment will not be linearly dependent on  $i$ . The results of our theory are in qualitative agreement with experimental results, and a paper covering the experiments and their comparison with theory is being prepared.

Manuscript submitted Oct. 13, 1967; revised manuscript received April 15, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 19. The work reported in this paper was performed at Argonne National Laboratory, operated by the University of Chicago under the auspices of the U. S. Atomic Energy Commission, Contract No. W-31-109-eng-38.

## Correction

In the paper "Accommodation of Lattice Mismatch at Heterojunctions" by R. S. Mroczkowski, A. F. Witt, and H. C. Gatos which was published in the July 1968 issue of the *Journal* (Vol. 115, pp. 750-752) the Ac-

nowledgment should read as follows: "This work was supported by the Office of Naval Research under Contract Nonr-3963(05) and by the Advanced Research Projects Agency under Contract SD-90."

# Critical Potentials for Pitting Corrosion of Ni, Cr-Ni, Cr-Fe, and Related Stainless Steels

J. Horvath<sup>1</sup> and H. H. Uhlig\*

Department of Metallurgy and Materials Science,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

## ABSTRACT

Critical pitting potentials for the binary Cr-Fe and Cr-Ni alloys in 0.1N NaCl become more noble (correspondingly more resistant to pitting) with increasing Cr content, particularly in the region 25-40% Cr and 10-20% Cr, respectively. The potentials for 57.8% Cr-Fe and pure Cr fall within the transpassive region. Ni containing 3.2% Mo, to the contrary, shows a lower (more active) critical potential; higher per cent Mo-Ni alloys appear to fall within the transpassive region corroding anodically as  $\text{MoO}_4^{--}$  plus  $\text{Ni}^{++}$  without pitting. Ni alloyed with 15% Cr-Fe shifts the potential in the noble direction; Mo alloyed with 15% Cr, 13% Ni stainless steel has a similar but even greater effect. At 0°C, 15% Cr, 13% Ni stainless steel exhibits a potential 0.5v more noble than at 25°C, corresponding to greatly increased resistance to pitting. This shift is less pronounced for the stainless steels containing Mo; in fact, at or above 1.5% Mo, the critical potentials at 0°C are below those at 25°C. In 0.1N NaBr, alloyed Mo shifts the potentials slightly in the active direction, contrary to a marked noble shift in 0.1N NaCl. At 0°C the potentials are still more active. These trends correlate with observed pitting for 15% Cr, 13% Ni stainless steel and the similar alloy containing 2.4% Mo in 10%  $\text{FeBr}_3$  both at 0° and 25°C. Absence of pitting is observed in 10%  $\text{FeCl}_3$  at 0°C for 15% Cr, 13% Ni stainless steel, but not for the similar alloy containing 2.4% Mo, which pits. The over-all results are explained on the basis of competitive adsorption at the metal surface and an effect of temperature on the structure of the double layer.

The concept of a critical potential above which passive alloys are liable to pitting corrosion in halide solutions, but below which they resist pitting, presumably for an indefinite period of exposure, has been described by several investigators. This subject was reviewed, among others, in an earlier paper by Kolotyркиn (1) and briefly by Leckie and Uhlig (2). The latter reported the effect of various environmental factors on the observed critical potentials of 18-8 stainless steel in NaCl solutions.

In view of the electrochemical mechanism of pit initiation and growth, it is concluded that pitting should be observed in aerated halide solutions, e.g., sea water, only in those metals and alloys whose critical potentials lie below the reversible oxygen electrode (approximately 0.8v in air). This is supported by data of Table I listing critical potentials for several metals in 0.1N NaCl. In sea water (approximately 0.5N NaCl) these values (1, 2) would be expected to be a few centivolts more active. Metals such as Cr and Ti, therefore, having critical potentials above 1v successfully resist pitting corrosion in aerated sea water in contrast to the other listed metals with values below 0.8v. The only exceptions that may arise in practice result from crevices at which stagnant electrolyte of higher  $\text{Cl}^-$  concentration accumulates because of electrochemical transport (lowering the critical potential) and, more importantly, of lower pH and dissolved  $\text{O}_2$  concentration causing localized breakdown of passivity (7). In general, the more noble the critical potential, the more resistant is the metal to pitting attack. But how fast pits grow once initiated usually depends on rate of the cathodic reaction, which in aerated NaCl is dependent on rate of  $\text{O}_2$  diffusion and reduction. The over-all rate, in turn, is a function of available total cathode surface (8) and conductivity of the electrolyte.

In this paper, the effect of alloying on the critical potentials of the Cr-Fe-Ni-Mo system in aqueous NaCl solution is reported, first as exhibited by several binary

alloys and then by some of the ternary and quaternary alloys of the usual stainless alloy compositions. Data also include an interesting, perhaps unexpected, effect of temperature on the critical potentials of stainless steels containing alloyed Mo.

## Experimental Procedure

Alloys were prepared in the laboratory from pure components by vacuum melting in dense alumina crucibles. After allowing A or He to enter the furnace the melt was drawn into 7 mm diam Vycor tubes and quenched in water. The ingots were homogenized in A or He, usually at 1050°-1100°C for several hours after which each composition was determined chemically. Ingots of Ni-Cr, Ni-Mo, and Cr-Fe were cold rolled to 0.25 cm, then annealed at 1000°-1050°C and water quenched. The Cr-Fe alloys containing more than 40% Cr were difficult to roll or swage, hence electrodes were machined directly from the homogenized ingot. Ingots of the lower % Cr-Fe alloys and of the stainless steels were swaged to about 0.45 cm diam rods, annealed at 1050°C, and water quenched.<sup>2</sup> All electrodes measured approximately 2 cm long and were either 0.4 cm diam or 0.5 cm wide by 0.2 cm thick. They were mounted as described earlier (2) by a threaded member allowing attachment to a nickel

<sup>2</sup> A subsequent anneal after quenching to avoid intergranular attack was not necessary because of low carbon content (0.001-0.002%).

Table I. Critical pitting potentials for various metals in 0.1N NaCl, 25°C\*

Metal	Critical potential, v	Reference
Al	-0.45	(3)
Ni	0.28	Present data
18-8	0.26**	(2)
Zr	0.46	(1)
Cr	>1.0	(4)
Ti	>1.0	(5, 6)

\* Estimated from data for various  $\text{Cl}^-$  concentrations.

\*\* This value is characteristic of one commercial composition. Higher values are usually obtained for pure alloys as described later in this paper.

wire. The electrode was firmly pressed by means of the wire against a glass tube separated by a Teflon gasket, assuring exposure of only the electrode, Teflon, and glass surface to the electrolyte. The electrodes were abraded to a final 3/0 emery paper, and pickled usually in 15%  $\text{HNO}_3$ , 5%  $\text{HF}$  at  $80^\circ\text{C}$  for 5 min to remove the cold worked surface.

Iron used for the melts was electrolytic grade, first deoxidized then decarburized in  $\text{H}_2$  to approximately 0.001-0.002% C. Chromium was of special high purity obtained from Union Carbide Company. Carbonyl nickel was made available by courtesy of The International Nickel Company. Molybdenum was 99.9% and for some few alloys it was spectroscopic grade, but without differing results.

The electrolyte for most experiments was 0.1N NaCl deaerated with purified nitrogen (passed over Cu at  $450^\circ\text{C}$ ), but without flow of nitrogen during the time of actual measurements. The Pyrex cell, fitted with ground glass joints as described previously (2), was located in an air thermostat maintained at  $25^\circ \pm 0.2^\circ\text{C}$ , which could also be adjusted to constant temperatures higher or lower than room temperature. A Wenking potentiostat was employed in conjunction with a chart recorder. The electrolyte was usually maintained above the Teflon gasket-electrode interface. Several comparative measurements were made holding the electrolyte below the Teflon gasket allowing a meniscus to form at the gas-liquid interface. Under conditions of continuous potential sweep, such critical potentials were found in general to be higher (more noble) than for total immersion. However, for long-time or steady-state conditions, values tended to focus on the same potential for partially or totally immersed electrodes, hence in view of the shorter times needed to achieve steady state under conditions of total immersion, it was this procedure which was usually followed. Pitting was observed to initiate preferably at the Teflon-electrode interface, but was not restricted to such areas in long-time polarization runs.

The experimental procedure was to first polarize the electrode potentiostatically at the least noble potential within the passive region for at least 15 min in order to achieve steady-state passivity. The potential was then advanced in stages of 50 mv, allowing 5 min between each change. Initially the current decreased or remained constant after each potential adjustment, but eventually a steadily increasing current at some potential  $V_c$  indicated the onset of pitting (or of transpassivity). Steady-state values  $V_c$  were obtained subsequently by holding the potential for long times at a fixed value and then observing pitting or the lack of it under a low power microscope. The lowest potential for which pitting could not be observed after a 10-hr or longer period of constant polarization was considered to be the steady-state value  $V_c$ . Reproducibility was in the order of  $\pm 5$  mv.

## Results

**Binary alloys.**—Values of the steady-state critical potentials  $V_c$  for binary Cr-Fe alloys in 0.1N NaCl at  $25^\circ\text{C}$  are shown in Fig. 1. Similar potentials  $V_c$  obtained by changing potentials in 50 mv increments at 5-min intervals were only slightly more noble. Measurements began at 12% Cr because the alloys below this composition exhibited less or no passivity and hence localized breakdown of passivity, leading to pitting, did not occur under present experimental conditions. Values of  $V_c$  rise rapidly in the region of 25-40% Cr indicating appreciably greater resistance to pitting at and above this composition range. Some pitting was observed for the 48.8% Cr-Fe alloy, but not for 57.8% Cr-Fe nor for pure Cr. The latter electrodes corroded uniformly with production of  $\text{CrO}_4^{--}$  (transpassivity).

Although the general shape of the curve is the same, data for Cr-Fe alloys reported by Kolotytkin (1) in 0.1N NaCl show more noble values in the range  $>25\%$

Fig. 1. Critical pitting potentials for Cr-Fe alloys in 0.1N NaCl,  $25^\circ\text{C}$ .

Cr. These differences can probably be ascribed to use of more rapid polarization rates than we used, which shifted potentials prematurely into the transpassive region accompanied by  $\text{CrO}_4^{--}$  formation. The reported observation by Steigerwald (9) that anodic pitting in 0.1N NaCl does not occur on chromized steel surfaces containing above 29% Cr is not readily explained. Perhaps again, lack of steady state conditions in his experiments, which were achieved in our measurements only through long-time polarization runs, may be accountable for the discrepancy.

Values of steady state potentials  $V_c$ , and also of non-steady state values  $V_c$  obtained as described earlier, for Cr-Ni alloys in 0.1N NaCl are shown in Fig. 2. Because Ni itself is passive, measurements for this alloy series began with 0% Cr. Values of  $V_c$  rise to more noble values especially within the range 10-20% Cr. Pitting was observed for all compositions including the maximum 29.4% Cr alloy. Measurements were not extended to higher Ni compositions because a two-phase alloy region forms which complicates interpretation of any potential trend.

The Mo-Ni alloys behave quite differently as is shown by potentiostatic polarization curves of Fig. 3. The corrosion potentials, corrosion behavior, and galvanostatic anodic polarization of these alloys have been reported previously (10). Pure nickel exhibits a normal critical potential  $V_c$  at 0.3v, above which pitting occurs. The polarization curve beyond  $V_c$  is almost linear up to a current density of  $0.4 \text{ ma/cm}^2$  and no oscillations are observed. Addition of 3.2% Mo to nickel lowers the value of  $V_c$  to about 0.2v and the potential increases abruptly just above  $0.1 \text{ ma/cm}^2$ .

Fig. 2. Critical pitting potentials for Cr-Ni alloys in 0.1N NaCl,  $25^\circ\text{C}$ .

Fig. 3. Potentiostatic anodic polarization curves for Mo-Ni alloys in 0.1N NaCl, 25°C.

Alloys containing still larger Mo additions show no break, but exhibit instead an increasing current for small increments of potential beginning at values as active as  $-0.3\text{v}$ . No pitting was observed in alloys of 6.8% or higher Mo content. A long-time run during the initial period of polarization showed only a dark film, probably molybdenum oxide, covering the electrode surface. At about  $0.1\text{ ma/cm}^2$ , current oscillations occur, the peak values of which are indicated in Fig. 3. These cease at about  $0.9\text{v}$ , but the potential continues to rise steeply. It is concluded that  $\text{MoO}_4^{--}$  forms beginning at the potentials corresponding to current oscillations accompanied by periodic breakdown and formation of passivity, until on reaching a still higher potential range, conditions become stabilized. The upturn of potential at  $0.1\text{ ma/cm}^2$  for the 3.2% Mo-Ni alloy is probably also the result of  $\text{MoO}_4^{--}$  formation. The Pourbaix diagram (11) for pure molybdenum, for example, shows that molybdate formation at pH 7 begins at about  $-0.4$  to  $-0.5\text{v}$  in line with the formation of molybdates in the Ni-Mo alloys beginning at somewhat more noble values. Although molybdenum was detected by chemical analysis of the anolyte after polarization of the Mo-Ni alloys, it was not easy to determine its precise valence. However, the probability that molybdate formation is the cause of current oscillations in the  $0-0.9\text{v}$  range is supported by similar oscillations observed for the 15% Cr, 13% Ni stainless steel (Fig. 4) caused by chromate formation in the potential range of  $0.7-1.55\text{v}$ . The Pourbaix diagram for pure Cr (12) at pH 7 shows that  $\text{CrO}_4^{--}$  forms beginning at  $0.5-0.6\text{v}$  which is expectedly lower but in reasonable correspondence with the lower limit of the observed oscillations for the stainless alloy.

#### Cr-Fe-Ni Stainless Steels

The solid solution ternary 15% Cr alloys containing increasing amounts of alloyed Ni were prepared by H. Feller who reported their passive properties in  $1.28\text{N H}_2\text{SO}_4$  (13). The critical potentials for these alloys in  $0.1\text{N NaCl}$  at  $25^\circ\text{C}$  shift in the noble direction as Ni increases (Fig. 5). The shift is not as large as for equivalent Cr additions, but the potential change correlates with the well-known improved corrosion and pitting resistance of high Ni stainless steels in chloride media as compared to the nickel-free or low-nickel stainless steels.

Fig. 4. Potentiostatic anodic polarization curve for 15% Cr, 13% Ni stainless steel in 0.1N NaCl, 25°C.

Kolotyrykin (1) also reported more noble critical potentials for Cr-Ni-Fe stainless steels with increasing Ni content.

Alloyed Mo up to 2.4% in a 15% Cr, 13% Ni stainless steel at  $25^\circ\text{C}$  similarly shifts the critical potential toward more noble values (Fig. 6). The change of potential is relatively greater than for corresponding Ni additions, and accompanies the well-known improved resistance of the Mo-containing stainless steels (e.g. Type 316) to pitting corrosion in chlorides. According to Tomashov *et al.* (14),  $V_c$  becomes still more noble with increasing amounts of alloyed Mo above 2.4%. The quantitative interpretation of data for high Mo stainless steels is complicated, however, by the formation of a multiphase structure. The present alloys, relatively low in Cr and high in Ni, were chosen to preserve a single-phase structure, as was confirmed by metallographic examination.

The potentiostatic behavior of the 1.43% Mo stainless steel is shown in Fig. 7. Here current oscillations begin at the somewhat lower potential of  $0.55\text{v}$  compared to  $0.7\text{v}$  for Mo-free stainless steel (Fig. 4) and reach a similar upper value of  $1.5\text{v}$ . It is likely that both  $\text{MoO}_4^{--}$  and  $\text{CrO}_4^{--}$  form in this potential range.

Hospadaruk and Petrocelli (15) apparently obtained more active values of  $V_c$  in  $0.5\text{N NaCl}$  for commercial 18-8 (Type 301), 18% Cr-Fe and 17% Cr, 13% Ni, 2.2% Mo (Type 316) stainless steel than are indicated

Fig. 5. Critical pitting potentials for 15% Cr-Fe alloys with increasing Ni content, in  $0.1\text{N NaCl}$ ,  $25^\circ\text{C}$ .

Fig. 6. Critical pitting potentials for 15% Cr, 13% Ni stainless steel with increasing Mo content, in 0.1N NaCl, 25°C and 0°C.

Fig. 7. Potentiostatic anodic polarization curve for 15% Cr, 13% Ni, 1.43% Mo stainless steel in 0.1N NaCl, 25°C.

by our values in 0.1N NaCl. Although their data do not support an effect of Cl<sup>-</sup> concentration on  $V_c$  for 18-8, previous data of Leckie and Uhlig (2) show a shift of 0.07v in the active direction on going from 0.1 to 0.5N NaCl. This shift explains a large part of the difference in their results and those presently reported. It should be mentioned in addition that their use of austenitic alloys slowly cooled from the annealing temperature causes some degree of carbide precipitation and chromium depletion along grain boundaries. This effect would tend to artificially shift measured critical potentials in the active direction and, according to our experience, would also appreciably decrease reproducibility of the measurements.

At 40°C, values of  $V_c$  for the 15% Cr, 13% Ni stainless steel approximate those at 25°C. At 0°C, however,  $V_c$  shifts to the markedly more noble value of 0.78v (Fig. 6) which is 0.5v more noble than the value at 25°C. This appreciable shift was first reported for 18-8 by Leckie and Uhlig (2) who made the prediction, later confirmed, that pitting of 18-8 would not occur in 10% FeCl<sub>3</sub> at 0°C because the oxidation-reduction potential of 10% FeCl<sub>3</sub> is below the observed critical potential at this temperature.

Unexpectedly, the addition of Mo to stainless steel is found to reduce the shift in the noble direction occurring at 0°C. For the 1.3% Mo alloy, the values of  $V_c$  at 0°C and 25°C are the same, and for 2% Mo the value at 0°C approximates that for the Mo-free stainless steel at 25°C. At 0°C the 2.4% Mo alloy reaches the transpassive state and no definite critical potential is observed. Instead, current increases continu-

ously with potential and the electrode corrodes uniformly. Pitting can be induced, however, if the alloy is polarized to a value approaching 0.6v. Accordingly the alloy containing 2.4% Mo immersed in 10% FeCl<sub>3</sub> at 0°C, for which the oxidation-reduction potential lies above 0.6v, showed definite pitting after two days, contrary to the behavior of the alloy without Mo which was free of pitting. In similar tests at 25°C, the 2.4% Mo alloy did not pit within two days (it probably would have for longer time exposure), but the alloy free of Mo was pitted.

It was observed (16, 17) some years ago that the molybdenum-containing stainless steels, although relatively resistant to pitting in ferric chloride, tend to pit in much shorter time in equivalent bromide solutions. The critical potentials conform to this observation as shown in Fig. 8. The value of  $V_c$  (0.54v) for the 15% Cr, 13% Ni alloy in 0.1N NaBr at 25°C is 0.26v more noble than in 0.1N NaCl, hence pitting of this composition alloy is less pronounced in bromides than in chlorides. However, on adding molybdenum to the 15% Cr, 13% Ni steel, values of  $V_c$  change only slightly, tending toward more active values. This is in contrast to a marked shift in the noble direction in chloride solutions, hence pitting in >2% Mo stainless steels, as observed, is more pronounced in bromides than in chlorides. At 0°C, the value of  $V_c$  in bromides for the Mo-free stainless steel is definitely below the value at 25°C, opposite to the pronounced more noble shift observed in chlorides. The critical potential tends to decrease still further on addition of 0.43% Mo. Indefinite results are obtained at 1.43% Mo or above, no well established critical potentials being observed. Apparently the transpassive state of the Mo stainless steels is reached at relatively low potentials and the alloys corrode generally without pitting. Pitting, as before, could be induced by polarizing to a potential in the region of 0.6v. These trends of critical potential were confirmed by two-day pitting tests in 10% FeBr<sub>3</sub> solutions, pitting occurring at 0° and at 25°C for the 0%, 1.4%, and 2.4% Mo alloys.

### Discussion

The basic mechanism accounting for the critical potential appears to be one of Cl<sup>-</sup> adsorbing competitively with oxygen of the passive film for sites on the metal surface. As the potential is made more noble, Cl<sup>-</sup> ions move into the double layer of the electrode surface, eventually reaching at the critical potential the concentration required to displace adsorbed oxygen (or an oxygen-H<sub>2</sub>O complex) at favored locations. Adsorbed Cl<sup>-</sup> greatly reduces the overvoltage for anodic dissolution of metal, compared to the situation for adsorbed oxygen, thereby initiating a pit. This is essentially the mechanism described by Leckie and Uhlig (2), the Russian school (1) and by Brauns and

Fig. 8. Critical pitting potentials for 15% Cr, 13% Ni stainless steel with increasing Mo content in 0.1N NaBr, 25°C and 0°C.

Schwenk (18). A different model requiring penetration and breakdown of a supposed metal oxide passive film was described by Streicher (17) and by Hoar, Mears, and Rothwell (19).

According to the adsorption model, the observed more noble values of  $V_c$  for Cr-Fe alloys with increasing Cr content is ascribed to the increasing affinity of the alloys for oxygen compared to  $\text{Cl}^-$ . Since the Flade potential is a measure of passive film stability (20), it also changes with Cr content but in the negative or more active direction. The sharp rise of  $V_c$  at 25-40% Cr shown in Fig. 1 compared to the similar pronounced decrease of Flade potential at 10-30% Cr reported by King and Uhlig (21) suggests, however, that increased stability of the passive film is only one factor affecting  $V_c$ ; the relative affinity of the alloy for  $\text{Cl}^-$  is also a factor.

When  $V_c$  becomes sufficiently noble to overlap the transpassive region,  $\text{CrO}_4^{--}$  plus  $\text{Fe}^{+++}$  are produced as anodic products, and corrosion of the electrode surface may then proceed uniformly with little or no localized attack. Hence the 57.8% Cr-Fe alloy, and probably higher Cr alloys including pure Cr as well, do not pit at the noble potentials corresponding to pronounced rise of current in the potentiostatic curves, but they corrode uniformly instead. Whether pitting occurs in any of the Cr-Fe alloys at some potential within the transpassive region probably depends on whether  $V_c$  is exceeded for a particular alloy, the rate of stirring, and whether the uniform corrosion rate by  $\text{CrO}_4^{--}$  formation exceeds the rate of localized corrosion. Since pitting was observed in some Cr-Fe alloys and also in some of the Cr-Ni alloys polarized well into the transpassive region, it is apparently possible for  $\text{Cl}^-$  to adsorb despite simultaneous  $\text{CrO}_4^{--}$  formation. However, the two ions adsorb competitively and it is expected that for a sufficiently high surface concentration of  $\text{CrO}_4^{--}$ , adsorption of  $\text{Cl}^-$  would be less probable and  $\text{CrO}_4^{--}$  would act as a pitting inhibitor in the same sense as do other anions, e.g.,  $\text{SO}_4^{--}$ ,  $\text{ClO}_4^-$ , and  $\text{NO}_3^-$  (2).

Steigerwald (9) noted that >30% Cr-Fe alloys are resistant to pitting on immersion in 10%  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  at room temperature for 10 days. The measured oxidation-reduction potential of 18-8 in 10%  $\text{FeCl}_3$  inhibited with 5%  $\text{NaNO}_3$  to avoid pitting (which does not affect oxidation-reduction kinetics of  $\text{Fe}^{+++} \rightleftharpoons \text{Fe}^{++}$ ) (22) is about 0.8v (23). Lack of pitting is consistent with reported values of  $V_c$  shown in Fig. 1 equal to or greater than 0.8v at or above approximately 34% Cr.

The same considerations mentioned above apply to increasing values of  $V_c$  for Cr-Ni alloys (Fig. 2). In the 15% Cr-Fe series, alloyed Ni shifts  $V_c$  in the noble direction perhaps because Ni, for one reason, has less affinity for  $\text{Cl}^-$  than does Cr. This is shown by the relative free energies of formation for the metal chlorides (Table II). Molybdenum, similarly, but to a greater extent, shifts  $V_c$  of the 15% Cr, 13% Ni alloy series both because of decreased affinity of Mo for  $\text{Cl}^-$  and because of its increased affinity for oxygen. It is probable furthermore that the greater tendency of the Mo stainless steels to pit in bromide compared to chloride solutions corresponds to a relatively higher affinity of Mo for  $\text{Br}^-$ , although corresponding free energy data are not available.

The situation becomes more complex at low temperatures where the shift of  $V_c$  may be large but

where relative affinities are not expected to differ appreciably from those applying at room temperature. However, the structure of the double layer is probably sensitive to temperature, as for example occurs through relative hydration of ions in the outer and perhaps also the inner Helmholtz layers, as well as through hydration of the passive film itself. In other words, it is plausible that the relatively greater hydration of both the passive film and adsorbed ions (altering their effective radii) at low temperatures changes both concentration of ions in the double layer and their critical separation from oxygen of the passive film, thereby affecting conditions for competitive adsorption. Hence the critical potential is also changed, the direction of which is sensitive to specific chemical affinities, in particular accounted for by alloyed Mo. Any alternative mechanism based on relative ease of penetration of ions through a supposed passive oxide film brought about by similar temperature changes is considered to be less plausible.

#### Acknowledgment

The present research was aided by a grant from the Office of Saline Water, U.S. Department of the Interior. One of us (J. H.) is grateful for the award of a fellowship by the Ford Foundation. H. P. Leckie contributed some of the preliminary data and in particular the final data appearing in Fig. 5.

Manuscript submitted Nov. 29, 1967; revised manuscript received ca. April 30, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 77.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Thermodynamic Properties of the Oxides of Fe, Ni, Pb, Cu, and Mn, by EMF Measurements

G. G. Charette<sup>1</sup> and S. N. Flengas\*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

## ABSTRACT

A "closed system" solid electrolyte electrochemical cell has been designed to investigate the thermodynamic properties of metal oxides. The measurements with this cell are free of mixed potentials arising from nonequilibrium oxygen pressure conditions in the electrode compartments. The oxide systems investigated include Ni-NiO, Pb-PbO<sub>(S,L)</sub>, Cu-Cu<sub>2</sub>O, Cu<sub>2</sub>O-CuO, Fe-Fe<sub>x</sub>O, Fe<sub>y</sub>O-Fe<sub>3</sub>O<sub>4</sub>, Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>, MnO-Mn<sub>3</sub>O<sub>4</sub>, and Mn<sub>3</sub>O<sub>4</sub>-Mn<sub>2</sub>O<sub>3</sub>.

Calculation of equilibria involving oxide phases at high temperatures is often handicapped by the lack of reliable thermodynamic data on free energies. Most of the standard free energies of formation for oxides available in the literature have been calculated from enthalpies and heat capacities measured calorimetrically or from gas-solid equilibrium-type measurements. Quite often the high-temperature heat capacities are obtained by extrapolation from lower temperature data or estimated using semi-empirical rules. Calculations based on calorimetric data are often contradictory and include the rather wide error limits of the various thermal quantities involved in the calculation. For example, the free energies of formation of the oxides PbO, NiO, FeO, and Cu<sub>2</sub>O given by Kubaschewski and Evans (1), have an estimated uncertainty of  $\pm 3$ ,  $\pm 2$ ,  $\pm 3$ , and  $\pm 1$ , kcal/mole of oxide, respectively. Also, the free energies for these oxides found in thermodynamic tabulations by Wicks and Block (2) differ from the average values given by Kubaschewski and Evans (1) by about 1 kcal.

More recently, electrochemical measurements with galvanic cells using solid oxide electrolytes made possible the direct determination of free energies at elevated temperatures with a higher degree of accuracy. Particularly, the pioneering work by Kiukkola and Wagner (3) has demonstrated the usefulness of the solid solutions of calcium and zirconium oxides as selective oxygen anion electrolytes. These electrolytes have been used in solid oxide electrochemical cells to separate the two electrode compartments, to screen the electronic conductivity of the oxides at high temperatures, and to establish electrochemical contacts which are free of junction potentials. The systems investigated so far by this technique include the oxides of Ni (3-15, 21, 23), Fe (3-7, 9-12, 14-22), Cu (3, 4, 8, 12, 23), Pb (4, 8, 12), Mn (6), and many others.

These measurements have been conducted by the "open cell stacked pellet" technique described by Kiukkola and Wagner (3). In this method the indicating electrode consisted of a pelletized and sintered mixture of the metal-metal oxide system under investigation separated from the reference electrode by a pellet of the zirconia-calcia diaphragm. The reference electrode was another metal-metal oxide system of known free energy of formation. Most of these cells were operated under flow using an inert gas common for both electrodes.

Blumenthal and Whitmore (6) used the common open cell stacked pellet technique in a stream of purified inert gas along with a ZrO<sub>2</sub> based electrolyte to measure the systems Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> and MnO-Mn<sub>3</sub>O<sub>4</sub> between 750° and 1050°C. Their ranges of scatter amounted to  $\pm 5$  mv with the latter and  $\pm 7$

mv with the former, approximately two to four times the scatter observed by workers working with more conventional oxide systems.

Rezukhina *et al.* (24) modified the usual technique slightly and operated their cells under vacuum.

Rapp (7) determined the free energy of formation of MoO<sub>2</sub> from Mo using as reference half-cells the systems Fe-Fe<sub>x</sub>O and Ni-NiO along with ZrO<sub>2</sub> (0.15 CaO) as the solid electrolyte. When his cell was constructed simply by pressing together flat metal oxide and electrolyte tablets, he noted that the cell voltage was about 35 mv too low and very dependent on helium flow rate. His later results were greatly improved by fabricating the electrolyte in an H-form and fitting the sintered metal-metal oxide cylinders into each side.

Roeder and Smeltzer (9) mounted their stacked pellets of electrodes and electrolyte independently from the furnace assembly. Finally, Steele and Alcock (4) developed a cell whereby the two electrodes could be kept separate by pressing one side of the electrolyte against the open polished end of an alumina tube. Separate flows of inert gas were maintained within and without the alumina tube, thereby giving each half-cell compartment an independent oxygen potential. It is doubtful, however, whether the electrolyte to alumina contact could make the gas atmospheres over the two compartments truly independent of each other.

Although emf measurements have yielded much higher accuracies ( $\pm 100$ -200 cal) than available calorimetric data ( $\pm 1$ -3 kcal), some measurements on identical systems do not agree among themselves or show an abnormal scatter of points. Several workers have mentioned some practical difficulties encountered while measuring emf's with solid electrolyte cells, especially the variation of the cell emf while varying the rate of flow of inert gas, and the eventual drift in the potential after operating a cell for long periods of time at high temperatures. Such difficulties become particularly severe where the difference in oxygen pressures above the two metal-metal oxide pellets is large or when one of the oxides has a relatively high equilibrium oxygen pressure. This may explain why the typical open cell stacked pellet technique has not been as successful on oxide systems such as Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>, Cu<sub>2</sub>O-CuO, and MnO-Mn<sub>3</sub>O<sub>4</sub> (6).

The free energy for a spontaneous exchange reaction of the type

where M<sub>1</sub>O and M<sub>2</sub>O are the metal saturated phases of the two oxides, may be obtained directly from the emf of the following solid oxide electrochemical cell

The over-all reaction may be realized electrochemi-

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Quebec Iron and Titanium Corporation, Sorel, Quebec, Canada.

cally by considering either cationic or anionic half-cell reactions. Upon passage of two Faradays of electricity a cationic model predicts the following charge transfer operations

(a) at the (–ve) electrode:

(b) at the (+ve) electrode:

(c) oxygen anion transfer through the CaO-ZrO<sub>2</sub> membrane

The over-all cell reaction (A) is:  $M_1 + M_2\text{O} = M_2 + M_1\text{O}$ .

In the anionic model the half-cell reactions are written as:

(a) at the (–ve) electrode:

(b) at the (+ve) electrode:

(c) oxygen anion transfer through the CaO-ZrO<sub>2</sub> membrane:

The over-all cell reaction (B) is:

where  $P''_{O_2}$  and  $P'_{O_2}$  are the partial pressures of oxygen present over the oxide phases M<sub>2</sub>O and M<sub>1</sub>O, respectively. For the derivation it is assumed that the transport number of oxygen anions through the zirconia membrane is unity.

The cell potential  $E_A$ , for cell reaction (A), is given by the well-known expression

$$E_A = - \left[ \frac{\Delta G^\circ_{f, M_1O} - \Delta G^\circ_{f, M_2O}}{2F} \right] \quad [2]$$

where,  $\Delta G^\circ_{M_1O}$  and  $\Delta G^\circ_{M_2O}$ , are the standard free energies for the formation of the oxides M<sub>1</sub>O and M<sub>2</sub>O at the temperature of the measurement. Written in this manner, the cell appears to be a galvanic cell.

The cell potential  $E_B$ , for reaction (B), is given as

$$E_B = - \frac{RT}{2F} \ln \left[ \frac{P'_{O_2}}{P''_{O_2}} \right]^{1/2} \quad [3]$$

The cell in this case appears to be an oxygen concentration cell and the net cell reaction is the transfer of oxygen from the high- to the low-pressure side. The metallic electrodes are taken as truly inert electrodes. The two equations, [2] and [3], represent the same potential

$$E = E_A = E_B$$

only when the oxygen pressures over the oxide phases correspond to the true equilibrium pressures. For this case Eq. [3] may be converted to Eq. [2] by introducing the well-known relationship for the standard free energy of formation of an oxide

$$\Delta G^\circ_{f, MO} = - RT \ln (P_{O_2})^{1/2}_{\text{eq.}} \quad [4]$$

It appears, therefore, that under equilibrium oxygen pressure conditions the half-cell reactions could be described in terms of either the cationic or the anionic processes, and a cell of this type could be considered as either a galvanic or an oxygen concentration cell. However, if the oxygen content of the atmosphere surrounding each compartment is not at equilibrium with the metal-metal oxide system present, the measured

cell potential is not necessarily the thermodynamic potential of the system.

Considering the case of the open cell stacked pellet assembly used by previous investigators, it is unlikely that such cells could be operated under truly equilibrium conditions. For a given "purified" argon atmosphere, the oxygen level in the inert gas should cause either oxidation of the metal or reduction of the oxide. These effects should be more pronounced at the outer edges of the electrode pellets where charge transfer operations are also taking place, and in effect an oxygen potential gradient should be expected to exist within each compartment soon after starting an experiment. Although the magnitude of this effect cannot be estimated, it is evident that the potentials obtained under such conditions are best described as mixed potentials (25), and their departure from the true equilibrium values should depend on the nonequilibrium conditions and the self-adjusting capacity of each metal-metal oxide system.

Preliminary experiments in this investigation with a Pt, Fe<sub>2</sub>O<sub>3</sub>-Fe<sub>3</sub>O<sub>4</sub> open-type electrode have shown the validity of these considerations. The potentials in this system were found to drift with time when the flow rate of helium was kept constant and were also dependent on the flow rate of the gas.

For this reason the measurements reported in this paper were obtained with a "closed cell" designed to operate under truly equilibrium oxygen pressure conditions. These cells have been found to be extremely stable and could function for periods of several weeks without any detectable change in their emf. The present technique was first used on systems which had been successfully investigated previously, such as the Fe-Fe<sub>2</sub>O<sub>3</sub>, Ni-NiO, Fe<sub>2</sub>O-Fe<sub>3</sub>O<sub>4</sub>, and Cu-Cu<sub>2</sub>O, and was then used to obtain accurate data on the more doubtful systems Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>, Pb-PbO, MnO-Mn<sub>3</sub>O<sub>4</sub>, Mn<sub>3</sub>O<sub>4</sub>-Mn<sub>2</sub>O<sub>3</sub>, and Cu<sub>2</sub>O-CuO.

The calcia-doped zirconia electrolyte is a purely ionic conductor only within a specified range of oxygen pressures for each temperature. Measurements, therefore, were obtained only with oxide systems compatible with the oxygen pressure requirements.

Along with the results of the present investigation, data from various other sources are also shown for comparison when necessary. All information derived from the present work is tabulated in the form of free energy equations and sigma-functions.

## Experimental

The most important piece of equipment in the present study was a 24 in. long tube of calcia-stabilized zirconia, commercially available from the Zirconium Corporation of America. The tube can be described as having one closed end (flat) an OD of 1/2 in., an ID of 3/8 in., and a nominal wall thickness of 1/16 in. It is impervious and has been certified helium leak tested to  $5 \times 10^{-7}$  or less standard cc/sec at room temperature by the manufacturing company. In addition, all tubes used in the present investigation were subjected to helium leak detection tests in this laboratory, using a Veeco Mass Spectrometer Leak Detector (Model MS-9). The tubes were of the Zircoa-B grade material for which the following typical chemical analysis is given in weight per cent: 93.5 (ZrO<sub>2</sub> + HfO<sub>2</sub>), 4.8 CaO (10 m/o [mole per cent]), 0.62 SiO<sub>2</sub>, 0.25 MgO, 0.10 Fe<sub>2</sub>O<sub>3</sub>, 0.18 Al<sub>2</sub>O<sub>3</sub>, 0.11 TiO<sub>2</sub>. The material is described as being fully stabilized in the cubic crystal configuration and able to retain its crystal structure, even on repeated cycling, to its melting point (approximately 2625°C). Under experimental conditions of repeated heating and cooling the tubes behaved very well since no cracking due to thermal shock was ever detected, and there was no evidence of chemical attack from the various oxides used as electrode materials. Conductivity measurements on the tube material, performed in this laboratory by Etsell (26), could not detect any oxygen pressure effect on the conductivity

in an oxygen pressure range from 1 to  $10^{-18}$  atm and for temperatures up to  $1080^{\circ}\text{C}$ . In addition, McClaine and Coppel (27) have reported similar observations for the electrolyte containing 95 m/o  $\text{ZrO}_2$  and 5 m/o  $\text{CaO}$ .

Anticipating the results of the present investigation, the emf's measured with these commercially available tubes for the well-known systems Ni-NiO and  $\text{Fe-Fe}_x\text{O}$ , agreed within  $\pm 1$  mv with the results of Kiukkola and Wagner (3), Steel and Alcock (4), and others who utilized zirconia doped with 15 m/o  $\text{CaO}$  which is well established for its ionic behavior. Accordingly, it may be said with confidence that the zirconia material used in the present investigation was behaving like an ionic membrane permeable only to oxygen anions.

The cell design used for the emf measurements is shown in Fig. 1. It consists of two half-cell compartments separated by the calcium oxide stabilized zirconia diaphragm, both sealed under vacuum. The inner reference electrode is the closed-end zirconia tube containing the loosely packed nickel-nickel oxide powder. The top of this tube is closed by a tight fitting bell-shaped Pyrex tube which supports a tungsten electrode connection sealed into the glass. The bell is connected to the zirconia tube with De Khotinsky cement. The nickel electrode is a  $\frac{1}{8}$  in. diameter nickel rod pressed against the nickel oxide powder by means of a heavy spring and an aluminum insulating rod of  $\frac{1}{4}$  in. diameter.

The assembled Ni-NiO half-cell is first evacuated using the side arm tube shown in the diagram, heated to  $100^{\circ}\text{-}200^{\circ}\text{C}$ , and then the tube is flame-sealed under vacuum. The outer half-cell contains either a different metal-metal oxide system or a mixture of two different oxides of the same metal and an inert platinum foil electrode. The loosely packed oxides are contained in impervious thoria or recrystallized alumina crucibles placed inside a flat-bottom quartz tube. The top of this tube is again sealed with De Khotinsky cement to a larger bell-shaped Pyrex tube which supports two tungsten lead wire connectors sealed into glass.

The entire cell is assembled by inserting the Ni-NiO reference half-cell into the empty thoria or alumina crucible, pressing it against the Pt foil electrode, and packing the free volume of the crucible with the oxide mixture under investigation. The zirconia tube is kept tightly against the platinum foil by means of a second

Fig. 1. Closed cell for emf measurements

metal spring inserted between the inner and the outer bells. All electrode connections are silver soldered. Finally, the outer bell is cemented in place by melting the De Khotinsky cement in the ring container shown on the diagram, and the cement is allowed to solidify while pressing the outer bell against the spring. Then the outer compartment is also evacuated from a side arm tube and flame-sealed under vacuum.

For some of the more volatile systems, like  $\text{PbO}$ , vaporization losses could be minimized by sealing the compartment while under a pressure of argon gas not exceeding 100 mm Hg. The upper part of the cell, where the cement seals are located, remains at room temperature during measurements, as only the bottom 8 in. are in the furnace.

Cell runs below  $1150^{\circ}\text{C}$  were conducted in chromel wire wound electrical furnaces, controlled to  $\pm 1^{\circ}\text{C}$  using temperature controllers and thermocouples. Electric field effects were eliminated by shielding the interior of the furnaces with grounded Inconel tubing. Cell temperature measurements were taken on the outer wall of the cell at the level of the Ni-NiO powder using calibrated Pt-13% Rh thermocouples. Cell potentials were measured using a calibrated Radiometer pH meter connected to a scale expander that allowed the emf's to be read to  $\pm 0.1$  mv. All potential readings were corrected for thermal emf's, measured separately.

The runs which included measurements up to  $1300^{\circ}\text{C}$  were conducted in a platinum wound furnace of large heat capacity without metal shielding. Reading the emf's, in this case, required a temporary power shut-off. However, less than  $1^{\circ}\text{C}$  was lost during this time. The high-temperature version of the cell used in this furnace required only one modification: replacement of the outer quartz tubing with a closed-end impervious alumina tube. In addition, both compartments were evacuated and partially filled with argon before sealing. Radiation baffles and water cooling were also required at the top.

The elimination of mixed potentials in the "closed cell" technique can be attributed to two main factors:

1. The use of hermetically sealed half-cell compartments, where oxygen can reach an equilibrium pressure approaching as closely as possible that of the M-O system in the compartment. To this end a large excess of metal-metal oxide powder mixture is present to ensure that the system is capable of adjusting itself to the equilibrium conditions at the temperature of the electrodes. Thus, any excess oxygen due to desorption or diffusion through the quartz container should combine with the excess metal present.

2. The use of a "buried Pt electrode" imbedded at the bottom of the thoria crucible in the outer compartment and pressed directly against the zirconia electrolyte.

This technique gave a rapid cell response and highly stable potentials over periods of times occasionally exceeding two to three weeks.

## Results and Discussion

The results of the present investigation are plotted in Fig. 2 to 10, indicating at times the order in which the readings were taken (e.g. Fig. 3, 7-9). Least-squares lines were computed using a standard computer program and drawn through the points. The equation for each least-squares line is given in Table I along with the maximum deviation of the experimental results from the calculated line (i.e., the range, in  $\pm$ mv). In Table I may also be found the values for the free energies of oxidation as a function of temperature for all the systems investigated.

Data from a number of investigators have also been plotted along with our results, being converted when necessary using the emf measurements from the present investigation. The purpose in this listing is not to establish a complete review of thermodynamic values

or to search for wide variations in previously published data, but simply to compare the results from the present investigation with those that have been obtained more recently or quoted more liberally.

**Ni-NiO system.**—The system investigated represents the oxygen saturated metal phase in equilibrium with the metal saturated oxide phase. However, Ni-saturated NiO is known to be stoichiometric (28), and solid Ni metal dissolves very little oxygen until 1438°C (29), which contributes to making the Ni-NiO system ideal as a reference electrode for use with solid electrolytes at temperatures between 500° and 1400°C. The present results are in reasonably good agreement with other data. The standard free energies of formation of NiO calculated from thermochemical data have tended to agree increasingly with equilibrium measurements in the last few years, e.g., ±200 to ±500 cal at 1000°C (30, 2, 31-33) as shown in part by Chipman (34). The values of Coughlin (35) and Kubaschewski and Evans (1), however, are out by as much as 1.7 kcal at 1000°C.

The materials used in the present work were high-purity INCO nickel analyzing 99.9%+ Ni and NiO powder of Fisher Certified Reagent grade. The two were mixed in roughly equal amounts, added to the ZrO<sub>2</sub>+CaO tube and lightly pressed in the bottom. The cell described in Fig. 1 was operated with pure oxygen flowing in the outer compartment and hence the standard free energy of formation of pure NiO from pure Ni and oxygen at 1 atm was directly obtained. The results shown in Fig. 2 indicate the high accuracy (±50 cal) of the present investigation. The measurements obtained herein are in excellent agreement with Alcock and Belford (8) and Elliott and Gleiser (36). The Ni-NiO system was therefore chosen as a standard reference electrode for nearly all subsequent emf determinations.

**Pb-PbO system.**—The system investigated represents the oxygen saturated liquid metal phase in equilibrium with the metal saturated oxide phase. According to Hansen (29) PbO is a stoichiometric compound up to its melting point, reported variously as being

from 885° to 897°C (1, 2, 37-38). Richardson and Webb (39) reported that molten lead dissolved up to 1.04 a/o (atomic per cent) O at 900°C, 1.79 a/o O at 1000°C, and 2.89 a/o O at 1100°C. On the other hand, Barteld and Hofmann (40) and Sano and Minowa (41) independently reported different solubility values, e.g., 0.12 a/o O at 900°C, 0.10 a/o O at 800°C, and 0.04 a/o O at 700°C. Hence, the solubility of oxygen in liquid lead is still unresolved.

In view of the relatively high vapor pressures of Pb and PbO at elevated temperatures, it was believed that the present technique would be particularly suited for the determination of the free energy of formation for PbO from pure Pb and oxygen. A mixture of yellow PbO (Fisher Certified Reagent) and of Pb (British Drug Houses Certified) was placed inside the ZrO<sub>2</sub> tube and pure oxygen flowed in the outer com-

Fig. 2. Temperature dependence of emf for the Ni, NiO system

Fig. 3. Temperature dependence of emf for the Pb, PbO system

partment. In place of the Ni rod, an iridium wire served to establish electrical contact with the Pb-PbO since Ir has been shown to be insoluble in molten Pb (39).

Our data from three runs are shown in Fig. 3 along with those of several other investigators. The free energies of formation of solid PbO are available from several sources both thermochemical (1, 2, 42) and electrochemical (8). These have tended to agree well recently ( $\pm 150$  cal at  $1000^\circ\text{K}$ ) with few exceptions (1). On the other hand,  $\Delta G^\circ_f$  values for liquid PbO are in complete disagreement. On considering the results of Kvyatkovskii *et al.* (43), Delimarskii and Andreeva (44), Wicks and Block (2), JANAF (42), Elliott and Gleiser (36), Sridhar and Jeffes (45), and Matsusita and Goto (12), many of which are plotted and compared in Fig. 3, one finds a general spread of values of at least 2000 cal. For solid PbO, the results obtained are in good agreement with Belford and Alcock (8, 13), and with Wicks and Block (2).

**Fe-Fe<sub>x</sub>O system.**—The system represents the iron saturated Wüstite phase, as defined in the Fe-O phase diagram (46, 47). The triple point, where the Fe, Fe<sub>x</sub>O, and Fe<sub>3</sub>O<sub>4</sub> phases coexist was located by Vallet and Racciah (47) to be at  $611^\circ\text{C}$ . Thus, the system was investigated in the temperature range  $630^\circ\text{--}1270^\circ\text{C}$ , using the high-temperature cell arrangement in a Pt furnace. The starting materials in the outer compartments consisted of a mixture of electrolytic iron powder (Fisher) to which a small amount of Fe<sub>2</sub>O<sub>3</sub> powder (Fisher Certified) had been added. The results of this investigation are plotted in Fig. 4.

In general, the Ni-NiO/Fe-FeO cell has always been the most successful with solid electrolytes, as can be seen from the excellent agreement with several other publications (3, 4, 7, 9, 10, 21) with the exception of the data given by Wicks and Block (2).

**Fe<sub>2</sub>O-Fe<sub>3</sub>O<sub>4</sub> system.**—The system investigated represents the oxygen saturated Wüstite phase in equilibrium with metal saturated magnetite, as defined by the Fe-O phase diagram (46).

The magnetite (Fe<sub>3</sub>O<sub>4</sub>) was prepared by reducing Fe<sub>2</sub>O<sub>3</sub> (Fisher Certified) in a stream of CO/CO<sub>2</sub> (1:4) at  $900^\circ\text{C}$  for  $1\frac{1}{2}$  hr. The resulting material, crushed to  $-200$  mesh, was 99.9% magnetic. A mixture of this magnetite and of electrolytic iron powder (Fisher) was prepared in such proportions as to yield equal weights of FeO and Fe<sub>3</sub>O<sub>4</sub> at  $800^\circ\text{C}$ . The emf values (9, 11, 21), however, do not show as high a degree of agreement as might have been expected in this system, particularly at the higher temperatures. The occur-

Fig. 4. Temperature dependence of emf for the system Ni, NiO-Fe, FeO.

Fig. 5. Temperature dependence of emf for the system Ni, NiO-FeO, Fe<sub>3</sub>O<sub>4</sub>.

rence of mixed potentials in the other work is a strong possibility. Other data have also been plotted for comparison (46).

**Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> system.**—The system represents the oxygen saturated magnetite phase in equilibrium with hematite, as defined in the Fe-O phase diagram.

Magnetite, as produced in the manner described above, was mixed in equal proportion with hematite powder (Fe<sub>2</sub>O<sub>3</sub> Fisher Certified) and added to the ThO<sub>2</sub> crucible. The measurements obtained are plotted in Fig. 6. Although the range ( $\pm 1.5$  mv) is wider compared to the other systems investigated presently, the accuracy achieved by this investigation on the Fe<sub>3</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> system is greater than anything hitherto attainable in the temperature region of  $700^\circ\text{--}1100^\circ\text{C}$ . Except for Blumenthal and Whitmore's work (6), no other emf results are available. Mixed potentials are strongly suspected in the latter's investigation, and the disagreement with the present results is significant. Norton (48) and Salmon (49) used oxygen dissociation pressure measurements to obtain their values.

Because of the slow rates of reoxidation of magnetite, particularly after sintering above  $875^\circ\text{C}$ , a long

Fig. 6. Temperature dependence of emf for the system Ni, NiO- $\text{Fe}_3\text{O}_4$ ,  $\text{Fe}_2\text{O}_3$ .

time was required to return to the equilibrium pressure of oxygen in a closed system on lowering the temperature. In practice, a much shorter period of time was required to obtain equilibrium with an increasing temperature (decomposition of  $\text{Fe}_2\text{O}_3$ ). Hence, most of the measurements reported with this system were obtained on increasing the temperature.

It should be noted that free energies tabulations for the Fe-O system based on thermochemical information (1, 2, 36, 50, 51) differ from equilibrium measurements by 100-500 cal for  $\text{Fe}_x\text{O}$  and  $\text{Fe}_3\text{O}_4$ , and by as much as 1000 cal for  $\text{Fe}_2\text{O}_3$ .

**Cu-Cu<sub>2</sub>O system.**—The Cu-O phase diagram (52) indicates that the phases  $\text{Cu}_2\text{O}$  and CuO are of fixed composition up to their melting points and that Cu dissolves a negligible amount of oxygen below 1065°C.

An equal amount of Fisher Certified cuprous oxide powder was mixed and added to a crucible in the outer compartment. The results appear in Fig. 7 along with

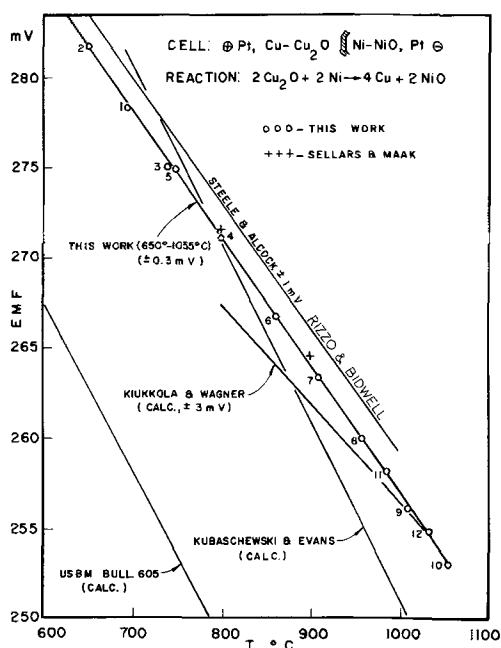

Fig. 7. Temperature dependence of emf for the system Ni, NiO-Cu,  $\text{Cu}_2\text{O}$ .

other emf (3, 4, 23, 65) and calorimetric (1, 2, 66) work. The agreement is fairly good among several values, particularly between those of (4), (23), (65), (66) and of the present investigation. Again the data found in Bulletin 605 of the U.S. Bureau of Mines and in Kubaschewski and Evans' tabulations (1) are in disagreement with the present work.

The recent calorimetric work by Mah *et al.* (66), where new Cp values have been obtained, shows a remarkable agreement with the equations given in Table I, the maximum deviation being 32 cal between 900°C and 1300°K for  $\Delta G^\circ_f$ . The cell design used by (65) was in some aspect similar to the present one.

**$\text{Cu}_2\text{O}$ -CuO system.**—Because of the high equilibrium pressures of oxygen involved, the present technique was particularly well suited. The cupric oxide utilized was of the Fisher Reagent grade. A very high degree of accuracy and reproducibility is evident from the plot of our experimental values in Fig. 8. The agreement amongst various workers (48, 53, 54, 55, 64) is also reasonably good. The data given in Bulletin 605 of the U.S. Bureau of Mines (2) are again in disagreement with the present work.

Mah's (6) values for the  $\Delta G^\circ_f$  of CuO again agree very well with the present ones. Between 900° and 1300°K the maximum difference is 57 cal/mole CuO. The work of Bidwell (64) also compares very well with the present results, and his experimental technique was similar in part.

**MnO-Mn<sub>3</sub>O<sub>4</sub> system.**—Although each of the previous metal oxide systems has a well-defined metal-oxygen phase diagram, this is not the case for the Mn-O system. Considerable disagreement exists concerning the stoichiometry of the various phases at different temperatures (56-60). It is not the purpose of this paper to suggest a Mn-O phase diagram, but simply to determine the free energy changes occurring from one oxide phase to the next, providing that there is no ambiguity as to which phases are involved. It is widely known that MnO,  $\text{Mn}_3\text{O}_4$ ,  $\text{Mn}_2\text{O}_3$ , and  $\text{MnO}_2$  exist as stable crystalline phases and can be converted to one another by suitable adjustments of temperature and oxygen partial pressure.

The manganese oxide with the approximate Mn:O ratio of 1:1 was prepared by decomposing  $\text{MnCO}_3$  (Fisher Reagent grade) in vacuum at 475°C. The manganese oxide corresponding to the approximate composition  $\text{Mn}_3\text{O}_4$  was prepared by decomposing  $\text{MnO}_2$  (Baker Analyzed Reagent) at 850°C in vacuum for 3 hr. Equal amounts of MnO and  $\text{Mn}_3\text{O}_4$  were mixed

Fig. 8. Temperature dependence of emf for the system Ni, NiO- $\text{Cu}_2\text{O}$ , CuO.

Fig. 9. Temperature dependence of emf for the system Ni, NiO-Mn, Mn, Mn<sub>3</sub>O<sub>4</sub>.

and packed in a crucible in the outer cell compartment. The two oxide phases were held long enough at each temperature to allow the emf values to stabilize completely and the equilibrium compositions to be established, the MnO phase being saturated with oxygen and the Mn<sub>3</sub>O<sub>4</sub> phase with Mn. Approaching the various temperature settings from opposite directions yielded a straight line, as illustrated by the results of this investigation in Fig. 9. Next to the Cu-Cu<sub>2</sub>O and Cu<sub>2</sub>O-CuO systems, the present MnO-Mn<sub>3</sub>O<sub>4</sub> system appears to be the most successful of those investigated. This is in contrast with the scatter evident in the emf results of Blumenthal and Whitmore (6), where mixed potentials are suspected and with the wide variations in other investigations (2, 58). The more recent results of Kim, Wilbert, and Marion (61), using a cobalt oxide resistance wire to measure low oxygen pressures in a gas, leads one to wonder whether metastable Mn-O phases are involved, or whether their method itself was subject to large errors.

**Mn<sub>3</sub>O<sub>4</sub>-Mn<sub>2</sub>O<sub>3</sub> system.**—Mn<sub>2</sub>O<sub>3</sub> powder was prepared by heating MnO<sub>2</sub> (Baker Analyzed Reagent) in air at 880°C for 18 hr. The resulting sinter was ground to -325 mesh and mixed with an equal amount of Mn<sub>3</sub>O<sub>4</sub> powder prepared as previously described. The two manganese oxides were packed in a crucible in the outer compartment of the cell and held at six different temperatures for periods of time up to a week. The emf response appeared to be very sluggish compared to previously described systems. Figure 10 is a plot of emf against temperature for the present Mn<sub>3</sub>O<sub>4</sub>-Mn<sub>2</sub>O<sub>3</sub> system. As may be ascertained from Fig. 10, a great deal of disagreement exists between authors concerning this system (55, 58, 61-63). From the work of Schmahl and Stemmler (62) at higher temperatures, it would seem possible that one of the two phases involved is a metastable one, thus explaining the scatter in the various data, particularly those obtained by the transportation method (55) at low temperatures. On the contrary, the present method allows for equilibration over long periods of time at high temperatures and should be considered the most accurate.

**Sigma-function calculations.**—The present experimental values have been combined with calorimetric data to calculate the sigma functions for all the metal-oxygen systems investigated. The sigma-function calculations are given in Table II.

By the nature of its derivation, the plot of sigma against 1/T should always give a straight line. Any

Fig. 10. Temperature dependence of emf for the system Ni, NiO-Mn<sub>2</sub>O<sub>3</sub>, Mn<sub>3</sub>O<sub>4</sub>.

deviations from linearity would indicate either (a) errors in the evaluation of the electrochemical potentials determined herein, or (b) experimental errors in the existing heat capacity data and in their temperature dependence, or both. A survey of the results given in Table II indicates that the functions are linear with fairly low standard deviations. The largest standard deviation can be found with the Pb-PbO<sub>(s)</sub> system, probably because of low accuracy in the heat capacity data.

The integration constant  $\Delta H^\circ$  of the sigma-function calculation can be used directly to calculate the standard heats of formation at 298°K. The heats of formation obtained in this manner have been compared with calorimetric values listed in Kubaschewski and Evans (1), Wicks and Block (2), and Elliott and Gleiser (36) and are listed in Table III. The agreement is excellent in most cases except for the Pb-O and the Fe-O systems which are not shown in the table. For the latter the calculation involves the numerous phase changes occurring in this system, and it is also possible that, due to the long extrapolations involved, small discrepancies in the heat capacity data could have a pronounced effect in the calculation of the heats of reactions at 298°K. The recent value of  $-40,830 \pm 300$  cal/mole published by Mah *et al.* (66) for  $\Delta H^\circ_f$  (Cu<sub>2</sub>O) compares well with the present value of  $-41,030$  cal/mole at 298°K.

### Conclusions

An emf technique, using a solid electrolyte tube of 10 m/o CaO-stabilized zirconia, has been developed to measure the pressure of oxygen above two metal-oxygen phases in equilibrium, where two half-cells are allowed to build up their own equilibrium oxygen pressure independently. This technique eliminates mixed potentials and provides for reproducible, accurate, and stable emf readings over periods of several weeks. Furthermore, it provides truly static measurements, thus allowing equilibrium conditions to be established.

The emf measurements have yielded accurate standard free energies of formation of NiO (911°-1371°K), PbO (772°-1371°K), FeO (903°-1540°K), Cu<sub>2</sub>O (924°-1328°K), and of Fe<sub>3</sub>O<sub>4</sub> (949°-1272°K), Fe<sub>2</sub>O<sub>3</sub> (967°-1373°K), CuO (892°-1320°K), Mn<sub>3</sub>O<sub>4</sub> (992°-1393°K), and Mn<sub>2</sub>O<sub>3</sub> (884°-1126°K) from the lower metal oxides. The data are compared with previously reported measurements, and the accuracy of the previously existing data is discussed in the light of the present results. Sigma-function calculations substantiate the claim of accuracy for the present work.

## The Experimental Requirements for Making Accurate High Pressure Conductance Measurements on Aqueous Solutions with Pt-in-Glass Cells

A. B. Gancy\* and S. B. Brummer\*

*Tyco Laboratories, Inc., Waltham, Massachusetts*

### ABSTRACT

Experimental procedures are described for obtaining accurate high pressure coefficients of conductance of dilute aqueous solutions of strong electrolytes ( $\geq 2$  mM) in the ranges 1-2250 atm and 3°-55°C. Procedures are developed such that an over-all accuracy of 0.1% in the high pressure conductance is obtained. It is shown that in order to obtain reproducible and accurate results great attention must be paid to the stability of the electrode seal through the body of the conductance cell. Pt foil of suitably small cross section has been sealed to the Pyrex cell wall using soft glass and ten intermediate grades. It is shown that this produces an electrode seal which is leak-free and stable over the entire range of temperature and pressure studied. Also incorporated into the seal is a multiple-wire cage design which imparts high mechanical stability to the external electrode terminals. A capillary cell is described which is compensated for anisotropic distortion under pressure and which is suitable for precise measurements with solutions more concentrated than 5 mM. It is shown that the cell constant variation with pressure, and the effects of anisotropic distortions of the electrodes under pressure, can be determined to within 0.02% for this and other compensated electrode configurations. The errors arising from contamination of the solutions with impurities are described. It is shown that a typical weak electrolyte impurity must be kept below ~1% of the (~2 mM) salt concentration if an over-all accuracy of 0.1% is to be attained at 2000 atm. Similarly, the concentration of dissolved O<sub>2</sub> must be maintained below ~50  $\mu$ M for a 2 mM salt solution.

The present research effort is directed at exploring very accurately the temperature and pressure coefficients of the limiting ionic conductance of aqueous solutions. The aim is to develop a treatment of the limiting ionic mobility involving transition state parameters along the lines suggested earlier (1-4). Experimentally, this involves the accurate determination of the conductance of dilute (1-20 mM) salt solutions in the range 0°-55°C and 1-2300 atm. For the mean-

ingful interpretation of the activation parameters, an accuracy of 0.1% is required.

Since ionic conductance is one of the most characteristic properties of electrolyte solutions and can readily be measured with high accuracy (~0.01%), this would not appear to be a difficult experimental problem. At high pressures, however, despite much interest, the data in the literature are very discordant and discrepancies of up to several per cent have been

\* Electrochemical Society Active Member.

observed, even in simple cases.<sup>1</sup> Some of the reasons which have been suggested to account for this variability are solution contamination<sup>2</sup> and variations of cell constant with pressure (10-12). In the present work we have explored these sources of errors and have shown how to eliminate them to the extent that the required 0.1% accuracy can be attained.

### Experimental

Much of the substance of this communication represents the testing of experimental procedures; these are described in the results section. The general procedures of containing the pressure and of measuring resistances (<0.05%) were described earlier (3). As before, pressure was generated by pumping oil with a hydraulic pump (Pressure Products, Inc., Hatboro, Pennsylvania). A significant improvement is in the measurement of pressure ( $\pm 3$  atm) on a Bourdon tube gauge (Heise Gauge Company, Newtown, Connecticut). Pressure vessels were thermostated to better than 0.01°C, although the absolute temperature was known only to 0.02°C.

Solutions were made from recrystallized salts in ion-exchange water (resistivity  $\geq 10$  megohm-cm). Before use, they were carefully deaerated. The high pressure conductance cells were filled by manipulating the solutions with helium gas in a closed, glass apparatus. These cells were inverted into Pyrex cups containing instrument grade mercury. The Hg functioned as the pressure transmitting fluid and prevented solution interaction with the hydraulic fluid.

### Results and Discussion

**High pressure Pt-in-Pyrex electrode seals.**—As will become apparent, a major reason for the irreproducibility and inaccuracy of high pressure conductance measurements is the inadequacy of electrode seals. Some of the earliest investigations of high pressure solution conductance utilized Pt-to-glass electrode seals (13, 14). Before the development of Pyrex, the glass used in making the cells was probably a Jena glass. Specific mention of glass type was made by Körber (15) who used "Jena Gerateglas." The thermal expansion coefficients of Pyrex, Gerateglas, and Pt are 3.3,  $\sim 4.8$ , and  $9.0 \times 10^{-6}/^\circ\text{C}$ , respectively, so that the modern day use of Pyrex instead of Jena glass should result in only a very slightly poorer seal. Yet, no mention was made in those papers of problems in obtaining accurate and reproducible conductance data originating from the Pt-glass seal. More recently, Hamann *et al.* (9-16) have demonstrated the use of conventional Pt-glass conductance cells to 3000 atm, with no mention of electrode seal problems. Most of the aims of our study can be achieved by working at pressures below 3000 atm and there seemed no reason not to use the high pressure conductance cell employing the conventional Pt-Pyrex electrode seals that have so frequently been described (2, 3, 9, 13-17).

The first results were disappointing. Specifically, it was found that after a pressure cycle the solution resistance did not return to the initial 1 atm value to within the desired 0.1%. Deviations of several tenths of a per cent were not uncommon, and they were generally in the direction of increasing resistance. In addition, the glass around the Pt was often observed to have cracked after a high pressure cycle and we were sometimes able to detect droplets of hydraulic oil inside the cells, especially after operating at the higher temperatures. Another problem was that the electrode seals were not stable to routine handling and electrodes often parted from the surrounding glass. It was evident that while such seals might have been adequate for the early investigations, where

highly dilute solutions were rarely examined, they are not acceptable for an accurate study. It is also apparent that some of the irreproducibility in the literature (5-7) may have been due to problems associated with Pt-glass electrode seals.

Several alternatives to the conventional Pt-in-Pyrex cell are available: One possibility would be to use soft glass instead of Pyrex. This is not generally favored for, although the use of soft glass may have solved the electrode seal problem, the contamination of dilute solutions through attack of the glass is expected. Zisman (8) did not use a Pt-glass seal but projected the electrodes through a layer of oil covering the electrolyte. The oil also functioned as the pressure transmitting medium. This method has been criticized (5, 8, 9) on the grounds that contamination may be introduced into the solution *via* the oil. Horne *et al.* (18) used a similar method. One possibility, following Jamieson (19), is to use a Teflon-bodied cell. This has the advantage that the electrode seals survive high pressures, due to the high compressibility of Teflon and consequently its high deformability around the Pt. On the other hand, this same high deformability leads to considerable uncertainties in knowing the cell constant as a function of pressure (10). Ellis (6) sought to solve this problem by using a Teflon-bodied cell in which the electrodes were fixed not to the body of the cell, but to a glass former inside the Teflon cylinder. To avoid distortion of the electrodes under pressure, electrical connection was made by passing fine platinum wire through the Teflon wall. The pressure coefficient of the cell constant was then largely determined by the compressibility of the glass, which is well-known. Although this technique would appear to be adequate, the results still showed considerable scatter (up to 0.3%). A variation on this design has recently been described (22).

Ovenden (11) took a different approach. He used Pt-in-Pyrex cells but sought to overcome the difficulties with the electrode seals. As is well-known, a channel is left between the Pt and the Pyrex, because of different coefficients for contraction on cooling. On compression and decompression, this channel closes and opens again ("breathes"). To narrow the channel, Ovenden sealed very thin Pt foil (5 x 40 mils) within the glass instead of the more usual heavier wires. This narrower channel should mitigate erratic changes in solution concentration. Rigidity was effected by joining the 5 mil foil to stout (40 mil) Pt wires which projected from the glass. An over-all accuracy of 0.1% was claimed.

An effort therefore was made to reproduce Ovenden's seal. Instead of using 5 x 40 mils foil, we used 10 mil wire having 4 mm sections pressed into 6 x 12 mil foil. These, being smaller, should function even better than Ovenden's foil. Four such wires were used per electrode. They were fashioned into a cage which terminated at the electrode inside the cell and at the electrical lead terminal outside (Fig. 1a). This cage provides for seals on fine wires, while at the same time it maintains a low electrical impedance. It has the particular advantage that any stresses inevitably applied to the external wire, in making electrical connections, etc., cause the wire to bend but not to break. Such stresses are not transmitted to the glass, and the annoying problem of glass cracking and chipping so common to ordinary seal designs is avoided. Using this design, we have also never experienced a cracking of the glass around the seal upon the application of pressure, a frequent occurrence in our experience with other configurations, including Ovenden's.

This seal showed no signs of oil intrusion over the experimental ranges 3°-55°C and 1-2250 atm. The reproducibility of the conductance data was also much improved. However, we noticed a downward drift of the resistance in one or more of the five cells used per experiment. This drifting phenomenon was ob-

<sup>1</sup> Much of the early work has been reviewed by Hamann (5). The discordant nature of the results in the literature has been brought out by Ellis (6) and by Horne *et al.* (7).

<sup>2</sup> Hamann (6) comments on solution contamination by the pressure-transmitting oil in Zisman's work (8), and the reaction of electrolytes with the pressure-transmitting Hg in the work of Buchanan *et al.* (9).

Fig. 1. Improved Pt-glass electrode seals; (a) cage structure for mechanical stability; (b) graded glass seal.

served most often at the highest temperatures ( $55^{\circ}\text{C}$ ) and was never experienced below  $25^{\circ}\text{C}$ . Exhaustive tests showed that such drifting was not due to localized heating within the cell during the electrical measurements. In one cell which contained three electrodes, such that any of three electrode pairs could be measured, it was found that one pair yielded constant resistance values while the other two pairs drifted. Thus, the drifting was not caused by accidental contamination of the cell solution.

It was observed that when the filled conductivity cells utilizing the Ovenden-type Pt-Pyrex seals were allowed to stand on the laboratory bench for several days, a salt crust appeared at the external seal. Correspondingly, the level of the Hg sealant rose within the cell neck. This indicates that there is capillary action past the seal. This same leaking could occur during the experiment itself within the oil-filled pressure vessel. In this case, however, instead of the solution's evaporating, it could creep along the glass cell exterior. Leaking could therefore result in a parallel impedance to the solution which would lower the measured cell resistance and would probably vary in an unpredictable fashion as the exterior solution film becomes more or less widespread. To test this parallel impedance hypothesis, a series of badly behaving cells was removed from the pressure vessel and given a thorough external washing. Resumption of the measurements showed the complete absence of the drifting phenomenon and a general increase of each cell resistance.

Because the seal in Ovenden's work was made around larger foil, the problem should have been more severe. He did not report the effect, however. We believe that this was because he used a gas rather than an oil hydraulic fluid. Hence his leaking electrolyte would evaporate rather than accumulate. His Pt-in-Pyrex seals were evidently adequate for gas-filled pressure systems. They can also be used for oil-filled systems, but this entails periodic removal of the cells for washing. It should be mentioned that Howard (12), who used an oil-filled pressure system, refills his Pt-Pyrex cells after each and every pressure cycle, although the reason for this enormously time consuming process is not given. A more acceptable solution is to lessen even further the clearance between the Pt and the glass. This can be accomplished by using very small cross-sectional Pt, which is very hard to work with, or with graded glass seals.

We have successfully sealed 3 x 20 mil foils through 10 grades of glass from Pyrex on the inside of the cell, to soft glass on the outside. The linear coefficient of expansion of soft glass ( $8.8 \times 10^{-6}^{\circ}\text{C}^{-1}$ ) compares closely with that of Pt ( $9.0 \times 10^{-6}^{\circ}\text{C}^{-1}$ ). The 3 x 20 mil foil can be routinely sealed without cracking of the intermediate glasses on cooling. Although these materials are compatible with respect to thermal expansion, however, there is still an appreciable divergence between the compressibilities of Pt and glass.

For this reason, a ribbon of foil wider than about 20 mil often failed under pressure. This size foil worked well up to 2250 atm, the highest pressure employed. The seal is shown in Fig. 1 (b). As before, the cage design is retained at the outside of the seal to avoid putting mechanical stresses on the seal during handling and electrical connection. Cells with these electrode seals showed no salt crust or rise in the level of the mercury sealant during standing, filled, for several weeks. Resistances were steady during measurement and, after a pressure cycle, the initial value is almost invariably reproduced to within 0.1% (Fig. 2). Such stability was found at all experimental temperatures and over the period of several weeks required to carry out 10 pressure cycles. We emphasize this long-term stability, since there is a major saving of time if we can avoid periodic washing or refilling of the cells.

We have demonstrated the reproducibility of given cells in terms of self-consistency. A more convincing test would be to show how well different cells agree with one another. Figure 3 shows the pressure coefficients of conductance for RbCl at  $20^{\circ}\text{C}$ . All five cells contained the same 6.4 mM solution. The consistency is excellent and within the 0.1% required. This result is typical of literally hundreds of data points and is in sharp contrast with the aforementioned discrepancies in the literature (5-7).

Another convincing test of cell performance is to measure the concentration dependence of the pressure coefficient of conductance in a group of cells. We have shown that the resistance ratio  $R_i/R_P$  should vary linearly with  $\sqrt{C_i}$  and that the slope of this relation should agree with that calculated from the Debye-Hückel limiting (21) law. Figure 4 shows plots for LiCl solutions at  $25^{\circ}\text{C}$  at 1000 and 2000 atm. We see that deviations of the experimental points from linearity are well within 0.1% and that the  $R_i/R_P$

vs.  $\sqrt{C_1}$  relations are appropriately linear. The slopes are 0.026 and 0.054 (liters/equiv.)<sup>1/2</sup> at 1000 and 2000 atm, respectively, in excellent agreement with those calculated from the limiting law, 0.031  $\pm$  0.005 and 0.056  $\pm$  0.005 (21) (liters/equiv.)<sup>1/2</sup>.

There can be little doubt then that these Pt-in-Pyrex seals are suitable for extrapolation of data to infinite dilution with a precision within 0.1%. To obtain this accuracy, however, some attention must be given to the change of the cell constant with pressure.

*Variation of cell constant with pressure.*—As mentioned, this is a serious problem for Teflon cells. For glass cells, the expected variation is  $\sim 0.1\%$  per 1000 atm (6) and only becomes important when high accuracy is required. This change of cell constant with pressure assumes isotropic compression of the glass and no anisotropic distortions of the electrode geometry due to differential compression of the electrode-glass seal. Ovenden (11) was concerned about the latter effect and suggested a configuration using a ring electrode and a coaxial rod (Fig. 5b). With this configuration, it was argued, circular symmetry should minimize the effects of possible small displacements of the rod relative to the ring. Ovenden also assumed that this configuration leads to a negligible change of cell constant with pressure as a result of isotropic compression. Howard (12) claimed to demonstrate this point by comparing the rod and ring cell with the parallel plate configuration (Fig. 5a); his results showed scatter of up to 0.4%, however. In our view, the cell constant of this configuration should vary with pressure, as a result of the isotropic compression of Pt (0.01% per 1000 atm).

Fig. 5. High pressure conductance cells

The problem with the rod and ring configuration is that with solutions of concentrations above about 5 mM, it yields resistances which are too low for convenient measurement. For this reason we have constructed a compensated capillary cell (Fig. 5c). Any effects of distortions of the electrode geometry should be minimized by this configuration. We would expect the constant of this cell to be determined by the linear compressibility of Pyrex, or  $\sim 0.1\%$ /1000 atm. Figure 5(d) shows a combination cell incorporating both configurations, whereby very accurate comparisons of the two cell types were made using the same solution at the same time. In Fig. 6 we show the quotient of the rod-ring and capillary cell data as a function of pressure, at various temperatures. It is evident that this quotient increases linearly with pressure, essentially independent of temperature. The slope of the line in Fig. 6 is  $0.70 \times 10^{-6}$  atm<sup>-1</sup>. To a good approximation, this should be equal to the difference between the compressibilities of Pyrex and Pt. According to Bridgman, the mean linear compressibilities of Pyrex (22) and Pt (23) over the temperature and pressure range of our experiments are 0.975 and  $0.114 \times 10^{-6}$  atm<sup>-1</sup>, respectively. The difference between these compressibilities,  $0.86 \times 10^{-6}$  atm<sup>-1</sup>, is in good agreement with our data; the discrepancy is equivalent to an uncertainty of 0.03% at 2000 atm.

It is clear then that the two types of cell can be used together for solutions of different concentrations but that different allowances must be made for the variation of their cell constants with pressure. Indeed, this is essential to do when we are exploring the concentration dependence of the pressure coefficient of conductance since errors of 0.1–0.2% in lower concentration ranges would lead to serious errors in extrapolating to infinite dilution (Fig. 4). The results of Fig. 6 also show that scatter from anisotropic distortion of the electrodes, etc. is less than  $\pm 0.02\%$  up to 2250 atm.

*Errors arising from solution contamination.*—There can be little doubt that many of the problems in early work arose from inadequacies in cell construction. Solution contamination from hydraulic fluid or from Hg pressure seals has been blamed for some of the difficulties, however, and some examination of this problem seems called for. We consider contamination with the following materials: strong electrolytes, Hg, weak electrolytes, and O<sub>2</sub>.

Minor strong electrolyte impurities with strong electrolyte subject salts obviously pose no problem. This is especially the case as the pressure coefficients of the conductance of most strong electrolytes are similar in magnitude (24).

Fig. 6. Relative pressure coefficients of the rod-ring and capillary cells, NaCl system;  $c = 3.6$  mM ( $\odot$ —35°C;  $\square$ —25°C;  $\triangle$ —10°C;  $\bullet$ —3°C).

Hg contamination has been blamed for irreproducibility in high pressure measurements, particularly in acid solutions (5, 8, 9). However, appreciable Hg dissolution in nonoxidizing media in the absence of  $O_2$  is not thermodynamically possible. Even in the presence of a fully air-saturated solution (see later), the effect (presumably *via* Hg solubility) is relatively minor and could not have been responsible for the most significant errors in the literature.

Normally, one would not need to worry about the effects of minor weak electrolyte impurities when making measurements with strong electrolytes. An exception is in measuring the pressure coefficient of conductance. This arises because weak electrolytes dissociate extensively at higher pressures (9). Ellis was the first to point out that this poses a problem for the case of  $CO_2$  in equilibrium water (6). To examine the extent of this effect, we deliberately doped 2.5 and 4.9 mM KCl solutions with 2 ppm of  $CH_3COOH$ . The pressure coefficients of the conductance of such solutions were compared with those of the corresponding uncontaminated KCl solutions. Results are shown in Fig. 7.

It is seen that the pressure coefficient of the contaminated solutions is higher than that of the uncontaminated solutions, and that the deviation increases linearly with pressure. The displacement of the contaminated solution data is such as to suggest that the dissociation constant of  $CH_3COOH$  increases by about 1.6 at 2000 atm. Hamann and Strauss (16) obtained a ratio of 2.3. According to these results, we must restrict the weak electrolyte impurity to less than 0.5 ppm ( $CH_3COOH$  equivalent), at a salt concentration of 2 mM, to obtain our required accuracy of 0.1%. Ion-exchange water, which may contain weak electrolyte, is evidently adequate in this respect. These data also show that in discussing the possible effects of contamination, it is not sufficient just to show, as has sometimes been done, that the 1 atm solution resistance is constant under the given treatment since large changes can occur under pressure.

In a further series of experiments, LiCl and  $(Et)_4NCl$  solutions were deliberately saturated with  $CO_2$ -free air. The following observations were made: The resistance of the aerated cell, in contrast to all the others, drifted slowly downward during the first few days after loading. When the drifting had apparently stopped, the first pressure cycle was carried out; during the ascending part of this cycle the pressure coefficient for the aerated solution was slightly too high ( $<0.1\%$ ). Upon lowering the pressure, the resistance of this solution fell  $\sim 0.5\%$ . In subsequent pressure cycles, the pressure coefficient for aerated solutions was low by about 0.06% per 1000 atm (Fig. 8).

Our tentative explanation of these phenomena is that initial reaction between Hg and  $O_2$  produces soluble mercury entities which supersaturate the

Fig. 8. The LiCl system: effect of solution aeration upon the pressure coefficient of conductance at 15°C (+ aerated solution).

solution (25). This is not unreasonable since  $Hg_2Cl_2$ , for example, does supersaturate when Hg is anodized at low current densities in HCl (26). When the pressure is lowered, the solution cools and the supersaturated salt crystallizes. Some such catastrophic fall in resistance (up to 0.5% in 2 mM solution) on cooling was always observed with aerated solutions. Once this had happened and all the  $O_2$  in the solution had been used up, however, the solution behavior was nearly normal with respect to pressure coefficient (Fig. 8). In our opinion, it is preferable to deaerate the solutions in order to avoid the aforementioned initial erratic behavior; at least, one should keep the  $O_2$  concentration to about 20% of its normal air-saturated level ( $\sim 50 \mu M$ ) to attain an accuracy of 0.1% in the pressure coefficient during all stages of the measurement.

### Summary

Methods of obtaining high pressure ( $>2000$  atm) coefficients of the conductance of dilute aqueous solutions ( $\geq 2$  mM) of strong electrolytes with an overall accuracy of 0.1% are described.

An important requirement to obtain reproducible and accurate results is the Pt-in-graded glass seal. The criterion for a stable, leak-free seal is that the Pt to be sealed is in the form of a thin strip of foil (0.003 x 0.020 in.). A novel cage structure for the seal, which combines good mechanical strength with small sealing diameters, is described.

A compensated capillary cell is described which is suitable for measurements with solutions  $\geq 5$  mM. This cell is compared with Ovenden's rod and ring configuration (11), and it is shown that correction for the variation of cell constants with pressure can be made within 0.02%. Anisotropic distortion errors are within this limit.

The effects of solution contamination are discussed. It is shown that weak electrolyte impurities (acetic acid or equivalent) in a 2 mM salt solution must be kept below  $\sim 1$  mole % of the salt concentration to maintain an accuracy of 0.1% in the conductance at 2000 atm. Similarly,  $O_2$  contamination must be kept below 50  $\mu M$ .

### Acknowledgments

We are pleased to thank Mr. H. Lingertat for assistance with the experimental work. This work was supported by the Office of Saline Water under Contracts OSW 14-01-0001-425 and 14-01-0001-966.

Manuscript submitted Feb. 29, 1968; revised manuscript received April 30, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Technical Notes

### Differences between the Combustion of Aluminum Droplets in Air and in an Oxygen-Argon Mixture

J. L. Prentice

*The Michelson Laboratories, U. S. Naval Weapons Center, China Lake, California*

and L. S. Nelson

*Sandia Laboratory, Albuquerque, New Mexico*

When aluminum droplets were burned during free fall in air and in its nitrogen-free analog, 20% oxygen in argon, keeping other conditions identical, marked differences between the combustions appeared and will be described in this communication.

Each droplet,  $377\mu$  in diameter, was prepared and ignited by exposing a small square of aluminum foil to a focused, millisecond pulse of radiation from a Nd-glass laser as described elsewhere (1). The squares of foil, 1.02 mm on a side and  $20\mu$  thick, were supported at the laser focus on crossed aluminum fibers. The air was obtained from a cylinder (Matheson, special dry), while the oxygen-argon mixture was made as used from ultra high purity cylinder gases (Linde). In both cases, the gaseous atmospheres were at a total pressure of  $625 \pm 5$  Torr, and were flowing upward slowly through a windowed combustion chamber 11 cm on each side and 36 cm high.

The experiments were performed in a manner that permitted observation of the light emitted by the burning particles from ignition to burn-out. The emission of radiation was recorded by high-speed photography, as a time exposure with a 102 x 127 mm view camera, and with an RCA 7102 (S-1 surface) photomultiplier-oscilloscope combination. A narrow band interference filter that peaked at  $8300\text{\AA}$  was placed before the photomultiplier, which viewed the falling particle from a distance of 3.7m. In a number of experiments, 2.5 mm-wide semi-opaque tapes spaced 38 mm apart were placed horizontally across the front window of the combustion chamber. Each time the particle passed behind a tape, a dip formed in the oscilloscope trace. These dips allowed us to correlate distance of fall with both combustion time and the intensity of light emitted by the burning droplet.

Time-exposed photographs of the trajectories of droplets burning in the two atmospheres are shown in Fig. 1a and 1b. The trace from the droplet that burned

in air was uneven with scalloped edges in the upper part and showed side traces and swerving in the lower part. In the nitrogen-free combustion, however, the trace was somewhat broader and shorter, but with smooth edges. High-speed photography has shown that the traces with scalloped edges are caused by spinning particles, while the side traces and swerving are associated with jetting and/or fragmentation of the droplets. Drops without spin had even traces.

The photomultiplier records of the light emitted by the particles burning in the two atmospheres were also different as shown in Fig. 2a and b. In air there usually was an initial rise of about 15 msec duration after which the trace oscillated rapidly. After a gradual second increase there was a very irregular emission of light which decayed altogether at about 275 msec for the droplet diameter used here. Although the gross features of each oscilloscope record were similar the individual traces varied greatly from experiment to experiment, especially in the frequency of oscillation.

In the 20% oxygen-argon atmosphere, however, the trace rose sharply after the laser pulse, and then decayed smoothly over a somewhat longer time of 400 msec. The peak intensity was about 12% greater than for the droplet that burned in air. Also, two irregularities were seen in this trace: the change in slope at about 200 msec, and the tiny peaks just before extinction. The over-all shape of the curve as well as the irregularities were reproducible when the experiments were repeated.

Distances of fall were determined from the dips on traces similar to those in Fig. 2a and 2b, and have been plotted in Fig. 3 against the square of time. The straight line has been drawn for a body in vacuo accelerating gravitationally from rest, where the distance is  $gt^2/2$ . The droplets fell slightly faster than gravitational at the beginning of the oxidation in both atmos-

Fig. 1. Time-exposed track photographs of  $377\mu$ -diameter aluminum droplets as they burned in free fall (a, left) in air and (b, right) in a mixture of 20% oxygen in argon, with total gas pressures in both cases at 625 Torr. Short traces emanating from holder arise from tiny droplets formed from crossed aluminum fiber support. Note the typical erratic trace that appears when an aluminum droplet burns in air.

pheres but then gradually slowed as time increased. The droplet that burned in 20% oxygen-argon fell more slowly than the droplet that burned in air and virtually stopped before the light emission died out.

When the droplets were allowed to impact glass plates at similar stages of the combustions in the two atmospheres, marked differences again appeared, as shown in the photomicrographs in Fig. 4. Here the droplet that had burned in the oxygen-argon mixture was a bare aluminum sphere surrounded by a circular smoke pattern. (The sphere had an indentation, presumably due to contraction on freezing.) The droplet that had been ignited in air, however, showed a glass-like hemispherical cap attached to one side of the aluminum sphere, forming a pronounced bilobate structure. Also, for the combustion in air, the smoke pattern on the glass plate was definitely nonsymmetric, being confined to the area nearest the aluminum end of the particle.

We now attempt to explain the following characteristics of the burning aluminum droplets: (i) the droplets spin in air but not in  $O_2/Ar$ ; (ii) the droplets jet in air but not in  $O_2/Ar$ ; (iii) the droplets radiate less intensely in air than in  $O_2/Ar$ ; (iv) the droplets fall more rapidly in air than in  $O_2/Ar$ . We suggest tentatively that the accumulation of the cap-like lobe of condensed phase product during combustion in air but not in  $O_2/Ar$  is responsible for the variations in behavior in each case.

Since the substitution of argon for nitrogen in the gas mixture was the only difference between the two systems reported here, nitrogen may be participating in the combustion as a reactive species. Recently, Michel *et al.* (2) have obtained aluminum oxynitrides

Fig. 2. Oscilloscope records of RCA 7102 photomultiplier output when it viewed  $377\mu$ -diameter aluminum droplets burning (a, top) in air and (b, bottom) in a mixture of 20% oxygen in argon at a total pressure of 625 Torr. Central traces were recorded with second beam of dual beam oscilloscope at an amplification 0.1 that used for other trace. Sharp dips in trace were formed as droplet passed behind strips of tape placed horizontally across front of combustion chamber. Intensity scales are identical in both traces.

by melting a mixture of alumina and aluminum in air with an induction heater. The similarity of their system to the one reported here suggests that the product which accumulates on aluminum droplets burning in the presence of nitrogen likewise might be some aluminum-oxygen-nitrogen species of as yet undetermined composition. [An analogous reaction occurs when zirconium droplets burn in air (3).] The assumption (4) that the product lobe of the bilobate configuration shown in Fig. 4a is aluminum oxide should be examined carefully in view of the experimental findings reported here.

Comparison of Fig. 1a and b and 4a and b indicates that an uneven track due to a spinning particle is recorded when condensed-phase product accumulates on the droplet's surface, while the even, smooth-edged trace appears when this product is absent. A possible explanation of this behavior is that when the product is present, an aerodynamically unstable situation arises, owing to the dissymmetry of the bilobate particle and the directional, possibly turbulent, vaporization of the aluminum. This could result in the observed spin. When the product lobe is absent, however, the droplet burns stably and spin is not observed.

The jetting seen toward the bottom of Fig. 1a when the specimen burns in air also may arise from the accumulated lobe of product. When quenched specimens similar to the one shown in Fig. 4a are examined with an optical microscope, considerable frothiness is seen in the product globule. Later in the burning, the frothiness is less evident, but larger bubbles appear,

Fig. 3. Distance of fall plotted against the square of time for aluminum droplets burning in air and in a mixture of 20% oxygen in argon at a total pressure of 625 Torr. Initial droplet diameter was 377  $\mu$ .

some of which seem to have burst at the surface. Both the frothiness and the larger bursting bubbles suggest gas-related processes which may cause the jets and fragmentation seen in Fig. 1a. Again, when there is no product lobe present, the jets and fragmentations are likewise absent.

The lower radiant emission from the droplets that burned in air (Fig. 2a and b) may be caused by an incomplete flame front around the droplets, due to reduced and directional vaporization of aluminum. Thus, if the smoke patterns shown in Fig. 4 are true indicators of the shape and magnitude of the flame that surrounds the burning droplet, the droplets that burned in air had only an approximately hemispherical flame zone, while those that burned in the oxygen-argon mixture had a fully spherical flame zone. Since it is thought that the radiation in burning aluminum droplets emanates mainly from the cloud of incandescent smoke particles formed in the combustion (5), it is not surprising that the peak light intensity measured photoelectrically is lower for the droplets that burned in air, where the product lobe seems to block roughly half of the flame front, than for droplets that burned in O<sub>2</sub>/Ar, where the complete flame front is present.

Perturbation of the symmetrical cloud of particles by the product cap may also explain the greater rate of fall of droplets that burn in air than in O<sub>2</sub>/Ar (Fig. 3). If it can be assumed that the cloud of hot gases that surrounds the particle adds a drag or buoyancy force opposed to gravity, it is possible that the more spherical cloud formed in O<sub>2</sub>/Ar would give rise to a slower rate of fall than would the partially spherical cloud thought to accompany the droplet while burning in air.

A paradox arises, however, when burning times in the two atmospheres are compared (see Fig. 2a and b). Thus, if the rate of vaporization of aluminum is reduced when the droplet burns in air, due to the presence of the product lobe on the droplet's surface, the over-all burning time might be expected to be longer in air than in O<sub>2</sub>/Ar. Actually the droplet burns to extinction of light emission more rapidly in air than in O<sub>2</sub>/Ar. A possible explanation for this is that in air, both oxygen and nitrogen can act as oxidizers. Then since the effective oxidizer concentration is greater, the droplet can reach a state of complete oxidation more rapidly in air than in O<sub>2</sub>/Ar. Perhaps in air, part of the reaction with the atmosphere occurs in the vapor phase flame front, while the rest is associated with the product lobe, where oxygen and ni-

Note the bilobate structure of the droplet that had burned in air, and the bare metallic appearance of the droplet that had burned in O<sub>2</sub>/Ar.

trogen pass into the lobe from the gas phase and aluminum oxidizes at the metal-product interface.

It should be emphasized that the explanations given here for the behavior of burning aluminum droplets are mostly speculative. Obviously, more study must be devoted to the basic chemical questions that arise in this work, namely, what is the nature of the product lobe, and why does it collect in the one atmosphere but not in the other. Nevertheless, these results strongly suggest that earlier work on the combustion of metal droplets in oxygen mixed with nitrogen or other reactive gases [e.g., flame ignition studies (6)] should be reexamined for possible complications due to transient or end-products other than the simple metal-oxygen compounds usually assumed to form.

## On the Mechanism of Oxidation of Cobalt Between 750° and 1000°C Using Inert Gold Spheroidal Markers

J. P. Foster\* and R. J. Reynik\*\*

Department of Metallurgical Engineering, Drexel Institute of Technology, Philadelphia, Pennsylvania

For the oxidation mechanism of cobalt there is conflicting evidence between thermogravimetric, electrical conductivity, and self-diffusion on the one hand, and marker studies on the other. The purpose of this note is to clarify the discrepancies associated with these marker studies.

Since the kinetics of oxidation is parabolic, the Wagner defect reaction theory is applicable. According to thermogravimetric (1, 2) and electrical conductivity studies (1) the exponent of the oxygen partial pressure dependence is positive, and Wagner's theory states that the oxide is a p-type semiconductor. Thus its defect structure can be either cation vacant or anion interstitial. Further, the oxygen partial pressure dependence for the diffusion of Co<sup>60</sup> in CoO is the same as that for the oxidation of Co to CoO. This indicates that the defect structure of CoO is cation vacancies.

Marker studies of the oxidation of Co are not in agreement with the above conclusions. Investigators using nichrome (3) and Pt (4) wires as markers report the final marker positions at the interface between the gray outer CoO scale and the brown, inner CoO scale. This interface between the two layers is coincident with the original metal surface (4). Hence these investigators (3, 4) conclude the outer layer is formed by the diffusion of Co ions and the inner brown CoO layer is supplied by O ion diffusion through the outer layer. The investigators (2) using a radioactive Pt slurry and Al<sub>2</sub>O<sub>3</sub> particles (5) on Co at 1200°C report no inner brown CoO scale, hence only observe a single layer, and final marker locations at the metal|gray CoO interface. They conclude that gray CoO forms by cobalt ion diffusion through oxide scale vacancies. This failure to observe an inner brown CoO scale is contrary to data reported by Phalnkar (3). No marker results have been reported below 900°C, where Co<sub>3</sub>O<sub>4</sub> forms together with gray CoO (but not brown CoO).

### Experimental

All details of specimen preparation and experimental technique are identical to that previously reported (6), except as noted. Three different weights of gold (Table I) were vapor-deposited onto carefully prepared as-cast cylindrical cobalt specimens. The gold films again spheroidized at 400°C. Gold-marked and unmarked specimens were simultaneously oxidized in static air at 750°, 850°, and 1000°C, for times in multiples of 24 hr, up to 144 hr.

### Results

For all specimens, the final marker location is at a well-defined demarcation line within the gray CoO

scale (see Fig. 1). On adjacent sides of the demarcation line, and yet completely within the gray CoO scale, there appears a compact CoO scale and a small void CoO scale, respectively. With the exceptions of the inert spheroids appearing within the inner CoO scale, the differences in spheroidal sizes (corresponding to different quantities of deposited gold film), and minor variations in random void appearances, the microstructures for the gold-marked and unmarked specimens were identical. Gold is soluble in Co (7). However, the size of the spheroids, depends solely on the initial quantity of deposited gold. Once formed, the spheroids remained approximately constant (Fig. 2) for different oxidation temperatures and times. If the gold spheroids were soluble in Co to any large extent, their size would necessarily decrease with increasing oxidation time. But this was not observed, hence gold spheroids can be used as inert markers in oxidation studies.

### Discussion

No comparison of final marker location is possible at 750° or 850°C. At 1000°C the final location of the gold spheroidal markers does not agree with the locations reported using nichrome (3) or Pt (4) wires and Al<sub>2</sub>O<sub>3</sub> particles (5). This difference is due to fragmentary contact of these markers with the original metal surface (8). The vapor deposited spheroidal gold layer has excellent surface contact. Disagreement with the radioactive Pt slurry on Co at 1200°C is probably due to the fact that a brown, inner CoO scale was not observed.

A more serious disagreement in final marker location at 750°, 850°, and 1000°C is with the predicted results of thermogravimetric, electrical conductivity, and self-diffusion studies. Since gray CoO is cation deficient, one would expect the final marker location to be found at the metal|oxide interface. However, this failure of inert markers to be found at metal|oxide interfaces is not confined to the cobalt system. In ox-

oxidation studies involving Ni (9) and in the sulfidation of Cu (10) and Ag (11) (all of which have been established as cation deficient), the final marker positions were always found at a position corresponding to the demarcation line observed in the present cobalt studies. It is proposed that the oxidation of Co to gray  $\text{CoO}$  follows a similar mechanism (12) to that proposed to describe the formation of  $\text{NiO}$ ,  $\text{CuS}$ , and  $\text{AgS}$ . Plastic flow at the metal|oxide interface is insufficient to remove the vacancies arriving as a consequence of cation migration. Cracks result at this interface, and this leads to a detachment of the marker from the metal|oxide interface causing it to be found at the demarcation line.

## Structure and Morphology of Electrodeposited Molybdenum Dendrites

Cletus J. Bechtoldt, Fielding Ogburn,\* and J. Smit

National Bureau of Standards, Washington, D. C.

The structure and morphology of electrodeposited dendrites have been the subject of a number of investigations (1). None of these studies, however, contain information on electrodeposited body centered cubic (bcc) dendrites. Recently this laboratory had the opportunity to examine electrodeposited molybdenum dendrites. The purpose of this note is to report on that study, particularly with respect to the twin structure phenomenon.

The dendrites, contributed by Senderoff, had been removed from the edges of cathodes on which molybdenum had been deposited. Deposition was made from a molten fluoride system similar to that described in a patent (2). Dendrites are not a normal product of this process and ceased to form after continued electrolysis. These molybdenum specimens were examined using Weissenberg, precession, back-reflection Laue, and divergent beam x-ray techniques and by optical goniometric and microscopic methods.

#### Observations

Precession patterns, one example of which is shown in Fig. 1, indicated that the dendrites had two ori-

entations with a common  $\langle 111 \rangle$  direction parallel to the direction of growth. Diffraction symmetry was that for the usual twin relation in a bcc lattice. Back-reflection Laue patterns showed the bounding facets parallel to the direction of growth to be  $\{110\}$  planes. Rotation of the dendrites about the growth axis produced clear signals at precise  $60^\circ$  intervals on an optical goniometer, consistent with the lateral surfaces being  $\{110\}$  planes.

The x-ray diffraction patterns were unusually sharp for electrodeposited material. A back reflection pseudo-Kossel pattern, Fig. 2 (divergent x-ray beam technique), revealed a crystal having a high degree of perfection. Each element of an ellipse in the pseudo-Kossel pattern represents diffraction from a different area on the dendrite. The degree of perfection of the dendrite is indicated by the sharpness and by the absence of irregularities on the curved elements in the pattern.

A typical molybdenum dendrite is shown in Fig. 3. The dendrites are characterized by flat-appearing lateral surfaces and a basically hexagonal cross-section. Frequently a cleft appears near the growing tip. The largest dendrites are approximately 20 mm long

Fig. 2. Back reflection pseudo-Kossel pattern showing degree of perfection of molybdenum dendrite. Cu radiation, 10 cm specimen to film distance taken on  $\{110\}$  surface containing twin boundary. Fragments of  $\{321\}$  ellipsoids are indicated by arrows.

and 2 mm wide. Many of the specimens are marked by striations on the lateral surfaces as shown in Fig. 4. These striations change direction on crossing from one lateral surface to another. Measurement of the angles formed by the striations on two adjacent surfaces with the common edge of these surfaces show them to be traces of  $\{100\}$  planes within one degree. The lateral surfaces of the dendrites appear to diverge gradually in the direction of growth, yet optical and diffraction examinations (alignment by auto collimator) indicated these surfaces to be parallel to the growth axis. The striations apparently mark successive growth layers which result in the appearance of divergence.

The striations show a change of direction on certain of the lateral surfaces in addition to the change in direction previously noted at the intersection of the lateral surfaces. In both cases the change in direction results in the formation of a herringbone pattern. When observed on a lateral surface the union of the striations in the herringbone pattern (that portion that would ordinarily be taken as a backbone) forms a quasi-boundary. This boundary is made up at times of short straight segments having a definite angular shape. At other times the boundary between the twins appears (microscopically) as a continuously curving line more characteristic of a grain boundary. Back-reflection Laue patterns obtained from a beam cen-

Fig. 3. Typical molybdenum approximately 20 mm long by 2 mm wide. A crevice near the tip is shown.

Fig. 4. Lateral face of molybdenum showing herringbone pattern and juncture of twin orientations.

tered on the boundary always showed a twin structure. At times the boundary crosses from one lateral surface to an adjacent surface, extending the full length of the dendrite. A second boundary can always be found on one of the other exterior surfaces. Figure 5 is an optical photomicrograph showing the boundary between the twinned crystals in a section taken perpendicular to the growth axis.

A common feature of these dendrites is a cleft or crevice near the tip and elongated voids in the interior. These voids and crevices always occurred between the two crystals of twin orientation and, in effect, are a broadening of the boundary. Careful optical examination of the surfaces of the crevices and

Fig. 5. Photomicrograph of a section of a molybdenum dendrite taken normal to the direction of growth showing internal juncture of twin orientations. A void contained in the boundary is shown.

voids revealed cubically shaped corners and  $\{110\}$  facets, the latter not always parallel to the direction of growth. Frequently the growth on one surface in the crevice overlapped those on an adjacent surface. The boundaries containing the angular shapes previously mentioned apparently arise due to continued growth and filling of these crevices.

The features of the growth tips varied substantially. Essentially the tip, containing step-like surfaces, starts as a point and grows to ultimately form a hexagonally shaped shaft. Optical goniometer measurements made on many of the tips showed them to contain numerous facets lying between the  $\{100\}$  and  $\{110\}$  planes on a 100 zone (see Fig. 6). The most prominent facets on the tip are  $\{100\}$  facets. Following the  $\{100\}$  facets in prominence were other extremely narrow facets making small angle steps along the  $\{100\}$  zone from the prominent  $\{100\}$  facets toward the  $\{110\}$  lateral bounding surfaces. These facets stopped abruptly  $10^\circ$  to  $14^\circ$  before the  $\{110\}$  lateral surface. Several distinct sequences of this kind appeared between the  $\{100\}$  planes of the growing tip and the bounding  $\{110\}$  lateral surfaces. To obtain increased resolution, the dendrites were mounted on a two circle goniometer and examined using a modified bench-type metallurgical microscope and a point light source. Long, slender facets differing by as little as half a degree were observed.

A detailed optical examination of the morphology of the as-grown tip of the dendrite was also under-

Fig. 6. The location of observed facets on the tip of molybdenum dendrites shown on a stereograph projection in the growth direction. Heavy lines indicate location of optical reflections along 100 zones.

taken. However, at the high magnification the depth of focus was much too shallow to permit accurate measurements of the growth front facets. In view of the possibility that the tips had been altered or damaged since growth, this examination was abandoned. However, the extreme tip on several dendrites was carefully polished mechanically and then electropolished. This produced a minute cross-section nearly normal to the direction of growth, as shown in Fig. 7. The configuration displayed on the tip section suggests traces of  $\{112\}$  composition planes forming a zig-zag. The angles between segments are approximately  $60^\circ$ , which is the angle between two  $\{112\}$  planes parallel to the direction of growth. The segments were perpendicular to a  $\{110\}$  bounding facet. Each segment is about 0.005 mm long and the distance between terminal points of the zig-zag is as long as 0.05 mm. At greater distances the boundary degenerates into the grain-like boundary previously described.

#### Discussion

Electrodeposited dendrites frequently appear to grow by the same mechanism as crystals pulled from supercooled solutions where a higher nucleation rate is achieved at a twin plane reentrant edge. In a recent paper, Faust and John (3) cited the following requirements or conditions as necessary to achieve crystal growth by the twin plane reentrant edge mechanism.

1. The embryo nucleus must contain one or more twin planes.
2. The growth front of the material must be faceted.
3. The reentrancies must be indestructible, *i.e.*, any initial reentrancy must not fill in to form a closed figure bounded by planes and sharp corners.
4. The twin plane must intersect one or more stable facets at an angle different from  $90^\circ$ .
5. The direction of growth must lie in the twin plane.

Presently these requirements are known to be met by dendrites with structures in the cubic, hexagonal, and orthorhombic crystal systems. Specifically, in the cubic system, only fcc dendrites having the copper, diamond, and zinc blend-type structures have been observed to fulfill the requirements. Molybdenum dendrites of the W-type structure with a body centered cubic lattice may represent a new structure that meets these conditions. Requirements 1 and 5, discussed in the preceding section, are met inasmuch as the molybdenum dendrites are twinned and the direction of growth is within the  $\{112\}$  composition plane.

The dendrites are well faceted and there is strong circumstantial evidence and hence is presumed their growth fronts are faceted (requirement 2). Direct evidence, positive or negative, however, could not be obtained.

Accepting the presumption that the growth front has stable facets (likely to be  $\{110\}$ ) the zig-zag configura-

Fig. 7. Photomicrograph of a molybdenum dendrite near the extreme tip showing  $\{112\}$  composition planes of the twin boundary formed.

tion provides for self perpetuation (requirement 3). This can be seen if we consider what would happen if the reentrant angles at the two composition planes filled in. New facets would develop and new reentrant angles would form probably within the acute angles between the zigs and zags. Continued growth at these new reentrant angles would reestablish the original facets at the composition planes. Continued growth in the new reentrant angle would establish a new set of reentrances, probably the original set, ignoring the {111} planes which do not form stable facets. Lastly there are a number of facets in a [100] zone which are not 90° to the composition plane, as called for by requirement 4. It seems reasonable for one of these to form at the growing tip.

These specimens appear to be examples of dendritic growth of a bcc material by the twin plane reentrant edge mechanism. This is consistent with the observations that all the dendrites grew in the <111> direction. The intersection of the boundaries in Fig. 7 have a <111> direction and if the intersecting boundaries are essential to the growth mechanism, the dendrites must grow in the same direction. The growth direction is also facilitated, or may even be determined, by the six lateral, closest packed slowest growing 110 facets.

## Brief Communication

### The Solubility of Silver (II) Oxide in Alkaline Solutions

Arthur Fleischer\*

Consultant, Orange, New Jersey

The solubility of AgO in potassium hydroxide solutions has been reported by Dirkse and Wiers (1) up to 5M KOH and by Hills (2) up to 12M KOH. The authors of both papers indicated that the solubility curve as a function of KOH concentration at 25°C was the same as that for the solubility of silver (I) oxide, Ag<sub>2</sub>O. Amlie and Ruetschi (3) indicated that there was an uncertainty with regard to the solubility of AgO. They considered the coincidence in the solubilities of the two oxides to be rather suspicious, citing that Dirkse *et al.* (1) did not show that the dissolved species was bivalent. Subsequently Hills (2) refers to the "proven presence of a higher valent species."

Application of the phase rule throws light on this problem of the apparently identical solubilities of the two silver oxides. Let an excess of these two oxides, Ag<sub>2</sub>O and AgO, be added to a potassium hydroxide solution for the determination of the silver concentration in the solution phase. At equilibrium, the system will consist of four phases, namely two solid phases representing the silver oxides, a solution (or liquid) phase, and a gas phase; the latter accommodates the equilibrium oxygen and water vapor pressures. The system will also have four components which may be selected as the compounds, Ag<sub>2</sub>O, AgO, KOH, and H<sub>2</sub>O, or any other four combinations which will yield all phases in any proportion.

The insertion of these values in the phase rule equation,  $P + F = C + 2$ , with the number of phases,

\* Electrochemical Society Active Member.

$P$ , equal to the number of components,  $C$ , yields 2 as the number of degrees of freedom,  $F$ . Experimentally, these two degrees of freedom are used up by selecting temperature and KOH concentration as the independent variables. Thus, the system is made invariant and the solubility or any other property of the system is fixed. In other words, it may be said that the activity of the silver species is fixed for any selection of temperature and KOH concentration in this system.

The published solubility curve for AgO in KOH solutions as a function of KOH concentration must therefore be interpreted as corresponding to the presence of two solid phases, namely AgO and Ag<sub>2</sub>O. This condition is not difficult to postulate for the cited work in view of the known instability of AgO at ambient temperature. On standing in the presence of KOH solution, AgO loses oxygen with the formation of Ag<sub>2</sub>O (1, 2).

Manuscript submitted April 15, 1968; revised manuscript received ca. May 2, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Chemical Reactions Involving Holes at the Zinc Oxide Single Crystal Anode

W. P. Gomes,<sup>1</sup> T. Freund, and S. R. Morrison

Stanford Research Institute, Menlo Park, California

## ABSTRACT

The anodic oxidation of various reactants dissolved in water was studied on a zinc oxide single-crystal electrode by electrical techniques. It was found that only a few substances inject electrons into the conduction band. However, many reactants are oxidized by holes, which are created in the crystal by illumination: A class of two- or multi-equivalent reducing agents, called current-doubling agents, undergoes oxidation by a two-step mechanism in which reaction with a hole leads to the formation of a radical-type intermediate, which then injects an electron in the conduction band. Relative hole reactivities for different reagents were determined by making current measurements during competitive oxidation of current-doubling and noncurrent-doubling reactants. The reactivity of different radical-type intermediates toward oxidizing agents was investigated. Experimental support is given for the idea that a common intermediate, the hydrogen atom, is formed during the oxidation of many organic current-doubling species. Differences in behavior depending on the crystal face are discussed.

Since the initial work of Brattain and Garrett (1) on the electrochemistry of germanium, there has been considerable interest in the behavior of semiconductor electrodes, as indicated by reviews by Gerischer (2), Boddy (3), and Myamlin and Pleskov (4). The first extensive investigation on the zinc oxide/electrolyte system in the absence of any reactant was made by Dewald (5). Cathodic reduction reactions on single-crystal zinc oxide were studied by Dewald (6), Freund and Morrison (7), and Lohmann (8). An effect called "current doubling" was reported by Morrison and Freund (9) in connection with the anodic behavior of aqueous formate ion on an illuminated zinc oxide electrode; the authors attributed it to the formation of a radical-type intermediate on the crystal surface and showed the role of this radical in the photocatalytic oxidation of formate by oxygen.

In the present contribution, the generality of the current-doubling effect for many multi-equivalent reducing agents is demonstrated. This new electrochemical effect can be utilized for studying reactions between electronic charge carriers of the solid and reactants at the surface, and between sorbed radicals and oxidizing species. We believe that these studies are pertinent to the field of heterogeneous catalysis (9), since charge transfer processes can be important steps in adsorption and chemical reactions on semiconductor catalysts. The current-doubling results are useful for predictions (10) of catalytic activity and selectivity.

## Method

In an aqueous electrochemical cell containing a zinc oxide electrode under anodic bias, a negligibly low current is observed in the dark in chemically inert solutions as well as in solutions containing various reducing agents. In Fig. 1, the band model of zinc oxide in an anodic condition is represented, including the surface. The lack of dark electron injection suggests that the energy level associated with the sorbed species is situated below the bottom of the conduction band, e.g., R.

When zinc oxide is illuminated with the light of  $\lambda < 385 \text{ m}\mu$  (the band gap is 3.2 eV), electron-hole pairs are formed within the crystal, according to

where e represents an electron in the conduction band

and p a hole in the valence band. Under anodic bias, only holes will move toward the surface. Therefore the flux of holes to the surface is primarily dependent on the bulk properties of the crystal and on the photon flux. The rate of oxidation reactions should be determined by the hole current at the surface and therefore be independent of the nature of the reducing agent in solution. The same current was observed experimentally at constant light intensity in electrochemically inert solutions as well as in the solutions of all one-equivalent and many two- or multiequivalent reducing agents. This current was found to be proportional to the light intensity and to increase only slightly with increasing anodic bias. When no reducing agent is present in solution, it has been shown (8, 11) that the reaction involved is the anodic photodissolution of zinc oxide resulting in the oxidation of the lattice oxide ion.

With some two- or multiequivalent reducing agents such as formate ion, the external anodic current,  $J$ , was found to approach  $2J_p$ . The mechanism suggested (9) is illustrated by Fig. 1. The assumption is that the one-equivalent oxidation of the current-doubling agent R will lead to the formation of a radical-type species  $R^+$  with an electron energy level above the bottom of the conduction band. Thus  $R^+$  can inject an electron into the semiconductor. This process is expressed by the surface reactions

where p is a hole in the valence band and e is an electron in the conduction band. Reactions [2] and

Fig. 1. The band model of ZnO with anodic bias

[3] represent<sup>2</sup> the two-equivalent oxidation of R. If a one-equivalent reducing agent is present, no process equivalent to reaction [3] may occur.

Thus, in principle, the anodic current  $J$  will have one of two values, either  $J_p$  or  $2J_p$ . The  $J_p$  case occurs without any reducing agent or with a one-equivalent reducing agent, and the  $2J_p$  case occurs with a current-doubling agent.

The mechanism of current doubling represented by reactions [2] and [3] suggests that two different types or reagents, when added to a solution of a current-doubling agent, could lower the steady-state rate of reaction [3] and thus lower the measured current  $J$ . The first, "X-type," reagents are reducing agents which are oxidized by holes solely. If X is, for instance, a one-equivalent reducing agent, its oxidation will be represented by

The competition between reactions [4] and [2] would lead to a decrease in the rate of the electron injection reaction. The second, "Y-type," reagents are oxidizing agents that react with the radical  $R^+$  according to the surface reaction

where the reduction of Y is assumed to be one-equivalent. The competition between reactions [5] and [3] would also lead to a decreased electron injection. It has previously been reported (9) that  $O_2$  acts as a Y-type reagent with respect to the current-doubling agent, formate ion, and the process was called "quenching."

These competitive reactions can be used to obtain qualitative and quantitative information about the behavior of various species at the zinc oxide anode. By current measurements with solutions containing current-doubling agents as a function of the addition of reagents of unknown behavior, species that are electrochemically active at the zinc oxide electrode can be detected. This is particularly useful for determining if a reducing agent exhibits X-type behavior, since X-type substances by themselves do not affect the photocurrent. The electrochemical activity of oxidizing agents toward sorbed radicals can also be detected by the decrease of the photocurrent due to current-doubling substances, i.e., quenching by Y-type substances. Previously (7) the electrochemical activity of oxidizing agents in the absence of reducing agents has been studied using a capacitance-current method. Quantitative current measurements during competitive reaction between current-doubling agents and other reactants, in steady-state conditions, can provide information about relative hole reactivities of various reactants and about relative reactivities of different radical-type species at the zinc oxide surface. This paper describes the results of quantitative current measurements for the purpose of determining relative hole reactivities and radical reactivities.

### Experimental

The apparatus consisted essentially of an electrochemical cell, an electrical measuring circuit, and a light source. The cell contained a zinc oxide single crystal as one electrode, a platinum working electrode, a saturated calomel reference electrode, and an electrolyte. The electrical circuit allowed the measurement of the voltage of the zinc oxide vs. SCE, the current through the zinc oxide, and the capacitance between the zinc oxide and platinum electrodes. The light source was an incandescent microscope lamp. Details have been given elsewhere (7, 9).

Zinc oxide single crystals about 5 mm in diameter and 1 mm thick, cut perpendicular to the c-axis, were obtained from Minnesota Mining and Manufacturing

<sup>2</sup> The possibility should not be excluded that, in some cases, reaction [2] gives more than one product and one of these is the injecting species.

Company. In most experiments, the (000 $\bar{1}$ ) face was in contact with the electrolyte. This face was prepared by lapping, and the lapping damage was then removed by etching for about 15 sec in concentrated HCl solution, which rapidly attacked the (000 $\bar{1}$ ) face, allowing its identification (12). Subsequently, the crystal was kept for several hours in 85%  $H_3PO_4$ , which we found to be a good polishing agent for the (000 $\bar{1}$ ) face. When the (0001) face was studied, the sequence of reagents was reversed, since 85%  $H_3PO_4$  preferentially attacks the (0001) face and concentrated HCl solutions polish it.

Most experiments were carried out on two zinc oxide samples, whose donor densities were on the order of  $10^{17} \text{ cm}^{-3}$  as determined by capacitance-voltage measurements (5). The surface area of the crystal in contact with the electrolyte ranged between 5 and 10 mm<sup>2</sup>. Except in the experiment with  $O_2$  as a reagent,  $N_2$  was bubbled through the solutions to remove dissolved  $O_2$  before each measurement. In experiments that involved current measurements during exposure to light, the gas bubbling was interrupted at regular intervals to read the current, until a constant current value was obtained. Unless otherwise stated, measurements were performed at +1.0v vs. SCE and at room temperature.

### Results

*Current-doubling agents.*—The following species have been found to show current doubling: arsenic (III), cyanide, borohydride, sulfide, formate, binoxalate, tartrate, acetaldehyde, and many aliphatic alcohols, such as methanol, ethanol, 1- and 2-propanol, 1-butanol, 1,2-ethanediol, and 1,2,3-propanetriol. It should be noted that neither oxalate ion nor 2-methyl-2-propanol exhibits current-doubling.

According to Reactions [2] and [3], for a solution of a current-doubling agent, the current should be  $J = 2J_p$  ( $J_p$  being determined at the same light intensity and voltage with a solution free of current-doubling agent). Experimentally,  $J$  is often found to be somewhat less than twice the hole current. If we define the electron current  $J_e$  by

$$J_e = J - J_p \quad [6]$$

this means that often  $J_e/J_p < 1$ . A competition with the anodic dissolution of zinc oxide could be the cause of this effect. The value of  $J_e/J_p$  depends on the nature and concentration of the current-doubling agent, in some cases on the pH of the solution (e.g.,  $J_e/J_p$  increases with pH in the case of alcohols), and in all cases on the crystal face exposed,  $J_e/J_p$  being much higher on the (000 $\bar{1}$ ) than on the (0001) face. The experimental conditions for quantitative work were chosen so that several current-doubling agents would have values of  $J_e/J_p$  equal or close to unity. In all the experiments discussed below, the (000 $\bar{1}$ ) face was in contact with the solutions and unless otherwise specified, the solutions were 1M in KCl and 0.05M in KOH.

*Competitive oxidation of current-doubling and non-current-doubling reducing agents.*—The following current-doubling agents were used:  $CH_3OH$ ,  $C_2H_5OH$ ,  $2-C_3H_7OH$ ,  $(CHOH-COO^-)_2$  as  $(CHOHCOOK)_2$ , and  $BH_4^-$  as  $KBH_4$ . The following noncurrent-doubling "X-type" reagents were used:  $Br^-$  as  $KBr$ ,  $SO_3^{2-}$  as  $Na_2SO_3$ , and  $I^-$  as  $KI$ .

*Current as a function of the concentration of X.*—The variation of the current  $J$  has been studied as a function of the concentration of noncurrent-doubling reducing agent, [X], in solutions of constant concentration of current-doubling agent, [R]. A typical result is presented in Fig. 2, where  $J_p/J_e$  has been plotted vs. [X]. A straight line is obtained, indicating a relationship

$$J_p/J_e = 1 + \alpha[X] \quad [7]$$

where  $\alpha$  is a constant. In cases where  $J_p/J_e > 1$  at

Fig. 2. Ratio of hole to electron currents,  $J_p/J_e$ , vs. concentration of bromide ion in solution in 0.01M  $C_2H_5OH/1M$  KCl/0.05M KOH.

$[X] = 0$ , a linear dependence of  $J_p/J_e$  on  $[X]$  is also found. A relationship of the type given by Eq. [7] appears to be obeyed in any of the combinations of one of the current-doubling agents with one of the noncurrent-doubling agents listed above.

*Current as a function of the concentration of R.*—Methanol and ethanol show the simplest quantitative behavior. In Fig. 3 the results are plotted as values of  $J_p/J_e$  vs. the ratio  $[X]/[R]$ , for three different experiments in which R was 0.02M, 0.1M, and 0.5M  $CH_3OH$  and in which X, being  $I^-$ , was added so that the ranges of  $[X]/[R]$  covered were the same. This procedure was chosen to avoid very narrow as well as very wide ranges of  $[X]/[R]$ , corresponding with very small and very large changes in  $J_p/J_e$  respectively,

Fig. 3. Ratio of hole to electron currents,  $J_p/J_e$ , vs. ratio of solution concentration of iodide to methanol.  $[I^-]/[CH_3OH]$ , in 1M KCl/0.05M KOH.  $\circ$  0.5M  $CH_3OH$ ,  $\triangle$  0.1M  $CH_3OH$ ,  $\square$  0.02M  $CH_3OH$ .

since both situations are subject to comparatively large experimental errors. It is seen in Fig. 3 that the following relationship holds

$$(J_p/J_e) = 1 + \beta[X]/[R] \quad [8]$$

where the reactivity ratio  $\beta$  is a constant. Relationship [8] has been found to be obeyed for ethanol as well as for methanol. The data are independent of the order of mixing.

Table I gives the values of  $\beta$  determined from separate experiments. In cases where  $J_p/J_e > 1$  for  $[X] = 0$ , a corrected value of  $J_p$  was used for the calculation of  $\beta$ . This correction was based on the assumption that a constant fraction of the holes, determined from the  $J_p/J_e$  value at  $[X] = 0$ , reacts by another pathway than that involving X and R, e.g., anodic dissolution of zinc oxide. In no case was the correction more than 25%. For  $SO_3^{2-}$ , a correction was made, when necessary, for a small dark injection current that was sometimes observed. Of the many substances investigated, only dithionite gave a high dark injection current. This dark current might be associated with the known (13) dissociation to the radical ion  $SO_2^{\cdot-}$ ; radicals may be expected to have an energy level above the bottom of the conduction band. The values of  $\beta$  are independent of the light intensity and the crystal as shown in Table I.

Relationship [7] seems to be more generally applicable than the more restrictive relationship [8]. In contrast to methanol and ethanol, the following substances obey [7] but not [8]: 2-propanol, tartrate ion, and borohydride ion. The nonconstancy of  $\beta$  is shown in Table I. For two  $(CH_3)_2CHOH$  vs.  $I^-$  experiments, changing the alcohol concentration by a factor of 10 resulted in a change of  $\beta$  by a factor of 3. In the case of tartrate ion,  $\beta$  is constant for iodide and sulfite but not for bromide. While borohydride was investigated at only one concentration, nonsimple behavior is illustrated by the  $\beta$  values with the three X substances. For sulfite and iodide the values are almost equal, in contrast to the other current-doubling agents where they differ by more than a factor of 4. For bromide, even at the solubility limit, no effect was found on current-doubling by borohydride.

*Qualitative results.*—By observing the current in alcohol solutions on addition of various reactants, it was established that, in addition to the reducing agents mentioned above, acetone, oxalate, and 2-methyl-2-propanol are oxidized by holes, whereas chloride, acetate, and phthalate are electrochemically inert.

*Quenching of current-doubling by an oxidizing agent.*—The number of systems suitable for quantitative studies is restricted here by the requirement that the oxidizing agent Y should react with the sorbed radical-type intermediate  $R^+$ , but not with the current-

Fig. 4. Ratio of electron to hole currents,  $J_e/J_p$  vs. copper (II) concentration in solution,  $[Cu(NH_3)_4^{+2}]$  for 1M  $C_2H_5OH/1M$  KCl/0.05M KOH.

doubling agent R; this eliminates, for instance, systems such as alcohol-permanganate or borohydride-ferricyanide. A Y-type reagent for which this requirement is met with respect to alcohols and formate as current-doubling agents is the tetramminecopper(II) ion. A typical quenching curve in which  $J_e/J_p$  is plotted against  $[Cu(NH_3)_4^{+2}]$  is shown in Fig. 4, indicating a relationship

$$J_e/J_p = 1 - \gamma[Y] \quad [9]$$

where  $[Y]$  is the concentration in solution and  $\gamma$  is a constant. Relationship [9] appears to be valid for the system  $Cu(NH_3)_4^{+2}$  vs. all current-doubling agents investigated, namely, methanol, ethanol, 2-propanol, and formate. In the cases in which the initial value (absence of Y) of  $J_e/J_p < 1$ , the same type of relationship holds, with the same value of  $\gamma$ , but of course with a different intercept. Relationship [9] was usually found to be obeyed down to about  $J_e/J_p = 0.2$ .

In Table II, values of the quenching coefficient,  $\gamma$ , are listed for different combinations of experimental conditions. It can be seen that  $\gamma$  is independent of the nature and concentration of the current-doubling agent, the hole current  $J_p$ , the light intensity  $I$ , and the zinc oxide crystal used.

Some work was also done with dissolved  $O_2$  as a quenching agent. The concentration of dissolved oxygen was varied by bubbling  $N_2-O_2$  mixtures of known composition through the solutions. The amount of quenching in alcohol solutions, even when saturated with  $O_2$  at 1 atm pressure, was, however, insufficient to permit drawing any quantitative conclusions.

### Discussion

*Competitive oxidation of current-doubling and non-current-doubling agents.*—A theoretical expression that

accounts for the experimental relationship [8], valid in the case of  $CH_3OH$  and  $C_2H_5OH$ , can be derived as follows. Consider the reactions

where R is assumed to be a two-equivalent, and X a one-equivalent reducing agent. Since reaction [1], whose rate is determined by the light intensity, is the rate-determining step, a steady state in p and  $R^+$  may be assumed. Considering that the currents are proportional to the rates, we can write

$$J_p/J_e = \{k_R[R_{ad}][p] + k_X[X_{ad}][p]\}/k_R[R_{ad}][p] \quad [10]$$

where  $k_R$  and  $k_X$  are the rate constants of reactions [2] and [4], respectively,  $[R_{ad}]$  and  $[X_{ad}]$  are the surface concentrations of sorbed R and X, and  $[p]$  is the formal hole concentration at the surface. If independent sorption of X and R according to linear sorption isotherms is assumed, which usually implies low degrees of coverage, relationship [10] becomes

$$J_p/J_e = 1 + (K_X/K_R) ([X]/[R]) \quad [11]$$

where  $K$ , the hole reactivity constant, is equal to the product of the sorption and the rate constants and the brackets refer to concentrations in solution. Relationship [11] is in agreement with the experimental expression [8], whereby

$$\beta = K_X/K_R \quad [12]$$

It should be pointed out that our use of a formal hole concentration on the surface should not be taken as evidence for the existence of sorbed holes in the sense of adsorbed chemical species. Conceptually, the hole in the valence band and the electron in the conduction band arise from ideas restricted to the bulk of the zinc oxide near, but not on, the surface. Experimentally, only flow rates of these carriers within the solid are measured. In the kinetic formulation given above, no problems arise with the use of a formal concentration on the surface because of the same dependence on both  $J_e$  and  $J_p$ .

From the values of  $\beta$  listed in Table I, relative values of hole reactivity can be calculated for all the reactants involved. For instance, a value of  $K$  for sulfite relative to iodide is found by dividing the  $\beta$  values obtained from sulfite vs. methanol and iodide vs. methanol. An important observation is that the same value is found, as required by theory, from the data involving ethanol. Similarly,  $K$  for the bromide relative to iodide can be calculated in two ways. Values of  $K$  as determined with different titrants are listed in Table III, where, arbitrarily,  $K = 100$  is chosen by iodide. By inserting the  $K$  values for iodide, sulfite, and bromide in the data of Table I,  $K$  values for methanol and ethanol are deduced in three ways. From Table III, it can be seen that all results are independent of the way they have been determined. This provides confidence in the competition concept and in the quantitative values of relative hole reac-

Table III. Hole reactivities

	18	$SO_3^{2-}$
	18	I

tivities. Thus, while it has not been possible to evaluate the absolute hole reactivity of a substance, it has been shown that unique reactivities can be assigned to several substances.

We shall now discuss the cases where relationship [8] does not hold. For 2-propanol, the dependence of  $\beta$  on  $[R]$  can be explained by a nonlinear isotherm. Relative values for  $K_X$  can still be found by comparing  $\beta$ -values calculated from experiments in which the 2-propanol concentrations are the same. By normalizing the data from row 3 of Table I to  $K_{I^-} = 100$ , we find  $K_{SO_3^{2-}} = 27$  and  $K_{Br^-} = 1.5$ , in fair agreement with the values calculated from the methanol and ethanol experiments. It may be remarked here that this result would not agree with another model for the sorption of X and R, which also results in a relationship of the type given by [11]. This model assumes complete coverage and competition for the same surface by X and R. Indeed, anomalies in the sorption of 2-propanol would, with these assumptions, lead to deviations in the  $[X]$  dependence.

With tartrate,  $K_{SO_3^{2-}}$  is 24; the behavior with  $Br^-$  cannot be interpreted at this time. With borohydride, the  $K$ -values for  $SO_3^{2-}$  and  $I^-$  are about equal, whereas the value for  $Br^-$  is zero. We think this could result from reduction of the oxidation products of the noncurrent-doubling reactants by  $BH_4^-$ , a powerful reducing agent, followed by electron injection from the radical product of  $BH_4^-$ . The net result with  $BH_4^-$  is a decrease, or the complete disappearance, of the influence of the noncurrent-doubling agent on  $J_p/J_e$ , since an electron-injection radical is produced independent of the  $[Br^-]$ . The oxidation products of  $Br^-$  are likely to be more reactive toward reducing agents than are the ones of  $I^-$ ; the oxidation products of  $SO_3^{2-}$  are probably not reactive at all.

Our results exclude an alternate mechanism for competitive oxidation by holes, in which the oxidation reaction of the noncurrent-doubling agent would be

Indeed, the current-concentration relationship in this case would not include any dependence on  $[R]$ , in contradiction with experimental observation (relationship [8]).

#### Quenching of Current Doubling by an Oxidizing Agent.

—The current-concentration characteristics of the Y-type reagent  $Cu(NH_3)_4^{+2}$  with three alcohols and formate ion can be described in terms of a competition between the conduction band and the oxidizing agent Y for the electron of the photoproduced radical  $R^+$ . These surface reactions can be represented as

The experimental result, Eq. [9], can be written to show that  $(J_p - J_e)/J_e$ , the ratio of chemical oxidation [14] to electron injection [3], equals the ratio  $\gamma[Y]$  to  $\{1 - \gamma[Y]\}$  where  $[Y]$  refers to concentration in solution and  $\gamma$  is a constant independent of light intensity and copper ion concentration. At least formally, this current-concentration relationship describes chemical oxidation by Y of the intermediate and inhibition by Y of the electron injection process. While we are still uncertain of the detailed interpretation of these results, some general characteristics seem to be clear. First, the ratio of chemical oxidation to inhibition by Y is independent of the rate of generation of the intermediate  $R^+$ . Second, the electrical results are independent of the concentration of R. Third, the value of  $\gamma$  is the same for the four different R substances investigated. The last characteristic is particularly noteworthy, since the implication is an identical rate-determining process for all four R substances. This may arise from the rate expression

being independent of R or from the generation of a common intermediate from all four R substances. We favor the latter explanation, with the intermediate,  $H\cdot$ , as  $R^+$ . In the next section chemical support for the idea of the hydrogen atom as a common intermediate will be given.

It should be noted that the possibility of the  $Cu(NH_3)_4^{+2}$  effect resulting from the reduction of the  $Cu(II)$  by conduction band electrons was ruled out by the absence of a cathodic current in the dark at the same voltage.

*Chemical considerations.*—In the foregoing section it was suggested that the radical-type intermediate formed during the oxidation of different alcohols and formate ion could be the hydrogen atom. For a primary alcohol, for instance, the two-equivalent oxidation would be the surface reactions<sup>3</sup>

In the case of formate, the first oxidation step would be

This hypothesis of  $H\cdot$  being the common electron injector in many current-doubling reactions is supported by the following chemical evidence: (I) For 12 of the current-doubling agents, the oxidation can be considered as a dehydrogenation. (II) Binoxalate,  $C_2O_4H^-$ , exhibits current doubling, whereas oxalate  $C_2O_4^{2-}$  is oxidized by two holes. (III) Acetaldehyde shows current doubling, and acetone is oxidized by a hole mechanism. (IV) 2-Methyl-2-propanol,  $(CH_3)_3COH$ , which has no  $\alpha$ -hydrogen, is oxidized without current doubling, in contrast with the primary and secondary alcohols investigated.

It was assumed that the oxidation of R is two-equivalent and that of X one-equivalent. No chemical analyses were made in order to support this hypothesis. In the case of 2-propanol, the electrical data indicated that the oxidation is two-equivalent. The argument is as follows. The two-equivalent oxidation product of 2-propanol is acetone. Our experiments show that acetone is oxidized solely by holes. Since at least two holes must be involved per acetone molecule, the ratio  $J_e/J_p$  could not be more than 1:3 if 2-propanol were oxidized beyond acetone. Experimentally,  $J_e/J_p$  for 2-propanol was found to be near unity, implying that the acetone formed must be desorbed. The small amount present on the surface because of the sorption equilibrium would not have any noticeable influence on the current doubling. For the other reactants investigated, our results do not provide evidence concerning desorption following the first oxidation step. The oxidation product at the electrode could, for instance, be  $I(O)$  as  $I_2$  or  $I(+1)$  as  $OI^-$  in the case of  $I^-$ , and  $S(+V)$  as  $S_2O_6^{2-}$  or  $S(+VI)$  as  $SO_4^{2-}$  in the case of  $SO_3^{2-}$ .

The lack of knowledge about the absolute amounts sorbed makes it impossible to isolate the rate constants for oxidation by holes from the experimental values of  $K$ . The type of numerical data available at present has a practical significance in that they allow certain predictions about selective oxidation of mixtures of reactants in contact with illuminated zinc oxide, not only in anodic, but also in catalytic conditions. Indeed, illuminated zinc oxide has been shown (14, 15) to be a catalyst for the reaction between oxygen and several of the reagents under investigation (alcohols, formate, oxalate) with formation of  $H_2O_2$ . Considering the mechanism suggested for one of these reactions (9), a direct correlation is likely to exist between the relative oxidation rates in a mixture of such reactants and the relative  $K$  values determined under anodic conditions.

<sup>3</sup> It is assumed here that the alcohols sorb in the form of the alcoholate anions; this view is supported by the pH dependence of current doubling with alcohols.

Manuscript submitted March 14, 1968; revised manuscript received April 25, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Intrinsic Stress in Evaporated Metal Films

E. Klokholm and B. S. Berry

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

## ABSTRACT

The sign and magnitude of the intrinsic stresses observed in evaporated metal films cannot be predicted from *a priori* knowledge. In an effort to correlate the observed intrinsic stress,  $S$ , with other physical parameters,  $S$  has been measured in films of fifteen different metals. The stress was measured *in situ* by the cantilevered substrate technique. The films were evaporated from an electron bombarded source in vacuums of  $10^{-6}$  to  $10^{-7}$  Torr onto glass substrates at room temperature. Under these conditions the intrinsic stress was generally found to be tensile, though exceptions were observed. The data obtained indicate that films of metals with higher melting temperatures and larger shear moduli have intrinsic stresses which approach a magnitude roughly equal to 0.01 of the shear modulus. It is suggested that such high values of stresses are generated by the annealing and constrained shrinkage of disordered material buried behind the advancing surface of the growing films. Reduction of the stress is predicted when surface rearrangements preempt the need for extensive subsequent internal annealing. This proposal is considered in the relation to the experimental observation that the intrinsic stress is small when the ratio of the (absolute) substrate and melting temperatures exceeds  $\frac{1}{4}$ .

The existence of large internal stress in thin films is of considerable importance in the use and application of thin films in microcircuit technologies. These stresses can cause film rupture, loss of adhesion, substrate cracking, and changes in the physical and chemical properties of the films. For films which have been deposited on substrates at temperatures above or below the temperatures at which the film is to be used, the internal stress consists of two terms. One of these is a thermal stress due to the difference in the thermal expansion of the film and the substrate. The second stress, generally called the intrinsic stress, is apparently a fundamental result of the manner of growth of the thin film. In the work presented here we will be concerned only with the intrinsic stress in films deposited on glass substrates at or near room temperature. It will become apparent that the intrinsic stress is often larger than the yield stress in bulk materials.

### Experimental

In an effort to correlate the intrinsic stress,  $S$ , with other physical parameters, the stress has been measured as a function of film thickness in 15 different metals deposited on glass substrates at room temperature. The cantilevered substrate technique was used to measure  $S$ . In this technique one end of a glass substrate is rigidly clamped in a fixed mount. The free end is connected to the arm of an electronic microbalance. A deflection,  $D$ , of the free end produces

an output from the microbalance which is proportional to  $D$ . A film deposited on one side of the substrate results in a deflection proportional to the bending moment exerted on the substrate by the film. The bending moment is in turn proportional to  $Sd$  where  $d$  is the film thickness and  $S$  is the average stress in the film. The sense of  $D$  is a direct indication of the kind of stress in the film. For a film deposited on the underside of the substrate, an upward  $D$  indicates a compressive stress in the film; a tensile stress causes a downwards deflection. To calibrate the substrate in order to obtain  $Sd$  from  $D$ , it is only necessary to note the response of the microbalance caused by the application of a known weight to the free end of the substrate. The sensitivity of the stress measuring instrumentation is such the  $Sd$  from 50 to greater than  $10^5$  d/cm can be continuously measured over the entire range. Finally, to obtain  $S$  from  $Sd$ , an independent measurement of the film thickness is necessary. The film thickness was determined from a calibrated oscillating quartz crystal film thickness monitor. The crystal monitor was calibrated by measuring the thickness of a film interferometrically and relating this thickness to the change in the resonant frequency of the quartz crystal. The entire apparatus is mounted in the upper portion of an oil pumped, liquid nitrogen trapped, 18-in. bell jar evaporator. An electron gun was used as the evaporation source; evaporation rates were from 2 to 5Å/sec. Chamber pressures during film

deposition were  $10^{-6}$  to  $10^{-7}$  Torr. The substrates prior to deposition were at room temperature; however, during deposition the substrate temperature increased by about  $25^{\circ}\text{C}$ . In order to maintain the temperature within this limit, the films had to be deposited sequentially in steps of about  $25\text{\AA}$ .

### Results and Discussion

The data for  $Sd$  as a function of  $d$  are presented in Fig. 1, 2, and 3. The thickness dependence of the average stress, calculated from these results using the definitional relationship  $S \equiv (Sd)/d$  for uniform continuous films, is shown in Fig. 4, 5, and 6. It should be noted that these plots magnify considerably small irregularities of doubtful significance which occur near the foot of the  $Sd$  vs.  $d$  curves. To avoid this region of uncertainty, relative comparisons of the stress in

different materials have been made at a film thickness of  $1000\text{\AA}$ . This information is given in Table I, together with values of melting point  $T_m$  and shear modulus  $\mu$ . Figure 7 shows the dependence of the data in Table I on position in the periodic table. The stress in Zr, Nb, V, Ti, Co, and Mn evaporated films have not been previously reported. Stress in the films of the other metals have been reported, and the values of  $S$  given here are in agreement with those quoted in the reviews by Hoffman (1-4).

From the above data, two empirical conclusions are possible; first, the stress in the harder, more refractory metals is very large, about  $10^{10}$  dynes/cm<sup>2</sup>, while in the softer, more fusible metals, Cu, Ag, Au, and La,  $S$  varies from about  $5 \times 10^9$  to less than  $10^9$  dynes/cm<sup>2</sup>. Second, there is a systematic gradation in the form of the  $Sd$  vs.  $d$  curves. The  $Sd$  for the softer, more fusible metals of Fig. 3 rises from a small value to either a broad maximum or to approximately a constant value. For most of the remaining metals of

Fig. 1 and 2,  $Sd$  increases almost linearly with  $d$ . A notable exception is  $Sd$  for Ti films which inexplicably is at first in compression, and at about 1000Å changes to tension with increasing  $d$ .

It is evident from Fig. 7 that some degree of correlation exists between  $S$ ,  $\mu$ , and  $T_m$ . The correlation of  $S$  jointly with  $\mu$  and  $T_m$  seems to be better than with  $T_m$  and  $\mu$  considered separately. As an empirical rule, it appears that, if  $T_m < 1500^\circ\text{K}$  and  $\mu \leq 4 \times 10^{11}$  d/cm<sup>2</sup> simultaneously, then the stress is relatively small, and  $Sd$  does not continuously increase with  $d$ . On the other hand, for  $T_m > 1500^\circ\text{K}$  and  $\mu \geq 4 \times 10^{11}$  d/cm<sup>2</sup>, the stress is large ( $\cong 0.01\mu$ ) and  $Sd$  increases linearly with  $d$ .

It is of interest to consider now the incremental stress,  $S_i$ , defined as the local slope at a point on the  $Sd$  vs.  $d$  curve

$$S_i \equiv \Delta Sd / \Delta d$$

This stress can be interpreted as the stress produced in an incremental layer  $\Delta d$  at the free surface of the film. In the refractory metals  $Sd$  is roughly linear in  $d$  and therefore  $S_i$  and the stored elastic energy density remains constant. Furthermore, since  $S_i$  is almost independent of  $d$ , an essentially uniform stress must also be present in such films. On the other hand,  $S_i$  in the more fusible metals first increases to a maximum, and decreases towards zero (or even changes sign), and hence the stored elastic energy decreases with  $d$  after the first few hundred Angstroms. The stage of decreasing  $S_i$  is thought to indicate that the stress in such films is due primarily to stresses at the film-substrate interface. For an idealized model (5), it has been shown that the interfacial stresses should decrease as  $1/d$ . In the thick, high melting point films, however, the observation that  $S_i$  is both large and approximately independent of thickness leads to the

Fig. 7. Stress in 1000Å films plotted as a function of atomic number for comparison with the melting temperature  $T_m$  and the shear modulus  $\mu$ .

conclusion that in this case the dominant contribution to the stress is not caused by interfacial effects but is caused by a second contribution whose magnitude is dependent on the deposition process.

It is suggested that this second contribution to the intrinsic stress (which we shall refer to as the growth stress) originates from the annealing and attendant shrinkage of disordered material buried behind the advancing surface of the growing film. The disordered material is envisaged to have a structure and density lying between the two extremes represented by a perfect crystal and a highly defective supercooled liquid. Consequently, any annealing which produces a more nearly perfect crystalline arrangement results in an attendant shrinkage strain which would occur isotropically if it were free to occur without restraint. Shrinkage in the plane of the film is, however, inhibited by the substrate, with the result that an isotropic stress is generated in the plane of the film. To account for the magnitude of the largest stresses encountered in this work ( $S_{\max} \cong 0.01\mu$ ) it is only necessary to postulate that annealing tends to produce a maximum density increase of a few per cent, which seems quite reasonable in view of its similarity to the density increase produced by freezing a liquid metal.<sup>1</sup> Further, since annealing will produce the same value of  $S_i$  in each incremental layer of the film, this explanation for the stress is consistent with the required prediction that the  $Sd$  vs.  $d$  curve should be approximately linear in all cases where the growth stress is the dominant contribution to the total intrinsic stress. It should also be noted that since the rough proportionality between  $S_{\max}$  and  $\mu$  implies that the maximum shrinkage strain has an approximately constant value of 1%, we infer that the maximum density change produced by annealing is also roughly constant from one material to another.

One of the most important features of any model for the origin of the growth stress is the insight it yields into the factors which may govern the dependence of the stress on the temperature of the substrate. In the present model, the stress is postulated to occur as a result of an internal rearrangement behind the growing surface of the film. It follows that if the rearrangement involves a thermally activated process, it could be inhibited (and the stress prevented from developing) by deposition on a substrate held at a sufficiently low temperature. However, since this temperature can be expected to be comparable with the very low temperatures needed to deposit an amorphous film (4.2°K or less for pure metals), we conclude that in the present experiments the annealing always proceeds very rapidly to completion, so that the magnitude of the growth stress reflects only the amount of disorder initially present on a surface layer before it becomes buried by the condensation of succeeding layers. For the purpose of rough estimation, consider a film growing under steady-state conditions at a rate  $R_0$  monolayers/sec. On the average, the atoms are exposed on the surface for a time  $R_0^{-1}$ , which in the present experiments is about 1 sec. We suppose that in this interval thermally activated movements occur in a manner tending to improve the crystalline order of the surface, and that these occur at a rate  $\Gamma$  given by an Arrhenius relationship (6), of the type

$$\Gamma = \nu_0 \exp - \frac{Q}{RT_s} \quad [1]$$

where  $\nu_0$  is a frequency factor,  $Q$  is an activation energy,  $R$  is the gas constant, and  $T_s$  the absolute substrate temperature. On this basis it can be argued that a high growth stress corresponds to the condition  $\Gamma \ll R_0$ , and a low stress to the condition  $\Gamma \gg R_0$ . Taking the order of magnitude of  $\nu_0$  as  $10^{14}$  sec<sup>-1</sup>, the effective transition temperature corresponding to

<sup>1</sup> It is interesting to note that for the case of gallium, a metal which expands on freezing, Buckel (7) has found the stress to be compressive in as-deposited films.

$\Gamma = R_0$  occurs when

$$\frac{Q}{RT_s} = 32 \quad [2]$$

Writing now, by analogy with an empirical rule for self-diffusion (6), that  $Q$  is proportional to the melting point  $T_m$ , i.e., that

$$Q \approx KT_m \quad [3]$$

Eq. [2] becomes

$$\frac{KT_m}{RT_s} \approx 32 \quad [4]$$

An examination of the experimental data indicates that the growth stress apparently decreases in the neighborhood of  $T_m/T_s \approx 4.5$ . Inserting this value in Eq. [4] yields  $K \approx 13$  cal/mole/°C. Since this value of  $K$  is about 0.4 of the  $K$ -value necessary to fit Eq. [3] to self-diffusion data, we obtain the result that  $Q$  in Eq. [1] is only 0.4 of that for self-diffusion. An activation energy of this magnitude is consistent with a mechanism involving surface diffusion and/or the movement of vacancies. Either one or both of these processes could provide a means for removing the disorder from the surface of the film, and hence govern the temperature dependence of the growth stress.

In summary, the present observations are believed to demonstrate that the intrinsic stress in metallic films should generally be regarded as being composed of two contributions. One of these is thought to be produced by the mismatch at the film-substrate interface, while the other contribution, the growth stress, is believed to result from the annealing and shrinkage of disordered material behind the surface of the growing film. A distinguishing feature of these two contributions is the different manner in which they cause the average stress to vary with film thickness. The

growth stress is predicted to be highly temperature dependent, and to become small when  $T_s/T_m \gtrsim 1/4$ .

#### Acknowledgments

The authors are indebted to Mr. Walter Pritchett for his invaluable assistance in the stress measurements, and especially to Dr. A. S. Nowick for suggesting a connection between defect annealing and stress generation in thin films.

## Ion Mobility in Crystals of a Mixed-Alkali Ferrite: $K_xNa_{1-x}Fe_7O_{11}$

K. O. Hever\*

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

#### ABSTRACT

A mixed alkali hexagonal ferrite phase  $K_{0.87}Na_{0.13}Fe_7O_{11}$ , is reported. The unit cell and crystal density show it to be closely related to the known phase,  $KFe_{11}O_{17}$ . In the temperature range 200°-500°C the  $Na^+$  ions are immobile, but the  $K^+$  ions exchange rapidly and completely with  $Na^+$  from molten salt. The self-diffusion coefficients for  $K^+$  in  $K_{0.87}Na_{0.13}Fe_7O_{11}$ , and  $Na^+$  in  $NaFe_7O_{11}$ , have been determined as a function of temperature. Exchange from aqueous solution was found to be inhibited. The mobility of alkali ions in these crystals also leads to dielectric loss effects. It is suggested that the new phase has a defect structure.

In a recent publication the exchange and self-diffusion of the sodium ion in beta-alumina have been reported (1). Beta-alumina has been given the formula  $Na_2O \cdot 11Al_2O_3$  (2) and the potassium ferrite,  $K_2O \cdot 11Fe_2O_3$ , is considered to be isomorphous with it (3). It was the purpose of this work to investigate  $K^+$  ion mobility in potassium ferrite.  $K_2O \cdot 11Fe_2O_3$  is one of four closely related phases that have been reported to exist in the  $K_2O$ - $Fe_2O_3$  system. If a particular phase is represented as  $K_2O \cdot \kappa Fe_2O_3$  then the values of  $\kappa$  reported are 5 (4), 6 (5), 7 (6-8), and 11 (8, 9). Of these phases the  $\kappa = 5$  compound is rhombohedral while the others are hexagonal. The unit cell dimensions, proposed unit cell formulae, calculated den-

sities and experimental densities have been summarized previously (4). The two end members,  $KFe_{11}O_{17}$  ( $\kappa = 11$ ) and  $KFe_5O_8$  ( $\kappa = 5$ ) have both been reported as products of cooling a melt of KF and  $\alpha$ - $Fe_2O_3$ , but neither has been prepared by heating  $K_2CO_3$  or  $KNO_3$  with  $\alpha$ - $Fe_2O_3$ , this technique yielding the compounds of intermediate composition ( $\kappa \approx 6$  or 7). The apparent dependence of the product on the method of preparation has led to an expression of doubt (5) as to the existence of the phase  $\kappa = 11$ , while other authors (8) maintain that it does exist, but is metastable with respect to the  $\kappa = 7$  compound above 700°C.

The preparation of two crystal types,  $M_2O \cdot 7Fe_2O_3$  and  $M_2O \cdot 5Fe_2O_3$ , where  $M^+$  represents the sum of

\* Electrochemical Society Active Member.

alkali ions present as  $\text{Na}^+$  and  $\text{K}^+$ , is reported below. Both types of crystals were obtained by cooling  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{Fe}_2\text{O}_3$  melts. Recourse to this melt followed the failure of several attempts to employ the KF melt method. The crystals obtained from KF were not reproducible in composition and were too small to analyze singly.

**Crystal preparation.**—A melt of molar composition  $2\text{Na}_2\text{O} \cdot \text{K}_2\text{O} \cdot 6\text{Fe}_2\text{O}_3$  was cooled at the rate of  $5^\circ\text{C}/\text{hr}$  from  $1250^\circ$  to  $1100^\circ\text{C}$  and then rapidly to room temperature. After removal of the solid from the platinum crucible, the crystals were extracted by dissolution of the melt component in boiling 100% nitric acid. The crystal form was that of thin platelets up to  $\sim 0.5$  cm in diameter. Single crystal and batch analyses were identical and corresponded to the formula  $\text{M}_2\text{O} \cdot 7\text{Fe}_2\text{O}_3$  where  $\text{M}^+ = 0.87 \text{K}^+ + 0.13 \text{Na}^+ \dots \{1\}$

The crystal density at  $30^\circ\text{C}$  was found to be 4.29. An attempt to reduce the amount of sodium in the crystals by exchange from molten  $\text{KNO}_3$  at  $400^\circ\text{C}$  led to an unchanged chemical analysis, even after five days of immersion, indicating that the  $\text{Na}^+$  ions were immobile. The exchange of  $\text{K}^+$  for  $\text{Na}^+$  by immersion of the crystals in molten  $2\text{NaNO}_2 \cdot \text{NaNO}_3$  eutectic at  $300^\circ\text{C}$  was found to be rapid ( $\sim 50\%$  exchange in a few minutes) and the final crystal composition, obtained after five days of immersion with several melt changes, corresponded to the formula  $\text{M}_2\text{O} \cdot 7\text{Fe}_2\text{O}_3$  where  $\text{M}^+ \cong 99.5\% \text{Na}^+ \dots \{2\}$

From the inability to exchange the sodium ions of crystals {1} it was thought that the crystals might involve two phases with perhaps an alkali-rich phase microdispersed in the major component phase. From the absence of lines that could not be indexed on the hexagonal unit cell:  $a = 5.931\text{\AA}$ ,  $c = 23.74\text{\AA}$  and from the consistency of the crystal composition after partial dissolution in acid, the material is presumed to have a single phase. The difference between  $\text{Na}^+$  and  $\text{K}^+$  mobilities is probably due to their different ionic sizes.

The dissolution experiments were performed, at room temperature, with 20% hydrochloric acid and crystals which had been ground to less than  $40\mu$  in size. After partial dissolution, the crystals were washed with water and treated with hot 20% KOH solution to replace protons that had entered the crystal by exchange. The composition of the crystals was found to be unchanged from {1}. The process of dissolution in acid, washing in alkali and chemical analysis was repeated. Again no change of composition was detected.

A rhombohedral mixed-alkali ferrite was found to crystallize together with small crystals of  $\alpha\text{-Fe}_2\text{O}_3$  when a melt of molar composition  $34\text{Na}_2\text{O} \cdot \text{K}_2\text{O} \cdot 74\text{Fe}_2\text{O}_3$  was cooled slowly. Large single crystals could be removed from the melt by hand, and their composition was found to correspond to the formula  $\text{M}_2\text{O} \cdot 5\text{Fe}_2\text{O}_3$  where  $\text{M}^+ = 0.89 \text{Na}^+ + 0.11 \text{K}^+$ . No other phases could be detected from the x-ray spectrum which could be completely indexed on the non-primitive hexagonal unit cell:  $a = 5.937\text{\AA}$ ,  $c = 35.77\text{\AA}$ . Most crystals were small and irregularly shaped and therefore unsuitable for self-diffusion measurements. They lost alkali when in contact with hot nitric acid and decomposed to  $\alpha\text{-Fe}_2\text{O}_3$  when heated in air above  $300^\circ\text{C}$ .

**Self-diffusion of alkali ions in crystals {1} and {2}.**—The self-diffusion of  $\text{K}^+$  in crystals {1} and  $\text{Na}^+$  in crystals {2} was measured at various temperatures by observation of the rate of loss from the crystals of  $\text{K}^{42}$  radioisotope into an inactive  $\text{KNO}_3$  or  $\text{KSCN}$  melt, and  $\text{Na}^{22}$  radioisotope into an inactive  $\text{NaNO}_2/\text{NaNO}_3$  melt, respectively. The crystals had previously been equilibrated with an active melt, and comparison was made between the activity of the equilibrated crystal and the activity of the crystal after immersion in the

inactive melt. All activity measurements were made in the direction perpendicular to the plane of the platelet, i.e., perpendicular to the plane of diffusion (1) so that corrections for absorption of radiation by the crystal were unnecessary.

$\text{K}^{42}$  was obtained in solid  $\text{KNO}_3$  by neutron irradiation at the Phoenix reactor of the University of Michigan. The  $\text{Na}^{22}$  was purchased from a commercial source. A  $\beta$ -particle Geiger counter was utilized for radioactivity measurements.

In order to determine diffusion constant ( $D$ ) values it was assumed that no serious error would be introduced by using the equation (10) for fractional loss of ions as a function of time ( $t$ ) for diffusion from an infinitely long cylinder of radius  $r$  into a bath of infinite volume

$$M(t)/M_{(\infty)} = 1 - 4\sum_{n=1}^{\infty} \frac{1}{\alpha_n^2} \exp(-D\alpha_n^2 t/r^2)$$

where  $M(t)/M_{(\infty)}$  is the fractional loss of radioactivity of the crystals and  $\alpha_n$  are the  $n^{\text{th}}$  roots of the zero order Bessel equation,  $\alpha_1 = 2.405$ ,  $\alpha_2 = 5.520$ ,  $\alpha_3 = 8.654$ , etc. The above equation was acceptable for diffusion in the platelets because their layer structure leads to radial diffusion only [this has been elegantly illustrated for " $\beta$ -alumina" previously (1)]. It was found that when the edge of platelet was obstructed by epoxy cement, exchange does not occur. The melts were stirred during exchange to maintain a near-zero concentration of radioactive tracer in them, and results were found to be independent of the rate of stirring. Interpolation from a curve (15) of  $M(t)/M_{(\infty)}$  vs.  $(Dt/r^2)^{1/2}$  gave, for measured  $M(t)/M_{(\infty)}$ , a value of  $Dt/r^2$ . An average value of  $r^2$  was determined from the area of the crystal obtained by planimeter integration from a photograph of the crystal taken through a microscope.  $D$  values were obtained at various temperatures and the activation energy determined (Fig. 1). The activation energies for  $\text{K}^+$  and  $\text{Na}^+$  self-diffusion in the ferrite crystals were found to be  $(7.21 \pm 0.3)$  and  $(13.7 \pm 0.7)$  kcal/mole, respectively, and the pre-exponential factors  $1.05 \times 10^{-3}$  and  $1.48 \text{ cm}^2/\text{sec}$ , respectively. Exchange from an aqueous solution of alkali ion was not observed even after 20 hr at  $84^\circ\text{C}$  for 1-2 mm diameter crystals either in the sodium case or in the potassium case, indicating that the apparent diffusion constants were less than  $10^{-11} \text{ cm}^2/\text{sec}$ . Room temperature diffusion of  $\text{Na}^{22}$  in crystals {2} was measured by diffusing a small amount of  $\text{Na}^{22}$  into one end of an approximately rectangular crystal; this was achieved by dipping the end of the crystal into a high

Fig. 1. Self-diffusion of  $\text{K}^+$  and  $\text{Na}^+$  ions in  $\text{M}_2\text{O} \cdot 0.7\text{Fe}_2\text{O}_3$  crystals.

specific activity  $\text{NaNO}_3$  melt ( $\sim 1$  mc in 50 mg) after protection of the other sides with an epoxy cement. After immersion for about 8 sec, the crystal was rapidly cooled to room temperature and the activity profile along the longest axis of the crystal estimated by shielding a portion of the crystal by 0.05 cm thick platinum foil and counting the exposed area. With 30% of the area at the "hot" end exposed, a count rate of 4,100 cpm was observed compared to a total count rate of 4,350 cpm for 100% exposed. Assuming that the platinum foil absorbed all  $\beta$  rays, but allowed complete transmission of  $\gamma$  rays, and noting the 0% exposed count of 310 cpm, we can state that at least 15/16 of the total count was observable in a 30% area at the hot end. This allows the increase in activity of a 30% exposed area at the cold end with time to be treated as the one-dimensional diffusion in a rod of length  $l$  cm of uniform cross section from an instantaneous source placed at the hot end ( $x = 0$ ). The required expression for fractional increase of activity at time  $t$ ,  $[M(t)/M(x)]$ , for an exposed fraction of length  $\Delta x$  is

$$\frac{M(t)}{M(x)} = 1 + \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{(-1)^n}{n} \frac{1}{\Delta x} \exp(-Dn^2\pi^2t/l^2) \sin(n\pi\Delta x)$$

This expression was summed by computer and a curve constructed of  $M(t)/M(x)$  against  $Dt$  for  $\Delta x = 0.3$  and  $l = 0.30$  cm. From the observed  $M(t)/M(x)$  value (correcting for background)  $Dt$  can be interpolated for several values of  $t$ . A plot of this  $Dt$  value against  $t$  gave a straight line which, due to the approximate nature of the assumption of instantaneous source, did not pass through the origin. The experimentally determined  $M(t)$  vs.  $t$  plot and the  $Dt$  vs.  $t$  plot appear in Fig. 2. The slope of this plot gave a value for  $D$  of  $2.6 \times 10^{-8}$  cm<sup>2</sup>/sec.

**Dielectric loss measurements.**—Additional evidence for ionic mobility was provided by measurement of dielectric loss for the crystals {1} and {2} undertaken by R. Radzilowski of this laboratory. The crystals were ground to between 100 to 200 mesh and mixed with powdered  $\alpha$ -alumina in the ratio 1:3 by weight, respectively. This powder was loosely packed between two concentric aluminum cylinders 2.3 mm apart and 13 cm long, with a mean diameter of  $\sim 2$  cm. The capacity and  $\tan \delta$  values were measured on a type 716-C General Radio Capacitance (Schering) bridge as a function of temperature at frequencies of 100, 1000, and 10,000 Hz. The  $C \tan \delta$ -temperature curves exhibited loss maxima (Fig. 3 and 4) and from a plot of  $\ln$  (frequency) against reciprocal temperature for the three points of maximum loss the activation energy

Fig. 2. Room temperature  $\text{Na}^{22}$  diffusion along a rectangular crystal of  $\text{Na}_{20.7}\text{Fe}_2\text{O}_3$ ; activity of exposed length vs. time.

Fig. 3. Dielectric loss curves,  $C \tan \delta$  vs. temperature for 25 w/o of crystals {1} in  $\alpha$ -alumina (cps = Hz).

Fig. 4. Dielectric loss curves,  $C \tan \delta$  vs. temperature for 25 w/o of crystals {2} in  $\alpha$ -alumina (cps = Hz).

Fig. 5. Frequency of maximum dielectric loss against reciprocal temperature.

was determined (Fig. 5). The activation energies were  $(2.94 \pm 0.5)$  kcal/mole for crystal {1} and  $(5.87 \pm 0.6)$  kcal/mole for crystal {2}. These values are substantially lower than the high-temperature activation energies for diffusion of 7.2 and 13.7 kcal/mole, respectively.

Thus these ferrite crystals show dielectric loss behavior similar to that of  $\beta$ -alumina crystals reported earlier (1). It is believed that the loss is of the Max-

well-Wagner type (14) which is the type to be expected from the presence of mobile changes. The discrepancy between activation energies determined from the tracer technique and dielectric loss curves is, at the moment, unexplained. The dielectric loss behavior will be the subject of a later paper.

### Discussion

The crystal structure of the compound  $\text{KFe}_{11}\text{O}_{17}$  ( $\kappa = 11$ ) has been discussed previously (3, 12, 13). The compound may be viewed as a substitutional solid solution of  $\text{K}_2\text{O}$  in  $\alpha\text{-Fe}_2\text{O}_3$  ( $\text{O}^-$  by  $\text{K}^+$ ) and the unit cell as a hexagonal superlattice of the spinel arrangement of  $\alpha\text{-Fe}_2\text{O}_3$  (12). The structures of the other potassium ferrite phases  $\kappa = 5, 6, 7$  are unknown. The corresponding sodium compounds are also unknown. The significant feature of the structure of  $\text{KFe}_{11}\text{O}_{17}$  with respect to ion mobility is that the  $\text{K}^+$  ions occur in layers of low density relative to the material between layers (9). Although the author has not been able to prepare crystals of  $\text{KFe}_{11}\text{O}_{17}$ , crystals of a mixed alkali ferrite,  $\text{K}_{0.87}\text{Na}_{0.13}\text{Fe}_7\text{O}_{11}$ , have been prepared.

A comparison of the data relating to  $\text{KFe}_{11}\text{O}_{17}$  and  $\text{K}_{0.87}\text{Na}_{0.13}\text{Fe}_7\text{O}_{11}$ , given in Table I shows the close similarity of the unit cell dimensions and experimental densities of the two compounds. Three alternative ways in which the compounds might be related, while preserving the unit cell dimensions, are given below. The theoretical densities ( $\delta$ ), calculated from the known unit cell volume and proposed unit cell formulae, are also given.

(a) Interstitial solid solution of  $\frac{1}{2}\text{M}_2\text{O}$  per unit cell.

(b) Substitutional solid solution.

(c) A defect structure with statistical occupation of  $\text{Fe}^{3+}$  sites.

Since the chemical composition,  $\text{M}_20.7\text{Fe}_2\text{O}_3$  where  $\text{M} = 0.87\text{K}^+ + 0.13\text{Na}^+$ , is slightly closer to alternatives (b) and (c) than to (a), and since only alternative (c) is consistent with the experimental density of 4.29, a defect structure is indicated. Although this argument is speculative it does suggest that order-disorder phenomena should be looked for in the alkali ferrite compounds. It is possible that an ordered defect compound has already been made by Roth and Cooper (7) who report the  $\text{K}_20.7\text{Fe}_2\text{O}_3$  'a' axis as 10.287 which is larger, by a factor of  $\sqrt{3}$ , than that normally observed.

The experiments to detect ion mobility in  $\text{M}_20.7\text{Fe}_2\text{O}_3$  crystals show the following features.

Table I. Comparison of the phases  $\text{KFe}_{11}\text{O}_{17}$  and  $\text{K}_{0.87}\text{Na}_{0.13}\text{Fe}_7\text{O}_{11}$

Unit cell		Proposed unit cell formula	Calc.	Exp.	Reference
a(Å)	c(Å)				
5.932	23.80	$\text{K}_2\text{Fe}_{22}\text{O}_{34}$	4.24	4.24	(8)
5.932	23.74	$\text{K}_2\text{Fe}_{22}\text{O}_{34}$	4.25	4.30	(9)
5.931	23.74	See text	See text	4.29	This work

1. Alkali ion mobility is high, the self-diffusion coefficients of  $\text{Na}^+$  and  $\text{K}^+$  at  $300^\circ$  are in the range  $10^{-5}$  to  $10^{-6}$   $\text{cm}^2/\text{sec}$  which is comparable to ion mobilities in  $\beta$ -alumina (1) and of the same order as ion mobilities in aqueous solution at room temperature. In the temperature range  $200^\circ\text{-}500^\circ\text{C}$  the diffusion constants of  $\text{K}^+$  and  $\text{Na}^+$  ions can be described as a function of temperature by Arrhenius equations. Although the activation energy for the  $\text{Na}^+$  is approximately twice that of ion  $\text{K}^+$  the pre-exponential factor is larger by a factor of  $10^3$ . The net effect is a higher mobility for  $\text{Na}^+$  than for  $\text{K}^+$ .

2. The room temperature  $\text{Na}^+$  diffusion coefficient of  $2.6 \times 10^{-8}$   $\text{cm}^2/\text{sec}$  is larger than the value of  $\sim 1.6 \times 10^{-10}$   $\text{cm}^2/\text{sec}$  predicted by extrapolation of the high-temperature  $D$  values down to room temperature. The discrepancy between these two values probably reflects a changeover from a high activation energy to a lower activation energy with decreasing temperature. The low values of the activation energy of  $\text{Na}^+$  and  $\text{K}^+$  for dielectric loss compared to those for diffusion also support a change of activation energy with temperature.

3. The exchange of  $\text{K}^+$  and  $\text{Na}^+$  between aqueous solution and the crystals, at  $85^\circ\text{C}$ , was not observed. The inhibition of exchange must occur at the solution-crystal interface since the diffusion constant within the crystal, for  $\text{Na}^+$  at room temperature, was measurable.

### Acknowledgment

The author is indebted to Dr. J. T. Kummer and Dr. Y. Yao for help in planning the experiments, to Dr. W. Pierson for the use of his laboratory facilities and to Mr. R. Radzilowski for performing the dielectric loss measurements.

Manuscript submitted Dec. 13, 1967; revised manuscript received March 22, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# A Solid-State Electrochemical Cell Based on Ion Conductive Ceramics

K. O. Hever\*

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

## ABSTRACT

A solid-state electrochemical cell has been devised using a ceramic ion conducting electrolyte and ceramic electrodes which are simultaneously ion and electron conducting. Charge/discharge of the cell occurs without chemical phase change and the reaction of the cell to an electric current is therefore capacitive. The origin of the capacitance is discussed in terms of the crystal structure of the ceramic used and the transient electrical characteristics described in terms of diffusion theory. Possible applications are suggested.

This paper reports an attempt to construct a secondary battery offering the advantages associated with ceramic materials. Mechanical and electrical stability leading to a long cycle life, operation over a wide temperature range, ease of construction, and cheapness of materials are the principal advantages ceramic materials offer.

An ionically conducting solid which has electronic conduction properties by virtue of a transition element in more than one valency state contained in its structure provides a solid-state electrode. Two such electrodes in contact with a solid permeable only to ions constitute a solid-state electrochemical cell. If the transition metals involved at each electrode are different, the primary energy storage mechanism will be associated with a solid-state oxidation-reduction. Example 1 illustrates this case.

### Example 1

In example 1 the transition metal ions are immobile and the  $Na^+$  ions mobile. The  $O^=$  ions of the ceramic are required only as host ions and do not take part in the reactions. Since the electrodes contain both the mobile electrons ( $\epsilon$ ) associated with donor ions and mobile  $Na^+$  ions they are written together as ion pairs ( $V^{4+} \cdot Na^+$ ,  $Ti^{3+} \cdot Na^+$ ). On discharge the  $Na^+$  ions flow from anode to cathode through the electrolyte and an equal number of electrons flow from anode to cathode through the external circuit. If the two electrodes are identical in composition, the cell will not exhibit a spontaneous voltage, but an electrostatic capacity to store energy will exist. Example 2 illustrates this case; a voltage will develop on charging the cell as  $Na^+$  ions and electrons are progressively removed from the anode and added to the cathode.

### Example 2

The ceramic electrodes which can be used to construct solid-state cells must allow ionic and electronic conductivity. An additional requirement is that the crystal structure must allow some degree of non-stoichiometry since ions have to be added or removed from the lattice without change of phase.

The requirements of ionic conductivity and non-stoichiometry appear to restrict useful materials to those transition metal oxides that can be made to crystallize in "tunnel" or "layer" structures in the presence of alkali. These compounds have been dis-

cussed in a review article (8) and typical examples are the vanadium bronzes, tungsten bronzes (tunnel), and alkali ferrites (layer). Ionic conduction has been established for the layer compounds  $\beta$ -alumina (7),  $Na_2O \cdot 11 Al_2O_3$ , and the mixed alkali ferrite  $(K,Na)_2O \cdot 7Fe_2O_3$  (15). This paper describes the preparation and properties of two electrochemical cells that depend for their operation on the ion conducting properties of these layer compounds. Alkali ion mobility in these compounds is a consequence of their unique crystal structure (11) in which the alkali ions are arranged in layers separated by blocks of atoms arranged in the manner of spinel. Although this structure has been proposed in terms of the compounds  $Na_2O \cdot x Al_2O_3$  (9) and  $K_2O \cdot x Fe_2O_3$  (1, 6, 10) where  $x = 11$ , compounds in which  $x = 6$  or 7 have been reported as having the same characteristic x-ray spectrum (2-5). The cells are of the type discussed under example 2 above in which the electrodes are of identical composition when the cell is discharged.

## Experimental Technique

The ceramic compositions of electrodes and electrolytes are given below, the powder x-ray diagrams indicated that the dominant phase present in each case was isomorphous with  $\beta$ -alumina.

	Mobile ion (presumed)	Electrolyte	Electrodes
Cell (a)	$Na^+$	"M Brick"	$Na_2O \cdot 5 (Fe_{0.95}Ti_{0.05}AlO_3)$
Cell (b)	$K^+$	$1.3K_2O \cdot 0.2Li_2O \cdot 10Al_2O_3$	$1.3K_2O \cdot 0.2Na_2O \cdot 10 (Fe_{1.9}Ti_{0.1}O_3)$

In cell (a) the electrolyte consisted of "M" brick which is a commercially available, fusion cast,  $\alpha$ -alumina,  $\beta$ -alumina eutectic. Preliminary experiments to produce electrodes having the characteristic x-ray spectrum of  $\beta$ -alumina by sintering mixtures of  $Na_2CO_3$ ,  $\alpha$ - $Fe_2O_3$ , and  $TiO_2$  failed. Inclusion of  $\alpha$ - $Al_2O_3$  in the electrode mixture produced materials having the desired x-ray spectrum. Presumably these materials contained substantial quantities of a sodium  $\beta$ -aluminate-ferrite solid solution (12).  $Ti^{4+}$  ions acted as doping agents causing the sintered material to show ferromagnetism and an n type thermoelectric effect. It was presumed that  $Ti^{4+}$  gave rise to  $Fe^{2+}$  donor ions, in the major phase of the ceramic, by charge compensation in the manner described for doped  $\alpha$ - $Fe_2O_3$  (13). A ceramic powdered material of composition  $Na_2O \cdot 5 (Fe_{0.95}Ti_{0.05}AlO_3)$  was prepared by mixing the appropriate proportions of  $Na_2CO_3$ ,  $\alpha$ - $Fe_2O_3$ ,  $TiO_2$ , and  $\alpha$ - $Al_2O_3$  powders and heating the mixture at  $1000^\circ C$  for 1 hr. The powder was then mixed with a binder, "carbowax," in benzene solution and the benzene was removed by evaporation. Approximately 0.4g of powder was compacted in a hydraulic press under a pressure of 20,000 lb/in.<sup>2</sup>, yielding a pellet of  $\frac{1}{2}$  in. diameter and 1 mm thick. The binder was then removed by heating the pellet at  $700^\circ C$  for 1 hr.

\* Electrochemical Society Active Member.

Two such pellets were placed on either side of a 2 mm thick,  $\frac{3}{8}$  in. square of "M" brick and the whole object wrapped in 0.0005 in. thick platinum foil. The sandwich in foil was then heated at 1400°C for 1 hr, cooled to room temperature, and the foil cut away to cover only the end electrode area to which it had bonded during the firing process.

A three-electrode cell using the materials of cell (a) was constructed by placing three electrode disks and two electrolyte squares in the sequence

The whole object was then wrapped in platinum foil and sintered as above.

In cell (b) it was found necessary to include  $\text{Na}_2\text{O}$  in the electrode components and  $\text{Li}_2\text{O}$  in the electrolyte components in order to promote sintering. The electrolyte disk was prepared from the appropriate proportions of  $\text{K}_2\text{CO}_3$ ,  $\text{Li}_2\text{CO}_3$ , and  $\alpha\text{-Al}_2\text{O}_3$  by the technique previously described and then sintered at 1960°C for  $\frac{1}{2}$  hr in a gas fired furnace. To limit the loss of alkali the disk was fired in a crucible containing a powder of the same composition. The electrodes were prepared and sintered onto the electrolyte disk as before.

Electrical measurements were made under conditions of potential control. The cell arrangement and a block diagram of the apparatus is shown in Fig. 1. The cell was clamped between two spring loaded platinum disks and the leads soldered into the glass metal seals of a Pyrex container. The Pyrex container was heated by a tube furnace and the cell temperature measured by a thermocouple touching the electrolyte disk. Current was supplied to the cell from the Wenking potentiostat and was measured by the voltage developed across the series decade resistance box,  $R_2$ . This voltage was displayed on a Honeywell "Elektronik 17" strip chart recorder equipped with voltage suppression. The integrated value of charge passed through the cell was measured by a Weston Instrument voltage integrator in parallel with the decade resistance box  $R_1$ . To measure the a-c impedance of the cell as a function of frequency a mechanical sinusoidal generator was inserted into the reference circuit of the potentiostat which was set to maintain zero potential difference between anode and reference electrodes. The generator was constructed from a 1.5v battery, a 20 kohm sinusoidal potentiometer, a synchronous motor, and a speed reducer. The output was continuous up to 1v at a choice of frequencies 1, 0.5, 0.2, 0.1, 0.05, . . . 0.001 cycles/min. Higher frequencies were obtained

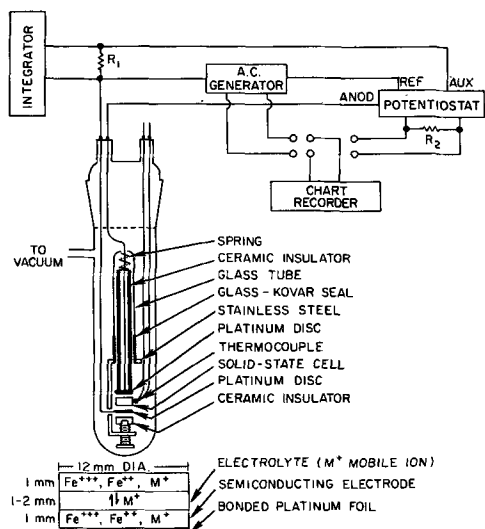

Fig. 1. Experimental arrangement for measurement of electrical properties of solid-state battery.

from an electronic oscillator. The cell impedance was calculated by division of the peak to peak generator voltage by the peak to peak output current of the potentiostat.

Measurements were made after the Pyrex container had been evacuated to a pressure of less than  $10^{-4}$  Torr, although the electrical characteristics were not dependent on the atmosphere pressure over periods of time up to 20 hr. Since the electrical characteristics of the two cells were qualitatively the same the experimental results are discussed in detail with reference to cell (a), the results for cell (a) and cell (b) are then compared.

### Results and Discussion

**Steady-state charge-voltage characteristic.**—The steady-state charge-voltage characteristic appears in Fig. 2 for cell (a) at 300°C. It was obtained by measurement of the charge required to increase, successively, the steady-state potential in 0.1v increments. It can be seen from Fig. 2 that up to 0.6v the device acts as an 18 Farad capacitor, but at voltages greater than 0.6v the capacitance decreases, i.e., the device is nonlinear. On open circuit a rate of loss of potential of about 1/3 mv/hr was observed, equivalent to an internal shorting resistance of  $\sim 3 \times 10^5$  ohms. This shorting may be due to the dissipative reaction caused by residual air,

which leads to a decrease in the quantity of mobile sodium. Such a loss would cause a loss of potential if the cell is regarded as a capacitor.

In order to estimate the capacitance of a cell, each electrode may be regarded as a parallel plate condenser where one set of plates are the  $\text{M}^+$  conducting layers and the other set are the spinel blocks containing the  $\text{Fe}^{++}$  donor ions. Each electrode can then be charged by electrons flowing into the semi-conducting spinel blocks and ions flowing between these blocks. 1 cc of the material would then have a capacitance of the order of

$$2 \times \frac{\text{Number of blocks/cm}}{\frac{1}{2} (\text{Distance between blocks})} \times 0.9 \times 10^{-13} \text{ Farad}$$

i.e.,

$$2 \times \frac{10^7}{2 \times 10^{-8}} \times 0.9 \times 10^{-13} \sim 80 \text{ Farads/cc}$$

For an electrode volume of 0.1 cc then, assuming a single phase material, capacitance  $\sim 8\text{F}$ . Two such electrodes in series would give a capacitance of  $\sim 4\text{F}$ , which is of the same order of magnitude as the experimental value (18F). Also, on this model, the ca-

Fig. 2. Steady-state charge-voltage characteristic of  $\text{Na}^+$  solid-state battery at 300°C.

capacitance ( $C$ ) should decrease with temperature due to the thermal expansion of the electrodes.

Values obtained for the temperature coefficient of steady-state voltage at constant charge  $(\partial V_o/\partial T)_Q$  where  $T$  is the temperature in  $^{\circ}\text{C}$ , were

$(\partial V_o/\partial T)_Q$ v/ $^{\circ}\text{C}$	$V_o$ v	$\frac{1}{V_o} (\partial V_o/\partial T)_Q$ $(^{\circ}\text{C})^{-1}$
$2.0 \times 10^{-4}$	0.34	$5.9 \times 10^{-4}$
$1.4 \times 10^{-4}$	0.26	$5.7 \times 10^{-4}$
$1.1 \times 10^{-4}$	0.17	$6.7 \times 10^{-4}$
		Ave. = $6.1 \times 10^{-4}$

Since  $C \propto 1/l$  where  $l$  = spacing of layers,  $C \times l$  = constant. With  $CV_o = Q$  = constant, then

$$\frac{1}{C} \frac{\partial C}{\partial T} = -\frac{1}{V_o} \frac{\partial V_o}{\partial T} = -\frac{1}{l} \frac{\partial l}{\partial T}$$

Since  $(1/l) (\partial l/\partial T)$ , the coefficient of expansion, is unlikely to have a value much greater than  $10^{-5}$ , thermal expansion alone seems insufficient to explain the effect of temperature on voltage at constant charge.

In order to establish which electrode is limiting the charging process and causing nonlinearity of the  $Q$ - $V_o$  characteristic in the high voltage region (0.6-1.0v) the three-electrode device was charged to a controlled voltage between the working electrodes and their potentials was then measured with respect to the reference electrode. Figure 3 shows the steady state  $Q$ - $V_o$  characteristics for each electrode, at  $300^{\circ}\text{C}$ , where the

Fig. 3. Steady-state single electrode potentials vs. charge for a three electrode cell with  $\text{Na}^+$  as mobile ion at  $300^{\circ}\text{C}$ .

assuming an infinitely thin electrolyte can be modified, rigorously, for finite thickness of electrolyte.

A case which is suitable for comparison to experiment is the solution of the diffusion equation for short times ( $Dt/h^2 < 0.2$ , where  $h$  is the electrode thickness) i.e., the semi-infinite case,  $-\infty < \kappa < \infty$ :

$$\kappa = -h \quad \kappa = 0 \quad \kappa = +h$$

Impermeable surfaces

Permeable interface

Boundary conditions

$$t = 0 \quad c = c_1 \quad \kappa < 0 \quad V = V_o$$

$$c = c_2 \quad \kappa > 0$$

$$t = \infty \quad c = \frac{(c_1 + c_2)}{2} \quad V = 0$$

voltage plotted is the absolute value of potential difference between the electrode and the reference (center) electrode. No current was withdrawn from this reference electrode at any time. Figure 3 shows that it is the positive electrode which is limiting the charging process independent of the direction of the current flow. This might be expected since at some point in the charging process the positive electrode will lose all its  $\text{Fe}^{++}$  donors and become electronically insulating at which time the charging process must stop.

**Charge-time characteristics, potential control.**—Figure 4 shows  $q$  vs.  $\sqrt{t}$  plots for cell (a) at  $300^{\circ}\text{C}$  and successive voltage jumps ( $\Delta V$ ) of 100 mv. The linearity of the  $q$  vs.  $\sqrt{t}$  characteristics indicate that the speed of response to an impressed field is diffusion controlled. By combining the solution of the one dimensional diffusion equation  $\partial c/\partial t = D \partial^2 c/\partial \kappa^2$ , where  $D$  is the mutual diffusion coefficient of the two mobile species, with the experimentally determined relationship,  $Q = CV_o$ , equations describing the electrical characteristics of the cell can be obtained. It will be assumed that  $D_1/D_2$  approaches unity or zero, where  $D_1, D_2$  are the self-diffusion coefficients of the two mobile species.

The validity of the diffusion equation will not be disturbed by the presence of an electrolyte of finite thickness since charge transport within the electrolyte can occur only by migration and not by diffusion. This fact is a consequence of the existence of only one species of charge carrier, the alkali ion, in  $\beta$ -alumina (7). Thus the presence of the electrolyte affects the electrical characteristics only as a series resistance and the solutions of the diffusion equation obtained

The solution of the semi infinite case when  $D$  is independent of  $c$  is

$$c = \frac{(c_1 + c_2)}{2} - \frac{(c_1 - c_2)}{2} \operatorname{erf} \left( \frac{\kappa}{2\sqrt{Dt}} \right),$$

$$\left( \frac{\partial c}{\partial \kappa} \right)_{\kappa=0} = \frac{-(c_1 - c_2)}{2\sqrt{Dt\pi}}$$

From Fick's first law and for a univalent mobile ion

$$\frac{i}{F} = -D \left( \frac{\partial c}{\partial \kappa} \right)_{\kappa=0}$$

where  $i$  = current per unit area,  $F$  = the Faraday in coulombs per mole, and  $c$  is expressed in mole/cm<sup>3</sup>.

From the steady-state relationship  $Q = CV_o$

$$\frac{(c_1 - c_2)}{2} Fh = CV_o$$

By combining these equations

$$i = \frac{CV_o}{h} \sqrt{\frac{D}{\pi t}}$$

and on integration therefore

$$q = \frac{2CV_o}{h} \sqrt{\frac{Dt}{\pi}}$$

The analysis can be generalized to any two equilibrium states by expressing the time dependent part of the general solutions as  $\Delta c \cdot \operatorname{erf} (\kappa/2\sqrt{Dt})$  where  $\Delta c$  is the change in concentration for any value of  $\kappa$  between  $t = 0$  and  $t = \infty$ . Relating  $\Delta c$  to the difference in voltage ( $\Delta V$ ) between the two equilibrium states

Fig. 4. Charge vs.  $(\text{time})^{1/2}$  for  $\text{Na}^+$  solid-state battery at  $300^\circ\text{C}$  under  $t=0$  potential drop of 0.1v from voltage indicated.

existing at  $t = 0$  and  $t = \infty$  by  $\Delta cFh = C\Delta V$  then the expression for  $q$  becomes

$$q = \frac{2C\Delta V}{h} \sqrt{\frac{Dt}{\pi}} \quad [1]$$

Equation [1] can be corrected for the finite electrolyte resistance,  $R$  ohms/cm<sup>2</sup>, by replacing  $\Delta V$  by  $\Delta V - iR$  and using  $i = dq/dt$ . Then Eq. [1] becomes, by successive approximation

$$q = \frac{\frac{2C\Delta V}{h} \sqrt{\frac{Dt}{\pi}}}{1 + \frac{RC}{h} \sqrt{\frac{D}{\pi t}}} \approx \frac{2C\Delta V}{h} \sqrt{\frac{Dt}{\pi}} - \frac{2C^2\Delta VDR}{h^2\pi} \quad [2]$$

From the slope and intercept of the  $q$  vs.  $\sqrt{t}$  curves, therefore,  $D$  and  $R$  can be determined if  $C$  is known from the steady state  $Q$  vs.  $V_0$  characteristic.  $R$  can also be determined by a high-frequency a-c measurement or from the value of the initial discharge current.  $R$  was found to be  $\sim 30$  ohms/cm<sup>2</sup>. The calculated values of  $D$  are plotted against voltage in Fig. 5. The values of  $D$  decrease with increasing voltage, i.e., decrease with increasing difference of concentration of mobile ion between anode and cathode.

The fact that  $D$  values are not independent of concentration is to be expected if the mechanism of alkali ion diffusion involves interstitial sites or vacancies since the extent to which such sites are occupied will be a function of over-all concentration. The addition of ion-electron pairs would be expected to alter the electrostatic energy and hence the unit cell dimensions

Fig. 5. Variation of diffusion parameter with voltage of  $\text{Na}^+$  solid-state battery at  $300^\circ\text{C}$ .

of the material. Evidence that self-diffusion coefficients of  $\beta$ -alumina are sensitive to the concentration of unoccupied sites and to the  $c$  axis dimension has been presented previously (7). Since the measured diffusion coefficient will be controlled primarily by the electrode of lowest individual  $D$  value the slope of Fig. 5 is in the expected direction. The fact that the measured value becomes negligibly small at high voltages probably reflects the fact that one electrode has become virtually impermeable due to one or both of the above effects.

For long times,  $Dt/h^2 > 0.2$ , the solution of the diffusion equation in series form can be used to yield expressions for current and charge as a function of time.

$$i = \frac{2C\Delta VD}{h^2} \sum_{n=1,3}^{\infty} \exp\left(\frac{-n^2\pi^2\tau}{4}\right) \text{ where } \tau = Dt/h^2$$

$$q = \frac{8}{\pi^2} C\Delta V \left( \sum_{n=1,3}^{\infty} \frac{1}{n^2} - \sum_{n=1,3}^{\infty} \frac{1}{n^2} \exp\left(\frac{-n^2\pi^2\tau}{4}\right) \right)$$

Thus the electrical characteristics measured near the steady-state condition can be described with two parameters,  $C$  and  $D/h^2$ , whereas the electrical characteristics measured far from the steady state can be described with one parameter,  $C/h\sqrt{D}$ . This result is seen to be a general one by calculating the response of the cell under other experimental conditions, e.g., constant current operation or alternating current operation.

**Constant load discharge characteristics.**—Figure 6 shows the constant load voltage-time curve for 1K and 5K ohm loads for cell (a) at  $300^\circ\text{C}$ , from a starting potential of 1v. The theoretical energy density of the device is  $\frac{1}{2} \times 18 \times (\frac{1}{2})^2 \sim 2$  joule/cc ( $\frac{1}{2} CV^2$  where  $C$  = capacity per unit volume,  $V = \frac{1}{2}v$ ), or, for a specific gravity of 4 g/cc, 240 joules/lb. This theoretical energy density is of the order of 0.2% of that afforded by conventional wet batteries which also have the advantage of constant voltage operation. The power density is limited by the internal resistance of the battery, which is about 30 ohms, at  $300^\circ\text{C}$ , and maximum power output is therefore  $\approx 0.25$  w/lb.

However no effort was made to prepare more highly conductive ceramic parts by variation of composition or sintering conditions, and it should be possible to improve these considerably. The instantaneous internal resistance of the device was equivalent to a resistivity  $\sim 60$  ohm cm at  $300^\circ\text{C}$ , probably all of this resistance residing in the electrolyte. An electrolyte resistivity of  $\sim 5$  ohm cm at  $300^\circ\text{C}$  can be prepared (14). Reduction of the electrolyte thickness from the present 2 mm down to  $\sim 0.5$  mm is also possible with present experimental techniques.

Fig. 6. Discharge (voltage-time) characteristic for  $\text{Na}^+$  solid-state battery at  $300^\circ\text{C}$  from a  $t=0$  voltage of 1v under 1-kohm and 5-kohm loads.

**A-C impedance characteristics.**—Figures 7, 8 show the variation of impedance ( $Z$ ) with frequency ( $w/2\pi$ ) for cell (a) at 500°C. The applied voltage was 100 mv peak to peak. The low-frequency range investigated was necessitated by the large capacitance involved, a phase angle of 45° occurred at a frequency  $\sim 1$  cpm. Measurements were taken after transient effects had become negligible. The a-c impedance measurements are consistent with equations developed from the solution of the diffusion equation with the appropriate bounding conditions.

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial \kappa^2}$$

Assume the solution  $c = f(\kappa) e^{i\omega t}$  where  $i = \sqrt{-1}$ . Then

$$\frac{\partial^2 c}{\partial \kappa^2} = a^2 c \text{ where } a = \left( \frac{i\omega}{D} \right)^{1/2}$$

The general solution is

$$c = [A_1 \cosh(a\kappa) + A_2 \sinh(a\kappa)] e^{i\omega t}$$

$$\frac{\partial c}{\partial \kappa} = a[A_1 \sinh(a\kappa) + A_2 \cosh(a\kappa)] e^{i\omega t}$$

From the boundary conditions

$$\kappa = \pm 0 \quad c = \pm c_0 e^{i\omega t} \quad \text{therefore } A_1 = \pm c_0$$

$$\kappa = \pm h \quad \frac{\partial c}{\partial \kappa} = 0 \quad \text{therefore } A_2 = -\frac{c_0 \sinh(ah)}{\cosh(ah)}$$

Assuming that  $Fh c_0 e^{i\omega t} = CV$  and  $i = -FD \left( \frac{\partial c}{\partial \kappa} \right)_{\kappa=0}$  then

Fig. 7. Dependence of impedance on frequency for frequencies  $w/2\pi \cong 0.2$  cpm for  $\text{Na}^+$  solid-state battery at 500°C.

Fig. 8. Variation of solid-state battery impedance with frequency ( $w/2\pi$ ) for  $\text{Na}^+$  solid-state battery at 500°C.

$$i = \frac{DCa}{h} \cdot \frac{\sinh(ah)}{\cosh(ah)} \cdot V$$

and the impedance is given by

$$z = \frac{\cosh(ah)}{\sinh(ah)} \cdot \frac{h}{CDA}$$

Replacing "a" by  $\left( \frac{i\omega}{D} \right)^{1/2}$  and noting  $\sqrt{i} = (1+i)/\sqrt{2}$  then

$$z = \frac{h}{C} \left( \frac{2}{wD} \right)^{1/2} (F_1 - iF_2) \quad [3]$$

where

$$2F_1 = \frac{\sinh(2w'h) - \sin(2w'h)}{\cosh(2w'h) - \cos(2w'h)}$$

$$2F_2 = \frac{\sinh(2w'h) + \sin(2w'h)}{\cosh(2w'h) - \cos(2w'h)}$$

and  $w'$  is a reduced frequency parameter

$$w' = \left( \frac{w}{2D} \right)^{1/2}$$

the total cell impedance ( $Z$ ) includes the in-phase electrolyte resistance  $R$

$$Z^2 = R^2 + \frac{2Rh}{C} \left( \frac{2}{wD} \right)^{1/2} F_1 + \frac{h^2}{C^2} \frac{2}{wD} (F_1^2 + F_2^2) \quad [4]$$

The shapes of the functions  $F_1$  and  $F_1^2 + F_2^2$  are shown in Fig. 9, 10.

Fig. 9. Variation of  $F_1$  with  $w'h$

Fig. 10. Variation of  $F_1^2 + F_2^2$  with  $(1/w'h)^2$

Two limiting cases occur

1.  $w'h \rightarrow 0$  i.e. (low frequency  $F_1 \rightarrow \frac{1}{3} w'h$   
 (high  $D$  value  
 (low  $h$  value  $F_1^2 + F_2^2 \rightarrow \frac{1}{4(w'h)^2}$

when

$$Z^2 = R^2 + \frac{2}{3} \frac{Rh^2}{CD} + \frac{1}{w^2 C^2} + \frac{1}{9} \frac{h^4}{C^2 D^2}, w'h < 0.5 \quad [5]$$

2.  $w'h \rightarrow \infty$  i.e. (high-frequency  $F_1 \rightarrow 0.5$   
 (low  $D$  value  
 (high  $h$  value  $F_1^2 + F_2^2 \rightarrow 0.5$

when

$$Z^2 = R^2 + \frac{Rh}{C} \left( \frac{2}{Dw} \right)^{1/2} + \frac{h^2}{C^2 Dw}, w'h > 2 \quad [6]$$

Qualitatively the impedance is in accord with Eq. [5] and [6],  $Z^2$  increasingly linearly with  $(2\pi/w)^{1/2}$  and rising rapidly at about  $w/2\pi = 0.05$  cpm ( $\sim 10^{-3}$  Hz). If  $w'h$  is put at  $\sim 2$  for the changeover point of the two limiting cases, then for  $w/2\pi = 10^{-3}$  Hz,  $D/h^2 \sim 7 \times 10^{-4} \text{ sec}^{-1}$ . From the value of the slope of Fig. 7, 120 ohm<sup>2</sup> sec<sup>1/2</sup> then  $C (D/h^2)^{1/2} \sim 0.14F \text{ sec}^{-1/2}$  and, therefore,  $C \sim 5F$ . Better estimates of the values of  $D/h^2$  and  $C$  were obtained by a least squares fitting method of Eq. [4] to the experimental points, the values obtained were  $D/h^2 = 1.3 \times 10^{-3} \text{ sec}^{-1}$  and  $C = 6.6F$ . The calculated curve and experimental points appear in Fig. 8 for the whole frequency range measured (50-0.01 cpm).

Figures 11 to 14 show the electrical characteristics of cell (b) at two temperatures: 300°, 500°C. The capacitance and diffusion parameter ( $D/h^2$ ) values are shown together with those of cell (a) in Table I.

The values of diffusion coefficient ( $D$ ) obtained from Table I by putting  $h = 0.1$  cm are of the same order of magnitude as those obtained by radioactive tracer techniques on single crystals of alkali aluminates (7) and ferrites (15) and of the same order as those observed in aqueous solution at room temperature.

The discrepancy in Table I between  $C$  and  $D/h^2$  values obtained by different electrical methods probably reflects the breakdown of the simplifying assumptions used in developing Eq. [1] to [6].

*Practical Applications*

It is doubtful that the power density of a ceramic cell could be increased sufficiently to provide a useful secondary battery unless high-temperature operation were a necessity.

The practical applications of the device considered as a capacitor rather than a battery are: (A) an electronic integrator for integrations over long periods of

Fig. 11. Steady-state charge-voltage characteristic of K<sup>+</sup> solid-state battery at 300°, 500°C.

time; (B) as a capacitor in filter circuits for d-c smoothing, phase correction, etc.

In (A) the main criteria would be stability, reliability and price; the present device offers advantages in reliability and price, but stability has not been fully investigated.

In (B) the power factor as a capacitor greatly detracts from its usefulness, power losses arise from the electrolyte resistance (independent of frequency) and

Table I. Capacitance values and diffusion parameter values for Na<sup>+</sup> and K<sup>+</sup> solid-state batteries

from the electrode resistance (increase with frequency). These losses may be reduced for a given frequency of operation by reduction of electrode thickness  $h$  (causing  $w'h$  to decrease) and by reduction of the electrolyte resistance. This could be achieved, possibly, by using a porous sintered body of low particle size in a solution of the appropriate alkali metal ion, the solution may have to be nonaqueous in view of the inhibition of ion exchange in aqueous solutions. Vacuum deposited thin films may be of use, but again a low resistance electrolyte is needed. The necessity of low operating voltage is a disadvantage to the device as compared to other capacitors, but the use of low voltage equipment is common (batteries, transistors), also the device does not polarize (compare electrolytic capacitors). Finally, the nonlinearity of the  $q$  vs.  $V$  characteristic seems of little use, as tunable capacitors have found application only at microwave frequencies. However its existence does offer, in principle, the construction of other circuit elements such as amplifiers and rectifiers.

## Foil Electrets and Their Use in Condenser Microphones

G. M. Sessler and J. E. West

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

#### ABSTRACT

New results are reported on polarization and depolarization characteristics of foil electrets made of polyester, fluorocarbon, polycarbonate, and polyimide. The foils (¼ to 1-mil thick) are polarized by exposure to d-c fields at high temperatures. Use of a depolarization technique made it possible to measure for the first time separately the decay characteristics of homocharge and heterocharge of foil electrets. Time constants for the homocharge decay of foil electrets at room temperature were found to be about 0.1 years for polyimide, one year for polyester, and more than 100 years for fluorocarbon and polycarbonate. The relaxation times of the heterocharge on polyester and fluorocarbon electrets at room temperature vary from 0.1 to 1 year. These results are compared with other data on the net decay of both charges, derived in part from measurements at room temperature taken over a five-year period and in part by extrapolating high-temperature data. All time constants depend somewhat on preconditioning of the electrets after forming. Condenser microphones built with fluorocarbon and polycarbonate foil electrets are expected to show little change in sensitivity over periods of the order of 100 years.

Electrets formed of disks of dielectric material have been known for a long time. It was not until 1962, however, that the polarization of thin films (about 1 mil thick or less) was reported in the literature (1). The first film electrets or foil electrets were made of polyester and had time constants of the charge decay of the order of one year. The polarization of dielectric films with substantially longer charge lifetimes, however, was reported only recently (2). Foil electrets, while having basically the same electrical properties as disk electrets, differ from these in their me-

chanical behavior, due to the flexibility of the foil. This flexibility turns out to be very important when foil electrets are used in condenser microphones, since it causes the microphone sensitivity to remain constant even if the polarization of the electret decays somewhat with time (2). Condenser microphones with foil electrets exhibit also a higher capacitance per unit area than transducers with disk electrets.

In this paper, we will discuss some new results on the polarization and depolarization characteristics of foil electrets, as determined by research in our lab-

oratory over the past years. Although many different polymers were investigated, emphasis is placed on those foil materials for which extensive measurements at room temperature have been obtained. This allows us to determine decay characteristics directly at room temperature and to compare these data with various results extrapolated from high-temperature measurements. In the final part of this paper, we will present the continuation of our long-term sensitivity measurements on electret microphones.

### Polarization and Measurement of Foil Electrets

Foil electrets have been polarized in our laboratory using a variety of dielectric materials, such as polyester,<sup>1</sup> fluorocarbon,<sup>2</sup> polyimide,<sup>3</sup> and polycarbonate,<sup>4</sup> usually 0.25-1 mil thick. The polarization is achieved by heating the foils to temperatures up to 150°C (polyester) or 230°C (polyimide, fluorocarbon, and polycarbonate) and exposing them to electrical fields between 10 and 100 kv/cm, as described elsewhere (2). The foil may also be interposed between two sheets of dielectric during the polarization process. In this case a higher polarizing voltage may be used.

The polarization of a thermoelectret consists in general of hetero- and homocharge. According to Gross and de Moraes (3), the homocharge is due to a surface effect involving the transfer of charge through the dielectric-electrode interface. Thus the homocharge consists of space charges located close to the surfaces of the dielectric. The heterocharge is due to a volume effect and can consist of a volume polarization caused by the orientation of dipoles or of a space charge polarization due to a migration of ions over distances comparable to the thickness of the sample. The heterocharge can also be caused by a migration of charge carriers over microscopic distances (3).

Two methods were employed to measure the polarity and the quantity of the surface charge on foil electrets. For most of the measurements, a dissectible capacitor (4) in connection with a ballistic galvanometer was used (2). Condenser plates of various sizes were utilized to determine the total charge on a foil as well as its spatial distribution.

Surface charges of foil electrets incorporated into microphones or loudspeakers have also been measured indirectly by a modified dynamic capacitor (5) method. The latter method, when applied to an electret microphone, uses an external d-c bias which is adjusted to a value  $V_B$  for which the microphone, exposed to a sound field, shows zero electric output (1). In the case of an electret loudspeaker, an external d-c bias in addition to a signal voltage is applied; here, the external voltage is adjusted to a value  $V_B$  for which the acoustic output of the loudspeaker consists only of the second harmonic of the signal voltage (6). In both cases, the surface charge  $q$  can be determined from the equation (7)

$$V_B = - (4\pi/\epsilon) qd \quad [1]$$

where  $\epsilon$  is the dielectric permittivity of the foil and  $d$  is the foil thickness. Equation [1] shows that the bias  $V_B$  does not depend on the thickness of the air gap between the electret foil and the back electrode of the transducer.

Measurements performed by these methods show that foil electrets, when formed with an air gap, generate fields corresponding to a net homocharge, i.e., the homocharge is the predominant charge in this case. However, when sheets of dielectric are interposed between foil and electrodes during the forma-

tion process, the foils exhibit occasionally an apparent heterocharge. On nonmetallized electrets, the charges on the two surfaces were found to have opposite sign and to be of comparable magnitude. Most electrets have an initial surface charge of a few  $10^{-8}$  C/cm<sup>2</sup>.

### Depolarization Experiments

More information about the nature of the charge on foil electrets can be gained from depolarization experiments (4) in which the foil electret is discharged between two metal disks in contact with the foil surfaces at elevated temperatures.

The depolarization current of a 1-mil polyester electret having initially a homocharge with a surface density of  $q_1 = 2.1 \times 10^{-8}$  C/cm<sup>2</sup> is shown in Fig. 1. The foil was polarized six days prior to the discharge experiment. The net discharge current shows a positive sign in the temperature range from about 70° to 105°C. This polarity corresponds, for the particular setup used in the experiment, to the depolarization of a heterocharge. The integrated positive current yields a charge density of  $1.6 \times 10^{-8}$  C/cm<sup>2</sup> (disk area 32 cm<sup>2</sup>). Considering the air gaps between foil and metal plates (7), this corresponds to a heterocharge density of  $q_2 = 4.0 \times 10^{-8}$  C/cm<sup>2</sup>. When the depolarization current reached zero at  $T = 105^\circ\text{C}$ , the foil was cooled down to room temperature. Then, using a dissectible capacitor, its surface charge was determined to be  $q_3 = 2.8 \times 10^{-8}$  C/cm<sup>2</sup> which is smaller than the expected value  $q_1 + q_2 = 6.1 \times 10^{-8}$  C/cm<sup>2</sup>. The difference has to be attributed to an external decay of part of the homocharge through the disk-electret interface. In this case, internal depolarization of the homocharge is negligibly small below 105°C.

The depolarization of the electret was then continued and carried to higher temperatures. At temperatures from 100° to 140°C, the discharge current has negative sign, indicating the internal decay of a homocharge. The surface charge density, as obtained from the integrated negative current, is  $2.4 \times 10^{-8}$  C/cm<sup>2</sup>, which is slightly below  $q_3$ , indicating some additional interfacial decay. The foil was found to be completely discharged after this phase of the depolarization experiment.

From Fig. 1 we can determine the time constants for heterocharge and internal homocharge decay. The results are discussed below.

Depolarization experiments on fluorocarbon and polycarbonate electrets show qualitatively the same results, although fluorocarbon usually does not exhibit a large heterocharge. The temperature range for depolarization of the homocharge on these materials is higher than for polyester.

### Decay of the Surface Charge at Elevated Temperatures

The decay processes for space charges and dipole alignments on electrets are controlled by the conductivity of the foil material and by its dielectric relaxation, respectively. In most organic substances, the temperature dependence of the conductivity  $\sigma$  can be

Fig. 1. Net depolarization current for a 1-mil polyester electret. The time dependence of the temperature is also shown.

<sup>4</sup> Manufactured under the name "K-1 polycarbonate" by Eastman Chemical Products, Inc. Bis-Phenol A Polycarbonate with low and high molecular weight was also supplied by Natvar Corporation and Farbenfabriken Bayer A. G., respectively.

expressed (8) by  $\sigma = \sigma_0 \exp(-E_1/kT)$ , where  $E_1$  is an activation energy. The time constant  $\tau_1$  of the homocharge decay is given by  $\tau_1 = \epsilon/4\pi\sigma$ , where  $\epsilon$  is the dielectric constant (2). For a dipole alignment, the temperature dependence of the relaxation time  $\tau_2$  can also be expressed by a relation  $\tau_2 = \tau_0 \exp(-E_2/kT)$ . This suggests Arrhenius plots  $\log(\sigma/\sigma_0) = -E_1/kT$  and  $\log(\tau_2/\tau_0) = -E_2/kT$  to determine time constants over a range in which the activation energies and  $\sigma_0$  and  $\tau_0$  do not change substantially.

Time constants at elevated temperatures have been obtained by two different methods. In one method (which we may call the current method), the foil electret is exposed to increasing temperatures between two disk electrodes in close contact to the foil surfaces, and the depolarization current is measured as a function of temperature (see previous section). The time constant  $\tau(T)$  at a temperature  $T$  reached at time  $t_1$  can then be obtained from the current  $I(t_1)$  at that temperature and the remaining quantity of charge  $Q(t_1)$  by the equation

$$\tau(T) = Q(t_1)/I(t_1) = \left( \int_{t=t_1}^{\infty} I(t) dt \right) / I(t_1) \quad [2]$$

Time constants obtained from such measurements for polyester and FEP fluorocarbon electrets are shown in Fig. 2 as a function of  $1/T$ . As expected,  $\log \tau$  is found to be proportional to  $1/T$ . If extrapolated to room temperature, the time constant for the homocharge decay of polyester is 1.5 years while that for the heterocharge decay is about 0.5 years. Activation energies may be determined from the slopes of the lines in Fig. 2. For the homocharge decay, the activation energies below and above the glass transition temperature of polyester at  $80^\circ\text{C}$  are apparently not too different. This is evident from the fact that the extrapolated time constant of the homocharge decay corresponds to that found directly at room temperature (see below) for the net charge decay.

For the homocharge decay of FEP fluorocarbon at room temperature, Fig. 2 yields an extrapolated time constant of about 50 years, corresponding again to that found directly at room temperature (see below). The

Fig. 2. Time constant of the homocharge and heterocharge decay of 1 mil polyester and FEP fluorocarbon electrets as a function of inverse temperature. Data for polyester were obtained from the depolarization current measurements shown in Fig. 1. Extrapolated time constant for FEP homocharge decay is 50 years.

time constant of the heterocharge decay at room temperature is found to be 0.5 years and is thus about equal to the dielectric relaxation time (9).

Homocharge and heterocharge decays are therefore of different nature. The heterocharge is thus expected to consist either of a dipole orientation or of a charge migration over microscopic distances (3) rather than of a space-charge polarization associated with a homocharge. On fluorocarbon, the heterocharge is apparently due to a dipole alignment and only important for some time after polarization of the electret. Later, only the homocharge prevails on this foil.

The second method for determining time constants at elevated temperatures consists of measurements of the surface charge before and after the electret has been exposed to temperatures above room temperature (charge method). In this case, the foil is heated either suspended freely or making contact to metal surfaces.

In Fig. 3 the time constants of the net charge decay of 1-mil polyester, H-film, fluorocarbon, and polycarbonate electrets, as determined with the charge method, are shown as a function of  $1/T$ . The foils were subjected to some aging at elevated temperatures after polarization, resulting in a loss of about 50% of the original electret charges, before these measurements were taken. This aging increases the measured time constants considerably. The polycarbonate foils were also baked before polarization in order to remove moisture. Measurements taken at room temperature are also included if available.

In Fig. 3, the straight line extrapolation of the time constants for polyester and FEP fluorocarbon electrets agrees well with the results obtained at room temperature (see below) indicating relatively constant activation energies in the temperature range under consideration. The time constant of FEP fluorocarbon seems to be about 100 years at room temperature. KI polycarbonate has also an extrapolated lifetime of about 100 years at room temperature; direct measurements at this temperature (see below) yield a time constant of the order of 10 years or more. H-film is clearly represented by two or more straight lines, indicating a change in activation energy at about  $100^\circ\text{C}$ .

Due to preheating, most of the heterocharge was removed prior to these experiments. The measured time

Fig. 3. Time constant of the net surface charge decay of 1-mil polyester, H-film, FEP fluorocarbon, and KI polycarbonate electrets as a function of inverse temperature. Data obtained by heating electrets freely suspended in air.

constants are therefore those related to the homocharge decay. They agree well with the corresponding time constants obtained with the current method.

The two methods discussed above differ in some important respects. First, the current method allows an independent measure of the time constants of homocharge and heterocharge decay as long as the depolarization of the two charges takes place in different temperature ranges. Measurement of both time constants is much more difficult with the charge method, where one can usually not assess the heterocharge decay in the presence of a large homocharge.

Another difference between the two methods is obvious when extrapolations to room temperature are considered. Results on the time constants of homocharge and heterocharge decay obtained with the current method at elevated temperatures can be extrapolated to room temperature by Arrhenius-plots if, as has been previously mentioned, the activation energies do not change substantially over the temperature range of interest and the temperature dependence of the time constants is essentially exponential. On the other hand, the charge method allows, under these conditions, only an extrapolation of the time constant of the longer lasting charge. Even this is only possible if this charge has a substantially greater lifetime than the other charge over the entire temperature range of interest and if the shorter-lasting charge is initially removed by aging.

A third difference is that the current method provides a good contact between the foil and the metal disks. Thus, some of the homocharge may decay externally through the plates. In the charge method this may be avoided by suspending the foil freely in air. The two methods yield therefore somewhat different information.

#### Surface Charge Decay of Foil Electrets at Room Temperature

The decay of the surface charge of foil electrets as a function of time at room temperature is shown in Fig. 4 and 5 for several polyester, fluorocarbon, polycarbonate, and H-film electrets. Previous measurements (2) have been extended to periods of about five years with the foils stored unshorted and in normal room atmosphere. Aging at elevated temperatures after polarization (to remove less resistant charges) was not applied to these foils. All foils have an initial surface charge of a few  $10^{-8}$  C/cm<sup>2</sup>. Most of the decays are nonexponential.

For polyester, the time "constant" of the decay has initial values of about 0.2 years and increases to about one year. For fluorocarbon and fluorocarbon FEP, the

Fig. 4. Variation of surface charge of several fluorocarbon and polyester electrets at room temperature. Electrets kept unshorted. The electrets were not aged at elevated temperatures after polarization.

Fig. 5. Variation of surface charge on H-film, KI polycarbonate and BPA polycarbonate of high and low molecular weight at room temperature. Electrets kept unshorted. The electrets were not aged at elevated temperature after polarization.

time constants over the last year of the measurements are about twenty and fifty years, respectively. BPA-polycarbonate has time constants of about two to ten years, while KI polycarbonate, although only measured over a period of about 1.5 years, seems to have a lifetime of more than 10 years. H-film has a time constant of only 0.1 years. The small fluctuations superimposed on the decays are probably due to environmental changes. Aged foils show initially larger time constants.

Existing theories of the time variation of electret charges (10), which take into consideration the resistive decay of the homocharge and the thermal relaxation of the dipole polarization, predict a time-dependence of the surface charge given by

$$q(t) = A_1 \exp(-t/\tau_1) - A_2 \exp(-t/\tau_2) \quad [3]$$

where  $t$  is time,  $\tau_1$  and  $\tau_2$  are the time constants for homocharge and heterocharge decay and  $A_1$  and  $A_2$  are constants depending on  $\tau_1$  and  $\tau_2$  and the relative amount of both charges. These theories can, however, not account for the observed temporal increase of the time "constants" of the surface charge decay, since they assume a field-independent conductivity of the foil material. Another assumption is that the dipole polarization decays independent of the electric field. Both assumptions are, however, known to be invalid for fields larger than  $10^3$  v/cm.

In foil electrets with surface charges of the order of  $10^{-8}$  C/cm<sup>2</sup>, the field strength  $E$  in the sample is between  $10^4$  and  $10^5$  v/cm. Since the conductivity of many organic materials increases (8) strongly with  $E$  in this range, we expect a nonexponential decay of the surface charge with a temporal increase of its time constant, as observed in the experiments (see Fig. 4 and 5).

The nonexponential character of the decay is enhanced due to the fact that the surface charge density of the foil is not constant over the entire area. An example is shown in Fig. 6. Similar results have also been obtained elsewhere (11). Thus areas with high surface charge density will lose their charge at a faster rate than areas with low density. A third reason for expecting nonexponential decays is that the conductivity of the foil material is not uniform over the entire surface. Thin dielectric foils seem to consist of small domains having different electrical properties. This has been substantiated by measurements of the dielectric strength of polymers (12). Thus it is possible that the time constant for the charge decay of foil electrets is first determined by domains having relatively small volume resistivity. After these domains have lost most of their charge, other domains having larger volume resistivity will determine

Fig. 6. Surface charge density on a 1 mil polyester electret polarized two days prior to measurements. Dashed circle, polarized area; diameter 7.4 cm.

the rate of the decay. A fourth factor causing nonexponential decays may be the difference between external and internal decay rates of the homocharge.

The increase of the time constant of the decay is also responsible for the somewhat different results obtained in Fig. 3 and 4. While the time constant of FEP fluorocarbon electrets at room temperature was found by extrapolation (see Fig. 3) to be about 200 years, it seems to be only about 50 years when measured directly at room temperature (see Fig. 4). Indications are, however, that the time constants in Fig. 4 and 5 will further increase with time and will finally reach the higher values determined in Fig. 3.

The conductivity for polyester, as determined from the initial slope in Fig. 4, is of the order of  $10^{-19}$  (ohm cm) $^{-1}$ . This is, as expected, somewhat smaller than the value of  $10^{-18}$  (ohm cm) $^{-1}$ , obtained with standard methods by using fields greater than those corresponding to surface charges of  $10^{-8}$  C/cm $^2$ .

### The Electret Microphone

The diaphragm in the electret microphone consists of a foil electret covered with an optically thin metal layer on one side. The foil electret is stretched across a metallic backplate with the metal side facing out. A sound wave impinging on the microphone changes the air layer between foil and backplate and thus disturbs the electric fields. This gives rise to a voltage across a terminating resistor. Details on microphone construction and performance are given elsewhere (2).

The decay of the sensitivity of various polyester and fluorocarbon microphones is shown in Fig. 7. Measure-

Fig. 7. Sensitivity of various fluorocarbon and polyester electret microphones as a function of time, under normal environmental conditions.

ments have now been extended to periods of up to five years with the microphones stored in normal room atmosphere. The polyester systems show a relatively constant sensitivity for a period of about 1 year. Thereafter, the sensitivity decreases more or less exponentially with time constants from one to two years, corresponding to the time constants found for the decay of the net surface charge. The fluorocarbon systems exhibit smaller fluctuations in sensitivity and show no decay for the time measured (about 4 years). The foils used in these microphones were not aged at elevated temperatures after polarization. Obviously, such aging is not necessary for constant sensitivity of fluorocarbon systems.

Thus, the decay of the surface charge, as evident from Fig. 4 and 5, is not reflected in a corresponding loss in microphone sensitivity. The apparent difference in foil and microphone behavior has been explained previously (2) by a mechanical slackening of the foil which compensates for some time the drop in sensitivity expected due to the charge decay. This compensating mechanism is effective as long as the voltage corresponding to the surface charge is within a range over which the sensitivity does not depend very much on the bias [see Fig. 7 of ref. (13)]. Later, the sensitivity decreases proportional with the surface charge. The compensation is only possible because of the flexibility of the thin foils used in these microphones.

### Conclusions

Various methods have been used to measure time constants of the charge decay of foil electrets. A method utilizing measurements of the depolarization current at elevated temperatures (current method) made it possible for the first time to determine separately the decay characteristics of homo- and heterocharge of foil electrets. In many cases, results on the time constants of homo- and heterocharge decay at elevated temperatures can be extrapolated to room temperature by Arrhenius-plots. Other measurements of the life-times were made by determining the change in net surface charge of the electret after repeated exposure to elevated temperature (charge method). This method measures therefore the net decay of homo- and heterocharge. As has been shown above, an extrapolation to room temperatures is in this case at best possible for the longer-lasting charge. Time constants of the net surface charge decay have also been determined directly at room temperature.

Measurements performed with the different methods yield similar results. In some cases, the time constants and activation energies obtained from these measurements allow to determine the nature of the polarization.

The forming of fluorocarbon and polycarbonate foil electrets, which have time constants of the charge decay of about 100 years, made possible electret microphones with correspondingly long lifetimes.

### Acknowledgment

The authors are grateful to Dr. G. L. Link and Dr. S. Matsuoka for stimulating discussions.

Manuscript submitted Sept. 6, 1967; revised manuscript received April 8, 1968. This paper was presented at the Electret Symposium at the Chicago Meeting, Oct. 15-19, 1967, as Paper 140.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Phosphors Based on Rare Earth Phosphates

### I. Spectral Properties of Some Rare Earth Phosphates

R. C. Ropp\*

Westinghouse Electric Corporation, Bloomfield, New Jersey

#### ABSTRACT

Spectral properties of rare earth phosphate phosphors are presented and compared to rare earth oxide phosphors studied previously. It is shown that changing to a phosphate host does not affect the wavelengths produced, but has a major effect on the total energy efficiency as well as the intensity of the emission lines produced relative to one another. The latter observation is attributed to site symmetry effects on transition probabilities from an emitting energy level.

The lanthanides have been found in various natural states, some of which include the mineral monazite, which has the approximate composition  $(\text{Ce}, \text{La})\text{PO}_4$ , and xenotime, which is primarily an yttrium phosphate. Despite the wide occurrence of these minerals, little is known concerning the spectral properties of the pure rare earth phosphates or specific rare earth phosphates activated by small quantities of other rare earths. Phosphors as  $\text{CePO}_4$  (1) and  $\text{EuPO}_4$  (2) have been prepared, and more recently single crystals of rare earth orthophosphates have been described (3), yet remarkably little has appeared in the literature concerning the fluorescence properties of these materials.

Perhaps the most extensive discussion to date has been presented by Brill and Wanmaker (4) on the physical properties of  $\text{GdPO}_4:\text{Eu}$  as well as the luminescence properties of  $\text{EuPO}_4$ . Details of preparation, decay times, diffraction patterns, and quantum efficiencies were given, but the discussion was limited to gadolinium phosphate as a matrix. In later publication, Brixner and Flournoy (5) mention some of the properties of the  $\text{GdPO}_4:\text{Eu}$  phosphor and compare the emission of  $\text{Eu}^{+3}$  in different hosts. However, with these exceptions, a description of the fluorescence properties of rare earth phosphates has not been available heretofore.

Rare earth orthophosphates, in addition to being found in nature, have been synthesized in the laboratory by fusion methods (6), hydrothermal crystallization from aqueous solutions (7, 8), and chemical reaction (9-11). Phosphates of the cerium subgroup (La to Gd) have been found to possess the monoclinic monazite structure (isomorphous with  $\text{SrCrO}_4$ ), while those of the yttrium subgroup (Dy to Lu) have the tetragonal xenotime structure (isomorphous with  $\text{ZrSiO}_4$ ).

Prior discussions by the author have been concerned with the fluorescence of rare earth oxide phosphors (12, 13). The present work is an extension of a survey of the spectral properties of rare earth phosphors in which the properties of rare earth phosphates will be compared with those of corresponding rare earth oxides.

#### Experimental Methods

**Preparation of phosphors.**—The nitrates (or the oxides dissolved in concentrated nitric acid) of the

requisite rare earths were dissolved to form 0.40-2.0M solutions, depending on the particular preparation desired. Mixtures of the ions in solutions were made and the activators were maintained at a 5 m/o (mol per cent) concentration. Because of the method of preparation, no mixing or blending steps were necessary prior to firing to obtain uniform and homogeneous materials. Phosphoric acid was employed as the source of soluble phosphate and was diluted in requisite proportions so that an excess of phosphate was maintained at all times. The materials as produced were fired in air to form the phosphor composed of the desired solid solution of phosphates.

Thermogravimetric analyses of typical raw materials obtained are shown in Fig. 1. The precipitation conditions yielded  $\text{LaPO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ , whereas  $\text{YPO}_4 \cdot \text{H}_2\text{O}$  was obtained under the same conditions.

**Measurements.**—Excitation and emission spectra were obtained with the aid of a commercial instrument having two monochromators. The excitation monochromator provided a constant energy excitation beam over the range of 20,000-50,000  $\text{cm}^{-1}$ . Either monochromator could be programmed separately to

Fig. 1. Thermal decomposition of precipitated rare earth phosphates

\* Electrochemical Society Active Member.

provide excitation or emission spectra. In the case of multiple fluorescence peaks, a separate excitation spectrum was obtained and compared to the others. In most cases they were identical, but in a few cases they were not, as detailed below. Emission spectra were obtained directly, already corrected for instrumental energy losses and photomultiplier response. Resolution in the instrument varied from a few angstroms in the ultraviolet to about 10Å in the red region of the spectrum.

### Experimental Results

The rare earth phosphate phosphors prepared in this study were precipitated as crystalline stoichiometric materials. In considering the rare earth phosphates as phosphors, two possibilities present themselves. One involves rare earth phosphate compositions such as  $\text{ErPO}_4$  or  $\text{HoPO}_4$ , and the other, specific rare earth phosphates containing small amounts of "unlike" rare earth cations as activators, i.e.,  $\text{LnPO}_4:\text{X}$ . Of the two, the latter type of phosphor would be expected to produce the most intense fluorescence. A study of the absorption excitation, and fluorescence properties of  $\text{LnPO}_4$  materials will be the subject of a subsequent report (Part II).

In the case of the  $\text{LnPO}_4:\text{X}$  type of phosphor, Ln must include only those cations containing paired electrons, i.e.,  $\text{Y}^{+3}$  or  $\text{La}^{+3}$ , since unpaired electrons give rise to vibronic coupling processes and possess intermediate levels for cascading of energy to produce infrared and phonon emission (14).

**Relative intensities of emission.**—In observing the spectroscopic properties of the rare earths, Dieke and co-workers (15) have shown that rare earths such as  $\text{Pr}^{+3}$ ,  $\text{Nd}^{+3}$ ,  $\text{Ho}^{+3}$ , and  $\text{Er}^{+3}$  possess numerous intermediate f-electron energy levels, so dissipation of excitation energy by a cascade process can result in up to three possible modes: (i) infrared photon emission (low energy); (ii) phonon emission; and (iii) visible photon emission (high energy). Thus, only the intermediate trivalent cations, such as  $\text{Sm}^{+3}$ ,  $\text{Eu}^{+3}$ ,  $\text{Tb}^{+3}$ , and  $\text{Dy}^{+3}$ , would be expected to produce room temperature fluorescence in the visible region of the spectrum because of the relatively wide gaps which appear between their energy levels.

The data obtained and given in Table I show that this is indeed the case and that the same relative pattern of intensity is followed in the phosphates as observed for the oxides, namely, that  $\text{Sm}^{+3}$ ,  $\text{Eu}^{+3}$ ,  $\text{Tb}^{+3}$ , and  $\text{Dy}^{+3}$  produce the strongest visible emission intensity. However, the total emission intensity is a function of the matrix as well as the activator, as will be shown below. In general, phosphates are lower in both intensity and quantum efficiency than the corresponding oxide phosphors.

**Europium-Activated rare earth phosphates.**—The excitation and emission properties of the europium-activated rare earth phosphates are given in Fig. 2. There are five sets of emission lines, three of major intensity and two of low intensity, as well as minor

Fig. 2. Europium activated rare earth phosphates

variations in the emission wavelengths as a function of matrix composition. A comparison of the emission of  $\text{Eu}^{+3}$  in  $\text{YPO}_4$  and  $\text{Y}_2\text{O}_3$  is made in Fig. 3. Emission lines are observed in the same general region of the spectrum for both the oxide and the phosphate phosphors, with the exception that the emission at  $7100 \text{ \AA}$  in  $\text{YPO}_4:\text{Eu}$  now contains a considerable part of the total emission energy. In Fig. 3, the emission spectra are plotted as to indicate that the same transitions occur but that the relative emission energy in each is a function of the matrix and site symmetry.

A comparison of the emission intensities can be made as follows:

Phosphor	Excitation, Å (constant energy)	Integrated emission output ( $\mu$ watts)	Quantum efficiency, %
$\text{Y}_2\text{O}_3:\text{Eu}_{0.05}$	2537	306 (100%)	72
$\text{YPO}_4:\text{Eu}_{0.05}$	2370	140 (45.8%)	38

The integrated emission output was obtained by instrumental integration of the emission curves.

The excitation spectra are the more interesting of the measured properties. The usual low level peaks resulting from transitions between the  $4f^6$  energy levels of  $\text{Eu}^{+3}$  occur below  $34,000 \text{ cm}^{-1}$ . In the  $\text{GdPO}_4:\text{Eu}$  phosphor, excitation of the  $\text{Gd}^{+3}$  levels ( $^8\text{S}_{7/2} \rightarrow ^6\text{I}_J$ ) can also be seen. In addition, there are broad excitation bands which occur at various wavelengths, depending on the matrix in which  $\text{Eu}^{+3}$  finds itself. These are the charge-transfer bands, typical for the  $\text{Eu}^{+3}$ -oxygen center (16), for which indirect evidence has been presented by the author and co-workers (17). The mechanism can be written

Close examination of the excitation spectra leads to the conclusion that structure has a significant effect on these charge-transfer states. This is explained as

Table I. Relative emission peak at constant energy excitation

Activator (0.05 mol)	Color	Excitation wave- length (Å)	Comparison of main emission peak heights

\* Not detected (between 2800 and 7400 Å).

Fig. 3. Fluorescent properties of  $\text{Eu}^{+3}$  activated phosphors

follows: In  $\text{GdPO}_4$  and  $\text{LaPO}_4$ , which have the Monazite structure (monoclinic-site symmetry of cation is  $C_1$ ) the broad excitation peak occurs at  $2570\text{\AA}$  for the former and  $2650\text{\AA}$  for the latter, whereas in yttrium phosphate, which has the xenotime structure (tetragonal-site symmetry of  $\text{Y}^{3+}$  is  $D_{2d}$ ) a different peak position near to  $2370\text{\AA}$  is observed and only a narrow low intensity  $4f^6$  excitation line can be seen at  $2537\text{\AA}$  (the dotted line). Thus structure (oxygen symmetry around the  $\text{Eu}^{+3}$  in a cation site) plays a major role in determining the positions of these broad bands.

Since it has already been demonstrated that matrix excitation bands in the more ionic oxide hosts occur at  $45,500\text{ cm}^{-1}$  ( $2198\text{\AA}$ ),  $47,600\text{ cm}^{-1}$  ( $2100\text{\AA}$ ),  $58,100\text{ cm}^{-1}$  ( $2079\text{\AA}$ ) for the lanthanum, gadolinium, and yttrium oxides, it is likely that the broad excitation bands of the present phosphors are not related to exciton mechanisms, particularly in view of the evidence presented in the next section.

**Gadolinium-activated rare earth phosphates.**—When solid solutions containing 5 m/o gadolinium phosphate in lanthanum phosphate or yttrium phosphate are prepared and spectral properties measured, the results shown in Fig. 4 are obtained. There is a single set of emission lines near to  $32,000\text{ cm}^{-1}$  caused by the  ${}^6P_1 \rightarrow {}^8S_{7/2}$  transition within the  $\text{Gd}^{3+}$  ion. The excitation bands at  $36,000\text{ cm}^{-1}$  represent the transitions  ${}^8S_{7/2} \rightarrow {}^6I_7$ , while the low intensity bands at  $40,000$  and  $44,000\text{ cm}^{-1}$  are probably caused by upper  $4f^7$  electron-excited state transitions within the  $\text{Gd}^{3+}$  ion. There are also two other bands at  $46,400\text{ cm}^{-1}$  ( $\text{LaPO}_4$ ) and  $49,000\text{ cm}^{-1}$  ( $\text{YPO}_4$ ), whose existence have very interesting implications. Because they disappear when measured at liquid nitrogen temperature, and because of their similarity to intense bands measured previously in oxide phosphors (12, 13), I have surmized that these excitation bands represent cation exciton bands, rather than charge transfer bands between cations and oxygen sites. In the oxide phosphors, these bands were called "matrix" bands and were present in all phosphors irrespective of activator. The positions of the bands were dependent on the nature of the cation indicating that these bands involved cationic rather than anionic sites. A change from oxide to phosphate adversely affects the intensity but not the position of these bands. If the bands were charge-transfer bands, they should get stronger in the phosphates, as compared to the oxides. Experimentally, the reverse occurs. Note that a change in structure and point symmetry [cubic oxide ( $C_{2v}$ ) to tetragonal ( $D_{2d}$ ) or monoclinic ( $C_1$ ) phosphate] has no effect on the positions of these bands contrary to the effect observed for  $\text{Eu}^{+3}$ -oxygen charge-transfer bands, as given above.

**Cerium-Activated rare earth phosphates.**—The trivalent ion,  $\text{Ce}^{+3}$ , has an electronic structure containing one  $4f$  electron, and as an activator, generally results in phosphors having broad-band ultraviolet emission. In the rare earth phosphates, the emission bands of  $\text{Ce}^{+3}$  are not unlike those found for other materials.

Fig. 4. Gadolinium activated rare earth phosphates

Fig. 5. Cerium activated rare earth phosphates

The spectral properties of these phosphors are shown in Fig. 5 where differences in the emission band produced by  $\text{Ce}^{+3}$  are emphasized. In the monazite structure ( $\text{LaPO}_4$  and  $\text{GdPO}_4$ ) emission bands peaking at about  $3150\text{--}3200\text{\AA}$  are seen. However, in the xenotime structure ( $\text{YPO}_4$ ), two emission bands are produced at  $3300$  and  $3550\text{\AA}$ .

The excitation bands are interesting in that they show considerable variation. For example, in  $\text{LaPO}_4$ , the excitation bands arise from the excited state of the activator and probably involve crystal field splitting of the  $5d$  excited state. It is noteworthy that the excitation spectra of  $\text{LaPO}_4:\text{Ce}$  and  $\text{GdPO}_4:\text{Ce}$  are quite different in spite of the similarity in structure and, therefore, point symmetry at the  $\text{Ce}^{+3}$  site. These materials (18) are fast decay phosphors ( $\sim 40 \times 10^{-9}$  sec).

**Terbium activated rare earth phosphates.**—The spectral properties of terbium activated rare earth phosphates are given in Fig. 6. Nearly the same emission spectra are seen for all of the phosphors. However, major differences are observed for the excitation bands because of the crystal field affect on the  $4f \rightarrow 5d$  transition. In  $\text{YPO}_4:\text{Tb}$  there are two excitation bands, depending on which emission line is being observed. Three separate samples of  $\text{YPO}_4:\text{Tb}$  were measured and found to give identical results, leaving little doubt that the data presented in Fig. 6 represent a reasonably accurate picture of the excitation spectra observed for  $\text{YPO}_4:\text{Tb}$ . Such behavior is unusual.

Fig. 6. Terbium activated rare earth phosphates

For the  $\text{LaPO}_4:\text{Tb}$  phosphor, the usual low level excitation bands due to transitions between the  $4f^8$  electron energy levels were seen, as well as the broad band peaking at about  $46,000\text{ cm}^{-1}$ , an activator  $4f \rightarrow 5d$  excitation transition. The side band at about  $44,000\text{ cm}^{-1}$  which appears in  $\text{LaPO}_4:\text{Tb}$  is probably due to upper energy transitions of  $\text{Tb}^{3+}$ . In  $\text{GdPO}_4:\text{Tb}$ , a broad band at  $46,200\text{ cm}^{-1}$  appears, in addition to the usual  $\text{Gd}^{3+}$  excitation levels. It becomes apparent that the  $\text{Tb}^{3+}$  ( $4f \rightarrow 5d$ ) excitation bands are the only bands observed in these phosphors, in contrast to the oxide systems in which exciton mechanisms were the major feature. As will be shown in a later paper, drastic changes in the excitation bands occur as the Tb becomes 100%, as in  $\text{TbPO}_4$ .

**Dysprosium-activated rare earth phosphates.**—In the rare earth phosphates, dysprosium produces a yellow emission which consists of two groups appearing at 4800 and 5740 Å (see Fig. 7). Changes in the matrix produce slight changes in the position of these emission peaks. The position of the emission lines of dysprosium in the rare earth phosphates is not as greatly affected by the matrix as is that of cerium, terbium, or europium (having  $4f \rightarrow 5d$  and charge-transfer mechanism, respectively). In the monazite structures ( $\text{LaPO}_4:\text{Dy}$  and  $\text{GdPO}_4:\text{Dy}$ ), the major emission lines occur at about 4730 and 5740 Å, while in the xenotime structure ( $\text{YPO}_4:\text{Dy}$ ), there is a shift of about 100 Å to the longer wavelengths. The excitation spectra are easily recognized as being essentially excitation transitions within the  $4f^9$  multiplets of  $\text{Dy}^{3+}$ . The identity of the broad excitation bands beyond  $46,000\text{ cm}^{-1}$  remains unknown. The major excitation band in  $\text{GdPO}_4:\text{Dy}$  is due to transitions within the  $\text{Gd}^{3+}$  ion.

**Holmium and erbium activated rare earth phosphates.**— $\text{Ho}^{3+}$  did not produce any measurable fluorescence in the rare earth phosphates. Wavelengths between 2900 and 8400 Å were scanned, using various excitation wavelengths, but if fluorescence was produced, it was below the limit of the detection of the instrument.

The emission intensity of  $\text{Er}^{3+}$  was extremely weak but measurable and consisted of a major line at 4010 Å with others at 4700 and 5290 Å. Other than this, the spectra were featureless, such that they are not presented herein. In  $\text{GdPO}_4:\text{Er}$ , the major emission line at 3100 Å is caused by transitions within the  $\text{Gd}^{3+}$  cation. There are also very low-level-intensity emission lines due to  $\text{Er}^{3+}$ .

**Neodymium and praseodymium activated rare earth phosphates.**—The intensity of emission of  $\text{Nd}^{3+}$  was found to be very weak, such that the spectra of the  $\text{GdPO}_4:\text{Nd}$  phosphor could not be measured. In  $\text{YPO}_4:\text{Nd}$  and  $\text{LaPO}_4:\text{Nd}$ , only one emission line at

Fig. 7. Dysprosium activated rare earth phosphates

Fig. 8. Samarium activated rare earth phosphates

7240 and 7200 Å, respectively, was observed. Excitation is maximum in the green region of the spectrum.

Phosphors activated by  $\text{Pr}^{3+}$  produced fluorescence too weak to measure.

**Samarium activated rare earth phosphates.**— $\text{Sm}^{3+}$  produces a series of four emission lines in the visible region of the spectrum, as shown in Fig. 8. A slight shift toward longer wavelengths was observed for  $\text{YPO}_4:\text{Sm}$  (xenotime structure) as compared with  $\text{LaPO}_4:\text{Sm}$  (monazite structure). The excitation spectra consist mostly of narrow bands between 3000 and 5000 Å, caused by interlevel transitions of  $4f^5$  electrons within the  $\text{Sm}^{3+}$  ion. No broad bands due to the  $\text{Sm}^{3+}$  were noted. In  $\text{GdPO}_4$ , the major lines and major excitation bands are caused by transitions within  $\text{Gd}^{3+}$ , including that at  $36,600\text{ cm}^{-1}$ .

**Thulium activated rare earth phosphates.**— $\text{Tm}^{3+}$  produces an ultraviolet emission line at 3680 Å in  $\text{LaPO}_4$ , and at 3660 Å in  $\text{YPO}_4$ , as shown in Fig. 9. This spectrum differs considerably from that found for  $\text{Tm}^{3+}$  in the rare earth oxides. In  $\text{Y}_2\text{O}_3:\text{Tm}$ , a blue emission line at  $21,700\text{ cm}^{-1}$  was dominant, whereas in  $\text{YPO}_4:\text{Tm}$ , the major emission line is positioned at  $28,700\text{ cm}^{-1}$ . The excitation spectrum generally consists of narrow bands representing transitions within the  $\text{Tm}^{3+}$  ion. In  $\text{GdPO}_4:\text{Tm}$  the major emission line is due to transitions within the  $\text{Gd}^{3+}$  ion. The excitation band of  $\text{Gd}^{3+}$  is likewise the major feature in the excitation spectrum.

### Discussion of Results

It has been shown that the brightest phosphors are the rare earth phosphates activated by  $\text{Gd}^{3+}$ ,  $\text{Eu}^{3+}$ , or  $\text{Tb}^{3+}$ .  $\text{Dy}^{3+}$  may be classified as possessing intermediate intensity, but the other activators produce only a very low degree of fluorescence. Of immediate interest is a comparison of the fluorescent peaks produced in the phosphates and in the oxides. It is obvious from Fig. 3 that the same transitions which produce fluorescence in the  $\text{Y}_2\text{O}_3:\text{Eu}$  phosphor take place in the phosphate as well. However, the emission of  $\text{Tb}^{3+}$  does not show as great a variation as noted for  $\text{Eu}^{3+}$ . The major emission lines as a function of host lattice are given for the various activators in Table II. Only those lines containing a major portion of the emission energy (50%) are cited, with the exception of a few, such as  $\text{Sm}^{3+}$ , where a single emission line contains but 15-25% of the total energy. Also noted are those activators, such as  $\text{Dy}^{3+}$ , whose emission spectra change considerably as a function of host lattice.

It may be concluded that structure and site symmetry are the major factors which determine the amount of energy concentrated in any transition that results in fluorescence. Some activators are materially

Fig. 9. Thulium activated rare earth phosphates

affected by the matrix, while others such as  $Gd^{+3}$  or  $Tb^{+3}$ , do not show significant changes in emission when incorporated into a cubic lattice ( $Y_2O_3-C_{2v}$ ) as compared to a tetragonal lattice ( $YPO_4-D_{2d}$ ). It is apparent that the same transitions occur for most activators, but that the relative amount of energy concentrated in each is a function of site symmetry.  $Eu^{+3}$  shows the most variation, as presented in Table III. Blasse *et al.* (21) have also commented on this in regard to the  $Eu^{+3}$  ion as an activator.

Of the excitation spectra, only  $Eu^{+3}$  and  $Tb^{+3}$  show broad bands, denoting perturbation of electronic states (charge-transfer and  $4f \rightarrow 5d$  transitions, respectively) by the electric field of the host lattice. Only the po-

sition of the bands change in the phosphates, as compared to the oxides.

$Y_2O_3:Eu$  has a quantum efficiency of 72% (22) and  $YPO_4:Eu$  has a quantum efficiency of 38%. Brill and Wanmaker (4) report a quantum efficiency of 28% for  $GdPO_4:Eu$ . Thus, we can conclude that the incorporation of  $Eu^{+3}$  into what is presumably a more covalent matrix results in a phosphor only 50% as efficient as that produced when  $Eu^{+3}$  is incorporated into a more ionic host such as  $Y_2O_3$ .

The most probable explanation is: (a) europium in oxygen-dominated lattices forms a charge-transfer center with its nearest neighbor oxygen atoms, *i.e.*,  $Eu^{+3}O_n^{-2n}$ . This accounts for the relatively high optimum activator concentrations observed by many authors (15 m/o in  $Y_2O_3$ ), in contrast to the other rare earths (14); (b) in phosphates, it is already known by ESR measurements that the oxygen atoms are tightly bound within the  $PO_4$  group. Therefore, they would not be expected to be available for sharing to form a charge-transfer center with  $Eu^{+3}$ . Since the high efficiency associated with  $Eu^{+3}$  arises because of these Laporte-allowed transitions, rather than from the  $4f \rightarrow 4f$  forbidden transitions, it is not surprising that the inclusion of  $Eu^{+3}$  in a lattice wherein the oxygen orbitals are bound more tightly and are less polarizable, has the effect of producing a phosphor of lower efficiency.

# Growth of ZnSe-ZnTe Solid Solutions in Te<sub>2</sub> Atmosphere

M. Aven, R. B. Hall,<sup>1</sup> and J. S. Prener\*

General Electric Research and Development Center, Schenectady, New York

## ABSTRACT

The solid-vapor equilibria in the Zn-Se-Te system are examined under conditions of near-stoichiometry and under excess chalcogen pressure. It is shown that the best conditions for growing ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals of uniform composition occur in the presence of intentionally added excess Te. The crystallographic and compositional characteristics of doped and undoped ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals grown in vacuum and in the presence of excess Te are described.

There are nine possible ternary compound combinations involving a pair of Zn or Cd chalcogenides. All of these, with the exception of CdS-CdTe and ZnS-ZnTe have been reported to be miscible in the solid state in all proportions (1). The combinations having a common chalcogen atom, *e.g.*, ZnS-CdS (2) or ZnSe-CdSe (3) have been grown from the vapor phase as single crystals without serious segregation problems during the growth. Of the combinations having a common metal, the sulfo-selenides, *e.g.*, CdS-CdSe (4, 5), have also been obtained in unsegregated single crystal form. The seleno-tellurides, *i.e.*, CdSe-CdTe (6) and ZnSe-ZnTe (7-10), on the other hand, have shown considerable tendency toward segregation into Se and Te-rich components during growth from both the melt and vapor phase. Some improvement in vapor phase synthesis of ZnSe-ZnTe crystals was achieved by a two-step procedure (11) in which polycrystalline but relatively unsegregated boules were first grown by a modified Piper-Polich technique (12) using a fast growth rate (~0.4 mm/hr), followed by their epitaxial regrowth on ZnSe single crystal seed plates at a slower growth rate (~0.1 mm/hr). Although boules having reasonably uniform single crystalline sections as large as 0.3 cm<sup>3</sup> had been grown by this technique, the poorly defined relationship between the composition of the charge and the grown crystal, and the tendency toward polycrystallinity in the last-grown end of the boule made it desirable to look for better techniques for the growth of ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals. The incentive for this effort has been the unique property of ZnSe<sub>x</sub>Te<sub>1-x</sub> among the wide band gap II-VI compounds of being synthesizable in both p- and n-type forms, which makes it suitable as a material for light-emitting and semiconducting p-n junction devices.

The present report will describe a vapor phase synthesis method in which ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals are grown in an excess Te atmosphere using a very small temperature gradient. The method has yielded boules having good compositional uniformity, reproducibility in the Se/Te ratio, and very few large angle grain boundaries. It will be shown that these results cannot be derived from equilibrium thermodynamics of the ZnSe<sub>x</sub>Te<sub>1-x</sub> solid-vapor system, and that kinetic factors have to be considered in trying to understand the behavior of the system.

## Experimental Technique

The starting materials for the ZnSe<sub>x</sub>Te<sub>1-x</sub> crystal growth have been ZnSe powder obtained from GE Chemical Products Plant, Merck Company, Eagle-Picher Company, or synthesized in this Laboratory; and ZnTe powder obtained from Eagle-Picher Company or synthesized in this Laboratory. No significant dif-

ferences in the growth habit or crystalline perfection were found between the crystals grown from the materials obtained from these various sources.

The powders were dry mixed by passing them a few times through a No. 90 mesh silk screen, and pre-fired at 850°C in flowing purified H<sub>2</sub> for 1-2 hr. If desired, nonvolatile dopants such as Li were added to the powder mix in the form of aqueous solutions prior to the H<sub>2</sub>-firing step. Volatile dopants such as P were best added during the next step, which involved sintering the pre-fired powder in closed tubes under a Te pressure of about 5 x 10<sup>-2</sup> atm. The sintering, performed at temperatures between 925° and 1025°C for times ranging from 60 to 80 hr, increased the bulk density of the pre-fired powder from about 40% to between 80 and 95% of the bulk density of the ZnSe<sub>x</sub>Te<sub>1-x</sub>. The sintered powder compact was then transferred to a growth tube containing a ZnSe<sub>x</sub>Te<sub>1-x</sub> seed crystal, and enough Te to give about 5 x 10<sup>-2</sup> atm Te pressure at the growth temperature. The tube was evacuated, the charge and the seed positioned at the opposite ends of the tube, and the system transferred to the growth furnace.

As shown in Fig. 1, the initial position of the tube in the growth tube was such as to effect a thermal etching of the seed crystal, the temperature difference between the seed end and the charge end of the tube being approximately 7°C. After about one quarter of the seed had etched away, the tube was repositioned, with the seed now in a region approximately 5°C cooler than the bulk of the charge. In this position growth on the seed occurred at the rate of approximately 100 mg/day in 7 mm ID growth tubes and 200 mg/day in 10 mm ID growth tubes at 5 x 10<sup>-2</sup> atm Te pressure. A few runs attempted at higher Te pressures showed that the growth was extremely slow under such conditions.

Fig. 1. Temperature profile, geometry of the growth tube, and the location of the charge and the seed in (a) the seed etch position, and (b) the growth position. Tube diameter, 7 mm; tube length, 7.5 cm; weight of charge, 2g.

<sup>1</sup> Present address: University of Delaware, Newark, Delaware.

\* Electrochemical Society Active Member.

The temperature gradient between the seed and the charge was kept low for two reasons. First, in order to have the system as close as possible to thermodynamic equilibrium conditions (see Discussion) large temperature gradients were to be avoided. Second, the minimum temperature difference at which spontaneous nucleation was found to occur is 18°C. Hence, in order to avoid spurious nucleation on the walls of the quartz tube and to have the growth confined exclusively to the seed crystal, the temperature gradient between the seed and the charge had to be kept below 18°C. Small temperature gradients for the closed tube growth of II-VI compound crystals have also been recommended by Shiozawa and Jost (3) on the basis of their experience with the growth of ZnSe-CdSe solid solutions.

### Results

Table I intercompares the starting compositions, the x-ray lattice constants, and the compositions of the grown crystals of a few representative growth runs in the presence and in the absence of excess Te. The relative amounts of Se and Te in the grown crystals were calculated from their lattice constants on the basis of the data of Larach *et al.* (13). The lattice constants were determined from x-ray powder patterns on approximately 5 mg (crushed) pieces cut from the grown boules. The first line in the table represents data obtained for the remaining charge, and the nose and the rear portion of a 1.2 cm long crystal having a diameter of about 2 mm. The constancy of the  $x$ -values over this distance demonstrates the uniformity in composition parallel to the growth direction. The next line of data is for a flat cylinder-shaped crystal 3 mm thick and 7 mm in diameter, with samples taken from its upper, middle, and lower portions. The close agreement between the values of  $x$  for these samples indicate that the composition is also uniform in the direction perpendicular to the direction of growth. The third line, representing the data for a crystal grown without the addition of extra Te, shows the large disparity between a piece taken from the left-over charge and two portions of the grown crystal. A significant variation in composition is also seen in the data for a crystal grown without the addition of extra Te, but under  $5 \times 10^{-2}$  atm pressure of argon. The beneficial effect of the Te addition on the uniformity of composition is also evidenced by the considerably sharper x-ray diffraction lines for the first two crystals (standard deviations in the lattice constant determinations for the individual pieces range from 0.0002 to 0.0006 Å) as compared with the third (standard deviation 0.002 Å).

Figure 2 shows a photograph of a ZnSe<sub>0.30</sub>Te<sub>0.70</sub> crystal. It was grown in a direction approximately normal to the plane of the photograph. The large face on the right is a (110) face; its Laue spot pattern, shown in Fig. 3 demonstrates a fairly good short range crystalline perfection. The growth steps clearly visible on this face indicate that the growth of the crystal is occurring in the  $\langle 110 \rangle$  direction, having possibly started from a screw dislocation at the apex of the triangular area at the right hand side of the (110) face [cf. ref. (3)].

Figure 4 illustrates the relationship between the initial compositions of doped and undoped mixed powders of ZnSe and ZnTe, and the compositions of the boules grown from them. There appears to be no

Fig. 2. Photomicrograph of a ZnSe<sub>0.30</sub>Te<sub>0.70</sub> crystal. The faces at the right and upper left are (110), the one on top is (100). Magnification, 10X.

systematic difference between the behavior of the doped and undoped crystals. All points lie below the (dashed) line representing equal  $x$  values in the charges and the grown crystals, indicating that the crystals have always a somewhat higher Te content than the charge from which they were grown. This may be a consequence of having had to make a compromise between the maximum tolerable Te pressure and a reasonable growth rate (higher Te pressures presumably favoring a closer correspondence between the charge and crystal compositions). The solid line represents a least squares fit of the data and the points corresponding to pure ZnTe and ZnSe to a polynomial of the form  $x_c = a + bx_p + cx_p^2$ , where  $x_c$  indicates the composition of the grown crystal, and  $x_p$  that of the mixed powders of ZnSe and ZnTe. The standard deviation of the data points from this line ( $a = 0.0063$ ,  $b = 0.673$ ,  $c = 0.319$ ) is 0.03.

### Discussion

The most important quantity characterizing the evaporation rate of a solid is the magnitude of the constant  $K_p$  which expresses the equilibrium between the solid and its vapor.

Investigations by several workers (14, 15) have shown that the vapor over subliming binary II-VI compounds consists almost entirely of separate metal and chalcogen species, with no evidence of any molecular compounds. The equilibrium between solid ZnSe and the vapor phase over it can then be written as<sup>2</sup>

The equilibrium constant for this reaction is

$$K_p^{\text{ZnSe}} = p_{\text{Zn}} \cdot p_{\text{Se}_2}^{1/2} \quad [2]$$

<sup>2</sup> For the present discussion we will neglect the presence of the higher molecular weight Se molecules, i.e., Se<sub>4</sub>, Se<sub>6</sub>, Se<sub>8</sub>, etc.

Fig. 3. X-ray diffraction pattern of a (110) face of the  $\text{ZnSe}_{0.30}\text{Te}_{0.70}$  crystal shown in Fig. 2.

Fig. 4. Relationship between the initial composition of the mixed powders of ZnSe and ZnTe,  $x_p$ , and the composition of the crystals grown from them,  $x_c$ . Circles, undoped; triangles, doped with P; square, doped with Li. The dashed line corresponds to the relationship  $x_c = x_p$ , the solid line represents a least squares fit to  $x_c = a + bx_p + cx_p^2$ .

Similarly, for ZnTe, we have

$$K_p^{\text{ZnTe}} = p_{\text{Zn}} \cdot p_{\text{Te}_2}^{1/2} \quad [4]$$

Table II lists the equilibrium constants,  $K_p$ , at 970°C for the chalcogenides of Zn and Cd. Examination of the equilibrium constants for the pairs ZnS-ZnSe or CdS-CdSe, for example, shows that they are roughly

Table II. Equilibrium constants ( $K_p = p_{\text{Met.}} \cdot p^{1/2}_{\text{Chalc.}}$ ) Zn and Cd chalcogenides

Compound	( $K_p$ ) 970°C
ZnS	$2.0 \times 10^{-6}$
ZnSe	$4.7 \times 10^{-6}$
CdS	$3.7 \times 10^{-4}$
ZnTe	$5.0 \times 10^{-4}$
CdSe	$5.1 \times 10^{-4}$
CdTe	$4.0 \times 10^{-3}$

within a factor of two of each other. This indicates that the volatilities of the two compounds making up the pair are very close to each other, and that there should be no serious segregation problems in growing  $\text{ZnS}_x\text{Se}_{1-x}$  or  $\text{CdS}_x\text{Se}_{1-x}$ . Indeed, as was mentioned in the introduction, these solid solutions have been obtained in good quality single crystal form. The equilibrium constants for ZnSe and ZnTe, on the other hand, differ by almost a factor of a hundred, indicating that these compounds have quite different volatilities.

Suppose we have a quantity of  $\text{ZnSe}_x\text{Te}_{1-x}$ , with, say,  $x = 0.5$  in a sealed evacuated tube. To the first approximation, the vapor pressures of Zn and  $\text{Te}_2$  can be assumed to be equal to those over the more volatile compound making up the solid solution, i.e., ZnTe. At 970°C these vapor pressures are  $p_{\text{Te}_2} = 4.1 \times 10^{-3}$  atm and  $p_{\text{Zn}} = 8.2 \times 10^{-3}$  atm, respectively. This relatively high pressure of Zn will, by virtue of Eq. [2], suppress the pressure of  $\text{Se}_2$  to about  $10^{-7}$  atm. The saturated vapor over the evaporating  $\text{ZnSe}_x\text{Te}_{1-x}$  will thus contain Zn and  $\text{Te}_2$  in the ratio of 2/1, whereas the Zn to  $\text{Se}_2$  ratio is about  $2/10^{-4}$ . The consequence of this is, of course, the preferential evaporation of ZnTe out of the charge, with a corresponding enrichment with respect to ZnSe, as has been found to be the case experimentally.<sup>3</sup>

This qualitative conclusion is in accord with thermodynamic calculations based on a model which assumes that (i) both the evaporating solid and the growing crystal are in thermodynamic equilibrium with the gas phase in its immediate vicinity, (ii) there is no gradient in total pressure, (iii) Zn,  $\text{Se}_2$ , and  $\text{Te}_2$  are the predominant gaseous species, and (iv) that the  $\text{ZnSe}_x\text{Te}_{1-x}$  is close to stoichiometric. The solution of the integral equation expressing the composition of the growing crystal as a function of the fraction of charge evaporated based on this model predicts that the growing crystal should start out considerably richer in ZnTe than the initial composition of the evaporating charge and that, as the growth proceeds, the later-grown parts of the crystal should become increasingly richer in ZnSe. If an appropriate term expressing the presence of excess Te is introduced into the integral equation, it is found, however, that the addition of Te makes no difference in the degree of segregation.<sup>3</sup> This contradicts the experimental evidence presented.

This finding as well as the past experience of several workers shows that care has to be exercised in applying equilibrium thermodynamics to the growth of II-VI compounds. As shown recently by Toyama (16) the rate of material transport in the growth of II-VI compounds can either be limited by the vaporization and condensation processes, or by the gaseous diffusion along the growth tube. The vaporization rate can generally not be calculated from the Herz-Knudsen-Langmuir equations using equilibrium constant data. For CdS, for example, Somorjai and Epsen (17) find that its vacuum evaporation rate is only about a tenth of that calculated from the equilibrium constant and is a strong function of the stoichiometry of the compound. The suggested reasons for this are

<sup>3</sup> We are not presenting the development of the appropriate mathematical formalism in this paper because, although quite straightforward, it involves quite lengthy algebraic manipulations and because it did not lead to a realistic representation of the system studied.

surface reactions involving rearrangement, association and dissociation of surface atoms before vaporization. The surface reaction is often the slow step in the evaporation sequence and is followed by rapid desorption of surface species. Similar interactions involving among other things, temperature and pressure-dependent "sticking coefficients," occur in the condensation process at the cold end of the growth tube. These relationships are expected to be even more complex when more than two atomic species are present, as is the case with solid solutions, and when the deviation from stoichiometry is as large as is encountered in tellurides under excess Te pressure.

In examining the possible effect of excess Te on the way in which thermodynamic equilibrium is established in the ZnSe<sub>x</sub>Te<sub>1-x</sub> system, the role of the SeTe gaseous species should be considered. The phase diagram of the Se-Te system indicates miscibility in all proportions in the liquid state. This suggests that the vapor phase over liquid Se-Te solutions contains SeTe molecules in concentration comparable to that of Se<sub>2</sub> and Te<sub>2</sub>. As far as the ZnSe<sub>x</sub>Te<sub>1-x</sub> system is concerned, it can be shown that the ratio of  $p_{\text{Se}_2}$  to  $p_{\text{Te}_2}$  is

$$\frac{p_{\text{Se}_2}}{p_{\text{Te}_2}} = (K_p^{\text{ZnSe}}/K_p^{\text{ZnTe}})^2 (x/1-x)^2$$

whereas the ratio of  $p_{\text{SeTe}}$  to  $p_{\text{Te}_2}$  can be written as

$$\frac{p_{\text{SeTe}}}{p_{\text{Te}_2}} = (K_p^{\text{ZnSe}}/K_p^{\text{ZnTe}}) (x/1-x) K_p^{\text{Se}_2} K_p^{\text{Te}_2} / (K_p^{\text{SeTe}})^2$$

where

$$K_p^{\text{Se}_2} = p_{\text{Se}}/p_{\text{Se}_2}^{1/2}$$

$$K_p^{\text{Te}_2} = p_{\text{Te}}/p_{\text{Te}_2}^{1/2}$$

$$K_p^{\text{SeTe}} = p_{\text{Se}}^{1/2} p_{\text{Te}}^{1/2} / p_{\text{SeTe}}^{1/2}$$

Using these equations at 970°C for  $x = 0.5$  gives  $p_{\text{Se}_2}/p_{\text{Te}_2} = 10^{-4}$ , and  $p_{\text{SeTe}}/p_{\text{Te}_2} = 10^{-2}$  [ $K_p^{\text{Se}_2} K_p^{\text{Te}_2} / (K_p^{\text{SeTe}})^2$ ]. As  $K_p^{\text{SeTe}}$  is not available from literature, we will consider the cases where  $(K_p^{\text{Se}_2} K_p^{\text{Te}_2})^{1/2} / K_p^{\text{SeTe}} < 1$  and  $(K_p^{\text{Se}_2} K_p^{\text{Te}_2})^{1/2} / K_p^{\text{SeTe}} > 1$ . In the former case  $p_{\text{SeTe}}/p_{\text{Te}_2} < 10^{-2}$ , i.e., the ratio of the total Se to total Te in the gas phase is still very small. If, however,  $(K_p^{\text{Se}_2} K_p^{\text{Te}_2})^{1/2} / K_p^{\text{SeTe}}$  should be substantially larger than unity, the ratio  $p_{\text{SeTe}}/p_{\text{Te}_2}$  may get large enough to provide a better balance between the supply of Se and Te to the gas phase, with an accompanying reduction in the degree of segregation. Since the addition of Te cannot change the magnitude of the equilibrium constants this would, of course, be true in the presence as well as in the absence of excess Te, if the system is close to equilibrium in both cases.

It is possible, however, that there exist kinetic limitations to the formation of SeTe species in the vacuum growth conditions. It could be, for example, that in the absence of excess Te the formation of SeTe species by a surface reaction is improbable because the surface Zn-Se bonds are much stronger than the surface Zn-Te bonds, and the probability of formation of SeTe by a gaseous collision between Se<sub>2</sub> and Te<sub>2</sub> molecules is low because of low partial pressure ( $10^{-7}$  atm) of Se<sub>2</sub>. The addition of excess Te would increase both the gaseous collision frequency between Se<sub>2</sub> and Te<sub>2</sub>, and may additionally modify the reactions on or near the surface of the evaporating charge in such a way as to promote the formation of the SeTe species.

Two other factors besides the enhanced formation of the SeTe species may contribute to the improvement of the uniformity of ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals grown in Te atmosphere. First, calculations have shown that under equilibrium conditions the tendency to segregate decreases with decreasing temperature difference between the charge and the growing crystal. As the presence of a denser gas atmosphere is expected to enhance the heat exchange between the charge and the crystal, the temperature gradient in the presence of Te should be less than in vacuum. That the segregation

was not quite as severe in argon atmosphere as it was in vacuum (see Table I) may be due to the same effect. Second, it has been demonstrated (18) that chalcogen self-diffusion rate in II-VI compounds increases with the vapor pressure of chalcogen over the solid compound. The intermixing of Te and Se atoms in the growing crystal by solid state diffusion would therefore proceed at a faster rate in Te atmosphere than in vacuum. Which of these factors is the dominant one will have to be resolved by further experimental work.

### Summary

When ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals are grown in vacuum, one finds that the first-grown portions of the crystals are invariably richer in ZnTe than the later grown portions and that the charge becomes increasingly richer in ZnSe as the growth proceeds. This undesirable feature can be largely eliminated by growing the crystals with deliberate addition of excess Te to the growth tube. Various sections of the crystals grown under such conditions were subjected to lattice constant determination by x-ray diffraction analysis, and were found, in most cases, to differ from each other by no more than  $x = \pm 0.01$ . Only slight enrichment of the grown crystals with respect to ZnTe as compared to the charge material was observed. The degree of enrichment, as well as the uniformity in composition of the grown crystals was found to be independent of the species, and the concentration of the sometimes added dopants, Li and P.

### Acknowledgments

The ideas presented in this paper evolved from discussions with Professors J. Mitchell and H. H. Woodbury, whose contribution to the present work is herewith gratefully acknowledged. We also want to thank L. M. Osika for the extensive x-ray work on the ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals carried out under his supervision. W. Garwacki assisted in the preparation of the ZnSe and ZnTe powders, and in the growth of the ZnSe<sub>x</sub>Te<sub>1-x</sub> crystals. The work reported in this paper was sponsored in part by the AFCRL Contract No. 19(618)-4976.

Manuscript received April 19, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Epitaxial Growth of Zinc- and Cadmium-Doped Gallium Phosphide by Gallium Chloride Vapor Transport

Lars C. Luther and D. D. Roccasecca

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

### ABSTRACT

Zinc- and cadmium-doped gallium phosphide crystals have been grown by an open tube halogen transport process at 805°-875°C. The zinc-doping varied from  $10^{17}$  to  $10^{19}$  cm<sup>-3</sup> while cadmium could be incorporated at levels ranging from  $10^{16}$  to  $10^{18}$  cm<sup>-3</sup>. We observed a linear dependence of zinc and cadmium concentration on the partial pressure of the dopant in the growth ambient. This linear dependence is evidence for a nonequilibrium, kinetically controlled process. The structural and electrical properties are compared with the properties of crystals grown by the wet hydrogen process. A study of the gallium consumption as a function of experimental variables yielded a Ga to PCl<sub>3</sub> ratio of  $2.5 \pm 0.2$ , independent of PCl<sub>3</sub> feed rate and carrier gas flow. A ratio of 2.64 is predicted from thermodynamic data provided the species GaCl<sub>2</sub>(g) can be neglected in the initial reaction between HCl and Ga.

At the present time the open tube vapor transport technique used to produce large single crystals of gallium phosphide relies on two sets of volatile gallium compounds: the oxide (Ga<sub>2</sub>O) and the halides. In the moist hydrogen system (1) the oxide is the transporting medium. For the halogen systems (2-5) conditions are created to preferentially form the mono-halide which subsequently disproportionates to give the phosphide and the trihalide. In this study of the chloride-phosphide system the reactants were phosphorus trichloride and elemental gallium.

### Experimental

Pure phosphorus trichloride was obtained from Asarco Intermetallics Company (6). Other starting materials were 99.9999% gallium from Alusuisse and zinc and cadmium from United Mineral and Chemical Company, both 99.9998%. Tank hydrogen was used as carrier gas. The apparatus consists of a quartz furnace tube connected by means of ground quartz joints and Beckman Teflon tube fittings to a phosphorus trichloride bubbler and flowmeters. A schematic is given in Fig. 1. The hydrogen carrier gas was passed over a platinum catalyst followed by a phosphorus pentoxide absorber to suppress the oxygen content. A high loss, low temperature furnace was placed upstream of the one-zone principal furnace to vaporize the dopant. The partial pressure of the dopant was determined from weight loss measurements of the dopant source boat (quartz). The gallium source (50g) was heated in a 125 mm boron nitride boat.

The gallium arsenide seed crystals supplied by Monsanto and Asarco Intermetallics Company, were in the form of (111) oriented 0.4 mm thick slices cut from undoped, boat-grown ingots. Preparation of the seed crystals consisted of a 5-12 min etch at 85°C in mixture of concentrated sulfuric acid, water, and 30%

hydrogen peroxide (3:1:3). During the etching about 0.1 mm of material was removed. Often a highly polished (111) Ga surface was obtained while the (111) As face became wavy. A similar etchant (3:1:1) is often used under milder conditions to produce etch pits on the gallium face in order to differentiate between (111) faces. The more drastic conditions employed here result in a faster dissolution of material on both faces and reduce the preferential dissolution near imperfections. The primary objective of the etch was to remove mechanical damage. A highly perfect polish of the substrate was not deemed essential for epitaxial growth.

The seed crystals had the dimensions 32 by 16 mm. They were placed Ga-face up on an L-shaped quartz support at an angle of about 30° to the flow direction. Only the bottom and top edges of the crystal were in contact with the quartz support. The gallium boat

was placed in a 21 mm ID quartz tube in a region corresponding to the flat zone of the furnace, 7.5 cm upstream of the seed. The 15 cm long flat zone was maintained at 935°C controlled to within  $\pm 1^\circ\text{C}$  while the seed spanned a temperature gradient of  $70^\circ\text{C}$  centered at  $840^\circ\text{C}$ . The quartz tube with gallium source and seed was pushed into the furnace with nitrogen flowing. The furnace tube was then closed with a bubbler cap. After a 10 min heat-up period the atmosphere in the furnace was changed to hydrogen and after an additional period of 10 min a  $\text{PCl}_3$ -carrying, second hydrogen stream which bypassed the cadmium or zinc source was admitted. The dopant source boat was pushed into the high loss furnace after allowing  $\frac{1}{2}$  hr of growth. Cadmium or zinc vapor is carried by the dry hydrogen stream into the main furnace where it is mixed into the  $\text{PCl}_3/\text{H}_2$  stream at about  $800^\circ\text{C}$  before passing over the gallium boat.

In a leak free system the atmosphere in the furnace would remain clear. Though a glass plate in the bubbler cap condensation of  $\text{GaCl}_2$  could be observed. Persistent formation of heavy white smoke after admission of  $\text{PCl}_3$  signalled the presence of oxygen or moisture and polycrystalline growth.

Unless effects of feed and flow rate variation were being studied the flow rates of the two feeding hydrogen streams were kept constant: 140 cc/min dry hydrogen and 100 cc/min hydrogen bubbled through  $0^\circ\text{PCl}_3$ . Epitaxial growth was usually allowed to continue for 6-10 hr during which a 1 mm thick layer was deposited under standard conditions. Longer runs proved unprofitable because large amounts of gallium chloride accumulated and clogged the reaction tube.

Flowmeters were calibrated by measuring the rate of motion of soap films in glass tubes. In separate experiments the vapor pressure of  $\text{PCl}_3$  was determined by weight loss to be 36 mm at  $0^\circ\text{C}$ . The hydrogen carrier gas was found to be saturated even at flow rates higher than any used for crystal growth.

A large number of experimental data on the rate of consumption of the two initial reactants, Ga and  $\text{PCl}_3$  was collected. The rate of consumption of Ga in mM/min was determined by dividing the weight loss of the source by the duration of the run. The  $\text{PCl}_3$  rate of consumption in mM/min was obtained from the average flow rate of hydrogen saturated with  $\text{PCl}_3$  at  $0^\circ\text{C}$ . In the presence of a liner tube with an estimated furnace tube clearance of 0.5 to 1 mm a small amount of HCl and  $\text{P}_4$  from the decomposition of  $\text{PCl}_3$  may bypass the gallium source and remain unreacted. Since the mole ratio of the reactants is an important characteristic of the system, special experiments were carried out in which the gallium boat and the seed were placed directly into the furnace tube. In four such runs in which the  $\text{PCl}_3$  feed rate was varied from 0.073 to 0.26 mM/min the Ga/ $\text{PCl}_3$  mole ratio did not deviate significantly from the mean of the ratios obtained in the experimental runs in which a liner tube was used.

An experimental analysis of the cool effluent gas in these special runs was made. The gas was passed through a dry ice trap to remove  $\text{GaCl}_3$  and the remaining HCl was absorbed in an alkaline solution. The total amount of unreacted HCl carried over in a run could then be determined by precipitation as  $\text{AgCl}$  and was found to correspond to a vapor pressure of  $3 \times 10^{-4}$  atm or to 0.5% of the reacted  $\text{PCl}_3$ .

### Results and Discussion

**Crystal growth and perfection.**—The best crystals grown by the halogen transport process were about 1 mm thick with  $45^\circ$  bevelled edges on the (111) A or Ga growth face as shown in the upper crystal of Fig. 2 together with a typical water vapor transported crystal. The as-grown halogen transported crystal is transparent because the GaAs substrate was etched off during the deposition process. The other crystal was lapped to remove the GaAs substrate. The pits seen on

Fig. 2. Single crystals of GaP grown by vapor transport on GaAs seeds. The upper crystal is grown by halogen transport and is here shown as grown. The lower crystal is grown by the moist hydrogen method and displays typical flats, terraces and, at the left, non-epitaxial growth. The GaAs substrate has been removed from the lower crystal by lapping.

the lower left of the growth side of the halogen transported crystal are characteristic of the "hot" end. With higher  $\text{PCl}_3$  feed rates this pitting could be eliminated but instead polycrystalline growth occurred at the "cold" end. Note that the dense pitting seen in the upper left part is on the backside. Even the best "flats" grown by halogen transport have a mosaic structure characterized by relatively large flats inclined at small angles to an average plane. In comparison the flats developed in the wet hydrogen process are more nearly perfect but generally smaller.

Several crystals were grown on the (111) B or As face of seed crystals. Typically the final crystal face would show large, axially symmetric hillocks (a cobble stone, rather than fish scale pattern). In comparing epitaxial growth on the A and B faces a significant orientation effect on sulfur doping was noted. The sulfur was unintentionally introduced through the use of low-purity  $\text{PCl}_3$  in initial experiments. Crystals grown from the sulfur contaminated  $\text{PCl}_3$  were n-type with a carrier concentration between  $10^{16}$  and  $10^{17}$   $\text{cm}^{-3}$ . The C-line (7) due to sulfur appeared in the spectrum. With a cadmium pressure of several Torr, low mobility, p-type crystals could be obtained if epitaxial growth occurred on the A face. If, however, growth took place on the B face the epitaxial layer would be n-type. Thus from an atmosphere containing both sulfur and cadmium n- and p-type crystals can be grown depending upon seed orientation. A strong orientation effect on donor doping has previously been discussed by Groves (8).

Usually the epitaxial layer grown on the (111) A face was thicker at the cold end. In some cases it was twice as thick as the hot end. Since the seed crystal was oriented within  $\frac{1}{2}^\circ$  the final growth face was considerably off (111).

Inclusions were rarely observed in the halogen transported GaP and, in contrast to wet hydrogen transported material, voids were never encountered. The GaAs seed was extensively and irregularly etched and converted to a brittle layer of porous GaP. During

Fig. 3. Photomicrographs of etched GaP. The etchant is a mixture of hot chromic and hydrofluoric acids in the presence of silver ions. All magnifications ca. 60X. longer runs the seed evaporated completely and the exposed backside of the GaP crystal began to erode.

Figure 3 is a collection of photomicrographs of etched GaP surfaces. The etchant used is a mixture of 1g chromic acid in 2 ml of water, 1 ml hydrofluoric acid, and 8 mg silver nitrate (9). The crystals are etched for ½ to 1 hr at 90°C. Water vapor grown GaP (111) B faces shown in Fig. 3A respond to the etchant with individual etch pits. In Fig. 3B and C virgin (111) A faces of halogen transported GaP typically show rows of overlapping etch pits in two out of three symmetry directions with few randomly distributed individual etch pits. The (111) B face shown in Fig. 3D was prepared by lapping the heavily pitted backside of a halogen transported crystal, polishing it with chlorine bubbling through methanol, and then etching it in the chromic acid etchant as above.

The etch grooves appearing on micrographs Fig. 3B, 3C, and 3D probably correspond to stacking faults. Wet hydrogen transported material never showed such etch grooves on either growth or substrate face. We therefore conclude that wet hydrogen transported material possesses a higher degree of structural perfection. Comparison of micrographs Fig. 3C and 3D which show the response of the growth and substrate side of the same crystal suggests that there is a reduction in the number of stacking faults during growth. However, the difference in defect density may also have been brought about by a difference in the effectiveness of the etch to reveal faults on the two polar faces.

The higher degree of structural imperfection in the halogen transported GaP is perhaps related to the difference in growth conditions. The halogen transported crystals studied here were grown at a temperature 200°C lower than the moist hydrogen grown material. Since the moist hydrogen grown crystals also grow more slowly it was interesting to evaluate the effect of growth rate on etch behavior for halogen transported GaP. Here it was found that although the growth rate could be varied by a factor of ten no

Fig. 4. Growth rate of epitaxial GaP under the following experimental conditions: seed temperature; 840°C in a gradient of 18°C/cm, carrier gas flow 0.240 l/min in a 21 mm ID quartz tube, PCl<sub>3</sub> feed rate variable.

significant change in the appearance of etched growth surfaces was observed.

The thickness of the epitaxial deposits was measured at different points and divided by the growth time in order to obtain an average growth rate. Experiments showed this to be a meaningful number. Two crystals grown at the same PCl<sub>3</sub> feed rate but over different periods of time (3 and 6 hr) gave the same growth rate. Figure 4 indicates that the macroscopic growth rate depends linearly on the PCl<sub>3</sub> feed rate even up to the highest feed rates used. Feed rates exceeding 0.4 mM/min tended to give polycrystalline deposits. The vertical spread in the data collected on Fig. 4 reflects the higher growth rates at the colder end of the crystal.

Resistance measurements of doped GaP crystals were made by the Van der Pauw method. The contacts used were Au and W wire pressure contacts to gallium dots or directly to the crystal. By applying d-c pulses the contacts could be made ohmic. The ohmic behavior of the contact resistances was verified by varying the applied current in the measuring circuit.

*Transport mechanism.*—In a recent paper Seki and Araki (10) have given a detailed theoretical analysis of the GaP-Cl<sub>2</sub>-H<sub>2</sub> system. They calculated the partial pressures of all important species [ignoring GaCl<sub>2</sub>(g)] and presented the results graphically as functions of temperature and hydrogen-chlorine ratio at a selected set of conditions. At high temperatures (>1100°K) only HCl, GaCl, P<sub>2</sub>, and P<sub>4</sub> were found to be present in the gas phase in significant amounts. At lower temperatures (<900°K) the species HCl, GaCl<sub>3</sub>, and P<sub>4</sub> predominated. In order to explain our data we have made a simplified analysis of the same system using the same sources (11-13) of thermodynamic information as Seki and Araki. This was necessary because their results were obtained for a set of representative conditions which differed somewhat from our experimental conditions.

By independently varying the flow rates of dry hydrogen and PCl<sub>3</sub>-saturated hydrogen the PCl<sub>3</sub> feed rate was varied while keeping the total carrier gas flow constant. Alternately the PCl<sub>3</sub> feed rate was kept constant while the total carrier gas flow rate was varied. The Ga/PCl<sub>3</sub> consumption ratios determined experimentally in these two sets of experiments are summarized on Fig. 5 and Table I. The ratio is independent of PCl<sub>3</sub> feed rate and total carrier gas flow rate. The average ratio determined from 34 measurements is 2.5 with a standard deviation of 0.2. The data from the special runs in which no liner tube was used are included on Fig. 5 and indicate that there is negli-

Fig. 5. Gallium/ $\text{PCl}_3$  consumption ratio as a function of  $\text{PCl}_3$  feed rate. The straight line drawn through the data points represents the average ratio 2.5. The standard deviation is 0.2.

gible bypass of reactants as discussed in the experimental section.

During a transport run the gallium source boat is heated in a phosphorus partial pressure several orders of magnitude higher than the decomposition pressure of GaP which is  $8 \times 10^{-6}$  atm at  $1200^\circ\text{K}$  (14). One might therefore have expected to find extensive conversion of gallium to GaP. When the gallium source is pulled out of the reaction zone after a run, a skin of GaP can be observed to form during cooling. However, upon digestion of the gallium it is found that there is no GaP precipitate in the source boat other than the skin on the surface. The weight of this skin corresponds closely to the solubility (14) of phosphorus in gallium at the source temperature. We can therefore rule out the possibility that conversion of gallium to GaP is prevented by slow diffusion of phosphorus in gallium. There is no GaP precipitate on or in the gallium during the run. This conclusion is important in the subsequent argument.

The  $\text{PCl}_3$  carried into the reaction chamber by the hydrogen carrier gas is decomposed according to the equation

Even at room temperature the equilibrium of this reaction lies far to the right. Slow kinetics, however, prevent phosphorus deposition in the cold zone of the apparatus. At higher temperatures the phosphorus tetramers dissociate

Table I. Gallium and  $\text{PCl}_3$  consumption rates and ratio vs. total carrier gas flow

Total carrier gas flow, cc/min	Gallium consumption, mM/min	$\text{PCl}_3$ consumption, mM/min	Mole ratio
180	0.69	0.28	2.5
175	0.73	0.29	2.5
190	0.70	0.27	2.6
220	0.64	0.25	2.6
225	0.63	0.25	2.5
260	0.54	0.25	2.2
315	0.74	0.29	2.6

380	0.75	0.29	2.6

From the phosphorus balance equation

$$p_{\text{PCl}_3} = 4p_{\text{P}_4} + 2p_{\text{P}_2} = \frac{36}{760} \frac{100}{240} \text{ atm} = 2 \times 10^{-2} \text{ atm}$$

which together with

$$K_2 (1200^\circ\text{K}) = 10^{-2}$$

yields the pressures of the two species in the reaction zone

$$p_{\text{P}_2} = 5 \times 10^{-3} \text{ atm}$$

$$p_{\text{P}_4} = 2.5 \times 10^{-3} \text{ atm}$$

One of the initial reactions in the hot zone is undoubtedly

$$K_3 = \frac{p^2_{\text{GaCl}} p_{\text{H}_2}}{p^2_{\text{HCl}}} \quad [3]$$

At  $1200^\circ\text{K}$  the equilibrium coefficient is so large ( $10^4$ ) that one would expect quantitative conversion of the HCl provided the gallium source in the reaction zone is long enough. However, in the presence of phosphorus at a pressure higher than the decomposition pressure of GaP, solid GaP should coexist with the gallium. The following reaction must therefore be considered.

$$K_4 = \frac{p^2_{\text{GaCl}} p_{\text{H}_2} p_{\text{P}_2}}{p^2_{\text{HCl}}} \quad [4]$$

Let the superscript  $i$  denote incoming pressure while unscripted  $p$  denotes equilibrium pressure. If HCl and GaCl are the only chlorine-containing species in the reaction zone

$$p_{\text{HCl}} = p^i_{\text{HCl}} - p_{\text{GaCl}}$$

Typical experimental conditions are

$$p_{\text{H}_2} \simeq 1 \text{ atm}$$

$$p_{\text{P}_2} = 5 \times 10^{-3} \text{ atm}$$

and  $K_4(1200^\circ\text{K}) = 2.5 \times 10^{-1}$ . At equilibrium in the presence of solid GaP

$$p^i_{\text{HCl}} - p_{\text{GaCl}} = \frac{p_{\text{GaCl}} \times 1 \times (5 \times 10^{-3})^{1/2}}{(2.5 \times 10^{-1})^{1/2}}$$

$$p_{\text{GaCl}} = \frac{p^i_{\text{HCl}}}{1.14}, \quad p_{\text{HCl}} = 0.12 p^i_{\text{HCl}}$$

It is apparent from Eq. [4] that solid GaP will precipitate when the HCl pressure drops below the equilibrium value. Since this is not observed to happen in the experiment

$$p_{\text{HCl}}(\text{exp}) \geq 0.12 p^i_{\text{HCl}}$$

from which follows that the gallium consumption is

$$\frac{\text{moles Ga}}{\text{min}} \leq \frac{\text{moles PCl}_3}{\text{min}} 3(1-0.12)$$

or

$$\frac{\text{Ga}}{\text{min}} \leq 2.64 \frac{\text{moles}}{\text{min}}$$

$$\frac{\text{moles}}{\text{min}} \text{ PCl}_3$$

It may be argued that the absence of GaP precipitate is not significant since supersaturation could have occurred. Another observation is relevant here. A small amount of GaP was placed in a boat immediately down stream to the gallium source within the constant temperature zone. During two normal runs only negligible amounts of GaP were consumed (0.38 and 0.06g compared to gallium losses of 20 and 15g). This

indicates that the phosphorus-saturated gallium is very close to being in equilibrium with solid GaP.

The theoretical consumption ratio was derived for a given phosphorus pressure. However, the variation of the ratio with  $\text{PCl}_3$  feed rate is small. Over the experimentally used range of  $\text{PCl}_3$  feed rates (0.10 to 0.45 mM/min) the theoretical Ga/ $\text{PCl}_3$  consumption ratio calculated from Eq. [2] and [4] varies from 2.73 to 2.54. Such a variation is within experimental error and therefore not evident.

In the above discussion we have made the important assumption that only HCl and GaCl are present in the reaction zone in significant amounts. The pressure of  $\text{GaCl}_3$  is indeed negligible as shown by Seki and Araki (10). The absence of the dihalide has been assumed in previous discussions (10, 13, 15, 16). The agreement observed in this study between the theoretical Ga/ $\text{PCl}_3$  ratio (neglecting  $\text{GaCl}_2$ ) and the experimental value can be used as evidence that no significant amount of dichloride is present in the Ga-Cl system at 1200°K if the system studied was at equilibrium. We believe that equilibrium was established on the strength of the data collected in Table I and Fig. 5 according to which the Ga/ $\text{PCl}_3$  ratio is constant for a wide range of feed and flow rates.

In the experimental section it was pointed out that the HCl partial pressure of the effluent gases was negligible. Since a significant fraction (0.12) of the incoming HCl does not react with the gallium, according to the analysis presented above, there must be subsequent reactions taking place in the seed region further downstream. One such reaction may be

**Distribution of dopants.**—Because the dopants passed over the gallium boat in the reaction zone, some loss of dopant to the gallium source must have occurred in these experiments. The metal vapor (Zn or Cd) will react to form the gaseous chloride immediately after mixing with the hydrogen chloride gas. Subsequently, upon passing over the gallium boat, a reduction will occur

where  $\text{M} = \text{Zn}, \text{Cd}$ . Using the thermodynamic data for  $\text{ZnCl}_2(g)$  and  $\text{CdCl}_2(g)$  given in ref. (17), together with those for  $\text{GaCl}(g)$  from ref. (13), the equilibrium constants at 1200°K for reaction 7 were calculated. For an experimental GaCl pressure of  $5 \times 10^{-2}$  atm it was found that half of the zinc and virtually all the cadmium would be present in the elemental state at equilibrium. This would in turn result in a solution of dopant in the gallium source. An estimate of the required equilibrium concentrations of dopant in the gallium source was made on the basis of Raoult's law. The total amount of zinc or cadmium required to saturate the gallium source in both cases turned out to be about 3% of the total amount of dopant transported during the run. Thus the loss of dopant to the gallium source is negligible.

**Zinc-doping.**—The electrical properties of several zinc-doped samples were studied in detail by Casey and Ermanis (18). From their data, the bulk of which will be published elsewhere, we selected the room temperature Hall mobility. A straight line has been drawn through the experimental points displayed in Fig. 6. There is no theoretical significance attached to this straight line; it is helpful in obtaining interpolated mobilities for samples for which only the room temperature resistivity is known. Using these estimated mobilities with the measured resistivities, the plot of Fig. 7 was constructed, showing the room temperature hole concentration as a function of the zinc partial pressure of the growth ambient.

Several crystals were cleaved into smaller pieces and samples were taken from opposite ends of the crystal to study the effect of the temperature gradient

Fig. 6. Room temperature Hall mobility as a function of hole concentration of Zn-doped GaP(X) and Cd-doped GaP(O).

Fig. 7. Hole concentration of Zn-doped GaP as a function of Zn partial pressure of growth ambient.

on the doping. In Fig. 7, data from the same crystal are connected by straight vertical lines. Although a spread in the resistivities is noticed, no systematic variation with growth temperature could be observed. In this respect, the zinc-doped crystals differed notably from the cadmium-doped crystals, which will be described below.

Casey and Ermanis (18) analyzed the temperature dependence of the hole concentration of several zinc-doped crystals in terms of a three parameter model (ionization energy and zinc and donor concentrations). For these samples the measured hole concentration and the estimated total zinc concentration are given as follows: ( $4.2 \times 10^{16}$ ,  $8.1 \times 10^{16}$ ), ( $1.6 \times 10^{17}$ ,  $3.0 \times 10^{17}$ ), ( $7.0 \times 10^{17}$ ,  $3 \times 10^{18}$ ), ( $2.3 \times 10^{18}$ ,  $6 \times 10^{18}$ ), ( $3.3 \times 10^{18}$ ,  $8 \times 10^{18}$ ) all in  $\text{cm}^{-3}$ . For one of these samples the total zinc concentration was determined experimentally by neutron activation analysis and found to agree with the curve fitting estimate to within a few per cent.

Wet chemical analyses of two heavily zinc-doped GaP crystals were performed. The analytical method developed by Luke (19) employs coprecipitation of zinc with copper as carbamates. The precipitate is filtered off and analyzed directly on the micropore filter using x-ray spectrochemical analysis. Three samples from one crystal were used to obtain a total zinc concentration of  $6.0 \pm 0.2 \times 10^{18} \text{ cm}^{-3}$  and hole concentrations of  $3.9$  and  $4.9 \times 10^{18} \text{ cm}^{-3}$ . Similarly, another crystal contained  $2.0 \pm 0.1 \times 10^{19} \text{ cm}^{-3}$  zinc and yielded hole concentrations of  $1.2$  and  $1.5 \times 10^{19} \text{ cm}^{-3}$ .

The estimates of Casey and Ermanis (18) and the results of the chemical analysis show that the total zinc concentration consistently is two to three times larger than the hole concentration over the entire doping range. We conclude from Fig. 7 that the zinc con-

centration increases linearly with the zinc partial pressure of the growth ambient.

The room temperature mobilities of the halogen transported GaP crystals were found to be identical within experimental error with those of zinc-doped crystals grown by wet hydrogen transport (20). For both materials the mobility dropped from  $100 \text{ cm}^2/\text{v-sec}$  at a doping level of  $2 \times 10^{17} \text{ cm}^{-3}$  [holes to  $50 \text{ cm}^2/\text{v-sec}$  at a doping level of  $2 \times 10^{18} \text{ cm}^{-3}$  (holes)]. This indicates that the difference in structural perfection observed by means of etch-studies does not noticeably influence the room temperature Hall mobility.

**Cadmium doping.**—One of the low cadmium-doped samples was studied thoroughly by Ermanis and Casey (21). From the temperature dependence of the Hall mobility and the resistivity they calculated:  $N_A = 2.3 \times 10^{16} \text{ cm}^{-3}$ ,  $N_D = 7.5 \times 10^{15} \text{ cm}^{-3}$ , hole concentration at room temperature  $1.0 \times 10^{16} \text{ cm}^{-3}$ , Hall mobility at room temperature  $120 \text{ cm}^2/\text{v-sec}$ , maximum Hall mobility ( $\sim 80^\circ\text{K}$ )  $1600 \text{ cm}^2/\text{v-sec}$ , and a cadmium ionization energy of 0.09 eV.

Room temperature mobilities obtained on several samples were used with the measured resistivities to calculate hole concentrations. Figure 6 shows a plot of Hall mobilities vs. hole concentration. Comparison of these room temperature mobilities with those of zinc-doped GaP crystals shows that the scatter of the mobility data is larger for the Cd-doped crystals and that the mobilities at a given hole concentration are higher for the zinc-doped crystals. These observations could be explained by a larger amount of compensation in the Cd-doped crystals. The dashed line of Fig. 6 was used to convert resistivity measurements obtained on other samples to hole concentrations. The hole concentrations obtained in this manner were then plotted as a function of the cadmium partial pressure of the growth ambient, Fig. 8. The spread in the hole concentrations at low cadmium pressures is significant. Several of the crystals were cleaved into smaller pieces and samples were taken from hot, cold, and intermediate regions. Data from the same crystal are connected by straight lines. In all cases the colder regions had a higher hole concentration than the  $70^\circ\text{C}$  hotter front edge of the crystal. Samples from the center gave intermediate values. With higher cad-

Fig. 8. Hole concentration of cadmium-doped epitaxial GaP as a function of cadmium partial pressure [● data of this study, ○ data of Alferov *et al.* (16)].

mium pressures the concentration variation narrowed down considerably.

For comparison, data obtained by Alferov *et al.* (22) are included on Fig. 8. Their crystals were grown epitaxially by a closed tube vapor transport technique using  $\text{CdCl}_2$  as dopant. The exact growth temperature is not known. Some of the samples grew at temperatures as low as  $730^\circ\text{C}$ . The growth rate was 10 times slower than that of the crystals described here.

The fact that Alferov *et al.* used different growth temperatures yet obtained the same linear dependence of hole concentration for a given cadmium partial pressure is compatible with our observation that for high cadmium pressures growth temperature differences are unimportant.

Using the experimental ionization energy of 0.09 eV and a hole mass of  $0.5m_e$  one may calculate the total cadmium concentration. For a hole concentration of  $1 \times 10^{18} \text{ cm}^{-3}$  a total cadmium concentration of  $6 \times 10^{18} \text{ cm}^{-3}$  is obtained, while at the  $10^{16} \text{ cm}^{-3}$  level practically all the cadmium is ionized. When the theoretically calculated correction factors were applied to the hole concentrations of Fig. 8 the cadmium concentration data plotted in Fig. 9 resulted. The line drawn through the data points has a slope of unity.

**Incorporation of dopant.**—The total acceptor concentration is expected to equal the ionized acceptor concentration at the growth temperature. At equilibrium, for an extrinsic semiconductor, one expects a square root dependence of the ionized acceptor concentration on the partial pressure of the doping impurity. Such a square root dependence has been observed for zinc-doped GaP both in solution (23) and at  $1080^\circ\text{C}$  in moist hydrogen vapor growth (20). Thus the first power dependence displayed in Fig. 7 and 9 is surprising.

Consider the possibility that in the halogen transport system described, growth rates are fast enough so that the incorporation of acceptor is not an equilibrium process. Nonequilibrium effects on doping have been noted previously. Orientation effects have been described by Williams (24) and Moest (25) for GaAs crystals grown from the vapor and for GaP by Groves (8). In our case, assume specifically that the equilibrium between cadmium or zinc atoms adsorbed on the growing surface and those incorporated in the bulk of the crystal is not established because diffusion of the dopants is slow. To check whether this is a reasonable assumption, we may compare diffusion and growth rates for the zinc-doped GaP grown at  $1080^\circ\text{C}$  with those of zinc- and cadmium-doped crystals grown at  $880^\circ\text{C}$ .

Fig. 9. Total cadmium concentration of cadmium-doped epitaxial GaP as a function of cadmium partial pressure.

Table II. Comparison of diffusion coefficients and growth rate

	D (cm <sup>2</sup> /sec)	Growth rate (cm/sec)
Zn in GaP (1080°C)	$3 \times 10^{-9}$	$3 \times 10^{-6}$
Cd in GaP (880°C)	$1 \times 10^{-12}$	$3 \times 10^{-5}$
Zn in GaP (880°C)	$3 \times 10^{-10}$	$3 \times 10^{-5}$

No data are available on the diffusion of cadmium in GaP. In GaAs, however, parallel studies of both zinc and cadmium diffusion have been made (26). The diffusion activation energies for zinc and cadmium were found to be equal, while the pre-exponential factor  $D_0$  for zinc was much higher than for cadmium. This suggests that the mechanism of diffusion is the same for both impurities. Using the  $D_0$  ratio for Cd and Zn diffusion in GaAs as an estimate for the corresponding quantity for GaP and assuming that the activation energies for Zn and Cd diffusion also are identical in GaP, we can estimate a diffusion coefficient for Cd in GaP to be used below 900°C.

$$D(\text{Cd in GaAs}) = 0.05 \times e^{-2.43/kT} \text{ cm}^2/\text{sec} \quad [\text{Ref. (26)}]$$

$$D(\text{Zn in GaAs}) = 15 \times e^{-2.43/kT} \text{ cm}^2/\text{sec} \quad [\text{Ref. (26)}]$$

$$D(\text{Zn in GaP}) = 7.5 \times 10^{-8} C^{0.45} e^{-2.50/kT} \quad [\text{Ref. (27)}]$$

$$= 27 \times e^{-2.50/kT} \text{ cm}^2/\text{sec} \text{ for } C = 10^{19} \text{ cm}^{-3}$$

$$D(\text{Cd in GaP}) = 0.1 \times e^{-2.50/kT} \text{ cm}^2/\text{sec} \quad [\text{Estimated}]$$

We can now compare diffusion coefficients and growth rates, Table II. The differences in diffusion coefficients and growth rates at the two temperatures suggests that the processes of impurity incorporation may be qualitatively different in the two cases. Zinc incorporated at 1080°C can be homogeneously distributed throughout the crystal during growth. Cadmium and zinc incorporated at 880°C diffuse too slowly to equilibrate with the ambient pressure. The cadmium or zinc concentration of the bulk crystal reflects the density of dopant atoms adsorbed on the growing surface. Even the ten times slower growth rates employed by Alferov *et al.* are not slow enough to ensure equilibrium concentrations.

#### Acknowledgments

We are grateful to H. C. Casey for the permission to use selected data prior to publication, to F. Ermanis for Hall measurements, and to Miss S. Vincent for the chemical analysis. The assistance of H. C. Montgomery in making Hall measurements is gratefully acknowledged. We wish to thank F. A. Trumbore, K. L. Lawley, C. J. Frosch, and L. J. Varnerin for comments and valuable suggestions.

Manuscript submitted March 18, 1968; revised manuscript received April 15, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 101.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Formation of Thick Semi-Insulating GaAs Films by Flash Evaporation

T. B. Light, E. M. Hull, and R. Gereth<sup>1</sup>

IBM Watson Research Center, Yorktown Heights, New York

## ABSTRACT

Highly oriented films of semi-insulating GaAs, up to 40  $\mu\text{m}$  thick, have been grown on single crystal Ge and semi-insulating GaAs substrates using a modified flash evaporation process. The GaAs films were obtained by flash evaporation of chromium doped GaAs powder with excess As admixed. The quality of the evaporated films was evaluated for degree of crystallinity using x-ray diffraction, and for resistivity using spreading resistance measurements. The voltage-current characteristics have also been determined. Both the degree of polycrystallinity and the resistivity of the evaporated GaAs films are dependent on the substrate temperature and the ratio of As:GaAs in the source material. A maximum in film resistivity *vs.* substrate temperature is observed which coincides with a structural change from polycrystalline to highly oriented growth. Optimum film growth conditions are typically represented by an As:GaAs volume ratio of 1:1 in the source material and by substrate temperatures between 525° and 575°C. At substrate temperatures above 575°C, the measured spreading resistance of the films drops sharply even though they are increasingly oriented.

The successful epitaxial growth of smooth Ge layers on semi-insulating GaAs substrates (1,2) makes it possible to consider dielectric isolation for integrated circuits using Ge devices. Isolated planar structures of Ge on semi-insulating GaAs can be fabricated by etching islands of Ge and then back-filling with an insulator. A potentially useful technique for achieving this backfilling is via a flash evaporation method. Such a technique for depositing films of GaAs has indeed been reported by Richards *et al.* (3). Because of the incongruent manner in which GaAs evaporates, it has been suggested by Muller and Richards (4) that the stoichiometry of the films could be best controlled by the addition of As to the source material. No reference has, however, been found regarding the use of Cr doped semi-insulating GaAs as a source material for flash evaporation of semi-insulating GaAs layers.

The present work describes the use of Cr doped semi-insulating GaAs, with As added, in a "reactive" flash evaporation mode to obtain layers of semi-insulating GaAs. The results of electrical and structural evaluation are presented.

## Experimental Procedure

**Preparation of GaAs Layers.**—The apparatus used is shown schematically in Fig. 1. Powdered (40-60 mesh size) chromium doped high resistivity GaAs source material, with powdered As admixed, is fed from a micrometer screw operated metering device into a vibrating feed trough. The barrel of the feed device is rotated to provide a tumbling action for uniform powder feed. The powder drops from the feed trough through a tantalum guide (collimating) funnel and a tantalum guide tube, then into the input opening of an enclosed and shielded tantalum high temperature box source. Inside the box source, the particles encounter a surface at 45° to the angle of incidence. They are deflected from this surface toward the exit and vaporized. The vaporized GaAs is baffled before reaching the exit opening which is positioned beneath the substrate holder. The box source heater is surrounded by a water cooled jacket so that extended runs can be made in the vacuum system without excessive radiant heating effects. The substrate is mounted onto a tantalum substrate heater using molybdenum spring clips.

The guide funnel and guide tube are necessary to limit the amount of GaAs powder which is diverted

by back streaming vapor. A guide tube connected directly to the input opening of the source heater is not desirable because a temperature gradient due to radiation losses develops along the tube between the source and the opening. Consequently, a certain portion of the guide tube would reach a critical temperature at which As evaporates rapidly, leaving a liquid Ga film behind. This film is capable of entrapping GaAs powder which could block the entrance to the source boat eventually. To avoid this problem, the guide tube was supported on an open framework above the source heater shield. In this way, the "critical" temperature zone is located within the gap between the guide tube and the source heater input opening. The standard evaporation conditions were as follows: (i) rate of deposition, (0.05-0.15)  $\mu\text{m}/\text{min}$ ; (ii) source temperature, 1325°C (505w); (iii) source to substrate distance, 10 cm; (iv) pressure during evaporation,  $10^{-5}$  Torr initially, decreasing to  $4 \times 10^{-6}$  Torr; (v) deposition time, 90 min (vi) substrates used, (110) Ge, (110) and (111) Cr doped semi-insulating GaAs. If excess As powder were not added to the GaAs source powder, deposition times of only 10 min duration were possible, using many combinations of source designs and temperatures, before a film of excess Ga accumulated on the substrate. Excess As vapor has also been introduced by using a separate controlled temperature oven type source.

**Structural characteristics.**—The structure of the layers has been characterized by x-ray diffraction techniques in order to determine whether they were

Fig. 1. Schematic representation of flash evaporation feed, source, and substrate.

<sup>1</sup> Present address: AEG-Telefunken, Heilbronn, Germany.

polycrystalline or highly oriented. The wafers were mounted in a Debye-Scherrer powder camera with the incident x-ray beam intersecting the film surface at a small angle from horizontal. This geometry was chosen to maximize the diffracting volume of the layer relative to the substrate diffracting volume. The occurrence and nature of the observed powder pattern lines or Laue spots can be used as an indicator of the degree of polycrystallinity or preferred orientation in the layers.

**Electrical characteristics.**—The relative resistivities of the layers were determined by measuring the spreading resistance using two fine tungsten probes in contact with the layer surface. (The measured resistance is thus twice the spreading resistance for one probe.) For the case of a semi-infinite piece of material the spreading resistance,  $R_s$ , is related to the resistivity,  $\rho$ , by the relation  $R_s = \rho/2d$ ; where  $d$  is the diameter of the contact area [see ref. (5)]. For a layered structure, such as a film on a substrate, with resistivities  $\rho_f$  and  $\rho_s$ , respectively, the spreading resistance also depends on the layer thickness and the substrate resistivity. In the case of Ge substrates,  $\rho_s \ll \rho_f$ . The Ge substrate shunts part of the current and thus lowers the effective spreading resistance. This effect increases with decreasing thickness. In the case of semi-insulating GaAs substrates,  $\rho_s \cong \rho_f$  and the relation  $R_s = \rho/2d$  is a reasonable approximation. The factor  $2d$  was determined approximately by making both four terminal and spreading resistance measurements on the same samples of semi-insulating GaAs. Very clean surfaces are necessary to avoid surface shunting effects.

The maximum applied voltage for spreading resistance determination was 5v. Voltage-current characteristics were investigated using the same probe configuration and using applied voltages up to 90v. A Tektronix model 575 transistor curve tracer was used to determine breakdown voltage up to a maximum of 200v.

**Deposition parameters investigated.**—Two kinds of experiments were carried out. In the first set the volumetric ratio of As powder to GaAs powder in the source material was varied, keeping the metered feed rate constant and using a substrate temperature of 625°C. In the second set of experiments the substrate temperature was varied for two constant volume ratios of As to GaAs, namely 1:1 and 1:5.

## Results

**Ratio of As to GaAs.**—The volume ratio of As to GaAs in the source material was varied from 1:10 to 2:1, while keeping the substrate temperature constant at 625°C. All ratios less than 1:2 resulted in polycrystalline films. All ratios greater than 1:2 yielded highly oriented films. The spreading resistance of the films did not vary by more than an order of magnitude for any ratio except the smallest (1:10). The latter resulted in films having significantly lower resistances.

**Substrate temperature.**—The spreading resistance as a function of substrate temperature during film deposition is shown in Fig. 2. The solid lines are for (110) oriented GaAs substrates and the dashed line is for (110) oriented Ge substrates. The vertical bars represent the range of spreading resistance data observed for each sample. The Cr doped semi-insulating GaAs used for source and substrate material had a spreading resistance in the range  $1-3 \times 10^{10}$  ohms ( $10^8$  ohm cm range). The ratios 1:1 and 1:5 listed in Fig. 2 refer to the As to GaAs volume ratios used in the source material.

A feature common to all of the curves in Fig. 2 is the increase of the spreading resistance with substrate temperature up to a maximum value at a characteristic temperature, and a very rapid fall off at higher substrate temperatures. In all cases the characteristic temperature region correlates with a change in the

Fig. 2. Spreading resistance vs. substrate temperature for deposits on Ge (dashed line) and on GaAs (solid lines), using two different volume ratios of As:GaAs in the source.

film structure from a polycrystalline to an oriented state. The film structure will be discussed in greater detail below. One can see from Fig. 2 that the onset of oriented growth on GaAs substrates occurs at a 75°C higher substrate temperature if the As to GaAs volume ratio in the source is decreased from 1:1 to 1:5. It is also evident that the substrate temperature must be raised by 40°C to achieve oriented growth on a Ge substrate using a 1:1 source As/GaAs ratio. The following results all refer to films made using a 1:1 source As/GaAs ratio.

**Structure.**—Typical x-ray powder pattern results are shown in Fig. 3 for substrate temperatures below and above the polycrystalline-oriented growth characteristic temperature range. The greater line broadening observed for the lower temperature deposit indicates a smaller particle size.

Deposits were also made on (111) GaAs substrates and Fig. 4 shows the surface of an oriented deposit formed at a substrate temperature of 625°C.

The amount of Cr in the deposited layers was determined by spark source mass spectrometry and was found to be the same as in the source material ( $\sim 3 \times 10^{17}/\text{cm}^3$ ).

Fig. 3. Typical Debye-Scherrer powder patterns (region of 111, 220 and 311 reflections only) for deposits made on GaAs substrates using substrate temperatures of (a)  $\sim 450^\circ\text{C}$ , (b)  $\sim 500^\circ\text{C}$ , and (c)  $\sim 625^\circ\text{C}$ ; and a source As/GaAs ratio of 1:1.

Fig. 4. Surface of deposit on (111) GaAs surface using a substrate temperature of 625°C, and a source As/GaAs ratio of 1:1.

**Electrical characteristics.**—Figure 5 shows current-voltage characteristics that were measured for layers deposited on semi-insulating GaAs substrates at different substrate temperatures. Log  $V$  vs. log  $I$  is linear for voltages up to 90v, and the slope is nearly unity indicating essentially ohmic behavior for those films deposited at 575°C and lower. For a given voltage, the current decreases with increasing deposition temperature to a minimum and then increases rapidly. This corresponds to the spreading resistance behavior shown in Fig. 2. The behavior is no longer linear beyond 2v for films deposited at 625°C.

The current-voltage characteristics of layers deposited under optimum conditions (highest spreading resistance and oriented growth) on Ge and semi-insulating GaAs substrates are compared with those of bulk Cr doped semi-insulating GaAs in Fig. 6. The increasingly larger currents with increasing voltage for the layer on the Ge substrate is interpreted as due to the effect of the low resistivity Ge substrate on the spreading resistance measurements as discussed ear-

Fig. 5. Log current vs. log voltage for deposits on GaAs substrates using substrate temperatures in the range 500°-625°C, and a source As/GaAs ratio of 1:1.

Fig. 6. Log current vs. log voltage for deposits made under optimum conditions on Ge and GaAs substrates, compared with bulk Cr doped semi-insulating GaAs.

lier. The breakdown voltage for layers on semi-insulating GaAs substrates is greater than 200v. These current-voltage characteristics indicate that the deposited layer behaves in a similar manner to the bulk material. They are also consistent with the results published by Haisty and Hoyt (6) for bulk Cr doped semi-insulating GaAs, using electron injecting contacts, except that these authors observed an  $I \propto V^3$  region at higher voltages.

Further work is in progress concerning the effects of annealing in different ambients on the properties of Cr doped semi-insulating GaAs in both bulk and film samples. This work also encompasses an effort to understand the effect of substrate temperature on spreading resistance in the region of rapidly decreasing spreading resistance. The results will be the subject of a forthcoming paper.

### Conclusions

Thick highly oriented layers of Cr doped semi-insulating GaAs can be grown on GaAs and Ge substrates by reactive evaporation, in which excess As powder is added to Cr doped GaAs powder evaporated in the flash evaporation mode. Optimum film growth conditions are represented by substrate temperatures between 525° and 575°C and by a 1:1 volume ratio of As to GaAs in the source material. Judging from the close similarity of the current-voltage characteristics, the conduction mechanism in the film appears to be the same as in bulk Cr doped semi-insulating GaAs.

## Behavior of Dislocations in Silicon Semiconductor Devices: Diffusion, Electrical

J. E. Lawrence

*Fairchild Semiconductor, Division of Fairchild Camera & Instrument Corporation, Palo Alto, California*

### ABSTRACT

Stationary dislocations did not influence the diffusion of boron to a measurable extent in tests conducted to amplify the dislocation-core diffusion effect and the vacancy source action of the fixed dislocations in silicon. In contrast, moving dislocations contributed to large enhanced diffusion effects apparently by acting as sources of excess vacancies. Very high concentrations of stable dislocations, without impurity precipitates, have very slight effects on p-n junction reverse currents ( $\sim +2X$ ), transistor gain ( $\sim -0.2X$ ), and the storage time ( $\sim -3X$ ) of nongold doped npn transistors. Unstable dislocations are slightly more electrically active than low energy stable dislocations. The precipitation of metallic contaminants such as copper can greatly alter the electrical properties of dislocations. Devices formed in material with few dislocations are more likely to degrade due to metal precipitate formation. The degradations attributed to metal precipitates are large p-n junction reverse currents, emitter to collector short circuits and wide variations in transistor gain.

Discontinuities in a periodic lattice may be centers at which nonuniform solute diffusion can occur and significant electrical activity can be generated. Dislocations are of particular interest since they consist of a chain of discontinuities which, it has been proposed, may provide a preferential path for solute and charge migration over great distances within a semiconductor material. Unanimous agreement does not exist for the manner and extent to which dislocations influence solute diffusion in disordered silicon. A dislocation core diffusion mechanism has been advanced by Queisser *et al.* (1) and Kartensen (2), who investigated solute diffusion along the grain boundaries of semiconductor bicrystals. These investigators considered low angle grain boundaries as consisting of planar arrays of dislocations after a model proposed by Bragg (3) and Burgers (4). Other workers have reported that stationary dislocations produced by bending (5) and loading (6) single crystals do not contribute to a measurably enhanced solute diffusion. Dislocations forced to move under the influence of an externally applied force have been shown to contribute to enhance solute diffusion effects (6,7).

General agreement does not exist for the manner and extent to which dislocations influence the electrical characteristics of npn transistors. This is due in part to the difficulty of separating the contribution of dislocations from the often associated effects of point defects and impurity precipitates. The low-temperature deformation of silicon creates generation-recombination centers which annihilate quickly at 300°C (8). These centers are very likely point defects for similar electrical activity and annealing properties which have been found for Frenkel defects formed by electron bombardment (9). A single, large impurity precipitate has been shown to cause much greater p-n junction reverse currents than a large cluster of very small precipitates (10). However, all precipitates whether tightly packed units or not could be ex-

pected to be more active electrically than a dislocation free of impurity precipitation. The early reports on lattice disorders in germanium concluded that dislocations do influence the generation-recombination and mobility of free charges (11).

The present work was conducted to determine the manner and extent to which stationary and moving dislocations influence solute diffusion during thermal treatments commonly used in the fabrication of simple double-diffused npn transistors. The second purpose of this investigation was to determine the extent to which (a) stable dislocations, (b) newly formed unstable dislocations, and (c) dislocations with associated impurity precipitates, influence p-n junction reverse currents, transistor gain, and the storage time of nongold-doped npn transistors. The terms "stable" and "stationary" in this discussion refer to dislocations which do not exhibit a detectable movement during the thermal treatments necessary for device fabrication. In contrast, "unstable" dislocations are defined as those which move extensively during a thermal treatment.

### Experimental Procedure

The test material consisted of (111) silicon wafers growth doped with phosphorus to 20-50 ohm-cm n-type. The starting wafers were cut from dislocation-free ingots and chemically polished to remove the random lattice damage generated during the wafer shaping treatments. In this investigation, dislocations were created in otherwise disorder-free material by either thermal quenching, mechanical loading, or solute diffusion.

A gettering procedure was employed which renders undesired junction degrading metals electrically inactive without introducing the gettering agent to the silicon lattice (12). This was achieved by forming a phosphorus glass on the surface of the SiO<sub>2</sub> film which covered both sides of a silicon test wafer.

Fig. 1. Preferential etch delineated distribution of low energy stable dislocations. The light region contains  $> 5 \times 10^7$  disl/cm<sup>2</sup>; the dark region contains  $< 10^3$  disl/cm<sup>2</sup>.

The thermal quenching treatment produced greater than  $5 \times 10^7$  disl/cm<sup>2</sup> in one region of a wafer while leaving the remainder of the wafer with fewer than  $10^3$  disl/cm<sup>2</sup> as shown in Fig. 1. This treatment consisted of repeatedly inserting and extracting a standing test wafer from a 1270°C furnace. The quenched wafers were then annealed at 1270°C to allow the newly formed dislocations to obtain a low energy state. The quenching act produced a thermal gradient at which the top of the wafer cooled 500°C the first second while the portion of the wafer in contact with the quartz boat cooled at 20°C/sec, as determined by an optical pyrometer. The dislocations which formed to relieve this thermally induced lattice stress generally lay in the crystal's inclined {111} planes. The resulting dislocation arrays passed from one wafer face to the opposite wafer surface. These wafers were used to analyze the effects of stable dislocations on solute diffusion and the electrical properties of semiconductor devices.

The effects of moving dislocations on solute diffusion was investigated by externally stressing a wafer during a 1200°C boron diffusion treatment. The loading apparatus used to stress a silicon wafer at 1200°C consisted of a silicon stylus with silicon weights and a quartz stabilizing assembly (6). The loading tests were performed by placing the silicon stylus on the (111) surface of n-type wafers into which boron had been diffused to a depth of  $\frac{1}{2}\mu$  from a constant source. The silicon wafer with the weighted pin in position was then placed in the 1200°C furnace for the diffusion test. This high-temperature loading treatment created  $>4 \times 10^9$  disl/cm<sup>2</sup> in a highly localized region beneath the weighted stylus.

High concentrations of diffused solutes were also used to generate the lattice stress necessary for dislocation formation and motion. This source of moving dislocation was discussed in earlier papers considering their effect on single (13) and double diffused structures (7). An interaction between the possible influences of stationary and moving dislocations on boron diffusion was investigated by forming double diffused npn structures in wafers such as that shown in Fig. 1.

The effect of new unstable dislocations on the reverse current of a p-n junction was investigated on test structures where the concentration of dislocations in a junction's depletion region was governed by the strain relaxation mode within the diffused region. It has been shown (13) that diffusion induced stresses are relieved by the formation of either of two distinct types of dislocation networks within the diffused region: hexagonal networks of predominantly edge dislocations, or arrays of concentric loops. In those cases where the hexagonal networks are generated within the diffused region, extensive arrays of unstable loops

are simultaneously formed outside the diffused region. In contrast, no such arrays are formed outside the diffused regions in those cases where concentric loop networks are generated within the diffused region.

The single and double diffused structures used to determine the electrical effects of stable dislocations were formed by the planar diffusion of low concentrations of boron and phosphorus to avoid the electrical effects associated with boron or phosphorus precipitates. The quantity of diffused boron in the base regions was near  $Q \simeq 2 \times 10^{15}$ /cm<sup>2</sup>. Similarly, the phosphorus emitter concentrations were near  $Q \simeq 1 \times 10^{16}$ /cm<sup>2</sup>. The depth of boron penetration in the single and double diffused structures was generally  $5.5\mu$ . Two phosphorus emitter depths were used: (i)  $X_{je} = 5.0\mu$  to create a narrow basewidth punch-through limited structure and (ii)  $X_{je} = 1.0\mu$  to create a structure with a  $4.5\mu$  basewidth.

Copper was introduced to some test wafers to determine the effect of copper on devices formed in highly dislocated material as well as in material relatively free of dislocations. The junction-degrading metal was introduced after the electrical characteristics of "clean" devices had been determined. The gas transfer method of copper diffusion described earlier (10) was employed. The actual concentration of copper in the test wafers was not resolved, though it was likely above the solubility limit at 1100°C since precipitation did occur.

The extent of enhanced p-n junction penetration was determined by comparing the depths of stain-delineated boundaries resolved by counting interference fringes on low angle grooved sections. Electrical measurements of the transistor gain and emitter-to-collector reverse bias characteristics (14) supported the sensitivity ( $\pm 0.1\mu$ ) of the data acquired by the p-n junction staining method of junction delineation.

#### Experimental Results: Diffusion

The diffusion of boron at a constant 1200°C into a wafer similar to that shown in Fig. 1 showed no detectable enhanced diffusion due to stationary dislocations. Likewise, the diffusion of boron into similar material during a thermal treatment in which the wafer temperature was repeatedly cycled between 1200° and 30°C also failed to exhibit an enhanced diffusion effect from stationary dislocations. In each test the depths of stained p-n junction were equal (within  $0.1\mu$ ) in both regions with  $> 5 \times 10^7$  stable disl/cm<sup>2</sup> and with  $< 10^3$  disl/cm<sup>2</sup>. Phosphorus was diffused into these boron-diffused wafers to form narrow basewidth npn transistors with  $X_{jb} = 5.5\mu$  and  $X_{je} = 5.0\mu$ . No diffusion spikes were delineated. Electrical measurements indicated very good uniformity of transistor gain and an absence of emitter-to-collector shorts in the narrow basewidth npn transistors with the above widely different concentrations of stationary dislocations. These electrical measurements indicate the absence of any diffusion anomalies beyond the resolving power of the p-n stain delineation technique employed.

The contribution of moving dislocations to solute diffusion was analyzed in this investigation by determining the extent of enhanced diffusion of boron in a lattice undergoing dynamic lattice deformation during loaded-lattice diffusion tests. The initial 10 min of the loading tests provided a condition for boron diffusion in a localized region containing moving dislocations. After the initial 10 min the dislocations which had moved due to the external stress became comparatively stationary (6). The results of the loading tests, presented in Fig. 2, identify boron solutes as exhibiting a significantly enhanced penetration within the locally deformed region which formed to relieve the externally applied stress.

Lattice stresses generated by diffused dopants were employed to determine if moving dislocations interacted with pinned stationary dislocations to create a measurable net effect on solute diffusion. Earlier work (13) had identified the quantity of diffused boron re-

Fig. 2A. Dislocation-dependent boron diffusion effect achieved in the 1200°C loaded lattice diffusion tests. Schematic diagram illustrating: 1, weighted silicon stylus; 2, penetration of boron prior to loading; 3, penetration of boron outside stressed region; 4, periphery of locally deformed lattice; 5, enhanced diffusion of boron within deformed lattice; and 6, retarded penetration of boron at periphery of deformed lattice.

quired to strain silicon sufficiently to form and move dislocations beyond the dopant diffusion front as being  $Q \cong 2.6 \times 10^{16}$  boron/cm<sup>2</sup>. Test structures were formed by diffusing very high concentrations of boron, i.e.,  $Q > 3 \times 10^{16}$ /cm<sup>2</sup>, into wafers containing widely different concentrations of stationary dislocations, such as that shown in Fig. 1. The results of these tests disclosed the same amount of enhanced base diffusion associated with moving dislocations regardless of the concentration of pinned stationary dislocations, viz.,  $> 5 \times 10^7$ /cm<sup>2</sup> or  $< 10^3$ /cm<sup>2</sup>. The electrical analysis of these wafers disclosed transistor gain uniformity and an absence of emitter-to-collector short circuits which would indicate the absence of any localized enhanced

diffusion fronts below the resolving power of the metallographic analysis, viz., 0.1μ.

#### Experimental Results: Electrical

The contribution of (a) stable dislocations, (b) newly formed unstable dislocations, and (c) copper precipitates at dislocations to the reverse current of p-n junctions was determined on structures deeply diffused (5μ) with boron. Wafers of the type shown in Fig. 1 were used to determine the electrical effects of low energy stable dislocations. The reverse I-V characteristics of p-n junctions formed in dislocation-free material coincided with the curve obtained from junctions formed in regions with a uniform distribution of  $10^3$  disl/cm<sup>2</sup> (5 disl/device). P-N junctions with a uniform distribution of  $> 5 \times 10^7$  disl/cm<sup>2</sup> ( $2.5 \times 10^5$  disl/device) were found to have slightly greater than two times the reverse currents of similar p-n junctions formed in dislocation-free material. The reverse I-V characteristics of typical p-n junctions containing high and low concentrations of low energy stable dislocations appear in Fig. 3.

Also shown in Fig. 3 is a typical curve of the I-V characteristics of a p-n junction which contained newly formed, unstable dislocations in initially "dislocation-free" material; i.e., the initial material was free of dislocation etch pits after SIRTLE etching. These dislocations were formed to relieve the stress generated by a high concentration of diffused boron. The p-n junctions with newly formed, unstable dislocations in their depletion regions had higher reverse currents than similar p-n junctions without such lattice disorder in their depletion regions.

Copper impurities which precipitate at a dislocation and obtain a tightly packed configuration contribute to very high reverse currents as shown in Fig. 3. Such electrically active precipitates commonly form when the only crystalline disorder is localized near the wafer surface and copper is abundant. However, the addition of copper to a highly dislocated wafer, such as that shown in Fig. 1, contributed to only approximately five times the reverse current of a copper-free, low disorder p-n junction.

The contribution of low energy, stable dislocations to the electrical characteristics of narrow and wide basewidth npn transistors was investigated by recording the base-collector leakage, transistor gain, and storage time. The results of this analysis are tabulated in Table I. The percentage differences between the parameter values in each column were observed for three duplicate tests. The actual parameter values in Table I are the mean values of twenty units made in both highly and lowly dislocated portions of the same wafer. The measured parameter values were within 50% of the mean value in all cases. The base-collector junctions of transistors

formed in a lattice with  $> 5 \times 10^7$  disl/cm<sup>2</sup> were found to have approximately two times the reverse current at 150v compared to similar transistors formed in a portion of the same wafer having  $< 10^8$  disl/cm<sup>2</sup>. Similarly, transistors in the highly dislocated regions were found to have slightly lower transistor gains and storage times than identical transistors formed in the near dislocation-free portions of the same wafers. The contributions of new unstable dislocations to the transistor parameter values were considered to be a constant for all regions of the same wafer and therefore should not appear in the difference in parameter values attributed to the low energy, stable dislocations tabulated in Table I. The concentration of new unstable dislocations was assumed uniform since their necessary formation condition, i.e., solute concentration, was assumed to be constant. Whereas, the concentration of stable dislocations was not uniform since the initial quench/anneal treatment successfully created a difference of four orders of magnitude.

The addition of copper to narrow basewidth npn structures in near dislocation-free material contributed to the random development of emitter-to-collector short circuits and widely differing transistor gains. Copper precipitates were delineated in the base regions of transistors in such wafers. The similar addition of copper to narrow basewidth npn structures which had  $> 5 \times 10^7$  disl/cm<sup>2</sup> in the starting material contributed to fewer devices failing due to emitter collector short circuits and widely differing transistor gains than found in the less dislocated structures.

### Discussion

The above results show considerable differences as to the influence of dislocations on solute diffusion and the electrical characteristics of semiconductor devices. The following discussion will attempt to describe why (a) moving dislocations contributed to large enhanced diffusion effects; (b) stationary dislocations did not influence solute diffusion to a measurable extent; (c) dislocations free of large precipitates were quite electrically inactive; and (d) metallic contaminants were less electrically active in highly dislocated material than in dislocation-free material.

Moving dislocations were found to contribute to an enhanced diffusion of boron in the loaded-lattice diffusion tests. This was deduced from the observation that enhanced boron diffusion occurred beneath the weighted stylus only during the period of great dislocation motion after which the dislocations became comparatively stationary. These stationary dislocations of concentration  $> 4 \times 10^9$  disl/cm<sup>2</sup> did not enhance the diffusion of boron after the initial 10 min of loaded-lattice diffusion within the experimental limits of the measurements used, as shown in Fig. 2C. The contour of the boron penetration front just outside the periphery of the localized region of great lattice disorder exhibits a slight retardation. This area is identified by No. 6 in the schematic diagram in Fig. 2A and by the arrows in the micrograph in Fig. 2B. The retarded penetration cannot be attributed to the movement of the solute atoms being directly influenced by dislocation motion since the region of retarded penetration is relatively free of dislocations (6). However, this effect is associated with dislocations since it occurs only during the period of great dislocation motion. The retarded penetration of boron outside the locally deformed region and the enhanced penetration of boron in the region of great dislocation motion

could be explained by a mechanism which related these abnormal diffusion effects to excess vacancies generated by moving dislocations. These vacancies will have a net flux out of the localized cylinder of moving dislocations. The boron solutes around the locally deformed region will have a net flux into the deformation cylinder, thus depleting the surrounding region of boron dopants.

Dislocations which move by climbing will generate vacancies by the atomic shifts shown in the schematic diagrams in Fig. 4. These illustrations show how the translation of a substitutional atom to the dislocation core will create a dislocation jog, an element of climb, and a vacancy. This model has been discussed in detail by Thomson and Balluffi (15). The movement of a dislocation by gliding may not contribute to vacancy formation since no atomic movement away from the glide plane is required.

Stationary dislocations were not found to influence the diffusion of boron or phosphorus in tests employing stable dislocations. Since boron and phosphorus diffuse by the vacancy mechanism in silicon (16), a model justifying the absence of a diffusion effect dependent on stationary dislocation in a system of continually changing temperature must explain the absence of a net vacancy action of stationary dislocations. Three considerations seem possible. One consideration is that the vacancy-source action of a stationary dislocation during its heating period is equal to the vacancy sink action of the same dislocation during the cooling period of the diffusion cycle. By this hypothesis, the enhanced diffusion of boron near a dislocation during wafer heating would be countered by the retarded diffusion of boron near a dislocation during wafer cooling. Another possibility is that the vacancies generated at the wafer surface saturate the boron diffused region quickly, thus rendering the vacancy source action of stationary dislocations within the crystal insignificant relative to boron diffusion. This might occur if the diffusion of vacancies is many times faster than the diffusion of boron. However, this is not the case since the diffusion coefficient of boron (17) at 1200°C is nearly six times greater than the reported self-diffusion of a silicon (18). The third, and most likely, explanation for the absence of a measurable vacancy action of stationary dislocations suggests the

Fig. 4. Schematic representation of a dislocated crystal lattice: (a) dislocation lying perpendicular to drawing with core at  $D_1$ ; (b) atom shifts required to form a jog  $D_2$  and vacancy "V"; (c) new dislocation core position  $D_2$  and vacancy "V" following jog formation; (d) likely positions of Cottrell-captured "S" small impurities, "L" large impurities, and "I" very small impurities.

dislocations do not form jogs for vacancy formation due to their being pinned by a "Cottrell"-captured impurity, as illustrated in Fig. 5(D), and hence cannot climb. An unpinned dislocation could form a jog and contribute a vacancy to a system without an externally applied force.

Cottrell's model (19) concerns the strain energy interaction between impurities of size different from silicon and edge dislocations. The region around an edge dislocation is one of both lattice tension and compression. Therefore, both large (Sb, Ga) and small (B, P, O) impurities, relative to silicon, would be attracted to the dislocation to achieve a lower combined-energy of lattice distortion. The interaction energy between the dislocation and the impurity varies inversely with distance but should be felt over large distances depending on the wafer temperature.

Stationary dislocations were not found to contribute to enhanced solute diffusion by providing a preferential path for the passage of small solutes. The dislocation core diffusion model very likely did not dominate the diffusion process due to an impurity clogging action of the type proposed by Ruoff and Balluffi (20). The Cottrell capture of an impurity by a dislocation would restrict the size of the dislocation core, thus restricting the passage of diffused dopant impurities.

Boron diffusion tests were performed in a system containing moving dislocations within a background of stationary dislocations to determine if the two dislocation states would interact in a manner which would cause an additional dislocation-dependent solute diffusion effect. Two interactions seem possible: first, the excess vacancies generated by moving dislocations could be annihilated at the stationary dislocations before they influence boron diffusion. This would be detected as a reduction of the enhanced boron diffusion compared to that caused by newly formed dislocations sweeping through otherwise dislocation-free material. Second, the lattice stress which causes the dislocations to move could cause the stationary dislocations to oscillate and thus generate an additional source of vacancies. This would contribute to an enhanced boron diffusion greater than that associated with moving dislocations in a system free of stable dislocations. However possible these two models may be, the boron diffusion test results did not support the existence of an interaction between stable dislocations and the effect of moving dislocations on boron diffusion in silicon. Thus, it is very likely that the stationary dislocations were firmly pinned and not capable of any vacancy action.

Because of the very small influence of dislocations on the reverse current, transistor gain, and storage time of nongold-doped npn transistors observed in this work, this discussion of the electrical activity of dislocations in semiconductor devices will be quite general. The slight increase in electrical activity of devices with  $>5 \times 10^7$  low energy, stable dislocations/cm<sup>2</sup> could be due to (a) the dislocations providing a path for channeling injected minority carriers through a p-n junction's depletion region or (b) the dislocations creating current by the generation-recombination process. A common denominator for both of these causes for excess reverse current is an energy level associated with the dislocation. Shockley (21) and Read (22) proposed a model for the electrical activity of dislocations in semiconductors based on dangling bonds at the core of dislocations having some edge component. The space charge barrier surrounding a dislocation may have a dominant effect in determining the hole-electron recombination characteristics as reported recently by Morrison (23). The contribution of a channel current to the reverse current of a p-n junction would be reduced by an interruption in the sequence of dangling bonds. Dislocations which have not been fully annealed would be expected to have far more dangling bonds than a fully annealed dislocation. The dislocation with the fewest

dangling bonds is the most stable and, by the Shockley-Read model, is less electrically active. Hornstra (24) has shown that high-temperature annealing can provide for the diffusion of vacancies and interstitials which can transform an edge dislocation with atoms having two dangling bonds to an edge dislocation with no dangling bonds.

The foregoing model relating the electrical characteristics of a dislocation to dangling bonds has been considered by some to be a highly restricting model (25, 26). Read had shown that pure edge dislocations should have a maximum number of dangling bonds while pure screw dislocations would have no dangling bonds. By this model, edge dislocations would be highly charged while screw dislocations would have no charge. This hypothesis does not appear to agree with recent experimental work using bicrystals and compound semiconductors. The latter work identified both edge and screw dislocations as having similar charges (26). Heine (26) has proposed a general model for charge accumulation at dislocations in semiconductors which attributes an energy level to localized atomic strain at a dislocation. This model and the earlier "dangling bond" model behave, electrically, similarly in that the lattice strain about a nonannealed dislocation is greater than the localized lattice deformation which surrounds an annealed dislocation.

The high reverse currents of p-n junctions in nonannealed dislocated material reported in this work can be attributed to large lattice strain and dangling bonds associated with individual dislocations. Similarly, the lower reverse currents associated with stable dislocations can be attributed to a reduction in lattice strain and fewer dangling bonds.

The influence of dislocations on the generation-recombination of electrons and holes in transistor structures has been of great interest since Chynoweth and Pearson (27) reported that avalanche breakdown microplasmas occurred preferentially at dislocations in silicon p-n junctions. They also reported dislocations as contributing to enhanced internal field emission and, consequently, a soft reverse characteristic. Recent investigations (10, 13) using lightly doped n-type silicon have shown that microplasma emission and soft reverse characteristics are caused by tightly packed precipitates in a junction's depletion region, not simply lattice disorders. Precipitates are believed to cause localized high electric fields, thus making it likely for both avalanche breakdown and field emission. Copper precipitates in this investigation were found to cause emitter-collector shorts and a variability of transistor gain. Interesting, though, is the low level of electrical parameter variability associated with copper when the metal was added to highly dislocated wafers. This is attributed to the large concentration of available copper precipitation sites away from the transistor's depletion regions in highly dislocated material. In nearly disorder-free material, copper is attracted to the diffused regions of a transistor since these regions contain the only available precipitation sites.

The principal conclusion from this study is that dislocations in starting material do not significantly influence p-n junction reverse currents, transistor gain, and the storage time of finished nongold-doped semiconductor devices.

#### Acknowledgment

The author wishes to express his appreciation to Dr. R. N. Tucker for his stimulating suggestions during the development of this investigation. The continuing interest in this work provided by Dr. H. Sello made this investigation possible. The experimental assistance of Miss B. Johnston in all phases of this work was very helpful.

Manuscript submitted Jan. 22, 1968; revised manuscript received March 26, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 174.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Structure and Sodium Migration in Silicon Nitride Films

J. V. Dalton\* and J. Drobek

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey and Allentown, Pennsylvania

## ABSTRACT

Silicon nitride films deposited on silicon substrates by several techniques were studied. Electron diffraction studies of the films revealed that films varied in crystallite size from  $<10$  to  $\sim 100\text{\AA}$ . Radiotracer diffusion experiments using  $\text{Na}^{22}$  as diffusant revealed that the smaller crystallite films were better barriers to sodium diffusion than the larger crystallite films. Field enhanced drift of sodium was not observed in any of the silicon nitride films regardless of crystallite size. Silicon nitride films composed of large crystallites appeared to etch faster than smaller crystallite films in dilute buffered hydrofluoric acid.

Thin films of silicon nitride are of interest in the fabrication of semiconductor devices because they have been found to be relatively impermeable to the highly mobile ionic species which degrade devices using silicon dioxide as an insulating or passivating film (1,2) Sodium, because of its high mobility and common occurrence as contamination, is a common cause of instabilities in these devices (3-5).

Several methods of depositing silicon nitride films have been reported (6-9). The object of this investigation was to determine to what extent and in what ways silicon nitride is superior to silicon dioxide in inhibiting the movement of sodium. During the investigation silicon nitride films deposited by a variety of techniques were studied, and within each deposition technique conditions were varied to yield films of slightly different physical properties. A large number of such variations were studied; experiments and results reported are sufficient to detail the advantages and disadvantages of silicon nitride as compared to silicon dioxide.

Films of silicon nitride over silicon dioxide and mixed oxide-nitride films were not studied during this investigation; in fact, efforts were made to exclude oxides from all films studied by using specially dried gases and moisture free conditions.

### Deposition of Silicon Nitride Films

Thin films of silicon nitride may be deposited on silicon substrates by several techniques including:

- Pyrolytically by the reaction of  $\text{SiH}_4$  and  $\text{NH}_3$  (6).

- Pyrolytically by the reaction of  $\text{SiCl}_4$  and  $\text{NH}_3$  (7).
- Microwave plasma deposition (silicon sputtered through a nitrogen plasma) (8).
- D-C plasma deposition (silicon halide vapor in a nitrogen plasma) (9).

Several parameters may be varied in each of these deposition systems: temperature, flow rate, plasma density, etc. Only those parameters which influence the ability of the film to block sodium motion are discussed in this paper.

The silicon nitride films studied during this investigation were deposited on the (111) face of high resistivity (5-50 ohm-cm) silicon wafers  $> 0.75$  in. in diameter and 0.010 in. thick. Substrate preparation include a mechanical lap followed by a mechanical polish and in some cases a chemical polish. Wafers were given typical semiconductor preoxidation cleaning immediately before silicon nitride film deposition.

### Electron Diffraction Studies

Glancing angle electron diffraction photographs were taken of the surface of each film using an RCA type EMD2 electron diffraction unit operated at 50 kv. The film was then etched in small increments, and after each etch a diffraction pattern was recorded. In this manner the structural characteristics of the film (degree and type of crystallinity) were mapped as a function of film thickness.

The structure of silicon nitride has been studied by Forgeng and Decker (10). Accurate values of the interplanar spacings obtained from powder as well as single crystal samples are available. Both  $\alpha$  and  $\beta$   $\text{Si}_3\text{N}_4$  have several high intensity reflections which are

\* Electrochemical Society Active Member.

specific for one or the other type. Therefore,  $\alpha$ ,  $\beta$  or  $\alpha$ - $\beta$  forms of  $\text{Si}_3\text{N}_4$  can be identified (15). The evidence that  $\alpha$   $\text{Si}_3\text{N}_4$  forms first on elemental silicon in a nitriding atmosphere was established by a number of experiments carried out by Turkdogan *et al.* (15). As the reaction proceeds the  $\alpha$ - $\text{Si}_3\text{N}_4$  now in direct contact with the gaseous phase is converted to  $\beta$ - $\text{Si}_3\text{N}_4$ . Turkdogan's experiments were conducted at 1450°C.

Crystallite size in the film was determined by line broadening in the diffraction pattern; the lines (rings) become broader if there are too few coherently scattering atoms to yield sharp rings or spots. For electron diffraction the following expression for crystallite diameter ( $\sigma$ ) is used

$$\sigma = \frac{C}{\Delta S}$$

where  $C = L\lambda$  (camera constant),  $L$  = distance from specimen to photographic plate,  $\lambda$  = wavelength used,  $\Delta S$  = line broadening.

The possible error in our estimation of crystal size is  $\pm 15\%$ . The mass penetration depth of a 50 keV electron is  $\sim 3 \times 10^{-3} \text{ gcm}^{-2}$ . For silicon nitride (density  $\approx 3$ ) this yields a total penetration of  $10^{-3} \text{ cm}$ . Effective penetration for diffraction studies is less than total penetration because of scattering. In glancing angle electron diffraction the effective penetration in amorphous or small crystallite films has been found to be about 1% of the total penetration, in our case,  $10^{-5} \text{ cm}$  or 1000Å; this is the penetration along the beam. The angle of incidence of the beam with the surface of the film was varied between 0.02 and 0.1 radians. Therefore, the beam penetration in the direction normal to the surface was about 20-100Å. A more detailed discussion of the interaction of electron beams with thin films has been presented by Calbick (11).

#### Radiotracer Experiments

Movement of sodium in the nitride films was studied by deliberately contaminating the films with radioactive sodium, etching the film in small increments and counting the  $\gamma$  activity remaining in the sample after each etch. The sodium contaminated samples were treated in two general ways. They were either heated to cause the sodium to diffuse through the films or they were heated while a field was applied to enhance the sodium motion.

The isotope used in the tracer studies was  $\text{Na}^{22}$  ( $T_{1/2} = 2.60$  years). The isotope was purchased as an acid solution of  $\text{NaCl}$  and total sodium concentration was specified by the vendor, New England Nuclear Corporation. This permitted calibration of activity with total sodium content of the solution so that a specific gamma emission from a sample could be converted to a specific sodium concentration. This method does not account for unintentional  $\text{Na}^{23}$  contamination of the sample. However, intentional contamination was approximately 100 times higher than the level of unintentional  $\text{Na}$  contamination measured at these laboratories by Buck *et al.* (5).

Sodium<sup>22</sup> was detected and counted by means of a  $3 \times 3$  in. well-type Na I (Th activated) scintillation crystal connected to a Technical Measurement Corporation Model 102 analyzer. Sensitivity was typically  $3.0 \times 10^{10}$  sodium atoms/count/min and background was usually 50 counts/min. The 0.51 MeV peak of  $\text{Na}^{22}$  was traced and an energy range of 0.491 to 0.520 MeV was counted in order to maximize the sample to background activity. In order to minimize the statistical error of the measurements and yet complete the studies in a reasonable period of time each count was made for 60 min or 10,000 counts whichever came first. The standard deviations in the concentration plot (Fig. 1) show that this system yields statistically significant concentration points.

Autoradiographs were taken of samples after application of the radioactive sodium, after diffusion,

Fig. 1. Sodium diffusion profiles in silicon nitride and silicon dioxide.

after field enhanced drift, and at any step where it was desirable to determine uniformity of  $\text{Na}^{22}$  distribution across the surface of the sample or, in the case of drift experiments, to study localized field enhancement of diffusion. All autoradiographs were obtained by placing the sample in direct contact with Kodak No-screen x-ray film for a length of time sufficient to yield a high contrast picture.

**Diffusion Experiments.**—Sodium was applied to the silicon nitride films ( $1 \text{ cm}^2$ ) by evaporation in a vacuum from a platinum boat (at 1000°C) on which a few drops of tracer solution had been dried. This method was found to yield a relatively uniform sodium deposition. After deposition of the sodium the wafers were heated to 600°C for 22 hr in forming gas (85% nitrogen, 15% hydrogen). After diffusion, the wafers were water washed, autoradiographed, and incrementally etched in HF. Activity was counted after each etch until no activity above background remained in the sample.

**Drift experiments.**—For field enhanced diffusion (drift) experiments sodium was applied to silicon nitride films in the same manner as for the diffusion experiments. Gold dots were vacuum evaporated over the sodium and silver was evaporated onto the exposed silicon back surface of the wafer to provide contacts. A potential was applied to most of the dots on a wafer (20-30 square dots, 0.025 in. on a side), one at a time, with +4v (on the gold dots) for 1 min each. Field strengths ranged from  $7 \times 10^4$  to  $1 \times 10^5$  v/cm under these conditions. Most drift experiments were done while the samples were at 400°C in room air; however, some experiments were done at higher temperatures, some in forming gas, and some at higher voltages. The total time that a sample was at elevated temperature during these field enhanced diffusion experiments was 60-90 min. Current flow was recorded while the potential was applied, and on some dots I-V scans were run over a range of -4 to +4v to confirm the absence of charge storage effects normally seen in  $\text{SiO}_2$  films (12).

The samples were counted before and after removal of the metal contacts with aqua regia and after further

water washing. Autoradiographs were taken to determine if the sodium had diffused into the silicon nitride under the dots. The nitride film was then removed by HF in small increments, counting after each etch until all the active sodium was removed.

**Etching.**—The silicon nitride films were etched in dilute buffered hydrofluoric acid (13). In most cases a wafer was quartered so that diffusion, drift, and diffraction studies could be made on the same film. Etch rates were determined during the diffraction studies and also during the drift and diffusion experiment; results agreed well.

Film thickness measurements were made during the diffraction experiments using a spectrophotometer (14) and during the diffusion and drift experiments by comparison with a color chart.

### Experimental Results

**Diffraction.**—Electron diffraction studies revealed that the silicon nitride films varied considerably in crystallite size and structure.  $\alpha$ ,  $\beta$ , and  $\alpha\beta$  mixtures of silicon nitride were found. Crystallite sizes ranged from  $< 10$  to  $\sim 100\text{\AA}$ . Films of crystallites  $< 20\text{\AA}$  will arbitrarily be called amorphous.

Pyrolytically deposited (silane or silicon tetrachloride) films were usually amorphous; however, if these films were deposited at temperatures  $< 900^\circ\text{C}$  on improperly cleaned substrates they were crystalline and invariably  $\alpha$   $\text{Si}_3\text{N}_4$ . The crystallite size in these crystalline, pyrolytic films ranged from 20–40 $\text{\AA}$ .

The structure of  $\text{Si}_3\text{N}_4$  films prepared by d-c plasma discharge was also studied. Several of them were crystalline; some were amorphous. These crystalline films ranged from 20–80 $\text{\AA}$  in crystallite size and were usually  $\beta$  or  $\alpha$ - $\beta$  mixtures. Occasionally  $\alpha$   $\text{Si}_3\text{N}_4$  which forms first and then a transition form  $\alpha$  to  $\beta$  (15) was observed at the interface.

Microwave plasma deposited films were usually crystalline ( $\alpha$  or  $\alpha\beta$ ), and average crystallite size ranged from 40 to several hundred angstroms.

The diffraction studies also revealed that the films were not uniform in crystallite size throughout their thickness. Some went from amorphous at the top to crystalline at the  $\text{Si}$ - $\text{Si}_3\text{N}_4$  interface, but more often they were amorphous at the interface and crystalline at the top. These transitions in crystallite size may be partly attributed to contamination or fallout in the reaction vessel or the gas streams providing nucleation sites for the formation of large crystallites.

**Diffusion.**—The ability of sodium to penetrate the silicon nitride films was found to be related to the crystallite size of the film. Sodium was found to diffuse more easily into the films composed of larger crystallites. Figure 1 shows four diffusion profiles of Na in silicon nitride films of different crystallite sizes. A diffusion profile of Na in steam grown  $\text{SiO}_2$  [from ref. (5)] is shown on the same plot for comparison. The  $\text{SiO}_2$  diffusion conditions were identical to the nitride diffusion conditions. In silicon nitride films where the crystallite size changed in the interior of the film sodium diffusions were carried out twice, once at the outer surface and on another piece after etching to the point where a significant difference in crystallite size was detected by electron diffraction. In these experiments the same relationship was observed; that is, the films composed of larger crystallites were penetrated more easily by Na.

**Drift.**—No field enhancement of the diffusion of sodium was detected in any of the silicon nitride films studied regardless of crystallite size or type. In some cases sodium activity remained after removal of the metal contacts and thorough washing, but autoradiographs showed that this remaining activity was a random spottiness or in some cases a uniform darkening of the film due to slight diffusion of sodium at the elevated temperature. Temperatures as high as  $700^\circ\text{C}$ , voltages as high as 10v, or ambients of nitrogen or forming gas or any permutation of these

conditions did not cause enhanced motion of the sodium into the film.

Figure 2a shows a drawing of a silicon nitride coated wafer with a gold dot pattern applied. Figure 2b is the autoradiograph of this sample after removal of the gold dots and water washing of the surface. Most of the activity of drifted silicon nitride films was removed by water washing. The general darkening of this picture is due to background radiation. The larger dark spots, indicating  $\text{Na}^{22}$  activity do not correspond to the positions of the dots which had been subjected to the +4v, but may be due to nonuniform sodium deposition or flaws in the film.

In contrast, Fig. 3a, b depicts the dot patterns and autoradiograph of a 6000 $\text{\AA}$   $\text{SiO}_2$  film [from ref. (5)]. Deposition and drift conditions were identical to those for the nitride sample. In this case an image of each dot which had seen the +4v is reproduced in the autoradiograph. Incremental etching and counting of this film revealed that 90% of the  $\text{Na}^{22}$  was within 800 $\text{\AA}$  of the  $\text{Si}$ - $\text{SiO}_2$  interface. Autoradiographs taken after several etching steps showed that the activity patterns shown in Fig. 3b persisted throughout the film.

**Etch rate.**—Etch rates of silicon nitride films in dilute HF were found to be related to crystallite size in the film. Amorphous films were the slowest etching. Figure 4 is a plot of etch rate vs. crystallite size for several silicon nitride films. The fast etching of the

Fig. 2a (top). Gold dot pattern on silicon nitride film; b (bottom) autoradiograph after removal of gold dots.

Fig. 3a (top) Gold dot pattern on silicon dioxide film; b (bottom) autoradiograph after removal of gold dots.

Fig. 4. Etch rate vs. crystallite size of silicon nitride films

more crystalline films may be caused by diffusion of the etchant along grain boundaries and actual lifting of crystallites. Evidence for this type of etching was seen in the crystalline films; pitting and nonuniform preferential etching occurred.

It has been reported (16) that the etch rate of silicon nitride films is strongly dependent on the oxygen content of the film. No evidence for the presence of oxygen was found in the pyrolytic films either by infrared or scanning electron beam analysis; however, the plasma films were found to contain 1% oxygen by weight. This level of oxygen is quite low and moreover this same 1% was found in a group of plasma films which had a wide range of etch rates.

**Error analysis.**—Standard deviations are indicated as flags on each plotted point on distribution plots (Fig. 1).

The error in estimation of film thickness by comparison with a color chart is approximately  $\pm 50\text{\AA}$  for each point.

### Summary and Conclusions

Electron diffraction studies revealed that pyrolytically deposited silicon nitride films were amorphous except when deposited on dirty substrates. D.C. plasma deposited films, we observed, were both amorphous and crystalline. Microwave plasma deposited silicon nitride films were usually crystalline.

Etch rate and sodium penetration were related to crystallite size in the films. Films composed of large crystallites were found to be more easily penetrated by sodium (under our diffusion conditions) and generally faster and less uniformly etched than films composed of small crystallites.

Grain boundaries may be considered as surfaces whose atomic arrangement is irregular. Several authors have reported that diffusion proceeds more rapidly in grain boundaries than in the body of the grains (17-22). Moreover, it has been reported that diffusion enhancement is greater in wide grain boundaries (18) which are usually associated with large crystallites. We therefore conclude that the increase in sodium diffusion with grain size (within the range of crystallite sizes observed,  $\sim 20$  to  $\sim 100\text{\AA}$ ) is due to rapid diffusion in wide grain boundaries. The apparent high etch rate and pitting of the large crystallite films is probably caused by etchant penetrating the wide grain boundaries and lifting out crystallites.

The field enhanced drift experiments on silicon nitride films indicate that these films, regardless of deposition technique, provide a barrier to sodium drift under the conditions of voltage, time and temperature described.

# A Study on Making Abrupt Heterojunctions by Solution Growth

Kazuhiro Kurata and Tadamasa Hirai

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

## ABSTRACT

Ge-Si and Ge-GaAs abrupt heterojunctions without intermediate layers have been fabricated by a new alloying technique which was developed from metallographic consideration on the base-solvent-solute ternary phase system in solution growth. The alloying was carried out under the condition of no penetration occurring at the interface between the base crystal and the molten alloy. To maintain this condition, the compositions of the starting alloy which would be melted on the base crystal were selected as follows. The Ag-Ge alloy containing 45 atomic % Ge and the Al-Ge alloy containing 40 atomic % Ge were melted on Si and GaAs wafers respectively. The rectifying V-I characteristics and the results of the junction capacitance measurements showed that these junctions were abrupt and the crystallized Ge layers were heavily doped with solvent metals.

Since the work of Kroemer (1, 2), epitaxial heterojunctions between two semiconductors have aroused great interest. Many applications which have been proposed for these junctions are, for example, wide bandgap emitter transistors (3, 4), majority carrier rectifiers (5), high speed and window effect photo-detectors (6), and optical transistors (7).

Conventional methods which have been reported for producing these junctions are the vapor phase depositions. Recently they have also been obtained by the regrowth from liquid phases. Wei and Shewchun (8) have reported the electrical properties of alloyed heterojunctions between Ge and Si in which the former is fully melted on the latter. A simple technique to make heterojunctions where only the interface between the two semiconductors is melted has been reported by Rediker *et al.* (9) and Hinkley *et al.* (10).

On the other hand, Takeda *et al.* (11) have reported the phase diagram for the pseudobinary system Ge-GaAs determined by means of thermal analysis, microscopic observation, and x-ray microanalysis. They have shown that it was of a simple eutectic type, and the eutectic point lay at 15 m/o (mole per cent) GaAs, and its temperature  $865^{\circ} \pm 2^{\circ}\text{C}$  stood lower than the melting points of both semiconductors.

Therefore, it is impossible to make a metallographically perfect heterojunction between Ge and GaAs by a simple alloying technique. If the Ge crystal which is in contact with the GaAs crystal is heated to a temperature above the eutectic point, both crystals begin to melt at the contact region, and then the eutectic composition of GaAs-Ge molten solution is formed. Therefore the eutectic solid layer is formed between the recrystallized Ge and GaAs layers when the melt is cooled. In fact, intermediate layers like this have been observed by some researchers (12, 13).

In the present work, a metallographic analysis of the preparation of the alloy or the solution growth heterojunctions was made, and the conditions to guarantee making abrupt heterojunctions with no other undesirable junctions near the interface between two semiconductors were described. The results of the analysis were experimentally applied to producing Ge-Si and Ge-GaAs junctions.

## Principle of the Method

Desirable properties of the alloy-melt on the base wafer for making single crystal heterojunctions by a simple alloying technique, shown in Fig. 1, are as follows: (I) the alloy shown in Fig. 1a should contain a considerable amount of semiconductor  $S_1$  which is to be crystallized on the base wafer  $S_2$ , to ensure a satisfying growth rate without constitutional super-

cooling. (II) The base semiconductor  $S_2$  in Fig. 1b should not dissolve into the alloy-melt on it in order that the crystallized layer in Fig. 1c will make neither a eutectic structure nor a regrown homojunction between  $S_1$  and  $S_2$ .

The conditions ensuring the above properties are occasionally satisfied by the selection of the components and composition of the melt. When the alloy-melt which was composed of C% of metallic solvent M and (100-C)% of semiconductor  $S_1$  as a solute contacts with the base semiconductor  $S_2$ , the necessary conditions of "no penetration" can be seen in the phase diagram of the ternary M- $S_1$ - $S_2$  alloy system, as shown in Fig. 2.

In the binary M- $S_1$  system, if the melt of this composition is cooled down to the temperature of  $t$  from a higher temperature, then the solute  $S_1$  begins to crystallize as the primary crystal.

In the ternary M- $S_1$ - $S_2$  system, however, the composition C can vary along the line C  $S_2$  with dissolution of  $S_2$ , if the liquidus temperatures on this line are equal to  $t$  or lower than  $t$ . Figure 2a shows that this composition-dominating line C  $S_2$  contacts with the "pond" (hatched region) at the one point C, and so the composition of the melt is kept at C. Here the "pond" means a region which is enclosed with an equitemperature line at the liquidus point  $t$  of the binary M- $S_1$  alloy with the initial concentration C.

In the case of Fig. 2b, however, the line C  $S_2$  which is dominating the mole ratio of  $S_1$  vs. M in the ternary M- $S_1$ - $S_2$  system so as to be C by initial contents of  $S_1$  and M, crosses the pond at two parts and even more, and so the alloy melt dissolves the base crystal  $S_2$ . Therefore the concentration C moves toward  $S_2$  along the line C  $S_2$ , then to the another portion C' which is also on the equitemperature line of  $t$ . In this case, it is clearly impossible to crystallize  $S_1$  on  $S_2$  as a primary crystal by cooling, and we can make neither abrupt heterojunctions nor epitaxial growths.

In conclusion, the necessary conditions for the alloying technique have been shown above. The experi-

Fig. 1. Simple alloying technique for making single crystal heterojunction between  $S_1$  and  $S_2$ .

Fig. 2. Necessary condition of "no penetration" for making alloy or solution growth heterojunctions between  $S_1$  and  $S_2$ .

mental determination of the ternary phase diagrams, however, must be difficult. Therefore it was assumed from each of the three binary systems as shown in Fig. 2c.

#### Fabrication of Ge-Si Heterojunction

As shown in Fig. 3a, the Ge-Si alloy system exhibits a complete solid solubility, and the lowest solidus temperature in this system is equal to the melting point of Ge. Therefore, to prevent the dissolving of the base Si, it is essential that the eutectic temperatures of the Si-M and Ge-M systems are lower than the melting point of Si and that the alloying temperature is still lower than the eutectic line of the Si-M system.

Figure 3b and c show the composition of the initial solution C, in which case Ag is used as solvent and C is free to be selected by its solidus point  $t$  within the range of the temperature difference  $\Delta T$  between the two eutectic lines.

An Ag-Ge alloy containing 40 a/o (atomic per cent) Ge, whose liquidus point is  $750^\circ\text{C}$ , was prepared by vacuum melting of the pure elements in a quartz ampoule and quenching in water. The alloy was rolled to the thickness of  $1 \sim 3$  mm, and then cut into many pieces whose sizes were about  $8 \times 8$  mm each. Single crystal silicon wafers which had (111) surfaces were used as the base. The wafers were lapped mechanically to be approximately 0.5 mm thick with silicon carbide abrasives, and then etched in CP4 (4 parts  $\text{HNO}_3$ , 3 parts  $\text{CH}_3\text{COOH}$ , 3 parts  $\text{HF}$ ) to get a mirror finish. After rinsing in deionized water, the wafers were dried and broken into about  $10 \times 10$  mm pieces suitable for the alloy procedure.

Fig. 3. The temperature difference,  $\Delta T$ , between two alloy systems  $S_1$ -M and  $S_2$ -M.

The alloying was carried out by placing a silicon wafer on an Ag-Ge alloy piece which was placed on a quartz disk in a vertical type electric furnace as shown in Fig. 4. In order to obtain good wetting between the silicon and the alloy melt, the alloying was carried out in an atmosphere of dry argon mixed with hydrogen as high as 20%. The alloy process consisted of heating to  $770^\circ\text{C}$ , which is a little higher than the liquidus point of the alloy, and slow cooling to  $650^\circ\text{C}$ . To ensure a completely homogeneous solution, the melt was kept at  $770^\circ\text{C}$  for 30 min. After fusion, the melt was cooled at the rate of  $100^\circ\text{C/hr}$  to the eutectic temperature of the Ag-Ge system, and then the electric power was turned off.

By this procedure, single crystal germanium layers over 0.5 mm thick were epitaxially crystallized on the (111) surfaces of the silicon seeds. The growth rates were approximately 0.4 mm/hr rather faster than the travelling solvent method. Figure 5 shows a polished cross section of the junction. The front of the grown germanium layer was parallel to the (111) surface of the seed, and often exhibited crack-like regions which were presumably formed during cooling from the liquidus temperature, because of constitutional supercooling of the solution.

Figure 6a shows several terraces which were formed at the front of the grown layer. The areas of the terraces were hexagonal. Figure 6b shows a cross section of one of the terraces by lapping and polishing parallel to the junction area. It is probable that the concentration of solute germanium in the Ag-Ge alloy solution was decreased near the crystallizing front during the cooling and then the terrace structure was formed.

#### Fabrication of Ge-GaAs Heterojunction

Ag and Al were tested as the solvents in this experiment. Although the phase diagrams between each solvent and the gallium arsenide are unknown, the eutectic temperatures appearing on both phase diagrams of Ag-Ge and Al-Ge alloy system are fairly lower than the melting point of the elements as shown in Fig. 7. Ag is an acceptor impurity in Ge, but its influence is negligibly small, because the solid solubilities of Ag in Ge are only  $4 \times 10^{13}$  to  $3.5 \times 10^{14}$  atoms/cm<sup>3</sup> at  $700^\circ \sim 800^\circ\text{C}$ . Although the solid solubility of Al in Ge is much higher, the Al is a neutral impurity to the base GaAs. The composition of the

Fig. 4. Furnace for alloying

Fig. 5. Polished cross section of the Ge-Si heterojunction

Fig. 6. Terrace structures formed at the front of the grown Ge layer.

Fig. 7. Phase diagrams of the alloy systems GaAs-Ge, Al-Ge, and Ag-Ge.

Ag-Ge alloy was the same as that used in the fabrication of Ge-Si junctions.

For another purpose, an Al-Ge alloy containing 40 a/o Ge, whose liquidus temperature was 560°C, was prepared by vacuum melting in a graphite crucible.

Fig. 8. Photomicrostructure of the Al-Ge (40 a/o) alloy quenched in water from 600°C.

Figure 8 shows a photomicrograph of the structure of the alloy quenched in water from 600°C. As the dendritic primary crystallites were suitably distributed in the matrix of eutectic, the average composition was ensured when the alloy was rolled and cut into small pieces suitable for the alloy process.

The seed GaAs was used in the form of 0.5 ~ 1.0 mm thick wafers whose areas were approximately 6 x 6 mm. In order to remove surface damage, the wafers were etched and polished chemically in a 2 : 2 : 1 volumetric mixture of H<sub>2</sub>SO<sub>4</sub>, H<sub>2</sub>O<sub>2</sub>, and H<sub>2</sub>O. These wafers were cut from a single crystal ingot grown by the free surface method (14).

Similar procedures were taken to crystallize the germanium layers on the gallium arsenide seeds from the solutions. Initially, the alloy on the seeds was fully melted at a temperature higher than its liquidus point, and cooled slowly to near the eutectic temperature for crystallization and then allowed to cool spontaneously to room temperature. The initial heating for the Ag and Al solutions were 770°C for 0.5 hr and 580°C for 0.5 hr, respectively. The cooling rate for crystallization was about 200°C/hr. All these cycles were carried out in an atmosphere of dry argon.

After the junction had been formed, several samples were cross-sectioned by mounting them in a casting resin and lapping them with silicon carbide abrasives. A mirror finish was obtained by mechanical polishing with diamond paste.

Figure 9 shows a polished cross section of the Ge-GaAs heterojunction fabricated by crystallization of Ge from the Al-Ge alloy solution. Striations appearing in the GaAs region were caused by mechanical lapping. The polyphase region consists of small primary crystallites and matrix eutectics of the Ge-Al system, which indicates the same structure as that in the photograph of Fig. 8. Since the luster of polished germanium was considerably different from that of gallium arsenide, it was relatively easy to distinguish between the two semiconductors. The junction appeared as an interface line, and the transition from

Fig. 9. Polished cross section of the Ge-GaAs heterojunction fabricated by crystallization of Ge from the Al-Ge alloy solution.

Fig. 10. Polished cross section of the Ge-GaAs junction fabricated by crystallization of Ge from the Al-Ge alloy solution. (Higher magnification).

gallium arsenide to germanium was abrupt. Higher magnifications of the junction region, as in Fig. 10, will show that no intermediate layers exist, such as eutectics between the two semiconductors.

However, in the case of the Ag-Ge alloy melt, an intermediate phase layer between the seed gallium arsenide and the crystallized germanium was formed, as shown in Fig. 11, and its magnified photograph in Fig. 12. From this result, it is supposed that a eutectic line of the Ag-GaAs alloy system may exist at a lower temperature than expected, and so the necessary conditions described in Fig. 2 are not satisfied in this case.

#### Electrical Measurements

The capacity and current-voltage characteristics of the Ge-GaAs heterojunctions have been measured. In the case of the Ge-Si junction, it was difficult to fabricate the diodes by the method we used because of the largeness of the junction area which tended to cause an electrical short through the crack-like regions in the grown layer of germanium.

The diodes used in this experiment were made from the heterocrystal wafers fabricated by the method described above. The wafers were cut into approximately 2.5 x 2.5 mm chips by an ultrasonic cutting machine, and then ohmic electrical contacts were achieved as shown in Fig. 13. In this figure, the junction is clearly seen as the interface between the two

Fig. 11. Polished cross section of the Ge-GaAs structure fabricated by crystallization of Ge from the Ag-Ge solution.

Fig. 12. Polished cross section of the Ge-GaAs structure fabricated by crystallization of Ge from the Ag-Ge solution. (Higher magnification).

Fig. 13. Diodes made from the heterocrystal wafers

different lusters. The ohmic contact to the n-type base GaAs region was achieved by the following procedure: (i) electroplating with Sn onto the lapped surface, (ii) electroplating with Ni onto the Sn, and then, (iii) soldering the Ni to a copper lead wire with ordinary Pb-Sn solder. The contact to the opposite side of the junction, which was the Al-Ge eutectic alloy surface, was achieved by soldering to the copper lead wire or a conventional diode header with aluminum chloride as a flux.

In the case of the Ge-Si junction, chemical plating with Ni to the n-type base Si and soldering with Pb-Sn alloy to the Ag-Ge eutectic side were done.

The base crystals used were n-type GaAs wafers of 0.002 ohm-cm and n-type Si wafers of 5 ohm-cm. After fabrication, the diodes were carefully coated with Apiezon wax except the junction region. They were then etched chemically and rinsed with deionized water.

Typical I-V characteristics of these diodes observed on a curve tracer are shown in Fig. 14 and 15. Both junctions have a soft breakdown, and their breakdown voltage increases with decreasing temperature as expected of a Zener breakdown. Because of high doping of Al in the Ge layer, the diffusion voltages in the forward characteristic of Ge-GaAs junction, 0.8v at 300°K and 1.0v at 77°K are somewhat higher than those measured for the vapor grown junctions by Anderson (5).

The circuit used to measure the low current I-V characteristics of the Ge-GaAs diodes is shown in Fig. 16. A Boonton model 74C capacitance bridge was used to measure the C-V characteristics of the Ge-GaAs structures at the frequency of 100 kHz.

#### Results and Discussion

The low current I-V characteristics measured at 300° and 77°K of typical Ge-GaAs p-n heterojunction diodes fabricated by this method are shown in Fig. 17. Forward conduction occurred in all junctions when the Ge was biased positively, as was the case with Ge-Si p-n heterojunctions. From the ordinary diode theory, the current-voltage characteristics can be described by the following empirical formula

Fig. 14. Typical I-V characteristics of the Ge-Si heterojunction diodes observed on a curve tracer, at 300°K.

Fig. 15. Typical I-V characteristics of the Ge-GaAs diodes observed on a curve tracer, at 300° and 77°K.

Fig. 16. Circuit used to measure the low current I-V characteristics of the Ge-GaAs diodes.

$$I = I_0 [\exp (qV/\eta kT) - 1] \quad [1]$$

where  $I_0$  is the saturation current and  $\eta$  is a nondimensional coefficient. From the formula, the forward and the reverse current of the junctions can be written as follows

$$I \approx I_0 \exp (qV/\eta kT) \text{ (forward)} \quad [2]$$

$$I \approx I_0 \text{ (reverse)} \quad [3]$$

The nondimensional coefficient  $\eta$  depends on the conduction mechanism, and it takes the value 1 or 2 with the diffusion or recombination current respectively. The values obtained from the forward characteristics shown in Fig. 17 were  $\eta = 1.67$  for 300°K and  $\eta = 7.50$  for 77°K. Although the room temperature value can be explained as a combination of diffusion and recombination current, the value for 77°K cannot be explained. As can be seen from Fig. 17, the forward current for both diodes varies as seen in

$$I = I_0 \exp (\alpha V) \quad [4]$$

where  $\alpha$  is relatively independent of temperature.

$$\alpha \approx 2.0 \sim 2.3 \quad (77^\circ \sim 300^\circ\text{K}) \quad [5]$$

Fig. 17. Low current I-V characteristics of typical Ge-GaAs p-n heterojunction diodes.

Therefore, it rather may be possible to explain the current by a tunneling mechanism as described by Rediker *et al.* (9) for GaAs-GaSb interface-alloy heterojunctions.

The junction capacitance on the Ge-GaAs p-n heterodiodes was measured at room temperature as a function of bias voltage. Typical plots of  $C^{-2}$  vs.  $V$  for the two diodes are shown in Fig. 18. As can be seen from the figure, the capacitance varies as the reciprocal square root of the voltage, as expected of an abrupt junction.

As the grown germanium layer contains the concentration of the limit of solid solubility of aluminum which is as high as  $10^{20}$  atoms/cm<sup>3</sup>, it can be assumed that the depletion region is extended to the base GaAs region. The width of the depletion region  $w$  is

$$w = \left( \frac{2\epsilon V}{q N_D} \right)^{1/2} \quad [6]$$

$$w = \epsilon A/C \quad [7]$$

where  $A$  is the area of the junction and  $\epsilon$  is the dielectric constant of GaAs. Referring to Fig. 18, the capacities depending on bias voltage are

$$C = 2250 \text{ pF} \quad (\text{at } -2v)$$

and

$$C = 3670 \text{ pF} \quad (\text{at } 0v)$$

$$\text{As the junction area } A \text{ is } 4 \times 10^{-2} \text{ cm}^2$$

$$w = 1890 \text{ \AA} \quad (\text{at } -2v)$$

and

$$w = 1160 \text{ \AA} \quad (\text{at } 0v)$$

It may be possible to explain the forward current of the junction by means of tunneling.

### Summary

Metallographical considerations on the base-solvent-solute ternary phase system for solution growth

Fig. 18. Typical C-V characteristics of the Ge-GaAs p-n heterojunction diodes.

of heterocrystals were made, and the conditions to ensure a metallurgically perfect junction were described. From this result, Ge-Si and Ge-GaAs heterojunctions have been fabricated by crystallizing Ge from Ag and Al solutions onto the base crystals, using simple alloying techniques. The conditions employed were as shown in Table I, where M is the solvent metal;  $t$  is the liquidus point of the M-S<sub>1</sub> alloy used;  $T_1$ ,  $T_2$ , and  $T_3$  are the eutectic lines in the binary alloy systems of S<sub>1</sub>-M, S<sub>2</sub>-M, and S<sub>1</sub>-S<sub>2</sub>, respectively; and C is the content of S<sub>1</sub> in S<sub>1</sub>-M solution.

Microscopic observations of these junctions showed that there is no intermediate phase between the two semiconductors, and that the growth of the Ge layers may be epitaxial to the base crystals as shown in Fig.

Table I. Alloying conditions employed for making heterojunctions

Junction, S <sub>1</sub> on S <sub>2</sub>	M	$t$ , °C	$T_2$ , °C	$T_3$ , °C	C, a/o	$T_1$ , °C	Solubility, M in S <sub>1</sub>
Ge-Si	Ag	650	830	(937)	45	790	$10^{13}/\text{cm}^3$
Ge-GaAs	Al	424	660	865	40	550	$10^{20}/\text{cm}^3$

6. As the crystallized Ge layer is saturated with the solvent metals, the diffusion voltage in the forward drop of the I-V characteristic for the Ge-GaAs junctions is appreciably lower than that measured for vapor phase grown junctions, and the major mechanism of the current flow is found to be due to tunneling. The breakdown in the reverse characteristic of the junction is soft and of a Zener type. The C-V characteristics show that the junctions are abrupt, as expected from the metallurgical considerations.

## Brief Communication

### Self-Registered Molybdenum-Gate MOSFET

D. M. Brown,\* W. E. Engeler, M. Garfinkel, and P. V. Gray

General Electric Research and Development Center, Schenectady, New York

The use of Mo films as etch masks to pattern Si<sub>3</sub>N<sub>4</sub> films has been described previously (1). In this study, KPR and potassium ferricyanide etch<sup>1</sup> was used to first pattern the Mo film and the underlying Si<sub>3</sub>N<sub>4</sub> film was subsequently etched away and patterned by using concentrated HF (48%) which dissolves Si<sub>3</sub>N<sub>4</sub> but does not dissolve Mo. That the unique chemical prop-

erties of Mo can be used to form patterns in multiple layers of Mo, Si<sub>3</sub>N<sub>4</sub>, and SiO<sub>2</sub> has also been pointed out (2).

It is the purpose of this short article to show that Mo films can also be used as high temperature diffusion masks; and that this, in turn, makes it possible to fabricate self-registered enhancement mode MOSFETs by utilizing a portion of the Mo diffusion mask as the gate electrode.

\* Electrochemical Society Active Member.  
<sup>1</sup> 92g K<sub>3</sub>Fe(CN)<sub>6</sub>, 20g KOH, 300g H<sub>2</sub>O.

### Mo Film Diffusion Masking

Having shown the usefulness of Mo as an etch mask, we next turned our attention to the use of Mo as a diffusion mask to see if patterned Mo films could be utilized as diffusion masks against some of the standard silicon dopants at high diffusion temperatures. Mo, of course, is a refractory metal with a melting point of  $2600^{\circ}\text{C}$ . Diffusion experiments were done with films of Mo over thin films of thermal silicon dioxide to prevent the formation of  $\text{MoSi}_2$ . There was no danger of the Mo reducing the silicon dioxide film since silicon dioxide is more stable than any of the Mo oxides.

Figure 1 shows a result of this investigation by using angle lapping and staining to delineate the converted regions. The remaining portions of the Mo mask which is  $5000\text{\AA}$  thick are shown in the upper corners of the picture. This Mo film was deposited over  $1200\text{\AA}$  of thermal oxide grown on a 1 ohm-cm n-type silicon wafer. After patterning the Mo film, a thin layer of undoped oxide was deposited over the Mo pattern and diffusion was carried out for 16 hr at  $1100^{\circ}\text{C}$  in a closed tube using elemental boron. The diffused p-type material is stained almost black in the picture. And, indeed, we see that the Mo film is acting as a diffusion mask. The angle lapping and staining give a junction depth of  $6.3\mu$  wherever the Mo film was removed, whereas it is only  $1.1\mu$  deep under the Mo mask. Other experiments indicated that Mo films are an even better mask against phosphorus diffusion.

### Self-Registered Mo-Gate MOSFET

The next step was to make MOSFETs utilizing these discoveries. In this case Mo can be used as the metal gate electrode: Mo, after all, is a good metal with a room-temperature resistivity of only  $5\ \mu\text{ohm-cm}$ . Furthermore, by utilizing a Mo film as the diffusion mask to define source and drain, and subsequently as the gate electrode, two important things can be achieved. All critical alignment steps are eliminated during the fabrication of these devices since such a process automatically registers the source and drain junctions under the edges of the Mo gate electrode, and the devices can therefore be formed with a minimum of gate to source and drain region overlap which is important for the reduction of the gate to drain feedback capacitance. This, of course, increases the gain-bandwidth product of the device.

How this has been done is shown schematically in Fig. 2. First, we grow a high quality thin thermal oxide on a Si wafer; this oxide will subsequently be

Fig. 1. Angle lapped and stained section showing Mo diffusion masking of boron. Underlying Si wafer is 1 ohm-cm n-type. Converted p-type regions are stained dark. Junction depth under oxide covered Si is  $6.3\mu$ ;  $1.1\mu$  under Mo-covered oxide. Bevel magnification is  $\approx 5X$ .

Fig. 2. Schematic diagram of fabrication steps used to make a type of self-registering Mo-gate MOSFET.

used as the gate dielectric. Next we deposit and pattern a Mo film to form the channel adjacent source and drain region patterns. We then deposit a doped glass which is utilized as the diffusion source and diffuse the dopant through the thermal oxide and into the Si to form the source and drain, thus achieving automatic self-registration of the source and drain junctions under the Mo gate. All that needs to be done to finish the device is to subsequently make contact to the source and drain and buried Mo gate. Contact apertures are etched in the deposited glass in the conventional manner using photoresist and buffered HF. Final metalization is also conventionally formed by patterning an evaporated metal film (e.g., Al).

In Fig. 3 we show a picture of a finished device with circular geometry. We have removed the Al contacts here; the gate buried within the oxide layers in this instance is a ring of Mo 1 mil wide. The source and drain regions are covered with glass. Showing within these regions are the dig-down apertures used to contact the FET's source and drain. Surrounding the device is glass-covered Mo. The deposited glass was doped with phosphorus, and the underlying wafer is 1 ohm-cm p-type silicon.

Figure 4 shows an angle lapped and stained device. The original p-type material is dark, and the diffused source and drain regions being n-type are light. Here

Fig. 3. Finished device. Al contacts removed. Buried Mo gate is a ring 1 mil ( $25\mu$ ) wide. Channel aspect ratio ( $W/L$ ) is 20. Small dots are remaining portions of Al contacts or colored glass crystallites in deposited glass.

Fig. 4. Angle lapped and stained device like that of Fig. 3 showing automatic source and drain junction registration under edges of circular Mo gate electrode. Underlying wafer is 1 ohm-cm p-type Si (dark) and diffused n-type source and drain regions are light. Junction depth is  $2.5\mu$ . Bevel magnification is 17.6X.

we see the self-registry of the source and drain junctions with the Mo gate. The junction depth is about  $2.5\mu$ , whereas the source and drain region overlap with the Mo gate is  $2\mu$ .

These devices are n-channel enhancement mode and after  $H_2$  annealing exhibit low threshold voltages and have channel mobilities of  $200\text{--}400\text{ cm}^2/\text{v}\cdot\text{sec}$ . Some characteristic curves are shown in Fig. 5. The scale for the source to drain current is  $20\text{ }\mu\text{a}/\text{div}$  and for source-drain voltage it is  $1\text{ v}/\text{div}$  with gate steps starting at zero and increasing upwards at  $0.2\text{ v}/\text{step}$ . The  $20\mu$  threshold is about  $+0.8\text{v}$ . The MOS-C ( $V_G$ ) curve of the device whose characteristic curves are shown in Fig. 5 indicates a fixed charge,  $Q_{so}$ , of about  $1 \times 10^{12}/\text{cm}^2$ . A very small amount of channel current is observed at  $V_G = 0$ . Strong surface inversion occurs for  $V_G > 0$ .

#### Summary

These experiments have shown the following:

Thin films of Mo deposited upon thin oxides can mask against both phosphorus and boron.

Therefore, thin films of Mo can be used not only as etch masks to pattern silicon nitride and silicon dioxide films, but can also be used as diffusion masks and therefore be utilized to form converted conductivity-type regions within the underlying silicon by high temperature diffusion techniques.

The use of Mo films in this manner has some very substantial advantages in the fabrication of MOS-FETs:

1. Part of the Mo diffusion mask can be utilized subsequent to source-drain formation as the gate

Fig. 5. Source-drain characteristic curves for n-channel enhancement mode device shown in Fig. 3. Scales are:  $I_{SD} = 20\mu\text{ amp}/\text{div}$ ;  $V_{SD} = 1\text{ v}/\text{div}$ ;  $V_G = +0.2\text{ v}/\text{step}$ , 12 steps.

electrode. This therefore: (a) provides for automatic self-registration of the source and drain junctions under the Mo gate for every MOSFET device on the wafer, (b) in turn this eliminates excessive feedback capacity, and (c) also eliminates the need for any critical mask alignments during FET processing.

2. Mo is easily patterned and the high resolution of the photoresist mask is readily transferred to the moly film, this has been shown previously (1).

3. Mo is a metal with a high conductivity, which means that contact to the gate electrode need not be extensive. That is, contact can be made at a single point and because of all of the above features, the Mo gate can therefore be very complicated in form in order to create devices with very large aspect ratios and large figures of merit.

Manuscript submitted March 10, 1968; revised manuscript received April 26, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as a Recent News Paper, Electronics Div., Paper 7.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Correction

In the paper "SiSiO<sub>2</sub> Fast Interface State Measurements" by Dale M. Brown and Peter V. Gray, which was published in Vol. 115, pp. 760-766, July 1968, on p. 764 the third from the last sentence in the Summary should read: "These defect centers when present can

drastically alter even the room temperature performance of MOSFETs since their production has been shown to raise the threshold and greatly reduce the channel mobility of a MOSFET."

### The Early History of the Electrodeposition and Separation of Particles

Myron Robinson

*Research-Cottrell, Incorporated, Bound Brook, New Jersey*

#### ABSTRACT

The existence of electrostatic forces of attraction had been known to classical antiquity, but the first reported observations in the electrostatics of airborne particles date from about 1600. Closely associated with studies of smoke and other fine suspended particles in an electric field was the discovery of the man-made corona discharge after 1670. A review is presented of the contributions of the very early investigators of electrodeposition, electroseparation, and the high-voltage discharge, among whom are some of the foremost names in the history of science: Gilbert, Boyle, Newton, Coulomb, and Faraday.

Electrostatic dust precipitation, liquid spraying, mineral separation, xerography, and other widespread applications of the electrodeposition and separation of particles are, for the most part, developments of the twentieth century. But as is commonly the case in the history of science, the essential phenomena had been demonstrated in principle long before an advancing technology provided the ancillary equipment required for effective commercial utilization.

The following survey briefly reviews the older historical background of the subject, from the earliest times to 1907, the year marking the first successful commercial application of electrostatic precipitation.

#### The Beginnings of Particle Electrostatics and the Discovery of the Corona Discharge

Thales of Miletus, one of the seven wise men of Greece and founder of the school whence Socrates came, is commonly mentioned as the discoverer of electrostatic attraction. This claim, particularly frequent in textbooks on electrostatics, is not, however, well documented by the literary remains available to us. No writings of Thales have survived, and it is to Diogenes Laertius, the third century biographer of the philosophers, that we are indebted for information on Thales' electrical "researches." In this connection, Diogenes notes simply that ". . . Aristotle and Hippias [Greek sophist, fifth century B.C.] say that he [Thales] attributed souls also to lifeless things, forming his conjecture from the nature of the magnet, and of amber" (1). Aristotle, on the other hand, speaks only of the animation of the magnet as an opinion that originated with Thales, and even of this he is not altogether certain: "Thales, too, apparently judging from the anecdotes related of him, conceived soul as a cause of motion, if it be true that he affirmed the loadstone to possess soul, because it attracts iron" (2).

Since the two foregoing quotations comprise the known evidence linking Thales to the discovery of electrostatic attraction, the association of Thales with amber may well have been an invention of Diogenes

800 years after the alleged event. That this could have been so is not strange, for the early writers closely associated electric and magnetic phenomena, often speaking of electricity as a kind of magnetism, and considering magnetic action the general case of attractive mechanism. As late as 1600, for example, William Gilbert, the "Galileo of magnetism," still preserved this already old tradition by having in his "De Magnete" (Fig. 1) a chapter entitled "On the Magnetic Coition," of which the first segment was subtitled "On the Attraction of Amber" (3).

It is clear, in any case, that the existence of electrostatic forces of attraction had been known to classical antiquity, for the observation that a rubbed amber attracts straws, dried leaves, and other light bodies ostensibly in the same way a magnet attracts iron is variously credited to Theophrastus (ca. 300 B. C.), Pliny (first century), and Solinus (third century), as well as other ancients, Greek and Roman (4). But owing to the deficiency of scientific method and to the absorbing interests of practical life, repeated accounts of electrostatic attraction from the earliest times to the advent of Gilbert, revealed little in the way of novelty either in observation or interpretation. Indeed, it remained for Gilbert to observe specifically that electrostatic forces could deflect particulate matter from an aerosol. Discussing the attractive power of amber, sulfur, diamond, and other "electric" (i.e., dielectrics) "when stimulated by friction," Gilbert reported that such materials would "entice smoke sent out by an extinguished light" (3). ("Electric" for-

merly designated a nonconductor. The term originated with Gilbert who applied it to substances capable of receiving a charge by rubbing. "Nonelectric" referred to a conductor.)

Three quarters of a century later the experiment was repeated by the Irish natural philosopher Robert Boyle (Fig. 2): "For having well-lighted a Wax-taper, which I preferred to a common Candle to avoid the stink of the snuff, I blew out the flame; and when the smoak ascended in a slender stream, held, at a convenient distance from it, an excited piece of Amber or a chafed Diamond, which would manifestly make the ascending smoak deviate from its former line, and turn aside, to beat, as it were, against the Electric, which, if it were vigorous would act at a considerable distance . . ." (5).

In both foregoing examples, the smoke was attracted to the dielectric either by virtue of a charge acquired by the particles in the incomplete combustion process, or as a result of the polarization of the electrically neutral particles in the nonuniform electric field surrounding the dielectric. Since a corona discharge was not used to impart a net charge to the particles, neither instance can be regarded as a true forerunner of electrostatic precipitation or liquid spraying in the conventional present-day sense. Nevertheless, Boyle may not have missed the mark by much. As Joseph Priestly informs us in his celebrated history of electricity, "Mr. Boyle got a glimpse, as we may say, of the electric light: for he found that a curious diamond . . . brought from Italy, gave light in the dark when it was rubbed against any kind of stuff; and . . . it became electrical" (6).

Together with his predecessors, Boyle noted the ability of amber to draw "not only Sand and Mineral Powders, but Filings of Steel and Copper, and beaten Gold it self." He supported the contention, first put forth by Gilbert, that magnets attract iron whereas amber "draws indifferently all bodies whatsoever" (6). There was at this early time, however, no mention of the possibility of electrostatic mineral separation,

Fig. 2. Title page of Boyle's book treating his electrical researches. The term "mechanical" refers to the frictional origin of electricity. This was the first printed book on electricity to appear in English.

or any suggestion that particles of unlike physical characteristics might behave differently in the presence of amber.

Production of a substantial man-made corona could not have antedated the development of the high-voltage generating machine. A frictional machine consisting of a sulfur sphere mounted on a crankshaft was described in 1672 by Otto von Guericke, better known for his invention of the vacuum pump and Magdeburg hemispheres. The sulfur sphere was charged by rubbing the hand against it while it was rotated in a wooden frame (Fig. 3). Using this apparatus, von Guericke made the important discovery of the effectiveness of pointed conductors in attracting charged bodies. He noted further that the rubbed globe glowed in the dark and that when it was brought

Fig. 3. Von Guericke's frictional electrostatic machine is on the right. On the left, the burgomeister is demonstrating how a feather *a*, first charged by contact with the sphere, may be made to move about in the air as he chose. This is probably the earliest example of achieving the directed motion of a particle under the action of an electric field (7).

to the ear "roaring and crashings" were heard in it (7).

The experiments of Boyle and von Guericke were made about the same time, neither deriving advantage from the labors of the other. Their observations seem to be the earliest recorded of the corona discharge.

Von Guericke's frictional machine and subsequent improvements on it were to accelerate the progress of electrical science, but the more primitive charging methods lingered tenaciously. In 1709, Francis Hauksbee, curator of instruments for the Royal Society of London, reported that he had experienced a weak sensation of pressure, presumably the electric wind, by holding a charged tube close to his face (Fig. 4). Hauksbee's announcement of his discovery throws interesting light on the state of electrical knowledge and experimental technique at the time. "Having procured a Tube, or hollow Cylinder, of fine Flint Glass," he wrote, "about one Inch diameter, and thirty in length; I rubb'd it pretty vigorously with paper in my hand until it had acquired some Degree of Heat . . . When the Tube became hottest by the strongest Attrition, the Force of the [electrical] Effluvia was render'd manifest to . . . [the] Sense . . . of feeling. They . . . were plainly to be felt upon the Face or any other tender part, if the rubb'd Tube were held near it. And they seemed to make very nearly such sort of stroaks upon the Skin, as a number of fine limber Hairs pushing against it might be suppos'd to do. This vigorous Action of the Effluvia put me upon an attempt, to find in what manner such a motion was propagated, and in what figure or sort of track it went along. For which end I held the rubb'd Tube near the Flame of a Candle, Smoke, Dust and surfaces of Liquids; but without any manner of success."

Hauksbee's efforts to employ smoke-tracer and similar techniques to follow the flow pattern of the electric wind failed. In fact, he gives the impression that the drag force of the wind was so weak and the electric attractive force on the smoke particles and other substances so strong that the particles and liquid moved against the air current to deposit on

the tube. In Hauksbee's view this deposition confined the electric effluvia within the tube and thereby suppressed the wind: "For the small parts of Dust and Powders, the streams of Liquids, the oleaginous Fumes of Flame, and the like sort of parts of Smoke it self, immediately adher'd to the surface of the Tube, and so kept in the Effluvia: which therefore requir'd the assistance of a fresh Attrition to open their passage and give them vent again" (8).

Once again, the principle of the modern electrostatic sprayer or precipitator, the charging of particles to the same polarity as that of the discharge electrode and their subsequent repulsion from that electrode, was yet to be clearly demonstrated. It is possible, though, that a step in the right direction had already been taken by the savants of the Academy del Cimento of Tuscany, contemporaries of Boyle and von Guericke (Fig. 5). To these gentlemen "we are indebted for several observations on the subject of electricity," among them a report of 1667 that a stream of smoke rising near a piece of rubbed amber would in part "bend . . . and be arrested by the Amber and in part, as if reflected from a Glass . . . mount upwards." The attracted portion, "as the Amber cools, rises in *smoak* again, and vanishes" (9). The latter statement may be the first recognition of a frequent problem in commercial electrostatic precipitation, the failure of particles of low resistivity to adhere to a collecting electrode. The twin columns suggest the smoke is of mixed charge, particles of opposite sign being drawn off in different directions.

The splitting of a column of smoke in an electric field, a phenomenon vaguely reminiscent of the important Stark and Zeeman discoveries of a later period, has since been noted time and again in the literature. As late as 1839 Faraday regarded this experiment worthy of mention in his "Experimental Researches:" "If a smoking wax taper be held . . . towards a charged prime conductor . . . two currents will [often] form, . . . one . . . passing to the conductor, and the other . . . outwards, and from the conductor . . ." (10) (A prime conductor is a high-capacity, corona-free conductor for storing charge generated by an electrostatic machine. See Fig. 6.)

Shortly after Hauksbee, Isaac Newton performed a similar corona experiment. "The electric Vapour," he wrote, ". . . excited by the friction of the . . . [Sphere] against the Hand will . . . be put into such an agitation as to emit Light . . . and in pushing out of the . . . [Sphere] will sometimes push against the Finger so as to be felt" (11). No mention is made,

Fig. 4. Hauksbee's title page. The *Light* referred to is that emitted in an electrical discharge.

Fig. 5. English translation, authorized by the Royal Society of London, of "Saggi di naturali esperienzi" which originally appeared in Florence in 1667. The frontispiece illustrates the timelessness and universality of science: The personified Academy del Cimento is handing a copy of the *Essayes* to the seated Royal Society while Aristotle and the goddess of nature look on.

Fig. 6. A frictional electrostatic machine circa 1767 (16). The glass sphere at the left replaces von Guericke's sulfur ball. A fine chain dragging against the sphere transfers charge from the surface of the latter to the suspended prime conductor.

however, of the action of the "electric Vapour" on aerosols.

In 1746, the French philosopher Jean Antoine Nollet revealed his findings that electrified points displayed "brushes of light" (12). A year later, Benjamin Franklin revealed in a letter to his friend Peter Collinson of the Royal Society, "the wonderful effect of pointed bodies, both in drawing off and throwing off the electrical fire" (13). Nollet's and Franklin's observations were largely a rediscovery of a phenomenon noted earlier by von Guericke and long since forgotten. But this time, the corona discharge was to be established as a favorite subject of experimental study among the electrical investigators of the day. (The term "corona," with reference to a gaseous discharge, is of comparatively recent origin, commonly appearing in the literature only after 1900.)

In 1771, the Italian electrician-astronomer, Giambattista Becarria, succeeded where Hauksbee had not. "The movements that the electric wind can excite," he noted, ". . . repel the hot smoke of a candle just blown out, and if you present a strongly electrified point to the flame of a candle . . . the flame will . . . be repelled by the wind." Becarria thus seems to have been the first to bring about the repulsion of suspended particles from a high-voltage electrode by means of a corona discharge. However, he was concerned with observing the flow patterns of the electric wind issuing from a point and was apparently unaware that Coulombic forces as well as aerodynamic drag played a direct role in the repulsion of the particles. "It is false," Becarria asserted with but partial accuracy, "that it be the outflowing electrical matter that itself directly thrusts away the smoke, blows out the candle or . . . constitutes the electric wind, an opinion in which I see some people firmly persist" (14).

Experiments with a candle are not as straightforward as they may seem. Analysis is complicated by the ionized structure of the flame: the tip and mantle are positively charged whereas the core exhibits a surplus negative charge. Consequently, a candle flame may be subjected to conflicting electrostatic and aerodynamic forces in the presence of a point discharge.

#### Electrical Characteristics of Gasborne Particles

The electrical conductivity of dust and smoke particles, today a matter of chief importance in elec-

trodepositional devices, particularly precipitators and conductance separators, was early an object of scientific inquiry. In 1746 the English physician William Watson, "the most distinguished name in this period in the history of electricity," reported to the Royal Society that a charge is acquired by an insulated conductor placed in a column of smoke rising out of an electrified vessel of burning turpentine. The doctor's experimental set-up was quaintly animate: holding vessel or conductor at each end of the bizarre transmission line was an "electrified man" suitably isolated from ground. Watson concluded, with some surprise, "here we find the smoke of an originally-electric a conductor of Electricity" (15).

Nine years later, the subject was again brought to the attention of the Royal Society with an account of a modification of the foregoing experiment, but now yielding a contrary result. "Mr. Henry Eeles of Lismore in Ireland . . . electrified a piece of down, suspended in the middle of a long silk string, and made steam and smoke of several kinds pass . . . through it, and observed that its electricity was not in the least diminished, as he thought it would have been, if the vapour had been non electric, and consequently had taken away with it part of the electric matter with which the down was loaded" (16).

Eeles flatly concluded that "exhalations of all kinds are electrical [i.e., nonconducting]." Further clarification on this score awaited the Anglo-Italian electrical researcher Tiberius Cavallo. Repeating the smoke-attraction experiment, but using a charged metal sphere in place of his forerunners' rubbed dielectric, Cavallo wrote, in 1777, "the smoak . . . will be attracted by the electrified body and . . . form a kind of atmosphere about it. This atmosphere will remain for a few seconds . . . and gradually vanish, . . . diffus[ing] . . . itself into space." No previous performer of this now popular demonstration had offered an adequate explanation of the mechanism involved. Cavallo's views, on the other hand, are remarkably up to date and go so far as to reveal an appreciation of the concept of charging time constant: "The smoak is attracted by the electrified body . . . for the same reason that other bodies are attracted by it . . . It . . . is not immediately repelled, because it is a bad Conductor, and acquires Electricity very slowly; but having acquired a sufficient quantity . . . it begins to quit the electrified body, and ascending into the air, extends itself into a large space, in consequence of the repulsion existing between its own electrified particles" (17).

Elsewhere Cavallo proceeded to obtain a semi-quantitative measurement of aerosol conductivity. Suspending a cork-ball electrometer over the prime conductor of an electrostatic machine, he noted that the balls did not diverge. But putting "upon the prime conductor a wax-taper just blown out, so that its smoke may ascend to the electrometer . . . the balls . . . will immediately separate a little . . . which shows that smoke is a Conductor in a small degree" (18). (An electrometer is an instrument consisting of two cork balls suspended from a common point by insulating threads. Like charges on the balls cause them to diverge. See Fig. 7.)

A few decades later Michael Faraday could speak of "the power of particles of dust to carry off electricity in cases of high tension" as being "well known," (19) and cautions that high-voltage apparatus "be perfectly free from dust or small loose particles, for these very rapidly lower the charge and interfere on occasions when their presence and action would hardly be expected" (20).

#### The Dust Controversy and Gaseous Conductivity

The problem of the electrification of dust, without specific reference to intentional electrodeposition, played a curious role in the history of gaseous electronics. Coulomb, who in 1785 investigated the loss of electricity from a charged body suspended by in-

Fig. 7. Illustrations of Cavallo's apparatus (17). In the electrostatic machine, Fig. 1, the earlier manually rubbed glass sphere has been replaced by a cylinder F rubbed by a silk cushion G stuffed with hair. Charge is drawn off onto the prime conductor, Fig. 2, by means of the corona points L. Fig. 4 C shows a cork-ball electrometer.

sulating strings, thought that after allowing for leakage along the supports, some lost charge still remained to be accounted for by a convective discharge through the air (21). Convective discharge or electrical convection were the terms applied to the passage of electricity from one place to another by the motion of charge-bearing particles of ordinarily uncharged matter, e.g., gas molecules, dust, etc. Coulomb supposed that air particles in contact with a charged body acquired an electrical charge of the same sign as the body and that the particles were then repelled by the body. Accordingly, molecules of air could be charged with electricity, much like bits of metal.

Here and there an occasional question was raised regarding the validity of this charging theory. Faraday, though voicing some reservations, went along with the prevailing belief. Kinnersley and Franklin had objected more strongly. As Priestly tells us, "Mr. Kinnersley of Philadelphia, in a letter dated March 1761, informs his friend and correspondent Dr. Franklin, then in England, that he could not electrify anything by means of steam from electrified boiling water; from whence he concluded that, contrary to what had been supposed by himself and his friend, steam was so far from rising electrified that it left its share of common electricity behind" (16, 22).

In time, however, experimental data accumulated which seemed to be explicable only on the hypothesis that molecules of gases or vapors resisted electrification. Warburg in 1872, supported by Nahrwold in 1887, adduced compelling evidence that the loss of charge from an isolated electrified body could be accounted for by the presence of dust in the ambient air (23, 24). These researchers held that it was the dust and not the air striking the charged body that was responsible for carrying off the electricity. In this newer view the dust did not even have to be present in the original air. It might, it was believed, be given off by the charged conductors under investigation. Thus, Lenard and Wolf demonstrated in 1889 that when ultraviolet light fell on a negatively electrified platinum surface, a steam jet in the neighborhood of the surface showed by its change of color that the vapor had been condensed (25). Lenard and Wolf attributed the condensation of the jet to dust or metallic vapor emitted from the illuminated surface, the dust producing condensation by forming nuclei around which the water droplets coalesced. The experimenters were, of course, observing the photoemission of electrons from the metallic surface by means of a primitive cloud chamber. But being unaware of the existence of electrons or gaseous

ions and supposing that dust was indispensable to droplet condensation, Lenard and Wolf were led to conclude that the metal was disintegrating under the action of the light, the metallic vapor carrying off the negative electricity and leaving behind the positive. The belief that air molecules could not be charged was further supported by the experimental results of Blake in 1882 and Sohncke in 1888 (26, 27). These studies seemed to show that not only is there no electricity produced by the evaporation of an unelectrified liquid, but also that the vapor rising from an electrified liquid does not carry a charge. It was natural enough to argue that if molecules of vapor are capable of receiving a charge under any circumstances, they should be expected to do so in this case.

Lord Kelvin and Magnus MacLean further observed in 1894, "That air can be electrified either positively or negatively is obvious from the fact that an isolated spherule of pure water, electrified either positively or negatively, can be wholly evaporated in the air . . . This demonstrates an affirmative answer to the question, can a molecule of gas be charged with electricity? It shows that the experiments referred to as pointing to the opposite conclusion are to be explained otherwise" (28). Despite this, F. Braun could write as late as 1896, "The question of whether a gas can be electrified is answered mostly in the negative, at least among German investigators. All phenomena indicating the possibility of electrification can be explained by the presence of dust particles that might have been contained in the gas from the outset or else introduced during the process of electrification" (29). It was not long, however, before the last vestige of doubt on this score was eliminated. X-rays were discovered in 1895. Almost immediately J. J. Thomson, at the head of a brilliant group of young scientists at the Cavendish Laboratory of Cambridge, undertook to answer the question of how dust-free gases are made conductive by the new radiation. It was quickly found that gas rendered conducting this way lost all its conductivity when filtered through glass wool or traversed by a current-producing electric field. The conclusion was inevitable that gaseous conductivity was due to the presence of electrified particles. These particles were called ions by analogy with the term coined by Faraday in 1834 with reference to the charge carriers of electrolytic solutions (30).

### Practical Electrodeposition

Credit for the earliest electrodepositional device comprising both a corona discharge electrode and a particle-collecting surface belongs to a German teacher of mathematics, M. Hohlfeld. Having observed in thunderstorms that increased rainfall usually followed closely after lightning discharges, Hohlfeld speculated in 1820 that electric discharges simulated in the laboratory might produce a corresponding effect. Filling a bottle with smoke from burning paper, he "corked the bottle, passing through the cork a wire . . . extending to within three inches of the bottom of the bottle. The . . . [wire] was connected to . . . [an electrostatic machine] so that the electricity was silently transferred into the bottle and brought in contact with the smoke . . . With the passing of the first spark the smoke vanished, the water from the smoke appearing on the bottom of the bottle" (31).

Hohlfeld evidently thought that a spark discharge was required to achieve his purpose because he was trying to simulate thunder. That a (relatively) silent corona would accomplish the same result was reported 30 years later by C. F. Guitard, unaware that any attention had previously been drawn to the subject. In his words: "It . . . struck me, that if I brought a wire from an electrifying machine into . . . [a glass] cylinder [filled with tobacco smoke] the air would immediately become charged with electricity, which would cause each portion of smoke to fly to the

sides of the cylinder . . . The [experimental] effect produced was perfectly magical; the slightest turn of a small electrifying machine produced immediate condensation. It was astonishing to see how small a quantity of electricity produced a most powerful effect" (32).

Experimental studies of the behavior of aerosols in electric fields, with or without a corona discharge, are seen to have been pursued sporadically and largely independently by workers in several countries from 1600 on into the 19th Century. But not until 1883 do we find the proposal put forth (by Oliver Lodge, professor of physics at University College, Liverpool) that the charging and precipitation of dust in a corona might offer an effective means of suppressing atmospheric contamination (33). In 1870, John Tyndall, the British physicist whose name brings to mind the well-known light-scattering effect, had noted that a dust-free space formed over a hot body in strongly illuminated dusty air. Further study of this phenomenon, which is now known to be a consequence of differential molecular bombardment (radiometry), was undertaken by Oliver Lodge. Professor Lodge's lecture demonstrator, J. A. Clark, hypothesized that air streaming over a hot surface might become electrified by friction, and that from air so charged, dust could somehow be expelled. To test this supposition, a rod mounted in a smoke-filled box was raised to a few thousand volts. With the appearance of corona "a very violent and remarkable effect was noticed; the . . . [clear region] widened enormously and tumultuously and the whole box was rapidly cleared of smoke" (34). Electrical precipitation had once again been brought to light.

In a letter to *Nature* in 1883 in which he announced Clark's discovery, Lodge, unlike his predecessors, went on to suggest several practical ideas. "It is somewhat surprising," he noted, "considering the perfection to which electrostatic machines have been brought that they have not received any practical application. The electrical clearing of the air of smoke rooms, or of tunnels, is perhaps not an impractical notion. The close relationship between fogs, epidemics, &c., and the suspension of solid particles in the air, suggests the use of electrical means for sanitation and for weather improvement" (33).

Lodge's first thoughts centered on treatment of the already polluted atmosphere rather than on the true offender, the actual sources of pollution. A proposal that this latter approach might offer the solution to a vexing problem was made by Alfred Walker, a lead smelter who, with Lodge's advice, promptly undertook the construction of a full-sized precipitator at his furnaces in Bagillt in Wales (35, 36). Here, Lodge recalled years later, clouds of lead oxide fume had been escaping into the air "to the damage of the neighboring agriculture. But the method of producing high-tension electricity in those days was rather primitive, and by no means of an engineering character. [The 50-kv, 0.3-ma Wimshurst machines which had then only recently been developed, and of which much was expected, proved to be less than satisfactory for the application at hand.] Moreover, the difficulties of insulation were not properly appreciated. . . . It is doubtful if any real electrification was communicated to the flues, along which the hot, flaming, and smoky gases were rushing at a considerable pace from the smelting furnaces: so that the first attempt at practical application was unsuccessful, and . . . was discontinued" (37).

There is some question as to whether Walker would have succeeded in any case. Modern experience has shown that the highly resistive, finely divided, lead oxide fume is one of the most troublesome of aerosols to precipitate.

Lodge was not dismayed by the disappointing outcome of Walker's attempt. Over the ensuing years, with his son, he carried forward his researches. But despite his many large-scale experiments leading to

various improvements (e.g., introduction of the transformer and tube rectifier and development of suitable high-voltage insulators), the technical breakthrough on which the birth of a new industry hinged was to be made elsewhere.

The widespread publicity attendant on the investigations of Lodge and his associates stimulated activity by others. Over the next two decades, in addition to Walker's patents in half a dozen countries, additional patents and an occasional publication served to keep alive interest in the "electrical condensation" of smoke. It remained ultimately for Frederick Cottrell, professor of physical chemistry at the University of California, to bring to fruition the process of electrostatic precipitation that now bears his name. Avenues of technical communication open to Cottrell at the turn of the century were so far from adequate that not until he constructed his first commercial precipitator did he become aware of Lodge's work antedating his own by some 20 years. Cottrell himself appears to have had no clear-cut recollection of how the idea of precipitation came to him. Nevertheless, he fully acknowledged Lodge's priority and characteristically minimized his own considerable contribution (38). Writing in 1914 of his introduction to the subject, Cottrell had this to say: "Some eight years ago, while studying various methods for the removal of acid mists in the contact sulphuric process . . . the author had occasion to [independently] repeat the early experiments of Lodge and became convinced of the possibility of developing them into commercial realities. The subsequent work may fairly be considered as the reduction to engineering practice as regards equipment and construction of the fundamental process long since laid open to us by the splendid pioneer work of Lodge, a feat vastly easier to-day than at the time of Lodge and Walker's original attempt" (39).

In 1907, following impressive laboratory demonstrations, Cottrell set out "to duplicate these experiments on a scale some two hundred-fold larger. This was carried out . . . at the E. I. duPont de Nemours Powder Co. at Pinole, on San Francisco Bay, where the contact gases from one of their . . . sulphuric acid units were employed" (39). The operation was an unqualified success.

### Epilogue

Practical electrostatic precipitation on a commercial scale had been born. In a much broader sense, though, the accumulated effort of the preceding two millennia and more now heralded an era in which particulate electrodeposition and separation were to find commonplace and diverse application. The subsequent explosive industrial expansion of fine particle electrostatics calls to mind Lodge's prophetic words before the Royal Dublin Society in 1884: "Whether anything comes of it [electrodeposition] practically or not, it is an instructive example of how the smallest and most unpromising beginnings may, if only followed up long enough, lead to suggestions for large practical application. When we began the investigation into the dust-free spaces found above warm bodies we were not only without expectation, but without hope or idea of any sort, that anything practical was likely to come of it . . . [And so] it may happen that the yet unapplied and unfruitful results evoke a sneer, and the question . . . ["What good is it?"] the only answer to which question seems to be: No one is wise enough to tell beforehand what gigantic developments may not spring from the most insignificant fact" (40).

Developments in recent decades in the application of particle electrostatics have indeed been impressive: among typical electrodepositional or separating devices may be numbered mineral and foodstuff separators, electrostatic flock coaters and particle orientors, electrostatic painting, coating, and printing devices, gas and liquid filters, and still others. But

these achievements of the more recent past comprise a story of their own, one that is told, under appropriate headings, in other papers of this series.

### Acknowledgments

The author is indebted to George A. Carkhuff whose careful photographic work under adverse conditions provided the illustrations for this paper, and to the Institute of Electrical and Electronic Engineers and the American Institute of Physics in whose publications portions of this history have previously appeared.

Manuscript received Nov. 28, 1967. This paper was presented at the Chicago Meeting, October 15-19, 1967 as Abstract 144.

## SECTION NEWS

### Boston Section

The Boston Section held its second meeting of the 1967-1968 season at the Ledgemont Laboratory of the Kennecott Copper Corp., Lexington, Mass., on November 14, 1967.

Mr. Ralph B. Soper was presented with a Past-Chairman's pin in appreciation of his services in that office during 1966-1967.

The speaker for the evening was Ivor E. Campbell, Vice-President of The Electrochemical Society, who spoke on "Vapor Deposition, Past, Present, and Future." Dr. Campbell reviewed the development of vapor deposition processes, their present commercial status, and opportunities for further utilization. The relative advantages of chemical and physical vapor deposition were discussed as well as the relationship of these processes to other coating processes.

Secretary

### Cleveland Section

During the year 1967-1968 the Cleveland Section, as usual, has had a wonderful year of programs arranged by Program Chairman R. J. Brodd. Dinner meetings are held monthly on the second Tuesdays from September to June except in October and May when the National Meetings of the Society are in session.

The principle speakers and titles for meetings are as follows:

September—"Current Distribution on and in Porous Electrodes," R. J. Brodd, Union Carbide.

November—"Edison plus TEFLON—Application of New Material to Electrochemical Cells," G. Frysinger, U. S. Army Electronic-Command.

December—"A Chemical View of Semiconductors," D. Trivich, Wayne State University.

January—"Conduction and Electroluminescence in Oxide Films," T. W. Hickmott, I.B.M. Corp.

February—"Electrochemistry and Reactive Intermediates in Electrosynthesis in Nonaqueous Solvents," M. E. Peover, National Physical Lab., Teddington, England.

March—"The Influence of Adsorp-

tion on Electrode Reactions at the dropping Mercury Electrode," J. Kuta, Heyrovsky Polarographic Institute, Czechoslovakia.

April—"Between Science and Art—Recent Research in Nonaqueous Solvents and Electrochemical Calorimetry," R. T. Foley, American University.

The June meeting will be "Ladies Night" with a subject of general interest.

It has been a custom of the Cleveland Section to have a short after dinner talk at each meeting. The subjects for the year are of great variety, ranging from "Recent Advance on CdS Thin Film Cell," by W. Bower, "Comments on the World-Wide Chlorine Industry," L. E. Vaaler, "Some Recent Developments in Electroplating," K. Willson, to "Society Affairs," by Vice-President N. Corey Cahoon.

T. S. Lee,  
Secretary

### Detroit Section

The annual joint dinner meeting of the Detroit Section and the National Association of Corrosion Engineers was

### The Study of Surface Chemistry by the Mossbauer Effect\*

M. C. Hobson, Jr.

*Virginia Institute for Scientific Research, Richmond, Virginia*

To define a surface precisely is difficult, to measure its properties, arduous. A single crystal provides a close approximation to a known surface. But experimental difficulties obtain because of the minute amount of material provided by the surface atoms of a single crystal. If the knowledge of the surface geometry provided by single crystals can be abandoned, some of the difficulties can be overcome by dispersing the material in the form of microcrystals having high surface to bulk atom ratios. Samples of this type may or may not be supported on inert material with a high surface area, but, in either case, an increasing number of instrumental techniques become applicable to the study of surface chemistry by virtue of the increase in the quantity of surface atoms present. One of these, Mössbauer Effect spectroscopy, is capable of supplying us with much detailed information on surface structures; information often difficult, if not impossible, to obtain by any other experimental method.

The Mössbauer Effect is the name given to the recoilless emission and resonant reabsorption of low energy gamma rays, and was discovered by Rudolf Mössbauer in 1958. It was rapidly recognized as a powerful and versatile technique for the study of the physical properties of matter; particularly, for the study of the structure of solids. Since several excellent reviews have appeared recently on the basic physics of the technique only those points that apply to an understanding of the chemical information that can be obtained from the measurements will be discussed. Applications of the technique will include studies on the valence states of surface atoms, chemisorption on surfaces, size measurements on microcrystals, lattice dynamics of surface atoms and, an allied area, the structure of surface layers much more than one atom thick, but having properties that differ from the bulk.

The most important property of a Mössbauer gamma ray is its very narrow line width. The sharpness of the absorption band not only permits high resolution of hyperfine interactions, but it also permits a simple modulation technique for sweeping the gamma ray energy through resonance; namely, by using the Doppler Effect. By starting at zero velocity and moving the source or the sample relative to the other through a range of velocities to a maximum of a few mm/sec the gamma ray energy is modulated by many times its line width and spectra containing multiple resonance absorptions are readily observed. These resonance absorptions may be observed experimentally in either of two geometrical configurations as shown schematically in Fig. 1. Illustrated in diagram A is the usual arrange-

ment for studying thin samples by transmission. An absorption spectrum is obtained which manifests itself as a drop in the count rate on passing through resonance as the velocity is varied. As shown in diagram B the primary gamma radiation is not observed directly, but the absorbed gamma rays are observed on re-emission. A plot of count rate *vs.* velocity results in an increase in the count rate on passing through resonance and an emission spectrum is obtained.

There are some 34 or more elements for which the Mössbauer Effect has been observed and a number of others for which it is predicted. All together about half the elements in the periodic table should exhibit the effect, but, in practice, only a few elements can be studied readily outside of laboratories having very large radiochemical facilities. Currently the most useful isotopes are iron-57, tin-119, antimony-121, iodine-127, iodine-129, and gold-197. Unfortunately, the effect is not found in any of the lighter elements in the periodic table up through argon.

The changes that take place in Mössbauer spectra of different compounds of the same element are the result of hyperfine interactions between the nucleus and the extranuclear electrons. For chemical applications the most useful observables are the chemical shift, the electric quadrupole splitting, and the magnetic dipole splitting (Zeeman splitting). In discussing these we will assume the nuclear ground state has a spin of 1/2 and the excited state a spin of 3/2; a situation which occurs frequently among Mössbauer nuclei.

The chemical shift,  $\delta$ , is a consequence of the finite size of the nucleus. The common practice of assuming a point charge for the nucleus is not a valid approximation for this type of measurement. Since the gamma ray emitted by the nucleus represents a change in the electrostatic energy of the nucleus on going from a higher to a lower energy level those parameters which affect the nuclear energy levels will govern the energy of the gamma ray. One of these is the radius of the nucleus which is usually different for each energy level. The other is the electron density at the

nucleus resulting from its finite size. The relationships are given by

$$\delta = \left[ \frac{4}{5} \pi Z e^2 R^2 \right] \cdot \frac{\Delta R}{R} \cdot [\Delta |\psi_0|^2]$$

where the first term on the right is a collection of physical constants, the second, the change in the radius of the nucleus on going from the ground to the first excited state and the third, the difference between the wave function that gives the electron density at the nucleus of the source and the wave function that gives the electron density at the nucleus of the absorber. Therefore, the gamma ray energy is directly proportional to the electron density at the nucleus and the change in the radius of the nucleus on undergoing a transition. The change in radius is a characteristic of the isotope, but the electron density will vary with chemical changes that the element may undergo. The latter effect is produced primarily by s-electrons and indirectly by p and d-electrons via their screening effects on the s-electrons. The maximum change in the electron density at the nucleus on going from one valence state to another will not result in energy shifts large enough to measure directly, but it is relatively easy to measure the difference in the shifts between a standard and an unknown. Single crystals of sodium nitroprusside have been adopted by the National Bureau of Standards as reference material for Mössbauer studies on Fe-57. The term differential chemical shift,  $\delta_0$ , has been proposed for reporting spectral shifts relative to standard sodium nitroprusside.

When the nuclear spin quantum number,  $I$ , is greater than  $1/2$  the nucleus is not spherically symmetrical and the nuclear quadrupole moment takes on non-zero values. Coupling of this quadrupole moment with the gradient of an unsymmetrical electric field lifts the nuclear spin degeneracy and additional peaks appear in the spectrum. For the case of  $I = 3/2$ , the excited state of Fe-57, and an axially symmetric electric field gradient this energy level splits into an upper and lower level. The absorption peak splits into a symmetrical doublet and the magnitude of the splitting between the two peaks is a measure of the coupling of the excited nucleus with the electric field gradient. For this special, but often observed, case the energy difference between the two peaks is given by

$$\Delta E_Q = \frac{e^2 q Q}{2}$$

where  $Q$  is the nuclear moment and  $eq$  is the electric field gradient. These two quantities are independent and to obtain the value of one of them the other must be either calculated or measured by another experimental method; a situation similar to the interpretation of the chemical shift. Once the value of the nuclear quadrupole moment is established the splitting may be used to calculate the magnitude of the electric field gradient. The presence of more than one type of crystallographic site and the structure of the orbitals used in the bonding of the compound may be deduced from these data in some cases.

Finally, the presence of an internal magnetic field will cause a hyperfine Zeeman splitting of the nuclear energy levels similar to the splitting observed for unpaired extranuclear electrons in an applied magnetic field. Again consider the case of the iron  $1/2$  to  $3/2$  transition. The spin  $1/2$  level will split into two substates and the spin  $3/2$  split into four substates. The transitions are governed by the selection rules for magnetic dipole transitions; namely,  $\Delta m = 0, \pm 1$  and six equally spaced lines are observed. If an electric field gradient is superimposed on such a spectrum, the spacing between the peaks will no longer be equal. The effect is complex, and information on the quadrupole coupling cannot be deduced without independent knowledge of the crystal structure and the relationship between the electric field gradient and the magnetic field.

The problems associated with applying this technique to the study of surface structures are those generally applicable to all resonance absorption methods used in the investigation of surfaces. The amount of material on the surface is small compared to the bulk which makes it difficult to resolve those features in the spectrum unique to the surface structures. To overcome this measurements are made on very porous materials, or materials highly dispersed on the surface of porous materials. However, the Mössbauer Effect, by virtue of its radioactive nature, has a certain versatility not common to other spectroscopic methods. Not only can it be applied to systems of a highly dispersed nature, but the surfaces of single crystals can be studied as well. If the radioactive nuclei, that normally are the source of the  $\gamma$ -rays, are deposited on the surface of a single crystal in a monatomic layer or less, the structure and chemical bonding of the atoms in this surface source may be studied using a standard absorber. The former type of measurement has been carried out in our laboratory utilizing the Fe-57 isotope dispersed on alumina and on silica gel (1, 2).

Highly dispersed samples of metals or metal oxides are commonly prepared by impregnating a porous material; such as, silica gel or alumina, with a salt of the metal that can be readily decomposed thermally. The catalytically active surface is obtained by calcination followed by oxidation-reduction cycles as desired. Shown in Fig. 2 is a typical example of iron-on-alumina. The sample is 23% iron and the top spectrum is the initial preparation following a calcination at  $500^\circ\text{C}$ . In this form the iron exists as  $\alpha$ -ferric oxide with an average crystallite diameter of  $300\text{\AA}$  as determined by x-ray line broadening. The six line Zeeman pattern produced by the antiferromagnetic structure of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> is superimposed on a doublet in the center of the spectrum. The doublet has a differential chemical shift of  $+0.51$  mm/sec and a quadrupole splitting of  $1.07$  mm/sec. These values fall in the general range for high-spin ferric compounds, and the doublet is believed to represent  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> crystallites so small that the magnetic field has collapsed.

Reduction of the oxide to magnetite is easily done in flowing hydrogen at temperatures in the  $200^\circ$  to  $300^\circ\text{C}$  range. The identification of the magnetite struc-

Fig. 2. Spectra of an  $\text{Fe-Al}_2\text{O}_3$  catalyst undergoing an oxidation-reduction cycle. 1. initial preparation, 2. partial reduction to magnetite, 3. completed reduction to metallic iron, and 4. re-oxidation to ferric oxide.

ture by the Mössbauer spectrum is evidenced by a splitting of the six line Zeeman pattern into two partially superimposed Zeeman patterns as seen in the second spectrum. Further reduction is more difficult, but the third spectrum in Fig. 2 is obtained after a prolonged treatment at  $500^\circ$  to  $600^\circ\text{C}$ . The change in the positions of the six lines of the Zeeman pattern indicates the formation of a metallic iron phase. At the same time the doublet has increased in relative size and shifted in a positive velocity direction. Its differential chemical shift is  $+0.98$  mm/sec and its quadrupole splitting is  $1.73$  mm/sec. These values and the relatively large size of the doublet indicate that a large fraction of the total amount of iron present is in the form of ferrous ions; probably, a ferrous oxide. Further treatment in flowing hydrogen does not change this spectrum. The phase containing the ferrous ions appears to be stabilized by the surface of the alumina making the complete reduction to the metallic state impossible. This state of affairs has been suspected in previous studies of supported iron catalysts, but never established since the ferrous phase has not been found in x-ray diffraction analysis of similar samples.

The fourth spectrum in Fig. 2 is obtained on re-oxidation of the sample. The positions of the peaks in the six line Zeeman pattern and the differential chemical shift and quadrupole splitting of the doublet are similar to the initial spectrum. However, the relative size of the doublet compared to the Zeeman pattern has changed drastically. Could it be that the structural details observable by Mössbauer spectroscopy will make it possible to determine the thermal history of any given sample? The deactivation of a catalyst during use is a continuing industrial problem. Irreversible structural changes as observed here certainly suggest that the technique may be useful as a quality control method and further investigation in this area seems worthwhile.

The surface effects can be made to stand out quite sharply by using very dilute solutions enriched in Fe-57 for the preparation of the samples. Very small crystallites that are highly dispersed over the surface can be obtained, and consequently a high surface to bulk atom ratio. In these samples only a doublet is obtained similar to the doublet in the middle of the bottom spectrum in Fig. 2. Usually the quadrupole splitting is large and the chemical shift less positive for the smaller crystallite sizes. On reduction in flowing hydrogen above  $400^\circ\text{C}$  the doublet transforms into an unsymmetrical triplet with a general shifting of the spectrum in a positive velocity direction as shown in the top spectrum of Fig. 3. This triplet appears to be the superposition of two doublets. The values of the differential chemical shift and quadrupole splitting for the one consisting of peaks 1 and 2 are characteristic of high-spin ferric ions, and for the other, peaks 1 and 3, high spin ferrous ions. On adsorption of ammonia spectrum B is obtained. Peak 2 has almost vanished and the splitting between peaks 1 and 3 has increased indicating additional polarization of the 3d electrons.

Kinetic studies on ammonia decomposition over iron catalysts indicate that dissociative chemisorption of ammonia takes place. If one assumes that ammine radicals are formed by chemisorption of ammonia on this catalyst, then peak 2 of spectrum A is probably produced by a high-spin ferric state. The ammine radical, with its strong tendency to donate electrons to the adsorption site, complexes with the 3d orbitals of the ferric ions and produces a high-spin ferrous complex on the surface, as indicated in spectrum B. The reversible nature of the surface complex is demonstrated by obtaining spectrum C on out-gassing the sample.

Adsorption on the surface has also been studied from the standpoint of the adsorbate instead of the adsorbent. Karasev and co-workers (3) adsorbed tetramethyl tin on  $\gamma$ -alumina and observed the

Fig. 3. Spectra of ammonia chemisorption on a highly dispersed  $\text{Fe-SiO}_2$  sample. (A) initial sample reduced in  $\text{H}_2$ , (B) after adding  $\text{NH}_3$  to 1.35 Torr, and (C) after outgassing at  $100^\circ\text{C}$ . (Ref. 2).

formation of a doublet. They interpreted this result in terms of two different chemisorbed species, each producing a singlet rather than the quadrupole splitting of one species to produce the doublet. One peak results from the reaction of the tetramethyl tin with surface hydroxyl groups with the formation of methane and leaving tin in a position on the surface normally occupied by an aluminum ion. The other peak is produced by dissociative chemisorption to form hydrogen and an aluminum-methyl-tin surface complex.

Similar studies could be made using volatile compounds of iodine for the adsorbate. Both I-127 and I-129 isotopes are usable for Mössbauer Effect studies. The technique is very attractive for further studies on the structure of surface complexes.

The catalytic activity of supported metals is more complex than would be expected for a simple picture of small crystallites of the metal resting on the surface of an inert support. To gain insight into the nature of these catalysts one needs to know the surface area of the metal and the size and size distribution of the metal crystallites. Magnetically ordered structures, such as iron and some of its oxides, produce six line Zeeman patterns. However, there is a critical size below which the magnetic ordering cannot be maintained and the six lines collapse into a doublet. Since this effect is also a function of temperature an average crystallite size can be obtained by observing the per cent area under the doublet *vs.* the Zeeman pattern in spectra similar to the bottom one in Fig. 2, and when the ratio is 1:1 a calculation of the size can be made. Kündig and co-workers (4) have developed this method and applied it to microcrystalline ferric oxide on silica gel. In fact, a number of Mössbauer studies have been made on microcrystalline materials, and many of these are discussed in ref. (4). With the exception of Kündig's extensive investigation, correlations with surface properties were not made directly, but only implied.

A second method, also proposed by Kündig, is based on the observation that the magnitude of the splitting of the doublet appears to increase with decreasing crystallite size. This is a particularly interesting observation since it would be usable for microcrystallites smaller than those which can be measured by x-ray line broadening, and it becomes important when all of the crystallites are so small that no Zeeman pattern is observed. We have proposed a simple mathematical model for calculating the average crystallite size from the magnitude of the quadrupole splitting observed for the doublet. The observed splitting is calculated as the weighted sum of the theoretical splitting produced in the iron nucleus of an iron ion on the surface with one oxygen ion removed from its coordination sphere plus the splitting of an ion in the bulk. The weighting factors consist of the ratio of the volume of a spherical shell containing the surface iron ions to the total volume and the volume of the rest of the interior of the sphere to the total volume. As the particles become smaller the amount of iron in the surface shell to that in the bulk becomes larger and, consequently, the splitting of the doublet increases. Kündig has made similar estimates, but obtained his results by an empirical fit of the data rather than calculation from a model. On plotting the results for known samples we find that the fit of the data to the theoretical curve is good for ferric oxide on silica gel, but only fair for ferric oxide on alumina. However, there is some question as to the extent of interaction with the support when the crystallite size becomes so small that a large fraction of the iron ions are on the surface of the crystallite. In both of the methods outlined above the result is critically dependent on the assumption that the observed doublet is produced by, and only by, the small size of the alpha-ferric oxide crystallites. Any interaction with the support has been ignored. This assumption is far from being firmly es-

tablished. Certainly, the changes found in the sequence of spectra in Fig. 2 demonstrate that one does not recover the identical starting material following an oxidation-reduction cycle. Since iron ions can replace aluminum ions in the alumina lattice it is not surprising that these drastic changes are observed for iron-on-alumina samples, but not for iron-on-silica samples. However, some features of the iron-on-silica spectra do change; such as, an increase in the splitting of the doublet on undergoing an oxidation-reduction cycle. It does not seem possible to derive these changes from a sintering process. The crystallites seem to be growing smaller rather than larger, contrary to expectations. Perhaps it will be necessary to abandon the concept of very small, highly dispersed crystallites, and correlate catalytic activity with the features of the spectra rather than structures derived from the spectra. The question begs further investigation.

The highly dispersed systems discussed so far suffer from a valid criticism. They cannot be considered as "clean" surfaces with known crystalline surface structure. For fundamental studies of bonding and lattice dynamics carefully prepared surfaces of single crystals must be used. It is possible to employ the Mössbauer Effect in the study of surfaces of single crystals by depositing the gamma ray source on the surface and using a known single line absorber; such as, a stainless steel foil. The only published work in this area has been reported by Burton and Godwin (5). They deposited Co-57 by vacuum evaporation on the surfaces of tungsten and silver and recorded the spectra of the gamma rays emitted in a direction normal to the surface and at an angle  $60^\circ$  from the normal. They considered three possible situations which would affect the recoil free fraction of the gamma ray emission. For a nucleus bound in a lattice the recoil free fraction will be smallest along the direction of largest displacement. In the bulk of a cubic crystal this will be isotropic and a single line is obtained which does not change with orientation of the crystal. If the nucleus is just in the surface, its largest displacement will be normal to the surface and the lowest intensity for the absorption peak will be normal to the surface. However, if the nucleus is on the surface, its largest displacement will be parallel to the surface and the intensity smallest in that direction.

The result obtained by Burton and Godwin for a polycrystalline tungsten surface is shown in Fig. 4. The observed spectrum is found to be the sum of three components with the middle line caused by atoms that diffused into the bulk. The doublet is the result of the coupling of the nuclear quadrupole moment with an electric field gradient axially symmetric to the normal of the surface. The asymmetry of the doublet may be attributed to the angular dependence of the intensities of the two transitions. The spectrum observed at  $60^\circ$  from the normal is similar, but the relative intensities of the components has changed. The decrease in the low velocity peak relative to the high velocity peak indicates that the electric field gradient is negative. When the experiment was repeated using the (310) surface of a single crystal of tungsten the bulk component disappeared. The lack of grain boundaries in the single crystal presumably prevents the diffusion into the bulk under the conditions of sample preparation.

Using a single crystal of silver as the substrate a broad peak was obtained, but no angular dependence was observed. The authors suggest that this might be caused by poor surface preparation, or by the collection of the cobalt atoms into small islands. The combination of Mössbauer Effect measurements and low energy electron diffraction measurements simultaneously on a given system of this type would be a natural extension of this work. The LEED measurements would indicate the type of surface lattice the evaporated cobalt atoms had formed, or if they had formed dispersed islands, and the Mössbauer measure-

Fig. 4. Spectra of Co-57 vacuum evaporated onto polycrystalline tungsten, measured at 100°K. (Ref. 5).

ments would give information on the type of bonding and the magnitude of the lattice vibrations on the surface. At present the latter cannot be obtained with much precision from intensity measurements of LEED patterns. Although this approach has been suggested by several workers, nothing on these highly complementary measurements has, as yet, been reported in the literature.

Closely allied to the surface itself is the formation of thin films on a surface. These may be corrosion products, deposited material, or metallurgical samples that have been treated in some manner that is expected to change the structure of a surface layer relative to that of the bulk. For such samples an interesting modification of the experimental technique may be used to advantage.

Instead of observing the absorption of the gamma radiation on passing through the sample the detector is placed to one side of the sample and shielded from the gamma ray source. The nuclei that absorb the radiation have a short half-life in the excited state and then re-emit the radiation on decaying to the ground state. The detector observes the re-emitted radiation, and one obtains an emission spectrum as opposed to an absorption spectrum obtained by the usual technique of transmission. The low energy gamma rays that will reach the detector without additional scattering will be those from a thin surface layer. In the case of iron the thickness of the detected layer may be reduced many fold by preparing the sample with enriched Fe-57 on the surface.

It is seldom easy or desirable to prepare samples of optimum thickness for transmission spectra; e.g., 0.5 to 1.0 mils for iron, when studying corrosion or metallurgical processes. For thicker samples, if a

Fig. 5. Spectra of the same sample run in the two experimental modes illustrated in Fig. 1. Top corresponds to diagram A and bottom, to diagram B.

transmission spectrum can be obtained at all, the peaks will be broadened, and, consequently, there is a loss in resolution. In the backscatter method the resolution is inherently better for such samples since thickness broadening is not a factor. Comparison of the two methods is under study in our laboratory, and an example of a highly alloyed steel is shown in Fig. 5. The sample was approximately 4 mils thick. The loss in resolution from thickness broadening in the absorption spectrum compared to the emission spectrum is quite evident. A disadvantage which is not obvious in this illustration is the low counting rate that occurs in the backscatter geometry. Thus, it takes much longer to obtain an emission spectrum comparable to one obtained by transmission. Nevertheless, one can visualize a number of applications in which sample preparation is an important part of the experimental problem and the backscatter method the best answer. Publications from several laboratories working on this technique may be anticipated in the near future.

The application of Mössbauer Effect spectrometry to chemical problems is in its infancy, and this is particularly true in the studies on surface chemistry. The existing literature on its application to surface studies is, at best, meager. However, the examples discussed herein demonstrate the power of the technique for producing detailed information on structure and bonding in surfaces that would be difficult, if not impossible, to obtain by any other method. This additional information permits a deeper insight into the fundamental processes taking place in surface reactions. Exploitation is recommended.

Manuscript received Dec. 11, 1967; revised manuscript received Jan. 11, 1968. This manuscript was based on an invited lecture presented at the Chicago Meeting, October 15-19, 1967 as paper 69.

# The Scientific Society Through the Centuries<sup>1</sup>

Harry C. Gatos<sup>†</sup>

*Massachusetts Institute of Technology, Cambridge, Massachusetts*

I would like to share with you this evening some thoughts and observations on the scientific societies as they have functioned and evolved in years past. I found it rewarding to view the present day societies, including our own, in the light of their intellectual origins. Furthermore, I subscribe to the view that in planning the future there is much gain to be derived from examining the past.

In reflecting on, and tracing its origin, it becomes immediately apparent that the scientific society was the springboard for the scientific and engineering revolution that set apart the last three centuries from the rest of human history. In many important aspects it has served as the central stage on which the scientific tale has unfolded.

It is certainly tempting to ask whether such a stage was a predetermined consequence of the emerging science or whether it was conceived by some visionaries who proceeded to recruit potential protagonists and provided the catalytic actions necessary to overcome the barriers of past centuries. Although there is an element of rhetoric in such a question there is indeed much to ponder over in both of its parts.

The scientific society as we know it now was distinctly established in the second half of the seventeenth century. Within about ten years three major scientific societies were organized in Europe: the Accademia del Cimento of Florence in Italy (1657), the Royal Society in England (1660), and the Academy of Sciences in France (1666). The simultaneous appearance of these societies at this particular time was certainly not a statistical coincidence. We must view it as the natural product of the times and as a manifestation of a broader intellectual revolution.

Before we look at the prevailing over-all climate and the specific circumstances that brought about the launching of the scientific society, it should be interesting to take a brief look at the scientific activities during the preceding centuries.

Very early civilizations like the Mesopotamian, Egyptian, Chinese, and Greek achieved truly high intellectual and technological levels. Yet in those

civilizations the scientific method of deliberate experimentation to complement concepts and theories did not reach the stage of an organized effort and, thus, did not achieve critical dimensions.

Plato's Academy in the fourth century B.C. can be considered as the first formal effort for communicating knowledge, for exchanging thoughts and for carrying out scientific research. The topics dealt with extended through all aspects of pure and applied philosophy; subjects of scientific nature were treated within the framework of the prevailing philosophical patterns. The informal approach to intellectual exchange did, without doubt, reach its zenith during that golden age of Athens where very long discussions on all types of subjects were held over eating and drinking sessions. Such sessions of dining and wining are called in Greek, Symposia. I must observe that our present day Symposia have degenerated into just technical sessions.

During the second century B.C. the Greeks came very close to setting off the scientific revolution which was not destined to come about until many centuries later. Archimedes had shown the way to the experimental application of natural principles in measuring the density of irregularly shaped objects. He also applied scientific principles to military developments in defending Syracuse from the attacking Romans. During that period there were large public libraries in many cities, the most famous of which was at the Museum at Alexandria. This institution's four departments, mathematics, astronomy, medicine, and literature were functioning much like research institutes and were served by 400,000 volumes, or rather rolls, the largest library of the ancient world.

Here is how the editors of *Life* magazine refer to this period in their "Guide to Science" (1967). "Theoretical knowledge was increasing along with practical technology, and each was stimulating the other in the modern manner. The Greeks of the Second Century B.C. were entitled to feel that they lived in a wonderful age of discovery when nature was yielding on every side to the power of human intellect. If this spirit had been maintained the present era of explosive change, which began about 1600 A.D. might have begun 1700 years earlier and perhaps the earth's first colony on the moon would have spoken Greek."<sup>2</sup>

But that spirit was not maintained and the Greeks were conquered by the practical minded Romans. Then followed the early stages of Christianity encouraging mysticism rather than the scientific approach. Then followed the dark ages, then the middle ages: in all seventeen centuries of intellectual stagnation.

Through all these periods Europe's scientific needs were formally served by the Aristotelian scientific system which through the years became totally rigid. In fact Aristotle's teachings were turned into mummies and were, thus, deprived from either natural erosion or development. There lived great individuals with far reaching ideas and fertile minds but they could not change the course of events. The communities at large were rendered completely sterile to the seeding of new forward looking thinking. Roger Bacon in the 13th century was outstanding among the visionaries and came forth with truly revolutionary teachings. Nothing, he proclaimed, should be accepted except through open-eyed observation and experimentation. But great minds and great ideas need a ready

environment to take hold. Bacon's environment needed three more centuries of seasoning. In his time scientific knowledge was not communicated nor was it discussed in the open. In fact the scientists were a mixture of sorcerers and chemists working in secret laboratories on the "philosophers stone" which would turn base metals into gold and "the elixir of life" which would prolong life indefinitely.

A sharp change in the scientific attitude can unmistakably be observed about 1600 A.D. I do not believe that a complete analysis of all the evolutionary and revolutionary forces that brought about the change can be formulated. It is clear, however, that central to this change and to the scientific revolution that followed was the conscious introduction of the scientific experiment not only as a means for testing principles, laws, or theories, but also as an end in itself.

This experimental attitude heralded by Roger Bacon and practiced by the great Leonardo da Vinci was adopted by a number of master scientists and their disciples during the second half of the 16th and the first half of the 17th centuries. The realization of the merits of the experimental approach and of its complexities brought scientists together. They became anxious to join forces and thus better plan the experiment, construct the needed instruments and carry out the measurement. It was on this basis that the first formal scientific society was born in Italy in 1657, the Accademia del Cimento of Florence, which means the Academy of Experiment. Here nine scientists joined their efforts and their hopes to develop and construct instruments to acquire experimental skills and to establish fundamental truths. Although the Accademia del Cimento is usually considered as the forefather of the scientific societies there were earlier scientific organizations in Italy. Among them was the Accademia dei Lincei in Rome, organized in 1603. The academicians carried out studies on insects and plants and collected natural objects. Galileo became its member in 1609 and constructed a microscope for the society which was the first ever to be used in the study of zoology. The proceedings of the society *Gesta Lynceorum* represent a very early systematic record of scientific studies. But the death of the Society's founder and patron Duke Federigo Cesi in 1630 and the events that led to the condemnation of Galileo brought the Academy's functions to an end.

The Accademia del Cimento is certainly a descendent of the Accademia dei Lincei. The two Medici brothers that sponsored the Accademia del Cimento were pupils of Galileo and of Galileo's renown disciples Viviani and Torricelli. The meetings took place in the Medici residence in a room which was essentially a research laboratory with the most modern equipment of the day. In 1667, ten years of experiments and results were published in the "*Saggi di naturali esperienza fatte nel Accademia del Cimento.*" This is a remarkable account of original experiments performed with respectable accuracy. Instruments such as thermometers and hygrometers are described in detail. The pendulum is presented as a tool for the precise measuring of time. Experiments dealing with the variation of atmospheric pressure and vacuum are discussed. Many other experiments are recorded intended to test the views of thinkers like Galileo and Torricelli.

The Accademia del Cimento ceased to function ten years after its foundation. Like the earlier smaller academies, it did not survive its sponsors. Yet its charter, its activities, and its records constitute a milestone in the maturing of scientific thought. Remarkable among the Academy's functions was its contact with science outside Florence. Distinguished scientists in other parts of Italy as well as in France and in England were elected corresponding members. In this capacity they were in effective communication with the Academy, exchanging information on experimental results and discussing their significance.

The Accademia del Cimento like the societies that followed, was primarily dedicated to performing of experiments and obtaining accurate measurements. But at the same time it developed a definitive mechanism for exchanging and developing scientific thought, for submitting it to objective testing and for communicating the result to the scientific community at large.

In other parts of Europe the climate was now also ready for detached scientific inquiry. In England, Francis Bacon in his fable "New Atlantis" put forth a "Solomon's House" whose riches consisted of ideal laboratories for experimental research and whose fellows would investigate all branches of human knowledge. Francis Bacon was certainly an immense intellectual force in establishing free scientific thought.

The Royal Society in England was established in 1660 following a long series of informal meetings of men deeply concerned with experimental knowledge. It was conceived and organized as a scientific society by private individuals rather than by the state; King Charles II established by Charter the Society as a Royal Society in 1662. However, this formal act was a mere recognition of the Society's mission. Here is how one of its founders John Wallis describes the Society's early activities: "Our business was (precluding matters of theology and state affairs) to discourse and consider Philosophical Inquiries and such as related there unto: as Physick, Anatomy, Geometry, Astronomy, Navigation, Staticks, Magneticks, Chymicks, Mechanicks, and Natural experiment; . . . We then discoursed . . . on the improvement of telescopes, and grinding of glasses for that purpose, the weight of air, the possibility of impossibility of vacuities, and nature's abhorrence theory, the Torricellian experiment in quick silver, the descent of heavy bodies and the degrees of acceleration therein; and diverse other things of like nature."

In the preamble to the King's charter all of the founders dreams and labors were given Royal acceptance and blessing: "And whereas we are informed that a competent number of persons of eminent learning, ingenuity and honour, concurring in their inclinations and studies toward this employment, have for some time accustomed themselves to meet weekly and orderly to confer about the hidden causes of things, with a design to establish certain and correct uncertain theories in philosophy and by their labour in the disquisition of nature to prove themselves real benefactors to mankind; and that they have already made a considerable progress by diverse useful and remarkable discoveries, inventions and experiments in the improvement of Mathematics, Mechanics, Astronomy, Navigation, Physics, and Chemistry, we have determined to grant our Royal favour, patronage and all the encouragement to this illustrious assembly and so beneficial and laudable and enterprise."

Encouragement was, thus, granted but not the needed funds. Experiments considered of importance were still carried out at the meeting places largely at the members expense. At the same time the members and guests were urged to bring and demonstrate any experiments which they were performing on their own. Thus, Boyle demonstrated his famous experiments on gases and Dr. Clark demonstrated his studies of injecting liquid in the veins of animals. New instruments were presented to the Society by their inventors for its use like Newton's telescope, Huygens lens, and others. Furthermore, books written by its members were critically discussed and if found worthy of publication they were sponsored. Another important function of the Society was to acquire information on the prevailing philosophical and scientific systems in other lands through formal correspondence and planned voyages. Written records of foreign societies and of individual writers were translated, reviewed, and evaluated. An international exchange of ideas and results was now on a sound footing in England also.

The Royal Society made an early decision for the publication of a journal, but the plans did not materialize until its secretary undertook to publish monthly, as a private enterprise, the important communications made to the Society. Thus, in 1665, the first number of the *Philosophical Transactions* was published marking another milestone toward securing the foundation of the scientific revolution. Some time later Thomas H. Huxley wrote: "If all the books in the world except the *Philosophical Transactions* were destroyed, it is safe to say that the foundations of physical science would remain unshaken, and that the vast intellectual progress of the last two centuries would be largely, though incompletely recorded."

Before leaving the Royal Society of the 17th century I wish to underscore that its members discussed extensively the possibility of assuming educational responsibilities including the establishment of their College. The Society concluded that educational functions would detract from its research character or its dedication to the discovery of scientific truths and their practical applications. This decision was a far reaching one. It identified for all times the scientific society with original research and development.

A few years after the formation of the Royal Society the Academy of Sciences was organized in France, in 1666. Unlike the Royal Society, the French Academy was founded as a royal institution. It was funded by the royal treasury and its members were compensated like state servants. However, like its sister societies in other countries, the French Academy of Sciences was born in small private meetings of strong believers in the cause of science; it was then adopted by one of Europe's greatest monarchs Louis the 14th. During his reign, it developed into the major scientific institution in all of Europe.

Colbert is considered the spiritual father of the French Academy; he lived completely dedicated to its organization and functions. The membership was varied, ranging from broadly based scholars to men skilled in specific experimental studies. As with the other academies of the 17th century here also performing experiments was a major function and many famous scientists participated. Marriotte's studies of the phenomena of air pressure, Roemer's calculation of the velocity of light from the satellites of Jupiter, Huygen's development of the pendulum clock and the wave theory of light represent a small sampling of the Academy's work. The important happenings in the Academy including new instruments, new results, and new communications in general appeared in the *Journal of the Savants* which was published outside the Academy and edited by one of its members.

The French Academy with government funding became involved in activities which were too costly for the privately organized societies. The observatory of Paris built by the state at the recommendation of academicians was put under the Academy's complete direction. Similarly the Academy undertook expensive scientific expeditions for astronomical and other observations. Furthermore, it often sponsored foreign scientists to come to Paris and partake in experiments and discussions.

In Germany during the 17th century the pursuit of science and original experimental research did not reach the broad dimensions found in Italy, England, and France. There were of course learned societies functioning and great thinkers like Kepler and Leibniz were contributing to the rapidly advancing scientific thought. However, the first scientific society with the scope of the Royal Society and the French Academy of Sciences was not established until 1700.

Of the earlier societies that existed in Germany during the 17th century it is interesting to mention the Collegium Naturae Curiosorum founded in 1652 and still existing today. It was organized in Schweinfurt by a local physician and its mission was focused to advancement of medicine and pharmacy. Consistent with

the times, direct observation and experimentation were adopted as a means for progress. The society did not have its own laboratory for experimental research, but its members undertook on their own or were assigned by the president a topic for investigation. The results were discussed, corrected, and further elaborated before they were published. Within a few years the society's membership and activities extended beyond the limits of Schweinfurt. In 1677 the Emperor became its patron and by 1687 the Academy adopted the name of Academia Caesarea Leopoldina. Its periodic publication *Miscellanea Naturae Curiosorum* was most highly regarded not only in Germany but throughout Europe. The role of this Academy was certainly a limited one and evolved only about medicine. However, it was a role with subtleties of extraordinary importance. The Academy advocated and practiced the view that medicine must be based on scientific research and experimental observation. In those years medicine was even in greater need than the natural sciences to be liberated from mysticism and witchcraft.

The first broadly based scientific society in Germany was organized under circumstances appreciably different from those which prevailed earlier in other countries. By the end of the 17th century the financial factor had become a very important one in the life of scientific academies. Gottfried Leibniz in advocating the organization of scientific societies across Germany was well aware of this factor. Thus, in 1699, when the calendar was reformed from the Protestant to the Roman Catholic, he proposed to the Elector of Brandenburg that a monopoly of calendars be established and that the proceeds be used for the founding and support of a scientific society. The proposal was readily accepted. An interesting condition was imposed by the Elector, that German be the official language of the Society rather than Latin which was commonly used in scientific matters. The introduction of the vernacular into scientific writing in Germany and in other countries was an essential step in broadening the basis for communicating scientific findings.

In July, 1700, the charter was obtained and the Berlin Academy was established. The plans called for a library, an observatory and a research laboratory. Drawing on the experiences of the Royal Society and the French Academy of Sciences the organization and functions of the new academy were spelled out in great detail. There was a significant deviation, however, from the existing societies: the expressed intent of the Berlin Academy was to be concerned with things useful and not just with matters purely scientific. Agriculture, commerce, and manufacturing were to be central to the Academy's interests. This is perhaps the first organized participation of scientists in matters not entirely scientific.

In spite of the dedication of Leibniz and the Elector's support the Academy was slow in taking hold. The publication of the first volume of its proceedings *Miscellanea* did not appear until 1710. Soon after the Academy experienced additional difficulties when Frederick William I ascended to the throne of Prussia. He considered science effeminateness and thought Leibniz a totally unworthy individual. Leibniz remained unshaken in his beliefs and visions on the vital role of the scientific society in the growth of science and the well being of mankind. In his travels he brought his convictions to Russia and Austria where he found sympathetic and even grateful ears. In fact, he is responsible for the Academy of St. Petersburg which was officially founded in 1724. In Vienna he obtained an imperial protocol for the foundation of an Academy but the plan was finally defeated and the Academy of Vienna was not to be organized until the middle of the 19th century. Leibniz died disappointed; but his labors were not in vain. The Berlin Academy was to achieve a high place indeed among the learned

societies in Europe and contributed heavily in giving to science its modern status.

Here in America, during the colonial years the scientists were served by the Royal Society through correspondence or travel to England, and over the years a small number of distinguished colonists were elected members of the Royal Society: Cotton Mather, the three John Winthrops, James Bowdoin, Paul Dudley, Roger Williams, Zabdiel Boylston of New England; Benjamin Franklin, David Rittenhouse and John Morgan of Pennsylvania; William Byrd II, John Mitchell and John Tennent of Virginia; and Alexander Garden of South Carolina.

Several early attempts were made by the colonists to found local learned organizations. For example, in 1683, the Boston Philosophical Society was established which according to Cotton Mather was "A Philosophical Society of Agreeable Gentlemen who met once a Fortnight for a Conference upon Improvements in Philosophy and Additions to the stores of Natural History." But this society was very short lived like other early ones.

The master mind and main force behind the lasting foundation of learned organizations in this country was one of the greatest intellects it has produced, the Boston born, and Philadelphia raised Benjamin Franklin. In 1727 he formed his secret Junto, about which he wrote: "I had formed most of my ingenious acquaintance into a club of mutual improvement which we called Junto; we met on Friday evenings. The rules that I drew up required that every member, in his turn, should produce one or more queries on any point of Morals, Politics or Natural Philosophy, to be discussed by the company; and once in three months produce and read an essay of his own writing on any subject he pleased. Our debates were to be under the direction of the President, and were to be conducted in the sincere spirit of inquiry after truth without fondness of dispute or desire of victory."

Franklin kept his Junto a secret organization to protect it from intruders. He soon recognized, however, that the implications of a learned society were reaching far beyond the interests of their small select group. Accordingly, each member was encouraged to form a subsidiary club to function like the parent Junto. Several such clubs were successfully established. But a few years later, in 1743, he proposed the establishment of the American Philosophical Society and to this end he circulated throughout the colonies a memorandum with the title: "A Proposal for Promoting Useful Knowledge among the British Plantations in America." This memorandum said in part "That one society be formed of virtuosi or ingenious men, residing in the several colonies, to be called the American Philosophical Society, who are to maintain in constant correspondence. That these members meet once a month, or oftener, . . . to communicate to each other their observations and experiments, to receive, read and consider such letters, communications or queries as shall be sent from distant members, to direct the dispersing of copies of such communications, as are valuable, to other distant members in order to procure their sentiments there upon." The following year 1744, the American Philosophical Society came into existence and still functions as a distinguished learned society.

In the meantime the Junto club developed into the American Society Held at Philadelphia for Promoting Useful Knowledge. Then in 1769, it united with the American Philosophical Society under the new name, American Philosophical Society Held at Philadelphia for Promoting Useful Knowledge. This remains its official name to date although it is known with its shorter name, American Philosophical Society. During the 18th century, the Society played a very significant role in the advancement of science here and in Europe. In its observatory at the State House Yard, David Rittenhouse and his fellow astronomers secured the

first accurate data for determining the astronomical unit, that is the distance of the sun from the earth. The big clock that Rittenhouse devised for his experiments still runs in the Society's quarters in Philadelphia. Important communications in various scientific areas were discussed before the Society and the most brilliant minds here and abroad were honored with membership including the father of modern chemistry Antoine Lavoisier.

With the closing of the revolutionary war a new society was incorporated in Boston (1780) the American Academy of Art and Sciences which is still in existence with quarters in Newton, a suburb of Boston. John Adams provided the organizing force, and he was a charter member along with James Bowdoin, John Hancock, and Samuel Adams. Among the early elected fellows were George Washington, Benjamin Franklin, David Rittenhouse, and Thomas Jefferson. The objectives of the new Academy were similar to those of the other learned societies founded in the 17th and 18th century: Direct involvement in experimentation for the discovery of scientific truths, critical discussions of new discoveries and other matters of intellectual challenge which might contribute to the advancement of knowledge and (quoting from its charter) "may tend to advance the interest, honor, dignity and happiness of a free independent and virtuous people."

The National Academy of Science was founded in Washington much later, in 1863, with President Lincoln authorizing the Federal Charter. In its one century old life, the Academy has honored with membership the most distinguished scientists of the country. It has been a most important source emanating scientific guide lines to the government and to the scientific community at large.

I believe that before we pursue the scientific societies into the 19th and 20th centuries we should examine the orientation of the universities as intellectual centers in the light of the emerging detached scientific approach and with respect to the scientific societies.

The European universities of the 17th century had established a deeply rooted and closely guarded tradition in their instruction spectrum. Grammar, logic, and rhetoric were taught along with the four mathematical subjects—arithmetic, geometry, music, and astronomy. Natural philosophy was another major area of instruction, usually reserved for advanced studies. Similarly medicine and theology were treated as what we might call today post graduate subjects.

Although there were variations among the major European countries, by and large, mathematics consisted essentially in Euclid's work, astronomy was based on Ptolemy's writings, and natural philosophy was the contents of "Aristotle's Physica." As for medicine the writings of Galen and Hippocrates were heavily drawn upon. The whole intellectual activity within the university was most tightly bound to systems put forth many many centuries earlier.

The factors that kept the university in a sphere intellectually polarized to the distant past are not straight forward and we shall not pursue them here. We must recall, however, that the universities were generally under the auspices of the church. Accordingly, the theological faculties were the leading academic bodies and the key administrative positions were held by theologians. It is generally agreed that the theologians of the 17th century were not particularly suited to champion the cause of free scientific inquiry.

The conclusion is inescapable that the university of the 17th century could not possibly serve as a breeding ground for revolutionary minds nor as the home for the now insuppressible scientific method.

There were, of course, isolated instances of great minds being affiliated with universities like Isaac Newton who became a professor in Cambridge Uni-

versity. However, their short range impact on the over-all university activities was rather small. Such scholars took their creative work for discussion and criticism outside the university walls, and into the scientific societies. Great scientists like Bacon, Boyle, Huygens, Van Helmont, Kepler, Leibniz, Descartes, Pascal, Marriotte, and many others never became university faculty members.

It is significant to point out, however, that the universities did not enter in open polemics with the scientific societies and the new scientific attitude. They simply guarded the traditional curricula and resisted the infiltration of the new philosophies with great determination. The conservatism of the universities persisted through the 18th century. The statutes of Oxford University remained unchanged for three centuries (from 1570 to 1858) and those of the theological faculty of Bologna for over four centuries (from 1360 to 1783).

Clearly in the 17th century the scientific societies were the home of all that was science and its broad implications. They believed in original thought, they provided for complex and accurate experiments, they evaluated and recorded the results, they communicated the new information to the world, they studied applied aspects of sciences as pertaining to agriculture and commerce, and in all these ways they brought science to the conscience of the community at large.

I wish to quote from the book of Martha Ornstein on the "Role of Scientific Societies in the Seventeenth Century" (The University of Chicago Press, 1918): "These societies provided the advance guard of civilization in the second half of the seventeenth century. . . . They were the concentrated expression of the new spirit which was to gain the supremacy in the realm of thought and life. They typify this age drunk with the fullness of new knowledge, busy with the uprooting of superannuated superstitions, breaking loose from traditions of the past, embracing most extravagant hopes for the future. In their midst the spirit of minute scientific inquiry is developed; here the charlatany and curiosity of the alchemist and magician are transformed into methodical investigation; here the critical faculty is developed so that the disclosure of an error is as important as the discovery of a new truth; here exact observation is put as high-nay, higher-than generalization; here the individual scientist learned to be contented and proud to have added an infinitesimal part to the sum of knowledge; here, in short, the modern scientist was evolved."

By the end of the 18th century the conservatism of the university had noticeably succumbed to natural erosion. The Aristotelian system was quietly put aside. Chairs in Chemistry, in Physics, and other scientific disciplines were being created and occupied by individuals reared in the spirit of the scientific societies and committed only to free scientific inquiry. The metamorphosis was slow and perhaps painful but it was complete and the universities did in turn become the primary centers for science and technology. They built their observatories and their research laboratories. Universities such as that of Cambridge, Oxford, Paris, Berlin, Leipzig, Vienna, St. Petersburg, Leyden, Harvard, and many others became the homes and centers of activities of some of the brightest stars in the stardom of science. At the same time they trained new scientists to carry on the scientific search and to meet the new needs of the young industrial revolution.

Thus, in the 19th century the scientific society passed on the torch to the University; but it did not run out its course. The scientific societies remained the exciting forum for the presentation, evaluation and permanent recording of the new experimental and theoretical results. Their meetings continued to be,

and still are, the most fertile grounds for the cross-fertilization of ideas and results.

With the increasing numbers of scientists, and scientific centers, the scientific societies evolved to meet the new needs. The original academies had and still have a limited membership. It was only through one of the academicians that the formal presentation of new work could be made. Furthermore with the rapidly expanding areas of research the spectrum of scientific societies needed to be extended. Thus, new societies began to spin off the original ones and many were independently founded; they were devoted to one branch of science with a broader basis for membership. New members joined not just by invitation, as in the academies, but after requesting admission provided certain requirements were met. Thus, the Geological Society of London was established in 1807; the British Chemical Society, in 1841; the French Chemical Society in 1857; the German Physical Society in 1845; the American Chemical Society in 1876; the American Physical Society in 1899, and so on. The list has grown to very large numbers, perhaps to many thousands and it is still growing. Only a few weeks ago a new sister society was founded in England, the Society for Electrochemistry.

Our own Electrochemical Society was founded at the turn of the present century along the same pattern established two and one-half centuries earlier: the need for a new society was diagnosed by a few imaginative individuals who proceeded to transform an idea into a living mechanism. Six scientists from Pennsylvania addressed a circular letter dated October 19, 1901, to scientists in the United States, just as Benjamin Franklin had done 150 years before them in proposing the foundation of the first scientific society in this country. The letter pointed out that "The rapidly growing importance of the subject of electrochemistry and the want of suitable occasions in this country for the discussion of papers and questions pertaining thereto by those especially interested, have suggested the advisability of founding a National Electrochemical Society similar in its organization to the American Chemical Society and the American Institute of Electrical Engineers . . ."

As a result of this letter eleven electrochemists met in Philadelphia on November 1, 1901, and agreed to meet again in Philadelphia, in April, 1902; this time 52 individuals attended. It was at that meeting that the Society was formally founded under the name American Electrochemical Society. In 1930 the Society was incorporated and its name was shortened to the present name: The Electrochemical Society, Inc. Eliminating the word American from the name was consistent with the Society's international membership which now exceeds 4000.

It is in this general pattern that scientific academies and scientific societies continue to be formed: to meet an oncoming need and rise to the scientific and technological challenges of the times. The academies, like the National Academy of Sciences in Washington, have been and still are deeply involved in providing a vital interface between the government and science at large, in war and in peace. The scientific societies like ours provide for meetings to bring forth the new results, the new thoughts, and the new trends. They provide the great forum where young minds are stimulated and mature ones are challenged. They provide what I believe will continue to be central to the life of science and engineering, an opportunity for personal communication, for personal exchange of thought, for personal contact, and for good fellowship.<sup>3</sup>

<sup>3</sup> I wish to record my amazement at the large amount of literature available on the foundation and development of scientific societies. I have chosen not to present a list of references since numerous volumes with pertinent information and containing the quotations included here are widely available.

# Rates of Dissociation of $\text{Ag}_2\text{O}_2$

Earl M. Otto\*

National Bureau of Standards, Washington, D. C.

## ABSTRACT

The dissociation of  $\text{Ag}_2\text{O}_2$  into  $\text{Ag}_2\text{O}$  and  $\text{O}_2$  has been investigated over the temperature range from 22° to 100°C for the dry material, for water slurries, and for slurries in KOH solutions of concentrations from 1 to 13M. The method consisted in measuring the  $\text{O}_2$  volume while the dissociation was progressing, and in most cases very smooth curves were obtained when the volume of dry  $\text{O}_2$ , corrected to 0°C, 760 Torr, per gram of sample was plotted against time.  $\text{Ag}_2\text{O}_2$  in water had the lowest rate of evolution, dry  $\text{Ag}_2\text{O}_2$  had an intermediate rate, and  $\text{Ag}_2\text{O}_2$  in the high concentrations of KOH solution, such as are used in Ag-Cd cells, had the highest rate. The rates ranged from 0.0001 to 1.8 ml hr<sup>-1</sup> g<sup>-1</sup>.

Although in the past two decades considerable interest has been shown in silver-silver oxide cathodes in primary and secondary batteries and reports on the investigations have appeared in the chemical literature (1-5), there has been no extensive study of the instability of  $\text{Ag}_2\text{O}_2$  dry, wet with water, and wet with solutions of KOH. The presently reported study was undertaken because the author had been working with silver-cadmium cells stored at various temperatures for different periods of time and wished to understand better the reactions taking place during the cycling of these cells.

It has long been known that there is an oxide of silver wherein the valence of the silver is greater than unity. The chemically made product has an empirical formula of approximately  $\text{Ag}_2\text{O}_{1.97}$ , and the writer chooses to accept the evidence given by Cohen and Ostrander (6) (and certain references quoted by them) for the existence of  $\text{Ag}^{+3}$  and  $\text{Ag}^{+1}$  with the absence of  $\text{Ag}^{+2}$ . Hence the formula will be written herein as  $\text{Ag}_2\text{O}_2$ .

## Experimental

The study consisted in subjecting samples of chemically prepared  $\text{Ag}_2\text{O}_2$  to periods of standing in closed systems at room temperature, 30°, 50°, 70°, and 100°C. The oxide used came from three commercial sources. Samples from two of these were analyzed by the author by means of  $\text{O}_2$  evolution. The results indicated 95-97%  $\text{Ag}_2\text{O}_2$ . The results of Ag determinations on one sample by Cohen (6) and the assay supplied by one manufacturer were also within the 95-97% range. A commercial laboratory determined by the use of a mercury porosimeter that the one product had a total pore volume of 0.525 cm<sup>3</sup>/g, an area of 2.73 m<sup>2</sup>/g, and a real density of 7.74 g/cm<sup>3</sup> at 15,000 psi pressure. The media surrounding the samples were air, water, and KOH solutions of various concentrations ranging from 1 to 13M (5 to 50%) KOH. The volumes of  $\text{O}_2$  were measured over mercury, water, or the KOH solution, whichever was the most suitable and convenient.

Three types of apparatus were employed. For 30°, 50°, and some 70°C runs the apparatus previously used by the author (7) for determining the rates of gassing of dry cells was adopted, with 10 to 13g samples employed. For 100°C and the remaining 70°C runs the samples (1-2g) were placed in long, narrow-necked bulbs to which reflux condensers were attached. The bulbs were immersed in glycerine in a clear glass wide-mouth Dewar flask in which a heating element had been located. Current to the heating element was regulated by means of a mercury thermometer and a mercury-level sensing device set at the desired temperature. Delivery tubes from the tops of the condensers led to gas burettes and leveling bulbs filled

with water. For room temperature the best arrangement was to place the sample in an inverted polypropylene test tube having a one-holed rubber stopper through which passed a plastic tube to serve as a leveling device. A small hole was drilled in the bottom of the test tube and an inverted polypropylene measuring pipette attached to the test tube bottom by epoxy cement. The tip of the pipette was closed with the cement. As  $\text{O}_2$  evolved it moved upward into the pipette, displacing the KOH solution, where its volume could be measured easily.

The investigation was begun with  $\text{Ag}_2\text{O}_2$  in 11.6M KOH solution (44%) at 50°C, since this concentration of KOH is commonly used in Ag-Cd cells and cell temperatures are not expected to exceed 50°C. From these conditions the study was extended to lower and to higher concentrations to see if there is a concentration for maximum rate of oxygen evolution, just as there is such a concentration (6M) for specific conductance of KOH. Then the question arose as to the instability of  $\text{Ag}_2\text{O}_2$  at room temperature dry, wet with water, and wet with KOH solutions. Since the dissociation of  $\text{Ag}_2\text{O}_2$  was found to be slow at 50°C, it was decided to increase temperatures to as high as 100°C.

All volumes of  $\text{O}_2$  have been calculated on a dry basis and corrected to 0°C, 760 Torr. Water vapor pressures at the several temperatures and KOH concentrations were obtained by interpolations of plots of  $\log p$  vs.  $1/T$ , using the data given in the International Critical Tables. Rates of reaction are expressed in milliliters of dry  $\text{O}_2$  (STP) per hour per gram of  $\text{Ag}_2\text{O}_2$  at the stated temperature and concentration. In order to keep the number of graphs to a minimum and yet present in graphic form most of the recorded data, the dissociation curves have been grouped by like orders of magnitude of gas volumes for like periods of time.

The zero times of the experiments were the times at which temperature equilibration and water vapor saturation of the air in the closed systems were judged to have occurred.

The results of the major investigation are given in Fig. 1 to 6.

Attention should be called to illustrations of reproducibility of measurements. Curves 1-3 and 1-4 (the number before the hyphen refers to figure and the number after hyphen to curve) have essentially the same slope. Likewise, curves 2-1 and 2-2 are nearly the same. Curves 6-2 and 6-3 were obtained from the same materials and temperature, but with different arrangements of apparatus and slightly different conditions of experimentation. Another factor in this last case was the extremely small volume of oxygen evolved (0.6 ml). One would think that curves 4-1 and 4-2 should be similar. Apparently, however, company "B"  $\text{Ag}_2\text{O}_2$  released its  $\text{O}_2$  more slowly than did the company "A" material. Had the company "B"

Key words: silver oxides,  $\text{Ag}_2\text{O}_2$ ,  $\text{Ag}_2\text{O}$ , dissociation, rates, aqueous potassium hydroxide.

\* Electrochemical Society Emeritus Member.

oxide been investigated a few thousand hours more, it might have yielded just as much  $\text{O}_2$  as the other oxide did.

In one instance a mixture of 47.4% Ag powder with 52.6%  $\text{Ag}_2\text{O}_2$  was allowed to dissociate in 11.6M KOH at 25°C. Surprisingly the initial rate per gram of  $\text{Ag}_2\text{O}_2$  was much greater than that of  $\text{Ag}_2\text{O}_2$  with no additive.<sup>1</sup> (See curve 6-5.) Apparently, metallic silver serves as a catalyst, but possibly only in the early stages of dissociation (the first 300 hr in this case). A similar observation was made with a 50% Ag/50%  $\text{Ag}_2\text{O}_2$  mixture at 70°C, except that the rate (which was five times that of  $\text{Ag}_2\text{O}_2$  having no Ag powder) began to decrease after 20 hr and came to zero at 240 hr and then the  $\text{O}_2$  began to be consumed. Curve 5-6 shows a plot of the data obtained. In another instance  $\text{Ag}_2\text{O}$  was used with 11.6M KOH at 45°C. In this instance a mercury lamp was placed adjacent to the reaction bulb containing the  $\text{Ag}_2\text{O}$  and caused to shine on the sample in order to give full opportunity for dissociation to be catalyzed by light energy. However, even in one month there was no evidence of oxygen evolution. This lack of oxygen evolution is somewhat in contrast to the observations reported elsewhere (5a): (i) that a greater amount of  $\text{O}_2$  was obtained than could be accounted for by the dissociation

<sup>1</sup> Wagner (5b) reported that  $\text{Ag}_2\text{O}_2$  ground with powdered Ag in a ball mill and let stand dry at room temperature was largely converted to  $\text{Ag}_2\text{O}$ .

Fig. 7. Rates of dissociation of  $\text{Ag}_2\text{O}_2$ . Effect of temperature and KOH concentration. Curve 1, Water only. Curve 2, 1.06M KOH. Curve 3, Dry  $\text{Ag}_2\text{O}_2$  only. Curve 4, 4.0M KOH. Curve 5, 7.9M KOH. Curve 6, 11.6M KOH. Curve 7, 13.2M KOH. Circled dot, Amie and Rüetschi point. X's, NOL points for 11.6M. All rates are for 1g samples.

of  $\text{Ag}_2\text{O}_2$  into  $\text{Ag}_2\text{O}$ , and (ii) that free Ag was detected. The authors of ref. (5a) expressed concern about the possibility of gas leakage, but proved in one case that the leakage was inconsequential. In the present work Apiezon-T grease was the lubricant-sealant for all ground-glass joints and the presence of a continuous surface of the brown grease was sufficient evidence that no leaks ever occurred.

The positive plate material (with grid removed) of a fully charged silver-cadmium cell was heated in 11.6M KOH at 100°C until no more  $\text{O}_2$  was evolved. The time required was the same as that for  $\text{Ag}_2\text{O}_2$  but the volume of  $\text{O}_2$  indicated only about 40% of  $\text{Ag}_2\text{O}_2$ . This is in close agreement with the per cent of time the discharge of a cell is at the higher of the two voltage levels. At 25° and 50°C, positive plate material dissociated, on a per gram basis, at about one third the rate obtained for the 97%  $\text{Ag}_2\text{O}_2$  material.

Figure 7 and Table I give initial steady gassing rates calculated at regions "R" shown in Fig. 1 to 6. Table I also shows where the various curves may be found. In all figures the points shown on the curves are the actual experimental values. It can be seen that in most instances the curves consist essentially of lines drawn through the points.

Figure 8 gives the rates of  $\text{O}_2$  evolution plotted against the KOH concentration at 50° and 100°C. In the latter case a straight line is obtained, if the rate (unexplainably low) for 11.6M KOH is ignored. For 50°C, if the rate (unexplainably high) for 11.6M is also ignored, a smooth curve can be drawn through

Fig. 8. Rates of dissociation of  $\text{Ag}_2\text{O}_2$ . Effect of concentration of KOH on  $\text{Ag}_2\text{O}_2$  at 100°C, shown by dots; at 50°C, shown by X's (use ordinates at left and abscissas at bottom). Effect of temperature on  $\text{Ag}_2\text{O}_2$  in 11.6M KOH shown by circled dots (use ordinates at right and abscissas at top).

the remaining 5 points. The behavior at 70°C is similar to that at 100°C but the line through the points is nearer to being straight.

The broken lines have been drawn to show the effect of not ignoring any of the data. Figure 8 also shows a plot of the log of the rate against  $1/T$ , but for 11.6M KOH only, since this is the only concentration which was used at all temperatures. A line through all the points is practically straight. This fact gives more credence to all rates determined with 11.6M KOH.

### Discussion

Since the rate of oxygen evolution is a direct function of the concentration of KOH, KOH must take part in the reaction, but since there are long periods of constant rate, the KOH must be regenerated to keep the concentration constant.

It is very noteworthy that many curves have straight line segments (i.e., constant slopes), indicating zero order or pseudo zero order reactions are taking place. Most remarkable is curve 5-3 where the rate of dissociation of  $\text{Ag}_2\text{O}_2$  in 11.6M KOH at 70°C remained constant for 24 days and then dropped to zero in about 5 more hours. The zero time of this graph does not indicate the beginning of  $\text{O}_2$  evolution, but merely when temperature equilibration was reached and the stop-

cock over the Hg was closed. The controlling condition could hardly be the surface of the  $\text{Ag}_2\text{O}_2$  because this would have to be much less when 90% dissociation has taken place. The author is led to speculate that the dissociation reaction takes place in the dissolved portion of the  $\text{Ag}_2\text{O}_2$ . The KOH is thought to cause the  $\text{Ag}_2\text{O}_2$  to go into solution by a reaction such as

Then two  $\text{O}-\text{Ag}=\text{O}-$  ions dissociate and give  $\text{O}_2$  and two  $\text{AgO}^-$  ions. Needless to say these ions may really exist in hydrated forms, as  $\text{Ag}(\text{OH})_4^-$  and  $\text{Ag}(\text{OH})_2^-$ , respectively. The  $\text{AgO}^-$  may react with the  $\text{AgOH}$  to form  $\text{Ag}_2\text{O}$  and regenerate the  $\text{OH}^-$ . If the temperature is  $100^\circ\text{C}$ , it may be that the loss of oxygen takes place so fast that the solvent action demand is too great toward the end of the dissociation. Of course the rate of the solvent action necessarily is a function of the surface of the  $\text{Ag}_2\text{O}_2$ . At lower temperatures and low concentrations there could be concurrent side reactions which interfere with the progress of the dissociation. One of these could be the deposition of the  $\text{AgOH}$  or  $\text{Ag}_2\text{O}$  causing a blocking action. Curve 3-3 is odd in that the rate of dissociation increased perceptibly with time. (Note that this is  $\text{Ag}_2\text{O}_2$  with no added water or KOH.) Needless to say, the mechanism of this dissociation has to be different. It could be that moisture in the original sample is slowly lost and any residual ionic substances (e.g., KOH) accelerate dissociation of  $\text{Ag}_2\text{O}_2$ . Curve 3-4 is peculiar in that there appear to be three notably different slopes and the change of one to another takes place suddenly. No explanation is offered at present.

Curve 5-6 must be compared with curve 5-3 since the only difference is that the former resulted from addition of powdered Ag. Again it is the considered opinion that the free Ag has served to catalyze greatly the dissociation of  $\text{Ag}_2\text{O}_2$  into  $\text{Ag}_2\text{O}$  and  $\text{O}_2$ .  $\text{O}_2$  begins slowly to oxidize Ag to  $\text{Ag}_2\text{O}$ . At 240 hr these two reactions became equal and thereafter  $\text{O}_2$  was consumed faster than it was formed. No doubt this sequence of reactions would have continued until the available free Ag or the  $\text{O}_2$  became exhausted. This observation is in contradiction to NOLTR 62-187 where it is stated that some free Ag was produced simply by the dissociation of  $\text{Ag}_2\text{O}_2$  in 10N KOH at  $71^\circ\text{C}$ .

The slope of the curve shown by Amlie and Rüetschi (4b) for 40% KOH at  $30^\circ\text{C}$  in their Fig. 7 appears to be about  $0.003 \text{ ml hr}^{-1} \text{ g}^{-1}$ . This rate is shown in Fig. 7 as the  $\odot$  point. However, it is not known if the data of these investigators were calculated to a dry basis. The presently reported rate for 11.6M (44%) solution at  $30^\circ\text{C}$  is  $0.002 \text{ ml hr}^{-1} \text{ g}^{-1}$ .

The data given by the NOL investigators (5) are shown as curve 5-7, curve 4-3, and curve 5-5 for  $\text{Ag}_2\text{O}_2$  in 40% KOH at  $32.2^\circ$ ,  $47.5^\circ$ , and  $71^\circ\text{C}$ , respectively. The rates have been calculated and included in Fig. 7 as the

x points. The greatest discrepancy between the NOL data and the present author's data occurs in the lower temperature region. At the higher temperatures discrepancies may be due to different activities of different  $\text{Ag}_2\text{O}_2$  samples. The NOL report does not mention any corrections having been made for water vapor in the evolved oxygen.

### Conclusions

The rate of dissociation of  $\text{Ag}_2\text{O}_2$  increases markedly with KOH concentration up to 11.6M, but there is less effect at higher concentrations.

The rate of dissociation of  $\text{Ag}_2\text{O}_2$  is much greater at high temperatures than at low temperatures.

Dry  $\text{Ag}_2\text{O}_2$  presumably is unstable at room temperature and would largely decompose in a few years (5-10). It has approximately the same rate of dissociation as in 4.0M KOH.

The rate of dissociation is slowest when the  $\text{Ag}_2\text{O}_2$  is wet with water and hence, for longest shelf life of this substance unmixed with anything else, it should be stored this way.

### Acknowledgments

This work was supported in large part by NASA Goddard Space Flight Center. Thanks are due to M. Ames Chemical Works for furnishing most of the  $\text{Ag}_2\text{O}_2$ . The laboratory assistance given by Kenneth Kramer and William Seelig is much appreciated.

Manuscript submitted Oct. 30, 1967; revised manuscript received April 29, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Analysis of the Uhlig Defect Model of Oxidation Kinetics

A. T. Fromhold, Jr.\*

Department of Physics, Auburn University, Auburn, Alabama

## ABSTRACT

A self-consistent development is given of a model of oxidation kinetics in which growth rate is determined by thermionic emission of electrons over a potential barrier due to the metal-oxide work-function and modified by space charge due to trapped electrons in the oxide and compensating surface charge at the metal-oxide interface. The following expression is derived for the growth rate

$$dy(t)/dt = B_0 \exp\{-y(t)^2/y_0^2\}$$

where  $y(t)$  is the oxide film thickness at time  $t$ , and  $y_0 = (\epsilon kT/2\pi e^2 n_0)^{1/2}$  is the characteristic thickness at which a uniform concentration  $n_0$  of trapped electrons of charge  $-e$  attenuates the growth rate significantly at temperature  $T$ ,  $\epsilon$  is the relative dielectric constant of the oxide, and  $k$  is the Boltzmann constant. The parameter  $B_0 = \beta A' \exp(-e\phi/kT)$  can be considered to determine the time scale, where  $A'$  is the flux of electrons (or charge) in the parent metal which impinges on the potential barrier of height  $\phi$  represented by the oxide, and  $\beta$  is the volume of oxide formed per electron (or per unit of charge) which traverses the oxide film. This growth-rate expression clearly does not lead to a direct-logarithmic growth law. Moreover, the characteristic film thickness  $y_0$  at which rate is significantly attenuated is of the order of the Debye length, in contrast with the conclusion reached by Nwoko and Uhlig that space-charge effects should be much larger. A development of the activation barrier for electron emission illustrates that the electron affinity of adsorbed oxygen is not a factor in the activation energy for electron emission when the emission process is rate-limiting. This results in a modification of the time scale for the kinetics by many orders of magnitude relative to that of Uhlig and Nwoko. Finally, the nonzero ionic current will perturb the rate-limiting electron current; the "coupled currents" method previously developed by the present author, in which the currents are balanced by the surface charge field, is suggested to be appropriate for studying this effect.

An analysis of the kinetics of oxide film growth published by Uhlig (1) some ten years ago is based on the idea contained in the quotation (2), "When the oxidation rate, therefore, is controlled by electron flow from the metal, an increasing negative space charge (or decreasing positive space charge) obviously enters as an important factor in establishing the rate of electron flow, tending in general to slow down escape of electrons as the oxide grows, and, therefore, simultaneously slowing down escape of metal ions and the oxidation process itself." The kinetics of oxide growth were considered by Uhlig to be determined by the well-known semi-empirical equation (3) for electron current across the contact of a metal and a semi-conducting oxide

$$i = A' \exp(-e\phi/kT) \{\exp(ev'/kT) - 1\} \quad [1.1]$$

where  $A'$  is a constant,  $\phi$  is the metal-oxide work function,  $e$  is the electronic charge magnitude,  $v'$  is an applied voltage across the metal-oxide junction,  $k$  is Boltzmann's constant, and  $T$  is the absolute temperature. If  $\exp(ev'/kT)$  is much larger than unity, Eq. [1.1] reduces to

$$i \simeq A' \exp\{-e(\phi - v')/kT\} \quad [1.2]$$

Equation [1.2] is also applicable to certain cases for which  $ev'$  is negative, including that for the Uhlig model. (This is discussed in the section on Electron Activation Energies of the present paper.) The effect of space charge on the kinetics was introduced by considering  $v'$  in Eq. [1.2] to be the potential drop established across the film by space charge, which can be computed from Poisson's equation (4-7). For the sake of simplicity, the space charge was considered to be uniformly distributed throughout the oxide in the case of thin films; in the case of thick films, a diffuse region

of space charge was postulated in addition to the region of uniform space charge.

The basic idea that space charge exerts an important effect on oxidation rate is good. However, Uhlig's mathematical development of the model outlined above has been criticized (8) by the present author on the following points:

1. The position coordinate  $x$  in Poisson's equation of electrostatics was misinterpreted to be the total film thickness  $y(t)$ , which led to the application of physically meaningless boundary conditions. This misinterpretation is evidenced most clearly by the fact that the Uhlig treatment leads to a nonconservation of electrical charge during growth. In addition, numerical errors of several orders of magnitude are introduced into the computation of the space-charge electric field for a given defect concentration in the oxide film, so that space-charge effects for charged particle transport are predicted to be enormous relative to computations based on the proper application of Poisson's equation.

2. The electron affinity  $\tilde{v}$  of adsorbed oxygen at the oxide-oxygen interface was considered to reduce the activation energy for electron transfer from metal to adsorbed oxygen, thus effectively reducing the metal-oxide work function  $\phi$  at the metal-oxide interface by  $\tilde{v}$ . It was pointed out in the criticism that this can be true only for special cases; it cannot be generally true if one accepts the usual thermodynamic concept of an activation barrier.

3. Ionic transport was not included in the treatment. The present author argues that it is necessary to make assumptions regarding this matter even in cases for which electrons represent the rate-limiting species. That is, a concentration gradient of ions across the oxide represents a diffusion potential; this diffusion potential should contribute to the establishment of an

\* Electrochemical Society Active Member.

electrostatic potential across the oxide, especially whenever the ionic species is not rate-limiting as in the case of the Uhlig model.

In the discussion section of a paper by Nwoko and Uhlig (9) entitled "Logarithmic Oxidation Kinetics of Zinc," a rebuttal to the criticism (8) is given, and the original Uhlig treatment is employed in unmodified form to interpret experimental data. The present communication summarizes the results of a re-examination of the topic and attempts to clarify several misconceptions introduced by the rebuttal of Nwoko and Uhlig (9).

It is to be emphasized that the purpose of the present communication is not to present a new model of oxidation kinetics. Instead, it represents a clarification of the matter of the electron current over Schottky-type barriers appropriate for the Uhlig model. Such an electron current, when properly coupled (10, 11) with the ionic current according to our concept of the oxidation process, does provide the basis for a new model.

The section of the present paper on Poisson's Equation as Applied to an Oxide Film clarifies the matter of Poisson's equation as utilized to compute potentials in the oxide film; appropriate boundary conditions are employed to derive the growth equation appropriate for the Uhlig model. The section on Electron Activation Energies is a discussion of electron activation barriers; the relationship between such barriers and the free energy of electron transport through the oxide and the free energy of formation of the oxide is clarified therein. The section on the Possibility of Obtaining the Direct-Logarithmic Law constitutes an examination of (and effective argument against) two possible *ad hoc* hypotheses which can lead to a direct logarithmic growth law for the Uhlig model. The section on the Effect of the Ionic Current on the Electron Current due to Coupling treats the question of whether the ionic current can be validly ignored whenever the electronic current is rate-limiting. The section on the Misconceptions in Uhlig and Nwoko Paper is a clarification of misconceptions introduced in the paper of Nwoko and Uhlig (9), and the section, Conclusions, is a brief statement of the principal conclusions of the present work.

### Poisson's Equation as Applied to an Oxide Film

According to classical electromagnetic theory (4), Poisson's equation in Gaussian units is

$$\nabla^2\varphi = -4\pi\rho/\epsilon \quad [2.1]$$

where  $\varphi$  is the scalar electrostatic potential which can vary from point to point in the medium,  $\rho$  is the charge density which may also be a function of position in the medium,  $\epsilon$  is the relative dielectric constant of the medium, and  $\nabla^2$  is the Laplacian (5-7).

A planar oxide film of thickness  $y(t)$  is considered as a one-dimensional problem with the origin at the metal surface. The position in the oxide normal to the metal surface is represented by  $x$ . The electrostatic potential will be independent of position parallel to the metal surface, so that  $\varphi = \varphi(x)$  only. If trapped electrons (charge  $-e$ ) of density  $n(x)$  constitute the sole contribution to the space charge, as was assumed by Uhlig (1), then  $\rho = -n(x)e$ . Equation [2.1] in this case reduces to

$$\frac{d^2\varphi(x)}{dx^2} = \frac{4\pi n(x)e}{\epsilon} \quad [2.2]$$

This equation yields the electrostatic potential as a function of  $x$  for any arbitrary position in the planar oxide film. Clearly the independent variable  $x$  denoting the position in the film normal to the metal surface cannot be replaced in this equation by the total thickness  $y(t)$  of the film, as was done by Uhlig (12). The proper way to obtain the total electrostatic potential  $v'$  impressed across the film is to solve Eq. [2.2] for

the  $n(x)$  in question; then  $v'$  is given by the difference in  $\varphi(x)$  as evaluated at the interface  $x = y(t)$  and  $x = 0$

$$v' = \varphi(x)|_{x=y(t)} - \varphi(x)|_{x=0} \quad [2.3]$$

The effective voltage for electron emission is given by  $v'$  only when the maximum in the thermionic barrier occurs at or very near  $x = y(t)$ . This excludes the case where the barrier maximum occurs at (or very near)  $x = 0$ , and also excludes cases in which the barrier maximum occurs at some intermediate position in the oxide film. For the Uhlig model, however,  $v'$  as defined by Eq. [2.3] gives an adequate representation of the effective voltage for electron emission, as will be shown later in the present work.

Specification of the two boundary conditions for the second-order differential equation [2.2] at all time  $t$  must be made consistent with the physical situation at hand. Since the zero of potential is arbitrary, it can be chosen to be zero inside the parent metal. For the common case of a semiconducting oxide growing on a metal, there is no sudden discontinuity in potential across the metal-oxide interface. This is due to the relatively low conductivity of the semiconducting oxide relative to the metal, so the interfacial dipole layer with its accompanying potential discontinuity at the interface between two different metals is replaced in the case of a metal-oxide interface by a single surface-charge layer on the metal accompanied by a volume distribution of charge of the opposite sign in the oxide. The extent of the charge distribution in the oxide is given approximately by the Debye length  $L_D$  in the semiconducting oxide (13, 14)

$$L_D = (\epsilon kT/8\pi e^2 n_0)^{1/2} \quad [2.4]$$

where  $n_0$  is  $n(x)$  in the limit of a uniform charge distribution. This parameter  $L_D$  is approximately 27Å for  $n_0 = 10^{18} \text{ cm}^{-3}$  and approximately 27,000Å for  $n_0 = 10^{12} \text{ cm}^{-3}$ , assuming  $T = 300^\circ\text{K}$  and  $\epsilon = 10$ . Therefore the change in electrostatic potential which takes place from the interior of the metal to the interior of the semiconductor occurs gradually over a distance of the order of  $L_D$ , with no sudden discontinuity occurring within a lattice parameter or so of the metal-semiconductor interface. Therefore  $\varphi(0)$ , the potential in the oxide immediately adjacent to the metal interface, is for all practical purposes equal to the potential inside the interior of the metal, which is chosen to be the zero potential point. Hence  $\varphi(0) = 0$  can be chosen as one of the required physically meaningful boundary conditions for the present problem, although Eq. [2.3] shows that  $v'$  is actually independent of the choice of  $\varphi(0)$ . It should be noted that this boundary condition is independent of time of growth of the oxide and hence independent of the thickness of the oxide.

This specification of a boundary condition for the complete period of time over which oxidation occurs is necessary; otherwise the potential  $\varphi(x)$  would not be determined for the entire period of oxidation. This is a critical weakness of the Uhlig theory (1), where the boundary conditions on the potential are specified for only two values of the film thickness ( $y = 0$  and  $y = l$ , where  $l$  is a length determined by the criterion (15) that the field be "zero at the metal surface when the assumed thickness of the constant charge density film is  $l$ "). Since the boundary conditions are specified for only two film thicknesses, it follows immediately that they are specified for only two points in time, namely, the time at which oxidation begins and the time at which  $y(t)$  reaches the thickness  $l$ . The electrostatic potential utilized by Uhlig is therefore mathematically undefined.

A second boundary condition for the electrostatic potential could be the specification during the period of oxidation of the value of  $\varphi$  at any position  $x_0(t)$  (which may be constant or else specified as a function of time) other than  $x = 0$ , or it could be  $d\varphi/dx$  evaluated at such a position or at  $x = 0$ . The choice of a

second boundary condition valid for the period of oxidation is not an easy one in the Uhlig theory; it is somewhat more straightforward in the approach proposed by the present author (10), where ion transport is explicitly included in the formulation of the problem, and the surface-charge field  $-d\varphi(x)/dx|_{x=0}$  is determined as a function of film thickness  $y(t)$  by the coupling condition that the charge currents of the ionic and the electronic species must be equal in magnitude. No such coupling is present in the Uhlig theory; this constitutes the basis for the present author's criticism (8) that ionic transport is ignored in the Uhlig theory. To quote from Uhlig and Nwoko (9), "Furthermore, ionic transport was justifiably ignored in our treatment [reference 1] because it is considered to be the faster process during initial oxidation, with electron transfer being controlling." In the absence of coupling with the ionic current, and with an absence of experimental measurements for the total potential  $v'$  across the film (Eq. [2.3]), it seems clear that the second boundary condition must involve some reasonable assumption regarding either  $\varphi(x)|_{x=y(t)}$ ,  $-d\varphi(x)/dx|_{x=0}$ , or  $-d\varphi(x)/dx|_{x=y(t)}$ . The latter two quantities represent the electrostatic field  $E(x)$  at  $x = 0$  and  $x = y(t)$ , respectively.

Before making a specific choice of boundary condition, and thereby restricting the generality of all subsequent results, it is helpful to examine first the relationship between values of the electric field at different points in the film imposed by Poisson's equation. During film growth, the total charge of the system must be maintained constant; for oxidation of a charge-neutral metal, the total charge must therefore remain zero

$$q_0\sigma_0 + q_y\sigma_y - e \int_0^{y(t)} n(x) dx = 0 \quad [2.5]$$

where  $\sigma_0$  and  $\sigma_y$  are the surface densities of charged particles with charge per particle of  $q_0$  and  $q_y$  at  $x = 0$  and  $x = y$ , respectively. Therefore, one or both of the surface charge densities must vary with  $y(t)$ , which in turn represents a dependence of  $E(0)$  and/or  $E(x)|_{x=y(t)}$  on  $y(t)$  since according to elementary electrostatics and Eq. [2.2]

$$E(x) = -\frac{d\varphi(x)}{dx} = \frac{4\pi q_0\sigma_0}{\epsilon} - \frac{4\pi e}{\epsilon} \int_0^x n(x) dx \quad [2.6]$$

The combination of Eq. [2.5] and [2.6] yields the results

$$E(0) = 4\pi q_0\sigma_0/\epsilon \quad [2.7]$$

and

$$E(x)|_{x=y(t)} = -4\pi q_y\sigma_y/\epsilon \quad [2.8]$$

Clearly if the surface charge density  $q\sigma$  could be specified from physical considerations at either interface for the period of oxidation, the surface-charge fields at both interfaces would be given by the above equations for the period of oxidation for any  $n(x)$  appropriate for the system.

The matter of a proper choice for  $n(x)$  is a non-trivial matter. The  $n(x)$  is defined by Uhlig (1) as density of electrons in the oxide which are trapped at impurities or defects, thereby constituting an excess charge density in the oxide. Uhlig (1) makes the assumption that  $n(x)$  has a uniform value  $n_0$  for positions in the oxide less than a distance  $L$ , at which there is a discontinuity in  $n(x)$ , following which  $n(x)$  decreases exponentially with  $x$ . These distributions for  $n(x)$  as well as the assumed discontinuity are clearly *ad hoc* assumptions resulting in a two-stage growth law. Although each of these distributions may be physically realistic in certain limiting cases, the concept of an abrupt transition between the two is clearly nonphysical. Nwoko and Uhlig (9), in their section entitled "Cause of Two-Stage Oxidation Behavior," explain the abrupt transition as occurring at the point at which "the electrostatic energy in the outer oxide approaches the thermal energy  $kT$ ."

Clearly this represents some fundamental misunderstanding of the nature of a Boltzmann distribution, since this classical distribution adequately describes the competition between electrostatic and thermal energies, but contains no discontinuity of the type postulated by Uhlig. The present development will be based on the uniform distribution  $n_0$ , since this serves to illustrate the basic errors in the Uhlig treatment while retaining the advantages of simplified mathematical expressions. The corrected treatment can be readily extended to the case of a diffuse distribution of space charge (16). The value of  $n_0$  for a given physical system is assumed to be determined by experimental conditions of oxidation and sample preparation; the computed potentials with the corresponding space-charge effects can be compared with experimental studies of the kinetics.

With  $n(x) = n_0$ , Eq. [2.5] yields

$$q_0\sigma_0 + q_y\sigma_y = en_0 y(t) \quad [2.9]$$

and Eq. [2.6] yields

$$E(x) = -\frac{d\varphi(x)}{dx} = (4\pi q_0\sigma_0/\epsilon) - (4\pi e/\epsilon)n_0 x \quad [2.10]$$

A further integration of Eq. [2.10] and application of the previously developed boundary condition  $\varphi(0) = 0$  yields

$$\varphi(x) = -(4\pi q_0\sigma_0/\epsilon)x + (2\pi e/\epsilon)n_0 x^2 \quad [2.11]$$

Evaluation of Eq. [2.11] at  $x = y(t)$  and substitution into Eq. [2.3] yields

$$v' = -(4\pi q_0\sigma_0/\epsilon)y + (2\pi e/\epsilon)n_0 y^2 \quad [2.12]$$

According to the Uhlig theory it is the change in this potential with increasing  $y(t)$  that results in a retarding effect on the flow of electrons from metal to oxide which steadily increases with increasing  $y(t)$ , ultimately resulting in a limiting-thickness type growth law. It is quite informative to utilize Eq. [2.12] to compute realistic values for  $v'$ . The first term in Eq. [2.12] represents the surface-charge contribution to the potential across the film, while the second term represents the space-charge contribution. For example, assume that  $y(t)$  is 50 Å and  $n_0 = 0.24 \times 10^{18} \text{ cm}^{-3}$ , which are obtained from the data and analysis of Nwoko and Uhlig (9) for cold rolled zinc sheet (abraded, and etched in HCl) oxidized for approximately 450 min at 206°C in oxygen pressures in the neighborhood of 0.56 Torr. The value of the space-charge term in Eq. [2.12] is thus approximately  $\pm 5.4 \times 10^{-3} \text{ v}$  for  $\epsilon = 10$ . The corresponding ratio  $ev'/kT$  occurring in Eq. [1.2] at 206°C is approximately  $\pm 0.13$ . The term  $\exp(ev'/kT)$  differs from unity by only  $\approx 13$  parts in 100, so that the difference in current  $i$  for zero film thickness  $y(t)$ , for which  $v'$  is zero due to the lack of space charge, and the current  $i$  for  $y(t) = 50 \text{ Å}$ , is only 13%. In other words, the current as computed for the 50 Å film is 0.87 or 1.13 times the current with no space charge, so that the space charge for all practical purposes provides an insignificant attenuation of the current. This is in contrast to the conclusions of Nwoko and Uhlig (9) that the space charge has attenuated the current so markedly that the film has almost ceased to grow.

Up to this point, no boundary conditions have been utilized, so that the conclusions are generally valid under all conditions. The development can be carried no further, however, without some additional assumption which will allow the choice of the second boundary condition. The specification of either  $q_0\sigma_0$  or  $q_y\sigma_y$  for fixed  $n_0$  and for all  $y(t)$  would be sufficient, since Eq. [2.9] would then yield the surface-charge density at the opposite interface. The additional assumption which will be invoked at this point to fix the second boundary condition is that the electric charge  $q_y\sigma_y$  at the outer interface is a constant during the oxidation process. Although this is not in general accordance

with the concept of the oxidation process held by the present author (10, 11), it is apparently in accordance with the concept of Uhlig (15, 17) and therefore appears to be the most reasonable choice necessary to remove the arbitrariness in the matter of the second boundary condition for the Uhlig theory. To quote from the paper by Uhlig (15), "Interpretation of Volta potential measurements as described above assumes that electric charge at the air-oxide interface remains essentially constant, which is a reasonable assumption for constant partial pressure of oxygen; and that major change of potential is accounted for by changing electric charge in the thin oxide films." Since  $q_{y\sigma_y}$  thus is assumed independent of  $y(t)$ , it has the same value in the limit that  $y(t)$  approaches zero. Equation [2.9] thus yields  $q_{y\sigma_y} = -q_{o\sigma_o}|_{t=0}$ . However the point  $y(t) = 0$  corresponds to the bare metal, uncovered by oxide, and because the metal is initially charge-neutral,  $q_{o\sigma_o}|_{t=0}$  is zero. Hence  $q_{y\sigma_y}$  can be chosen to be zero initially, and also subsequently during the oxidation process, in complete accordance with the principles underlying the Uhlig formulation. (Since coupling between species is not considered in the Uhlig theory, any other choice would be either arbitrary or *ad hoc*.) For this case, Eq. [2.9] yields

$$q_{o\sigma_o} = en_0 y(t) \quad [2.13]$$

which when substituted into Eq. [2.12], yields

$$v' = -(2\pi en_0/\epsilon) y(t)^2 \quad [2.14]$$

This is the effective voltage, provided the maximum in  $\nabla(x)$  occurs at  $x_m \cong y(t)$ , as mentioned previously. Substituting Eq. [2.11] for  $\nabla(x)$  into the condition

$$\left. \frac{d\nabla(x)}{dx} \right|_{x=x_m} = 0 \quad [2.15]$$

yields

$$x_m = q_{o\sigma_o}/en_0 \quad [2.16]$$

Substitution of Eq. [2.13] into this expression then gives the result  $x_m = y(t)$ , thus satisfying the condition  $x_m \cong y(t)$ . It is therefore concluded that Eq. [2.14] represents a valid expression for the effective voltage for electron transport in the Uhlig model.

Substituting Eq. [2.14] into Eq. [1.2] gives

$$i = A' \exp(-e\phi/kT) \exp\{-y(t)^2/y_0^2\} \quad [2.17]$$

where

$$y_0 = (\epsilon kT/2\pi e^2 n_0)^{1/2} \quad [2.18]$$

The oxide growth rate is proportional to the electron current, so that

$$\frac{dy(t)}{dt} = \beta i \quad [2.19]$$

where  $i$  is given by Eq. [2.17] and  $\beta$  is the proportionality constant involving the volume of oxide formed for each electron which traverses the oxide film. Defining the quantity  $B_0$  as

$$B_0 = \beta A' \exp(-e\phi/kT) \quad [2.20]$$

the growth equation becomes simply

$$\frac{dy(t)}{dt} = B_0 \exp\{-y(t)^2/y_0^2\} \quad [2.21]$$

The parameter  $y_0$  defined by Eq. [2.18] can be seen to be equal to twice the Debye length  $L_D$  as given by Eq. [2.4]. Integration of Eq. [2.21] does not yield a direct-logarithmic growth law. It is therefore concluded that the Uhlig model does not properly yield a direct-logarithmic growth law (or a two-stage logarithmic growth law) unless additional assumptions are employed.

Furthermore, the thickness  $y_0$  at which the space charge begins to attenuate the growth rate appreciably, and also the pre-exponential factor  $B_0$ , differ by orders-of-magnitude from the corresponding quantities

$y'_0$  and  $B'_0$ , which occur in the Uhlig growth rate expression (18)

$$dy(t)/dt = B'_0 \exp\{-y(t)/y'_0\} \quad [2.22]$$

where

$$B'_0 = \beta A' \exp(-e\phi/kT) \exp(\tilde{v}/kT) \quad [2.23]$$

and

$$y'_0 = \epsilon kT/4\pi e^2 n_0 l \quad [2.24]$$

The newly introduced parameters are  $\tilde{v}$  and  $l$ . (The quantity  $\tilde{v}$  is to be carefully distinguished from the effective voltage  $v'$  given by Eq. [2.12].) The quantity  $\tilde{v}$  is defined somewhat ambiguously in the Uhlig theory

as follows (19): "...  $\tilde{v}$  is the apparent positive potential at the metal surface created by the growing oxide.

The term  $\tilde{v}$ , in general, is numerically equal to the potential difference between the metal-oxide interface and the oxide-oxygen interface for metal-oxide systems in which lattice diffusion of oxygen ions toward

the metal is negligible. As will be shown later,  $\tilde{v}$  is approximated by the electron affinity of oxygen adsorbed on the oxide; it is, therefore, a constant independent of oxide thickness and, like the work function, it is substantially independent of temperature." The value quoted for this parameter (20) is 3.6 ev. The quantity  $l$  is defined by Uhlig (15) as the assumed thickness of the constant charge density film at which the field is zero at the metal surface, and values deduced for this parameter (21) are of the order of 1,000 to 100,000 Å.

From Eq. [2.18], [2.20], [2.23], and [2.24]

$$y'_0/y_0 = y_0/2l = (\epsilon kT/2\pi e^2 n_0)^{1/2}/2l \quad [2.25]$$

and

$$B'_0/B_0 = \exp(\tilde{v}/kT) \quad [2.26]$$

For  $n_0 = 10^{16} \text{ cm}^{-3}$ ,  $\epsilon = 10$ ,  $T = 300^\circ \text{K}$ ,  $l = 10,000 \text{ Å}$ ,

and  $\tilde{v} = 3.6 \text{ ev}$ , the above ratios have the approximate values  $y'_0/y_0 \cong 0.03$  and  $B'_0/B_0 \cong \exp(140) \cong 10^{60}$ , which emphasizes the tremendous discrepancy between the predicted effects of space charge on growth rate, even neglecting the fact that the growth laws have a different functional form.

At this point, it is helpful to analyze the source of the parameter  $l$ , which is one of the two parameters which cause large excursions in the Uhlig theory relative to the present development. The parameter  $l$  comes about through the incorrect usage of  $y(t)$  in place of  $x$  in Poisson's equation, since a boundary condition was imposed at one very large film thickness  $y(t) = l$  corresponding to one point in time instead of at a point  $x_0(t)$  for the entire time of growth. The thickness  $l$  corresponded by definition to the point at which  $E(O) = 0$ . Referring to Eq. [2.7] and [2.9], it can be seen that if  $q_{y\sigma_y} = 0$  as was argued previously, then  $E(O)$  can never be zero for finite film thicknesses and nonzero values of  $n_0$  without violating the principle of conservation of total charge (Eq. [2.9]) for the system. That is, for nonzero space charge, the surface charge at the two interfaces must be equal and opposite to the total space charge for over-all charge conservation; this precludes the surface-charge density from being zero simultaneously at both interfaces for a nonzero value of  $n_0$ . This matter of nonconservation of total electrical charge immediately illustrates the necessity of a proper choice of boundary conditions.

The parameter  $\tilde{v}$  is the second quantity in the Uhlig theory which results in such a large difference from the present development. Basically it is claimed by Uhlig (1) that the electron affinity of adsorbed oxygen at the oxide-oxygen interface lowers the activation energy for electron transfer from the metal through the oxide, which therefore results in an in-

crease in the electron flux through the film by a factor of approximately  $\exp(140)$ . This matter, which is simply a confusion of the thermodynamic concepts of activation energy and free energy of reaction (22), is considered in detail in the following section.

### Electron Activation Energies

Referring to the standard activation barrier illustrated in Fig. 1, it can be seen that the activation energies for forward and reverse reactions are  $W_f$  and  $W_r$ , respectively, while the free energy change  $\Delta U$  for the reaction is  $\Delta U = W_r - W_f$ . The rate  $R_f$  of forward reaction is

$$R_f = n_f \nu_f \exp(-W_f/kT) \quad [3.1]$$

and the rate  $R_r$  of the reverse reaction is

$$R_r = n_r \nu_r \exp(-W_r/kT) \quad [3.2]$$

$n_f$  is the number of particles in the position of the first potential minimum,  $\nu_f$  is the attempt frequency of these particles, and  $W_f$  is the potential barrier height in the forward direction, while  $n_r$  is the number of particles in the position of the second potential minimum,  $\nu_r$  the attempt frequency of these particles, and  $W_r$  is the potential barrier height in the reverse direction. The net rate of the reaction is

$$R_{\text{net}} = R_f - R_r \quad [3.3]$$

which of course is zero in the limit of chemical equilibrium. For equilibrium, the forward and reverse rates are equal

$$n_f \nu_f \exp(-W_f/kT) = n_r \nu_r \exp(-W_r/kT) \quad [3.4]$$

so that

$$(n_r/n_f) = (\nu_f/\nu_r) \exp(\Delta U/kT) \quad [3.5]$$

Clearly the right-hand side has the standard form for an equilibrium constant (22) for the reaction, and this depends only on  $\Delta U$  and not on the individual values of  $W_f$  and  $W_r$ .

For a strongly nonequilibrium process, however, the reaction is predominantly in the forward direction. That is, at the start of the reaction,  $n_r = 0$ , so the net rate of the reaction is given by Eq. [3.1]. This involves only the activation energy  $W_f$ , and is independent of  $W_r$  and hence of  $\Delta U$ .

The oxidation of metals is clearly a strongly nonequilibrium process, at least so long as the oxidation proceeds, as evidenced by an appreciable growth rate of the oxide film. Hence the rate-limiting step for oxidation, which is postulated to be electron transport in the Uhlig theory, must be strongly nonequilibrium. Therefore, on the basis of the Uhlig theory, the rate of oxidation must be determined by the activation energy for electron transport in the forward direction instead of the free energy change  $\Delta U_e$  for electron transport through the oxide as postulated by Uhlig (1). Only in the case of theories based on ionic rate-limit-

ing transport does  $\Delta U_e$  become the important quantity for electron transport, since only then does the electronic species approach equilibrium. The free energy of formation of the oxide,  $\Delta U_{\text{oxide}}$ , does not occur explicitly in the rate equations, since this includes not only the free energy change  $\Delta U_e$  for transport of electrons through the oxide, but also includes the free energy change  $\Delta U_i$  for transport of an equivalent number of ions (i.e., equivalent in charge) through the film

$$\Delta U_{\text{oxide}} = \Delta U_e + \Delta U_i \quad [3.6]$$

This point does not seem to have been clarified previously in the literature; it represents a subject of much present-day discussion (23).

The relevant electron energy diagram is illustrated in Fig. 2. The diagram clearly is analogous to the schematic reaction barrier shown in Fig. 1 and discussed above. Initially the electrons are in the conduction band of the metal, with the oxide representing an activation barrier in the forward direction. With no electric fields in the system (Fig. 2a, 2b) the activation energy for electron transport in the forward direction is the metal-oxide work function  $\phi$ ; this parameter is the energy difference between the conduction band in the oxide and the Fermi level in the metal. The activation energy for electron motion in the

reverse direction is shown in Fig. 2a,b to be  $\tilde{v}$ , and the net energy change effected in electron transport from the Fermi level of the metal to the  $O^-$  state in

adsorbed oxygen is  $\Delta U_e = \tilde{v} - \phi$ . [Note that this is positive for Fig. 2a and negative for Fig. 2b. Mott (24) considers the former picture while Uhlig (25) prefers the latter.] The quantity  $\Delta U_e$  is unimportant for computing the net rate of electron transport, however, when this is the rate-limiting step for the process, as was argued for the reaction barrier in Fig. 1. Hence the activation energy in zero field in the Uhlig theory

should be  $\phi$  and not  $\phi - \tilde{v}$ , as was employed by Uhlig (19). With nonzero space charge, the activation barrier for electron transport is modified by the electrostatic potential in the oxide. Figure 2b is thus modified to the form illustrated in Fig. 2c or Fig. 2d. Figure 2c illustrates the case in which all compensating surface charge is located at the metal-oxide interface while

Fig. 1. Standard activation barriers  $W_f$  for the forward direction and  $W_r$  for the reverse direction. (a) Positive free energy change  $\Delta U$  for reaction in the forward direction. (b) Negative free energy change  $\Delta U$  for reaction in the forward direction.

Fig. 2. Electron energy diagrams for metal-oxide-oxygen system. (a)  $O^-$  level below metal Fermi level. (b)  $O^-$  level above metal Fermi level. (c) Negative space charge with compensating positive charge at the metal-oxide interface. (d) Negative space charge with compensating positive charge at the oxide-oxygen interface.

Fig. 2d illustrates the case in which all compensating surface charge is located at the oxide-oxygen interface. It can be noted that the activation barrier in the forward direction is increased by  $v'$  for the case of Fig. 2c, but is unmodified in Fig. 2d. The activation barrier in the reverse direction is unchanged in Fig. 2c but increased by  $v'$  in Fig. 2d; these modifications of the reverse barrier are unimportant for the Uhlig theory, however, as argued above. [These conclusions must be modified slightly when image potentials are included (11); such complicating effects were neglected by Uhlig.] It is interesting to note that if surface charge at  $x = 0$  is ignored (Fig. 2d), the potential maximum occurs at  $x = 0$ , and the space charge contribution to the potential has no effect on the electron current. This emphasizes the importance of the surface charge. It is therefore seen that the Uhlig concept of trapped electrons causing a continuous increase in height of the activation barrier as the film thickness increases is most closely approximated by the case illustrated in Fig. 2c, so that the activation energy for this case is  $e(\phi - v') = e(\phi + |v'|)$ , a

quantity independent of the electron affinity  $\tilde{v}$  of adsorbed oxygen. For an electron flux  $A'$  with a Boltzmann-type distribution in energy (i.e., the high energy "tail" due to  $kT$  spreading of the Fermi-Dirac distribution function) incident on the barrier, the electron current over the barrier is given by

$$i = A' \exp\{-e(\phi - v')/kT\} \quad [3.7]$$

which is identical to Eq. [1.2]. This equation therefore represents a valid expression for the electron current in the Uhlig model provided there is no reverse electron current, i.e., no thermal excitation of electrons from filled  $O^-$  states at  $x = y(t)$  into the oxide conduction band toward the metal-oxide interface. This will indeed be the case if the electron current is rate-limiting, as in the Uhlig model, since the oxide growth is presumably being retarded due to a deficiency of electrons at the oxide-oxygen interface.

The physical situation represented by Fig. 2c is also the one in accordance with the Uhlig assumption of an unchanging surface charge at the oxide-air interface (15, 17). The development leading to the growth law of Eq. [2.21] represents this situation. The fact remains, however, that a direct-logarithmic growth law is not obtained, contrary to the development by Uhlig (1). In addition, the factor of  $\exp(140)$  introduced by the inclusion of  $\tilde{v}$  into the activation energy in the Uhlig development is definitely absent in the present development.

### On the Possibility of Obtaining the Direct-Logarithmic Law

The origin of the direct-logarithmic growth law in the Uhlig development rests on the fact that the parameter  $l$  introduced in the application of improper boundary conditions in Poisson's equation resulted in a very large term in  $v'$  which was linear in  $y$ , so that the quadratic term could be neglected. It can be seen from Eq. [2.14] that  $v'$  obtained in the present development is purely quadratic in  $y(t)$ , with no linear term; hence the growth law represented by Eq. [2.21] is not of the direct logarithmic form. A considerable effort was made in ref. (8) to find a physical situation for which a term linear in  $y(t)$  would be obtained for  $v'$ , so that the Uhlig result of a direct-logarithmic law could still be valid, albeit with greatly modified values of the parameters. To this end, an additional factor was introduced into the development, this being the electron tunneling distance or scattering length in the oxide. It is clear that the simple activation barrier theory discussed up to this point assumes that the electron is thermally excited from the Fermi level of the metal into the conduction band of the oxide, and the rate of transport deduced thereby presumes

that the electron neither penetrates the classically inaccessible region in the barrier nor is scattered in the conduction band of the oxide before surmounting the potential maximum. Clearly, both quantum-mechanical tunneling as well as electron scattering are real effects; it was therefore believed (8) that the introduction of one or the other of these factors could perhaps modify the physical picture in such a direction as to yield a direct-logarithmic growth law.

It is certain that a uniform space charge will always contribute a term to the potential which is parabolic in  $x$  (see Eq. [2.11]); the surface-charge field, however, contributes a term linear in  $x$ . Thus the total potential drop across the film is proportional to  $y(t)^2$  for the space charge contribution and is proportional to  $E(O)y(t)$  for the surface charge field. Therefore, one way to obtain a linear term in  $y(t)$  which is needed to obtain the direct-logarithmic growth law is for  $E(O)$  to be independent of  $y(t)$  and to be large relative to the space-charge term. However, neither of these conditions are met in the present development: The  $E(O)$  increases linearly with  $y(t)$  if all of the compensating surface charge is located at  $x = 0$  (see Eq. [2.7] and [2.9]), thus yielding a parabolic contribution [ $E(O)y(t) \propto y(t)^2$ ] to the potential; furthermore this term is of the same order of magnitude as the space charge term. If all compensating surface charge is located at  $x = y(t)$ , then  $E(O) = 0$  and again there is no large linear contribution to the potential. Hence, the assumption of a constant  $E(O)$  requires the introduction of some physical mechanism not now included in the Uhlig theory. In addition, it requires surface-charge fields much larger than the space-charge field in order to neglect properly the space-charge contribution to the potential; this in itself would be inconsistent with the basic hypothesis of Uhlig that space charge due to trapped electrons is the mechanism responsible for the direct-logarithmic growth kinetics. Nevertheless, this is essentially what was done in the Uhlig treatment (1), since the value of  $E(O)$  was computed from the criterion that the uncompensated charge at  $x = 0$  for all film thicknesses be equal in magnitude but opposite in sign to the total space charge in some film of arbitrary but enormous thickness  $l$  (of the order of  $10^4$  to  $10^5 \text{ \AA}$ ). Thus  $q_o\sigma_o$  was given the value  $en_ol$ , corresponding to  $E(O) = 4\pi en_ol/\epsilon$ . When this is coupled with the assumption that  $q_y\sigma_y$  is independent of film thickness, the condition for conservation of charge (Eq. [2.9]) is violated. Clearly this approach cannot be considered to be valid.

Another possible way in which a surface-charge contribution to the potential can be obtained which is linear in  $y(t)$  and which predominates over the space-charge term, and which has the additional advantage of being due entirely to a surface-charge at  $x = 0$  not exceeding the total space charge, is for the electrostatic potential effective in reducing the activation barrier to be that potential developed over a fixed distance  $\delta$  which is independent of  $y(t)$ . Admittedly this would be an *ad hoc* assumption, although it is perhaps not quite so artificial when one thinks of  $\delta$  as a maximum distance in the oxide characteristic of easy electron tunneling between traps or of electron scattering in the conduction band of the oxide.

For example, electron tunneling can occur quite readily through barriers 10-15Å in thickness for the barrier heights less than several electron-volts normally encountered in metal-oxide systems; thus sharp spikes and corners in the simplified electron energy diagrams illustrated in Fig. 2 can be ignored, since thermal excitation to an energy below the barrier maximum can still result in transport across the barrier provided the electron can tunnel readily through the classically disallowed region. This matter of combined mechanisms for electron transport has been formulated quite generally by Murphy and Good (26). In such a case, the effective activation energy may

well be modified by  $\tilde{v}$  (see Fig. 2b), as claimed by Uhlig, provided the film thickness is less than a distance  $\delta_{\text{tun}}$  characteristic of easy electron tunneling, i.e.,  $y(t) \lesssim 50\text{\AA}$ , since the classically disallowed region no longer represents the true activation barrier. However, easy electron tunneling precludes the possibility of rate being limited by electron emission, so the Uhlig theory would be inapplicable in this case.

For films much thicker than the characteristic scattering length  $\delta_s$  for electrons in the conduction band of the oxide, the electrostatic potential developed across the region ( $0 \leq x \leq \delta_s$ ) is almost entirely due to the surface-charge contribution for the case in which the distribution of space charge is uniform and the total compensating surface charge is located at  $x = 0$ . Furthermore the total space charge increases linearly with  $y(t)$ , so  $E(O)$  also increases linearly with  $y(t)$ . The potential drop across the region  $0 \leq x \leq \delta_s$  is closely approximated by  $-E(O)\delta_s$ , so that we have the desired result of a large linear term in  $y(t)$ . This was the approach employed in ref. (8) to obtain a direct-logarithmic growth law, although it was realized at that time and is reiterated now that the result is quite artificial because of the *ad hoc* assumptions involved. For example, the appropriate energy diagram is given by Fig. 2c; note that easy transport of electrons from  $x = 0$  to  $x = \delta_s$  does not guarantee subsequent transport through the film, since the transport of electrons from  $x = \delta_s$  to  $x = y(t)$  must take place against an opposing electric field.

In light of the above discussion, it is concluded that even the inclusion of additional physical considerations in the Uhlig theory does not lead to a direct-logarithmic growth law in any straightforward manner. Hence this growth law as based on the Uhlig postulates must be considered to be theoretically unfounded. The alternate growth law given by Eq. [2.21] is more in keeping with the basic postulates of the theory and with elementary electrostatics.

The physical and mathematical treatments by Uhlig (27) of the diffuse space charge distribution and the cubic equation, as well as the derivation of the Rideal-Jones relation, are based on reasoning similar to that which he utilized for the uniform space charge development and hence are subject to the same type of errors which have been pointed out above. In addition, many *ad hoc* manipulations and approximations are made by Uhlig (27, 28) which are neither mathematically nor physically justifiable. It is not worth the additional effort, and indeed is beyond the scope of the present communication, to consider these sections in detail.

### Effect of Ionic Current on Electron Current due to Coupling

The present author has proposed (10) a technique for obtaining the oxidation kinetics for formation of a coherent oxide on a metal whenever transport takes place by currents of the oppositely charged species through the oxide. This method consists in coupling the transport equations through the macroscopic electric field in the oxide, imposing the condition of equal charge currents as the criterion for obtaining the surface-charge field, and numerically or analytically integrating the system of equations. The hypothesis of equal charge currents utilized to obtain the surface-charge field is intuitively reasonable since this is the quasi-stable situation for a given film thickness in which the currents do not change the surface-charge field. This method has also been justified by numerical computations (29). Now, in the Uhlig model, the space-charge fields are presumed to be large, so that both current equations must include the effects of this nonhomogeneous space-charge field. This can be accomplished readily for the ionic species through an averaging technique (16), so that integrated current equations, although admittedly approximate, are still

available. A better approach would be to perform exact numerical computations.

Let us denote the electronic and ionic charge currents as  $i = -eJ_e$  and  $q_iJ_i$ , respectively, where the electronic and ionic charges are  $-e$  and  $q_i$ , and  $J_e$  and  $J_i$  are the corresponding particle currents. Then the "kinetic condition" of equal but opposite charge currents which determines  $E(O)$  as a function of film thickness  $y(t)$  is (11)

$$q_iJ_i - eJ_e = 0 \quad [5.1]$$

The dependence of  $E(O)$  on  $y(t)$  thereby obtained is to be substituted into one of the two currents  $J_i$  and  $J_e$  to obtain the growth rate

$$\frac{dy(t)}{dt} = R_cJ_c \quad [5.2]$$

where  $J_c$  is the rate-limiting particle current, and  $R_c$  is the volume of oxide formed per particle of the flux  $J_c$  which is transported from  $x = 0$  to  $x = y(t)$ . (In the Uhlig theory,  $\beta$  is related in a simple manner to  $R_c$ , depending on whether  $i$  and  $A'$  are interpreted to be charge or particle fluxes.)

In practice, the solution of the above equations must usually be performed numerically. This is the case for an ionic diffusion current coupled with the electron current treated in the preceding sections. The electrostatic potential obtained from combining Poisson's equation with the  $E(O)$  deduced utilizing this approach is designated the "kinetic potential" to reflect its function of equalizing the charge current magnitudes.

This "coupled currents" approach is considered to give a much more accurate picture of the kinetics than the conventional approach of assuming one current to be rate-limiting, and then integrating the corresponding growth equation by making some arbitrary (or *ad hoc*) assumption regarding the film-thickness dependence of the surface-charge field. For this reason, the integration of Eq. [2.21] and a computation of characteristic growth curves is not deemed advisable at this time. It is clear that Eq. [2.21] represents a growth law which has a sharper decrease in the growth rate in the neighborhood of  $y_0$  than the corresponding logarithmic growth law. The "coupled currents" approach has been utilized successfully (11, 30) for several models of the growth kinetics applicable at different temperature and film-thickness ranges, and is currently being utilized to obtain the kinetics for a model based on the presently discussed electron current. The results, together with appropriate comparisons with the predictions of Eq. [2.21] and experimental results, will be presented subsequently.

### Misconceptions in Uhlig and Nwoko Paper

Several misconceptions were introduced in the rebuttal given in the paper by Nwoko and Uhlig (9). The purpose of the present section is to counteract the most serious of these.

To quote from Uhlig and Nwoko (9): "In our opinion there is no physical or theoretical reason to believe that an electron entering the oxide at the metal-oxide interface cannot migrate through the conduction band of the oxide to the oxide-oxygen interface in order to ionize adsorbed oxygen, where indeed the electron must go if oxidation is to proceed. In a p-type oxide, a positive hole migrates through the oxide thickness in the opposite direction." This statement is completely inapplicable to the Uhlig theory of oxidation, which is based on the postulate that rate is limited by the transfer of electrons from the metal across the oxide, so that the rate-limiting step is the thermal excitation of electrons from the metal over the energy barrier represented by the oxide. Hence there cannot be a significant migration (i.e., simple diffusion or field-assisted diffusion) of electrons (or holes) in the conduction (or valence) band whenever

this theory is applicable. On the other hand, if the oxide is not of the insulator-type, but instead is a good electronic conductor or semiconductor, then the Uhlig model cannot be valid since ions instead of electrons will limit the growth rate. For example, this would be the case in Fig. 2a whenever the  $O^-$  levels are below the top of the filled valence band in the oxide; the electrons then flow from the filled band into the empty  $O^-$  levels, so that p-type semiconductor through the partially depleted valence band becomes possible. The Uhlig model is clearly inapplicable since electron emission does not then limit the rate.

Even if the oxide is an insulator-type oxide in which electrons (or holes) can be the rate-limiting species, the energy imparted to the electron (or hole) by thermal excitation will be lost on the average in a distance  $\delta_s$  if the oxide thickness  $y(t)$  is much greater than the electron scattering length  $\delta_s$  of electrons in the conduction band of the oxide (or holes in the valence band of the oxide). The electrons (or holes) must then be transported the remainder of the distance  $\delta_s \leq x \leq y(t)$  by some other transport process, and the Uhlig theory becomes inapplicable (30). Two processes can then possibly be effective: electric field migration, and diffusion under a concentration gradient. Electric field migration is definitely eliminated for the Uhlig theory, since the net field has polarity such as to drive electrons in the negative x-direction instead of in the positive x-direction [see Fig. 2c, which illustrates that in the Uhlig model electrons are required to migrate up a potential hill created by the electric field (30)]. Furthermore, in this case there is no electron concentration gradient created which can serve as a force to drive electrons up the potential hill, since, according to the Uhlig model, the electrons are rate-limited by thermal emission at the metal-oxide interface. Whenever rate is no longer limited by electron emission at the metal-oxide interface due to scattering of electrons in the conduction band of the oxide  $\{y(t) \gg \delta_s\}$ , the transport process can then become diffusion-controlled by the concentration gradient and space charge fields due to the scattered electrons. Such a mechanism, however, yields results (10) which must be entirely different from Eq. [2.21], the latter being applicable only for thermal excitation of electrons over an activation barrier.

A point which should be emphasized is that the parameter  $\tilde{v}$  is ineffective for the thermal emission process of the Uhlig theory regardless of whether the electron traverses the film in a one-step process, or whether thermal emission is effective only for a distance  $\delta_s$  before scattering, with subsequent diffusion under a concentration gradient. This confusion of the concept of activation energy for electron transport with the net free energy change which results from such transport is emphasized by a further quotation from Nwoko and Uhlig (9): "We consider that the activation energy for oxidation is equivalent to transfer of an electron from metal to oxide to oxygen adsorbed on oxide, given by  $e(\phi - \tilde{v})$  where  $e$  is the electronic charge,  $\phi$  is the metal work function  $\phi_0$  modified by amount  $\chi$  through contact with the oxide such that  $\phi = \phi_0 - \chi$ , and  $\tilde{v}$  is related to the electron affinity of adsorbed oxygen (approximately 3.6 eV). The total energy of electron transfer is increased by the growing more negative space charge in the oxide accounting for a decreasing oxidation rate as the oxide grows." Clearly the energy  $e(\phi - \tilde{v})$  is the free energy change and not the activation energy; confusion of such concepts is the source of the orders-of-magnitude discrepancy between predicted and physically reasonable effects of space charge on the growth kinetics in the Uhlig theory. As can be seen

from Fig. 2b, the free energy change  $e(\phi - \tilde{v})$  can be equal to the activation energy only if this quantity is positive and the electron traverses the classically disallowed region by tunneling, a process which is of importance only if the thickness  $y(t)$  is less than  $\delta_{\text{tun}} \leq 50\text{\AA}$ .

### Conclusions

The results of our careful re-examination of the Uhlig model and its original mathematical treatment are threefold:

1. Our conclusions remain unchanged that errors in the original Uhlig treatment lead to a prediction of space-charge effects which are orders of magnitude too large to be physically realistic for the space-charge concentrations in question.
2. The present consideration of electron tunneling distances and electron scattering lengths in the oxide fails to justify the appropriate *ad hoc* assumption necessary for obtaining a direct-logarithmic (or two-stage logarithmic) growth law from the Uhlig model; it is concluded, therefore, that such a growth law is presently theoretically unfounded for the case of oxide films too thick ( $\geq 100\text{\AA}$ ) for appreciable electron tunneling.
3. The perturbations to the surface-charge field, electronic current, and oxidation kinetics which are introduced by the current of the ionic species should be examined numerically by the "coupled currents" approach to the theory of oxidation kinetics to ascertain whether or not these effects can be validly neglected.

Manuscript submitted Jan. 29, 1968; revised manuscript received May 21, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Stress Corrosion Cracking of Titanium Alloys

## II. An Electrochemical Mechanism

T. R. Beck\*

Boeing Scientific Research Laboratories, Seattle, Washington

### ABSTRACT

Kinetic measurements were made under potentiostatic conditions for hydrogen ion reduction on and oxidation of newly generated surfaces of a titanium alloy in aqueous solutions. Approximate kinetic parameters were obtained during the growth of the first monolayer of oxide and for growth of thicker films. These kinetic data were used in an approximate model in an attempt to simulate the electrochemical events in a stress corrosion crack propagating through the titanium alloy in aqueous solution. The observed current flowing into a crack could be semiquantitatively accounted for in the model by oxidation of the crack walls. The oxide cracking and wedging mechanisms of crack propagation can be rejected in the model and, if the assumptions are valid, in the real metal. Further work will be required to define other mechanisms at the crack tip.

An experimental investigation of the effect of potential and various ions in aqueous solution on stress corrosion cracking (SCC) of titanium: 8% Al-1% Mo-1% V alloy (Ti:8-1-1) was reported in a prior paper (1). A similar effect of potential on the strength of another titanium alloy in seawater has also been reported (2). The purpose of the present paper is to present new data on kinetics of oxidation of freshly generated Ti:8-1-1 alloy surface and kinetics of hydrogen ion reduction thereon, and to illustrate how these data can be used in a preliminary interpretation of the electrochemistry in a propagating stress corrosion crack. A more rigorous analysis will follow in another paper (3).

The usual four SCC mechanisms were proposed at the start of this work as possibilities for titanium alloys (4):

1. A mechanism involving a titanium oxide:
  - (a) stepwise formation and fracture of brittle titanium dioxide layer at the tip of a crack;
  - (b) wedging of a crack by formation of titanium dioxide.
2. A mechanism involving hydrogen:
  - (a) stepwise formation and fracture of brittle surface hydride layer at the tip of a crack;
  - (b) precipitation of a hydride phase within the plastic zone due to a more rapid diffusion and/or easier nucleation, leading to a degradation of properties in this region.
3. Preferential anodic dissolution at specific electrochemically active sites at the tip of a crack.
4. A surface energy lowering mechanism involving adsorption of a species from the electrolyte phase in contact with the metal.

The electrochemical kinetics experiments and the analysis presented in the paper provide a basis for rejecting the brittle oxide and oxide wedging mechanisms for Ti:8-1-1 in aqueous solution as will be shown. Further work must be done before a definitive statement can be made about the applicability of mechanisms 2 through 4 to titanium alloys.

Unless otherwise stated, potentials are given in millivolts and the saturated calomel electrode (SCE)

is the zero standard of reference. A table of nomenclature is given.

### Experimental

Two types of kinetics experiments were made: studies of multiple monolayer (multilayer) oxide growth; and studies of growth of the first monolayer and of hydrogen ion reduction during the growth of the first monolayer. In addition, open-circuit mixed potentials for the monolayer oxide formation and hydrogen ion reduction were determined. All experiments were made with Ti:8-1-1 alloy in the mill-annealed condition, having the composition and properties previously listed (1).

The stress corrosion cracking specimens and cell previously described (1) were used in studies of multilayer oxide growth. The essential difference between the kinetics experiments and the previously described SCC experiments was that a higher cross-head velocity (0.5 cm/min) was used and a very rapid fracture at a higher load occurred. Current was recorded on an x-y plotter using an x-axis speed of 5 cm/sec at fracture. The experiments were run potentiostatically using a Wenking Model 6379TR potentiostat (1). The oxidation current to the new surface was that current measured after final fracture [Fig. 5, ref. (1)] corrected for the small current to the preexisting exterior surface. The specimens were usually anodized to minimize the correction for background current to the preexisting surface. In later experiments a Tektronix type 545 A oscilloscope and Polaroid camera were used to record the current transient at less than  $10^{-1}$  sec from fracture.

Kinetics of oxidation and hydrogen ion reduction on new metal surface during the formation of the first monolayer of oxide were studied in the smaller Teflon cell illustrated in Fig. 1. The smaller specimens were used to avoid excessively high currents from the high current density initial reactions. The new area generated for the two surfaces was approximately 0.05 cm<sup>2</sup>. A coating of epoxy resin was applied to the small specimens to avoid reaction on the preexisting surface. The resin was scored over the notch in the metal to localize the break in the resin and minimize adhesion failure and exposure of preexisting titanium surface.

\* Electrochemical Society Active Member.

Fig. 1. Cell for monolayer kinetics experiments

A sudden break was caused by dropping a 45 kg (100 lb) weight connected through a 5:1 lever arm to the specimen. Travel of the lever arm was limited so that the new fracture surfaces separated by 1 to 2 mm. Movement of the lever arm closed a microswitch that triggered the sweep in the Tektronix type 545 A oscilloscope. The camera shutter was open on time exposure during the run.

Runs were made in 0.6M potassium chloride and concentrated (approx. 12M) hydrochloric acid. Concentrated HCl was used because initial analysis of events in a propagating stress corrosion crack indicated that the electrolyte becomes acid. The preliminary data thus far obtained are not precise, but nevertheless are suitable for order of magnitude estimates of oxidation current density, exchange current density, and mixed potential. Refinements to improve the accuracy of the experiments are underway.

The IR drop in the electrolyte between the new surfaces and the Luggin capillary tip at the high current densities observed threw some doubt into the precise value of the mixed potential as determined from the kinetics experiments. To avoid the IR drop, the mixed potential, just after fracture and exposure of new metal surface, was measured at open circuit with a Tektronix type 545 A oscilloscope. The input impedance was about  $10^6$  ohms so that the oscilloscope should have had little influence on an electrode with an initial current on the order of 5 ma ( $10^{-1}$  amp/cm<sup>2</sup> current density) and a high conductivity electrolyte.

## Results

**Multilayer oxide growth.**—Results of the kinetic experiments using the 2.54 cm wide 0.152 cm thick mill-annealed specimens are shown in Fig. 2. At a potential of 0 mv to SCE applied to the titanium specimen, the 0.6M chloride, bromide, and iodide solutions gave essentially the same current *vs.* time relationship. The initial, approximately horizontal, part of the curve corresponds to formation of about a monolayer of oxide ions. The charge density is ( $3.5 \times 10^{-1}$  amp/cm<sup>2</sup>) ( $2.5 \times 10^{-3}$  sec) =  $880 \times 10^{-6}$  coulomb/cm<sup>2</sup>. Monolayer coverage of oxide ion is equivalent to about  $425 \times 10^{-6}$  coulomb/cm<sup>2</sup> on the basal plane of  $\alpha$ -Ti assuming one double charged oxide ion per titanium atom. The difference between these two values may be due to surface roughness, parallel formation of soluble titanium species, and experimental error. Thereafter the current decays approximately with the reciprocal of time.

Fig. 2. Kinetic data on oxidation of Ti:8-1-1 in 0.6M halide solutions.

From the coincidence of the curves at a potential of 0 mv to SCE the same mechanism appears to apply for the chloride, bromide, and iodide solutions, assumed to be the oxidation of titanium by water. The current density *vs.* time relation is displaced toward higher current densities with increased positive potential in 0.6M chloride as expected.

Considerable deviations in the direction of increased current density were observed in 0.6M bromide and iodide solutions at a specimen potential of +1000 mv. This is consistent with observed onset of pitting corrosion (1), the rise of current density with time in 0.6M bromide apparently being due to increase in number and/or size of pits. Although specimens in iodide solution did not show visible evidence of pits to the eye in the specimen at +1000 mv, incipient pitting is suspected at a micro scale. Further studies on pitting corrosion of titanium will be reported elsewhere (5).

With 0.6M fluoride solution the current density *vs.* potential curves at +1000 mv and 0 mv (not shown) were considerably above the curves for chloride, consistent with the known corrosiveness of fluoride to titanium and the formation of soluble  $TiF_6^{2-}$  ions (6).

It is appropriate at this point to compare the data to the theoretical oxide growth rate based on the high-field conduction equation using constants for titanium available in the literature. The growth rate of an anodic oxide film starting from a molecular thickness is (7)

$$\frac{dt}{d\tau} = A(i - i_K) \quad [1]$$

where the current density can be expressed by the high-field conduction equation

$$i = i_0 \exp\left(\frac{\beta \Delta \phi}{t}\right) \quad [2]$$

A solution of these equations may be obtained for a plane electrode under potentiostatic conditions ( $\Delta \phi = \text{constant}$ ). Assuming that  $i \gg i_K$  during the initial period of film growth, gives

$$d\tau = - \left( \frac{\beta \Delta \phi}{A i_0} \right) \left[ \frac{d \ln I}{I (\ln I)^2} \right] \quad [3]$$

The solution to the right-hand term in brackets is available in tables (8).

The solution to Eq. [3] is compared to the experimental data for Ti:8-1-1 at 0 mv to SCE in Fig. 3. The following values were used in the constant in Eq. [3]:

$$\begin{aligned} A &= 4.85 \times 10^{-5} \text{ cm}^3/\text{coulomb for rutile.} \\ \beta &= 6 \times 10^{-6} \text{ cm/v [average experimental value for oxidation of commercially pure Ti (9)].} \\ i_0 &= 2 \times 10^{-13} \text{ amp/cm}^2 \text{ [average experimental value for oxidation of commercially pure Ti (9)].} \end{aligned}$$

Fig. 3. Comparison of kinetic data on oxidation of titanium to theory using constants from literature.

$\Delta\phi = 1v$  [In neutral solution the reversible potential for titanium oxidation is about  $-1.5v$  vs. SCE (6). Assuming the Flade potential is  $0.5v$  (10) and neglecting the overpotential for the oxide to electrolyte reaction, which becomes small as the film thickness increases, gives  $\Delta\phi \approx 1v$  across the film for an applied potential of  $0v$  to SCE).

There appears to be a reasonable correspondence between the experimental data and the theory using the constants from Johanson *et al.* (9). It is therefore considered that the kinetic data for Ti:8-1-1 in chloride, bromide, and iodide at  $0$  mv in Fig. 3 represent the formation of titanium dioxide. The displacement of the experimental data for Ti:8-1-1 to higher current densities could be due to higher conductivity of the oxide corresponding to its higher defect concentration.

An alternate interpretation for the experimental current density for Ti:8-1-1 being above the theory as well as having a greater slope could be that there is a parallel corrosion current to form soluble titanium species. In other words,  $i \approx i_k$ . Thermodynamically the formation of soluble species appears very likely (11), and further work is underway to resolve this question.

**Growth of first monolayer of oxide and hydrogen ion reduction.**—Determining the kinetics of formation of the first monolayer of oxide and of hydrogen ion reduction on the newly generated bare metal surface was difficult in experiment and interpretation. The difficulties are due to the high current densities with resultant high ohmic drops in the electrolyte, the short time to complete the monolayer, and the possibility of more than one anodic reaction. Nevertheless some order of magnitude data for newly generated titanium surface, heretofore unavailable, were obtained for a concentrated HCl electrolyte.

According to the potential-pH diagram for titanium (11) divalent titanium ion is the thermodynamically stable species that should be formed by oxidation of titanium at the potentials used for the experiments in concentrated HCl. Titanium dioxide can form, however, at potentials positive to its reversible potential, also in the range of the experiments. Formation of  $TiO_2$  apparently blocks further rapid formation of  $Ti^{++}$ . Dissolution of oxide covered titanium in acid solution is known to proceed at relatively low rates (in the range of  $1-10 \mu a/cm$  at room temp) (12).

The reactions that are possible in the potential range of the experiments and their standard reversible potentials (SCE scale) are (6)

Formation of  $TiO$  ( $E^\circ = -1550$  mv) is an alternate to reaction 2 at high negative potentials. In the 12M HCl used, all of the potentials would be about  $64$  mv more positive. The range of potentials used in the experiments was  $-1050$  to  $-500$  mv. In this range it would appear that reaction 1 should be favored over reaction 2 because of a much larger driving force, but the titanium was observed to passivate. As will be seen from the quantity of charge passed and the rate of passivation it appears that reaction 1 proceeds at a rate of no greater order of magnitude than reaction 2. Because there was no way of determining the exact extent of reaction 1, it was not considered in the analysis. More sophisticated experiments will have to be devised to get rate data for reaction 1 on newly generated bare metal surface.

Typical current-time oscilloscope traces for potentiostatic experiments are shown in Fig. 4 for a net anodic current and a net cathodic current. In all of the experiments there was an initial peak (items 1 and 3) followed by a decay in current. Because the observed peak current densities were very high (about  $10^{-1}$  to  $1$  amp/cm<sup>2</sup>) it is assumed that the electrical double layer charging component (13) is a minor contribution. Furthermore, analysis of the data based on Reactions 2 and 3 gives a self-consistent picture.

The net current density measured is, of course, the difference between the anodic and cathodic current densities

$$i = i_a - i_c \quad [4]$$

Near the mixed potential, where many of the experiments were conducted, the net external current is not a good measure of the actual current density, but there was an independent method of estimating the anodic current as described below.

The initial decay in potential is assumed to be due to coverage by oxide. The potentials are far enough from the reversible that the kinetics can be described by the Tafel equation. Therefore

$$i_a = (1 - \theta) i_m \exp \left( \frac{\alpha_m n_m F \eta_m}{RT} \right) \quad [5]$$

Fig. 4. Current-time oscillographs. 1, Initial oxidation peak on bare Ti; 2, time to form oxide monolayer at initial oxidation current density; 3, Initial  $H^+$  reduction peak on bare Ti; 4,  $H^+$  reduction on  $TiO_2$ .

and

$$i_c = (1 - \theta) i_H \exp \left( \frac{\alpha_H n_H F \eta_H}{RT} \right) \quad [6]$$

It is assumed that Eq. [5] is valid for low coverage because a considerably increased overpotential would be needed to form oxide on oxide as compared to bare metal. The fraction coverage,  $\theta$ , is related to the anodic current by

$$\frac{d\theta}{d\tau} = \frac{i_a}{Q_o} \quad [7]$$

The value of the coulombic charge,  $Q_o$ , is based on a layer of adsorbed oxide ions or of  $TiO$ , assumed to be the precursor of  $TiO_2$ .

Extrapolation of the limiting slope at time zero of the current-time curves to zero current gives the time to form a monolayer at a constant current equal to the initial value (item 2, Fig. 4). The initial current density for oxide formation based on Eq. [7] is therefore

$$i_a = \frac{Q_o}{\tau_o} \quad [8]$$

If this analysis is correct, Eq. [8] should give the true anodic oxide current density, even in the mixed potential and net cathodic reaction regions.

Values of peak anodic current density (open circles) and of anodic current density calculated from Eq. [8] (closed circles) are plotted in Fig. 5. Although there is considerable scatter in the values from Eq. [8], as might be expected from a first derivative of experimental data and from changing surface potential due to changing IR drop, the agreement between the two values is reasonably good. The implication of this is that the order of magnitude of the rate of formation of  $Ti^{++}$  cannot be greater than the rate of formation of oxide. The dashed Tafel line was drawn with a slope of 120 mv/decade using an estimated IR drop correction described in the Appendix. The exchange current density,  $i_m$ , appears to be between  $10^{-2}$  and  $10^{-1}$  amp/cm<sup>2</sup>, but this must be a lower limit because of the uncertainty in estimating IR drop. By way of comparison for another active metal, Hagyard and Earl (14) obtained an exchange current density of about  $10^{-3}$  amp/cm<sup>2</sup> for oxidation of freshly cut aluminum surface in 1M KCl.

It could be questioned whether species other than oxide on the surface could cause the decrease in current density with time. That the rate of change of

coverage increases with potential in the positive direction indicates that it is not hydrogen. An adsorbed charged species such as  $Ti^{++}$  might have the observed effect on the kinetics (15), and its presence cannot be disproved based on the work done thus far. However, oxide is known to form and lead into multilayer growth so it appears to be the more likely species.

Values of peak cathodic current density (squares) are plotted in Fig. 6. The plateau current density after several seconds (item 4, Fig. 4) is also plotted (circles). This approximately steady-state current density on thinly oxidized surface was lower than the peak value by about an order of magnitude and is in fair agreement with extrapolations from lower current density hydrogen ion reduction on oxide covered titanium (12, 16). The net cathodic current shown in Fig. 4b went through a minimum, further evidence of a substantial initial anodic current component.

The mixed potential for hydrogen ion reduction and titanium oxidation on newly generated bare metal in 12M HCl appeared to be about -800 mv from Fig. 5 and 6. The initial open-circuit mixed potential observed in 12M HCl was in the range of -650 to -800 mv. Stern and Wissenberg (12) obtained a mixed potential on oxide covered surface in hydrogen-saturated 20% (2.3M)  $H_2SO_4$  of -720 mv (SCE). This appears to be a reasonable agreement between these values obtained in acid solution. Although the present work was done with solutions that were not de-aerated the current densities on bare metal (estimated from Fig. 5 and 6 are on the order of  $10^{-1}$  to 1 amp/cm<sup>2</sup>) were so much higher than the diffusion limited current density for oxygen reduction ( $\approx 10^{-5}$  amp/cm<sup>2</sup>) that the latter can be ignored.

### Discussion

The purpose here is to utilize the data obtained on kinetics of oxidation of newly generated titanium metal surface to interpret the electrochemistry in a stress corrosion crack. Results in the prior paper (1) showed that there is an electrochemical process involved in SCC of titanium alloy that affects velocity of crack propagation.

*Model.*—The configuration of the stress corrosion crack used in the analysis is shown in Fig. 7. A uniform small-angle crack from the mouth to the tip is assumed. Visual observation of crack opening and optical photomicrographs show that this is a reasonable assumption to a distance of  $10^{-4}$  cm from the crack tip. An angle of 3° or 0.05 radians is also a reasonable

Fig. 5. Kinetics of oxidation of new Ti:8-1-1 surface in 12M HCl. (○ Item 1, Fig. 4; ● Eq. [5] and item 2, Fig. 4).

Fig. 6. Kinetics of  $H^+$  ion reduction on new Ti:8-1-1 surface in 12M HCl (□ Item 3, Fig. 4; ○ item 4, Fig. 4).

$w$  = thickness of metal specimen  
 $l$  = length of crack  
 $y$  = distance from tip  
 $\delta$  = length of zone with less than one monolayer of oxide  
 $\gamma$  = included angle of crack, radians  
 $I^o$  = current flowing into crack  
 $V$  = velocity of propagation

Fig. 7. Configuration of crack in metal used in the analysis

average from observed cracks. The crack propagates through the metal at a velocity  $V$  and a value of  $10^{-2}$  cm/sec will be chosen as a basis for calculation.

Based on the results of the oxidation kinetics studies on newly generated titanium surface the crack is divided into two parts; a "monolayer zone" from the tip to a position  $\delta$  where the first monolayer of oxide is completed, and a "multilayer zone" extending from  $\delta$  to the crack length. The high current density observed for reactions 2 and 3 at the mixed potential leads to the assumption that the mixed potential is established in the monolayer zone. With an applied potential more positive than the mixed potential, however, reaction 2 will dominate in the multilayer zone making the electrolyte in the crack become acid.

These assumptions are consistent with the observations that the zero-current intercept for a propagating crack occurs at about  $-800$  mv (1), as the mixed potential for reactions 2 and 3 is about  $-800$  mv in acid solution. A crack propagating at open circuit spontaneously approaches a potential of about  $-800$  mv from a previously potentiostated level either higher or lower than  $-800$  mv. Apparently the driving force for oxidation of the new titanium surface within the crack is so high that enough cathodic reaction occurs exterior to the crack that there is a net anodic acid-forming reaction within the crack at open circuit.

Only the oxidation of titanium is considered in this analysis as it is the major constituent in the alloy. The chemistry of other constituents may be delineated when kinetic data for oxidation of new surfaces of other alloys are obtained.

*Current for oxidation of walls of crack.*—In this simplified analysis a lumped current for the formation of the first monolayer of oxide will be used rather than considering the detailed kinetics. This is acceptable because the current for the formation of the first monolayer is a small fraction of the total current. This current required for formation of the first monolayer of oxide on the two walls of the crack is

$$I^s = 2wVQ_o \quad [9]$$

The actual value of  $I^o$  should be smaller than that calculated from Eq. [9] if there is some hydrogen ion reduction to establish a mixed potential.

The current flowing to the two walls in the multilayer zone can be described by

$$Iw = 2w \int_{\delta}^l i dy \quad [10]$$

The experimentally observed current density for oxide growth at a potential of 0 mv to SCE shown in Fig. 3 can be described approximately by the following expression

$$i = \frac{8.8 \times 10^{-4}}{\tau} \text{ amp/cm}^2 \quad [11]$$

Potential, of course, varies with position  $y$  in the crack and would thus affect the kinetic expression and

complicate the analysis, but the limiting case of a constant potential will be assumed sufficiently accurate for the present analysis. The "age" of the surface at a point  $y$  distance from the tip is

$$\tau(y) = \frac{y}{V} \quad [12]$$

Eliminating  $i$  and  $\tau$  from Eq. [10], [11], and [12] and solving gives

$$Iw = 2(8.8 \times 10^{-4}) wV \ln \frac{l}{\delta} \quad [13]$$

Combining Eq. [9] and [13] to obtain total anodic current gives

$$I^o = 2wV \left( Q_o + 8.8 \times 10^{-4} \ln \frac{l}{\delta} \right) \quad [14]$$

Appropriate values of the parameters can be put in Eq. [14] to test it in respect to observed current in SCC experiments. At a velocity of  $10^{-2}$  cm/sec in a 0.127 cm thick specimen the observed current is about  $25 \mu\text{a}$  for a crack length of about 0.1 cm [ref. (1), Fig. 12 and 13]. Using a value of  $Q_o = 4.25 \times 10^{-4}$  coulomb/cm<sup>2</sup> and an assumed value of  $\delta = 10^{-4}$  cm, based on the monolayer zone being near the mixed potential (Fig. 4), gives a calculated  $I^o = 16.5 \mu\text{a}$  from Eq. [14]. This is in reasonable (order of magnitude) agreement with experiment considering that there is some branching observed in actual stress corrosion cracks and that this is a very much oversimplified approach.

An interesting consequence of this analysis is that for the wedge-shaped crack geometry used in the model, the oxide mechanisms of crack propagation can be eliminated. Because the crack propagation velocity is high ( $\sim 10^{-2}$  cm/sec) the first monolayer is not complete on the wall for a considerable distance from the tip. This eliminates the concept of the brittle oxide film at the tip in the model. It can also be shown that the thickness of oxide that does form on the walls is small compared to the crack width, thus eliminating the oxide wedging mechanism in the model. Because the observed SCC current can be semi-quantitatively accounted for in the model, it is suggested that these oxide mechanisms are not involved in the SCC of titanium alloys in aqueous solutions. The work done thus far, however, is not definitive regarding the anodic dissolution, surface energy or hydride mechanisms.

*Potential drop in crack.*—The resistance of a uniform-resistivity electrolyte in a small constant-angle crack from the mouth to a position,  $y$ , is

$$R_e = \frac{\rho_e}{w\gamma} \ln \frac{l}{y} \quad [15]$$

Because the anodizing current falls off very rapidly with time (Fig. 3) or distance from first monolayer coverage, it can be assumed that most of the current flows to a region at a distance about the order of magnitude  $\delta$  from the tip. Therefore, the potential drop in the electrolyte in the crack would be

$$\Delta\phi \approx I^o R_e \quad [16]$$

Combining Eq. [14], [15], and [16] making the approximation that  $Q_o$  can be neglected compared to  $8.8 \times 10^{-4} \ln l/\delta$  gives

$$\Delta\phi \approx \frac{2(8.8 \times 10^{-4})\rho_e V}{\gamma} (\ln l/\delta)^2 \quad [17]$$

Using bulk resistivity of 15 ohm cm for 0.6M alkali halide (17), a crack angle of 0.05 radians,  $V = 10^{-2}$  cm/sec,  $l = 0.1$  cm, and  $\delta = 10^{-4}$  cm gives  $\Delta E = 0.25v$ . This can be compared to 0.5v in SCC experiments [ref. (1), Fig. 12] assuming the monolayer zone is at the mixed potential for reactions 2 and 3 in acid

solution. Again this appears to be a reasonable check for such an oversimplified model. Furthermore, Eq. [17] predicts a linear relationship between velocity and potential and Eq. [14] and [17] give a linear relationship between current and potential, in agreement with observations (1). However, there is one basic flaw; the increase in acidity of the electrolyte in the crack due to reaction 2 will give a considerably lower resistivity and thus a lower calculated potential drop. Therefore, it must be concluded that this simple analysis of the potential drop in a crack is inadequate.

**General.**—The lesson in this simple analysis of the electrochemistry on the walls of a stress corrosion crack is that the electrochemical conditions at the crack tip, where the decision of slip *vs.* fracture is made, may be very different than the macroscopic conditions outside of a crack. Because it is not possible to examine experimentally the microscopic conditions at the tip of a moving crack it would appear that a more rigorous analysis of the electrochemical kinetics and transport processes in a crack is in order (3). Some of the interrelationships between the potential and concentration gradients in a moving crack are illustrated qualitatively in Fig. 8.

As with the electrochemistry, the macroscopic stress and metallurgical conditions are different than those at atomic dimensions at the tip of a crack. It would seem that quantitative models which treat the transmission of stress and strain through the plastic zone around a crack tip to the metal atoms at the crack tip need to be developed. Some of the factors presumably involved are also listed in Fig. 8. Furthermore, Fig. 8 suggests that the complete solution to this interdisciplinary problem of stress corrosion cracking will require close cooperation between electrochemists, metallurgists, and mechanical engineers both in design of experiments and in theoretical analysis.

### Conclusions

Electrochemical kinetics experiments at constant applied potential on new surfaces generated by fast fracture of titanium: 8% Al-1% Mo-1% V alloy in 0.6M KCl and in 12M HCl showed

1. Growth of a passivating film after completion of the first monolayer appeared to be reasonably consistent with high-field conduction kinetics and literature values for  $i_0$  and  $\beta$  determined for thicker oxide films on titanium.
2. The exchange current density for formation of the first anodic monolayer in 12M HCl is on the order of  $10^{-2}$  to  $10^{-1}$  amp/cm<sup>2</sup> or larger.
3. The rate of hydrogen ion reduction on the bare metal surface is an order of magnitude or more higher than on oxide covered surface at the same applied potential.
4. A mixed potential is observed on open circuit with new surface that is compatible with hydrogen ion

reduction and titanium oxide formation and for which the current density of the anode and cathode current reactions appear to be on the order of  $10^{-1}$  to 1 amp/cm<sup>2</sup>.

An approximate model attempting to simulate the electrochemistry in a propagating stress corrosion crack, suggested by the kinetic data, showed:

5. The anodic current flowing into a propagating stress corrosion crack under potentiostatic conditions can be semiquantitatively accounted for in the model by anodic current to the walls of the crack.
6. The open-circuit potential of a propagating stress corrosion crack in Ti:8-1-1 coincides with the mixed potential for hydrogen ion reduction and titanium oxidation in an acid solution. It is suggested, based on the high current density at the mixed potential on bare metal surface, that the crack tip potential approaches this mixed potential.
7. The oxide wedging and brittle oxide mechanisms can be rejected in the model because the crack velocity is so high that the tip outruns the oxide. Because the observed SCC current can be semiquantitatively accounted for in the model, it is suggested that these oxide mechanisms are not involved in the SCC of titanium alloys in aqueous solutions. It is not possible based on the work completed thus far to pass judgment on the relevance of the hydrogen, anodic attack and adsorption mechanisms of SCC in titanium alloys.

A more rigorous analysis of the electrochemical mass transport and kinetic processes is presently underway as a consequence of the approximate analysis reported herein (3).

## APPENDIX

An approximation to the resistance of the electrolyte in the kinetics experiments for the first layers of oxide is made here. A more rigorous treatment of this very complex current distribution problem does not appear to be justified. Assume that the two new square shaped surfaces formed are replaced by a sphere of equal area. The resistance of a spherical body of electrolyte surrounding the new surface to a counter electrode remotely removed would be

$$R_e = \frac{\rho_e}{4\pi r_1}$$

where

$$r_1 = \sqrt{\frac{S}{4\pi}}$$

Therefore

$$R_e = \frac{\rho_e}{2\sqrt{\pi S}}$$

It is evident that the actual resistance for the two new surfaces should be larger than this value because they face each other at close range giving interference of the current flow lines in solution and because the current density is not uniform across the surfaces. The ratio of apparent resistance from a plot of initial peak current vs. potential to calculated current is larger by a factor of 2 to 5 as shown in Table I. It is therefore concluded that the apparent resistance is largely IR drop in solution and that the initial current peak is limited in part by IR drop.

# Passivation of Anodic Reactions

Sigmund Schuldiner\*

Naval Research Laboratory, Washington, D. C.

## ABSTRACT

Extending the Wagner (1) definition of passivity to anodic reactions of chemical species on inert electrodes, it is shown that initiation of passivation of a Pt electrode for the hydrogen oxidation reaction can be explained by small amounts (fraction of a monolayer) of adsorbed anions. Anion adsorption can effectively reduce the active electrode area, but the major passivation effect is the poisoning of catalytic sites which retards the catalytic reaction so that in most of the region where passivation occurs the reaction rate is controlled by the increased free energy of activation with increased potential. The change in sign from positive to negative of the  $dE/d(\log i)$  kinetic relation can be explained by adsorption of a small number of anions and is limited when the active sites are essentially saturated. Desorbed oxygen atoms in addition to sulfate ions can have a strong effect on the catalytic activity of Pt for the hydrogen oxidation reaction. This concept may be extended to other retarded anodic reactions and to the passivation of iron in particular.

Wagner (1) has given the following phenomenological definition of passivity: "A metal may be called passive when the amount of metal consumed by a chemical or electrochemical reaction at a given time is significantly less under conditions corresponding to a higher affinity of the reaction (*i.e.*, a greater decrease in free energy) than under conditions corresponding to a lower affinity." An electrochemical example given by Wagner is that the steady-state rate of anodic dissolution of a metal in a given environment is lower at a more noble single electrode potential than at a less noble potential.

This definition of passivity has been extended by Gilroy and Conway (2) to include reactions other than the oxidation of metals. Oxidation reactions of chemical species at an inert metal surface also can decrease under conditions corresponding to a higher affinity of the reaction. A well-known example of this is the oxidation of hydrogen on a platinum electrode in sulfuric acid solution under an atmosphere of hydrogen gas (3). Under potentiostatic steady-state conditions (Fig. 1) as the overvoltage is increased in a noble direction the rate of hydrogen oxidation increases until a potential of 0.04v (*vs.* NHE) is reached. At increasingly noble potentials the current density (reaction rate) remains constant ( $i = 2 \text{ ma/cm}^2$ , true area) up to a potential of about 0.7v. At potentials greater than 0.7v the rate of oxidation of hydrogen decreases until a potential of 1.2v is reached. We (3) concluded that the decrease in the rate of hydrogen oxidation in this range was due to the adsorption of sulfate ion which caused an increase in the free energy of activation of the anodic hydrogen reaction. As the potential was changed from 0.7 to 1.2v the increased coverage of the Pt electrode with sulfate ion further retarded the reaction.

It was shown (3) that passivation of the hydrogen oxidation reaction in the potential range from 0.7 to 1.2v could not be due to the formation of oxygen species on the electrode surface. This is because the rate of the chemical reaction of such oxygen species on Pt with hydrogen would be orders of magnitude faster than their rate of formation. In addition, hydrogen oxidation is much faster than water oxidation. Hence, from 0.7 to 1.2v the existence of adsorbed oxygen atoms, other oxygen species or Pt oxides would be very short-lived and the accumulation of such species on the surface could not occur.

In passing, an explanation should be given as to why water will be rapidly oxidized to oxygen atoms which deposit on the Pt surface with a high current density anodic pulse starting at a potential of about

0.9v (4), whereas, at steady-state potentiostatic conditions, the rate of water oxidation is so slow (5) in the potential range from 0.7 to 1.2v and the rate of hydrogen oxidation and reduction of oxygen atoms with hydrogen is so fast (3) that oxygen atoms cannot exist on the surface in this potential range. A high current density anodic pulse only sees the hydrogen and water adsorbed on the Pt surface. These surface species are all very rapidly oxidized with high current density anodic pulses. Thus, water, or water fragments, which is strongly adsorbed on the Pt surface can be rapidly oxidized with such anodic pulses.

In short, the reactivity of species initially associated with a surface before a rapid current or voltage perturbation is applied may be quite different from the steady-state reactivity of like species or their parents coming to the surface from the solution. Another example of this is the very fast reaction of chemisorbed organic species under high current density pulses, organic species which react very slowly under steady-state conditions.

Fig. 1. Steady-state potentiostatic current density vs. potential relation on Pt in hydrogen-saturated 1M  $\text{H}_2\text{SO}_4$ .  $\text{H}_2$  flow rate  $> 1000 \text{ ml/min}$ :  $\circ$  cathodic current;  $\triangle$  anodic current, increasing applied potentials;  $\nabla$  anodic current, decreasing applied potentials. Broken line is relation in He-saturated solution (5), where hysteresis line to the right is for increasing applied potentials, to the left for decreasing applied potentials [from ref. (3)].

\* Electrochemical Society Active Member.

For the over-all reaction,

Following Parson's (7) analysis, and since at high anodic potentials the amount of coverage of the electrode with adsorbed H atoms will approach zero, the Langmuir adsorption isotherm is approximated, we can express the reaction rate as

$$i = kP_{\text{H}_2} \theta^n \exp(-\Delta G^\circ/RT) \exp(\alpha\phi F/nRT) \quad [2]^1$$

where  $k$  is a constant,  $P_{\text{H}_2}$  is the partial pressure of hydrogen,  $\theta$  is the effective fraction of sites on the Pt surface where oxidation can occur,  $n$  is the reaction order,  $\Delta G^\circ$  is the standard free energy of activation for the reaction when  $\phi = 0$ ,  $\phi$  is the inner potential difference between metal and solution,  $\alpha$  is the transfer coefficient,  $F$ ,  $R$ , and  $T$  are the faraday, gas constant, and Kelvin temperature, respectively. Under given conditions of concentration of reactants one would normally expect the exponential term containing the potential to determine the reaction rate,  $i$ . As the applied potential is increased the reaction rate will increase until a limiting condition is reached where the reaction rate will remain independent of increased potential. If under certain potential conditions, the reaction, or reaction mechanism, or the rate-controlling step of the over-all reaction changes, then  $\Delta G^\circ$  can change and therefore affect the current density. However, such a change is normally reflected in a change of Tafel  $b$  [=  $dE/d(\log i)$ ] slope rather than a retardation of the reaction rate. This is because the controlling free energy of activation of an anodic reaction is decreased as the potential is made more noble. However, under passivation,  $dE/d(\log i)$  changes from a positive to a negative value.

### Experimental Data

Figure 2 shows the number of coulombs of charge required to saturate a potentiostated Pt bead electrode with adsorbed oxygen atoms. The experiment was carried out in 1M  $\text{H}_2\text{SO}_4$  saturated with hydrogen at 1 atm. [The experimental conditions were the same as previously reported (3).] The  $q_0$  value is the number of  $\mu\text{coul}/\text{cm}^2$  of charge required to fill the available Pt sites with adsorbed oxygen atoms. This was determined by potentiostating the Pt electrode at a given potential, then very rapidly (1  $\mu\text{sec}$ ) switching from potentiostatic control to a high current density anodic charging pulse [see ref. (6) for instrumentation.]

Figure 2 shows that up to potentials of about 0.4v the number of sites on the Pt surface which can adsorb oxygen atoms remains constant and is equivalent to about one monolayer. At potentials more noble than 0.4v the number of available sites decreases and remains essentially constant at about 3/4 of the monolayer value between 0.6 and 0.7v. At potentials above 0.7v the number of available sites drops further and is equal to zero at about 1.5v. The decrease in available Pt sites apparently occurs in two phases. Whatever is causing the drop in available sites in the potential region between 0.4 and 0.6v does not affect the rate of hydrogen oxidation. However, at potentials beyond 0.7v the rate of hydrogen oxidation decreases. The cause of the hysteresis shown in both Fig. 1 and 2 is believed to be dermasorption of oxygen atoms at higher potentials (3). This dermasorbed oxygen decreases the number of surface sites which can adsorb oxygen (Fig. 2).

<sup>1</sup> This equation represents the various kinetic factors which may influence the measured current density. In fact, since in the potential region from 0.04 to 0.7v, current density is independent of potential, and if the rate-controlling mechanism remained the same above 0.7v, the only effect of potential may be on anion adsorption. Of importance is that because of the changes on the electrode surface induced by potential changes in the passivating region, the reaction rate is dependent primarily on the effective electrode area and a nominal free energy of activation required to oxidize hydrogen under the given surface states.

Fig. 2. Amount of oxygen formed on a potentiostated Pt electrode. 1M  $\text{H}_2\text{SO}_4$ ,  $P_{\text{H}_2} = 1$  atm. Anodic charging current density pulse = 1.8 a/cm<sup>2</sup>.

### Discussion

The data in Fig. 1 and 2 demonstrate that the onset of passivity is accompanied by a decrease in the number of sites available for oxygen atom adsorption with an anodic charging pulse. At 1.2v where a limiting current density is reached, the number of such sites is small. Since it was previously shown (3) that steady-state passivation due to oxygen species or oxide formation in a hydrogen-saturated sulfuric acid solution was not feasible, those sites which are unavailable for oxygen atom adsorption with a high current charging pulse are considered occupied by sulfate ions under steady-state potentiostatic conditions.

In the light of the Wagner definition of passivity and Eq. [2], we can conclude that two possible factors cause passivation of the hydrogen oxidation reaction. One is a decrease in the number of available active sites and the other is an increase in the free energy of activation for each increment of potential increase. The data in Fig. 2 indicate a drop in the number of sites available for oxygen atom adsorption between 0.4 and 0.6v, however there is no accompanying retardation of the hydrogen oxidation rate in this potential range (Fig. 1). This means that active hydrogen oxidation sites are not affected in this potential range. The potential-increasing arm in Fig. 1 shows a relatively small retardation of the hydrogen oxidation rate in the potential range from 0.7 to 1.0v followed by a sharp exponential decrease ( $b = -0.11$ ) from 1.0 to 1.2v. The potential decreasing arm of the data in Fig. 1 shows in the potential range from 0.9 to 0.75v a much higher dependence of reaction rate on potential ( $b = -0.04$ ).

For the rising potential range from 0.7 to 1.0v the fraction of available sites for oxygen atom adsorption (Fig. 2) changes from about 0.6 to 0.25. In this same potential range Fig. 1 (rising potentials) shows a decrease in hydrogen oxidation rate from  $2 \times 10^{-3}$  to  $7 \times 10^{-4}$  a/cm<sup>2</sup>. If we consider the change in available oxygen sites as a change in available reaction sites for hydrogen oxidation it will amount to a reduction in area of about 0.4, the accompanying reduction in reaction rate is about 0.35. In terms of Eq. [2], this amounts to a  $n \approx 1$  and satisfactorily explains the reduction in hydrogen oxidation rate on a change in  $\theta$ .

The changes in reaction rate from 1.0 to 1.2v on the increasing potential arm (Fig. 1) corresponds to a 0.2 reduction in sites available for oxygen deposition with a decrease in reaction rate by a factor of 50. The decreasing potential arm from 0.9 to 0.75v showed a 0.4 increase in sites with about a 1000 time increase in reaction rate. Neither the passivation in the linear log ( $b = -0.11$ ) increasing potential arm nor the activation in the linear log ( $b = -0.04$ ) decreasing potential arm can be attributed to the  $\theta$  term in Eq. [2]. This is based on the previous discussion of Fig. 2.

We can therefore conclude that the passivation in these potential ranges must be due to a condition where each small increment of potential causes a significant change in the free energy of activation,  $\Delta G^\circ$ , for the hydrogen oxidation reaction. The exponential term containing  $\Delta G$  must override the exponential potential term.

The number of catalytically active sites on a clean Pt electrode is very small (as is evident from the fact that the rate of the hydrogen reaction on Pt is very sensitive to trace amounts of impurities). It appears that on the increasing potential arm of Fig. 1 up to a potential of 1.0v, adsorption of sulfate ion merely blocks part of the catalytically active sites. At potentials above 1.0v, however, the sulfate ion must be so strongly adsorbed that it acts like a catalytic poison and causes a large increase in the free energy of activation for the hydrogen oxidation reaction. On the decreasing potential arm shown in Fig. 1 and in the potential range from 0.9 to 0.75v ( $b = -0.04$ ), the Pt contains a small amount of dermasorbed oxygen (3, 5). This trace of dermasorbed oxygen evidently has an important effect on the value of the free energy of activation. Dermisorbed oxygen in combination with adsorbed sulfate ion therefore acts as a very strong catalytic poison.

Uhlig (8) has for some time offered as an explanation of passivity the combined effects of chemisorbed oxygen species and resultant decreases in catalytic activity. Our work on the anodic oxidation of hydrogen on Pt confirms Uhlig's hypothesis and extends the possible catalytic poisons to anion adsorption.

### Conclusions

The data on the anodic oxidation of hydrogen on Pt evaluated in terms of the extended Wagner definition of passivity show that passivation can be initiated by small increases (a fraction of a monolayer) in the amount of anion adsorbed and that the passivation process is limited when the Pt surface is essentially saturated with these adsorbed anions. Small amounts of sorbed species may cause large changes in the free energy of activation for the reaction and lead to the conclusion that since the role played by active Pt sites is that of a catalyst for the hydrogen reaction, the adsorption of anions (and dermasorption of oxygen atoms) can effect a poisoning of active sites and a subsequent rate-controlling increase in the free energy of activation for the reaction.

One can extend this analysis to the passivation of iron. Here the dissolution of iron can be considered to involve a catalytic step which may be retarded by chemisorption of poisons at a given potential. The influence of oxygen species associated with the iron could also have a large effect.

The primary purpose of this paper is to demonstrate that the Wagner definition of passivation naturally leads to the conclusion that passivity, so defined, is initiated by adsorption of small amounts (a fraction of a monolayer) of species which can either reduce the active surface area or act as catalytic poisons. The primary effect for large passivation effects appears to be the adsorption of catalytic poisons which cause large increases in the free energy of activation of the reaction. The passivation process itself [ $b = -dE/d(\log i)$ ] is limited by saturation of the active sites with such poisons.

This, of course, does not mean that there are not other reasons and processes for slow oxidation reactions under other conditions. The value of the extended Wagner definition is that it leads to a reasonable explanation of an unusual kinetic occurrence, the reversal of the  $dE/d(\log i)$  slope.

# Passivity in Cu-Ni-Al Alloys—A Confirmation of the Electron Configuration Theory

F. Mansfeld and H. H. Uhlig\*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

## ABSTRACT

Potentiostatic anodic polarization data show that a transition from active to passive state is observed for Ni-Cu and Ni-Cu-Zn alloys only when the 3d band of energy levels in the alloy is unfilled. At and above a critical alloy composition, electrons from Cu or Zn completely fill the d band and the passive state disappears. Previous data showed that the calculated critical composition comes close to the observed value assuming that alloyed Cu donates one electron and alloyed Zn two electrons per atom. Present measurements for the 45% Ni-Cu-Al ternary alloys show that Al contributes three electrons per atom. Secondary passivity, which is observed for pure nickel in a potential region noble to that for primary passivity, is similarly observed in the Cu-Ni-Al alloys, but again only when the d band of energy levels is unfilled. Potential decay curves confirm that a passive film, either in the primary or secondary region, exists only on alloys with an unfilled d band. Decay potentials corresponding either to secondary or to primary passivity (Flade potentials) are not greatly sensitive to aluminum content nor to the absolute number of electron vacancies. However, alloyed aluminum affects the passive current density for the 45% Ni ternary alloys accounting for a minimum at 2.35% Al.

The primary and secondary passive films are considered to have an adsorbed structure consisting mainly of oxygen in mono- or multilayers which increase the overvoltage for anodic dissolution of the alloy. The film corresponding to secondary passivity is less stable and presumably thicker than that corresponding to primary passivity. Both films are considered to be intermediates in the formation of stoichiometric metal oxides.

The present work on passivity in the Cu-Ni-Al alloys continues a research program on the general mechanism of passivity in metals and alloys. Osterwald and Uhlig (1) confirmed previous reports (2, 3) that there is a critical composition for passivity in the binary Cu-Ni alloys; Stolica and Uhlig (4) found later that there also exists a critical composition in the ternary Cu-Ni-Zn alloys. In both cases the critical compositions for passivity were determined by measuring anodic potentiostatic polarization curves in 1N H<sub>2</sub>SO<sub>4</sub> at 25°C.

According to the electron configuration theory of passivity (3), a metal or alloy should be capable of becoming passive so long as it has unfilled d-orbitals or an unfilled d band which favors chemisorption of oxygen. It is suggested that the chemisorbed oxygen markedly decreases the exchange current density thereby increasing the overvoltage for metal dissolution in the passive region. When the d band is filled, as in the nontransition metals, the overvoltage for anodic dissolution remains small, and the metal or alloy tends to form stoichiometric oxides in preference to chemisorbed oxygen films. Oxide films, if they form, are not thought to be a major source of corrosion protection.

From this it follows that the critical composition for passivity in Cu-Ni alloys should appear when the d electron vacancies in the 3d band of Ni at the surface of the alloy (0.6 vacancy per Ni atom plus 1 vacancy created by an adsorbed oxygen atom) are just filled by available donor electrons from Cu (one 4s electron per Cu atom). In other words, so long as the atomic ratio of Cu to Ni is smaller than 1.6, the alloy should be passive; otherwise it should be active. The same is true for the Cu-Ni-Zn alloys where passivity occurs so long as the atomic ratio holds:  $(\text{Cu} + 2\text{Zn})/\text{Ni} < 1.6$  where Zn donates two 4s electrons per atom. This was confirmed by the experiments of Stolica and Uhlig (4).

To explore the electron configuration theory further, Cu-Ni-Al alloys were prepared and both the

critical c.d. for passivity  $i(\text{crit})$  and the passive c.d.  $i(\text{pass})$  were measured by potentiostatic anodic polarization curves in 1N H<sub>2</sub>SO<sub>4</sub> at 25°C. Both saturation magnetic moments of Ni-Al alloys and the Hume-Rothery rules for structure of intermetallic compounds have shown that Al contributes 3 electrons to Ni compared to 2 electrons from Zn and 1 electron from Cu. It is predicted, therefore, that Cu-Ni-Al alloys should remain passive so long as the atomic ratio holds:  $(\text{Cu} + 3\text{Al})/\text{Ni} < 1.6$ ; otherwise the alloys should be active.

## Preparation of Alloys

In order to check the effect of alloyed Al on the passive properties of Cu-Ni alloys, two conditions must be met. The first is that the maximum added amount of Al should supply electrons sufficient to fill the surface d band of Ni; the second is that the added Al should not exceed solubility limits for a single-phase alloy, otherwise galvanic interaction of the separate phases tends to destroy passivity and complicates interpretation of the measurements. By referring to the binary phase diagrams, it was concluded that the required conditions were likely to be satisfied in alloys with 45 w/o (weight per cent) Ni, 1-9 w/o Al, balance Cu. Their single-phase structure was confirmed by examining polished and etched specimens under the microscope.

The alloys were prepared from electrolytic Cu, 99.99+ % Al and carbonyl Ni. They were melted in dense alumina crucibles under vacuum by induction heating. After filling the furnace with purified argon, the melt was drawn into 7 mm Vycor tubes and water quenched. The ingots were homogenized in argon at 950°C for 24 hr, swaged to 0.15 in. (0.39 cm) diameter, annealed in argon at 950°C for 1 hr, and then air cooled while remaining in an argon atmosphere within a quartz tube. They were swaged to a final 0.14 in. (0.37 cm) diameter then annealed and cooled as before.

The chemical analyses of the alloys are given in Table I which also lists values of the atomic ratios and per cent d band filled. The latter is obtained by di-

\* Electrochemical Society Active Member.

viding the value of the atomic ratio by 1.6 and multiplying by 100. On this basis of calculation, assuming Al to contribute 3 electrons per atom, 4 alloys were prepared with an unfilled d band and 4 alloys with a filled d band.

#### Experimental Procedure

Electrodes from annealed rods were machined to cylinders approximately 1 cm long and 0.3 cm in diameter. They were cleaned in boiling benzene and pickled in conc. HCl at 90°C for 1 min which served to remove surface oxides.

The electrolyte consisting of 1N H<sub>2</sub>SO<sub>4</sub> was deaerated with N<sub>2</sub> which had been passed over Cu-turnings at 450°C. Nitrogen also served to stir the electrolyte before each polarization run until the corrosion potential became constant. All experiments were carried out in a constant temperature room at 25° ± 0.5°C, using a Wenking potentiostat and various recorders. The potentials were measured with reference to a saturated calomel electrode, 1N H<sub>2</sub>SO<sub>4</sub> salt bridge, but are reported on the standard hydrogen scale without correction for the small liquid junction potential.

#### Results

Polarization curves were obtained both with a continuous sweep rate of 20 mv/min, and also employing quasi-stationary measurements for which the potential was kept at a fixed value until the current was relatively constant for at least 2 min. For the latter, potentials were changed in steps of 20 mv in the active region and 40 mv in the passive and transpassive regions. Figure 1 shows potentiostatic anodic

Fig. 1. Potentiostatic anodic polarization curves for 45.4% Ni-2.35% Al-Cu alloy in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C.

polarization curves at 25°C obtained both ways for an alloy containing 2.35 w/o Al having an atomic ratio (Cu + 3 Al)/Ni equal to 1.40. All three curves have Tafel lines in the active region with a slope of approximately 30 mv. After reaching a maximum, the c.d. drops sharply to small values (200-500  $\mu\text{a}/\text{cm}^2$ ) in the passive region and increases again in the transpassive region with a slope of about 120 mv. At still higher potentials the c.d. drops again, conforming to a region of secondary passivity. At these noble potentials the current starts to oscillate and the first small bubbles of oxygen are observed. The oscillations stop when the minimum c.d. in the region of secondary passivity is reached. During the oscillations, black-appearing rings, presumably caused by transient oxides, pass over the surface of the electrode. While this happens the c.d. reaches a maximum and O<sub>2</sub> evolution a minimum. Each time a black ring disappears, O<sub>2</sub> evolution reaches a maximum. Secondary passivity is not unique to these alloys; it has also been observed in pure Ni (1, 5-9), Ni-Mo (10), Ni-Cr (11), and Fe-Cr alloys (12-14).

Shapes of the polarization curves depend in general on direction of potential sweep. Differences of this kind were also observed by Stolica and Uhlig (4) for the passive Cu-Ni-Zn alloys. A contributing factor could be a green-brown film, probably a salt layer, which is formed in the active region when the potential is changed from the corrosion potential to more noble values, but which becomes dislodged from the electrode surface when the maximum c.d. is reached. No such film is observed when the potential is changed from the passive to the active direction. It is also possible that the invisible passive film formed at more noble potentials is not completely disrupted when the potential is changed from the passive to active direction, thereby lowering the observed critical c.d. and corresponding potential.

Because the stepwise technique takes a long time, and corresponding corrosion of the test specimen therefore is rather high, we carried out most of our experiments with a compromise constant sweep rate of 20 mv/min. Figure 2 shows polarization curves for three of the Cu-Ni-Al alloys and also for pure Cu starting in the noble region at a potential slightly more active than the potential where oxygen evolution begins. The 45% Ni-Cu alloy with 0% Al and the alloy with 2.35% Al have an atomic ratio smaller than 1.6. They show a marked transition from passive to active state. The passive c.d.  $i(\text{pass})$ , defined as the minimum c.d. in the passive region, is smaller for the alloy containing Al. The alloy containing 4.65 w/o Al, on the other hand, has an atomic ratio greater than 1.6, and although it shows some small variations of current which are not reproducible as the potential is adjusted, it does not undergo a true

Fig. 2. Potentiostatic anodic polarization curves for Cu and for 45% Ni-Al-Cu alloys in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C; 20 mV/min noble to active direction.

Fig. 3. Potentiostatic anodic polarization curves for Cu and for 45% Ni-Al-Cu alloys in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C; 20 mv/min active to noble direction.

transition from passive to active state. It behaves similarly to Cu, the polarization curve of which is shown for comparison. The small loop appearing in the active region for the 4.65% Al alloy becomes smaller using slower sweep rates and disappears entirely with quasi-stationary measurements.<sup>1</sup> It is probably not related to any property of passivity. In Fig. 3 the results for the same alloys are presented with runs now starting in the active region. It can be seen that the alloys for which a passive current density is observed also exhibit a region of secondary passivity, contrary to the behavior of either the alloys which do not exhibit passivity, or of pure Cu.

In Fig. 4,  $i(\text{crit})$ , defined as the maximum value in the active region, and  $i(\text{pass})$  for all the alloys are plotted against the atomic ratio. Each point is the average value for 3 to 7 independent runs. Although the observed values of  $i(\text{crit})$  are lower for polarization runs going from the noble to active direction compared to the reverse direction, an observed  $i(\text{pass})$  exists only between 0% Al (at. ratio 1.11) and 3.49% Al (at. ratio 1.53). For higher Al alloys, only a maximum c.d. in the active region is detected which falls on the extrapolated line for  $i(\text{crit})$  values of lower Al alloys. The composition for intersection of  $i(\text{crit})$  and  $i(\text{pass})$  at which a passive c.d. is no longer observed is close to an atomic ratio of 1.6.

For the region of secondary passivity and for oxygen evolution, the behavior depends on alloy composition in a manner quite similar to that of normal passivity (Fig. 5). Only alloys with atomic ratios smaller than 1.6 which are correspondingly passive, show the phenomenon of secondary passivity. It is noted that addition of Al to Ni-Cu alloys lowers the c.d. which has to be reached in order to achieve secondary passivity. The minimum c.d. in this region corresponds to 2.35% Al, which is also the composition at which a minimum occurs in  $i(\text{pass})$ . The points plotted in Fig. 5 for the alloys with atomic ratio greater than 1.6 correspond to values where the c.d. starts to increase again and oxygen evolution begins.

It is significant that potential decay curves show discontinuities but only for alloys of atomic ratio < 1.6. A typical decay curve for the 45% Ni-2.35%

<sup>1</sup> In this particular potential region the current has a complicated time dependence following a prescribed change of potential. A thick, porous oxide is formed, which is not observed for the passive alloys.

Fig. 4. Values of  $i(\text{crit})$  and  $i(\text{pass})$  for 45% Ni-Al-Cu alloys in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C, showing passive behavior below but not above atomic ratio 1.6 (100% d band filled).

Fig. 5. Maximum and minimum current densities in the region of secondary passivity for 45% Ni-Al-Cu alloys in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C, showing disappearance of secondary passivity above atomic ratio 1.6 (> 100% d band filled).

Al-bal. Cu alloy (atomic ratio 1.40) in 1N H<sub>2</sub>SO<sub>4</sub> at 1.5°C is shown in Fig. 6 starting from either the passive or transpassive region. The more noble potential at 1.7v corresponds to breakdown of the secondary passive film whereas 0.62v corresponds to breakdown of the primary passive film and hence the latter is the Flade potential. The secondary passive film breaks down independent of subsequent breakdown of the primary film. The decay curve is also shown for the 4.65% Al alloy (atomic ratio 1.68) showing a smooth transition from noble to active values and the com-

Fig. 6. Potential decay curves for 45.4% Ni-2.35% Al-Cu, atomic ratio 1.40 (unfilled d band) and 45.5% Ni-4.65% Al-Cu, atomic ratio 1.68 (filled d band) in 1N H<sub>2</sub>SO<sub>4</sub>, 1.5°C.

plete absence of any discernible change of slope marking breakdown of surface films.

A summary of the potential decay data at 1.5° and at 25°C is given in Table II. The lower temperature was chosen in addition to room temperature because of the more pronounced discontinuities in potential at 1.5°C resulting most likely from the greater stability of the passive film at low temperatures. Discontinuities were not observed for any of the alloys of atomic ratio >1.6 at either high or low temperatures. The relatively small observed temperature effect of Flade potential parallels the small temperature dependence noted previously for the Flade potentials of Fe (15) and of Ni (1).

### Discussion

The atomic ratio of approximately 1.6 separates alloys which exhibit a passive current density from those which do not, and it separates those alloys whose decay potentials show discontinuities corresponding to breakdown of passive films from those alloys whose potential decay curves do not show any discontinuities. Since the ratio 1.6 corresponds to 100% d band filled as described earlier, the original assumption that Al contributes 3 electrons per atom is confirmed. No other assumption of donor electrons leads to similar agreement. An atomic ratio >1.6 indicates that more donor electrons are available than are needed to fill electron vacancies (>100% d band filled).

The requirement of 3 electrons per Al atom to fill the d band, parallel to two electrons per Zn atom or 1 electron per Cu atom is considered to be a significant result.

Several incidental phenomena were observed which also deserve discussion. For example, the minimum in  $i(\text{pass})$  (Fig. 4) at 2.35% Al is also the approximate composition at which a minimum appears in the c.d. corresponding to secondary passivity (Fig. 5). This plus the fact that secondary passivity is observed only in alloys which have an unfilled d band lend support to the conclusion that whatever is the cause of secondary passivity, it is also related to the cause of

primary passivity. If the passive film has an adsorbed structure, as seems likely, rather than being composed of a diffusion-barrier stoichiometric metal oxide, then the film accounting for secondary passivity is also plausibly related to an adsorbed structure and its properties are tied in with the electron configuration of the underlying alloy.

In accord with quantitative data obtained for Ni in 1N H<sub>2</sub>SO<sub>4</sub> by Vetter and Arnold (5), an increasingly noble applied potential beyond the potential corresponding to  $i(\text{pass})$  but below secondary passivity is attended by increasing current accounted for entirely by increasing dissolution of metal ions. When the potential corresponding to secondary passivity is reached, an increased amount of adsorbed oxygen or a change in the structure of the adsorbed layers (including OH and H<sub>2</sub>O) making up the passive film acts to increase anodic overvoltage for metal dissolution. The current decreases, therefore, as observed. Vetter and Arnold's data show that this decrease cannot be attributed to an IR drop through an oxide film in view of the observed low resistivity of the film substance (<1 ohm-cm). On applying a still more noble potential, the current increases again attended predominantly by oxygen evolution. The average potential corresponding to minimum c.d. is  $1.74 \pm 0.03\text{v}$  and that corresponding to maximum c.d. is  $1.52 \pm 0.03\text{v}$  showing a slight trend toward more active values with per cent d band filled. At these noble potentials, the discharge of OH<sup>-</sup> or decomposition of adsorbed H<sub>2</sub>O to O<sub>2</sub> and H<sup>+</sup> becomes the preferred process, and hence oxidation of the alloy electrode tends to favor metal oxides rather than hydrated metal ions. The metal oxides are soluble, however, leading to momentarily visible black surface films, the presence or absence of which presumably causes the observed oscillations of c.d. and O<sub>2</sub> evolution.

For alloys with a filled d band, the rate of metal dissolution and oxide formation is not sensitive to potential throughout the noble region. Presumably in absence of an adsorbed film, the observed c.d., contrary to alloys with an unfilled d band, does not decrease under conditions corresponding otherwise to primary or secondary passivity. Visible dark porous oxides form in contrast to bright appearing surfaces characteristic of the passive alloys. The insensitivity of anodic processes to potential beyond the maximum c.d. suggests that the rate of reaction for non-passive alloys in the noble region is regulated by (i) an insulating barrier film whose thickness is more or less proportional to applied potential or by (ii) a slow process not involving electron transfer, e.g., acid dissolution of a metal oxide. The measured good conductivity of the passive film substance (5) on Ni and the corresponding good conductivity on the present alloys as indicated by Tafel behavior in the O<sub>2</sub> evolution region make (ii) a more likely explanation than (i).

In the binary Ni-Cu alloys, filling of the d band by electrons from alloyed Cu increases both  $i(\text{crit})$  and, even more,  $i(\text{pass})$  (1). Filling of the d band by electrons from alloyed Al, to the contrary, tends to decrease  $i(\text{crit})$  and also, at least up to a certain atomic ratio,  $i(\text{pass})$  as well. The potentials corresponding to  $i(\text{crit})$ , decrease on the noble-to-active polarization curves from about 0.52v for 0% Al (69.6% d band filled) to 0.41v for 3.49% Al (95.9% d band filled). Corresponding potentials for alloys with a filled d band marking a change of slope in the active region, fall between 0.45 and 0.53v with no discernible trend. Potentials corresponding to  $i(\text{pass})$  are 0.96v for 0% Al and 0.82v for 3.49% Al showing an almost linear relation with per cent d band filled. Explanations of these effects are complicated, and at present only speculative suggestions are possible. It might be said, for example, that alloyed Al appears to exert two opposing effects. The one is to increase  $i(\text{crit})$  and  $i(\text{pass})$  by reason of filling of the d band; the other is

to specifically impede dissolution rates by reason of the passive properties of Al itself. The latter effect might occur either through changes in activation energy for metal ion dissolution induced by alloyed Al, or perhaps through formation of  $\text{Al}_2\text{O}_3$  or similar films. At the noble potentials corresponding to passivity, the two opposing effects lead to a minimum in  $i(\text{pass})$ . The minimum is not observed with Ni-Zn-Cu alloys.

At less noble potentials and higher c.d. corresponding to transition from the active to passive state, the specifically retarding effect of Al dominates leading to a continuous decrease in  $i(\text{crit})$  with increasing alloyed Al. The opposite trend, that of increasing values of  $i(\text{crit})$ , is observed with alloyed Zn (4) or Cu (1). It should be noted that the effect of Al on  $i(\text{crit})$  is not related to d band structure because values for alloys with an unfilled d band fall on the same line as the maximum c.d. in the active region for alloys with a filled d band (Fig. 4). The appreciable change of  $i(\text{crit})$  with alloying additions may be taken as evidence that a critical c.d. does not result alone from concentration polarization, but that activation polarization and perhaps IR drop through surface films must also play a role.

The more noble Flade potentials for the alloys (Table II) than for pure Ni in 1N  $\text{H}_2\text{SO}_4$  (0.2v, 25°C) (1) imply that passivity in the alloys is less stable than for Ni (16). The surface film corresponding to secondary passivity in turn is less stable than the primary film and it decomposes at 1.7v leaving a residual primary passive film which decomposes at the Flade potential. The relatively small trend, if any, in the potentials corresponding to primary and secondary passivity, despite change of alloy composition, suggests that the stability of passive films in the 45% Ni-Al-Cu alloys is sensitive mostly to whether d electron vacancies exist, and not to the absolute number of d electron vacancies per atom.

The observed Flade potentials for the passive alloys in 1N  $\text{H}_2\text{SO}_4$ , pH 0.3, 25°C, are more noble than corresponds to a reaction such as

the standard potential (pH = 0) of which, as calculated from free energy data, is 0.57v. The corresponding potential for  $\text{Cu}_2\text{O}$  or NiO formation is 0.47 and 0.11v, respectively. The improbability of such reactions as a possible explanation of the Flade potential is also indicated by lack of an observed Flade potential in alloys with a filled d band, although their thermodynamic tendency to form  $\text{CuO}$ , NiO or similar oxide films differs but little from that of alloys of almost the same composition with an unfilled d band. The same considerations apply to formation of higher metal oxides as a possible cause of secondary passivity. Hence the reaction corresponding to the Flade potential is more likely

where  $\text{O}(\text{ads}) \cdot \text{M}$  represents the adsorbed passive film on metal M (of either less than monolayer or of multilayer dimensions, hence of unspecified ratio O to M) (17) and which forms only on alloys having an unfilled d band. The film forming in the region of secondary passivity is also assumed to have an adsorbed structure but of multilayer dimensions and probably of higher O to M ratio than in the primary film. In addition to adsorbed oxygen, it may also include mobile metal ions. A film of this kind is considered to be an intermediate, preceding formation of a stoichiometric higher metal oxide. Its structure does not appear to require incorporation of  $\text{SO}_4^{2-}$  or  $\text{S}_2\text{O}_8^{2-}$  ions, because secondary passivity was also observed in the 45% Ni-Cu and 45% Ni-2.35% Al-Cu alloys when anodically polarized in 1N  $\text{HClO}_4$  instead of 1N  $\text{H}_2\text{SO}_4$ . Details will be reported in a later paper.

### Acknowledgment

The authors are pleased to acknowledge support by the Shell Companies Foundation and by the Corrosion Research Council. They are grateful to David Duquette for help in preparing the alloys.

# Comparative Study of the Electrocrystallization of Tantalum and Niobium from Molten Fluoride Mixtures

Cl. Decroly,<sup>†</sup> A. Mukhtar, and R. Winand

Laboratory of Metallurgy and Electrochemistry, Free University of Brussels, Brussels, Belgium

## ABSTRACT

A comparison has been made of the electrocrystallization of tantalum and niobium from baths containing either KF and  $K_2TaF_7$  or KF and  $K_2NbF_7$ . The main purpose of the work was to determine why current efficiencies are generally much lower for niobium than for tantalum under the same experimental conditions. The phase diagram of the system KF- $K_2NbF_7$  has been drawn. Comparison with the diagrams of the system KF- $K_2TaF_7$  found in the literature does not give any evidence for a basic difference in the nature of the ionic species present in both types of baths. The results of the electrolyses performed have led to the following main conclusions: (A) An increase of the  $K_2NbF_7$  or  $K_2TaF_7$  content of the bath results in a considerable decrease of the current efficiency. This effect is much more striking for niobium than for tantalum. The grain size decreases also when the  $K_2NbF_7$  or  $K_2TaF_7$  content of the bath increases. (B) The current efficiency increases roughly with the cathodic current density while the grain size shows a very complex behavior against the same parameter. (C) The current efficiency decreases and the grain size increases when the length of the electrolysis increases. (D) The grain size decreases regularly when the temperature increases, while the current efficiency passes through a maximum at about 900°C.

Cathodic polarization curves drawn in both types of bath have shown a rather complex behavior of the ionic species to be discharged at the cathode. It appears that some part of the metallic deposit at the cathode is removed from it by the agitation of the bath and by its own weight and is redissolved in the bath through a chemical reaction giving rise to lower valency species. A part of these species is reoxidized at the anode, and another part of them participates again in the cathodic process. This phenomenon is much more effective for niobium than for tantalum in the same type of bath. All the experimental observations are interpreted in terms of this mechanism.

It is well known that tantalum and niobium have very similar chemical properties, so similar indeed that it is necessary to use very elaborate methods to separate them during the mineral and chemical processing of their ores.

It is thus quite astonishing that, while tantalum can be prepared economically by fused salt electrolysis, all the attempts to prepare niobium in the same way failed, the current efficiency being very low. It should of course be very interesting to know why there is such a big difference in the behavior of the two metals during the electrolysis. In this respect, although the literature (1) contains a rather large number of papers on the electrowinning of tantalum and niobium, it is rather difficult to draw any general conclusion from the published results. This is mainly due to the fact that most of the researchers have worked only on one of the two metals and generally under conditions so different that any valuable comparison of the results is impossible. It should be pointed out however that Chuk-Ching Ma (2) has studied the deposition of both tantalum and niobium in the same electrolytic cell, using a similar mixture for the electrolytic bath and the same washing technique to recover the metallic powders. He investigated the effect of current density and temperature on the particle size of these metals. In the case of tantalum, the bath contained 1 part potassium fluotantalate, 1 part potassium chloride, and 0.1 part tantalum pentoxide (by weight), while for niobium it contained 1 part fluoxyniobate ( $K_2NbOF_5$ ) and 1 part potassium chloride. Between 800° and 950°C, and with cathodic current densities from 10 to 40 amp/dm<sup>2</sup>, he found an increase of the grain size with the increase of temperature, while at high current densities the grains are finer than those obtained when working at lower values of this variable. However, this work does not give any information with regard to the current efficiencies. Moreover,

his results are in contradiction with those of Myers (3) concerning the effect of the current density on the grain size in the case of tantalum.

From another point of view, any complete study of electrocrystallization should be made in such a way as to enable one to establish a relation between the observed metallic crystals and the cathodic polarization curves (4) drawn under the same conditions as those under which the electrolyses were carried out. This seems perhaps more necessary in fused salts than in aqueous solutions (5), because of the rather large number of secondary factors which can influence the cathodic process. Among them, mechanical losses of the metal powder deposited at the cathode, redissolution of this metal in the bath, chemical reactions of the bath with the atmosphere of the furnace, and anode effect are certainly of considerable importance.

Therefore, although the cathodic mechanism of the electrodeposition of tantalum and niobium has already been studied by various authors (6-15), we cannot take the conclusions drawn in the literature as immediately useful for the interpretation of results of electrolyses done by other researchers.

We thus decided to start a research program with the purpose of ensuring a complete comparison of the electrocrystallization of the two metals. In order to simplify the problem as far as possible, we decided to study two similar all-fluoride baths, KF- $K_2TaF_7$  and KF- $K_2NbF_7$ , although it is evident from the literature that much better current efficiencies can be achieved when a certain amount of the oxide of the metal to be deposited is added to the bath and/or when some alkali chloride is present (16).

The present work being mainly a fundamental research, the economic aspects have been neglected in the attempt to obtain some information concerning the nature of the ionic species present in the bath. But we hope to have the opportunity in the near future to go further in this study by the investigation of the systems KF- $K_2TaF_7$ - $Ta_2O_5$  and KF- $K_2NbF_7$ - $Nb_2O_5$ , as

<sup>†</sup> Deceased.

well as  $\text{KF-KCl-K}_2\text{TaF}_7$  and  $\text{KF-KCl-K}_2\text{NbF}_7$  with or without additions of  $\text{Ta}_2\text{O}_5$  or  $\text{Nb}_2\text{O}_5$ .

In the present paper, we will make successively the comparison between the systems  $\text{KF-K}_2\text{TaF}_7$  and  $\text{KF-K}_2\text{NbF}_7$  with regard to their phase diagrams and probable ionic species present in the liquid state, the influence of bath composition, current density, duration of the electrolysis and temperature on the current efficiency, particle size, and shape of the crystals obtained by electrolysis, and the cathodic polarization curves and probable cathodic mechanism of electrodeposition.

*Phase Diagrams of the Systems  $\text{KF-K}_2\text{TaF}_7$  and  $\text{KF-K}_2\text{NbF}_7$  and the Probable Ionic Species Present in the Melts of Each Mixture*

The phase diagram for the system  $\text{KF-K}_2\text{TaF}_7$  has been drawn by three groups of workers (17-19). While their results are not quite concordant, the general shape of the diagrams is the same. All the authors found a definite compound corresponding to the formula  $\text{KF}\cdot\text{K}_2\text{TaF}_7$  with a congruent melting point at  $776^\circ\text{--}780^\circ\text{C}$ . Two eutectic points are present in the diagrams. The first one is found at 22 to 25.5 m/o (mole per cent) of  $\text{K}_2\text{TaF}_7$  with a melting point included between  $718^\circ$  and  $727^\circ\text{C}$ . The second one is found at 70-79.5 m/o  $\text{K}_2\text{TaF}_7$ , with a melting point included between  $695^\circ$  and  $717^\circ\text{C}$ . The accuracy of the diagrams is said to be better on the side rich in  $\text{KF}$  than on the other one.

The phase diagram for the system  $\text{KF-K}_2\text{NbF}_7$  was not reported in the literature. Thus, we have drawn it by differential thermal analysis and by x-ray diffraction, according to the method previously used by one of the present authors (20), but somewhat improved in sensitivity and modified to cope with the corrosiveness of the melts. Our results were published recently (21). The phase diagram obtained is quite similar to that obtained for  $\text{KF-K}_2\text{TaF}_7$ . A definite compound corresponding to the formula  $\text{KF}\cdot\text{K}_2\text{NbF}_7$  is found, with a congruent melting point at  $760^\circ\text{C}$ . Two eutectic points are also found, the first one at 23 m/o  $\text{K}_2\text{NbF}_7$  with a melting point at  $723^\circ\text{C}$ ; the second one at 80 m/o  $\text{K}_2\text{NbF}_7$  with a melting point at  $707^\circ\text{C}$ .

Using the equation of the freezing point depression expressed in terms of Temkin's ionic mole fractions to analyze the alkali side of their phase diagram for  $\text{KF-K}_2\text{TaF}_7$ , Iuchi and Ono (17) suggested that the formation of the ionic species  $\text{TaF}_8^{3-}$  according to the reaction

is quite possible, the remaining ionic species being  $\text{K}^+$  and  $\text{F}^-$  ions. We have made the same calculations for the system  $\text{KF-K}_2\text{NbF}_7$ , and we came to the same conclusions as Iuchi and Ono. However, we are not completely convinced of the possibility of establishing without any doubt the nature of the ionic species present in the bath by this kind of calculations: all the possible modes of dissociation of the initial molecular compounds are not taken into consideration, and, finally, the decision concerning the type of ionic species present is a function of the accuracy of the determination of the liquidus curve of the phase diagram. We would thus prefer to say that the dissolution of  $\text{K}_2\text{TaF}_7$  and  $\text{K}_2\text{NbF}_7$  in  $\text{KF}$  occurs in such a way that only one new species seems to appear in the molten bath.

However, what is the most important for the comparison of the electrocrystallization of the two metals is that by the freezing point depression method, and, within its limits of accuracy, we did not find any noticeable difference between the two types of melts. This has been confirmed recently by spectrophotometry at high temperature on similar systems by Fordyce and Baum (22). They have found  $\text{TaF}_7^{2-}$  and  $\text{NbF}_7^{2-}$  to be the predominant species in the liquid.

### Experimental Study of Electrodeposition of Tantalum and Niobium from the Mixtures $\text{KF} + \text{K}_2\text{TaF}_7$ and $\text{KF} + \text{K}_2\text{NbF}_7$

*Apparatus.*—The main part of the apparatus has already been described elsewhere (5). We will recall here only its main characteristics and point out the few modifications that have been made.

Figure 1 shows a vertical section through the electrolytic cell of the interior of the furnace and its cover, with its accessories. The furnace is a water-cooled double-walled stainless steel vessel. It is vacuum tight so that the atmosphere can be controlled easily. The graphite crucible is heated by medium frequency induction (8000 Hz) and acts as the anode of the electrolytic cell. The cathode is a low carbon steel rod dipping in the bath. Since we did not find any suitable material to insulate the internal bottom part of the crucible, as we had in previous research (5), we were not able to ensure the cylindrical homogeneity of distribution of the current flow between the cathode and the anode.

The temperature of the bath is measured by two thermocouples protected by graphite-covered alumina sheaths dipping into the electrolytic bath. One of these thermocouples is used for the automatic temperature control which acts on the excitation of the medium frequency alternator.

The furnace is connected to a vacuum pump and also to argon bottles. Before reaching the furnace, argon is purified by passing successively through five tubes containing phosphoric oxide spread on glass wool, one tube containing copper turnings heated at  $500^\circ\text{C}$  and, finally, a second tube containing active calcium heated at  $450^\circ\text{C}$ .

Fig. 1. Electrolytic furnace: 1, Main entry for argon; 2, auxiliary entry for argon; 3, entry (below) and exit (above) of the cooling water for the cathode assembly; 4, entry of the cooling water for the furnace body; 5, terminals for the medium frequency current; 6, negative pole for the electrolytic current; 7, positive pole for the electrolytic current; 8, exit for the gases (passage toward the cylinder); 9, assembly for the control and movements of the thermocouple rods; 10, cathode holding assembly; 11, viewing windows; 12, emptying orifice with its lid; A, quartz plate; B, quartz cylinder; C, quartz cylinder; D, quartz disk; E, water-cooled copper ring.

The direct current circuit for electrolysis is a very simple one. It is fed by a 20v — 500 amp dynamo with separate excitation, and contains the usual ammeter and volt meter.

**Experimental technique.—Raw materials.**—Potassium fluoride — p.a., E. Merck AG., Darmstadt.

Potassium fluotantalate ( $K_2TaF_7$ ), Fansteel-Hoboken, Antwerp (The analysis given by the manufacturers is: Ta > 45.5%; Nb < 0.01%; Ti < 0.01%; Si < 0.01%; Fe < 0.01%; W < 0.01%).

Potassium fluoniobate ( $K_2NbF_7$ ), Herman C. Stark, Berlin, Werk Goslar [No analysis is given, but it melts as a pure compound (21)].

Graphite, grade AGR, degassed thoroughly by heating under vacuum at a temperature 50°C higher than the working temperature.

**Description of an electrolysis run.**—After having placed a charge of 1500g of the required mixture of fluorides in the graphite crucible, the vessel is closed and the vacuum pump started. The charge is brought under vacuum to its melting point in about an hour. As soon as the charge begins to melt, the vacuum pump is stopped and purified argon is introduced into the furnace. When atmospheric pressure is reached, a flow of argon of 3 l/min is maintained. The cathode is then lowered into the bath under tension until it reaches a well-determined level, and the electrolysis is started. At the end of the experiment, the cathode is raised out of the bath, and the whole furnace is allowed to cool under purified argon.

No preelectrolysis is performed, because it could produce low valency ions in the bath prior to the start of the main electrolysis, thus changing the nature of the melt.

**Washing of cathodic deposits.**—After having tried different washing techniques described in the literature (1, 9, 16, 23, 24), we found (25) that the best method was as follows:

The deposits are broken by hammer and chisel and crushed in a mechanical crusher in the presence of a small amount of water. The crushed deposit is allowed to stay overnight in tap water; it is then crushed in a pebble mill. The fine metallic powder is washed for 1 hr with tap water in such a way as to ensure that only particles finer than 20 $\mu$  are lost.

Subsequent washing is done with hydrochloric acid of increasing concentrations (from 0.02 to 3N) in tap water. Finally, the powder is washed with distilled water and acetone before drying slowly under an infrared lamp. Only plastic jugs and beakers are used for the washing, to avoid any possible reaction of the fluorides with glass containers.

**Granulometric analysis and characteristic grain size.**—A standard Tyler sieves series was used, corresponding to mesh No. 28, 35, 48, 65, 100, 150, 200, 270, and 400.

Results have been plotted as the percentage of the different fractions retained between two sieves against the arithmetic mean diameter of the fraction. All the curves obtained have the same shape as the one represented on Fig. 2. To determine the characteristic grain diameter of the powder, a line is drawn from the maximum A of the curve parallel to the ordinate. Another line, parallel to the abscissa, is drawn from the center of the previous line cutting the curve at B and C. The center M of the segment BC gives the characteristic diameter  $\phi_{char}$  of the powder.

**Remarks concerning the current density  $J_c$  and the current efficiency  $r_c$ .**—The cathodic current density  $J_c$  is in fact the initial cathodic current density, unless otherwise stated.

The current efficiency  $r_c$  is based on the quantity of metal recovered after washing and is calculated by assuming that the valency of either tantalum or niobium is 5.

**Experimental program and results obtained.**—Influence of bath composition on current efficiency and

Fig. 2. Plot of a typical screen analysis showing the determination of the characteristic grain diameter ( $\phi_{char}$ ). Electrolyte, KF- $K_2TaF_7$  containing 25 m/o  $K_2TaF_7$ ; temperature, 900°C; initial cathodic current density, 480 amp/dm<sup>2</sup>; length of the electrolysis; corresponding to 177 amp hr.

**on characteristic grain diameter.**—All the experiments were carried out with the same initial current density of 400 amp/dm<sup>2</sup> corresponding to a current of 50 amp, the initial cathode area being 0.125 dm<sup>2</sup>. The bath temperature was kept near 900°C. All the electrolyses were performed with a quantity of electricity corresponding, at a theoretical current efficiency of 100%, to half depletion of the metal (tantalum or niobium) present in the bath. Thus, the duration of the electrolysis, and consequently the quantity of electricity passed through the cell, varied from one experiment to the other.

Figures 3 and 4 show the variation of the current efficiency and of the characteristic grain diameter against the molar composition of the bath. It can be seen that both  $r_c$  and  $\phi_{char}$  decrease when the initial content of tantalum or niobium of the bath increases. This effect is much more striking for niobium than for tantalum. From another point of view, the external aspect of the crystals gets worse when the tantalum or niobium content of the bath decreases.

It should be noted that the current efficiency falls almost to zero in the case of niobium as soon as the bath contains more than 25 m/o  $K_2NbF_7$ . It was also observed in this case that the steel cathode is severely corroded by baths containing more than 50 m/o  $K_2NbF_7$ . The color of the bath at the end of the electrolysis was yellowish green, while the walls of the

Fig. 3. Plot of the current efficiency against the molar composition of the baths for the systems KF- $K_2TaF_7$  (curve 1) and KF- $K_2NbF_7$  (curve 2). Weight of electrolyte, 1500 grains; duration, corresponding to half theoretical depletion of tantalum or niobium; initial cathodic current density, 400 amp/dm<sup>2</sup>; temperature, 900°C.

Fig. 4. Plot of the characteristic grain diameter against the molar composition of the baths for the systems  $KF-K_2TaF_7$  (curve 1) and  $KF-K_2NbF_7$  (curve 2); electrolysis conditions; see Fig. 3.

furnace were covered by a rather large quantity of a blue condensate.

At 10 m/o  $K_2NbF_7$ , these phenomena were practically negligible. In particular, the condensate on the walls of the furnace was white and in small quantity. It contained mainly  $K_2NbF_7$  and  $KF$ .

Two special runs were done with graphite cathodes and gave the same results as above stated, except for the yellowish color of the bath which was absent. It is thus probable that this color was due to an iron fluorocomplex whose formula is still unknown. On the other hand, it is probable that the blue condensate on the walls of the furnace contained some low valency niobium compound, such as  $NbF_3$ , but we did not succeed in identifying this compound by x-ray diffraction analysis. This point should be further investigated by additional research.

In the case of tantalum, no corrosion of the cathode was observed, and the condensate on the walls of the furnace remained always white. It seemed to contain essentially  $K_2TaF_7$  and  $KF$  and was produced in rather small quantity.

All the electrolyses described in this section were performed with anode effect. At the end of each run, the bath was covered by a black fluffy material consisting essentially of amorphous carbon.

*Influence of the initial cathodic current density on the current efficiency and on the characteristic grain diameter.*—The experiments were carried out with initial cathodic current density between 50 and 500 amp/dm<sup>2</sup>, at 900°C, and for a duration corresponding to the half theoretical depletion of the bath. For each type of baths, two compositions have been chosen: for  $KF-K_2TaF_7$ , 5 and 25 m/o  $K_2TaF_7$ ; for  $KF-K_2NbF_7$ , 5 and 10 m/o  $K_2NbF_7$ .

It was of course impossible to study the bath at 25 m/o  $K_2NbF_7$  because, as we have seen in the preceding section, it gives practically no deposit at all.

The plots shown on Fig. 5 and 6 are rather intricate; we will come back to this point in the general discussion at the end of the paper. We can see that the current efficiency increases with the cathodic current density in every case and that the results described in the preceding section are confirmed. Concerning the characteristic grain diameter, a problem arises due to the formation of polycrystalline grains. It is thus difficult to say whether the size of the true grains increases or decreases with the cathodic current density. In particular, in the case of the bath at 5 m/o  $K_2TaF_7$ , it is impossible to use the definition of the characteristic grain diameter as given above, because the shape of the distribution curve was not the usual one. The grains are coarser than in the other cases.

Fig. 5. Plot of the current efficiency against the initial cathodic current density for the following baths:  $KF-K_2TaF_7$  (75-25 m/o curve 1; 95-5 m/o, curve 2) and  $KF-K_2NbF_7$  (90-10 m/o curve 3; 95-5 m/o curve 4). Weight of electrolyte, 1500 grains; duration, corresponding to half theoretical depletion of tantalum or niobium; temperature, 900°C.

Fig. 6. Plot of the characteristic grain diameter against the initial current density for the following baths:  $KF-K_2TaF_7$  (75-25 m/o curve 1; 95-5 m/o curve 2) and  $KF-K_2NbF_7$  (90-10 m/o curve 3; 95-5 m/o curve 4); electrolysis conditions, see Fig. 5.

*Influence of duration of electrolysis on current efficiency and on characteristic grain diameter.*—The experiments were made with mixtures of  $KF-K_2TaF_7$  (75-25 m/o) and  $KF-K_2NbF_7$  (95-5 m/o) up to about two thirds of the theoretical depletion of the bath. Figures 7 and 8 show the results obtained under identical conditions for the two baths (initial cathodic current density, 240 amp/dm<sup>2</sup>; temperature, 900°C, 1500 gr. electrolyte).

It can be said that the two baths have roughly the same behavior: the current efficiency decreases and the grain size increases when the duration of the electrolysis increases. However, it should be noted that tantalum gives rise to polycrystalline grains which are bigger than those obtained for niobium. Moreover, the current efficiency is generally lower for niobium than for tantalum at equivalent percentages of the theoretical depletion of the bath.

*Influence of temperature on current efficiency and on characteristic grain diameter.*—The experiments have been run for  $KF-K_2TaF_7$  (75-25 m/o) and  $KF-K_2NbF_7$  (95-5 m/o) up to about 20-25% of the theoretical depletion of the bath. Figures 9 and 10 show the results obtained at 240 amp/dm<sup>2</sup> initial cathodic current den-

sity. The curve is limited to 900°C in the case of niobium because the bath melts at 840°C.

The two types of baths have the same behavior: the current efficiency seems to reach a maximum at about 900°C, while the grain size decreases regularly when the temperature increases.

#### Cathodic Polarization Curves for Deposition of Tantalum and Niobium from Pure Fluoride Baths

Cathodic polarization curves were drawn for the main baths used for the electrolyses described above using an "on" and "off" method to eliminate the ohmic drop between the cathode and the comparison electrode. The apparatus used has already been described previously by (5, 26) and has been used for other works similar to the present one (5, 13, 26-28). In this work, the rotating photographic recorder has been replaced by a Honeywell visicorder (29). The cathodic potentials measured just after switching off the current have been controlled in a few cases by making use of a double-beam Philips oscilloscope.

On the other hand, we have used comparison electrodes made of a silver wire dipping into a mixture of sodium chloride with 10 m/o silver chloride held in a boron nitride cylinder closed by a plug made of sintered boron nitride, bonded with a little sodium borate to ensure electrical conductivity (30).

Figure 11 summarizes the results obtained at 900°C for pure KF,  $\text{KF-K}_2\text{TaF}_7$  (75-25 m/o), fresh and after an electrolysis of 90 amp-hr and  $\text{KF-K}_2\text{NbF}_7$  (95-5 m/o), fresh and after an electrolysis of 60 amp-hr.

It can be seen that potassium is deposited at a potential of about 1.22v vs. the comparison electrode, and that the behavior of tantalum and niobium seems to be rather complex. We will come back to this problem in the general discussion.

#### General Discussion

*Electrochemical processes.*—In the present section, we shall see whether it is possible, on the basis of our experimental results, to give an answer to the question that we have put forward at the beginning of this paper: Why are the current efficiencies much lower for niobium than for tantalum under the same electrolysis conditions?

From the section on Phase Diagrams of the Systems it appears that the ionic species present in both types of baths ( $\text{KF-K}_2\text{TaF}_7$  and  $\text{KF-K}_2\text{NbF}_7$ ) should not be very different, at least at the beginning of the electrolysis. There must thus be another cause of the difference observed between tantalum and niobium in this respect.

Fig. 11. Cathodic polarization curves for the deposition of: potassium, from pure KF (curve 1); tantalum, from  $\text{KF-K}_2\text{TaF}_7$  (75-25 m/o): fresh bath (curve 2) after an electrolysis of 90 amp hr (curve 3); niobium, from  $\text{KF-K}_2\text{NbF}_7$  (95-5 m/o): fresh bath (curve 4) after an electrolysis of 60 amp hr (curve 5). The ordinates give the potentials of the cathode against the "BN" comparison electrode ( $-V_{\text{cath/comp. el.}}$ ). The temperature is  $900^\circ\text{C}$ .

In fact, it is possible to explain all the experimental results in terms of the redissolution of the metal deposited at the cathode into the bath through a chemical reaction giving rise to lower valency species, this reaction being much more active for niobium than for tantalum.

Let us first consider the cathodic polarization curves of Fig. 11. Several authors (6-15) have found that the cathodic deposition of tantalum occurs through the medium of one reduced valency stage, while for niobium two intermediate reduced valency stages appear. However, these authors do not agree as to the charge of the metal ions in these several steps ( $\text{Ta}^{3+}$  or  $\text{Ta}^{2+}$ ;  $\text{Nb}^{4+}$ ,  $\text{Nb}^{3+}$  or  $\text{Nb}^{2+}$ ), nor do they agree about the corresponding ionic or molecular species. Even though it would be very interesting to have more detailed information on this problem, we do not think it necessary to discuss them more thoroughly at the present stage of our work.

Senderoff and Mellors (14, 15) have confirmed by chronopotentiometry that, in all-fluoride baths somewhat similar to those used in the present work ( $\text{LiF-NaF-KF} + \text{K}_2\text{NbF}_7$  or  $\text{K}_2\text{TaF}_7$ ), the deposition of tantalum or niobium occurs effectively through the above-mentioned intermediate steps. They are found as transients only and in a range of current density not exceeding  $35 \text{ amp/dm}^2$ . Thus it seems to us that, as our curves of polarization are drawn in such a way that they correspond to steady-state conditions as soon as the initial cathodic current density is higher than about  $50 \text{ amp/dm}^2$ , the observed potentials should correspond to the over-all reduction of the initial ionic species present in the bath to the metal and we should only observe one flat part on the curves before going up to the potential needed for the deposition of potassium, at least without making allowance for a secondary reaction. But, if we suppose that the cathodic deposit does not hold very tightly to the base metal, and that some part of the deposit is removed from it because of the bath agitation and its own weight,<sup>1</sup> then we must consider the possibility of a chemical reaction between the metal and the bath to form in the bulk of the melt the above-mentioned lower valency species.<sup>2</sup>

According to Senderoff *et al.* (14), tantalum metal is not attacked by  $\text{TaF}_7^{2-}$  in pure molten fluoride solutions. Instead, they have shown that a more oxidizing substance than  $\text{TaF}_7^{2-}$ , probably  $\text{Ta}^{6+}$  or a perfluoro-

compound, may be formed at the anode (31). This strong oxidizing substance, migrating and diffusing to the cathode, might be responsible, in the case of tantalum, for the dissolution of the metal to  $\text{TaF}_7^{2-}$  or  $\text{TaF}_2$ .

Anyway, the lower valency species can be partly re-oxidized at the anode, but they can of course take part in the cathodic process and give rise to a certain cathodic depolarization, at least as far as we do not exceed the limiting current density for their mass transfer from the bath to the cathode. According to this theory, we should thus observe two flat parts in the cathodic polarization curve for tantalum, and three for niobium. This is indeed the case.

The comparison between the polarization curves obtained for tantalum and niobium demonstrates that the limiting current density for the discharge of the lower valency species formed in the bulk of the bath is much higher for niobium than for tantalum, although the molar content in  $\text{K}_2\text{NbF}_7$  is five times lower than it is for  $\text{K}_2\text{TaF}_7$ . This suggests immediately that the secondary chemical reaction leading to the redissolution of the metal in the bath is much more active for niobium than for tantalum. Another point is that the current density limits for the deposition of the metal without depolarization or codeposition of potassium are much narrower for niobium than for tantalum. Finally, the comparison between the potential for the deposition of potassium and those observed for the deposition of tantalum and niobium without depolarization nor potassium codeposition leads to the conclusion that both metals seem to be deposited with a rather high overvoltage (about 0.7). This point should be investigated in another research program.

Let us now come back to the results of the electrolysis that we have performed.

We have found (Fig. 3) that the current efficiency decreases sharply with an increase of the molar content of the bath in  $\text{K}_2\text{TaF}_7$  or  $\text{K}_2\text{NbF}_7$ . This can certainly be explained by the redissolution chemical reaction that we have mentioned: it certainly will proceed at a higher speed if one of the components taking part in the reaction is present in higher concentration. Moreover, the long metallic needles that are observed at higher concentrations (Fig. 4) can probably be removed from the cathode more easily than the polycrystalline grains observed at low concentration. It appears clearly from Fig. 3 and 4 that the results are the same for both types of baths, but at much lower concentrations for  $\text{K}_2\text{NbF}_7$  than for  $\text{K}_2\text{TaF}_7$ . This certainly confirms our opinion that the redissolution chemical reaction occurs at a higher speed for niobium than for tantalum.

From another point of view, according to our hypothesis, we should observe an increase in current efficiency when the cathodic current density increases, at least as far as no potassium codeposition occurs. This is in fact what is shown on Fig. 5 (curves 1, 2, and 3). But for the bath at 5 m/o  $\text{K}_2\text{NbF}_7$ , it is probable that some potassium codeposition occurs at current densities higher than  $400 \text{ amp/dm}^2$ .

We can see in Fig. 7 that the current efficiency decreases when the duration of the electrolysis increases, at least after a certain length of time. This can be attributed to the fact that the mean cathodic current density for the whole electrolysis decreases with duration and this, according to Fig. 5, leads to a decrease in current efficiency in the range of current densities used in the experiments presented on Fig. 7. As the electrolysis goes on, the bath is progressively depleted in  $\text{K}_2\text{NbF}_7$  or  $\text{K}_2\text{TaF}_7$ , so that, according to Fig. 3, the current efficiency should, on the contrary, increase. These two opposite actions may account for the maximum observed in the case of tantalum.

Concerning the effect of temperature on current efficiency (Fig. 9), as the temperature increases the chemical reaction of redissolution proceeds faster; however, when the temperature is too low, the vis-

<sup>1</sup> In fact we have done an electrolysis with a small insulated graphite crucible hung under the cathode, and we have recovered a certain amount of metallic grains in it.

<sup>2</sup> In the case of niobium a blue color appears generally at the bottom of the bath, suggesting the presence of these reduced valency species in the bath.

cosity of bath increases and the deposited metal can be removed more easily from the cathode, so that a maximum could be observed on the curve, as it is the fact for tantalum. The decrease in current efficiency at low temperature could also be due to the lower speed of the mass transfer of the ions to be discharged to the cathode, leading thus to a partial codeposition of potassium.

We think we have been able to explain our experimental results in terms of the redissolution of the metal deposited at the cathode into the bath by a chemical reaction which is much more active for niobium than for tantalum. This is also in accordance with observations published recently (14, 15).

*Grain size and crystalline shape.*—We shall now discuss briefly the grain size and crystalline shape observed in terms of the general electrocrystallization theory (4, 5).

Generally, all the crystals observed are rounded grains or polycrystalline grains. This form of deposit occurs in fact at rather high overvoltages and correspond to the so called UD-type deposit (Unorientierter Dispersionstyp, *i.e.*, dispersed crystals, without any preferred orientation). Long needles, corresponding to the so called FI-type deposit (Feldorientierter Isolationstyp, *i.e.*, isolated crystals, oriented in the field), have only been found where the current efficiency was very low, because of the high concentration in  $K_2TaF_7$  or  $K_2NbF_7$  (see Fig. 4). This form of deposit can only be observed at low overvoltages, and it is probable that they are obtained through the lower valency species present in the electrolyte.

Concerning the variation of the grain size *vs.* the factors of the electrolysis, the discussion is somewhat difficult because of the formation on one hand of polycrystalline grains, and on the other, of very acicular crystals.

According to Fig. 4, the grain size seems to decrease when the concentration in the metallic ion to be discharged increases; this is of course the opposite of what could be expected from the theory: the germination speed should decrease and the growing speed of crystals should increase with an increase in concentration. The observations are somewhat confused because of the change in the nature of the grains obtained. Thus we think that the general theory still holds in our case, but that one should be extremely careful in the discussion of curves giving the characteristic grain diameter against any electrolysis factors: one should be sure, through microscopic examination, that the nature of the crystals did not change over the investigated range. In the case of Fig. 4, the polycrystalline grains observed at low concentration in  $K_2TaF_7$  or  $K_2NbF_7$  may be attributed to a high germination rate due to the rather high overvoltage. We have already explained the formation of the long needles observed at higher concentrations.

According to the theory, we should observe in Fig. 6 a decrease in the grain size with an increase in current density. In fact, the general behavior seems to be much more intricate. Again, we think that the theory is still valid, but we are not able to show it easily on a curve because of the formation of polycrystalline grains. These are found at rather high overvoltages, and they seem to be biggest in the range of current density where no cathodic depolarization occurs and where the codeposition of potassium does not occur.

Figure 8 shows, according to the theory, an increase in the size of the crystals with the duration of electrolysis, whereas Fig. 10 shows a decrease in the size of the crystals when the temperature increases, as can be expected when the inhibition is low.

Finally, from a practical point of view, it appears from Fig. 3 that it should, perhaps, be possible to deposit niobium from  $KF-K_2NbF_7$  baths with a rather good current efficiency, but that it should be necessary to work at a very low  $K_2NbF_7$  concentration, adding

continuously this compound in the immediate vicinity of the cathode.

### General Conclusions

We think that the reason for the low current efficiencies observed in the case of the electrodeposition of niobium from  $KF-K_2NbF_7$  is that some part of the niobium deposited at the cathode is removed from it by the agitation of the bath and by its own weight and is redissolved in the bath through a chemical reaction, giving rise to lower valency species. Some part of these species are reoxidized at the anode, and another part of them participate again in the cathodic process.

This phenomenon is much more effective for niobium than for tantalum in the same type of bath.

Further study should now be done with the same types of baths, but with the addition of  $Nb_2O_5$  or  $Ta_2O_5$ , and afterward in the presence of some alkaline chlorides.

### Acknowledgments

Our thanks are due to the Belgian Government which gave us a partial financial support. In particular, the subsistence of one of the authors was sponsored by the Pakistan Atomic Energy Commission from an O.C.D. scholarship given by the Belgian Government.

We are glad to acknowledge the help of the technicians of the laboratory, and especially of Mr. A. Verraghen.

Manuscript submitted Nov. 14, 1967; revised manuscript received May 28, 1968. This paper is part of the thesis presented by one of the authors (A.M.) in partial fulfillment of the requirements for the Ph.D. degree at the Free University of Brussels.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Contact Resistance of Electroless Nickel on Silicon

Iwao Teramoto, Hitoo Iwasa, and Hideo Tai<sup>1\*</sup>

Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka, Japan

### ABSTRACT

The electric resistance of electroless nickel contacts to p-type silicon is investigated. The contact resistance increases by a factor of 100 when the resistivity of substrate silicon increases 10 times. It is also found that the contact resistance greatly increases on increasing the heat treatment temperature except for an intermediate temperature range between 450° and 600°C. The x-ray and chemical analyses show that the heat treatment at high temperatures causes a sharp increase in content of the nickel silicide phase accompanied by a decrease in the nickel phase. The observed change in contact resistance due to heat treatment is discussed in relation to the chemical transformations in the nickel-silicon-phosphorus system.

For fabrication of silicon devices, it has become increasingly important to establish processes for obtaining electrical contacts to silicon with an ohmic or very low resistance. The most successful contacts so far obtained are the vacuum deposition of a metal such as aluminum, gold, silver, nickel, or molybdenum onto the silicon surface, followed by heat treatment to diffuse in or to alloy with silicon. Hooper *et al.* (1) reported the contact resistances between silicon with a wide range of resistivities and several different metals which were evaporated in vacuum of  $10^{-5}$  Torr at substrate temperatures of 250°-300°C. They mention that the heat treatment after evaporation produces considerable lowering of the contact resistance in the case of nickel or palladium contacts while for most of the other metals changes in the contact resistance are small.

The electroless plating of nickel to silicon was first applied by Sullivan and Eigler (2) who reported that after annealing at a temperature above 400°C the contact resistance of electroless nickel greatly increases for p-type substrates while it decreases for n-type. The great majority of work on electroless nickel, however, has dealt with chemical reactions involved in the plating process or effects of incorporated phosphorus on the structure and mechanical properties of the film (3-6).

In this paper, chemical changes of the electroless nickel p-type silicon system on heat treatment are discussed in relation to the contact resistance.

### Experimental

Single crystals of p-type silicon with the carrier concentration of  $10^{18}$ - $10^{19}$  cm<sup>-3</sup>, which is of the order

of surface carrier concentration of practical diffused devices, were used. For the contact resistance measurement, the crystals were sawed into wafers and both surfaces of each wafer were lapped with 1200 mesh alumina to a thickness of about 200 $\mu$ . They were cleaned by degreasing, slight etching with a mixture of 5 parts of concentrated HNO<sub>3</sub> and 1 part of 48% HF, and rinsing with distilled water and methyl alcohol. The wafers were then stored in iso-propyl alcohol. Prior to plating, the wafer was dipped in NH<sub>4</sub>F solution (50%) for 30 sec and again rinsed thoroughly with methyl alcohol. This pretreatment was found to make the resultant contact resistance most reproducible. Since the thickness of plated films was not thick (about 1000Å) enough to obtain x-ray diffraction patterns on the surfaces, powdered silicon was plated in a similar way, but to a greater thickness for the x-ray and chemical analyses.

The detailed procedure and discussion of electroless nickel plating used are described elsewhere (7). The plating solution for making electric contacts to silicon consists of 30 g/l of NiCl<sub>2</sub>·6H<sub>2</sub>O, 50 g/l of NH<sub>4</sub>Cl, 65 g/l of (NH<sub>4</sub>)<sub>2</sub>HC<sub>6</sub>H<sub>5</sub>O<sub>7</sub>, 10 g/l of NaH<sub>2</sub>PO<sub>2</sub>·H<sub>2</sub>O, and 10 g/l of EDTA. Just before plating about 200 ml NH<sub>4</sub>OH was added to 1000 ml of the solution. The heat-treating of the nickel film plated onto silicon was performed in a flow of hydrogen (0.5 l/min), for 30 min in most cases. For contact resistance measurements, a second plating by conventional acidic solution was applied in order to facilitate soldering through which electric connections to outer copper plates were made. After the second plating, the silicon wafers were cut to 3 mm squares, each of which was sandwiched by 60/40 tin-lead solder pellets and copper plates outermost, being followed by soldering in a hydrogen flow at 340°C for 6 min. Possible protrusion

<sup>1</sup> Present address: Faculty of Engineering, Osaka University, Osaka, Japan.

sions of solder were removed by grinding all edges. A micrometer capable of 0.01 mm resolution was used for surface area measurement. The resistance, that is the d-c voltage drop between two outermost copper plates divided by the d-c current (0.1-1 amp) was then measured on this sample. The contact resistance in ohm-cm<sup>2</sup> was estimated by subtracting the resistance attributable to the bulk silicon from the measured resistance.

The chemical and x-ray analyses were performed on powder samples which were electroless nickel plated and heat treated in order to identify the phases present and determine the elemental composition.

### Results

The contact resistance was measured as a function of soldering temperature on the samples with hole concentration of  $1 \times 10^{18} \text{ cm}^{-3}$  and  $1 \times 10^{19} \text{ cm}^{-3}$ . The results are shown in Fig. 1. The electroless nickel films were heat-treated at a temperature of 450°C for 30 min. The contact resistance decreases with increasing soldering temperature, but at high temperatures a considerable amount of nickel may dissolve in the liquid solder. The solubility of nickel in the 60/40 tin-lead solder was determined by the chemical analysis of nickel in the solders which were equilibrated with solid nickel at constant temperatures and quenched. As shown in Fig. 2, the solubility of nickel in the liquid solder below 600°C is significantly lower than that in pure tin (8), and even than that in pure lead (9). Considering these two results concerning the soldering temperature, use was made of 340° or 400°C as the soldering temperature for further experiments.

Figure 3 represents the effect of carrier concentration in substrate silicon on the contact resistance. Heat-treating and soldering were made at 450° and 400°C, respectively. The contact resistance increases by a factor of  $10^2$  if the carrier concentration in substrate silicon is one order of magnitude lower. This result is comparable with the case of aluminum contact evaporated onto p-type silicon, reported by Hooper *et al.* (1), in which contact resistance of 0.005 ohm-cm silicon is higher and to 0.05 ohm-cm is lower than those of the respective present electroless nickel contacts. It is to be noted that a measurement of electroless nickel contact to n-type silicon with  $1 \times 10^{18}$  carriers  $\text{cm}^{-3}$  gave a contact resistance of  $2.5 \times 10^{-5}$  ohm-cm<sup>2</sup> which is remarkably lower than that of evaporated nickel contact.

The effect of heat-treating temperature on the contact resistance was studied and the result is shown in Fig. 4. The samples which contain  $1 \times 10^{18}$  holes  $\text{cm}^{-3}$

Fig. 1. Contact resistance of electroless nickel on silicon as a function of soldering temperature.

Fig. 2. Solubility of nickel in tin [after Hansen (4)], lead [after Elliott (5)] and 60/40 tin-lead solder.

Fig. 3. Contact resistance of electroless nickel as a function of carrier concentration in silicon substrates.

were plated and followed by heat-treatment for a period of 30 min and soldering at 340°C. The contact resistance increases with increasing heat-treatment temperature except for the intermediate temperature range between 450°-600°C where it can be seen that the contact resistance is nearly independent of the temperature. This irregularity occurs in the temperature range, in which a peak and a steep increase of contact resistance were observed by Sullivan and Eigler for n-type and p-type silicon, respectively (2).

The present x-ray examination on the powder samples showed amorphous patterns for as-deposited electroless nickel, in accordance with the result of Goldenstein *et al.* (3), although proof of crystallinity by electron diffraction has been reported (4). After heat-treatment above 450°C, a new phase different from nickel or silicon was found, which was most probably NiSi on the basis of three peaks observed in the diffraction pattern. No Ni<sub>3</sub>P phase was detected. For the quantitative analysis of the NiSi phase, 40 w/o (weight per cent) of tungsten powder as a reference was admixed with the nickel-plated powder samples after heating. The diffraction intensity was measured on the (220) peak for tungsten and the (111) peak for nickel, and for NiSi the peak appearing at  $45.6^\circ$  of  $2\theta_{\text{CuK}\alpha}$  was used. Figure 5 shows the variation of

Fig. 4. Contact resistance of electroless nickel on silicon as a function of heat-treatment temperature.

Fig. 5. Diffraction intensity ratio NiSi/Ni as a function of heating time.

NiSi content relative to nickel phase with the heating time, where the growth curves can be approximated by the logarithmic law. The x-ray intensity of NiSi and nickel phases as a function of heat-treatment temperature is shown in Fig. 6. As expected, the amount of NiSi sharply increases with increasing the heat-treatment temperature. On the other hand, the con-

Fig. 6. Relative diffraction intensity of NiSi and Ni as a function of heat-treatment temperature.

tent of nickel phase passes through a broad peak in the vicinity of 600°C. Below the temperature of this peak, the amount of the nickel phase increases on increasing the heat-treatment temperature as a result of crystallization of amorphous nickel. Above the peak temperature, the content of the nickel phase approaches zero as the temperature is increased toward the value at which all of the nickel reacts with silicon to form nickel silicides.

The chemical analysis of nickel and phosphorus was made in two stages as follows. After the plated and heated silicon powders were immersed in aqua regia, the dissolved nickel and phosphorus were analyzed. These are named "soluble" elements. The undissolved powders were alkali-fused and dissolved in acid. The nickel and phosphorus in this acid solution were named "insoluble" elements. The results are shown in Fig. 7 and 8. At low heat-treatment temperatures almost all the nickel exists in "soluble" form, but the soluble nickel content goes down as a result of high temperature heating above 450°C where at the same time the insoluble nickel content increases. The apparent decrease of total nickel at high temperatures may be attributed to formation of a material unattacked by the alkali-fusion. This fact again suggests formation of the nickel silicides from the nickel phase, because the solid solubility of nickel in silicon, which may be in "insoluble" form, is far below these observed values. Figure 8 indicates that the content of "insoluble" phosphorus is invariably low, being comparable with the detectability in the present analysis, and that of "soluble" phosphorus is nearly proportional to the "soluble" nickel content. Thus it is suggested that most of the phosphorus component is associated with the "soluble" nickel regardless of possible formation of nickel phosphides. The decrease in the total phosphorus content above 600°C could be attributed to evaporation during heat treatment.

Fig. 8. Chemical analysis of phosphorus content "soluble" and "insoluble" in aqua regia (--- see text) as a function of heat-treatment temperature.

### Discussion

According to Hansen's phase diagram for the nickel-silicon system (8), there exist at least six intermediate compounds, of which NiSi is the silicon-richest one next to NiSi<sub>2</sub>. The latter compound is formed by a peritectic reaction which is usually quite slow in rate. This may be the reason that NiSi<sub>2</sub> was not detected by the present x-ray examination. Since nickel deposits on silicon substrates tend to become silicon rich at higher temperatures, it appears that nickel easily diffuses through the silicon lattice to form nickel silicides. This supposition is confirmed by the recent study of diffusion of nickel into silicon single crystals by Bonzel who obtained a diffusion coefficient at 450°C as large as 10<sup>-14</sup> cm<sup>2</sup>/sec (10).

As deposited the nickel-silicon interface comprises an intimate contact between the metal and the undisturbed semiconductor with no intervening layers. It was, in fact, observed that such a contact is unambiguously rectifying and has a reverse breakdown voltage of about 10v. By heat treatment below 450°C, nickel diffuses into the silicon substrate and creates an impurity gradient beneath the contact, which effectively impairs the rectifying property of the contact. However, since the solid solubility of nickel in silicon at a temperature below 450°C is deduced to be much lower than 10<sup>15</sup> atoms cm<sup>-3</sup> (11, 12), no "soluble" nickel was observed by the chemical analysis. According to Goldenstein *et al.* (3), on the other hand, phosphorus incorporated in the plated nickel film reacts with the nickel to form Ni<sub>3</sub>P at 300°C or above. Formation of this compound in the "soluble" film may effectively suppress the nickel diffusion into silicon, resulting in an increase in contact resistance with heat-treatment temperature.

Previous investigations as to the change in mechanical properties of electroless nickel during heat treatment have indicated that the equilibrium between nickel and Ni<sub>3</sub>P above 450°C is reached in as little as 30 min (3, 4). Approximately 30 w/o free nickel remains in the film after completion of the reaction with phosphorus to stoichiometric Ni<sub>3</sub>P, because the phosphorus content as deposited was found to be about 10 w/o in the present experiment. The observed facts regarding both the x-ray diffraction intensity corresponding to the NiSi phase and the "insoluble" nickel content increase above 450°C can be explained by the transformation of the free nickel remaining in the film to the NiSi phase. However, the room temperature resistivity of nickel silicides and the absolute value of thermoelectric power are so low that each of the silicides can be assumed to be either a metal or a degenerated semiconductor (13). Since the observed contact resistance is much higher than that estimated from the series resistance of silicides, the remarkable increase in contact resistance on heat treatment at temperatures above 600°C cannot be attributed to the NiSi formation from free nickel only. There is a further possibility for NiSi formation, *i.e.*

thus giving rise to a release of phosphorus. This assumption is based on an increase in free energies of formation of nickel phosphides with temperature (14), although they are still negative even at their melting points. It may be also supported by the fact that a remarkable decrease in hardness attributable to the Ni<sub>3</sub>P phase has been observed during heat treatment at temperatures above 450°C (4, 6). The released phosphorus could diffuse into the p-type silicon substrate, resulting in high contact resistance. This model explains the reported result that for the n-type substrate the contact resistance remarkably decreases during high temperature annealing (2). It is interest-

ing to note that if the effective hole concentration in the p-type substrate decreases by a factor of ten the contact resistance becomes 100 times higher as seen in Fig. 3. The solid solubility of phosphorus in silicon above 600°C is higher than 10<sup>19</sup> atoms cm<sup>-3</sup> (11, 12), but the diffusivity is not so high that the "insoluble" phosphorus content can be detected. The decrease of "soluble" phosphorus at temperatures higher than 550°C may be owing to evaporation of released phosphorus.

At the intermediate temperatures between 450° and 600°C no significant extent of phosphorus diffusion occurs because of the extremely small value of the diffusion coefficient, in accordance with the observed slight change in contact resistance. In this temperature range, the predominant chemical change is NiSi formation due to reaction of free nickel or Ni<sub>3</sub>P with substrate silicon, whereas phosphorus incorporated during plating can be assumed to have completely transformed to the Ni<sub>3</sub>P phase upon heat treatment for 30 min.

The above discussion can qualitatively explain all the results of x-ray and chemical analyses by regarding the free element and the Ni<sub>3</sub>P phase in the film as the "soluble" components and diffused elements into the substrate and the NiSi phase as the "insoluble" ones.

### Conclusion

The contact of electroless nickel plated onto p-type silicon has a rectifying character as deposited, but the resistance is greatly decreased by heat treatment at temperatures above 300°C as a result of the diffusion of nickel into the silicon substrate. From the practical point of view for obtaining a low contact resistance, it can be concluded that the most favorable temperature range of heat-treatment is between 450° and 600°C. Below 450°C no apparent NiSi phase is formed and consequently the mechanical contact may not be tight for the soldering process. Heat treatment at temperatures above 600°C brings forth a remarkable increase in contact resistance caused by diffusion of phosphorus into p-type silicon.

# Anodic Oxidation of Hydrogen on Iron and Platinum in Sodium Hydroxide Solution

Sigmund Schuldiner\* and Clarence M. Shepherd\*

Naval Research Laboratory, Washington, D. C.

## ABSTRACT

In a rigorously controlled high-purity closed system, the electrochemical behavior of Fe and Pt electrodes for the hydrogen oxidation reaction showed marked differences both in the active and passive regions. The catalytic behavior of the two metals reflects the differences in metallic properties and anion adsorption. Iron was found to be a far better catalyst with a much less pronounced passive region. Iron corrosion was insignificant. Small amounts of platinum on iron strongly retarded hydrogen oxidation. Significant Pt dissolution and deposition on the iron working electrode was not found.

Recent work at this Laboratory (1, 2) has indicated that the passivation of the hydrogen oxidation reaction on platinum in acid solution is caused by anion adsorption. (Passivation is herein defined (2) as the anodic region in which  $dE/d(\log i)$  is negative). Anion adsorption initially caused rather moderate passivation effects due to the blocking of active sites in such a way as to cause a reduction in the effective electrode area. The major passivation effect, however, was due to a poisoning of catalytically active sites with strongly adsorbed anions and under proper conditions a combination of dermasorbed oxygen atoms and adsorbed anions.

The present work was undertaken to relate these findings to both Pt and Fe electrodes in alkaline solution. In addition, the question was considered of the effects of trace amounts of Pt deposited on pure iron in alkaline solutions on the behavior of the iron. This is an important question inasmuch as Pt counter and reference electrodes are commonly used in such experimental studies. Malachuk *et al.* (3) have indicated that anodic polarization of Pt in alkaline solutions can cause deposition of Pt on the working electrode.

## Experimental

The high-purity closed electrochemical system and experimental conditions were the same as reported (1, 4) with the exception that the solution was 0.2M NaOH. The working electrodes were a Pt wire (99.99%, 20 mil diameter, geometric area = 0.65 cm<sup>2</sup>); an Fe wire (fabricated from 3 pass electron beam zone refined iron with less than 4 ppm total metallic impurities, 20 mil diameter, geometric area = 0.65 cm<sup>2</sup>); and a similar Fe wire with about 1 cm of 3 mil Pt wire spot welded to the Fe wire and wound around its tip (Fe  $\gg$  Pt electrode). Each of these electrodes was connected to Pt leads and sealed off in lead-free soft glass tubes. The counter electrode was a large Pt gauze electrode. The reference electrodes were in an arm off the main cell compartment and were a calibrated miniature glass electrode and a Pd wire charged with hydrogen to a potential of about 50 mv positive to a hydrogen electrode in the same solution. This Pd-H wire electrode was used as the potentiostatic reference.

After the cell was cleaned with hot concentrated nitric acid, it was rinsed for at least 24 hr by continually distilling triply distilled water into it. About 100 ml of water was then distilled into the cell and cooled. A capsule of sodium metal (99.95% with <55 ppm heavy metals, sealed under argon) was broken in two and introduced into the cell under an atmosphere of purified helium. The two halves of the capsule were placed so that the open ends were at the bottom of the cell. Thus as sodium metal dissolved, the hydrogen gas generated filled the capsule ends and regulated the introduction of water into the capsule. This allowed a rather slow solution

of sodium metal. The resulting sodium hydroxide solution was 0.2M.

Before the Fe electrode was introduced into the cell, a Pt wire cathode was used with the Pt gauze electrode as an anode, and the solution was pre-electrolyzed at about 50 ma for several days under a pure helium atmosphere. On completion of the pre-electrolysis, the pre-electrolysis cathode was removed. Upon completion of the pre-electrolysis, the pre-electrolysis cathode was removed. The Pt electrode was then submitted to a potentiostatic polarization sequence of increasing and decreasing applied potentials until steady-state, reproducible values were obtained. This treatment took about 1 month. The helium flow was then replaced with hydrogen (purified by passing through heated Pd-Ag tubes). The potentials of the Pt wire, Pt gauze, and Pd wire were then determined against the glass electrode. After the Pt/H<sub>2</sub> electrodes reached their equilibrium values and the Pd wire was 50 mv positive to the Pt/H<sub>2</sub> potentials, the Fe wire (cleaned in 1M H<sub>2</sub>SO<sub>4</sub> and rinsed with triply distilled water) was introduced into the cell and was made the working electrode. After the open-circuit potential was determined, the gauze Pt electrode as the counter electrode and the Pd wire as the reference electrode were connected into the potentiostatic circuit. The glass reference electrode continuously monitored the potential on the Fe working electrode via a Keithley 610B electrometer. Current flow under potentiostatic conditions was determined with a Keithley 601 electrometer and recorded. Potentiostatic current-voltage curves were then determined after steady-state currents were achieved. Numerous runs under increasing and decreasing potential sequences were determined until reproducible results were obtained.

Similar measurements were made for a pure Pt wire working electrode. Another series of measurements was made with the iron wire with the small amount of attached Pt wire (Fe  $\gg$  Pt electrode).

While the electrodes were being held at a constant potential, the hydrogen (P<sub>H<sub>2</sub></sub> = 1 atm) flow was about 40 ml/min. When steady-state currents were obtained the hydrogen flow rate was increased to >1000 ml/min in order to minimize diffusion-controlled reaction rates. The currents shown in the figures were determined under these conditions. The temperature was 25° ± 2°C. All potentials were converted to the normal hydrogen electrode (NHE) scale.

## Experimental Results

The open-circuit potential for the Pt, Fe, and Fe  $\gg$  Pt electrodes were each the equilibrium potential of -0.78v for the H<sub>2</sub>O/H<sub>2</sub> reaction in the 13.2 pH, 0.2M NaOH solution. There was no visible sign of corrosion on the pure Fe wire even though the electrode was exposed for several weeks. However, the Fe  $\gg$  Pt electrode did show a very small amount of a yellowish brown corrosion product in the vicinity

\* Electrochemical Society Active Member.

of the Pt. Tests for iron in solution (thiocyanate) were always negative.

The steady-state potentiostatic current-voltage curves for the three working electrodes are shown in Fig. 1, 2, and 3. In each case there was some hysteresis on the decreasing potential sequence as compared to the increasing potential sequence. All of the electrodes showed Tafel regions at low anodic potentials where the rate of hydrogen oxidation was increased as the potential became more noble. At about  $-0.2\text{v}$  for the Pt electrode (Fig. 1) there was a sharp passivation and a large drop in hydrogen oxidation rate until a potential of about  $0.3\text{v}$  was reached. This was followed by a limiting current density of about  $3 \times 10^{-8}\text{ amp/cm}^2$  and at  $0.8\text{v}$  a Tafel region ( $b = 0.06$  slope) at which the predominant reaction is the oxidation of water to oxygen. The

Fig. 1. Potentiostatic anodic current density vs. potential relation on Pt electrode.  $\Delta$ , increasing potential sequence;  $\nabla$ , decreasing potential sequence.

Fig. 2. Potentiostatic anodic current density vs. potential relation on Fe electrode. See Fig. 1 for meaning of symbols.

Fig. 3. Potentiostatic anodic current density vs. potential relation on Fe  $\gg$  Pt electrode. See Fig. 1 for meaning of symbols.

hysteresis for the decreasing potential sequence is most likely caused by dermasorbed oxygen (1, 4) until a potential of  $-0.3\text{v}$  where the hysteresis effect vanishes.

Figure 2 shows that the potentiostatic current-voltage relation for Fe is very different from that of Pt. The transition to a passive state is not as sharp, and the retardation of the hydrogen oxidation reaction in the passive region is rather moderate. An  $\text{O}_2$  formation region is reached at about  $0.9\text{v}$ . The hysteresis on the decreasing potential sequence may be due to either dermasorbed oxygen or an invisible layer of oxide. In any case, as the potential reaches about  $0.2\text{v}$  of the equilibrium value, the hysteresis becomes insignificant and the state of the iron surface is essentially the same as for the increasing potential sequence.

The data for the Fe  $\gg$  Pt electrode shown in Fig. 3 indicates that the very small relative area of Pt played a dominant role. The similarity to pure iron is evident at low potentials only.

### Discussion

The most striking feature of the potentiostatic current-voltage relations comparing pure Fe with Pt is the fact that Fe is a far more active electrode for the hydrogen oxidation reaction at all potentials. Figure 4 shows a comparison of the potentiostatic curves for the three working electrodes for an increasing potential sequence.

The effect of a small area of Pt on the Fe wire was to decrease its activity so that it behaved more like a Pt than Fe electrode. At low polarizations, however, the Fe  $\gg$  Pt electrode behaved more like the pure iron, especially in the decreasing potential sequence. The reduction in the limiting current density compared to both the Fe and Pt electrodes (Fig. 4) is surprising, but probably reflects the small amount of iron corrosion product formed near the Fe/Pt interface. It is evident from these experiments that trace amounts of Pt would have a marked effect on the electrode behavior of pure iron. It is evident also that under the experimental conditions using the high-purity system dissolution of Pt from electrodes during pre-electrolysis or during a run and the subsequent deposition of part of this Pt on the iron electrode must have been insignificant. There is, in fact, no evidence of Pt impurity affecting the results on the pure iron working electrode. Similarly there is no evidence of traces of iron in solution depositing on the Pt working electrode and affecting its behavior significantly.

The sharpness of the onset of passivity on the Pt electrode and the almost three orders of magnitude drop in hydrogen oxidation rate in this passive region ( $-0.1$  to  $0.3\text{v}$ ) indicate that the passivation is due primarily to the increase in the free energy of activation of the hydrogen oxidation reaction. This effect

Fig. 4. Comparison of Pt, Fe, and Fe  $\gg$  Pt electrodes for increasing potential sequence.

is most likely due to the poisoning of catalytically active sites by anion ( $\text{OH}^-$ ) adsorption (2). The increase in activity in the potential range from about 0.1 to 0.0v for the decreasing potential sequence verifies this interpretation and, as in acid solution, shows the increased poisoning effect due to dermasorbed oxygen (2). These results are similar to those found for hydrogen oxidation passivation on Pt in sulfuric acid solution (1, 2) except that the alkaline solution results are more pronounced. This is evidently due to the higher heat of adsorption of  $\text{OH}^-$  over  $\text{SO}_4^{2-}$  ions. The much steeper Tafel slope ( $b = 0.22$ ) shown in Fig. 1, compared to the sulfuric acid result ( $b = 0.025$ ) reflects the fact that the rate-controlling step in alkaline solution is much more sensitive to polarization than in the acid. The 0.025 Tafel slope can be interpreted as a slow hydrogen dissociation to  $\text{H}_{\text{ad}}$  atoms, whereas the  $b = 0.22$  slope indicates that the rate is due to a complex hydrogen discharge. The hydrogen discharge must be affected by the sodium ions (5). The passivation as the potential becomes more noble indicates that the influence of adsorbed hydroxyl ions is probably not felt until the onset of passivity.

The surprisingly moderate passivation of the Fe electrode (Fig. 2) indicates that any anion adsorption or other effects at the passivation potential did not cause a poisoning of catalytically active sites and that the retardation of the hydrogen oxidation was due primarily to reduction in the active area (2) due to either weak anion adsorption or the formation of iron complexes with  $\text{OH}^-$  or other oxygen species. We do not, of course, know definitely that the iron electrode is free of oxide even at the open-circuit potential. However, the fact that it acts like a reversible hydrogen electrode and its low polarization eliminate the possibility of a high resistance oxide. Indeed, it is quite feasible that in the presence of hydrogen the iron is virtually free of oxides or oxygen species. The hydrogen equilibrium potential indicates an oxide-free metal, and the Tafel slope of 0.06 is likely due to a slow hydrogen discharge-controlled step. Additional work, however, is required to determine the state of the iron surface, both at the hydrogen equilibrium potential and under anodic polarization.

### Conclusions

This work has shown that the behavior of pure Pt and Fe electrodes under the rigorously controlled high-purity closed system environment is markedly different in both the active and passive hydrogen oxidation regions. The differences in catalytic behavior of the two metals are great, and their passivation behavior strongly reflect the differences in metallic properties and the influence of anion adsorption. No significant corrosion of iron was found, and iron was found to be a far better catalyst for the hydrogen oxidation reaction at all anodic potentials. Despite this the anion poisoning of catalytically active sites on iron was much less pronounced than on platinum. This means that anion adsorption has less effect on the surface states of iron than on platinum. Further work is required to define better the iron surface under the experimental conditions used so that its remarkable catalytic properties are understood. Under the conditions used, significant electrochemical effects due to dissolution and deposition of Fe or Pt on each other were not found.

## Solid Electrolyte Coulometry; Silver Bromide Electrolyte

John H. Kennedy and Fred Chen

*University of California, Santa Barbara, California*

and Andy Clifton

*Bissett-Berman Corporation, Santa Monica, California*

### ABSTRACT

The properties of a new type of coulometer utilizing a solid electrolyte have been investigated. The system consists of silver bromide electrolyte between a silver and a gold electrode. Coulombs of charge are recorded by plating silver on the gold electrode and then recovered by stripping the silver from the gold electrolytically. A voltage rise when the gold electrode is depleted of silver serves as the end-point indicator. Under carefully controlled conditions, more than 99% of the silver plated on the gold could be stripped off. However, long charging periods or idle periods between charging and stripping gave low results.

During recent years, considerable interest has developed in two fields, solid electrolyte materials (1-3) and miniature coulometers for integrating and timing circuit components (4). It has been the aim of this research to examine the problems associated with and

Key words: coulometer; coulometry; electrolyte; solid; silver bromide.

advantages of such devices, using solid electrolytes in place of the conventional liquid electrolytes.

The problems can be divided into three areas: (I) Preparation of solid electrolytes with acceptable conductivity over the required temperature range. (II) Achievement of high current efficiency over the required temperature range to yield cells with high

accuracy, long charge hold capability and also sufficient charge capacity. (III) Achievement of acceptable voltage cut-off characteristics for a practical system. This is primarily a function of electrode-solid electrolyte interface effects and electrolyte decomposition.

Of the many compounds which have been studied as solid electrolytes, silver compounds have two properties which make them attractive as silver coulometers; (i) conductivities are generally quite high compared to other solid materials, and (ii) conduction mechanism is via silver ion transference. Thus, it was concluded that initial studies should be made using silver compounds as electrolytes for coulometers.

The basic concept of these coulometers is quite simple. The system consists of a silver electrode, electrolyte, and gold electrode. An amount of silver is transferred electrolytically to the gold (charging operation). Then the silver is transferred back to the silver electrode (stripping operation). While silver remains on the gold electrode the system is essentially a silver-silver couple and the voltage is predominantly  $iR$  drop through the electrolyte. As the silver becomes depleted, the silver activity on the gold drops and the voltage begins to rise. Finally, when the silver is completely stripped off, the voltage may rise to over 1v as the gold begins to oxidize. This voltage rise can be used to activate a trigger circuit. When the charging and stripping operations are carried out at constant current, the process is used for timing. However, the voltage rise occurs when a specific number of coulombs have been transferred. Thus, when the charging cycle is carried out at variable current, integration can be accomplished by stripping at constant current

$$\int_0^{t_{\text{charge}}} i dt = i_{\text{strip}} t_{\text{strip}}$$

Since the process is electrolytic, the electrolyte must be an ionic conductor with a negligible electronic conductivity. Theoretically, if the same fraction of the current was electronic in both charge and strip, accurate timing could still be accomplished. However, any idle time between charging and stripping, called charge hold, would allow the electronic contribution to act as a short, changing the charge setting until the open-circuit voltage reached exactly zero. Also, in practice, the voltage drops are different for charge and strip because of electrode polarizations, which would cause the electronic contribution to be different. This consideration rules out pure  $\text{Ag}_2\text{S}$ ,  $\text{Ag}_2\text{Te}$ , and other silver compounds which are known to be electronic conductors, or have significant electronic contributions to their conductivity.

Silver halides, especially  $\text{AgI}$ , exhibit high conductivities and have been used in various solid electrolyte batteries (2, 5). Compounds of the type  $\text{MAg}_4\text{I}_5$  show conductivities similar to aqueous solutions (6, 7). On the other hand,  $\text{AgI}$  decomposes at 0.7v and thus, end-point signals would have to be significantly below this value to minimize electrolyte decomposition, and  $\text{KAg}_4\text{I}_5$  may not be stable at room temperature (7), which could cause undesirable time effects. Pure silver bromide has a low intrinsic conductivity,  $3 \times 10^{-8}$  mho-cm<sup>-1</sup> calculated at room temperature, but several studies have shown that higher conductivities can be achieved by the addition of impurities as doping agents. Especially effective are divalent ions,  $\text{Cd}^{++}$  (8) or  $\text{S}^{=}$  (9). Also, polycrystalline silver bromide exhibits much higher conductivities from grain boundary conduction (10). This study examines the characteristics of silver bromide as an electrolyte for solid electrolyte silver coulometers.

### Experimental

**Silver Bromide.**—Commercial  $\text{AgBr}$  (Matheson, Coleman, and Bell) was used for the studies labeled MC&B  $\text{AgBr}$ . Drying the material for 0, 2, 24, or 48 hr

was examined, but the results were identical. Bromine purification was used to eliminate reduced silver content. This was accomplished by contacting the material with bromine vapor at room temperature for  $\frac{1}{2}$  to 1 hr.

Silver bromide was also prepared from reagent grade  $\text{AgNO}_3$  and alkali bromide ( $\text{NaBr}$  and  $\text{KBr}$ ) by the following procedure. Solutions of 200 ml of approximately 1M  $\text{AgNO}_3$  and 1M  $\text{MBr}$  were mixed by pouring together into an empty beaker. The precipitate was digested near the boiling point for 1 hr and then allowed to stand for 12 hr. The silver bromide was filtered and dried for 3 hr at 135°C. Samples were prepared using stoichiometric ratios, 20% excess  $\text{AgNO}_3$ , and 10% excess  $\text{MBr}$ .

Silver bromide doped with  $\text{CdBr}_2$  was prepared by grinding together MC&B  $\text{AgBr}$  and  $\text{CdBr}_2$  [0.1, 0.2, 0.5 m/o (mole per cent)]. A preparation containing 0.2%  $\text{CdBr}_2$  was also prepared by heating the mixture at 280°C for 110 hr. No difference in results was observed.

Silver bromide doped with 0.2%  $\text{Ag}_2\text{S}$  was prepared by grinding the commercial materials together and heating at 280°C for 100 hr.

**Pellet preparation.**—Pellets were prepared with a Perkin-Elmer evacuable die, 0.5 in. diameter. As an example, 0.25g powdered silver (5-10 $\mu$ ) was pressed at 8000 psi followed by 0.50g silver bromide sample pressed at 8000 psi, and finally 0.50g powdered gold (5-15 $\mu$ ) pressed at 8000 psi. The whole pellet was then pressed under vacuum at 60,000 psi and held under these conditions for 1 min. After removal from the die, the edges of the pellet were sanded to remove any metal which would act as an electrical short.

Some of the pellets were sectioned and examined by photomicrography. The boundary lines between electrolyte and electrode were extremely sharp in all cases.

**Grain boundary examination.**—Grain size was determined for the  $\text{AgBr}$  electrolyte after pressing by etching the surface and examining microscopically. The surface was polished first with a metallurgical polishing wheel and then etched with a concentrated solution of sodium thiosulfate in water. The solution was rubbed on the silver bromide surface which was preferentially attacked along the grain boundaries.

**Electrode contacts.**—The first conductivity measurements were made by mechanically pressing gold and silver foils against the silver bromide pellet. The results were irreproducible and resistances were about 20,000 ohms for the normal pellet. The same pellets pressed between silver and gold powders had resistances of about 3000 ohms. The rest of the resistance when using foils was attributed to the electrode-electrolyte interface. This was also shown by the fact that the resistance was not linearly dependent on pellet thickness. All the work reported in this paper was done on pellets pressed between gold and silver powder. This method of electrode contact was reproducible, and the resistance was linearly dependent on pellet thickness.

In most cases, the pellets were then clamped between plastic plates containing metal lead wires. Pellets with spot-welded leads showed operating voltages which were pressure dependent after long periods of charge.

**Electrochemical measurements.**—A Beckman Electroscan-30 was used for controlled potential electrolysis, cyclic voltammetry, and recorded charge-strip cycles at constant current. Specialized test equipment with trigger circuit cut-off was provided by Bissett-Berman Corporation for constant current charge-strip cycles. This equipment was especially useful for long cycles because the current was automatically stopped when the voltage reached a predetermined value (0.5-0.8v). Although the Electroscan-30 is designed as a 3-electrode system, the pellets did not normally contain a reference, and

thus, all measurements are voltage drops between working anode and cathode. An experiment is described in which a silver reference was placed next to the working silver electrode to study electrode polarization.

### Results

**Resistivity measurements.**—Resistance of the pellets was measured with a General Radio No. 1650A Impedance Bridge using 1000 cycle a-c signal. The resistance consists of three terms, two electrode-electrolyte contacts and the electrolyte itself. Since the contact resistance should be independent of pellet thickness, resistance measurements on MC&B AgBr ( $\text{Br}_2$  purified) pellets of various thicknesses from 0.015 to 0.254 cm were made and are shown in Fig. 1. Within experimental error, the points lie on a straight line with the intercept at zero indicating little, if any, contact resistance.

The resistivity was about a thousand times smaller than that calculated from the intrinsic conductivity measured at higher temperatures. This result is in agreement with previous studies (10) which attributed the enhanced conductivity to grain boundary conduction. Silver bromide prepared from  $\text{AgNO}_3$  and alkali bromide gave widely varying results, and the resistance rose rapidly with time (Fig. 2). Heating the

Fig. 1. Resistance of AgBr pellets, MC&B AgBr,  $\text{Br}_2$  purified

Fig. 2. Aging effects for AgBr pellets. (A) MC&B, no  $\text{Br}_2$  purification, (B) MC&B,  $\text{Br}_2$  purified, (C) Precipitated AgBr, NaBr, excess  $\text{Ag}^+$ ,  $\text{Br}_2$  purified, (D) Precipitated AgBr, NaBr, stoichiometric,  $\text{Br}_2$  purified, (E) Precipitated AgBr, KBr, excess  $\text{Ag}^+$ ,  $\text{Br}_2$  purified, (F) Precipitated AgBr, KBr, excess  $\text{Br}^-$ , no  $\text{Br}_2$  purification.

pellet to  $200^\circ\text{C}$  for 2-3 hr increased the resistivity up to  $6 \times 10^6$  ohm-cm. The heat treatment was not a drying effect; pellets made from AgBr powder dried at  $200^\circ\text{C}$  for 48 hr had resistances only slightly higher than the powder dried at  $130^\circ\text{C}$ . Pellets of commercial AgBr heated to  $100^\circ\text{C}$  for short periods of time showed little or no change in resistance when cooled to room temperature, but a marked increase to  $> 10^6$  ohm-cm occurred when treated at  $200^\circ\text{C}$ . The increase in resistance after heat treating was not due to an electrode-electrolyte interface effect, since thicker pellets showed a proportionate increase, too. The grain size of precipitated AgBr was 8-20  $\mu$  diameter while MC&B was 2.6-3.5  $\mu$  diameter. MC&B heated to  $200^\circ\text{C}$  had a grain size of 12-13.5  $\mu$ . Thus, it appeared that the larger the grain size, the lower the conductivity.

The resistivity of MC&B AgBr as a function of temperature is shown in Fig. 3 for the temperature range  $-40^\circ$  to  $+100^\circ\text{C}$ . At room temperature the resistivity compares closely with the freshly precipitated material of Shapiro and Kolthoff (10), but the slope was not as great, resulting in higher conductivities at low temperatures.

Samples of MC&B AgBr were treated with bromine vapor to eliminate the presence of reduced silver from photodecomposition. The powder turned from light green to bright yellow and was handled in the dark after the bromine treatment. The resistivity increased from  $0.60 \times 10^5$  to  $0.98 \times 10^5$  ohm-cm, but again no aging effects were observed at room temperature. In order to standardize preparative procedures, all samples, except where noted, were bromine treated to eliminate reduced silver.

Addition of 0.1-0.5%  $\text{CdBr}_2$  to MC&B AgBr decreased the conductivity 10-30%, while 0.2%  $\text{Ag}_2\text{S}$  increased the conductivity 10%. All of the samples, including MC&B AgBr, contained small amounts of sulfur, but there was no apparent correlation between sulfur content and conductivity. Addition of KBr decreased the conductivity markedly.

It is concluded that MC&B AgBr exhibits high conductivity primarily because of grain boundary conduction, since it loses the conductivity upon heat treating at  $200^\circ\text{C}$ . However, the crystallite surface properties must be less active than freshly precipitated AgBr, because room temperature annealing was not observed. Finally, it cannot be overlooked that small concentration of impurities, specifically  $\text{Ag}_2\text{S}$  and  $\text{Ag}_2\text{O}$ , may be enhancing the conductivity of the commercial AgBr and causing the surface passivity. In any case, the material gave reproducible results from bottle to bottle and showed no aging effects when kept below  $100^\circ\text{C}$ . Thus, it was a convenient material to use for solid electrolyte coulometry studies.

Fig. 3. Temperature dependence for AgBr conductivity, MC&B AgBr,  $\text{Br}_2$  purified.

Fig. 4. Stripping curve for AgBr, MC&B AgBr, Br<sub>2</sub> purified. Charge: 1000 sec at 5  $\mu$ a; stripping current: 5  $\mu$ a.

**Charge-strip curves.**—The voltage drop during the stripping cycle should remain equal to  $iR$  until the gold surface becomes depleted of silver, at which time the voltage will rise until it reaches the Ag/AgBr, AuBr/Au potential plus  $iR$ , or until Br<sub>2</sub> discharge occurs at the Au electrode. Figure 4 shows a stripping curve for a charge of 1000 sec at 5  $\mu$ a. The gold surface had been oxidized to 500 mv vs. Ag before charging. As can be seen, the voltage starts to rise about 200 sec before the 500 mv end-point and reached the end-point at 980 sec, a -2% error.

During the charge cycle, the system is a silver-silver couple and the only voltage drop, in principle, should be from internal resistance. In practice, the voltage drop was somewhat higher than that predicted from a-c conductivity measurements because of polarization effects. Conductivity measurements taken at various stages of the charging cycle showed small changes in resistance (< 5%), but not enough to account for the voltage drop during d-c current flow. Polarization and increased resistance during long charge cycles was significant, the voltage sometimes rising to the decomposition voltage of the electrolyte.

**Cyclic voltammetry.**—Cyclic voltammetry was used to examine the electrode reactions which took place on the gold electrode. The pellet coulometers did not contain a reference electrode, and thus, the curves shown in Fig. 5 contain  $iR$  drop contribution. The silver electrode was assumed to be a stable reference electrode, since the curves were completed in less than 2-3 min which would not allow sufficient time to deplete the silver electrode of active sites. In general, three anodic peaks were observed before the final cut-off (Fig. 5). The anodic peak voltages corrected for  $iR$  drop were +0.095v, +0.30v, +0.63v while the final cut off was about +0.8v vs. the silver electrode. The first peak was usually observed on the first cycle only and would remain as only a shoulder on succeeding cycles. This peak was attributed to silver metal present on the gold being oxidized to AgBr. For a reversible couple, the peak voltage should be  $E_{1/2} + 0.028/n$ . The  $E_{1/2}$  value for silver oxidation is zero volts vs. the silver reference, and this shift to +0.067v probably indicates a lower silver activity on the gold compared to the pure silver electrode although irreversibility would also give rise to a voltage shift.

The final cut-off could be due to any of the following three reactions

Fig. 5. Cyclic voltammetry, MC&B AgBr, no Br<sub>2</sub> purification, scan rate = 200 sec/v.

At high current densities all three may occur, but at equilibrium the most stable product would be AuBr.

The two small peaks at +0.30 and +0.63v were probably due to impurities. The following reactions are considered

The peak heights and positions were affected by scan rate, indicative of irreversibility. Also, the peak separation between anodic and cathodic scan was 0.14v (corrected for  $iR$  drop) for both peaks, again indicating irreversibility. It should be stressed that since a third reference was not present, voltage values are open to question, and with the irreversible nature, it is impossible to assign the peaks on the basis of voltage alone. However, addition of Ag<sub>2</sub>S to AgBr increased the peak height at +0.30v, which is compatible with reaction [6]. Also, addition of Ag<sub>2</sub>O did not increase the peak height at +0.30v, but introduced a new peak at +0.75v. Thus, it is concluded that the peak was caused by the presence of sulfide, and that the samples (both MC&B and precipitated AgBr) contained little or no Ag<sub>2</sub>O.

**Controlled potential electrolysis.**—Anodic stripping of the gold electrode at controlled potential was carried out to determine residual currents for the pellets. Current which flows at the cut-off voltage will determine the lower limit at which the coulometer can be used. In addition, the residual current can be used to calculate the upper limit of the electronic conductivity contribution. This limit was calculated by the method described by Ilschner (11) for single crystals of AgBr. The plateau region was not as well-defined for the polycrystalline material but little change in residual current was observed between 0.5 and 0.7v. The results in Table I show that the electronic conductivity for MC&B is about 0.2% of the total conductivity.

Controlled potential electrolysis was used to clean the pellet electrolytically prior to use and after a series of experiments. The technique was also used to recover silver charge on the gold electrode which was not found using constant current.

**Leakage current.**—After a cell was driven to a high voltage (0.5–0.8v) the open-circuit voltage would decay slowly with time, and a number of  $\mu\text{coul}$  of charge had to be passed to return the cell to the original voltage. A representation of the process is shown in Fig. 6. The charge lost could be thought of as a leakage current and Table I shows the results for a number of AgBr pellets.

Several identical pellets (MC&B, Br<sub>2</sub> purified) were given waiting periods of 2–200 hr to determine charge lost as a function of time. The leakage current ( $i_L = Q/T_{o.c.}$ ) was higher at the beginning of the open-circuit period than at the end, indicating that the leakage current was a function of open-circuit voltage. Also, the leakage current was higher for pellets having closer electrode spacing, indicating that the leakage current was a function of cell resistance. These results are consistent with the idea of a small electronic contribution to the total conductivity. Since the leakage current was much lower than the residual current, the residual current must be predominantly ionic in nature. Based on the leakage current value, the electronic conductivity must be less than  $< 10^{-10}$  (ohm-cm)<sup>-1</sup> or 0.01% of the total conductivity for MC&B AgBr.

**Timing accuracy.**—Timing accuracy for the silver bromide coulometers was checked at currents of 1–100  $\mu\text{a}$  and for periods of 50–200 sec. This charge ranged from less than a monolayer (approximately 300  $\mu\text{coulombs}$ ) to about 70 atomic layers on the average. In the current range 5–50  $\mu\text{a}$ , the average error was less than  $\pm 1\%$  in almost all cases (Table II). At 1–2  $\mu\text{a}$  a positive error of about 25  $\mu\text{coul}$  was observed. The negative errors observed at high charge settings were shown to be predominantly silver remaining on the gold by stripping the gold at controlled potential, in which case the remaining  $\mu\text{coul}$  were recovered at very low current.

**Charge hold.**—Though the pellets showed high accuracy when stripping was carried out immediately, it is necessary that the charge be stored and stripped at a later time for most practical applications. Time at open-circuit between charging and stripping is called

charge hold. Silver bromide pellets gave negative errors as charge hold time increased. The results are shown in Fig. 7. Actually, the charge was not lost since the remaining silver could be removed at very low currents by using controlled potential electrolysis. This phenomenon is considered in detail in the discussion section.

**Charge capacity.**—Another practical consideration is the amount of charge which can be transferred to the gold and subsequently stripped without losing accuracy or shorting from silver growth. Table II shows that negative errors of 10% were observed with charges of 20,000  $\mu\text{coul}$  (5.56  $\mu\text{a-hr}$ ). Also, charge hold experiments indicated that negative errors were encountered as charge hold time increased (Fig. 7). Thus, it would be expected that negative errors would be observed when the cells were charged for long periods of time. Results shown in Fig. 8 confirm this prediction. Again the use of low currents, 1  $\mu\text{a}$ , was helpful in stripping the more inactive silver.

No shorting was observed up to 850  $\mu\text{a-hr}$  of charge transferred to the gold, and photomicrographs of the sectioned pellet showed a fairly smooth silver deposit on the gold. The thickness (9.27 $\mu$ ) was about three times that calculated from the amount of silver present (2.6 $\mu$ ), indicating that the silver layer was mixed with AgBr electrolyte. However, when an attempt was made to strip the silver from the gold, shorting occurred after half of the silver had been transferred. A thickness determination of silver on the gold after shorting gave the same results as the beginning. This would indicate that silver nearer the gold was being stripped first, leaving needles extending into the silver bromide. Needles growing on the silver electrode during the stripping operation would finally touch and short the cell. Needle growth on the silver must be much more pronounced, since the ratio of distances was about 50:1. The shorting needles were so thin that they were not detected under the microscope.

The operating voltage during long periods of charge would shift from the  $iR$  drop value to the decomposition voltage of the electrolyte. The time at which

Note: Results represent average of 8-10 determinations.

this voltage shift occurred depended on the current, clamping pressure and previous history of the pellet, but was 1-2 hr at 20  $\mu\text{a}$  for a fresh pellet (Fig. 9). Voltage measurements taken with an oscilloscope immediately after current interruption showed that only part of the observed high charging voltage was due to iR drop. The remainder was polarization with a very fast decay (half of the decay occurred during the first 20 msec). Charge transferred under these conditions showed the same type of negative error observed before the shift, i.e., no discontinuity in accuracy was found at the voltage shift point.

**Reference electrode experiments.**—In an effort to explain the high operating voltage during charge and the existence of seemingly inactive silver after storage, pellets were prepared with a gold and two silver electrodes by cutting the silver layer. One silver electrode was operated in the usual manner while

Fig. 7. Charge hold results. (A) MC&B AgBr dried powder,  $\text{Br}_2$  purified, 0.03 cm thick, (B) MC&B AgBr,  $\text{Br}_2$  purified, 0.06 cm thick, (C) MC&B AgBr, 0.2%  $\text{CdBr}_2$ ,  $\text{Br}_2$  purified, (D) MC&B AgBr, 0.5%  $\text{CdBr}_2$ ,  $\text{Br}_2$  purified.

the smaller section was used as a reference electrode. The potentials of the working silver and gold electrodes vs. the silver reference were recorded during charge and strip cycles.

At low currents ( $< 5 \mu\text{a}$ ), the voltage rise at the end of stripping was due to an increasing potential at the gold electrode as expected. However, polarization at the silver electrode was pronounced at higher currents during charge and some polarization was observed during stripping. Current interruption during charge showed a rapid decay to zero volts, while during stripping, decay was considerably slower.

No polarization ( $< 10$ -20 mv) was observed at the gold electrode during charge. Potential changes at the gold electrode during stripping occurred near the end-point, but the rise began earlier if a charge hold period had been present. A very slow decay took place when the current was interrupted.

Unclamped cells exhibited much larger voltages after long periods of charge which were pressure dependent. All of the voltage was accounted for by increased iR drop (checked by a-c conductivity measurement) and polarization at the silver electrode.

## Discussion

Although the solid electrolyte coulometer operated essentially as the simple concept predicted, several characteristics were observed which did not fit this picture. These were especially significant in the high charge capacity and charge hold experiments.

There are four electrochemical reactions which take place during operation. These are silver plating and stripping at the silver electrode, and silver plating and stripping at the gold electrode. In addition to contact problems when the cells were not clamped, reference electrode experiments indicated severe polarization while stripping silver from the silver electrode. Some polarization was also observed during silver plating at the silver electrode. These results suggest that only a small fraction of the silver electrode was available for electrolysis, and thus, high current densities at these few active sites greatly magnified concentration polarization effects. The high current density at a few sites on silver also explains the needle growth during stripping which caused shorting.

Electrodeposited silver is active (12) and would be deposited at active electrolyte sites. Thus, at the gold electrode, silver could be plated and stripped with high efficiency, provided the cycle time was short. When the charging time was long, or if a charge hold time was present, migrations in the electrolyte and on the silver surface allowed some of the silver to become inactive. This would contribute to the low results observed. This same effect was observed in aqueous solutions (13-15). Stripping at very low currents at controlled potential would allow much of this

silver to be recovered. After a charge-discharge cycle, electrodeposited silver would be present at the silver electrode and polarization should be less. This was also observed.

Another effect could cause low results during stripping. When large charges were used, the silver plate might be thick enough to allow under-cutting. That is, silver would be oxidized close to the gold leaving silver metal in the electrolyte region not connected electrically to the gold electrode. This silver would be lost permanently, and not recovered by controlled potential electrolysis. Under-cutting appeared to be significant (> 5% lost) only when charges of > 50-100  $\mu\text{a-hr}$  were attempted.

### Conclusion

Commercial AgBr (MC&B) when pressed between silver and gold metal powders exhibits adequate conductivity at room temperature to be useful as a solid electrolyte for coulometers. This conductivity appears to be predominantly along grain boundaries, but the material is sufficiently passive to show no room temperature annealing effects, and in fact, can be used at temperatures up to 100°C.

Silver coulometers containing AgBr as a solid electrolyte can be used under carefully controlled conditions. These conditions include current densities of 4-40  $\mu\text{a/cm}^2$ , preconditioning of the gold electrode to the cut-off voltage, charge capacities of 400-10,000  $\mu\text{coul/cm}^2$ , and immediate read-out (i.e., < 1 hr charge hold). Under these conditions, coulometer error will

be < 1%. Less stringent conditions can be applied if accuracy requirements are less demanding.

Manuscript submitted Feb. 9, 1968, revised manuscript received April 15, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Membrane Potentials of Pyrex Glass Electrodes

R. H. Doremus

General Electric Research and Development Center, Schenectady, New York

### ABSTRACT

Potentials across Pyrex glass electrodes immersed in fused sodium-silver nitrates were measured. The membrane potential across the glass was small, so that the total cell potential was close to the electrode potential. The membrane potential showed a minimum at low silver concentration, which was attributed to the two-phase structure of the glass. These potentials were shown to be roughly consistent with the ion exchange theory for membrane potentials and measurements of ionic distribution and mobility in the Pyrex, although exact quantitative calculations of the potentials were not possible.

Several studies have been made of Pyrex borosilicate glass as a reference electrode for molten salts (1-6). However, in none of these papers was it made clear how much of the cell potential resulted from electrode potentials and how much from the glass. To test theories of the glass electrode potential it is important that the membrane potential of the glass itself be separately calculated and compared to the properties of the glass (7).

In the ion exchange theory the membrane potential of a glass electrode results from the exchange of ions between a solution and the glass (8, 9). This theory was found to be valid for a fused silica electrode in molten nitrates (7). In the present study membrane potentials across Pyrex glass electrodes immersed in fused sodium-silver nitrates were related to the ionic selectivity and mobility ratios in the glass.

Application of the equations for membrane potentials to Pyrex glass is complicated by phase separation in it. The presence of two phases in Pyrex has been deduced from electrical (10) and ion exchange measurements (11). Other borosilicate glasses show two phases in the electron microscope, but the scale of separation is too fine in Pyrex to be seen in this way. The membrane potential in Pyrex was apparently

influenced by the two phases present, and a completely satisfactory interpretation of the data was not possible.

### Equations for Glass Electrode Potentials

This section is based on a review article (9) which should be consulted for further details.

In the ion exchange theory the potential developed across a "fixed-charge" membrane with different solutions on either side of it can be separated into two portions, a phase boundary (Donnan or surface) potential and a diffusion potential. The surface potential arises because of differences in activities of ions between the solutions and the glass, while the diffusion potential results from differences in mobilities of different ions in the glass.

In most silicate glasses only monovalent cations can exchange and contribute to the membrane potential, so that present treatment is limited to these ions. The equilibrium distribution of A and B ions exchanging between solution and glass can be represented by the coefficient

$$K_{AB} = \frac{a'b''}{b'a''} \quad [1]$$

where  $a$  and  $b$  are the ionic activities in the solution (one prime) and the glass (two primes). The phase boundary potential depends on this selectivity coefficient, and the diffusion potential is determined by the ratio of mobilities  $u_B/u_A$  of the two ions in the glass. If a glass membrane separates two solutions 1 and 2 containing different ions A and B, the total membrane potential  $V_M$  in the case of constant activity coefficients and mobility ratio in the glass is (8, 9)

$$V_M = \frac{RT}{F} \ln \frac{a_1' + K_{AB}(u_B/u_A)b_1'}{a_2' + K_{AB}(u_B/u_A)b_2'} \quad [3]$$

where  $R$  is the gas constant,  $T$  the temperature, and  $F$  the Faraday. If the mobility ratio and activity coefficients of the ions in the glass are functions of concentration, the equations for the potential cannot be integrated without knowledge of the functionality. Even in this case the membrane potential is constant with time as soon as equilibrium between the solutions and glass surfaces is established and does not depend on the concentration profile of diffusing ions.

### Experimental Methods

Tubes of Pyrex glass of outside diameter 1.28 cm and wall thickness 0.11 cm were annealed at about 550°C and cooled slowly (1–2°/min) to room temperature. The composition of this glass was about 81% SiO<sub>2</sub>, 13% B<sub>2</sub>O<sub>3</sub>, 4% Na<sub>2</sub>O, 2% alumina, and small amounts of minor constituents. The Na<sub>2</sub>O concentration was found to be 4.22% with the flame photometer. The density of the glass at room temperature was 2.2 g/cm<sup>3</sup>.

The electrical potential across the glass was measured with the cell described previously (7, 9). An inner Pyrex tube contained pure molten silver nitrate, while the outer bath contained mixed silver-sodium nitrate in a fused silica cup. The composition of this solution was determined by weighing the salts as they were successively added to the outer melt. The electrodes were thin silver wires wound on fine silica tubes. Cell potentials were measured with a Keithley 610 B electrometer, or with a Rubicon potentiometer with the electrometer as a null indicator when more accuracy was desired. Cell potentials for a particular tube were reproducible to about ±1 mv. Temperatures were measured with a platinum: platinum-rhodium thermocouple immersed in the melt.

### Experimental Results and Discussion

To calculate the electrode potentials of the silver-silver nitrate electrodes, and thus to determine the membrane potentials of the glass from the total measured cell potentials, it was necessary to know the thermodynamic activities of the ions in the silver-sodium nitrate melts. Several investigators have measured the activity of silver ion in these melts (12–15); in ref. (12), (13) and (15) the following equation is given for the activity coefficient  $\gamma_{Ag}$  of this ion

$$\ln \gamma_{Ag} = \frac{840}{RT} X_{Na}^2 \quad [4]$$

where  $X_{Na}$  is the mole fraction of sodium nitrate in the melt. This result assumes negligible diffusion potentials in the cells with transference used to measure the electrode potentials. A very small diffusion potential was reported in ref. (15), using cells with and without transference. Application of the Gibbs-Duhem relation to Eq. [4] gives the following equation for the sodium ion activity coefficient

$$\ln \gamma_{Na} = \frac{840}{RT} X_{Ag}^2 \quad [5]$$

A somewhat lower value than 840 was found in ref. (14), and also in this reference and ref. (13) there is some evidence that Eq. [4] and [5] (implying a regular solution) do not apply over the whole concentra-

tion range. These small uncertainties do not affect the conclusions found here, except as noted below.

The total cell potentials measured for two different Pyrex tubes in various silver-sodium nitrate mixtures are given in Fig. 1. The electrode potentials  $V_e$  were calculated from the usual equation

$$V_e = \frac{RT}{F} \ln \frac{b_2}{b_1} \quad [6]$$

where the  $b$ 's are the thermodynamic activities of the silver ions in the two solutions, calculated from Eq. [4]. Since one solution was pure silver nitrate, it was taken as the standard state and considered positive, so that  $b_2 = 1$ . The calculated electrode potential as a function of ionic concentration is also shown in Fig. 1. The membrane potential  $V_m$  is the difference between the measured cell potential and the electrode potential and is plotted in Fig. 2.

If the activity data of Liquornik and Marcus (14) are used, the calculated electrode potential is up to 4

Fig. 1. Total measured cell potential at 340°C for two different Pyrex glass tubes containing pure silver nitrate and immersed in different silver-sodium nitrate solutions. Line, electrode potential calculated from Eq. [6].

Fig. 2. Membrane potential of two Pyrex glass tubes containing pure silver nitrate and immersed in different silver-sodium nitrate solutions.

or 5 mv higher. While this is not a large fraction of the total potential, it does shift the membrane potentials at the lower silver concentrations to values 4 or 5 mv more negative, with progressively smaller shifts for higher silver concentrations. The general shape of the curve is not changed.

The membrane potentials shown in Fig. 2 are small, being only a few millivolts over the entire concentration range studied. This result is particularly striking at low silver concentrations, where the total measured potentials were larger than 200 mv. This small membrane potential implies that the product  $K_{\text{NaAg}}(u_{\text{Ag}}/u_{\text{Na}}) = p$  is close to one, if the melt is not too far from ideal thermodynamically. The value of  $p$  can also be estimated from the measured cell potential  $V$ , which is the sum of the electrode potentials  $V_e$  and the membrane potential  $V_M$ . From Eq. [3] and [6]

$$V = V_e + V_M = \frac{RT}{F} \left\{ \ln \frac{a_1 + pb_1}{a_2 + pb_2} + \ln \frac{b_2}{b_1} \right\} \quad [7]$$

or

$$\exp \frac{VF}{RT} = \frac{(a_1/b_1) + p}{(a_2/b_2) + p} \quad [8]$$

If the activities in solution 2 are held constant, a plot of  $\exp VF/RT$  against  $a_1/b_1$  should be a straight line. A plot of this kind for some of the present data is shown in Fig. 3. Since  $b_2 = 1$  and  $a_2$  is small, the slope of the line in Fig. 3 should equal to  $1/p$ , and the intercept unity. From the data in Fig. 3,  $p$  is about one.

However, the functional dependence of potential on melt concentration, shown in Fig. 2, does not fit Eq. [3] very well. This is because the plot of membrane potential in Fig. 2 is more sensitive to deviations from Eq. [3] than is the plot of total cell potential in Fig. 3, particularly for small membrane potentials. The minimum in the potential curve shown in Fig. 2 is not much beyond the experimental error, but it is believed to be real, since it was reproducible and was found on several different samples.

The equilibrium distribution of sodium and silver ions between nitrate melts and Pyrex was measured and reported elsewhere (11). The  $K_{\text{NaAg}}$  values of Eq. [1] calculated from these results are shown in Table I, using concentrations in the glass in place of activities. The resulting variation in  $K_{\text{NaAg}}$  at low silver concentrations shows that the glass was not ideal with respect to these ions, so that the concentrations are not equivalent to activities, particularly at lower silver concentrations. In ref. (11) this behavior was related to the two-phase nature of Pyrex glass, and it was shown that a simple model of two ideal phases

Fig. 3. Exponential of the measured cell potential as a function of melt activity ratio for a Pyrex tube containing silver nitrate and immersed in different silver-sodium nitrate melts.

Table I. Exchange of silver ions in a sodium nitrate melt with Pyrex glass

Mole fraction of silver nitrate in melt	Exchange coefficient, $K$
0.398	1.97
0.310	1.87
0.153	1.98
0.0475	2.05
0.0022	7.06
$3(10)^{-3}$	12.2

gives reasonable agreement with the data in Table I. In this model one phase is primarily sodium borosilicate, and contains 95% of the sodium ions in the unexchanged glass, while the second phase is high in silica and retains the rest of the sodium. It is the strong attraction of this silica phase for the silver ions that causes the change in  $K$  at lower silver concentrations.

The glass can be treated as a single nonideal phase; then the deviations shown in Table I are absorbed in activity coefficients of the ions in the glass. In this way a  $K'_{\text{NaAg}}$  that is constant and can be used in the equations for the membrane potential was found to equal 1.8 for the data in Table I (11). It was also found that the mobility ratio  $u_{\text{Ag}}/u_{\text{Na}}$  is about one in Pyrex when the mole fraction of silver in the glass is above about 0.2, and decreases for lower concentrations (16). Thus  $K'_{\text{NaAg}}(u_{\text{Ag}}/u_{\text{Na}})$  is not far from one at higher silver concentrations, in qualitative agreement with the values of  $p$  found above. It seems likely that the unusual dependence of the membrane potential on silver concentration shown in Fig. 2, as well as the difference between  $p$  and  $K'_{\text{NaAg}}(u_{\text{Ag}}/u_{\text{Na}})$ , are related to the two-phase nature of the Pyrex glass, but it was not possible to relate this dependence to the measured  $K'_{\text{NaAg}}$  and  $u_{\text{Ag}}/u_{\text{Na}}$  values in any simple way.

The temperature dependence for the total cell potential at different silver concentrations is shown in Fig. 4. The potential is proportional to  $RT/F$ , indicating that there is no large change in  $K'_{\text{NaAg}}$  or  $u_{\text{Ag}}/u_{\text{Na}}$  with temperature.

The low membrane potentials found suggest that the total potential of a cell with a Pyrex membrane immersed in a fused nitrate using silver-silver nitrate electrodes should follow Eq. [6] fairly well,

Fig. 4. Total measured cell potential for Pyrex glass tubes containing silver nitrate and immersed in silver-sodium nitrate solutions, as a function of temperature. The mole fraction of silver nitrate in the melt is noted on the graph.

especially at low silver concentrations. This agrees with the results of ref. (3) and (6).

In ref. (5) the cell

was studied. The two end solutions were ternary eutectics containing sodium, lithium, and potassium nitrates. For silver concentrations up to 12 mole % in the center compartment, a modification of Eq. [8] was obeyed, using concentrations instead of activities. A selectivity ratio of 0.32 was found for sodium and silver ions. However, this value is not directly comparable with the present  $p = 1$ , since the activities of sodium and silver ions may be quite different in ammonium nitrate than in mixed silver-sodium nitrate.

In further work these authors measured the potentials of cells similar to the present ones, using an equimolar sodium-silver nitrate melt inside the Pyrex tube (6). A plot of  $\exp(VF/RT)$  against  $a_1/b_1$ , using the authors' activity data, was close to a straight line, but showed some definite curvature. A value of about 0.8 for  $p$  was found. However, a plot of the membrane potential  $V_M$ , calculated from these data, as a function of melt composition shows deviations from expected behavior similar to those shown in Fig. 2, confirming the present results.

## Technical Notes

### Breakaway Oxidation Transition for a Zirconium-2.7 w/o Niobium Alloy

M. G. Cowgill,<sup>1</sup> S. H. Wong,<sup>2</sup> and W. W. Smeltzer\*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

The oxidation rates and the properties of the oxide films formed on a Zr-2.7 w/o Nb alloy in the temperature range 300°-500°C were shown to be dependent on the phases introduced into the metal by vacuum annealing and quenching from temperatures corresponding to the  $\beta$ -solid solution and the  $\alpha + \beta$  phase regions of the binary phase diagram (1,2). Martensitic specimens oxidized more rapidly than Widmanstätten alloys, the oxidation rate continually decreasing by formation of a protective film until a transition range was attained in which the rate subsequently increased to a maximum value associated with linear kinetics. The objective of the experiments reported here was to determine if  $\alpha$  and  $\beta$ -Zr could be distributed in the alloy by diffusion processes to influence the reaction kinetics within brief exposure periods at high temperatures in the range 870°-1000°C. It is demonstrated that this objective is feasible because, first, the solubilities of oxygen in the alloy phases differ by large factors, and second, the temperature coefficient for oxygen diffusion in  $\alpha$ -Zr is of a relatively high value.

The alloy was received as 2 mm thick sheet. Analyses for impurities, the oxygen content being 1100 ppm

maximum, and the method of specimen preparation by metallographic polishing have been reported (1). Specimens  $2 \times 2 \times 0.1$  cm were oxidized in oxygen at 400 mm Hg pressure in a volumetric apparatus (3). Once a specimen was in place, the assembly was evacuated at  $10^{-6}$  mm Hg for 4 hr at room temperature and the furnace at the reaction temperature then positioned about the reaction tube. After 15 min, oxygen was admitted to react with the specimen and its uptake was determined by means of the gas buret. The specimen after reaction was then rapidly cooled to room temperature by removing the furnace from the reaction tube. Oxidized specimen surfaces were examined by x-rays using a recording diffractometer and nickel-filtered copper radiation.

Results from the oxidation tests at 870°, 900°, 912°, 950°, and 990°C for exposures up to 170 min are presented in Fig. 1. At all temperatures, the curves were initially parabolic. At and below 912°, this type of oxidation for exposures up to 60 min was followed by a breakaway transition leading to more rapid reaction kinetics. Parabolic oxidation was obeyed up to the longest time observed at 950° and 990°. Those specimens oxidized at the three lower temperatures were characterized by a network of white on black oxide or white oxide while those specimens oxidized at 950° and 990° were black with white oxide only

occurring along the edges, Fig. 2. A reflection at 2.94-2.95Å in addition to those for monoclinic zirconia was observed in the oxide x-ray diffraction pattern which could be indexed as a tetragonal oxide, an allotropic modification of zirconia or the mixed oxide  $6\text{ZrO}_2 \cdot \text{Nb}_2\text{O}_5$  (2).

Oxidation was associated with scale formation and oxygen solution in the metal. As illustrated in Fig. 3, specimens oxidized at 870° and 912° exhibited after transition from parabolic kinetics uneven oxide growths with many cracks present in the scale. In agreement with the findings of Richter *et al.* (4), a residual oxygen content of 1000 ppm in the alloy was sufficient to stabilize the  $\alpha$  and  $\beta$  phases at the temperature of 870°. The former phase in the specimen exposed at 900° appeared to form beneath the scale by oxygen diffusion at the reaction temperature. The photomicrograph of Fig. 4 illustrated the alloy microstructure developed beneath the oxide scale at these lower temperatures in greater detail.  $\beta$ -Zr was present over areas of the metal surface despite the precipitation of  $\alpha$ -Zr in the alloy matrix.

The reaction at 950° and 990° proceeded by parabolic kinetics without a breakaway transition as at the lower temperatures. Under these conditions, the scales formed on specimens were of relatively even thicknesses and of a compact structure, Fig. 5. An alloy microstructure at these temperatures was characterized by distinct layers of oxygen stabilized  $\alpha$ -Zr plates extending inwards from the metal surface into the  $\beta$ -Zr matrix.

These results are consistent with the reasoning that the different oxidation characteristics and alloy microstructures found at the extreme temperatures in the

Fig. 2. Topographies of specimens oxidized for 170 min at 870°, 912°, and 990°C (left to right) (Magnification ca. 1.4X).

Fig. 3. Cross sections of specimens oxidized at 870°C for 170 min (top micrograph, 250X) and 900°C (bottom micrograph, 80X). White and dark phases in alloy represents  $\alpha$ -Zr and  $\beta$ -Zr, respectively.

Fig. 4. Alloy microstructure beneath oxide scale in specimen oxidized at 870°C (400X).

range 870°-990° were dependent on the oxygen solubilities and the rates for oxygen diffusion in the alloy phases. The solubility of oxygen in  $\beta$ -Zr is very low at 870° increasing to only 0.3 w/o at 1000° based on figures for unalloyed zirconium (5). Most of the oxygen entering the alloy therefore stabilizes and dissolves in

Fig. 5. Cross sections of specimens oxidized for 170 min at 950°C (top micrograph) and 990°C (bottom micrograph) (160X).

$\alpha$ -Zr, the solubility limit in this case being much larger and of the order of 7 w/o. Thus the alloy beneath the scale became a mixture of oxygen stabilized  $\alpha$  and  $\beta$ -Zr. The former phase has a low solubility for niobium, the maximum being about 1 w/o at the eutectic temperature of 610°C. Consequently, as  $\alpha$ -Zr is formed niobium segregates into the  $\beta$ -Zr matrix. The microstructure of the alloy at the metal/oxide interface then becomes dependent on the relative rates for diffusion of oxygen in  $\alpha$ -Zr and inward migration of the external scale.

The inward migration rates of the external scale at temperatures less than 912° were sufficiently rapid for  $\beta$ -Zr over relatively large areas surrounding the  $\alpha$ -Zr precipitates to remain in contact with a scale, its rapid oxidation leading to the breakaway oxidation transition (Fig. 4). On the other hand, oxygen diffusion becomes much more rapid at higher temperatures. The activation energies for oxygen diffusion in  $\alpha$ -Zr and the oxide scale formed on this metal phase are 52 and 29 kcal/g atom, respectively (7,8). Consequently, sufficient oxygen diffused into the alloy at temperatures higher than 950°C for stabilization of the distinct columnar layers of  $\alpha$ -Zr plates beneath the oxide scales,  $\beta$ -Zr being concentrated in narrow regions between these plates (Fig. 5). These regions, which would be enriched by segregated niobium if rapid boundary diffusion of metal did not occur, appeared to be of insufficient area for their oxidation to lead to a transition from parabolic kinetics. Accordingly, diffusion processes occurring during the breakaway oxidation transition of this alloy may be studied by investigating oxidation behavior for relatively brief exposures at high temperatures. It is also possible that quenched  $\beta$ -Zr specimens with a layer of  $\alpha$ -Zr plates formed in the alloy at and beneath its surface by oxygen solution may oxidize at slow rates for long exposures typical of Widmanstatten structures in the temperature range 300° - 500°C (1).

## Nucleating Ability of Grain Boundaries During Electrodeposition

T. Kilner<sup>1</sup> and A. Plumtree

Materials Science Laboratory, Department of Mechanical Engineering,  
University of Waterloo, Waterloo, Ontario, Canada

When crystallization occurs by the addition of successive layers of atoms, as in the electrodeposition of metals, the rate-controlling mechanism is the formation of nuclei for each new layer. If, however, sites are already present, growth may occur almost as fast as the atoms (or ions) arrive at the surface. The ideal condition for continuous and rapid growth of crystals

<sup>1</sup> Present address: Ontario Research Foundation, Sheridan Park, Ontario, Canada.

is that the growing faces shall always contain a self-perpetuating step or groove. Nucleation occurs readily in the step at the center-line of the groove, and atom layers then spread rapidly over the entire faces of the groove (1,2). A re-entrant groove is formed by the intersection of a twinned boundary with the growing interface (3). The presence of two or more twin boundaries in materials possessing face-centered or diamond-centered structures can produce a self-per-

petuating system of re-entrant grooves. For silver, therefore, it is not surprising that multiple twin boundaries have been observed in dendrites grown from fused salt electrolytes (4-7) and aqueous electrolytes (8-11).

Little is known, however, about the nucleating ability of a re-entrant groove formed by the intersection of the interface with high angle grain boundaries and also with annealing twins as opposed to growth twins. It is the purpose of this note to report the investigations made during the very early stages of electrodeposition of silver from an aqueous solution on a substrate containing both high angle grain boundaries and annealing twins.

Both cathode and anode were prepared from cold worked 99.98% silver. Sheet silver 0.010 in. thick cut in the form of a washer was used for the anode, whereas the cathodes were prepared from approximately 2 mm cubes annealed for one week at 900°C. By this means large grained cathode samples were produced, each containing approximately 10 grains/sample and numerous annealing twins. After silver soldering to copper wire for electrical connection, each cathode was mounted in a cold setting resin. The samples were then ground, mechanically polished down to 1/4 $\mu$  diamond paste, chemically polished using the solution of Gilpin and Worzala (12), and then etched to produce grain boundary grooves using the solution of Kilner and Plumtree (13). These silver cathodes were placed in a specially constructed cell, 2 cm deep by 3 cm in diameter, designed to fit under the objective lens of a Zeiss photomicroscope. A transparent Plexiglas lens shield was used to keep the solution (1M AgNO<sub>3</sub> + 2M NH<sub>4</sub>NO<sub>3</sub>) from touching the lens. By this arrangement, the objective lens could be immersed in the electrolyte to prevent the free surface from affecting image quality. The silver anode was made in the shape of a washer so that it would fit on the lens shield and allow photomicrographs to be taken of the cathode through the central hole.

Electrodeposition took place at room temperature using cell voltages ranging from 10 to 200 mv and currents from 0.1 to 25 ma. Current densities varied from approximately 0.001 to 2.5 amp/cm<sup>2</sup>. The solution was not stirred mechanically. Photomicrographs of the cathode were taken during the early stages of electrodeposition. Figure 1a and 1b show the freshly electrodeposited crystals as black spots on two different twinned substrates after 60 sec using a cell potential of 25 mv, current of 0.1 ma, and current density of 1 ma/cm<sup>2</sup>. Figures 1a and 1b indicate that preferential nucleation of silver crystals can occur at the high angle and twin boundaries. In the upper left section of each photograph which corresponds to the outer region of the cathode where the current density was higher due to anode shape, nucleation within the grains is quite noticeable. In this case, it is interesting to note that some crystal faces appear to be more receptive to nucleation than others. By comparing the number of new crystals along the random high angle grain boundaries, to those along twin boundaries, it becomes evident that the high angle grain boundaries offer better nucleation sites. This effect may be explained by the etchant producing a more pronounced groove and hence better nucleation site at these higher energy boundaries.

# The Analysis and Solubility of Cuprous Chloride in Hydrochloric Acid Solutions

John J. O'Connor, Anahid Thomasian, and Alton F. Armington

Air Force Cambridge Research Laboratories, Office of Aerospace Research,  
L. G. Hanscom Field, Bedford, Massachusetts

In a study on the crystal growth of CuCl (1), it has become necessary to determine the concentration of this material in the presence of HCl. Since the presence of the cuprous ion will interfere with the hydrogen ion determination, a method was devised in which both ions could be rapidly determined without interference.

## Analytical Procedure

In this procedure, the solution to be analyzed is diluted in a 250-ml beaker to about 40 ml. Oxygen is bubbled into the solution to convert the cuprous ion to cupric ion. The bubbling is continued for about 5 min after all the cuprous chloride precipitated by the dilution has dissolved and the solution has turned blue. After oxidation, the solution is titrated with 0.1F NaOH to an endpoint (measured by a pH meter) in the 4.5-4.8 pH range. After the titration, 3 additional ml of the NaOH solution is added, followed by 7 ml of 6F acetic acid, lowering the pH to about 2.5-3.0. Three grams of KI are added to the solution and the liberated  $I_3^-$  ion is titrated with 0.1F  $Na_2S_2O_3$ , using a starch indicator. Since, in the presence of oxygen, CuCl in HCl undergoes the following reaction

the number of millimoles of CuCl found must be added to the number of millimoles found in the NaOH titration in order to arrive at the true value of the hydrogen ion concentration. Reproducibility of duplicate samples was within 1%.

Several methods have been used to test the accuracy of the procedure. First, known amounts of CuCl and HCl were mixed in closed containers and analyses for hydrogen ion were made on the resulting solutions (Table I). No apparent trend can be found between the error and the concentrations used. Second, as there is no observable endpoint for the oxidation step, the solution must be oxygenated for sufficient time to ensure complete oxidation. Since HCl could conceivably be vaporized during this step, tests were made to determine if extensive treatment would cause any loss in hydrogen ion concentration. No loss in HCl could be detected even when oxygen was bubbled through the solution for 20 min after the appearance of the blue color. Finally, samples were analyzed for copper using both a standard technique and the technique described here. In the standard method, CuCl was oxidized with ferric ammonium sulfate and the resulting ferrous ion was titrated with standard potassium permanganate (2). Comparative results agreed within 1%.

Certain precautions are necessary when employing this procedure. First, sufficient time must be allowed during the oxygen addition to be certain that all cuprous ion is converted to cupric ion since only the cupric ion will react with KI to produce the  $I_3^-$  ion against which the thiosulfate is titrated. Since this method actually measures total copper, the presence of cupric ion will give erroneous results both for cuprous ion and hydrogen ion concentrations. Experiments have shown, however, that if the solution is colorless or only light yellow in color, the amount of cupric ion present will not cause a detectable

Table I. Comparison of calculated and experimental results from hydrogen ion concentration

	Calculated millimoles HCl/ml	Experimental millimoles HCl/ml
1.	0.953	0.954
2.	1.934	1.927
3.	2.771	2.799
4.	3.730	3.704
5.	4.663	4.607
6.	5.331	5.377
7.	6.375	6.426

error. Finally, care must be taken not to titrate beyond a pH of 4.5-4.8 during the hydrogen ion determination since beyond this point the formation of cupric hydroxide will interfere with the titration.

## Solubility of CuCl in HCl Solutions

Since the degree of saturation is important in a crystal growth study, a solubility curve was determined using the procedure outlined. A stock solution of 6F HCl saturated with CuCl was prepared at 30°C and cooled to room temperature (22°C). The test solutions were then prepared by diluting the stock solution to the desired formality. In all cases excess CuCl precipitated out. The solutions were held in closed vials containing copper turnings for three days with intermittent shaking. After allowing a day for the precipitate to settle to the bottom, samples of the supernatant were pipetted out for analyses.

The solubility of CuCl as a function of HCl formality is shown in Fig. 1. Since the method described here is not affected by the oxidation of the cuprous ion, the authors believe it to be more reliable than the previously published data (3) where the oxidation of the cuprous ion may have resulted in higher values for the solubility of CuCl. This could effect the determination in two ways. First, if the analyses were based on total copper, the amount of copper present as  $CuCl_2$  would be included. Second, the solubility of CuCl is increased when  $CuCl_2$  is present

Fig. 1. Solubility of CuCl as a function of HCl concentration in water at 22°C. Moles in diagram are moles/liter.

Key words: Cuprous chloride, chemical complex, solubility analysis.

(4). This would increase the saturation value for CuCl.

## Conductivity Cell for Use with Dense Gaseous Electrolytes

S. Naiditch, R. A. Williams, and K. P. Luke

*Unified Science Associates, Inc., Pasadena, California*

The principal problem in the measurement of conductivities of supercritical electrolytes is that of containing the electrolyte at the high temperatures and pressures involved. One approach is to use a cell with sufficient strength to withstand these conditions. This generally involves a massive steel cell having electrical insulators and a chemically inert lining to avoid reaction with the electrolyte (1). In our studies of supercritical electrolytes having ammonia ( $\text{NH}_3$ ) as the solvent, we have used a glass conductivity cell and avoided rupture of the cell by matching the internal pressure of the electrolyte with an external pressure. The critical properties of ammonia (132.9°C, 112 atm) are convenient for this method, while the use of glass simplifies the handling of ammonia and leads to a cleaner system than could be easily obtained with a metal cell.

In order to apply the required external pressure the cell must be placed in a high-pressure vessel and hence must be compatible with the interior dimensions of this vessel. In the present case the high-pressure chamber was 38 mm in diameter. The spatial restrictions made the use of a d-c conductivity measurement attractive, as difficulties due to high interelectrode capacitance would then be avoided. D-C measurements are best carried out using the four probe method (2) in which two electrodes produce a current through the electrolyte while two additional electrodes, positioned between the current carrying electrodes, are used to measure the voltage gradient set up in the electrolyte. The voltage measuring electrodes should be reversible in the electrolyte being investigated and no current should be drawn through them when the voltage is measured.

The cell is shown in Fig. 1. It is divided into four electrode compartments joined by the central cylindrical section, hereafter called the conductivity tube. The two extreme electrodes (1 and 4) are used to carry the current, which flows through the conductivity tube. The intermediate electrodes (2 and 3) measure the voltage across the middle section of the conductivity tube. This potential difference is measured through a pair of narrow slit apertures perpendicular to and encompassing the whole circumference of the conductivity tube.

The end portions of the conductivity tube serve to reduce end effects and to allow the current density to become constant and uniform through the middle section. The use of slits rather than holes for the measuring electrode serves to average out any non-uniformities still existing, as well as being much narrower for the same area. The cell constant is therefore geometrically well defined and can be taken as equal to  $K = 4L/(\pi d^2)$  where  $L$  is the separation of the measuring slits and  $d$  is the internal diameter of the tube.

Key words: Conductivity cell, dense gaseous electrolytes, supercritical electrolytes, ammonia.

The electrode leads are brought into the cell through tungsten-uranium glass seals. The electrode compartments are suitable for containing amalgam electrodes of the sort sometimes used in ammonia (3), in which case the tip of the tungsten feedthrough is left bare and completely immersed in the amalgam. If solid metal electrodes are to be used, platinum wire is fused to the tungsten. All of the tungsten and part of the platinum are covered with glass. The exposed platinum is then welded to the electrode material.

The freeze cup was used in the sealing-off operation after filling the cell with ammonia. The ammonia was condensed in the cell and held there with the cell at  $-78^\circ\text{C}$  in a dry ice, alcohol bath. Liquid nitrogen was poured into the freeze cup causing a plug of solid ammonia to form in the capillary. The system above this plug was then pumped to a high vacuum and the cell sealed off by fusion of the capillary above the freeze cup. This procedure allows the seal off to be made under high vacuum, reducing the impurities trapped in the cell. Its usefulness depends on the properties of the solvent being used.

The main problem in fabrication was making the conductivity tube, which must be sealed through the walls separating the electrode compartments without changing its internal dimensions. This was accomplished by collapsing a piece of ordinary glass tubing over a drill rod of the desired diameter by heating the tubing while maintaining a partial vacuum inside it. With the tube hot and the drill rod still inside, glass flanges were built up on the tube at the desired locations. These flanges were then sealed to the outer tubing and became the walls between the electrode

Table I. Effect of slit width on cell constant

Cell	d, cm	L, cm	W, cm	K, mhos/cm	K <sub>Hg</sub> , mhos/cm	K <sub>KCl</sub> , mhos/cm
A	0.4727	4.720	0.416	26.90	27.69	27.35
B	0.4747	4.774	0.041	26.98	26.94	25.56
C	0.4762	4.761	0.012	26.73	26.66	26.03

compartments. The different sections of the conductivity tube were held in alignment during cell fabrication by a carbon rod. When made in this way, the conductivity tube had a constant diameter over its whole length and could be made with very narrow voltage measuring slits.

The choice of slit widths is governed by the desired accuracy of the cell constant, the maximum allowable resistance between the measuring electrodes, and the requirement that good diffusion exist between the various parts of the cell. In order to examine the effect of slit width on the cell constant, three cells with different slit widths, *W* were built and the cell constants determined both geometrically and by measuring the cell resistance with known materials, namely, mercury and 1*N* KCl solution. Results are shown in Table I.

It is apparent that the slits in cell A, which are of about the same width as the diameter of the conductivity tube, are too wide for the geometrical cell constant to be meaningful. With cells B and C, however, the agreement between calculated and observed cell constants is good, particularly in the case of mercury. It should be noted that no special precautions were taken in the preparation of the KCl solution, ordinary reagent grade KCl and commercially bottled distilled water being the ingredients used. The conductivity of mercury is much less sensitive to the precautions taken than KCl solutions, and the values of the cell constant with mercury are therefore considered much more accurate. The tests indicate that for conductivity tubes whose length is much greater than their diameter, the use of voltage measuring slits of width 10% of the conductivity tube diameter or less will give a cell constant which can be easily calculated to better than ½%.

The cell has been used for conductivity measurements of solutions of AgNO<sub>3</sub> in NH<sub>3</sub> at temperatures well above the critical point of NH<sub>3</sub>. Figure 2 shows the voltage drop measured across the conductivity tube as a function of the cell current obtained with a supercritical AgNO<sub>3</sub>-NH<sub>3</sub> solution and using electrodes of high purity silver wire throughout. The linearity of the graph indicates that the cell is well behaved.

Fig. 2. Voltage drop across conductivity tube vs. cell current. Electrolyte is AgNO<sub>3</sub> at 0.02 moles/liter in dense gaseous NH<sub>3</sub> at 22 moles/liter and 151°C. Positive current flows upward.

The small emf (~ 1 mv) between the voltage probes may be due to surface impurities on the electrodes or to a small difference in the compositions of the electrolytes in the two electrode compartments. The cell used had 0.1 cm slits and a cell constant of 24 cm<sup>-1</sup>. Conductivity cells suitable for d-c measurements with dense gaseous electrolytes can thus be fabricated with the desired, geometrically defined cell constant.

## Limitation of the Use of CaF<sub>2</sub> in Galvanic Cells for Thermodynamic Measurements due to the Onset of Electronic Conduction under Reducing Conditions

Carl Wagner\*

Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

During the last ten years, galvanic cells involving solid electrolytes have been used with considerable success in order to obtain Gibbs energy data at elevated temperatures from measured emf values (1-3). Under highly reducing conditions an appreciable contribution of n-type electronic conduction in addition to ionic conduction may occur. Then the usual evaluation becomes invalid (4, 5) as has been discussed especially for ZrO<sub>2</sub>(+CaO) as solid electrolyte (6-8).

\* Electrochemical Society Active Member.

Also CaF<sub>2</sub> has been found to be a suitable solid electrolyte (9-13). For instance, the Gibbs energy change of the reaction Th + 2C = ThC<sub>2</sub> has been obtained from the emf of the cell (10)

The following calculation is made in order to find out under which conditions the onset of electronic con-

duction in  $\text{CaF}_2$  interferes with a straightforward thermodynamic evaluation of emf values.

According to Ure (14) pure  $\text{CaF}_2$  involves virtually equal concentrations of interstitial anions and anion vacancies. On exposure of  $\text{CaF}_2$  to Ca vapor, an excess of calcium is dissolved (15-18). As an analogue to the uptake of excess metal by alkali halides, one may formulate the chemical equation

where in accord with Kröger's notation (19)  $\text{F}_F^\times$  is a fluoride ion on a regular anion site and  $e_{F^\times}$  is an electron substituted for an anion also known as a color center (= F center). This interpretation of the structure of a color center is in accord with electron spin resonance investigations (20). Applying the law of mass action to the reaction in Eq. [1] it follows that the number of color centers per cubic centimeter,  $n_{e_{F^\times}}$ , is proportional to the square root of the partial pressure  $p_{\text{Ca}}$  of calcium, or the activity  $a_{\text{Ca}}$

$$n_{e_{F^\times}} \sim p_{\text{Ca}}^{1/2} \sim a_{\text{Ca}}^{1/2} \quad [2]$$

In addition to electrons trapped on anion sites, there is a small fraction of mobile excess electrons  $e'$  formed by the reaction

where  $V_F$  is an anion vacancy. The equilibrium condition is

$$\frac{n_{V_F} \cdot n_{e'}}{n_{e_{F^\times}}} = K \quad [4]$$

When an electrical field is applied, fluoride ions migrate as interstitials and via vacancies toward the anode. Likewise electrons migrate toward the anode. Thus the boundary between a colorless zone of virtually pure  $\text{CaF}_2$  and a colored zone of  $\text{CaF}_2$  involving an excess of calcium moves toward the anode at a velocity proportional to the electrical field strength. Observations may be evaluated in terms of the apparent mobility (16)  $u_{e_{F^\times}}$  of the color centers, which is related to the mobility  $u_{e'}$  of excess electrons by

$$n_{e_{F^\times}} \cdot u_{e_{F^\times}} = n_{e'} \cdot u_{e'} \quad [5]$$

In view of Eq. [3] to [5], the partial electronic conductivity  $\sigma_e$  of  $\text{CaF}_2$  with excess calcium may be written as

$$\sigma_e = n_{e'} \cdot u_{e'} \cdot e = n_{e_{F^\times}} \cdot u_{e_{F^\times}} \cdot e = n_{e_{F^\times}}^\circ \cdot u_{e_{F^\times}} \cdot e \cdot a_{\text{Ca}}^{1/2} \quad [6]$$

where  $e$  is the electronic charge and  $n_{e_{F^\times}}^\circ$  is the number of electrons substituted for fluoride ions per  $\text{cm}^3$  at  $a_{\text{Ca}} = 1$  corresponding to saturated calcium vapor. Thus the transference number  $t_e$  of electrons is found to be

$$t_e = \frac{\sigma_e}{\sigma_{\text{ion}} + \sigma_e} \cong \frac{\sigma_e}{\sigma_{\text{ion}}} = \frac{n_{e_{F^\times}}^\circ \cdot u_{e_{F^\times}} \cdot e}{\sigma_{\text{ion}}} a_{\text{Ca}}^{1/2} \quad \text{if } \sigma_e \ll \sigma_{\text{ion}} \quad [7]$$

where  $\sigma_{\text{ion}}$  is the ionic conductivity of pure  $\text{CaF}_2$ .

From Eq. [7] one may readily calculate values of  $a_{\text{Ca}}$  at which  $t_e$  is sufficiently low for neglect of electronic conduction in the thermodynamic evaluation of emf values, see Table I.

For the evaluation of Eq. [7], values of  $n_{e_{F^\times}}^\circ$  have been taken from Mollwo's paper (16). If, in view of results obtained by Lichter and Bredig (18) between 1060° and 1265°C a lower value of  $n_{e_{F^\times}}^\circ$  at 840°C is used in Eq. [7], higher values of  $a_{\text{Ca}}$  for  $t_e = 10^{-2}$  and  $10^{-3}$  are obtained. Thus values of  $a_{\text{Ca}}$  listed in Table I are to be considered as lower limiting values for the onset of electronic conduction.

As an example consider cell I where  $a_{\text{Ca}}$  on the left-hand side is determined by the virtual equilibrium

Table I. Calcium activities  $a_{\text{Ca}}$  for  $t_e = 10^{-2}$  and  $t_e = 10^{-3}$

Temp, °C	$n_{e_{F^\times}}^\circ$ (16) cm <sup>-3</sup>	$u_{e_{F^\times}}^\times$ (16)	$\sigma_{\text{ion}}$ (14) ohm <sup>-1</sup> cm <sup>-1</sup>	$a_{\text{Ca}}$ for $t_e = 10^{-2}$	$a_{\text{Ca}}$ for $t_e = 10^{-3}$
		cm <sup>2</sup> volt · sec			
600	$1 \cdot 10^{18}$	$2 \cdot 10^{-4}$	$1 \cdot 10^{-5}$	$1 \cdot 10^{-5}$	$1 \cdot 10^{-7}$
840	$2 \cdot 10^{20}$	$5 \cdot 10^{-4}$	$4 \cdot 10^{-3}$	$6 \cdot 10^{-6}$	$6 \cdot 10^{-8}$

The reference state is solid calcium with  $a_{\text{Ca}} = 1$ . Thus  $a_{\text{Ca}}$  may be calculated from the standard Gibbs energies of formation (21)  $\Delta G_{\text{CaF}_2(s)}^\circ$  and  $\Delta G_{\text{ThF}_4(s)}^\circ$  of  $\text{CaF}_2$  and  $\text{ThF}_4$ , respectively,

$$\log a_{\text{Ca}} = \frac{\Delta G_{\text{CaF}_2}^\circ - \frac{1}{2} \Delta G_{\text{ThF}_4}^\circ}{2.30 RT} \quad [9]$$

Thus one obtains  $a_{\text{Ca}} = 6 \cdot 10^{-13}$  at 600°C and  $a_{\text{Ca}} = 4 \cdot 10^{-10}$  at 840°C. On comparing these values with values listed in Table I, it follows that electronic conduction in  $\text{CaF}_2$  equilibrated with Th +  $\text{ThF}_4$  is insignificant. On the right-hand side of cell I with a mixture of  $\text{ThC}_2$  and graphite, the thorium activity is less than unity, and accordingly  $a_{\text{Ca}}$  is still lower than the value on the left-hand side. Therefore, no significant interference due to partial electronic conduction is expected.

In other cells investigated by Heus and Egan (12) conditions are even more favorable since the metal fluorides involved such as  $\text{UF}_3$ ,  $\text{AlF}_3$ ,  $\text{NiF}_2$  have standard Gibbs energies of formation per equivalent which are less negative than that of  $\text{ThF}_4$  and, therefore, activities of calcium are much lower than in cell I. Conditions are somewhat less favorable at an electrode Mg,  $\text{MgF}_2/\text{CaF}_2$  since the Gibbs energy of formation of  $\text{MgF}_2$  per equivalent is more negative than that of  $\text{ThF}_4$  (12). Even in  $\text{CaF}_2$  equilibrated with Mg +  $\text{MgF}_2$  at 600°C,  $t_e$  is less than  $10^{-3}$ .

Electronic conduction in  $\text{CaF}_2$ , however, would interfere in cells involving metallic Ca with  $a_{\text{Ca}} = 1$  on one side, e.g., in the hypothetical cell

which has not been investigated so far.

## An Irreversible Photogalvanic Cell Utilizing Iron(III) and Iron(II) Oxalate

William M. Riggs and Clark E. Bricker

*The University of Kansas, Department of Chemistry, Lawrence, Kansas*

Since the photolysis of ferrioxalate solutions with light of wavelength of 4300Å and shorter results in the efficient reduction of iron(III) to iron(II) (1-3) this system can be used as the basis for a photogalvanic cell or to illustrate the Becquerel effect. The purpose of this note is to report the design and operating characteristics of such a cell.

If a platinum electrode is immersed in an iron (III) oxalate solution that is irradiated with light of a wavelength of 4300Å or shorter and a second platinum electrode is placed in another portion of the solution that is not exposed to radiation, a concentration cell will be established. Because of the increased iron(II) concentration around it, the electrode in the irradiated portion will assume a more negative potential than the other electrode and electrons will flow through an external circuit. When irradiation is stopped, the concentration cell will be depleted eventually by diffusion processes and the electrode reactions which will cause the flow of electrons to cease.

A U-shaped cell having a volume of approximately 240 ml with a sintered disk in the base of the U was filled with a solution that was 0.1M in iron(III), 0.1M in  $\text{H}_2\text{C}_2\text{O}_4$  and 0.5M in  $\text{H}_2\text{SO}_4$ . Platinum foil electrodes having an area of 4.7  $\text{cm}^2$  were placed in the arms of the cell. One side of the cell was shielded from the light while the other side was irradiated from a distance of about 8 in. with a 100w medium pressure mercury vapor lamp. After less than 10-min exposure, this cell developed a potential in excess of 0.5v on open circuit or produced a current of 0.3-0.4 ma through a resistance load of 600 ohms. Even though no provision was made for thermostating the cell, the temperature of the solution in the two arms of the U-tube was always within 5° of room temperature.

The variation of the electrical output of the photogalvanic cell with changes in the initial concentrations of reactants is summarized in Table I. These results suggest that any of the reactant concentrations can be varied over a five- to tenfold range without causing any major change in the electrical output. It is important, however, not to use too high a concentration of oxalic acid or too low a sulfuric acid concentration since solid ferrous oxalate will form under these conditions and coat the electrode in the irradiated compartment. This coating appears to decrease the efficiency of current passage by reducing the available electrode area.

In all cells with constant exposure, the maximum potential and maximum current develop in approximately 10 min and persist for 30 to 45 min. After this period, there is a slow decrease in these values as the concentration of iron(II) increases in the dark cell.

As long as excess oxalate remains in the irradiated cell, the iron(III) formed at the electrode will be rapidly photoreduced by oxalate, resulting in a constant iron(II) concentration in this compartment. The initial 10-min period during which the current and voltage rise to their maximum values corresponds to the time required for the initial reduction of iron (III) to iron(II) in the irradiated cell.

Increasing the electrode area by substituting platinum gauze for the platinum foil electrodes increases the current that can be obtained. Also, stirring the portion of the solution that is irradiated produces a tenfold increase in the current output.

To evaluate the increase in output obtainable with stirring and larger electrodes, a cell containing 0.1M iron(III), 0.1M  $\text{H}_2\text{C}_2\text{O}_4$ , and 0.5M  $\text{H}_2\text{SO}_4$  was irradiated and monitored continuously for 48 hr. The platinum gauze electrodes were shorted through a 20-ohm resistor, and the irradiated portion of the cell was stirred. The maximum current for the 48-hr period was 3.6 ma. The maximum power thus produced by the cell was  $9.8 \times 10^{-4}\text{w}$ , and the average power was  $2.6 \times 10^{-4}\text{w}$ . During the 48-hr period, a total of 624 coulombs passed through the external circuit.

It should be noted that since the free energy change of the reaction,  $2\text{Fe}(\text{C}_2\text{O}_4)^+ \rightarrow 2\text{Fe}^{++} + 2\text{CO}_2 + \text{C}_2\text{O}_4^{=}$ , is negative ( $\Delta G = -38.96$  kcal/mole) (4), the cell described is not a solar energy converter. The energy from the irradiation is necessary to overcome

## Brief Communications

### The Specific Conductivity of Molten Lead Bromide

J. J. McNicholas\*

Brookhaven National Laboratory, Upton, New York

As part of a program to investigate the properties of the system lead, lead bromide and bromine, the specific conductivity of molten lead bromide was determined over the temperature range from 370° to 900°C at 1 atm.

Lead purity was 99.999%. This metal was cleaned in hydrobromic acid. The salt was prepared by direct chemical reaction from the elements. Silica glass was used as the container for the reaction since it had been previously shown to be completely resistant to chemical attack from molten lead, lead bromide and bromine simultaneously even at 900°C (1). Liquid bromine was 99.98% pure with a chlorine content below 20 ppm. The liquid was stored in equilibrium with the vapor in a Monel vessel submerged in a constant temperature water bath. This gave a constant pressure bromine source whose pressure level could be altered when desired by a change in the prescribed water bath temperature. The lead was slowly heated under vacuum until molten. When liquid it was observed to be shiny and clean. Bromine gas was admitted and the reaction was conducted at 900° until all lead had been reacted. The salt was cooled to circa 400°C, the vessel was evacuated and refilled with argon. The salt was then quenched under argon. Analysis of salt indicated 3 ppm Cu + Ni. The silica glass conductance cell is shown in Fig. 1. The design incorporated an external jacket which was filled with lead metal to insure temperature uniformity. The temperature control was better than  $\pm 0.25^\circ\text{C}$ . The inverted U-tube containing the salt used electrodes of tungsten welded to molybdenum ribbon-silica seals.

Conductance measurements were made using a General Radio 1608 Impedance bridge whose accuracy was 0.1% at 1000 Hz. The frequency was varied to 20 kHz but measured resistances did not change so all data was taken at 1 kHz. The terminal voltage was adjusted to 5-10 mv and the wave form was observed on an oscilloscope. Measurements were made with

Fig. 1. Silica glass conductance cell

Key words: conductance, molten, fused, lead bromide, salt.

Fig. 2. Values of specific conductivity

increasing and decreasing temperature with excellent reproducibility of data. The cell constant determined at 25°C using 0.1N KCl was 63.3 cm<sup>-1</sup>. Values of the specific conductivity are plotted in Fig. 2 to provide a

comparison with ref. (2-4). This work extends the temperature range of measured conductance from 650° to 900°C which approaches the boiling point of the salt at 1 atm. A least squares fit to this experimental data gives

$$k = -2.918 + 7.162 \left( \frac{T}{1000} \right) - 2.696 \left( \frac{T}{1000} \right)^2$$

where  $k$  = conductivity —mho/cm and  $T$  = absolute temperature °K. The standard deviation was 0.0088.

## Electrodeposition of Manganese from Aqueous Solution of MnBr<sub>2</sub>

Gianfranco Pistoia and Gianfranco Pecci

Istituto Elettrotecnico, Università di Roma, Rome, Italy

For the manufacture of storage batteries of high specific energy, an element of the type

would have some interest in that it can supply a theoretical energy of 560 whr/kg (considering only the electrode active materials) while that of the lead-acid batteries is 250 whr/kg.

The principal problem in this system is that of satisfactory electrodeposition of manganese, possibly in a cell of a single compartment, in order to avoid contributions to the internal resistance from the presence of diaphragms.

One can obtain deposits of manganese from baths of the chloride (1-4) or sulfate (4-9) salts, usually separating the anodic from the cathodic zone. When using MnBr<sub>2</sub> it is most important to be able to reduce the Br<sub>2</sub> content of the solution to the point where the corrosive effects at the cathode are minimal. By using an organic solvent such as bromoform, in which Br<sub>2</sub> is highly soluble (10), it is possible to obtain this condition. Naturally, one can later recover the Br<sub>2</sub> from the organic layer by physical methods.

The experimental technique consisted of performing the electrolyses in a cell of about 70 cm<sup>3</sup> volume containing 20 cm<sup>3</sup> CHBr<sub>3</sub> and 40 cm<sup>3</sup> MnBr<sub>2</sub> solution. Magnetic stirrers in both phases allowed a continuous exchange of the two layers through a perforated membrane of PVC. A solution containing 330 g/l of MnBr<sub>2</sub>

was preelectrolyzed for an hour in the presence of CHBr<sub>3</sub> using graphite electrodes and a current density of 8 amp/dm<sup>2</sup>. This treatment was necessary to eliminate certain impurities that tend to poison the metallic deposit.

After filtration the concentration of the solution was reduced to 315 g/l. This solution was then electrolyzed with graphite electrodes without additives. Dark deposits which did not adhere well to the electrodes were still obtained. On the addition of NH<sub>4</sub>Cl, which acts as a buffering agent on the pH and also increases the conductivity, only clearly metallic deposits were obtained. There was further improvement when small amounts of NH<sub>2</sub>OH·HCl (11) and of H<sub>2</sub>SeO<sub>3</sub> (4) (0.1 g/l) were added. The first acts as an antioxidant, giving a brightness to the deposits; the second affects the structure of the deposits, making it fine. The immersion of the cathode, immediately after electrodeposition, in a 5% solution of Na<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> (6) kept the deposit bright and shiny.

The quantity of added NH<sub>4</sub>Cl was determined empirically: when it was too small the deposits were unsatisfactory and the pH decreased rapidly; when in excess the current efficiency fell off, since one must work with a low current density. In Table I are shown the results obtained from solutions containing 20, 30, 40, and 50 g/l of NH<sub>4</sub>Cl at an initial pH 2.8-3.0 using graphite electrodes and varying the current density from 5.5 to 18 amp/dm<sup>2</sup>. On variation of the NH<sub>4</sub>Cl concentration it was always possible to obtain good

Table I. Manganese deposition from bromide bath: effect of current density and of ammonium chloride

MnBr<sub>2</sub>: 315 g/l; graphite electrodes (2.2 × 2.4 cm); initial pH, 2.8-3.0; temperature ~20°C; plating period, 10 min; quite vigorous agitation

deposits, but one had, at the same time, to vary the current density for this purpose. In the range of concentration studied the optimum current seemed to diminish with the increase of NH<sub>4</sub>Cl concentration. The pH, after an initial increase, tended to drop in every case; however the rate of this change varied, depending on the concentration of NH<sub>4</sub>Cl. This behavior stems from an increase in concentration of Br<sub>2</sub> which is hydrolyzed as

In this initial investigation it was decided to examine more closely the solution of 30 g/l NH<sub>4</sub>Cl at a current density of about 14 amp/dm<sup>2</sup> and at an initial pH of 2.8-3.0. The purity of the deposits so obtained was determined by the method of Sandell, Kolthoff, and Lingane (11), based on the oxidation of Mn to HMnO<sub>4</sub> by (NH<sub>4</sub>)<sub>2</sub>S<sub>2</sub>O<sub>8</sub> in the presence of AgNO<sub>3</sub> catalyst and by titrating the HMnO<sub>4</sub> with a solution of sodium nitrite + sodium arsenite. The purity of the deposits so obtained was greater than 99.5%. On the other hand, since only traces of lead and iron were found on spectrographic analysis, we can infer that a total inhibition of oxidation would give a yield of 100% purity, i.e., the major impurities are oxidation products of the deposits.

The current efficiency with graphite (14 amp/dm<sup>2</sup>; initial pH = 2.9, final = 2.2; d.d.p. at the electrodes = 4.4v) was 63% after 10 min and 44% after 60 min. On platinum (best current density : 7.5 amp/dm<sup>2</sup>; initial pH = 3.0, final = 1.6; d.d.p. at the electrodes = 4.5v) the efficiency was 52% after 10 and 40% after 60 min. The decrease of the current efficiency with time can be attributed to the production of Br<sub>2</sub> which both changes the acidity of the bath and is itself corrosive (although most of this is extracted by the organic solvent). The ions Br<sub>3</sub><sup>-</sup> and Br<sub>5</sub><sup>-</sup> produced may also make an unwelcome contribution.

The physical state of the deposit is seen in Fig. 1, which shows a cross section of the deposit on graphite which appears to be both compact and uniform. The regular form of the surface layer suggests that the

Fig. 1. Micrograph of a cross section of the manganese deposit on graphite. Original magnification 410X.

corrosive action of the Br<sub>2</sub> produced has been limited by its dissolution into the organic solvent.

At the present moment the advantages of this technique are: (a) the ability to produce deposits of Mn of high purity and good texture in a single-cell compartment; (b) the ability to isolate and recover the major part of the Br<sub>2</sub> formed.

A drawback of this technique is the relatively low current efficiency.

Further investigation is necessary, in particular the effect of pH, temperature, composition of the electrolyte, type of electrode, and stirring system are of interest.

#### Acknowledgment

The authors wish to thank Professor Ing. Mario DeRossi for his helpful suggestions and Dr. Roberto Bruno who made the micrograph.

# Spectra of Some Rare Earth Vanadates

R. C. Ropp\*

Westinghouse Electric Corporation, Bloomfield, New Jersey

## ABSTRACT

Spectra of some rare earth activated  $\text{LnVO}_4$  phosphors, where Ln may be Y, Gd, or La, are presented. The most efficient phosphors, particularly in the  $\text{YVO}_4$  matrix, are those activated by  $\text{Sm}^{+3}$ ,  $\text{Eu}^{+3}$ , and  $\text{Dy}^{+3}$ . It is shown that  $\text{YVO}_4:\text{Dy}$  has an output efficiency comparable to commercial phosphors.  $\text{LaVO}_4:\text{Eu}$ , when properly prepared, has an output intensity exceeding that of  $\text{YVO}_4:\text{Eu}$ . The major energy absorption mechanism involves a charge transfer transition within the vanadate matrix from which energy is transferred *via* an exchange coupling mechanism resulting in excitation of the rare earth centers and subsequent emission of characteristic radiation.

The rare earth vanadates, *i.e.*,  $\text{LnVO}_4$ , where Ln may be Y, Gd, or La, are interesting as hosts for rare earth activators because the major excitation mechanism is considerably different from any previously reported in the literature. As pointed out in a prior paper on rare earth oxides (1), the cation in  $\text{LnVO}_4$  must possess a rare-gas configuration since unpaired electrons offer an alternate route for energy dissipation by spin coupling exchange rather than the desired photon-emission process.

A large number of recent papers on rare earth vanadates have appeared in the literature because of the adoption of  $\text{YVO}_4:\text{Eu}$  for color television and high pressure mercury vapor lamp applications. Among the more pertinent are those of VanUitert *et al.* (2), Brill *et al.* (3), Paililla *et al.* (4), Brixner *et al.* (5), and Blasse *et al.* (6). The present paper represents a continuation of the study of rare earth luminescence and the energy transport processes affecting these activators in various matrices.

## Experimental Methods

The raw materials were obtained as oxides in a pure form (described as at least 99.97% pure except for  $\text{Gd}_2\text{O}_3$  which was available only as 99.9% pure). The phosphors were prepared by mechanically mixing the desired coprecipitated rare earth oxalates with a suitable source of vanadium, usually  $\text{V}_2\text{O}_5$ , and firing the mixture in air for a few hours at a suitable temperature ranging between 800° and 1400°C, depending on the  $\text{V}_2\text{O}_5$  to  $\text{Ln}_2\text{O}_3$  ratio (7). Spectral measurements were obtained with a commercial spectrofluorimeter, Perkin Elmer Model 195, which measures excitation and emission spectra directly and presents them in a form already corrected for energy. Reflectance measurements were made with a double beam spectrophotometer, equipped with diffuse reflectance heads, coated with  $\text{BaSO}_4$ . A high intensity Xe-lamp was employed which provided ample radiation to operate at small slit widths so as to obtain high resolution.

A comparison of emission spectra was obtained by instrumentally integrating the spectra produced (via a Disc Instrument Model 303 integrator attached to the recorder) while illuminating the sample surface with a beam of ultraviolet radiation, monitored to maintain constant energy. Emission output could be directly compared on a microwatt basis.

X-ray measurements were made with a calibrated Philips-Norelco diffractometer using Ni-filtered Cu-K $\alpha$  radiation. Scanning rate was one degree  $2\theta$  per minute.

## Experimental Results

**Structure.**—Reviews of the literature on the structures of rare earth vanadates have been published recently (8, 9). Unit-cell dimensions observed in this work agreed closely with those of Schwarz (8).  $\text{YVO}_4$  and  $\text{GdVO}_4$  have the tetragonal Xenotime structure while  $\text{LaVO}_4$  has the monoclinic Monazite structure.

**Relative efficiencies.**—The addition of 5 m/o (mol per cent) rare earth activator to either  $\text{YVO}_4$ ,  $\text{GdVO}_4$ , or  $\text{LaVO}_4$ , resulted in emission characteristic of the rare earth. Very similar results were obtained in each of the three matrices, although there were individual differences, as noted below. Figure 1 shows the relative energy output in microwatts for each activator in  $\text{LaVO}_4$  and  $\text{GdVO}_4$  matrices. Note that the relative outputs of any given activator in these matrices are not materially affected by the excitation wavelengths used. (These outputs are not directly comparable for the two matrices because of the method of measurement, but are compared below for the several activators.)

$\text{YVO}_4$ , as a matrix, also has a moderate intensity blue emission band which is only slightly intensified at liquid  $\text{N}_2$  temperatures. Figure 2 shows the excitation-emission properties of  $\text{YVO}_4$  while Fig. 3 shows spectral properties of  $\text{YVO}_4:\text{Dy}$  at room and liquid nitrogen temperatures. The vanadate emission band is quenched at room temperature in favor of the rare earth line emission. This is good evidence for a phonon assistance mechanism since low temperatures, *i.e.*, phonon quenching, favors vanadate band emission. Very similar results were found for both the  $\text{Dy}^{+3}$  or  $\text{Sm}^{+3}$  ion in the  $\text{YVO}_4$  matrix, as exemplified by the emission band of  $\text{YVO}_4:\text{Dy}$  at 78°K (Fig. 3) and the excitation band of  $\text{YVO}_4:\text{Sm}$  at 78°K (Fig. 4), but at different activator concentrations. At 0.01 g-atom

Fig. 2. Spectral properties of  $YVO_4$ —unactivatedFig. 3. Excitation-emission of  $YVO_4:Dy_{0.05}$  as a function of temperature.Fig. 4. Excitation-emission of  $YVO_4:Sm_{0.05}$  as a function of temperature.

$Dy^{3+}$ /mol  $YVO_4$  and at 0.005 g-atom  $Sm^{3+}$ /mol  $YVO_4$ , the spectra were very similar in that the vanadate band emission was noted at 78°K and the broad excitation band at 293°K changed at 78°K to a rather narrow band, similar to that of the pure  $YVO_4$  material. In general, it was found that the coupling between vanadate and the rare earth activator varied according to the ion present and its concentration. It is thus clear that the degree of energy transfer depends on the nature of the rare earth present, each rare earth having its own optimum concentration for maximum luminescent efficiency, as will be shown below.

**Effect of composition.**—The effect of composition on luminescence intensity may be demonstrated, using  $YVO_4:Eu$  as an example, in the following manner. Starting with  $Y_2O_3:Eu_{0.10}$  as shown in Fig. 5, the addition of  $V_2O_5$  causes the appearance of  $YVO_4$  according to the solid state reaction

The formation of  $YVO_4$  is proportional to the amount of  $V_2O_5$  added, a mixture of  $Y_2O_3$  and  $YVO_4$  being ob-

Fig. 5. Effect of phosphor composition on plaque brightness

served, according to x-ray diffraction analysis. The luminescence intensity decreases and then increases with vanadate concentration. The maximum intensity is observed near stoichiometry and then drops off when excess  $V_2O_5$  appears in the fired product. The stoichiometric vanadate has a "white" reflectance color which changes to a yellow color due to the appearance of an absorption band centered near 4000 Å, as shown in Fig. 6. The intensity of this band is inversely proportional to the vanadate content, the materials becoming more and more yellow in reflectance color as the vanadate decreases. Furthermore, the position of the absorption edge of vanadate is dependent on composition, as shown in Fig. 7. The excitation (or absorption) transition probably involves a charge transfer mechanism, such as:  $|(V^{5+}O_n^{-2n})| \rightarrow |(V^{4+}O_n^{-2n+1})|$ . The dependence of wavelength position on vanadium composition implies an interaction between vanadium centers.

**Rare earth spectra.**— $Ce^{3+}$  and  $Tb^{3+}$ .—Neither  $Ce^{3+}$  nor  $Tb^{3+}$  will activate any of the  $LnVO_4$  matrices ( $Ln = Y, Gd, \text{ or } La$ ). This behavior may be contrasted to the  $LnPO_4$  matrices, wherein  $Tb^{3+}$  produces a green emission of moderate intensity and  $Ce^{3+}$  produces a very strong ultraviolet emission (10). Since both matrices have the same structure, the difference must be related to the effect of the presence of the vanadate groups. It should be noted that these

Fig. 6. Reflectance spectra of  $YVO_4:Eu$  phosphorsFig. 7. Correlation of edge absorption with composition— $\lambda_{1/2}$  of vanadate excitation band shown.

Fig. 8. Spectral properties of some rare earth vanadates

rare earths possess the same major energy transition, namely,  $4f^8 \rightarrow 4f^7 5d$  ( $Tb^{+3}$ ) and  $4f^1 \rightarrow 5d^1$  ( $Ce^{+3}$ ).  $Pr^{+3}$  and  $Nd^{+3}$ .— Both  $Pr^{+3}$  and  $Nd^{+3}$  produce a luminescence intensity so weak that measurement proved difficult. For this reason, the spectra are not included.  $Sm^{+3}$ .—Characteristic spectra consisting of four lines are produced by the  $Sm^{+3}$  activator in  $LnVO_4$  matrices, as shown in Fig. 8. The behavior of  $Sm^{+3}$  in the  $YVO_4$  matrix as a constant quantum emitter has already been commented upon (11). It is noteworthy that neither of the other matrices produces the same effect. In  $LaVO_4$ , the absorption edge of vanadate remains the prominent feature in the excitation spectrum for both of the major emission lines, whereas in  $GdVO_4$ , these same lines have dissimilar excitation spectra. This behavior can be interpreted as a difference in coupling between the vanadate and the  $Sm^{+3}$  excited states associated with the separate emission lines. The same phenomenon does not occur in  $YVO_4$  or  $LaVO_4$ . There is a considerable difference in comparative emission intensities, as shown in Table I. Thus, the most efficient phosphor is based on  $YVO_4$ . Also given, for comparison, is the  $YVO_4:Dy$  phosphor (see below). The optimum activator concentration for  $Sm^{+3}$  in  $LaVO_4$  is about ten times that required for the  $YVO_4$  matrix, as shown in Fig. 9. This behavior seems to be characteristic for the  $LaVO_4$  matrix.

$Eu^{+3}$ .—The inclusion of  $Eu^{+3}$  in  $LnVO_4$  matrices produces the typical red line emission, as shown in Fig. 10. The emission of  $Eu^{+3}$  in these matrices differs somewhat from oxide systems studied previously (1) in that the site symmetry in  $YVO_4$  splits the  ${}^7F_2$  level so that two narrow emission lines are observed instead of the one major line seen in the  $Y_2O_3$  phosphor for the  ${}^5D_0 \rightarrow {}^7F_2$  transition. A recent paper by Briffaut (12) analyzes the splitting of the  ${}^7F_2$  level by calculating the crystal field parameters using a  $42m$  symmetry. In our work, a total of five lines were observed for the  ${}^7F_2$  multiplet (spectrum not given) in agreement with the work by Briffaut. The major lines in  $YVO_4:Eu$  correspond to transitions between  ${}^5D_0$  and the  $A_1$  and  $B_1$  Stark levels of the  ${}^7F_2$  multiplet. According to Briffaut, these lines have electric dipole character,

Table I. Comparison of the output of  $Sm^{+3}$  in the three vanadate matrices

Phosphor	Emission color	Excitation wavelength			
		2537Å	%	3210Å	%
$LaVO_4:Sm_{0.025}$	Pink	57 $\mu$ watt	5.0	90 $\mu$ watt	8.0
$GdVO_4:Sm_{0.05}$	Orange	258	24		
$YVO_4:Sm_{0.0025}$	Orange	745	69	702	62
$YVO_4:Dy_{0.005}$	Yellow	1085	100	1126	100

Fig. 9. Optimum activator concentrations in  $LnVO_4$  matrices

Fig. 10. Spectral properties of some rare earth vanadates

which accounts for their strong intensity in relation to the other Stark components.

Note, however, that the  $LaVO_4$  matrix (monazite structure) apparently does not cause the same splitting (see Fig. 10) since only one major line is seen. This is about the only notable effect in the  $Eu^{+3}$  spectra. The optimum activator concentration for  $Eu^{+3}$  in  $YVO_4$  is about 0.05 g-atom/mol  $YVO_4$  and for  $LaVO_4$  is about 0.10 g-atom/mol  $LaVO_4$ , as shown in Fig. 11 for ultraviolet excitation (the latter being shown for two exciting wavelengths). The relative emission intensities are given in Table II for the various  $Eu^{+3}$  phosphors employing constant energy excitation beam. Thus, although Palilla *et al.* (4) have stated that the low intensity of  $Eu^{+3}$  emission in  $LaVO_4$  is due to structure effects, it is obvious that this phosphor can be prepared so that it is just as efficient as those based on  $YVO_4$ .

$Dy^{+3}$ .—The incorporation of  $Dy^{+3}$  in  $LnVO_4$  matrices results in line emission composed of several Stark components, as shown in Fig. 12. The constant quantum emission behavior of  $Dy^{+3}$  in  $YVO_4$  has already been presented (11). Note that this behavior is not ob-

Phosphor	Output, $\mu\text{watt}$ (2537Å excitation)	Per cent	Relative peak height
$\text{YVO}_4:\text{Eu}_{0.05}$	182	100	85
$\text{GdVO}_4:\text{Eu}_{0.05}$	152	84	69
$\text{LaVO}_4:\text{Eu}_{0.05}$	40	22	10
$\text{LaVO}_4:\text{Eu}_{0.10}$	186	102	87
$\text{Y}_2\text{O}_3:\text{Eu}_{0.10}$	219	120	100

served in  $\text{LaVO}_4$  or  $\text{GdVO}_4$ . The optimum activator concentration is, again typically, ten times larger in the  $\text{LaVO}_4$  matrix than it is in the  $\text{YVO}_4$  matrix, as shown in Fig. 13. (The ordinates in this figure are not comparable because of the method of measurement.) Even at the optimum level,  $\text{Dy}^{+3}$  produces a low efficiency in  $\text{LaVO}_4$  as may be seen by inspection of the data in Table III, which compares the relative efficiency of the various phosphors. In this case, the xenotime structure does seem to have a demonstrable effect on the luminescent intensity, as compared to the monazite structure ( $\text{LaVO}_4$ ). It has already been shown that interaction of activator sites, possibly through exchange effects, leads to self-quenching in  $\text{Y}_2\text{O}_3$  (13) at rather low concentrations of  $\text{Dy}^{+3}$ . Thus it is possible that the low luminescent intensity experienced for the  $\text{LaVO}_4$  matrix is due to the same effects.

Nevertheless,  $\text{Dy}^{+3}$  in  $\text{YVO}_4$  is remarkably efficient, as may be seen by inspection of Fig. 14. (The integrator employed for these measurements was originally designed for integration of lines such as those

Table III. Radiometric comparison of  $\text{Dy}^{+3}$  activated phosphors

Phosphor	Output 2537Å excitation, $\mu\text{watts}$	Per cent	Relative peak height
$\text{YVO}_4:\text{Dy}_{0.0025}$	237	100	94
$\text{GdVO}_4:\text{Dy}_{0.0025}$	250	105	96
$\text{LaVO}_4:\text{Dy}_{0.025}$	22	9	5

encountered in gas chromatography and should produce more accurate data for lines than for bands.) The  $\text{Dy}^{+3}$ -activated phosphors are at least as efficient as a commercial halophosphate phosphor, containing a high  $\text{Mn}^{+2}$  content so as to obtain a yellow emission color. Therefore, it would be expected that  $\text{YVO}_4:\text{Dy}$ , whose spectrum consists of 5720Å emission lines containing approximately 85% of the total output would produce a lamp of very high brightness, because the luminosity of these photons is very high. However, we achieved a rather disappointing result in that about 3000 lumens resulted after 100 hr burning in 40 watt fluorescent lamps, whereas the halophosphate phosphor produced a lamp with over 3400 lumens.

$\text{Er}^{+3}$  and  $\text{Ho}^{+3}$ .—Both of these activators produce characteristic line spectra in the  $\text{LnVO}_4$  matrices, as shown in Fig. 15 and 16. These spectra are similar to those seen for the  $\text{LnPO}_4$  matrices, except that the vanadate excitation band exists in the former. As a result, the  $\text{Er}^{+3}$  and  $\text{Ho}^{+3}$  activators are considerably more efficient in the  $\text{LnVO}_4$  lattices than in the  $\text{LnPO}_4$  lattices, due to absorption and transfer of energy within the vanadate centers. It is probable that the absorption coefficient of the vanadate matrix remains about the same, regardless of which activator is present, but in the case of  $\text{Er}^{+3}$  and  $\text{Ho}^{+3}$ , the exchange coupling coefficient is moderate to low, resulting in little energy transfer. The ground states of both of

Fig. 14. Comparison of emission intensities— $\text{YVO}_4:\text{Dy}$  and yellow halophosphate.

Fig. 15. Spectral properties of some rare earth vanadates

Fig. 16. Spectral properties of some rare earth vanadates

these ions are vibronically coupled to the lattice, a fact which further precludes high efficiency (13).

$\text{Tm}^{+3}$ .—The spectrum of  $\text{Tm}^{+3}$  in  $\text{LnVO}_4$  matrices consists of a single blue line at  $4500\text{\AA}$ , as shown in Fig. 17. The emission intensity is low (see Fig. 1). In  $\text{LnPO}_4$  matrices, the spectra were composed of the blue line and an ultraviolet line as well. The fact that only one line was observed in  $\text{LnVO}_4$  matrices must be attributed to the effect of local site symmetry on transition probabilities.

### Discussion

The spectra of various rare earth activators in  $\text{LnVO}_4$  matrices have been presented. The most efficient phosphors are those activated by  $\text{Eu}^{+3}$ ,  $\text{Sm}^{+3}$ , and  $\text{Dy}^{+3}$ .

The energy processes in these rare earth phosphors are considerably different from any previously reported by the author. The major absorption process occurs in the vanadate group probably via a charge transfer mechanism

Once the vanadate center becomes excited, it can either emit the energy as luminescence or transfer the energy to a rare earth center, which subsequently emits its own characteristic radiation. The latter mechanism is phonon regulated, as shown by the data given for  $\text{Sm}^{+3}$  and  $\text{Dy}^{+3}$  activated phosphors. It is particularly

Fig. 17. Spectral properties of some rare earth vanadates

Fig. 18. Possible energy transport processes in  $\text{YVO}_4:\text{Dy}$  phosphors

noteworthy that  $\text{Eu}^{+3}$ , whose excitation mechanism can be classified as a charge transfer band, is the most efficient activator in the vanadate phosphors. In contrast, those activators involving a  $4f \rightarrow 5d$  transition as the main energy transition are not effective at all.

It is of interest to compare the present results which contradict those already published. Brixner and Abramson (5) showed line emission for  $\text{YVO}_4$  at  $300^\circ\text{K}$  and O'Conner (14) confirmed these observations. For a charge-transfer excitation mechanism, one expects a broad band emission at  $300^\circ\text{K}$ . The present results show a broad emission band for  $\text{YVO}_4$  and even in  $\text{YVO}_4:\text{Dy}$  or  $\text{YVO}_4:\text{Sm}$ , a broad emission band arises at  $78^\circ\text{K}$  because the  $|\text{VO}_4| \rightarrow \text{Ln}^{+3}$  energy transfer mechanism is hindered. Furthermore, the same 4800 and  $5720\text{\AA}$  lines, due to  $\text{Dy}^{+3}$  emission occur in the oxide and phosphate phosphors (1, 10). In all of the cases investigated by the author to date, the emission spectrum of  $\text{Dy}^{+3}$  has been distinctive, regardless of matrix. In addition, quantities as low as 10 ppm  $\text{Dy}^{+3}$  cause a moderate-intensity emission in  $\text{YVO}_4$ . Thus the prior data given by Brixner *et al.* and by O'Conner are incorrect and are due to impurity concentrations of  $\text{Dy}^{+3}$ .

Although Palilla and Levine (4) attribute the low output of  $\text{LaVO}_4:\text{Eu}$  to structural effects, we have shown that it can be prepared so that its output is as high as  $\text{YVO}_4:\text{Eu}$ .

For  $\text{Tb}^{+3}$  activated phosphors, no luminescence was noted in  $\text{LnVO}_4$  matrices ( $\text{Ln} = \text{Y, Gd, or La}$ ), where the initial  $\text{V}_2\text{O}_5/\text{Ln}_2\text{O}_3$  ratio was 1:1 or larger, prior to firing. At ratios less than 1:1, some  $\text{Tb}^{+3}$  emission was noted, particularly in  $\text{LaVO}_4$ , becoming greater as the ratio decreased. Thus, the results of Brill *et al.* (3) can be explained as activation of the oxide normally present in low  $\text{V}_2\text{O}_5/\text{Ln}_2\text{O}_3$  compositions but no activation of the vanadate.

Of those phosphors which behave as constant quantum emitters, it is interesting that such behavior implies that all of the upper energy excited states, of  $\text{Dy}^{+3}$  for example, may be coupled in the same manner to the emitting state. This is more easily seen by reference to Fig. 17. The transition from the  $4^1\text{D}_{3/2}$  state to the  $6^1\text{H}_{7/2}$  component of the ground state multiplet results in emission of  $5720\text{\AA}$  photons. Excitation occurs either in the vanadate absorption band or in the yttrium band, depending on energy. The exact positioning of the yttrium band remains uncertain, although it is shown in Fig. 17 near to  $2200\text{\AA}$ . That it

exists in the oxides has already been shown [ref. (1, 13)]. It is assumed to be present here.

The exact path of the energy transfer has not been proven. For example,  $44,000\text{ cm}^{-1}$  energy causes excitation in the yttrium band. This excited center may then decay by phonon processes to the vanadate band level, from which energy transfer may occur by phonon-regulated exchange processes to a  $\text{Dy}^{+3}$  level. Alternately, the excited yttrium center may exchange couple directly to an upper  $\text{Dy}^{+3}$  state, which would decay, again by phonon processes, to the  ${}^4\text{D}_{3/2}$  emitting state. However, in the latter mechanism, the emitting state is required to be coupled to all of the upper energy states of the  $\text{Dy}^{+3}$  ion, in the same manner, because of the constant quantum efficiency observed. In the former mechanism, the phonon-regulated exchange could occur via the  ${}^4\text{D}_J$  multiplet. The  ${}^4\text{D}_{1/2}$  level occurs near to  $31,000\text{ cm}^{-1}$  which could then relax to the emitting state  ${}^4\text{D}_{3/2}$ . The data presented herein are not sufficiently definitive to be able to delineate the correct mechanism. Whether the yttrium band is a charge transfer band remains uncertain, although an exciton band involving yttrium sites seems more likely, particularly because yttrium does not have a stable divalent state.

## Vapor Phase Growth and Properties of Aluminum Phosphide

D. Richman

RCA Laboratories, Princeton, New Jersey

#### ABSTRACT

Aluminum phosphide epitaxial layers on Si and single crystal needles and platelets have been synthesized by a vapor transport reaction, utilizing the disproportionation of  $\text{AlCl}$ . Lattice constant determinations yielded a value of  $5.4625 \pm 0.0005\text{ \AA}$ . The optical band gap was found to be  $2.43 \pm 0.2\text{ eV}$ . Hall constant and resistivity measurements indicate that the as grown material is n-type with carrier concentrations in the  $1 \times 10^{18}$  range and mobilities of the value of  $70\text{ cm}^2/\text{v-sec}$ . Evidence was obtained for effects of variations in stoichiometry. The material as grown varies between pale yellow and a light green in color. Optical absorption studies revealed an infrared band in the green material with maximum absorption at  $11,800\text{ \AA}$ . The color could not be associated with the presence of foreign atoms. However, on annealing in vacuum at  $1000^\circ\text{C}$ , the color of the AlP changed from green to yellow, and the absorption band decreased in intensity. On annealing in a phosphorus atmosphere, these effects reversed.

Among the series of III-V compounds, the phosphides of boron, aluminum, and gallium are characterized by their high melting points and high dissociation pressures. These properties are known accurately only for GaP, the lowest melting of the three. Even for this material, its melting point of  $1467^\circ\text{C}$  and dissociation pressure of 35 atm are very high (1). For the other compounds, the melting points and pressures are even higher so that synthesis methods other than growth from the melt must be used.

One technique which appears to have great versatility is vapor phase synthesis. In this technique, gaseous species are reacted to form the solid of interest at temperatures and pressures considerably below those at the melting point of the solid. This approach has been used successfully for the synthesis

of GaAs from the elements as well as for the transport and epitaxial growth of Ge, Si, GaAs, GaP, and GaAs-GaP alloys.

Because of the difficulty in preparing single crystals of AlP(2), it is one of the least studied of the III-V compounds, and basic parameters such as band-gap and lattice constant are not well established. The use of vapor phase synthesis seemed to be well suited to overcome the difficulty of preparation, and therefore work was begun to synthesize single crystals of AlP of sufficient size to allow evaluation of the optical and electrical properties of this III-V semiconductor. In this research the chemical reactions in the vapor growth are different from that previously reported (2a), and more complete results concerning the properties of AlP are presented.

### Synthesis of AlP

The apparatus used for the synthesis of AlP is shown in Fig. 1. The use of an alumina reaction tube is necessary since AlCl reacts with quartz. Because alumina is not easily fabricated into various shapes, an apparatus with a straight-line geometry was used for these experiments. The procedure consisted of heating the reaction zone and the deposition zone to the desired temperature during a constant flow of hydrogen gas. When thermal equilibrium was established, the flow of HCl and PH<sub>3</sub> was started and with the H<sub>2</sub> was adjusted to give the desired concentration of gases in the two zones. It should be noted that the reactive gases were not mixed until they were in the deposition zone. This prevented reaction of the phosphorus with the liquid aluminum and the formation of AlP in the melt.

The gaseous aluminum halide species responsible for transport was determined for various temperatures and HCl flow rates, by metering the HCl flow and weighing the aluminum source before and after each run. Table I presents the results of several of these determinations.

The close one to one relationship between gram atoms of aluminum and moles of HCl indicates that AlCl is the molecular species responsible for the transport. Therefore, the equations for transport of aluminum and synthesis of AlP can be derived as follows:

(I) Source zone; high temperature

(II) Deposition zone; low temperature

The temperature of the deposition zone was held in the range 1200°-1250°C. The amount and rate of deposition could be controlled by varying the concentration of the AlCl in the deposition zone. This was done by varying the amount of hydrogen carrier gas that was introduced into the deposition zone through the PH<sub>3</sub> feed line. In this manner, deposition rates between 0 and 40 mg/cm<sup>2</sup>/hr could be obtained. The higher rates being obtained at high AlCl concentrations.

The two substrates used to nucleate growth were polished sapphire and silicon. The sapphire was used to support thin polycrystalline layers that would be suitable for optical absorption studies. Silicon was used as a substrate for the epitaxial growth of AlP. It was felt that, in this manner, large area single crystals of AlP could be prepared. In addition, needles and platelets of AlP were produced due to nucleation on the walls of the reaction tube. From these growths, samples were obtained for lattice constant determinations as well as samples suitable for optical absorption studies and electrical measurements, the results of which are described below.

Fig. 1. Growth apparatus and temperature profile for AlP synthesis.

Table I. Consumption of aluminum as a function of temperature and moles of HCl used

Run	Temperature of aluminum source, °C	Wt. of aluminum lost from source, g	Gram atoms of aluminum consumed	Moles of HCl used
1	1420	0.84669	$3.14 \times 10^{-2}$	$3.16 \times 10^{-2}$
2	1330	0.81872	$3.04 \times 10^{-2}$	$3.16 \times 10^{-2}$
3	1507	0.85732	$3.18 \times 10^{-2}$	$3.16 \times 10^{-2}$
4	1460	0.52027	$1.93 \times 10^{-2}$	$2.06 \times 10^{-2}$
5	1470	1.25706	$4.66 \times 10^{-2}$	$6.15 \times 10^{-2}$

### Properties of AlP

**Lattice constant.**—Nine different samples of AlP comprising needles, platelets, and epitaxial material were submitted for x-ray lattice constant determinations. The results from all of these determinations yield a lattice constant for AlP of  $5.4625 \pm 0.0005\text{Å}$ . This is somewhat larger than the value of  $5.451\text{Å}$  reported by Addamiano (3), and is closer to, but smaller than, the value of  $5.467 \pm 0.002\text{Å}$  reported by Wang *et al.* (4).

**Optical properties.**—The bandgap of AlP has been reported to be either 2.42 eV (5) or 3.0 eV (6). A material of this bandgap should be a pale yellow. Observation of the material prepared here and elsewhere (3,4) indicates that some of the AlP is green. Emission spectrographic analysis shows no observable difference between the impurity content of the green and yellow crystals. A typical analysis shows the presence of Cu, Si, Mg, and Fe with the total impurity content in the 100-200 ppm range. In order to study this color difference, as well as to determine the optical band edge, absorption studies of polycrystalline layers on sapphire and unsupported single crystal platelets were undertaken. For this work, a Cary Model 14 double-beam spectrometer was used. Similar spectra were obtained from the supported and unsupported material. Figure 2 shows a typical spectrum for green AlP. The spectrum for yellow AlP lacks the band at  $11,800\text{Å}$ . The absorption in the region of the band edge does not increase rapidly. Such behavior is indicative of an indirect gap material, although more work must be done to establish this conclusion. The best fit to a plot of optical density vs.  $(h\nu - E_g)^2$  yields a bandgap of 2.43 eV at room temperature. One spectrum run at 77°K gave a shift in the band edge of  $260\text{Å}$  or 0.13 eV. This would indicate a liquid-nitrogen gap of 2.56 eV and so  $(dE/dT)_p = 5.8 \times 10^{-4} \text{ eV/deg}$ .

The effect of various heat treatments on the absorption band at  $11,800\text{Å}$  is shown in Fig. 3. It can be seen that vacuum annealing causes the intensity of the absorption band to decrease markedly. Also apparent is the increase in the band intensity on reheating in a phosphorus atmosphere. This behavior indicates that the color effects in AlP arise from non-stoichiometry, and most probably an excess of phosphorus leads to the green color. At present it has not

Fig. 2. Optical absorption spectrum of green AlP

Fig. 3. Effects of various heat treatments on the infrared absorption band in green AIP.

been possible to correlate these optical effects with electrical measurements on this material. This is the first time that such evidence for deviations from stoichiometry have been observed in a III-V compound semiconductor.

**Electrical properties.**—Hall samples were shaped from single crystal needle specimens by hand lapping under dry kerosene. Ohmic contact to the AIP was achieved by ultrasonically soldering indium dots to the freshly prepared surface. All the AIP tested was n-type. Carrier concentrations were between  $4 \times 10^{17}$  and  $5 \times 10^{18}$  electrons/cm<sup>3</sup> with associated mobilities varying between 80 and 65 cm<sup>2</sup>/v-sec, respectively. No significant deionization was observed on cooling to liquid nitrogen temperature; however, a definite decrease of 20 to 50% of the room temperature mobility was observed in all cases.

Effects of annealing in vacuum could not be conclusively established. Preliminary findings indicate that a 45-hr anneal at 1090°C causes an increase in

carrier concentration by a factor of 2 or 3. For material with the lowest as-grown carrier concentration annealing resulted in a definite increase in the room-temperature and liquid-nitrogen mobilities. However, for the more heavily doped material the opposite effect was observed.

### Conclusion

The AIP is the first of the III-V compounds to show a reversible deviation from stoichiometry. This deviation is associated with the color of the material which varies from yellow to green with increasing phosphorus content. The bandgap of AIP is 2.43 eV and is an indirect transition. The low mobility for electrons in AIP is in agreement with this conclusion.

# Electrical Characteristics of Silicon Nitride Films Prepared by Silane-Ammonia Reaction

George A. Brown, W. C. Robinette, Jr.,\* and H. G. Carlson\*

Texas Instruments Inc., Dallas, Texas

## ABSTRACT

The d-c conduction and complex dielectric constant of silicon nitride films prepared by silane-ammonia reaction have been studied as a function of the composition of the gaseous ambient in which they were formed. The d-c conductivity of the material increases sharply when the silane-ammonia ratio increases above 0.1. The increased conductivity is characterized by a lowering of the activation energy to about 1.0 eV from 1.5 eV for high resistivity nitride. The current-voltage characteristics display a  $\ln I-V^{1/2}$  dependence at high fields in the temperature range 200°-500°K. Measurement of the magnitude of the slope of this characteristic and its dependence on film thickness, index of refraction, temperature, and bias polarity suggests that conduction arises from field aided thermal ionization of trapping centers in the bulk of the film, the Poole-Frenkel effect. It is noted that the magnitudes of the slopes of the experimental  $\ln I-V^{1/2}$  plots, which are twice as large as Schottky emission slopes, are derivable within the framework of the Poole-Frenkel mechanism only under a special assumption regarding the statistics governing the occupancy of the traps.

The relative dielectric constant,  $\epsilon'_r$ , of the films has a constant value of approximately 7 for silane-ammonia ratios below 0.1 and increases gradually to about 10 for a silane-ammonia ratio of unity. Very small variations in  $\epsilon'_r$  with frequency and temperature were noted in the range of the measurements,  $5 \times 10^2 - 10^6$  Hz and 200°-500°K. Values of dielectric loss,  $\epsilon''_r$ , lower than  $10^{-3}$  have been observed for the low silane-ammonia ratio films, but these are also dependent on substrate surface preparation. An observed dependence of  $\epsilon''_r$  on sample area in some cases suggests the presence of localized film defects in the less carefully prepared samples. No structure in the loss-frequency-temperature characteristics of the material has been observed in the above-mentioned ranges of temperature and frequency that cannot be related to the d-c conductance of the silicon nitride or to the substrate resistance.

Electrical characteristics of silicon nitride films prepared by silane-ammonia reaction have been measured. Parameters studied include d-c conduction and complex dielectric constant as a function of composition of the gaseous ambient during film formation and of applied electric field and temperature during measurement.

The preparation of silicon nitride in thin films by the reaction of silane and ammonia in hydrogen diluent has been reported by several workers (1-4) and is one of several techniques by which films of the material have been formed (5, 6). While all of these films have certain similar characteristics, important differences exist (7). Indeed, as might be expected, the physical and electrical properties of films formed by silane-ammonia reaction have been found to vary with reactant composition during growth (2, 8, 9). In this work, samples formed from various silane-ammonia ratios in the gas were chosen to relate electrical characteristics to the parameters of film formation and to material properties.

The samples described in this study were prepared in the laboratory of Bean, Gleim, Yeakley, and Runyan (9), who have detailed many of the physical properties of the material. Deposition conditions for the films in the present study are given in ref. (9). All the films evaluated electrically were formed at  $850^\circ \pm 50^\circ\text{C}$  in a region of growth parameters found to produce amorphous films as determined by x-ray diffraction. Within the growth parameter region described by Bean *et al.*, it has been found that the physical and electrical characteristics vary only with the ratio of silane to ammonia in the gaseous ambient. No variation in behavior was found to result from changing film thickness or growth rate by varying total percentage of silane and ammonia in the gas

stream by a factor of two about normal levels while maintaining a fixed ratio.

Silicon nitride was formed on both molybdenum and silicon substrates. The silicon starting material varied from 0.01 to 5 ohm-cm n- and p-type of several crystal orientations and was usually etched in  $\text{H}_2\text{-HCl}$  vapor in situ immediately prior to film deposition. Commercial grade molybdenum sheet was cut into  $1 \times 2$  cm substrates and mechanically polished to a thickness of approximately  $260\mu$ . The substrates were degreased and cleaned prior to silicon nitride deposition.

The thickness of the deposited silicon nitride films ranged from 600 to 6000Å. The index of refraction and thickness of all samples used was measured with an ellipsometer using either a mercury arc source ( $\lambda = 5461\text{Å}$ ) or a laser source ( $\lambda = 6328\text{Å}$ ).

Capacitor structures for the electrical measurements were formed by vacuum evaporation of either aluminum or chromium on the surface of the nitride film and subsequent photolithographic definition of a pattern of circular dots ranging in area from  $1.8 \times 10^{-4}$   $\text{cm}^2$  to  $1.8 \times 10^{-2}$   $\text{cm}^2$ . None of the parameters in this study was found to depend on the metal contact material used.

Most of the electrical measurements were made on complete slices using a shielded probe in a darkened chamber. In some cases, however, 0.25 cm square chips were scribed and mounted in TO-60 headers for measurement.

## D-C Conduction

*Experimental results.*—The test set for d-c conduction measurements employed a resistance-programmed Kepco ABC 1000 voltage source and a Hewlett-Packard Model 425A micro-microammeter. For measurements at temperatures other than room temperature, a Statham SD-6 oven with temperature range between

\* Electrochemical Society Active Member.

Fig. 1. Typical current-voltage-temperature data for a silicon nitride film.

200° and 575°K was used for packaged units, while a controlled ambient, hot stage probe chamber was used for slice-form studies in the range 300° to 500°K.

Current-voltage-temperature data representative of samples of all compositions studied are shown in Fig. 1. The silane-ammonia ratio for this sample is 0.01. From this  $\ln I-V^{1/2}$  plot, often called a Schottky plot, it is seen that the high field conduction in the temperature range from 300° to 468°K may be expressed as

$$I \sim I_0 \exp \left( \frac{\beta V^{1/2} - \Psi}{kT} \right) \quad [1]$$

where  $I$  is the measured current,  $V$  the applied voltage,  $\beta$  and  $\Psi$  are constants with temperature dependences to be explored,  $k$  is Boltzmann's constant, and  $T$  is the absolute temperature. The parameter  $\Psi$ , a low field activation energy for the current, is obtained from curves like those in Fig. 1 by extrapolation to the zero voltage intercept. The values of this intercept current,  $I_0$ , are shown plotted vs. reciprocal temperature in Fig. 2.

This activation energy is found to vary in value from about 1.5 eV for high resistivity silicon nitride samples like that shown in Fig. 1 to approximately 1 eV for

Fig. 2. Zero-volt-intercept current,  $I_0$ , plotted vs. inverse temperature, yielding activation energies for the conduction mechanism.

more conductive samples. Apparent activation energies as low as 0.5 eV have been observed for units characterized for a temperature dependent  $\beta$  in Eq. [1]. Such units will be discussed below. Measurements on capacitors varying in area as described above have established that this conduction is of a uniform, area-dependent nature. Hence the d-c resistivity of the films defined by the relation

$$\rho = \frac{E}{J} \quad [2]$$

can be determined from the data of Fig. 1.

It is found that the resistivity is a very strong function of the silane-ammonia ratio of the deposition ambient, as shown in Fig. 3 where the logarithm of the room temperature current density is plotted vs. the square root of the applied electric field for samples with silane-ammonia ratios of 0.01 to 1.2. Because of the strongly non-ohmic nature of these characteristics, the resistivity varies with field strength, and comparison of resistivities must be made at a fixed field. Figure 4 shows the d-c resistivity at  $E = 4 \times 10^6$  v/cm for films of the above-mentioned silane-ammonia ratio range. These values, like the refractive index and etch rate values reported by Bean *et al.*, saturate abruptly for silane-ammonia ratios of 0.1 and below. The dielectric strength of these films was found to be very close to  $10^7$  v/cm at room temperature for all the films, regardless of silane-ammonia ratio. It was observed that the uniformity of the d-c conduction data on molybdenum-substrate samples was in general inferior to that found with silicon substrates, although the form of the  $I-V$  relationship was unchanged. Residual

Fig. 3. Log current density plotted vs. the square root of the electric field, showing the dependence of conductance on silane-ammonia ratio.

Fig. 4. The d-c resistivity of the silicon nitride films at an applied field of  $4 \times 10^6$  v/cm, as a function of silane-ammonia ratio.

irregularities on the molybdenum surface which could not be removed are thought to be the cause of this behavior. Because of the scatter in the molybdenum-substrate data, results obtained for films on silicon substrates are used in the quantitative characterization of the silicon nitride films.

*Model.*—On the basis of the strong dependence of the conductivity on film composition, independence of electrode materials and the analysis of the data to be given below, it is proposed that the conduction is electronic in nature and is limited by a bulk film mechanism. This mechanism is apparently a form of field-aided thermal ionization of trapping levels in the film, a process which in its simplest form is known as the Poole-Frenkel effect. The title arises from the work of Poole (10), who reported an exponential dependence of conductivity on applied electric field in mica and certain other insulators, and that of Frenkel (11), who proposed the model and derived the expression showing the  $\sigma \sim \exp(\beta E^{1/2})$  relationship. The mechanism has since been invoked by many workers studying conduction in thicker films of a variety of materials. Among them are Vermilyea (12) ( $ZrO_2$ ), Mead (13) ( $Ta_2O_5$ ), Hirose and Wada (14) (SiO), and Hartman *et al.* (15) (SiO). The applicability of the mechanism to silicon nitride films was pointed out by the authors (16), and other workers (17, 18) studying silicon nitride films fabricated by a variety of techniques have suggested this interpretation of their conductivity data.

The assumption of an electronic rather than ionic mechanism is based on experiments in which currents of  $10^{-3}$  amp/cm<sup>2</sup> of both polarities were maintained in samples for extended periods of time without observing any current decay due to ionic pileup near an electrode. Present data do not, however, permit differentiation between hole and electron currents. For definiteness, an electron transport mechanism will be assumed throughout the discussions.

The basic derivation of the Poole-Frenkel characteristics has appeared in the literature in brief form (11,12) and will not be presented here in detail. A few remarks will be made relative to the model.

Consider an occupied donor-like electron trap located in energy  $qU$  below the conduction band of an insulator as shown in Fig. 5. The main premise of the derivation is that under the influence of an applied electric field (indicated by the tilted bands of Fig. 5), an electron being excited from the trap is acted on by first, the applied field, and second, the coulomb attractive force of the positively charged center that it is escaping. The resultant of these two forces forms a potential distribution seen by the electron like that shown in the heavy line in Fig. 5.

Note the energy barrier that the electron must overcome to escape the center has been lowered by  $q\Delta U$ , making the escape more probable.

Frenkel showed that this potential barrier lowering,  $\Delta U_{p-f}$ , was given by

$$\Delta U_{p-f} = \left( \frac{qV}{\pi\epsilon d} \right)^{1/2}$$

where  $q$  = electronic charge,  $V$  = applied voltage across the film,  $\epsilon$  = dielectric constant of film, and  $d$  = film thickness. This may be compared with the case

Fig. 5. Potential distribution acting on an electron escaping a donor-like trap.

of Schottky emission, the thermal excitation of carriers over an interfacial barrier lowered by the carrier's image force. Here a similar expression applies, with a barrier lowering,  $\Delta U_s$ , given by

$$\Delta U_s = \left( \frac{qV}{4\pi\epsilon d} \right)^{1/2}$$

where all quantities are as defined above. This quantity is a factor of two smaller than  $\Delta U_{p-f}$  because in the Schottky emission case, the carrier's image charge recedes as the carrier escapes the barrier, while in the Poole-Frenkel situation, the positively charged center is immobile.

The conductivity of a sample due to Poole-Frenkel emission was expressed by Frenkel (11) in the form

$$\sigma = \sigma_0 \exp[-q(U_{p-f} - \Delta U_{p-f})/2kT] \quad [3]$$

where  $U_{p-f}$  is the trap depth below the conduction band. The factor of two in the denominator of the exponent arises from a statistical description of the electron population above a donor-like center, under the assumption that at low temperatures, all the centers will be occupied by electrons (19). Thus the thermal activation energy for the low field conductivity is equal to one-half of the potential well depth. On the other hand, Schottky emission currents are commonly described by the expression

$$I = AT^2 \exp[-q(U_s - \Delta U_s)/kT]$$

where  $A$  = Richardson's constant,  $T$  = absolute temperature, and  $U_s$  = equilibrium barrier height. Thus it is seen that the magnitudes of the slopes of  $\ln I-V^{1/2}$  plots for normal Poole-Frenkel and Schottky emission are identical, since the factor of two in the denominator of Eq. [3] cancels the factor of two by which  $\Delta U_{p-f}$  exceeds  $\Delta U_s$ .

However, in the case of the Poole-Frenkel mechanism, a more general treatment is possible if it is postulated that the number of electrons available for excitation be smaller than the number of donor-like centers. The statistics describing the excited density in such a system were first worked out by deBoer and vanGeel (20) and Nijboer (21). Mott and Gurney (22) have outlined the derivation, and point out that such conditions might be expected to arise in a material containing an excess of its metallic ion over the stoichiometric requirement. This situation almost certainly applies to the films in this study formed at a high silane-ammonia ratio and could conceivably occur to some degree throughout the range of the investigation.

Following Mott and Gurney (19), consider a system of unit volume containing  $N$  donor-like centers located an energy  $E$  below the conduction band,  $N_e$  electrons available for excitations from these centers ( $N_e < N$ ), and  $n$  electrons of the  $N_e$  excited to the conduction band. Neglecting spin degeneracy, set  $N_c = (2\pi mkT/h^2)^{3/2}$ . Minimizing the free energy of the system with respect to the carrier concentration and assuming that only a small fraction of the available electrons will be excited to the conduction band leads to two possible expressions for the excited carrier density,  $n$ , depending on the relative magnitudes of the quantities  $n$  and  $(N - N_e)$ . If  $n \gg (N - N_e)$ , that is, the excited carrier density is greater than the electron deficiency of the donor-like centers,

$$n = \sqrt{N_e N_c} \exp(-E/2kT)$$

This expression is of the same form as that employed by Frenkel (11), and becomes exactly equivalent when the electron deficiency disappears,  $N_e = N$ . On the other hand, if  $n \ll (N - N_e)$ , that is, the electron deficiency of the donorlike centers is greater than the excited electron density, then this density becomes

$$n = \frac{N_e N_c}{N - N_e} \exp(-E/kT)$$

Note that there is no factor of two in the denominator of the exponential in this expression, and hence the low field thermal activation energy of the conductivity becomes equal to the energy difference between the donor-like levels and the conduction band. Therefore the Poole-Frenkel conductivity for the case of  $n \ll (N - N_e)$  is given by

$$\sigma = q\bar{\mu} \frac{N_e N_c}{N - N_e} \exp \left[ -q(U_{p-f} - \Delta U_{p-f})/kT \right]$$

$$\sigma = \sigma_o \exp \left[ q \left( \sqrt{\frac{qV}{\pi\epsilon d}} - U_{p-f} \right) / kT \right] \quad [4]$$

where  $\bar{\mu}$  = effective carrier mobility. The current-voltage relationship will be in this case

$$I = G_o V \exp \left[ q \left( \sqrt{\frac{q}{\pi\epsilon d}} V^{1/2} - U_{p-f} \right) / kT \right] \quad [5]$$

where  $G_o = \sigma_o A/d$ ,  $A$  = sample area, and  $d$  = sample thickness. The slope of a  $\ln I - V^{1/2}$  plot from Eq. [5] is seen to be twice as great as that for Schottky emission or the "normal" Poole-Frenkel effect. Hence in summary, a bulk-limited Poole-Frenkel effect may be characterized under the above generalization by a  $\ln I - V^{1/2}$  plot slope equal to 1 to 2 times the slope of a similar plot derived from Schottky emission in the same structure.

A treatment equivalent to that quoted above has recently been given by Mark and Hartman (23), who describe the electron deficiency of the donor-like centers in terms of partial compensation by an acceptor level. A multilevel model has also been discussed in this regard by Simmons (24).

**Data analysis.**—Equation [5], above, is of the same form as the empirical Eq. [1], with

$$\beta = \left[ \frac{q^3}{\pi\epsilon d} \right]^{1/2}$$

$$\Psi = q U_{p-f}$$

This fact is by no means sufficient evidence on which to conclude that the model represents a valid interpretation of the data, as is clear from the discussion above. Also, other choices beside simple Poole-Frenkel and Schottky emission mechanisms exist. O'Dwyer (25) has shown that conduction in thin dielectric structures in which carrier injection is due to either Schottky or Fowler-Nordheim emission can give rise to  $\ln I - V^{1/2}$  plots linear over many orders of magnitude of current. A combination of mechanisms, Schottky emission from the surface of agglomerated silicon particles imbedded in silicon monoxide films, has also been proposed by Johansen (26).

In order to justify the Poole-Frenkel interpretation, it is thus necessary to test all the dependences predicted in Eq. [5] experimentally, particularly with reference to the slope of the  $\ln I - V^{1/2}$  characteristics. The parameters available are seen to be the film thickness, dielectric constant (index of refraction), and temperature. The capability of varying the thickness and index of refraction by control of deposition parameters in the silane-ammonia reactor process as described by Bean *et al.* (9) facilitates the investigation.

It should be noted that the dielectric constant,  $\epsilon$ , enters the derivation only with reference to the field due to the ionized center. If the electron leaves the vicinity of the positively charged center before ionic polarization due to its creation can occur, as is likely, the optical dielectric constant, given by the square of the index of refraction, should be used here as is pointed out by Frenkel (11).

**Dependence of Schottky-plot slope on film thickness, index of refraction.**—The measured slopes of

Fig. 6. Schottky plot slope at room temperature vs. silicon nitride film thickness. The points represent experimental data while the lines are calculated from Eq. [5].

$\ln I - V^{1/2}$  plots for samples of thickness between 600 and 6000 Å and indices of refraction of 2.0 to 2.4 are shown in Fig. 6. The values of thickness and index of refraction were obtained with an ellipsometer as described above. Superimposed on the data in Fig. 6 are three curves calculated from Eq. [5] using the relation  $\epsilon = n^2$  together with indices of refraction,  $n$ , of 1.8, 2.0, and 2.4. While there is scatter in the data it can be concluded that: (i) the predicted dependence of slope on film thickness is observed, (ii) for a given thickness, the films with higher indices of refraction have lower slopes, and (iii) all the experimental points lie within approximately 15% of the value predicted by Eq. [5]. There is an apparent trend toward experimental slope values about 10% higher than those predicted. A similar observation was made by Mead (13) for some of the thicker Ta<sub>2</sub>O<sub>5</sub> samples. He suggested that field intensification due to structural nonuniformities might cause this effect. For the silicon nitride films in the present case, the uniformity of current density measurements on metal dots of different areas indicates that if defects are controlling the conduction behavior, they must be uniformly distributed on a scale small compared to the dot sizes ( $1.8 \times 10^{-4} \text{ cm}^2 < A < 1.8 \times 10^{-2} \text{ cm}^2$ ). However, dielectric loss measurements to be discussed below do show an anomalous dependence on dot area for some slices, which might indicate the presence of defects. Defect density analysis on samples similar to those under study here, done by Tefteller (27) using an electrophoretic decoration technique, reveals densities of the order of  $10^2/\text{cm}^2$ . Assuming this value, a fair probability should exist of finding units free of these defects for all but the largest dot sizes.

With regard to the high slope values it should be noted that a decay in current lasting a few seconds to a minute or so was observed after increasing the applied voltage in the measurement of the current-voltage characteristics. While the measurements presented here are apparent steady-state values, if space charge regions associated with the contacts persist, their width will decrease the effective thickness of the films. This would cause the  $\ln I - V^{1/2}$  curve slopes to be anomalously high, as shown in Eq. [5].

Examination of the Poole-Frenkel effect expression, Eq. [5], shows that for accurate comparison, experimental values of the d-c conductance,  $I/V$ , should be plotted logarithmically vs.  $V^{1/2}$ . This has not been done for two reasons. First, for the great bulk of the films, those of fairly high resistivity, the correction makes a negligibly small change in the experimentally determined value of the curve slope, of the order of 1%. Second, it is found experimentally that for the most conductive films, where the division by  $V$  has the greatest effect on the form of the current characteris-

tics, in  $I-V^{1/2}$  plots are linear while  $\ln I/V$  vs.  $V^{1/2}$  plots depart from linearity to some degree.

The pre-exponential factor of  $V$  in the treatment leading to Eq. [5] arises from consideration of the average velocity of a carrier in transit of the film. The usual approach is to assign a constant mobility to the carriers. For an electron hopping model this mobility is of the form (28)

$$\bar{\mu} = \nu q \frac{R^2}{kT}$$

where  $\nu$  = attempt-to-escape frequency of electron in trap and  $R$  = hopping distance. Thus, the average carrier velocity is

$$\bar{\mu}E = \frac{\nu qR^2}{kT} \frac{V}{d}$$

where  $E = V/d$  = electric field strength in film and hence the pre-exponential portion of the Poole-Frenkel relationship, Eq. [5] is linear in applied voltage. A similar voltage dependence has been shown to apply to Schottky emission by Simmons (29) for the case of insulator thicknesses greater than the mean free path of the carrier.

On the other hand, Hill (30) has derived a modified Poole-Frenkel relationship on the basis of electron acceleration by the applied field between traps separated by a constant distance. This expression has a pre-exponential factor dependent on the square root of the applied field.

A model is conceivable in which the pre-exponential factor is independent of voltage if one chooses to assume both a fixed hopping distance and a mean escape time for the electrons from the trap that is much longer than the transit time between traps. However, such a model might be difficult to justify theoretically or verify experimentally.

**Temperature dependence.**—The general form of the temperature dependence of  $\ln I-V^{1/2}$  characteristics of these films was illustrated in Fig. 1. The variation of the slopes of some of these Schottky plots with temperature in the range 300°–470°C is illustrated in Fig. 7a for samples of various thicknesses and compositions. The  $T^{-1}$  lines drawn through the points indicate that the measured dependence is consistent with that predicted by Eq. [5] where a temperature-independent index of refraction and thickness are assumed. These measurements were made on slice-form samples in a controlled ambient hot stage. However, samples that had been scribed and broken into 0.25 cm chips and mounted in headers for measurement, displayed anomalous temperature dependences. Two examples are given in Fig. 7b. In particular, the upper curve of Fig. 7b is representative of four chips scribed from a slice that yielded the middle curve of Fig. 7a in the hot stage before scribing. It has been observed that the effect of scribing and breaking is to raise the level of conductance of a sample by a factor as great as 3 to 4 without changing the form of the  $I-V$  relationship. It is postulated that structural defects of some kind are propagated through the film during the scribe and break operation. The slopes of the room temperature Schottky plots are not usually changed. This is borne out in the case of the two curves referred to above in Fig. 7a and b, where the 300°K slope value is 4.2  $v^{-1/2}$  in each instance. This suggests that the observation of well-behaved  $\ln I-V^{1/2}$  dependences does not preclude the participation or even dominance of defects in the conductance characteristics.

The lower curve in Fig. 7b was observed on a scribed chip from a slice on which silicon nitride was deposited with a silane-ammonia ratio of 0.5. Analysis of  $I-V-T$  data on this sample revealed a thermal activation energy for conductance of 0.5 eV. Here again, the scribe and break operation is apparently the source of the behavior, since unscribed films of the same composition have consistently yielded activation energies of 1.0 eV (see Fig. 2) and temperature-independent values of  $\beta$ .

Fig. 7. Temperature dependence of the Schottky plot slopes of a variety of samples. (a) Slice-form measurements in agreement with Eq. [5]. (b) Anomalous results observed on scribed units.

**Polarity dependence.**—A typical example of the polarity dependence of the  $\log I-V^{1/2}$  characteristics is shown in Fig. 8. In general, it has been observed for metal-nitride-silicon structures that there is no consistent dependence of the slope of these plots on polarity, but that a slightly higher current is observed for a given applied voltage when the metal is positive rather than negative. Mead (13) has pointed out that a bulk-limited, thermal ionization mechanism, such as that proposed above, should have characteristics such that a plot of the negative vs. the positive voltage drop at a fixed current for samples of various thicknesses would have unity slope and abscissa intercept equal to twice the difference of the contact barrier heights. This situation is compared to one in which conduction is limited by field emission. In this latter case a plot of the type described above would have a slope proportional to the ratio of the contact barrier heights, to twice the difference of the contact barrier heights.

Such a plot for the aluminum-silicon nitride-silicon system is given in Fig. 9. The silane-ammonia ratio during fabrication of these films was 0.5, and thicknesses varied from 600 to 4000 Å. Positive and negative voltages at a current density of  $10^{-6}$  amp/cm<sup>2</sup> were extracted from  $\ln J-V^{1/2}$  plots made at room temperature.

Fig. 8. Polarity dependence of d-c conduction data

Fig. 9. Plot of the negative vs. positive voltage across samples of various nitride thickness at a fixed current density of  $10^{-6}$  amp/cm<sup>2</sup>. The unity slope is consistent with a bulk-limited transport mechanism.

It was determined that hysteresis effects were not of major importance in these results.

The line of unity slope passing very near the origin indicates that the data is consistent with the model proposed in this regard. Similar samples with chromium outer contacts yield points that fall along the same line.

**Pre-exponential factor.**—The value of the pre-exponential factor,  $I_0$ , in the experimental characteristics described in Eq. [1] can be determined by extrapolation of curves like those shown in Fig. 2 back to their ordinate intercepts.

Typically these values range from  $10^{-4}$  to  $10^{-1}$  amp/cm<sup>2</sup>. This is more than eight orders of magnitude smaller than the pre-exponential factor predicted for a Schottky emission mechanism in which the carrier mean free path is greater than the insulator thickness. In this case the value should be the Richardson constant, 120 amp/cm<sup>2</sup>, times the square of the absolute temperature. Application of the mobility limitation described by Simmons (29) would require mobility values of the order of  $10^{-8}$  cm<sup>2</sup>/v-sec to fit the model.

In general, the intercepts of high silane-ammonia ratio samples are larger than those of low ratio samples, within the limits given above. This is reasonable since in any model for the phenomenon like that proposed above, the pre-exponential factor should include the trap density.

### Complex Dielectric Constant

The response of a lossless dielectric to sinusoidal electrical excitation may be expressed as

$$J = i\omega\epsilon E \quad [6]$$

where  $J$  = current density,  $E$  = electric field strength,  $\omega$  = radian frequency,  $\epsilon$  = dielectric constant, and  $i$  = imaginary operator,  $\sqrt{-1}$ . If loss mechanisms are operative, resulting in an in-phase component of the current, these may be included in the formulation by definition of a complex dielectric constant

$$\epsilon^* \equiv \epsilon' - i\epsilon'' = (\epsilon'_r - i\epsilon''_r) \epsilon_0 \quad [7]$$

where  $\epsilon_0$  = permittivity of free space. The current density expression then becomes

$$J = i\omega(\epsilon' - i\epsilon'')E = \omega\epsilon''E + i\omega\epsilon'E \quad [8]$$

and it is seen that the real part of the current is proportional to the imaginary part of the dielectric constant,  $\epsilon''$ , while the real part of the dielectric constant,  $\epsilon'$ , describes the polarization or charge storage properties of the material. The physical mechanisms from

which these properties arise may be explored by measurement of the frequency and temperature dependence of these quantities (31, 32).

Such measurements have been made on the silicon nitride samples described above in the frequency range  $5 \times 10^2$  to  $10^5$  Hz and at temperatures from  $200^\circ$  to  $400^\circ\text{K}$ . A General Radio Model 1615A capacitance bridge fitted with a d-c voltage supply for sample biasing was employed. For samples on silicon substrates, a small bias was used to accumulate the silicon surface, increasing its capacitance. The bias was small enough that high-field effects were not induced in the dielectric, except in experiments designed to explore them, reported below. Samples on molybdenum substrates had voltage-independent characteristics, except for the high-field effects. The complex dielectric constant characterization of the silicon nitride was not dependent on the substrate material of the samples. The same probes and packaging techniques used for the conduction measurements were employed here.

**Real part,  $\epsilon'_r$ .**—The dependence of the real part of the complex dielectric constant of these silicon nitride films on silane-ammonia ratio in the reaction ambient is shown in Fig. 10. These measurements were made at a frequency of  $10^5$  Hz at room temperature. The values obtained were found to be very nearly frequency-independent in the range covered in these experiments. These results were derived from determination of capacitance-to-area ratios on slices with dots having four areas varying from  $7.3 \times 10^{-4}$  to  $1.8 \times 10^{-2}$  cm<sup>2</sup>, together with ellipsometric thickness measurement as described above. The error in the values is no more than  $\pm 5\%$ , and is limited by the variation of film thickness across a slice.

The saturated value of 7 for the relative dielectric constant at low silane-ammonia ratio is appreciably greater than the square of the index of refraction of the films, which is 4 in this region. This is evidence of appreciable atomic or orientational polarization in the material. The dependence of  $n^2$  on silane-ammonia ratio is very similar to that of  $\epsilon'_r$ , remaining smaller by a fairly constant amount. The location of the knee of the dielectric constant characteristic, at silane-ammonia ratios of 0.1-0.2, is like that of the  $n^2$  dependence and also of the static resistivity dependence, shown in Fig. 4. Etch rate studies done as a function of nitride preparation by Bean *et al.* (9) and by Harap (33) also indicate a change in material properties and behavior at this silane-ammonia ratio. It is thus postulated that all the above-mentioned characteristics are interrelated and attributable to the incorporation of excess silicon into the film structure at silane-ammonia ratios greater than about 0.1. These properties have been observed in films prepared in three reactors of differing configuration, so that it is believed that the results are descriptive of the nature of the

Fig. 10. Relative dielectric constant and the square of the index of refraction of silicon nitride films as a function of silane-ammonia ratio during growth.

chemical reaction involved and not merely the characteristics of a particular system.

The temperature dependence of the real part of the dielectric constant may be adequately described by a positive coefficient of approximately  $5 \times 10^{-4}/^\circ\text{K}$  between  $200^\circ$  and  $400^\circ\text{K}$  for films of low silane-ammonia ratio. At a silane-ammonia ratio of 0.5, the value of this coefficient increases to  $\sim 3 \times 10^{-3}/^\circ\text{K}$ .

**Dielectric loss,  $\epsilon''$ .**—Values of dielectric loss,  $\epsilon''$ , or loss tangent, the ratio  $\epsilon''/\epsilon'$ , were not as well behaved as the d-c conductance or  $\epsilon'$  measurements described above. On certain samples, predominantly those in which less care was taken in substrate surface preparation, an anomalous dependence of loss tangent on sample area was observed. Samples on substrates that were vapor etched in situ immediately prior to nitride deposition rarely exhibited this anomaly, but run-to-run variations in values obtained still precludes an exact characterization of a dielectric loss dependence on silane-ammonia ratio. Such a relationship is believed to exist, however, with values of  $\epsilon''$  at  $10^5$  Hz,  $300^\circ\text{K}$  of about  $10^{-3}$  for silane-ammonia ratios of 0.01 increasing to about  $3 \times 10^{-2}$  at a silane-ammonia ratio of unity.

Some typical examples of the frequency dependence of the dielectric loss characteristics are shown in Fig. 11. Curve (a) represents a sample with a degenerate n-type substrate while the curve (b) came from a sample having a 5 ohm-cm n-type substrate. Extension of the frequency range of measurement of curve (b) upward to 1 MHz shows that the high-frequency increase in  $\epsilon''$  is due to a component linearly dependent on frequency. Other experiments have shown that this difference between curves (a) and (b) is not due to the change in silane-ammonia ratio from 0.01 to 0.05, a region in which characteristics are constant.

Films on molybdenum substrates exhibit little or no frequency dependence as indicated by curve c. For a given film composition, however, the level of loss is generally somewhat higher for the molybdenum substrates than for the silicon. This may be related to the generally poorer finish of the molybdenum surface.

Fig. 11. Dielectric loss-frequency characteristics of various metal-nitride-silicon and metal-nitride-molybdenum structures. (a) Low silane-ammonia ratio nitride on degenerate silicon substrate. (b) Silicon nitride on 5 ohm-cm n-type silicon substrate. A small d-c bias used for (a) and (b) to accumulate the silicon surface. (c) Silicon nitride on moly substrate. This characteristic is bias-independent for low fields. (d) High field characteristic for a conductive silicon nitride film, displaying  $f^{-1}$  dependence. Here, bias polarity accumulates the silicon substrate.

If high electric fields are applied to the nitride film during measurement, a loss characteristic decreasing linearly with frequency like that shown in the curve (d) is observed. This low resistivity nitride sample was made with a silane-ammonia ratio of 0.5 and was biased with an electric field of  $3 \times 10^6$  v/cm, accumulating the silicon substrate. These characteristics can be understood by considering an equivalent circuit of the sample that includes a resistive component  $R_s$  due to the substrate in series with a parallel combination of a perfect capacitor  $C_i$  and a stationary resistance  $R_i$  representing the silicon nitride film. It can be shown that the dielectric loss-frequency characteristics of such a structure is given by the expression

$$\epsilon'' = \frac{(1 + \omega^2 R_s R_i C_i^2) d}{(1 + \omega^2 R_s^2 C_i^2) \omega R_i A} \quad [9]$$

where  $\omega$  = radian frequency,  $d$  = film thickness, and  $A$  = sample area, and it is assumed that  $R_s \ll R_i$ .

At low frequencies the  $\omega^2$  terms in brackets are much less than unity, leading to the simple  $\omega^{-1}$  expression involving the resistance of the insulator. Comparison of the  $R_i$  value derived from the  $\omega^{-1}$  component with the slope of a linear  $V$ - $I$  plot taken at the same bias level yields agreement with experimental error. Because of the nonlinear nature of the  $I$ - $V$  characteristic, the dynamic resistance of the films decreases with increased applied field strength. This is reflected in the loss-frequency characteristics given in Fig. 12, which shows the variation of the  $\omega^{-1}$  component of loss with increasing bias.

Because the insulator resistance in general is so much higher than the series substrate resistance, a range of frequency will exist in which the  $\omega^2$  term in the numerator of Eq. [9] will become larger than unity while the one in the denominator term remains smaller. In this regime, a linear increase in  $\epsilon''$  with frequency is predicted. Evaluating  $R_s$  from the value of the coefficient of the linear component of  $\epsilon''$  obtained from the extension of curve (b), Fig. 11, to 1 MHz yields a value of about 10 ohms, a reasonable value in terms of the parameters of the structure.

## Conclusions

It is felt that the results given above, taken together with those of Bean *et al.* (9), form a fairly consistent, unified picture of the behavior of silicon nitride films formed from the reaction of silane and ammonia.

Below a silane-ammonia ratio of 0.1 there is a range of ambient composition in which the physical and electrical properties of the material are invariant.

Fig. 12. Low frequency dielectric loss-frequency characteristics of a nitride film as a function of applied d-c field strength.

In this region, the films have a dielectric constant of  $7.0 \pm 0.1$ , very low loss, and a d-c resistivity of greater than  $10^{16}$  ohm-cm at fields below  $4 \times 10^6$  v/cm.

It is postulated that inclusion of excess silicon in the nitride films at silane-ammonia ratios above about 0.1 is responsible for the increase in dielectric constant and d-c conductivity observed. The increased conductivity is characterized by a lowering of the thermal activation energy for the process from 1.5 to 1.0 ev.

A second parameter effecting the conductance as well as the loss characteristics of the material is the scribe-and-break operation, which is assumed to act through the formation of structural imperfections or defects. Here the effect is an increase in conductivity by a factor of three or four without changing the form of the current-voltage relationship, and a dependence of dielectric loss on sample area in the range,  $1.8 \times 10^{-4} - 1.8 \times 10^{-2}$  cm<sup>2</sup>. The latter effect has also been observed in some cases in which silicon substrates were not vapor etched immediately prior to silicon nitride deposition and in cases in which molybdenum substrates were used.

The d-c conduction mechanism is found to be predominantly electronic, as opposed to ionic, under the conditions of these measurements. The choice of a model for the conduction data is based on the following considerations. First, the observation of well-behaved  $\ln I-V^{1/2}$  dependences which are linear over many orders of magnitude of current suggests the predominance of a single transport mechanism described by this relationship. Detailed measurements indicate that within experimental error the magnitude of the slope of the  $\ln I-V^{1/2}$  characteristics can be expressed as  $(q^3/\pi\epsilon d)^{1/2}/kT$ , where specific dependences upon film thickness,  $d$ ; dielectric constant,  $\epsilon = n^2$ ; and temperature,  $T$ , have been verified quantitatively. This slope value is larger by a factor of two than that predicted for Schottky emission or for the "normal" Poole-Frenkel effect as described by Frenkel (11). However, within the framework of the Poole-Frenkel effect, a condition may exist in which a slope value twice that found in the "normal" case is predicted. This condition implies a low-field thermal activation energy for conduction equal to the energy barrier for electron emission from the trap, instead of one-half the barrier as in the "normal" case. This higher slope value, which is in agreement with the experimental results, presented above, is the slope attributed to the Poole-Frenkel effect by many workers (13-15, 24, 26). It is not known whether these workers have tacitly assumed the physical conditions bringing about the change in activation energy (20, 23), or have merely misquoted Frenkel (11).

In the interpretation of the conduction data, the possibility of the interplay of competing transport mechanisms cannot be overlooked. Conduction results on the scribed material suggest the operation of a Poole-Frenkel type mechanism in which the centers are associated with structural defects in the nitride films. Also, in all samples, internal field emission of carriers trapped in centers like those described in Fig. 5 might be expected at lower temperatures where thermal excitation is inhibited. Some deviations from the  $\ln I-V^{1/2}$  dependence has been observed for samples at very high fields and low temperatures, but a satisfactory fitting of the data to a Fowler-Nordheim characteristic has not been possible at temperatures of 200°K and above.

# The Diffusion of Nickel and Chlorine into P-Type Lead Telluride at 700°C

Thomas D. George<sup>1</sup> and J. Bruce Wagner, Jr.\*

Department of Materials Science and Materials Research Center, Northwestern University, Evanston, Illinois

## ABSTRACT

The diffusion of nickel and of chlorine into single crystals of p-type lead telluride has been measured at 700°C. When nickel and chlorine diffuse simultaneously, there is an interaction between them such that the concentration profile of the nickel exhibits a sharp minimum. In addition, a p to n junction is formed within the crystal, and both the minimum and the p-n junction migrate through the crystal in proportion to the square root of time. In the absence of chlorine, no minimum or p-n junction is formed by the in-diffusing nickel. In the presence of chlorine the diffusion coefficient was approximately  $2 \times 10^{-10}$  cm<sup>2</sup>/sec for the p-n junction and approximately  $9 \times 10^{-11}$  cm<sup>2</sup>/sec for the minimum in the nickel concentration.

Because of the effect small concentrations of impurities have on the electrical properties of semiconductors, a great deal of information has been collected on diffusion of impurities into these materials. In general, researchers have either applied the usual radiotracer technique or have followed the migration of a p-n junction if the impurity induces an electrical character different from the base material. In cases where p-n junction migration was used, it usually has been assumed that the penetration profile of the impurity resembled that obtained as a solution to Fick's law with the assumption of a constant diffusion coefficient. Cunnell and Gooch (1) were among the first to show that this type of penetration profile is not obtained for diffusion of zinc into gallium arsenide. Even though the migration of the p-n junction gave a straight line when plotted against the square root of time, the penetration profile for radioactive zinc showed that a constant value for the diffusion coefficient,  $D_{Zn}$ , could not be assumed. The problem of zinc diffusion into gallium arsenide has recently been analyzed by Casey, Panish, and Chang (2), who showed that  $D_{Zn}$  is a function of the zinc concentration and the activity coefficient of holes.

When two impurities are simultaneously diffused into gallium arsenide, there can be a striking interaction. Larrabee and Osborne (3) observed that when manganese and copper or when zinc and copper were simultaneously diffused into initially n-type GaAs, the concentration profile of copper exhibited a sharp minimum. The minimum appeared to migrate through the crystal with the square root of time. No minimum was observed when copper was diffused in the absence of manganese or zinc. Peart *et al.* (4) showed that essentially the same behavior was obtained when zinc was diffused into manganese-doped GaAs. The zinc concentration profile appeared to follow the expected error function type curve, but the manganese, which was initially uniform through the crystal, redistributed during the diffusion to produce a sharp concentration minimum behind the advancing zinc front. Peart *et al.* did not follow the redistribution as a function of time, but analyzed the results in terms of the Longini and Greene theory of ionization interaction between impurities in semiconductors (5). They concluded that if manganese behaves as an amphoteric impurity in GaAs, that it can act as either a donor or acceptor, a solubility minimum should exist just behind the advancing zinc front.

It is the purpose of the present paper to report another such impurity-impurity interaction, that of nickel and chlorine in lead telluride, and to show the

importance that experimental conditions play in the study of impurity diffusion in semiconductors.

## Experimental

Single crystals of lead telluride used in this investigation were grown by the Bridgman technique from the melt. The ingots were grown in quartz ampoules 7 mm ID. Each ingot weighed about 10g. Silver-doped ingots were grown in the same way. The silver was added in the form of a Pb-Ag alloy to give a final concentration of 0.05 m/o (mole per cent) Ag<sub>2</sub>Te in PbTe.

Wafers 2-3 mm thick were cleaved from the ingot and annealed approximately 100 hr at 700°C in a dynamic argon atmosphere. This treatment corresponds to equilibrating the crystal along the P(min) line. According to the P-T-x diagram of Fujimoto and Sato (6), crystals equilibrated in this way should be p-type. Checks with a hot probe showed that all crystals were p-type following the equilibration. Seebeck and Hall measurements made on the undoped crystals after annealing in argon indicated a carrier concentration of about  $2 \times 10^{18}$  holes/cm<sup>3</sup>. This value is somewhat higher than indicated by Fujimoto and Sato (6), but they made no measurements on samples equilibrated in argon. The P(min) line they reported was calculated from free energy of formation data.

Before carrying out the diffusion anneal, each wafer was ground flat on both faces. The thickness of each wafer was approximately 2 mm. The wafers were polished using 0.1 $\mu$  alumina on felt, and rinsed in a 1:1 volume mixture of acetic acid and 30% hydrogen peroxide to remove any oxide film. The radiotracer, nickel-63, was originally in an HCl solution which was neutralized with NH<sub>4</sub>OH. The tracer was applied either by allowing the neutral <sup>63</sup>NiCl<sub>2</sub> solution to evaporate to dryness on the wafer or by electroplating from the same solution. In either case the tracer was applied to only one face of the wafer. The chlorine-36 tracer was deposited on one face of the wafer by allowing a neutral solution of Ni<sup>36</sup>Cl<sub>2</sub> to evaporate to dryness.

Several experiments were carried out using <sup>63</sup>NiCl<sub>2</sub> as a vapor source. A drop of <sup>63</sup>NiCl<sub>2</sub> solution was placed in quartz wool and allowed to dry. The wool was placed in the bottom of the diffusion ampoule followed by a quartz spacer. The PbTe wafer was placed on the spacer so that the only source of nickel or chlorine was through the vapor.

Diffusion anneals were carried out at 700°C, either in flowing argon or in sealed ampoules evacuated to 10<sup>-6</sup> Torr. The total volume of each ampoule was less than 2 cm<sup>3</sup>.

<sup>1</sup> NASA Trainee.

After the diffusion anneal the periphery of each wafer was ground down by approximately  $500\mu$  to reduce the edge effects in counting, and the wafer was mounted in a stainless steel ring. The nickel-63 and chlorine-36 activities were determined using the residual activity method in a flowing gas geiger detector with a window thickness of  $800\ \mu\text{g}/\text{cm}^2$ . After each layer was counted, a new surface was exposed by grinding off a thickness of  $2\text{--}10\mu$  using fine SiC paper and  $0.1\mu$  alumina on felt. The layer thickness was determined from changes in the focal point of a metal-lurgical microscope (400X) fitted with a dial gauge calibrated in microns. The thickness was taken from the average of three readings across the diameter of the wafer. After counting, the p-n character of the surface was determined with a hot probe attached to a microvoltmeter. The position of the p-n junction, when one formed, was determined by plotting the readings of the microvoltmeter *vs.* the penetration depth and drawing a smooth curve through the points.

### Results

The first attempt to study the diffusion of nickel into lead telluride was made on Ag-doped PbTe ( $\approx 1.9 \times 10^{19}$  Ag atoms/cm<sup>3</sup>). The <sup>63</sup>Ni was introduced by placing a drop of neutral <sup>63</sup>NiCl<sub>2</sub> solution on one face of the wafer and evaporating to dryness. The diffusion anneal was carried out in an evacuated ampoule. The results were striking in that the <sup>63</sup>Ni profile showed a sharp minimum followed by a region of relatively constant nickel concentration. Additional experiments showed that the minimum migrated through the crystal with the square root of time, and furthermore, the opposite face of the crystal showed a similar nickel concentration profile, even though the <sup>63</sup>Ni had been applied to only one face. These results (for a 12 hr diffusion anneal) are shown in Fig. 1. The diffusion coefficient for the migration of the minimum in the concentration profile was approximated by

$$D = x^2/t \quad [1]$$

where  $x$  is the position of the minimum relative to the initial surface, and  $t$  is the time of the diffusion anneal in seconds. A value of  $D_{\text{min}} = 4 \times 10^{-11}$  cm<sup>2</sup>/sec was obtained. In addition to the minimum in the concentration profile, a p-n junction was formed to the right, or at a deeper penetration in the crystal. No p-n junction migration rates were measured on the Ag-doped crystals.

In order to determine the origin of the minimum in the nickel concentration profile and the p-n junction, a series of experiments were designed to check out each of the experimental variables. For these experiments all crystals were undoped p-type PbTe,

Fig. 1. Nickel profile for Ag-doped PbTe, 12 hr at 700°C (activity in counts per minute).

having initial carrier concentration of about  $2 \times 10^{18}/\text{cm}^3$ . All experiments were carried out at 700°C.

*Diffusion in an open system.*—To compare the diffusion of nickel in open and closed systems, several anneals were made in a dynamic argon atmosphere. Both electroplated <sup>63</sup>Ni and <sup>63</sup>NiCl<sub>2</sub> deposited on one face by evaporating a solution were used as diffusion sources. The initial <sup>63</sup>Ni activity was approximately the same for each set of experiments (100,000 counts/min). The results for the two different sources were the same. After a 24 hr anneal the nickel concentration profile could be represented by a curve of the type marked A in Fig. 2. The nickel concentration initially decreased relative to the concentration at the surface. At a depth of about  $20\mu$  the concentration became constant and remained so up to about  $20\mu$  from the opposite surface. The concentration of nickel near the opposite face of the wafer also showed a higher concentration than in the center of the wafer, even though no nickel was initially applied to this face. No p-n junction was formed under these experimental conditions. The crystals were entirely p-type, including the original surfaces, at the end of the diffusion anneal. This result is in contrast to the behavior observed by Bloem and Kröger (7) in their study of diffusion of nickel into PbS in the temperature range of 300°C. Bloem and Kröger reported that the crystal became n-type as the nickel diffused into it. No attempt was made to deduce a diffusion coefficient for nickel from the <sup>63</sup>Ni profiles in the present study.

*Diffusion in a closed system.*—Diffusion anneals were carried out in small evacuated ampoules. Both electroplated <sup>63</sup>Ni and <sup>63</sup>NiCl<sub>2</sub> deposited on one surface by evaporating a neutral solution were used as diffusion sources. The concentration profile from the electroplated nickel source was the same as those obtained in an open system (curve A of Fig. 1). When <sup>63</sup>NiCl<sub>2</sub> was used as the diffusion source, the nickel concentration profile shown in curve B of Fig. 2 was obtained for a 10 hr anneal. Note the existence of both a sharp minimum in the concentration profile and the p-n junction.

Using <sup>63</sup>NiCl<sub>2</sub> as the diffusion source, the time dependence of the position of the p-n junction and also the minimum in the nickel concentration profile were measured by varying the diffusion times from 2 to 24 hr. The results are shown in Fig. 3. Both the p-n junction and the minimum migrate in proportion to the square root of time, although not at the same rate. In addition the peak width containing the minimum

Fig. 3. Migration of [Ni] minimum and p-n junction through PbTe crystal, for  $^{63}\text{NiCl}_2$  deposited on wafer. —●— p-n junction. —○— [Ni] minimum.

became broader as the diffusion time was increased. Using Eq. [1] the values for the diffusion coefficients have been estimated as  $D_{p-n} = 2 \times 10^{-10}$  cm<sup>2</sup>/sec and  $D_{\text{min}} = 9 \times 10^{-11}$  cm<sup>2</sup>/sec.

**Results using  $^{63}\text{NiCl}_2$  vapor.**—Several experiments were carried out using  $^{63}\text{NiCl}_2$  which was not in direct contact with the PbTe crystal. A drop of  $^{63}\text{NiCl}_2$  solution was placed on quartz wool and allowed to dry. The quartz wool was placed in the bottom of the ampoule followed by a quartz spacer. The PbTe wafer rested on the spacer away from the quartz wool. The partial pressure of chlorine from the dissociation of  $\text{NiCl}_2$  is  $1.7 \times 10^{-6}$  Torr (8), and the vapor pressure of the  $\text{NiCl}_2$  molecule is on the order of 1 Torr (9, 10).

It was found that p-type PbTe can be converted to n-type by heating in an evacuated ampoule containing  $\text{NiCl}_2$  even when the  $\text{NiCl}_2$  is not in direct contact with the crystal. The position of the p-n junction as a function of annealing time is shown in Fig. 4, curve A. Curve B of Fig. 4 is the p-n junction migration data taken from Fig. 3 and shown for comparison. When  $\text{NiCl}_2$  is not in direct contact with the PbTe wafer, the best fit to the data points does not extrapolate back to zero at zero time. It is not known whether the difference is due to experimental error or due to some sort of time lag brought about by the fact that  $\text{NiCl}_2$  was not initially in direct contact with the sample. The amount by which the curve misses the origin corresponds to approximately 25 min.

Fig. 4. Migration of p-n junction. —●—  $^{63}\text{NiCl}_2$  deposited on wafer (see Fig. 3). —○—  $^{63}\text{NiCl}_2$  from vapor. X  $\text{Ni}^{36}\text{Cl}_2$  (48 hr).

Crystals treated in this way had nickel-63 concentrations in the bulk which ranged from 25 to 50% of that found in crystals when  $^{63}\text{NiCl}_2$  was initially deposited onto a PbTe wafer. The nickel profiles seemed to have a minimum as was observed in samples described in section B above, but the activity was too low (on the order of 25–60 cpm above the background) to allow quantitative measurements to be made.

A parameter which could be measured easily was the initial surface activity of nickel after the diffusion anneal. These results are shown in Fig. 5. The concentration of nickel on the surface increases with the length of time of the diffusion anneal.

**Diffusion of chlorine.**—The concentration profile of chlorine was determined using  $\text{Ni}^{36}\text{Cl}_2$  deposited on one face of a PbTe wafer. Figure 6 shows the chlorine-36 distribution as well as the nickel-63 distribution obtained under similar conditions (24 hr anneals). With the counting equipment available it was not possible to obtain both profiles simultaneously because both  $^{63}\text{Ni}$  and  $^{36}\text{Cl}$  are  $\beta$ -emitters. The  $^{36}\text{Cl}$  profile is of the usual kind, i.e., it can be fitted to a plane source solution to Fick's law. The diffusion coefficient determined from the chlorine-36 profile was  $2.3 \times 10^{-10}$  cm<sup>2</sup>/sec. This value is essentially the same as found for the migration of the p-n junction.

**The effect of chlorine on nickel-doped PbTe.**—A wafer which had been previously diffused with  $^{63}\text{Ni}$  from an electroplated source (see Fig. 2, curve A) was ground down until the  $^{63}\text{Ni}$  activity was the same on both faces. This crystal was then placed in an evacuated ampoule containing  $^{63}\text{NiCl}_2$  and re-annealed for 24 hr at 700°C. The source and sample were not in con-

Fig. 5. Initial nickel-63 surface activity (counts per minute) after anneal in  $^{63}\text{NiCl}_2$  vapor.

Fig. 7. Effect of chlorine on the distribution of nickel in nickel-doped PbTe (activity in counts per minute). A. Nickel-63 activity before anneal in  $^{63}\text{NiCl}_2$  vapor. Crystal p-type throughout. B. Distribution of nickel-63 after 24 hr in  $^{63}\text{NiCl}_2$  vapor.

tact with each other but corresponded to the same arrangement as described in section C above. The results are shown in Fig. 7, where the dashed line A represents the approximate  $^{63}\text{Ni}$  activity before the re-anneal with the  $^{63}\text{NiCl}_2$  source. Curve B represents the distribution of nickel in the crystal after 24 hr. While it is almost certain that some nickel entered the crystal from the vapor, there has been an obvious redistribution of the nickel with an apparent increase in the nickel concentration, particularly at the surface. The opposite face of the wafer showed the same redistribution. The p-n junction was found just ahead of the minimum, although closer to the original surface than for samples initially containing no nickel. The p-n junction of curve B, Fig. 7 occurs at  $20\mu$ . For the same diffusion time (24 hr), the p-n junction for samples initially containing no nickel occurs at about  $40\mu$ .

### Discussion

The results obtained, while not representing a complete or quantitative picture of the interaction of chlorine and nickel in p-type lead telluride, allow a qualitative interpretation of this interaction. Several observations can be made based on the p-n behavior after diffusion and the relative rates of diffusion. First, the nickel can be assumed to occupy lead sites since interstitial nickel should produce n-type conductivity, but crystals into which nickel was diffused in the absence of chlorine retained their p-type character. Second, the chlorine is assumed to occupy tellurium sites since interstitial chlorine ions should produce p-type conductivity, in contrast to what is observed. Third, under the diffusion conditions imposed here, the nickel is assumed to migrate through the lattice via interstitials. This assumption is based on the mechanism proposed by Bloem and Kröger (7) following their low temperature studies of nickel diffusion in PbS. They proposed that nickel migrates via interstitials but occupies lead sites in the crystal. The n-type conductivity produced by the nickel was presumed to be due to that interstitial nickel which entered the lattice in excess of the available lead vacancies. The fact that in the present study nickel alone was not found to produce n-type conductivity may simply indicate a smaller nickel concentration in our crystals. The chlorine, on the other hand, is assumed to migrate via anion vacancies. This assumption is based partly on the magnitude of the diffusion coefficient for the p-n junction observed in this study and partly on the work of Fedorovick (11) who measured the tracer diffusion coefficient of chlorine-36 in

n-type PbSe and sodium-doped ( $\frac{1}{2}$  m/o  $\text{Na}_2\text{Se}$ ), p-type PbSe. He found that the energy of activation for diffusion in p-type material was 0.86 eV while in n-type it was 0.45 eV. At  $700^\circ\text{C}$  the diffusion coefficients for  $^{36}\text{Cl}$  calculated from Fedorovick's data are  $1 \times 10^{-10}$   $\text{cm}^2/\text{sec}$  for sodium doped, p-type crystals and  $7.5 \times 10^{-11}$   $\text{cm}^2/\text{sec}$  for n-type crystals. Assuming that chlorine migrates via anion vacancies, one would expect a higher diffusion coefficient in the case of the sodium-doped PbSe due to the larger number of anion vacancies in the doped material.

If a singly ionized chlorine atom enters the lattice and occupies an anion lattice site, it will produce the observed n-type conductivity because of the difference in valence states between the tellurium and chlorine. In order to preserve the electroneutrality of the crystal, however, one of two subsequent reactions must occur for each two chlorine atoms added. Either a tellurium interstitial must be produced or a lead vacancy created. The latter reaction will be assumed to occur as was also assumed by Koval'chik and Maslakorets from bromine in PbTe (12). In the Kröger-Vink notation this reaction can be represented by

assuming a singly ionized lead vacancy.

If nickel occupies vacancies on the lead sublattice, then an increase in the chlorine concentration, and hence an increase in the number of available lead vacancies, should signal an increase in the solubility of nickel in lead telluride. Qualitatively this is what is observed. Figure 7 shows the result of exposing a PbTe crystal containing nickel to a chlorine atmosphere. The surface concentration of nickel increases by nearly ten fold and there is a smaller increase in the nickel concentration to the right of the p-n junction. In addition, it was found that the surface concentration of nickel was a time dependent function when crystals of PbTe were exposed to  $^{63}\text{NiCl}_2$  vapor, see Fig. 5. This observation also supports the earlier assumption that chlorine causes the production of lead vacancies rather than tellurium interstitials. Some of the increase at the surface may be due to nickel being transferred from the vapor phase as was discussed in the previous section. By comparing the surface concentration of curve B in Fig. 7 with Fig. 5 it is seen that even accounting for vapor transport of nickel-63, there is still about a six fold increase in the surface concentration following the re-anneal.

The most important question of the minimum in the nickel concentration profile must now be examined. This involves both solubility and migration. The introduction of chlorine into the lattice necessitates the creation of lead vacancies. Concurrently, the lead ions in the lattice must migrate away from the created cation vacancies in the region of the passing chlorine front. Since the region near the surface of the crystal already contains a larger number of vacancies than the bulk crystal because of the migrating chlorine front, it is probable that the excess lead atoms would migrate back toward the surface of the crystal. An attempt was made to confirm this point by determining the diffusion profile of  $^{210}\text{Pb}$  into a crystal that was exposed to an atmosphere of  $\text{NiCl}_2$ . It was expected that there would be an observable effect on the  $^{210}\text{Pb}$  distribution curve. Within experimental error, however, the  $^{210}\text{Pb}$  concentration profiles obtained in the presence of  $\text{NiCl}_2$  were the same as those obtained when  $\text{NiCl}_2$  was not present. The fact that very little difference was observed in the  $^{210}\text{Pb}$  concentration profile may be due in part to the small variation in cation vacancy concentration across the PbTe phase field. According to Fujimoto *et al.* (6) the lead vacancy concentration varies by only a factor of three in going from the Pb/PbTe phase boundary to the Te/PbTe phase boundary. The effect of chlorine on the cation vacancy concentration in the present experiments

may be expected to be smaller than this factor of three.

All that is really required, however, to produce a minimum in the nickel concentration profile is that the migration of lead cations toward the surface be slower than the in-diffusion of chlorine. In this event, there will be a pile-up of cations behind the advancing p-n front. In this region, too, there will be a minimum in the number of available lead vacancies which nickel can occupy and a resulting decrease in the nickel concentration with a concurrent concentration increase at deeper penetration (Fig. 6). It was pointed out earlier that the position of the minimum nickel concentration and the advancing p-n front tend to move away from each other. That is, the p-n front migrates through the crystal faster than the minimum. This would be the case if the in-diffusion of chlorine were faster than the out-diffusion of the cations resulting from the required increase in cation vacancy concentration. Further, it was observed that the migration of the minimum in the Ag-doped PbTe was somewhat slower ( $D_{\min} = 4 \times 10^{-11}$  cm<sup>2</sup>/sec) than in undoped PbTe ( $D_{\min} = 9 \times 10^{-11}$  cm<sup>2</sup>/sec) as would be expected if cation vacancy migration were the controlling factor for the migration of the minimum.

Experiments in this laboratory indicate that in undoped crystals equilibrated under argon, the diffusion coefficient for <sup>210</sup>Pb is about  $2 \times 10^{-11}$  cm<sup>2</sup>/sec at 700°C. As mentioned earlier the presence of NiCl<sub>2</sub> in the ampoule does not appear to affect this result. Boltaks (13) gives the diffusion coefficient of tellurium as  $3 \times 10^{-10}$  cm<sup>2</sup>/sec at 700°C. In the absence of other influencing factors, then, anion migration is faster than cation migration in lead telluride at 700°C. While the simultaneous diffusion of nickel and chlorine cannot be fully explained in such simple terms, the relative migrative rates for the minimum in the nickel concentration profile and the p-n junction differ in the same direction as the two self-diffusion coefficients. ( $D_{\min} = 9 \times 10^{-11}$  cm<sup>2</sup>/sec,  $D_{p-n} = 2 \times 10^{-10}$  cm<sup>2</sup>/sec). Further it may be expected that any effect which retards anion migration will enhance cation migration.

One other observation was made which deserves comment. When nickel-63 alone was allowed to diffuse into PbTe under flowing argon, the nickel concentration was found to be higher near both surfaces of the wafer than in the bulk of the crystal. In the bulk of the crystal away from the surfaces the nickel concentration appeared to be uniform throughout the wafer. There are two possible explanations of these results. First it is possible that nickel migrates rapidly on the surface of PbTe and enters the crystal from the unplated surface after diffusing around the edge of the crystal. Alternatively the explanation may lie in a thermodynamic argument. If nickel behaves similarly to lead in the lattice as suggested by Kowal'chik and Maslakorets (12), then increasing the nickel concentration via diffusion would upset the defect equilibrium in the crystal. Specifically, nickel would decrease the cation vacancy concentration. At the same time, however, thermodynamics demands that the defect equilibrium constant (either the Schottky constant or Frenkel constant) be maintained. The crystal will begin changing its composition in order to satisfy the defect equilibrium constant. The cation vacancy concentration would be expected to begin increasing at the surface and migrate into the crystal. Since nickel appears to be very mobile at 700°C, it would then be expected to migrate to regions of higher vacancy concentrations, thus restoring the defect equilibrium both in the bulk of the crystal and near the surface.

### Summary

The diffusion of nickel and the simultaneous diffusion of nickel and chlorine from a NiCl<sub>2</sub> source have been studied in p-type lead telluride at 700°C. Marked

differences in the results were obtained depending on the experimental conditions employed.

When the diffusion anneal was carried out in an open system under flowing argon, the same results were obtained with both an electroplated <sup>63</sup>Ni source and when <sup>63</sup>NiCl<sub>2</sub> was deposited on one face of the crystal. Nickel diffuses through the lattice very rapidly. The nickel concentration was found to be higher on both faces of the wafer than in the bulk of the crystal even though nickel was initially deposited on only one face of the wafer. Under both of these experimental conditions, the crystal remained p-type throughout.

When diffusion anneals were carried out in a sealed ampoule two different results were obtained. When <sup>63</sup>Ni was electroplated onto one face of the PbTe wafer, the results were identical to those obtained in an open system. However, when <sup>63</sup>NiCl<sub>2</sub> was deposited on one face of the wafer by evaporation of the neutral solution, the <sup>63</sup>Ni concentration profile showed a sharp minimum followed by a region of relatively constant nickel concentration. The minimum in the <sup>63</sup>Ni profile was present near both faces of the wafer even though the <sup>63</sup>NiCl<sub>2</sub> was applied initially to only one face. The minima migrated through the crystal in proportion to the square root of time with an apparent  $D_{\min} = 9 \times 10^{-11}$  cm<sup>2</sup>/sec. In addition to the minimum in the nickel concentration profile, a p-n junction was formed at slightly deeper penetration in the crystal. The p-n junction also migrated through the crystal in proportion to the square root of time but with an apparent diffusion coefficient of  $2 \times 10^{-10}$  cm<sup>2</sup>/sec.

An experiment was carried out using a nickel-63 doped PbTe crystal. NiCl<sub>2</sub> was placed in the sealed ampoule but not in contact with the crystal. The <sup>63</sup>Ni concentration profile at the end of 24 hr was similar to those obtained when <sup>63</sup>NiCl<sub>2</sub> was evaporated onto an undoped crystal showing that the chlorine caused a redistribution of nickel behind the advancing chlorine front.

These results illustrate another impurity-impurity interaction in semiconductors and emphasize the role which experimental conditions play in altering diffusion in semiconductors.

## Epitaxial Deposition of Germanium onto Semi-Insulating GaAs

S. A. Papazian\* and A. Reisman\*

IBM Watson Research Center, Yorktown Heights, New York

### ABSTRACT

Smooth layers of epitaxial Ge have been grown on semi-insulating GaAs using the pyrolysis of  $\text{GeH}_4$ . Depositions were made between  $600^\circ$  and  $850^\circ\text{C}$  and the range most suitable for obtaining good growth was defined as  $650^\circ$ – $750^\circ\text{C}$ . Other factors affecting smoothness were substrate preparation, gas purity, and the total thickness of the deposit. The conductivity type profile of the deposits was determined using a traveling thermal probe on a beveled portion of the deposit, and it showed evidence of outdiffusion of both As and Ga from the substrate into the deposit in addition to As incorporation from the vapor phase. The semi-insulating properties of the GaAs wafers were measured before and after depositions, and it was found that no degradation of the resistivity occurred if the substrates were treated in a  $90\text{H}_2\text{SO}_4:5\text{H}_2\text{O}_2:5\text{H}_2\text{O}$  solution prior to depositions.

The recent interest in planar devices fabricated in Ge has prompted this investigation which is concerned with the possibility of defining a dielectric isolation scheme for this semiconductor. Since dielectric isolation approaches are expected to reduce stray capacitance effects encountered in junction isolated integrated circuits, a Ge/insulating substrate couple could be very useful if high quality epitaxy of Ge could be achieved. Semi-insulating GaAs is an attractive substrate for Ge because of the close match of the room temperature lattice constants ( $a_{\text{Ge}} = 5.6575\text{\AA}$ ,  $a_{\text{GaAs}} = 5.6533\text{\AA}$  (1)), and the apparent similarity in thermal expansion coefficients of the two materials (2).

The method used for depositing Ge epitaxially onto semi-insulating GaAs in this study was the pyrolytic decomposition of  $\text{GeH}_4$  in a  $\text{H}_2$  atmosphere according

to the reaction  $\text{GeH}_4(\text{g}) \xrightarrow{\text{heat}} \text{Ge}(\text{s}) + 2\text{H}_2(\text{g})$ . This reaction has been reported previously for deposition of Ge epitaxially onto Ge (3), onto conventional GaAs (4), and onto spinel (5), with some preliminary studies involving the use of semi-insulating GaAs (6).

The pyrolysis of  $\text{GeH}_4$  offers an advantage in the present instance over other deposition methods in that no possibility of vapor back-etching due to the presence of halogens or halogen acids exists. It has been found, for example, that in a  $\text{GeCl}_4$  reduction process for the deposition of Ge onto GaAs, extensive attack of GaAs occurs and degenerately doped n-type Ge layers result.

The purpose of this investigation was to define growth conditions necessary for achieving high quality Ge epitaxy on semi-insulating GaAs and to determine whether this process was amenable to controlled doping of the deposits, and if the high temperatures used were compatible with the semi-insulating properties of the GaAs.

### Experimental

The experiments were performed in a single wafer, vertical, flow type reactor shown in Fig. 1. Only quartz, Pyrex, and stainless steel have been used in constructing the system. Undoped  $\text{GeH}_4$ , obtained from the Matheson Company, enters the system at point A, after passing through a submicron filter to re-

move particulate matter. At point B the  $\text{GeH}_4$  is diluted with a small quantity of  $\text{H}_2$ . Part of this mixture is then introduced into the rest of the system at point C, the rest being bled out of a chimney and burned off. The  $\text{GeH}_4$ - $\text{H}_2$  mixture is diluted further with large quantities of  $\text{H}_2$  (which makes up most of the total flow rate through the reactor) at point D, before entering the reaction tube through a nozzle. This double dilution of  $\text{GeH}_4$  with  $\text{H}_2$  enables us to obtain good control over a wide range of  $\text{GeH}_4$  fluxes. Dopants can be introduced at points E and F. Of the two sources of  $\text{H}_2$  (Matheson, ultra high purity) seen in Fig. 1, the one passing through the Pd-Ag purifier is used for depositions while the other is used for continuous flushing of the system when not in operation. The pump line is used for evacuating the  $\text{GeH}_4$  lines before and after replacing  $\text{GeH}_4$  tanks. Failure to evacuate the lines thoroughly before and after exposure to the atmosphere resulted in coating of the lines with  $\text{GeO}_2$ .

The wafers are supported on a single crystal Ge pedestal which also acts as a susceptor for R. F. heating. The semi-insulating Cr doped GaAs wafers, which were obtained either from the Monsanto Company or from in-house crystal growing facilities, were polished in  $\text{NaOCl}$  using the method described by Reisman and Rohr (7). The single crystal Ge pedestals were etched in a  $5\text{HNO}_3:1\text{HF}$  solution, lapped and degreased in organic solvents after each run, and

cleaned ultrasonically in a  $1\text{NaOCl}:3\text{H}_2\text{O}$  solution just prior to depositions. The deposition temperature was measured and controlled via a thermocouple housed in a quartz well imbedded in the Ge pedestal. After loading the wafer, the system was flushed for a suitable length of time with purified  $\text{H}_2$  prior to a 30 min bake-out at the deposition temperature, after which  $\text{GeH}_4$  was admitted to the reactor. At the end of the depositions the  $\text{GeH}_4$  was turned off and the system flushed with purified  $\text{H}_2$  at temperature for approximately 20 min.

### Results and Discussion

Smooth layers of epitaxial Ge such as shown in Fig. 2 were grown on the (110) surface of semi-insulating GaAs under a variety of growth conditions. The pattern discernible in Fig. 2 is localized around slip lines in the  $\langle 1\bar{1}0 \rangle$ ,  $\langle 1\bar{1}\bar{2} \rangle$ , and  $\langle 1\bar{1}\bar{2} \rangle$  directions. The step height of this pattern is  $< 50\text{\AA}$  as was determined by using an interferometer with a laser attachment. The parameters affecting the surface quality of the epitaxial layers are discussed below.

**Effect of substrate preparation.**—The preparation of the GaAs substrates prior to depositions was found to be a very critical step. It was necessary to treat the NaOCl polished wafers in a  $90:5:5 = \text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$  solution just before epitaxy as described by Berkenblit *et al.* (8) in order to remove a possible residue left on the surface after polishing. The criticality of this step can be seen from a comparison of Fig. 2 and 3 showing two  $8\mu$  deposits grown under

Fig. 3. Ge deposit grown on a semi-insulating GaAs substrate which was used without any additional treatment after NaOCl polishing.

identical conditions. The layer shown in Fig. 2 was grown using a substrate treated in  $90:5:5 = \text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$  solution whereas the substrate used in Fig. 3 was not treated following polishing.

**Effect of gas purity.**—The purity of both the  $\text{H}_2$  and the  $\text{GeH}_4$  had pronounced effects on surface quality. It was necessary, for instance, to purify the "ultra high purity"  $\text{H}_2$  further through a Pd-Ag diffuser, since failure to do so resulted in rough deposits. It was also important that the  $\text{GeH}_4$  be free of contaminants such as  $\text{B}_2\text{H}_6$ ,  $\text{HCl}$ ,  $\text{CO}_2$ ,  $\text{O}_2$ , and  $\text{H}_2\text{O}$  which were sometimes present in earlier  $\text{GeH}_4$  samples as by-products of the manufacturing process. These impurities caused undesirable nucleation and/or etching.

**Effect of total thickness of the deposit.**—The thicker a deposit, the more structured it became as can be seen on a  $20\mu$  deposit shown in Fig. 4. The growth pattern which is not very strong in deposits of up to  $10\mu$ , begins to affect surface quality above this thickness. The step height of the lines seen in Fig. 4 were measured to be approximately  $2000\text{\AA}$  by a Tally surf machine.

**Effect of deposition temperature.**—The temperature was found to be a most important parameter, since it not only affected the surface quality, but also the electrical characteristics of the deposits. Depositions were made between  $600^{\circ}\text{C}$ – $850^{\circ}\text{C}$  measured on the thermocouple, with surface temperatures approximately  $50^{\circ}$  lower, as was ascertained with an infrared pyrometer under simulated growth conditions. The temperatures mentioned in this paper refer to the values measured on the thermocouple. Good epitaxy, such as seen in Fig. 2, was achieved in the temperature range of  $650^{\circ}$ – $750^{\circ}\text{C}$ . However,  $750^{\circ}\text{C}$  was found to be a borderline case, since the results were erratic. Figure 5 depicts a deposit grown at  $600^{\circ}\text{C}$ . Its thickness,  $9\mu$ , is about the same as that of the deposit shown in Fig. 2, but faceted rather than smooth growth is observed. Figure 6, on the other hand, shows a  $4\mu$  deposit grown at  $775^{\circ}\text{C}$ . The structure on the surface consists of depressions, some of which extend through the deposit into the substrate as much as  $5\mu$ . Similar behavior is observed with thicker deposits grown at this temperature. It was observed, on beveling these layers, that the pits were coated by what is believed to be a Ge-Ga alloy. This assumption is based on the fact that a  $\text{H}_2$ -bake out of a GaAs wafer at ca.  $775^{\circ}\text{C}$  showed surface etching and evidence of liquid Ga droplets on the Ge pedestal, around the edge of the wafer. The fact that GaAs vaporizes incongruently above approximately  $680^{\circ}\text{C}$  (9,10) thus making the presence of a free Ga phase possible, supports this

interpretation. Depositions made at above 800°C resulted in extensive alloying of the GaAs substrate with both the Ge deposit and the pedestal.

*Effects of  $\text{GeH}_4$  concentration, growth rate, and total flow rate (or linear gas stream velocity).*—Results indicated that in the temperature range of 650°–700°C, varying the concentration, and therefore the growth rate, between 0.02–0.14%  $\text{GeH}_4$  by volume in  $\text{H}_2$  total flow rates ranging between 1.5–7 l/min, which corresponds to linear gas stream velocities of 150–720 cm/min at room temperature, does not affect surface quality.

In Fig. 7 and 8 growth rate *vs.* concentration curves are shown using two different techniques for varying the  $\text{GeH}_4$  concentration. The data for Fig. 7 were acquired using a constant input flow rate of  $\text{GeH}_4$  (constant flux) and varying the concentration by varying the flow rate of the diluent gas. The data points for this figure are therefore each at a different linear gas stream velocity. As might be anticipated, because the residency time of  $\text{GeH}_4$  molecules in the vicinity of the pedestal decreases with increasing linear gas stream velocity, the reaction efficiency decreases. At the higher flow rates, in addition, surface cooling probably plays a part in decreasing the growth rate. In Fig. 8, the data were acquired at constant total flow rate, the  $\text{GeH}_4$  concentration being varied by varying the  $\text{GeH}_4$  input flow rate. It is seen from Fig. 8

Fig. 7. Growth rate vs. total flow rate at constant  $\text{GeH}_4$  flux

Fig. 8. Growth rate vs.  $\text{GeH}_4$  concentration at constant total flow rate.

that the curve is sublinear indicating that as the concentration is increased, the growth tends to become surface rather than mass transport controlled (11). Figure 9 shows a semi-log plot of growth rate as a function of  $1/T \times 10^3$  in the interval 600°–750°C using the conditions ca. 0.03%  $\text{GeH}_4$  at a total flow rate of 6.9 l/min. Since this flow rate is referenced to 25°C and 1 atm, the data of Fig. 9 are obviously each at a different linear gas stream velocity due to the temperature effect. Because of the latter and because the growth rate data do not cover even one decade, the apparent linearity of growth rate with  $1/T$  is considered fortuitous and not valid for obtaining an activation energy. Furthermore, since the data at 650°C and 0.03%, Fig. 8, appear to lie in a mass transport controlled region of growth, an extracted activation energy from Fig. 9 would not be related to the growth kinetics at the GaAs surface.

Fig. 9. Growth rate vs.  $10^3/T$  (concentration:  $\sim 0.03\%$   $\text{GeH}_4$  by volume).

At 750°C an apparent linear gas stream velocity effect was observed, where with decreasing total flow rates, surfaces became more structured. Since no flow rate effects were observed at the lower temperatures, this effect at 750°C may be attributed to differences in surface cooling, which was measured to be 15°-20°, between the highest and lowest flow rates, i.e., from 1.5 l/min to 7 l/min (linear gas stream velocity, 150 cm/min—720 cm/min at room temperature). Thus, at the low flow rates, the surface temperature is in the region where the onset of micro-alloying is suspected, whereas at the higher flow rates the surface is sufficiently cooled to place it in an insensitive temperature region.

**Random surface defects.**—The most commonly encountered random defect on the surface of the deposits is shown in Fig. 10. The flat, platelet type growths seen are attributed to imperfections on the starting substrate. In addition to this type of random defect, conglomerates of crystallites are also observed. These latter spurious nucleations seem to be due to dusting from the vapor phase. These random defects have been observed under all growth conditions. The density of these defects on deposits grown on Ge substrates is considerably less than on the GaAs.

**Crystalline perfection.**—The crystalline perfection of the deposits was determined by x-ray diffractometry using the method described by Cole and Stemple (12). Using this method, a perfection number is obtained which gives an indication of dislocations, strains, and other imperfections in the material. The x-ray perfection scale ranges from 1.45 for a perfect crystal to 6.0 for a mosaic crystal on (110) oriented single crystals. Both the GaAs substrates and the Ge deposits had perfection numbers ranging between 2-3.5 which, however, did not show an obvious dependence on either substrate preparation or on the growth parameters discussed.

**Electrical characteristics.**—The suitability of the GeH<sub>4</sub> pyrolysis process for controlled doping was investigated in an attempt to gain some insight into problems such as possible out-diffusion of As and/or Ga from the interface into the deposit and incorporation of As and/or Ga from the vapor phase during growth due to the incongruent vaporization of GaAs. The background impurity contribution from the undoped GeH<sub>4</sub> source and from the system was determined by depositing Ge onto high resistivity (~ 8 ohm-cm), p-type Ge substrates using similar conditions. The deposits were measured to be approximately 7 ohm-cm, p-type corresponding to a background im-

Fig. 10. Random defects encountered on Ge deposits grown on semi-insulating GaAs.

purity concentration of approximately  $4.5 \times 10^{14}$  acceptors/cc.

Ge deposits of up to approximately  $10\mu$  grown on semi-insulating GaAs below 750°C for most cases showed n-type surfaces. The resistivity, measured at the surface using a spreading resistance technique, varied between 0.05-0.2 ohm-cm, depending on growth conditions. However, a few growths were obtained in which regions of both n- and p-type conductivity were observed at the surface.

Deposits grown at 750°C, on the other hand, generally exhibited all p-type surfaces, with the exception of a few samples which showed either all n-type conductivity or both p- and n-type regions. Those deposits grown at above 750°C, where surface alloying occurred, were degenerately p-type. The occasional nonreproducibility of surface characteristics obtained on deposits below 750° and at 750°C indicates that more than one mechanism is responsible for impurities being incorporated into the growing layer.

Profiles of conductivity type throughout the deposit were next determined using a traveling thermal probe on beveled samples. A schematic representation of typical traveling thermal probe traces for deposits grown at temperatures lower than 750°C is shown in Fig. 11. As can be seen from this diagram, starting at the Ge/GaAs interface, a p-type layer extends into the deposit, approximately  $0.1\mu$ . This interface layer gives way to an n-type region that continues to the surface.

The following considerations are involved in interpreting the existence of such a profile. If we assume that only a fraction of the available As at the Ge/GaAs interface [ $\sim 4.6 \times 10^{14}$  As atoms/cm<sup>2</sup> on (110) GaAs] diffused into the Ge deposit, this amount would indeed be sufficient to account for all of the n-type impurities in the deposit, assuming the entire n-layer to have the same carrier concentration as the one measured at the surface. Furthermore, because of the vast difference in the diffusion constants of Ga and As in Ge, e.g., at 700°C,  $D_{As} \approx 2.5 \times 10^{-12}$  cm<sup>2</sup>/sec, whereas  $D_{Ga} \approx 5 \times 10^{-15}$  cm<sup>2</sup>/sec, the Ga moving into the deposit more slowly than the As would give rise to the small p-type layer detected at the interface. A comparison of the thickness of this layer with diffusion calculations supports this argument. However, the above argument does not explain all the data. For example, if we consider the duration of depositions (1-3 hr), the thickness of the deposits and the As diffusion constants involved, not all the n-type impurity can be attributed simply to out-diffusion from the GaAs surface. Because of the p-type nature of the impurities contributed from both the GeH<sub>4</sub> and the system, the only other source of n-type doping is believed to be As in the vapor resulting from GaAs dissociation. This dissociated As is then incorporated into the growing layer before the wafer is completely covered with deposited Ge. This As now serves as a second source for As diffusion in the deposit. Thus, it is assumed that both an interfacial out-diffusion of Ga and As plus a less systematic vapor phase impurity incorporation are responsible for the observed general conductivity type profile and surface conductivity type variations.

Fig. 11. Schematic representation of the conductivity type profile of Ge layers grown on semi-insulating GaAs at  $< 750^\circ\text{C}$ .

It was observed on thicker deposits, i.e.,  $> 16\mu$ , that the n-type region gave way finally to a p-layer that continued to the surface. This is attributed to the fact that once the wafer is completely covered with Ge, the only source of As is that out-diffusing at the GaAs-Ge interface in addition to that already incorporated from the vapor due to incongruent GaAs vaporization. At this point then, the  $\text{GeH}_4$  background impurity concentration of approximately  $10^{14}$  acceptors/cc is the only source of contamination and further growth is p-type in nature.

For depositions made at  $750^\circ\text{C}$  the above picture is somewhat unsatisfactory. The conductivity type profiles of the deposits in general again show the small p-type region at the Ge/GaAs interface leading into the n-type region, followed finally by the p-type top layer. This profile, however, is present on thin deposits, i.e.,  $5\text{-}10\mu$ . Furthermore, the surface p-type conductivity is much greater than could be supplied by the p-impurity present in the  $\text{GeH}_4$ ; while the latter would yield approximately 7 ohm-cm material, the surfaces were measured to be about 0.01 ohm-cm. A possible explanation is the following. During growth at  $750^\circ\text{C}$  and before the substrate is completely covered with Ge, the GaAs is vaporizing incongruently at a rapid rate with tiny pools of Ga forming on the Ge pedestal (possibly as a Ge-Ga alloy). In fact, such globules are visually observed on the pedestal after growth at higher temperatures. Once the wafer is overcoated with Ge, the pools of Ga on the pedestal now represent the primary source of contamination. This source exerts a sufficient vapor pressure to cause the heavy p-type doping. Even though the vapor pressure of Ga is very low at  $750^\circ\text{C}$ , it is sufficiently high for conducting p-type diffusions into Ge.

The deposits grown above  $750^\circ\text{C}$  which showed surface alloying were degenerately p-type throughout the deposit. The results given above imply that on depositions made below  $750^\circ\text{C}$ , the impurity levels are such that controlled doping can be obtained whereas at  $750^\circ\text{C}$  one would run into considerable difficulty.

*Semi-insulating properties.*—The compatibility of the  $\text{GeH}_4$  process with retention of semi-insulating properties of GaAs was investigated by measuring the spreading resistance of the substrates before and after deposition. The measurements after deposition were made by either etching islands in the deposit and measuring the spreading resistance between them, or by etching away the entire deposit and measuring the bare GaAs.

No degradation of the spreading resistance of the semi-insulating GaAs was observed if the substrates had been treated in the  $90\text{H}_2\text{SO}_4:5\text{H}_2\text{O}_2:5\text{H}_2\text{O}$  solution prior to deposition, regardless of growth condi-

tions in the deposition range  $650^\circ\text{-}750^\circ\text{C}$ . Some degradation was observed on as-polished substrates. This degradation was only a surface effect, however, since removal of several microns of the GaAs surface in the  $90\text{H}_2\text{SO}_4:5\text{H}_2\text{O}_2:5\text{H}_2\text{O}$  solution restored the semi-insulating properties of the substrate to their original value.

### Summary

It appears then, in summary, that smooth epitaxial Ge films of approximately  $10\mu$  can be deposited on semi-insulating GaAs in the temperature range of  $650^\circ\text{-}750^\circ\text{C}$  under a variety of growth conditions with good potential for controlled doping and without damaging the semi-insulating properties of the GaAs.

### Acknowledgment

The authors are greatly indebted to Messrs. M. Berkenblit and M. Sampogna for preparation of the substrates, Messrs. R. P. McGouey and B. J. Stoeber for their assistance with the experiments, Dr. A. G. Blachman and Mr. M. E. Cowher for the electrical characterizations, and Drs. T. B. Light and S. Krongelb for helpful discussions.

Manuscript submitted Feb. 2, 1968; revised manuscript received ca. May 8, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 159.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Epitaxial Growth of Mirror Smooth Ge on GaAs and Ge by the Low Temperature $\text{GeI}_2$ Disproportionation Reaction

M. Berkenblit,\* A. Reisman,\* and T. B. Light

IBM Watson Research Center, Yorktown Heights, New York

## ABSTRACT

Ge epitaxial layers were grown by the  $\text{GeI}_2$  disproportionation reaction at  $350^\circ\text{C}$  on (110) semi-insulating GaAs and Ge substrates. The epitaxial surfaces are comparable in quality to those obtained by the higher temperature hydrogen reduction of  $\text{GeCl}_4$  on Ge substrates. Modifications of previously reported apparatus and growing conditions which lead to the enhanced surface qualities are described. These modifications include an increase in average linear gas stream velocity and  $\text{GeI}_2$  concentrations, improved substrate surface preparation techniques, and the protection of the wafer surface from spurious nucleation during the growth process.

There has been considerable recent interest in the use of planar Ge for ultra high performance switching circuit applications at these laboratories as well as for other device applications elsewhere. Ge grown on semi-insulating GaAs is being investigated as a starting material for an alternate, improved approach to device isolation over the presently employed junction isolation schemes. The Ge/GaAs system is potentially useful because of the apparent close structural match of the two materials, the semi-insulating properties of Cr doped GaAs, and the retention of these insulating properties during low temperature Ge deposition processes and subsequent device fabrication steps.

Among the potential methods for the deposition of Ge on GaAs (*i.e.*, pyrolytic reduction of the tetrahalide, decomposition of  $\text{GeH}_4$ , and the dihalide disproportionation reaction) the  $\text{GeI}_2$  disproportionation reaction is attractive because of the associated low temperatures. Notably, low temperature reactions have led in the past to poor surface qualities when compared to higher temperature processes. In addition, the surface characteristics showed a marked dependency on substrate orientation (1, 2).

This paper describes a method by which n- and p-type Ge epitaxial layers may be grown via the iodine process at a substrate temperature of  $350^\circ\text{C}$  on (110) semi-insulating GaAs and Ge substrates. The grown surfaces are mirror smooth and shiny, and are comparable to those obtained by the higher temperature hydrogen reduction of  $\text{GeCl}_4$  on Ge substrates. Changes in deposition parameters, improved substrate preparation and modifications of the apparatus previously reported on (2) are described which have led to the enhanced surface qualities. Of note also, is the fact that growth rates using the new procedure are comparable to those obtained in higher temperature epitaxial growth techniques.

## Experimental Procedure

**Flow and temperature.**—The Ge layers were grown in a horizontal system with a 1 in. diameter deposition chamber. The pertinent thermodynamics and basic flow system have been described earlier by the authors (2-4). The substrates were maintained at a temperature of  $350^\circ\text{--}355^\circ\text{C}$  and the Ge source bed was held at  $600^\circ\text{--}620^\circ\text{C}$ . A 15%  $\text{H}_2$ -85% He mixture was used as a carrier gas at an input flow rate of 915 cc/min which, expressed as a room temperature linear gas stream velocity at the substrate, is 190 cm/min. The  $\text{I}_2$  source for the HI generator was maintained at  $65^\circ\text{--}75^\circ\text{C}$  ( $\pm 0.2^\circ\text{C}$  at a given temperature) which encompasses a range of HI pressures of 11.0-20.5 Torr.

**Reagents.**—The carrier gas was mixed in the system (Matheson ultra pure  $\text{H}_2$  and He). Traces of  $\text{O}_2$  and  $\text{H}_2\text{O}$  were removed by passing this mixture through a heated Pt bed ( $450^\circ\text{C}$ ) in series with a liquid nitrogen freeze out trap. The HI generator used was the modified version described in ref. (5).

The Ge source material was Eagle-Picher intrinsic grade (40 ohm-cm or better). In order to extend the time between reloading Ge charges, a larger source bed was constructed to replace the one employed in the previously reported system. This new design also offers a more efficient reaction path through the crushed Ge to accommodate the higher flows employed in the present work. As shown in Fig. 1 the source bed was made up of a number of interconnected chambers in a 1 in. diameter tube. The openings in each chamber were positioned in such a way as to insure passage of the gas through the crushed Ge.

GaAs wafers were prepared both from Monsanto (horizontal Bridgeman) Cr doped and from Czochralski pulled Cr doped single crystals grown by S. Blum of our laboratories. Ge substrates, which were used as controls, were obtained from Czochralski pulled single crystals grown in house by C. Lent. Both the GaAs and Ge bulk single crystals were oriented to within  $0.5^\circ$  of the (110), sliced, lapped, and then polished using the  $\text{NaOCl}$  method of Reisman and Rohr (6). In the case of p-type Ge substrates, electropolishing in a KOH solution was used to assess effects of polishing on subsequent deposits. None were noted.

**Additional surface preparation.**—It was found that in order to obtain mirror smooth epitaxial deposits, both the GaAs and Ge wafers, after polishing and storage, required an additional chemical treatment immediately prior to being loaded into the epitaxial reactor. GaAs wafers were treated in a solution of  $90\text{H}_2\text{SO}_4:5\text{H}_2\text{O}_2:5\text{H}_2\text{O}$  (7, 8) in a hanging basket arrangement as shown in Fig. 2. The substrates were suspended in the solution in the basket, and stirring was effected via a rotating magnetic bar. The basket consists of a shallow quartz dish supported by rods and permits the cleaned wafer to be water quenched in

Fig. 1. Germanium source bed

\* Electrochemical Society Active Member.

Fig. 2. Hanging basket used for cleaning GaAs substrates

situ immediately following the chemical treatment. A marked difference in surface texture was observed with different methods of agitation. For example, a pronounced degradation in the form of an orange peel texture results with the use of ultrasonic agitation in place of the method described.

Ge substrates, however, could be cleaned satisfactorily by a 90 sec treatment in a 3:1 solution of  $H_2O$ :NaOCl stock solution (5% available chlorine) using ultrasonic agitation. A final degree of surface cleaning was achieved by heating both the Ge and GaAs substrates, in situ, in a  $H_2$  ambient for 30 min ( $600^\circ C$  for GaAs and  $700^\circ C$  for Ge) prior to deposition.

One further factor that markedly affected deposit quality is the method employed for drying the substrates following chemical treatment and rinsing. If done improperly, it will invariably result in an epitaxial deposit marred by many surface imperfections. A procedure that yielded good results consistently is as follows. After chemical treatment, and quenching the chemical action in deionized water, the wafer is transferred from the etching basket to a vacuum chuck. During this transfer procedure a stream of deionized water is played on the wafer surface to prevent partial drying of the wafer. Simultaneously, the hosing action is stopped and a jet of high pressure clean nitrogen is directed onto the wafer surface to roll the water off. This enables almost instantaneous removal of liquid from the surface with a minimum amount of evaporation being permitted to take place. An example of the effects of a poor drying technique is shown in Fig. 3. In this case water was allowed to ball to the center of the substrate resulting in some drying of the edges before the surface was completely dried. Both photographs show the sharp difference in density of surface contamination. A grown layer on such a surface clearly replicates the two distinctly different areas.

**Vacuum chuck substrate holder.**—Previously, epitaxially deposited films were subject to the formation of large spurious overgrowths or "spikes" during the deposition process. Spikes as high as  $20\text{--}30\mu$  were observed on  $5\mu$  thick deposits when the substrates were placed face up in the horizontal deposition chamber. Because deposition in a disproportionation growth process is not confined to the substrate, but occurs on the walls of the reactor also, minute particles can flake off and serve as nuclei for these coarse protrusions. To eliminate the problem of dusting from the walls of the reactor and the attendant growth of spikes, a vacuum chuck was used to hold the substrate face down in the gas stream. The wafer holder, shown in Fig. 4, consists of a semicylindrical quartz piece and a support tube extending out of the system

Fig. 4. Deposition chamber showing the position of vacuum chuck and dopant line.

to a vacuum line. The flat face is lapped and has a 25 mil vacuum orifice.

**Doping.**—Both n- and p-type Ge layers were grown using  $AsH_3$  and  $BI_3$ , respectively, as the dopant sources. The impurities were introduced into the system through a separate gas line as shown in Fig. 4.

### Experimental Results

In our earlier work, the low temperature HI-Ge vapor transport system was used at relatively low linear gas stream velocities (l.g.s.v.) and low hydrogen iodide vapor pressures (15-30 cm/min and HI in the range of 2-4 Torr). Velocities and concentrations were chosen so that the source was maintained at equilibrium, and deposition was in a quasi equilibrium or mass transport limited condition. Growth rates were in the range of  $0.3\text{--}0.8\ \mu/hr$ . The epitaxial films on (110) surfaces had a dull matte appearance that was unsuitable for application of small dimension photo-masking techniques. Deposits, exhibiting improved but still inadequate surface characteristics, were grown under these low growth rate conditions on several orientations other than the (110). The best surfaces under these conditions were obtained on wafers that were cut  $25^\circ$  off (100)  $\rightarrow$  (110).

The first significant improvement in surface quality of deposits on (110) substrates was obtained by increasing both the l.g.s.v. and simultaneously increasing the vapor phase concentration of  $GeI_2$ . (As a matter of convenience the concentrations are expressed in terms of HI vapor pressures or temperature of the iodine source bed.) Attending these changes, the growth rate increased to a value ranging between 5 and  $10\ \mu/hr$  depending on the exact conditions of the experiment. This increase in growth rate was, however, less than would have been predicted theoretically (3) indicating a lowered efficiency of deposition. For example, the set of conditions leading to a  $10\ \mu/hr$  growth rate should have yielded a value of  $18\ \mu/hr$ . Such a result is not unexpected since with increasing l.g.s.v. and gas phase reactant concentration the deposition tends to become surface limited in the manner described by the authors (5). The improvement of surface smoothness coincident with changing the growth parameters in the direction of a surface rather than a mass transport regime is in clear distinction to observations made by Silvestri for hydrogen reduction of  $GeCl_4$  (9). In such a system he found that enhanced surface smoothness was directly related to maintaining the deposition in a mass transport controlled regime.

A range of operating conditions were determined which were suitable for obtaining mirror smooth surfaces. At a constant  $GeI_2$  concentration (11.0 Torr HI), depositions were of excellent quality in the l.g.s.v. range from 95 to 190 cm/min. No experiments were

Fig. 3. Example of poor drying technique.

Fig. 5(a, left). Surface obtained using full process; (b, center). surface obtained without pretreatment of substrate; (c, right). surface obtained using low l.g.s.v. and low  $\text{GeI}_2$  concentration.

conducted above 190 cm/min, and it was observed that at 50 cm/min surface quality had already degraded noticeably. At a constant velocity of 190 cm/min, smooth and shiny surfaces were obtained with HI pressures ranging between 5 and 35 Torr. Using HI pressures in the range 35 to 50 Torr resulted in visually mirror smooth surfaces which exhibited microscopic etch structures. The etching phenomenon at these higher HI pressures is believed to be due to incomplete equilibration at the Ge source.

In order to demonstrate the necessity for the several cleaning and growth condition steps described above, a series of  $5\mu$  layers of Ge were deposited on (110) semi-insulating GaAs. The three cases presented for comparison essentially summarize the over-all process. Figure 5a shows a surface obtained using the full process. Figure 5b is a micrograph of a deposit using all the critical procedures except that the substrate was not chemically treated prior to loading into the reactor. The deposit shown in Fig. 5c was obtained on a substrate which had the full cleaning procedure, but where both low l.g.s.v. and  $\text{GeI}_2$  concentration were employed for deposition. As is evident, only the surface obtained by employing all of the critical steps is shiny and smooth. The others vary in texture from hazy to dull matte.

Stacking faults were not observed either by interference contrast microscopy or by x-ray topography. In addition, the crystal perfection of the as-grown layers were equal to that of the starting substrate as determined by the x-ray crystallographic technique of Cole and Stemple (10).

Once conditions were established for obtaining reproducibly good Ge layers, the behavior of these layers in subsequent heating cycles (*i.e.*, oxide deposition, diffusions) was examined. Ge deposits on GaAs sub-

strates show signs of plastic deformation after heating to  $500^\circ\text{C}$  or higher. This behavior is attributed to strain due to a mismatch in the thermal coefficients of expansions between the GaAs substrates and the Ge epitaxial layers. Strain relief then occurs along slip planes during the heating cycle. An example of such slip line formation is shown in Fig. 6. As-grown layers were slip free, Fig. 5a.

Plastic deformation was not observed in Ge grown on Ge substrates, nor would it be expected if the strain is due to a thermal expansion mismatch. Ge grown on GaAs by the pyrolysis of  $\text{GeH}_4$  at  $650^\circ\text{C}$ , as reported by Reisman and Papazian (11), shows slip line formation after the initial deposition heat cycle.

Annealing or slow heat cycling did not appreciably change the extent of plastic deformation. A much thicker Ge deposit ( $33\mu$ ), than normally grown ( $5-10\mu$ ), shows the minimum decrease in crystal perfection after heating to above  $500^\circ\text{C}$ . The use of thin substrates ( $< 5$  mils) prevented slip line formation because the strain relief in such a structure occurs by elastic bending of the substrate.

A complete discussion of the plastic deformation characteristics of the epitaxial films and a calculation of the stress and extent of the thermal mismatch is discussed by the authors in a separate paper (12).

In an attempt to extend the usefulness of the deposition process, several experiments were performed on orientations other than (110). It was found that the growth conditions which provided mirror smooth deposits on (110) surfaces yielded structured surfaces on (111) and (100) oriented substrates. Since our interest at the present time is confined to (110) surfaces in conjunction with their use in fabricating Post Alloy Diffused transistors (13), no attempt was made to define growth parameters applicable to other orientations.

The Ge layers deposited in the undoped state were all n-type having a carrier concentration of the order of mid  $10^{14}$  to low  $10^{15}/\text{cc}$ . The preparation of more heavily doped n-type material is readily achieved with use of  $\text{AsH}_3$  as an arsenic source. The decomposition of  $\text{AsH}_3$  occurs at the growth temperatures employed and the addition of  $\text{AsH}_3$  to the vapor phase did not perturb the deposition process.

The use of  $\text{B}_2\text{H}_6$  as a p-type dopant source is standard in the high temperature  $\text{GeCl}_4$  process and was examined in the disproportionation growth.  $\text{B}_2\text{H}_6$  was found usable in obtaining deposits with resistivities varying between 1-0.005 ohm-cm under low growth rate conditions. However, at the growth rates arrived at for the present work, B addition via  $\text{B}_2\text{H}_6$  presented a problem. The maximum doping achieved was 0.02 ohm-cm and with further increase in  $\text{B}_2\text{H}_6$  concentrations the surface quality of the epitaxial deposits degraded.

At the low temperatures of the disproportionation reaction, the incorporation of B into the growing

Fig. 6. Example of slip line formation

layer is assumed to occur via an intermediate formation of  $BI_3$  by the reaction of  $B_2H_6$  with HI (14, 15) in the gas stream. The  $BI_3$  yield is limited by the HI available in the gas stream and the efficiency of the reaction at the temperature of the epitaxial reactor. Therefore, in order to produce the necessary  $BI_3$  concentrations a large excess of  $B_2H_6$  is required which in turn perturbs the epitaxial reaction. To eliminate the dependence on this reaction, a source of  $BI_3$  was substituted for the  $B_2H_6$ . A range of concentrations were then obtained, sufficient for all doping levels required, by passing He or  $H_2$ -He mixtures at varying flow rates through a bed of solid  $BI_3$  maintained at room temperature. In the range of operation there was no degradation in surface quality with increasing  $BI_3$  concentrations.

Impurity concentration profiles were not measured. However, samples of Ge grown with high and low B concentrations on semi-insulating GaAs were angle lapped. Traveling hot probe measurements did not indicate the presence of any n-type regions near the interface. This implies a negligible back etching reaction. In addition, after etching the Ge deposit away, there was no measurable degradation of the insulating properties of the substrate material.

#### Summary

A low temperature process for the deposition of smooth and shiny Ge epitaxial layers at  $350^\circ C$  has been evolved. Each of the process steps are important and are necessary for good surfaces. These process steps include: (I) Chemical treatment to clean surfaces. (II) Rinsing and drying with care to avoid evaporative drying. (III) Holding the wafer in an upside down position during growth, to prevent dusting and attendant spike formation. (IV)  $GeI_2$  concentrations, expressed in terms of HI pressure, in the range 5-35 Torr. (V) Linear gas stream velocities, referred to room temperature, greater than 50 cm/min.

## Plastic Deformation in Epitaxial Ge Layers Grown on Single Crystal Semi-Insulating GaAs

T. B. Light, M. Berkenblit,\* and A. Reisman\*

IBM Watson Research Center, Yorktown Heights, New York

#### ABSTRACT

The compatibility of Ge and GaAs, in terms of their temperature dependent mechanical properties, is described in this paper. Examination at room temperature of epitaxial Ge layers grown on wafers of single crystal, semi-insulating GaAs, at substrate temperatures of  $700^\circ C$  by pyrolytic dissociation of  $GeH_4$ , reveals evidence of plastic deformation immediately following the epitaxial deposition process. Plastic deformation is observed in epitaxial Ge layers grown at  $350^\circ C$ , by disproportionation of  $GeI_2$ , only after a subsequent annealing cycle to at least  $500^\circ C$ . The low substrate temperature Ge films, however, show elastic bending of thin substrates after deposition and cooling to room temperature. Based on these observations, it is possible to estimate the differential thermal expansion coefficient between Ge and GaAs ( $1 \times 10^{-6}/^\circ C$ ), and to use this result to estimate the critical shear stress for plastic deformation under low strain rate conditions ( $6.7 \times 10^7$  dynes/cm<sup>2</sup>). Interface dislocations are not observed.

The present work was prompted by observations made during the course of the work described by Papazian and Reisman (1), and by the present authors (2). Plastic deformation of the Ge epitaxial layers

grown on semi-insulating GaAs substrates was observed. This observation seemed inconsistent with the considerations that have motivated much work with the Ge/GaAs hetero-epitaxial system. These considerations, which were discussed by Amick (3) are: (i) same

\* Electrochemical Society Active Member.

crystal type; (ii) lattice parameter match within 1/10%; and (iii) indications of a good coefficient of thermal expansion match. The last assumption is questionable, at least as to whether the match is good enough.

In the present work, observations are made regarding the presence or absence of plastic deformation in Ge layers on GaAs substrates as a function of deposition temperature or annealing treatments. Slip line observations are correlated with the known slip planes and directions. Observations made from elastically bowed and plastically deformed samples are used to estimate the differential thermal coefficient of expansion between Ge and GaAs and to estimate the critical shear stress for Ge under low strain rate conditions.

### Experimental Procedure

The substrates used in this study were fabricated from Cr doped semi-insulating GaAs single crystals obtained from Monsanto or grown by S. E. Blum of this laboratory. (110) oriented substrates were prepared for epitaxial growth as described by Berkenblit *et al.* (2), and 5-10  $\mu\text{m}$  thick Ge epitaxial layers were grown using the  $\text{GeI}_2$  disproportionation reaction at 350°C (2) and the  $\text{GeH}_4$  pyrolytic decomposition reaction at 600°-700°C as described by Papazian and Reisman (1).

Slip steps resulting from plastic deformation were observed using the Nomarski interference contrast technique. This technique is capable of resolving step heights as small as 30Å (4). The presence of plastic deformation was inferred from the presence of slip steps. The validity of this inference was checked using x-ray topographs obtained with the scanning oscillator technique (5).

Elastic bowing of thin GaAs substrates after epitaxial Ge deposition was detected by measuring the surface profile across the front and back surfaces of the substrates before and after Ge deposition. A microscope with a 45X objective and vertical fine focus adjustment with 1  $\mu\text{m}$  scale divisions was used. The microscope stage was used to translate the wafer by 1 mm intervals as profile readings were made. The method was capable of determining profiles to within  $\pm 2 \mu\text{m}$ .

In some instances, Ge was selectively removed from the GaAs substrate using standard photolithographic masking techniques and etching with a 1:2 solution of 30%  $\text{H}_2\text{O}_2$  in water at a temperature of 40°C. The ratio of Ge to GaAs etch rates in this etchant is greater than 1800:1.

**Crystallographic considerations.**—Germanium plastically deforms by glide (slip) on the {111} planes, in the  $\langle 110 \rangle$  directions (6) (see Appendix.).

Figure 1 shows the situation as it applies to a (110) oriented wafer. Two {111} slip planes are perpendicular to the surface of the wafer along lines of intersection in the  $[\bar{1}12]$  and  $[\bar{1}\bar{2}1]$  directions (Fig. 1a), and two intersect the surface at 35° 16' along lines of intersection that are parallel and along the  $[\bar{1}10]$  direction (Fig. 1b).

Fig. 1. Relationship between {111} slip planes and (110) surface of wafer. (a) {111} planes intersecting along lines in  $\langle 112 \rangle$  directions; (b) {111} planes intersecting along lines in  $\langle 1\bar{1}0 \rangle$  direction.

### Results

**Low-temperature deposition (350°C).**—After the Ge layer was grown (at 350°C) and the sample cooled to room temperature, no slip steps were observable. X-ray transmission topographs (Fig. 2) showed no evidence for plastic deformation or interface dislocations. The Ge layer was, however, in elastic compression. Figure 3 shows the profile of a 63  $\mu\text{m}$  thick GaAs wafer with a 10  $\mu\text{m}$  thick Ge epitaxial layer. Before deposition the profile was flat within  $\pm 2 \mu\text{m}$ . The maximum deflection in this case is 160  $\mu\text{m}$ . Assuming a mismatch of the thermal coefficients of expansion, the resulting configuration (Ge side convex) indicates that the GaAs has contracted a larger amount during cooling from the growth temperature. The GaAs exerts a compressive force on the Ge layer.

If a sample is heated to 500°C or above, either directly after growth at 350°C or after first cooling to room temperature, the Ge layer shows slip lines along the  $[\bar{1}10]$  direction as shown in Fig. 4. There are two resolvable sets of slip lines, with the lines of one set having the opposite contrast compared to those of the other set. The presence of two sets of slip lines is more clearly demonstrated if the surface is about 2° off orientation with respect to the (110) planes as shown in Fig. 5. In this case the light and dark contrast lines are not parallel. Consideration of Fig. 1b will show that if the wafer surface is not parallel to the (110) plane, the slip lines due to one set of planes (111) will not be parallel to the slip

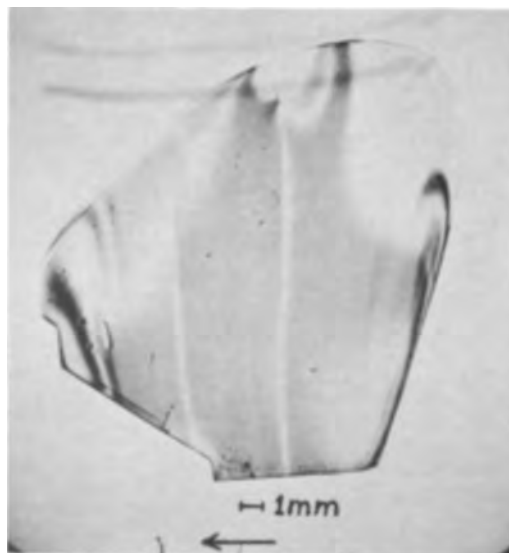

Fig. 2. Transmission (SOT) x-ray topograph of low-temperature Ge deposit (10  $\mu\text{m}$ ) on GaAs substrate (125  $\mu\text{m}$ ). The arrow indicates the direction of the  $[220]$  diffraction vector ( $\text{AgK}\alpha$  radiation).

Fig. 3. Elastic deflection profile of low-temperature Ge deposit on a thin GaAs substrate.

Fig. 4. Photomicrograph showing slip steps parallel to  $[1\bar{1}0]$  direction in low-temperature Ge deposit on GaAs substrate after heating to  $500^\circ\text{C}$ .

lines due to the other set of planes  $(1\bar{1}\bar{1})$ . This is true except when the line of intersection between the tilted surface and the  $(110)$  plane is the  $[1\bar{1}0]$  direction.

If the Ge layer is selectively removed from the GaAs substrate by masking and etching in  $\text{H}_2\text{O}_2$  solution (Fig. 6), the offsets of the slip lines at the  $10\ \mu\text{m}$  Ge-GaAs steps due to the  $35^\circ 16'$  inclinations of the  $\{111\}$  slip planes with respect to the  $(110)$  surface can be observed. Note that the light and dark contrast slip lines correspond to opposite offsets. In this figure, the slip steps are still visible on the GaAs surface. The 1800:1 ratio of Ge etch rate to GaAs etch rate and the length of exposure of the bare GaAs surface to the etch precludes the possibility that these steps are due

Fig. 6. Photomicrograph showing slip steps on original Ge deposit surface (4 islands) and on GaAs substrate surface after selective removal of Ge layer.

to replication of the surface topography, and the offset would not be observed if replication were occurring. Thus the presence of these slip steps on the GaAs surface indicates that the GaAs had been plastically deformed near the Ge/GaAs interface. A Berg-Barrett x-ray reflection topograph (Fig. 7) of a sample with the Ge layer removed in the central region confirmed that plastic deformation had occurred in the GaAs substrate.

*High-temperature deposition ( $600^\circ\text{--}700^\circ\text{C}$ ).*—In samples deposited at  $600^\circ\text{--}700^\circ\text{C}$ , three sets of slip steps were observed in the Ge layer after it was cooled to room temperature. This indicates that all four  $\{111\}$  slip planes were active at the higher temperatures. The slip steps due to the perpendicular slip planes,  $(\bar{1}11)$  and  $(111)$ , are more difficult to detect. The area in Fig. 8 has all three sets but only two can be seen clearly. An x-ray reflection topograph (Fig. 9) shows all three sets clearly.

### Discussion

The results can be summarized with the help of Fig. 10. The solid curve indicates schematically the variation with temperature of the critical stress for plastic yielding in the Ge layer. Assuming a difference in the thermal coefficients of expansion for Ge and GaAs, the dashed curves indicate schematically how the stress in the Ge layer would build up as the

Fig. 8. Photomicrograph showing two visible sets of slip steps in high-temperature deposit of Ge on GaAs substrate; third set is not visible.

Fig. 9. Berg-Barrett reflection topograph of high-temperature Ge deposit on GaAs substrate. The arrow indicates the projection of the  $[333]$  diffraction vector onto the wafer surface (CuK $\alpha$  radiation).

Fig. 10. Schematic showing behavior of critical yield stress and stress due to thermal expansion as a function of temperature. Solid line, schematic behavior of critical yield stress for Ge vs. temperature; dashed lines, stress due to differential thermal expansion between Ge and GaAs (assumed zero at deposition temperature).

temperature increases or decreases from the deposition temperature.

An elastic compressive stress was present after the sample had been cooled to room temperature after deposition at 350°C (curve 1). When the sample was heated from its deposition temperature of 350°C to higher temperatures (curve 2), a tensile stress was expected, and it has been determined that plastic yielding occurs at 500°C, *i.e.*, curve 2 intersects the critical yield stress curve at 500°C. If the Ge layer was deposited at high temperature and cooled to room temperature (curve 3), it was expected that the film would be stressed in compression and it has been determined that the film yields plastically at some relatively high temperature.

In the case of low-temperature Ge deposits heated to 500°C, plastic deformation occurred only by slip on two,  $(111)$  and  $(1\bar{1}\bar{1})$ , out of the four possible slip planes, whereas the high temperature Ge deposits plastically deformed by slip on all four  $\{111\}$  slip planes. This difference of behavior indicates that in the first case the critical shear stress (at 500°C) was exceeded in the  $(111)$  and  $(1\bar{1}\bar{1})$  slip planes only, while in the second case the critical shear stress (at approx. 600°C) was exceeded on all four slip planes. If the thermal coefficient of expansion mismatch provides the driving force for stress in the Ge layer, it can be assumed as a first approximation that the stress is confined to directions in the  $(110)$  plane.

From the discussion in the Appendix, and referring to Fig. 1, it is seen that the  $(\bar{1}\bar{1}\bar{1})$  and  $(1\bar{1}\bar{1})$  planes are perpendicular to the  $(110)$  plane (Fig. 1a). Considering the  $(\bar{1}\bar{1}\bar{1})$  plane, the component of stress in the  $[110]$  slip direction normal to the  $(110)$  plane is nominally zero. The components of stress in the  $[0\bar{1}\bar{1}]$  and  $[10\bar{1}]$

slip directions are in metastable equilibrium with the components in the  $[01\bar{1}]$  and  $[\bar{1}0\bar{1}]$  directions respectively so that there is no net slip, but this balance is easily upset by deviations from the assumed ideal situation. The same argument holds for the  $(111)$  plane.

The  $(111)$  and  $(1\bar{1}\bar{1})$  planes are at an angle of 35°16' with the  $(110)$  plane (Appendix). Considering the  $(111)$  plane, for example, there is a finite component of stress parallel to the  $[0\bar{1}\bar{1}]$  and  $[\bar{1}0\bar{1}]$  directions which gives rise to a shear couple acting across the slip plane. The resulting slip will cause slip steps parallel to the  $[1\bar{1}0]$  direction. The same argument holds for the  $(1\bar{1}\bar{1})$  plane except that the shear couple is reversed and a slip step of opposite sign will develop on the same surface and parallel to the  $[1\bar{1}0]$  direction.

The observed slip line configuration on the low-temperature Ge deposits heated to 500°C is that which would be expected from the above considerations. The observed slip on all four  $\{111\}$  slip planes for the high-temperature Ge deposit is probably the combined result of the lower critical yield stress at higher temperature and deviations from the idealized planar stress configuration assumed.

**Stress calculations.**—Some quantitative estimates of stress buildup and differential coefficient of expansion can be obtained from measurement of substrate bowing following deposition of low temperature films. Thus, the stress in the film can be calculated knowing the maximum substrate deflection. If it is then assumed that this stress is due to the differential coefficient of expansion,  $\Delta\alpha = \alpha_{\text{GaAs}} - \alpha_{\text{Ge}}$ , then  $\Delta\alpha$  can also be estimated from the maximum deflection. An estimate of the critical yield stress of the film at 500°C can then be obtained from this value of  $\Delta\alpha$ .

The formulas relating maximum deflection ( $\delta_{\text{max}}$ ),  $\Delta\alpha$  and the maximum stress ( $\sigma_{\text{max}}$ ) in bimetallic elements have been developed by Timoshenko (7). They hold for cases from thin films on thick substrates up to cases involving layers of equal thickness. Consequently, these equations are applicable to the present results where the ratio of film to substrate thickness is 10/63. The maximum deflection is given by

$$\delta_{\text{max}} = 3A \cdot \Delta\alpha \cdot \Delta T \cdot d^2/4(t_f + t_s) \quad [1]$$

where  $\Delta T$  is the temperature difference between the temperatures of deposition and measurement,  $d$  is the wafer diameter,  $t_f$  is the film thickness,  $t_s$  is the substrate thickness, and  $A$  is a function of the ratios  $t_f/t_s$  and  $E_f/E_s$ , where  $E$  is Young's modulus. For a measured deflection of 160  $\mu\text{m}$  and  $\Delta T = 325^\circ\text{C}$ , the estimated differential thermal expansion is  $\Delta\alpha = 1.2 \times 10^{-6}/^\circ\text{C}$ .

The maximum stress in the film,  $\sigma_{\text{max}}$ , is given by

$$\sigma_{\text{max}} = \frac{8 \delta_{\text{max}}}{d^2(1-\nu)} \left[ \frac{1}{6(t_f + t_s)t_f} (E_f t_f^3 + E_s t_s^3) + \frac{t_f E_f}{2} \right] \quad [2]$$

where the symbols have the same meaning as in Eq. [1], and  $\nu$  is Poisson's ratio (assumed the same for both materials and = 0.27). For the measured deflection of 160  $\mu\text{m}$  the estimated stress is  $\sigma_{\text{max}} = 4.8 \times 10^8$  dynes/cm $^2$ .

Equation [2] can be simplified by neglecting  $t_f$  compared to  $t_s$ , yielding Eq. [3] (8)

$$\sigma_{\text{max}} = \frac{4E_s t_s^2 \delta_{\text{max}}}{3(1-\nu)t_f d^2} \quad [3]$$

The calculation using this simplified relation results in the value  $\sigma_{\text{max}} = 5.1 \times 10^8$  dynes/cm $^2$  which is in excellent agreement with the result using Eq. [2].

Combining Eq. [1] and [3] yields an expression for the stress in terms of  $\Delta\alpha$  and  $\Delta T$ . An estimate of the

critical yield stress of the Ge film at 500°C can be made using the calculated differential thermal expansion ( $\Delta\alpha \approx 1 \times 10^{-6}/^\circ\text{C}$ ) and  $\Delta T = 150^\circ\text{C}$  (350°-500°C). The value estimated is  $1.9 \times 10^8$  dynes/cm<sup>2</sup>, which is equivalent to a critical resolved shear stress (i.e., component in the slip plane along the slip direction) of  $6.7 \times 10^7$  dynes/cm<sup>2</sup>. The estimated strain rate, which is calculated from the heating rate, is  $2 \times 10^{-6}$ /sec. The data of Bell and Bonfield (9) yields an extrapolated value of  $5.5 \times 10^7$  dynes/cm<sup>2</sup> at the same strain rate and temperature, for Ge with a dislocation density of approx.  $1 \times 10^6/\text{cm}^2$ .

**Relative coefficients of thermal expansion.**—Fig. 11 shows the available data for the coefficients of thermal expansion of polycrystalline Ge (solid line) and GaAs (dashed lines). The horizontal lines indicate that a constant value was quoted for the temperature range shown. The referenced data are for powdered (3, 10, 11) or polycrystalline (12, 13) specimens, except for the portion of the Ge curve below room temperature which was determined using a single crystal with  $\langle 100 \rangle$  orientation (14). The results given as a constant were determined by x-ray lattice parameter measurements (3, 10, 11), and the rest were determined using interference dilatometry.

The value,  $\Delta\alpha \approx 1 \times 10^{-6}/^\circ\text{C}$ , calculated above seems consistent with the GaAs data of Pierron, Parker, and McNeely (11) relative to the data for Ge. The data points shown in Fig. 11 were determined by Feder and Light (15) for a  $\langle 110 \rangle$  oriented single crystal of Cr doped semi-insulating GaAs, using a Fizeau type interferometer with a laser light source (16). The calculated value for  $\Delta\alpha$  is not consistent with the GaAs data of Feder and Light relative to the data for polycrystalline Ge. Efforts to obtain data for single crystal Ge above room temperature are in progress.

**Slip and lattice parameter mismatch.**—No evidence for mismatch dislocations, due to the small lattice parameter mismatch between Ge and GaAs, has been found in this study. Two previous studies have been concerned with the nature of imperfections in Ge/GaAs couples. Meieran studied GaAs layers on Ge substrates (17), and found slip which he concluded probably was due to the mismatch between lattice parameters. Krause and Teague studied Ge layers on semi-insulating GaAs substrates (18), and found effects that they concluded were due to misfit dislocations at the interface. In both cases the epitaxial deposition temperature was greater than 700°C. It is evident from the present study that plastic deformation due to the differential coefficient of thermal expansion is present in both of these previous studies. It is also evident from the present study that, if plastic deformation can be avoided by deposition at lower substrate temperatures, the presence of interface dislocations can be determined unambiguously.

Fig. 11. Thermal coefficient of expansion as a function of temperature for Ge and GaAs.

Fig. 12. Unit cubes showing relationship between  $\{111\}$  slip planes,  $\langle 110 \rangle$  slip directions, and  $(110)$  orientation of wafers.

X-ray topographs (Fig. 2) indeed show no evidence for interface dislocations and indicate that the interface is completely coherent.

### Conclusions

1. Ge layers deposited at low temperature (350°C) on semi-insulating GaAs substrates are not plastically deformed, but are under elastic compressive stress.
2. The low deposition temperature Ge layers plastically deform when heated to 500°C or above.
3. Ge layers deposited at higher temperatures (600°-700°C) are plastically deformed when observed at room temperature.
4. The driving force for stress is the differential coefficient of thermal expansion between Ge and GaAs.
5. Interface dislocations are not present at the Ge/GaAs interface.

### APPENDIX

**Diamond cubic structure, slip planes, and slip directions.**—There are four sets of  $(111)$  planes in the diamond cubic (Ge) crystal structure. These are the  $(111)$ ,  $(1\bar{1}\bar{1})$ ,  $(\bar{1}11)$  and  $(\bar{1}\bar{1}1)$  planes indicated by shading in Fig. 12a and 12b. The six-slip directions  $[0\bar{1}1]$ ,  $[\bar{1}01]$ ,  $[011]$ ,  $[101]$ ,  $[110]$  and  $[\bar{1}\bar{1}0]$  in Fig. 12a and 12b are indicated by arrows. The  $(110)$  plane, which corresponds to the wafer surface under observation, and its relation to the unit cubic cell is shown by the dashed outline which extends out of the cube. The  $(111)$  and  $(1\bar{1}\bar{1})$  planes, shaded in Fig. 12a, intersect the  $(110)$  plane along parallel lines in the  $[\bar{1}\bar{1}0]$  direction. The acute angle between either of these slip planes and the  $(110)$  plane is  $35^\circ 16'$ . The  $(\bar{1}11)$  and  $(\bar{1}\bar{1}1)$  planes, shaded in Fig. 12b, intersect the  $(110)$  plane along lines in the  $[\bar{1}\bar{1}2]$  and  $[\bar{1}12]$  directions, and are perpendicular to the  $(110)$  plane. These directions make an acute angle of  $54^\circ 44'$  with the  $[110]$  direction.

All of the  $\langle 110 \rangle$  slip directions, except the  $[110]$  direction, have a component perpendicular to the  $(110)$  plane and can thus give rise to slip steps observable on a  $(110)$  oriented surface. Slip on the  $(111)$  and  $(1\bar{1}\bar{1})$  planes would result in slip steps parallel to the  $[110]$  direction, and slip on the  $(\bar{1}11)$  and  $(\bar{1}\bar{1}1)$  planes would result in slip steps parallel to the  $[\bar{1}\bar{1}2]$  and  $[\bar{1}12]$  directions, respectively.

# Technical Notes

## Implantation and Detection of Low Energy Argon Ions in Silicon Single Crystals

James Comas<sup>1</sup> and Carmine A. Carosella

Naval Research Laboratory, Washington, D. C.

Although there have been many applications of the sputtering technique, *e.g.*, the production of thin semiconducting films, the cleaning of surfaces, and the formation of thin protective layers on solar devices, there is still much to be learned about the interaction between the bombarding primary and the target. The sequence of events leading to the ejection of surface atoms as the target is subjected to energetic gas bombardment has not yet been clearly established. One of the present problems in the construction of a consistent sputtering model is to determine the fate of the bombarding species.

Work focused on this aspect of the sputtering phenomenon has been based primarily on the detection of the released primary with a mass analyzer. Thermal desorption or resputtering the target with a different gas and recording the release of the first bombarding species are the methods usually employed. Primary release spectra obtained by Kornelson and Sinha (1), Erent and Carter (2), and Colligon and Leck (3) show peaks which are believed due to different trapping configurations and penetration depths. Re-emission investigations indicate that the damage produced by the bombarding species can act as trapping sites. Carmichael and Trendelenburg (4) have used ion induced re-emission to investigate the depth distribution of trapped atoms. From pumping speed measurements Winters (5) has obtained the sticking probability as a function of argon ion energy in the 80-300 ev range for Ni and Mo. This paper reports on a method of bombarding silicon in the 100-2200 ev range with argon and the detection of the implanted species *in situ*.

### Experiment

A schematic of the bombarding apparatus is shown in Fig. 1. The means of obtaining an argon plasma is similar to that previously used in sputtering experiments (6), the major difference being the extraction and further acceleration of the argon ions. The arrangement is placed in a 12-in. bell jar vacuum system which is evacuated with a 300 liter/sec frac-

tionating oil diffusion pump. The system is initially pumped down to a base pressure of about  $5 \times 10^{-6}$  Torr and then argon is leaked continuously into the system to a pressure of about  $5 \times 10^{-4}$  Torr. Electrons emitted from the tungsten filament F are accelerated through a slit in the ionization chamber I; the accelerating potential is adjusted (60v) to minimize the  $A^{++}$  content. This primary electron beam is collimated along the slit-filament alignment E-E by the magnetic field B (100 gauss). Under proper operating conditions a thermionically sustained, magnetically confined, arc discharge is struck and is spatially confined in the ionization chamber.

The stainless steel screen S, which is placed about 3 mm below the primary electron beam, acts essentially as a Langmuir probe when biased negative with respect to the plasma. Argon ions are drawn out of the plasma region, and those that pass through the screen are further accelerated between the screen and the target by applying a negative potential to the target with respect to the screen. A graphite ring is placed above the target and is at the same potential. This guard ring eliminates misleading edge effects and clearly defines the area of bombardment. With such an arrangement the bombarding energy range can be extended from 100 to 2200 ev with target currents in the order of 1-2 ma.

Fig. 1. Schematic of the bombarding apparatus

<sup>1</sup> NRC Postdoctoral Research Associate.

The targets used were thin (111) n-type (0.1 ohm cm) silicon wafers about 1 in. in diameter. They were chemically etched in a hydrofluoric, nitric, acetic acid solution and rinsed with ethyl alcohol prior to being sputtered. Aquadag was used to contact the samples to a stainless steel target mount. Various experiments, e.g., heating aquadag coated Si targets in an argon plasma, were performed to ensure that the observed argon was not due to adsorption by the contacts or the target. Erosion of a surface by noble gas bombardment releases trapped atoms, however, an equilibrium is soon reached between the trapping and implantation rates (3). Sputtering times were long enough to ensure an equilibrium condition between the impinging argon and the trapped argon being released as the surface is sputtered away. All samples were bombarded for 2 hr with a current of 1.3 ma.

After argon bombardment the targets were removed from the sputtering apparatus and placed in NRL's nuclear reactor for activation. The samples were placed in a neutron flux of  $10^{13}$  n/sec for 1 hr. The neutron activation produces  $A^{41}$ , which in the decay process emits a 1.293 gamma ray. A lithium-drifted germanium detector, used in conjunction with a multichannel analyzer, was used to obtain the gamma spectrum in this energy region. The system can resolve peaks 5 kev apart, which is sufficient to separate the only interfering gamma ray, a 1.265 Mev gamma from the decay of  $Si^{31}$ . To ensure that the counting geometry is the same for all samples they are placed in a Plexiglas holder fixed to the detector.

One of the main problems in making an absolute measurement of the argon content was in obtaining a suitable standard having the same geometry as the bombarded silicon. Containers for encapsulating air proved impracticable due to the masking of the argon signal by the container's high radioactivity. A method, very similar to that used by Woodman (7), was devised so as to irradiate air (0.94% argon) in a sealed quartz capsule and then to transfer the air into an evacuated glass container for counting. The glass container into which the irradiated air is transferred has approximately the same geometry as a silicon disk. A manometer was used to measure the air pressure in the transfer system. The activated argon in the irradiated air was counted in the same geometrical arrangement as the bombarded silicon. The activity of the argon in the container was then used as a standard to calculate the amount of trapped argon in the bombarded silicon samples.

### Results and Discussion

Typical data are shown in Fig. 2. The argon peak, identified by energy calibration of the detector with a  $Co^{60}$  source, as well as half-life measurements, is clearly resolved. Background counts due to the activation of natural argon by the reactor are eliminated by continuously flushing air from an external compressor through a sealed plastic bag surrounding the detector and sample, and by lead shielding. The initial

Fig. 2. Gamma ray spectrum of Si and A obtained from a Li drifted Ge detector 121 min after neutron activation.

Fig. 3. Argon content in (111) Si vs. argon ion energy. Targets were bombarded for 2 hr with an argon ion beam of 1.3 ma.

argon activity in each sample is obtained from the extrapolation of half-life curves, the points being plotted as integrated argon peaks. It is estimated that the minimum amount of argon detectable is about  $10^{13}$  atoms.

Results of a series of bombarding experiments from 100 to 2200 ev are shown in Fig. 3. The argon content rises very sharply around 225 ev and appears to begin to reach a plateau around 2200 ev. No argon was detected at 100 ev. Winters, however, measured a sticking threshold at about 80 ev for  $A^+$  on Ni and Mo. At the present we are improving the sensitivity of the counting system and plan to investigate the low energy region in Si further.

The relative amount of argon trapped as a function of bombarding energy is consistent and reproducible. It is estimated, however, that a 20% error in the absolute argon content is possible due to errors in the calibration technique. At energies around 100 ev it may be that the argon does not penetrate far enough below the surface to be trapped. It may be that at low energies (around 100 ev) the sputtering process is a result of a surface rebounding mechanism as described by Harrison *et al.* (8). As the energy is increased the penetration depth is sufficient to cause disturbances several layers beneath the surface. The energy from these disturbances that reaches the surface can cause the ejection of a surface atom. The primary, having lost its energy in collisions with the target atoms, is trapped in an interstitial or substitutional position.

The data clearly show the applicability of the technique for the *in situ* measurement of trapped argon in sputtering studies. The possibility of subjecting the data to quantitative analysis allows one to calculate the probability of penetration as a function of bombarding energy.

## Luminescence of $\text{Eu}^{3+}$ Activated Thorium, Alkali Metal Vanadates

H. L. Burrus and A. G. Paulusz

*Osram (G.E.C.) Research Laboratories, The General Electric Company Limited, Hirst Research Centre, Wembley, England*

Europium activated yttrium orthovanadate ( $\text{YVO}_4:\text{Eu}$ ) belongs to the class of host sensitized phosphors in which the exciting energy is absorbed mainly by the  $(\text{VO}_4)^{3-}$  groups and is subsequently transferred to the  $\text{Eu}^{3+}$  ion whence it is emitted as characteristic europium fluorescence (1). The efficiency of this process as a function of crystal structure has been discussed by Blasse (2). In  $\text{YVO}_4:\text{Eu}$  which has the zircon structure the transfer is particularly efficient (2). Other vanadates with this structure are therefore of interest in view of the current commercial applications of this phosphor in the television (3) and lighting industries (4). Such materials have been synthesized by Schwarz (5), and Avella has recently described the  $\text{Eu}^{3+}$  emission from compounds of the type  $\text{M}^{\text{IV}}\text{M}^{\text{II}}(\text{VO}_4)_2:\text{Eu}$  where  $\text{M}^{\text{II}}$  and  $\text{M}^{\text{IV}}$  are, respectively, divalent and tetravalent metals (6). We report here briefly on other vanadates with the zircon structure having the general formula  $\text{M}_2^{\text{IV}}\text{M}^{\text{I}}(\text{VO}_4)_3$ , where  $\text{M}^{\text{IV}}$  is thorium and  $\text{M}^{\text{I}}$  is a univalent alkali metal.

The materials were prepared by firing stoichiometric quantities of the appropriate luminescent grade oxides or carbonates with ammonium metavanadate in air at  $700^\circ\text{--}900^\circ\text{C}$  for up to 20 hr. X-ray diffraction examination of the products showed that  $\text{Th}_2\text{Li}(\text{VO}_4)_3$  and  $\text{Th}_2\text{Na}(\text{VO}_4)_3$  have the zircon-type crystal structure while the intended  $\text{Th}_2\text{K}(\text{VO}_4)_3$  proved to be a complex mixture of phases. The ionic radii of thorium (0.95Å) and sodium (0.95Å) are very close to that of yttrium (0.93Å). Lithium at 0.6Å is slightly smaller, but can fit into the structure quite well. Potassium (1.33Å) and the heavier alkali metals are apparently too large.

We briefly surveyed other possible compositions using in place of thorium the ions  $\text{Ge}^{4+}$ ,  $\text{Sn}^{4+}$ ,  $\text{Pb}^{4+}$ ,  $\text{Ti}^{4+}$ ,  $\text{Zr}^{4+}$  and  $\text{Ce}^{4+}$ , combining each in turn with  $\text{Li}^+$ ,  $\text{Na}^+$  and  $\text{K}^+$ . As the products in all cases were dark sintered masses, even when prepared with a 20% deficiency of vanadium, we did not examine them further.

When the thorium lithium and thorium sodium vanadates were prepared with a slight deficiency of vanadium the products had white body colors above  $300^\circ\text{C}$  but darkened rapidly on cooling below  $280^\circ\text{C}$ . As the change was reversible it may represent a phase transition at this temperature. Schwarz has found three phases in the system  $\text{PbTh}(\text{VO}_4)_2$  at different temperatures (5). The change can be prevented by incorporating an excess of cation (thorium and alkali metal), but as expected x-ray diffraction confirms the presence of excess thorium in the products.

The room temperature excitation and emission characteristics of the thorium lithium and thorium sodium compounds are compared with those of  $\text{YVO}_4$  in Fig. 1.

Under 365 nm excitation, the unactivated compounds give broad band yellowish green luminescence, peaking at 550 and 540 nm in the lithium and sodium compounds, respectively, and qualitatively similar to that reported for other vanadates (7). Addition of europium quenches this emission and gives rise to a brilliant  $\text{Eu}^{3+}$  spectrum similar in structure to that of  $\text{YVO}_4:\text{Eu}$ . However the lines are broadened approximately fivefold as was also reported by Avella for the II-IV vanadates. (Samarium and dysprosium give characteristic, but somewhat less intense emissions.) If europium is added according to the scheme  $2\text{Th}^{4+} + \text{M}^+ \rightarrow 3\text{Eu}^{3+}$ , charge compensation is unnecessary and the formula can then be written  $\text{Th}_{2-2x}\text{M}_{1-x}\text{Eu}_{3x}(\text{VO}_4)_3$ . The europium emission is at its brightest between  $x = 0.10$  and  $x = 0.25$ , with a maximum near  $x = 0.15$ . This is as expected for europium in the zircon structure according to the self-quenching mechanism proposed by Van Uitert and Johnson (8).

The excitation spectrum of  $\text{YVO}_4:\text{Eu}$  shows two prominent peaks at 320 nm and 250 nm. These have been ascribed to the first allowed electronic transition of the  $\text{VO}_4^{3-}$  group,  ${}^1\text{A}_1 - {}^1\text{T}_2$ , and a transition in the Y—O interaction center, respectively (1). The thorium lithium and thorium sodium compounds have excitation peaks at 330 and 336 nm respectively with a slight unresolved shoulder at approximately 275 nm.

Fig. 1. Excitation and emission spectra of (a)  $\text{YVO}_4:0.05 \text{Eu}$ , (b)  $\text{Th}_2\text{Li}(\text{VO}_4)_3:0.15 \text{Eu}$ , (c)  $\text{Th}_2\text{Na}(\text{VO}_4)_3:0.15 \text{Eu}^{3+}$ . Dotted lines show the emission of the unactivated vanadates. All curves are normalized to 100 and discrete  $\text{Eu}^{3+}$  line absorptions have been omitted from the excitation spectra.

If the peaks correspond to the same transitions responsible for the  $\text{YVO}_4$  excitation spectrum, they have been shifted to longer wave lengths by 10-25 nm. The excitation at short wavelengths corresponding to the Y — O interaction in  $\text{YVO}_4$  is rather weak, and the phosphors are only poorly excited by 254 nm radiation and cathode rays.

Under 365 nm excitation,  $\text{YVO}_4:\text{Eu}$  shows a sharp increase in brightness as the temperature is raised. In all the complex vanadates we have examined there is a steady fall in brightness as the temperature is raised. An exception is  $\text{CaTh}(\text{VO}_4)$ , a compound reported by Avella (6), which peaks at about 160°C. However, the over-all brightness of this vanadate is rather poor. In contrast the thorium vanadates with lithium and sodium are much brighter than  $\text{YVO}_4:\text{Eu}$  at room temperature so that, although they fall in brightness with increasing temperature, they are about equal in brightness to  $\text{YVO}_4:\text{Eu}$  at 200°C. This is within the range of the bulb wall operating temperature of low wattage high-pressure mercury vapor lamps, so these phosphors could possibly find application for color correction in this type of lamp.

## Fluorescence of $\text{Eu}^{2+}$ -Activated Barium Octaborate

G. Blasse, A. Brill, and J. de Vries

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

A large number of  $\text{Eu}^{2+}$ -activated phosphors with high efficiencies for ultraviolet excitation have been reported recently by these laboratories (1-4). In this note the results of a study on the fluorescence of  $\text{Eu}^{2+}$ -activated alkaline earth borates are given. Five types of alkaline-earth borates exist, viz.,  $\text{Me}_3\text{B}_2\text{O}_6$  (Me = Ca, Sr, Ba),  $\text{Me}_2\text{B}_2\text{O}_5$  (Me = Ca, Sr),  $\text{MeB}_2\text{O}_4$  (Me = Ca, Sr, Ba),  $\text{MeB}_4\text{O}_7$  (Me = Ca, Sr, Ba), and  $\text{BaB}_8\text{O}_{13}$ . [For a list of these compounds see ref. (5)].

Only one efficient phosphor was found, viz.,  $\text{BaB}_8\text{O}_{13}:\text{Eu}^{2+}$ . This material shows a deep-blue emission under short-wavelength uv excitation.

#### Experimental

Samples were prepared by firing intimate mixtures of  $\text{CaCO}_3$ ,  $\text{SrCO}_3$ ,  $\text{BaCO}_3$ ,  $\text{Eu}_2\text{O}_3$ , and  $\text{H}_3\text{BO}_3$  as described before (5). The firing atmosphere consisted of  $\text{N}_2$  containing a few per cent of  $\text{H}_2$ . Samples were checked by x-ray analysis. The measurement of the optical properties was performed as indicated previously (6).

#### Results and Discussion

Samples of all the alkaline earth borates doped with 1 a/o of  $\text{Eu}^{2+}$  showed only weak fluorescence

Fig. 1. Spectral energy distribution of the emission under 254 nm excitation, diffuse reflection spectrum and relative excitation spectrum of the emission of  $\text{Ba}_{0.99}\text{Eu}_{0.01}\text{B}_8\text{O}_{13}$ . The radiant power per constant wavelength interval ( $I$ ) is plotted in arbitrary units along the ordinate.

Fig. 2. Temperature dependence of the fluorescence of  $\text{Ba}_{0.99}\text{Eu}_{0.01}\text{B}_8\text{O}_{13}$  under 254 nm excitation.

under uv or cathode-ray excitation with one exception. Barium octaborate activated with  $\text{Eu}^{2+}$  ( $\text{Ba}_{1-x}\text{Eu}_x\text{B}_8\text{O}_{13}$ ) shows efficient blue fluorescence under 254 nm excitation. Figure 1 contains the spectral energy distribution of the emission, the diffuse reflection spectrum, and the relative excitation spectrum of the emission. The emission band peaks at about 400 nm. Because unactivated  $\text{BaB}_8\text{O}_{13}$  does not absorb in the uv region, the strong and broad absorption band in short-wavelength uv region must be due to the  $\text{Eu}^{2+}$  ion [ $4f \rightarrow 5d$  transition, see ref. (3)]. A strong excitation band corresponds with this absorption band. In view of the position of this band the phosphor is excited efficiently with 254 nm radiation.

The temperature dependence of the new phosphor (Fig. 2) is comparable to that of the best temperature-persistent  $\text{Eu}^{2+}$ -activated phosphors, for example  $\text{Sr}_{0.8}\text{Mg}_{1.2}\text{P}_2\text{O}_7:\text{Eu}^{2+}$  and  $\text{BaAl}_{12}\text{O}_{19}:\text{Eu}$  (4).

The energy efficiency for cathode-ray excitation (20 kv) of several samples varied between 0.5 and 1.0%. The quantum efficiency for 250-270 nm excitation of samples  $\text{Ba}_{1-x}\text{Eu}_x\text{B}_8\text{O}_{13}$  is 60% for values of  $x$  up to 0.01. For higher values of  $x$  the quantum efficiency decreases. For  $x = 0.02$ , for example, it is 45%.

In conclusion it can be stated that  $\text{BaB}_8\text{O}_{13}:\text{Eu}^{2+}$  is an efficient photoluminescent material.

Manuscript received May 13, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## The Hydrothermal Synthesis of Single Domain Lithium Niobate Crystals by Transport Reactions

V. G. Hill and K. Gerald Zimmerman

*Tem-Pres Research/The Carborundum Company, State College, Pennsylvania*

Lithium niobate single crystals are of interest because of the observed second harmonic generation and optical parametric effects. The successful growth of this material by high-temperature methods has been reported (1-5). Nassau and co-workers (4, 5) using the Czochralski technique, obtained large single domain  $\text{LiNbO}_3$  crystals by (a) the addition of low concentrations of  $\text{MoO}_3$  to the melt, (b) growth of the crystals in an electric field, and (c) poling polydomain crystals at  $1090^\circ\text{-}1210^\circ\text{C}$ . However, it is desirable to grow single domain  $\text{LiNbO}_3$  crystals at lower temperatures to determine if any further improvement in crystal quality can be achieved. The hydrothermal method is one approach.

The alternatives for hydrothermal growth of  $\text{LiNbO}_3$  single crystals were (a) the use of a mineralizer which will dissolve and transport  $\text{LiNbO}_3$  or (b) the formation of  $\text{LiNbO}_3$  by reacting phases whose bulk composition is along the join  $\text{LiNbO}_3\text{-H}_2\text{O}$ . Preliminary work with solutions of  $\text{NaOH}$ ,  $\text{KOH}$ ,  $\text{RbOH}$ ,  $\text{NH}_4\text{OH}$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HCl}$ ,  $\text{HNO}_3$ ,  $\text{HF}$ ,  $\text{LiCl}$ ,  $\text{NH}_4\text{Cl}$ , and  $\text{NH}_4\text{Cl-NH}_4\text{OH}$  as mineralizers resulted, in all cases, in the formation of new phases, and so the second alternative was the only choice. This technique is simply a controlled precipitation caused by reacting two solutions. It may be contrasted with the usual hydrothermal crystal growth method where a material is dissolved and transported in solution across a thermal gradient, and then precipitated. It is, however, desirable to refine the reaction so that only one phase can crystallize, and if possible, arrange the conditions so that the precipitation occurs as an overgrowth onto a seed. The latter arrangement will permit the growth of larger crystals once the basic techniques are established. The Tem-Pres hydrothermal research units (Model HR-1B), equipped with the cold seal "test tube" vessels, were used for the investigation. The reactions were done in sealed 5 and 10 mm gold tubes. The binocular and petrographic microscopes and x-ray diffractometer were used for the identification and characterization of the phases formed, including the crystals grown. The initial starting materials used were  $\text{Li}_2\text{CO}_3$  (99.9%),<sup>1</sup>  $\text{LiOH}\cdot\text{H}_2\text{O}$  (99.8%),<sup>1</sup>  $\text{Nb}_2\text{O}_5$  (99.9%).<sup>2</sup>  $\text{Li}_2\text{O}:4\text{Nb}_2\text{O}_5$  and  $3\text{Li}_2\text{O}:\text{Nb}_2\text{O}_5$  were prepared by firing stoichiometric mixtures of  $\text{Li}_2\text{CO}_3$  and  $\text{Nb}_2\text{O}_5$  at  $450^\circ\text{C}$  for two weeks and then slowly increasing the temperature to  $700^\circ\text{C}$ .

Lithium niobate was synthesized hydrothermally from  $\text{LiOH}$  and  $\text{Nb}_2\text{O}_5$ .  $\text{LiOH}\cdot\text{H}_2\text{O}$  was placed in a partially sealed 2.5-mm diameter gold tube. This tube was sealed inside a 5-mm diameter gold tube containing the calculated amount of  $\text{Nb}_2\text{O}_5$  to react stoichiometrically with the  $\text{LiOH}\cdot\text{H}_2\text{O}$  and also a small volume of water. The charge was reacted at temperatures between  $400^\circ$  and  $650^\circ\text{C}$ , and pressures up to 2 kb. The  $\text{LiNbO}_3$  crystals formed in these runs were always

of microscopic size and did not increase in size when the method of mixing the reactants were varied.

In an effort to control the rate of precipitation of  $\text{LiNbO}_3$  from solution by restricting the possible products and reaction paths, the use of other starting materials was tried.  $\text{Li}_2\text{O}:4\text{Nb}_2\text{O}_5$  and  $3\text{Li}_2\text{O}:\text{Nb}_2\text{O}_5$  were selected as the most suitable reactants. A (1:1) mixture of  $3\text{Li}_2\text{O}:\text{Nb}_2\text{O}_5$  and  $\text{LiOH}$  was placed in a 10-mm gold tube. The equivalent amount of  $\text{Li}_2\text{O}:4\text{Nb}_2\text{O}_5$  was then weighed into a 5-mm diameter gold tube. The 5-mm tube was suspended inside the 10-mm tube, sufficient water added to almost fill the 10 mm tube at temperature and pressure; then it was welded shut. The sealed tubes with contents were heated at temperatures between  $500^\circ$  and  $600^\circ\text{C}$  and 2 kb.  $\text{LiNbO}_3$  crystals measuring up to  $1 \times 0.2$  mm were formed in runs of two to three weeks duration (Fig. 1). These crystals were larger than those obtained by reacting  $\text{LiOH}$  with  $\text{Nb}_2\text{O}_5$ , showing that the rate of precipitation has been significantly decreased. Prolonged heating did not promote recrystallization since water was the only solvent remaining once the precipitation reaction had ceased. Attempts to slow down the precipitation rate further did not cause a noticeable improvement in crystal size. Similarly, satisfactory overgrowth on seeds was not achieved. The crystals formed were of high quality, and examination with a polarizing microscope indicated that they were single domain.

# Brief Communication

## Rate Characteristics of Constant Voltage Anodization of Yttrium

R. M. Goldstein and W. J. Pettit

McDonnell Company, St. Louis, Missouri

The constant voltage anodization of thin film yttrium for use in thin film capacitors has recently been reported (1). Since then more experimental data have been evaluated, and certain aspects of the anodization theory can be given.

The experimental procedure is as follows. Yttrium metal is electron-beam-evaporated through a metal mask on to a Corning 7059 slide. The resulting pattern of 18 metal leads is then masked by a nonconductive Alpha Stripecoat to prevent sparking at the air electrolyte interface, and anodized at 100v in an electrolytic cell. The cell consists of a platinum foil cathode, the slide as anode, another electrode in common with the anode to measure electrolyte voltage drop, and an electrolyte cooled to 1°C whose concentration is 6.4% ammonium pentaborate, 57.1% ethylene glycol, and 36.5% deionized water by weight. The voltage drop across the electrolyte and the current through the oxide film during anodization are monitored simultaneously by means of recorders of sufficiently high input impedance (1 Mohm) to avoid any appreciable loading. After the yttrium has been anodized, aluminum leads are evaporated so as to form 18 capacitors, each of area 0.02 cm<sup>2</sup>. The oxide thickness is calculated from the capacitance with an assumed dielectric constant of 17.1 (1).

From Fig. 1a, the initial current decay (less than 5 sec) may be represented by

$$I = I_s e^{-\alpha t} \quad [1]$$

where

$$\alpha = 0.18 \text{ sec}^{-1}$$

$$I_s = 250 \text{ mA/cm}^2$$

From Fig. 1b, the current at longer times (greater than 50 sec) may be represented by

$$I = I_L t^{-\beta} \quad [2]$$

where

$$\beta = 0.6$$

$$I_L = 30 \text{ mA/cm}^2$$

The measured current consists of ionic current,  $I_i(t)$ , and electronic current,  $I_e(t)$

$$I(t) = I_i(t) + I_e(t) \quad [3]$$

Only the ionic current contributes to the oxide growth. The two over-all reactions occurring at the

anode are

The former reaction takes place when there is ion motion through the oxide film. The latter reaction occurs especially at high voltages when the electrons from the oxygen ion are split off and pass through the film resulting in oxygen gas given off at the anode rather than anodization taking place. As the oxide becomes thicker, ionic transport becomes less and the electron current becomes more dominant.

Fig. 1a. Short time current decay

Fig. 1b. Total current decay

We relate the ionic current to the total current by means of the ionic efficiency,  $\eta(t)$

$$I_i(t) = \eta(t) I(t) \quad [6]$$

The ionic current may then be related to the oxide thickness by means of Faraday's law:

$$\int_0^t I_i(t) dt = x/\lambda \quad [7]$$

where

$$\lambda = \frac{M}{F(2z)\rho A}$$

$x$  = oxide thickness,  $M$  = molecular weight,  $z$  = effective valence of the yttrium ion,  $\rho$  = density of yttrium oxide,  $A$  = area of yttrium film,  $F$  = Faraday constant = 96,486.82 coulomb/mole.

As a first approximation to calculating the oxide thickness, assume the ionic efficiency to be independent of time. Then from Eq. [6] and [7]

$$\frac{dx}{dt} = \lambda\eta(t)I(t) \quad [8]$$

where  $I(t)$  is given by Eq. [1] or [2] depending on the time interval. Using a value of  $z=3$ , which is the value expected from the chemical half reaction, we have calculated the theoretically expected thicknesses of the oxide film for short time growth. These results, when compared with the experimental ones (Fig. 2) illustrate that the efficiencies are not independent of time and that for short times are much greater than one, e.g., they vary from 2.3 at 0.4 sec to 0.9 at 4.0 sec. The probable explanation for this result is that in the initial stages of anodization the effective valence of yttrium is less than three (incomplete ionization) or else that electrons are initially flowing through the oxide film unattached to the yttrium ions. This is in concurrence with the work by Dreiner, Lehovec, and Schimmel (2) on tantalum metal, except their hypothesis of efficiencies greater than one due to electron tunneling cannot be correct in our case as evidenced by the large oxide thickness (1000 Å) obtained in the first few seconds where our efficiencies are greater than one.

To establish the basis for short time current behavior we have plotted in Fig. 3 the logarithm of time as a function of reciprocal thickness. These data indicate that the short time growth is governed by a reciprocal logarithmic rate, i.e.,

$$1/x = A - B \ln t \quad [9]$$

where

$$A = 1.23 \times 10^{-3} \text{ \AA}^{-1}$$

$$B = 0.38 \times 10^{-3} \text{ \AA}^{-1}$$

Fig. 2. Yttrium oxide growth rate

Fig. 3. Reciprocal logarithmic rate law for the anodization of yttrium metal.

Although this law is generally characteristic of thin tarnishing layers, a law of this type will occur if the two phase-boundary reactions, namely, (i) entry of a chemisorbed oxygen ion into a vacancy in the  $Y_2O_3$  at the yttrium oxide-electrolyte phase boundary or (ii) formation of an oxygen ion vacancy in the  $Y_2O_3$  at the yttrium oxide-yttrium phase boundary, proceed more quickly than the field transport of ionic defects leaving the latter as the rate determining step.

It is felt that after a very short time (5 sec) the phase boundary reaction probably becomes the limiting step. However, this law is only applicable to the point where the diffusion rate becomes comparable with the phase boundary reaction, which in the case of nonporous oxide growth is often so early in the reaction that the former is not observed (3).

In the long time range the theory of Dreiner *et al.* (2), which is developed from the Mott-Cabera equation and Faraday's law, the high field Frenkel defect model (4) and the "dielectric mosaic" theory (5) predict currents inversely proportional to time, while our experimental results predict a long time current decay proportional to  $t^{-0.6}$  (Eq. [2]). For these long times the growth rate is thought to be diffusion limited as evidenced by a small ionic efficiency and an ionic current approaching a  $t^{-0.5}$  dependence. This mechanism of current behavior is in agreement with Eq. [2].

The significance of this barrier oxide (16-18 Å/v) is that it can be grown rapidly enough (e.g., 1300 Å in 3 sec) and with superior electrical characteristics as field strength of  $4.4 \times 10^6$  v/cm (dry), dielectric constant of 17.1 and a low dissipation factor of 0.008 to find use as the dielectric in thin film capacitors.

# X-ray Study of the Active Materials in the Lead-Acid Storage Battery

Takewo Chiku\*

Toyota Central Research & Development Laboratories, Inc., Nagoya, Japan

## ABSTRACT

The structural change of the active materials in the lead-acid storage battery due to charge and discharge was examined by x-ray analysis. It is found that Pb and PbO<sub>2</sub> when charged are in a strained state which finds gradual release with time of discharge. The ratios of the integrated intensities Pb/PbSO<sub>4</sub> or PbO<sub>2</sub>/PbSO<sub>4</sub> in the negative and positive plates were measured, and it is pointed out that the value Pb/PbSO<sub>4</sub> in the fully charged state is closely connected to the life time of the battery, becoming very small with usage.

About three decades ago the present author (1) studied the active materials of negative plates in the lead-acid storage battery by an x-ray method and reported a slight change of the lattice constant of lead with time of discharge, which reached a minimum value at a period nearly corresponding to that of zero terminal voltage of the battery. The present author interpreted these results in terms of the generation of internal strains in the matrix. From a crystallographical point of view this phenomenon is thought to be very interesting inasmuch as it may throw light on the structural changes of lead crystals subjected to an electrochemical reaction. Unfortunately the experimental observation reported by Chiku seems to have been disregarded by many researchers, presumably because it appeared to be restricted to a problem in crystallography rather than to relate to a problem in electrochemistry.

The present study was carried out to reexamine Chiku's previous results by using recent techniques of x-ray analysis and to make a detailed observation of the internal structure of the active materials in the lead-acid storage battery as a function of progressive stages of charge and discharge.

## Experimental Procedure

Samples used for x-ray measurements were taken from the same type of commercial battery, described in another paper (2) at various stages of the discharge as shown in Fig. 1; they were put into a small polyethylene bag together with the electrolyte solution of the battery and were then mounted on a specimen holder; the size of specimen being of the order of 10 x 15 x 2 mm<sup>3</sup>. The thickness of polyethylene was 0.1 mm, and the total time to carry out an x-ray examination for one specimen took approximately 1 hr. The specimens prepared and examined in this manner will be referred to as "case 1" unless otherwise mentioned.

The change in interplanar spacing and in the integrated intensity of the specimens as a function of the depth from the surface was observed on specimens dried in vacuum at room temperature after having been washed in water to remove any measurable sulfate ion in the specimen. The specimens prepared and examined in this manner will be referred to as "case 2".

Measurements of x-ray diffraction were performed with the GF-D2 diffractometer made by Rigaku Denki Company in Japan using Cu-K $\alpha$  radiation, and profiles of various diffraction lines for Pb, PbO<sub>2</sub>, and PbSO<sub>4</sub> were measured as a function of progressive electrochemical reaction.

## Experimental Results

Figure 2a shows the changes in interplanar spacing of some lattice planes in lead crystals with time of

discharge in the negative plate, whereby the change of interplanar spacing of each measured (hkl) plane is referred to the change of the lattice parameter  $a_0$ . It will be seen from Fig. 2a that the interplanar spacings decrease gradually with time but that this decrease is different for different (hkl) planes, approaching the value of metallic lead irrespective of the type of (hkl) planes. This result agrees qualitatively with that reported previously (1). The interplanar spacing of PbO<sub>2</sub> in the positive plate also changes and with time of discharge approaches the interplanar spacing distance of each lattice plane of lead dioxide (tetragonal lattice:  $a$ , 4.941Å;  $c$ , 3.374Å). Figure 2b shows these results in which it should be noted that the change in lattice spacing with time of discharge is different for different planes, showing an anisotropy of lattice distortion in the crystal. The spacing of PbSO<sub>4</sub> created on both negative and positive plates changes slightly with progress in the reaction, showing a decreasing tendency toward the lattice spacing of lead sulfate with the time.

It is very interesting to note that Pb and PbO<sub>2</sub> in the state of charge are in a strained state, which is released gradually with time of discharge, or with decreasing terminal voltage in the battery.

At an early stage of discharge, the diffraction intensity of Pb was very weak, and some additional strong diffraction lines of unknown nature were detected. These additional diffraction lines could not be observed in the plate after a discharge of 2 hr. However, no measurable diffraction lines except those of Pb and PbSO<sub>4</sub> were found in the study of case 1. These results suggest that some unknown substances are produced during the process of sampling denoted by case 2.

Figure 3 shows the interplanar spacing of {111} and {200} as a function of the depth from the surface of the

negative plate taken from stages B and D listed in Table I. It will be noted that the interplanar spacing remains constant irrespective of the depth. It is well known that the peak shift and the line broadening due to deformation are scarcely observable in lead because the recrystallization in lead crystal occurs even at room temperature. A slight increase of the integral breadth of the {200} diffraction, however, is obtained as shown in Fig. 4. This effect may be closely related

to the nucleation and growth of  $PbSO_4$  during the process of discharge.

The integrated diffracted intensity of various (hkl) planes of the active materials in the negative and positive plate was measured as a function of time of discharge, the results of which are shown in Fig. 5a and 5b. The ratio of the integrated intensity of  $PbO_2$  to  $PbSO_4$  in the positive plate and that of Pb to  $PbSO_4$

in the negative plate (notation Pb/PbSO<sub>4</sub> and PbO<sub>2</sub>/PbSO<sub>4</sub> are used unless otherwise stated) were plotted against the time of discharge and powders of Pb, PbO<sub>2</sub>, and PbSO<sub>4</sub> of extra pure reagents were used as standards to estimate the change which each active material undergoes with time. It can be seen from these results that Pb/PbSO<sub>4</sub> or PbO<sub>2</sub>/PbSO<sub>4</sub> decreases with time of discharge, at first very rapidly and then gradually and that after 10 hr, corresponding to the period of nearly zero terminal voltage, the value reaches about 0.5 for the negative plate and about 2.3 for the positive plate. These values do not correspond to the per cent changes of Pb, PbO<sub>2</sub>, and PbSO<sub>4</sub> in the negative or positive plate because the effect of absorption of x-rays due to PbSO<sub>4</sub> are not being considered in the present case.

One might expect that self-discharging in the battery may also bring about changes in the interatomic spacing, in the integral breadth, and in the integrated intensity of the active materials. Figure 6 represents the result obtained for the negative plate, from which may be seen, however, that the interplanar spacing remains virtually constant irrespective of the lapse of time. Figure 7 shows Pb/PbSO<sub>4</sub> for the negative plate calculated from the x-ray diffracted intensity, showing a similar tendency, but a very gradual decrease compared with that in the case of discharge. These results imply that the structural change of the active materials in the discharging process are different from those of the process of self-discharging.

The ratio PbO<sub>2</sub>/PbSO<sub>4</sub> in the positive or Pb/PbSO<sub>4</sub> in the negative becomes infinity at the fully charged state as shown in Fig. 5 and 7. These values, however, are thought to be a function of the numbers of repeti-

Fig. 6. Dependence of interatomic spacing of Pb and PbSO<sub>4</sub> in the negative plate on lapse of time, case 1.

tion of charges and discharges. Table I shows a decreasing tendency for Pb/PbSO<sub>4</sub> with time of battery usage.

### Discussion

As shown in Fig. 2a and 2b, a highly strained state is produced in the electrode plate due to charging which finds gradual release with time of discharge. An approximate value of the stored energy per unit volume in lead may be estimated from the elastic strains by the following consideration: Taking the lattice strain  $\left(\frac{a_0 - a}{a_0}\right)^2$  as the mean square strain, where  $a_0$  and  $a$  are the lattice constant of metallic lead and Pb as the active material, respectively,  $V$  is expressed by

$$V = \frac{3}{2} ES^2$$

where  $E$  is Young's modulus, and  $S$  the root mean square strain. Using the experimental data the result obtained turned out to be of the order of 0.05 cal/g.

The elastic stored energies of metals and alloys due to cold-working are usually within 0.1-0.5 cal/g (3, 4), and consequently the present elastic stored energy is small compared to values obtained for cold-worked specimens. The stored energy corresponding to the fully charged state was shown to be completely released when subjected to an anneal of 150°C for 1 hr in vacuum.

It is not known as yet how PbSO<sub>4</sub> crystallites nucleate and grow on Pb and how they dissolve during the process of discharging or charging. Burbank (5) studied the anodic oxidation of several compounds which existed in the positive plate of a lead-acid cell by electron microscopy and observed dendritic PbO<sub>2</sub> formed from PbSO<sub>4</sub>. Using an electron microscope the present author (6) recently observed the crystal growth of PbSO<sub>4</sub> on several kinds of crystal surfaces of lead. He found a dendritic growth of PbSO<sub>4</sub> crystallites, especially on the (100) plane of Pb crystal as the reaction progressed, but a shapeless growth when the specimen was merely soaked in the electrolytic solution. The results obtained in the present study suggest that the production of the lattice strain and its release may play an important part in solving the mechanism of the formation of PbSO<sub>4</sub> crystallites on Pb or PbO<sub>2</sub> resulting from the electrochemical reaction.

### Summary

Active materials in the lead-acid storage battery were examined by means of x-ray diffraction techniques, and the results were as follows:

1. The interplanar spacings of Pb, PbO<sub>2</sub>, and PbSO<sub>4</sub> in the electrode plate were changed with progressive discharge reaching at the period of nearly zero terminal voltage the spacing of metallic lead, lead dioxide, and lead sulphate, respectively.
2. The lifetime of a battery may be estimated from the value of Pb/PbSO<sub>4</sub>, the latter being small in old batteries even for the fully charged state.

### Acknowledgment

The author wishes to express his sincere thanks to Dr. K. Ninomiya and Dr. K. Nakajima for helpful discussion, and to Messrs. H. Haba and M. Kimura for their diligent aid throughout the course of the work.

Manuscript submitted Feb. 2, 1968; revised manuscript received June 21, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Charging the Silver Oxide Electrode with Periodically Varying Current

### IV. Intermittent Constant Current Reversals During Charge

Charles P. Wales\*

*Naval Research Laboratory, Washington, D. C.*

#### ABSTRACT

Sintered silver electrodes of the type used in storage batteries were charged by a constant current that was interrupted by periodic constant current discharges. Comparison to results from constant current charges showed a large capacity increase when the 20-hr constant charge current was reversed for 15 min out of every 60 min, but the total time required for a charge had increased greatly. Capacity could be improved a smaller amount, without charge time becoming excessive, by partly discharging the silver electrodes the first one or two times that potential reached a chosen value near the end of a constant current charge. In general, capacity improvement decreased as KOH concentration increased. Commercial silver-zinc cells always gave less improvement than the test cells.

Alkaline storage batteries containing silver oxide electrodes are used because of their high capacity compared to the more common storage battery systems. The discharge capacity of silver oxide electrodes is, however, strongly influenced by conditions of the preceding charge (anodic oxidation). Previous work at this Laboratory has shown several ways for charging silver electrodes that will give a capacity greater than the capacity obtained by a constant current charge. The electrode capacity can be increased if pulses of charge current are added to a constant charging current, using the proper conditions (1). Either increased capacity or faster recharging can result from interrupting the current periodically throughout a charge (2). The largest improvements were obtained following charges with 60 cps asymmetric sinusoidal a.c. derived from commercial a.c. (3). This asymmetric a.c. was composed of two half-wave rectified currents which flowed in opposite directions and were 180 degrees out of phase. Capacity improvements were smaller when silver electrodes were charged by an asymmetric a.c. which was obtained by superimposing a half-wave 60 cps current in the discharge direction on a larger constant charge current. The present work describes the results of relatively long constant current reversals which were separated by long periods of constant current charge.

#### Experimental Procedure

The test cells contained one of two sizes of sintered Ag plaques, depending on the size available when the cells were constructed. The plaques were either 30.5 x 63.5 x 0.8 mm or 41.5 x 38.0 x 0.8 mm. The sintered Ag had an average weight of 7.9 or 5.8g, respectively, not including the grid of expanded Ag metal. The weight of sintered Ag corresponds to a theoretical electrode capacity of 3.9 or 2.9 amp-hr, respectively. The electrodes were wrapped individually with cellulosic separator material, instead of being wrapped in pairs as is the common practice in Ag-Zn cells. The separator was folded around the electrode in such a way that 5 layers of separator covered both

sides of the electrode. The separator was held in place by wrapping with a small Ag wire and was open only at the top of the electrode. The sintered Ag plaques and the separator had been manufactured for use in commercial Ag-Zn storage batteries.

The wrapped Ag electrodes were used as both test electrodes and counter electrodes, and were about 2 cm apart. Each cell contained one test electrode. Five of the test cells contained one counter electrode and one cell contained two connected in parallel, placed on each side of the test electrode. Microscopic examination of similar Ag electrodes, at various states of charge, showed that the electrodes were highly porous and, at the relatively low cd's used, having only one side of these electrodes face the counter electrode did not favor reactions at that side (4). The test cells contained an excess of either 35% KOH or 50% KOH as the electrolyte and a Ag/Ag<sub>2</sub>O reference electrode. There was little gas production in a cell since a counter electrode was being reduced at the same time as a test electrode was being oxidized, and vice versa. All work was done at 25° ± 1°C.

As in the previous work (1-3) the constant current which resulted in a complete charge or discharge of the test electrode lasting approximately 20 hr was arbitrarily taken as the standard, or normal, charge and discharge current. Before any charges with a periodically reversed current were tried, the test cells were charged and discharged for 8 to 10 complete cycles at the 20-hr current, until capacity became relatively constant. After the tenth cycle, the same current was used for the rest of the life of these cells, and corrections were not made for deviations in charge and discharge time from 20 hr.

Complete normal charges (using the 20-hr rate as defined above) were alternated with complete charges which used one of two reversal conditions. Under one set of conditions, the current was reversed periodically during a charge at the 20-hr rate with the test electrode being discharged at the 20-hr rate for 0.01 to 15 min during this reversal period before the charge was resumed. These reversals were repeated throughout the charge at intervals varying from 1 min to 4 hr, with only one reversal length and interval used in any single charge. In another set of reversal

Fig. 1. Some excerpts of potentials measured in 35% KOH during a constant current charge of a silver electrode at the 20-hr rate with current reversed for 3 sec every 60 sec. Numbers by the curves give the total elapsed time in hours at the end of reversals for each excerpt.

conditions, the electrode was partly discharged the first two times that charge potential reached a chosen value near the end of a charge with up to 5% of the electrode capacity being removed in each of the two partial discharges. All charges were continued until oxygen evolution was occurring and potential had stopped changing rapidly. After a charge was completed, a cell was immediately discharged at approximately the 20-hr rate of constant current to a final potential which was 300 mv negative to the Ag/Ag<sub>2</sub>O reference. Charge and discharge currents were obtained from controlled power supplies.

To minimize variations in capacity the discharge capacities of the four normal cycles (20-hr constant current charge and discharge) that were nearest each discharge were averaged. This moving average was then taken as the normal capacity at that particular point in the life of a cell and is the capacity referred to whenever normal capacity is mentioned. The capacity of each discharge was calculated as a per cent of this varying average. Thus, the discharge capacity which followed a charge with current reversals could be compared to a value which was representative of actual cell capacity, regardless of changes in normal capacity over the life of a cell.

Some of the charges with current reversal which resulted in increased test cell capacity were tried with one model of a commercial silver-zinc secondary cell. The commercial cells contained either 35% KOH or 45% KOH. Each commercial cell had five zinc electrodes and four sintered silver electrodes of the same size as the test electrodes which had a theoretical capacity of 2.9 amp-hr. The silver electrodes limited cell capacity and gave a theoretical cell capacity of about 11.5 amp-hr, although the nominal rated cell capacity given by the manufacturer was only 5 amp-hr. The silver-zinc cells were charged individually

Fig. 2. Some excerpts of potentials measured in 35% KOH during a constant current charge of a silver electrode at the 20-hr rate with current reversed for 0.5 min every 30 min. Numbers by the curves give the total elapsed time in hours at the end of reversals for each excerpt.

until cell potential reached 2.05v. Complete charges at the 20-hr rate of constant current (as defined above) were alternated with charges which had current reversals. The cells were discharged at the 20-hr constant current to 1.10v. Since capacity of these cells varied from one charge-discharge cycle to the next, the 20-hr current was recalculated after each constant current cycle and a different current was used for the following cycle whenever actual charge and discharge time had deviated greatly from 20 hr.

## Results

Current reversals that were repeated every 1, 10, or 30 min during a constant current charge of a silver electrode had comparatively little effect on charge acceptance (Table I). In contrast, the relatively long reversal time of 15 min had a strong effect on charge acceptance when the reversal was repeated every 60 min (Table I). Since the reversal time of 15 min repeated every 60 min was effective for increasing capacity, this reversal was also tried with the commercial silver-zinc cells but the average discharge capacity obtained with 35% KOH was 114% of the normal capacity and with 45% KOH it was only 95% of normal capacity (averages of two measurements).

In a modification to shorten the time required for a complete charge, the silver electrodes in the test cells were discharged at the 6-hr rate for 5 min after every 45 min of charge at the 20-hr rate in 35% KOH. Three complete charges gave an average capacity only 102% of normal. This contrasts with the 143% average given in Table I for the same quantity of reversal done at the 20-hr rate after every 45 min of charge.

Except for the charges with 15 min reversals, the charges listed in Table I had potentials that tended to resemble each other. Figures 1 and 2 gave excerpts from two typical charges having periodic current reversals and show potentials during some of the brief reversals and potentials after charge was resumed. The five excerpts given on each figure show potentials from approximately the same five periods during a charge. The earliest portion (0.017 or 0.50 hr) shows the first reversal after the charge began. The second portion (5.0 or 4.0 hr) shows potentials obtained near the end of the Ag/Ag<sub>2</sub>O potential plateau of the charge, shortly before AgO began to form. The third portion (6.0 hr) shows potentials soon after the charge potential made the rapid rise to the Ag<sub>2</sub>O/AgO potential plateau. The fourth portion (20.0 or 18.0 hr) shows potentials obtained near the end of the Ag<sub>2</sub>O/AgO potential plateau. The final portion shown on Fig. 1 and 2 (22.4 or 21.5 hr) gives potentials after strong oxygen evolution was reached.

Figures 3 and 4 give excerpts of silver electrode potentials taken from two charges that had current

\* Values in brackets give the number of measurements made.

reversed for 0.25 hr every 1.5 hr. As shown in Table I, this charge procedure gave a discharge capacity in 35% KOH that averaged 109% of the normal capacity. There was, however, considerable variation in the seven individual capacities that were averaged to give 109%. Four of the seven charges that had 0.25-hr reversals every 1.5 hr gave discharge capacities from 95 to 98% of normal capacity, but the other three charges gave 116, 128, and 133% of normal capacity. The discharges that gave 95 and 133% of normal capacity represented 58 and 79% of the capacity theoretically possible, respectively. The solid lines in Fig. 4 show that reversal potentials of a charge which gave improved capacity tended to be at successively lower values during the first half of a charge at the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau (in contrast to reversals during a charge which gave normal capacity, shown by dashed lines), although the amount of  $\text{AgO}$  that was present on the electrode increased in this period. This resembles previous results when charge current was interrupted periodically throughout a charge (2). Under these conditions the open-circuit potentials also reached successively lower values as the amount of  $\text{AgO}$  present increased for half of a charge at the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau.

It seemed likely that reversal had more effect near the end of a charge than in the earlier part of a charge, judging by potential changes observed during and after reversals. If the number of reversals were lowered, the time required for a complete charge of the silver electrode would be decreased, because the time spent in reversal and the charge time spent in replacing the capacity removed during reversal would both be decreased. Therefore, a series of charges were done in which current was reversed the first two times that a given electrode potential was reached. The potentials chosen were 400, 440, 480, and 510 mv vs. the  $\text{Ag}/\text{Ag}_2\text{O}$  reference electrode. These potentials were not reached until near the end of a charge.

Some of the results of partially discharging silver electrodes the first two times that a particular charge potential was reached are given in Table II. After the capacity removed by the reversal was replaced, additional charge was accepted before charge potential again reached the reversal point. Table II is arranged according to the additional charge accepted after the first reversal. The additional charge time was a better measure of capacity than was the average discharge capacity, because normal capacity after a constant current charge varied irregularly by several per cent. Since charges were done at the 20-hr rate of constant

Table II. Effect of reversing current the first two times that potential reached a particular value during a charge at the 20-hr rate. Charge potential of silver oxide electrode at reversal point was 440, 480, or 510 mv vs.  $\text{Ag}/\text{Ag}_2\text{O}$

<sup>a</sup> Average time required for reversal point to be recovered after replacing capacity that was removed during the brief reversal.

<sup>b</sup> Values in brackets give the number of measurements made.

<sup>c</sup> Open-circuit stand.

<sup>d</sup> In 50% KOH solution. All other results were obtained in 35% KOH solution.

Fig. 3. Some excerpts of potentials measured in 35% KOH during two constant current charges of a silver electrode at the 20-hr rate. Charge current was reversed for 0.25 hr every 1.5 hr. Numbers by the curves give the total elapsed time in hours at the beginning of each excerpt. Charges produced 133% of normal capacity (solid lines) and 95% (dashed lines).

current, each additional hour of charge gave approximately 5% additional capacity. Table II includes a few open-circuit stands for comparison, although stands were quite ineffective for increasing capacity under these conditions. There was no significant difference between the results when the reversal potential was 440, 480, or 510 mv vs. the  $\text{Ag}/\text{Ag}_2\text{O}$  reference electrode; therefore, the results for these potentials are combined and summarized in Table II. Only five charges were done with 400 mv as the reversal potential, because the additional charge accepted when using this reversal potential was only 70 to 80% of the additional charge accepted at 440 to 510 mv. The results with 400 mv are not included in Table II. All reversal conditions listed in Table II resulted in increased capacity, although the increase was very small under some conditions.

The effect of two 30-min reversals at the 20-hr rate was tried with the commercial silver-zinc cells. The additional charge time in 35% KOH averaged 0.54 and 0.15 hr after the first and second reversals, respectively. These values were much less than the values obtained with the test cells in 35% KOH (top line of Table II). For the commercial silver-zinc cells containing 45% KOH, the additional charge averaged 0.21 and 0.08 hr after the first and second reversal, respectively.

## Discussion

The results obtained with relatively long reversals using a constant current (Table I) were, in general, markedly inferior to the results when the reverse current was derived from 60 cps asymmetric a.c. (3). No increase in capacity was obtained with most of

Fig. 4. Reversal potentials during the two charges shown in Fig. 3. Solid lines give reversal potentials during the charge which produced 133% of normal capacity and dashed lines give reversal potentials during the charge which produced 95%.

the long reversals that were tried. The only consistent and large increase came after a charge in which current was reversed for 15 out of every 60 min. This charge gave a capacity averaging 143% of the normal capacity, a value very close to the maximum capacity obtained following a charge in which current has held constant for long periods and then was increased for a few seconds (1). Approximately the same capacity was obtained when the electrode was charged by a rapidly pulsating unidirectional current (2), but a slightly larger capacity could be obtained following a charge with 60 cps asymmetric a.c. (3).

Although a large capacity was obtained by reversing the charge current for 15 out of every 60 min, a disadvantage of using long reversals was that the time required for a complete charge always exceeded 20 hr because of the necessity to replace the capacity removed during each reversal. Time could be shortened by having long charge periods between the reversal periods, but then it often happened that no reversal occurred near the end of a charge, at the point where potential changes during and after reversals seemed to indicate that reversals were most effective for increasing capacity. Although long reversals were the most beneficial reversals, not many charges with repeated discharges were tried in which over 1% of the capacity was removed with each reversal, because time required for a complete charge became excessive. For example, when the 20-hr charge current was used with current reversed for 15 out of every 60 min, 40 hr were required before a cell had a net charge of even 100% of normal capacity, and nearly 2.5 days were required for a complete charge. It should be noted, however, that the capacity averaging 143% of normal capacity obtained with this charge-discharge parameter was much larger than the 112% of normal capacity obtained after an electrode was charged using a steady constant current at the 2.5-day rate.

If maximum capacity is desired and total charge time is relatively unimportant, this charge with long reversals is preferable to a charge at a low constant current. If a constant discharge potential is desired, a low rate of constant charge current or the asymmetric a.c. (3) may be preferable. An electrode charged at a low current has less surface area than an electrode charged at a high current (5). The initial potential plateau during discharge of an electrode with small surface area is at a relatively low potential, because AgO on the surface is rapidly covered by Ag<sub>2</sub>O during discharge, judging by the results of x-ray diffraction (5); most of the discharge takes place at the Ag<sub>2</sub>O/Ag potential even though part of the current still is produced by the reduction of AgO. A low charge rate is preferable if the electrolyte concentration is high, for example 45 or 50% KOH. As charge current density increases, i.e., as charge time decreases, capacity falls more rapidly in concentrated KOH than in more dilute KOH. For example, when the commercial silver-zinc cells were charged at the 40-hr rate, a cell containing 45% KOH gave about 112% of normal (20-hr) capacity, while a cell containing 35% KOH gave only 105% of normal capacity.

Normal charge acceptance of a silver oxide electrode could be increased 15%, without charge time becoming excessive, by partially discharging the electrode once or twice near the end of a charge (Table II). The second reversal was not worth attempting unless a large amount of charge had been accepted after the first reversal. The additional charge after a second reversal was usually only 10 to 25% of the charge added after the first reversal. The few times that a third reversal was done at the same potential, added charge was less than it had been after the second reversal. Effectiveness of the reversals generally correlated with the amount of capacity removed. To obtain a capacity improvement that exceeded 10%,

the capacity removed during each reversal had to be over 1% of the normal electrode capacity. This result correlated with results found when reversals were repeated periodically throughout a charge (Table I). For a specific amount of reversal near the end of a charge, the rate of reversal current was also an important factor (Table II). Another important factor was electrolyte concentration. Although the added capacity was small under many of the conditions used, the recharge did always exceed the capacity removed during each of the two partial discharges.

Reports differ as to whether porous silver electrodes react first at the conducting grid or at the electrode surface. Romanov (6) used pressed silver powder electrodes and reported that the oxides were concentrated at the grid after a direct current charge. Dirkse (7, 8) reported that pellets of pressed Ag<sub>2</sub>O or AgO gave the potential of material next to the grid and not the potential of the bulk composition of the pellets. These results when pressed materials were used contrast with results obtained by x-ray diffraction of sintered silver electrodes (9) and of roughened sheet silver (5). Here the potentials were determined by the material on the surface, and oxidation of Ag<sub>2</sub>O and reduction of AgO took place initially on the surface of the electrode next to the solution. The newly formed oxide could be detected when it was present in a smaller amount than was necessary for detecting one component of a mixture by using x-ray diffraction. This indicated that when Ag<sub>2</sub>O was oxidized or AgO was reduced the initial formation must have been concentrated on the electrode surface. The initial formation of Ag<sub>2</sub>O on Ag was not detected as readily in x-ray diffraction patterns, because the initial oxidation occurred on the surface of silver particles which were distributed throughout the electrode. Similarly, the use of x-ray diffraction showed that when Ag<sub>2</sub>O was reduced relatively little Ag formed on the surface at first.

Microscopic examination of sintered silver electrodes has confirmed that the reactions are not concentrated at the grids. Microscopic examination of electrodes in various states of discharge indicated that Ag<sub>2</sub>O and Ag did not tend to form first at the grids and be concentrated there (4) nor did Ag<sub>2</sub>O and AgO tend to form first at the grids during a constant current charge (10). A large amount of unoxidized silver was still present in the vicinity of the grids at the end of a charge. Higher electrical resistance in some unsintered pressed powders may be the cause for the different behaviors that have been reported in the literature. All reactions may take place at the conducting grid with some pressed powder electrodes merely because there is less IR drop near the grid of these electrodes than there is at the electrode surface.

A large part of the silver had been oxidized to AgO by the time a normal charge of a sintered silver electrode ended, although substantial amounts of metallic silver remained with a thin coating of Ag<sub>2</sub>O separating the AgO from this Ag (4, 10). Much of the surface and many internal cavities were partially or completely filled with AgO crystals. When a nearly charged electrode was discharged briefly under the conditions in Table II, part of the AgO was converted to Ag<sub>2</sub>O. This reduction may have exposed some areas of the Ag<sub>2</sub>O-coated Ag that had been tightly covered by AgO crystals. Significant changes in crystal size and shape occur as the silver oxides are reduced or silver is oxidized (4, 10). AgO tends to form into much larger crystals than does Ag<sub>2</sub>O. Although the change in total volume is only slight as AgO is reduced to Ag<sub>2</sub>O, the crystal lattice is distorted as dimensions change in going from monoclinic to face-centered cubic crystals. Lattice dimensions indicate that a large expansion of the crystal occurs as metallic silver is oxidized to Ag<sub>2</sub>O and recent coulometric measurements have confirmed

that a large volume change occurs (11).

When a charge was resumed after a reversal near the end of a charge, current may have been divided between oxidizing the  $\text{Ag}_2\text{O}$  formed during the reversal and oxidizing  $\text{Ag}_2\text{O}$ -coated Ag that had been exposed where openings had formed in the AgO coating. A long reversal, during which relatively large amounts of AgO were reduced, probably exposed larger areas of  $\text{Ag}_2\text{O}$ -coated Ag than were exposed after short reversals. The excess of charge capacity over reversal capacity was, therefore, significantly larger after a long reversal than after a short reversal (Table II). Much of the current during a second reversal would probably reduce the same areas of AgO that were reduced after the first reversal. A second reversal was, therefore, much less effective than the first reversal in exposing Ag and promoting formation of additional AgO after the charge was resumed.

Although most of the periodic reversals repeated throughout a charge were not effective for increasing total charge capacity (Table I), the charges were of some interest because of the potentials observed. Figures 1 and 2 give potentials that were typical of all charges listed in Table I except for the charges with 15-min reversals. The potentials shown in Fig. 1 and 2 are generally similar, despite differences in reversal length, reversal repetition frequency, and per cent of time that current was reversed. During the early portion of the  $\text{Ag}_2\text{O}/\text{AgO}$  potential plateau, charge potential rose gradually after a reversal until a potential was reached which slightly exceeded the value measured just before reversal, and then potential slowly fell (Fig. 1 and 2). Later in the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau the charge potential developed two steps after each brief reversal. During the first step the electrode charged at a potential only slightly above the  $\text{Ag}_2\text{O}/\text{AgO}$  equilibrium<sup>1</sup> until approximately 100% of the capacity lost during reversal had been replaced. Probably almost all current was oxidizing  $\text{Ag}_2\text{O}$  that had formed at readily accessible sites during the reversal. Then the reaction shifted to oxidation of sites which required more energy. Potential rose rapidly, passed through a maximum, and decreased slowly until a steady charging potential was reached again.

When current was reversed for 0.25 hr every 1.5 hr, the potential pattern obtained from the silver electrode during charges which gave improved capacity differed from the pattern during charges which gave normal capacity. During the charges which gave improved capacity, there was a potential maximum when charge current was resumed following each reversal at the  $\text{Ag}_2\text{O}/\text{AgO}$  potential plateau, except the final reversal before reaching oxygen evolution (solid lines in Fig. 3). Following these initial maxima, potentials fell to relatively low values during charges having improved capacity. There were only one or two such maxima during charges that gave normal capacity (dashed lines in Fig. 3) and the potential tended to have successively lower values as charge was resumed after each reversal. Charges having the highest capacity had low reversal potentials during most of the charge (Fig. 4) and high gas evolution potentials at the end of a charge (Fig. 3). A charge that gave the intermediate capacity of 116% had most reversal potentials in the range from 215 to 195 mv, intermediate between the two sets of values shown in Fig. 4. Thus, the relative discharge capacity that was going to be obtained could be predicted before this type of charge was half completed.

These potential changes during charges with relatively long reversals gave an indication of possible electrode conditions. After  $\text{Ag}_2\text{O}$  had started to oxidize to AgO, the first reversal began at a potential close to the  $\text{AgO}/\text{Ag}_2\text{O}$  equilibrium (Fig. 3, 4). At this time the electrode contained relatively large

amounts of  $\text{Ag}_2\text{O}$  and Ag, with a small amount of AgO present. Then, in the charges which gave improved capacity, came a series of reversals in which potentials were successively lower although increasing amounts of AgO were present on the electrode. Microscopic examination of electrodes during constant current charges indicated that all areas do not react simultaneously (10). AgO may form in one area while an adjacent area has no AgO. In charges with reversals which resulted in improved capacity, the AgO may have had a tendency to form a tighter coating or a thicker coating that blocked electrolyte channels more than usual and hindered ion movements. The successively lower discharge potentials probably resulted from a progressive hindrance to the reduction of AgO as the amount of AgO increased. The unusually low potentials during reversal were followed by charge potentials that began at a high value. Since the same amount of  $\text{Ag}_2\text{O}$  was produced during the reversal periods of both charges shown in Fig. 3, it was unlikely that the potential maxima on resuming charge were due to resistance of  $\text{Ag}_2\text{O}$ .

A change must then have occurred in the charges which gave improved capacity. Perhaps formation of AgO was initiated at new sites by the high potentials, or perhaps oxygen from the surface layers could penetrate deeper into the oxide layer under the influence of a high charging potential and could oxidize additional silver. When charge potential reached a maximum and then decreased, possibly the potential fall resulted from decreasing local current densities as AgO began to form in a larger number of sites, or possibly a blocking AgO coating cracked as a result of expansion as oxides formed below the AgO surface. Increased porosity would allow the electrolyte to penetrate nearer to the metallic silver that remained and result in decreased concentration gradients in the AgO layer. Charge potential fell to a value close to equilibrium values, lower than the potential of normal charges. Although the exact nature of the process is unknown, it apparently took place repeatedly and allowed more AgO than usual to be formed before diffusion through the AgO became sufficiently difficult that electrode potential rose to the oxygen evolution value. The few charges with periodic reversals which resulted in improved capacity (Table I) may have had charge and reversal periods proportioned correctly to give a potential maximum each time that charge was resumed.

After the initial potential maximum when charge was resumed, the charges which gave improved capacity often had additional smaller maxima as gradually rising potentials reached 351 to 355 mv (Fig. 3). Potentials dropped 4 to 10 mv after reaching the maxima and then again increased gradually. Many more of these slow potential fluctuations occurred in charges that gave the high capacity than in other charges. Charges at the 20-hr rate which gave normal capacity usually exceeded 355 mv only when potential made the sharp rise from the  $\text{Ag}/\text{Ag}_2\text{O}$  plateau to the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau and again as potential rose slowly near the end of a charge (Fig. 1 and 2).

The differences between results with the commercial silver-zinc cells and the test cells were probably due mainly to different concentration gradients, but the exact nature of the process is unknown. The commercial cells were tightly packed and had little free electrolyte. This arrangement should result in concentration gradients near the electrode surface being larger in the commercial cells than they were in the test cells at the same current density. It is possible that zincate ions had diffused through the separator and reached the electrolyte which contacted the Ag electrodes, but it is doubtful that the presence or absence of zinc was an important factor.

### Summary

During charges of sintered silver electrodes of the type used in storage batteries, in one set of condi-

<sup>1</sup>The equilibrium potential of the  $\text{Ag}_2\text{O}/\text{AgO}$  couple vs.  $\text{Ag}/\text{Ag}_2\text{O}$  has been given as 261 mv (8) and as 262 mv (12).

tions periods of constant current charge were separated by shorter periods of constant current discharge. Current reversals lasting 0.01 to 3 min repeated every 1 to 30 min at the 20-hr rate had little effect on charge acceptance. Reversals of 15 min repeated every 60 min during a charge at the 20-hr rate increased capacity of test cells by an average of 43% in 35% KOH, but had the disadvantage of greatly increasing the total time required for a charge. Capacity was, however, much larger than the capacity obtained from an uninterrupted constant current charge requiring the same total time. More widely separated reversals of 15 min gave less improvement. Reversals seemed most effective for increasing capacity when they occurred near the end of a charge.

In another set of conditions, the silver electrodes were partly discharged the first two times that charge potential reached a chosen value near the end of a charge. Average capacity of test cells was improved by up to 16% without charge time becoming excessive. Effectiveness of reversals near the end of a charge correlated with the amount of capacity removed and was also affected by the rate of the reversal current. The second reversal gave much less added capacity than the first reversal gave.

In general, as KOH concentration increased, capacity improvement decreased. Commercial silver-zinc cells always gave less increase in capacity than the test cells gave.

## A Coulogravimetric Investigation of the Zinc Electrode in Potassium Hydroxide

A. Langer\* and E. A. Pantier

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

#### ABSTRACT

The presented results obtained by weighing the zinc electrode in the electrolyte during the discharge cycle agree with data of others and explain why the capacity of the zinc electrode is a function of the amount of electrolyte used and roughly linearly dependent on the concentration of the potassium hydroxide up to about 10M. Previous results, that part of the zinc goes into solution, part is precipitated out as oxide or hydroxide, and that some adherent layer is formed which finally forces the potential of the plate to drop sharply, are substantiated on a more quantitative basis. The experiments also indicate that the relatively thick scale formed might not be the sole cause of the passivation phenomena.

The zinc electrode dissolves on discharge in an alkali electrolyte to form the tetrahydroxo zincate ion. This reaction was first proposed by Dirkse (1) and has been confirmed by such recent investigations as nuclear magnetic resonance (2) and infrared absorption spectra (3). Polynuclear forms, however, have been suggested from diffusion measurements (4). The formation of oversaturated solutions is favored by anodic action.

One can also observe that the surface of the electrode becomes covered during its working cycle, usually with a dark colored substance (5), and that a precipitate appears in the electrolyte. These solid substances have been identified as zinc hydroxides, oxides, or oxyhydroxides (6), but according to Feitknecht (7) there are many modifications of each. As the work of Flerov (8) indicates, only one form imparts passivity to the zinc electrode.

To gain some additional information about the behavior of the zinc electrode in potassium hydroxide electrolyte, coullogravimetric analysis was used. The underlying principle of the method has been described (9) and is based on the continuous weighing

of the electrode in the electrolyte during the discharge cycle of the zinc electrode. The weight loss, considering buoyancy, is correlated with other simultaneously recorded parameters such as the quantity of electricity passed and electrode potential.

For the recording of weight change, a torsion balance was converted for automatic weight registration. The current from the cell was passed through the torsion bands without any noticeable effect on the weighing (Fig. 1). The whole assembly including the cell was encased in an air-tight box. Thus, by maintaining a controlled atmosphere, the electrolyte was protected during long runs from the influence of carbon dioxide in air and from excessive evaporation. It should be mentioned that the hunting tendencies of the automatic weighing arrangement do impart small but noticeable vibrations to the sample which may slightly stir the solution, enough so that density gradients around the electrode might be minimized (10).

#### Experimental

The half cell consisted of a flat thin zinc sheet of high purity (Fisher Certified A.C.S.), with 100 cm total area counting both sides, and weighing about

\* Electrochemical Society Active Member.

Fig. 1. Automatic weighing arrangement for coulgravimetry with torsion balance.

20g. Sintered silver plates of the same dimension (7 x 7 cm) but of large capacity by combining several plates in parallel were wrapped in cellophane and placed on both sides of the zinc. The spacing between the plates was rather narrow, so that 50 ml of the electrolyte, used throughout the experiments, completely covered the electrodes. Potassium hydroxide solutions, as carbonate free as possible, were prepared of different strength and the concentration determined by titration. These solutions were then saturated with zinc oxide (Fisher certified A.C.S.) by shaking for several days at room temperature. The zinc content was found polarographically after dilution of 1 or 2 ml to 50 ml with 1M KOH. Some care has to be exercised in the polarographic zinc determination, because the diffusion current decreases appreciably with increasing alkali concentration of the supporting electrolyte. Determinations of zinc were performed in a like manner on centrifuged solutions obtained after the cell ceased to function. Density of the electrolyte saturated with zinc oxide was also measured before and after the zinc electrode reacted in the discharge cycle until it became passivated. The results of these measurements are shown in Fig. 2. There was a noticeable increase in density of the electrolyte after the zinc plate was discharged. The values of density were used to apply the buoyancy corrections to the measured weight values. Similar data have already been published (11).

The silver electrode was always freshly charged and wrapped in new cellophane. A new zinc plate, abraded with fine steel wool and washed with acetone and water and new electrolyte, was also used for each experiment. An Hg/HgO reference electrode, connected by a bridge, confirmed that it was always

Fig. 2. Specific gravity of KOH solutions saturated with ZnO (a), saturated by discharging a zinc electrode until passivation (b).

the zinc electrode which failed in these experiments. The current flowing through the cell was calculated by Ohm's law from the continuously monitored potential across a calibrated 5.00 ohm resistance, which was also used to limit the discharge rate. The potentials across the resistance are represented by the upper graph A in Fig. 3, whereas the weight change as measured in the different electrolytes is shown by the lower graph B as a chronogravimetric relation. Just a few such relations are discussed.

Curve (a) represents a discharge in 40g KOH/liter. The current was low from the start and relatively little zinc was lost since the battery failed very early. Using 174g KOH/liter, it can be clearly seen that the weight of the electrode first decreases with time as shown in solid curve (b). From the ampere-hours passed one can also determine a theoretical curve for zinc loss by using Faraday's law, assuming no side reaction, and making correction for the buoyancy effect in the given electrolyte of known density. The dashed curve (b') was thus obtained. The two curves coincide at the beginning quite well but after a certain time the measured weight loss starts to decrease and the two curves deviate, until the zinc electrode loses no weight at all, although still delivering the same current as before. Only when the weight of the zinc plate actually starts to increase slightly does the potential and therefore the current output of the cell drop sharply, indicating that the electrode has reached a state of passivation.

An electrode in a solution of 213g KOH/liter behaved similarly, as indicated by curves c in Fig. 3. The total amount of reacted zinc was greater in this case. Again at the beginning of discharge, the electrode loses weight according to Faraday's law, but later the weight loss diminishes, finally leveling off. Only when the weight curve starts to bend upward is there a sharp drop in potential registered and the battery fails. From the current delivered, the weight loss should follow dashed curve c'.

The same trends can be observed with 310g KOH/liter and the electrode is active for a still longer time (Fig. 4, curve a). The upward swing in the weight curve forecasting the end of the reaction is no longer pronounced. At even higher electrolyte concentrations (490 and 595g KOH/liter) the electrode behaves somewhat differently as shown in the curves (b) and (c) of Fig. 4. The zinc electrode loses weight almost constantly during the entire discharge life and levels off only at the very end, followed by a sharp decrease in current output. The weight loss seems to proceed even at a slightly faster rate than calculated from the ampere-hours

delivered, as shown in dashed curves b' and c', which could mean an additional purely chemical attack, although no visible gas evolution was detected. The difference is not large enough to be caused by varying density factors. Still another phenomenon was noted. After some discharge had occurred, the weight loss did not proceed smoothly as in the beginning but in a rather irregular fashion. This behavior was traced to the formation of large blisters on the surface of the electrode which were flaking off, resulting in the erratic weight curve. Similar curves were obtained at higher concentrations of KOH but without a substantial increase in the amount of zinc reacted.

### Discussion

Let us correlate the concentration of the electrolyte with the weight loss of the electrode. First consider the leveling off of the weight curve. Figure 5 represents the idealized behavior of a zinc electrode in an electrolyte of 1.25 specific gravity, or about 5M. If a soluble complex is formed, the electrode should lose  $m = 1.22\text{g}$  of zinc for each ampere hour. Due to the buoyancy effect, taking into account the density of the zinc ( $d_{\text{Zn}}$ ) and the electrolyte ( $d_s$ ), the observed loss in the electrolyte will be only about 1g, calculated by the equation  $m^s = m(1 - d_s/d_{\text{Zn}})$ . In case ZnO were formed as an adhering compound, the increase in weight per ampere-hour would be close to 0.3g by weighing in air or, with buoyancy correction, an indicated increase of only 0.23g. Similar relations can be found for the formation of  $\text{Zn}(\text{OH})_2$  or any other compound, provided the density of the compound is known. Since at a certain time the balance registers no weight change, this must mean that the rate of zinc dissolution is equal to the oxide or hydroxide formation at the surface. We can easily calculate that at this point of no weight loss over 80% of the reacting zinc must be converted to a compound adhering to the electrode while less than 20% is still dissolving in the electrolyte.

Figure 6 shows the relation between potassium hydroxide concentration and the amount of Zn found in the electrolyte. This graph was derived from many more experiments of the type just described. It can be seen on the curve with circles that the amount of zinc dissolved in potassium hydroxide by shaking with zinc oxide is rising with increasing hydroxide concentration. At 800g KOH/liter, almost 180g Zn/liter is in the solution at room temperature. These

Fig. 5. Idealized behavior of a zinc electrode in an electrolyte of 1.25 density. Solid lines, weight change in air; dashed lines, weight change with buoyancy effect of electrolyte.

Fig. 6. Solubility of zinc oxide and of the zinc electrode in potassium hydroxide of increasing concentration.

results, of course, apply to the particular form of oxide used.

On the same graph the upper curve with squares is a plot of the zinc concentration in the electrolyte after the cell has been drained to the point of passivation. As can be noticed, quite an additional amount of zinc is present now in the electrolyte. Actually at lower KOH concentrations, almost the same amount of the zinc electrode dissolves during the discharge cycle as is derived from the solubility of zinc oxide directly. At higher KOH concentration this amount has diminished.

The increase in zinc concentration by battery action is usually referred to as the formation of a supersaturated solution. But under the prevailing conditions of relative stability one could consider, since the amount of zinc present in the solution is about twice the concentration of a ZnO-saturated solution, the formation of a soluble zinc-zincate ion or a complex

Fig. 7. Reaction of the zinc electrode as a function of KOH concentration.

of the type  $[\text{Zn}_2(\text{OH})_6]^-$  may also be possible. This complex only slowly decomposes to zinc oxide on standing. It should be mentioned that the same total amount of zinc in the electrolyte is obtained by anodic action whether one takes a zinc oxide saturated solution or an electrolyte initially free from zinc ions as indicated by the black squares. Without the zinc oxide dissolved, the capacity of the cell is correspondingly larger. This condition would be advantageous for primary batteries, but for fast recharging in secondary batteries it is advantageous to have an excess of zinc ions in the electrolyte.

If we now plot the difference between these two curves we obtain curve (a) indicated by squares in Fig. 7. This is the amount of zinc introduced into the electrolyte strictly by the dissolution of the zinc electrode into a zinc oxide saturated solution of potassium hydroxide. The circles (curve b) represent the amount of zinc reacted as calculated from the ampere-hours the battery has delivered. This latter value is as seen quite higher. Both are a function of electrolyte concentration as was indicated in previous findings by Shepherd (12) and Sanghi (13). The difference between the two curves must represent the amount of precipitated zinc compound, either adhering to the electrode, dispersed in the electrolyte, or settled to the bottom of the cell. The difference between the weight of the electrode as determined by direct weighing in the electrolyte with buoyancy correction (curve c, Fig. 7), and by calculating from Faraday's law must contain the weight of the zinc tied up as a precipitate adhering to the surface of the electrode. It is a relatively small fraction of the total as indicated on the graph and surprisingly constant through the large range of KOH concentra-

tions. The data are probably not too precise, but attempts to weigh the precipitate in the solution failed, because the compound was also dispersed within the cellophane wrapping around the silver. Also, partial disintegration of the adhering layer on the zinc plate, when taken out of the electrolyte, made the weighings of the zinc electrode in air before and after the reaction rather indecisive. One conclusion that can be drawn from Fig. 7 is that the zinc electrode does not derive its whole capacity from dissolution as zincate but a large portion by the formation of a nonadhering precipitate. The output of the cell increases markedly from low values with the increasing KOH concentrations and a maximum is reached at around 10M potassium hydroxide.

By the weighing procedure it was indicated that a surface layer must be formed which adheres at lower concentrations of potassium hydroxide KOH and peels off easily at high concentrations, in order to explain the leveling off of the weight curve as shown in Fig. 3 and 4. But this relatively thick layer cannot solely be responsible for the passivation of the electrode. The fact that passivation occurs rather abruptly and always when the weight-coulomb curve is on a slight increase might indicate that a thinner and denser layer is formed which blocks the electrochemical reaction. This film could be formed independently as a new phase on the surface of the zinc under the existing scale or by a recrystallization of the layer already present.

# Characterization of a Porous Graphite Cl<sub>2</sub> Electrode

Dominicus A. J. Swinkels\*<sup>1</sup> and Randall N. Seefurth<sup>2</sup>

General Motors Research Laboratories, Electric Powerplants Department, Indianapolis, Indiana

## ABSTRACT

An experimental grade of porous graphite known as Poco-AX has been characterized. The model previously developed for Cl<sub>2</sub> electrodes in fused LiCl was found to hold well under the conditions used. Although the material is 57% porous, its strength and machinability are excellent. Data are given for the pore size distribution, gas flow resistance, and electrical conductivity of the material. Performance as a Cl<sub>2</sub> electrode under various conditions of electrode thickness, Cl<sub>2</sub> pressure, and Cl<sub>2</sub> purity is described and compared with the theoretical model. It was demonstrated that current densities in excess of 10 amp/cm<sup>2</sup> can readily be obtained.

The requirements for gas diffusion fuel cell electrodes has led to the development and characterization of a variety of porous carbon and graphite materials (1, 2). Some of these materials have also been tested as Cl<sub>2</sub> electrodes for application in high power density and high energy density fused salt batteries such as the Li-Cl<sub>2</sub> battery (3, 4). The performance of various porous structures as Cl<sub>2</sub> electrodes in LiCl has been discussed in terms of the electrode porosity and pore size distribution (3) as well as the purity of the Cl<sub>2</sub> gas. The latter becomes particularly important when the porous carbon or graphite structure is optimized for high current density operations, since small amounts of inert impurities normally present in Cl<sub>2</sub> will then quickly build up in the electrode and poison it (5).

This paper reports on the characterization of a porous graphite known as Poco-AX,<sup>3</sup> which has demonstrated superior performance as a Cl<sub>2</sub> electrode in fused LiCl.

The AX grade is made by heating grade AC porous carbon to graphitization temperatures (2300°C) (6). The grade AC material has been previously described and tested for aqueous fuel cell applications (7). Both of these materials differ from the usual porous carbon and graphite materials in that they combine high porosity with very small pores and a very narrow pore size distribution. Table I shows a comparison with a more conventional material.

The materials from which AC and AX are prepared are considered proprietary by the manufacturer. The filler material used is smaller (less than 0.001 in. diameter) than that used in conventional graphites and the particles tend to be rounded (6). This seems to result in the narrower pore size distribution and the small pore size seen in AC and AX. Although no measurements have been made of the strength of these materials, general experience indicates that they are stronger than most porous carbons of similar porosity and can be machined to high tolerances. The graphitized material (AX) is preferred for use in high current density electrodes mainly because of its lower electrical resistivity. Therefore this material was tested extensively as a Cl<sub>2</sub> electrode in fused LiCl.

The pore size distribution of the AX material as determined by Hg intrusion measurements is shown in Fig. 1, together with a stepwise approximation which will be used in the theoretical treatment. The average tortuosity of the pores was determined by measuring the flow rate of N<sub>2</sub> through disks of the AX material at room temperature at various pressures across the disks and comparing them to calcu-

lated flow rates. The theoretical flow rates for a given porosity and pore size, taking into account both viscous (Poiseuille) flow and molecular streaming (Knudsen flow) (3), is given by

$$Q(r) = \phi(r) \left( \frac{\Delta P}{P} \right) \left[ \left( \frac{1.013 \times 10^6 r^2 (P_1 + P_2)}{16 \mu \tau t} \right) + \frac{4\delta r}{3\tau t} \left( \frac{2RT}{\pi M} \right)^{1/2} \right] \quad [1]$$

where  $Q(r)$  = the flow of gas in cc/sec through pores of radius  $r$  at pressure  $P$ ,  $\phi(r)$  = the volume of pores or radius  $r$  per cm<sup>3</sup> of electrode,  $P_1$  = the entrance pressure (atm),  $P_2$  = the exit pressure (atm),  $\Delta P = P_1 - P_2$ ,  $\mu$  = the gas viscosity (poise),  $\tau$  = the tortuosity of the pores,  $t$  = the thickness of the electrode (cm) in the direction of the gas flow,  $\delta$  = constant = 0.9,  $R$  = gas constant =  $8.317 \times 10^7$  erg/°K mole,  $T$  = temperature (°K), and  $M$  = the molecular weight of the gas.

The total theoretical flow rate through a piece of graphite with a range of different pore sizes is then given by

$$Q(\text{total}) = \sum_r Q(r) \quad [2]$$

The ratio of this calculated total flow using the step approximation of the pore size distribution to the experimentally determined flow leads to a tortuosity of 3.75. This is an unusually high tortuosity for so porous a material and is no doubt related to the method of manufacturing this material. It should be noted that the tortuosity found by a flow measurement heavily favors the tortuosity of the larger pores so that the tortuosity of the small pores may be quite different. However, a tortuosity of 3.75 will be used in all calculations.

## Cl<sub>2</sub> Electrode Model

A model has been developed describing the reaction kinetics at the porous graphite Cl<sub>2</sub> cathode (3). Because the fused LiCl electrolyte does not wet carbon or graphite, it is postulated that the reaction takes place in the interface region between the porous elec-

trode and the electrolyte and not deep within the pores as is the case in most aqueous porous electrodes.

The over-all process at the Cl<sub>2</sub> electrode can be divided into the following five steps: (i) flow and diffusion of Cl<sub>2</sub> gas through the porous plug, (ii) dissolution of Cl<sub>2</sub> at the gas-liquid interface, (iii) diffusion of dissolved Cl<sub>2</sub> to the carbon-LiCl interface, (iv) dissociation and charge transfer, and (v) migration of Cl<sup>-</sup> ions into the bulk electrolyte. Steps (ii) and (v) are fast mass transport steps which have negligible effect on the polarization. Step (iv) occurs at the actual electrode-electrolyte interface and gives rise to the activation polarization. Steps (i) and (iii) give rise to the concentration polarization with the relative contribution of these two steps being determined mainly by the pore radius.

The maximum current density (amp/cm<sup>2</sup>) which a nonwetted electrode with pores of radius  $r$  (cm) can support is given by Eq. [3]

$$i_L(r) = \frac{AnFDKP_2\phi(r)}{r} \quad [3]$$

where  $A$  = constant  $\approx 8$ ;  $n$  = number of electrons, 2;  $F$  = Faraday, 96487 coul mole<sup>-1</sup>;  $D$  = diffusion coefficient of Cl<sub>2</sub> (in LiCl at 650°C  $D \approx 4 \times 10^{-5}$  sec<sup>-1</sup>);  $K$  = Henry's law constant, 10<sup>-6</sup> moles cm<sup>-3</sup> atm<sup>-1</sup> at 650°C;  $P_2$  = Cl<sub>2</sub> pressure at the gas-liquid interface; and  $\phi(r)$  = volume of pores of radius  $r$ /cm<sup>3</sup> of electrode.

The total current density for an electrode with a range of different pore sizes is then given by

$$i_L(\text{total}) = \sum_r i_L(r) \quad [4]$$

The partial pressure of Cl<sub>2</sub> at the gas-liquid interface ( $P_2$ ) is equal to the total pressure ( $P_T$ ) in the gas-stream feeding the electrode minus the pressure drop ( $\Delta P$ ) across the electrode and minus the partial pressure of impurities  $P_s(i)$  in the gas at the gas-liquid interface, i.e.,

$$P_2 = P_T - \Delta P - P_s(i) \quad [5]$$

The pressure drop  $\Delta P$  is determined by the flow resistance in the pores to the Poiseuille flow (viscous) and the Knudsen flow (molecular streaming).

For a single pore size,  $r$

$$\Delta P(r) = \frac{i_L R T L}{n F \phi(r)} \left[ \frac{16\mu}{1.013 r^2 [2P_T - \Delta P(r)]} + \frac{3}{48r} \left( \frac{\pi M}{1.6634T} \right)^{1/2} \right] \quad [6]$$

where  $R$  = gas const = 82.082 cm<sup>3</sup> atm deg<sup>-1</sup> mole<sup>-1</sup>, and  $L$  = pore length =  $\tau r$ .

For a piece of carbon with a variety of parallel flow paths of different radii, Eq. [6] becomes

$$\Delta P = \frac{1}{\sum_r \frac{1}{\Delta P(r)}}$$

The viscosity of Cl<sub>2</sub> gas ( $\mu$ ) used in Eq. [6] is given in centipoise by (8)

$$\mu = 1.4329 \times 10^{-4} + 4.6979 \times 10^{-5} T - 3.7158 \times 10^{-9} T^2 - 4.0541 \times 10^{-12} T^3 \quad [8]$$

The build-up of electroinactive impurities in flow-by electrodes, i.e., electrodes which have an excess of chlorine flowing behind the porous electrode to remove impurities from the electrode, has been previously treated (5) and is given by

$$P_s(i_L) = N_o P_T \exp \left( \frac{i_L R T \tau t}{n F P_T \phi_T D'} \right) \quad [9]$$

where  $P_s(i_L)$  = impurity pressure in the gas at the gas-liquid interface at the limiting current density  $i_L$  (amp/cm<sup>2</sup>),  $N_o$  = impurity mole fraction in the feed gas, and  $\phi_T$  = total porosity.

The diffusion coefficient  $D'$  for a binary gas mixture may be calculated (9) from

$$D' = \frac{0.001858 T^{(3/2)} \left( \frac{M_1 + M_2}{M_1 M_2} \right)^{1/2}}{\Omega_D P \left( \frac{\sigma_1 + \sigma_2}{2} \right)^2} \quad [10]$$

where  $T$  = temperature (°K),  $M_1$ ,  $M_2$  = molecular weights of the two gases,  $\sigma_1 \sigma_2$  = collision diameters (angstroms), and  $\Omega_D$  = collision integral available from tables.

For a mixture of Ar and Cl<sub>2</sub>,  $M_1 = 39.95$ ,  $M_2 = 70.91$ ,  $\sigma_1 = 3.418$ ,  $\sigma_2 = 4.115$ , and  $\Omega_D = 0.8652$ . This leads to  $D' = 0.84/P$ , where  $P$  = total pressure in atmospheres. This value of  $D'$  for the diffusion of impurities in the gas phase was entered in Eq. [9] and used in the calculations of the limiting current density for the POCO-AX graphite.

It is clear that  $P_2$  of Eq. [3] is a complex function of  $i_L$  and no explicit equation, therefore, can be written for  $i_L$ . A computer program was written to calculate  $i_L$  by an iteration process. The results of these calculations will be compared with the experimental data in the Discussion section. Inputs to the program consisted of the porosity and pore size distribution of the POCO-AX material and the various constants used in Eq. [1] to [10].

The pore size distribution was approximated by an 11 step staircase function also shown in Fig. 1. If we assume a random distribution of these pores throughout the bulk of the porous graphite then the same distribution will occur at any plane through the graphite such as the surface of the electrode. When current is drawn the total pressure in the pores is reduced and the electrolyte is drawn some distance into the larger pores thus contacting additional small pores. Since these small pores are very active (Eq. [3]) it is necessary to include them in the calculation of the limiting current density. This effective roughness due to penetration of LiCl into the larger pores was allowed for in the calculations by multiplying the number of small pores calculated from the measured porosity by a factor of 2 to 5. The effective roughness is really a variable quantity which should increase with increasing  $\Delta P$ . However, this added complexity of a variable roughness factor was not used. Table II shows the steps used in the computer program.

### Experimental Cells

Concentration polarizations were determined for POCO-AX porous graphite electrodes 1/8 in. and 1/16 in. thick at 1, 2, and 5 atm pressure each at 4 impurity levels.

A schematic diagram of the working parts of the cell used for these studies is shown in Fig. 2. LiCl electrolyte was contained in a Graph-i-tite A<sup>4</sup> crucible with a porous graphite bottom made of the Poco-AX test material. This porous graphite, to which Cl<sub>2</sub> or varying mixtures of Cl<sub>2</sub> and Ar could be fed, was the working electrode. A Graphite-i-tite A flow-by adaptor below the porous graphite disk ensured uniform gas flow past the entire inner electrode surface; a quartz tube on top of the electrode exactly defined the electrode area. The reference and counter electrodes were mounted concentrically. The reference electrode was electrically isolated by means of a quartz tube and was slipped inside a hollow counter electrode which was grooved to permit maximum surface area and slotted to prevent pressure differences between the inside and outside of the electrode. The entire assembly was placed inside a Vycor tube and heated by means of clamshell heaters outside the Vycor container for most of the 1 atm tests.

For the 2 and 5 atm tests, the Vycor tube was replaced by an outer stainless steel container (Type 316) with a Graph-i-tite A liner to protect the stainless steel from attack by hot Cl<sub>2</sub>. Flanges and cooling coils were welded on at both ends of the stainless steel pipe and the inside was bored out to a uniform circular diameter. A 0.5 in. wall Graph-i-tite A tube was machined to match the stainless steel pipe so that an average spacing of 0.010 in. existed between the graphite liner and the container. This space was filled with a suspension of Corning solder glass No. 7570 which was subsequently fused to provide an impervious coating between the graphite liner and the stainless steel.

Clamshell heaters around the center portion of the container provided the heat to raise the cell temperature to 650°C, while cooling coils near the flange cooled the ends sufficiently so that Teflon gaskets and insulators could be used. All gas lines to and from the cell were stainless steel tubing with Al<sub>2</sub>O<sub>3</sub> electrical isolators where necessary.

The gas mixtures used were prepared by mixing the required amounts of high purity Cl<sub>2</sub><sup>5</sup> and argon and checking the composition of the exit gas from the cell by gas chromatography.

#### Electrical Instrumentation

The method used to obtain polarization data was to pass a d-c current between the working and counter electrodes. This current was interrupted for less than 10<sup>-3</sup> sec about 10 times per second by means of a pulse generator, during which time the polarization was observed on an oscilloscope while no current flowed.

The over-all electrical circuit is shown in Fig. 3. The current flowing through the cell at any time is drawn from lead-acid batteries through the current controller. The working to reference electrode voltage

and the working to counter electrode voltage were monitored continuously on digital voltmeters.

Two current controllers of the same general design were used. The first one was capable of controlling currents up to 70 amp which was sufficient for the early one atmosphere part of the work. However, as the work progressed, it became necessary to use higher currents to produce the desired polarization and a 150 amp current controller was constructed. This controller was designed to allow currents up to 150 amp to be cut off in less than 100  $\mu$ sec. A simplified block diagram of the controller is shown in Fig. 4.

Current in the controller is provided by either a battery or low ripple d-c supply. Control of this current is accomplished by 15 germanium power transistors in parallel to provide reasonable power dissipating capabilities. Current flow through the 150 amp shunt provides a 0 to 50 mv current signal which is connected through feedback resistor R<sub>4</sub> to the operational amplifier input. A d-c voltage from the current adjust potentiometer and external signals from a ramp or pulse generator are also connected to the amplifier input.

Normal operation is to set the current adjust potentiometer to obtain the required steady-state current flow through the cell. The pulse and ramp signals are zero at this time. The output of the operational amplifier goes negative just enough to make the currents in R<sub>3</sub> and R<sub>4</sub> equal. If a negative pulse of sufficient amplitude is fed in, the output power transistors are turned off and the current through the cell is reduced to essentially zero.<sup>6</sup> The time required for the cell current to be turned off varies from 30 to 80 μsec depending on the initial d-c current flow, and the cell impedance.

#### Testing Procedure

After the cell was assembled, it was placed inside the furnace and connected to the gas feed system, the gas analysis system, and the electrical system. The cell was then purged with Ar and heated gradually to 400°C to remove any water vapor. Cl<sub>2</sub> was then purged through the cell and the temperature was increased to 650°C. The cell was kept at operating temperature with Cl<sub>2</sub> passing through it for 16-20 hr to treat the electrodes and purge the system. After this Cl<sub>2</sub> bake treatment was completed, the Cl<sub>2</sub> was flushed out with Ar, the reference electrode was removed, and the LiCl electrolyte was added to the cell through the hollow counter electrode. When the electrolyte had melted, the reference electrode was replaced in the cell. While the system was reaching thermal equilibrium, Cl<sub>2</sub> and Ar flows were started and adjusted to give the required gas composition as determined by the gas chromatograph. After all systems had reached equilibrium, sufficient current was passed to polarize the working electrode to 0.5v. The flow rates of the gases were then adjusted to give 100% excess Cl<sub>2</sub> over that required to support the current being drawn at 0.5v polarization while maintaining the gas composition. Data were taken after the new flow rates had been reached. The method used in taking data was to increase the current until the electrode showed various values of polarization between 0.1 and 1.0v as shown on the oscilloscope screen.

The oscilloscope trace was photographed and the concentration polarization was determined by extrapolating the recorded polarization back to the moment the current interruption started. This usually meant an extrapolation of 10<sup>-4</sup> sec which is the time required for the current to go to zero and for any activation polarization to decay.

<sup>6</sup> There is a small leakage current passing through the transistors at this time, but it is negligible through the current range in which measurements were taken.

#### Results

In this way, concentration polarization data were obtained for Poco-AX porous graphite electrodes 1/8 and 1/16 in. thick at total pressures of 1, 2, and 5 atm using gas mixtures containing 50, 80, 95, and 99.9% Cl<sub>2</sub>. Table III gives a summary of all the data. Each data point is the average of at least 10 determinations taken with both increasing and decreasing currents. All the data were obtained at a nominal temperature of 650°C. However, at high current densities the temperature rose unavoidably due to I<sup>2</sup>R, TΔS, and Iη heating in the cell. Since the temperature affects a number of the properties which determine the Cl<sub>2</sub> electrode performance, these higher temperature data are not strictly comparable to the 650°C data and are shown in brackets in Table III. At low polarizations, the 1/8 in. thick electrode performed better at 5 atm than the 1/16 in. thick electrode. Similar behavior has been observed in complete Li-Cl<sub>2</sub> cells. This is probably due to the greater penetration of electrolyte into the porous electrode due to a greater ΔP developed across the thicker electrode. Such increased penetration is equivalent to an increase in area; it results in improved performance in a manner similar to grooving the electrode.

#### Discussion

The concentration polarization data shown in Fig. 5 through 7 are of a form typical of concentration polarizations. For a plane electrode, the *i* - η relationship is

$$\eta = \frac{RT}{nF} \ln \left( \frac{i_L}{i_L - i} \right) \quad [11]$$

Fig. 5. Concentration polarization vs. current density for a 1/8-in. electrode at 1 atm.

Fig. 6. Concentration polarization vs. current density for a  $\frac{1}{8}$ -in. electrode at 2 atm.

Fig. 7. Concentration polarization vs. current density for a  $\frac{1}{16}$ -in. electrode at 1 atm.

The smooth curves drawn through the experimental points in Fig. 5 through 7 have the same general shape as Eq. [11] but deviate in detail, particularly at high current densities. This is probably due to the fact that the electrode has a range of different pore sizes each with its own characteristic limiting current density. Therefore, the  $i - \eta$  relationship in this case is a complex average of a large number of individual relationships similar to Eq. [11]. The average would be a complex one since the pores of different sizes (and, therefore, different activities) are interconnected not only electronically through the graphite but also ionically through the electrolyte. They are also connected in the gas phase and, hence,  $\text{Cl}_2$  and impurities can flow and diffuse from one pore to another, and the average is not a simple average of parallel paths. No detailed theoretical treatment of the shape of the  $i - \eta$

curve has been made. The theoretical treatment attempts to predict the limiting current density which can be obtained under various conditions of pressure, impurity level, and electrode thickness. The results of these calculations are compared with the experimental limiting current densities in Table IV. The experimental limiting current density is arbitrarily taken as the current density at 0.5v polarization which is obtained by interpolation from the experimental data in Table III.

Fig. 8. Limiting current densities for a  $\frac{1}{8}$ -in. thick Poco-AX electrode.

Fig. 9. Limiting current density at an impurity level of 0.1% for Poco-AX porous graphite.

For the  $\frac{1}{8}$  in. thick electrode, the agreement is within the precision of the experimental data, which is about  $\pm 10\%$  except for the 5 atm pure  $\text{Cl}_2$  points. For the  $\frac{1}{16}$  in. thick electrode, the calculated values of  $i_L$  are generally higher than the experimental data by 25 to 40%. A possible explanation of this is that for the thinner electrode the  $\Delta P$  developed across the electrode will be less. Therefore, the effective roughness of the electrode will be less since less electrolyte penetration will occur. By reducing the roughness factor used in the calculations from 5 to 3, the calculated values are reduced sufficiently so that the calculated limiting current densities are on the average high by only 12%. This is close to the precision of the experimental data. However, the roughness factor of 5 has been retained in the calculated values shown in the succeeding plots of  $i_L$  vs. various parameters. Figure 8 shows  $i_L$  for a  $\frac{1}{8}$  in. thick electrode as a function of pressure and impurity level, while Fig. 9 shows  $i_L$  at a fixed impurity level (0.1% impurities) as a function of pressure and electrode thickness. In each case, relevant experimental points are also shown. Figure 8 clearly shows that increasing the total pressure beyond 5 atm results in little or no improvement in electrode performance. Even pressure increases above 2 atm are only useful when the  $\text{Cl}_2$  contains less than 5% impurities. The effect of reducing electrode thickness is demonstrated by Fig. 9; however, lower values of  $i_L$  were often observed on the thinner electrodes due to the decreased effective roughness factor.

### Acknowledgment

This work was supported in part by the U.S. Air Force Aero Propulsion Laboratory, Wright-Patterson AFB, Ohio, under Contract No. AF33(615)-5343. The authors also wish to acknowledge the assistance of M. S. Lin in providing the specially designed gas chromatograph used in the  $\text{Cl}_2$  analysis and R. O. Whitaker and R. L. McNew in designing and building the current controllers.

Manuscript submitted April 11, 1968; revised manuscript received June 7, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Behavior of Dimethyl Sulfitte as a Potential Nonaqueous Battery Solvent

N. P. Yao,<sup>†</sup> E. D'Orsay,<sup>1\*</sup> and D. N. Bennion\*

*Department of Engineering, University of California, Los Angeles, California*

### ABSTRACT

A potentially useful high energy battery electrolyte solvent, dimethyl sulfitte, was investigated. The conductivities, viscosities, and densities of sodium trifluoromethane sulfonate salt in dimethyl sulfitte are reported in the concentration range 0.01-0.20 mole  $\text{CF}_3\text{SO}_3\text{Na}/\text{Kg}$  solution and for the temperature range  $30^\circ\text{-}80^\circ\text{C}$ . The dielectric constant of dimethyl sulfitte is 22.5 at  $23.3^\circ\text{C}$ . Sodium trifluoromethane sulfonate is weakly ionized in this solvent yielding conductivities in the  $10^{-3}$  mho/cm range. Results of charging and discharging four different cell couples indicate this solvent is stable at cell potentials of over 4v vs. lithium.

One common feature of most nonaqueous organic solvents (1) which are stable with high energy density electrodes and which dissolve electrolytes is that they have functional groups containing a central carbon atom. Replacement of the central carbon atom by a sulfur atom, in either the plus four or six valence, generates a new class of organic solvents which are expected to yield equally useful properties. Physical and transport properties of the sulfur containing organic solvents have been recently explored (2, 3). The results indicate that many of the sulfur-containing organic solvents are potentially useful for high energy density battery applications. The properties of tetramethylene sulfoxide,  $(\text{CH}_2)_4\text{SO}$ , which is the sulfur analog of cyclopentanone,  $(\text{CH}_2)_4\text{CO}$ , has already been reported elsewhere (2). We report here some physical and transport properties of dimethyl sulfitte,  $(\text{CH}_3\text{O})_2\text{SO}$ , a sulfur analog of dimethyl carbonate,  $(\text{CH}_3\text{O})_2\text{CO}$ , and  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfitte mixtures.

Preliminary battery tests indicate that electrolyte solutions in dimethyl sulfitte can be used for secondary battery applications.

### Experimental

**Chemicals.**—Dimethyl sulfitte of high-purity grade was supplied by Eastman Organic Chemicals (Distillation Products Industries). They were unable to supply purity specifications except that it was prepared by a method described by Vogel and Cowan (13) in which thionyl chloride is reacted with methanol at  $0^\circ\text{C}$ . Karl Fisher titration (KFT) showed 196 ppm  $\text{H}_2\text{O}$  in the as-received material. A sample of the dimethyl sulfitte was distilled under 54 mm Hg nitrogen pressure at  $53^\circ\text{C}$ . The middle 75% of the material was retained for further tests. After purification, KFT showed 79 ppm water.

NMR spectra were run on the as received and purified dimethyl sulfitte. Using the carbon 13 peak as a calibration reference, two impurity peaks were observed at 18 and 85 Hz displaced from the principal dimethyl sulfitte peak. Each of these peaks represented

<sup>†</sup> Electrochemical Society Student Associate.

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: SEV Marchal, Issy-les-Moulineaux, France.

just under 0.5% impurity or a total of 1% impurity. For the purified dimethyl sulfite the peak at 16 Hz disappeared while the 85 Hz peak remain unchanged.

Most of the results are reported for the as-received dimethyl sulfite. Check runs were made using purified dimethyl sulfite for viscosity, density, and specific conductance. Variations were within experimental uncertainty. A check on the solvent remaining in the bottle at the end of the experiments showed 300 ppm water.

Sodium trifluoromethane sulfonate ( $\text{CF}_3\text{SO}_3\text{Na}$ ) was synthesized in this laboratory by chemical conversion from barium trifluoromethane sulfonate which was supplied by Minnesota Mining & Manufacturing Company.  $\text{CF}_3\text{SO}_3\text{Na}$  was recrystallized twice from acetone, dried in vacuum for 24 hr, and was stored in a desiccator above silica gel. The melting point of  $\text{CF}_3\text{SO}_3\text{Na}$  was  $248^\circ \pm 1^\circ\text{C}$  which agrees well with that reported by Gramstad and Haszeldine (4),  $248^\circ\text{C}$ .

**Apparatus and equipment.**—The experimental cells and equipment for the measurement of melting point, dielectric constant, density, viscosity, and conductance were previously described (2). The same battery cell (2) was also used to test the charging and discharging characteristics for a number of battery couples. These couples were fabricated in the discharged condition and then activated electrochemically. In each case  $\text{LiClO}_4$  was the principle electrolyte, and Li was deposited and removed from an aluminum substrate at the negative. Copper ribbon mixed with  $\text{LiF}$ , Ag wire in a compartment saturated with  $\text{LiCl}$ , a mixture of  $\text{K}_2\text{SO}_4$  and graphite particles in a Pt cup, and a mixture of KI and graphite in a Pt cup were the four positives tested. The positive and negative compartments were separated by a glass frit.

### Results and Discussion

**Dimethyl sulfite.**—Dimethyl sulfite is a clear liquid at room temperature with typical ester-like odor. The melting point of dimethyl sulfite as determined in this laboratory is  $-141^\circ \pm 2^\circ\text{C}$ . The following physical properties are reported by Kyrides (5): boiling point is  $126^\circ\text{C}$  at 760 mm pressure and  $52^\circ\text{C}$  at 45 mm pressure, density is  $1.2073 \text{ g/cm}^3$  at  $24^\circ\text{C}$ , and the index of refraction is 1.4093 at  $20^\circ\text{C}$ . The dielectric constant of dimethyl sulfite as determined in this laboratory is  $\epsilon_{23.3} = 22.5 \pm 2\%$ . Specific conductance of dimethyl sulfite, as received, was  $1.8 \times 10^{-5} \text{ mho/cm}$ . Density data and viscosity data as functions of temperature were also determined and are presented in Fig. 1 and Fig. 2, respectively. The density value at  $24^\circ\text{C}$  as extrapolated from density data determined here agrees very well with the single reported value of  $d_{24} = 1.2073$  (5). The viscosity of dimethyl sulfite varies between 0.7715 (at  $30^\circ\text{C}$ ) and 0.4361 (at  $80^\circ\text{C}$ ) centipoise.

As a check on the effects of impurities, extra runs were made using purified dimethyl sulfite. There was

Fig. 1. Density of dimethyl sulfite as a function of temperature

Fig. 2. Viscosity of dimethyl sulfite as a function of temperature

no detectable change in density, i.e., agreement was within 0.2%. Correspondence between the measurements of viscosity is shown in Table I. It is to be noted that there is a small but possibly significant increase in viscosity of the purified material compared to the as-received solvent.

**Dimethyl sulfite- $\text{CF}_3\text{SO}_3\text{Na}$  mixture.**—Density, kinematic viscosity, and ionic conductance were determined for mixtures of dimethyl sulfite and sodium trifluoromethane sulfonate in the concentration range 0.0098 up to 0.20 mole/kg solution for the temperature range  $30^\circ\text{--}80^\circ\text{C}$ .

Figure 3 shows variation of density as a function of concentration,  $m$  (in moles of  $\text{CF}_3\text{SO}_3\text{Na}$ /kg solution), and temperature (in  $^\circ\text{C}$ ). The linear variation of density at constant temperature, represented by the equation  $d = d_0 + \psi m$  where  $d_0$  is the density of dimethyl sulfite and  $\psi$  is the density increment, was found to be valid. The density increment  $\psi$  was  $(10.0 \pm 0.5) \times 10^{-2}$  and was constant within the temperature range studied.

Figure 4 shows variation of kinematic viscosity  $\nu$  (in centistokes) as a function of temperature and concentration. Applicability of the Jones-Dole equation (6)

$$\frac{\eta}{\eta_0} - 1/C^{1/2} = A + BC^{1/2} \quad [1]$$

was examined where  $\eta_0$  is the real viscosity of the solvent in centipoises,  $\eta$  is the real viscosity of the electrolyte solution in centipoises at concentration  $C$  (in moles  $\text{CF}_3\text{SO}_3\text{Na}$ /liter), and  $A$  and  $B$  are the viscosity coefficients which are specific to a particular electrolyte-solvent system (7). Figure 5 shows the  $\eta/\eta_0 - 1/C^{1/2}$  vs.  $C^{1/2}$  plot. It should be noted that a 0.3% experimental error in  $\eta$  gives as much as 12% error in  $\eta/\eta_0 - 1/C^{1/2}$  at  $C = 0.04$ . The lower the concentration the greater the error in  $\eta/\eta_0 - 1/C^{1/2}$  for a constant experimental error in the measurement. A best fit straight-line as shown in Fig. 5 was drawn through the present data while taking into consideration that the intercept  $A$  of the line must lie within Falkenhagen's theoretical value (8), i.e., between 0.01 and 0.025. The straight line obtained in this manner had a slope of 0.74 which is the  $B$  viscosity coefficient. The  $B$  coefficient in dimethyl sulfite- $\text{CF}_3\text{SO}_3\text{Na}$  mixtures appears to be independent of temperature with perhaps a slight decrease at  $60^\circ$  and  $80^\circ\text{C}$ . This indicates that the ion-solvent interaction in the mixtures is only slightly affected by the thermal motion of the molecules. This finding is in contrast to the  $B$  coefficients found in  $\text{LiClO}_4$ -tetramethylene sulfoxide mixtures (2) which were decreasing functions of temperature

Table I. Correspondence between measurements of viscosity

	Eastman grade	Purified	% Deviation
30	0.645	0.652	1.07
45	0.543	0.552	1.63
60	0.465	0.478	2.72

Fig. 3. Density of  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixturesFig. 4. Kinematic viscosity of  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixtures.Fig. 5.  $\eta/\eta_0 - 1/C^{1/2}$  vs.  $C^{1/2}$  plot for  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixtures.

indicating a decrease in the effective ionic volume with temperature. The  $B$  coefficient as determined for  $\text{CF}_3\text{SO}_3\text{Na}$  salt should be split into its respective ionic  $B$  coefficients for  $\text{Na}^+$  and  $\text{CF}_3\text{SO}_3^-$  ions in order to have a more meaningful interpretation. This was not done due to lack of individual mobility data of these ions in the medium studied. The apparent energy of activation for viscous flow in the mixtures was calculated from a  $\log \eta$  vs.  $1/T$  plot. The value was constant at  $2.44 \pm 0.04$  kcal/mole for the temperature and concentration range studied.

Specific conductance of dimethyl sulfite- $\text{CF}_3\text{SO}_3\text{Na}$  mixtures was determined and plotted as shown in Fig. 6. The specific conductance increased monotonically and seemed to approach some maximum value at about the saturation concentration, i.e., about 0.4 mole/kg solution at room temperature.

As a final check on the effects of impurities on dimethyl sulfite behavior, selected values of specific conductance were obtained for 0.11 mole/kg solution

Fig. 6. Specific conductance of  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixtures.

$\text{NaCF}_3\text{SO}_3$  in purified dimethyl sulfite. Comparisons are shown in Table II.

The maximum specific conductance, measured in this work,  $3 \times 10^{-3}$  mho/cm, was obtained at a concentration 0.1987 mole/kg solution at  $80^\circ\text{C}$ . Using  $\text{LiClO}_4$  as the solute, a conductivity of  $10^{-2}$  mho/cm was measured for a concentration of 1.3 mole/kg of solution. Equivalent conductances,  $\Lambda$ , for the dimethyl sulfite mixtures are tabulated in Table III. A plot of  $\eta_0/\Lambda\eta$  vs.  $C\Lambda\eta/\eta_0$  is shown in Fig. 7. A straight-line is obtained for data at  $30^\circ\text{C}$  indicating the validity of the equation (2)

$$\frac{1}{\Lambda} \frac{\eta_0}{\eta} = \frac{1}{\Lambda_0} + \frac{1}{K_{\text{eq}}\Lambda_0^2} \frac{C\Lambda\eta}{\eta_0}$$

Negative deviations from straight-lines at higher concentration and at higher temperature indicate that the viscosity correction,  $\eta/\eta_0$ , is not sufficient to account for the variation of conductance with temperature at higher concentrations. Since the plots appear valid at low concentration where linear behavior is observed, extrapolation of the straight-lines to  $C = 0$  yields  $1/\Lambda_0$  as the intercepts on the ordinate for each temperature. From the slope of the straight-line (slope =  $1/\Lambda_0^2 K_{\text{eq}}$ ), the equilibrium dissociation constant,  $K_{\text{eq}}$ , for the ionization reaction  $\text{CF}_3\text{SO}_3\text{Na} \rightleftharpoons \text{CF}_3\text{SO}_3^- + \text{Na}^+$  was obtained for each temperature. The values of equivalent conductance at infinite dilution,  $\Lambda_0$ , and the equilibrium dissociation constant,  $K_{\text{eq}}$ , are tabulated in Table IV. It is seen from Table IV that the equilibrium dissociation constant,  $K_{\text{eq}}$ , for  $\text{CF}_3\text{SO}_3\text{Na}$  salt in dimethyl sulfite is considerably lower than for  $\text{LiClO}_4$  in a  $\text{LiClO}_4$ -tetramethylene sulfoxide mixture (2). This is expected since the dielectric constant of dimethyl sulfite is  $\epsilon_{23.3^\circ} = 22.5$  compared to  $\epsilon_{23.3^\circ} = 42.5$  for tetramethylene sulfoxide. Using the definition  $\alpha = \Lambda\eta/\Lambda_0\eta_0$ , where  $\alpha$  is interpreted as the fraction of ion-

ization,  $\alpha$  is found to be 0.708 and 0.245 at 30°C for concentrations of 0.009779 mole/kg solution and 0.1987 mole/kg solution, respectively, in this mixture. This indicates that the  $\text{CF}_3\text{SO}_3\text{Na}$  salt behaves as a weak electrolyte in dimethyl sulfite. The values of  $\Lambda_0$  as tabulated in Table IV varied from 44  $\text{cm}^2/\text{ohm}$  equivalent at 30°C to 112  $\text{cm}^2/\text{ohm}$  equivalent at 80°C. The values reported here must be taken as approximate, since such an extrapolation is often misleading in weak electrolyte systems. It is, therefore, possible that  $\Lambda_0$  values are greater than reported here.

The Walden product,  $\Delta\eta$ , is shown as a function of temperature in Fig. 8. The Walden product decreases exponentially as a function of concentration indicating the typical behavior of a weak electrolyte solution. The plot cannot satisfactorily be extrapolated to obtain the Walden product,  $\Lambda_0\eta_0$ , at infinite dilution. However, the  $\Lambda_0\eta_0$  values were calculated from values of  $\Lambda_0$  obtained by extrapolation in Fig. 7 and tabulated in Table IV and the experimental value  $\eta_0$  of dimethyl sulfite. The Walden product,  $\Lambda_0\eta_0$ , at infinite dilution vs. temperature is plotted in Fig. 9. The  $\Lambda_0\eta_0$  product appeared to remain constant at lower temperature and increased when temperature was raised above 60°C. This positive temperature coefficient of the  $\Lambda_0\eta_0$  product for the salt means that the average Stokes ionic radius (9) decreases as a function of temperature. Strictly speaking only ionic Walden products  $\lambda_{o+}\eta_0$  or  $\lambda_{o-}\eta_0$  are meaningful, but this requires accurate data of individual ionic mobilities  $\lambda_{o+}$  and  $\lambda_{o-}$ . Decrease of Stokes ionic radii at temperatures above 60°C also means the decrease of specific interaction between the ion and the solvent molecule, *i.e.*, decrease of solvation number at these temperatures. This in turn means that the  $B$  viscosity coefficient must decrease at these temperatures since the  $B$  viscosity coefficient is related to the effective molar ionic volume (2). Decrease of the  $B$  viscosity coefficient is indeed observed for dimethyl sulfite- $\text{CF}_3\text{SO}_3\text{Na}$  mixtures at temperatures between

Fig. 8. Walden product,  $\Delta\eta$ , for  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixtures.

Fig. 9. Temperature dependence of Walden product,  $\Lambda_0\eta_0$ , at infinite dilution for  $\text{CF}_3\text{SO}_3\text{Na}$ -dimethyl sulfite mixtures.

60° and 80° (see Fig. 5). Similar behavior, *i.e.*,  $(\partial\Lambda_0\eta_0)/\partial T \propto \partial T/\partial B$  has been observed in other non-aqueous media (10). Apparent activation energy for ionic conduction was calculated from the slope of  $\log K_{sp}$  vs.  $1/T$  plot for dimethyl sulfite- $\text{CF}_3\text{SO}_3\text{Na}$  mixtures. The value was found to be constant at  $0.66 \pm 0.002$  kcal/mole for all concentrations. The ratio of activation energy for ionic conductance and for viscous flow in the mixtures was  $\xi = E_K/E_\eta = 0.27$  at 0.04 mole/kg solution.

**Battery tests.**—Four battery couples were tested in dimethyl sulfite-lithium perchlorate solutions. They were built in the discharged state and then charged as described in the Apparatus and Equipment section. All the cells accepted charge and delivered small currents at rather large voltages. The coulombic or charge efficiencies (coulombs in during charge divided by coulombs out to complete discharge) varied between 30 and 70%. Open-circuit voltages of between 3 and just over 4v were observed. These voltages were stable and the cells would return to these voltages after brief discharge periods.

These results must be considered preliminary in nature. However, they offer two important conclusions regarding dimethyl sulfite-lithium perchlorate solutions. Potentially useful secondary battery reactions can be carried out in this solution yielding high voltages and promising charge efficiencies. The discharge curves in each case were quite flat. Since the open-circuit voltages of over 4v could be maintained for periods of many minutes (up to 30 min for example), this solution has at least short term stability to oxidation or reduction over a wide potential range of interest for construction of high energy, secondary batteries. It has already been established that dimethyl sulfite is stable toward lithium (12). Thus, its stability to oxidation is also established.

#### Acknowledgment

The assistance of Mr. Allen Dodge and Mr. Avinoam Hershkowitz in performing the experiments is gratefully acknowledged. Financial support for this work has been provided by the U.S. Army Mobility Equipment Research and Development Center, Fort Belvoir,

## Cathodic Reduction Mechanism of MnOOH to Mn(OH)<sub>2</sub> in Alkaline Electrolyte

A. Kozawa\* and J. F. Yeager\*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio

#### ABSTRACT

The cathodic reduction process of MnOOH, which is produced from  $\gamma$ -MnO<sub>2</sub> or  $\beta$ -MnO<sub>2</sub> by electrochemical reduction, was studied in 9M KOH with various particle sizes of the original  $\gamma$ -MnO<sub>2</sub> and various depths of discharge. The polarization of MnOOH produced from electrolytic  $\gamma$ -MnO<sub>2</sub> is small, less than 60 mv, until a certain current density is reached. Above the current density, a limiting current is reached and polarization increases sharply. There are two possible reduction mechanisms for the process from MnOOH to Mn(OH)<sub>2</sub>, i.e.: (i) reduction through Mn(III) ion dissolved in the electrolyte, and (ii) reduction of MnOOH directly to Mn(OH)<sub>2</sub> in solid state. It was concluded that most of the discharge current is attributed to the dissolved Mn(III) ion mechanism.

In previous publications (1-4) concerning the discharge process of MnO<sub>2</sub> in alkaline electrolyte, some discharge behavior of MnOOH, which is equivalent to MnO<sub>1.5</sub> (or Mn<sub>2</sub>O<sub>3</sub>), has been described. However, those investigations have been done mainly to study the discharge process from MnO<sub>2</sub> to MnOOH, i.e., the first step shown in Fig. 1 which gives a schematic summary of previously observed discharge curves for  $\gamma$ - and  $\beta$ -MnO<sub>2</sub>.

The purpose of the present study was to obtain more detailed polarization characteristics of the second step (see Fig. 1) and to determine the discharge mechanism of the second-step process from MnOOH to Mn(OH)<sub>2</sub>. The normal discharge curve of  $\gamma$ -MnO<sub>2</sub> or  $\beta$ -MnO<sub>2</sub> consists of two steps as shown in Fig. 1, although

multistep discharge curves are obtained under certain conditions (5). The discharge mechanism of the major part of the first step very likely involves solid state discharge, namely the proton-electron mechanism as discussed previously (1-4). On the other hand, it had not been determined whether the discharge mechanism of the second step involved a solid state discharge [direct reduction of MnOOH to Mn(OH)<sub>2</sub>] or discharge through dissolved Mn(III) ion, although some evidence in favor of the latter mechanism was presented by Kozawa and Yeager (1). Steps involved in these two possible mechanisms are given in Fig. 2. The solubility of Mn(III) and Mn(II) ions in 5-13M KOH has been determined (6).

In this investigation, MnOOH was first produced by electroreduction of  $\gamma$ -MnO<sub>2</sub> or  $\beta$ -MnO<sub>2</sub> in 9M KOH, and

Fig. 2. Steps involved in the two possible discharge mechanisms: (i) direct solid state reduction mechanism, (a), and (ii) reduction through dissolved species, (b), (c), (d), and (e), where (b): dissolution of Mn(III) ion from  $\text{MnOOH}$ , (c): diffusion of Mn(III) ion onto the graphite surface, (d): charge transfer step, and (e): precipitation of  $\text{Mn(OH)}_2$ .

subsequently the cathodic polarization was measured in the same electrolyte in the same cell under various conditions. The effect of particle size of the original manganese dioxide sample, and depth of discharge ( $\text{MnO}_{1.45}$ - $\text{MnO}_{1.2}$ ) was investigated. Based on the limiting current densities for three particle size samples (13, 70, and 200 $\mu$ ), the discharge mechanism has been determined to be the one which involves the Mn(III) species dissolved in the electrolyte.

### Experimental

**Discharge cell.**—The discharge cell used in the present work was the same as that in the previous work (3-5). One hundred milligrams of each  $\text{MnO}_2$  sample were mixed with 1.00g of battery grade graphite powder and 2.0g of porous coke. This mixture was ground in a glass mortar and transferred into the cell. Then 0.7 ml of 9M KOH was added to the mixture and blended thoroughly and the mixture was spread evenly over the bottom of the cell. Then three layers of separator paper and a perforated Lucite disk were placed on the mixture. The mixture was pressed at 380 kg/cm<sup>2</sup> (5000 psi) with a plastic rod. After removing the rod, a threaded Lucite plug was screwed down tightly. More electrolyte was added from the top. The counter electrode used during discharge was a platinum wire contained in a glass tube having a glass frit at the end [see Fig. 4 of ref (3)].

The graphite powder had a particle size distribution as follows: 20% by weight was less than 9 $\mu$ , 40% by weight was less than 15 $\mu$ , and 60% by weight was less than 23 $\mu$ . Under these packing conditions, the total electrolyte retained between the graphite, coke, and  $\text{MnO}_2$  particles was approximately 0.7 ml. The volume occupied by the  $\text{MnO}_2$  sample in the mixture was only a few per cent.

**Preparation of  $\text{MnOOH}$ .**—In order to produce  $\text{MnOOH}$  by electrochemical reduction from  $\gamma$ - $\text{MnO}_2$ , the  $\text{MnO}_2$  sample packed in the cell was discharged at a constant current (1.00 or 2.00 ma) continuously at 23°C for 30 ma-hr. After this reduction, the oxide

should be approximately  $\text{MnO}_{1.45}$  (see Fig. 1); namely, the system should be composed of 90%  $\text{MnOOH}$  and 10%  $\text{Mn(OH)}_2$ . At this discharge stage, the circuit was kept open at least overnight in order to obtain the open circuit voltage (OCV). The OCV was usually  $-0.385 \pm 0.005\text{v}$  vs. Hg/HgO (9M KOH) in the case of  $\gamma$ - $\text{MnO}_2$  samples.

**Polarization measurement.**—Polarization was measured by passing a constant current for 5 min and then leaving the circuit open for the next 5 min. Immediately after the open circuit period, another constant current which was greater than the previous current was passed for 5 min and again the circuit was kept open for the next 5 min. This was repeated for the following currents: 0.1, 0.3, 1.0, 3.0, 10.0, 20.0, and 30.0 ma. Figure 3 shows a typical example of such a series of measurements: the curves show recorded closed circuit voltage (CCV) not corrected for IR-drop.

At the end of the 5 min discharge, the CCV (IR-free) was measured by interrupting the current for 1 or 2 sec at a fast chart speed of the recorder (Sargent MR recorder). The potential difference between the CCV (IR-free) and the initial OCV ( $-0.385 \pm 0.005\text{v}$ ) was taken as the polarization at each current. The details and errors associated with CCV (IR-free) measurements were described previously (3, 4).

**Samples.**—The five  $\text{MnO}_2$  samples used in this investigation are designated as follows:  $\gamma$ - $\text{MnO}_2$ ,  $\beta$ - $\text{MnO}_2$ (III),  $\gamma$ - $\text{MnO}_2$ (13 $\mu$ ),  $\gamma$ - $\text{MnO}_2$ (70 $\mu$ ), and  $\gamma$ - $\text{MnO}_2$ (200 $\mu$ ). The  $\gamma$ - $\text{MnO}_2$  was a typical electrolytic  $\text{MnO}_2$  for battery use, and the  $\beta$ - $\text{MnO}_2$ (III) was prepared from the  $\gamma$ - $\text{MnO}_2$  by heating at 400°C in air for 10 days and subsequently washing with  $\text{H}_2\text{SO}_4$  solution. The chemical and physical properties of these two samples [ $\gamma$ - $\text{MnO}_2$ , and  $\beta$ - $\text{MnO}_2$ (III)] have been published previously (3). The other three samples were prepared from a single batch of an electrolytic deposit of  $\gamma$ - $\text{MnO}_2$  simply by sieving at different stages of grinding. The particle size (diameter of the particle) shown in the brackets is an average value. The range of particle size was as follows:  $\gamma$ - $\text{MnO}_2$ (13 $\mu$ ) was from 2 to 38 $\mu$ ,  $\gamma$ - $\text{MnO}_2$ (70 $\mu$ ) was in a range of 50-100 $\mu$ , and  $\gamma$ - $\text{MnO}_2$ (200 $\mu$ ) was in a range of 150-300 $\mu$ . Chemical analysis of the three samples gave a  $\text{MnO}_2$  content 87.5  $\pm$  0.5% and the BET surface area was approximately 39 m<sup>2</sup>/g regardless of the particle size. This is understandable since the large surface area of electrolytic  $\text{MnO}_2$  is due to presence of fine pores of approximately 50Å in diameter (3), and grinding to finer particles (5  $\sim$  20 $\mu$ ) does not materially influence the surface area or the  $x$  value in  $\text{MnO}_x$ . The  $\gamma$ - $\text{MnO}_2$  had an average particle size of 15 $\mu$ , and the particle size distribution is very similar to that of the  $\gamma$ - $\text{MnO}_2$  (13 $\mu$ ). The  $\beta$ -

Fig. 3. Potential during constant current discharge and subsequent open circuit period. The numbers on the curves indicate constant currents passed for 5 min. This was measured with cells containing 100 mg of  $\gamma$ - $\text{MnO}_2$  at the 30 ma-hr discharge stage (90%  $\text{MnOOH}$  and 10%  $\text{Mn(OH)}_2$ ).

MnO<sub>2</sub>(III) was essentially the same in particle size distribution as the  $\gamma$ -MnO<sub>2</sub>.

### Results

Figure 3 and Fig. 5 show the potential changes during the polarization measurements at two different depths of discharge: 30 ma-hr ( $\approx$  MnO<sub>1.45</sub>) and 43 ma-hr ( $\approx$  MnO<sub>1.22</sub>), respectively. At 30 ma-hr (Fig. 3), the potential on the passage of constant current reaches a steady value in a minute or so except for 30 ma discharge; whereas, at 43 ma-hr (Fig. 5) the potential tends to decrease without showing a steady potential except at very low currents (0.3 and 1.0 ma). Above a certain current (for example, 30 ma in the case of Fig. 3 and 10 ma in the case of Fig. 5) a steady potential is not obtained during the 5 min discharge, indicating that the limiting current value has been exceeded. This will be discussed later.

As seen in Fig. 3 and 5, on open circuit, the potential returns to OCV, within experimental error, regardless of the depth of the discharge. However, the recovery rate of the deep discharged system (Fig. 5) is much slower than that of the slightly discharged system (Fig. 3).

Figures 4 and 6 show the polarization curves based on the CCV (IR-free) data at the end of 5 min discharge at each current. Curve (a) in Fig. 4 and curve (d) in Fig. 6 correspond to the measurements shown in Fig. 3 and Fig. 5, respectively. All the polarization curves shown in Fig. 4 and 6 have a similar general shape; i.e., up to a certain current, the curves (curves

Fig. 4. Effect of particle size on polarization curve of MnO<sub>1.45</sub> derived from  $\gamma$ -MnO<sub>2</sub>. These polarization curves were taken with cells originally containing 100 mg of the manganese dioxide samples listed below, at the 30 ma-hr discharge stage (90% MnOOH and 10% Mn(OH)<sub>2</sub>). Curve a:  $\gamma$ -MnO<sub>2</sub>, curve b:  $\gamma$ -MnO<sub>2</sub>(13 $\mu$ ), curve c:  $\gamma$ -MnO<sub>2</sub>(70 $\mu$ ), curve d:  $\gamma$ -MnO<sub>2</sub>(200 $\mu$ ). See text for explanation of the schematic models shown in this figure.

Fig. 5. Potential during constant current discharge and subsequent open circuit period. The numbers on the curves indicate the discharge current. This was measured with cells containing 100 mg of  $\gamma$ -MnO<sub>2</sub> at the 43 ma-hr discharge stage (44% MnOOH and 56% Mn(OH)<sub>2</sub>).

Fig. 6. Effect of the depth of discharge on the polarization curves

a, b in Fig. 4; a, b, c in Fig. 6) show a straight line portion with a slope of 30-33 mv per decade. Above a certain current, in every case a limiting current is reached and polarization increases sharply.

Figure 4 shows the effect of particle size of the original manganese dioxide. The limiting current decreases with increasing particle size of the original manganese dioxide sample. Curve (a) and curve (b) in Fig. 4 are almost identical. This is not surprising, because the particle sizes of the two samples is almost the same as pointed out earlier. The schematic models (A and B) for the fine and coarse MnO<sub>2</sub> samples packed with graphite particles are shown in Fig. 4. These will be discussed later.

Figure 6 shows the effects of discharge depth. The limiting current value decreases with increasing depth of discharge, although the general shape of the polarization curve remains the same up to 40 ma-hr. Also, the OCV's at various discharge depths remain almost constant as shown in Fig. 6.

Figure 7 shows a typical polarization curve of MnO<sub>1.45</sub> derived from  $\beta$ -MnO<sub>2</sub>(III) at 2 ma constant current discharge. The curve shows two steps; one up to 3 ma and the other from 3 ma to the limiting current, 27 ma. It should be noted that the open circuit potential (-0.315v) is much different (see the right side potential scale in Fig. 7) from those shown in Fig. 6, and also that the limiting current value is approximately the same as that of curves (a) and (b) for the  $\gamma$ -MnO<sub>2</sub> sample shown in Fig. 4.

### Discussion

Before discussing the details on the discharge mechanism of the second step (see Fig. 1) in which MnOOH is reduced electrochemically to Mn(OH)<sub>2</sub>, let us consider a few principal aspects of the electroreduction of metal oxides or other solid battery active materials.

When one solid phase (e.g., MnOOH, PbSO<sub>4</sub>, etc.) is electrochemically reduced to another solid phase (e.g.,

Fig. 7. Polarization curve of MnO<sub>1.45</sub> (30 ma-hr discharge) derived from  $\beta$ -MnO<sub>2</sub> at 2 ma discharge. This curve was measured after 103 hr storage at the 30 ma-hr discharge stage.

Mn(OH)<sub>2</sub>, Pb, etc.) at unit activity (absence of solid solution formation), the OCV of the system should remain constant as long as both phases [for example, MnOOH and Mn(OH)<sub>2</sub>, or PbSO<sub>4</sub> and Pb] co-exist, regardless of both the ratio of amounts of higher to lower valency material and the potential generating mechanism [e.g., potential arising directly from the solid system such as MnOOH-Mn(OH)<sub>2</sub>, or from a dissolved species such as the saturated Mn(III) ion-Mn(II) ion system]. This is a basic thermodynamic requirement as discussed previously (2). Therefore, the open circuit potential measurement itself should have no value in differentiating between the two discharge mechanisms shown in Fig. 2. Such a mechanism study must be based on kinetic behavior in the process.

When the solubility of the solid active material is in the order of 10<sup>-5</sup> mole/liter or higher, one must consider in addition to a solid state reduction mechanism, a mechanism in which a dissolved species is reduced on the surface of graphite or some other conductive network. The discharge current could now either be attributed entirely to one of the two mechanisms or apportioned between both.

Another important factor which must be taken into account is the electrical conductivity of the active material. If the solid active materials involved in the discharge [MnOOH and Mn(OH)<sub>2</sub> in the case shown in Fig. 2] are good electrical conductors, a dissolved Mn(III) ion can be reduced on the MnOOH surface instead of on graphite. This is equivalent to reduction of a surface Mn(III) atom to the Mn(II) state, and one cannot meaningfully distinguish between the two mechanisms. If the solid active materials involved are very poor conductors, the discharge current must be attributed only to the dissolved species mechanism. If the solid active materials have intermediate electrical conductivity, the true situation is rather complicated. The part which one mechanism plays in determining the total current should depend on the conductivity, solubility, and surface area as well as the current density.

Let us discuss now the details of the electrochemical reduction process of MnOOH. During this discussion we shall keep the schematic model (Fig. 4) in mind. We tentatively assume that the electrical conductivity of the MnOOH-Mn(OH)<sub>2</sub> system is very poor and that the MnOOH particles are surrounded by graphite particles in the present system as shown schematically in Fig. 4. Based on these assumptions and the solubilities of Mn(III) and Mn(II) in 9M KOH [4.4 × 10<sup>-3</sup>M for Mn(III) ion, and 0.4 × 10<sup>-3</sup>M for Mn(II)] as reported previously (6), the authors would like to prove here from the limiting current data for different particle sizes (Fig. 4) that the discharge current in the second step (Fig. 1) can be attributed essentially to the dissolved species mechanism.

Let us consider first the nature of the limiting current from the standpoint of the steps involved in the dissolved species mechanism of Fig. 2; b: dissolution of Mn(II), c: diffusion of Mn(III) ion, to the graphite surface, d: discharge of the Mn(III) ion, and e: precipitation of Mn(OH)<sub>2</sub>. The limiting current cannot be attributed to the charge transfer step because of the low polarization at the current densities below the limiting current density. The limiting current is not likely to be attributed to the diffusion process, because the MnOOH particles are in intimate contact with fine graphite particles and the diffusion path must be extremely short. Therefore, the limiting current under this situation is likely to be a measure of the dissolution rate of Mn(III) ion from the MnOOH.

With the highly porous oxide used, Mn(III) ion dissolution from all the fine pores which are filled with 9M KOH might contribute to the discharge current, but there should be very little influence on the limiting current value. The Mn(III) ion dissolved in the electrolyte in the fine pores has to diffuse some distance (depending on the particle size) in order to discharge

on the graphite surface. Therefore, the limiting current value will be determined essentially by the apparent surface area of the oxide. Therefore, if the average particle size is decreased by grinding the coarse manganese dioxide particles, the apparent surface area per unit weight should increase. This is shown schematically as systems A and B in Fig. 4. The relation between the total apparent surface area, *S<sub>a</sub>*, and the particle size (radius, *r*) is given by the following equation

$$S_a = \left[ \left( \frac{W}{d} \right) \div \left( \frac{4\pi r^3}{3} \right) \right] \times 4\pi r^2 = \frac{3W}{d} \frac{1}{r}$$

where *W* is the weight of sample, *d* the density of the oxide, and *r* the radius of the particle.

The limiting current value, *i<sub>l</sub>*, should be proportional to 1/*r*, since *S<sub>a</sub>* ∝ *i<sub>l</sub>*, or *i<sub>l</sub>* · *r* = constant should be held.

On the other hand, if the solid particle has a fair or good electrical conductivity and the discharge proceeds entirely or partly through a solid state mechanism; namely, the charge transfer reaction takes place at the entire solid-solution interface, the limiting current will be proportional to the true surface area. In such a case, the particle size should not be influential as long as the total true surface area remains the same regardless of the particle size. The present samples of different particle sizes have the same true surface area (39 m<sup>2</sup>/g).

If the real situation is a mixture of the two mechanisms in a certain proportion, *i<sub>l</sub>* · *r* = constant will not be true. Let us test the experimentally observed *i<sub>l</sub>* values for the relation. Table I shows the results in which there is a reasonably good constancy for the product, *r* · *i<sub>l</sub>*. This means the observed *i<sub>l</sub>* values for such a wide range of particle size can be well explained by the dissolved species mechanism.

The dissolved species mechanism was previously proposed based on some experimental evidence (1); namely, discharge during the second step was possible only at high KOH concentrations, or at low KOH concentrations with added triethanol amine (TEA). Both the high KOH concentration and the addition of TEA increase the dissolved Mn(III) ion concentration in KOH electrolyte. The limiting current data obtained in this study for different particle size samples and the discussion provided above support the dissolved species mechanism.

Two additional facts which lend further support to the present conclusion should be mentioned here. The first point concerns whether a system containing Mn(III) and Mn(II) ions in 9M KOH has a redox potential around -0.385v vs. Hg/HgO (9M KOH). This was experimentally investigated with a dropping mercury electrode and also with a platinum electrode. The half wave potential of the Mn(III)-Mn(II) system in 9M KOH was found to be -0.40v at a platinum electrode [Fig. 8 of ref. (6)] and -0.395v as a mean value of the anodic and the cathodic wave of the polarogram [Fig. 8 of ref. (1)].

The second point concerns whether or not the graphite surface is really responsible for the reduction reaction. In order to check this point, the amount of graphite mixed with 100 mg MnO<sub>2</sub> samples was varied from 0.1-1.0g without using coke. The limiting currents in these cells were measured with a potentiostat. The results (Fig. 8) show that the limiting current is pro-

Table I. Limiting current values (Fig. 4) and the product, *r* · *i<sub>l</sub>*

	<i>i<sub>l</sub></i> * (ma)	<i>r</i> · <i>i<sub>l</sub></i> **
γ-MnO <sub>2</sub> (13μ ± 3)	26 ± 3	348
γ-MnO <sub>2</sub> (70μ ± 10)	4.2 ± 0.5	294
γ-MnO <sub>2</sub> (200μ ± 20)	1.5 ± 0.2	300

\* *i<sub>l</sub>* (= limiting current) per 100 mg of sample MnO<sub>2</sub>.

\*\* *r* in μ and *i<sub>l</sub>* in ma.

Fig. 8. Effect of amount of graphite mixed with 100 mg of  $\gamma$ -MnO samples (no coke was used in these experiments). The limiting currents were measured at 30 ma-hr discharge by a potentiostat 6 min after applying a constant potential which is 350 mv negative relative to the OCV [ $-0.385 \pm 0.005$ v vs. Hg/HgO (9M KOH)].

portional to the amount of graphite used up to a certain amount. This result is additional evidence in support of the schematic model (A in Fig. 4) of this powder packed system and shows that the graphite particle surrounding the MnO<sub>2</sub> particle is responsible for the electrochemical reaction [Mn(III) ion + e<sup>-</sup> → Mn(II) ion].

The two-step polarization curve seen in Fig. 7 can be explained as follows. As can be seen in the 2 ma discharge curve ( $\beta$ -MnO<sub>2</sub>) of Fig. 1, the potential during the early stage of discharge decreases to the point where the second step discharge reaction (MnOOH → Mn(OH)<sub>2</sub>) occurs before the reduction of tetravalent to trivalent oxide is completed. Therefore, at the 30 ma-hr discharge stage, the system contains Mn(IV)

oxide, Mn(III) oxide and Mn(OH)<sub>2</sub>. Under these conditions, the OCV should be determined by the Mn(IV) oxide instead of the Mn(III)-Mn(II) system (observed OCV:  $-0.315$ v) and the first step in the polarization curve (Fig. 7) is probably a discharge of the remaining Mn(IV) oxide. The second step in the polarization curve seems to be the discharge of dissolved Mn(III) ion. This is substantiated by the observed limiting current value for  $\beta$ -MnO<sub>2</sub>(III), 28 ma, which is close to that from  $\gamma$ -MnO<sub>2</sub>. Since the  $\beta$ -MnO<sub>2</sub>(III) and the  $\gamma$ -MnO<sub>2</sub> have almost the same particle size distribution, the  $i_L$  values for the two samples should be the same. It is worth noting that the undischarged Mn(IV) oxide does not appear to react with Mn(OH)<sub>2</sub> in 9M KOH on standing at 23°C over a long period (e.g., 103 hr).

#### Acknowledgment

The authors wish to thank Dr. R. A. Powers and Mrs. H. M. Joseph for suggestions in the preparation of the manuscripts and also to Mr. W. L. Adams for his experimental assistance.

Manuscript submitted Mar. 22, 1968; revised manuscript received ca. June 17, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Structure Effects of Many-Membered Polymethyleneimine on Corrosion Inhibition

Kunitsugu Aramaki and Norman Hackerman\*

Department of Chemistry, The University of Texas at Austin, Austin, Texas

#### ABSTRACT

Corrosion rates of pure iron in HCl solution with and without corrosion inhibitors were determined by polarization measurements, volumetric measurements of evolved hydrogen, and weight loss measurements. C<sub>5</sub> and C<sub>8</sub> to C<sub>14</sub> polymethyleneimines and C<sub>6</sub> to C<sub>14</sub> symmetric secondary amines were tested as the inhibitor. Basicity values and relative molecular areas of these inhibitors were also determined. A comparison of the inhibition effectiveness within these two series indicates that the inhibition effect of the medium-sized cyclic imines (C<sub>9</sub> to C<sub>12</sub>) is closely related to the angle of the C-N-C bond in their molecules and thus to strain in the ring.

Some of the effective factors in the molecular structure of cyclic polymethyleneimines containing four to ten methylene groups on their corrosion inhibition of iron or steel in acid solution have been studied (1, 2). It was clearly established that polymethyleneimines having eight to ten methylene groups had a markedly higher inhibition efficiency than those of secondary amines containing the same number of groups. It was suggested (2) that this higher efficiency was closely related to strain in the ring of the imine molecule, since the strain of the polymethylene ring becomes maximum at the ten-membered ring (3). Further, it

was indicated that the enhanced inhibition could be attributed to improved adsorption. The larger C-N-C angle, due to greater ring strain, provides sp<sup>2</sup> hybrid orbital geometry in the nitrogen atom, giving rise to a  $\pi$ -electron bonding possibility between nitrogen and metal (2, 4).

In order to confirm these relationships with more cyclic imines, especially some beyond C<sub>10</sub> in which the strain does not exist, two groups of experiments were carried out. The first was a comparative study of inhibition effectiveness within the series of polymethyleneimines and within the series of symmetric secondary amines. These differ in structure only by the

\* Electrochemical Society Active Member.

presence of a ring closing bond and of two hydrogen atoms. Polymethyleneimines,<sup>1</sup> represented by the general formula  $(\overline{\text{CH}_2})_n\text{NH}$  and containing five and eight to fourteen methylene groups, were tested as corrosion inhibitors. Symmetric secondary amines,<sup>1</sup>  $(\text{C}_{n/2}\text{H}_{n+1})_2\text{NH}$ , where  $n$  is 6, 8, 10, 12, or 14, were also used.

In the second group of experiments, the inhibition efficiencies of cyclic compounds with nine methylene groups were measured and compared with that of  $\text{C}_9$  imine. These compounds were 1,2,3,4-tetrahydroquinoline, 1,2,3,4-tetrahydroisoquinoline and *cis*- and *trans*-decahydroquinoline.

Three kinds of corrosion rate measurements of pure iron wire in 6.1M HCl solution at 30°C were made with several concentrations of the inhibitors. The rates were determined by polarization measurement, volumetric measurement of evolved hydrogen, and weight loss measurement of the wire.

Basicity values of the inhibitors and approximate areas of metal surface which each inhibitor molecule effectively covered in the adsorbed position were determined.

### Experimental

**Corrosion inhibitors.**—Cyclic imines containing from nine to fourteen methylene groups were synthesized from the corresponding dibasic acids as starting materials. Cycloketone isooximes were obtained through the Schmidt reaction (5) with cycloketones (6) derived from cycloketonealcohols. The latter were produced through acyloin condensation (7) with methyl esters of the dibasic acids. The cycloketone isooximes were reduced with lithium aluminum hydride to cyclic imines (8). These products were repeatedly purified by fractional distillation or by recrystallization. Absence of impurities was shown by infrared spectra.

Piperidine, octamethyleneimine, dipropylamine, dibutylamine, dipentylamine, dihexylamine, diheptylamine, *trans*-decahydroquinoline, 1,2,3,4-tetrahydroquinoline, and 1,2,3,4-tetrahydroisoquinoline were obtained as high-grade commercial reagents and carefully purified by distillation before use. *Trans*-decahydroquinoline was further purified by recrystallization of its hydrochloride derivative (9). *Cis*-decahydroquinoline, obtained as the mixture of *cis*- and *trans*-isomers, was isolated and purified by recrystallization of its hydrochloride derivative (9).

Inhibitor solutions were prepared by dissolving a known weight of the inhibitors in an appropriate volume of constant boiling (107°C) HCl solution which was obtained by diluting the reagent grade solution (2).

**Polarization measurements.**—Pure iron wire (99.5%, Mallinckrodt analytical reagent grade, 0.36 mm diameter) was used. The wire was fixed at an end of a glass tubing with a Teflon joint and then cut to a length giving a calculated surface area of 0.25 cm<sup>2</sup> to provide an electrode assembly. This was washed with pentane, dipped in phosphoric acid (1:3), carefully rinsed with distilled water and then with acetone, and dried in a vacuum desiccator. Electrical contact was made by means of mercury inside the tubing of the electrode assembly.

A small glass cell in which the anode and cathode compartments were separated by fritted glass was used for these measurements. Coiled platinum wire was used as a counter electrode. The polarization current was supplied by a 90v battery and a series of variable resistances and determined with a Keithley electrometer. The potential of the test electrode was measured by using a saturated calomel electrode and a Keithley electrometer. In all runs the HCl solution was de-aerated by passing nitrogen gas through it for long periods.

<sup>1</sup>The term cyclic imine is used for polymethyleneimine in this study as are  $\text{C}_n$  imine and amine; for example,  $\text{C}_{10}$  imine for decamethyleneimine and  $\text{C}_{10}$  amine for dipentylamine.

Each whole polarization run was completed in 15 min before the surface area of the test electrode became small enough to affect the results. Several runs were made, both with and without the inhibitor in solution at each of the concentrations.

**Weight loss and hydrogen evolution measurements.**—Four iron wires were mounted through small holes in a Teflon disk with a glass rod hanger and cut into 5.0 cm lengths. This test wire assembly was washed with pentane, dipped into phosphoric acid (1:3) for about 15 sec, washed thoroughly with distilled water, cleaned with acetone, dried in vacuum, and then weighed. Thirty milliliters of the inhibitor solution was placed in a small flask equipped with a glass rod hook and a graduated gas buret, and the assembly was immersed in this solution at 30°C. From information obtained in a few trial experiments, the volume of the solution was adjusted to give a quantity of HCl large enough so that the  $\text{H}^+$  consumption would be less than 1% of  $\text{H}^+$  in the solution. These experiments were done without deaeration.

Hydrogen evolved from the iron wire in the solution was measured with the graduated gas buret. At the end of a given period, the test assembly was removed from the flask quickly, washed with a large volume of water, rinsed thoroughly with acetone, dried in vacuum, and weighed. Corrosion rates were calculated both from the volume of hydrogen evolved and from the loss in weight of the iron wire.

To estimate the approximate area of metal surface which the inhibitor molecule would effectively cover in the adsorbed position, relative areas were determined with molecular models. Stuart-Briegleb models of each inhibitor were arranged on a plane in a position corresponding to the possible configuration of the molecule adsorbed on the metal surface by formation of the coordinated bond between the metal and its nitrogen atom. Therefore, the bonding geometry of the nitrogen atom was based on that of the  $\text{sp}^3$  hybrid orbitals. The metal-nitrogen bond was assumed to be perpendicular to the metal surface. Thus, the arranged model was projected on the plane and the distance from the metal-nitrogen bond to the most extreme portion of the molecule was measured on the chart. The effective area covered by the molecule was calculated as the area of the circle with this distance as a radius. This simply assumes that the molecule is free to rotate on the metal-nitrogen bond as an axis. The area of piperidine with the ring placed parallel to the metal surface was also determined. The ratio of the area of each inhibitor to this piperidine area is defined as the relative molecular area. Since there are many possible configurations, the maximum and minimum relative molecular area for each of the inhibitors was determined to provide limits.

In order to compare the adsorption abilities of these inhibitors,  $\text{pK}_a$  values were determined by titration with  $\text{HClO}_4$  in 50% diethyleneglycol-water solution at 30°C. The pH of the solution was followed with a glass electrode and a Beckman Model H pH meter.

### Results

Polarization curves showed well-defined Tafel regions extending over more than a decade on the current axis. The slopes were high but consistent. The corrosion current,  $i_{\text{corr}}$ , and the corrosion potential were given by the intersection of extrapolated anodic and cathodic Tafel lines. Good reproducibility for  $i_{\text{corr}}$  was obtained with less than  $\pm 4\%$ .

Corrosion currents are shown as a function of inhibitor concentration in Fig. 1 for cyclic imines, in Fig. 2 for secondary amines, and in Fig. 3 for several  $\text{C}_9$  cyclic compounds, including the  $\text{C}_9$  imine. Concentrations of the  $\text{C}_{13}$  and  $\text{C}_{14}$  imines and  $\text{C}_{12}$  and  $\text{C}_{14}$  amines are limited by their solubility in the solution. For the secondary amines,  $i_{\text{corr}}$  decreases regularly with increase in number of carbons and irregularly for the cyclic imines. Thus,  $i_{\text{corr}}$  for  $\text{C}_{10}$  imine is smaller

Fig. 1. Effect of cyclic imines  $[(CH_2)_nNH]$  on corrosion current. S = saturation; n = carbon number.

Fig. 2. Effect of secondary amines  $[(C_{n/2}H_{n+1})_2NH]$  on corrosion current. S = saturation; n = carbon number.

than for  $C_{11}$  and  $C_{12}$  imines. Also, Fig. 3 shows much lower corrosion currents for the  $C_9$  imine than for any of the other four  $C_9$  inhibitors. These measurements were also obtained by hydrogen evolution and weight loss, and the data were in essential agreement insofar as their general dependency was concerned.

Hydrogen evolution rates increased with time for about 20 min after the corrosion reaction had begun and then decreased gradually. Satisfactory reproducibility could not be obtained for the initial 20-min period or after some 120 min, deviation being more than  $\pm 5\%$ . Consequently, the rates of hydrogen evolution were measured by using the average slopes of  $H_2$  volume vs. time curves between 30 and 120 min after the test wires were immersed in the solution. The data were reproducible to  $\pm 4\%$ .

There was no effect due to oxygen as shown by measurements with the system thoroughly deaerated with nitrogen gas.

The hydrogen evolution rate data show the comparative inhibitive effects for each of the inhibitors to be the same as that shown by polarization measurement. In fact, inhibition efficiencies were the same for each compound by all three experimental methods used.

Weight loss measurements were made along with the hydrogen evolution measurements, so the im-

Fig. 3. Effect of  $C_9$  cyclic compounds on corrosion current

ersion time was 120 min. Reproducibility was good, again with a maximum deviation of  $\pm 4\%$ .

The data from each type of experiment were self-consistent with the electrochemical method giving high rates, but as already stated with the degree of inhibition being the same by all three methods. The inhibition effectiveness increases with the carbon number of the inhibitor for both series, the exception being that the  $C_{10}$  imine is more effective than the  $C_{11}$  or  $C_{12}$  imine.

For the  $C_9$  cyclic compounds, the inhibition order observed was tetrahydroisoquinoline > *cis*-decahydroquinoline > *trans*-decahydroquinoline > tetrahydroquinoline, but with the  $C_9$  imine notably more effective than the other four.

Molecular areas are shown in Fig. 4 for the cyclic imines and in Fig. 5 for the secondary amines. The maximum and minimum values shown arise from the different molecular configurations. Although the actual configuration on the metal surface is not known, the value must be between their limits.

The relative molecular areas were determined in duplicate and these values were within  $\pm 2.5\%$  of the average. Maximum and minimum values of  $C_5$  to  $C_9$  imine differ little since a lack of steric flexibility in their molecular structures restricts the configuration

Fig. 4. Relative molecular area of cyclic imines

Fig. 5. Relative molecular area of secondary amines

of the imine molecules adsorbed on metal surface. For the imine series  $C_{10}$  and higher, however, there are large differences since the structures are more flexible. The differences are even greater in the case of the secondary amines. Hence, simple areal comparison is not suitable.

In order to compare these areas effectively, reasonable configurations must be assumed. These were chosen as follows: analogous configurations to those of cycloparaffin derivatives represented by Dunitz and Prelog (10) for the series of the cyclic imines containing less than twelve members and configurations involving less transannular interaction of hydrogen atoms for the cyclic imines with more than thirteen members. Configurational detail for the  $C_{11}$  imine is available (11).

The secondary amines have many "reasonable" configurations due to flexible deformation of their alkyl radicals, but two series of configurations were assumed. One, configuration-1, is of the type in which all of the methylene groups in alkyl radicals keep a staggered form as shown in Fig. 6A and the other, configuration-2, is the same except for an eclipsed form at the 3 and 4 position as shown in Fig. 6B. The former is an extended form and the latter a compacted one more like that of the cyclic imine. The relative molecular areas of these configurations were determined and are also given in Fig. 4 and 5, respectively.

The maximum and minimum relative molecular areas of the  $C_9$  cyclic compounds, as well as those of  $C_9$  imine, are listed in Table I. From the molecular geom-

Fig. 6. Configurations of secondary amines

Table I. Relative molecular area and  $pK_a$  values of  $C_9$  cyclic compounds

Compounds	Relative molecular area	$pK_a$
<chem>C1CN(C)CC1</chem> 1,2,3,4-Tetrahydroquinoline	1.73-2.09	4.87
<chem>C1CN(C)C(C)C1</chem> 1,2,3,4-Tetrahydroisoquinoline	1.23-2.22	9.32
<chem>C1CN(C)CC1</chem> <i>cis</i> -Decahydroquinoline	1.33-1.56	10.41
<chem>C1CN(C)CC1</chem> <i>trans</i> -Decahydroquinoline	1.49-1.75	10.47
<chem>C1CN(C)CC1</chem> $C_9$ imine	1.11-1.48	9.86

etry it is likely that for tetrahydroquinoline and *cis*- and *trans*-decahydroquinoline adsorption via the nitrogen atom requires the hydrocarbon parts to be nearly parallel to the metal surface, while the tetrahydroisoquinoline can be placed either parallel or perpendicular to the surface. Consequently, the minimum relative molecular areas of the first three are larger than that of the last one. The relative molecular area of the  $C_9$  imine is similar to or smaller than that of the other four.

The study of the arrangement of these molecular models on the metal plane suggested an effect of steric hindrance by hydrogen atoms bonded to carbon atoms adjacent to nitrogen on the adsorption of nitrogen atoms in tetrahydroquinoline, *cis*-decahydroquinoline and especially in *trans*-decahydroquinoline. This effect may decrease their inhibition effectiveness.

The  $pK_a$  values, measured in duplicate for each of the inhibitors, were reproducible to within  $\pm 1.5\%$  of the average. These are shown in Fig. 7. The data for the series of the cyclic imines agree with those given in a previous paper (2) and correspond well to those measured by Ruzicka, Kobelt, Häfliger, and Prelog (8). However, the values for the series of the secondary amines are inconsistent with those reported earlier (2) but correspond to others (12, 13).

From these results it is apparent that the electron donating propensities for these two series are nearly equal, and that the  $pK_a$  value for the series of the cyclic imines reaches a minimum at  $C_{10}$ . The basic strengths of the  $C_9$  cyclic compounds are also shown in Table I together with those of the  $C_9$  imine.

### Discussion

To compare the corrosion rates measured by the three different methods more easily, all were converted to mdd. The corrosion rates of iron wire in uninhibited 6.1M HCl solution at  $30^\circ C$  are 43,600 mdd by polarization ( $R_1$ ), 15,380 mdd by gas evolution ( $R_v$ ),

Fig. 7.  $pK_a$  values of cyclic imines and secondary amines. Cyclic imines, —; secondary amines, - - - -.

and 14,450 mdd by weight loss ( $R_w$ ). The reason for this disagreement will not be discussed here since the inhibition efficiency is in good agreement with each method.

Two corrosion inhibitor concentrations were selected as typical of high and low inhibition effectiveness, 0.001 and 0.01M. For most of the inhibitors the effectiveness was markedly greater at the higher concentrations; for example, rates of 11,700 mdd for  $C_{10}$  imine and 12,750 mdd for  $C_{12}$  amine at 0.001M, but 921 mdd and 1540 mdd at 0.01M. The corrosion rates by all three means are plotted in logarithmic scale in Fig. 8 and 9 (for convenience) as a function of carbon number of the inhibitor.

Inhibition efficiencies, defined as  $100 [(R_0 - R)/R_0] \%$  where  $R_0$  is the uninhibited rate and  $R$  the inhibited rate, were calculated with each of the three kinds of measurements. Inhibition efficiencies for a given inhibitor and concentration agree with each other with differences less than  $\pm 5\%$  at concentrations in excess of 0.003M. Consequently, the trend of the three curves derived from the three corrosion measurements for each of the inhibitor series are comparable at 0.01M as

Fig. 8. Corrosion rates at the concentration of 0.01M. Cyclic imines, —; secondary amines, - - - -; S = saturation.

Fig. 9. Corrosion rates at the concentration of 0.001M. Cyclic imines, —; secondary amines, - - - -.

shown in Fig. 8. However, at 0.001M all of the inhibition efficiencies derived from  $R_1$  are larger than those from  $R_v$  and  $R_w$ . This disagreement may be attributed to the high Tafel slopes in the uninhibited system: the cathodic Tafel slope,  $b_c$ , being 0.127 and the anodic,  $b_a$ , 0.082 v/log  $i$ . This is probably due to the shape of the electrode because the normal Tafel slopes ( $b_c$ , 0.068;  $b_a$ , 0.053 v/log  $i$ ) and the corrosion current corresponding to the corrosion rate determined by the hydrogen evolution measurement were found in the experiments by using a pure iron rod (3.0 mm diameter). However, no further amplification was tried. Nonetheless, the trend of the corrosion rates derived from the three kinds of experiments was similar even at 0.001M as shown in Fig. 9. Therefore, all of the corrosion inhibition experiments are discussed by using the corrosion current as a typical corrosion rate. Both Fig. 8 and Fig. 9 show a minimum in corrosion rate at  $C_{10}$  for the cyclic imines, but none for the secondary amines.

An irregularity is found in the melting points for  $C_{10}$  to  $C_{13}$  imine; they are less than  $25^\circ\text{C}$  for  $C_{10}$  and  $C_{12}$  imine,  $41^\circ\text{C}$  for  $C_{11}$  imine,  $50^\circ\text{C}$  for  $C_{13}$  imine, and  $53^\circ\text{C}$  for  $C_{14}$  imine. Molecular association, which results in the high melting point, may also account for decrease of inhibition effectiveness (14). However, association of  $C_{11}$  imine was not detected at 0.1M in carbon tetrachloride using infrared spectra.

To estimate the effect of the area of metal surface covered with the inhibitor on the corrosion rate,  $\log i_{\text{corr}}$  values were plotted at 0.001M inhibitor vs. relative molecular areas of the assumed configurations for the two series of inhibitors (Fig. 10). A simple curve can be drawn through all of the points for the secondary amines in configuration-1, but not through all of them for the cyclic imines. A remarkable irregularity of  $i_{\text{corr}}$  values for the cyclic imines is found between nine and twelve carbons.

A curve similar in form to that for the secondary amine series is drawn through the points for  $C_5$  and  $C_{14}$  imine (Fig. 10). This curve is assumed to be that for a series of cyclic imines which are free from ring strain because six and fifteen membered rings are almost free from the ring strain (3) and all of the secondary amines are free of the strain.

Deviations of each point for the cyclic imines from this curve were measured on the graph and plotted vs. carbon number in Fig. 11. This deviation,  $\Delta \log i_{\text{corr}}$ , then means the decrease of  $\log i_{\text{corr}}$  due to the imine

Fig. 10.  $\log i_{\text{corr}}$  vs. relative molecular area at the concentration 0.001M. Cyclic imines, —; secondary amines, - - - -; number indicates the carbon number.

Fig. 11.  $\Delta \log i_{\text{corr}}$  vs. carbon number at the concentration 0.001M

strain. Notable differences appear for nine to twelve carbons with maximum effect at ten.

Figure 12 shows the  $\log i_{\text{corr}}$  vs. relative molecular area curves for the series of cyclic imines and secondary amines in their configurations described above at 0.01M concentration. As before (Fig. 10), there is the same irregularity for the cyclic imine series. A curve for the strain-free cyclic imines could not be obtained since  $i_{\text{corr}}$  for  $C_{14}$  imine and  $C_{14}$  amine could not be determined at 0.01M due to solubility limitation. This curve may be assumed to resemble that for secondary amines in configuration-2. As can be seen in Fig. 13,  $\Delta \log i_{\text{corr}}$  for the cyclic imines reaches a maximum at ten carbons. The  $\Delta \log i_{\text{corr}}$  derived from  $R_v$  or  $R_w$  also agreed with these results.

Fig. 12.  $\log i_{\text{corr}}$  vs. relative molecular area at the concentration 0.01M. Cyclic imines, —; secondary amines (configuration-1), - - - -, (configuration-2), - · - · - ·; S = saturation; number indicates the carbon number.

Fig. 13.  $\Delta \log i_{\text{corr}}$  vs. carbon number at the concentration 0.01M.

The  $\Delta \log i_{\text{corr}}$  vs. number of carbons parallels that for  $pK_a$  (Fig. 7). Thus, both of these properties of the cyclic imines as well as many of those reported by Prelog (15) may be due to the same effect of molecular structure.

As compared to  $C_5$  imine, the difference in equilibrium constants and rate constants between  $C_{10}$  and  $C_6$  cyclic compounds appear to be due to strain (16). The strain causes the angle of the C-N-C bond in the  $C_{10}$  imine to be larger than in the other. Data on the angles are not available for the whole series. The ones chosen here were assumed on the basis of C-C-C bond angle in cycloparaffin derivatives as determined by x-ray diffraction (17). This assumption is justified by comparison of the angle of the C-N-C bond in azacyclododecane ( $C_{11}$  imine) hydrochloride (11).

The angle of C-N-C bond in the  $C_5$  imine ring is about  $112^\circ$  (18) and is not too different from the bond angle of  $109^\circ 18'$  in the theoretical  $sp^3$  hybrid orbital geometry. Since  $C_5$  imine reacts with proton to form the stable ammonium ion without change of the geometry in the nitrogen atom, as shown in Fig. 14A, the equilibrium of this reversible reaction shifts toward the right side in acid solutions.

The C-N-C bond angle in the  $C_{10}$  imine is believed to be near  $120^\circ$ , which represents  $sp^2$  hybrid orbital geometry in the nitrogen atom. When the reaction of  $C_{10}$  imine with proton occurs to form the ammonium ion, the  $sp^2$  geometry in the nitrogen atom must change to the deformed  $sp^3$  geometry which is less stable than that in the piperidinium ion. Consequently, the equilibrium of this reaction for  $C_{10}$  imine shifts to the left side, resulting in a lower  $pK_a$  value. Thus, the relationship between  $pK_a$  and  $\Delta \log i_{\text{corr}}$  may be said to depend on the angle of C-N-C bond. In other words, the inhibition efficiency of the cyclic imines containing from nine to twelve methylene groups is related to the angle of C-N-C bond.

To verify this, the inhibition effectiveness of the four  $C_9$  cyclic compounds was compared with that of  $C_9$  imine taking their relative molecular areas and  $pK_a$  values into account. All the results in the three kinds

Fig. 14. Geometry of nitrogen atom in cyclic imines reacting with proton.

of measurements show the order of their inhibition effectiveness as tetrahydroquinoline < *trans*-decahydroquinoline < *cis*-decahydroquinoline < tetrahydroisoquinoline << C<sub>9</sub> imine.

As the pK<sub>a</sub> value of tetrahydroquinoline is much lower than the others, the low adsorbability on metal results in lower inhibition effectiveness. The order of the effectiveness among *trans*- and *cis*-decahydroquinoline and tetrahydroisoquinoline may be attributed to the configuration of their molecules adsorbed on metal surface. Hydrogen atoms near nitrogen atoms interfere with the adsorption of the nitrogen in decahydroquinoline, especially in the *trans*-isomer, by their steric hindrance (19). Tetrahydroisoquinoline is a better inhibitor than decahydroquinoline because there is less steric hindrance. However, in comparison, C<sub>9</sub> imine is an excellent corrosion inhibitor. The relative molecular areas of C<sub>9</sub> imine are similar to or smaller than those of the others and the pK<sub>a</sub> of C<sub>9</sub> imine lies between those of the other compounds. Thus, the strain in the ring must be the reason for the difference since there is strain only in the C<sub>9</sub> imine.

### Conclusion

From these results, it is concluded that the angle of the C-N-C bond, which is closely related to the strain in the ring of cyclic imines containing from nine to twelve methylene groups, is important in the corrosion inhibition effectiveness of these compounds. But there is no firm basis for explaining how the angle of the C-N-C bond or the strain in the ring of medium-sized cyclic imines affects the inhibition. Hackerman, Hurd, and Annand (2) believe that it can be attributed to an improved metal-nitrogen bond formed by chemisorption. This bond arises from the greater possibility for  $\pi$ -electron bond formation of the unshared pair of electrons due to the sp<sup>2</sup> hybrid orbital geometry of its nitrogen atoms (4). From generalization on addition reactions to a double bond, the sp<sup>2</sup> geometry of its nitrogen atom should be changed to the sp<sup>3</sup> geometry to form the metal-nitrogen bond by chemisorption. The strong adsorption of the medium-sized cyclic imine cannot be attributed to formation of the unstable, deformed sp<sup>3</sup> geometry. The formation of stable metal-nitrogen bond in which the sp<sup>2</sup> geometry remains in the nitrogen atom may be required to explain strong adsorption.

It can also be assumed that the higher energy associated with strained bonds in the medium-sized ring promotes a reaction for opening the ring, resulting in polymerization of the cyclic imine. The polymerized compound is expected to favor the inhibition effect (20). There is no evidence to confirm the polymerization of the cyclic imine adsorbed on iron surface in acid solution. But formation of resinous matter during distillation of the medium-sized cyclic imine suggests this probability. Further work is required to confirm this suggestion. Corrosion inhibition study on quaternary ammonium compounds of N-substituted derivatives of the medium-sized cyclic imines would be applicable.

# Electrochemical Oxidation of Adenine: Reaction Products and Mechanisms

Glenn Dryhurst<sup>1</sup> and Philip J. Elving\*

Department of Chemistry, University of Michigan, Ann Arbor, Michigan

## ABSTRACT

The electrochemical oxidation of adenine (6-aminopurine), which gives a single well-defined voltammetric wave at the pyrolytic graphite electrode (PGE), was investigated by macroscale controlled electrode potential at the PGE in aqueous 1M acetic acid solution (pH 2.3) with exhaustive isolation, identification, and determination of reaction products and intermediates. The electrochemical oxidation of adenine appears to follow initially the same path as the enzymatic oxidation, but further oxidation and fragmentation of the purine ring system occur. Thus, adenine is oxidized in a process involving a total of 6 electrons per adenine molecule to give as the primary product a dicarbonium ion intermediate, which, being unstable, undergoes a further series of reactions: (a) electrochemical oxidation to parabanic acid (some of which is further hydrolyzed to oxaluric acid), urea, carbon dioxide, and ammonia; (b) electrochemical reduction to give ultimately 4-aminopurpuric acid, carbon dioxide, and ammonia; and (c) hydrolysis to allantoin, carbon dioxide, and ammonia.

Adenine (6-aminopurine)<sup>2</sup> is one of the two principal purines found in nucleic acid and, in the form of adenosine triphosphate (ATP), plays an important role in many metabolic processes. Because of the experimental similarities between conditions in the two heterogeneous oxidation processes based on enzymes and electrochemistry (1, 2), the electrochemical oxidation of adenine was investigated.

Few studies of the chemical oxidation of purines have been reported apart from those on uric acid (2,6,8-trihydropurine). Oxidation of adenine with an aqueous manganese dioxide suspension at 100° gives urea and biuret (3). Irradiation of aqueous adenine solutions gives 4,6-diamino-5-formamidopyrimidine and 8-hydroxy-6-amino-purine as the main products (4).

The enzymatic and biological oxidations of adenine have been more extensively examined and are covered in part in the reviews by Lister (5) and Robins (6). Adenine is directly oxidized *in vivo* to 2,8-dihydroxyadenine (7). Intravenously injected adenine is partially converted to uric acid, probably via 4-amino-5-imidazole-carboxamide ribotide (8). Oxidation by the enzyme xanthine oxidase gives 8-hydroxyadenine as an intermediate in the formation of 2,8-dihydroxyadenine (9). The main oxidative pathway with mammalian xanthine oxidase was shown to depend on the position of the oxygen atom first introduced (10); the first attack on purine, for example, occurs at position 6; hypoxanthine (6-hydroxy-purine) is then further attacked at position 2; however, positions 2 and 8 appear to be closely related and oxidation at one of these positions leads to attack of the other in the next step; thus, purine would be oxidized finally to uric acid. Oxidation of adenine with xanthine oxidase has been applied to the analytical determination of adenine (11). Adenine is also oxidized in various plants, *e.g.*, allantoin and allantoinic acid are the main products in silver maple leaves (12).

Investigation of the mechanism of the electrochemical oxidation of the purines is limited to two reports. Fichter and Kern (13) studied the oxidation of theophylline, theobromine, and caffeine under conditions

of constant current electrolysis; anode potentials were not specified and the probable occurrence of oxygen evolution with concomitant chemical oxidation makes the relevance of this work in relation to recent studies at controlled potential difficult to assess. Struck and Elving (2) found that uric acid was oxidized at controlled potential at the graphite electrode in 1M acetic acid, initially in a 2e process to a primary short-lived dicarbonium ion intermediate, which could undergo three simultaneous transformations: (a) hydrolysis to an allantoin precursor, (b) hydrolysis to alloxan and urea, and (c) further electrolytic oxidation and hydrolysis leading to parabanic acid and urea; each mole of uric acid produced on electrolysis 0.25 mole CO<sub>2</sub>, 0.25 mole of allantoin precursor, 0.75 mole urea, 0.3 mole parabanic acid, and 0.3 mole alloxan. The authors concluded that the electrochemical oxidation of uric acid resembles the enzymatic oxidation more closely than the chemical.

The present study of the electrochemical oxidation of adenine at controlled electrode potential at the pyrolytic graphite electrode (PGE) indicates a mechanism whereby adenine is oxidized in an over-all 6e process to a primary intermediate dicarbonium ion of the same type as that postulated for uric acid (2), but which is more complicated in terms of the further electrolytic and chemical steps involved. The electrochemical oxidation appears, thus, to follow initially the same path as enzymatic oxidation, but with subsequent further oxidation and fragmentation.

## Results and Discussion

The single well formed anodic voltammetric peak or wave shown by adenine (I) at the stationary PGE in aqueous solution between pH 0 and 11 in suitable background media is very close to background discharge in alkaline media, where it tends to be smaller than at lower pH (14, 15). Below pH 3, the discharge of certain background electrolytes masks the anodic wave; thus, no peak is observed in chloride background between pH 1 and 3, although a well formed peak is seen in 1M acetic acid (pH 2.3) and at low pH in sulphate buffers. The reaction was, accordingly, studied in detail in acetate background at pH 4.7 (buffered acetate solution) and 2.3 (1M acetic acid); the latter solvent is of particular value because of the favorable positive potential range that it affords and its ready removal by lyophilization (freeze-drying).

Voltammetric studies were supplemented by coulometry and exhaustive electrolysis at large electrodes. The detailed examination of the changes in the com-

<sup>2</sup> Commonly accepted structural formulas of the principal compounds discussed are given in Fig 2; allowance must be made for alteration due to keto-enol and acid-base equilibria. Roman numerals cited in parentheses in the text refer to the structural formulas presented in Fig. 2. The *Chemical Abstracts* numbering system is used.

position of an adenine solution during electrolytic oxidation at a fixed anode potential allowed identification and quantitative determination of the ultimate products as well as characterization of probable intermediate species.

**Stability studies.**—Because of the possible decomposition of some of the expected products from the electrolytic oxidation of adenine, the stability of parabanic acid (V), oxaluric acid (VI), and alloxan (2,4,5,6-tetraoxypyrimidine) in 1M acetic acid and in pH 4.7 acetate buffer solutions was investigated; concentrations of the compounds were measured polarographically.

Parabanic acid (V) is fairly stable in 1M HOAc with some slow hydrolysis to oxaluric acid (VI); at pH 4.7, a 2 mM parabanic acid solution is completely hydrolyzed to oxaluric acid in six days.

Oxaluric acid is stable in both media for several days as evidenced by the constancy of the polarographic limiting current.

When alloxan was examined in 1M HOAc under electrolysis conditions, *i.e.*, at a potential of 1.3v, a 9.6 mM solution decreased in concentration to 4.6 mM after 164 hr, although the parabanic acid wave which appeared was only equivalent to a mM concentration. This discrepancy indicates the formation of other products, *e.g.*, alloxanic acid. Subsequent work showed that in 1M HOAc alloxan partially decomposes to parabanic acid in the absence of an applied potential. The instability of alloxan at low pH may explain Sartori and Liberti's (16) observation of a polarographic wave for alloxan  $E_{1/2} = -0.7v$ , which Struck and Elving (17) could not find; since the pH of the solution in which alloxan is stored affects its stability, the former authors probably observed a wave due to parabanic acid rather than to alloxan. The apparent nonstoichiometry of the alloxan to parabanic acid conversion is further evidenced by the large decrease in the alloxan limiting current on bubbling air through pH 4.0 acetate solution, when no parabanic acid was noted (17).

#### Voltammetry

Adenine (I) gives a well defined anodic voltammetric peak at the stationary PGE in 1M acetic acid (Fig. 1) and pH 4.7 acetate buffer. The peak potentials,  $E_p$ , of 1.30 and 1.14v, respectively, for 1mM adenine solution indicate the difficulty with which it is oxidized.  $E_p$  shifts to more positive potential at higher adenine concentration; thus, in 1M HOAc a 20 mM adenine solution gives an  $E_p > 1.5v$ .

Adenine gives a peak current,  $i_p$ , at the 1 mM level with a current density of  $2.4 \mu a/mM/mm^2$ , which, by comparison to earlier studies (18), suggests the involvement of about 4e per adenine molecule. However, adenine or its electrolysis product(s) are apparently adsorbed at the PGE (14,15), which results in exponential  $i_p$ -C curves even at scan rates as low as 3 mv/sec. On cyclic voltammetry at the PGE,  $E_p$  shifts 51 mv/pH unit more negative at a scan rate of

Fig. 1. Voltammogram of 1 mM adenine (A) in 1M acetic acid solution (background alone: B) at a stationary graphite electrode.

0.06 v/sec and 56 mv/pH unit at 0.6 v/sec, indicating that the numbers of protons and of electrons involved in the rate-determining step of the oxidation are the same. These shifts agree with that observed for  $E_p$  on normal voltammetry (*cf. supra*); assuming linear dependence in the region of measurement (pH 2.3 and 4.7)

$$E_p = 1.45 - 0.067 \text{ pH} \quad [1]$$

#### Macroscale Electrolysis

**Coulometry.**—At both pH 2.3 and 4.7, coulometry at appropriate controlled potential shows that 5.6-5.8 electrons ( $\pm 5-10$  relative per cent) are involved in the over-all oxidation (Table I). Electrolysis of 1 mM adenine solution usually takes about 2 days to reach completion; this is indicative of a very slow intermediate step in the oxidation, deposition of an insoluble reaction product, film formation on the electrode surface, or a combination of these phenomena. Cyclic voltammetry of adenine indicates that the current reaches a limiting value at about 1 mM (14); this, the behavior of adenine on alternating current polarography (14) and the deposit of a film on the electrode on macroscale electrolysis (*cf. below*) support the presence of adsorption and slow chemical intermediate step (or steps) in the over-all process.

**Preparative electrolysis.**—Exhaustive electrolysis of adenine solutions at fixed anodic potential allowed the preparation of sufficiently large amounts of products to permit their isolation, identification, characterization, and quantitative determination. A variety of isolation and measurement approaches, including lyophilization, ion-exchange, paper and thin layer chromatography, polarography, spectrophotometry, and other physical and chemical phenomena showed that urea, parabanic acid (V), oxaluric acid (VI), ammonia, 4-aminopurpuric acid (IX), and possibly one of the group of allantoin (X), uroxanic acid or alloxanic acid, were present in the electrolyzed solution.

On completion of the electrolyses, the working electrode was colored bright red, green, and blue, showing flow lines in the direction of stirring. The colored material could be extracted into dilute ammonia to give a yellow-green solution, which showed no sharp spectral peaks, although general absorption occurred at lower wavelengths; the extract showed no polarographic activity. Consequently, the colored electrode surface film differs chemically from the principal products isolated or identified in the electrolysis solution.

The procedures used and results obtained in examining electrolyzed solutions are given in the Experimental section. Certain important results identifying the principal products are summarized in the following sections.

**Polarographic behavior of electrolyzed solution.**—After exhaustive electrolysis of 1 mM adenine in 1M HOAc solution, polarography at the dropping mercury electrode (DME) shows two waves with  $E_{1/2}$  of  $-0.69$  and  $-1.12v$ . When the pH is adjusted to 5.1 by addition of pH 8 McIlvaine buffer, three waves appear with  $E_{1/2}$  of  $-0.80$ ,  $-1.07$ , and  $-1.42v$ . The first and largest wave is due to parabanic acid as

shown by its pH-dependence and tendency to hydrolyze to oxaluric acid at low pH (Table II). The second wave is the split parabanic acid wave observed in mixed buffers, which is attributed to reduction of free acid and anion with the anion giving the postwave (19) and to complexation of part of the parabanic acid with phosphate (20). The most negative wave is due to oxaluric acid as evidenced by its pH-dependence (Table II); a mechanism for this reduction has been proposed (21). The parabanic acid wave in the polarographed sample of the electrolyzed HOAc solution corresponds to a concentration of approximately 0.3 mM; that of oxaluric acid to approximately 0.1 mM.

Oxaluric acid arises as a hydrolysis product of parabanic acid rather than as a direct oxidation product from adenine; as previously noted, parabanic acid is moderately rapidly hydrolyzed even at pH 4.7. Throughout the polarographic examination of dilute electrolysis solutions, no substantial evidence for the presence of alloxan was found.

**Lyophilization of oxidation products.**—Lyophilization of the solution after electrolysis of 2 millimoles of adenine gives initially a pale buff colored residue, which almost immediately turns bright violet-red even while still under vacuum; this same material was obtained on lyophilization of the product of electrolysis of 0.1 millimole of adenine. The residue is extremely hygroscopic and readily water soluble to give a bright red solution of pH 2.2-2.3 with  $\lambda_{\max}$  at 510 m $\mu$  (identical to visible spectrum of murexide) and with no absorption peaks in the ultraviolet but with increasing general absorption over the range of 400-270 m $\mu$  with strong absorption; such behavior indicates a system containing multiple double bonds (murexide shows two characteristic ultraviolet absorption peaks). The red color of the aqueous solution is stable for many days. Polarography shows the presence of comparable concentrations of parabanic and oxaluric acids. Attempts to isolate the red-producing product, e.g., by solvent extraction and ion exchange, were unsuccessful and usually resulted in the disappearance of the red color.

The red material had a number of characteristic reactions (cf. Experimental section), which, when combined with its hygroscopic nature and instability on basic ion-exchange columns and with subsequently discussed analytical data, indicate that it is 4-aminopurpuric acid (IX), which has all of the physical and chemical properties of the red electrolysis product (22).

Paper and thin layer chromatography indicate that urea is the most characteristic product. Minor products identified by these techniques are uroxanic acid and one or more of the group of allantoin, allantoic acid, and oxaluric acid (cf. Experimental).

The high acidity of the electrolysis product is due to the presence of oxaluric acid,  $pK_a$  5-5.3 (19,21),

parabanic acid,  $pK_a$  6.1 (23), and, possibly, small quantities of either uroxanic or alloxanic acid.

### Material Balance

In view of the complexity of the reaction as indicated by the variety of products identified, the rates of disappearance of reactant and of appearance of certain products and the analytical composition of the final mixture were determined; this approach was helpful in developing a reaction scheme which would identify the primary oxidation product, which had to be a short-lived species and whose subsequent reactions would lead to the ultimate products. As electrolysis proceeds, the ratio of adenine electrolyzed to urea and ammonia liberated, which is initially 1:0.4:1.5 (Table III), changes to 1:0.3:1.65 at completion of electrolysis. The final electrolysis solution contains, on the basis of each mole of adenine oxidized, 0.3 mole urea, 0.3 mole parabanic acid, 0.1 mole allantoin, 1.65 mole of ammonia, 0.1 mole of oxaluric acid, and traces of uroxanic acid; more accurately, the sum of the parabanic and oxaluric acids produced is about 0.4 mole/mole of adenine with the ratio depending on the actual electrolysis time.

The figures cited for urea, parabanic and oxaluric acids, and allantoin, account for 0.5 mole of adenine per mole of adenine electrolytically oxidized. Additional fission of adenine occurs to give 0.6 mole of  $NH_3$  above that expected for complete deamination of each mole of adenine at position 6.

It is not possible to account satisfactorily for the other 0.5 mole of adenine by assuming that alloxan and 4,5-diamino-2,6-dihydropyrimidine are produced, since this requires liberation of 0.25 mole urea above that measured, although these two compounds have been shown to condense to give 4-aminopurpuric acid (22). A more satisfactory hypothesis is that the postulated dicarbonium ion intermediate (cf. next section) reacts to give 5-amino-2,4,6-trihydropyrimidine and 4-amino-2,5,6-trihydropyrimidine, which condense to 4-aminopurpuric acid; this route involves the liberation of 0.5 mole  $NH_3$  and no further urea formation.

### Mechanism

The characteristic ultraviolet absorption spectrum of adenine ( $\lambda_{\max} = 263 m\mu$  in 1M HOAc) is due mainly to the  $-C(4)=C(5)-C(6)=N(1)$ -chromophoric group (24,25). Consequently, disappearance of this peak after electrolysis indicates that the  $-C(4)=C(5)-$  bond is oxidized.

Removal of six electrons from adenine suggests that the process proceeds initially (Fig. 2A) by sequential two-electron, two-proton oxidations to 2-hydroxyadenine (II) and then rapidly to 2,8-dihydroxyadenine (III) [these processes are presumably of the type suggested by Bergmann and Dikstein (10) for enzymatic purine oxidation]. The latter compound is similar to uric acid except for the presence of an amino group in place of an hydroxyl group at the 6-position. Further removal of two electrons results in oxidation

Table III. Course of controlled potential electrolysis of adenine<sup>a</sup>

<sup>a</sup> Electrolysis of 1 mM adenine in 1M acetic acid.

<sup>b</sup> Mechanism postulated in text assumes molar ratios of 0.4 for urea production and of 1.5 for  $NH_3$  production; the former ratio will decrease and the latter increase on hydrolysis of 1 mole of urea to 2 moles of  $NH_3$ .

<sup>c</sup> Corrected for hydrolysis of 9% urea.

Fig. 2. Proposed pathways for electrochemical oxidation of adenine in 1M acetic acid solution and subsequent transformations. The molar quantities refer to the amount involved per mole of adenine (I) converted to the dicarbonium ion (IV). Other compounds listed are as follows: II, 2-hydroxyadenine; III, 2,8-dihydroxyadenine; V, parabanic acid; VI, oxaluric acid; VII, 4-amino-2,5,6-trihydroxypyrimidine; VIII, 5-amino-2,4,5-trihydroxypyrimidine; IX, 4-aminopurpuric acid; X, allantoin.

of the 4,5 double bond and formation of a dicarbonium ion (IV) of the same type as that postulated for the electrochemical oxidation of uric acid (2).

Continuation of oxidation to the dicarbonium ion stage, as soon as the electrolytic oxidation of adenine is initiated, is due to the fact that the ease of oxidation of purines generally increases with the number of hydroxyl groups on the molecule, *e.g.*,  $E_{p/2}$  for oxidation of the hydroxypurines at pH 3.7 are 1.14v for 6-hydroxypurine (hypoxanthine), 0.84v for 2,6-dihydroxypurine (xanthine) and 0.45v for 2,6,8-trihydroxypurine (uric acid) (26). Thus, 2-hydroxy- and 2,8-dihydroxyadenine are probably more easily oxidized electrolytically than adenine itself and consequently are unstable in respect to oxidation at the potential at which adenine is oxidized.

There is no evidence for deamination of 2,8-dihydroxyadenine under the reaction conditions; indeed, this highly insoluble compound (27) may possibly deposit on the electrode surface, causing the apparent voltammetric involvement of  $4e$  rather than of  $6e$  and the effects associated with the previously mentioned adsorbed layer. The yellow color noted on occasion during the electrolysis of fairly concentrated adenine solutions may have been due to 2,8-dihydroxyadenine (27).

The present investigation does not supply direct evidence for any other intermediate such as the symmetrical intermediate postulated for both the enzymatic (28-30) and electrolytic (2) oxidation of uric acid. However, since allantoin (X) is produced in the oxidation of adenine and since allantoin arises in uric acid oxidation via a symmetrical intermediate (31), a small quantity of such an intermediate may be produced.

Following the primary electrochemical oxidation to the dicarbonium ion (Fig. 2A), the nature and ratio of the products ultimately produced indicate that at least three further distinct chemical and electrolytic reactions occur. First, further electrochemical oxidation of the dicarbonium ion (VI) leads to parabanic and oxaluric acids, urea, and ammonia (Fig. 2B; the postulated amounts produced per mole of adenine electrolytically oxidized are noted).

Analytical data and the formation of 4-aminopurpuric acid (IX) indicate that some of the primary oxidation product is reduced to 4-amino-2,5,6-trihydroxy-(VII) and 5-amino-2,4,6-trihydroxypyrimidine (VIII) (Fig. 2C), which subsequently condense to form 4-aminopurpuric acid; such a series of reactions involves the liberation of 1 mole  $\text{NH}_3$  and consumption of  $1e$  per 0.5 mole of dicarbonium ion reduced. The

electrochemical reduction could occur at the counter electrode.

Formation of allantoin (X) results from acid hydrolysis of the dicarbonium ion, liberating  $\text{NH}_3$  and  $\text{CO}_2$  (Fig. 2D).

Summation of the molar quantities given in Fig. 2 shows that the postulated mechanism predicts that 1 mole adenine should yield 0.4 mole urea, 1.5 mole  $\text{NH}_3$ , 0.35-0.4 mole of parabanic and oxaluric acids (usually 0.3 mole parabanic and 0.1 mole oxaluric), 0.1 mole allantoin, 1 mole  $\text{CO}_2$ , and 0.25 mole 4-aminopurpuric acid with an over-all consumption of  $6.3e$ . These predicted products agree with the experimental data (*cf.* Material Balance), especially if allowance is made for the hydrolysis of urea during the long electrolysis, *e.g.*, *cf.* Table III and composition of final electrolysis solution. The mechanism does not preclude other reactions but merely indicates the predominant routes under the experimental conditions employed.

### Experimental

**Chemicals.**—Oxaluric acid, potassium alloxanate, and uroxic acid were prepared following Struck (32); uramil was prepared according to Koppel and Robins (33). Other chemicals were obtained from the sources listed: adenine (Nutritional Biochemicals); murexide, alloxan, allantoin, *p*-dimethylaminobenzaldehyde, phenylhydrazine hydrochloride, 2,3-butanedione monoxime, and sodium dithionite (Eastman); acetic acid, butanol, and ammonium chloride (Mallinckrodt); allantoinic acid (K & K Laboratories); parabanic acid (Mann); barbituric acid (Aldrich); urea (J. T. Baker); Dowex 2-X8 and 50W-X8 (Dow).

Two solvent systems were used in paper and thin layer chromatography: 1-BuOH-HOAc- $\text{H}_2\text{O}$  (12:3:5) and iso-PrOH- $\text{NH}_3$ - $\text{H}_2\text{O}$  (10:5:1). Ehrlich's reagent (10% w/v *p*-dimethylaminobenzaldehyde in concentrated HCl) (34) was used undiluted with acetone. Bromocresol green was prepared according to Smith (34).

Ion-exchange columns were prepared from Dowex 2-X8 (50-100 mesh) converted to the hydroxyl form by washing with 1M NaOH until the effluent was free of chloride ion, and then with water until the effluent was neutral to litmus. Dowex 50W-X8 (50-100 mesh) was used after being washed several times with distilled water.

Buffer solutions, prepared from analytical grade chemicals, had an ionic strength of 0.5M. Argon used for deoxygenation was equilibrated with water; no other purification was necessary.

**Apparatus.**—Polarograms were recorded on a Sargent Model XXI Polarograph, using a water-jacketed

H-cell maintained at  $25^\circ \pm 0.2^\circ\text{C}$ , which contained a saturated calomel reference electrode (SCE) in one leg. All potentials quoted are *vs.* SCE at  $25^\circ\text{C}$ . The dropping mercury electrode had normal *m* and *t* values.

Graphite indicating electrodes were prepared from General Electric pyrolytic graphite; 4-mm rods were sealed into 6-mm (OD) soft glass tubes with epoxy resin (Hysol Corporation Epoxy-Patch). The electrode was resurfaced before each voltammogram by polishing on a silicon carbide paper (600 grade, Carborundum Company) mounted on a rotating disk. For coulometry and macroscale electrolysis, 3-in. by 0.75-in. plates of pyrolytic graphite were used (1/32-1/8 in. thick); after each run, these electrodes were carefully washed and resurfaced by polishing with silicon carbide paper.

The most satisfactory of the various electrolysis cells used for coulometry was a large two-compartment cell; diffusion between compartments was minimized by a medium porosity fritted disk and a 1-in. KCl-saturated agar plug. The counter electrode was a cylindrical platinum gauze ( $1 \times 3$  in.). The working electrode consisted of five graphite plates connected together and mounted into a rubber stopper. The reference electrode was a Beckman calomel electrode. Stirring was done magnetically, using a Teflon-coated stirring bar.

The large single compartment cell generally used for macroscale electrolysis was fitted with a rubber stopper into which six graphite plates were mounted; three plates served as counter electrodes and three as working electrodes. In order to minimize KCl diffusion into the cell, the latter was connected to a large calomel electrode by a salt bridge made from a length of 3-mm nylon tubing plugged at the cell end with Corning Vycor Thirsty glass.

In preliminary studies and for coulometry, the anode potential was controlled by a Fisher controlled potential "Electro-Analyzer"; in macroscale electrolysis, where the IR drop was large, a unit with higher voltage output (maximum of about 100v and 40 ma), based on operational amplifier circuits (35), was used.

Current integration during coulometry utilized a Dymec Model DY-2210 voltage-to-frequency converter and a Hewlett-Packard Model 521-AR electronic counter; current flowing through the working electrode was measured in terms of the voltage drop across a 1-ohm resistor. The time of electrolysis was recorded with an Industrial Timer Corporation Model CMO elapse time counter.

The pH was measured with a Beckman Model G pH meter. Infrared spectra were obtained with a Perkin-Elmer Infracord spectrophotometer using Nujol mulls and KCl or KBr pellets prepared with a Wilks Mini Press. Ultraviolet spectra were recorded on a Beckman Model DB spectrophotometer, using 1-cm stoppered quartz cells. Melting points were obtained with a Fisher-Johns apparatus. Lyophilization was accomplished using a Cenco-Hyvac-7 vacuum pump; cooling traps contained 2-propanol-dry ice; the lyophilization vessel was usually a 1-liter round-bottom distillation flask, on whose walls the solutions were shell frozen.

Paper chromatography (ascending) utilized Whatman No. 1 filter paper cut into strips. Eastman Chromagram Type K 301R (silica gel) thin layer sheets were used.

**Coulometry.**—A measured volume of appropriate background solution was electrolyzed for several hours in the working electrode compartment until the current integrator gave a constant count per unit time (background counting rate). The integrator was reset and 0.02-0.1 millimole of adenine was introduced without altering the stirring; the applied potential, integrator, and timer were then set in operation simultaneously, and electrolysis was continued until the counting rate decayed to background or a low, con-

stant level. Completion of electrolysis was always confirmed by the disappearance of the characteristic adenine absorption peak at  $263\text{ m}\mu$ . Subtraction of the product of background counting rate and time required for electrolysis from the total count gave the counts proportional to the electron flow involved in the adenine oxidation.

**Macroscale electrolysis.**—As an indication of the long electrolysis time required, *e.g.*, complete electrolysis of 100 ml of 20-30 mM adenine solutions in 1M HOAc usually took 3-5 weeks, 20-30 mM uric acid solutions were completely electrolyzed (2) in about the same time required to electrolyze 0.2-2 mM adenine solutions, even though a larger electrode area was utilized in the present study; however, it should be pointed out that spectroscopic type graphite was employed in the earlier study and pyrolytic graphite in the present study. Consequently, 5-10 mM adenine solutions were generally employed; exhaustive electrolysis at 1.4v usually took 1-2 weeks. At times, development of a pale yellow color was noted after some time during electrolysis; however, it disappeared near completion of the electrolysis.

Use of separate counter and working electrode compartments in the electrolysis cell allowed movement of reactant and products into the former compartment. In addition, considerable quantities of KCl diffused from the salt bridges and reference electrode compartment into the other compartments contaminating the products; it was not possible to remove the KCl, *e.g.*, by ion-exchange or solvent extraction, without markedly altering the nature of the products. Accordingly, the working and counter electrodes were often housed in the same compartment.

**Paper and thin layer chromatography.**—With the exception of urea, which was spotted as a solution (1 mg/ml), all reference compounds were applied as very small crystals and were dissolved by repeated addition of water via a small loop of platinum wire, which deposited about  $5\ \mu\text{l}$  of water. Because of the high KCl content of the solid product obtained on lyophilization, it was usually necessary to load the spot heavily by repeated addition of crystals, which were also sequentially dissolved. Ascending development was used with two spots per strip, which was immersed in the solvent to a depth of about 0.6 cm; development for paper usually took about 12 hr. Reagents were applied by spraying, identification being based on parallel behavior of reference and unknown on the same chromatogram. When solvents containing acetic acid were used on paper, followed by application of bromocresol green reagent, the steaming technique recommended by Struck and Elving (2) was employed, although on no occasion was thoroughly satisfactory removal of acetic acid obtained.

Urea was identified as a major product with Ehrlich's reagent;  $R_f$  values for two solvent systems were identical on both supports to authentic urea, *e.g.*,  $R_f = 0.54$  on paper and 0.52 on silica gel thin layer plates with a BuOH-HOAc-H<sub>2</sub>O solvent.

Two other less intense spots, detected with Ehrlich's reagent on paper chromatograms using BuOH-HOAc-H<sub>2</sub>O solvent, have  $R_f$  values of 0.19 and 0.28. Of the probable reaction products, the former corresponds to uroxic acid ( $R_f$ , 0.19) and the latter to allantoin ( $R_f$ , 0.27), allantoic acid ( $R_f$ , 0.29) or oxaluric acid ( $R_f$ , 0.29). Spraying similar papers with bromocresol green reagent after very prolonged steaming to remove acetic acid (2) gave rather ill-defined results, although the presence of oxaluric acid was indicated.

**Ion-exchange isolation and identification of urea.**—Chromatography indicated that urea was a principal oxidation product; since many of the other products appeared to be acidic, isolation of the urea was attempted.

The lyophilized product from electrolysis of 1.0 millimole adenine, which contained at least an equal

quantity of KCl, was dissolved in 50 ml water and was passed through a Dowex 2-X8 column (hydroxide form); the column was washed with water until the total eluate was 150 ml. Lyophilization of the latter gave a fluffy white, strongly basic product, which was predominantly KOH formed by exchange of chloride. This product was dissolved in 20 ml water and passed through a column of Dowex 50W-X8 resin (strongly acid, hydrogen form), which was washed with water to a total volume of 125 ml; lyophilization of this eluate gave no solid material. The acid column was then washed with 50 ml 1M HOAc; lyophilization of this eluate gave a white fluffy material, mp 128°C, whose infrared spectrum was identical to that of authentic urea. Urea apparently forms a fairly weakly bound adduct on the acid resin, probably of the same type as urea oxalate and nitrate. Because of the high KCl concentration in the product, no estimate of the yield of urea was made.

The total acidic components of the product, retained on the basic column, was eluted with 125 ml 1M HCl; lyophilization gave a small quantity of a yellow deliquescent product, which could not be identified, *e.g.*, on dissolution in a very small volume of water no precipitate appeared on standing although oxaluric acid was undoubtedly present. It is probable that, because of the minute amounts of product used, the solubility of oxaluric acid was never exceeded.

Attempts to isolate allantoin by the methods of Struck and Elving (2) were unsuccessful, although subsequent analytical data showed the presence of allantoin. The lower initial concentrations of adenine, the relatively lower proportion of allantoin produced and the presence of considerable quantities of KCl would explain the failure to isolate allantoin.

*Characterization of 4-aminopurpuric acid.*—The residue obtained on lyophilization of an electrolyzed solution gave, as described, a bright red solution in water, whose color has been ascribed to the presence of 4-aminopurpuric acid on the basis of evidence which included a number of very characteristic reactions shown by the red material when in admixture with the other electrolytic products; in particular, it is red-violet and hygroscopic, and, on treatment with hot dilute HCl or NaOH, gives bisalloxazine, which is pale yellow, melts above 300°C, and is stable to nitric acid evaporation. Specific separation and confirmatory identification of 4-aminopurpuric acid was not possible because of its general instability and because of the small quantities of electrolysis product. Some of the experiments just summarized were as follows:

1. Addition of 1M HOAc gave initially a bright red solution, which decolorized in about 15-20 min. Polarography of such a solution showed that, immediately on addition of the red product, a small but distinct wave ( $E_{1/2} = -0.06v$ ) appeared, which decreased in height as the intensity of the red color diminished; murexide (ammonium purpurate) under the same conditions behaves identically. The wave at  $-0.06v$  is probably due to small quantities of alloxan (16,19), which appears to decompose, apparently to products other than parabanic acid; after 60 min, a murexide solution showed no wave at  $-0.7v$  which could be attributed to parabanic acid.

2. After dissolution in 1M HOAc and decolorization, the original red product is recovered on lyophilization, even if the solution is allowed to stand for a few days. Thus, the decolorization process in acetic acid is reversible.

3. Heating a solution of the oxidation products in 1M HOAc with nitric acid or treatment with sodium nitrite and nitric acid in the cold and then boiling to remove nitrogen oxides results in a significant increase in the parabanic acid wave; parabanic acid itself is partially oxidized to polarographically inactive products under the same conditions.

4. Treatment of the red product with 1M NaOH gives initially a blue-violet solution, which slowly

turns yellow. The yellow color is stable for many days.

5. Treatment of the product with hot 20% hydrochloric acid gives a yellow solution; after standing for some time, a small quantity of pale yellow crystals are produced. Evaporating this solution (without removing any crystals that may have formed) to dryness results in a yellow-brown residue which is stable to temperatures above 250°C, treatment of this residue with 1:1 HNO<sub>3</sub> gives a bright yellow solution, whose evaporation to dryness gives a small quantity of pale yellow crystals which do not melt below 300°C. The former yellow-brown product gives a deep yellow solution on 1M Na<sub>2</sub>CO<sub>3</sub>; cooling for several days at 10°C did not produce any precipitate.

The behavior just summarized indicates that the product is similar in some respects to murexide, *e.g.*, it decomposes to a very small extent to alloxan in 1M HOAc; however, spectra suggest that, even though multiple double bonds may be present, the product is not murexide. Bathochromic shifts in acid and alkaline solution are similar to those observed with murexide. The product is at least partially oxidizable to parabanic acid, probably via alloxan. The reversible color reaction in 1M HOAc suggests that the red material may decompose to simpler products in dilute solution, which recombine on concentration (lyophilization), although protonation and accompanying equilibria may be involved.

*Analytical examination of course of electrolysis.*—The solution electrolyzed at 1.3v, which originally was 100 ml of 1 mM adenine in 1M acetic acid, was analyzed during the course of electrolysis as described in the following sections. This volume of solution was insufficient to allow removal of several aliquots for polarographic determination of parabanic and oxaluric acids, thus, these compounds were only determined at the completion of electrolysis.

*Determination of residual adenine.*—A 1.00-ml sample of electrolysis solution was withdrawn and diluted with 1M HOAc (from 1:20 dilution at the beginning of the electrolysis to 1:5 dilution at the end). The adenine concentration was calculated from its ultraviolet absorption:  $\epsilon = 1.274 \times 10^4$  at 263 m $\mu$ .

*Determination of urea.*—Urea was determined by a modification of Rosenthal's method (36). One milliliter of electrolysis solution was diluted in a 70-ml test tube to exactly 5.00 ml with water; 3.00 ml As(V) solution (10 ml concentrated HCl saturated with As<sub>2</sub>O<sub>5</sub> and then diluted to 35 ml with HCl), 1.00 ml 2,3-butanedione monoxime (2.5% w/v in 5% HOAc) and 1:00 ml water were added. The tube was placed in boiling water for 30 min and then cooled for 3 min; the absorbance at 480 m $\mu$  was measured, using a water blank carried through the entire procedure. For each measurement, a calibration curve was prepared, using control samples of 10, 20, 30, 40, and 50  $\mu$ g urea per 5 ml water. Interference by allantoin was corrected for by carrying known concentrations of allantoin through the procedure and correcting on the basis of a subsequent allantoin determination (*vide infra*), as recommended (2).

*Determination of ammonia.*—Since addition of Nessler's reagent to a portion of the electrolyzed solution gave a bright yellow precipitate and no precipitate was produced with any of the expected organic products at the concentration levels anticipated, ammonia was measured by the Nessler method, following King and Faulconer (37). Nessler reagent was prepared by slowly adding a saturated mercuric chloride solution to a solution of 50g KI in 35 ml cold water until a slight precipitate of red mercuric iodide persisted. Then, 400 ml of clarified 9M NaOH was added and the resultant solution diluted to one liter with water. After standing at room temperature for 24 hr, the clear supernatant liquid was decanted and was ready for use.

A 1.00-ml sample of electrolysis solution was placed in a 70-ml test tube, followed by addition, while swirling, of 8.00 ml water and 1.00 ml Nessler reagent; after 5 min, the absorbance at 400 m $\mu$  was measured. Often at the end of an electrolysis the 1.00-ml sample aliquot was appropriately diluted with water and a 1.00-ml aliquot of the resultant solution run through the procedure.

A blank carried through the Nesslerization and photometry consisted of an aliquot of 1M HOAc, which had been left open to the atmosphere in order to compensate for the effect of ammoniacal fumes. A calibration curve was prepared by diluting aliquots of a stock solution (10 mg NH<sub>4</sub>Cl/1000 ml water) so that the weight of NH<sub>3</sub> in the final solution was 5 to 30  $\mu$ g.

Formation of an orange-yellow precipitate on addition of Nessler's reagent to the test solution indicates that the latter is too concentrated in ammonia or that the swirling during addition of reagent was insufficient; such samples were discarded.

**Determination of allantoin.**—Allantoin (or allantoin precursor) (2) was determined by a modified Young and Conway procedure (38). Because of the poor sensitivity of the latter procedure and the low yield of allantoin, the analysis was only run at the completion of an electrolysis. A 5.00-ml aliquot of electrolysis solution was transferred to a 70-ml test tube, 1.5 ml 5M NaOH added, and the solution heated on a boiling water bath for 7 min, after which the tube was rapidly cooled in ice and acidified with 2.0 ml 5M HCl. Then, 1.0 ml phenylhydrazine hydrochloride solution (40 mg/30 ml H<sub>2</sub>O) was added, the tube placed in boiling water for exactly 2 min and then cooled in ice-salt mixture ( $-10^{\circ}\text{C}$ ) for a few minutes, and 1.00 ml potassium ferricyanide (100 mg/30 ml H<sub>2</sub>O) added. The solution was thoroughly mixed and allowed to stand at room temperature for 40 min, when the absorbance at 515 m $\mu$  was measured. In order to correct for uroxic acid (or alloxanic acid), one 5-ml aliquot of test solution was not treated with NaOH but rather with 3.0 ml H<sub>2</sub>O and, after heating for 7 min, with 0.5 ml 5M HCl; the procedure was finished as usual.

Calibration curves were prepared with allantoin or allantoic acid solutions, which were 0.005 to 0.15 mM with respect to the initial 5-ml aliquot.

**Determination of parabanic and oxaluric acids.**—Parabanic acid was determined at the completion of the electrolysis by transferring about 20 ml of the electrolysis solution to the polarographic cell, deaerating, running a polarogram between 0 and  $-1.4\text{v}$ , and comparing the height of the wave at  $-0.7\text{v}$  with a calibration curve prepared from authentic parabanic acid.

Oxaluric acid was determined at the completion of an electrolysis in the same way, using the height of the wave at  $-1.12\text{v}$ .

# The Standard Free Energy of Formation of $UI_3$ from EMF Measurements on a Solid Electrolyte Galvanic Cell

J. O. Tveekrem and M. S. Chandrasekharaiah<sup>1</sup>

Brookhaven National Laboratory, Associated Universities, Inc., Upton, New York

## ABSTRACT

The first known experimental measurements of the  $\Delta F^\circ_f$  of  $UI_3$  are described. The emf of the solid electrolyte galvanic cell, Pt/ $U, UI_3(s)$ / $NaI(s)$ / $AgI(s)$ / $Ag(s)$ /Pt, was measured over the temperature range of 220°-370°C. The  $\Delta F$  values of the cell reaction  $U(s) + 3AgI(s) \rightleftharpoons UI_3(s) + 3Ag(s)$ , derived from the emf data from six cells, were combined with the  $\Delta F^\circ_f$  values of AgI to obtain the  $\Delta F^\circ_f$  of  $UI_3$ . This resulted in a value of  $-98.8 \pm 0.4$  kcal/mole at 370°C, which was 6.7 kcal/mole more positive than previously published estimated values.

The uranium iodides have been shown to be significant species in studies of fission products released from simulated reactor fuel meltdowns (1). In investigations of this nature, accurate thermodynamic values of the various chemical species are often necessary. In the case of the uranium iodides, the only values available are based on estimates rather than experimental data.

We have employed the technique of emf measurements on a solid electrolyte galvanic cell to obtain the standard free energy of formation of  $UI_3$ . The general technique has been thoroughly discussed by Kiukkola and Wagner (2). The cell utilized for these experiments was

The over-all cell reaction on passing three Faradays is

The free energy change of this reaction is given by the expression  $\Delta F = -3F\mathcal{E}$  where  $\mathcal{E}$  is the cell emf in volts and  $F = 23.06$  kcal/volt equivalent. The free energy can also be written

$$\Delta F_{\text{cell}} = \Delta F^\circ_f UI_3 - 3\Delta F^\circ_f AgI$$

Therefore, by combining the known standard free energy of formation of AgI (3) with the measured free energy change of the cell reaction, the standard free energy of formation of  $UI_3$  may be obtained.

The NaI serves as an auxiliary electrolyte and forms a chemically inert conducting bridge between the two sides of the cell. The auxiliary electrolyte must exhibit purely ionic conduction and preferably have a common anion with the other cell constituents. The stoichiometric alkali iodides meet these requirements (4, 5). An additional prerequisite is the lack of solid solution or compound formation between the auxiliary electrolyte and the adjacent phases in order to eliminate the possibility of appreciable junction potentials. This eliminated LiI, which forms a solid solution with AgI, and KI, which forms a congruently melting compound,  $KAg_3I_4$ , with AgI. No compound formation occurs between NaI and AgI, but a eutectic is formed at 384°C (6). This eutectic establishes the maximum temperature limit at which the cell can be operated. No literature data were available on compound formation between NaI and  $UI_3$ . To check on this possibility, x-ray diffraction analysis was applied to two types of sample: (i) a powdered mixture of the two salts which had been heated at 400°C for 24 hr and

(ii) samples of the material at the NaI/ $UI_3$  interface of two of the cells which had been operated for three months. None of the samples showed any compound formation between NaI and  $UI_3$ .

The ideal stoichiometric alkali halides are ionic conductors but do exhibit some electronic conduction if they contain excess alkali metal or halogen (4). The ionic conduction is predominantly via the cations until temperatures approaching their melting points are attained. No literature data were available on the electronic conductivity of NaI as a function of chemical potential, but conservative estimates based on the behavior of other alkali halides indicated that it should be completely negligible in this system. NaI has an ionic conductivity of  $10^{-8}$  to  $10^{-6}$  ohm<sup>-1</sup>cm<sup>-1</sup> in the temperature range of our experiments (7). The AgI is also an ionic conductor, conducting via the silver ions, with a very high conductivity of 1.7 to 2.2 ohms<sup>-1</sup>cm<sup>-1</sup> in this temperature range (8, 9).

The uranium and  $UI_3$  were intimately mixed to hasten the equilibration of any subhalide formation and thus eliminate any mixed potentials that might conceivably occur. Corbett *et al.* (10) have studied the U,  $UI_3$  system and found a solubility of 5.7% U in  $UI_3$  in the liquid state. The solubility of U in solid  $UI_3$  is undoubtedly much lower than this, as is true in the alkali halides and alkaline earth halides. Therefore, no appreciable stoichiometry change in the  $UI_3$  is anticipated, and the system is thermodynamically well defined. X-ray diffraction spectra of U- $UI_3$  pellets from two cells which had been operated for three months showed only uranium and  $UI_3$  patterns, indicating that no appreciable subhalide formation occurred in the cells.

## Experimental

$UI_3$  was prepared by a method similar to that described by Gregory (11). Uranium turnings which had been deoxidized by washing in dilute nitric acid were heated under vacuum in a quartz tube at 550°C. Iodine from a reservoir at room temperature ( $\approx 23^\circ\text{C}$ ) was pumped across the hot uranium, and  $UI_3$  was condensed immediately downstream where the temperature was maintained at 400°C by a second furnace. Approximately 48 hr of heating was required to prepare 30g of  $UI_3$ . The quartz tube was then sealed off under vacuum at both ends and transferred to a dry box for subsequent removal of the  $UI_3$ .

There was generally a slight amount of  $UI_4$  and some  $UO_2$  from reaction with the quartz, present in the  $UI_3$ . The crude product was purified by heating it under vacuum to 600°C in a linear temperature gradient Marshall furnace. This decomposed the  $UI_4$  to

<sup>1</sup> Present address: Atomic Energy Establishment, Trombay, Bombay, India.

UI<sub>3</sub> and distilled the UI<sub>3</sub> away from the UO<sub>2</sub>. The final product analyzed as UI<sub>3.0</sub>.

All operations involving the handling of UI<sub>3</sub> were performed under an argon atmosphere in a dry box because of the high reactivity of UI<sub>3</sub> with moisture. Uranium filings and powdered UI<sub>3</sub> were intimately mixed in U/UI<sub>3</sub> mole ratios of 5:1 for the earlier cells and 15:1 for the last three cells. The mixture was pelleted in a hand-operated hydraulic press inside the dry box. Powdered AgI (Fisher Scientific Company) was pelleted in the same manner. Single crystal NaI (Harshaw Chemical Company) was used.

The cell design is shown in Fig. 1. A platinum wafer with a platinum wire welded to one side of it was wrapped first with platinum foil and then with silver foil. The AgI pellet, NaI crystal and U, UI<sub>3</sub> pellet were stacked consecutively above the Ag foil. A tantalum wafer was placed between the U, UI<sub>3</sub> pellet and the upper platinum electrode to prevent possible alloying of the uranium and platinum. The entire assembly was held tightly together by a spring loaded quartz retainer.

A Pt/Pt-10% Rh thermocouple was located several millimeters from the center of the cell constituents, and its leads were sealed through the top of the cell container with Apiezon W wax. The platinum lead-in wires were brought to the top of the container and clasped with spring clips attached to tungsten wires which were sealed through the Pyrex top. The top of the cell container was sealed to the Pyrex body with Apiezon W wax.

The cell assembly was evacuated to  $<10^{-5}$  Torr at 200°C to thoroughly degas it, argon was introduced to a pressure of 500 Torr and the cell temperature adjusted to 370°C. The readings of the emf and temperature were made with a L&N K-3 potentiometer.

The argon used in the dry box was dried by passing it through a bed of Linde 5A molecular sieve. The argon which was introduced into the cell during a run was purified by passing it first through a furnace containing calcium chips at 600°C, then through a bed of Ascarite and finally through a bed of Linde 5A molecular sieve.

### Results and Discussion

The emf of the cell was followed as a function of time at constant temperature until a constant value

Fig. 1. Solid electrolytic cell

was maintained for two or three days. This emf was then considered to be the equilibrium value at that temperature. In general, when a cell was started, the emf would rise to within 0.05v of its equilibrium value during the first 24 hr and then require an average of three weeks to attain the final emf. Subsequent measurements at different cell temperatures required only one or two days to reach equilibrium. Measurements were continued on a cell until its emf rapidly decreased over a period of a few days. The operating time of individual cells varied widely, ranging from several weeks to four or five months.

The long equilibration time of the cell was not surprising since all the components were solids well below their melting points. Thus diffusion coefficients were orders of magnitude lower than in cells involving liquids. The U and UI<sub>3</sub> powders were intimately mixed to speed up the equilibration, but the diffusion was still quite slow. The cell emf deteriorated when the Ag<sup>+</sup> had diffused through the NaI and reached the UI<sub>3</sub>. This process required a longer time than the U-UI<sub>3</sub> equilibration because its path length was much longer. Meaningful emf data were obtained after the equilibration of U-UI<sub>3</sub> and before the Ag<sup>+</sup> diffused to the UI<sub>3</sub>.

The standard free energy of formation values for UI<sub>3</sub> obtained from six cells over the temperature range of 220°-370°C are plotted in Fig. 2. The average value of  $\Delta F_f^\circ$  at 370°C was -98.8 kcal/mole.

MacWood (12) obtained the standard heats of formation of the uranium halides from calorimetric measurements of several reactions in 12N HCl solvents containing either 10% FeCl<sub>3</sub> or saturated I<sub>2</sub>. He then estimated heat capacities and obtained the standard free energies as a function of temperature. Brewer, Bromley, Gilles, and Lofgren (13) used MacWood's heat of formation for UI<sub>3</sub> and slightly different heat capacity estimates to obtain the standard free energy as a function of temperature. The estimates of the free energy given by Brewer *et al.* and MacWood are also shown in Fig. 2 as a function of temperature.

Egan *et al.* (14) measured the standard free energy of formation of UCl<sub>3</sub> by a solid electrolyte galvanic cell technique over the temperature range of 400°-600°C and found it to be 10 kcal/mole more positive than those listed by Brewer *et al.* They obtained the same entropy change; therefore, it would seem that the major discrepancy lies in the heat of formation of UCl<sub>3</sub>. MacWood's calculation of the heat of formation

Fig. 2. Standard free energy of formation of UI<sub>3</sub> as a function of temperature.

of  $UI_3$  included his value for the heat of formation of  $UCl_3$ . Thus it would be expected, as a first approximation, that the heat of formation of  $UI_3$  would also be 10 kcal more positive than MacWood's value. Our results indicate a value  $\approx 6.7$  kcal/mole more positive.

The accuracy of our results for the  $\Delta F^\circ_f$  of  $UI_3$  involves not only the accuracy of the measured cell emf but also that of the literature value of  $\Delta F^\circ_f$  of  $AgI$  employed in the calculations. The recent compilation by Hamer, Malmberg, and Rubin (3) contains the best available thermochemically determined values in the form of the emf of the theoretical formation cell  $Ag/AgI/I_2(g)$  over the temperature range 25°-1500°C. There are, in addition, three papers (15-17) in the literature where the emf on the cell  $Ag/AgI/I_2(g),C$  has been determined experimentally. Reinhold measured the emf over the temperature range of 145°-350°C, obtained values  $\approx 100$  mv higher than those of Hamer *et al.*, and found a positive rather than negative temperature coefficient. Czepinski determined the emf over the temperature range 320°-740°C and obtained values  $\approx 35$  mv lower than those listed by Hamer *et al.*, but with approximately the same temperature coefficient. Sternberg *et al.* measured the emf over the temperature range 580°-650°C and obtained values 15 mv lower than those of Hamer *et al.* and also with approximately the same temperature coefficient.

This discrepancy between the thermochemically and electrochemically determined values prompted us to also make some emf measurements on the cell  $Ag/AgI/I_2(g),C$ . Our preliminary data agree within 5 mv with the values given by Hamer *et al.* over the temperature range 200°-400°C but with a slightly different temperature coefficient. This  $Ag/AgI/I_2(g),C$  cell will be further studied and fully reported at a later date, but the preliminary data convinced us to employ the values given by Hamer *et al.* in arriving at the  $\Delta F^\circ_f$  of  $UI_3$  reported herein.

The final emf values of the cells were constant to  $\pm 1$  mv, corresponding to  $\pm 0.07$  kcal/mole. The  $AgI$  data appear to be accurate to within  $\pm 5$  mv or  $\pm 0.35$  kcal/3 moles. Therefore, individual values from a given cell should be accurate to  $\pm 0.36$  kcal/mole. Calculation of the standard deviation of the mean value of the data at 370°C gives  $\pm 0.33$  kcal/mole. Thus, the  $\Delta F^\circ_f$  of  $UI_3$  at 370°C is  $-98.8 \pm 0.4$  kcal/mole.

#### Acknowledgments

The authors are deeply indebted to Dr. J. J. Egan and Dr. J. D. Van Norman for many helpful and stimu-

lating discussions. The aid of Dr. J. T. Clarke in arriving at the final cell design and his constant encouragement throughout the program is greatly appreciated. They are also extremely grateful for the valuable services of Mr. R. Watson, who carried out much of the experimental work. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript submitted May 6, 1968; revised manuscript received June 19, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Behavior of Tin Oxide Semiconducting Electrodes Under Conditions of Linear Potential Scan

H. A. Laitinen,\* C. A. Vincent,<sup>1</sup> and T. M. Bednarski<sup>2</sup>

University of Illinois, Urbana, Illinois

## ABSTRACT

Linear sweep voltammetric studies of thin layer semiconducting tin oxide layers on glass substrates revealed three regions of electrochemical interest. In the anodic region, oxygen or chlorine evolution occurs without disruption of the surface. In the intermediate region of potentials, cathodic-anodic processes attributable to charging and discharging of positive surface states occur. The charging-discharging process is most pronounced in the presence of high concentrations of hydrogen ions and chloride ions and is closely related to the specific adsorption of chloride ion. In the cathodic region, hydrogen ion discharge is accompanied by a disruption of the tin oxide layer, which is reduced to metallic tin.

This investigation describes the charging and discharging of the double layer on the semiconductor side of the semiconductor-solution interface under conditions of linear potential scan. Also included is a brief study of the cathodic decomposition of the tin oxide electrode to metallic tin.

While pure polycrystalline tin oxide is an insulator, the addition of certain electron donating species can render the material into a broad-band n-type semiconductor. These doped or unstoichiometric tin oxides with free carrier densities of approximately  $10^{19}$   $\text{cm}^{-3}$  are ideally suited for use as indicator electrodes in electrochemical investigations.

Thin semiconducting tin oxide films on glass or quartz substrates have been used as indicator electrodes for potentiometry (1), coulometry, and amperometry (2, 3). Kuwana and co-workers (4, 5) have taken advantage of the transparent nature of the tin oxide film electrodes in the visible region of the spectrum to directly observe electroactive species at the electrode-solution interface using internal reflection spectroscopy.

The literature also contains several papers describing the electrical and optical properties of stannic oxide-based semiconductors (6-13). The physical properties of this material have been described in detail, and several mechanisms of electron conduction have been proposed.

## Experimental

Glasses coated with semiconducting tin oxide were used as indicating electrodes for all the electrochemical studies included in this investigation. These antimony or fluoride doped tin oxides were manufactured by Corning Glass Company and obtained through F. J. Gray Company. The thickness of the tin oxide coating was determined by measuring the maxima and minima of interference fringes in visible light. Knowing the refractive index,  $\mu$ , of the tin oxide coating and the difference between successive maxima measured in wave numbers, the thickness can be obtained from the following equation according to Tolansky (14)

$$t = \frac{1}{2\mu \Delta\nu} \quad [1]$$

where  $t$  is the thickness in Angstroms and  $\Delta\nu$  the difference between successive maxima. The refractive index was taken as two (9), and the thickness of the tin oxide film was found to be between 6,000 and 10,000 Å depending on the sample. The specific resistivity calculated from a-c and d-c bridge mea-

surements was approximately  $6 \times 10^{-4}$  ohm cm. X-ray diffraction patterns indicated the material to be microcrystalline with a mean particle size of  $\sim 10$  m $\mu$  in diameter. Electron microscopic investigations indicated a homogeneous and compact surface free of any repeatable surface structure or grain boundaries.

To insure a clean and reproducible electrode surface, either of two pretreatment procedures was employed. The  $\text{SnO}_2$  coated glasses were either steam cleaned for 1 hr followed by drying at  $110^\circ\text{C}$  or washed with absolute ethanol followed by thorough washing in distilled water. When an electrode was subjected to either procedure, reproducible electrochemical characteristics were observed. If the electrode surface was subjected to either oxidizing or reducing media in the pretreatment procedure irreproducible electrochemical characteristics were noted. Although pre-electrolysis was used in some of the preliminary work, it was found later that preparation of solutions using doubly distilled water gave equally reproducible results.

Contact to the  $\text{SnO}_2$  surface was made by a specially designed silver ring. It is important that the metal-semiconductor contact be especially good, so that the contact impedance on the metal-semiconductor interface be negligible. Using the pressure contact shown in Fig. 1, the measured series capacitive reactance at a frequency of 1 kHz was  $\leq 10^{-4}$  ohm, and the resistive series component was negligible.

The cell consisted of cone-shaped Pyrex glass vessel with an optically flat surface at the narrow end. The  $\text{SnO}_2$  coated glass was then mounted *via* a Teflon

Fig. 1. Electrolysis cell assembly

<sup>2</sup> Present address: Hercules, Inc., Wilmington, Delaware.

washer to the optically flat surface and tightly assembled to insure a leakproof seal. The electrode area was taken to be the same as the geometric area of the washer opening. This was also verified by electrochemically decomposing the  $\text{SnO}_2$  surface in contact with the solution and measuring the area of the decomposed surface analytically. Areas computed in the above manners were found to correspond within experimental error. The cell was then mounted in a brass cylinder attached to a Teflon block which served as a cell top. The entire assembly was then placed in a lighttight brass container which could be thermostatted if desired.

A saturated calomel electrode (SCE) was used as the reference electrode. This was connected to the electrolysis cell by means of a salt bridge containing the cell solution. The counter electrode consisted of either a large area platinum foil electrode or a platinum mesh electrode.

Prepurified nitrogen which had also passed through a vanadous scrubbing train and a presaturator containing the cell solution was used to obtain oxygen-free solutions. A nitrogen atmosphere was also maintained above the solution while electrochemical measurements were being taken.

All voltammetric studies were carried out using conventional operational amplifier circuitry with Philbrick vacuum tube units. A Beckman pH meter with appropriate electrodes was used to measure the hydrogen ion activity.

### Results

The electrochemical behavior of tin oxide semiconducting electrodes in aqueous HCl solution under conditions of linear potential scan is shown in Fig. 2. The current-potential dependence can be conveniently divided into three separate regions; namely, the anodic decomposition region, the charging region, and the cathodic decomposition region. For reasons of clarity and ease in presentation each region will be discussed separately.

The anodic potential limit is attributed to either oxygen or chlorine evolution depending on the supporting electrolyte. In chlorine free solutions the anodic decomposition potential was pH dependent, increasing approximately 31 mv per pH unit in the anodic direction for  $1 < \text{pH} < 13$ .

The charging region was characterized by well-formed peaks having reproducible peak currents and potentials at slow scan rates. Qualitatively, the peak definition was enhanced by increasing the hydrogen ion activity, increasing the concentration of chloride ion, and by slowing the scanning rate (but not below 0.05 v/min). A more detailed reproduction of the peaks obtained in 2M HCl is shown in Fig. 3. The peaks are symmetrical in shape, indicative of an exhaustive surface electrolysis or charging process

Fig. 2. Current-voltage behavior in 2M HCl. Scan rate was 0.2 v/min; electrode area is 0.135  $\text{cm}^2$ .

Fig. 3. Current-voltage curve in 2M HCl. Rate of scan was 0.05 v/min.

rather than the oxidation or reduction of a soluble species diffusing to or from the electrode surface.

In Table I are listed the peak currents and potentials obtained in 0.1 and 2.0M HCl. Only after the tin oxide electrode remained in contact with the solution for periods of time  $> 6$  hr were reproducible values of peak currents and potentials obtained. The quantity ( $E_{pa} - E_{pc}$ ) increased with increasing scan rate indicating a slow electrochemical process. Even at a scan rate of 0.05 v/min the anodic and cathodic peak potentials are not quite coincident in 2M HCl and even more removed in 0.1M HCl. The peak currents in the more concentrated HCl solution were approximately 7X those observed in the more dilute acid. Analysis showed that the peak currents were not proportional to either the square root of scan rate or directly to the scan rate. The peak currents obtained in 2M HCl after the electrode remained in contact with the solution for prolonged periods of time were the same as in 12M HCl. This is indicative of a saturation-type phenomenon occurring at the tin oxide electrode. Also included in Table I are the number of coulombs consumed in the electrolysis. These quantities were measured by analytically determining the area under the current-potential peak with a planimeter and converting the potential axis to a time basis. The peak areas were independent of scan rate, although at the faster scan rates the peaks were not well defined and the measurements were correspondingly less accurate. The number of coulombs consumed in the process were approximately 5X greater in the 2M acid than in the 0.1M acid.

Fig. 4. Current-voltage curve in  $2M$   $HClO_4$ . Scan rate  $0.05$  v/min.

To differentiate the effect of hydrogen ion and chloride ion a number of experiments were carried out in  $2M$   $HClO_4$ . A typical current-potential curve obtained in this medium is shown in Fig. 4. The peaks are poorly developed in comparison to  $2M$   $HCl$ , and the separation of the anodic and cathodic peak potentials is greater.

Evidence for the specific adsorption of chloride ion on the tin oxide electrode was obtained from the following sequence of experiments. After normal linear scan voltammograms were obtained in  $2M$   $HCl$  the hydrochloric acid solution was removed, and the intact cell assembly was thoroughly washed with distilled water. Two molar perchloric acid was then added to the cell and the electrochemical behavior described in Fig. 5 was observed. Initially, peaks similar to those obtained in  $2M$   $HCl$  were observed. After various periods of standing, the peaks became broader and the peak potentials diverged. Curves 2, 3, and 4 in Fig. 5 were obtained after 2.5, 4.6, and 9.5 hr of standing, respectively. The peaks finally became very broad, and the peak separation in curve 4 became  $0.76$  v.

In another series of experiments after normal voltammograms were obtained in  $2M$   $HCl$ , the cell was thoroughly washed and a  $2M$   $HClO_4$  solution added. The electrode was then maintained at a potential anodic to the chlorine evolution potential for 2 min with a stream of nitrogen flowing through the cell. Linear sweep voltammograms then obtained were similar to curve 4 in Fig. 5, indicating that a short anodization completely removes the adsorbed chloride. To obtain a rough estimate as to the amount of specifically adsorbed chloride ions at the tin oxide

Fig. 5. Variation of current-voltage behavior with time in  $2M$   $HClO_4$  of an electrode which had been soaked in  $2M$   $HCl$ . Curve 1, 0.5 hr; curve 2, 2.5 hr; curve 3, 4.6 hr; curve 4, 9.5 hr.

electrode the following experiment was performed. After normal current-voltage curves were obtained in  $2M$   $HCl$ , the cell was thoroughly washed and an acetic acid-sodium acetate buffer of pH 4.03 was added. The potential applied to the indicator electrode was then scanned in an anodic direction, and a small hump due to the oxidation of chloride ions was observed. From the area under the current-voltage curve the number of coulombs in the oxidation could be determined. This corresponded to approximately the same number of coulombs as represented by the peak areas in  $2M$  hydrochloric acid. Because of the difficulty in determining the exact area of the chloride oxidation hump superimposed on the solvent decomposition current, quantitative evaluation was not possible.

Current-voltage curves obtained in solutions of higher pH in the absence of chloride ions were poorly defined and the peaks much smaller in magnitude and area. The peak definition was improved by adding varying amounts of  $LiCl$ , to a given buffer system; however, the quality of the peaks never approached those obtained in solutions when both hydrogen and chloride ions were present in concentrations  $> 1M$ .

The cathodic decomposition region is characterized by either the reduction of hydrogen ions from the solution or the solid-state reduction of the tin oxide layer to metallic tin or both concomitantly.

If a tin oxide semiconducting electrode is maintained at a constant potential of  $-0.75$  v vs. SCE in  $1M$   $HCl$ , the thin tin oxide layer is completely reduced to metallic tin. Metallic tin was positively identified by placing the reduced material in contact with mercury for a few days and then employing the resulting amalgam as the anode of an electrolysis cell. Stripping peak potentials obtained in this manner were then compared with those obtained from a tin amalgam of known composition and were found to agree within 5 mv. Qualitative observations of a partially decomposed tin oxide electrode with a binocular microscope at 50X magnification indicated the presence of square shaped crystals which could be indicative of  $\alpha$  gray tin which crystallizes in the cubic system (15).

In slow linear voltage sweep experiments with a cathodic limit of  $-0.7$  v, the return anodic sweep produces both sharp and broad anodic peaks, as shown in Fig. 6. The peak potential at approximately  $-0.5$  v vs. SCE varied linearly with pH at a rate of 58 mv per pH unit. The difference between the peak and half-peak potentials was 28 mv. The rather broad anodic peak with a peak potential of approximately  $0.5$  v vs. SCE in  $0.1M$   $HCl$  exhibited little measurable change with pH. A similarly shaped peak with a peak potential of  $+0.5$  v vs. SCE was obtained when

Fig. 6. Current-voltage curves in  $0.1M$   $HCl$  showing the behavior after the tin oxide electrode was subjected to an extreme cathodic potential. Scan rate is  $1.0$  v/min; electrode area is  $0.135$   $cm^2$ .

$\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$  was added to a 0.1M HCl solution. This peak is attributed to the oxidation of a soluble Sn (II) species to Sn (IV). The cathodic decomposition potential of both Sn (II) and Sn (IV) in 0.1M HCl occurred at approximately  $-0.45\text{v}$  which is approximately 0.35v more anodic than the solid  $\text{SnO}_2$  reduction. The sharp peak at  $-0.54\text{v}$  vs. SCE is attributed to the oxidation of metallic tin from an inert  $\text{SnO}_2$  electrode to a Sn (II) species in solution. When the direction of scan is immediately reversed after the anodic peak had been transversed a cathodic reduction peak was obtained with  $E_p = -0.575\text{v}$  vs. SCE and the quantity  $(E_p - E_{p2}) = 0.025\text{v}$ . A similar peak with the identical peak potential was obtained when  $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$  is added to solution.

Recent investigations by Kirkov (16) have indicated that when the electrode is maintained at potentials considerably anodic to those described above for relatively long periods of time in acid solutions (ca.  $-0.3\text{v}$  for 24 hr in 0.1N HCl) metallic tin is also produced. He attributes this to the formation of chemisorbed hydrogen atoms from the reduction of hydrogen ions in solution, which then slowly reduces the tin oxide layer. Thus, it appears that both processes can be occurring simultaneously at the cathodic decomposition potential. Whether metallic tin is produced by direct electrochemical reduction of the tin oxide at more negative potentials, or whether the process always proceeds through chemisorbed hydrogen atoms cannot be determined from the present experiments.

### Discussion

The symmetrical current-voltage peaks obtained under conditions of linear potential scan are attributed to the reduction and subsequent oxidation of surface tin species. Similar anodic-cathodic curves have been observed by Rouse and Weininger (17) for lithium-doped nickel oxide single crystals.

A situation of this type in which both the oxidized and reduced species are immobile would be analogous to the exhaustive electrolysis of thin layers of solutions. Recently, Hubbard and Anson (18) have derived the current-voltage expressions expected for the electrolysis of thin layers using linear sweep voltammetry, assuming that the concentrations of the soluble electroactive species could be described by the Nernst equation. It is expected that similar expressions would apply for the solid-state electrolysis of immobile species under linear potential scan.

Assuming the concentrations of the immobile species can be expressed by a Nernst-type relationship, and the reduction is independent of the diffusion of electrons through the space charge region, the cathodic current can be described by the following equation

$$i = n^2 A v C_{\text{ox}}^0 \frac{F^2}{RT} \frac{\exp \frac{nF}{RT} (E^0 - E)}{[\exp nF/RT (E^0 - E) + 1]^2} \quad [2]$$

where  $n$  is the number of electrons transferred,  $A$  the electrode area in  $\text{cm}^2$ ,  $v$  the rate of scan in volts/sec,  $C_{\text{ox}}^0$  the initial concentration in moles/ $\text{cm}^2$ ,  $E^0$  the formal potential of the immobile species, and the remaining symbols having their usual significance.

A graphical representation of  $i = f(E)$  would be bell-shaped and symmetrical about the peak potential  $E^0$ . The peak current,  $i_p$ , at  $E = E^0$  would be given by the following expression

$$i_p = \frac{n^2 C_{\text{ox}}^0 A v F^2}{4 RT} \quad [3]$$

Equation [3] can also be written in terms of the number of coulombs consumed in the Faradaic process to give Eq. [4].

$$i_p = \frac{n^2 v Q F}{4 RT} \quad [4]$$

where  $Q$  is the number of coulombs determined by graphical integration of the current-voltage curve.

To test the applicability of Eq. [4], the ratio  $i_p/n^2$  was determined for the current-voltage curve shown in Fig. 3. Obtaining  $Q$  by graphical integration of the current-voltage curve and knowing the rate of scan and the experimentally measured  $i_p$ , the calculated number of electrons transferred is 1.05. This is indicative of a Faradaic process involving one electron.

If the Faradaic process indeed corresponds to the reversible transfer of one electron, a cathodic current-voltage curve should correspond to the following equation

$$E = E^0 - \frac{0.059}{n} \log \frac{Q_E}{Q_{\text{total}}} \quad [5]$$

where  $Q_E$  is the number of coulombs consumed up to a potential  $E$  and  $Q_{\text{total}}$  the total number of coulombs under the cathodic current-voltage curve. Plotting  $E$  vs.  $\log Q_E/Q_{\text{total}}$  for the current-voltage curve shown in Fig. 3 a straight line was obtained with a slope of 0.061v. This is consistent with the postulation of a reversible one-electron surface reaction.

It is apparent from Eq. [2] that, under conditions of cyclic potential scan, the peak potentials of both waves should be identical if the reaction is free from kinetic complications. As is shown in Table I at the slowest scan rate, 0.05 v/min, the experimentally determined anodic and cathodic peak potentials are not identical but differ by 37 mv. This separation becomes more pronounced as the scan rate increases and the  $n$ -values calculated from the ratio  $i_p/n^2$  decrease to less than unity. The reason for this apparent irreversibility does not appear to be caused by the diffusion of electrons through the space charge region. With a specific resistivity of approximately  $6 \times 10^{-4}$  ohm cm, the number of carriers/ $\text{cm}^3$  in a tin oxide semiconductor is only one or two orders of magnitude less than of a metal and equivalent to that present in a strong electrolyte of one-tenth molar concentration. Instead, the observed behavior appears to be dependent on the rate of the surface recombination.

If the observed behavior is due to the oxidation or reduction of surface tin species, the number of coulombs under the current-voltage peak should be a reflection of the number of tin atoms at the electrode-solution interface. Assuming that one electron is transferred to each tin atom the number of available sites  $2M$  HCl calculated from the data reported in Table I is  $5.5 \times 10^{15}$  sites/ $\text{cm}^2$ . If one takes a mean surface layer of approximately  $3\text{\AA}$  and a roughness factor of unity, the number of tin atoms available at the electrode-solution interface is approximately  $1 \times 10^{15}$ . This value is five times smaller than that found experimentally so either a roughness factor of one is unrealistic or more than a monolayer of tin atoms is involved, or both.

As shown in the results section, the presence of chloride ion is necessary for the attainment of well-defined peaks. Evidence for the specific adsorption and desorption of chloride was presented and the number of coulombs consumed in the Faradaic process attributable to the peak behavior was found to be approximately equivalent to one electron per adsorbed chloride ion.

Based on this evidence, it is suggested that the observed peak behavior is due to the charging and discharging of positive surface states, i.e., tin atoms, caused by a dipole type interaction with the adsorbed chloride ions. Because of this induced positive charge, surface tin atoms now become traps or holes and can accept electrons from the bulk of the semiconductor but still retain a stable rutile configuration. This would be chemically equivalent to a change in the oxidation states of the surface tin atoms, and a Nernst-type relationship would apply. The number of surface states would be a function of the bulk chloride

ion concentration and would expect to increase in the manner reported in Table I.

The appearance of peaks in chloride free solutions can also be attributed to the charging and discharging of surface states. In this instance, positive surface states result from the protonation of surface oxide ions and in this sense become part of the semiconductor material in contrast to the chloride ion behavior. As shown in Fig. 4, the oxidation and reduction of the surface tin atoms containing protonated oxide ions does not proceed as reversibly as those formed by the dipole interaction.

The cathodic decomposition region is attributed to the reduction of the  $\text{SnO}_2$  matrix to metallic tin proceeding from the solid-solution interface into the bulk of the semiconductor. No separate peaks were obtained for the stepwise reduction of  $\text{SnO}_2$  through a Sn (II) intermediate using linear potential scan. However, when  $\text{SnCl}_2$  was present in solution, a definite peak with  $E_p = -0.575\text{v vs. SCE}$  was obtained.

On subsequent oxidation of the reduced  $\text{SnO}_2$  matrix, two peaks are obtained. The peak observed at  $-0.5\text{v vs. SCE}$  is attributed to the oxidation of tin metal to divalent tin. Since the peak potential shifts 58 mv per pH unit, the product of the electrode reaction must contain the equivalent of two hydrogen ions per tin atom. The exact composition of the divalent tin species was not determined. The broad anodic peak shown in Fig. 6 with a peak potential of  $+0.5\text{v vs. SCE}$  is attributed to the irreversible oxidation of a soluble divalent tin species to a soluble quadrivalent tin species. A similar peak with the corresponding peak potential was obtained when  $\text{SnCl}_2$  was added to the solution.

The specific adsorption of chloride and hydrogen ions play a decisive role in determining the steady state potential on open circuit. The open-circuit behavior will be described in a forthcoming publication.

## Cyclic Chronopotentiometry. Systems Involving Kinetic Complications

Harvey B. Herman\*

and Allen J. Bard\*

Department of Chemistry, The University of Texas, Austin, Texas

### ABSTRACT

The extension of cyclic chronopotentiometry to systems involving kinetic complications, including preceding, following, and catalytic reactions and combinations of these is described and tables are given which can be employed in a determination of the rate constants of these reactions. A general digital computer program is presented which allows calculation for any reaction scheme which conforms to the treatment of Ashley and Reilley. Experimental results for the electroreduction of p-nitrosophenol, an ECE-reaction, and the reduction of titanium (IV) in the presence of hydroxylamine, a catalytic reaction, are presented.

The technique of cyclic chronopotentiometry (CC) in which the applied current is successively reversed at each transition and the relative transition times determined, has been applied to simple diffusion controlled reactions (1), multicomponent systems (2), and electrode reactions with following chemical reactions (3). We recently discussed the application of CC to the study of electrode reaction mechanisms (4) and suggested qualitative guides for using CC as a diagnostic

aid. We present here a discussion of the methods for solving for the transition time ratios in CC for a number of different reaction schemes involving preceding, following, and intervening chemical reactions and give tables which can be employed in a determination of the rate constants of these reactions. A digital computer program is also described which can be used to determine the relative transition times for any reaction scheme amenable to the treatment of Ashley and Reilley (5).

\* Electrochemical Society Active Member.

## Theoretical Treatment

One approach which can be employed to compute tables of relative transition times for the different cases involves treatment of each possible reaction scheme separately. Concurrent chemical reactions require additional terms added to Fick's diffusion law. Thus, for the process

the following partial differential equations hold

$$\frac{\partial C_1}{\partial t} = D \frac{\partial^2 C_1}{\partial x^2} - k_{12}C_1 + k_{21}C_2 \quad [2]$$

$$\frac{\partial C_2}{\partial t} = D \frac{\partial^2 C_2}{\partial x^2} + k_{12}C_1 - k_{21}C_2 + k_{32}C_3 \quad [3]$$

$$\frac{\partial C_3}{\partial t} = D \frac{\partial^2 C_3}{\partial x^2} - k_{32}C_3 \quad [4]$$

assuming all diffusion coefficients are equal.  $C_n$  is the concentration of the  $A_n$  species and the other symbols have their usual meanings. The above system of partial differential equations can be solved by making suitable substitutions, namely  $\theta = C_1 + C_2 + C_3$ , which gives

$$\frac{\partial \theta}{\partial t} = D \frac{\partial^2 \theta}{\partial x^2} \quad [5]$$

$\gamma = C_3$  which gives

$$\frac{\partial \gamma}{\partial t} = D \frac{\partial^2 \gamma}{\partial x^2} - k\gamma \quad [6]$$

and  $\delta = C_3 + AC_2 + BC_1$ , which gives for proper choice of  $A$  and  $B$

$$\frac{\partial \delta}{\partial t} = D \frac{\partial^2 \delta}{\partial x^2} - k\delta \quad [7]$$

Further details concerning the solution of these equations are given by Hung, Delmastro, and Smith (6). Their results for the convolution integral will be used here. For example their solution for the concentrations of  $A_2$  and  $A_3$  for the above case (their equations 78, 79, 109-114 and  $k_{CY} = 0$ ) is the following

$$C_2 = C_2^0 - [nFA(D\pi)^{1/2}]^{-1}$$

$$\left[ L_1 \int_0^t e^{-k_{32}\lambda} i(t-\lambda) \lambda^{-1/2} d\lambda - L_2 \int_0^t e^{-(k_{12}+k_{21})\lambda} i(t-\lambda) \lambda^{-1/2} d\lambda \right] \quad [8]$$

$$C_3 = [nFA(D\pi)^{1/2}]^{-1} \int_0^t e^{-k_{32}\lambda} i(t-\lambda) \lambda^{-1/2} d\lambda \quad [9]$$

where

$$L_1 = \frac{k_{12} - k_{32}}{k_{12} + k_{21} - k_{32}} \text{ and } L_2 = \frac{k_{21}}{k_{12} + k_{21} - k_{32}}$$

Substitution of constant current boundary conditions and proper use of the step function theorem allows solution for the CC transition time ratios. The procedure is quite similar to the method used in earlier papers in this series where the computer programs were published (1-3).

In this case the computer program would generate the following equation for the third transition time

$$f(x) = k_{21}(k_{12} + k_{21})^{-1/2} [erf(\{(k_{12} + k_{21})x\}^{1/2})] + (k_{12} - k_{32})(k_{32})^{-1/2} [erf(\{k_{32}x\}^{1/2})] \quad [10]$$

and

$$f(\tau_1) = f(\tau_1 + \tau_2 + \tau_3) - Rf(\tau_2 + \tau_3) + Rf(\tau_3) \quad [11]$$

where  $\tau_1$  is one,  $erf(x) = 2\pi^{-1/2} \int_0^x e^{-\tau^2} d\tau$ ,  $R = (i_{Red} + i_{ox})/i_{Red}$  and  $\tau_2$  is calculated in the previous step from an equation representing  $A_2$ . The above nonlinear equation is solved using a standard numerical technique, e.g., the Newton-Raphsen method. Successive approximations are generated from evaluations of the function and its derivative. Occasionally this method does not converge and it is necessary to use our previous "brute force" method (1) which is quite a bit slower. While this approach works well and extensive tables of transition time ratios can be prepared in a comparatively short time using a digital computer, certain statements in the program have to be drastically modified each time a different mechanism is considered. Most of the theoretical calculations reported here were done using the above method and the convolution integrals reported by Hung, Delmastro, and Smith (6).

Recently Ashley and Reilly (5) showed how electrochemical systems coupled only by first order chemical reactions could be treated in a general way and general equations formulated. They considered subsystems of the form

and obtained the following equation for the concentration of the species in the Laplace transform plane

$$\bar{C}_n = \bar{C}_n^0 - D^{-1/2} \sum_g \sum_h \bar{i}_g K_{fgh} (s + \chi_h)^{-1/2} \quad [13]$$

where  $K_{fgh}$  and  $\chi_h$  are constants, which are determined by the rate constants of the coupled reactions in [12]. This equation is derived using substitutions such as those described before and applying matrix algebraic methods. The values of  $K_{fgh}$  and  $\chi_h$  in terms of the rate constants are given in (5). Inverse transformation of [13] gives the desired convolution integral. This is particularly easy for chronopotentiometry, because the fluxes of the components are constant.

The computer program discussed before was modified to treat the more general case embodied by Eq. [13]. A FORTRAN subroutine was written which evaluated the constants  $K_{fgh}$  and  $\chi_h$  and FORTRAN function subprograms were used to evaluate the summation and its derivative. The Newton-Raphsen method could then be used to solve for the individual transition time ratios. As expected, both methods gave the same results for selected systems. However, the general method is by far the more convenient. It is just necessary to label the species in a subsystem, decide which are oxidized or reduced and what values should be picked for the rate constants and the program does the rest. The only programming changes which are necessary when different reaction schemes are considered involve only input and output. A listing of this program for the system in Eq. [12] is available to interested readers and can easily be adapted to other mechanisms.

## Theoretical Results

The characteristics of each mechanism are treated separately. The mechanisms that are discussed include reversible chemical reactions preceding, following, and in parallel (catalytic), with the electrode process proper, as well as mixtures of each. The convolution integrals have been tabulated by Smith and co-workers (6) and will not be repeated. The familiar ECE case and its extension is also discussed. For all of the cases described we assume an initial reduction, equal diffusion coefficients for all species, and equal current densities for reduction and oxidation.

Preceding chemical reaction.—

Relative transition times ( $a_n = \tau_n/\tau_1$ ) for this case for different values of  $k_{12}$  and  $k_{21}$  are given in Table I. Note that in this case the second relative transition time ( $a_2$ ) is not affected by the chemical reaction, but  $a_3$  becomes larger than in the diffusion controlled case. In most cases the odd relative transition time decreases as in the diffusion case, but if the rate of the reverse reaction ( $k_{21}\tau_1$ ) is large, increases may be observed. If both values of the rate constant are quite large the diffusion controlled situation is approached again. This is true of many of the reversible mechanisms. A preceding chemical reaction can be positively differentiated from a catalytic type mechanism in which  $\tau_3$  may be larger than diffusion by its diffusion controlled value of  $a_2$  (1/3). In some of the reversible cases a steady state value for the relative transition times may be attained which can be used to calculate the rate constants, although convection might interfere with this measurement.

Parallel (catalytic) reversible reaction.—

The case of CC involving an irreversible catalytic reaction has been treated previously (3); we extend the work here to include a reversible reaction (Table II). Since  $A_1$  and  $A_2$  are in equilibrium before the application of the constant current, it is possible for the

<sup>a</sup> No reverse transition is observed for  $k_{12} \tau_1 = 1.0$  and  $k_{21} \tau_1 = 0.5$ .

second transition time to be larger than the first. Any reaction involving a reversible catalytic system can be identified by the fact that an equilibrium amount of reduced form is present. Initial oxidations can confirm this presence. The second transition time may be lower than the diffusion controlled value but the third is higher than would be expected from an irreversible catalytic or kinetic mechanism calculated for the same rate constant. Interestingly we have found empirically that no second transition can be calculated for values of the rate constants when

$$(k_{12}/k_{21}) \operatorname{erf} \{ (k_{12} \tau_1)^{1/2} \} \geq 1$$

Following reversible reaction.—

This case, treated previously for an irreversible following reaction [3], is characterized (Table III) by a second relative transition time which is smaller than 0.333. The even relative transition times calculated assuming this mechanism do not decay as fast as those found for an irreversible following reaction. No initial concentration of  $A_2$  would normally be observed with this system.

ECE mechanism.—

This reaction sequence is fundamentally different from the general sequence of Eq. [12], and cannot be treated by modification of the general computer program for a three component subsystem. The ECE mechanism under consideration here is the one in which  $A_3$  is reduced at potentials considerably less cathodic than those required to reduce  $A_1$ , so that on current reversal where  $A_2$  is oxidized,  $A_3$  continues to reduce. The treatment involves evaluating the cur-

rent transforms of  $A_1$  and  $A_2$  by the method described in detail in a previous paper (7). The relative transition times are determined in the same manner as before, after inverse transformation of the concentration response (Table IV).

Several recent communications have discussed methods of treating the ECE mechanism [see ref. (7-10) and references contained therein]. An ECE reaction is indicated when another electrode couple appears at potentials less cathodic than those of the main reduction wave. The third transition time, although smaller than that observed in a diffusion controlled reaction, is not as small as that of an irreversible following reaction.

Hawley and Feldberg (8) recently pointed out that for the ECE mechanism treated above, the following additional reaction should be considered

A preliminary investigation of relative transition times taking account of this reaction shows only very small differences with transition times in Table IV, so that CC is probably not useful in gauging the importance of [18] in a proposed ECE mechanism.

*Mixtures of the above cases.*—A large number of possible reaction schemes can result from the simultaneous occurrence of preceding, parallel, and following reactions. Some typical cases are shown in Table V. In general these more complicated cases are suggested when relative transition time trends similar to the simpler cases are observed, but a good fit to these simpler cases cannot be obtained with a given set of rate constants. However, as more complicated schemes are invoked to explain a reaction, more and more adjustable parameters (rate constants) are included and a better fit to the experimental data is expected. CC has the advantage over cyclic voltammetry that the rate constants of the electron transfer reactions do not enter into the consideration, but CC is probably more sensitive to adsorption of reactants, products, and intermediates. Certainly elucidation of a reaction mechanism requires that other electrochemical techniques, such as polarography and coulometry, and analysis of reaction products and intermediates, also be undertaken.

### Experimental Results

*Electroreduction of p-nitrosophenol.*—The electroreduction of p-nitrosophenol has been studied by various workers (7, 10, 11) using a variety of techniques and has been shown to follow the general ECE reaction scheme. The following reactions are given for the reaction

A comparison of experimental results for the relative transition times in CC with calculated ones are

given in Table VI. We also considered the possibility of the following reaction occurring in the reaction sequence, after the suggestion of Hawley and Feldberg (8)

fast

If the rate of Eq. [22] is assumed fast, calculated results assuming the sequence Eq. [19], [20], [22] fit the experimental data just as well as with an assumed ECE mechanism. The rate constant for Eq. [20] by either mechanism is about the same. This finding is in agreement with that for chronoamperometry (8) where it was found that for small values of  $kt$  (or in CC, small values of  $k\tau_1$ ) both mechanisms give almost the same working curves. Note that it is relatively easy to differentiate the ECE mechanism from other common possibilities with the use of cyclic chronopotentiometry. The decrease in the second relative transition time could be explained by a simple catalytic or kinetic mechanism. The 3rd transition time (and subsequent ones) serves to differentiate among these mechanisms.

*Electroreduction of titanium (IV)—hydroxylamine system.*—The reaction of electrochemically generated titanium (III) with hydroxylamine has been studied by several groups (3, 12-14). In a previous study in this series (3) we used this reaction as an example of a simple catalytic reaction scheme, i.e.

Some discrepancy was found between the theoretical calculations and the experimental results for that system. The experiments were done under conditions where the pseudo first-order rate constant ( $kC_Y$ ) had to be low because of the limitations imposed by the use of mechanical relays for switching. Because the hydroxylamine concentration had to be kept small, the ratio of hydroxylamine to titanium (IV) was only about 25 to 1. This may not have been a sufficient excess of reactant to maintain true pseudo first-order conditions. The experiments were repeated here using the electronic switching apparatus previously described (15) and ratios of hydroxylamine to titanium (IV) of 200 to 1. The relative transition times found under these conditions are in much better agreement with the simple catalytic mechanism than those given before (Table VII). The rate constant calculated from this data is also in good agreement with that reported by Christie and Lauer (12) at the concentration ratio. Further studies on this system to determine the range of pseudo first-order conditions is presently under investigation by one of us (HBH). Since this system does not give very well-defined complete chronopotentiograms, cyclic chronopotentiometry would probably not be the method of choice in an experimental study. Poor forward transitions are usually found for catalytic systems so that a method such as current reversal chronopotentiometry, which does not require going through a first transition, would be more suitable.

### Conclusion

Cyclic chronopotentiometry does appear to have some real advantages for study of complicated reactions over other techniques. Since the general solution for coupled chemical reactions in a three component subsystem has appeared (3), the method presented here can be used to prepare tables of transition times ratios for the systems discussed and many other possible reaction schemes. No assumptions are required about the rates of electron transfer, which complicate considerations in other techniques, such as cyclic volt-

ammety. The data for CC can be interpreted without knowing the applied current, electrode area, diffusion coefficient, or concentration. It is sufficient to measure the relative transition time ratios and the first transition time in order to calculate the chemical rate constants, if the mechanism is known. If the mechanism is not known, CC can be used as a diagnostic tool to eliminate all but a few plausible reactions.

Cyclic chronopotentiometry does appear to have some real disadvantages. The effect of double layer charging and of adsorption of electroactive species has been ignored. Both tend to reduce the fraction of the current (ideally one) which goes to the faradaic reaction. Ordinary CC can be improved by the addition of derivative readout and some work along these lines has been reported (16).

Experimental

The operational amplifier apparatus previously described (15) was used for cyclic chronopotentiometry.

The p-nitrosophenol was purified according to the directions of Alberts and Shain (11). Fischer purified titanium tetrachloride was used as-received. The potential-time curves were recorded on a Tektronix 564 storage oscilloscope and photographed with a Tektronix C27 oscilloscope camera equipped with a Polaroid back.

Acknowledgment

The support of the Robert A. Welch Foundation is gratefully acknowledged. The authors are indebted to Henry N. Blount for assistance in the experimental measurements.

Manuscript received June 7, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## A D-C Pulsed Bridge for Differential Capacity Measurements

G. M. Schmid\*

Department of Chemistry, University of Florida, Gainesville, Florida

## ABSTRACT

A d-c pulsed bridge is described for the measurement of the differential capacity,  $C_d$ , and parallel resistance,  $R_p$ , of the electrical double layer and the electrolyte resistance,  $R_e$ . The bridge consists of a d-c pulse generator, a suitable electrochemical cell, a comparison arm made up of a (variable) capacitor and a resistance box in parallel, and a resistance box in series, and an oscilloscope as null detector. Conditions of imbalance are detected separately for  $C_d$ ,  $R_p$ , and  $R_e$ . Operating on 100  $\mu$ sec pulses of about 10 ma, repetition rate 10 pulses/sec, and using a dummy circuit instead of an electrochemical cell, capacities  $< 3 \mu$ F can be measured with a precision of  $< 1$  p.p.t. Determinations of  $R_p$  and  $R_e$  are much less precise. For a "real" cell, Au in 1M HClO<sub>4</sub>, in the region 0.0 to 1.4v vs. SCE, the bridge can be balanced for capacities  $< 3 \mu$ F to  $\pm 0.01 \mu$ F and gives results in substantial agreement with, but of higher precision than, those obtained with short single d-c pulses.

Measurements of the differential capacity of electrode/electrolyte systems are usually made on conventional alternating current (a-c) bridges at frequencies  $< 100$  kHz. At ideally, or nearly ideally, polarizable interfaces this method is precise (to 0.1% or better), accurate, and entirely satisfactory, as shown by the pioneering work of Grahame (1). However, in the presence of a charge transfer reaction, and/or a charge

transfer adsorption reaction, the capacities measured are very large, are dominated by the charge transfer kinetics, and do not represent the "true" ionic double layer differential capacity (2). Also, on solid electrodes a frequency dispersion is observed, probably caused by the roughness of the electrode surface (3, 4). To obtain the ionic double layer capacity, without faradaic and frequency dispersion interference, measurements with frequencies in the MHz range are necessary, such

\* Electrochemical Society Active Member.

as those made on a transformer bridge by Lorenz (5). The interfacial impedance is then very small, typically  $< 0.01$  ohm, and precise and accurate measurements are difficult to make.

Differential capacities can also be obtained with voltage step (6) or direct current (d-c) pulse techniques (7, 8). In these methods the voltage or the current across an electrode is, at time zero, suddenly and abruptly stepped to a new value. The resulting current-time, or voltage-time, curve is observed, the slope of the curve being indicative of the capacity. It is easy to show in a Fourier analysis that the time necessary for observation represents half a cycle of an "equivalent" base frequency. Theoretically, extrapolating the current (or voltage)-time curves to zero time and measuring the slope at that point is equivalent to an a-c measurement at infinite frequency. In practice, reading a slope at one point is not possible and instrument rise times have to be considered as well, so that a minimum time span of  $0.1\text{--}1 \mu\text{sec}$  is needed to obtain meaningful data. Still, such measurements have an equivalent frequency of  $5\text{--}0.5$  MHz, are therefore relatively free of faradaic interference and are much easier to make than those on a-c bridges. Unfortunately, however, at such short times the current (or voltage)-time curves have to be displayed on oscilloscopes and the measurement suffers from the usual  $\pm 3\%$  error in the linearity of the scope amplifiers, unless extensive efforts at calibration are made.

Work on solid electrode/electrolyte interfaces has traditionally been plagued by irreproducibility. Therefore, even with their inherent  $\pm 3\%$  inaccuracy, voltage step and current pulse methods were quite useful in the study of such systems. Recently, however, work on at least one solid electrode, platinum, has become quite reproducible (9, 10), so much so that these methods can no longer be used because of their limitation in accuracy.

In the present paper a bridge type arrangement is proposed for the measurement of the differential capacity and parallel resistance operating on short ( $< 100 \mu\text{sec}$ ) repetitive (about 10 pulses/sec) d-c pulses. The bridge in its present form works at equivalent frequencies of only about 5 kHz and should therefore be used only for ideally or nearly ideally polarizable electrodes. However, we believe that extension to higher equivalent frequencies is possible. The bridge is comparable in accuracy to a conventional a-c bridge but still retains the advantages of a single d-c pulse differential capacity measurement.

#### Basic Circuit

The proposed bridge operates briefly as follows: A current pulse is divided into two equal parts, one of which flows through the cell, the other through a (variable) cell circuit analog. The potential-time function caused by the current passing through the cell is compared to that caused by the current through the cell circuit analog. If cell circuit and cell circuit analog are electrically equivalent the two potential-time curves are identical and their difference is zero at all times, thus indicating the bridge balance point.

The cell arm of the bridge (Fig. 1) consists of a voltage dropping resistor,  $R_d$ , and the electrolytic cell, represented here by the ionic differential capacity,  $C_d$ , and parallel resistor,  $R_p$ , of the test electrode, and the resistance of the electrolyte,  $R_e$ . The polarizing electrode is grounded and is assumed to be of very large area as compared to the test electrode so that it does not contribute to the electric characteristic of the cell. The second arm of the bridge is made up of a voltage dropping resistor,  $R_d'$ , identical to  $R_d$ , and a cell circuit analog of a variable capacitor,  $C_d'$ , and the variable resistors,  $R_p'$  and  $R_e'$ . A short rise time ( $< 0.1 \mu\text{sec}$ ) d-c pulse,  $i$ , is fed into point A, passes through a variable current regulator,  $R_r$ , and is divided at point B. The flow of current in the two arms of the bridge causes a potential to appear at C and at C'. These po-

Fig. 1. Schematic bridge circuit diagram.  $R_r$ ,  $R_d$ ,  $R_d'$ , voltage dropping resistors;  $C$ ,  $C'$ , potential take-off points; cell circuit, consisting of  $C_d$ , ionic double layer capacitance,  $R_p$ , parallel resistance,  $R_e$ , electrolyte resistance; cell circuit analog consisting of  $C_d'$ ,  $R_p'$ , and  $R_e'$ .

tentials are fed into the differential input of an oscilloscope (triggered by the pulse) and their difference is displayed on the screen.

Three separate adjustments,  $C_d'$ ,  $R_p'$ , and  $R_e'$  have to be made to achieve bridge balance. This is facilitated by the following considerations:

1.  $C_d = C_d'$ ,  $R_p = R_p'$ ,  $R_e \neq R_e'$

The potential-time function developed by the pulse across  $C_d - R_p$  and  $C_d' - R_p'$  will be identical. The  $iR_e$  drop due to  $R_e$  will be different from that due to  $R_e'$  but will be constant and independent of time. The difference signal observed on the scope will show an "instantaneous" jump of the rest spot on the screen followed by a horizontal trace (Fig. 2a).

2.  $C_d \neq C_d'$ ,  $R_p = R_p'$ ,  $R_e = R_e'$

Circuit analysis shows that the potential across  $C_d - R_p$  for charging with a constant current,  $i$ , as a function of time from beginning of charging,  $t$ , is given by

$$E = i R_p [1 - \exp(-t/R_p C_d)] \quad [1]$$

The difference signal,  $\Delta E = E - E'$  ( $E'$  across  $C_d' - R_p'$ ), appearing on the scope can be written

$$\Delta E = i R_p [\exp(-t/R_p C_d') - \exp(-t/R_p C_d)] \quad [2]$$

For any time  $t$ , the slope of this curve is

$$\begin{aligned} d(\Delta E)/dt \\ = (i/C_d) \exp(-t/R_p C_d) - (i/C_d') \exp(-t/R_p C_d') \end{aligned} \quad [3]$$

Fig. 2. Schematic oscilloscope traces expected for

- a:  $C_d = C_d'$ ,  $R_p = R_p'$ ,  $R_e \neq R_e'$  (case 1)
- b:  $C_d < C_d'$ ,  $R_p = R_p'$ ,  $R_e = R_e'$  (case 2)
- c:  $C_d = C_d'$ ,  $R_p < R_p'$ ,  $R_e = R_e'$  (case 3)

A: cathode ray beam rest spot.

and, at  $t = 0$

$$[d(\Delta E)/dt]_{t=0} = i(1/C_d - 1/C_d') \quad [4]$$

For  $t \ll R_p C_d'$ ,  $t \ll R_p C_d'$ , Eq. [2] can be linearized to

$$\Delta E = i(1/C_d - 1/C_d') t, t \ll R_p C_d, t \ll R_p C_d' \quad [5]$$

Thus, for short times,  $\Delta E$  is linear with time, the slope of the difference potential-time curve,  $d(\Delta E)/dt$ , is constant, starting at  $t = 0$  with a finite value (Eq. [4]). The slope is positive for  $C_d' > C_d$ , negative for  $C_d' < C_d$  ( $i > 0$ ) (Fig. 2b).

$$3. C_d = C_d', R_p \neq R_p', R_e = R_e'$$

For this case, the difference signal is given by (see Eq. [1])

$$\Delta E = i(R_p - R_p') + i [R_p' \exp(-t/R_p' C_d) - R_p \exp(-t/R_p C_d)] \quad [6]$$

and, for any time,  $t$

$$d(\Delta E)/dt = (i/C_d) [\exp(-t/R_p C_d) - \exp(-t/R_p' C_d)] \quad [7]$$

$$\text{For } t = 0, [d(\Delta E)/dt]_{t=0} = 0$$

At short times,  $t \ll R_p C_d$ ,  $t \ll R_p' C_d$ , after linearizing

$$E_{t \rightarrow 0} = 0 \quad [8]$$

i.e., for short times the slope of the  $\Delta E$  vs.  $t$  curve is zero, independent of  $t$ . Thus, for this condition, the oscilloscope trace will start from the rest point tangentially to the time axis. For longer times, Eq. [7], the slope will be  $> 0$  for  $R_p > R_p'$ ,  $< 0$  for  $R_p' > R_p$  ( $i > 0$ ) (Fig. 2c).

The difference between the two potential-time functions across  $C_d - R_p - R_e$  and  $C_d' - R_p' - R_e'$  will be zero only if all the circuit elements in the two bridge arms are individually identical. Using criteria 1 to 3 various conditions of unbalance can be detected and corrected.

Repetitive current pulses are needed to balance the bridge. It is assumed that repetition rate and pulse amplitude are selected such that the cell is not noticeably displaced from its equilibrium or its steady state.

As seen from the discussion of criteria 1 to 3 above, for short pulses, differences in capacity are much more readily detected than differences in parallel and series resistance. This is confirmed experimentally (see below). Therefore, in what follows, emphasis is placed on the measurement of the ionic differential capacity.
